DBT may decrease diastolic coronary filling pressure because of its vasodilation in contrast to the constriction produced by dopamine.[71] These studies suggest that dobutamine produces an overall favorable metabolic climate in the ischemic myocardium despite an increase in inotropism. Improvement is rate limited. Dobutamine has been used effectively to improve coronary flow to differentiate, by echocardiography, responsive or unresponsive areas of dyskinesia in patients following myocardial infarction.[93]

Dobutamine is highly controllable with a half-life of 2 minutes. Tachyphylaxis is rare but may be noted if given over 72 hours. The net hemodynamic effects of DBT include an increase in CO, a decrease in left ventricular filling pressure, and a decrease in systemic vascular resistance without a significant increase in chronotropism at lower doses.[94] It has been proven to be as effective as combined dopamine and nitroprusside in treating heart failure with infarction. It is even more effective when summated with the dopaminergic properties of DA. In contrast to dopamine, DBT seems to inhibit hypoxic pulmonary vasoconstriction. Like its parent compound isoproterenol, DBT may prove to be useful in managing right ventricular heart failure.

Dopamine offers some advantages over many sympathomimetics in treating the low-output syndrome.[95] It is a dose-related agonist to all three types of adrenoceptors, and the desired action can be selected by changing the infusion rate. The DA receptors are most sensitive followed by the β, and then α receptors. Dopamine dosage regimens have been traditionally, and arbitrarily, divided into low, medium, and high doses according to its dose-receptor sensitivity (see Table 12-14). Renal and mesenteric vascular dilatation and tubular cell natriuresis are mediated through the DA receptors at low-dose infusion rates of 0.5 to 2.0 µg/kg/min. This is often referred to as "renal dose dopamine" because of the purported enhanced renal blood flow and diuresis. However, the concept of "renal dose" DA may be more imagined than real. The diuresis may also be attributed, in part, to inhibition of aldosterone secretion seen with low-dose DA administration.[96] A general improvement in CO from afterload reduction also contributes to improvements in renal blood flow. These effects have been well demonstrated in patients with heart failure. However, the protective effects of DA on the development of renal failure in the critically ill or injured patient,

although an attractive principle, is much less certain. Prevention of renal failure by prophylactic "renal dose" DA (with or without furosemide) in the critically ill[97] or traumatized patient has not been conclusively demonstrated, and no longer tenable. This may be related to the adrenergic milieu into which the DA is given. The vasoconstrictive effects of DA are expected to occur only at relatively high doses. However, even relatively low doses of DA can cause renal vasoconstriction when added into pre-existing high plasma levels of endogenous catecholamines commonly seen in the critically ill or acutely injured patient or those already receiving intravenous sympathomimetics.

The hemodynamic effects of low-dose DA are primarily related to vasodilatation by activation of the DA1 and DA2 receptors. Activation of presynaptic DA2 adrenoceptors add to the vasodilating effect of the DA1 receptors by inhibiting presynaptic NE release in the renal and mesenteric vessels. The reduction of total systemic vascular resistance would be significant when one considers that 25% of the CO goes to the kidneys alone (Fig. 12-28). A reduced diastolic blood pressure is often noted with a slight reflex increase in HR. Increasing the infusion rate of DA to 2 to 5 μg/kg/min begins to activate *β*receptors increasing the CO by increasing chronotropism and contractility with early venoconstriction (preload) and systemic vasodilatation (afterload reduction). Blood pressure may not increase despite significant increases in CO. This dose range would appear optimal for managing congestive heart and lung failure because it combines inotropism and afterload reduction with possible diuresis. Further increases in dose activate *α* receptors, which will increase vascular resistance and blood pressure, but further improvements in CO may be attenuated. Infusion rates of greater than 10 μg/kg/min produce intense a activity, which may override any beneficial DA or *β* vasodilation effect on total flow. High-dose dopamine behaves much like NE and, in fact, causes NE release at this dose range.[98]

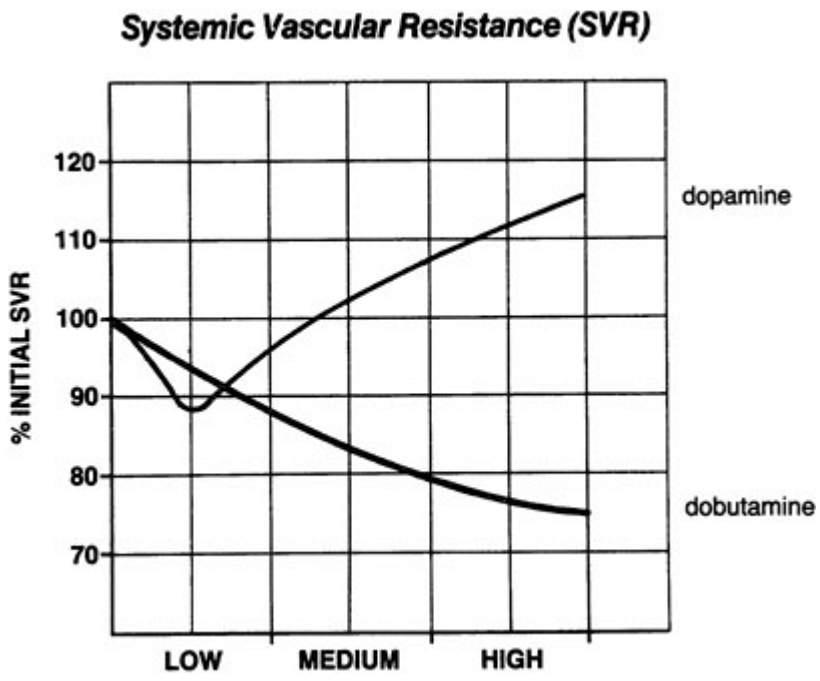

FIGURE 12-28. Dobutamine produces a net reduction in vascular resistance. Its weak *α* vasoconstrictive effects are balanced by a direct *β*-2 vasodilation with little change in vascular tone. However, further reflex arterial vasodilation occurs with increased CO. Low-dose dopamine dilates renal and mesentric arterial beds, which reduces afterload but increases resistance at increasing doses as a result of its predominant *α* effect.

Despite the apparent dose-response divisions of DA, a wide variability of individual responses has been noted. The *α*-adrenergic effects can be seen in some individuals in doses as low as 5 μg/kg/min, whereas doses as high as 20 μg/kg/min may be required to obtain this effect in shocked patients.[98] This wide variation in dose response has led to a reexamination of DA as a

primary adrenergic for patients in cardiogenic shock or failure. Increased venous return may not be desirable in this situation, but dopamine's hemodynamic versatility continues to be useful in cardiogenic shock when

combined with other complementary catecholamines such as dobutamine (Fig. 12-29) (see combinations). The venoconstriction, or distributive effects, of dopamine are useful in surgical patients in whom third-space edema and sepsis are the most common abnormalities. Dopamine increases mean pulmonary arterial pressure and is not recommended for sole support in patients with right heart failure, adult respiratory distress syndrome, or pulmonary hypertension.

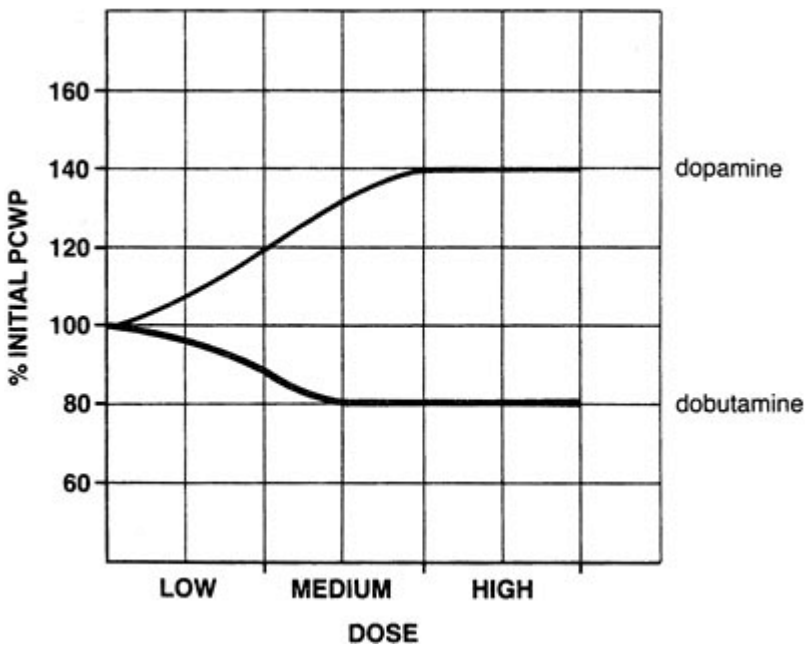

FIGURE 12-29. A decrease in venous capacitance has been demonstrated as an early effect of dopamine. An increase in pulmonary capillary wedge pressure may be noted. Dobutamine may decrease pulmonary capillary wedge pressure by increased inotropism as well as vasodilation with minimal effect on venous capacitance. (Redrawn with permission of Eli Lilly Co., Indianapolis, Indiana.)

Combination Therapy

Dopamine and DBT are two of the most popular inodilators in use today. A comparison of these two drugs will underscore the importance of the extracardiac side effects in selecting a drug either for use alone or in combination.[99] This comparison is particularly appropriate because dopamine and DBT are considered equipotent inotropic agents and are effective in the same dose range of 2 to 15 µg/kg/min. Their differences can be compared at low (0.5 to 4 µg/kg/min), medium (5 to 9 µg/kg/min), and high (10 to 15 µg/kg/min) doses. This comparison will illustrate the divergent effects of two drugs on preload and afterload while sharing the property of inotropism. Although they share several clinical indications, these drugs are pharmacologically distinct and not interchangeable. Their divergent properties, however, make them particularly valuable when used in combination.[100]

DBT is a direct-acting catecholamine that produces a positive inotropic β-1 effect but with minimal changes in β-2 HR or vascular resistance (β-2, α-1 counteraction). Thus, DBT may not alter blood pressure even though CO is markedly improved. Dopamine may do both. Low-dose dopamine can produce hemodynamic changes similar to those of DBT (inotropism and mesenteric vasodilatation) (see Fig. 12-28). Dopamine produces an increase in blood pressure at higher doses related to its direct and indirect α-1 activation. This increased afterload with dopamine may attenuate any

further increase in CO comparable to that of an equal dose of DBT. DBT does not have any clinically important venoconstrictor activity in contrast to dopamine in which an increase in ventricular filling pressure can be noted at low doses. This contrasting effect on preload is seen in Figure 12-29. The cardiac response to all vasodilators is dependent on the preexisting preload status. Patients who have acute failure with normal or only slightly elevated end-diastolic volumes may not respond to afterload reduction with an increase in CO. Balanced vasodilators such as nitroprusside or venodilators such as the nitrates may actually reduce CO in these patients. Patients with dilated left ventricles and elevated filling pressures usually have impressive improvement in CO with afterload reduction. This underscores the importance of monitored volume loading before proceeding apace with vasoactive drugs (see Table 12-13). It is possible, and indeed likely, that a portion of the reduced effectiveness of long-term vasodilator therapy results from inadequate preload, which in some circumstances can actually be a consequence of successful drug therapy. Clinical studies suggest that DBT is less likely to increase HR than dopamine for a given dose, a major concern in the patient with coronary artery disease. DBT is a coronary artery dilator, whereas dopamine is not. A dopamine-induced tachycardia, however, may be of less concern in the septic patient who commonly has a maldistribution of volume, low vascular resistance, a preexisting refractory tachycardia, but a previously healthy heart. The empiric preference of dopamine in surgical units and DBT in coronary units has been observed and is perhaps well founded. The surgical patient is more likely to have distributive defects and fluid shifts from major trauma and surgery. The hemodynamics of the septic patient are characterized by low vascular resistance, hypotension, high CO, and some degree of myocardial depression. The mesenteric distribution, inotropic, and pressor effects of dopamine would seem ideal for this condition. However, a shift of blood volume to the central circulation, tachycardia, or an unpredictable increase in afterload may not be appropriate for the patient in congestive heart failure or an acute infarct. DBT, with its dose-related inotropism, afterload reduction, and relative lack of chronotropism, would seem more appropriate for these circumstances.

Dobutamine does not cause NE release or stimulate DA receptors. Dopamine does both, but the effect is dose related.

Dopamine offers possible advantages over many sympathomimetics in managing the low-output syndrome with oliguria. This effect is ablated at higher doses. DBT does not selectively increase renal blood flow but does improve renal blood flow secondarily with improved CO and weak β-2 vasodilation. Much of the reduced afterload observed with the use of DBT may be related more to a reduced sympathetic tone with improved flow than that of active vasodilatation. DBT belongs on the opposite end of the spectrum from amrinone. DBT is a potent inotropic agent but a weak vasodilator, whereas amrinone is a potent vasodilator but weak inotrope.

Dopamine and DBT also have contrasting effects on the pulmonary vasculature. Dopamine has been noted to increase pulmonary artery pressure and does not inhibit the pulmonary hypoxic response. It is not recommended for patients in right heart failure. DBT does vasodilate the pulmonary vasculature and is helpful in treating right heart failure and cor pulmonale.[17] The adrenergic effects of combined sympathomimetics, like the solo drugs, also appear to be additive and competitive for receptor sites. Many combinations of adrenergic drugs have been described as having a synergistic effect. Synergism is the joint action of agents such that their combined effect is greater than the algebraic sum of their individual effects. This synergism may be a clinical interpretation of a summated receptor effect that appears synergistic. For example, infusions of the combination of dopamine and DBT have been noted to produce a greater improvement in CO, at lower doses, than can be achieved by either drug alone. Each drug, although equipotent inotropic agents, dilates different vascular beds. Therefore, the summation of afterload reduction by both drugs could produce a greater improvement in CO than could be achieved by either drug alone, even at the same level of inotropism. Summation is more consistent with current receptor pharmacology and can be used to advantage in avoiding unwanted side effects of one drug while supplementing its desired attributes with another. The summation principle obviates the necessity of knowing a large number of drugs. One need only become familiar with a few agents to manage most clinical situations.

Because of summation, many combinations of vasoactive drugs have been found useful in making fine hemodynamic adjustments in the critically ill. The available sympathomimetic agents provide a wide range of hemodynamic effects, particularly when combined with vasodilators. For example, if a larger positive inotropic action and less vasoconstriction are desired, DBT could be added to dopamine. Also, nitroprusside could be added to dopamine or combined with any other appropriate inodilator.[101] Combinations are also useful in redistributing the CO to vital organs. This is why the combination of DBT and dopamine has been helpful. Dopamine could distribute the CO to the renal and mesenteric vascular bed, whereas DBT could provide additional afterload reduction by opening up the vascular beds of skin and muscle (Fig. 12-30).[102] NE has been successfully used in combination with dopamine to increase vascular resistance in septic patients while distributing a greater portion of the CO to the renal and mesenteric bed.[103]

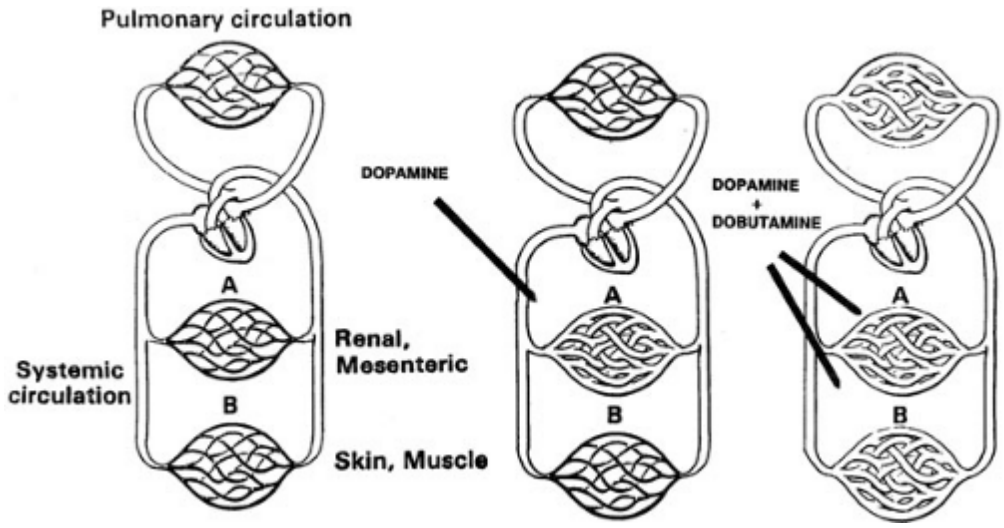

FIGURE 12-30. Combining low doses of dopamine and dobutamine may produce improvements in CO that are greater than can be achieved with either drug alone. This appears to be clinical synergism. However, the vasodilation of different vascular beds likely produces a summed reduction of afterload at the same level of inotropism that only appears to be synergistic. The second law of thermodynamics remains intact.

The studied use of adrenergic combinations in patients with cardiac failure has been proposed because pathophysiology cannot be approached with the attitude that β agonism is all good and a agonism is all bad. The objective is to increase coronary perfusion and CO while decreasing afterload. This is the effect achieved by the intra-aortic balloon pump. No single vasoactive agent can achieve this, but these conditions can be approached with combination therapy. Because of receptor summation during combination therapy, standard rates of infusion (as outlined in Table 12-14) no longer apply. Invasive hemodynamic monitoring is mandatory for success; otherwise, iatrogenic disasters can be expected. Other conditions necessary for success with vasoactive drugs also require that the failing myocardium or vasculature must have functional reserve, the reserve can be stimulated, and perfusion can be maintained.[104,105]

Fenoldopam

Fenoldopam, a benzazepine derivative, is a selective DA1 agonist with no α or β receptor activity compared to dopamine (see Table 12-15).[98,106] Oral bioavailability is poor, but it is an effective antihypertensive when given iv. Intravenous fenoldopam has direct natriuretic and diuretic properties that promote natriuresis, diuresis, and an increase in creatinine clearance. It offers advantages in the acute resolution of severe hypertension compared to sodium nitroprusside, particularly if the patient has preexisting renal impairment.[107] Aronson et al reported a comparative study using SNP and fenoldopam in dogs under general anesthesia. A 30% reduction

in mean arterial pressure was produced by either fenoldopam or SNP. Fenoldopam maintained renal blood flow while SNP showed a reduction.[106,108] Preservation or augmentation of renal blood flow during blood pressure reduction presents a potential for use during several situations in the perioperative period. Fenoldopam has an elimination half-life of 5 minutes. This property might well lend itself in producing hypotensive anesthesia while preserving renal function.[108]

Human studies have demonstrated that fenoldopam is a potent direct renal vasodilator. Left ventricular function has been noted to improve with afterload reduction. The study by Kien and colleagues suggests that the improvement in renal function is a direct vasodilator effect of the drug.[108] Intravenous fenoldopam may prove to be ideal for treating conditions in which renal vasoconstriction is an expected complication. Examples are cyclosporine-induced renal vasoconstriction, radiographic dye toxicity, and human kidney recipients.[109,110,111]

The onset of action with intravenous fenoldopam is about 5 minutes, reaching a steady state in about 20 minutes. The drug is rapidly metabolized in the liver and excreted in the urine. The elimination half-life is about 5 minutes. There has been no evidence of tolerance in reducing blood pressure for up to 24 hours. No rebound on withdrawal has been noted.

The most common adverse effects of fenoldopam are related to vasodilation, which include hypotension, flushing, dizziness, headache, and increases in heart rate, nausea, and hypokalemia. It should be used cautiously in patients with glaucoma as it can increase intraocular pressure. No significant drug interactions have been reported. Concomitant use with β-blockers will reduce the effective dose of fenoldopam.

Fenoldopam is diluted in normal saline or 5% dextrose and is given by continuous infusion without a bolus dose. The effective dosage range is 0.1 to 1.6 μg/kg/min. A reflex tachycardia may be produced. The dosage is titrated upward every 15 minutes according to patient response. Any change in infusion rate should be detectable within 15 minutes.

Clonidine

Clonidine is a centrally acting selective partial α-2 adrenergic agonist (220:1 α-2 to α-1). It is an antihypertensive drug by its ability to decrease central sympathetic outflow. Stimulation of α-2 receptors in the vasomotor centers of the medulla oblongata is thought to produce this effect.[112] It is not clear whether these are pre- or postsynaptic receptors. However, the end result is decreased SNS tone and enhanced vagal tone. Peripherally there is decreased plasma renin activity as well as decreased EPI and NE levels. This drug has been proven to be effective in the treatment of severe hypertension and renin-dependent hypertensive disease.

Clonidine is not available for intravenous use. The usual daily adult oral dose is 0.2 to 0.3 mg. A transdermal clonidine patch is available for use on a weekly basis for surgical patients unable to take oral medication.

Clonidine is clinically useful in anesthesiology in other ways. It has been found to produce dose-dependent analgesia when introduced into the epidural or subarachnoid space in doses of 150 to 450 μgs.[113] The addition of 75 to 150 μg of clonidine to subarachnoid tetracaine or bupivicaine can prolong the duration of sensory and motor blockade of the local anesthetics. Unlike the opioids, clonidine does not depress respiration or cause pruritis, nausea, vomiting, or delayed gastric emptying.[114] Clonidine and morphine do not produce cross-tolerance. Hypotension, sedation, and xerostomia may follow the neuraxial use of clonidine.[115,116]

Oral clonidine (5 μg/kg) when used as a premedicant enhances the postoperative analgesia provided by intrathecal morphine without adding to the side effects of the morphine.[117] Other additional benefits noted from a clonidine premedication include (1) blunted reflex tachycardia for intubation, (2) reduction of vasomotor liability, (3) decreased plasma catecholamines, and (4) dramatic decreases in MAC for inhaled gases or injected drugs.

Other uses of clonidine have been in the diagnosis of pheochromocytoma, treatment of opioid withdrawal, and shivering.[118] Clonidine, 0.3 mg orally, will decrease the plasma concentration of

catecholamines in normal patients but not in the presence of a pheochromocytoma. This reflects the ability of clonidine to suppress release of catecholamines from nerve endings but not from the pheochromocytoma. Its usefulness in suppressing opioid withdrawal is likewise attributed to its ability to replace the opioid-mediated inhibition with *a*-2–mediated inhibition of CNS sympathetic outflow. It may likewise be useful for nicotine withdrawal.

Clonidine is rapidly absorbed by mouth and reaches peak plasma levels within 60 to 90 minutes. The elimination half-life is between 9 to 12 hours. It is equally excreted in the liver and kidneys. The duration of the hypotensive effect after a single dose is about 8 hours. The transdermal administration of clonidine requires about 48 hours to achieve therapeutic levels. The decrease in systolic blood pressure is more prominent than the decrease in diastolic blood pressure. Homeostatic cardiovascular reflexes are maintained, avoiding problems of orthostatic hypotension. There seem to be no effects on glomerular filtration rate.

Side Effects. The most common side effects of clonidine are sedation and a dry mouth. However, skin rashes are frequent with chronic use. Impotence may be seen occasionally and orthostatic hypotension is rare. One of the more worrisome complications of chronic clonidine use is a withdrawal syndrome on acute discontinuation of the drug. This usually occurs about 18 hours after discontinuation. The symptoms are hypertension, tachycardia, insomnia, flushing, headache, apprehension, sweating, and tremulousness. It lasts for 24 to 72 hours and is most likely to occur in patients taking more than 1.2 mg/day of clonidine. The withdrawal syndrome has been noted postoperatively in patients who were withdrawn from clonidine before surgery. It can be confused with anesthesia emergence symptoms particularly in a patient with uncontrolled hypertension. Absent the availability of the oral route in the surgical patient, withdrawal can be treated with clonidine transdermally or more rapidly with rectal clonidine.

Dexmedetomidine

Dexmedetomidine is a more selective *a*-2 agonist than clonidine.[119] Its potent *a*-2-agonism is 1620:1 *a*-2 to *a*-1. Compared to clonidine, dexmedetomidine is seven times more selective for *a*-2 receptors and has a shorter half-life of 1.5 hours. It has a more rapid onset of action (less than 5 minutes). The time to peak effect is 15 minutes. It can be given intravenously and has many uses in anesthesiology. It provides excellent sedation, reduces blood pressure and HR, and profoundly decreases plasma catecholamines. Little respiratory depression is evident. Dexmedetomidine has been shown to be an effective anxiolytic and sedative when used as premedication. Pretreatment with dexmedetomidine, like, clonidine, attenuates hemodynamic responses to intubation. Likewise, it decreases the MAC for volatile anesthetics from 35 to 50% but increases the likelihood of hypotension. Dexmedetomidine, like clonidine, increases the range of temperatures not triggering theromoregulator defenses. It is likely to promote perioperative hypothermia but also is effective against shivering.[120]

The following properties of dexmedetomidine seem particularly valuable to the anesthesiologist.[121]

1. Potent analgesia
2. Sedation and anxiolysis
3. Antisialogogue
4. Promotes hemodynaimic stability
5. Homeostatic reflexes remain intact
6. Attenuates opioid rigidity (in animals)

Dexmedetomidine is provided in 2-mL vials (100 mcg/mL) and must be diluted in 48 mL of 0.9% sodium chloride to be used in a controlled infusion device. A loading infusion (1 mcg/kg) must be given over a 10-minute period in a

monitored setting. The loading dose should not be bolused. A transient and paradoxical hypertension may be seen during infusion of the loading dose. The HR may be seen to decrease. The increase in BP is attributed to an initial stimulation of *a*-2 receptors in vascular smooth muscle. The blood pressure usually decreases as the central blockade of central *a*-2 agonism overrides the peripheral effect.[120,121] The state of sedation must be monitored as episodes of obstructive apnea have occurred with the loading infusion related to the degree of sedation.

Nonadrenergic Sympathomimetic Agents

Table 12-4 classifies the drugs that mimic the SNS into two broad categories, adrenergic or nonadrenergic. Adrenergic agonists exert their action through adrenergic receptors by direct stimulation or indirectly via release of NE. Adrenergic agonists may be catecholamines or noncatecholamines by chemical configuration. Nonadrenergic sympathomimetic drugs also act indirectly by influencing the cAMP-calcium cascade, exclusive of the receptors (see Fig. 12-15). The function of the second messenger (cAMP) and the third messenger (Ca2+) nearly always goes together. This concept reinforces the recent appreciation of the homogeneity of action of a wide variety of drugs previously thought to be unrelated. Sympathomimetics have more pharmacologic similarities than differences.

Vasopressin. Vasopressin and its congener (desmopressin) are exogenous preparations of the endogenous antidiuretic hormone (ADH). ADH and oxytocin are the two principal hormones secreted by the posterior pituitary. Target sites for ADH are the renal-collecting ducts and vascular smooth muscle and cardiac myocytes. Water absorption is passively reabsorbed from renal-collecting ducts into extracellular fluid. Nonrenal actions include inotropism and intense vasoconstriction, accounting for its alternative designation as vasopressin.[122]

Arginine vasopressin (AVP) is the most active form of ADH. Historically, vasopressin has been used for (1) treatment of diabetes insipidus, (2) diagnosis of diabetes insipidus, (3) abdominal distention, (4) and as an adjunct in the treatment of GI hemorrhage and esophageal varices. Recently, three new indications for the use of vasopressin have emerged. These are (1) pressure support for septic shock, (2) cardiac arrest secondary to ventricular fibrillation, and (3) pulseless ventricular tachycardia and heart failure.[123] This discussion is limited to cardiac arrest.

Three AVP receptor subtypes are known. These are V1a, V1b, and V2 receptor subtypes. V1 receptors are found on vascular smooth muscle and cardiac muscle. The V2 receptors regulate renal function. Endogenous ADH is released from the posterior pituitary in response to changes in plasma osmolality or with baroreceptor response to changes in blood volume or pressure. Release is stimulated with a 5 to 10% decrease in blood volume, central blood volume, cardiac output, or blood pressure sensed by the carotid and aortic baroreceptors. Stretch receptors in the left atrium and pulmonary veins may also activate ADH release. It is also released when the osmoreceptors in the hypothalamus sense changes of as little as 1% in osmolality and mediated by the V2 receptors.

Epinephrine is universally the first-line drug applied to pulseless cardiac rhythms such as ventricular fibrillation (VF), ventricular tachycardia, electromechanical dissociation, and asystole. Despite good animal studies, there is little evidence from human data that epinephrine improves outcome from cardiac arrest. Controlled comparative studies in humans between high-dose EPI and standard-dose EPI showed no increase in survival or improved neurologic outcome in survivors receiving high-dose EPI. The search for a more effective vasopressor led to the current advocacy of vasopressin as a replacement for EPI in shock-refractory pulseless rhythms. Survivors of cardiac arrest, compared to nonsurvivors, had demonstrated higher levels of vasopressin both before and after receiving EPI.[124]

Animal studies have shown, both in open- and closed-chest models, vasopressin caused a larger increase in SVR, cerebral perfusion pressure, and coronary perfusion pressure than EPI. Vasopressin is a more effective vasoconstrictor than EPI in the presence of hypoxia and acidosis. In contrast to EPI, vasopressin does not seem to increase MV02 or lactate production.[122] In the 2000 guidelines for advanced cardiac life support (ACLS) of the American Heart Association, vasopressin was updated to a class IIb recommendation (acceptable, possibly helpful, not harmful

and supported by fair evidence) for treatment of cardiac arrest secondary to ventricular fibrillation and ventricular tachycardia. EPI was reassigned from a previous class IIb recommendation to "class indeterminate." At the time of this change, there was insufficient evidence to recommend vasopressin for the treatment of asystole or electromechanical dissociation (class indeterminate). However a recent study in out-of-hospital human cardiac arrests has demonstrated that vasopressin is superior to EPI in patients with asystole.[125] Vasopressin followed by EPI may be more effective than EPI alone in the treatment of refractory cardiac arrest. As yet, randomized trials have failed to demonstrate the superiority of vasopressin over EPI in survival of in-hospital cardiac arrest.[126] These data may be skewed by the co-morbid factors requiring hospitalization. Larger trials will be necessary as to whether survival to discharge will be improved by vasopressin.

Vasopressin used for cardiac arrest is known as "vasopressin injection USP" and is available in vials of 20 IU/mL. The dose in cardiac arrest is 40 IU in 40 mL intravenously as a single dose in a peripheral iv line. Extravasation may cause local tissue necrosis. Its use in vasodilated sepsis is by infusion pump starting at 0.04 IU/min.

Adenosine. Adenosine, available for more than 50 years, has been recognized recently as a clinically useful drug. It is a byproduct of ATP and is found in every cell in the body. It is composed of adenine and a pentose sugar. Production can be increased by stimuli such as hypoxia and ischemia. This ubiquitous nucleoside has potent electrophysiologic effects in addition to having a major role in regulation of vasomotor tone. Adenosine is believed to have a cardioprotective effect by regulating oxygen supply and demand. The cardiovascular effects of adenosine depend on which of two receptor sites is activated, α-1 or α-2. The α-1 receptors in the myocardial conduction system are the most sensitive and mediate SA node slowing and AV nodal conduction delay. The α-1 receptor inhibits production of cAMP whose formation is stimulated by β-adrenergic activity (see Table 12-7). The α-2 smooth muscle receptors require higher concentrations of adenosine, which mediate systemic and coronary vasodilatation. The α-2 receptor directly increases the rate of formation of cAMP (see Table 12-7) and functions independently of β activity. Intravenous adenosine, therefore, has significant negative chronotropic effects on the SA node as well as negative dromotropism on the AV node. Thus, adenosine regulates atrial and ventricular rates independently of each other.

Adenosine hyperpolarizes atrial myocytes and decreases their action potential duration via an increase in outward K+ current. These are the acetylcholine-regulated K+ channels. Adenosine mimics the effects of acetylcholine in many ways, including an extremely short plasma half-life of mere seconds. Adenosine also antagonizes the inward Ca2+ current produced by catecholamines. This antidysrhythmic mechanism of Ca2+ channel blockade is thought to be an indirect effect and important only when β stimulation is present. This trait suggests

a possible role in countering catecholamine-induced dysrhythmia. Thus, adenosine exhibits some of the traits of a Class IV antidysrhythmic. However, the primary antidysrhythmic effect of adenosine is to interrupt reentrant AV nodal tachycardia, which most likely relates to its K+ current, rather than Ca2+ current effects.

The chief indication for adenosine is paroxysmal supraventricular tachycardia (PSVT), which it may terminate in a matter of seconds. PSVT refers to a broad category of narrow complex tachycardias with acute onset and cessation. The most common forms are AV nodal reentry tachycardia and AV reciprocating tachycardia. PSVT accounts for about one-third of all cases of perioperative dysrhythmia. Clinical studies support the use of adenosine for the treatment of Wolff-Parkinson-White (W-P-W) syndrome and other reentrant tachycardias involving the AV node.[127] The same characteristics that make adenosine an effective therapeutic agent may also make it an ideal agent for diagnosing other types of dysrhythmia. The incidence of incorrect diagnosis of supraventricular dysrhythmia has been reported to be as high as 15% using conventional means.[128] This can lead to utilization of harmful medications. For example, a broad complex tachycardia can either be a VT or an SVT with aberrant conduction. Verapamil can be fatal if the dysrhythmia is VT because the drug is long lasting.[129] However, the fleeting action (9 to 10 seconds) of adenosine assures that no harm will be done if the broad complex is of ventricular

origin providing a combined therapeutic and diagnostic test. Adenosine will stop SVT in 90% of cases in which the AV node forms one of the limbs of the reentrant circuit such as AV reciprocating tachycardia and AV nodal reentry; 60% will convert with the first dose. However, adenosine has no effect on ectopic atrial dysrhythmia such as ectopic foci, multifocal SVT, or flutter/fibrillation. Approximately 10% of SVT do not involve AV nodal reentry. Adenosine will nevertheless slow AV nodal conduction in these cases, decrease the ventricular rate, and allow inspection of P waves. Thus, adenosine may be useful in unmasking atrial fibrillation when fast ventricular responses are noted.

A number of side effects have been reported with the use of adenosine, including flushing, headache, dyspnea, bronchospasm, and chest pain. The majority of these are brief (seconds) and not clinically significant. Transient new dysrhythmia (65%) will be noted at the time of cardioversion, but these disappear during the half-life of the drug. Major hemodynamic changes are rare but consist of hypotension and bradycardia. Adenosine should be given by means of a rapid iv bolus with flush because of its extremely short half-life of less than 10 seconds. The initial adult dose is 6 mg (100 to 150 mg/kg pediatrics), which can be followed by 12 mg within 1 to 2 minutes if the initial dose is without effect.[128] The 12-mg dose may be repeated once. The antidysrhythmic effects of adenosine occurs as soon as the drug reaches the AV node.

Phosphodiesterase Inhibitors. Phosphodiesterase inhibitors have pharmacologic properties approaching the characteristics of the ideal inotropic agent (see Table 12-17).[130,131] They do not rely on stimulation of *β* and/or *α* receptors. They are the product of a search for a nonglycosidic, noncatecholamine inotropic agent. These drugs combine positive inotropism with vasodilator activity. They selectively inhibit PDE III.[132,133] PDE I and II hydrolyze all cyclic nucleotides, whereas PDE III acts specifically on cAMP. The PDE III inhibitors apparently interact with PDE III at the cell membrane and impede the breakdown of cAMP.[132,134] cAMP levels increase and protein kinase are activated to promote phosphorylation of the SR in a cascade manner similar to the effects of adrenergic drugs. In cardiac muscle, phosphorylation increases the slow inward movement of calcium current, promoting increased intracellular calcium stores. Thus, inotropism increases. In vascular smooth muscle, increased cAMP activity accounts for the vasodilation, decreased peripheral vascular resistance, and lusitropism. Amrinone, like nitroprusside and nitroglycerin, promotes diastolic relaxation, which promotes ventricular filling.[135]

A variety of intravenous PDE inhibitors are undergoing clinical trials. The relative contribution of inotropism and vasodilation differs with each. Amrinone and milrinone are the only PDE inhibitors released for clinical use in the United States. Amrinone is the prototypical PDE III inhibitor. The degree of hemodynamic effect of these drugs depends on the dose, degree of inotropic reserve, and state of cAMP depletion.

Amrinone. Amrinone produces mild inotropic activity and strong vasodilatory effects. The characteristics of amrinone, compared with those of the ideal inotropic agent (see Table 12-12), rank it near the ideal drug. It is the first oral inotrope available since the introduction of digitalis. However, it is not currently prescribed in its oral form. Studies of single-dose and short-term oral and iv amrinone show dose-related improvements at rest in the cardiac index and the left ventricular stroke index (40 to 80% increase); left ventricular end-diastolic pressure (40% decrease); pulmonary capillary wedge pressure (16 to 44% decrease); pulmonary artery pressure (17 to 33% decrease); right atrial pressure (16 to 44% decrease); left ventricular ejection fraction (50% increase); and systemic vascular resistance (23 to 50% decrease). Significantly, HR and mean arterial pressure are not affected.

Peak response with an iv dose occurs after 5 minutes and reveals no evidence of tolerance over short-term trials (24 hours); it is compatible with other adrenergic agonists. It is an effective inotropic agent in patients receiving *β*-blockers. Its efficacy in the patient who has been digitalized has been demonstrated.

Intravenous amrinone therapy should be initiated with a 0.75-mg/kg bolus given over 2 to 3 minutes. It is continued with a maintenance infusion of 5 to 10 mg/kg/min, adjusted by hemodynamic monitoring. An additional bolus dose of 0.75 mg/kg may be given 30 minutes after initiation of therapy. Care must be taken not to give the bolus too quickly because sudden

decreases in peripheral vascular resistance may occur and result in severe hypotension. Hypotension is not a major clinical problem with appropriate monitoring of ventricular filling pressures. The infusion should not exceed a total daily dose of 10 mg/kg, including the bolus doses. Amrinone has the same range of infusion rates as dopamine and DBT, and dose calculation follows the "rule of six" described in Table 12-14.

Amrinone has two uncommon side effects. Dose-related thrombocytopenia occurs in some patients taking long-term oral medication. This usually responds to dose reduction. Acute iv amrinone has not produced thrombocytopenia.[136] Centrilobular hepatic necrosis occurs in dogs given high doses of amrinone for periods exceeding 3 months. There is no evidence of such an effect in humans.

Milrinone. Milrinone is a derivative of amrinone. It has nearly 20 times the inotropic potency of the parent compound. Milrinone is active both intravenously and orally and has beneficial short-term hemodynamic effects in patients with severe refractory congestive heart failure.[137] Improvement of CO appears to result from a combination of enhanced myocardial contractility and peripheral vasodilation. Treatment with oral milrinone for up to 11 months has been effective and well tolerated without evidence of fever, thrombocytopenia, or gastrointestinal effects.[138] Milrinone recently has been approved for short-term iv therapy of congestive heart failure.[139] It is administered with a loading dose of 50 mg/kg over 10 minutes. The maintenance iv infusion rate ranges from a minimum of 0.375 mg/kg/min to a maximum of 0.75 mg/kg/min (not to

exceed 1.13 mg/kg/day). Dosage must be adjusted in renal failure patients as milrinone is excreted in the urine primarily in unconjugated form.

Enoximone. Enoximone is a PDE III inhibitor that has proven beneficial in patients suffering from severely impaired myocardial function.[140] Enoximone is structurally unrelated to digitalis, catecholamines, or amrinone. It has not been implicated in platelet compromise. Its hemodynamic effects are similar to those produced by amrinone. It appears to be a more potent inotropic agent than amrinone, whose inotropic effect has been questioned. It produces pulmonary and systemic arteriolar vasodilation and can thus be classified as an inodilator. Any increase in myocardial oxygen consumption (MVO_2) by the increase in inotropism is countered by a decrease in afterload and reduced ventricular size. The drug has been administered by both the bolus technique and infusion. It has been used primarily in patients with cardiogenic shock and for weaning from cardiopulmonary bypass. Its use was instituted in patients who were proven refractory to catecholamine therapy. A definitive dosing therapy has not been established but several studies have given a 1- to 2-mg/kg bolus followed by an infusion of 3 to 10 μg/kg/min. In all cases CI and SV increased with a decrease in ventricular filling pressure, and PVR. No increase in heart rate was noted. The bolus technique alone has been helpful in weaning patients from cardiopulmonary bypass without affecting heart rate or producing arrhythmias.

Glucagon. Glucagon is a single-chain polypeptide of 29 amino acids that is secreted by pancreas a cells in response to hypoglycemia. The liver and kidney are responsible for its degradation. Known effects of this hormone in humans include the following:[82,141] (1) inhibition of gastric motility, (2) enhanced urinary excretion of inorganic electrolytes, (3) increased insulin secretion, (4) hepatic glycogenolysis and gluconeogenesis, (5) anorexia, (6) inotropic and chronotropic cardiac effects, and (7) relaxation of smooth muscle (biliary, i.e., sphincters).

Little attention was given to glucagon until 1968, when it was demonstrated to produce positive inotropic and chronotropic effects in the canine heart. Glucagon enhances the activation of adenyl cyclase in a manner similar to that of NE, EPI, and isoproterenol. These cardiac actions of glucagon are not blocked by β-blockade or catecholamine depletion. Glucagon, in contrast to the xanthines, rarely causes dysrhythmia, even in the face of ischemic heart disease, hypokalemia, and digitalis toxicity. Glucagon may possess antidysrhythmic activity in digitalis toxicity because it has been shown to enhance AV nodal conduction in patients with varying degrees of AV block. Thus, it should be used carefully in patients with atrial fibrillation. An iv dose of 1 to 5 mg of glucagon increases cardiac index, mean arterial pressure, and ventricular contractility, even in the presence of digitalis therapy. After a bolus dose, its action dissipates in approximately 30 minutes. A continuous infusion of 5 µg/kg/min is augmented by an initial bolus of 50 µg/kg. Onset

of action occurs in 1 to 3 minutes and peaks at 10 to 15 minutes.

Nausea and vomiting are common side effects in the awake patient, especially following a bolus dose. Hypokalemia, hypoglycemia, and hyperglycemia are also seen. Glucagon is also useful in treating insulin-induced hypoglycemia. Despite the obvious benefits of glucagon in cardiac patients, its use has not become popular. This may be related to its high cost and the multiple metabolic and physiologic effects that are common after its administration. This pancreatic hormone may be of hemodynamic benefit when more conventional approaches have proved refractory in the following settings: (1) low CO syndrome following cardiopulmonary bypass, (2) low CO syndrome with myocardial infarction, (3) chronic congestive heart failure, and (4) excessive β-adrenergic blockade.

Digitalis Glycosides. The most important actions of the digitalis glycosides are those affecting myocardial contractility, conduction, and rhythm. The glycoside most likely to be used by the anesthesiologist is digoxin. The principal uses of digoxin are for the treatment of congestive heart failure and to control supraventricular cardiac dysrhythmia such as atrial fibrillation. Digoxin is one of the few positive inotropes that does not increase HR. Digoxin enhances myocardial inotropism and automaticity but slows impulse propagation through the conduction tissues.[142] Despite nearly two centuries of use, its mechanism of action is only modestly certain. Digitalis reciprocally facilitates calcium entry into the myocardial cell by blocking the Na+, K+ adenosine triphosphatase pump. This calcium influx may account for its positive inotropic action because this inotropic response is not catecholamine- or β-receptor-dependent and is therefore effective in patients taking β-blocking drugs. The inhibition of this enzyme transport mechanism also results in a net K+ loss from the myocardial cell. This contributes to digitalis toxicity with hypokalemia. Calcium potentiates the toxic effects of digitalis. Extreme caution should be observed when calcium is given to a patient taking digitalis or when digitalis administration is contemplated in the patient with hypercalcemia.

Synchrony of the cardiac beat is an important determinant of CO, and digoxin can be beneficial when heart failure is caused by a tachydysrhythmia, even in ischemic myocardial disease. However, the use of β- or calcium channel blockers is increasing in this regard because they both reduce overall myocardial oxygen consumption.

Digitalis has been of no benefit in cardiogenic shock and has proved potentially injurious in patients with uncomplicated myocardial infarction because of its vasoconstrictive properties and effects on myocardial oxygen consumption in the absence of cardiomegaly.

Care must be taken to rule out conditions in which the use of digitalis is of no benefit and is potentially harmful. These include mitral stenosis with normal sinus rhythm and constrictive pericarditis with tamponade. Signs and symptoms of idiopathic hypertrophic subaortic stenosis are often exacerbated by digitalis. With increased strength of contraction, the muscular obstruction can be markedly increased. The same is true for the use of digitalis in patients with infundibular pulmonic stenosis, as occurs with tetralogy of Fallot. Any augmentation of contractility may further reduce an already diminished pulmonary blood flow. Beware of digitalis toxic reactions in the older age group and in patients suffering from arterial hypoxemia, acidosis, renal compromise, hypothyroidism, hypokalemia, or hypomagnesemia as well as in patients receiving quinidine or calcium channel blockers.

The issue of prophylactic digitalization of patients with diminished cardiac reserve who are about to undergo major surgical procedures remains controversial.[142] Indications for preoperative digitalis in which the prophylactic administration of digoxin should be considered include the following: (1) previous heart failure, (2) increased heart size, (3) coronary flow disturbances according to electrocardiogram, (4) age over 60 years, (5) age over 50 years before lung surgery, (6) anticipated massive blood loss, (7) atrial flutter or fibrillation, (8) cardiovascular surgery, and (9) rheumatic valvular lesions.

When entertaining the possibility of perioperative digitalis administration, the following points must be considered. (1) Myocardial oxygen balance is threatened in the nonfailing, nondilated heart. (2) The therapeutic-to-toxic ratio of digitalis is narrow. (3) Inotropic drugs that are less

toxic and reversible are readily available. (4) Verapamil or β-blockers are more efficacious for supraventricular tachydysrhythmias not initiated by heart failure. (5) Digitalis may cause serious dysrhythmia in the unstable patient. (6) Serum potassium concentrations may fluctuate in the surgical patient. (7) Any cardiac dysrhythmia

that occurs in the presence of digitalis must be considered a toxic phenomenon. (8) Digitalis-induced cardiac dysrhythmias are difficult to treat. (9) Renal compromise will result in toxic effects with standard maintenance doses. (10) Cardioversion may be dangerous after digitalis administration. (11) After initiation of digitalis therapy, the administration of alternative drugs becomes more complicated.

Calcium Salts. Calcium is of great importance in the genesis of the cardiac action potential and is the key to controlling intracellular energy storage and utilization. Movement of extracellular calcium across membranes also governs the function of uterine smooth muscle as well as the smooth muscle of the blood vessels. The sympathomimetic drugs promote the transmembrane influx of calcium, whereas the β-blockers and calcium channel blockers inhibit such movement.

The American Heart Association has recommended against the use of calcium during cardiac arrest except when hyperkalemia, hypocalcemia, or calcium-entry inhibitor toxicity is present.[143]

Traditionally, calcium gluconate has been preferred in pediatric patients and calcium chloride in adult patients. Previous data held that calcium chloride produced consistently higher and more predictable levels of ionized calcium.[144] Studies have shown, however, that ionization of any of the preparations is immediate and equally effective.[145] Intravenous calcium appears effective for the transient reversal of hypotension thought to be the result of myocardial depression from the potent volatile anesthetic drugs.[146] Some clinicians feel that recurrent intraoperative hypotension response to calcium chloride may be an indication for the administration of digoxin. Calcium chloride is also given at the termination of cardiopulmonary bypass to offset the myocardial depression associated with hypothermic potassium cardioplegia and citrate. The use of calcium salts is clearly indicated during rapid or massive transfusions of citrated blood.[147] Citrate binds calcium, and rapid infusion rates of citrated blood result in myocardial depression that is reversible by calcium.

Three forms of calcium salts are available: calcium chloride, calcium gluconate, and calcium gluceptate. Calcium chloride produces only transient (10 to 20 minutes) increases in CO.[142] If inotropic effects are needed for a longer period of time, other inotropic agents should be selected. Bolus doses of 2 to 10 mg/kg (1.5 mg/kg/min) of calcium chloride can produce moderate improvement in contractility. The rapid administration of calcium salts, if the heart is beating, can produce bradycardia and must be used cautiously in the patient who is digitalized because of the hazard of producing toxic effects. Calcium gluceptate can be given in a dose of 5 to 7 mL (4.5 to 6.3 mEq) and calcium gluconate in a dose of 10 to 15 mL (4.8 to 7.2 mEq). These doses are approximately equivalent to that suggested for calcium chloride. Calcium gluconate is unstable and is no longer in frequent use. All of the calcium salts will precipitate as calcium carbonate if mixed with sodium bicarbonate.

Antidepressant Drugs

Monoamine Oxidase Inhibitors. Monoamine oxidase inhibitors (MAOIs) and the tricyclic antidepressants are used to treat psychotic depression. These drugs are not used in the practice of anesthesia but are a source of potentially serious anesthetics interactions in patients who are taking them chronically. Their use is rapidly declining as the nontricyclic antidepressants such as Prozac are more efficacious and produce fewer side effects. Table 12-19 lists the antidepressants that have been in use and is offered only to be historically complete. Few of the MAO inhibitors or tricyclic antidepressants will be encountered in an anesthesia practice today with the exceptions of phenelzine (Nardil) and amitriptyline (Amitril, Elavil). Their pharmacologic actions and side effects are a direct result of their effect on the cascade of catacholamine metabolism. The nontricyclics also produce their antidepressant effects via this cascade but linked to their inhibition of CNS neuronal uptake of serotonin.

TABLE 12-19 Antidepressant Drugs

▪NONPROPRIETARY NAME	▪TRADE NAME
Monamine Oxidase Inhibitors	
Isocarboxazid	Marplan
Pargyline	Eutonyl
Phenelzine	Nardil
Tranylcypromine	Parnate
Tricyclic Antidepressants	
Imipramine	Imavate, Janimine, Presamine, SK-Pramine, Tofranil
Desipramine	Norpramin, Pertofrane
Amitriptyline	Amitril, Elavil, Endep
Nortriptyline	Aventyl, Pamelor
Doxepin	Adapin, Sinequan
Protriptyline	Vivactil
Amoxapine	Asendin
Maprotiline	Ludiomil
Nontricyclics	
Trazodone	Desyrel
Fluoxetine	Prozac
Buproprion	Wellbutrin

MAOIs (see Table 12-19) block the oxidative deamination of endogenous catecholamines into inactive vanillylmandelic acid (see Fig. 12-12). They do not inhibit synthesis. Thus, blockade of monoamine oxidase would produce an accumulation of NE, EPI, dopamine, and 5-hydroxytryptamine in adrenergically active tissues, including the brain. Alleviation of depression may be related to elevations of the endogenous catecholamines. Overdose with MAOIs is expressed as SNS hyperactivity. They may produce agitation, hallucinations, hyperpyrexia, convulsions, hypertension, and hypotension. Orthostatic hypotension is a common complaint in patients taking MAOIs.[148]

The action of sympathomimetic amines is potentiated in patients taking MAOIs. Indirect-acting sympathomimetics (ephedrine, tyramine) produce an exaggerated response as they trigger the release of accumulated catecholamines. Foods containing a high tyramine content such as cheese, red Italian wine, and pickled herring can also precipitate hypertensive crises.[148] SNS reflex stimulation is also intensified by tyramine. Meperidine has also been reported to produce hypertensive crisis, convulsions, and coma with MAO inhibitors. Hepatotoxicity has been reported that does not seem to be related to dosage or duration of treatment. Its incidence is low but remains a factor in selecting anesthesia.

The anesthetic management of patients taking MAOIs remains controversial, although the need to discontinue them preoperatively is in question. Currently, recommendations for management include discontinuation of the drugs for at least 2 weeks before surgery; however, this recommendation is not based on controlled studies but rather is the result of limited case reports that suggest potent drug interactions.[149] Few adverse effects in humans taking MAOIs given analgesics, opioid anesthesia, or regional blocks have been reported.

However, opioids that cause release of catecholamines (meperidine) should be avoided in these patients. Symptoms of SNS overdose or interactions because of MAOIs can be treated effectively with α- and β-blockers or direct-acting vasodilators.

Tricyclic Antidepressants. This group of antidepressant drugs is referred to as tricyclic antidepressants because of their structure. The important tricyclic antidepressants are listed in Table 12-19. These drugs have almost replaced the MAOIs because of fewer side effects. All of these agents block uptake of NE into adrenergic nerve endings. Just as with the MAOIs, high doses of the tricyclic antidepressants can induce seizure activity that is responsive to diazepam.

Neuroleptic drugs may potentiate the effects of tricyclic antidepressants by competition with metabolism in the liver. Chronic barbiturate use increases metabolism of the tricyclic antidepressants by microsomal enzyme induction. Other sedatives, however, potentiate the tricyclic antidepressants in a manner similar to that occurring with the MAOIs. Atropine also has an exaggerated effect because of the anticholinergic effect of tricyclic antidepressants. Prolonged sedation from thiopental has been reported. Ketamine may also be dangerous in patients taking tricyclic antidepressants by producing acute hypertension and cardiac dysrhythmia.

Despite these serious interactions, discontinuation of these drugs before surgery is probably not necessary. The latency of onset of these drugs is from 2 to 5 weeks; however, the excretion of tricyclic antidepressants is rapid, with approximately 70% of a dose appearing in the urine during the first 72 hours. One might consider a discontinuation of the drug for 72 hours, but the risk of recurrent depression may be greater than that of any untoward drug reaction. The long latency period for resumption of treatment militates against interrupted treatment. A thorough knowledge of the possible drug interactions and autonomic countermeasures now available obviates postponement.

Nontricyclic Antidepressants. The nontricyclic antidepressants are listed in Table 12-19. Their mechanism of action is not fully known but all have in common selective inhibition of neuronal uptake of serotonin. This potentates the behavioral changes induced by the serotonin precursor, 5-hydroxytryptophan.[150] The availability of sympathetic antagonists for possible side effects during anesthesia weighs in favor of continuation of therapy versus the risk of exacerbation of a severe depression.[151]

Prozac (fluoxetine) is a popular oral nontricyclic antidepressant. Unlike desyrel, the elimination half-life of prozac is 1 to 3 days and can lead to significant accumulation of the drug. Prozac's metabolism, like that of other compounds including tricyclic antidepressants, phenobarbital, ethanol, and pentothal, involves the P450IID6 system; concomitant therapy with drugs also metabolized by this enzyme system may lead to drug interactions and prolongation of effect of the benzodiazepines.

Wellbutrin® and Zyban® are the same drug, namely buproprion hydrochloride. Zyban, however, is a sustained-release drug. Wellbutrin® is used as an antidepressant whereas Zyban® is marketed as a nonnicotine aid to smoking cessation. These drugs should not be used concomitantly. Overdose is possible with resultant seizures. Seizure activity is dose related. The neurochemical mechanism of the antidepressant effect of buproprion is not known. It does not inhibit monoamine oxidase and is a weak blocker of the neuronal uptake of serotonin and norepinephrine. It also inhibits the neuronal uptake of dopamine to some extent. No systematic data have been collected on the interactions of buproprion and other drugs. The mechanism by which Zyban® enhances the ability to abstain from smoking is unknown but perhaps it assists the patient through the mental vicissitudes of nicotine withdrawal. High doses higher than 300 mg can result in seizures.[152]

Adrenergic Antagonists—Sympatholytics

α Antagonists. Drugs that bind selectively to *α*-adrenergic receptors block the action of endogenous catecholamines or moderate the effects of exogenous adrenergics. The resultant effects may be ascribed together the blockade effect to *α*-adrenergic agonists or to unopposed *β*-adrenergic receptor activity. The effect is smooth muscle relaxation. The response to the vasculature may vary over a wide range in a single vascular bed depending on its intrinsic state of constriction. Vessels with higher initial tone have a greater response to *α*-blockade. Prominent clinical effects of *α*-blockers include hypotension, orthostatic hypotension, tachycardia and miosis; nasal stuffiness, diarrhea, and inhibition of ejaculation are common side effects.

The *α*-blockers may be classified according to binding characteristics (Table 12-20). Phenoxybenzmine is an oral *α*-blocker that produces an irreversible blockade. It is a relatively nonselective *α*-blocker. Phentolamine, tolazoline, and prazosin are characterized by reversible binding and antagonism.

TABLE 12-20 α-Adrenergic Blocking Drugs

	·TYPE OF ANTAGONISM	·SELECTIVITY
Phenoxybenzamine	Noncompetitive	$\alpha_1 > \alpha_2$
Phentolamine	Competitive	$\alpha_1 = \alpha_2$
Tolazoline	Competitive	$\alpha_1 = \alpha_2$
Prazosin	Competitive	$\alpha_1 >> \alpha_2$
Yohimbine	Competitive	$\alpha_2 >> \alpha_1$

Phentolamine is 100 times more potent on *α*-1 receptors than on *α*-2 receptors. Prazosin is also markedly specific for *α*-1 receptors, whereas phentolamine has nearly equal blocking activity on both subsets. Phentolamine, by blocking presynaptic inhibitory *α*-2 receptors, causes greater NE

release from the presynaptic terminal.

There are many *α*-blockers in use today for benign prostatic hypertrophy as well as essential hypertension. When patients are taking these drugs chronically, one should keep in mind that the normal autonomic response to stress, inhalation anesthetics, or extensive regional anesthesia may be blunted. Elevations of catecholamines will not reflexly increase peripheral vascular resistance and may actually decrease if vascular *β* receptors are unopposed. The effects are similar to the acute sympatholysis seen with spinal or epidural anesthesia. *α*-blockers are often used in combination with diuretics and other antihypertensives. Volume depletion may not be evident on preoperative examination but unmasked with the induction of anesthesia and the onset of a marked hypotension. This hypotension is usually responsive to volume repletion and the temporary use of a direct acting *α*-agonist such as neosynephrine. There is no cause for discontinuation of these drugs before surgery but preloading with iv fluids is suggested to ensure adequate central volume.

Phentolamine. Phentolamine is used almost exclusively in the diagnosis and treatment of pheochromocytoma. It is a competitive antagonist at *α*-1 and *α*-2 receptors. Phentolamine may also have some antihistaminic and cholinomimetic activity. The cholinomimetic activity may result in abdominal cramping and diarrhea, both of which are blocked by atropine. Tachycardia and hypotension are also common side effects.

Intravenously, phentolamine produces peripheral vasodilatation and a decrease in systemic blood pressure within 2 minutes lasting from 10 to 15 minutes. Blood pressure reduction elicits baroreceptor reflexes and NE release, the result of

which is an increased heart rate and cardiac output. Cardiac arrhythmias and angina pectoris may accompany phentolamine administration. It can be given in does of 30 to 70 *μ*g/kg iv to produce a transient decrease in blood pressure. It can also be used as a continuous infusion to maintain blood pressure during resection of a pheochromocytoma.

Phenoxybenzamine (Dibenzyline). Phenoxybenzamine acts as a nonselective *α*-adrenergic antagonist. *α*-blockade is 100 times more potent on postsynaptic *α*-1 receptors than at *α*-2 receptors. The onset of *α*-blockade is slow, taking up to 60 minutes to reach peak effect even with iv administration. This is related to the time required for structural modification of the phenoxybenzamine molecule to become active. The elimination half-life is about 24 hours.

Orthostatic hypotension is prominent especially in the presence of preexisting hypertension or hypovolemia. Cardiac output is often increased and renal blood flow is not greatly altered except in preexisting renal vasoconstriction or stenosis. Coronary and cerebral vascular resistance is not changed. In the past it was the drug of choice for treating patients with pheochromocytoma in preparation for surgery. It has been replaced with shorter acting, more specific drugs such as phentolamine.

Prazocin (Minipres). Prazocin is relatively selective for *α*-1 receptors that leaves the inhibiting effect of *α*-2 receptor activity on norepinephrine release intact. As a result, it is less likely that nonselective *α*-antagonists evoke reflex tachycardia. Prazocin dilates both arterioles and veins.

Cardiovascular effects include total body reductions in systemic vascular resistance and venous return. When combined with a diuretic, it is an effective antihypertensive drug. It should not be used with clonidine or *α*-methylodopa as it appears to decrease their effectiveness. Prazosin may also cause bronchodilation.

Several new oral *α*-1-blockers are now on the market that have been found useful for benign prostatic hypertrophy (BPH) and hypertension. The anesthesiologist may commonly encounter patients taking these medications on a chronic basis and must be aware of their possible interactions with anesthetics. Doxazosin is a long-acting selective *α*-1-blocker used for both in treating benign prostatic hypertrophy and hypertension. The most common side effect, as with all *α*-blockers, is orthostatic hypotension and dizziness. Tamsulosin (flomax) is another *α*-blocker that is used for BPH. It is not indicated for hypertension but it is capable of producing orthostatic

hypotension.

***β* Antagonists.** *β*-adrenergic-blockers were introduced in the 1960s. Cardiovascular pharmacology has been dominated by the age of these sympatholytic agents that ushered out the age of the pressor. As more indications for their use have been found, more compounds have been developed. They are among the most common drugs used in the treatment of cardiac disease and hypertension. At present, there are *β*-blocking agents available for oral or intravenous use in the United States. A variety of drugs are available with *β*-blocking activity that may be distinguished by differing pharmacokinetic and pharmacodynamic properties. Examples of some of the drugs available and their diversity of actions are listed in Table 12-21.

TABLE 12-21 β-Adrenergic Blocking Drug

·DRUG	·TRADE NAME	·RELATIVE β_1 SELECTIVITY	·MEMBRANE-STABILIZING ACTIVITY	·INTRINSIC SYMPATHO-MIMETIC ACTIVITY	·PLASMA HALF-LIFE (hr)	·ORAL AVAILABIL (%)

[a]Primarily hepatic, but active metabolites are formed that must be renally excreted.

β-blocker with selective properties for the β-1 receptor would bind to the cardiac receptors, whereas a nonselective β-blocker would bind to both β-1 (cardiac) and β-2 (vascular, bronchial smooth muscle, and metabolic) receptors. Their biological potency and affinity for β receptor subtypes is determined by their ability to inhibit tachycardia and vasodilatation induced by isoproterenol, a pure nonselective β agonist. Nonselective β antagonists are referred to as first-generation β-blockers. These include propranolol, nadolol, sotalol, and timolol. Second-generation drugs are those considered selective for β-1 adrenergic blockade. These include atenolol, esmolol, and metoprolol.

Those β-blockers possessing ISA exert the partial effect of a partial β agonist while blocking β receptors by more potent β agonists. ISA might be advantageous in patients needing β-blockers but who are troubled by bradycardia or worsening ventricular failure.[153] A distinct advantage to ISA in β-blockers has not been shown in clinical studies.

Over the past decade, and because of their selectivity, the use of β-blockers has expanded to include the treatment of congestive heart failure (CHF).[154] CHF was once a contraindication for the use of β-blockers. This is the result of better understanding of the fluid nature of up- and downregulation of β receptor density once thought to be static.

Selective β-blockade could be of greater benefit in treatment of patients with obstructive airway disease, diabetes, or peripheral vascular disease. However, it must be emphasized that specificity is a relative term and not absolute. Nonselective blocking effects may be seen in all tissues if higher blood levels are reached with "selective" drugs (see Fig. 12-13). For example, the use of β-1 selective blockers in patients with obstructive or reactive airway disease remains controversial. Patients with reactive airway disease may develop serious reductions in ventilatory function even with β-1 selective antagonists.[155] Other drugs are available for treatment of supraventricular arrhythmias and hypertension in asthmatics.

Sympathetic activation generally results in increased circulating glucose levels secondary to enhanced glycogenolysis, lipolysis, and gluconeogensis. Administration of β-2-blockers to insulin-dependent diabetics reduces their ability to recover from hypoglycemic episodes.[156] β-2 antagonists are preferable.

β-blocker therapy should be continued until and after the time of surgery. This issue is no longer controversial for several reasons. Acute withdrawal of β antagonists may produce a hemodynamic withdrawal syndrome similar to thyrotoxicosis.[58] Control of HR and blood pressure perioperatively is easier if chronic medications are continued for the co-morbid factors for which they were prescribed. HR is a major determinant of myocardial oxygen demands. Tachycardia is known to increase the risk of poor outcome in patients with ischemic heart disease,[157] therefore hemodynamic control of HR and BP (work) is important in reducing perioperative risk. In a complete turnabout from a decade ago, several well-founded studies have shown the benefits of prophylactic β-blockade with atenolol in patients at risk for ischemic cardiac disease.[158] The reduction in perioperative morbidity and mortality in these groups of patients was significant.

Several of the β-blockers listed in Table 12-21 also have a local anesthetic-like effect on myocardial membranes at high doses. This effect is similar to that of quinidine in that phase 0 of the cardiac action potential is depressed, slowing conduction. This membrane-stabilizing activity is caused by the D-isomer, whereas the L-isomer is responsible for β-blocking activity. The clinical significance of membrane-stabilizing activity is unclear.

Propranolol. Propranolol is the prototype β-blocking drug against which all others are compared. It is nonselective and has no intrinsic sympathomimetic activity but does have membrane-stabilizing activity at higher doses. It is available in both iv and oral forms. It is highly lipophilic and is metabolized by the liver to more water-soluble metabolites, one of which, 17-OH propranolol, has weak β-blocking activity. There is a significant first-pass effect by the liver after oral administration of the drug. It is highly protein bound, and the free drug level may be altered by other highly bound drugs. The elimination half-life is approximately 4 hours, but the pharmacologic half-life is around 10 hours.

Hemodynamic effects include decreased HR and contractility. The major factors contributing to the decrease in blood pressure by propranolol are decreased CO and renin release. Systemic vascular resistance may increase on acute administration owing to blockade of β-2 receptors in the peripheral vasculature. With chronic administration, however, peripheral vascular resistance decreases. This is thought to be secondary to decreased renin release and, possibly, decreased central SNS outflow. Complications with the use of propranolol include bradycardia, heart block, worsening of congestive heart failure, bronchospasm, and sedation. During anesthesia with halothane, it may cause severe bradydysrhythmias.

Nadolol. Nadolol is a noncardioselective β-blocker with no membrane-stabilizing activity or intrinsic sympathomimetic activity. It is approximately equipotent to propranolol, but its effects are prolonged owing to slower elimination. It is relatively lipid insoluble and is excreted 70% unchanged in urine and 20% in the feces. The elimination half-life is 24 hours. Because it is lipid insoluble, it does not cross the blood-brain barrier, and sedation is less of a problem than with propranolol. Hemodynamic effects are the same as for propranolol. The main advantage of the drug is the capability for once per day dosing.

Timolol. Timolol is also noncardioselective with little intrinsic sympathomimetic activity and no membrane-stabilizing activity. It is the only β-blocker used as the l-isomer rather than the racemic mixture. It is 5 to 10 times as potent as propranolol. Hepatic metabolism accounts for approximately 66% of its elimination, and another 20% is found unchanged in the urine. The elimination half-life is 5.6 hours, and the pharmacologic half-life is approximately 15 hours. It was first used topically for treatment of glaucoma but is now used in hypertension and has been shown to decrease the risk of reinfarction and death following myocardial infarction.[159] Its hemodynamic effects and side effects are similar to those of other β-blockers. The anesthesiologist should also be aware that timolol eye drops may be absorbed systemically and cause bradycardia and hypotension that are refractory to treatment with atropine.[160]

Pindolol. Pindolol is a nonselective β-blocker with membrane-stabilizing activity and intrinsic sympathomimetic activity. It is 10 to 40 times as potent as propranolol. It is lipid soluble and metabolized by the liver but not as avidly extracted; therefore, its biologic availability after oral administration is more predictable. It is excreted 40% unchanged in the urine. The elimination half-life is 3.5 hours. It is useful in the treatment of angina pectoris, cardiac dysrhythmia, and hypertension. As discussed earlier, the clinical usefulness of the intrinsic sympathomimetic activity property is unclear.

Oxprenolol. Oxprenolol is similar to pindolol except for less intrinsic sympathomimetic activity and lower potency.

Metoprolol. Metoprolol is a relatively selective β-blocking drug with β-blocking effects at moderate and high doses. It has neither intrinsic sympathomimetic activity nor membrane-stabilizing activity. It has a possible advantage in patients with reactive airway disease at oral doses up to 100 mg/day^{-1}. In this case, it should probably be used with a β-2 mimetic drug. It is mostly metabolized in the liver, with only about 5% excreted unchanged in the urine. The elimination half-life is 3.5 hours. It has recently become available in iv as well as oral form; therefore, it may be useful during anesthesia.

Atenolol. Atenolol is similar to metoprolol in that it is relatively cardioselective and has no intrinsic sympathomimetic activity or membrane-stabilizing activity. It is less lipophilic, however, and is eliminated primarily by renal excretion. The elimination half-life is 6 to 7 hours. The lack of first-pass metabolism results in more predictable blood levels after oral dosing.

Acebutolol. Acebutolol is a cardioselective β-blocker with intrinsic sympathomimetic activity and membrane-stabilizing activity. It is metabolized in the liver and is subject to extensive first-pass metabolism. The primary metabolite is diacetolol, which has a pharmacologic profile similar to that of the parent drug and is excreted renally. The pharmacologic effects of the drug, therefore, are dependent on both hepatic transformation and renal excretion. The elimination half-life of acebutolol is 3 to 4 hours and of diacetolol 8 to 13 hours. Elimination is prolonged in the elderly

and patients with renal disease. Acebutolol, like pindolol, has intrinsic sympathetic activity that makes it more advantageous than the other β-blockers in patients with bradydysrhythmias or myocardial failure.

Esmolol. Esmolol has several uses in the perioperative period.[161] The most unique feature of the drug is the ester function incorporated into the phenoxypropanolamine structure. This allows for rapid degradation by esterases in the red blood cells and a resultant pharmacologic half-life of 10 to 20 minutes.[161] Esmolol is cardioselective and appears to have little effect on bronchial or vascular tone at doses that decrease HR in humans. It has been used successfully in low doses in patients with asthma[162] but caution is again advised when using β-blockers in these patients.[163] Esmolol is metabolized rapidly in the blood by an esterase located in the red blood cell cytoplasm. It is different from the plasma cholinesterase and is not inhibited to a significant degree by physostigmine or echothiophate but is markedly inhibited by sodium fluoride. There are no apparent important clinical interactions between esmolol and other ester-containing drugs. At the highest infusion rates (500 μg/kg/min), esmolol does not prolong neuromuscular blockade by succinylcholine.

Esmolol has proven to be useful in the perioperative period because of its capability to be administered intravenously and its short half-life.[164] This feature permits a trial of β-blockade in doubtful situations. Esmolol has been shown to blunt the response to intubation of the trachea[161] and is moderately effective in treating postoperative hypertension.[165] Most reported studies in humans have used doses of 50 to 500 μg/kg/min. The most beneficial approach seems to be a loading dose of 500 μg/kg over 30 seconds, followed by continuous infusion of 50 to 300 μg/kg/min. Peak blockade appears to occur within 5 minutes. On discontinuation of the infusion, serum levels decline with an elimination half-life of 9 minutes. The HR response to isoproterenol returns to control in 20 minutes.

Betaxolol. Betaxolol hydrochloride is a β-1 selective (cardioselective) adrenergic receptor antagonist and is freely soluble in water. It has weak membrane-stabilizing activity and no intrinsic sympathomimetic (partial agonist) activity. The preferential effect on β-1 receptors is not absolute. Some β-2 inhibitory activity can be expected in the bronchial and vascular musculature at higher doses. Absorption of an oral dose is complete, with an absolute bioavailability of 90% that is unaffected by ingestion of food or alcohol. The mean elimination half-life is from 11 to 22 hours. It is eliminated primarily by the liver but secondarily through the kidneys. Betaxolol is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents.

Penbutolol. Penbutolol is a synthetic β receptor antagonist for oral administration. It is a nonselective β receptor antagonist with some intrinsic sympathomimetic activity. Penbutolol does not appear to have any membrane-stabilizing properties, as does propranolol. Plasma elimination half-life is 5 hours in normal subjects. Ninety percent of radioactive penbutolol was found to be excreted in the urine. There is no change in the effective half-life of penbutolol in healthy patients versus those on renal dialysis. It is indicated primarily for the treatment of

hypertension and may be used in combination with other antihypertensives.

Carteolol. Carteolol is a synthetic, nonselective, β-adrenergic–receptor-blocking agent with intrinsic sympathetic activity. It possesses no significant membrane-stabilizing (local anesthetic) activity and is without value in treating intrinsic arrhythmias. Carteolol has equivocal effects on renin secretion because of its intrinsic sympathomimetic activity, in contrast to β-blockers without such activity, which inhibit renin. Carteolol is well absorbed with a half-life of approximately 6 hours. About 50 to 75% of the drug is eliminated by the kidneys; thus, renal impairment increases its half-life in proportion to the reduction in creatinine clearance. Carteolol is primarily indicated for the management of hypertension but may be used in combination with other potent drugs.

Mixed Antagonists

Labetalol. Labetalol is an antihypertensive drug with blocking activity at both α and β receptors. The relative α-/β-blocking effects are dependent on the route of administration. After oral

administration, the ratio of α/β effectiveness is 1:3; however, when given intravenously, it is 1:7 (i.e., it is three and seven times more potent on β than on α receptors, respectively). The α effects are primarily on α-1 receptors, whereas the β effects on nonselective.

Hemodynamic effects consist primarily of decreased peripheral resistance and decreased or unchanged HR with little change in CO. Serum renin activity is decreased. Maintenance of lower HRs in the presence of decreased systemic blood pressure is beneficial in controlling the myocardial oxygen supply/demand ratio and is a major benefit of labetalol in patients with coronary artery disease.

Labetalol is eliminated by hepatic glucuronide conjugation. The elimination half-life after iv administration is 5.5 hours and 6 to 8 hours after oral use. Elimination is not markedly prolonged in patients with hepatic or renal failure. Another advantage of the drug is the ability to convert from iv to oral forms of the same drug after the patient is stable. For treatment of hypertension when used as a bolus, the initial dose is 0.25 mg/kg iv over 2 minutes, then repeated every 10 minutes to a total of 300 mg. When used as a continuous infusion, it is usually started at 2 mg/min and titrated to effect. Because there is an enhanced effect by inhalation anesthetics, these doses should be decreased when used intraoperatively.

Complications and contraindications are similar to those for the β-blockers. Labetalol should be used with caution in patients with compromised myocardial function because it may worsen heart failure. Also, owing to β-blocking activity, the drug may induce bronchospasm in asthmatics. As with other β-blockers, abrupt withdrawal is not recommended.

Calcium Entry Blockers

Calcium is regarded as the universal messenger in cells and plays a critical role in a number of biologic processes. It is involved in blood coagulation, a broad array of enzymatic reactions, the metabolism of bone, neuromuscular transmission, the electrical activation of various excitable membranes, as well as endocrine secretion and muscle contraction. Calcium initiates several physiologic events in the specialized automatic and conducting cells in the heart. It is involved in the genesis of the cardiac action potential, and it links excitation to contraction and controls energy stores and utilization. Movement of extracellular calcium across membranes also governs the function of smooth muscle in bronchi and in coronary, pulmonary, and systemic arterioles.

Membrane calcium channels are known to exist that provide a pathway for calcium influx across cell membranes that differs from calcium efflux movements associated with active pumps or exchange. The inward calcium channel exhibits two distinguishing properties: (1) selectivity in that they have the ability to distinguish between ion species and (2) excitability in that they have the property of responding to changes in membrane potential. Separate, ion-specific, channels for sodium and calcium influx are thought to exist. The status of these channels can vary to produce three kinetic states: resting, activated, and inactivated. Sodium channels are referred to as fast channels because the transition among resting, activated, and inactivated states is more rapid than among the calcium channels. Thus, calcium channels are often referred to as membrane "slow channels."[166]

Classification of calcium entry blockers has been difficult since their discovery. They were initially thought to be β-adrenergic-blocking drugs because of their sympatholytic action. Later they were called calcium antagonists. It is clear, however, that these drugs are not true pharmacologic antagonists of calcium. Instead, they interact with the cell membrane to control the intracellular concentration of calcium. The correct terminology for this group of drugs appears to be calcium entry blockers. Slow channel inhibitors or calcium channel blockers are alternate terms. The molecular structures of three clinically useful calcium entry blockers are seen in Figure 12-31. Calcium entry blockers are a heterogeneous group of drugs with dissimilar structures and electrophysiologic and pharmacologic properties. Despite structural dissimilarities, this group shares some important actions that are consistent with the known importance of extracellular calcium and adrenergic function. Any drug that alters slow-channel kinetics could be expected to produce vasodilatation, to depress cardiac conduction velocity (dromotropism), to depress contractility (inotropism), and to decrease HR (chronotropism). All calcium entry blockers

do this, but with varying degrees of potency in the intact human and in vitro (Table 12-22).[167] Thus, despite their similarities, these drugs cannot be considered therapeutically interchangeable. Clinically, nifedipine is a potent coronary artery vasodilator with little direct effect on cardiac conduction. It may reduce dysrhythmia secondarily when increased coronary blood flow is of benefit. Verapamil is valued for its specific antidysrhythmic activity, but it is a myocardial depressant with little vasodilator activity. Verapamil also has slightly greater local anesthetic activity (fast-channel inhibition) than procaine on an equimolar basis.[168] The significance of this observation in humans has not been established. The structural heterogeneity of this group of drugs also suggests more than one site and mechanism of action. Although the molecular basis of the action of these compounds is unknown, they are lipophilic, and it appears likely that they work by producing conformational changes in the cell membranes.

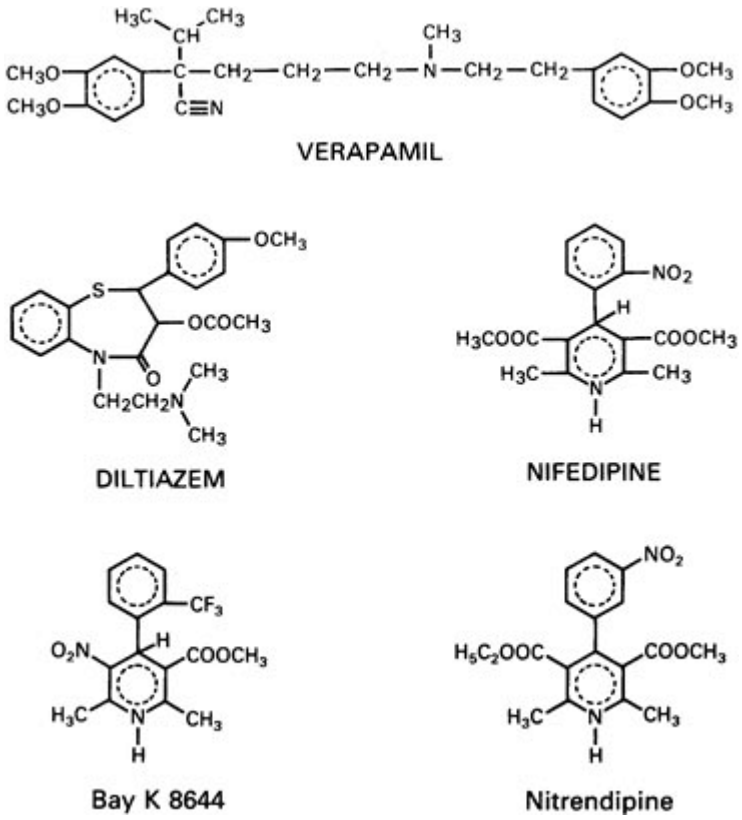

FIGURE 12-31. Structural formulas of the calcium entry blockers demonstrate dissimilar structures consistent with their dissimilar electrophysiologic and pharmacologic properties. They also share some similarities but cannot be considered therapeutically interchangeable. Nifedipine and nitrendipine are structurally similar and are both potent vasodilators; BAY K 8644 is also similar but is a calcium channel agonist.

TABLE 12-22 Autonomic Effects of Calcium Entry Blockers in Intact Humans

	·VERAPAMIL	·DILTIAZEM	·NIFEDIPINE	·LIDOFLAZINE
Negative inotropic	+	0/+	0	0
Negative chronotropic	+	0/+	0	0

Negative dromotropic	++++	+++	0	0
Coronary vasodilation	++	+++	++++	++++
Systemic vasodilation	++	++	++++	+++
Bronchodilation	0/+		0/+	

The useful pharmacologic effects of the calcium entry blockers have been confined almost solely to the cardiovascular system, although the list of uses will likely grow.[166] Table 12-23 lists some of the areas of investigation in which they appear to be of clinical benefit. Calcium entry blockers have been described, perhaps erroneously, as selective slow-channel blockers. A review of the literature, however, suggests that these agents are not selective but rather that the slow-channel effects on the cardiovascular system are just more apparent. Their lack of selectivity should not be surprising considering the critical role calcium plays in a wide variety of biologic processes. The sensitivity of a given tissue to the calcium entry blockers is related to that tissue's dependence on extracellular calcium for its function. This would explain the sensitivity of the calcium-dependent myocardium and smooth muscle to these blockers on the one hand and the apparent insensitivity of striated muscle on the other. Extracellular calcium is relatively insignificant in the function of striated muscle, where the SR is the major storage organelle of calcium. Striated muscle can recycle intracellular calcium for prolonged periods, which is in keeping with its function of sustained contraction as opposed to the rhythmic or cyclic contraction of the myocardium and smooth muscle.

TABLE 12-23 Uses of Calcium Channel Blockers

Vascular Disorders	**Nonvascular Disorders**
Systemic hypertension	Bronchial asthma
Pulmonary hypertension	Esophageal spasm
Cerebral arterial spasm	Dysmenorrhea
Raynaud's phenomenon	Premature labor
Migraine	

The drugs are all absorbed via the gastrointestinal tract, but the extensive first-pass hepatic extraction of verapamil limits its bioavailability orally (Table 12-24). Onset of action is equivalent for all three drugs and is consistent with rapid membrane transport. All three drugs are

extensively protein bound and subject to the effect of changes in plasma protein concentration and competition from other protein-bound drugs and metabolites, but final elimination of verapamil and nifedipine is primarily renal.

TABLE 12-24 Comparative Pharmacology of Calcium Entry Blockers

	▪VERAPAMIL	▪DILTIAZEM	▪NIFEDIPINE
Dose			
Oral	80–160 mg tid	60–90 mg tid	10–20 mg tid
iv	75–150 μg/kg	75–150 μg/kg	5–15 μg/kg
Absorption			
Oral (%)	>90%	>90%	>90%
Bioavailability			
Oral (%)	<20%	?<20%	60–70%[a]
Onset			
Oral	15–20 min	20–30 min	15–20 min
iv	1 min	?	1 min
Sublingual	—	—	3 min
Peak Effect			
Oral	5 hr	30 min	1–2 hr

Side effects	Constipation, headache, vertigo, hypotension, atrioventricular conduction disturbances	Headache, dizziness, flushing, atrioventricular conduction disturbances, constipation	Headache, hypotension, flushing, digital dysesthesias, leg edema
[a]Light sensitive.			

Verapamil

Verapamil is a calcium entry blocker that is administered intravenously for terminating supraventricular tachydysrhythmias. Nearly all forms of supraventricular tachydysrhythmias are caused by reentry using either the sinoatrial or the AV node as part of the circuit. Verapamil terminates these cardiac dysrhythmias by decreasing nodal conductivity, converting the unidirectional block of reentry to a bi-directional block. In this regard, its action on supraventricular dysrhythmia is similar to that of quinidine on ventricular reentry cardiac dysrhythmia.

Verapamil does not alter the action potential upstroke in fibers whose resting membrane potential is more negative than -60 mV (i.e., fast-action potentials).[169] It does slow or prevent depolarization in cardiac tissue with a resting membrane potential that is less negative than -50 mV (i.e., calcium-dependent upstroke). Verapamil, therefore, has profound effects on pacemaker cells, which depend on the calcium current for depolarization.[170] It depresses the rate of sinus discharge, reduces conduction velocity, and increases refractoriness of the AV node. A dose-dependent increase in the PR interval and AV interval is produced on the electrocardiogram. This has been described as a quinidine-like effect similar to that produced by Class IA antidysrhythmic drugs (e.g., procainamide), which are also effective for supraventricular dysrhythmia. In contrast to the procainamide, verapamil does not increase the QRS or Q-T interval because it lacks activity on the sodium-dependent action potentials.

Verapamil is a first-line drug for treatment of supraventricular tachydysrhythmias (Table 12-25). The incidence of successful termination of paroxysmal atrial tachycardia with verapamil in adults has approached 90%.[171] It is also effective in treating atrial fibrillation and atrial flutter by either converting to a sinus rhythm or slowing the ventricular response. The ventricular rate will slow as a result of decreased conduction velocity through the AV node even when conversion is not produced. Caution must be exercised in treating patients when the underlying cause of the atrial tachycardia, atrial fibrillation, or atrial flutter is the Wolff-Parkinson-White syndrome. An

accessory bypass tract lies near the AV node that participates in the re-entry of these tachydysrhythmias. Verapamil may terminate the tachydysrhythmia by its specific depressant effects on the AV node, which is one limb of the re-entrant pathway. It may also increase conduction velocity in the accessory tract, in which case the HR may actually increase.

TABLE 12-25 Actions of Calcium Entry Blockers

Verapamil
Vasodilator
↓ systemic vascular resistance → ↑ heart rate → ↑ ejection fraction and cardiac output
Small decrease in left ventricular dP/dt
Little or no change in coronary resistance ↓ conduction through atrioventricular node (↑ P-R interval)
Should not be given with digitalis or β blockers
Diltiazem
More like verapamil than nifedipine
Dilates coronary more than systemic vessels and has less marked hemodynamic effects than nifedipine or verapamil
Little effect on cardiac output
Does not cause tachycardia
Effects on conduction system similar to those of verapamil
Less inotropic effect than verapamil
Nifedipine
Rapid onset of action, may be used sublingually
Potent peripheral vasodilator, may be useful in treatment of hypertension
Has little clinically important negative inotropic activity
Less tendency to produce cardiac decompensation than verapamil
Little effect on nodal activity and no antiarrhythmic activity; therefore causes no electrocardiographic changes
Increased coronary blood flow in normal and ischemic myocardium

Verapamil has no adverse effects on bronchial asthma or obstructive lung disease and may be selected over propranolol in patients with these conditions. It should be avoided in patients with sick sinus syndrome, AV block, and the presence of heart failure, unless the heart failure is the result of a supraventricular tachycardia.

Studies further support the hypothesis that Ca^{2+} participates directly in the genesis of ventricular dysrhythmia.[172] When sodium channels are inactivated by hypoxia, stretch, or hyperkalemia, the remaining Ca^{2+} can produce a depolarizing current in these abnormal cells, especially in the presence of catecholamines. The conversion of a fast response cell to a cell with slow response characteristics presents all the necessary ingredients for the reentry phenomenon: slow depolarization and delayed conduction. The resulting ventricular dysrhythmia can usually be terminated with one of the Class I drugs as long as the resting membrane potential of the slow response is between −80 and −60 mV. Verapamil has been effective in terminating ventricular tachycardias and premature depolarizations in about two-thirds of the treatment trials when other drugs have failed. The resting membrane potential of these abnormal "slow response" foci has been postulated to be less negative than −60 mV, a range in which lidocaine would be ineffective on the calcium current conduction and depolarization. More information is needed before recommendations can be made for verapamil in treating dysrhythmia other than supraventricular tachydysrhythmias. Other drugs are

significantly more effective for the initial treatment of ventricular dysrhythmia.

The important side effects of verapamil are directly related to its predominant pharmacologic action (see Table 12-25). It may produce unwanted AV conduction delays and bradycardia, resulting in cardiovascular collapse. Verapamil must be used carefully, if at all, in the presence of propranolol. The combined effect has produced complete heart block in animals and humans. It must be used carefully in digitalized patients for the same reason. No such interactions exist with nifedipine. The combination of β-blockade and nifedipine may be beneficial in patients with ischemic heart disease because the reflex tachycardia seen with nifedipine can be countered with β-blockade.

Nifedipine

Nifedipine is the most potent calcium entry blocker when tested in isolated tissue preparations. It is an equipotent cardiac depressant and vasodilator. Depression of inotropism and cardiac conduction, however, is not evident in the intact human. It does not affect baroreflex mechanisms and, as a result, the marked vasodilation is accompanied by increased SNS tone and afterload reduction (see Table 12-25).[166] A compensatory tachycardia may result, and CO may actually increase as a result of the afterload reduction.

The most specific therapeutic application for nifedipine is coronary vasospasm (variant of Prinzmetal's angina). It has been more successful than nitroglycerin for this purpose because it produces a more profound and predictable coronary vasodilation. It has also been extremely useful in other types of ischemic heart disease, ranging from unstable angina to myocardial infarction. The decrease in myocardial oxygen demand that results from the reduced afterload and reduced left ventricular volume appears to be the mechanism for the relief of angina. Coronary vasodilation is another factor, but it is not known if this is the antianginal effect in patients with coronary artery disease. The dilating effect may last only 5 minutes, but the antianginal effect may last more than 1 hour.

Diltiazem

The hemodynamic effects of diltiazem lie somewhere between those of verapamil and nifedipine.[166] It is less potent than either of these two agents. Diltiazem is a good coronary artery dilator but a poor peripheral vasodilator. It often produces bradycardia and delayed conduction, and reflex tachycardia is not a problem. It appears to be an effective oral drug for the treatment of coronary disease in which cardiac dysrhythmias are troublesome. Cardiac dysrhythmias are noticeably a part of the clinical picture in patients suffering from coronary spasm. Intravenous administration of diltiazem is effective therapy for supraventricular tachycardias including PSVT, atrial fibrillation, atrial flutter, and reentrant tachycardias such as Wolff-Parkinson-White syndrome.[173] Like verapamil, diltiazem acts by prolonging AV nodal conduction. The peripheral vascular effects of diltiazem, though, are less severe, making it a more desirable therapeutic choice in most cases. A bolus dose of 0.25 mg/kg is administered over 2 minutes and may be repeated at 0.35 mg/kg if necessary after 15 minutes. An infusion of 5 to 15 mg/hr may be necessary to maintain the reduction of HR.

Nicardipine

Nicardipine hydrochloride is a calcium channel blocker that can be administered orally and intravenously. It is the only calcium channel blocker that can be titrated intravenously to achieve blood pressure response. Nicardipine is a smooth muscle relaxant producing vasodilation of peripheral and coronary arteries. It has a rapid onset of action, and the major effects last 10 to 15 minutes. Toxic metabolic products are not produced. It has minimal cardiodepressant effects and does not decrease the rate of the sinus node pacemaker or slow conduction through the AV node. Renal failure does not affect the dosage, but the dosage should be reduced in the elderly and those with hepatic dysfunction. It is compatible with most crystalloid solutions. Side effects of nicardipine include headache, lightheadedness, flushing, and hypotension. Reflex tachycardia is not a frequent finding with nicardipine, as is the case with nitroprusside, hydralazine, or nifedipine.

Nimodipine

Nimodipine is highly lipophilic. It has a greater vasodilating effect on cerebral arteries than on vessels elsewhere because of its lipophilism, which promotes crossing the blood-brain barrier. Clinical studies demonstrate a favorable effect on the severity of neurologic deficits caused by cerebral vasospasm following subarachnoid hemorrhage. However, no radiographic evidence has been presented that nimodipine either prevents or relieves spasm of these arteries. The mechanism for clinical improvement is not known. It is primarily an oral drug that is rapidly absorbed, with a T-terminal half-life of approximately 8 to 9 hours. Earlier elimination rates are much more rapid, which results in a need to redose every 4 hours. The bioavailability of an oral dose is only 13%. Dosage should be reduced in patients with hepatic dysfunction. The primary indication for nimodipine is for the improvement of neurologic deficits caused by spasm following subarachnoid hemorrhage from a ruptured aneurysm.

Felodipine

Felodipine is a second-generation calcium channel inhibitor. Nimodipine and felodipine have demonstrated selectivity for vascular tissue beds. Whereas nimodipine preferentially dilates cerebral vessels, felodipine preferentially dilates peripheral resistance vessels. Neither has significant effects on cardiac muscle. This has important clinical implications in the treatment of hypertension. Early studies indicate that 10 to 20 mg of felodipine daily will reduce blood pressure without reducing CO or HR. Coronary blood flow increases, but no effect on ventricular contraction or relaxation has been reported. This would make the drug appropriate for the active hypertensive patient.

Calcium Entry Blockers and Anesthesia

Evidence indicates that halothane depresses slow-channel kinetics. All of the potent inhalation anesthetics behave in a similar fashion in that they depress myocardial contractility and vascular tone in a dose-related manner. Most studies indicate that the calcium entry blockers and inhalation anesthetics exert additive effects on the inward calcium current.[167] Opioid anesthetics do not appear to add anything to the effects of the calcium entry blockers. Several recent studies indicate an interaction between the calcium entry blockers and the neuromuscular blocking drugs similar to that seen with the mycin antibiotics.[166] This interaction is not well defined, but in vitro and in vivo studies indicate a reduced margin of safety with these drug combinations. Calcium entry blockers appear to augment the effects of both depolarizing and nondepolarizing muscle relaxants.[174] These observations serve as a word of caution because their clinical significance has not been defined. Prolonged apnea and relaxation have been reported when verapamil was used to treat a supraventricular tachycardia in a patient with Duchenne's muscular dystrophy.[175]

Calcium entry blockers should be continued until the time of surgery to maintain control of angina pectoris, hypertension, or cardiac dysrhythmia.[166] It could be anticipated that sudden

discontinuation of these drugs theoretically could produce a rebound of symptoms, although this phenomenon has not been reported. Up-regulation of calcium receptors would probably occur during periods of entry blockade.

Verapamil may increase the toxicity of digoxin, the benzodiazepines, carbamazepine, oral hypoglycemics, and possibly quinidine and theophylline.[176] Cardiac failure, AV conduction disturbances, and sinus bradycardia may be more frequent with concurrent use of β-blockers, and severe hypotension and bradycardia may occur with bupivacaine. Decreased lithium effect and lithium neurotoxicity have both been reported with the concurrent use of verapamil.[177] The effects of verapamil may also be increased by cimetidine.

Vasodilators

Increased awareness and treatment of hypertension over the last 20 years has resulted in increasing numbers of patients presenting for anesthesia and surgery who are taking one or more

antihypertensive medications. These drugs are numerous, affect multiple organ systems, and have the potential for many deleterious interactions in the perioperative period. Most antihypertensive drugs blunt the ANS or its effector organs or cause reflex increases in ANS outflow. Most anesthetic agents also inhibit ANS tone to some degree and may therefore have additive effects with antihypertensive drugs. In addition, patients with hypertension may exhibit greater lability in blood pressure intraoperatively and rebound hypertension in the postoperative period. The anesthesiologist should therefore maintain a thorough understanding of the commonly used antihypertensive drugs. A rational approach to their perioperative use includes decisions as to holding or continuing them preoperatively, possible interactions with anesthetic drugs, and resumption of treatment postoperatively. The commonly used antihypertensive drugs are grouped below according to their primary mechanism of action and discussed briefly with emphasis on consideration for the anesthesiologist.

Diuretics

Diuretics are the most common prescribed drugs for hypertension. Their basic mechanisms of action are decreased plasma and extracellular volumes. Although the thiazides and furosemide have been shown to have vasodilating properties, the clinical significance of this effect is unclear. Chronic diuretic therapy results in decreased intravascular volume. The cardiovascular response to induction of anesthesia may therefore be accentuated, resulting in hypotension and tachycardia. Other problems associated with diuretic use include hypokalemia, hyponatremia, hypocalcemia, and hyperglycemia. Chronic hypokalemia is common with diuretic therapy and may predispose the patient to cardiac arrhythmias.[178] The clinical relevance of perioperative hypokalemia is unclear and has stirred considerable debate among anesthesiologists as to whether surgery should be postponed until plasma potassium levels are treated.[179]

Sympatholytics

Sympatholytic drugs include those that block central SNS outflow or NE release from the presynaptic neuron at the effector site. Currently included in this group are *α*-methyldopa and clonidine.

***α*-Methyldopa.** *α*-methyldopa is a catechol derivative that is enzymatically converted to active compounds by enzymes in the catecholamine synthesis chain (see Fig. 12-9). *α*-methyldopamine and *α*-methlynorepinephrine are the primary metabolites. The precise mechanism responsible for decreased SNS tone is unclear, but it is thought that *α*-methylnorepinephrine, which is stored in presynaptic vesicles, is released and stimulates presynaptic *α*-2 receptors, thereby inhibiting NE release. Because of the unique metabolism of *α*-methyldopa to the active compound and the storage of the metabolite in presynaptic vesicles, both the time to onset and duration of action are long. Even after iv administration, the peak effect may not be seen for several hours. Although the elimination half-life is 2 hours, the effect of an oral dose may last up to 24 hours.

Clonidine

Clonidine stimulates presynaptic *α*-2 receptors and inhibits NE release from both central and peripheral adrenergic terminals. It also has some *α*-1 agonist activity and in high oral doses may cause paradoxical hypertension by stimulating vascular *α*-1 receptors. Under normal circumstances, the *α*-2 effects predominate. The prominent antihypertensive effect is thought to be secondary to stimulation of *α*-2 receptors in the vasomotor centers of the medulla oblongata.[112] Whether these are presynaptic or postsynaptic receptors remains controversial; however, the end result is decreased SNS and enhanced vagal tone. Peripherally, there is decreased plasma renin activity as well as decreased EPI and NE levels.[180]

Cardiovascular effects of clonidine include decreased peripheral vascular resistance and HR. The cardiovascular response to exercise is usually maintained. Prominent side effects include hypotension, sedation, and dry mouth. One of the more worrisome complications of clonidine use is the occurrence of a withdrawal syndrome on acute discontinuation of the drug. This usually occurs about 18 hours after discontinuation and consists of hypertension, tachycardia, insomnia,

flushing, headache, apprehension, sweating, and tremulousness. It lasts for 24 to 72 hours and is most likely to occur in patients taking more than 1.2 mg/day of clonidine. The withdrawal syndrome has been noted postoperatively in patients who were taken off clonidine for surgery. It can be confused with anesthesia emergence symptoms, particularly in a patient with uncontrolled hypertension. Clonidine is not available for iv use, but symptoms of the withdrawal syndrome as well as routine postoperative hypertension can be treated with clonidine administered transdermally or rectally.[181] Withholding clonidine prior to surgery is not recommended.

Dexmedetomidine

Dexmedetomidine is a more selective *α*-2 agonist than clonidine.[119] It has a much shorter half-life (about 1.5 hours) and a more rapid onset of action (5 minutes). The time to peak effect is 15 minutes. Intravenous dexmedetomidine provides excellent sedation, lowering of blood pressure and HR, and profound decreases in plasma catecholamines. Little respiratory depression is evident. Other studies have shown it to be an effective anxiolytic and sedative when used as premedication for anesthesia for minor gynecologic surgery. In an animal model, dexmedetomidine produces stereospecific and dose-dependent decreases in MAC.[182]

Flacke listed the potential uses of sympatholytic drugs in the future. In addition to the reducing effect of MAC and the absent respiratory depression, the following properties seem particularly valuable to the anesthesiologist:[182] (1) They are potent analgesics. (2) They are sedatives and anxiolytics. (3) They are antisialogogues. (4) They may promote hemodynamic stability. (5) Homeostatic reflexes remain intact. (6) They attenuate opioid rigidity (in animals). (7) Their circulatory actions can be reversed. Clonidine has also been used successfully as a substitute for opiates and nicotine during withdrawal. It reduces sympathetic hyperactivity with head injury and can be used as an analgesic in the subarachnoid and epidural spaces for the treatment of pain.

Converting Enzyme Inhibitors

The renin–angiotensin system is integrally related to the ANS in controlling blood pressure (see Fig. 12-16). The central role of the renin-angiotensin-aldosterone system in the regulation of fluid balance and hemodynamics was not fully appreciated until the discovery and clinical application of inhibitors of the ACE. Captopril, enalapril, and lisinopril inhibit converting enzyme and thereby prevent the conversion of angiotensin I to the active angiotensin II. These drugs have been highly effective in the treatment of all levels of essential hypertension as well as renovascular and malignant hypertension. The cardiovascular effects normally involve only decreased peripheral vascular resistance. CO may remain normal or increase while the filling pressure remains unchanged. Thus, these drugs have been effective in the management of congestive heart failure as well.[183] There is usually no increase in SNS tone in response to the lowered blood pressure. ACE inhibition generally results in reductions in angiotensin–aldosterone, NE, and plasma antidiuretic hormone. This suppression is accompanied by a decrease in aldosterone and an improvement in cumulative plasma potassium levels, which are beneficial in both congestive heart failure and hypertension. It can be concluded that the major humoral responses to chronic congestive heart failure, even overlooking the effects of the diuretics, are affected by the release of angiotensin, aldosterone, and increased SNS tone.

Captopril, the first orally active compound, has proven highly effective in the treatment of all levels of hypertension and congestive heart failure (Table 12-26). Enalapril is a second-generation (nonsulfhydryl) ACE inhibitor. The omission of the sulfhydryl group possibly diminishes side effects. Both captopril and enalapril combine a high degree of clinical efficacy with a low rate of side effects. Both are eliminated via renal excretion and should be given in reduced doses in patients with renal dysfunction. Captopril has a shorter half-life and requires more frequent dosing than enalapril. Enalapril has to be converted by esterase in the liver and other tissues into the active compound enalaprilat. Many new ACE inhibitors are being developed that are eliminated via hepatic routes and may prove advantageous in renal failure. Lisinopril is one of these ACE inhibitors that is absorbed as the active form and is very long- acting.

TABLE 12-26 The Angiotensin-Converting Enzyme (ACE)

·AGENT	·MAJOR STUDIES	·CHARACTERISTICS
Captopril	Quality of life; SAVE; diabetic nephropathy; ISIS-IV (early Stage AMI, trial negative)	The first ACE inhibitor; overall the best studied
Enalapril	CONSENSUS; SOLVD (prevention and treatment arms); V-HeFT I and II	Longer acting; the best-studied in heart failure
Benazepril	None	Long plasma half-life (22 hr)
Cilazepril	None	Long tissue half-life
Fosinopril	None	Renal and hepatic elimination may allow safer use in renal or hepatic failure
Perindopril	None	Long plasma half-life (35 hr), less initial hypotension
Quinapril	QUIET (Quinapril Ischemic Event Trial: postangioplasty, end-points AMI, sudden death; ready 1995)	Potent binding to tissue ACE prolongs effective half-life
Ramipril	AIRE (acute infarction ramipril efficacy)	Long plasma half-life (>33 hr), proven use in postinfarct CHF
Trandolapril	TRACE Study (Trandolapril Cardiac Evaluation Study) on high-risk AMI patients; ready 1995	Long plasma half-life (20 hr); highly lipid soluble with potential for tissue binding
Lisinopril	GISSI-III: early-stage AMI, mortality reduced by 11%	Active as is; water soluble; long acting

CHF, congestive heart failure.

5 The ACE inhibitors are associated with few side effects and are increasingly popular in treating hypertension. Captopril may produce reversible neutropenia, dermatitis, and angioedema. Enalapril produces syncope, headache, and dizziness in about 1% of elderly patients. All ACE inhibitors may cause hypotension in patients who are hypovolemic and taking diuretic therapy. Diuretic therapy should be discontinued 1 week before starting ACE inhibitor therapy. The hypotensive effects are also enhanced by the concomitant use of calcium channel blockers. The

ACE inhibitors blunt the hypokalemic effects of thiazide diuretics and may magnify the potassium-sparing effects of spironolactone, triamterene, and amiloride. In addition, nonsteroidal anti-inflammatory drugs, including aspirin, may magnify the potassium-retaining effects of ACE inhibitors.

Vasodilators

The drugs that directly relax smooth muscle to cause vasodilation reflexively increase ANS tone and are included here for the sake of a complete discussion of antihypertensive drugs.[59] These are discussed with emphasis on perioperative use.

Hydralazine. Hydralazine is the most commonly used vasodilator and can be given by the im, iv, and oral routes. It relaxes smooth muscle tone directly, without interacting with adrenergic or cholinergic receptors. The mechanism of action is unknown. It is most potent in coronary, splanchnic, renal, and cerebral vessels, causing increased blood flow in each of these organs. The decrease in cardiac afterload is beneficial, but, unfortunately, there is usually a concomitant reflex tachycardia that may be severe. It is commonly combined with a β blocker such as propranolol. It may also cause fluid retention and is usually given chronically with a diuretic.[112] Hydralazine

is metabolized by hepatic acetylation, and oral bioavailability may be low owing to first-pass metabolism. The elimination half-life is about 4 hours, but the pharmacologic half-life is much longer as a result of avid binding of the drug to smooth muscle. The effective half-life is approximately 100 hours. Side effects include a lupus-like syndrome, drug fever, skin rash, pancytopenia, and peripheral neuropathy. The iv dose we recommend for perioperative use is 5 to 10 mg in an iv bolus every 15 to 20 minutes until blood pressure control is achieved. It may also be given 10 to 40 mg im, but the response is slower.

Sodium Nitroprusside. Sodium nitroprusside is an extremely potent vasodilator that is available only for iv administration. It acts directly on smooth muscle, causing both arterial and venous dilation.[59] The mechanism of action is not entirely clear but appears to involve binding to α receptor on the surface of the myocyte, followed by activation of an intracellular vasodilator intermediate. The action of sodium nitroprusside on both venous and arterial sides of the circulation causes decreases in cardiac preload as well as afterload. This results in decreased cardiac work; however, it has been suggested that sodium nitroprusside may further compromise ischemic myocardium in the presence of occlusive coronary artery disease by shunting blood away from the ischemic zone.[184]

Sodium nitroprusside is useful during the perioperative period. It lowers blood pressure within 1 to 2 minutes, with the effect dissipating within 2 minutes after infusion is stopped. It is extremely potent and should be administered through a central venous line by infusion pump while continuously monitoring arterial pressure. The starting dose is 0.25 to 0.5 μg/kg/min. It can be increased slowly as needed to control blood pressure, but chances for toxicity are greater if the dose of 10 μg/kg/min is exceeded. The dose required for steady-state–induced hypotension is variable.

Chemically, sodium nitroprusside consists of a ferrous iron atom bound with five cyanide molecules and one nitric group. The ferrous iron reacts with sulfhydryl groups in red blood cells and releases cyanide. Cyanide is reduced to thiocyanate in the liver and excreted in the urine. The half-life of thiocyanate is 4 days, and it accumulates in the presence of renal failure. There is no evidence, however, that preexisting hepatic or renal failure increases the likelihood of cyanide toxicity. Administration of high doses of sodium nitroprusside can result in cyanide toxicity. The cyanide molecule binds to cytochrome oxidase, interfering with electron transport and causing cellular hypoxia. This can be recognized by increasing tolerance to the drug, elevated mixed venous PaO_2, and metabolic acidosis. The treatment of cyanide toxicity consists of (1) administration of amyl nitrate (by inhalation or directly into the anesthesia circuit), (2) infusion of sodium nitrite 5 mg/kg over 4 to 5 minutes, and (3) administration of sodium thiosulfate 150 mg/kg in 50 mL water over 15 minutes.

The hypotensive effects of sodium nitroprusside may be potentiated by inhalation anesthetics and

blood loss; therefore, close perioperative monitoring is essential. It is commonly used to induce hypotension for decreasing blood loss in patients predisposed to major hemorrhage. Administration of sodium nitroprusside causes a reflex increase in sympathetic tone and renin release.[185] Drugs that blunt these reflexes markedly enhance its effects. Preoperative treatment with propranolol or captopril decreases the amount of sodium nitroprusside required for producing hypotension and thus decreases the potential for toxicity.[186]

Glyceril Trinitrate. Glyceril trinitrate, or nitroglycerin, is a venodilator used to treat myocardial ischemia. Its predominant action is on venules, causing increased venous capacitance and decreased cardiac preload. Effects on the arterial side are minimal except at very high doses. Upon iv administration effects can be seen within 2 minutes, and they usually resolve within 5 minutes of discontinuing the drug. Side effects are minimal, and there is no potential for cyanide toxicity as with nitroprusside. Use of nitroglycerin for control of perioperative hypertension has been reported[187] but because of its relatively weak arteriolar action, it is not as useful as other drugs as an antihypertensive agent. In obstetric patients with preeclampsia, however, it may be chosen over nitroprusside to circumvent potential cyanide toxicity to the fetus.[188]

Diazoxide. Diazoxide is a direct-acting vasodilator that may be given iv and is useful in hypertensive emergencies. It has a greater effect on resistance than capacitance vessels, thus decreasing cardiac afterload with little effect on preload. It also causes fluid retention and induces a reflex sympathetic response.[112] The hypotensive effect is potentiated by diuretics, sympatholytics, and hypovolemia. Diazoxide is usually administered as an iv bolus of 300 mg for a 70-kg adult. It is 90% bound to serum albumin; therefore, a substantial portion of the initial bolus may not reach the site of action. Rapid boluses (30 seconds) of 100 mg every 5 minutes are often recommended as an alternative to allow more free drug to reach the arterioles.[112] The hypotensive effect is usually obtained in 5 to 10 minutes and lasts 5 to 12 hours.

Calcium Entry Inhibitors

The calcium entry blockers verapamil, nifedipine, and nitrendipine may also be useful for treating hypertension in the perioperative period (see Adrenergic Antagonists: Calcium Channel Blockers section).

Treatment of Postoperative Hypertension

The wide variety of antihypertensive agents discussed previously makes the treatment of hypertension in the recovery room easier because we can now choose from among multiple routes of administration and variable onsets and durations of action of the different agents.[189] However, treatment may become confusing unless the basic pharmacology of each drug is understood. Those drugs available for only oral administration are not routinely used because of unreliable gastrointestinal function during this period. The etiology of postoperative hypertension in each case should be considered. A determination should be made if this requires emergency therapy or is just urgent. Pain should be eliminated by assurance of adequate analgesia prior to therapy with antihypertensive agents. Also, because of the complex pathophysiology of hypertension, a thorough knowledge of each patient and his or her condition is mandatory in choosing a treatment regimen. The medications required for preoperative control may provide the most information in determining what will be necessary postoperatively. In particular, the use of drugs that may have an associated withdrawal syndrome such as clonidine or β-blockers should be noted as well as if they were withheld prior to surgery. The volume status of the patient is also important. Fluid overload may require diuretic therapy. Volume depletion or hemorrhage may predispose to severe hypotension in response to routine doses of sympatholytics or vasodilators.

For severe elevations of blood pressure that require immediate treatment, sodium nitroprusside is the drug of choice. Intravenous nicardipine can be given and effective before a sodium nitroprusside infusion can be prepared. Labetalol, metoprolol, and esmolol may also be used intravenously. Esmolol has the advantage of being rapidly titratable.[190] α-methyldopa may be used intravenously but takes much longer to work than clonidine. Clonidine can be given per rectum and begins to act in 10 to 20 minutes.[181] If conditions permit, it is helpful to use the drugs the

patient was taking preoperatively to ease the transition in the postoperative period. Caution must be exercised if the hypertension is the result of excessive

exogenous catecholamines, pheochromocytoma, or thyrotoxicosis. *α*-blockade should be started before *β*-blockade. The hypertension may, in fact, worsen if *β* receptors are blocked first, leaving the *α* receptors unopposed.

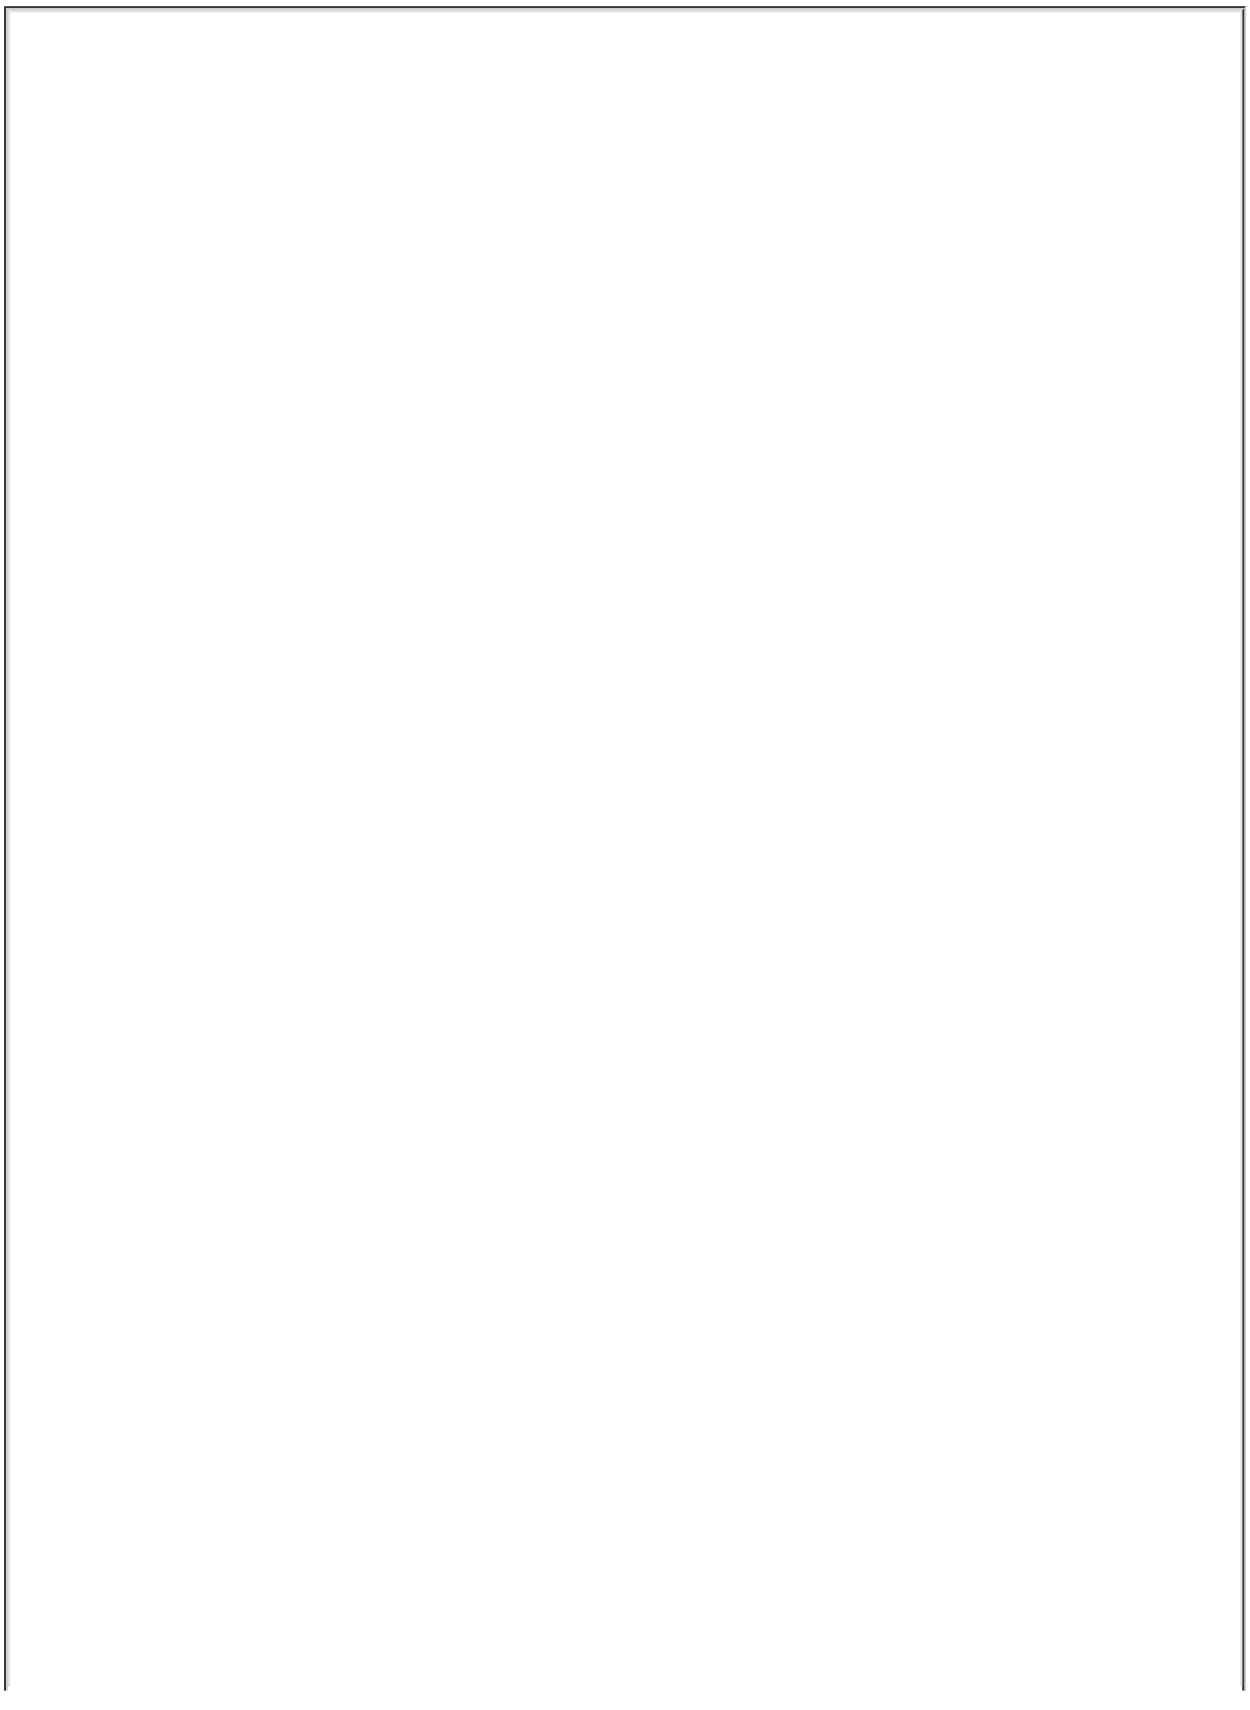
Chapter 13

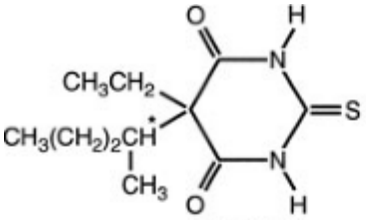
Nonopioid Intravenous Anesthesia

Paul F. White

Gladys Romero

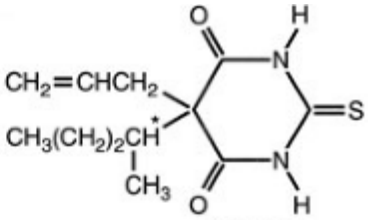


KEY POINTS



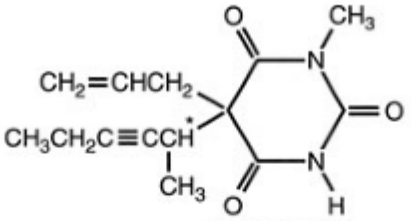
1	With the exception of ketamine, intravenous (IV) anesthetics lack analgesic properties.
2	Dexmedetomidine is an α-2 agonist with sedative and opioid-sparing effects.
3	Low doses of IV anesthetics produce sedation, while high doses produce hypnosis (or unconsciousness).
4	All nonopioid IV anesthetics produce dose-dependent central nervous system (CNS) depression.
5	Compared to thiopental and propofol, methohexital produces less CNS depression.
6	Propofol possesses unique antiemetic and appetite-stimulating properties.
7	Etomidate produces less cardiovascular depression than the barbiturates and propofol.
8	Ketamine possesses analgesic and psychomimetic properties.
9	Midazolam possesses amnestic and anxiolytic properties.
10	IV anesthetics in combination with potent opioid analgesics and/or local anesthetics can be used to produce total intravenous anesthesia (TIVA).

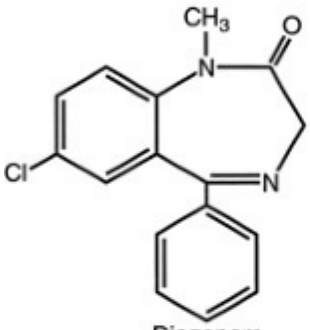
The concept of intravenous (IV) anesthesia has evolved from primarily induction of anesthesia to total IV anesthesia (TIVA). TIVA has assumed increasing importance for therapeutic, as well as



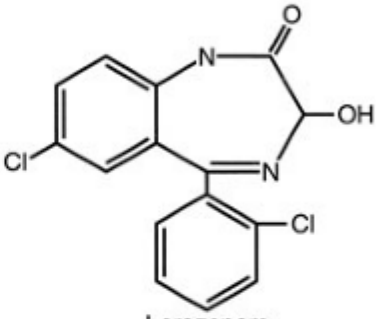
diagnostic, procedures in both adults and children. This change has been a result of the development of rapid, short-acting IV hypnotic, analgesic, and muscle relaxant drugs; the availability of pharmacokinetic and dynamic-based IV delivery systems; and the development of the electroencephalogram (EEG) base cerebral monitor, which measures the hypnotic component of the anesthetic state. This chapter focuses on the pharmacologic properties and clinical uses of the currently available nonopioid IV anesthetics.

Following its introduction into clinical practice, thiopental quickly became the gold standard of IV anesthetics against which all the newer IV drugs were compared. Many different hypnotic drugs are currently available for use during IV anesthesia (Fig. 13-1). However, the "ideal" IV anesthetic has not yet been developed. The physical and pharmacologic properties that an ideal IV anesthetic would possess include the following:

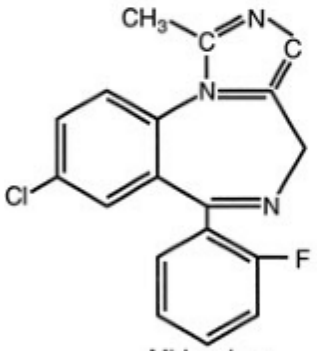




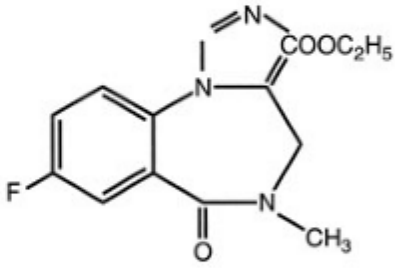
Thiopental



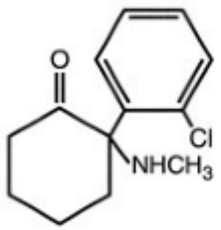
Thiamylal



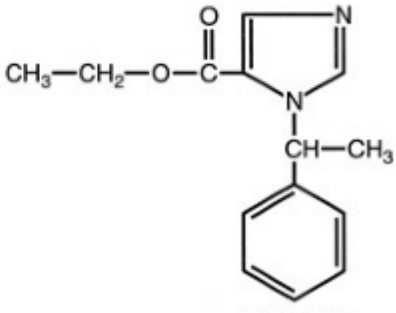
Methohexital



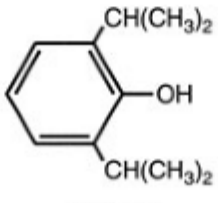
Diazepam



Lorazepam



Midazolam



Flumazenil

Ketamine

Etomidate

Propofol

FIGURE 13-1. Chemical structures of currently available nonopioid IV anesthetics.

1. Drug compatibility and stability in solution.
2. Lack of pain on injection, venoirritation, or local tissue damage from extravasation.
3. Low potential to release histamine or precipitate hypersensitivity reactions.
4. Rapid and smooth onset of hypnotic action without excitatory activity.
5. Rapid metabolism to pharmacologically inactive metabolites.
6. A steep dose-response relationship to enhance titratability and minimize accumulation.
7. Lack of acute cardiovascular and respiratory depression.
8. Decreases in cerebral metabolism and intracranial pressure.
9. Rapid and smooth return of consciousness and cognitive skills with residual analgesia.
10. Absence of postoperative nausea and vomiting, amnesia, psychomimetic reactions, dizziness, headache, or prolonged sedation ("hangover").

Despite thiopental's proven clinical usefulness, safety, and widespread acceptance over many decades, it is not the ideal IV anesthetic. The sedative–hypnotic drugs that have been more recently introduced into clinical practice (e.g., midazolam, ketamine, etomidate, propofol) have proven to be extremely valuable in specific clinical situations. These newer compounds combine many of the characteristics of the ideal IV anesthetic but fail in aspects where the other drugs succeed. For some of these IV sedative–hypnotics, disadvantages have led to "restricted" indications (e.g., ketamine, etomidate) or withdrawal

from clinical use (e.g., Althesin, propanidid, eltanolone). Because the optimal pharmacologic properties are not equally important in every clinical situation, the anesthesiologist must make the choice that best fits the needs of the individual patient and the operative procedure.

GENERAL PHARMACOLOGY OF INTRAVENOUS HYPNOTICS

Mechanism of Action

A widely accepted theory of anesthetic action is that both IV and inhalational anesthetics exert their primary sedative and hypnotic effects through an interaction with the inhibitory γ-aminobutyric acid (GABA) neurotransmitter system.[1] GABA is the principal inhibitory neurotransmitter within the CNS. The GABA and adrenergic neurotransmitter systems counterbalance the action of excitatory neurotransmitters. The GABA type A ($GABA_A$) receptor is a receptor complex consisting of up to five glycoprotein subunits. When the $GABA_A$ receptor is activated, transmembrane chloride conductance increases, resulting in hyperpolarization of the postsynaptic cell membrane and functional inhibition of the postsynaptic neuron. Sedative–hypnotic drugs interact with different components of the GABA-receptor complex (Fig. 13-2). However, the allosteric (structural) requirements for activation of the receptor are different for IV and volatile anesthetics.[2]

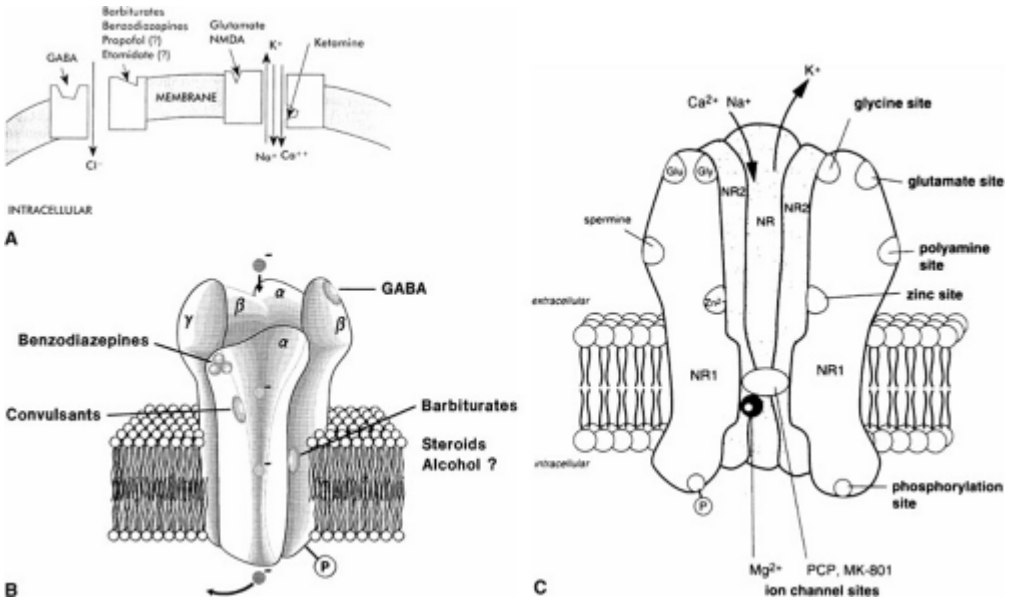


FIGURE 13-2. A. This model depicts the postsynaptic site of GABA and glutamate within the CNS. GABA decreases the excitability of neurons by its action at the $GABA_A$-receptor complex. When GABA occupies the binding site of this complex, it allows inward flux of chloride ion, resulting in hyperpolarizing of the cell and subsequent resistance of the neuron to stimulation by excitatory transmitters. Barbiturates, benzodiazepines, propofol, and etomidate decrease neuronal excitability by enhancing the effect of GABA at this complex, facilitating this inhibitory effect on the postsynaptic cell. Glutamate and its analog N-methyl-D-aspartate (NMDA) are excitatory amino acids. When glutamate occupies the binding site on the NMDA subtype of the glutamate receptor, the channel opens and allows Na^+, K^+, and Ca^{2+} to either enter or leave the cell. Flux of these ions leads to depolarization of the postsynaptic neuron and initiation of an action potential and activation of other pathways. Ketamine blocks this open channel and prevents further ion flux, thus inhibiting the excitatory response to glutamate. (Reprinted with permission from Van Hemelrijck J, Gonzales JM, White PF: Use of intravenous sedative agents. In Rogers MC, Tinker JH, Covino BG, Longnecker DE (eds): Principles and Practice of Anesthesiology, p 1131. St. Louis, Mosby, 1992.) **B.** Schematic model of the $GABA_A$-receptor complex illustrating recognition sites for many of the substances that bind to the receptor. C. Model of the NMDA receptor showing sites for antagonist action. Ketamine binds to the site labeled PCP (phencyclidine). The pentameric structure of the receptor, composed of a combination of the subunits NR 1 and NR 2, is illustrated. (Altered with permission from Leeson TD, Iversen LL. The glycine site on the NMDA receptor: Structure-activity relationships and therapeutic potential. J Med Chem 37:4054, 1994.)

Benzodiazepines bind to specific receptor sites that are part of the $GABA_A$-receptor complex. The binding of benzodiazepines to their receptor site increases the efficiency of the coupling between the GABA receptor and the chloride ion channel. The degree of modulation of the GABA-receptor function is limited, which explains the "ceiling effect" produced by benzodiazepines with respect to CNS depression. The CNS properties of benzodiazepines (e.g., hypnosis, sedation, anxiolysis, and anticonvulsant effects) are presumed to be associated with stimulation of different receptor subtypes and/or concentration-dependent receptor occupancy. It has been suggested that a benzodiazepine receptor occupancy of 20% provides anxiolysis, while 30 to 50% receptor occupancy is associated with sedation, and 60% receptor occupancy is required for hypnosis (or unconsciousness).

The interaction of barbiturates and propofol with specific membrane structures appears to decrease the rate of dissociation of GABA from its receptor, thereby increasing the duration of the

GABA-activated opening of the chloride ion channel (Fig. 13-2). Barbiturates can also mimic the action of GABA by directly activating the chloride channels. The proposed mechanism of action of thiopental relates to its ability to function as a competitive inhibitor at the nicotic acetytcholine receptors (AChRs) in the CNS.[3] Etomidate augments GABA-gated chloride currents (i.e., indirect modulation) and at higher concentrations evokes chloride currents in the absence of GABA (i.e., direct activation). Although the mechanism of action of propofol is similar to that of the barbiturates (i.e., enhancing the activity of the GABA-activated chloride channel), it also possesses ion channel–blocking effects in cerebral cortex tissue and nicotinic acetylcholine receptors, as well as an inhibitory effect on lysophosphatidate signaling in lipid mediator receptors.[4]

1 Ketamine produces a functional dissociation between the thalamocortical and limbic systems, a state that has been termed "dissociative" anesthesia. Ketamine depresses neuronal function in the cerebral cortex and thalamus, while simultaneously activating the limbic system. Ketamine's effect on the medial medullary reticular formation may be involved in the affective component of its nociceptive activity. The CNS effects of ketamine appear to be primarily related to its antagonistic

activity at the *N*-methyl-D-aspartate (NMDA) receptor (Fig. 13-2). Unlike the other IV anesthetics, ketamine does not interact with GABA receptors; however, it binds to non-NMDA glutamate receptors and nicotinic, muscarinic, monoaminergic, and opioid receptors. In addition, it also inhibits neuronal sodium channels (producing a modest local anesthetic action) and calcium channels (causing cerebral vasodilatation).

2 The centrally active α-2 adrenergic receptor agonist, dexmedetomidine, has potent sedative and analgesic-sparing properties. The drug also has effects on the perioperal α-2 receptors involved in regulating the cardiovascular system by inhibiting norepinephrine release. This class of anesthetic drugs can also reduce the tonic levels of sympathetic outflow from the CNS and augment cardiac vagal activity.[5,6]

Pharmacokinetics and Metabolism

An understanding of basic pharmacokinetic principles is integral to the understanding the pharmacologic actions and interactions of IV anesthetic and adjunctive drugs and will allow the anesthesiologist to develop more optimal dosing strategies when using IV techniques. Although lipid solubility facilitates diffusion of IV anesthetics across cellular membranes including the blood–brain barrier, only the nonionized form is able to readily cross neuronal membranes. The ratio of the un-ionized-to-ionized fraction depends on the pKa of the drug and the pH of the body fluids.

The rapid onset of the CNS effect of most IV anesthetics can be explained by their high lipid solubility and the relatively high proportion of the cardiac output (20%) perfusing the brain. However, a variable degree of hysteresis exists between the blood concentration of the hypnotic drug and its onset of action on the CNS. The hysteresis is related in part to diffusion of these drugs into brain tissue and nonspecific CNS receptor binding. However, the number of CNS binding sites is usually saturable and only a small fraction of the available binding sites needs to be occupied to produce clinical effects. Although the total amount of drug in the blood is available for diffusion, the diffusion rate will be more limited for IV anesthetics with

a high degree of plasma protein binding (90%) because only the "free" unbound drug can diffuse across membranes and exert central effects. When several drugs compete for the same binding sites, or when the protein concentration in the blood is decreased by preexisting disease (e.g., hepatic failure), a higher fraction of the unbound drug will be available to exert an effect on the CNS. Since only unbound drug is available for uptake and metabolism in the liver, highly protein-bound drugs may have a lower rate of hepatic metabolism as a result of their decreased hepatic extraction ratio (i.e., the fraction of the hepatic blood flow that is cleared of the drug).

The pharmacokinetics of IV hypnotics are characterized by rapid distribution and subsequent

redistribution into several hypothetical compartments, followed by elimination (Table 13-1). The initial pharmacologic effects are related to the activity of the drug in the central compartment. The primary mechanism for terminating the central effects of IV anesthetics administered for induction of anesthesia is redistribution from the central highly perfused compartment (brain) to the larger but less well perfused "peripheral" compartments (muscle, fat). Even for drugs with a high hepatic extraction ratio, elimination does not usually play a major role in terminating the drug's CNS effects because elimination of the drug can only occur from the central compartment. The rate of elimination from the central compartment, the amount of drug present in the peripheral compartments, and the rate of redistribution from the peripheral compartments "back" into the central compartment determine the time necessary to eliminate the drug from the body.

TABLE 13-1 Pharmacokinetic Values for the Currently Available Intravenous Sedative–Hypnotic Drugs

·DRUG NAME	·DISTRIBUTION HALF-LIFE (min)	·PROTEIN BINDING (%)	·DISTRIBUTION VOLUME AT STEADY STATE (L/kg)	·CLEARANCE (mL/kg/min)	·ELIMINATION HALF-LIFE (h)
Thiopental	2–4	85	2.5	3.4	11
Methohexital	5–6	85	2.2	11	4
Propofol	2–4	98	2–10	20–30	4–23
Midazolam	7–15	94	1.1–1.7	6.4–11	1.7–2.6
Diazepam	10–15	98	0.7–1.7	0.2–0.5	20–50
Lorazepam	3–10	98	0.8–1.3	0.8–1.8	11–22
Etomidate	2–4	75	2.5–4.5	18–25	2.9–5.3
Ketamine	11–16	12	2.5–3.5	12–17	2–4

Most IV anesthetic agents are eliminated via hepatic metabolism followed by renal excretion of more water-soluble metabolites. Some metabolites have pharmacologic activity and can produce prolonged drug effects (e.g., oxazepam, desmethyldiazepam, norketamine). Moreover, there is considerable interpatient variability in the clearance rates for commonly used IV anesthetic drugs. The elimination clearance is the distribution volume cleared of drug over time and is a measure of the efficacy of the elimination process. The slow elimination of some anesthetics is due in part to their high degree of protein binding that reduces their hepatic extraction ratio. Other drugs may have a high hepatic extraction ratio and elimination clearance despite extensive plasma protein binding (e.g., propofol), indicating that protein binding is not always a rate limiting factor.

For most drugs, the hepatic enzyme systems are not saturated at clinically relevant drug concentrations, and the rate of drug elimination will decrease as an exponential function of the drug's plasma concentration (first-order kinetics). However, when high steady-state plasma

TABLE 13-1 Pharmacokinetic Values for the Currently Available Intravenous Sedative–Hypnotic Drugs

DRUG NAME	DISTRIBUTION HALF-LIFE (min)	PROTEIN BINDING (%)	DISTRIBUTION VOLUME AT STEADY STATE (L/kg)	CLEARANCE (mL/kg/min)	ELIMINATION HALF-LIFE (h)
Thiopental	2–4	85	2.5	3.4	11
Methohexital	5–6	85	2.2	11	4
Propofol	2–4	98	2–10	20–30	4–23
Midazolam	7–15	94	1.1–1.7	6.4–11	1.7–2.6
Diazepam	10–15	98	0.7–1.7	0.2–0.5	20–50

Ketamine	11–16	12	2.5–3.5	12–17	2–4

concentrations are achieved with prolonged infusions, hepatic enzyme systems can become saturated and the elimination rate becomes independent of the drug concentration (zero-order kinetics). The elimination half-life ($t_{1/2}\beta$) is the time required for the anesthetic concentration to decrease by 50% during the terminal phase of the plasma decay curve. The $t_{1/2}\beta$ is dependent on the volume to be cleared (the distribution volume) and the efficiency of the metabolic clearance system. Because their volumes of distribution are similar, the wide variation in elimination half-life values for the IV anesthetics is a reflection of differences in their clearance values.

When a drug infusion is administered without a loading dose, 3 to 5 times the $t_{1/2}\beta$ value may be required to reach a "steady-state" plasma concentration. The steady-state concentration obtained during an anesthetic infusion depends on the rate of drug administration and its clearance rate. When an infusion is discontinued, the rate at which the plasma concentration decreases is largely dependent on the clearance rate (as reflected by the terminal elimination half-life value). For drugs with shorter elimination half-lives, plasma concentration will decrease at a rate that allows for a more rapid recovery (e.g., propofol). Drugs with long elimination half-life values (e.g., thiopental and diazepam) are usually only administered by continuous IV infusion when the medical condition requires long-term treatment (e.g., elevated intracranial pressure [ICP] as a result of brain injury or prolonged sedation in the ICU because of respiratory failure).

3 Careful titration of an anesthetic drug to achieve the desired clinical effect is necessary to avoid drug accumulation and the resultant prolonged CNS effects after the infusion has been discontinued. Although the value of the terminal half-life indicates how fast a drug is eliminated from the body, a more useful indicator of the acceptability of a hypnotic infusion for maintenance of anesthesia or sedation is the context-sensitive half-time, a value derived from computer simulations of drug infusions.[7] The context-sensitive half-time is defined as the time necessary for the effect-compartment (i.e., effect site) concentration to decrease by 50% in relation to the duration of the infusion. The context-sensitive half-time becomes particularly important in determining recovery after prolonged infusions of sedative–hypnotic drugs. Drugs (e.g., propofol) may have a relatively short context-sensitive half-time despite the fact that a large amount of drug remains present in the "deep" (less well perfused) compartment. The slow return of the anesthetic from the deep compartment contributes little to the concentration of drug in the central compartment from which it is rapidly cleared. Therefore, the concentration in the central compartment rapidly declines below the hypnotic threshold after discontinuation of the infusion, contributing to short emergence times despite the fact that a substantial quantity of anesthetic drug may remain in the body.

Marked interpatient variability exists in the pharmacokinetics of IV sedative–hypnotic drugs. Factors that can influence anesthetic drug disposition include the degree of protein binding, the efficiency of hepatic and renal elimination processes, physiologic changes with aging, preexisting disease states, the operative site, body temperature, and drug interactions (e.g., coadministration of volatile anesthetics). For example, increased age, lean body (muscle) mass and total body water decrease, results in an increase in the steady-state volume of distribution of most IV anesthetics. The increased distribution volume and decreased hepatic clearance leads to a prolongation of their $t_{1/2}\beta$ values. Moreover, a decrease of the volume of the central compartment may result in higher initial drug concentrations and can at least partially explain the decreased induction requirement in the elderly. Additionally, the slower redistribution from the vessel-rich tissues to intermediate compartments (muscles) also contributes to the age-related decrease in the induction dose requirements.[7] Although prolongation of the elimination half-time does not provide an explanation for the decreased induction dose requirement, it is responsible for producing higher steady-state plasma concentrations at any given infusion rate.

The hepatic clearance of IV anesthetics with a high (e.g., etomidate, propofol, ketamine) or intermediate (e.g., methohexital, midazolam) extraction ratio is largely dependent on hepatic blood flow, with most of the drug being removed from the blood as it flows through the liver (so-called perfusion-limited clearance). The elimination rate of drugs with low hepatic extraction ratios (e.g., thiopental, diazepam, lorazepam) is dependent on the enzymatic activity of the liver and is less dependent of hepatic blood flow (so-called capacity-limited clearance). Hepatic blood flow

decreases during upper abdominal surgery and, as a result, higher blood levels of drugs with perfusion-limited clearance are achieved at any given infusion rate. With aging, a decreased cardiac output and a redistribution of blood flow can partly explain the lower clearance rate for drugs with perfusion-limited clearance. While concomitant administration of volatile anesthetics (which are known to decrease liver blood flow) has little influence on the elimination of thiopental, they can decrease the clearance of etomidate, ketamine, methohexital, and propofol. Other factors that decrease hepatic blood flow include hypocapnia, congestive heart failure, intravascular volume depletion, circulatory collapse, β-adrenergic blockade, and norepinephrine administration.

Hepatic disease can influence the pharmacokinetics of drugs by: (1) altering the plasma protein content and changing the degree of protein binding, (2) decreasing hepatic blood flow and producing intrahepatic shunting, and (3) depressing the metabolic enzymatic activity of the liver. Therefore, the influence of hepatic disease on pharmacokinetics and dynamics of IV anesthetics is difficult to predict. Renal disease can also alter the concentration of plasma and tissue proteins, as well as the degree of protein binding, thereby producing changes in free drug concentrations. Because IV anesthetic agents are primarily metabolized by the liver, renal insufficiency has little influence on their rate of metabolic inactivation or elimination of the primary compound.

Pharmacodynamic Effects

4 The principal pharmacologic effect of IV anesthetics is to produce progressively increasing sedation and ultimately hypnosis as a result of dose-dependent CNS depression. However, all sedative–hypnotics also directly or indirectly affect other major organ systems. The relationship between the dose of a sedative–hypnotic and its CNS effects can be defined by dose-response curves. Although most IV anesthetics are characterized by steep dose-response curves, they are not always parallel (Fig. 13-3). The characteristics of a dose-response curve can only be interpreted in relation to the specific response for which it was constructed.

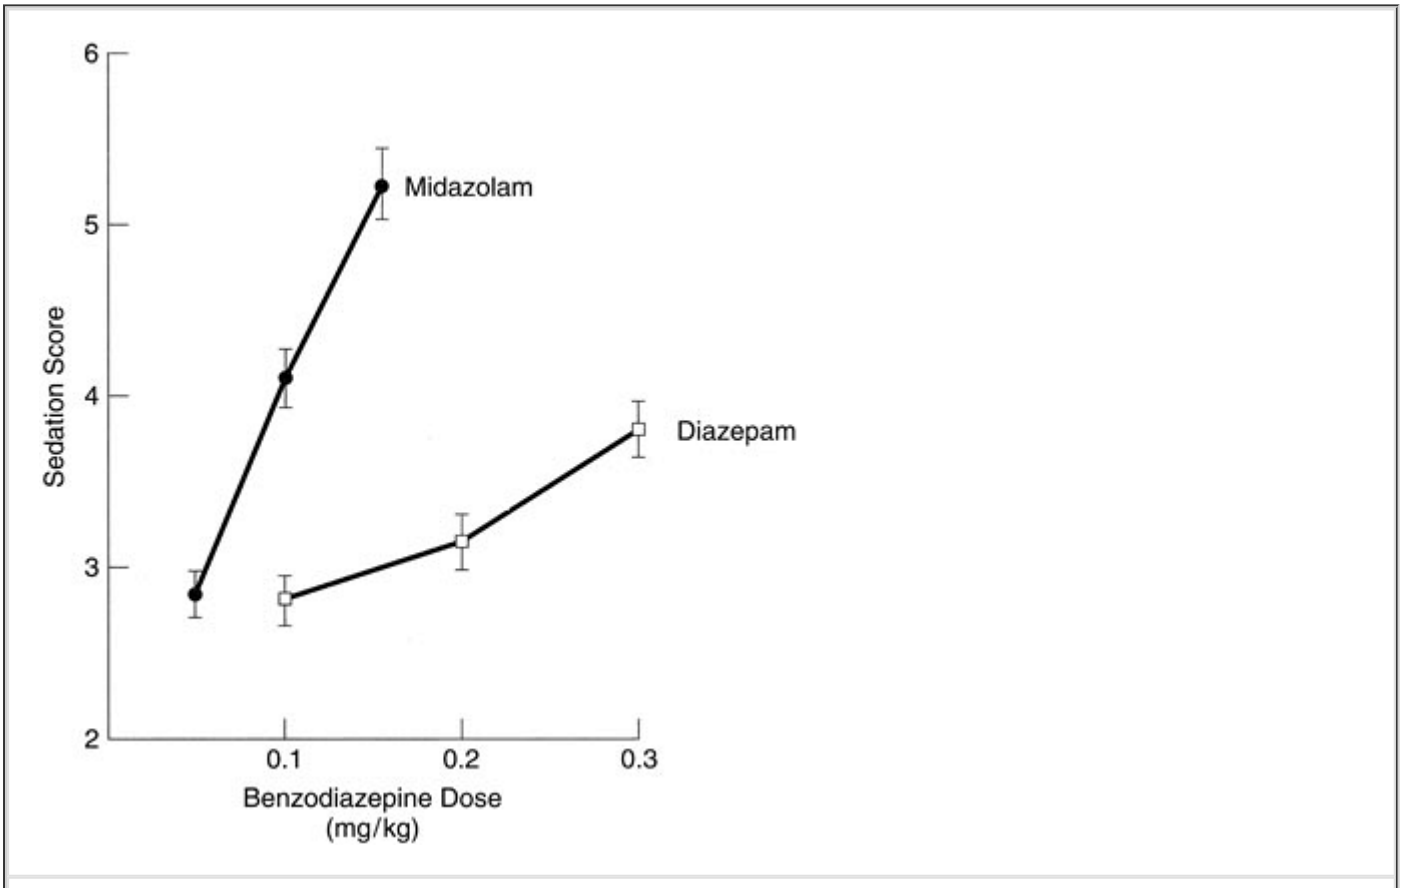

FIGURE 13-3. Dose-response relationships for sedation with midazolam (•) and diazepam (•). The level of sedation (2 = awake and alert to 6 = asleep and unarousable) was assessed 5 minutes after bolus doses of midazolam (0.05, 0.1, or 0.15 mg/kg) or diazepam (0.1, 0.2, or 0.3 mg/kg). Values represent mean values ± SEM. (Reprinted with permission from White

PF, Vascones LO, Mathes SA, et al: Comparison of midazolam and diazepam for sedation during plastic surgery. J Plast Reconstruct Surg 81:703, 1988.)

When steady-state plasma concentrations are achieved, it can be presumed that the plasma concentration is in quasi-equilibrium with the effect-site concentration. Under these circumstances, it is possible to describe the relationship between drug and effect using a concentration-effect curve (Fig. 13-4). Because of the pharmacodynamic variability that exists among individuals, the plasma drug concentration necessary to obtain a particular effect is often described in terms of an effective concentration range, the so-called therapeutic window. Efficacy of an IV anesthetic relates to the maximum effect that can be achieved with respect to some measure of CNS function. Depending on the drug effect under consideration, the efficacy of sedative–hypnotics may appear to be less than 100%. For example, it is virtually impossible to produce a burst-suppressive EEG pattern with a benzodiazepine. Potency, on the other hand, relates to the quantity of drug necessary to obtain the maximum CNS effect. The relative potency of sedative–hypnotics also varies depending on the end point chosen. In the presence of an antagonist drug (e.g., flumazenil), the maximal response that can be obtained with a benzodiazepine agonist is further reduced because of competition for the same CNS receptor binding sites.

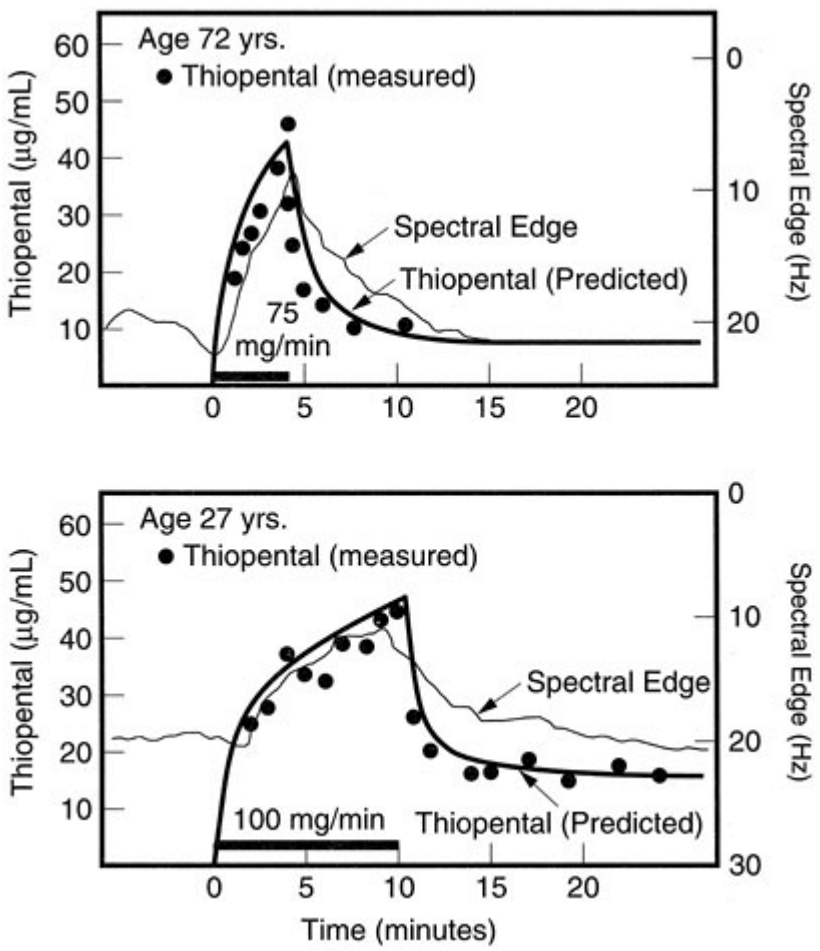

FIGURE 13-4. The concentration of thiopental versus time and spectral edge in an elderly patient (**top**) and in a younger patient (**bottom**). Solid horizontal bars represent the length of thiopental infusion. Filled circles represent the measured thiopental concentration (linear scale), and the solid line next to them represents the fitted data from the pharmacokinetic model. The axis for spectral edge has been inverted for visual clarity. (Reprinted with permission from Homer TD, Stanski DR: The effect of increasing age on thiopental disposition

and anesthetic requirement. Anesthesiology 62:714, 1985.)

The influence of sedative–hypnotics on cerebral metabolism, cerebral hemodynamics, and ICP is of particular importance during neuroanesthesia. In patients with reduced cerebral compliance, a small increase in cerebral blood volume can cause a life-threatening increase in ICP. Most sedative–hypnotic drugs cause a proportional reduction in cerebral metabolism ($CMRO_2$) and cerebral blood flow (CBF), resulting in a decrease in ICP. Although a decrease in $CMRO_2$ probably provides only a modest degree of protection against

CNS ischemia or hypoxia, some hypnotics appear to possess cerebroprotective potential. Explanations for the alleged neuroprotective effects of these compounds include a biochemical role as free-radical scavengers and membrane stabilizers (barbiturates and propofol) or NMDA-receptor antagonists (ketamine). With the exception of ketamine, all sedative–hypnotics also lower intraocular pressure (IOP). The changes in IOP generally reflect the effects of the IV agent on systemic arterial pressure and intracranial hemodynamics. However, none of the available sedative–hypnotic drugs protect against the transient increase in IOP that occurs with laryngoscopy and intubation.

Most IV hypnotics have similar EEG effects. Activation of high-frequency EEG activity (15 to 30 Hz) is characteristic of low concentrations (so-called sedative doses) of IV anesthetics. At higher concentrations, an increase in the relative contribution of the lower frequency higher amplitude waves is observed. At high concentrations, a burst-suppressive pattern develops with an increase in the isoelectric periods. Most sedative–hypnotic drugs have been reported to cause occasional EEG seizure-like activity. Interestingly, the same drugs also possess anticonvulsant properties.[8] When considering possible epileptogenic properties of CNS-depressant drugs, it is important to differentiate between true epileptogenic activity (e.g., methohexital) and myoclonic-like phenomena (e.g., etomidate). Myoclonic activity is generally considered to be the result of an imbalance between excitatory and inhibitory subcortical centers, produced by an unequal degree of suppression of these brain centers by low concentrations of hypnotic drugs. Epileptic activity refers to a sudden alteration in CNS seizure-like activity resulting from a high voltage electrical discharge at either cortical or subcortical sites, with subsequent spreading to the thalamic and brainstem centers. As a result of its vasoconstrictive effects on the cerebral vasculature, propofol may be useful for treatment of intractable migraine headaches.[9]

Although some induction drugs can increase airway sensitivity, coughing and airway irritation (e.g., bronchospasm) are usually a result of manipulation of the airway during "light" levels of anesthesia rather than to a direct drug effect. With the exception of ketamine (and to a lesser extent etomidate), IV anesthetics produce dose-dependent respiratory depression, which is enhanced in patients with chronic obstructive pulmonary disease. The respiratory depression is characterized by a decrease in tidal volume and minute ventilation, as well as a transient rightward shift in the CO_2 response curve. Following the rapid injection of a large bolus dose of an IV anesthetic, transient apnea lasting 30 to 90 seconds is usually produced. Ketamine causes minimal respiratory depression when administered in the usual induction doses, while etomidate is associated with less respiratory depressant effects than the barbiturate compounds or propofol. Preliminary experience has demonstrated that dexmedetomidine has minimal depressant effects on respiratory function.[10]

Many different factors contribute to the hemodynamic changes associated with IV induction of anesthesia, including the patient's preexisting cardiovascular and fluid status, resting sympathetic nervous system tone, chronic cardiovascular drugs, preanesthetic medication, the speed of drug injection, and the onset of unconsciousness. In addition, cardiovascular changes can be attributed to the direct pharmacologic actions of anesthetic and analgesic drugs on the heart and peripheral vasculature. Intravenous anesthetics can depress the CNS and peripheral nervous system responses, blunt the compensatory baroreceptor reflex mechanisms, produce direct myocardial

depression, and lower peripheral vascular resistance (and/or dilate venous capacitance vessels), thereby decreasing venous return. Profound hemodynamic effects occur at induction in the presence of hypovolemia because a higher than expected drug concentration is achieved in the central compartment. Not surprisingly, the acute cardiocirculatory depressant effects of all IV anesthetics are accentuated in the elderly, as well as in the presence of preexisting cardiovascular disease (e.g., hypertension).

The sympatholytic effects of dexmedetomidine may be useful for producing controlled hypotension.[10] The effects of IV anesthetics on neuroendocrine function are also influenced by the surgical stimuli. Although IV anesthetics are alleged to increase antidiuretic hormone (vasopressin) secretion, it is probably secondary to the surgical stress. Increases in this stress hormone can result in increased peripheral vascular resistance and a reduction of urine output. Similarly, glucose tolerance appears to be decreased by surgical stress, resulting in elevations in the glucose concentration. Most IV sedative–hypnotic drugs lack intrinsic analgesic activity. In fact, thiopental has been alleged to possess so-called antianalgesic activity (i.e., appearing to lower the pain threshold). In contrast to the other drugs in this class, ketamine, and dexmedetomidine, appears to possess analgesic-like activity.

Hypersensitivity (Allergic) Reactions

Allergic reactions to IV anesthetics are rare but can be severe and even life threatening. Intravenous drug administration bypasses the normal "protective barriers" against entrance of foreign molecules into the body. With the exception of etomidate, all IV induction agents have been alleged to cause some histamine release. However, the incidence of severe anaphylactic

reactions is extremely low with the currently available IV induction agents. The high frequency of allergic reactions to the cremophor EL–containing formulations led to the early withdrawal of several IV anesthetics containing this solubilizing agent (e.g., propofol EL, propanidid, Althesin). The possible mechanisms for immunologic reactions include: (1) direct action on mast cells, (2) classic complement activation after previous exposure and antibody formation, (3) complement activation through the alternative pathway without previous antigen exposure, (4) antigen–antibody reactions, and (5) the "mixed type" of anaphylactoid reactions.

Severe anaphylactic reactions to IV anesthetics are extremely uncommon; however, profound hypotension attributed to nonimmunologically mediated histamine release has been reported with thiopental use. Although anaphylactic reactions to etomidate have been reported, it does not appear to release histamine and is considered to be the most "immunologically safe" IV anesthetic. While propofol does not normally trigger histamine release, life-threatening anaphylactoid reactions have been reported in patients with a previous history of multiple drug allergies. Barbiturates can also precipitate episodes of acute intermittent porphyria (AIP) and their use is contraindicated in patients who are predisposed to AIP. Although benzodiazepines, ketamine, and etomidate are reported to be safe in humans, these drugs have been shown to be porphyrogenic in animal models.

COMPARATIVE PHYSICO-CHEMICAL AND CLINICAL PHARMACOLOGIC PROPERTIES

Barbiturates

The most commonly used barbiturates are thiopental (5-ethyl-5-[1-methylbutyl]-2-thiobarbituric acid), methohexital (1-methyl-5-allyl-5-[1-methyl-2-pentynyl] barbituric acid), and thiamylal (5-allyl-5-[1-methylbutyl]-2-thiobarbituric acid). Thiopental (Pentothal) and thiamylal (Surital) are thiobarbiturates, while methohexital (Brevital) is an oxybarbiturate. Thiamylal is slightly more potent than thiopental but has a similar pharmacologic profile. Although the l-isomers of thiopental and thyamylal are twice as potent as the D-isomers, both hypnotics are commercially available as racemic mixtures. Because methohexital has two asymmetric centers, it has four stereoisomers. The β-l-isomer is 4 to 5 times more potent than the α-l-isomer, but it produces excessive motor responses. Therefore, methohexital is marketed as the racemic mixture of the two

α-isomers.

All three barbiturates are available as sodium salts and must be dissolved in isotonic sodium chloride (0.9%) or water to prepare solutions of 2.5% thiopental, 1 to 2% methohexital, and 2% thiamylal. If refrigerated, solutions of the thiobarbiturates are stable for up to 2 weeks. Solutions of methohexital are stable for up to 6 weeks. When barbiturates are added to Ringer's lactate or an acidic solution containing other water-soluble drugs, precipitation will occur and can occlude the IV catheter. Although the typical solution of thiopental (2.5%) is highly alkaline (pH 9) and can be irritating to the tissues if injected extravenously, it does not cause pain on injection and venoirritation is rare. In contrast, a 1% methohexital solution frequently causes discomfort when injected into small veins. Intra-arterial injection of thiobarbiturates is a serious complication as crystals can form in the arterioles and capillaries, causing intense vasoconstriction, thrombosis, and even tissue necrosis. Accidental intra-arterial injections should be treated promptly with intra-arterial administration of papaverine and lidocaine (or procaine), as well as a regional anesthesia-induced sympathectomy (stellate ganglion block, brachial plexus block) and heparinization.

5 Thiopental is metabolized in the liver to hydroxythiopental and the carboxylic acid derivative, which are more water soluble and have little CNS activity. When high doses of thiopental are administered, a desulfuration reaction can occur with the production of pentobarbital, which has long-lasting CNS-depressant activity. The low elimination clearance of thiopental (3.4 mL/kg/min) contributes to a long elimination half-life ($t_{1/2}\beta$ of 12 h). Preexisting hepatic and renal disease results in decreased plasma protein binding, thereby increasing the free fraction of thiopental and enhancing its CNS and cardiovascular-depressant properties. During prolonged continuous administration of thiopental, the concentration in the tissues approaches the concentration in the central compartment, with termination of its CNS effects becoming solely dependent on elimination by nonlinear hepatic metabolism. Methohexital is metabolized in the liver to inactive hydroxyderivatives. The clearance of methohexital (11 mL/kg/min) is higher and more dependent on hepatic blood flow than thiopental, resulting in a shorter elimination half-life ($t_{1/2}\beta$ 3–6 h).

The usual induction dose of thiopental is 3 to 5 mg/kg in adults, 5 to 6 mg/kg in children, and 6 to 8 mg/kg in infants. Because methohexital is approximately 2.7 times more potent than thiopental, a dose of 1.5 mg/kg is equivalent to 4 mg/kg of thiopental in adults. The dose of barbiturates necessary to induce anesthesia is reduced in premedicated patients, patients in early pregnancy (7 to 13 weeks' gestation), and those of more advanced ASA (American Society of Anesthesiologists) physical status (III or IV). Geriatric patients require a 30 to 40% reduction in the usual adult dose because of a decrease of the volume of the central compartment and slowed redistribution of thiopental from the vessel-rich tissues to lean muscle.[11] When the calculation of the induction dose is based on the lean body mass rather than total body weight, dosage adjustments for age, sex, or obesity are not necessary. Thiopental infusion is seldom used to maintain anesthesia because of the long context-sensitive half-time and prolonged recovery period. Plasma thiopental levels necessary to maintain a hypnotic state range between 10 and 20 mg/mL. A typical infusion rate necessary to treat intracranial hypertension or intractable convulsions is 2 to 4 mg/kg/h. The plasma concentration of methohexital needed to maintain hypnosis during anesthesia ranges between 3 and 5 mg/mL and can be achieved with an infusion rate of 50 to 120 mg/kg/min.

Barbiturates produce a proportional decrease in $CMRO_2$ and CBF, thereby lowering ICP. The maximal decrease in $CMRO_2$ (55%) occurs when the EEG becomes isoelectric (burst-suppressive pattern). An isoelectric EEG can be maintained with a thiopental infusion rate of 4 to 6 mg/kg/h (resulting in plasma concentrations of 30 to 50 mg/mL). Because the decrease in systemic arterial pressure is usually less than the reduction in ICP, thiopental should improve cerebral perfusion and compliance. Therefore, thiopental is widely used to improve brain relaxation during neurosurgery and to improve cerebral perfusion pressure (CPP) after acute brain injury. Although barbiturate therapy is widely used to control ICP after brain injury, the results of outcome studies are no better than with other aggressive forms of cerebral antihypertensive therapy.

It has been suggested that barbiturates also possess “neuroprotective” properties secondary to their ability to decrease oxygen demand. Alternative explanations have been suggested, including

a reverse steal (“Robin Hood effect”) on CBF, free-radical scavenging, stabilization of liposomal membranes, as well as excitatory amino acid (EAA) receptor blockade. Based

on evidence from experimental studies and a large randomized prospective multiinstitutional study,[12] it has been concluded that barbiturates have no place in the therapy following resuscitation of a cardiac arrest patient. In contrast, barbiturates are frequently used for cerebroprotection during incomplete brain ischemia (e.g., carotid endarterectomy, temporary occlusion of cerebral arteries, profound hypotension, and cardiopulmonary bypass). By improving the brain's tolerance of incomplete ischemia in patients undergoing open heart surgery with cardiopulmonary bypass, barbiturates are alleged to decrease the incidence of postbypass neuropsychiatric disorders.[13] However, during valvular open heart cardiac surgery, a protective effect of barbiturate loading could not be demonstrated.[14] The routine use of barbiturates during cardiac surgery is not recommended because recent evidence would suggest that the use of moderate degrees of hypothermia (33 to 34°C) may provide superior neuroprotection without prolonging recovery.

Barbiturates cause predictable, dose-dependent EEG changes and possess potent anticonvulsant activity. Continuous infusions of thiopental have been used to treat refractory status epilepticus. However, low doses of thiopental may induce spike wave activity in epileptic patients. Methohexital has well-established epileptogenic effects in patients with psychomotor epilepsy. Low-dose methohexital infusions are frequently used to activate cortical EEG seizure discharges in patients with temporal lobe epilepsy. It is also the IV anesthetic of choice for electroconvulsive therapy.[15] Since the frequency of epileptiform EEG activity during induction of anesthesia with methohexital is significantly less than that which occurs during normal periods of sleep in epileptic patients, this suggests that higher doses of methohexital produces anticonvulsant activity. Methohexital also causes myoclonic-like muscle tremors and other signs of excitatory activity (e.g., hiccoughing).

Barbiturates cause dose-dependent respiratory depression.[16] However, bronchospasm or laryngospasm following induction with thiopental is usually the result of airway manipulation in “lightly” anesthetized patients. Laryngeal reflexes appear to be more active after induction with thiopental than with propofol. The cardiovascular effects of thiopental and methohexital include decreases in cardiac output, systemic arterial pressure, and peripheral vascular resistance. The depressant effects of thiopental on cardiac output are primarily a result of a decrease in venous return caused by peripheral pooling, as well as a result of a direct myocardial depressant effect, which assumes increasing importance in the presence of hypovolemia and myocardial disease.[17] Use of appropriate doses can minimize the cardiodepressant effects of thiopental, even in infants. Bhutada et al demonstrated that thiopental could be used for induction in infants without important changes in heart rate and blood pressure during the intubation period.[18] An equipotent dose of methohexital produces even less hypotension than thiopental because of a greater tachycardic response to the blood pressure lowering effects of the drug. If the blood pressure remains stable, the myocardial oxygen demand–supply ratio remains normal despite the increase in heart rate because of a concurrent decrease in coronary vascular resistance.

Propofol

Propofol (2,6-disopropylphenol), an alkylphenol compound, is virtually insoluble in aqueous solution. The initial cremophor EL formulation of propofol was withdrawn from clinical testing because of the high incidence of anaphylactic reactions. Subsequently, propofol (10 mg/mL) was reintroduced as an egg lecithin emulsion formulation (Diprivan), consisting of 10% soybean oil, 2.25% glycerol, and 1.2% egg phosphatide. Pain on injection occurs in 32 to 67% of patients when injected into small hand veins but can be minimized by injection into larger veins and by prior administration of either lidocaine or a potent opioid analgesic (e.g., fentanyl or remifentanil). A wide variety of drugs have been used for reducing pain on injection of propofol (e.g., metoprolol,[19] granisetron,[20] dolasetron,[21] and even thiopental[22]). Diluting the formulation with additional solvent (Intralipid) or changing the lipid carrier (Lipofundin) also reduced propofol-induced injection pain, probably because of a decrease in the concentration of free propofol in the

acqueous phase of the emulsion. A new propofol formulation with sodium metabisulphite (instead of disodium edetate) as an antimicrobial has recently been shown to be associated with less severe pain on injection. Although the presence of the metabisulphite has raised concerns regarding its use in sulphite-allergic patients, this does not appear to be a clinically important problem. Of interest, a 2% formulation is available for long-term sedation to decrease the fluid volume infused as well as the lipid load. Recently, a lower-lipid formulation of propofol (Ampofol) has been introduced into clinical practice for both general anesthesia[23] and sedation.[24] The increased "free" fraction of propofol leads to increased pain when it is injected into small veins. Therefore, it is important to add lidocaine to the Ampofol formulation to minimize the pain on injection. A new water-soluble prodrug of propofol (Aquavan) is rapidly hydrolized in the circulation to release propofol.[25] It has a slower onset than propofol but a similar recovery profile. Although Aquavan does not produce injection site discomfort, a burning perineal sensation has been reported.

Propofol's pharmacokinetics has been studied using single bolus dosing and continuous infusions.[26] In studies using a two-compartment kinetic model, the initial distribution half-life is 2 to 8 minutes and the elimination half-life is 1 to 3 hours. Using a three-compartment model, the initial and slow distribution half-life values are 1 to 8 minutes and 30 to 70 minutes, respectively. The elimination half-life depends largely on the sampling time after discontinuing the administration of propofol and ranges from 2 to 24 hours. This long elimination half-life is indicative of the existence of a poorly perfused compartment from which propofol slowly diffuses back into the central compartment. Propofol is rapidly cleared from the central compartment by hepatic metabolism and the context-sensitive half-life for propofol infusions up to 8 hours is less than 40 minutes. Propofol is rapidly and extensively metabolized to inactive, water-soluble sulphate and glucuronic acid metabolites, which are eliminated by the kidneys. Propofol's clearance rate (1.5 to 2.2 l/min) exceeds hepatic blood flow, suggesting that an extrahepatic route of elimination (lungs) also contributes to its clearance. Nevertheless, changes in liver blood flow would be expected to produce marked alterations in propofol's clearance rate. Surprisingly, few changes in propofol's pharmacokinetics have been reported in the presence of hepatic or renal disease.

The induction dose of propofol in healthy adults is 1.5 to 2.5 mg/kg, with blood levels of 2 to 6 µg/mL producing unconsciousness depending on the concomitant medications (e.g., opioid analgesics), the patient's age and physical status, and the extent of the surgical stimulation.[27] In one of the first reports describing the use of propofol for induction and maintenance of anesthesia with nitrous oxide, an average infusion rate of 120 µg/kg/min was required.[28] The recommended maintenance infusion rate of propofol varies between 100 and 200 µg/kg/min for hypnosis and 25 to 75 µg/kg/min for sedation. Awakening typically occurs at plasma propofol concentrations of 1 to 1.5 µg/mL.[29] Because a 50% decrease in the plasma propofol concentration is usually required for awakening, emergence following anesthesia is rapid even following prolonged infusions.

Analogous to the barbiturates, children require higher induction and maintenance doses of propofol on a mg/kg basis as a result of their larger central distribution volume and higher

clearance rate. Elderly and patients in poor health require lower induction and maintenance doses of propofol as a result of their smaller central distribution volume and decreased clearance rate. Although subhypnotic doses of propofol produce sedation and amnesia,[29] awareness has been reported even at higher infusion rates when propofol is used as the sole anesthetic.[30] Propofol often produces a subjective feeling of well-being and even euphoria, and may have some abuse potential as a result of these effects.[31] Propofol possesses dose-dependent effects on thalamocortical transfer of nociceptive information. However, pain-evoked cortical activity remains intact after loss of consciousness.[32]

Propofol decreases $CMRO_2$ and CBF, as well as ICP.[33] However, when larger doses are administered, the marked depressant effect on systemic arterial pressure can significantly decrease CPP. Cerebrovascular autoregulation in response to changes in systemic arterial pressure and reactivity of the cerebral blood flow to changes in carbon dioxide tension are not affected by propofol. Evidence for a possible neuroprotective effect has been reported in in vitro preparations, and the use of propofol to produce EEG burst suppression has been proposed as a method for

providing neuroprotection during aneurysm surgery. Its neuroprotective effect may at least partially be related to the antioxidant potential of propofol's phenol ring structure, which may act as a free-radical scavenger, decreasing free-radical induced lipid peroxidation. A recent study reported that this antioxidant activity may offer many advantages in preventing the hypoperfusion/reperfusion phenomenon that can occur during major laproscopic surgery.[34] Although TIVA with propofol and an opioid analgesic is a safe and effective alternative to standard inhalation techniques (i.e., volatile anesthetic with nitrous oxide) for maintenance of anesthesia, concerns have been raised regarding the cost-effectiveness of this technique.[35]

Propofol produces cortical EEG changes that are similar to thiopental. However, sedative doses of propofol increase β-wave activity analogous to the benzodiazepines. Induction of anesthesia with propofol is occasionally accompanied by excitatory motor activity (so-called nonepileptic myoclonia). In a study involving patients without a history of seizure disorders, excitatory movements following propofol were not associated with EEG seizure activity.[36] Propofol appears to possess profound anticonvulsant properties.[37] Propofol has been reported to decrease spike activity in patients with cortical electrodes implanted for resection of epileptogenic foci and has been used successfully to terminate status epilepticus. The duration of motor and EEG seizure activity following electroconvulsive therapy is significantly shorter with propofol than with other IV anesthetics. Propofol produces a decrease in the early components of somatosensory and motor-evoked potentials but does not influence the early components of the auditory evoked potentials.

Propofol produces dose-dependent respiratory depression, with apnea occurring in 25 to 35% of patients after a typical induction dose. A maintenance infusion of propofol decreases tidal volume and increases respiratory rate. The ventilatory response to carbon dioxide and hypoxia is also significantly decreased by propofol. Propofol can produce bronchodilation in patients with chronic obstructive pulmonary disease and does not inhibit hypoxic pulmonary vasoconstriction.

Propofol's cardiovascular depressant effects are generally considered to be more profound than those of thiopental. Both direct myocardial depressant effects and decreased systemic vascular resistance have been implemented as important factors in producing cardiovascular depression. Direct myocardial depression and peripheral vasodilation are dose and concentration dependent. In addition to arterial vasodilation, propofol produces venodilation (due both to a reduction in sympathetic activity and to a direct effect on the vascular smooth muscle), which further contributes to its hypotensive effect. The relaxation of the vascular smooth muscle may be because of an effect on intracellular calcium mobilization or because of an increase in the production of nitric oxide. Experiments in isolated myocardium suggest that the negative inotropic effect of propofol results from a decrease in intracellular calcium availability secondary to inhibition of transsarcolemmal calcium influx.

Propofol also alters the baroreflex mechanism, resulting in a smaller increase in heart rate for a given decrease in arterial pressure.[38] The smaller increase in heart rate with propofol may account for the larger decrease in arterial pressure than with an equipotent dose of thiopental. Recent studies suggest that induction of anesthesia with propofol attenuates desflurane-mediated sympathetic activation.[39] Age enhances the cardiodepressant response to propofol and a reduced dosage is required in the elderly. Patients with limited cardiac reserve seem to tolerate the cardiac depression and systemic vasodilation produced by carefully titrated doses of propofol and maintenance infusions are increasingly used at the end of cardiac surgery when early extubation is desired.

6 Propofol appears to possess antiemetic properties that contribute to a lower incidence of emetic sequelae after general anesthesia. In fact, subanesthetic doses of propofol (10 to 20 mg) have also been successfully used to treat nausea and emesis in the early postoperative period.[40] The postulated mechanisms include antidopaminergic activity, depressant effect on the chemoreceptor trigger zone and vagal nuclei, decreased release of glutamate and aspartate in the olfactory cortex, and reduction of serotonin concentrations in the area postrema. Interestingly, propofol also decreases the pruritus produced by spinal opioids.

Propofol does not trigger malignant hyperthermia (MH) and may be considered the induction agent of choice in MH-susceptible patients. The use of propofol infusions for sedation in the pediatric

intensive care unit has been linked to several deaths following prolonged administration because of lipid accumulation and hypotension. Although clinical doses of propofol do not affect cortisol synthesis or the response to adrenocorticotropic hormone (ACTH) stimulation, propofol has been reported to inhibit phagocytosis and killing of bacteria in vitro and to reduce proliferative responses when added to lymphocytes from critically ill patients.[41] Because fat emulsions are known to support the growth of microorganisms, contamination can occur as a result of dilution or fractionated use.[42]

Benzodiazepines

The parenteral benzodiazepines include diazepam (Valium), lorazepam (Ativan), and midazolam (Versed), as well as the antagonist flumazenil (Romazicon). Diazepam and lorazepam are insoluble in water and their formulation contains propylene glycol, a tissue irritant that causes pain on injection and venous irritation. Diazepam is available in a lipid emulsion formulation, which does not cause pain or thrombophlebitis but is associated with a slightly lower bioavailability. Midazolam is a water-soluble benzodiazepine that is available in an acidified (pH 3.5) aqueous formulation that produces minimal local irritation after IV or intramuscular (IM) injection.[43] At physiologic pH, an intramolecular rearrangement occurs that changes the physicochemical properties of midazolam such that it becomes more lipid soluble.

Benzodiazepines undergo hepatic metabolism via oxidation and glucuronide conjugation. Oxidation reactions are susceptible to hepatic dysfunction and coadministration of other anesthetic drugs. Diazepam is metabolized to active metabolites (desmethyldiazepam, 3-hydroxydiazepam), which can prolong diazepam's residual sedative effects because of their long $t_{1/2}$ β values. These metabolites undergo secondary conjugation to

form inactive water-soluble glucuronide conjugates. Drugs that inhibit the oxidative metabolism of diazepam include the H_2-receptor blocking drug cimetidine. Severe liver disease reduces diazepam's protein-binding and hepatic clearance rate, increases its volume of distribution, and thereby further prolongs the $t_{1/2}\beta$ value. Chronic renal disease decreases protein binding and increases the free drug fraction, resulting in enhanced hepatic metabolism and a shorter $t_{1/2}\beta$ value. In elderly patients, the clearance rate of diazepam is significantly decreased, prolonging its $t_{1/2}\beta$ to 75 to 150 hours.

Lorazepam is directly conjugated to glucuronic acid to form pharmacologically inactive metabolites. Age and renal disease have little influence on the kinetics of lorazepam; however, severe hepatic disease decreases its clearance rate.

Midazolam undergoes extensive oxidation by hepatic enzymes to form water-soluble hydroxylated metabolites, which are excreted in the urine. However, the primary metabolite, 1-hydroxymethylmidazolam, has mild CNS-depressant activity. The hepatic clearance rate of midazolam is five times greater than lorazepam and 10 times greater than diazepam. Although changes in liver blood flow can affect the clearance of midazolam, age has relatively little influence on midazolam's elimination half-life.

The benzodiazepines used in anesthesia are classified as either short- (midazolam, flumazenil), intermediate- (diazepam), or long-acting (lorazepam). Because the distribution volumes are similar, the large difference in the elimination half-times is because of differences in their differing clearance rates (see Table 13-1). The context-sensitive half-times for diazepam and lorazepam are very long; therefore, only midazolam should be used by continuous infusion to avoid excessive accumulation.

All benzodiazepines have anxiolytic, amnestic, sedative, hypnotic, anticonvulsant, and spinally mediated muscle relaxant properties. Benzodiazepines differ in potency and efficacy with regard to their distinctive pharmacologic properties.[43] The dose-dependent pharmacologic activity implies that the CNS effects of various benzodiazepine compounds depend on the affinity for receptor subtypes and their degree of receptor binding. Although benzodiazepines can be used as hypnotics, they are primarily used as premedicants and adjuvant drugs because of their anxiolytic, sedative, and amnestic properties. For example, midazolam (0.04 to 0.08 mg/kg IV/IM) is the

most commonly used premedicant. In addition, midazolam, 0.4 to 0.8 mg/kg administered orally 10 to 15 minutes before parental separation, is an excellent premedicant in children. In contrast to lorazepam, both diazepam and midazolam can be used to induce anesthesia because they have a relatively short onset time after IV administration. The half-life of equilibration between the plasma concentration of midazolam and its maximal EEG effect is only 2 to 3 minutes. The therapeutic window to maintain unconsciousness with midazolam is reported to be 100 to 200 ng/mL, with awakening occurring at plasma concentrations below 50 ng/mL. However, significant hypnotic synergism occurs when midazolam and opioid analgesics are administered in combination.

The usual induction dose of midazolam in premedicated patients is 0.1 to 0.2 mg/kg IV, with infusion rates of 0.25 to 1 mg/kg/min required to maintain hypnosis and amnesia in combination with inhalational agents and/or opioid analgesics. Higher maintenance infusion rates and prolonged administration will result in accumulation and prolonged recovery times. Lower infusion rates are sufficient to provide sedation and amnesia during local and regional anesthesia.[44] Patient-controlled administration of midazolam during procedures under local anesthesia is well accepted by patients and associated with few perioperative complications.[45]

Benzodiazepines decrease both $CMRO_2$ and CBF analogous to the barbiturates and propofol. However, in contrast to these compounds, midazolam is unable to produce a burst-suppressive (isoelectric) pattern on the EEG. Accordingly, there is a "ceiling" effect with respect to the decrease in $CMRO_2$ produced by increasing doses of midazolam. Midazolam induces dose-dependent changes in regional cerebral perfusion in the parts of the brain that subserve arousal, attention, and memory. Cerebral vasomotor responsiveness to carbon dioxide is preserved during midazolam anesthesia. In patients with severe head injury, a bolus dose of midazolam may decrease CPP with little effect on ICP. Although midazolam may improve neurologic outcome after incomplete ischemia in animal experiments, benzodiazepines have not been shown to possess neuroprotective activity in humans. Like the other sedative–hypnotic drugs, the benzodiazepines are potent anticonvulsants that are commonly used to treat status epilepticus.

Benzodiazepines produce dose-dependent respiratory depression. In healthy patients, the respiratory depression associated with benzodiazepine premedication is insignificant. However, the depressant effect is enhanced in patients with chronic respiratory disease, and synergistic depressant effects occur when benzodiazepines are coadministered with opioid analgesics. Benzodiazepines also depress the swallowing reflex and decrease upper airway reflex activity.

Both midazolam and diazepam produce decreases in systemic vascular resistance and blood pressure when large doses are administered for induction of anesthesia. However, the cardiovascular depressant effects of benzodiazepines are frequently "masked" by the stimulus of laryngoscopy and intubation. The cardiovascular depressant effects are directly related to the plasma concentration; however, a plateau plasma concentration appears to exist above which little further change in arterial blood pressure occurs. In the presence of heart failure, the decrease in preload and afterload produced by benzodiazepines may be beneficial in improving cardiac output. However, the cardiodepressant effect of benzodiazepines may be more marked in hypovolemic patients.

Ro 48-6791, a so-called short-acting intravenous sedative (SAIVS), is a new water-soluble benzodiazepine that has full agonistic activity at CNS benzodiazepine receptors. Compared with midazolam, it is 2- to 2.5-fold more potent, has a higher plasma clearance rate, and has a similar onset and duration of action.[46] In a recent study involving outpatients undergoing endoscopy procedures, the times to ambulation and to recovery from psychomotor impairment were decreased compared to midazolam, although the later recovery end points (e.g., "fitness-for-discharge") were similar.[47]

In contrast to all other sedative–hypnotic drugs, there is a specific antagonist for benzodiazepines. Flumazenil, a 1,4-imidazobenzodiazepine derivative, has a high affinity for the benzodiazepine receptor but minimal intrinsic activity.[48] Flumazenil's molecular structure is similar to other benzodiazepines except for the absence of a phenyl group, which is replaced by a carbonyl group. It is water soluble and possesses moderate lipid solubility at physiologic pH.

Flumazenil is rapidly metabolized in the liver, and its metabolites are excreted in the urine as glucuronide conjugates. Flumazenil acts as a competitive antagonist in the presence of benzodiazepine agonist compounds. The residual activity of the benzodiazepines in the presence of flumazenil depends on the relative concentrations of the agonist and antagonist drugs. As a result, it is possible to reverse benzodiazepine-induced anesthesia (or deep sedation) either completely or partially depending on the dose of flumazenil. Flumazenil is short acting, with an elimination half-life of ~1 hour.

Recurrence of the central effects of benzodiazepines (resedation) may occur after a single dose of flumazenil because of residual effects of the more slowly eliminated agonist drug.[49] If sustained antagonism is desired, it may be necessary to administer flumazenil as repeated bolus doses or a continuous infusion. In general, 45 to 90 minutes of antagonism can be expected

following flumazenil 1 to 3 mg IV. However, the respiratory depression produced by benzodiazepines is not completely reversed by flumazenil.[50] Reversal of benzodiazepine sedation with flumazenil is not associated with adverse cardiovascular effects or evidence of an acute stress response.[51] Although flumazenil does not appear to change CBF or $CMRO_2$ following midazolam anesthesia for craniotomy, acute increases in ICP have been reported in head-injured patients receiving flumazenil.

Etomidate

Etomidate is a carboxylated imidazole-containing anesthetic compound (R-1-ethyl-1-[a-methylbenzyl] imidazole-5-carboxylate) that is structurally unrelated to any other IV anesthetic. Only the D-isomer of etomidate possesses anesthetic activity. Analogous to midazolam (which also contains an imidazole nucleus), etomidate undergoes an intramolecular rearrangement at physiologic pH, resulting in a closed-ring structure with enhanced lipid solubility. The aqueous solution of etomidate (Amidate) is unstable at physiologic pH and is formulated in a 0.2% solution with 35% propylene glycol (pH 6.9), contributing to a high incidence of pain on injection, venoirritation, and hemolysis. A new lipid emulsion formulation (Etomidate-Lipuro) has recently been introduced in Europe and appears to be associated with a lower incidence of side effects compared to the original propylene glycol formulation.

The standard induction dose of etomidate (0.2 to 0.4 mg/kg IV) produces a rapid onset of anesthesia. Involuntary myoclonic movements are common during the induction period as a result of subcortical disinhibition and are unrelated to cortical seizure activity. The frequency of this myoclonic-like activity can be attenuated by prior administration of opioid analgesics, benzodiazepines, or small sedative doses (0.03 to 0.05 mg/kg) prior to induction of anesthesia.[52] Emergence time after etomidate anesthesia is dose dependent but remains short even after administration of repeated bolus doses or continuous infusions. For maintenance of hypnosis, the target concentration is 300 to 500 $ng \cdot mL^{-1}$ and can be rapidly achieved by administering a two- or three-stage infusion (e.g., 100 mg/kg/min for 10 min followed by 10 mg/kg/min or 100 mg/kg/min for 3 to 5 minutes, followed by 20 mg/kg/min for 20 to 30 minutes, and then 10 mg/kg/min). The pharmacokinetics of etomidate are optimally described by a three-compartment open model.[53] The high clearance rate of etomidate (18 to 25 mL/kg/min) is a result of extensive ester hydrolysis in the liver (forming inactive water-soluble metabolites). A significant decrease in plasma protein binding has been reported in the presence of uremia and hepatic cirrhosis. Severe hepatic disease causes a prolongation of the elimination half-life secondary to an increased volume of distribution and a decreased plasma clearance rate.

Analogous to the barbiturates, etomidate decreases $CMRO_2$, CBF, and ICP. However, the hemodynamic stability associated with etomidate will maintain adequate CPP. Etomidate has been used successfully for both induction and maintenance of anesthesia for neurosurgery. Etomidate's well-known inhibitory effect on adrenocortical synthetic function[54] limits its clinical usefulness for long-term treatment of elevated ICP. Although clear evidence for a neuroprotective effect in humans is lacking, etomidate is frequently used during temporary arterial occlusion and intraoperative angiography (for the treatment of cerebral aneurysms). Etomidate produces an EEG pattern that is similar to thiopental except for the absence of increased β activity at lower doses.

Etomidate can induce convulsion-like EEG potentials in epileptic patients without the appearance of myoclonic or convulsant-like motor activity, a property that has been proven useful for intraoperative mapping of seizure foci. Etomidate also possesses anticonvulsant properties and it has been used to terminate status epilepticus. Etomidate produces a significant increase of the amplitude of somatosensory evoked potentials while only minimally increasing their latency. Consequently, etomidate can be used to facilitate the interpretation of somatosensory evoked potentials when the signal quality is poor.

7 Etomidate causes minimal cardiorespiratory depression even in the presence of cardiovascular and pulmonary disease.[55] The drug does not induce histamine release and can be safely used in patients with reactive airway disease. Consequently, etomidate is considered to be the induction agent of choice for poor-risk patients with cardiorespiratory disease, as well as in those situations in which preservation of a normal blood pressure is crucial (e.g., cerebrovascular disease). However, etomidate does not effectively blunt the sympathetic response to laryngoscopy and intubation unless combined with a potent opioid analgesic.

Etomidate is associated with a high incidence of postoperative nausea and emesis when used in combination with opioids for short outpatient procedures. In addition, the increased mortality in critically ill patients sedated with an etomidate infusion has been attributed to its inhibitory effect on cortisol synthesis.[56] Etomidate inhibits the activity of 11-β-hydroxylase, an enzyme necessary for the synthesis of cortisol, aldosterone, 17-hydroxyprogesterone, and corticosterone. Even after a single induction dose of etomidate,[56] adrenal suppression persists for 5 to 8 hours. Although the clinical significance of short-term blockade of cortisol synthesis is not known, the use of etomidate for maintenance of anesthesia has been questioned. Recently, etomidate has been reported to inhibit platelet function, resulting in prolongation of the bleeding time.[57] In spite of its side effect profile, etomidate remains a valuable induction drug still for specific indications (in patients with severe cardiovascular and cerebrovascular disease).

Ketamine

Ketamine (Ketalar or Ketaject) is an arylcyclohexylamine that is structurally related to phencyclidine.[58] Ketamine is a water-soluble compound with a pKa of 7.5 and is available in 1%, 5%, and 10% aqueous solutions. The ketamine molecule contains a chiral center producing two optical isomers. The S(+) isomer of ketamine possesses more potent anesthetic and analgesic properties despite having a similar pharmacokinetic and pharmacodynamic profile as the racemic mixture (or the R[-] isomer).[59,60] Although the S(+)-ketamine is approved for clinical use in Europe, the commonly used solution is a racemic mixture of the two isomers. Ketamine is extensively metabolized by hepatic microsomal cytochrome P-450 enzymes and its primary metabolite, norketamine, is one third to one fifth as potent as the parent compound. The metabolites of norketamine are excreted by the kidney as water-soluble hydroxylated and glucuronidated conjugates. Analogous to the barbiturates and propofol, ketamine has relatively short distribution and redistribution half-life values. Ketamine also has a high hepatic clearance rate (1 L/min) and a large distribution volume (3 L/kg), resulting in an elimination half-life of 2 to 3 hours. The high hepatic extraction ratio suggests that alterations in hepatic blood flow can significantly influence ketamine's clearance rate.

8 Ketamine produces dose-dependent CNS depression leading to a so-called dissociative anesthetic state characterized by profound analgesia and amnesia, even though patients may be conscious and maintain protective reflexes. The proposed mechanism for this cataleptic state includes electrophysiologic

inhibition of thalamocortical pathways and stimulation of the limbic system. Although it is most commonly administered parenterally, oral and intranasal administration of ketamine (6 mg/kg) has been used for premedication of pediatric patients. Following benzodiazepine premedication, ketamine 1 to 2 mg/kg IV (or 4 to 8 mg/kg IM) can be used for induction of anesthesia. The duration of ketamine-induced anesthesia is in the range of 10 to 20 minutes after a single induction dose; however, recovery to full orientation may require an additional 60 to 90 minutes. Emergence times are even longer following repeated bolus injections or a continuous infusion. S

(+)-ketamine has a shorter recovery time compared with the racemic mixture. The therapeutic window for maintenance of unconsciousness with ketamine is between 0.6 and 2 mg/mL in adults and between 0.8 and 4 mg/mL in children. Analgesic effects are evident at subanesthetic doses of 0.1 to 0.5 mg/kg IV and plasma concentrations of between 85 and 160 ng/mL. A low-dose infusion of 4 μg/kg/min IV was reported to result in equivalent postoperative analgesia as an IV morphine infusion of 2 mg/h.

As a result of its NMDA-receptor blocking activity, it has been suggested that ketamine should be highly effective for preemptive analgesia and opioid-resistant chronic pain states.[61] Unfortunately, a well-controlled study failed to demonstrate a preemptive effect when ketamine was administered prior to the surgical incision.[62]

An important consideration in the use of ketamine anesthesia relates to the high incidence of psychomimetic reactions (namely, hallucinations, nightmares, altered short-term memory and cognition) during the early recovery period. The incidence of these reactions is dose dependent and can be reduced by coadministration of benzodiazepines, barbiturates, or propofol. Ketamine has been traditionally contraindicated for patients with increased ICP or reduced cerebral compliance because it increases $CMRO_2$, CBF, and ICP. However, there is recent evidence that IV induction doses of ketamine actually increases ICP in traumatic–brain-injury patients during controlled ventilation with propofol sedation.[63] Prior administration of thiopental or benzodiazepines can blunt ketamine-induced increases in CBF. Since ketamine has antagonistic activity at the NMDA receptor, it has been suggested that it possesses some inherent protective effects against brain ischemia. Nevertheless, ketamine can adversely affect neurologic outcome in the presence of brain ischemia despite its NMDA-receptor blocking activity. Cortical EEG recordings following ketamine induction are characterized by the appearance of fast β activity (30 to 40 Hz) followed by moderate-voltage θ activity, mixed with high-voltage δ waves recurring at 3 to 4 second intervals. At higher dosages, ketamine produces a unique EEG burst-suppression pattern (Fig. 13-5). Although ketamine-induced myoclonic and seizure-like activity has been observed in normal (nonepileptic) patients, ketamine appears to possess anticonvulsant activity.[8] Recently, several have demonstrated the opioid-sparing effects of low-dose Ketamine (75 to 200 mcg/kg) when administered as an adjuvant during anesthesia.[64,65] Interestingly, small-dose ketamine has also been used in the treatment of severe depression in patients with chronic pain syndromes.[66] However, ketamine can produce adverse effects when administered in the presence of triciclyic antidepressants because both drugs inhibit norepinephrine reuptake and could produce severe hypotension, heart failure, and/or myocardial ischemia.[67,68]

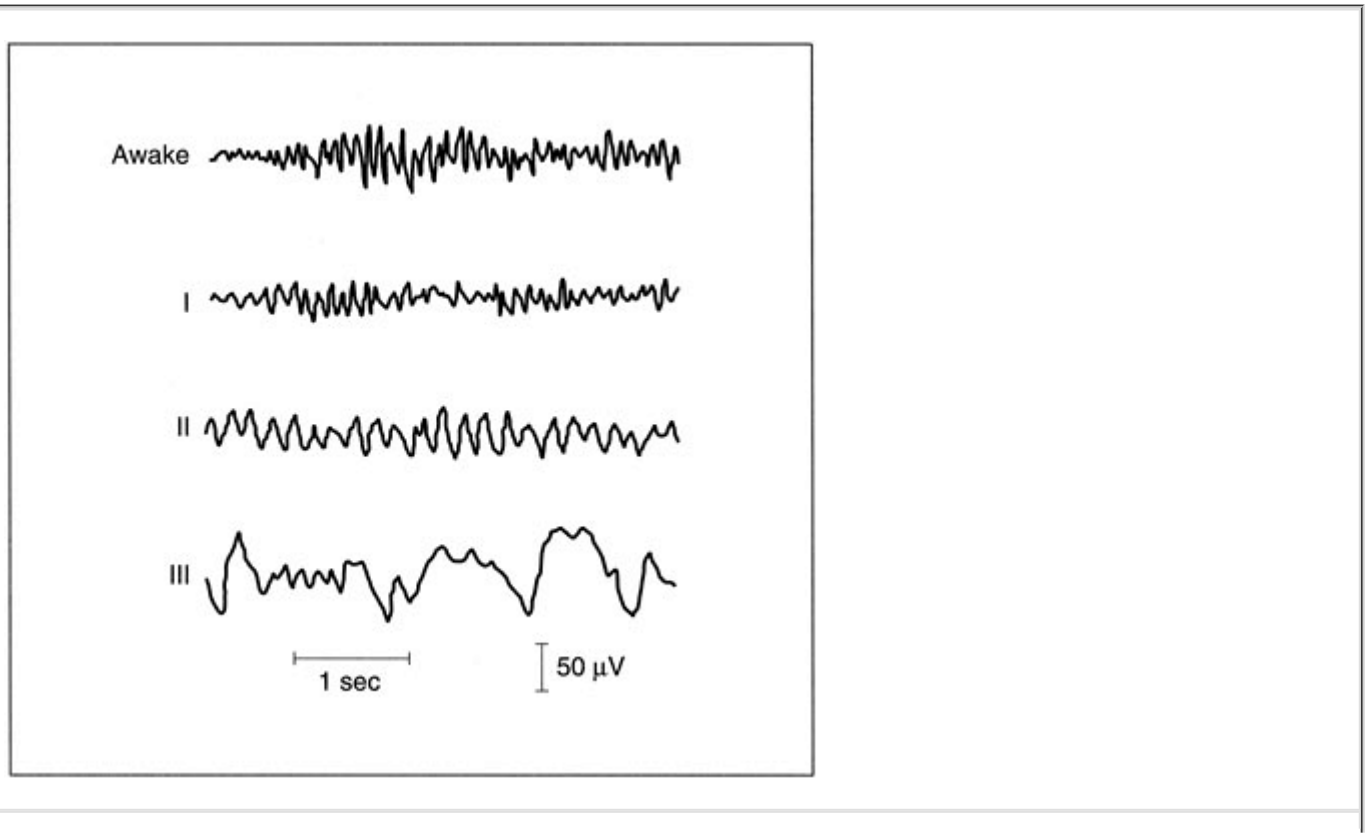

FIGURE 13-5. Progressive changes in the EEG produced by ketamine. Stages I through III are achieved with racemic ketamine and its S(+)isomer. With R(-)ketamine, Stage II was the maximal EEG depression produced. (Reprinted with permission from Shüttler J, Stanski DR, White PF, et al: Pharmacodynamic modeling of the EEG effect of ketamine and its enantiomers in man. J Pharmacokinet Biopharm 15:241, 1987.)

Ketamine has well-characterized bronchodilatory activity. In the presence of active bronchospasm, ketamine is considered to be the IV induction agent of choice. Ketamine has been used in subanesthetic dosages to treat persistent bronchospasm in the operating room and ICU. It is also used in combination with midazolam to provide sedation and analgesia for asthmatic patients. In contrast to the other IV anesthetics, protective airway reflexes are more likely to be preserved with ketamine. However, it must be emphasized that the use of ketamine does not obviate the need for tracheal intubation in the patient with a full stomach (because tracheal soiling has been reported in this situation). Ketamine causes minimal respiratory depression in clinically relevant doses and can facilitate the transition from mechanical to spontaneous ventilation after anesthesia. However, its ability to increase oral secretions can lead to laryngospasm during "light" anesthesia.

Ketamine has prominent cardiovascular stimulating effects secondary to direct stimulation of the sympathetic nervous system. Ketamine is the only anesthetic that actually increases peripheral arteriolar resistance. As a result of its vasoconstrictive properties, ketamine can reduce the magnitude of redistribution hypothermia.[69] Induction of anesthesia with ketamine often produces significant increases in arterial blood pressure and heart rate. Although the mechanism of the cardiovascular stimulation is not entirely clear, it appears to be centrally mediated. There is evidence to suggest that ketamine attenuates baroreceptor activity via an effect on NMDA receptors in the nucleus tractus solitarius. Because of the increased cardiac work and myocardial oxygen consumption, ketamine negatively affects the balance between myocardial oxygen supply and demand. Consequently, its use is not recommended in patients with severe coronary artery disease. In contrast to the secondary cardiovascular stimulation, ketamine has intrinsic myocardial depressant properties that only become apparent in the seriously ill patient with depleted catecholamine reserves. Because ketamine can also increase pulmonary artery pressure, its use is contraindicated in adult patients with poor right ventricular reserve. Interestingly, the effect on the pulmonary vasculature seems to be attenuated in children.

The anesthetic and analgesic potency of S(+)-ketamine is three times greater than R(-)-ketamine and twice that of the racemic mixture (Fig. 13-6), reflecting its fourfold greater affinity at the phencyclidine binding site on the NMDA receptor compared with the R(-) isomer.[70] The therapeutic index of S(+)-ketamine is 2.5 times greater than both the R(-)

and the racemic forms. In addition, hepatic biotransformation of S(+)-ketamine occurs 20% faster than that of the R(-) enantiomer, contributing to shorter emergence times and a faster return of cognitive function. Both isomers produce similar cardiovascular stimulating effects and hormonal responses during surgery. Although the incidence of dreaming is similar with S(+)-ketamine and the racemic mixture, subjective mood and patient acceptance are higher with the S(+) isomer.

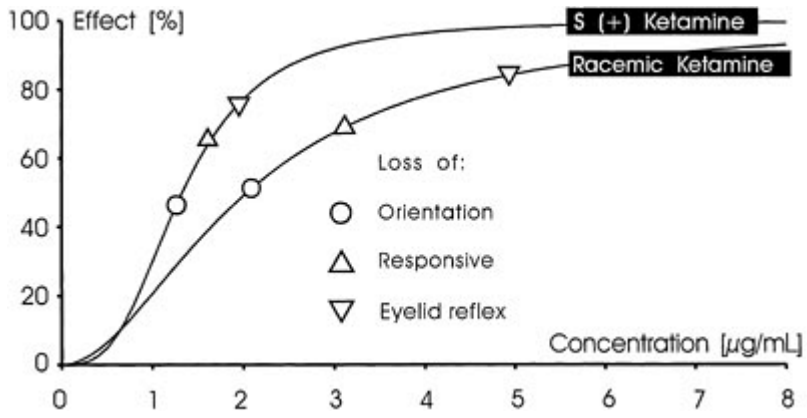

FIGURE 13-6. Concentration-response relationship for racemic ketamine and S(+)ketamine in relation to specific clinical end points. The slowing of the median EEG frequency was used as the effect (end point) and was related to the arterial blood concentrations of ketamine. (Reprinted with permission from Schüttler J, Kloos S, Ihmsen H, et al: Pharmacokinetic-pharmacodynamic properties of S(+)-ketamine versus racemic ketamine: A randomized double-blind study in volunteers. Anesthesiology 77:A330, 1992.)

CLINICAL USES OF INTRAVENOUS ANESTHETICS

Use of Intravenous Anesthetics As Induction Agents

The induction characteristics and recommended dosages of the available IV anesthetic agents are summarized in Table 13-2. As a result of differences in pharmacokinetic (e.g., altered clearance and distribution volumes) and pharmacodynamic (altered brain sensitivity) variables, the induction dosages of all IV anesthetics need to be adjusted to meet the needs of individual patients. For example, advanced age, preexisting diseases (e.g., hypothyroidism, hypovolemia), premedication (e.g., benzodiazepines), and coadministration of adjuvant drugs (e.g., opioids, (α-2 agonists) decrease the induction dose requirements. When there is concern regarding a possible abnormal response, assessing the effect of a small "test dose" (equal to 10 to 20% of the usual induction dose) will often identify those patients for whom a dosage adjustment is required. Before administering additional medication, adequate time should be allowed for the anesthetic to exert its effect, especially when using drugs with a slow onset of action (midazolam) or in the presence of a "slow" circulation time in elderly patients and those with congestive heart failure.

†↓ = decrease; ↑ = increase.

The clinical uses of propofol have expanded greatly since its introduction into clinical practice in 1989.[71] Intravenous administration of propofol results in a rapid loss of consciousness (usually within one arm-to-brain circulation) that is comparable to the barbiturates. Although an induction dose of 2.5 mg/kg was initially recommended, the use of smaller induction doses of propofol (1 to 2 mg/kg) has minimized its acute cardiovascular and respiratory depressant effects. Recovery from propofol's sedative–hypnotic effects is rapid with less residual sedation, fatigue ("hangover"), and cognitive impairment than with other available sedative–hypnotic drugs after short surgical procedures. Consequently, propofol has become the IV drug of choice for outpatients undergoing ambulatory surgery.

With benzodiazepines, there is wide variation in the dose-response relationships in unpremedicated elective surgery patients. Compared to midazolam, diazepam and lorazepam have slower onset times to achieve a peak effect and their dose-effect relationship is less predictable. As a result, diazepam and lorazepam are rarely used for induction of general anesthesia. In addition, the slow hepatic clearance of diazepam and lorazepam may contribute to prolonged residual effects (sedation, amnesia, fatigue) when they are used for premedication. Midazolam has a slightly more rapid onset and may be a useful induction agent for special indications (when nitrous oxide is contraindicated, or as part of a total IV anesthetic technique). However, when midazolam is used for induction and/or maintenance of anesthesia, return of consciousness takes substantially longer than with other sedative–hypnotic drugs. In spite of its extensive hepatic metabolism, recovery of cognitive function is still slower after midazolam compared with thiopental, methohexital, etomidate, or propofol.

9 In an effort to optimize the clinical use of midazolam during the induction period, it is utilized increasingly as a coinduction agent with other sedative–hypnotic drugs (propofol, ketamine). Midazolam 2 to 5 mg IV can provide for increased sedation, amnesia, and anxiolysis during the preinduction period. When midazolam is used in combination with propofol, 1.5 to 2 mg/kg IV, or ketamine, 0.75 to 1 mg/kg IV, it facilitates the onset of anesthesia without delaying emergence times.[72]

Midazolam attenuates the cardiostimulatory response to ketamine, as well as its psychomimetic

emergence reactions. Use of midazolam, 2 to 3 mg IV with propofol reduces recall during the induction period; however, larger doses of midazolam (5 mg IV) will delay emergence after brief surgical procedures.

As a result of their side effect profiles, the clinical use of etomidate and ketamine for induction of anesthesia is restricted to specific situations where their unique pharmacologic profiles offer advantages over other available IV anesthetics. For example, etomidate can facilitate maintenance of a stable blood pressure in high-risk patients with critical stenosis of the cerebral vasculature and in patients with severe cardiac impairment or unstable angina. Ketamine is a useful induction agent for hypovolemic patients, as well as in patients with reactive airway disease or a compromised upper airway.

Use of Intravenous Drugs for Maintenance of Anesthesia

The continued popularity of volatile anesthetics for maintenance of anesthesia is due primarily to their rapid reversibility and ease of administration when using conventional vaporizer delivery system for titrating to the desired end point. The availability of IV drugs with more rapid onset and shorter recovery profiles, as well as user-friendly infusion delivery systems, has facilitated the maintenance of anesthesia with continuous infusions of IV drugs, producing an anesthetic state (namely, TIVA) that compares favorably with the volatile anesthetics. In a comparison of the requirement of postoperative analgesics after inhalation and TIVA techniques, not surprisingly, the postoperative pain was reduced after TIVA.[73] For example, in morbidly obese patients undergoing bariatric surgery, the use of TIVA technique was associated with a superior recovery profile compared to a sevoflurane-based inhalation technique.[74] However, TIVA techniques are more expensive than inhalation or "balanced" anesthetic techniques.[35]

The traditional intermittent bolus administration of IV drugs results in a "depth" of anesthesia (and analgesia) that oscillates above and below the desired level.[75] Because of rapid distribution and redistribution of the IV anesthetics, the high peak blood concentration after each bolus is followed by a rapid decrease, producing fluctuating drug levels in the blood and hence the brain. The magnitude of the drug level fluctuation is dependent on the size of the bolus dose and the frequency of its administration. Wide variation in the plasma drug concentrations can result in hemodynamic and respiratory instability as a result of changes in the depth of anesthesia or sedation. By providing more stable blood (and brain) concentrations with a continuous IV infusion, it might be possible to improve anesthetic conditions and hemodynamic stability, as well as decreasing side effects and recovery times with IV anesthetics.[76] Administration of IV anesthetics by a variable-rate infusion is a logical extension of the incremental bolus method of drug titration, as a continuous infusion is equivalent to the sequential administration of infinitely small bolus doses.

Although an IV anesthetic can be titrated to achieve and maintain the desired clinical effect, a knowledge of basic pharmacokinetic principles is helpful in more accurately predicting the optimal dosage requirements. The required plasma concentration depends on the desired pharmacological effect (hypnosis, sedation), the concomitant use of other adjunctive drugs (opioid analgesics, muscle relaxants, cardiovascular drugs), the type of operation (superficial, intra-abdominal, intracranial), and the patient's sensitivity to the drug (age, drug history, preexisting diseases). Preexisting diseases (cirrhosis, congestive heart failure, renal failure) can markedly alter the pharmacokinetic variables of the highly protein-bound, lipophilic IV anesthetic drugs. In general, children have higher clearance rates, while the elderly have reduced clearance values. Various intraoperative interventions (laryngoscopy, tracheal intubation, skin incision, entry into body cavities) transiently increase the anesthetic and/or analgesic requirements. Therefore, the infusion scheme should be tailored to provide peak drug concentrations during the periods of most intense stimulation. For specific surgical interventions, the so-called therapeutic window of an IV anesthetic is defined as the blood concentration range required to produce a given effect (Table 13-3). It must be emphasized that the therapeutic window for Sedative–hypnotics is markedly influenced by the presence of adjunctive drugs (opioids, α_2 agonists, nitrous oxide).

TABLE 13-3 Therapeutic Blood Concentrations When Intravenous Anesthetics are Infused for Hypnosis or Sedation

▪DRUG NAME	▪MAJOR SURGERY PROCEDURES	▪MINOR SURGERY PROCEDURES	▪SEDATIVE CONCENTRATION	▪AWAKENING CONCENTRATION
Thiopental	10–20 µg/mL	10–20 µg/mL	4–8 µg/mL	4–8 µg/mL
Methohexital	6–15 µg/mL	5–10 µg/mL	1–3 µg/mL	1–3 µg/mL
Propofol	4–6 µg/mL	2–4 µg/mL	1–2 µg/mL	1–1.5 µg/mL
Midazolam	100–200 ng/mL	50–200 ng/mL	40–100 ng/mL	50–150 ng/mL
Etomidate	500–1000 ng/mL	300–600 ng/mL	100–300 ng/mL	200–350 ng/mL
Ketamine	1–4 µg/mL	0.6–2 µg/mL	0.1–1 µg/mL	NA

NA = not available.

The use of IV anesthetic techniques requires continuous titration of the drug infusion rate to the desired pharmacodynamic end point.[72] Most anesthesiologists rely on somatic and autonomic signs for assessing depth of IV anesthesia, analogous to the manner in which they titrate the volatile anesthetics. The most sensitive clinical signs of depth of anesthesia appear to be changes in muscle tone (i.e., electromyography [EMG]) and ventilatory rate and pattern.[77] However, if the patient has been given muscle relaxants, the anesthesiologist must rely on signs of autonomic hyperactivity (tachycardia, hypertension, lacrimation, diaphoresis). Unfortunately, the anesthetic drugs (ketamine), as well as adjunctive agents (α_2 agonists, β blockers, adenosine, calcium-channel blockers), can directly influence the cardiovascular response to surgical stimulation. Although the cardiovascular signs of autonomic nervous system hyperactivity may be masked, other autonomic signs (e.g., diaphoresis) and purposeful movements may be more reliable indicators of depth of anesthesia than blood pressure because the latter depends on the ability of the heart to maintain the cardiac output in the face of acute changes in afterload. The heart rate response to surgical stimulation appears to be more useful than the blood pressure response in determining the need for additional analgesic medication. Moreover, it

would appear that blood pressure and heart rate responses to surgical stimulation are a less useful guide with IV techniques than with volatile anesthetics.

The clinical assessment of anesthetic depth has become more challenging because IV anesthetic techniques involve a combination of hypnotics, opioids, muscle relaxants, and adjuvant drugs. The interactions between these drugs can result in additive, supra-additive, infra-additive, or even antagonistic effects. An ideal "depth of anesthesia" indicator would integrate the physiologic and neurologic information from all aspects of the anesthetic state. In the absence of a global cerebral

function monitor, the "depth of anesthesia" device should provide an indication of one or more of the key components of general anesthesia (e.g., hypnosis, analgesia, amnesia, suppression of the stress response, or muscle relaxation). A simple, noninvasive monitor of the depth of anesthesia, which would reliably predict a patient's response to surgical stimulation, would be extremely valuable when utilizing IV anesthetic techniques.

The EMG activity of the frontalis muscles increases significantly in patients who move in response to specific surgical stimuli.[77] However, EMG changes occur late and their interpretation is obscured by muscle relaxant drugs. The EEG changes depend largely on the type of anesthetic drugs used. Although a common EEG pattern can be recognized with increasing depression of CNS function by sedative–hypnotics and opioid analgesics, there is no characteristic EEG pattern associated with unconscious and amnestic states.[78] Univariate descriptors of EEG activity appear to be of limited clinical usefulness, and no meaningful correlation could be found between EEG spectral edge frequency and hemodynamic response to surgical stimuli during propofol anesthesia.[79] Although EEG variables (spectral edge frequency, median frequency) appear to be useful indicators of the CNS effects of anesthetic and analgesic drugs in the experimental setting, their usefulness in clinical practice is limited because the many confounding factors during the operation (changing drug levels and surgical stimulation). The EEG-based bispectral index (BIS), patient state index (PSI), state entropy (SE), and response entropy (RE) monitors represent newer approaches to the analysis of the spontaneous EEG, have proved to be a useful indicator of anesthetic (hypnotic) depth.[80] Recent studies have demonstrated that the BIS index can improve filtration of both IV and volatile anesthetics during surgery, thereby facilitating the recovery process. Using EEG-based monitoring can reduce the time required to achieve fast-track eligibility after ambulatory surgery.[81,82]

An attractive alternative to the spontaneous EEG is the evoked response of the EEG to sensory stimuli (e.g., auditory evoked potential [AEP] monitors). The ability to quantitatively assess the response of the body to varying levels of stimulation (sensory or auditory evoked responses) may be useful in improving the assessment of depth of anesthesia.[83] Although all sedative–hypnotic drugs affect the brainstem evoked potentials, uncertainty still exists regarding the most useful evoked response(s) to measure. The complexity associated with recording evoked responses is much greater than recording the spontaneous EEG because the value is critically dependent on technical factors (e.g., stimulus intensity, stimulus rate, electrode position), body temperature, as well as the anesthetic drugs. Although most IV anesthetics produce dose-dependent changes in the somatosensory evoked potentials, the correlation between the acute hemodynamic changes to surgical stimuli and the early auditory evoked responses is poor. However, the early cortical (mid-latency) auditory evoked response might be useful in detecting awareness under anesthesia. Furthermore, the auditory evoked potential index (AEPi) may be more discriminatory than BIS in characterizing the transition from wakefulness to unresponsiveness.[84]

As a result of the availability of more rapid and shorter acting sedative–hypnotics, sophisticated computer technology, and new insights into pharmacokinetic–dynamic interactions, use of TIVA techniques has been steadily increasing during the last decade. When utilizing constant rate IV infusions, 4 to 5 half-lives may be required to achieve a steady state anesthetic concentration (Fig. 13-7). To more rapidly achieve a therapeutic blood concentration, it is necessary to administer a loading (priming) dose and to maintain the desired drug concentration using a maintenance infusion. The loading dose (LD) and initial maintenance infusion rate (MIR) can be calculated from previously determined population kinetic values using the following equations:

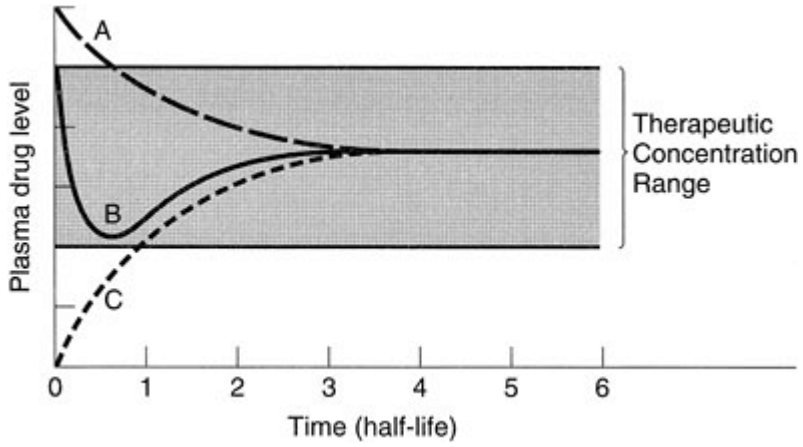

FIGURE 13-7. Simulated drug level curves when a constant infusion is administered following a "full" loading dose equal to [Cp] × Vd_{ss} (*Curve A*), a smaller loading dose equal to [Cp] × Vc (*Curve B*), or in the absence of a loading (*Curve C*). (Reprinted with permission from White PF: Clinical uses of intravenous anesthetic and analgesic infusions. Anesth Analg 68:161, 1989.)

LD = Cp (mg/mL) · Vd (mL/kg)

MIR = Cp (mL/kg) · Cl (mL/kg/min)

where Cp = plasma drug concentration; Vd = distribution volume; Cl = drug clearance.

The use of the smaller central volume of distribution (Vc) for the Vd component of the LD equation will underestimate the LD, whereas use of the larger steady-state volume of distribution (Vd_{ss}) will result in drug levels that transiently exceed those that are desired. If a smaller LD is administered, a higher initial MIR will be required to compensate for the drug that is removed from the brain by both redistribution and elimination processes. As the redistribution phase assumes less importance, the MIR will decrease because it becomes solely dependent on the drug's elimination and the desired plasma concentration.

An alternative approach is to begin with a rapid loading infusion with a bolus-elimination transfer (BET) scheme that combines three functions, as shown in the following equation:

$$\text{Input} = V1 \cdot C_{ss} + Cl \cdot C_{ss} + V1 \cdot C_{ss} (k_{21} \cdot e^{-k21t})$$

where V1 = distribution volume of the central compartment; C_{ss} = steady-state plasma concentration; Cl = drug clearance; k_{21} = redistribution constant from the central to the peripheral compartment; k_{21} = redistribution constant from the peripheral to the central compartment. Implementation of the BET infusion scheme requires the use of a microprocessor-controlled pump. If a continuous infusion is to be used in an optimal manner to suppress responses to surgical stimuli, the MIR should be varied according to the individual patient responses (Fig. 13-8). Using an MIR large enough to suppress responses to the most intense surgical stimuli will lead to excessive drug accumulation, postoperative side effects, and delayed recovery. More gradual signs of inadequate or excessive anesthesia can be treated by making 50 to 100% changes in the MIR. Abrupt increases in autonomic activity can be treated by giving a small

bolus dose equal to 10 to 25% of the initial loading dose and increasing the MIR.

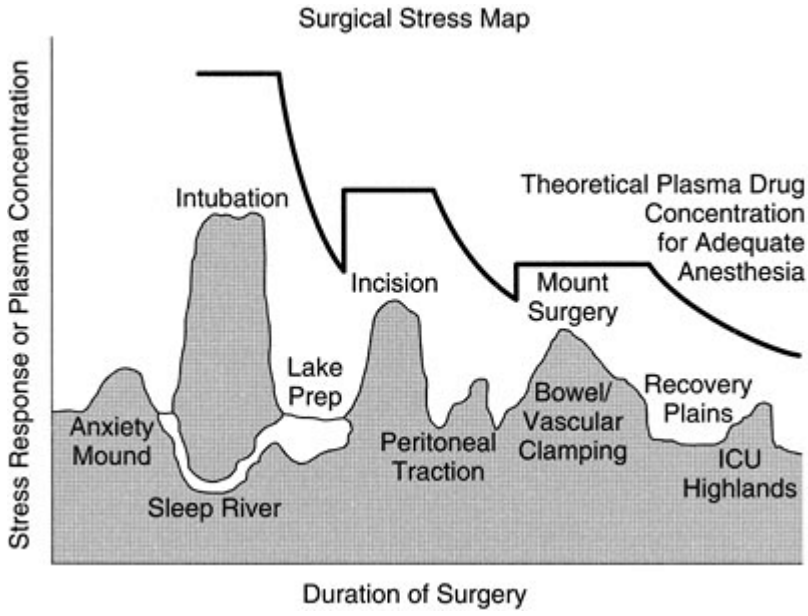

FIGURE 13-8. The "landscape" of surgical anesthesia. The surgical stimuli are not constant during an operation; therefore, the plasma concentration of an IV anesthetic should be titrated to match the needs of the individual patient. (Reprinted with permission from Glass PSA, Shafer SL, Jacobs JR, et al: Intravenous drug delivery systems. In Miller's Anesthesia, 4th ed, p 391. New York, Churchill Livingstone, 1994.)

Despite the marked pharmacokinetic and pharmacodynamic variability that exists among surgical patients, computer programs have been developed that allow reasonable predictions of concentration-time profiles for IV anesthetics and analgesics. This new technology has led to the development of target-controlled infusions (TCI), whereby the anesthesiologist chooses a "target" blood or brain (effective site) drug concentration and the micropressor-controlled infusion pump infuses the drug at the rate needed to rapidly achieve and maintain the desired concentration based on population pharmacokinetic-dynamic data.[84] It is obvious that the target concentration must be altered depending on the observed pharmacodynamic effect and the anticipated changes in surgical stimulation.

Closed-loop control based on plasma drug concentrations is not possible because there is no available methodology to obtain frequent measurements of drug concentrations in real time. A more advanced form of TCI uses a feedback signal generated by simulating a mathematical model of the control process. Clearly, the precision of control achievable with a model-based system is only as accurate as the model. An example of a model-based drug delivery system is the computer-assisted continuous infusion (CACI) system. An ideal automatic anesthesia delivery device would titrate anesthetic to meet the needs of the individual patient using an acquired feedback signal which accurately reflects the effect site concentration of the drug. The most successful efforts at feedback control of anesthesia have utilized the BIS and cortical auditory evoked responses to assess the pharmacodynamic end point.[83]

The rapid, short-acting, sedative–hypnotics (e.g., methohexital, propofol) and opioids (e.g., alfentanil, remifentanil) are better suited for continuous administration techniques than the more traditional anesthetic and analgesic agents because they can be more precisely titrated to meet the unique and changing needs of the individual patient. Traditionally, the elimination half-life of a particular drug has been used in attempting to predict the duration of drug action and the time to awakening after discontinuation of the anesthetic infusion. Using conceptual modeling techniques, it has been shown that the concept of context-sensitive half-time is more appropriate in choosing drugs for continuous IV administration (Fig. 13-9). Because none of the currently available IV drugs can provide for a complete anesthetic state without producing prolonged recovery times and

undesirable side effects, it is necessary to administer a combination of IV drugs that provide for hypnosis, amnesia, hemodynamic stability, analgesia, and muscle relaxation. Selecting a combination of drugs with similar pharmacokinetics and compatible pharmacodynamic profiles should improve the anesthetic and surgical conditions. Sedative–hypnotics (methohexital, midazolam, propofol, etomidate, ketamine), opioids (fentanyl, alfentanil, sufentanil, remifentanil), and muscle relaxants (cis-atracurium, mivacurium, rocuronium) can be successfully administered using continuous infusion TIVA techniques as alternatives to the volatile anesthetics and nitrous oxide.

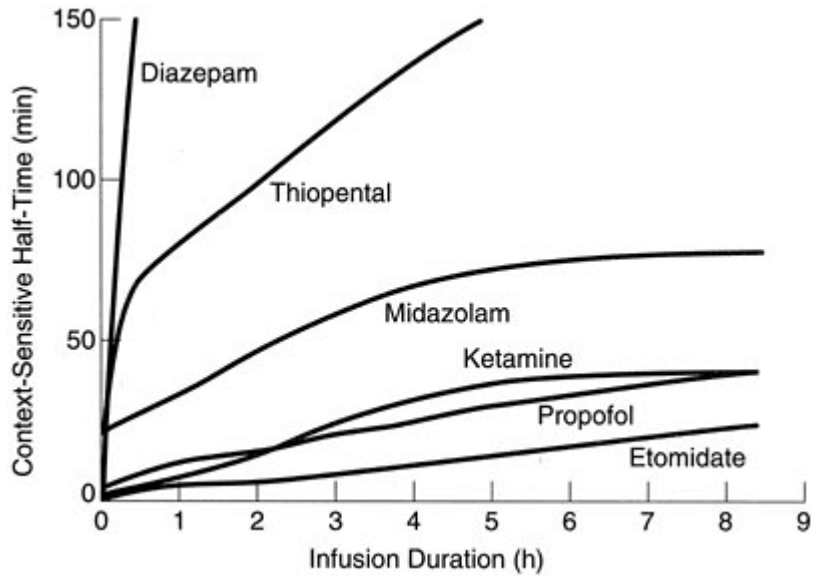

FIGURE 13-9. Context-sensitive half-time values as a function of infusion duration for IV anesthetics, including thiopental, midazolam, diazepam, ketamine, etomidate, and propofol. The context-sensitive half-time for thiopental and diazepam is significantly longer compared with etomidate, propofol, and midazolam with an increasing infusion duration increase. (Reprinted with permission from Hughes MA, Jacobs JR, Glass PSA: Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthesia. Anesthesiology 76: 334, 1992.)

Use of Intravenous Anesthetics for Sedation

The use of sedative–hypnotic drugs as part of a monitored anesthesia care (MAC) technique in combination with local anesthetics is becoming increasingly popular.[85,86,87] During local or regional anesthesia, subhypnotic dosages of IV anesthetics can be infused to produce sedation, anxiolysis, and amnesia and enhance patient comfort. The optimum sedation technique achieves the desired clinical end points without producing perioperative side effects (respiratory depression, nausea, and vomiting). In addition, it should provide for ease of titration to the desired level of sedation while providing for a rapid return to a "clear headed" state on completion of the surgical procedure. Sedation also constitutes an essential element in the management of patients in the ICU. The ideal sedative agent for critically ill patients would have minimal depressant effects on the respiratory and cardiovascular systems, would not influence biodegradation of other drugs, and would be independent of renal and hepatic function for its elimination. Recently, the BIS monitor has been used to monitor the depth of sedation in the ICU. For patients undergoing cardiac surgery, rapid reversibility of the sedative state may result in earlier extubation and lead to a shorter stay in the ICU. Although intermittent bolus injections of sedative–hypnotic drugs (e.g., diazepam 2.5 to

5 mg, lorazepam 0.5 to 1 mg, midazolam 1.25 to 2.5 mg) have been administered during local anesthesia, continuous infusion techniques with propofol are becoming increasingly popular for

maintaining a stable level of sedation in the OR and ICU settings.

Benzodiazepines, particularly midazolam, are still the most widely used for sedation in the ICU and for relief of acute situational anxiety during local and regional anesthesia. Midazolam has a steeper dose-response curve than diazepam (Fig. 13-3), and therefore, careful titration is necessary to avoid oversedation and respiratory depression. Midazolam infusion, 0.05 to 5 mg/kg/min, can be highly effective in providing sedation for hemodynamically unstable patients in the ICU.[88] Use of a midazolam infusion has been shown to control agitation and decrease analgesic requirements without producing cardiovascular or respiratory instability. However, marked variability exists for midazolam in the individual patient dose-effect relationships.[88] In addition, marked tolerance may develop to the CNS effects of midazolam with prolonged administration.

Propofol sedation offers advantages over the other sedative–hypnotics (including midazolam) because of its rapid recovery and favorable side effect profile. In addition, the degree of sedation is readily changeable from "light" to "deep" levels by varying the MIR. Following a propofol LD of 0.25 to 0.5 mg/kg, a carefully titrated subhypnotic infusion of 25 to 75 mg/kg/min produces a stable level of sedation with minimal cardiorespiratory depression and a short recovery period. Because even low concentrations of propofol can depress the ventilatory response to hypoxia, supplemental oxygen should always be provided. Sedative infusions of propofol produce less perioperative amnesia than midazolam, and propofol-induced amnesia appears to be directly related to the infusion rate.

A small dose of midazolam (2 mg IV) administered immediately before a variable-rate infusion of propofol has also been shown to significantly decrease intraoperative anxiety and recall of uncomfortable events without compromising the rapid recovery from propofol sedation.[89] Propofol sedation can also be supplemented with potent opioid and nonopioid analgesics to provide sedation analgesia. In comparing propofol and midazolam for patient-controlled sedation, midazolam was associated with less intraoperative recall and pain on injection than propofol, while propofol was associated with less residual impairment of cognitive function. Compared with midazolam in the ICU setting, use of propofol sedation allowed for more rapid weaning of critically ill patients from artificial ventilation.[90] It has been suggested that the more rapid weaning after propofol sedation may be cost-saving compared with midazolam when only a limited period of sedation (<48 hour) is required.[91] Although a pharmacokinetic study yielded no evidence of a change in receptor sensitivity or drug accumulation over a 4-day study period, preliminary data suggest that tolerance to the CNS effects of propofol may develop with more prolonged administration (>1 week).

Concerns have been raised about elevated lipid plasma levels in patients sedated with propofol for several days, especially when high infusion rates (>6 mg/kg/h) are utilized. However, the availability of a propofol formulation with reduced lipid content (Ampofol) should decrease the risk of this problem in the future. Because of conflicting evidence regarding increased mortality as a result of myocardial failure when propofol was used for sedation in the neonatal ICU,[92,93,94] more safety data are needed to define the indications for the use of prolonged propofol infusions, especially in the pediatric population. Low-dose ketamine infusions (5 to 25 mg/kg/min) can also be used for sedation and analgesia during local or regional anesthetic procedures, as well as in the ICU setting.[59] Midazolam, 0.07 to 0.15 mg/kg infused over 3 to 5 min, followed by ketamine, 0.25 to 0.5 mg/kg IV over 1 to 3 min, produced excellent sedation, amnesia, and analgesia without significant cardiorespiratory depression.

CONCLUSION

It is obvious that many of the goals desirable in an ideal IV anesthetic have not been achieved with the currently available drugs. Nevertheless, each of these sedative–hypnotic drugs possesses characteristics that may be useful in specific clinical situations. For example, thiopental remains a widely used IV anesthetic even though it is unstable in solution and produces a high incidence of postoperative drowsiness and sedation. In situations where a rapid recovery is not essential (e.g., inpatient procedures), the barbiturates may be the most cost-effective IV anesthetics. Although recovery from anesthesia with methohexital is more rapid than with thiopental (and compares

favorably with propofol), excitatory side effects (e.g., myoclonus, hiccoughing) are more prominent than with the other barbiturates or propofol. Importantly, methohexital remains the anesthetic of choice for ECT procedures.

10 Propofol is the IV drug of choice when a rapid and smooth recovery is required (e.g., outpatient [ambulatory] anesthesia). Recovery from propofol anesthesia is characterized by the absence of a "hangover effect" and less PONV. The cardiovascular depressant effects produced by propofol appear to be more pronounced than those of thiopental, but can be minimized by careful titration and the use of a variable-rate infusion during the maintenance period. The ability to combine propofol with potent, rapid and short-acting opioid analgesics (e.g., remifentanil) has facilitated the use of TIVA techniques. Improvements in the ability to deliver IV anesthetics (propofol) and analgesics (remifentanil) will lead to a greater acceptance of these techniques in the future.[95]

When administered alone for induction of anesthesia, benzodiazepines are associated with a prolonged recovery profile. In the usual induction doses, benzodiazepines are associated with minimal cardiorespiratory depression and the reliable amnestic effect may be valuable during TIVA (e.g., for acute sedation prior to induction of anesthesia, for maintenance in the absence of nitrous oxide). When administered in smaller doses, midazolam can also be a valuable adjunct as part of a coinduction and/or maintenance technique. Other short-acting benzodiazepines may be developed in the future (e.g., Ro 48-6791).

Etomidate has minimal cardiovascular and respiratory depressant effects and is therefore, an extremely useful induction agent in high-risk patients. It is also used as an alternative to methohexital for ECT procedures. Unfortunately, pain on injection, excitatory phenomena, adrenocortical suppression, and a high incidence of PONV have limited the use of etomidate to special situations in which it offers significant advantages over other available IV anesthetics. The new lipid formulation of etomidate is associated with its fewer side effects and may allow this IV anesthetic to gain wider clinical acceptance in the future.

Ketamine is a unique IV anesthetic that produces a wide spectrum of pharmacologic effects (including sedation, hypnosis, somatic analgesia, bronchodilation, and sympathetic nervous system stimulation). Induction of anesthesia can be rapidly achieved following parenteral injection, making it the drug of choice when IV access is difficult to establish in an emergency situation. Ketamine is also indicated for induction of anesthesia in the presence of hypovolemic shock, acute bronchospastic states, right-to-left intracardiac shunts, and cardiac tamponade. The adverse cardiovascular, cerebro-dynamic, and psychomimetic effects of ketamine can be minimized by prior administration of a benzodiazepine (e.g., midazolam) or sedative–hypnotic drugs (e.g., thiopental,

propofol), making it useful as part of coinduction and maintenance anesthetic techniques. The introduction of the more potent S(+)-ketamine may increase use of ketamine in small-doses (75 to 250 µg/kg) or by continuous infusion (10 to 25 µg/kg/min) as an IV adjuvant during general anesthesia because of its anesthetic and analgesic-sparing activity.

Intravenous anesthesia has evolved from being used mainly for induction of anesthesia to providing unconsciousness and amnesia for surgical procedures performed under local, regional, and general anesthesia. New insights into the pharmacokinetics and dynamics of IV anesthetics, as well as the development of computer technology to facilitate IV drug delivery (e.g., TCI), have greatly enhanced the use of TIVA techniques. The shorter context-sensitive half-life values of the newer sedative–hypnotic drugs make these compounds more useful as continuous infusions for maintenance of anesthesia or sedation. While the search for the ideal IV anesthetic continues, the challenge for the anesthesiologist is to choose the most cost-effective sedative–hypnotic that most closely matches the needs of a specific clinical situation.

Chapter 14
Opioids

Barbara A. Coda

KEY POINTS

1	The term "opioid" designates all drugs, both natural and synthetic, including endogenous peptides, which have morphine-like properties. In its broadest sense, it refers to agonists, partial agonists, and mixed agonist–antagonists at one or more of the opioid receptors.
2	Opioid receptor classification is based on binding activity of specific ligands: morphine at mu (μ), ketocyclazocine at kappa (κ), enkephalins at delta (δ), and endorphin at epsilon (ε) receptors, and specific opioid receptors are responsible for different opioid effects. Most opioids used in clinical anesthesia today (e.g., fentanyl and morphine and their derivatives) are highly selective for μ opioid receptors. Naloxone, the most commonly used opioid antagonist, is not selective for opioid receptor type. Very few endogenous opioids exhibit great selectivity for a single receptor type.
3	Opioids are administered primarily for their analgesic effect, which results from complex interactions at discrete sites in the brain, spinal cord, and under certain conditions, peripheral tissues, and involves both μ_1 and μ_2 opioid effects. For the mixed agonist–antagonist opioids, analgesic effects are also mediated at κ receptors. Opioids act selectively on neurons that transmit and modulate nociception, leaving other sensory modalities and motor functions intact.
4	Opioids are used in combination with volatile anesthetics with or without nitrous oxide to produce balanced anesthesia. Fentanyl and its derivatives reduce the minimum alveolar concentration (MAC) of volatile agents in a dose-dependent fashion. An apparent ceiling effect is seen at 70% MAC reduction, although reduction of up to 90% has been reported for sufentanil and remifentanil.
5	Fentanyl and its derivatives can be combined with a sedative–hypnotic agent to provide total intravenous anesthesia (TIVA). Alfentanil and remifentanil are particularly suited for TIVA because of their rapid onset and short duration of action.
	Fentanyl and its derivatives can be given in very high doses for "opioid

6	anesthesia," but even at extremely high doses, i.e., those that produce profound analgesia as well as apnea, unconsciousness is not assured.
7	Muscle hypertonus occurs with high-dose opioid administration, and severe chest wall rigidity can interfere with ventilation. It is seen most often on induction with rapid-acting opioids. Opioid-induced muscle rigidity is increased in the presence of nitrous oxide and can be prevented or treated with sedative–hypnotics or low-dose muscle relaxants.
8	All opioids depress respiratory drive in a dose-dependent manner, and ventilatory depression is seen even at doses associated with mild analgesia. Equianalgesic opioid doses produce equivalent magnitudes of respiratory depression. When given in combination with benzodiazepines, opioids can blunt hypoxic drive to a greater extent than the hypercarbic drive and produce profound respiratory depression.
9	Fentanyl or one of its derivatives is often used as a component of anesthetic induction. Small opioid doses reduce the dosage requirements of sedative–hypnotics, and blunt airway reflexes (sympathetic activity in response to laryngoscopy).
10	In low doses, opioids have minimal cardiovascular effects, but bradycardia and hypotension are seen with higher doses. A prominent feature of fentanyl and its derivatives is their remarkable hemodynamic stability. Morphine and meperidine cause histamine release, and high doses of these opioids can produce greater hypotension than fentanyl and its derivatives.
11	All opioids can produce nausea and vomiting through complex interactions at nausea and vomiting centers in the medulla. In general, equianalgesic doses of opioids produce similar magnitude of nausea. Opioid-induced nausea can be exacerbated by vestibular input, and is particularly problematic in ambulatory patients.
12	Opioids produce smooth muscle spasm throughout the gastrointestinal tract. They decrease gastric secretions and delay gastric emptying. Opioids increase the tone of the common bile duct and sphincter of Oddi, although meperidine and the mixed agonist-antagonists cause less biliary spasm than morphine and fentanyl.

HISTORY

Opioids have been used in the treatment of pain for thousands of years. The drug opium, which contains more than 20 alkaloids, is obtained from the exudate of *Papaver somniferum* seed pods, and the word "opium" is derived from *opos*, the Greek word for juice. The first undisputed reference to poppy juice is found in the third century (BCE) writings of Theophrastus.[1] The German pharmacist Sertuener isolated what he called the "soporific principle" in opium in 1806, and in

1817 named it morphine, after the Greek god of dreams, Morpheus.[2] Isolation of other opium alkaloids followed, and by the mid 1800s, the medical use of pure alkaloids rather than crude opium preparations began to spread.[1] Morphine was used widely to treat wounded soldiers during the American Civil War, and in 1869, its use as a premedication was described by Claude Bernard. However, in the absence of muscle relaxants and controlled ventilation, opioids were associated with a significant risk of severe respiratory depression and death. Thus their use in anesthesia was limited at that time.

With the advent of cardiac surgery in the late 1950s came the development of "opioid anesthesia." A decade later, Lowenstein reported the use of progressively higher doses of morphine (0.5 to 3 mg/kg), but found limitations including incomplete suppression of the stress response, hypotension, awareness during anesthesia, and increased fluid and blood requirements.[3]

Fentanyl, a 4-anilinopiperidine derivative of phenoperidine, was synthesized in 1960. The completely synthetic opioids were more potent and had a better safety margin (ratio of median lethal dose to lowest effective dose for surgery) than meperidine. Advances in surgical techniques created the need for potent opioids with a rapid onset, a brief, predictable duration, and a maximal safety margin for use in clinical anesthesia, and led to development of sufentanil, alfentanil, and other fentanyl derivatives between 1974 and 1976. The newest potent opioid, remifentanil, has an ultrashort duration of action because of rapid metabolism by ester hydrolysis and offers an advantage in specific clinical settings.

The search for opioid analgesics without potential for dependence was stimulated by concerns about opioid addiction and led to the identification of multiple opioid receptor types. In the mid 1960s, nalorphine, a morphine antagonist, was also found to have analgesic properties. Two other compounds, pentazocine and cyclazocine, antagonized some of morphine's effects. Pentazocine also produced analgesia, and both produced some psychotropic effects that morphine did not. These and other observations led Martin to propose the theory of receptor dualism. Intrinsic to this theory were two key concepts: (1) the existence of multiple opioid receptors (originally only two were proposed); and (2) the idea of pharmacologic redundancy (i.e., more than one receptor could mediate a physiologic function, such as analgesia).[4] Thus, a drug could be a strong agonist, a partial agonist, or a competitive antagonist at one or more of the different receptor types. Subsequent research has revealed three distinct families of opioid peptides and multiple categories of opioid receptors. Future research may identify compounds that provide potent analgesia but fewer side effects or propensity for abuse based on receptor selectivity.

TERMINOLOGY

1 The term "opiate" was originally used to refer to drugs derived from opium, including morphine, its semisynthetic derivatives, and codeine. The more general term "opioid" was introduced to designate all drugs, both natural and synthetic, with morphine-like properties, including endogenous peptides. The nonspecific term "narcotic" has been used to refer to morphine and morphine-like analgesics. However, because of its use in a legal context, referring to any drug (including nonopioids, such as cocaine) that can produce dependence, the term narcotic is not useful in a pharmacologic or clinical context.

In its broadest sense, the term opioid can refer to agonists, partial agonists, mixed agonist–antagonists, and competitive antagonists. Differentiation of these terms requires understanding of receptor–ligand interactions. Receptor theory states that drugs have two independent characteristics at receptor sites: *affinity*, the ability to bind a receptor to produce a stable complex, and intrinsic activity or *efficacy*, which is described by the dose-effect curve resulting from the drug–receptor combination. Efficacy can range from zero (i.e., no effect) to the maximum possible effect, depicted graphically as the plateau of the dose-effect curve (Fig. 14-1). Given a high enough dose, an *agonist* will produce the maximum possible effect of binding with the receptor, whereas an *antagonist* produces no direct effect when it binds the receptor. A *partial agonist* has a dose-effect ceiling that is lower than the maximum possible effect produced by a full agonist, as well as a dose-effect curve that is less steep than that of a full agonist. A *mixed agonist–antagonist* acts as an agonist (or partial agonist) at one receptor and an antagonist at

another. It is important to differentiate the term "potency" from "efficacy." Whereas efficacy defines the range in magnitude of an effect produced by a drug–receptor combination relative to the maximum possible effect, potency refers to the relative dose required to achieve an effect, and is related to receptor affinity. Thus, at the lower end of the effect range, a partial agonist may be more potent than a full agonist (see Fig. 14-1). However, even at very large doses the efficacy, or maximum effect achieved by the partial agonist, will be less than the maximum possible effect of a full agonist.

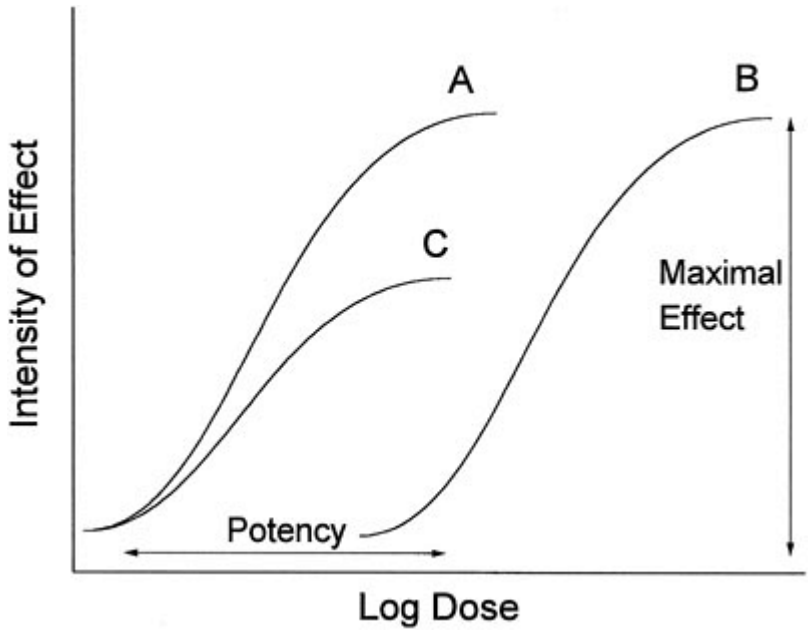

FIGURE 14-1. Log dose-effect curves for two agonists (*A* and *B*) with equal efficacy but different potency, and a partial agonist (*C*). Note that the potencies of A and C are similar, but the efficacy is less and the slope of the dose-response curve is shallower for the partial agonist. Note also that at lower doses, the partial agonist C is more potent than the full agonist B.

ENDOGENOUS OPIOIDS AND OPIOID RECEPTORS

All of the endogenous opioids are derived from three prohormones: proenkephalin, prodynorphin, and pro-opiomelanocortin (POMC). Each of these precursors is encoded by a separate gene. The three families of peptides differ in their distribution, receptor selectivity, and neurochemical role,[5] but

share some features. For example, all begin with the pentapeptide sequences of [Leu]- or [Met]-enkephalin. Proenkephalin includes the pentapeptide sequences for [Met]- and [Leu]-enkephalin, and cells that synthesize proenkephalin are widely distributed throughout the brain, spinal cord, and peripheral sites, particularly the adrenal medulla.[6] Pro-opiomelanocortin is the common precursor of β-endorphin, adrenocorticotropic hormone (ACTH), and melanocyte-stimulating hormone (MSH). The term *endorphin* is reserved for peptides of the POMC family. The major site of POMC synthesis is the pituitary, but it is also found in the pancreas and placenta. The dynorphin peptides all begin with the [Leu]-enkephalin sequence and are widely distributed throughout the brain, spinal cord, and peripheral sites.

2 Endogenous opioids bind to a number of opioid receptors to produce their effects. Martin's initial classification of opioid receptors into the three types was based on binding activity of the exogenous ligands morphine, ketocyclazocine, and SKF10,047 at mu (μ), kappa (κ), and sigma (σ) receptors, respectively. Other opioid receptors identified since that time are delta (δ) receptors, bound by enkephalins, and epsilon (ε) receptors, bound by endorphin.[5,6] There is also

evidence supporting the existence of two *μ*, two *δ*, and three *κ* receptor subtypes.[8] While it appears that specific opioid receptors are responsible for different opioid effects and that synthetic opioids may be highly selective for a receptor type or subtype, it is important to note that very few endogenous opioids exhibit great selectivity for a single receptor type.[7] Remember also, that the theory of receptor dualism includes the concept of pharmacologic redundancy of receptor function. Thus, observed opioid effects typically involve complex interactions among the different receptor systems at supraspinal, spinal, and peripheral sites. Table 14-1 summarizes our current understanding of which opioid receptors are responsible for mediating opioid analgesic and side effects. One caveat in interpreting this summary is that species differences in opioid receptor systems exist, so the results of animal studies, from which most of this information is derived, may not always be directly applicable to humans.

3 Most opioids used in clinical anesthesia today (e.g., fentanyl and morphine and their derivatives) are highly selective for *μ* opioid receptors. Naloxone, the most commonly used opioid antagonist, is not selective for opioid receptor type. In fact, current identification of an opioid-receptor–mediated drug effect requires demonstration of naloxone reversibility. Development of selective opioid receptor subtype antagonists will be helpful tools in improving our understanding of which receptor subtypes mediate specific opioid effects.

At the cellular level, endogenous and exogenous opioids produce their effects by altering patterns of interneuronal communication. Receptor binding initiates a series of physiologic functions resulting in cellular hyperpolarization and inhibition of neurotransmitter release, effects that are mediated by second messengers. All opioid receptors appear to be coupled to G-proteins,[5] which regulate the activity of adenylate cyclase among other functions. G-protein interactions, in turn, affect ion channels; different ion conductances may be involved at different opioid receptor types.[7]

STRUCTURE–ACTIVITY RELATIONSHIPS

The wide array of different molecules that produce morphine-like analgesia and side effects, including endogenous opioids, all share some common structural characteristics. Horn and

Rodgers[8] suggested that the tyrosine moiety at the amino terminal of the enkephalins formed the basis of a significant conformational relationship between the enkephalins and opiates. The structure of the phenanthrene class of opium alkaloids is complex and consists of five or six fused rings. Morphine, one of three phenanthrenes, has a rigid five-ring structure that conforms to a "T" shape (Fig. 14-2).[9] The other phenanthrenes are codeine, a derivative of morphine, and thebaine, a precursor of oxycodone and naloxone. Progressively reducing the number of fused rings from the phenanthrenes yields the morphinans, with four rings; the benzomorphans, with three rings; the phenylpiperidines, with two rings; and finally, the tyramine moiety of the endogenous opioid peptides, with a single hydroxylated ring. All of these distinct classes of drugs possess morphine-like activity. Thorpe's[9] opiate receptor model is based on these structural similarities with two aromatic binding sites and one anionic site responsible for binding the positively charged nitrogen. In this model, differences in binding at the aromatic or anionic sites could account for receptor specificity or for agonist versus antagonist activity. Structural modifications alter such important properties as opioid receptor affinity, agonist versus antagonist activity, resistance to metabolic breakdown, lipid solubility, and pharmacokinetics.[1]

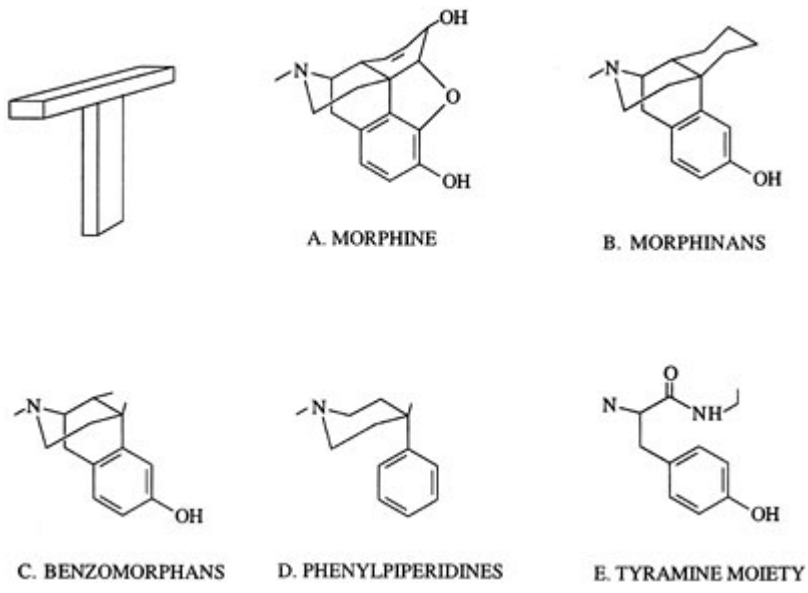

FIGURE 14-2. "T"-shape conformation of opioid molecules. **A.** Morphine, one of the phenanthrene alkaloids, has a rigid five-ring structure, with a phenylpiperidine ring forming a crossbar and a hydroxylated aromatic ring in the vertical axis. **B.** Reducing the number of fused rings to four yields the morphinan class of opium alkaloids. **C.** Benzomorphans have three fused rings. **D.** Phenylpiperidines and the 4-anilinopiperidines such as fentanyl have a flexible two-ring structure. **E.** Finally, the tyramine moiety, which is the amino terminal peptide of both [Leu]- and [Met]-enkephalin, is shown, with a single aromatic ring. Another key feature is the positively charged basic nitrogen equidistant (4.55Å) from the aromatic ring. (Adapted with permission from Thorpe DH: Opiate structures and activity: A guide to understanding the receptor. Anesth Analg 63:143, 1984.)

PHARMACOKINETICS AND PHARMACODYNAMICS

Basic Considerations

Opioid effects are initiated by the combination of an opioid with one or more receptors at specific tissue sites. The relationship between opioid dose and effects depends on both pharmacokinetic and pharmacodynamic variables. *Pharmacokinetics* determines the relationship between drug dose and its concentration at the effect site(s). *Pharmacodynamic* variables relate the concentration of a drug at its site of action, in this case opioid receptors in the brain and other tissues, and the intensity of its effects. Pharmacokinetics generally refers to the study of blood or plasma drug concentration versus time because blood is easy to sample, bears a definable relationship to tissue concentration, and is the medium by which drugs are distributed throughout the body. Changes in drug concentration over time in the blood, at the effect site and at other sites, are determined by physicochemical properties of the drug as well as the processes of absorption, redistribution, biotransformation, and elimination.

In clinical anesthesia practice, opioids are typically administered intravenously. After an intravenous bolus dose or brief infusion, peak plasma opioid concentrations occur within minutes. Plasma drug concentrations then fall rapidly as the drug is distributed to extravascular sites, including sites of action, noneliminating tissues, and eliminating organs. Compartmental models describe the time course of change in plasma concentration; typically, opioids used in anesthesia are characterized by two- or three-compartment models (see Chapter 11: Basic Principles of Clinical Pharmacology). The early rapid decline in plasma concentration after the peak is called the *distribution phase*, and the subsequent slower decline is the *elimination phase.* From a mathematical curve fitted to measured plasma concentration versus time data, distribution and

elimination half-lives, systemic clearance, compartment volumes, and intercompartmental transfer rate constants can be calculated. Table 14-2 summarizes the estimates of key pharmacokinetic parameters and physicochemical characteristics for the most commonly used opioids in clinical anesthesia.

Adapted from Bovill JG: Pharmacokinetics and pharmacodynamics of opioid agonists. Anaesth Pharmac 1:122, 1993.

It is important to note that there is tremendous variability in the values published for opioid pharmacokinetic parameters. This is due, in part, to real population differences (e.g., age, diseases), and in part to differences in study design (e.g., sampling site, duration, concomitant events such as surgery, or other drugs that may affect differential flow to sites of metabolism or elimination). In addition, the distributional and elimination half-lives are of limited use in predicting the onset and duration of opioid action in clinical anesthesia. Contributions of distribution processes between physiologic compartments vary with time. In an effort to relate pharmacokinetics to the time of onset and duration of action, concepts such as *effect compartment* in pharmacodynamic modeling[10] and *context-sensitive half-times*[11] have been developed. The application of these concepts are considered later in this chapter.

Physicochemical properties of opioids influence both pharmacokinetics and pharmacodynamics. To reach its effector sites in the central nervous system (CNS), an opioid must cross biologic membranes from the blood to receptors on neuronal cell membranes. The ability of opioids to cross this blood-brain barrier depends on such properties as molecular size, ionization, lipid solubility, and protein binding (see Table 14-2). Of these characteristics, lipid solubility and ionization assume major importance in determining the rate of penetration to the CNS. In the laboratory, lipid solubility is measured as an octanol:water or octanol:buffer partition coefficient. Drug ionization is also an important determinant of lipid solubility; nonionized drugs are 1,000 to 10,000 times more lipid-soluble than the ionized form.[12] The degree of ionization depends on the pK_a of the opioid and the pH of the environment. An opioid with a pK_a much lower than 7.4 will have a much greater nonionized fraction in plasma than one with a pK_a close to or greater than physiologic pH. While greater lipid solubility correlates with membrane permeability, the relationship is not simply a linear one. Hansch[13] has shown that there is an optimal hydrophobicity for blood-brain barrier penetration, and Bernards[14] has demonstrated a similar biphasic relationship between the octanol:buffer distribution coefficient and spinal meningeal

permeability. Plasma protein binding also affects opioid redistribution because only the unbound fraction is free to diffuse across cell membranes. The major plasma proteins to which opioids bind are albumin and α_1-acid glycoprotein (AAG). Alterations in AAG concentration occur in a variety of conditions and disease states and result in acute or chronic changes in opioid requirements.

Two main mechanisms are responsible for drug elimination: *biotransformation* and *excretion.* Opioids are biotransformed in the liver by two types of metabolic processes. Phase I reactions include oxidative and reductive reactions, such as those catalyzed by cytochrome P-450 system, and hydrolytic reactions. Phase II reactions involve conjugation of a drug or its metabolite to an endogenous substrate, such as D-glucuronic acid.[12] Remifentanil is metabolized via ester hydrolysis, which is unique for an opioid. With the exceptions of the *N*-deallylated metabolite of meperidine and the 6- and possibly 3-glucuronides of morphine, opioid metabolites are generally inactive. Opioid metabolites and, to a lesser extent, their parent compounds are excreted

primarily by the kidneys. The biliary system and gut are other routes of opioid excretion.

MORPHINE

Morphine produces its major effects in the CNS and the gastrointestinal system, but other systems are also affected. CNS effects include analgesia, sedation, changes in affect, respiratory depression, nausea and vomiting, pruritus, and changes in pupil size. Morphine also affects gastric secretions and gut motility, and has endocrine, urinary, and autonomic effects. It mimics the effects of endogenous opioids by acting as an agonist at μ_1 and μ_2 opioid receptors throughout the body and is considered the standard agonist to which other μ agonists are compared.

Analgesia

Opioids are administered primarily for their analgesic effect. Morphine analgesia results from complex interactions at a number of discrete sites in the brain, spinal cord, and under certain conditions, peripheral tissues, and involves both μ_1 and μ_2 opioid effects. Morphine and related opioids act selectively on neurons that transmit and modulate nociception, leaving other sensory modalities and motor functions intact. At the spinal cord level, morphine acts presynaptically on primary afferent nociceptors to decrease the release of substance P and also hyperpolarizes postsynaptic neurons in the substantia gelatinosa of the dorsal spinal cord to decrease afferent transmission of nociceptive impulses.[15] Spinal morphine analgesia is mediated by μ_2 opioid receptors. Supraspinal opioid analgesia originates in the periaqueductal gray matter (PAG), the locus ceruleus (LC), and nuclei within the medulla, notably the nucleus raphe magnus (NRM), and primarily involves μ_1 opioid receptors. Microinjections of morphine into any of these regions activates the respective descending modulatory systems to produce profound analgesia.[6,15] A more detailed description of the endogenous pain transmission and modulation pathways is given in Chapter 54. Morphine can act at a number of these discrete regions in the CNS to produce synergistic analgesic effects. For example, co-administration at the level of the brain and spinal cord increases morphine's analgesic potency nearly 10-fold,[16] an effect mediated by μ_2 opioid receptors.[6] There are also synergistic interactions between supraspinal sites of opioid action (e.g., between the PAG and the NRM).[6] When inflammation is present, morphine may also produce analgesia by activating opioid receptors on primary afferent neurons.[17]

Although rapidly changing plasma morphine concentrations, such as those that follow bolus dosing, do not correlate well with analgesic effects, constant or very slowly changing (i.e., steady-state) plasma concentrations do correlate with effect intensities. Dahlström measured the minimum effective analgesic concentration (MEAC) of morphine for postoperative pain relief at 10 to 15 ng/mL.[18] For more severe pain, plasma morphine concentrations of 30 to 50 ng/mL are needed to achieve adequate analgesia.[19]

Effect on Minimum Alveolar Concentration of Volatile Anesthetics

μ-agonists are used extensively in conjunction with nitrous oxide (N_2O) with or without volatile anesthetics to provide "balanced anesthesia." In animals, morphine decreases the minimum alveolar concentration (MAC) of volatile anesthetics in a dose-dependent manner,[20,21] but there appears to be a ceiling effect to the anesthetic-sparing ability of morphine, with a plateau at 65% MAC.[20] Measurement of the maximum effect of very high morphine doses on MAC is limited by undesirable side effects such as hypotension and abdominal wall rigidity. Morphine 1 mg/kg administered with 60% N_2O blocked the adrenergic response to skin incision in 50% of patients, a characteristic called MAC-BAR.[22] Neuraxial morphine may also reduce MAC. Epidural morphine 4 mg given 90 minutes prior

to incision reduced halothane MAC by nearly 30%.[23] The effect of intrathecal morphine on MAC is unclear. In one study, a relatively large dose of intrathecal morphine (750 μg) reduced halothane MAC approximately 40%,[24] but an equally large dose (15 μg/kg) failed to reduce halothane MAC in another.[25]

Other Central Nervous System Effects

Morphine can produce sedation, as well as cognitive and fine motor impairment, even at plasma concentrations commonly achieved during management of moderate to severe pain.[26] Other subjective side effects include euphoria, dysphoria, and sleep disturbances. High doses of morphine and similar opioids produce a slowing of electroencephalogram (EEG) activity associated with a marked shift toward increased voltage and decreased frequency.[1,27] In routine analgesic doses, morphine can produce sleep disturbances, including reduction in REM and slow wave sleep,[1] as well as vivid dreams. In extremely high doses, morphine can produce seizure activity in animals, but this toxic effect is not seen with doses used clinically in humans.

Morphine produces dose-dependent pupillary constriction (miosis) in humans. A near maximal degree of miosis is seen with 0.5 mg/kg of morphine.[28] In the absence of other drugs, miosis appears to correlate with opioid-induced ventilatory depression. However, hypoxemia from severe opioid-induced respiratory depression will cause pupillary dilation.

Systemic and neuraxial administration of morphine can produce pruritus, although this symptom is more common with spinal administration.[1] Pruritus appears to be a μ receptor–mediated effect produced at the level of the medullary dorsal horn (MDH).[29] Antihistamines are often used to treat this side effect, but pruritus induced by morphine microinjection into the MDH is not histamine mediated.[29] Thus, their effectiveness is probably related to nonspecific sedative effects.

Morphine can also affect the release of several pituitary hormones, both directly and indirectly. Inhibition of corticotropin-releasing factor and gonadotropin-releasing hormone decreases circulating concentrations of ACTH, β-endorphin, follicle-stimulating hormone, and luteinizing hormone. Prolactin and growth hormone concentrations may be increased by opioids, and antidiuretic hormone release is inhibited by opioids.[1]

Respiratory Depression

Morphine and other μ agonists produce dose-dependent ventilatory depression primarily by decreasing the responsivity of the medullary respiratory center to CO_2.[28] Standard therapeutic doses of morphine produces a shift to the right and a decrease in slope of the ventilatory response to CO_2 curve, as well as abnormal breathing patterns.[30,31] The respiratory depressant effects of morphine are similar for young and elderly patients,[30,31] but normal sleep markedly potentiates morphine-induced ventilatory depression.[32] Frequent periods of oxygen desaturation associated with obstructive apnea, paradoxic breathing, and slow respiratory rate have been reported in patients receiving morphine infusions for postoperative analgesia, but occurred only when the patients were asleep.[33] Such reports emphasize the need to consider both the expected severity of postoperative pain as well as diurnal variations in pain and opioid sensitivity when including long-acting opioids such as morphine in an anesthetic. Sleep apnea, seen with ever-increasing frequency in association with obesity, increases the risk of morphine-induced respiratory depression. With increasing morphine doses, periodic breathing resembling Cheyne-Stokes breathing, decreased hypoxic ventilatory drive, and apnea can occur.[34] However, even with severe ventilatory depression, patients are usually arousable and will breathe on command.

Cough Reflex

Morphine and related opioids depress the cough reflex, at least in part by a direct effect on the medullary cough center. Doses required to attenuate the cough reflex are smaller than the usual analgesic dosage, and receptors mediating this effect appear to be less stereospecific and less sensitive to naloxone than those responsible for analgesia.[1] Dextroisomers of opioids, which do not produce analgesia, are also effective cough suppressants.[1]

Muscle Rigidity

Large doses of intravenous morphine (2 mg/kg infused at 10 mg/min) can produce abdominal muscle rigidity and decrease thoracic compliance; this effect plateaus 10 minutes after morphine

administration is complete.[35] Subjects receiving smaller doses of intravenous morphine (10 to 15 mg) also report feelings of muscle tension, most frequently in the neck or legs, but occasionally in the chest wall (unpublished observations). Muscle rigidity is drastically increased by the addition of 70% N_2O.[35] Opioid-induced muscle rigidity appears to be mediated by μ receptors at supraspinal sites.[36] Myoclonus, sometimes resembling seizures, but without EEG evidence of seizure activity, has also been observed with high-dose opioids.[37] In clinical practice, opioid-induced muscle rigidity and myoclonus are most often observed on induction of anesthesia, but have been observed postoperatively[38] and can be severe enough to interfere with manual or mechanical ventilation. These effects are reduced or eliminated by naloxone,[38] drugs that facilitate GABA agonist activity (such as thiopental[35] and diazepam), and muscle relaxants.[38]

Nausea and Vomiting

Nausea and vomiting are among the most distressing side effects of morphine and its derivatives. Increased postoperative vomiting is seen with morphine premedication as well as with the use of intraoperative opioids.[39] The incidence of opioid-induced nausea appears to be similar irrespective of the route of administration, including oral, intravenous, intramuscular, subcutaneous, transmucosal, transdermal, intrathecal, and epidural.[39] Furthermore, laboratory and clinical studies comparing the incidence or severity of nausea and vomiting have found no differences among opioids in equianalgesic doses, including morphine, hydromorphone, meperidine, fentanyl, sufentanil, alfentanil, and remifentanil.[39,40,41,42] The physiology and neuropharmacology of opioid-induced nausea and vomiting are complex (Fig. 14-3). The vomiting center receives input from the chemotactic trigger zone (CTZ) in the area postrema of the medulla, the pharynx, gastrointestinal tract, mediastinum, and visual center.[39,43] The CTZ is rich in opioid, dopamine (D_2), serotonin (5-HT_3), histamine, and (muscarinic) acetylcholine receptors, and also receives input from the vestibular portion of the eighth cranial nerve. Morphine and related opioids induce nausea by direct stimulation of the CTZ and can also produce increased vestibular sensitivity.[1] Therefore, vestibular stimulation such as ambulation markedly increases the nauseant and emetic effects of morphine. This can be especially problematic in outpatient surgery, when early ambulation is a clinical priority. High doses of morphine and other opioids also have naloxone-reversible antiemetic effects at the level of the vomiting center.[44] In volunteer studies, morphine-induced nausea and vomiting increase after a morphine infusion is stopped,[45] which suggests that antiemetic effects are more short-lived than emetic effects. Another possible explanation for this observation is that the active metabolite morphine-6-glucuronide accumulates and worsens nausea. Prophylaxis and treatment of opioid-induced nausea and vomiting includes the use of drugs that act as antagonists at the various receptor

sites in the CTZ as well agents such as propofol and benzodiazepines, whose antiemetic mechanisms are unknown.[39]

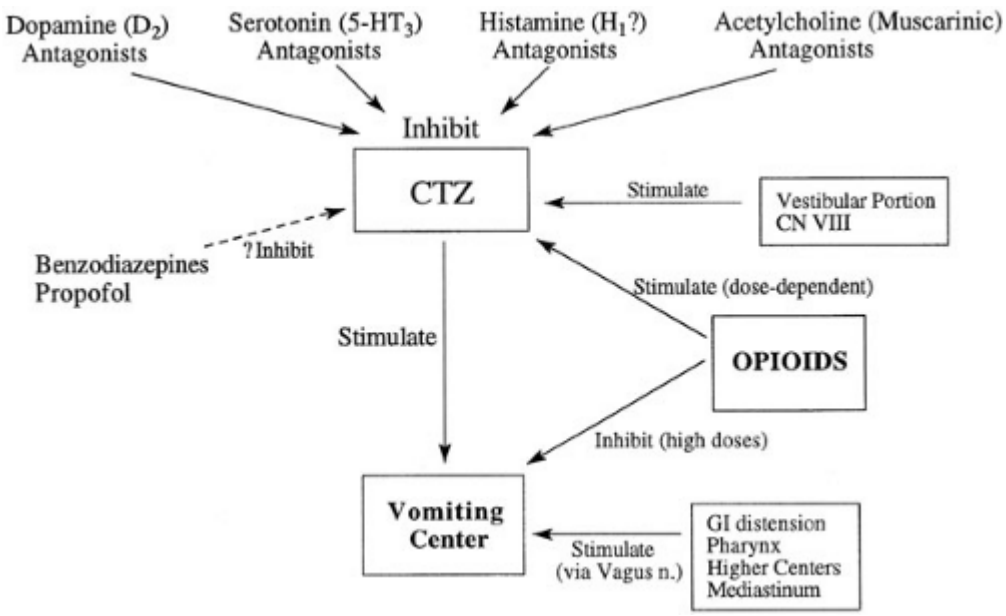

FIGURE 14-3. Pharmacology of nausea and vomiting. The chemotactic trigger zone (CTZ), located in the area postrema of the brainstem, contains dopamine, serotonin, histamine, and muscarinic acetylcholine as well as opioid receptors. The vomiting center receives input from the CTZ as well as peripheral sites via the vagus nerve. As illustrated, the role of opioids is complex, and they appear to have both emetic and antiemetic effects.

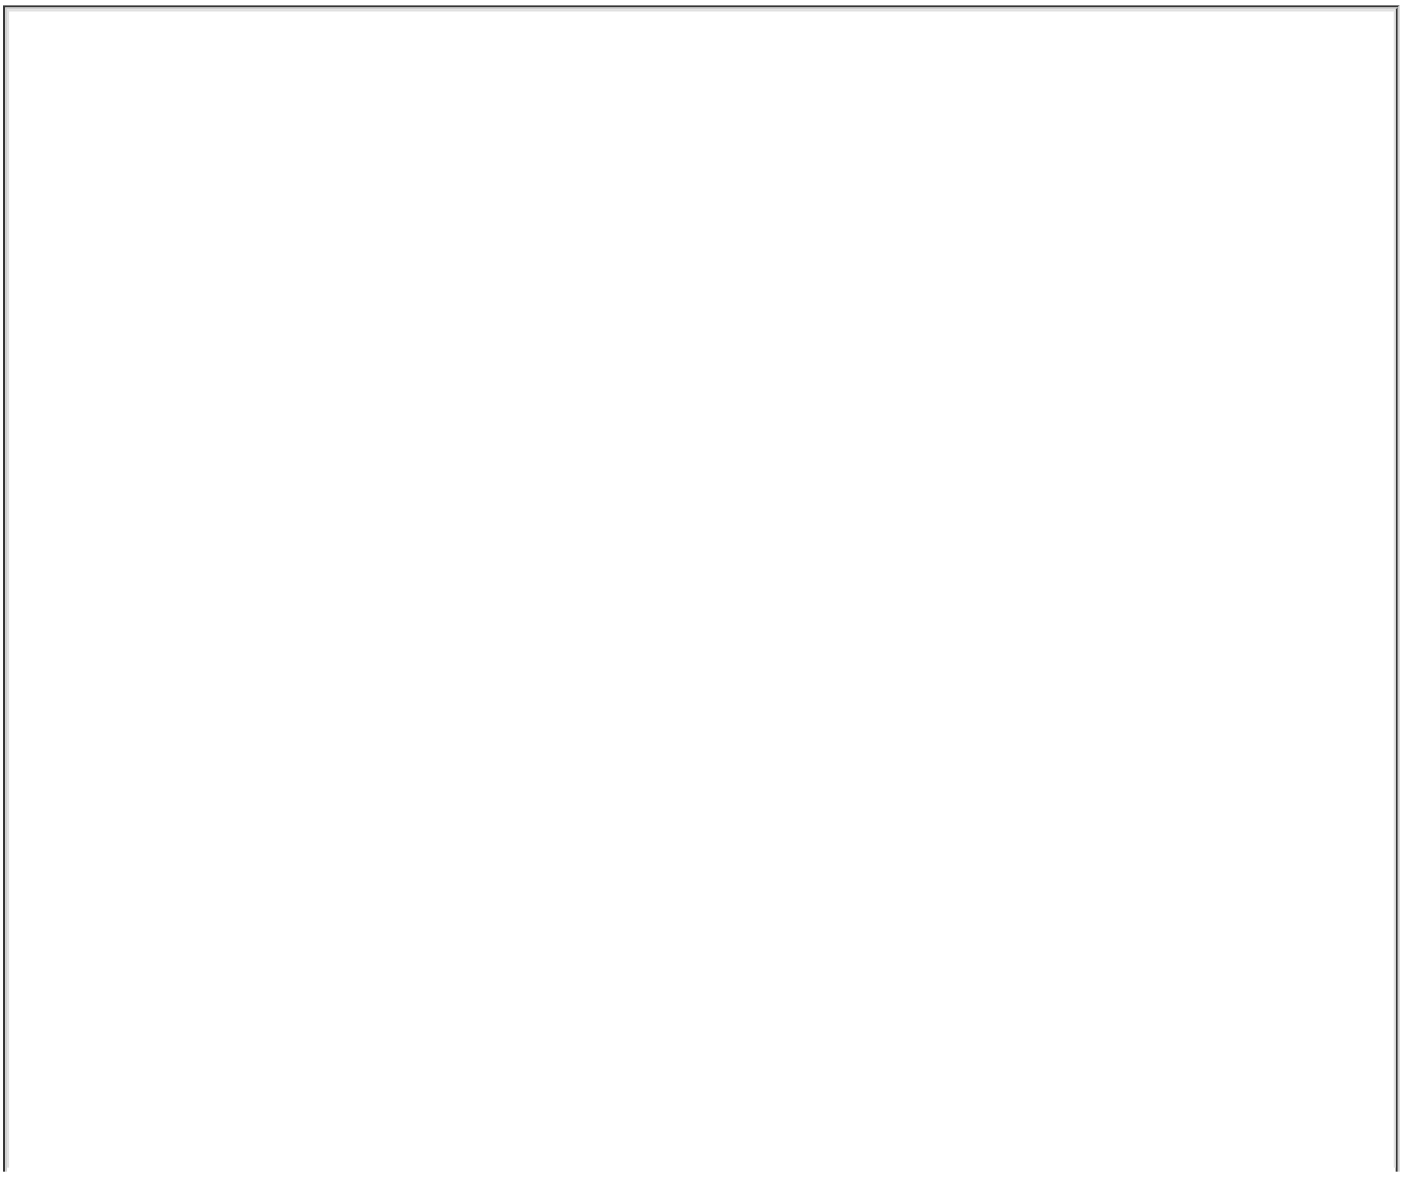
Gastrointestinal Motility and Secretion

Morphine and other opioids affect gastrointestinal motility and propulsion, as well as gastric and pancreatic secretions via stimulation of opioid receptors in the brain, spinal cord, enteric muscle, and smooth muscle,[34,46] and are mediated by μ, κ, and δ opioid receptors at different anatomic sites.[46] In rodents, μ agonists inhibit gastric secretion, decrease gastrointestinal motility and propulsion, and suppress diarrhea when administered by intracerebroventricular, intrathecal, and peripheral injection.[46] A study in human volunteers demonstrated that methylnaltrexone, an opioid antagonist that does not cross the blood-brain barrier, attenuated morphine-induced delay in gastric emptying,[47] suggesting that this effect is mediated primarily by a peripheral opioid mechanism. Morphine decreases lower esophageal sphincter tone and produces symptoms of gastroesophageal reflux,[34] and diamorphine significantly slows gastric emptying. Thus, preoperative opioid administration should be considered when evaluating the risk of regurgitation and aspiration of gastric contents in patients who will be anesthetized or sedated. Like other opioid effects, gastrointestinal effects are probably dose related. Tone in both the small and large bowel is increased, but propulsive activity is decreased, leading to constipation. Epidurally administered morphine can also delay gastric emptying. A single epidural dose (4 mg) of morphine slowed gastric emptying, while an intramuscular dose did not.[48] How the effects of equianalgesic or repeated doses would compare is unknown.

Biliary Tract

Morphine and other opioids increase the tone of the common bile duct and sphincter of Oddi. Symptoms accompanying increases in biliary pressure can vary from epigastric distress to typical biliary colic, and may even mimic angina. When produced, biliary spasm can elevate plasma amylase and lipase for up to 24 hours.[1] Morphine and other μ agonists such as fentanyl are used in provocative tests to evaluate sphincter of Oddi dysfunction and biliary-type pain. In volunteers, morphine caused a greater delay in gallbladder emptying[49] and an increase in contractions of the sphincter of Oddi[50] than meperidine. Nitroglycerine, atropine, and naloxone can reverse opioid-induced increases in biliary pressure.[1] It has been suggested that morphine causes biliary tract



contraction via histamine release, and antagonism of morphine's biliary effects by diphenhydramine supports this hypothesis.[51]

Genitourinary Effects

Urinary retention, seen after both systemic and spinal morphine administration, is because of complex effects on central and peripheral neurogenic mechanisms. It results in dyssynergia between the bladder detrusor muscle and the urethral sphincter because of a failure of sphincter relaxation.[1,52] Estimates of the incidence of this bothersome side effect vary widely and are confounded by the effects of anesthesia and surgery on urinary retention, but it is probably more common after spinal administration. Spinal morphine appears to cause naloxone-reversible urinary retention via μ and/or δ, but not κ opioid receptors.[52] In an animal study, cholinomimetic agents and α-adrenergic agonists aggravated morphine-induced high intravesical pressures, and therefore may be harmful agents to use for treatment of morphine-induced urinary retention.[53]

Histamine Release

Opioids stimulate the release of histamine from circulating basophils and from tissue mast cells in skin and lung.[54,55] Morphine-mediated histamine release is dose dependent; intradermal injection of morphine in a concentration of 1 mg/mL induces an urticarial wheal and flare.[55] Morphine-induced histamine release is not prevented by pretreatment with naloxone,[55] suggesting that histamine release is not mediated by opioid receptors. Morphine-induced histamine release has clinical relevance. The decrease in peripheral vascular resistance seen with high-dose morphine (1 mg/kg) correlates well with elevated plasma histamine concentration.[56] Furthermore, differences in the release of histamine could account for most of the hemodynamic differences between morphine and fentanyl (Fig. 14-4).[56]

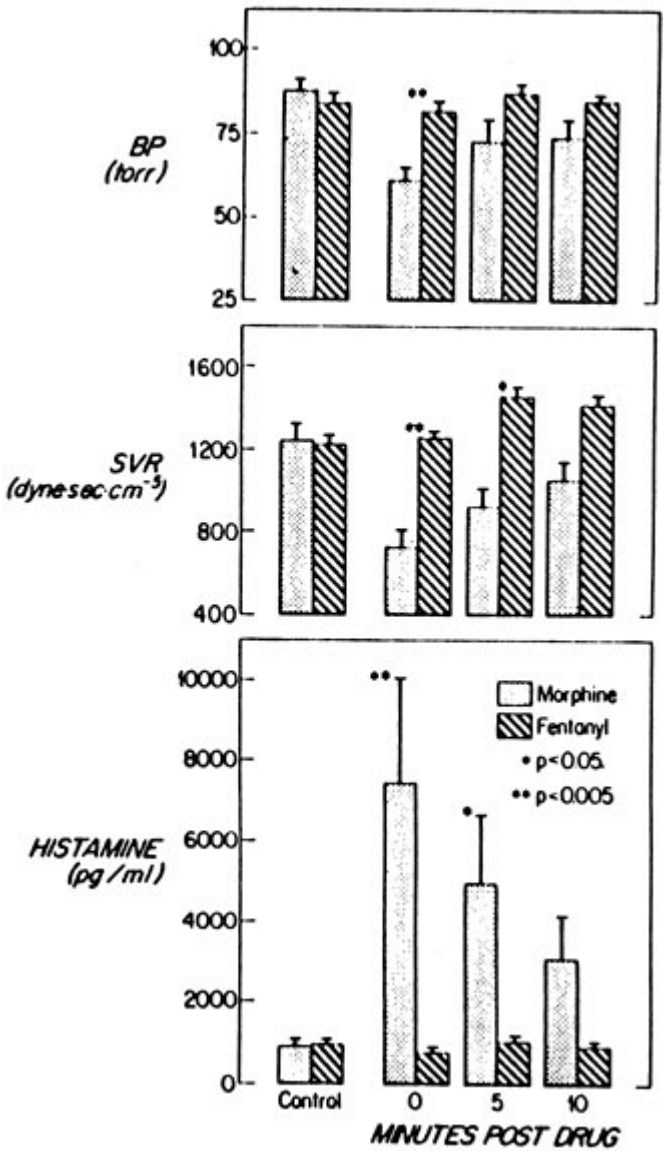


FIGURE 14-4. Mean arterial pressure (BP), systemic vascular resistance (SVR), and plasma histamine concentration (mean ± SE) before and after morphine 1 mg/kg and fentanyl 50 μg/kg (both infused over 10 minutes). Morphine, but not fentanyl, causes significant decrements in BP and SVR, which parallel the increase in plasma histamine concentration. (Reprinted with permission from Rosow CE, Moss J, Philbin DM *et al*: Histamine release during morphine and fentanyl anesthesia. Anesthesiology 56:93, 1982.)

Cardiovascular Effects

Opioids are popular in clinical anesthesia because they reliably produce analgesia with minimal changes in cardiovascular parameters. In doses typically used for pain management or as part of balanced anesthesia, morphine has little effect on blood pressure or heart rate and rhythm in the supine,

normovolemic patient. However, therapeutic doses of morphine can produce arteriolar and venous dilation, decreased peripheral resistance, and inhibition of baroreceptor reflexes,[1] which can lead to postural hypotension. In addition to histamine release, morphine-mediated central sympatholytic activity and direct action on vascular smooth muscle may also contribute to peripheral vasodilation.[57] Thus, morphine's effect on vascular resistance is greater under conditions of high sympathetic tone.[57] The clinical implications of this finding are important. Patients who are critically ill (e.g., patients with severe trauma or cardiac disease) can be

expected to have high sympathetic tone, and thus may experience hypotension in response to doses of morphine that would not normally produce hemodynamic instability. At clinically relevant doses, morphine does not suppress myocardial contractility.[1] However, opioids do produce dose-dependent bradycardia, probably by both sympatholytic and parasympathomimetic mechanisms.[58] In clinical anesthesia practice, opioids are often used to prevent tachycardia and reduce myocardial oxygen demand. Patients undergoing cardiovascular surgery who received morphine 1 to 2 mg/kg experienced minimal changes in heart rate, mean arterial pressure, cardiac index, and systemic vascular resistance. However, outcome was no different from that achieved with carefully administered inhalation-based anesthesia.[58]

Morphine does not directly affect cerebral circulation, but with morphine-induced respiratory depression, CO_2 retention causes cerebral vasodilation and an elevation in cerebrospinal fluid pressure. This effect is not seen when mechanical ventilation is used to prevent hypercarbia.[1] Thus, morphine and other μ agonists must be used cautiously in spontaneously breathing patients with head injury or other conditions associated with elevated intracranial pressure.

Disposition Kinetics

Morphine is rapidly absorbed after intramuscular, subcutaneous, and oral administration. Following intramuscular administration, peak plasma concentration is seen at 20 minutes and absorption half-life is estimated at 7.7 minutes (range 2 to 15 minutes).[59] After intravenous administration morphine undergoes rapid redistribution, with a mean redistribution half-time between 1.5 and 4.4 minutes in awake and anesthetized adults.[59,60,61] Morphine has a terminal elimination half-life between 1.7 and 3.3 hours.[60,61,62] Age affects morphine pharmacokinetics. The average elimination half-life of morphine is 7 to 8 hours in neonates less than 1 week of age, and 3 to 5 hours in older infants.[74] In patients between 61 and 80 years old, morphine's terminal elimination half-life was 4.5 hours compared to 2.9 hours in younger patients.[63]

Morphine is about 35% protein bound, mostly to albumin.[12] Its steady-state volume of distribution is large, with estimates in the range of 3 to 4 L/kg in normal adults.[59,60,61] Morphine's major metabolic pathway is hepatic phase II conjugation, to form morphine-3-glucuronide (M3G) and morphine-6β-glucuronide (M6G). 3-Glucuronidation is the predominant pathway, and following a single intravenous dose, 40% and 10% of the dose are excreted in the urine as M3G and M6G, respectively.[64] Unchanged morphine in the urine accounts for only about 10% of the dose. The rate of hepatic clearance of morphine is high, with a hepatic extraction ratio of 0.7.[59] Thus, morphine elimination may be slowed by processes that decrease hepatic blood flow.[61] Extrahepatic sites, such as kidney, intestine, and lung, have been suggested for morphine glucuronidation, but their importance in humans is unknown.

Active Metabolites

M6G possesses significant μ receptor affinity and potent antinociceptive activity. Appreciable plasma concentrations of M6G and M3G have been measured in cancer patients receiving high doses of oral morphine. During chronic oral morphine therapy, plasma M6G concentrations can be higher than those of the parent morphine compound.[65] Because morphine glucuronides are eliminated by the kidney, it is not surprising that very high M6G:morphine ratios have been reported in patients with renal dysfunction. This accumulation of the active metabolite is thought to be responsible for the unusual sensitivity of renal failure patients to morphine. While common wisdom suggests that glucuronide conjugates do not penetrate the blood-brain barrier, M6G concentration in cerebrospinal fluid (CSF) is 20 to 80% that of morphine.[66] Despite a mounting volume of animal literature demonstrating the analgesic potency of M6G, there is little information in humans concerning the magnitude of analgesia and side effects of M6G relative to morphine. Portenoy et al[66] demonstrated that in cancer patients receiving chronic morphine therapy, pain relief correlated positively with the M6G:morphine ratio, suggesting a contributing role of M6G to overall morphine analgesia. In a study of cancer patients who received synthetic M6G (up to 60 μg/kg), 17 of 19 patients experienced effective analgesia and no adverse effects.[67] However, dizziness, nausea, sedation, muscle aches, and respiratory depression have been reported in volunteers who received M6G.[65] While the contribution of M6G to morphine-induced analgesia and

to be determined, morphine should be administered cautiously to patients with renal failure.

Dosage and Administration of Morphine

In current clinical practice morphine is used mainly as a premedicant and for postoperative analgesia, and less often as a component of balanced or high-dose opioid anesthesia. Intravenous analgesic doses of morphine for adults typically range from 0.01 to 0.20 mg/kg. When used in a balanced anesthetic technique with N_2O, morphine can be given in total doses of up to 3 mg/kg with remarkable hemodynamic stability, but awareness under anesthesia is a risk. When combined with other inhalation agents, it is unlikely that more than 1 to 2 mg/kg of morphine is necessary. Because of its hydrophilicity, morphine crosses the blood-brain barrier relatively slowly; and while its onset can be observed within 5 minutes, peak effects may be delayed for 10 to 40 minutes. This delay makes morphine more difficult to titrate as an anesthetic supplement than the more rapidly acting opioids.

MEPERIDINE

Meperidine, a phenylpiperidine derivative (Fig. 14-5), was the first totally synthetic opioid. It was initially studied as an anticholinergic agent, but was found to have significant analgesic activity.[1]

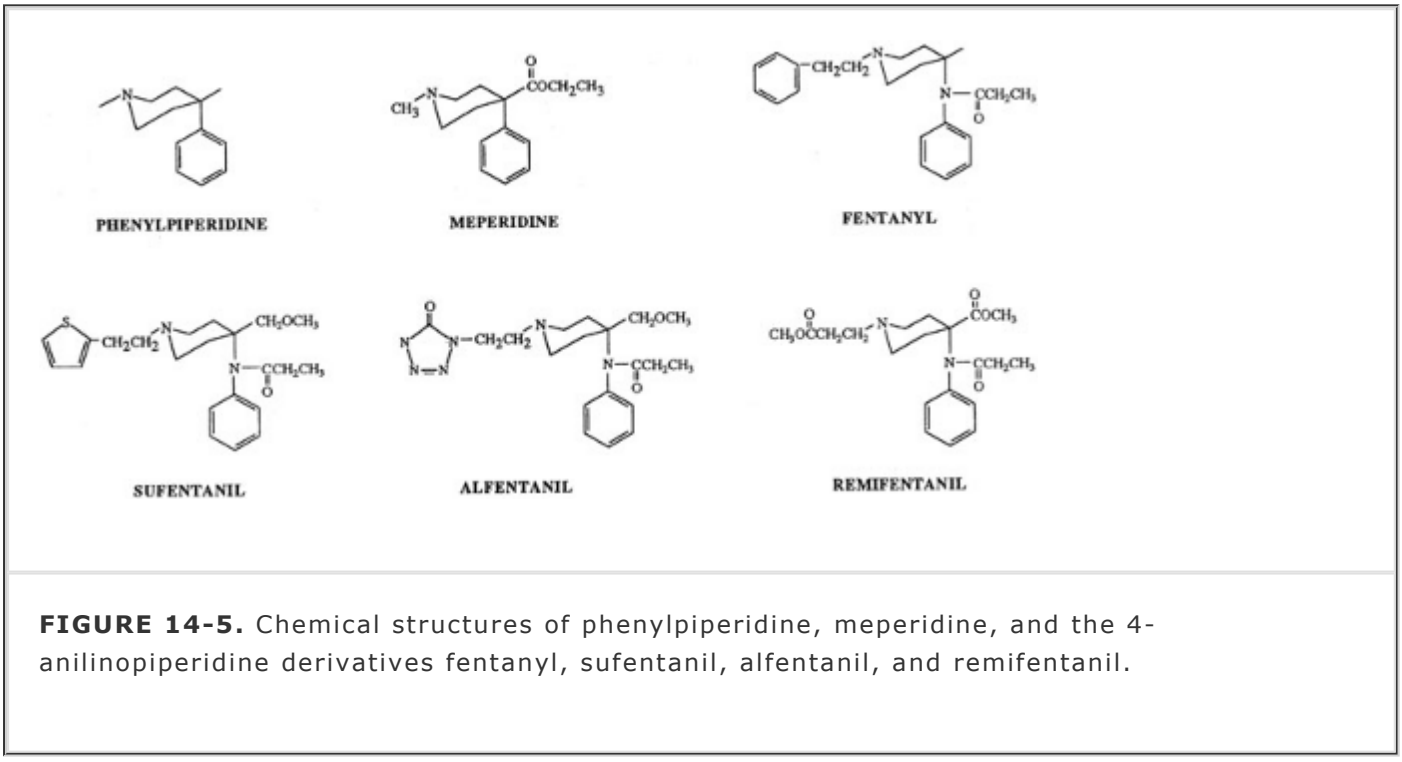

FIGURE 14-5. Chemical structures of phenylpiperidine, meperidine, and the 4-anilinopiperidine derivatives fentanyl, sufentanil, alfentanil, and remifentanil.

Analgesia and Effect on Minimum Alveolar Concentration of Volatile Anesthetics

Meperidine's analgesic potency is about one-tenth that of morphine's and is most likely mediated by μ opioid receptor activation. However, meperidine also has moderate affinity for κ and δ opioid receptors.[1,68] Unlike morphine, meperidine plasma concentrations correlate reasonably well with analgesic effects.[69] While there is considerable interpatient variability, the minimum effective analgesia concentration of meperidine is approximately 200 ng/mL. There is very little information available on the effect of meperidine on the MAC of inhaled anesthetics, but a study in dogs demonstrated a dose-dependent reduction in the MAC of halothane.[70]

Meperidine also has well recognized weak local anesthetic properties. Compared to morphine, fentanyl, and buprenorphine injected perineurally, only meperidine alters nerve conduction and produces analgesia.[71] This has led to some popularity for epidural and subarachnoid administration, particularly in obstetric anesthesia. But because of its local anesthetic effects,

neuraxial meperidine may also produce sensory and motor blockade as well as sympatholytic effects that are not seen with other opioids.

Side Effects

Like morphine, therapeutic doses of meperidine can produce sedation, pupillary constriction, and euphoria, and very high doses are associated with CNS excitement and seizures (see later). In equianalgesic doses, meperidine produces respiratory depression equal to that of morphine, as well as nausea, vomiting, and dizziness, particularly in ambulatory patients.[1]

Like other opioids, meperidine causes significant delay in gastric emptying. While meperidine does increase common bile duct pressure, this occurs to a lesser extent than with equianalgesic doses of morphine and fentanyl (Fig. 14-6).[49,72]

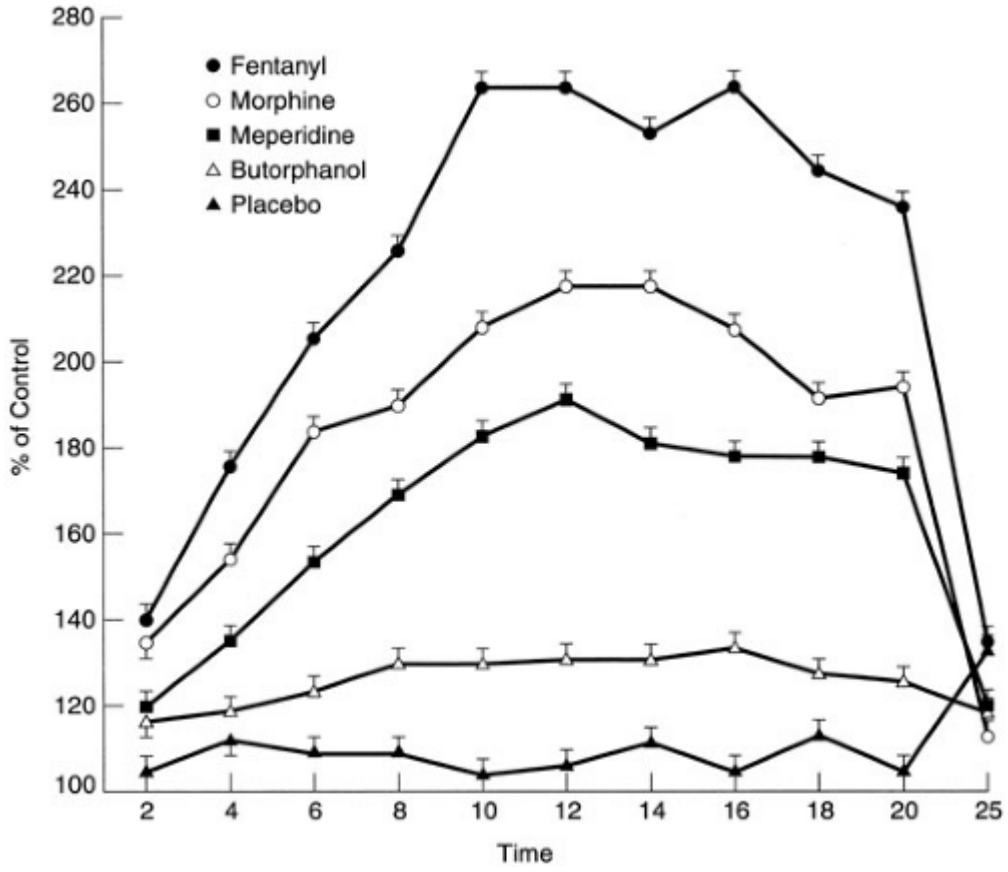

FIGURE 14-6. The effect of several opioids on common bile duct pressures in patients anesthetized with enflurane and N_2O–O_2. Patients received either fentanyl 100 μg/70 kg, morphine 10 mg/70 kg, meperidine 75 mg/70 kg, or butorphanol 2 mg/70 kg. After 20 minutes, the effects were reversed with naloxone. (Reprinted with permission from Radnay PA, Duncalf D, Novakovik M, Lesser ML: Common bile duct pressure changes after fentanyl, morphine, meperidine, butorphanol, and naloxone. Anesth Analg 63:441, 1984.)

Analgesic doses of meperidine in awake patients are not associated with hemodynamic instability, but 1 mg/kg in patients with cardiac disease decreased heart rate, cardiac index, and rate–pressure product.[73] In an isolated papillary muscle preparation, high concentrations of meperidine depressed contractility. This effect was not naloxone reversible and is consistent with a nonspecific, local anesthetic effect.[74] In higher doses, meperidine causes significantly more hemodynamic instability than morphine or fentanyl and its derivatives,[75] an effect at least partially related to histamine release. In a comparison of opioids administered as part of balanced anesthesia, Flacke et al[75] found that 25% patients in the meperidine group experienced severe hypotension and had abnormally elevated plasma histamine concentrations. Interestingly, only one

patient in the morphine group (0.6 mg/kg morphine given) had a similar histamine plasma concentration. Thus, meperidine is not recommended in high doses for clinical anesthesia.

Shivering

Meperidine is effective in reducing shivering from diverse causes, including general and epidural anesthesia, fever, hypothermia, transfusion reactions, and administration of amphotericin B. Meperidine reduces or eliminates visible shivering as well as the accompanying increase in oxygen consumption[76] following general and epidural anesthesia. Equianalgesic doses of fentanyl (25 μg) and morphine (2.5 mg) did not reduce postoperative shivering, suggesting that the antishivering effect of meperidine is not mediated by μ-opioid receptors. This effect

may be mediated by κ-opioid receptors. Butorphanol, a drug with significant κ agonist activity, effectively reduces postoperative shivering in a dose of 1 mg.[77] Furthermore, low doses of naloxone, sufficient to block μ receptors, did not reverse meperidine's antishivering effect, but high-dose naloxone, designed to block both μ and κ receptors, did reverse the antishivering effect.[68] The observation that other types of drugs, such as α_1-adrenergic agonists (clonidine 1.5 μg/kg), serotonin (5-HT_2) antagonists,[78] and propofol,[79] can reduce postoperative shivering suggests that a nonopioid mechanism may be involved. Physostigmine 0.04 mg/kg can also prevent postoperative shivering, suggesting a role for the cholinergic system. Perhaps meperidine's greater antishivering effect, relative to other opioids, is because of additive thermoregulatory impairment by more than one mechanism.

Disposition Kinetics

Following intravenous administration, meperidine plasma concentration falls rapidly. Meperidine's redistribution half-life is 4 to 16 minutes, and its terminal elimination half-life is between 3 and 5 hours.[81,82] The elimination half-life is not prolonged in patients 60 to 80 years old. However, in neonates and infants, a median elimination half-life, 8 to 10 hours, with greater individual variability (three- to fivefold) compared to adults. Absorption after intramuscular administration was complete in normal volunteers, with peak plasma concentration at 5 to 15 minutes after injection; but in postoperative patients, intramuscular meperidine absorption is quite variable, with time to reach peak concentration between 5 and 110 minutes.

Meperidine is moderately lipid soluble, and is 40 to 70% protein bound, mostly to albumin and α_1-acid glycoprotein (see Table 14-2).[83] Meperidine has a large steady-state volume of distribution, with estimates in the range of 3.5 to 5 L/kg in adults.[81,82] The high clearance rate (10 mL/kg/min) reflects a high hepatic extraction ratio; it is *N*-demethylated in the liver to form normeperidine, the principal metabolite, and also hydrolyzed to meperidinic acid. Both metabolites may then be conjugated[1] and excreted renally. Normeperidine is pharmacologically active and potentially toxic (see later).

Active Metabolites

Normeperidine has appreciable pharmacologic activity and can produce signs of central nervous system excitation. In humans, mood alterations such as apprehension and restlessness, as well as neurotoxic effects such as tremors, myoclonus, and seizures, have been reported.[84] The elimination half-life of the metabolite normeperidine (14 to 21 hours) is considerably longer than the parent compound, and therefore is likely to accumulate with repeated or prolonged administration, particularly in patients with renal dysfunction.[84] Myoclonus and seizures have been reported in patients receiving meperidine for postoperative or chronic pain. Patients who developed seizures had a mean plasma normeperidine concentration of 0.81 μg/mL,[84] and it appears that a total daily dosage of 1,000 mg is associated with an increased risk of seizures, even in patients without renal dysfunction.

Dosage and Administration of Meperidine

A single dose of meperidine is approximately one-tenth as potent as morphine when given

parenterally, but has a shorter duration of action. Intravenous analgesic doses of meperidine for adults typically range from 0.1 to 1 mg/kg. Intravenous doses of 12.5 to 50 mg are effective in reducing postoperative shivering. As discussed earlier, high doses of meperidine for intraoperative use are not recommended because of hemodynamic instability. In addition, very high single doses or prolonged administration may produce seizures because of the metabolite normeperidine; thus, the total daily dose should not exceed 1,000 mg/24 hours.

METHADONE

Methadone, a synthetic opioid introduced in the 1940s, is primarily a μ agonist with pharmacologic properties that are similar to morphine. While its chemical structure is very

different from that of morphine, steric factors force the molecule to simulate the pseudopiperidine ring conformation that appears to be required for opioid activity.[1] Because of its long elimination half-life, methadone is most often used for long-term pain management and in treatment of opioid abstinence syndromes.

Analgesia and Use in Anesthesia

Following parenteral administration, the onset of analgesia is rapid, within 10 to 20 minutes. After single doses of up to 10 mg, the duration of analgesia is similar to morphine,[1] but with large or repeated parenteral doses, prolonged analgesia can be obtained. Several investigators have administered methadone intra- and postoperatively with the aim of providing prolonged postoperative analgesia. Patients who received 20 mg methadone intraoperatively and up to 20 mg additional methadone in the immediate postoperative period had a median duration of postoperative analgesia of over 20 hours.[85,86] The effect of methadone on the MAC of volatile anesthetics has not been reported.

Side Effects

Side effects of methadone are similar in magnitude and frequency to those of morphine.[1,85] Patients who received 20 mg methadone at the beginning of surgery were sedated in the immediate postoperative period but did not appear to have clinically significant respiratory depression. About 50% experienced nausea or vomiting, which was easily treated with standard antiemetic therapy.[85] Methadone produces typical opioid effects on smooth muscle. Like morphine, it markedly decreases intestinal propulsive activity and can cause constipation as well as biliary spasm.[1]

Disposition Kinetics

Following an intravenous dose, the plasma concentration–time data for methadone are described by a biexponential equation. The mean redistribution half-time is 6 minutes (range 1 to 24 minutes), and the mean terminal elimination half-time is 34 hours (range 9 to 87 hours).[86] Methadone is well absorbed after an oral dose, with bioavailability approximately 90%, and reaches peak plasma concentration at 4 hours after oral administration.[1] It is nearly 90% plasma protein bound and undergoes extensive metabolism in the liver, mostly *N*-demethylation and cyclization to form pyrrolidines and pyrroline.[1]

Dosage and Administration of Methadone

The use of methadone in clinical anesthesia has focused on attempts to achieve prolonged postoperative analgesia, providing that an adequate initial dose is administered. Because adverse effects can also be prolonged, careful titration of the dose is necessary. In opioid-naïve patients, an initial single dose of 20 mg can provide analgesia without significant postoperative respiratory depression.[85] Wangler and Rosenblatt[87] described a technique to avoid respiratory depression in which 8 to 12 mg methadone is administered to the awake patient until the threshold of respiratory depression (respiratory rate of 6 to 8/min) is reached. Immediately prior to incision, an additional dose equal to half the initial dose is given. For administering supplemental analgesic

doses in the immediate postoperative period, it is essential to confirm that patients with ongoing significant pain have no depression of respiration or level of consciousness, and that a 30- to 40-minute interval should elapse between 5-mg doses to allow full assessment of adverse effects. It may be easier and safer to use a sustained release opioid preparation (containing oxycodone or morphine) with a shorter time to peak effect if a long-acting analgesic is desired. This is most easily accomplished by administering the oral medication preoperatively, but it is also important to note that these long-acting opioids are not currently approved for prophylaxis of postoperative pain.

FENTANYL

Fentanyl and its analogs sufentanil and alfentanil are the most frequently used opioids in clinical anesthesia today. Fentanyl, first synthesized in 1960, is structurally related to the phenylpiperidines (see Fig. 14-5) and has a clinical potency ratio 50 to 100 times that of morphine. Clear plasma concentration-effect relationships have been demonstrated for fentanyl (Table 14-3). Scott et al[88] demonstrated progressive EEG changes with increasing serum fentanyl concentration (Fig. 14-7). During a 5-minute fentanyl infusion, the time lag between increasing serum fentanyl concentration and EEG slowing was 3 to 5 minutes. After the infusion was stopped,

the resolution of EEG changes lagged behind decreasing serum fentanyl concentration by 10 to 20 minutes.

Analgesia

Fentanyl, a μ-opioid receptor agonist, produces profound dose-dependent analgesia, ventilatory depression, and sedation, and at high doses it can produce unconsciousness. In postoperative patients receiving fentanyl by a patient-controlled analgesia system, the mean fentanyl dose requirement was 55.8 μg/h, and mean minimum effective analgesic concentration (MEAC) in blood was 0.63 ng/mL.[89] A large interpatient variability in MEAC (0.23 to 1.18 ng/mL) typical of opioids was observed, but over the 2-day study period, the MEAC for any individual patient remained relatively constant. In a volunteer study, a mean plasma fentanyl concentration of 1.3 ng/mL reduced experimental pain intensity ratings by 50%.[40] This is consistent with other estimates of plasma fentanyl concentrations associated with moderate to strong analgesia.[90]

EFFECT ON MINIMUM ALVEOLAR CONCENTRATION OF

4 Fentanyl reduces the MAC of volatile anesthetics in a concentration- or dose-dependent fashion. A single iv bolus dose of fentanyl 3 μg/kg, given 25 to 30 minutes prior to incision, reduced both isoflurane and desflurane MAC by approximately 50%.[91] Fentanyl 1.5 μg/kg administered 5 minutes prior to skin incision reduces the minimum alveolar concentration that blocks adrenergic responses to stimuli (MAC-BAR) of isoflurane or desflurane in 60% N_2O by 60 to 70%.[92] No further drop is seen with an increase in fentanyl dose to 3 μg/kg. During constant plasma concentration of 0.5 to 1.7 ng/mL, fentanyl reduced isoflurane MAC by 50%.[93] Fentanyl produces a steep plasma concentration-related reduction in sevoflurane MAC[94]; (3 ng/mL provides a 59% reduction), but a ceiling effect is reached, such that a threefold increase to 10 ng/mL reduced MAC by only an additional 17%.

Epidural fentanyl also reduces halothane MAC.[95] Epidural fentanyl 1, 2, and 4 μg/kg reduced halothane MAC by 45, 58, and 71%, respectively, while the same doses of fentanyl given iv reduced halothane MAC by 8, 40, and 49%, respectively.

5 Combining opioids with propofol rather than an inhalation agent is another common technique for providing general anesthesia, referred to as *total intravenous anesthesia* or TIVA. For an intravenous anesthetic, the potency index is described as the plasma concentration required to prevent a response in 50% (CP_{50}) or 95% (CP_{95}) of patients to various surgical stimuli. Plasma concentrations of fentanyl and propofol that reduce hemodynamic or somatic responses to various surgical stimuli in 50% of patients have been determined using computer-assisted infusion.[96] Fentanyl plasma concentrations of 1.2, 1.8, and 2.8 ng/mL were required for 50% reductions in propofol's CP_{50}s for skin incision, peritoneal incision, and abdominal retraction, respectively. Greater fentanyl concentrations were required to suppress hemodynamic responses to these same stimuli. Thus, fentanyl reduces requirements for both volatile agents and propofol by a similar proportion.

Several other investigators have also used computer-assisted infusion to administer fentanyl as a component of a balanced anesthetic technique.[97,98] In combination with 50 to 70% N_2O in oxygen, loss of consciousness, and absence of response to skin incision are achieved at plasma fentanyl concentrations of 15 to 25 ng/mL and greater than 3.7 ng/mL, respectively. Intraoperative concentration requirements varied between 1 and 9 ng/mL. Finally, spontaneous ventilation was seen when the fentanyl concentration dropped to 1.5 to 2 ng/mL.[97,98]

6 Fentanyl has been used as the sole agent for anesthesia, a technique that requires a large initial dose of 50 to 150 μg/kg or stable plasma fentanyl concentrations in the range of 20 to 30 ng/mL.[90] The major advantage of this technique is reliable hemodynamic stability. High doses of fentanyl significantly blunt the "stress response"—that is, hemodynamic and hormonal responses to surgical stimuli—while producing only minimal cardiovascular depression. Thus, the technique is sometimes referred to as "stress-free anesthesia." There are also disadvantages to using high-dose fentanyl as the sole anesthetic agent. It appears that no dose of fentanyl will completely block hemodynamic or hormonal responses in all patients.[99] Furthermore, although high doses generally result in unconsciousness, there have been reports of intraoperative awareness and recall in patients who received very high doses (>50 μg/kg) of fentanyl. Because opioids do not produce muscle relaxation, and high-dose fentanyl can produce muscle rigidity, a muscle relaxant is generally required to achieve adequate surgical conditions. This can potentially increase the difficulty in detecting signs of intraoperative awareness. Direct and processed EEG monitoring have been used to assess the depth of anesthesia achieved with high-dose opioids.

Other Central Nervous System Effects

The effects of fentanyl on cerebral blood flow (CBF) and intracranial pressure (ICP) have been studied in normal patients and in those with neurologic disease. An induction dose of 16 μg/kg increased middle cerebral artery flow by 25% in normal patients having noncranial neurosurgery.[100] A smaller dose (3 μg/kg) resulted in an elevation in ICP in ventilated patients with head trauma.[101] However, in brain tumor patients anesthetized with N_2O–O_2, a dose of 5

μg/kg of fentanyl did not result in elevated ICP.[102] In all cases of elevation in ICP and CBF, there were decreases in mean arterial pressure, which may have contributed to these changes.

7 Muscle rigidity is often seen on induction with high-dose fentanyl and its derivatives. When rigidity is intense, it may be difficult or impossible to ventilate the patient. In a study in normal volunteers, 1,500 μg fentanyl infused over 10 minutes produced rigidity in 50% of subjects.[103] A similar incidence, 35%, was seen in patients receiving 750 to 1,000 μg fentanyl during induction of general anesthesia, and up to 80% of patients receiving 30 μg/kg developed moderate to severe rigidity.[104] Muscle rigidity seen with high doses of fentanyl increases with age[104] and is accompanied by unconsciousness and apnea,[103,104] but lower doses, 7 to 8 μg/kg, have produced chest wall rigidity without unconsciousness or apnea. Streisand et al[103] hypothesized that hypercarbia from fentanyl-induced respiratory depression may have influenced fentanyl ionization and cerebral blood flow and hence the delivery of fentanyl to brain tissue. It would follow that patients instructed to deep-breathe during fentanyl induction may experience less rigidity during induction of anesthesia. This is consistent with observations by Lunn et al.[105] During high-dose fentanyl induction (75 μg/kg), $PaCO_2$ was maintained at 35 to 40 torr by assisting and then controlling respirations. Although chest wall compliance was reduced in 4 of 18 patients, no patient developed rigidity sufficient to impair ventilation.

Fentanyl has been associated with seizure-like movements during anesthetic induction, which are not associated with seizure activity on the EEG.[106] Whereas fentanyl can induce seizures in other animals, the doses required to produce EEG-documented seizures is generally higher than that used in humans. Such activity may represent myoclonus, a result of opioid-mediated blockade of inhibitory motor pathways of cortical origin, or may represent exaggerations of opioid-induced muscle rigidity.[106] However, fentanyl can activate epileptiform EEG activity in patients having surgery for intractable temporal lobe epilepsy.[107]

Fentanyl-induced pruritus often presents as facial itching, but can be generalized. Equianalgesic plasma concentrations of fentanyl, morphine, and alfentanil produce equivalent intensity of pruritus.[40] Fentanyl has also been reported to have a tussive effect. Twenty-eight percent of patients coughed within 1 minute after receiving a bolus dose of fentanyl (1.5 μg/kg). The mechanism is unclear, and it was not attenuated by pretreatment with atropine or midazolam.[108]

Respiratory Depression

8 Fentanyl produces approximately the same degree of ventilatory depression as equianalgesic doses of morphine.[40] Respiratory depression—expressed as an elevation in end-tidal CO_2, a decrease in the slope of the CO_2 response curve, or the minute ventilation at an end-tidal CO_2 of 50 mmHg (V_E50)—develops rapidly, reaching a peak in ~5 minutes,[88,109,110] and the time course closely follows plasma fentanyl concentration.[109,111] Even at plasma concentrations associated with mild analgesia, ventilatory depression can be detected, and the magnitude of respiratory depression is linearly related to intensity of analgesia (see Table 14-3).[40,112] In postoperative patients, plasma fentanyl concentrations of 1.5 to 3.0 ng/mL were associated with a 50% reduction in CO_2 responsiveness.[113]

The magnitude of respiratory depression can be greatly increased when fentanyl is given in combination with another respiratory depressant such as midazolam. Bailey et al[110] determined that midazolam alone (0.05 mg/kg) did not depress ventilation or cause hypoxemia. Fentanyl alone (2 μg/kg) reduced the slope of the CO_2 response curve and the V_E50 by 50%, and 6 of 12 subjects became hypoxemic. Fentanyl and midazolam produced no greater depression of the ventilatory response to CO_2 than fentanyl alone, but 11 of 12 subjects became hypoxemic and 6 of 12 became apneic within 5 minutes. These observations suggest that this frequently used combination blunts the hypoxic ventilatory drive to a greater extent than the hypercarbic ventilatory drive. Precautions such as supplemental oxygen and pulse oximetry monitoring are recommended when such drug combinations are used.

Airway Reflexes

9 Although obtundation of airway reflexes by general inhalation anesthetics is well described,

little is known about the direct effects of opioids on these protective reflexes. Tagaito et al examined the dose-related effects of fentanyl on airway responses to laryngeal irritation during propofol anesthesia in humans.[114] All patients had laryngeal mask airways; half breathed spontaneously, and half had ventilation controlled to maintain an end-tidal CO_2 of 38 mm Hg. In both groups, stimulation of the larynx (application of water to mucosa) elicited a forced expiration, followed by spasmodic panting mingled with cough reflexes and brief laryngospasm. With three cumulative fentanyl doses (50, 50, and 100 μg), expiration, panting, and coughing decreased in a dose-dependent fashion. After the first dose of fentanyl, apnea with laryngospasm replaced the other reflexes, and with cumulative fentanyl dosing, the duration of laryngospasm shortened. These investigators also noted that cough was the airway reflex most vulnerable to depression by fentanyl. While attenuation of airway reflexes is desirable during general anesthesia, it is equally desirable that these protective reflexes return to baseline rapidly after emergence, and remain intact throughout conscious sedation. Doses required to suppress cough and other reflexes in awake or sedated individuals have not been characterized.

Cardiovascular and Endocrine Effects

10 Isolated heart muscle models have shown concentration-dependent negative inotropic effects of opioids, including morphine, meperidine, and fentanyl.[58] A fentanyl concentration of 10 μg/mL reduced contractility by 50%, but 1 μg/mL had no significant effects on papillary muscle mechanics. In clinical practice, high-dose fentanyl administration (up to 75 μg/kg) produces much lower plasma concentrations, that is, in the range of 50 ng/mL,[105] and is associated with remarkable hemodynamic stability. Patients who received 7 μg/kg fentanyl at induction of anesthesia had a slight decrease in heart rate, but no change in mean arterial pressure compared to control.[75] Fentanyl-induced bradycardia is more marked in anesthetized than conscious subjects, and usually resolves with atropine. With higher fentanyl doses, in the range of 20 to 25 μg/kg, decreases in heart rate, mean arterial pressure, systemic and pulmonary vascular resistance, and pulmonary capillary wedge pressure of approximately 15% were seen in patients with coronary artery disease.[105,115] Very high fentanyl doses, up to 75 μg/kg, produced no further hemodynamic changes. All of these patients had been premedicated with a diazepam or pentobarbital, and scopolamine or atropine. In unpremedicated patients undergoing noncardiac surgery, induction with fentanyl 30 μg/kg produced no changes in heart rate or systolic blood pressure.[104] Hypertension in

response to sternotomy is the most common hemodynamic disturbance during high-dose fentanyl anesthesia and occurs in 40 and 100% in patients receiving 50 to 100 μg/kg.[116] Unlike morphine and meperidine, which induce hypotension, at least in part because of histamine release,[57,117] high-dose fentanyl (50 μg/kg) is not associated with significant histamine release (see Fig. 14-4).

While high doses of fentanyl are associated with minimal cardiovascular changes, combining fentanyl with other drugs can compromise hemodynamic stability. The combination of fentanyl and diazepam produces significant cardiovascular depression.[104,115] Diazepam 10 mg given after 20 to 50 μg/kg of fentanyl decreased stroke volume, cardiac output, systemic vascular resistance, and mean arterial pressure, and increased central venous pressure significantly.[115] Adding 60% N_2O to high-dose fentanyl produced a significant decrease in cardiac output and increases in systemic and pulmonary vascular resistance.[105]

High-dose fentanyl (100 μg/kg) prevented increases in plasma epinephrine, cortisol, glucose, free fatty acids, and growth hormone (the "stress response") during surgery, but lower dose fentanyl (5 μg/kg followed by an infusion of 3 μg/kg/h) did not.[118]

Smooth Muscle and Gastrointestinal Effects

11 12

Fentanyl, like morphine and meperidine, significantly increases common bile duct pressure (see Fig. 14-6).[72] Like other opioids, fentanyl can cause nausea and vomiting, particularly in ambulatory patients, and can delay gastric emptying and intestinal transit.

Disposition Kinetics

Fentanyl's extreme lipid solubility (see Table 14-2) allows rapid crossing of biologic membranes uptake by highly perfused tissue groups, including the brain, heart, and lung. Thus, after a single bolus dose, the onset of effects is rapid and the duration brief. Hug and Murphy[119] determined the relationships between fentanyl effects and its concentration over time in plasma and various tissues in rats given fentanyl 50 μg/kg (Fig. 14-8). The onset of opioid effects occurred within 10 seconds, and correlated with a rapid increase in brain tissue fentanyl concentration, which equilibrated with plasma by 1.5 minutes. Recovery from fentanyl effects started within 5 minutes and was complete by 60 minutes. Elimination from the "central tissues" (brain, heart, and lung) was also rapid, as fentanyl was redistributed to other tissues, particularly muscle and fat. Peak muscle concentration was seen at 5 minutes, while fat concentration reached a maximum approximately 30 minutes after the dose. The delay in fat uptake despite fentanyl's high lipid solubility is because of the limited blood supply to that tissue. Thus, redistribution to muscle and fat limits the duration of a bolus dose of fentanyl, and accumulation in peripheral tissue compartments can be extensive because of the large mass of muscle and high affinity of fentanyl for fat. With prolonged administration of fentanyl, fat can act as a reservoir of drug.

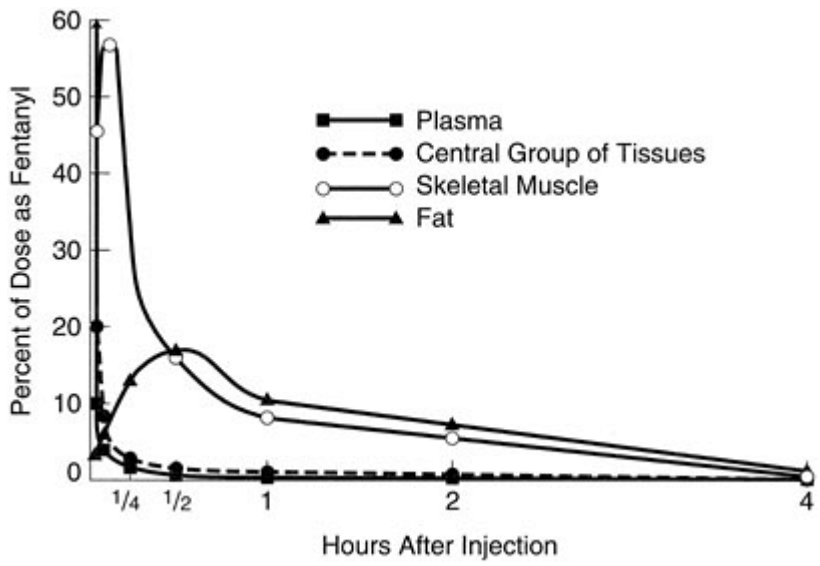

FIGURE 14-8. Fentanyl uptake and elimination in various tissues of the rat following intravenous injection. Unchanged fentanyl tissue concentrations (means for 6 rats) are expressed as percentage of dose. "Central" represents the combined content of brain, heart, and lung tissues. The large mass of muscle (50% body weight of the rat) and high affinity of fat for fentanyl (despite slow equilibration) serve as a drain on the central compartment. (Reprinted with permission from Hug CC, Murphy MR: Tissue redistribution of fentanyl in terms of its effects in rats. Anesthesiology 55:369, 1981.)

Fentanyl pharmacokinetics have been studied in normal volunteers as well as patients under general anesthesia. After an iv dose, plasma fentanyl concentration falls rapidly, and the concentration–time curve has been described by both two- and three-compartment models.[120] McClain and Hug[109] administered fentanyl 3.2 or 6.4 μg/kg to healthy male volunteers and found that nearly 99% of the dose was eliminated from plasma by 60 minutes. These investigators found both rapid and slower distribution phases, with half-times of 1.2 to 1.9 minutes and 9.2 to 19 minutes, respectively. The terminal elimination half-time ranged from 3.1 to 6.6 hours, somewhat longer than that for morphine. Similar values were noted in surgical patients less than 50 years old,[102,121] including morbidly obese patients.[102] Reports of age effects on fentanyl kinetics are conflicting. While fentanyl requirement decreases with increasing age (20 to 89 years), pharmacokinetic parameters do not change.[122] In contrast, Bentley et al[121] observed a marked

decrease in clearance and an increase in terminal elimination half-time to approximately 15 hours in patients over 60 years old compared to 4.4 hours in patients less than 50 years old.

Unlike its derivatives, fentanyl is significantly bound to red blood cells, approximately 40%, and has a blood:plasma partition coefficient of approximately 1.[120] Plasma fentanyl is highly protein bound, with estimates in the range of 79 to 87%. It binds avidly to α_1-acid glycoprotein but also binds to albumin.[120,123] Fentanyl protein binding is pH dependent, such that a decrease in pH will increase the proportion of fentanyl that is unbound.[120] Thus, a patient with respiratory acidosis will have a higher proportion of unbound (active) fentanyl, which could exacerbate respiratory depression. Clearance of fentanyl is primarily by rapid and extensive metabolism in the liver. Clearance estimates[109,122] of 8 to 21 mL/kg/min approach liver blood flow and indicate a high hepatic extraction ratio. Thus, hepatic metabolism of fentanyl is expected to be dependent on liver blood flow. Metabolism is primarily by *N*-dealkylation to norfentanyl and by hydroxylation of both the parent and norfentanyl.[120] Only about 6% of the dose of fentanyl is excreted unchanged in the urine.[109]

Dosage and Administration of Fentanyl

From administration as a single bolus dose, fentanyl developed an early reputation as a short-acting opioid, but experience with very large doses and multiple doses revealed that prolonged respiratory depression and delayed recovery could occur. These observations demonstrate that fentanyl's clinical duration is limited by redistribution, and that with prolonged administration, accumulation can occur as discussed later in this chapter.

Fentanyl can be useful as a sedative/analgesic premedication when given a short time prior to induction. For this use, incremental doses of 25 to 50 μg iv can be used and titrated until the desired effect is achieved. It is important to note that although the onset of fentanyl's effects is rapid, peak effect lags behind peak plasma concentration by up to 5 minutes.[88] A

transmucosal delivery system for fentanyl is also available and has been shown to be an effective premedicant for pediatric and adult patients as well as an effective treatment for "break-through" pain in chronic pain patients. In children, doses of 10 to 20 μg/kg, and in adults, 400 to 800 μg, administered 30 minutes prior to induction or a painful procedure are safe and effective, but dose-dependent side effects typical of opioids are reported.[124,125] Because respiratory depression and hypoxemia can occur, transmucosal fentanyl should usually be administered in a monitored environment.

When fentanyl was administered with 50% N_2O in oxygen for induction, the effective dose for loss of consciousness was 8 to 23 μg/kg.[98] Remember, however, that the combination of N_2O and a moderate to high dose of opioid may cause significant muscle rigidity, which can be attenuated by a variety of adjuvants, including benzodiazepines, barbiturates, and muscle relaxants.

Fentanyl is also used frequently as an adjunct to induction agents, such as thiopental and propofol, to blunt the hemodynamic response to laryngoscopy and tracheal intubation, which can be particularly severe in patients with hypertension or cardiovascular disease. Common clinical practice involves titration of fentanyl in doses of 1.5 to 5 μg/kg prior to administration of a barbiturate or other induction agent. Because fentanyl's peak effect lags behind peak plasma concentration by 3 to 5 minutes, fentanyl titration should be complete approximately 3 minutes prior to laryngoscopy to maximally blunt hemodynamic responses to tracheal intubation. Perhaps the most common clinical use of fentanyl and its derivatives is as an analgesic component of balanced general anesthesia. With this technique, incremental doses of fentanyl 0.5 to 2.5 μg/kg are administered intermittently as dictated by the intensity of the surgical stimulus and may be repeated approximately every 30 minutes. Generally, administration of up to 3 to 5 μg/kg/h will allow recovery of spontaneous ventilation at the end of surgery. As an alternative to intermittent dosing, a loading dose of 5 to 10 μg/kg and continuous fentanyl infusion at a rate between 2 and 10 μg/kg/h are recommended.[98] It is important to remember, however, that anesthetic requirements vary with age, concurrent diseases, and the surgical procedure. For example, fentanyl requirements decrease by 50% as age increases from 20 to 89 years.[122] Fentanyl

requirements can also be expected to decrease with the duration of infusion (see discussion of context-specific half-times at the end of this chapter).

Fentanyl combined with high-dose droperidol, and nitrous oxide, is a technique called *neuroleptanesthesia*.[126] Although used for many years, this technique has largely been replaced by the balanced anesthetic technique of fentanyl combined with low-dose inhaled anesthetics. Neuroleptanesthesia is not likely to regain popular use in the United States because of concerns about prolongation of the QT interval of the ECG by high dose droperidol.[127] High-dose (e.g., 50 to 150 μg/kg) fentanyl "anesthesia" has been used extensively for cardiac surgery. With this technique, a mean plasma fentanyl concentration of 15 ng/mL, which prevents hemodynamic changes in response to noxious stimuli,[128] can be achieved with a loading dose of 50 μg/kg, followed by a continuous infusion of 30 μg/kg/h. With high-dose fentanyl, muscle relaxants and mechanical ventilation are required. Whether opioids alone are suitable as the sole "anesthetic" agent continues to be debated.

Finally, fentanyl has been used as an analgesic in management of acute and chronic pain (see Chapters 54 and 55).

Dosage recommendations are summarized in Table 14-5.

SUFENTANIL

Sufentanil, a thienyl derivative of fentanyl (see Fig. 14-5) first described in the mid 1970s, has a clinical potency ratio 2,000 to 4,000 times that of morphine and 10 to 15 times that of fentanyl.[129,130] Like fentanyl, sufentanil equilibrates rapidly between blood and brain, and demonstrates clear plasma concentration-effect relationships. In a study comparing sufentanil and fentanyl effects on the EEG, Scott et al[130] noted similar pharmacodynamic profiles. During a 4-minute sufentanil infusion, the change in spectral edge lagged behind the rising sufentanil concentration by approximately 2 to 3 minutes, while resolution of the EEG changes lagged behind plasma concentration changes by 20 to 30 minutes.

Analgesia

Sufentanil is a highly selective μ-opioid receptor agonist and exerts potent analgesic effects in animals when given by either systemic or spinal routes. While the literature describing clinical experience with sufentanil as a component of general anesthesia is extensive, available information regarding the analgesic potency of systemically administered sufentanil in humans is limited. Geller et al[131] titrated an iv infusion rate to adequate postoperative analgesia, and noted that a mean rate of 8 to 17 μg/h was required during the first 48 hours. This was associated with a fivefold range in plasma sufentanil concentrations, between 0.02 and 0.1 ng/mL. Similar sufentanil requirements (including a wide interpatient variability) are noted in other studies of postoperative and cancer patients,[41,132] and Lehman estimated that the minimum effective analgesic concentration of sufentanil is near 0.03 ng/mL,[132] and the analgesic EC_{50} of sufentanil concentration is approximately 0.05 ng/mL.[133]

EFFECT ON MINIMUM ALVEOLAR CONCENTRATION OF VOLATILE ANESTHETICS AND USE IN ANESTHESIA

In animal studies, sufentanil decreases the MAC of volatile anesthetics in a dose-dependent manner, with the maximum MAC reduction between 70 and 90%.[134] In humans, a plasma sufentanil concentration of 0.145 ng/mL is associated with a 50% reduction in isoflurane MAC.[135] Increasing the plasma sufentanil concentration to 0.5 ng/mL reduced isoflurane MAC by 78%, and a ceiling effect was approached with greater plasma sufentanil concentrations. The maximum MAC reduction seen in humans was 89%, at a sufentanil concentration of 1.4 ng/mL.

In clinical anesthesia practice, sufentanil is used as a component of balanced anesthesia and has been employed extensively in high doses (10 to 30 μg/kg) with oxygen and muscle relaxants for cardiac surgery. In this dose range, sufentanil is at least as effective as fentanyl in its ability to produce and maintain hypnosis. In addition, hemodynamic stability appears to be as good as or

better than that achieved with fentanyl.[75,129] Bailey et al[136] used a computer-assisted continuous infusion system to determine the sufentanil plasma concentration response to various noxious stimuli during high-dose sufentanil anesthesia for cardiac surgery. They estimated the plasma concentration associated with a 50% probability of no response (movement, hemodynamic, or sympathetic) to intubation, incision, sternotomy, and mediastinal dissection (CP_{50}). The CP_{50} for intubation, incision, and sternotomy (pooled data) was 7.06 ng/mL, and for mediastinal dissection CP_{50} was 12.1 ng/mL. As is typical of opioids, a wide intersubject variability (3- to 10-fold) was noted in sufentanil concentration requirements. However, when used as the sole anesthetic agent, even high doses may not completely block the hemodyamic responses to noxious stimuli.[99]

Other Central Nervous System Effects

Equianalgesic doses of sufentanil and fentanyl produce similar changes in the EEG.[129,130] In patients who received sufentanil 15 μg/kg, *α* activity became prominent within a few seconds, and within 3 minutes, the EEG consisted almost entirely of

slow *δ* activity.[129] Rigidity and myoclonic activity resembling seizures have been reported during induction of, and on emergence from, anesthesia with sufentanil in doses of approximately 1 to 2 μg/kg.[37,38]

There has been considerable investigation of the effects of sufentanil on cerebral hemodynamics and intracranial pressure. In patients with intracranial tumors, sufentanil 1 μg/kg was associated with an elevation in spinal cerebrospinal pressure and a decrease in cerebral perfusion pressure.[137] As seen with fentanyl, mean arterial pressure had dropped significantly in these patients. In normal volunteers, a smaller dose of sufentanil (0.5 μg/kg) was not associated with changes in cerebral blood flow.[138] Very large doses of sufentanil (20 μg/kg) in dogs decreased cerebral blood flow in proportion to cerebral metabolism, and intracranial pressure did not change.[139]

Respiratory Depression

Like other *μ*-opioid agonists, sufentanil causes respiratory depression in doses associated with clinical analgesia.[111,112] Respiratory depression can be especially marked in the presence of inhalation anesthetics. In spontaneously breathing patients anesthetized with 1.5% halothane and N_2O, a small dose of sufentanil (approximately 2.5 μg) reduced mean minute ventilation by 50%, and 4 μg reduced mean respiratory rate by 50%.[140] Postoperative respiratory depression after apparent recovery from anesthesia has been reported for both fentanyl and sufentanil.[141] The lack of exogenous stimulation in the early postoperative period may be an important a factor during early recovery from anesthesia.

In normal volunteers who received bolus doses of fentanyl and sufentanil, changes in end-tidal CO_2 were the same for fentanyl and sufentanil, but the slope of the ventilatory response to CO_2 was depressed to a greater extent by fentanyl.[111] In another volunteer study, a fourfold range of equianalgesic plasma concentrations of morphine and sufentanil produced equivalent respiratory depression, measured as both increased end-tidal CO_2 and a decreased ventilatory response to CO_2.[133]

Cardiovascular and Endocrine Effects

In animal studies, sufentanil produces vasodilation by a sympatholytic mechanism but may also have a direct smooth muscle effect.[142] Clinically, a prominent feature of many trials involving sufentanil is the remarkable hemodynamic stability achieved during balanced and high-dose (up to 30 μg/kg) opioid anesthesia. Only a modest decrease in mean arterial pressure is observed when sufentanil (approximately 15 μg/kg) is used for induction of anesthesia.[75,143] In general, sufentanil and fentanyl have been found to be equivalent for use in balanced and high-dose opioid anesthesia,[99,144] but clinical comparisons between fentanyl and sufentanil suggest that sufentanil may be associated with less respiratory depression and better analgesia in the immediate

postoperative period.[145]

The choice of premedication and muscle relaxant may significantly affect hemodynamics during induction and maintenance of anesthesia with sufentanil. Combining vecuronium and sufentanil can cause a decrease in mean arterial pressure during induction,[146] and significant bradycardia and sinus arrest[147] have been reported. Bradycardia is not seen when pancuronium is used during anesthesia with sufentanil.

Sufentanil, like fentanyl, reduces the endocrine and metabolic responses to surgery.[129] However, even a large induction dose (20 μg/kg) did not prevent increases in cortisol, catecholamines, glucose, and free fatty acids during and after cardiopulmonary bypass.[148]

Disposition Kinetics

Sufentanil is extremely lipophilic and has pharmacokinetic properties similar to that of fentanyl. Because of a smaller degree of ionization at physiologic pH and higher degree of plasma protein binding, its volume of distribution is somewhat smaller and its elimination half-life shorter than that of fentanyl (see Table 14-2). Sufentanil pharmacokinetics has been studied in anesthetized patients who had received methohexital for anesthetic induction, followed by the sufentanil dose of 5 μg/kg, and N_2O in oxygen 33%.[149] Plasma sufentanil concentration drops very rapidly after an iv bolus dose, and 98% of the drug is cleared from plasma within 30 minutes. Plasma concentration–time data in this study were best fitted to a three-compartment model, with rapid and slower distribution half-times of 1.4 and 17.7 minutes, respectively, and an elimination half-life of 2.7 hours. In other pharmacokinetic studies with anesthetized patients, reported mean elimination half-lives were in the range of 2.2 to 4.6 hours.[150,151,152] Obese patients have a larger total volume of distribution and a longer elimination half-life (3.5 vs. 2.2 hours) compared to nonobese patients.[150]

Sufentanil is less red cell bound than fentanyl (22 compared to 40%) and has a whole blood:plasma concentration ratio of 0.741.[120] Plasma sufentanil is approximately 92% protein bound at pH 7.4, mostly to α_1-acid glycoprotein. Clearance of sufentanil is rapid, and like fentanyl has a high hepatic extraction ratio.[120] Metabolism in the liver is by *N*-dealkylation and *O*-demethylation. However, sufentanil clearance and elimination half-life in patients with cirrhosis are similar to controls.[151]

Dosage and Administration of Sufentanil

Like fentanyl, sufentanil is most often used as a component of balanced anesthesia, or as a single agent in high doses, particularly for cardiac surgery (Table 14-5). Several investigations have found similar sufentanil dose requirements for induction of anesthesia.[136,153,175] When sufentanil is titrated during induction, loss of consciousness is seen with total doses between 1.3 to 2.8 μg/kg. Doses in the range of 0.3 to 1.0 μg/kg given 1 to 3 minutes prior to laryngoscopy can be expected to blunt hemodynamic responses to intubation, but muscle rigidity can occur, particularly in the elderly, even at these lower doses.

Balanced anesthesia is maintained with intermittent bolus doses or a continuous infusion. With bolus doses of 0.1 to 0.5 μg/kg, mean maintenance requirements of 0.35 μg/kg/h have been reported.[75] Cork et al[152] administered an initial bolus of 0.5 μg/kg followed by an infusion of 0.5 μg/kg/h, titrated to patient need. This regimen of sufentanil in combination with N_2O 70% in oxygen, with or without isoflurane, provided satisfactory anesthesia with good hemodynamic stability. Thus, for balanced anesthesia, sufentanil-expected dose requirements for bolus administration and continuous infusion are similar, in the range of 0.3 to 1 μg/kg/h. Much higher bolus doses (10 μg/kg) and/or infusion rates (0.15 μg/kg/min) are required to achieve the plasma sufentanil concentration range of 6 to 60 ng/mL required during cardiac anesthesia using sufentanil as the sole agent.

ALFENTANIL

Alfentanil, a tetrazole derivative of fentanyl (see Fig. 14-5), was synthesized 2 years after

sufentanil and introduced into clinical practice in the early 1980s. On a milligram basis, its clinical potency is approximately ten times that of morphine and one-fourth to one-tenth that of fentanyl when given in single doses. Alfentanil differs from fentanyl in its pharmacokinetics

as well as in its speed of equilibration between plasma and effect site in the brain. In a comparison using EEG spectral edge effects to quantify fentanyl and alfentanil pharmacodynamics, Scott et al[88] demonstrated that alfentanil's effect followed serum drug concentration more closely than fentanyl (see Fig. 14-8). Peak effect lagged behind peak plasma concentration by less than 1 minute, and resolution of effect followed decreasing serum alfentanil concentration by no more than 10 minutes. Alfentanil is a μ-opioid receptor agonist and produces typical naloxone-reversible analgesia and side effects such as sedation, nausea, and respiratory depression.

Analgesia

Alfentanil has been administered intravenously for treatment of postoperative and cancer-related pain, as well as in laboratory pain models with normal volunteers. Clear concentration and dose-related analgesic effects have been demonstrated for alfentanil, but individual requirements in terms of dosage or plasma concentrations vary widely. For postoperative analgesia, the MEAC is approximately 10 ng/mL, with a range of 2 to >40 ng/mL.[154] In a laboratory investigation, 80 ng/mL was associated with a 50% reduction in pain intensity.[40] In clinical studies of patients receiving continuous iv infusion of alfentanil, mean plasma concentrations required for relief of moderate to severe pain are approximately 40 to 80 ng/mL (see Table 14-3).[155] Following an adequate loading dose, average alfentanil requirements for postoperative analgesia are approximately 10 to 20 μg/kg/h.[156,157]

Effect on Minimum Alveolar Concentration of Volatile Anesthetics and Use in Anesthesia

Like other opioids, alfentanil decreases the MAC of enflurane in a curvilinear fashion up to a plateau.[21,158] In dogs, an infusion rate of 8 μg/kg/min (plasma concentration 223 ng/mL) reduced enflurane MAC by 69%, but increasing the infusion rate fourfold did not reduce enflurane MAC further.[158]

In humans, alfentanil plasma concentrations required to supplement N_2O anesthesia for various noxious stimuli have been determined.[159] Patients received a loading dose of 150 μg/kg, followed by an infusion that was titrated between 25 and 150 μg/kg/h according to the patients' responses to surgical stimuli, and steep concentration-effect curves were demonstrated. Plasma concentrations required along with 66% N_2O to obtund somatic, autonomic, and hemodynamic responses to stimuli in 50% of patients were 475, 279, and 150 ng/mL for tracheal intubation, skin incision, and skin closure, respectively. The plasma alfentanil concentration associated with spontaneous ventilation after discontinuation of N_2O was 223 ng/mL. Nearly identical results were obtained in a similar study using computer-controlled infusions to deliver alfentanil (Fig. 14-9).[160] Plasma alfentanil concentrations required in combination with propofol to obtund responses to intubation and surgical stimuli have also been determined.[161] In contrast to combining alfentanil and N_2O, much lower alfentanil plasma concentrations (55 to 92 ng/mL) were required to prevent responses in 50% of patients when alfentanil was combined with propofol at a plasma concentration of 3 μg/mL (Fig. 14-10).

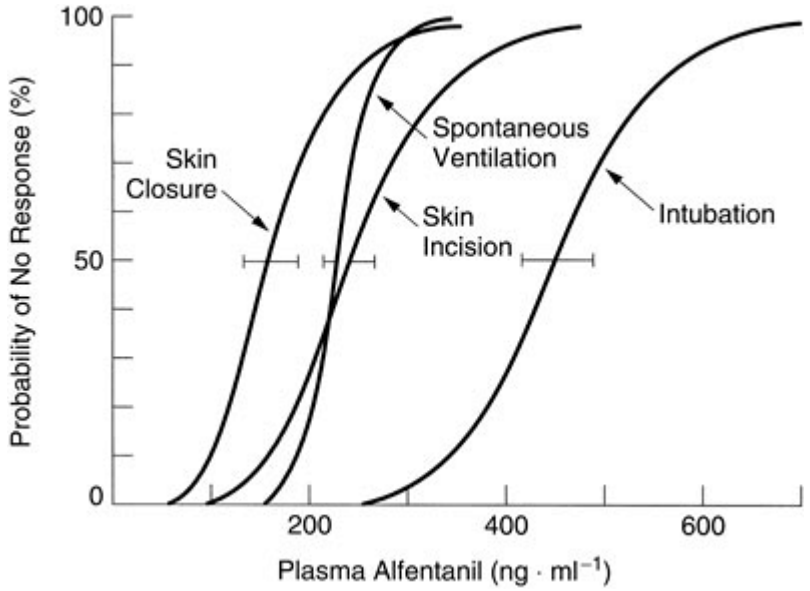

FIGURE 14-9. The relationship between alfentanil plasma concentration (with 66% N_2O) and the probability of no response for intubation, skin incision, and skin closure; and the relationship of plasma alfentanil concentration (without N_2O) and the recovery of adequate spontaneous ventilation. (Reprinted with permission from Vuyk J, Lim T, Engbers FHM *et al:* Pharmacodynamics of alfentanil as a supplement to propofol or nitrous oxide for lower abdominal surgery in female patients. Anesthesiology 78:1036, 1993.)

High-dose alfentanil has been used as an induction agent for patients with and without cardiac disease[162] and for induction and maintenance of cardiac anesthesia.[116,163] Patients with cardiac valvular or coronary artery disease required half as much alfentanil to induce unconsciousness.[162] When used as the sole anesthetic agent, mean plasma alfentanil concentrations required to significantly blunt hemodynamic responses to intubation and sternotomy were 700 to 830 ng/mL and 1,200 to 1,800 ng/mL, respectively.[164] These values are approximately twice those reported for alfentanil in combination with 66% nitrous oxide.[159,160] However, even doses that produced very high plasma alfentanil concentrations (1,200 to >2,000 ng/mL) did not eliminate responses to intubation and intraoperative stimuli in all patients.[199] In contrast to fentanyl and sufentanil, the duration of even very large doses of alfentanil is short, so repeated doses or a continuous infusion of alfentanil is required.

Other Central Nervous System Effects

Alfentanil produces the typical generalized slowing of the EEG;[88,165] a plasma concentration of approximately 1,400 ng/mL is associated with the onset of δ-wave activity. Like fentanyl, alfentanil can increase epileptiform EEG activity in patients with intractable temporal lope epilepsy having surgery under general anesthesia.[132] Like fentanyl and sufentanil, alfentanil can produce intense muscle rigidity accompanied by loss of consciousness. In 90 to 100% of patients, induction doses of 150 to 175 μg/kg were associated with muscle rigidity, which was not limited to the chest wall or trunk. Rather, electromyography has shown increased activity of comparable magnitude in muscles of the neck, extremities, chest wall, and abdomen.[137,166]

Alfentanil has been reported to increase cerebrospinal fluid pressure in patients with brain tumors, whereas fentanyl does not.[102] However, Mayberg et al[167] examined the effect of 25 and 50 μg/kg of alfentanil on cerebral blood flow velocity and intracranial pressure in neurosurgical and orthopaedic patients anesthetized with isoflurane and 50% N_2O. Ventilation was controlled to maintain normocapnea, and blood pressure was maintained at baseline for neurosurgical patients. No clinically significant changes in ICP and no evidence of cerebral vasodilation or vasoconstriction were seen.

Respiratory Depression

In animal and human studies, antinociceptive effects could not be separated from respiratory depression in volunteers; mild ventilatory depression (increased end-tidal CO_2; decreased

slope of the CO_2 response curve) was seen at plasma concentrations as low as 20 ng/mL. At plasma concentrations associated with 50% reduction in pain intensity, respiratory depression was equivalent for alfentanil, fentanyl, and morphine.[10] A clinical study examined postoperative analgesia and respiratory effects of alfentanil administered by a patient-controlled analgesia system.[168] In patients who received a continuous alfentanil infusion at 900 μg/h plus 100- to 200-μg doses as needed, 3 of 10 patients developed respiratory depression (respiratory rate <8/min). Mean alfentanil blood concentration in this group of patients was 80 ng/mL.

Two clinical studies examined the intensity and duration of respiratory depressant effects of alfentanil in the immediate postoperative period.[169,170] Patients received balanced anesthesia 67% N_2O with or without 0.5% halothane and alfentanil 20 to 100 μg/kg/h. At the end of surgery the infusion was decreased to 20 μg/kg/h, which produced plasma alfentanil concentrations between 106 and 120 ng/mL, and good analgesia. Ventilatory response to CO_2 was decreased to 50% of the

baseline value, but $PaCO_2$ was only moderately elevated (42 to 48 torr). By 2 hours after alfentanil was discontinued, respiratory function was near baseline. Recovery of ventilatory function was faster with alfentanil compared to fentanyl.[170] Another comparison found that for anesthetics of 1.5 to 2 hours duration, recovery of respiratory function was similar with alfentanil and fentanyl.[171] Like its congeners, alfentanil has been associated with apnea and unconsciousness after apparent recovery from anesthesia.[172]

Cardiovascular Effects

The cardiovascular effects of alfentanil are influenced by preoperative medication, muscle relaxant used, method of administration, and the degree of surgical stimulation. In general, heart rate and mean arterial pressure are unchanged or slightly decreased during induction with alfentanil 40 to 120 μg/kg,[162] but rapid induction with 150 to 175 μg/kg alfentanil can decrease mean arterial pressure by 15 to 20 torr. After induction with etomidate, alfentanil 120 μg/kg decreased mean arterial pressure by approximately 30 torr,[173] and following thiopental (3 to 5 mg/kg) induction, a smaller dose of alfentanil (40 μg/kg) decreased mean arterial pressure by approximately 40 torr.[174] Alfentanil does not appear to have negative inotropic effects,[173] but severe hypotension has been observed when alfentanil is given after 0.125 mg/kg diazepam.[175] In combination with lorazepam premedication or thiopental induction, moderate doses (10 to 50 μg/kg) of alfentanil blunt the cardiovascular and catecholamine responses to laryngoscopy and intubation,[164,174] but for patients over 70 years old, doses in this range given with thiopental can produce significant hypotension after induction.[176] Alfentanil can also cause bradycardia, but this effect is minimized by premedication with atropine and by the vagolytic effect of pancuronium. Alfentanil 50 μg/kg combined with propofol 1 mg/kg for induction of anesthesia can produce significant bradycardia and hypotension after intubation, but premedication with glycopyrrolate prevents these effects.[177]

Nausea and Vomiting

Early clinical reports noted frequent nausea during recovery from balanced anesthesia using alfentanil, but clinical comparisons between alfentanil and sufentanil[178] or fentanyl[179] and N_2O revealed the same incidence of nausea and vomiting. In normal volunteers receiving computer-controlled opioid infusions, the severity of nausea at equianalgesic plasma concentrations was equivalent for alfentanil, fentanyl, and morphine,[40] but alfentanil-induced nausea and

vomiting resolved more quickly (Coda BA, unpublished observations).

Disposition Kinetics

Alfentanil pharmacokinetics differs from fentanyl and sufentanil in several respects (see Table 14-3). A unique characteristic is that alfentanil is a weaker base than other opioids. Whereas other opioids have pK_a above 7.4, the pK_a of alfentanil is 6.8; consequently, nearly 90% of unbound plasma alfentanil is nonionized at pH 7.4.[120] This property, together with its moderate lipid solubility, enables alfentanil to cross the blood-brain barrier rapidly and accounts for its rapid onset of action. Compared to fentanyl and sufentanil, which have mean plasma-brain equilibration half-times of 6.4 and 6.2 minutes, respectively,[88,130] alfentanil has a blood-brain equilibration half-time of 1.1 minutes.[110] Alfentanil also has a smaller volume of distribution than fentanyl, which is a result of lower lipid solubility and high protein binding.[180] Approximately 92% of alfentanil is protein bound, mostly to α_1-acid glycoprotein.[120,123]

After iv administration, plasma alfentanil concentration falls rapidly; 90% of the administered dose has left the plasma by 30 minutes,[181] mostly because of distribution to highly perfused tissues. Plasma concentration decay curves in patients most often fit a three-compartment model.[19,181] Like fentanyl, alfentanil is quickly distributed, with rapid and slow distribution half-times of 1.0 to 3.5 minutes and 9.5 to 17 minutes, respectively. However, alfentanil has a terminal elimination half-life of 84 to 90 minutes, which is considerably shorter than those of fentanyl and sufentanil. Clearance of alfentanil, 6.4 mL/kg/min, is just half that of fentanyl, but because alfentanil's volume of distribution is 4 times smaller than fentanyl's, relatively more of the dose is available to the liver for metabolism.[182] Chauvin et al[183] found that alfentanil has an

intermediate hepatic extraction coefficient (32 to 53%) in humans, and that its elimination is dependent on hepatic plasma flow.

In animals, alfentanil undergoes *N*-dealkylation and *O*-demethylation in the liver to form inactive metabolites.[120] Liver disease can significantly prolong the elimination half-life of alfentanil. Patients with moderate hepatic insufficiency as a result of cirrhosis have reduced binding to α_1-acid glycoprotein and a plasma clearance one-half that of control patients. These changes result in a marked increase in the elimination half-life, 219 minutes versus 90 minutes in controls.[184] Renal disease also decreases alfentanil protein binding, but does not result in decreased plasma clearance or a prolonged terminal elimination half-life.[185] Alfentanil's elimination half-life is prolonged by about 30% in the elderly and appears to be much shorter (about 40 minutes) in children 5 to 8 years old.[186] Obesity is also associated with a 50% decrease in alfentanil clearance and a prolonged (172 minutes) elimination half-life.[186]

The combination of moderate lipid solubility and short elimination half-life suggests that both redistribution and elimination are important in the termination of alfentanil's effects.[182] After a single bolus dose, redistribution will be the most important mechanism, but after a very large dose, repeated small doses, or a continuous infusion, elimination will be a more important determinant of the duration of alfentanil's effects.

Dosage and Administration of Alfentanil

Because of its rapid onset, alfentanil has been used as an induction agent alone or in combination with other drugs. In healthy patients, doses of about 120 μg/kg produce unconsciousness in 2 to 2.5 minutes, but may also produce muscle rigidity. Premedication with a benzodiazepine (e.g., lorazepam 0.08 mg/kg) is associated with a lower dose requirement, 40 to 50 μg/kg, and a faster onset of unconsciousness, within 1.5 minutes,[162] but may also produce hypotension.

Because of its brief duration of action, alfentanil can be a useful component of general anesthesia in short surgical procedures, especially those associated with minimal postoperative pain, particularly in the outpatient surgery. In this setting, loading doses of 5 to 10 μg/kg provide good analgesia with rapid recovery.[180] For longer procedures, alfentanil can be administered as needed in repeated small bolus doses, but its pharmacokinetic properties make it ideal for administration as a continuous infusion. After induction of anesthesia, a loading dose of alfentanil 10 to 50 μg/kg is followed with supplemental bolus doses of 3 to 5 μg/kg as needed or a continuous infusion starting at 0.4 to 1.7 μg/kg/min with 60 to 70% N_2O or a propofol infusion.[159,160,180,187,188] A pediatric study reported use of similar doses of alfentanil and propofol,[189] while another used higher alfentanil doses (100 μg/kg loading dose followed by 2.5 μg/kg/min) combined with 70% N_2O without propofol.[190]

When high-dose alfentanil is used as the sole anesthetic agent, a continuous infusion of up to 150 to 600 μg/kg/h is adjusted according to the patient's responses to stimuli, but much lower doses can be effective for cardiac surgery if adequate premedication is given.[163] See Table 14-5 for a summary of dosage recommendations.

REMIFENTANIL

Remifentanil, a 4-anilidopiperidine with a methyl ester side chain (see Fig. 14-5) first described in 1990 and approved for clinical use in 1996, was developed to meet the need for an ultrashort-acting opioid. Because its ester side chain is susceptible to metabolism by blood and tissue esterases, remifentanil is rapidly metabolized to a substantially less active compound. Thus, because its ultrashort action is due to metabolism rather than to redistribution, it does not accumulate with repeated dosing or prolonged infusion. Remifentanil demonstrates potent, naloxone-reversible μ-selective opioid agonist activity in animal assays.[191]

Analgesia

In animals and humans, remifentanil produces dose-dependent analgesic effects. Human laboratory studies have examined analgesic effects of bolus iv doses (0.0625 to 2.0 μg/kg)[192] as

well as computer-controlled infusions with targeted plasma concentrations (0.75 to 3.0 ng/mL).[193] Bolus doses produced a peak analgesic effect between 1 and 3 minutes and a duration of approximately 10 minutes. In volunteers, MEAC is approximately 0.75 ng/mL, and analgesic EC_{50} is approximately 3 ng/mL.[193] Both studies found remifentanil to be about 40 times as potent as alfentanil.

Clinical investigations have evaluated early postoperative analgesia. One study reported that after remifentanil–propofol anesthesia, nearly 80% of patients were titrated to satisfactory analgesia with remifentanil infusion of 0.05 to 0.15 μg/kg/min.[194] Another early postoperative evaluation demonstrated effective analgesia with patient-controlled infusion of remifentanil to a mean target blood concentration of 2 ng/mL, but noted a fairly high incidence of nausea (26%) with this regimen.[195] Clinical evaluations of remifentanil for labor analgesia have produced conflicting results, and some have found prohibitive rates of unacceptable side effects such as nausea and respiratory depression. However, a dose-ranging study that used remifentanil via PCA reported a median effective bolus dose of 0.4 μg/kg (range 0.2 to 0.8 μg/kg) and consumption of 0.066 μg/kg/min (range 0.027 to 0.207 μg/kg/min).[196]

Effect on Minimum Alveolar Concentration of Volatile Anesthetics and Use in Anesthesia

The effect of remifentanil on the MAC of volatile anesthetics is characterized by steep dose-effect or concentration-effect curves typical of other μ-opioid agonists. In animals, remifentanil decreases enflurane and isoflurane MAC in a dose-dependent fashion up to a maximum near 65%, similar to fentanyl.[197,198] In humans, remifentanil reduces isoflurane MAC logarithmically in a blood concentration–dependent fashion.[199] A whole blood remifentanil concentration of 1.3 ng/mL reduced isoflurane MAC by 50%, with a maximum MAC reduction (91%) at 32 ng/mL. Remifentanil's effect on the MAC-BAR (requirement for blunting the sympathetic response to skin incision) of sevoflurane in 60% N_2O is similar.[200] A remifentanil plasma concentration of 1ng/mL sevoflurane reduced MAC-BAR by 60%, while 3 ng/mL decreased MAC-BAR another 30%.

The rapid onset and brief duration of remifentanil suggest that it is suitable for induction of anesthesia. Although a median ED_{50} of 12 μg/kg for loss of consciousness has been reported, clinical investigations have also found that, as with other opioids, loss of consciousness is not reliably achieved with remifentanil alone, even in doses of 20 μg/kg or more.[201,202] Furthermore, a high incidence of muscle rigidity and purposeless movement was seen. Even at 2 μg/kg remifentanil, moderate muscle rigidity was seen in 40% of patients, and at the 20 μg/kg, 60% of patients had severe muscle rigidity.[201]

Drover and Lemmens[203] used computer-assisted infusions to determine the blood concentrations of remifentanil required to supplement 66% N_2O in patients having abdominal surgery. A range of 0.5 to 7.8 ng/mL target remifentanil concentrations was used, and other than premedication with 1 to 2 mg midazolam, no sedatives or hypnotics were given. During surgery, the remifentanil blood concentration associated with a 50% probability of adequate anesthesia (EC_{50}) was 4.1 ng/mL for men and 7.5 ng/mL for women. The reason for gender differences in these results was not clear, but could have been related to different types of surgeries. A pediatric study of remifentanil and N_2O in O_2 reported an infusion rate twice that used for adults, and quality of anesthesia similar to alfentanil, propofol, and isoflurane, but noted that this regimen may have been an overestimate of remifentanil requirement.[190]

Investigations of remifentanil for balanced anesthesia, including combination with isoflurane,[204,205] sevoflurane,[206] and desflurane,[207] report similar findings of hemodynamic stability and easy titratability. A clinical trial of remifentanil and desflurane–N_2O identified blood remifentanil concentrations that provide an optimal balance between hemodynamic stability and blunting responses to noxious stimulation while permitting rapid recovery.[207] In the presence of 2.2 to 2.7% end-tidal desflurane and N_2O, optimal remifentanil plasma concentrations were 5 to 7 ng/mL for laryngoscopy and skin closure and 10 ng/mL during abdominal surgery. It is interesting to note that adjustments in remifentanil blunted the sympathetic response to noxious stimulation but did

not alter desflurane's effect on the bispectral index analysis of the EEG.

Remifentanil is frequently administered with propofol, to provide *total intravenous anesthesia* (TIVA). Both can be administered at fixed infusion rates or by computer-controlled systems that provide target plasma concentrations, commonly referred to as *target-controlled infusions* or TCI. The combination of remifentanil and propofol for TIVA has been used successfully for a variety of inpatient procedures, including coronary artery bypass graft (CABG); other major thoracic, neurosurgical, abdominal, and orthopaedic procedures; as well as ambulatory surgery and other painful procedures in adults and children. Two studies demonstrated that a fairly low plasma concentration of remifentanil, TCI at 3.4 to 4 ng/mL, reduces propofol EC_{50} for intubation by 66%, from approximately 6 ng/mL to 2 ng/mL.[202,208] However, further increases in remifentanil dosage only modestly reduced propofol dose requirements, an apparent ceiling effect.[208] An early clinical study[209] evaluated various combinations of remifentanil and propofol concentrations (EC_{50}) to prevent responses to laryngoscopy and surgical stimuli in 50% of patients. Remifentanil EC_{50} for laryngoscopy was 14.3 ng/mL and 1.4 ng/mL with propofol infusions of 44 and 200 μg/kg/min, respectively. Response to intubation was prevented in 80% of patients by approximately doubling the remifentanil.

Barvais and Sutcliffe reviewed the use of remifentanil for cardiac anesthesia.[210] While high-dose remifentanil (1 to 2 μg/kg/min) has been used as a single agent, it is more commonly administered with propofol or isoflurane for "fast-track cardiac anesthesia." Target remifentanil and propofol concentrations for cardiac surgery[210,211] are very similar to those for other procedures with low-dose propofol. In a study comparing remifentanil, sufentanil, and fentanyl for fast-track cardiac anesthesia, Engoren[212] found that remifentanil patients were more likely to require treatment for blood pressure fluctuations during and after surgery, but otherwise, the three regimens produced similar outcomes with respect to extubation, ICU stay, and cost.

One drawback of remifentanil use for general anesthesia is that patients require analgesics very soon after an infusion is stopped. A continuation of remifentanil to transition to postoperative analgesia can avoid early pain and accompanying detrimental sympatho-adrenal stimulation and is essential for patients undergoing cardiac or other major surgery.

Remifentanil administered by infusion also appears to be useful during monitored anesthesia care (MAC) for conscious sedation in procedures such as extracorporeal shock wave lithotripsy and colonoscopy,[213,214] or in conjunction with regional anesthesia.[215,216,217] When compared to propofol, remifentanil provides better analgesia, but more nausea and respiratory depression, whereas propofol causes more oversedation. Times required for readiness for discharge are clinically similar. For MAC, the ideal administration regimen appears to be small bolus doses of remifentanil with a continuous infusion combined with low-dose propofol or midazolam.

Other Central Nervous System Effects

Remifentanil produces classic μ-opioid agonist effects on the EEG, that is, a concentration-dependent slowing. The plasma concentration associated with 50% maximal EEG changes (EC_{50}) is 15 to 20 ng/mL.[218,219] Remifentanil's rapid onset and very short duration results in extremely close tracking of changes in EEG spectral edge with plasma remifentanil concentration.[218,219] Like other opioids, remifentanil can produce muscle rigidity, especially with bolus doses. This can be avoided with using smaller doses and injecting over 60 seconds or more.

Several clinical reports have described cerebral hemodynamics in humans. When bolus doses of remifentanil (0.5 or 1.0 μg/kg) or alfentanil (10 or 20 μg/kg) were given during isoflurane/N_2O anesthesia with controlled ventilation, neither opioid affected intracranial pressure and both produced modest, dose-dependent decreases in mean arterial pressure.[220] In another study, patients received higher remifentanil doses, followed by continuous infusion, while isocapnea and mean arterial pressure were maintained. Cerebral blood flow velocity decreased significantly in patients receiving 5 μg/kg, followed by 3 μg/kg/min, but not in those with 2 μg/kg, followed by 1 μg/kg/min remifentanil. A multicenter clinical trial comparing remifentanil/N_2O to fentanyl/N_2O anesthesia found that intracranial pressure (remifentanil 13 ± 10; fentanyl 14 ±

13 mm Hg) and cerebral perfusion pressure (remifentanil 78 ± 14; fentanyl 76 ± 19 mm Hg) were similar with the two regimens.[221] In a study comparing cerebrovascular autoregulation in the awake and anesthetized states, remifentanil 0.5μg/kg/min plus propofol preserved cerebral autoregulation, whereas isoflurane 1.8% did not.[222]

In many cranial and spinal neurosurgical procedures, the ability to monitor motor evoked potentials (MEPs) is important; opioids, sedative hypnotic drugs, and inhalation agents used in general anesthesia are known to suppress MEPs. A human and animal study compared the effects of phenylpiperadine opioids and hypnotics including thiopental, midazolam, and propofol on MEPs.[223] While all opioids and propofol suppressed MEPs in a dose-dependent fashion, remifentanil exerted less suppression than the other opioids and propofol. A target plasma concentration of 9 ng/mL reduced amplitude by 50%, but the quality and reproducibility of MEPs was preserved even at plasma concentration of 15 ng/mL, well within the plasma concentration range that provides surgical anesthesia.

Although remifentanil has not been shown to produce seizure activity, it can be used to reduce methohexital requirement in patients having electroconvulsive therapy. Remifentanil 1 μg/kg allowed a 50% reduction in methohexital dose, which results in seizure prolongation by 50%.[224]

Respiratory Depression

Remifentanil produces dose-dependent respiratory depression as measured by increases in end-tidal CO_2 and decreased oxygen saturation. In a dose-escalation study in normal volunteers, the respiratory depressant effects of remifentanil and alfentanil were compared.[192] Peak respiratory depression occurred at 5 minutes after each dose of remifentanil and alfentanil, and the maximal respiratory depressant effect seen after 2 μg/kg remifentanil was similar to that caused by 32 μg/kg alfentanil. The duration of respiratory depression, measured as time to return of blood gases to within 10% of baseline values, was 10 minutes after 1.5 μg/kg and 20 minutes after 2 μg/kg remifentanil compared to 30 minutes after 32 μg/kg alfentanil. During continuous opioid infusion, the ventilatory response to CO_2 decreased by approximately 30, 45, and 60% in response to 4-hour remifentanil infusions of 0.025, 0.050, and 0.075 μg/kg/min, respectively.[225] Recovery from remifentanil-induced respiratory depression was rapid, and minute ventilation returned to baseline by 8 (range 5 to 15) minutes after the infusion was stopped for all infusion rates. In contrast, a 50% decrease in minute ventilation produced by a 4-hour infusion of alfentanil at 0.5 μg/kg/min required 61 (range 5 to 90) minutes to return to baseline.[225] In a volunteer study, Glass et al reported that the blood remifentanil concentration needed to depress ventilatory response to inspired 8% CO_2 by 50% (EC_{50}) was 1.17 ng/mL.[226] Bouillon et al[227] reported a similar EC_{50} (0.92 ng/mL) determined by an indirect response model and also noted that remifentanil concentrations well tolerated at steady state will produce clinically significant respiratory depression when achieved with bolus dosing. In general, clinical comparisons report that respiratory parameters (respiratory rate, O_2 saturation and end-tidal CO_2) recover more rapidly after remifentanil compared to other opioids given in equipotent dosage.

An animal model suggested that in combination with sevoflurane, remifentanil depressed ventilation more than responses to noxious stimulation. Therefore, maintenance of spontaneous respiration during general anesthesia with remifentanil and volatile agents or propofol may not be feasible unless low doses of remifentanil are used.[228] Clinical experience in spontaneously breathing humans receiving remifentanil combined with either isoflurane or propofol demonstrates respiratory depression in 10 to 35% of patients receiving remifentanil at 0.025 μg/kg/min. It increases to nearly 50% in patients receiving 0.05 μg/kg/min and to >90% in patients receiving remifentanil at 0.075 μg/kg/min.[229] A similar rate of respiratory depression (20%) with need for assisted ventilation is seen in pediatric patients receiving remifentanil/propofol infusions for general anesthesia during bone marrow aspiration.[230] As discussed earlier, remifentanil alone or combined with low-dose propofol or midazolam can be used for conscious sedation and to supplement regional or local anesthesia during monitored anesthesia care. Clinical reports describing these regimens report respiratory depression (respiratory rate <8 or SpO2 <90%) in 2 to 30% of patients; but in all cases, recovery from respiratory depression with remifentanil is more rapid than other agents.[213,214,215,216] As with other opioids, higher rates of respiratory

depression are seen when propofol is combined with remifentanil (15 to 50% of patients) and careful monitoring and titration are required to minimize this side effect.

Hemodynamic Effects

In healthy volunteers, remifentanil in bolus doses greater than 1.0 μg/kg produces brief increases in systolic blood pressure (5 to 20 torr) and heart rate (10 to 25 beats/min).[192] In patients anesthetized with isoflurane and 66% N_2O in oxygen, remifentanil (up to 5 μg/kg) produces dose-dependent decreases in systolic blood pressure and heart rate. These effects are attenuated by premedication with glycopyrrolate 0.3 to 0.4 mg and are readily reversed with ephedrine or phenylephrine.[231] Sebel et al[232] evaluated hemodynamic responses in patients receiving remifentanil 2 to 30 μg/kg (escalating doses) given during general anesthesia and found that systolic heart rate decreased more than 20% for doses greater than 2 μg/kg. These hemodynamic effects were not mediated by histamine release. Clinical reports of experience with patients receiving opioid-based anesthetics have characterized hemodynamic changes during balanced anesthesia with remifentanil combined with isoflurane ± N_2O/O_2 or propofol. During a comparison of remifentanil- versus alfentanil-based TIVA, a 20% drop in mean arterial pressure, with minimal change in heart rate, was noted after induction, with 35 to 50% of patients experiencing at least one episode of mean arterial pressure less than 70 mmHg.[188] Decreases in blood pressure were transient and easily treated with fluids and downward titration of propofol. In a comparison of remifentanil- and fentanyl-based general anesthetics in more than 2,400 patients (80% ASA I and II), hypotension (systolic BP <80 or treated pharmacologically) occurred in 12% of patients receiving remifentanil compared to 4% with fentanyl.[204] Bradycardia was less common, 2% and 1% of patients in the remifentanil and fentanyl groups, respectively.

Greater hemodynamic changes can be seen in patients with coronary disease. In a comparison of high-dose remifentanil (2μg/kg/min) and remifentanil 0.5μg/kg/min plus propofol targeted to 2 μg/mL plasma concentration, both techniques produced similar changes: 30% drop in mean arterial pressure, and 25% drop in cardiac index. Myocardial blood flow and oxygen consumption decreased by about 30 and 40%, respectively. More moderate hemodynamic changes were reported with lower doses (remifentanil target-controlled infusion [TCI] 4 to -8 ng/mL and propofol 1.2 ng/mL).[211] Heart rate and cardiac index dropped 20 and 6%, respectively, and no hypotension was seen. In an early clinical report, DeSouza reported a series of six cases[233] of severe bradycardia (HR <30 beats/min) and hypotension (systolic BP <80 mmHg) in six patients who received a rapid injection of remifentanil 1 μg/kg followed by a continuous infusion at 0.1 to 0.2 μg/kg/min on induction for cardiac surgery.

Hypotension was effectively treated by ephedrine and temporary discontinuation of remifentanil. These severe effects can often be avoided by slower administration (more than 60 seconds or longer) of the loading dose, as smaller bolus doses of remifentanil (0.3 to 0.5 μg/kg) are apparently not associated with severe bradycardia and hypotension.

Gastrointestinal Effects

Like other μ agonists, remifentanil can cause nausea and vomiting, but the occurrence of these adverse effects is influenced to a large extent by surgery, adjuvant anesthetic agents, and antiemetic prophylaxis. In a volunteer study, high infusion rates (1 to 8 μg/kg/min) produced nausea in 70% of subjects.[218] However, much lower doses are typically used for general anesthesia. Philip et al[187] compared nausea and vomiting at multiple time points in outpatient adults for laparoscopic surgery who received remifentanil or alfentanil combined with N_2O and propofol. In this study remifentanil was infused at 0.25 to 0.5 μg/kg/min and alfentanil was infused at 1 to 2 μg/kg/min after induction. Overall, the incidence of nausea was 44 and 53% for remifentanil and alfentanil, respectively; the incidence of vomiting was 21 and 29% for remifentanil and alfentanil, respectively. In outpatients with similar opioid infusions combined with 0.8% isoflurane, nausea occurred in 18 and 20% of patients with remifentanil and alfentanil, respectively.[234] In contrast, a report summarizing adverse events in over 2,400 patients who received remifentanil (range 0.25 to 2 μg/kg/min) or fentanyl with isoflurane or propofol for a

variety of surgeries, nausea and vomiting were rare.[204] Another comparison of low-dose remifentanil (0.5 μg/kg and 0.1 μg/kg/min) plus propofol to alfentanil plus propofol reported very low incidence of nausea and vomiting (6 to 12%, mostly at home).[235] A study in 100 otorhinolaryngeal surgery patients who received either remifentanil or alfentanil and propofol reported an intermediate incidence that was equivalent for both opioids.[42] Nausea occurred in 16 and 22% of patients with remifentanil and alfentanil, respectively, and vomiting in 14 and 12% of patients receiving remifentanil and alfentanil, respectively. In a pediatric study, the addition of remifentanil 0.2 μg/kg/min to desflurane anesthesia produced no increase in the incidence of postoperative nausea or vomiting after dental surgery; nausea and vomiting occurred in <5% of patients who received remifentanil. For strabismus surgery in children, vomiting occurred with equal frequency (26 to 31%) with remifentanil, alfentanil, isoflurane, and propofol.[236] Thus, remifentanil appears to produce dose-dependent nausea and vomiting similar to other short-acting μ-agonist opioids that can be attenuated by propofol. Taken together, remifentanil studies confirm the wide variability in occurrence of nausea and vomiting in the clinical setting.

Like other opioids, remifentanil delays gastric emptying[237] and biliary drainage.[238] As expected, biliary effects resolve more quickly than biliary drainage delay from morphine of meperidine.

Other Side Effects

Postoperative shivering occurred in about 40% of patients undergoing otorhinolaryngeal surgery despite active warming, and independent of temperature,[42] while another noted shivering in 10% of outpatients.[234] In both of these studies, shivering was less common with alfentanil. One pediatric investigation reported pruritus in 12% of patients.[236]

In volunteers, remifentanil produced concentration-related subjective and psychomotor side effects typical of μ-opioids.[193] Subjective side effects induced by remifentanil included dry mouth, itching, flushing, sweating, and "turning of the stomach." Remifentanil also impaired performance of psychomotor tests and caused miosis and respiratory depression. Some of these effects lasted an hour or more after remifentanil administration was stopped.

Disposition Kinetics

The key structural feature of remifentanil is an ester functional group that is susceptible to hydrolysis by blood and tissue nonspecific esterases and results in very rapid metabolism. Because butyrocholinesterase (pseudocholinesterase) does not appear to metabolize remifentanil, plasma cholinesterase deficiency and anticholinergic administration do not affect remifentanil clearance.[237] Unlike other opioids, remifentanil clearance is mainly because of enzymatic hydrolysis, with redistribution playing only a minor role. This property reduces its pharmacokinetic variability compared to other opioids. Remifentanil has a small volume of distribution, approximately 0.3 to 0.5 L/kg,[192,240] or about 25 liters in an average adult.[241] Remifentanil's clearance, 3 to 5 L/min, is approximately 3 to 4 times normal hepatic blood flow.[192,240,241] Both two- and three-compartment models have been used to describe the plasma concentration decay curve of remifentanil. A rapid distribution phase of 0.9 minutes and a very short terminal elimination half-life of 9.5 minutes characterized a two-compartment model in adults.[192] In pediatrics, elimination half-life is about 3.5 to 6 minutes.[242] In the three-compartment model, rapid and slow distribution half-times were 0.4 to 0.9 and 2 to 6 minutes, respectively, and the elimination half-time was about 10 to 30 minutes.[219,240]

As for other fentanyl congeners, gender does not affect remifentanil pharmacokinetics, but advanced age is associated with a decrease in clearance and volume of distribution, as well as an apparent increase in potency.[243] Remifentanil pharmacokinetics are similar in lean (within 20% ideal body weight) and obese (at least 80% over ideal body weight) patients, indicating that remifentanil dosing should be based on lean body mass.[244] Although pharmacokinetic parameters of remifentanil are unchanged in patients with severe liver disease[245] or renal failure,[246] patients with hepatic disease appear to be more sensitive to remifentanil-induced respiratory depression.

Dosage and Administration of Remifentanil

Because of its extremely short duration of action, remifentanil is best administered as a continuous infusion, although administration as repeated bolus doses has also been reported to be effective. Outside the United States, remifentanil is often administered by TCI, a pump system designed to infuse the drug based on population kinetics to achieve desired target plasma concentrations. Theoretically, this makes sense especially for remifentanil, because its pharmacodynamic effects track plasma concentrations very closely. However, two studies have found that simple manually controlled infusion is as effective[247,248] and is more economical than computer-controlled infusions.

Numerous reports have described dosing regimens for remifentanil alone or in combination with intravenous and inhaled agents for induction and maintenance of general anesthesia, and as a component of sedation and monitored anesthesia care.

Induction Dosage, Intubation, LMA Placement. As described earlier, remifentanil alone has not been found to be a satisfactory single agent for induction of anesthesia because of unreliability in loss of consciousness as well as significant muscle rigidity.[201] However, induction of anesthesia with high-dose remifentanil 4 to 5 μg/kg, or an infusion of 2 μg/kg/min has been reported.[210] It is important to note that bolus doses of >2 μg/kg can drop arterial pressure 20 to 30%, while hemodynamic changes in cardiac patients receiving high-dose infusion are similar to remifentanil plus propofol.[249] Combined with a potent inhalation agent, a loading dose of 1 μg/kg given over 60 seconds can provide

adequate intubating conditions with hemodynamic stability. By far the most commonly reported remifentanil-based regimen for anesthetic induction and laryngoscopy consists of remifentanil 0.5 to 1 μg/kg given over 60 seconds plus propofol 1 to 2 mg/kg, followed by remifentanil infusion of 0.25 to 0.5 μg/kg/min.[204,205,250,251] This may be given with or without a midazolam 1- to 2-mg iv premedication. Similar regimens are recommended for pediatric patients, with substitution of oral midazolam premedication 0.5 mg/kg. In the elderly, dose reduction is indicated, with remifentanil 0.05 μg/kg over 60 seconds plus propofol titrated to loss of consciousness in 10-mg increments, followed by remifentanil infusion of 0.1 μg/kg/min. If TCI is used for induction of anesthesia, an initial remifentanil target of 5 to 7 ng/mL accompanied by 0.5 to 1 MAC inhaled anesthetic or propofol TCI of 2 ng/mL is recommended.[203,241]

Maintenance of General Anesthesia. In combination with 70% N_2O in O_2, remifentanil 0.6 μg/kg/min is generally adequate, but at least one study reported a wide range of infusion rates (0.025 to 2 μg/kg/min).[252] A similar infusion rate for remifentanil with N_2O is recommended for pediatric patients. A lower infusion rate (0.2 to 0.25 μg/kg/min) is needed when remifentanil is combined with sevoflurane (1 to 2%),[206] desflurane (3 to 3.6%),[207,253] or isoflurane (0.2 to 0.8%).[204,205,234] For TIVA, maintenance infusion rates for remifentanil and propofol are 0.25 to 0.5 μg/kg/min and 75 to 100 μg/kg/min, respectively.[188,204,250,254,255] If N_2O is added, remifentanil infusion rates as low as 0.125 μg/kg/min and propofol infusion of 50 to 75 μg/kg/min can be used.[254] For elderly patients or those with cardiac disease, a reduction in propofol by about 25% is recommended. For pediatric patients, reported infusion rates are similar to adults, with remifentanil at 0.25 μg/kg/min and propofol about 100 μg/kg/min. For high-dose opioid anesthesia for cardiac surgery, the remifentanil infusion is maintained at 1 to 3 μg/kg/min and should be adjusted downward for hypothermia as discussed earlier.[210] Adding a low-dose propofol infusion of 50 μg/kg/min to this high-infusion rate effectively suppressed responses to skin incision, sternotomy, and aortic cannulation.[256]

If TCI is used, a target range for remifentanil is 4 to 10 ng/mL for balanced anesthesia and TIVA, and a starting rate of 25 to 30 ng/mL is recommended for high-dose opioid anesthesia.[210,241]

A disadvantage of remifentanil, related to its short duration of action, is that patients may experience substantial pain on emergence from anesthesia. Thus, if moderate to severe postoperative pain is anticipated, continuing the remifentanil infusion between 0.05 and 0.15 μg/kg/min ensures adequate analgesia in most patients.[194] The use of local and regional anesthetic techniques are also effective. When only mild postoperative pain is anticipated, intraoperative administration of a nonsteroidal anti-inflammatory drug 30 to 60 minutes before the

end of surgery may provide effective analgesia without additional opioids.

Monitored Anesthesia Care (MAC). Remifentanil can also be used for conscious sedation/analgesia and as an adjunct for sedation or analgesia during regional anesthesia, or for block placement, as part of MAC. When local or regional anesthesia is not used, and the procedure is expected to be painful, remifentanil and propofol can be beneficial. During colonoscopy, a continuous remifentanil infusion of 0.2 to 0.25 μg/kg/min, supplemented with small (10-mg) doses of propofol, provided good analgesia but mild respiratory depression was common.[214] In another clinical evaluation, patients having extracorporeal shock wave lithotripsy received low-dose propofol (50 μg/kg/min) as well as remifentanil. Patients who received low-dose (12.5 to 25 μg) intermittent bolus injection of remifentanil with or without infusion at 0.05 μg/kg/min reported better analgesia than continuous infusion of 0.1 μg/kg/min alone.[213] Remifentanil 1 μg/kg with or without a subsequent infusion of 0.2 μg/kg/min administered 90 seconds prior to placement of ophthalmologic block resulted in excellent analgesia,[257] but 14% of patients who received an infusion experienced respiratory depression.

When used as an adjunct to local or regional anesthesia, a much lower maintenance infusion rate, 0.05 to 0.1 μg/kg/min, provides adequate sedation and analgesia.[216,217] Finally, the dose requirement of remifentanil for sedation/analgesia is reduced approximately 50% when combined with midazolam or propofol. When 1 to 2 mg of midazolam premedication is given, 0.01 to 0.07 μg/kg/min remifentanil provides good sedation/analgesia for procedures performed under local or regional anesthesia.[215,216]

Dosage recommendations are summarized in Table 14-5.

PARTIAL AGONISTS AND MIXED AGONIST–ANTAGONISTS

The partial agonist and mixed agonist–antagonist opioids are synthetic or semisynthetic compounds that are structurally related to morphine. They are characterized by binding activity at multiple opioid receptors and their differential effects (agonist, partial agonist, or antagonist) at each receptor type. The clinical effect of a partial agonist at the μ-opioid receptor is complex (Fig. 14-11). Administered alone, a partial agonist has a flatter dose-response curve and a lower maximal effect than a full agonist (see Fig. 14-1 and the lowermost curve in Fig. 14-11). Combined with a low concentration (compare the curve indicated by [Ag] = 0.25 in Fig. 14-11) of a full agonist, the effects of the partial agonist are additive up to the maximum effect of the partial agonist. Combined with increasing concentrations ([Ag] = 0.67 to 256) of full agonist, the partial

agonist will act as an antagonist. These drugs mediate their clinical effects via μ- and κ-opioid receptors, as summarized in Table 14-4. The classification scheme presented may change as our understanding of these drugs and of opioid receptors continues to grow. Bowdle extensively reviewed the pharmacology and clinical uses of these and other drugs in this class.[258] Only nalbuphine, butorphanol, and buprenorphine are considered in this chapter.

TABLE 14-4 Actions of the Nalbuphine, Butorphanol, and Buprenorphine at Opioid Receptors

▪DRUG	▪μ RECEPTOR	▪κ RECEPTOR
Nalbuphine	Partial agonist	Partial agonist
Butorphanol	Partial agonist	Partial agonist

Buprenorphine	Partial agonist	?Antagonist
Although nalbuphine and butorphanol have been reported to be antagonists at the μ-opioid receptor, they do cause respiratory depression, which is not a function of κ agonists. Thus, they appear to have at least partial agonist activity at the μ-opioid receptor.		
Adapted from Bowdle TA: Partial agonist and agonist–antagonist opioids: Basic pharmacology and clinical applications. Anesth Pharmacol Rev 1:135, 1993.		

TABLE 14-5 Dosage for Fentanyl, Sufentanil, Alfentanil, and Remifentanil during Elective Surgery in Adults Doses are guidelines for hemodynamically stable adults. They should be adjusted downward for elderly patients and those with cardiac dysfunction and hemodynamic instability

▪ANESTHETIC PHASE	▪FENTANYL	▪SUFENTANIL	▪ALFENTANIL	▪REMIFENTANIL
Premedication (μg)	25–50	2–5	250–500	
Induction				
With hypnotic (μg/kg)	1.5–5	0.1–1	10–50	0.5–1.0 +/or 0.25–0.5 μg/kg/min
With 60–70% N_2O (μg/kg)	8–23	1.3–2.8

Infusion (µg/kg/min)				0.01–0.2

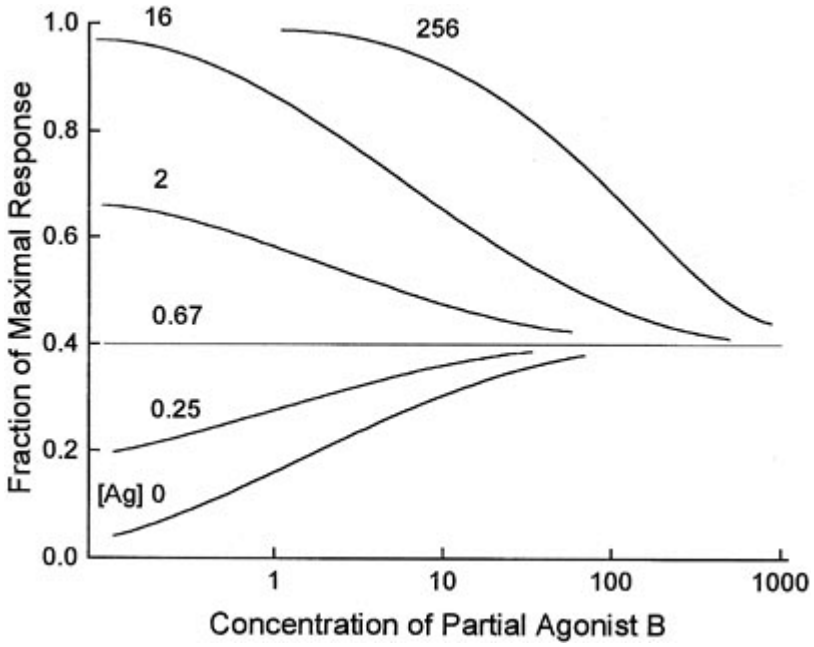

FIGURE 14-11. Hypothetical log dose-effect curves for the combination of a partial agonist, B (intrinsic efficacy of 0.4), with a range of concentrations of a full agonist, A. The observed effect of the combination of A and B is expressed as a fraction of the maximal effect of the full agonist. As the concentration of the partial agonist increases, the effect of the combination converges on the maximum effect of the partial agonist. When added to a low concentration (e.g., [A] = 0.25) of agonist, the partial agonist increases the response; but when added to a large concentration of the agonist, the response decreases—that is, B acts like an antagonist. (Modified with permission from Bowdle TA: Partial agonist and agonist–antagonist opioids: Basic pharmacology and clinical applications. Anaesth Pharmacol Rev 1:135, 1993.)

The major role of the opioid agonist–antagonist and partial agonist drugs continues to be in the provision of postoperative analgesia, but they have also been used for intraoperative sedation, as adjuncts during general anesthesia, and to antagonize some effects of full μ-opioid agonists.

Nalbuphine

Nalbuphine is a phenanthrene opioid derivative. Although it is often classified as a κ agonist and μ antagonist, it is more accurately described as a partial agonist at both κ and μ receptors.[258] While MAC reduction studies have not been done in humans, Murphy and Hug[20] reported that a 0.5 mg/kg dose reduced enflurane MAC by 8% in dogs. However, increasing the dose eightfold produced no further reduction in enflurane MAC. This modest MAC reduction, compared to 65% for morphine, suggests that nalbuphine may not be a useful adjunct for general anesthesia. However, several investigators have examined its effectiveness as a component of balanced anesthesia for cardiac[259] and lower abdominal surgery.[20,260] Combined with diazepam 0.4 mg/kg and 50% N_2O in oxygen, a loading dose of 3 mg/kg was followed by additional doses of 0.25 mg/kg as needed throughout surgery. No significant increases in blood pressure, stress hormones, or histamine were seen, and emergence from anesthesia was uncomplicated.[259] Nalbuphine 0.2 mg/kg was compared to meperidine 0.5 mg/kg as an adjuvant to general anesthesia with 1% halothane and 70% N_2O in oxygen in spontaneously breathing patients undergoing inguinal hernia repair.[261] Both drugs produced a similar degree of respiratory depression, postoperative analgesia, and side effects. The most common side effect was drowsiness. In a double-blind comparison with fentanyl for gynecologic surgery, fentanyl was found to better attenuate hypertensive responses to intubation and surgical stimulation.[260] However, significant respiratory depression was seen in 8 of 30 patients who received fentanyl, and 4 required naloxone, compared to no respiratory

depression in the nalbuphine group. Analgesia was similar, and as in other studies, postoperative sedation was common in the nalbuphine group.

The respiratory depression produced by nalbuphine, most likely mediated by μ-opioid receptors, has a ceiling effect equivalent to that produced by ~0.4 mg/kg morphine.[258] Analgesia is mediated by both κ and μ receptors. Because of these effects, nalbuphine has been used to antagonize the respiratory depressant effects of full agonists while still providing analgesic effects. In a double-blind comparison, nalbuphine and naloxone both effectively antagonized fentanyl-induced postoperative respiratory depression, but patients who received nalbuphine had less reversal of analgesia.[262] Nalbuphine has also been effective in antagonizing fentanyl-induced respiratory depression following high-dose (100 to 120 μg/kg) fentanyl anesthesia for cardiac surgery.[263] Only 3 of 21 patients experienced pain after nalbuphine administration, and this was adequately treated with additional nalbuphine. However, in a volunteer study, nalbuphine 0.21 mg/kg did not antagonize the respiratory depressant effects of 0.21 mg/kg morphine.[264] While nalbuphine and other agonist–antagonists have ceiling

analgesic and respiratory depressant effects, they can be as effective as full μ agonists in providing postoperative analgesia. Nalbuphine 5 to 10 mg has also been used to antagonize pruritus induced by epidural and intrathecal morphine. The usual adult dose of nalbuphine is 10 mg as often as every 3 hours. It is important to be aware that nalbuphine can precipitate withdrawal symptoms in patients who are physically dependent on opioids.

Butorphanol

Butorphanol, a morphinan congener, has partial agonist activity at κ and μ opioid receptors, similar to those of nalbuphine. Compared to nalbuphine and similar drugs, however, butorphanol has a pronounced sedative effect, which is probably mediated by κ receptors. In a laboratory study as well as in clinical use as a premedicant, butorphanol produced dose-dependent sedation comparable to that of midazolam.[265] Like nalbuphine, butorphanol decreases enflurane MAC, in dogs, by a modest amount, 11%, at 0.1 mg/kg.[25] Increasing the butorphanol dose 40-fold does not produce a further reduction. However, like nalbuphine, butorphanol has also been reported to be an effective component of balanced general anesthesia. Combined with diazepam and nitrous oxide, butorphanol and morphine provided equally satisfactory anesthesia.[258]

Given alone, butorphanol produces respiratory depression with a ceiling effect below that of full μ agonists. In postoperative patients a parenteral dose of 3 mg produces respiratory depression approximately equal to that of 10 mg morphine. In a clinical study examining its effectiveness in reversing fentanyl-induced respiratory depression,[266] patients anesthetized with isoflurane, nitrous oxide, and fentanyl 5 μg/kg followed by an infusion of 3 μg/kg/h received three sequential doses of butorphanol 1 mg at 10- to 15-minute intervals. After the first 1-mg dose, respiratory rate and ventilatory response to CO_2 increased, while end-tidal CO_2 decreased significantly. Further progressive changes were not significantly different from the initial response to butorphanol, and analgesia was not significantly affected in 21 of 22 patients.

In contrast to morphine, fentanyl, and even meperidine, butorphanol does not produce significant elevation in intrabiliary pressure[72] (see Fig. 14-6). Butorphanol has also been effective in the treatment of postoperative shivering,[77] but the mechanism for this effect is unknown.

Butorphanol is indicated for use as a sedative and in treatment of moderate postoperative pain. Preliminary clinical experience suggests that butorphanol administered as patient-controlled analgesia is associated with a lower incidence of opioid-induced ileus compared to μ-selective opioids (Dunbar PJ, personal communication). A dose as low as 0.5 mg can provide clinically useful sedation, while single analgesic doses range from 0.5 to 2 mg. Butorphanol has also been administered epidurally and transnasally.

Buprenorphine

Buprenorphine is a highly lipophilic thebaine derivative, which at small to moderate doses is 25 to 50 times more potent than morphine.[1] Unlike nalbuphine and butorphanol, buprenorphine does not

appear to have agonist, and may have antagonist, activity at the κ-opioid receptor (see Table 14-4).[258] Another unique characteristic of buprenorphine is its slow dissociation from μ receptors, which can lead to prolonged effects not easily antagonized by naloxone. Buprenorphine also appears to have an unusual bell-shaped dose-response curve such that, at very high doses, it produces progressively less analgesia.[258] In a clinical study, patients who received 10 or 20 μg/kg buprenorphine during surgery were pain-free postoperatively, but half of the patients who received 30 or 40 μg/kg had significant postoperative pain.[267] This observation is consistent with buprenorphine's bell-shaped dose-effect curve, and patients who received very high buprenorphine doses probably had plasma drug concentrations in the range at which declining analgesia is seen.

Buprenorphine also appears to have a ceiling effect to its respiratory depressant dose-response curve. However, although buprenorphine-induced respiratory depression can be prevented by prior naloxone administration, it is not easily reversed by naloxone once the effects have been produced.[1] A dose of 0.3 mg buprenorphine reduces CO_2 responsiveness to about 50% of control values.[268] Large doses of naloxone (5 to 10 mg) were required to antagonize buprenorphine respiratory depression in volunteers, while 1-mg doses were not effective. In addition, the maximum antagonist effect did not occur until 3 hours after naloxone administration, an observation consistent with buprenorphine's slow dissociation from μ receptors. Buprenorphine has been compared to naloxone in its ability to antagonize fentanyl-induced respiratory depression, and appears to increase respiratory rate without antagonizing analgesic effects in slowly administered doses up to 0.5 mg.[269]

Buprenorphine can be effective in treatment of moderate to severe pain. Its onset can be slow, but analgesic duration can be more than 6 hours. A single dose of 0.3 to 0.4 mg appears to produce analgesia equivalent to 10 mg morphine.[1]

Opioid Antagonists (Naloxone and Naltrexone)

Under normal conditions, opioid antagonists produce few effects. They are competitive inhibitors of the opioid agonists, so the effect profile depends on the type and dose of agonist administered as well as the degree to which physical dependence on the opioid agonist has developed. The most widely used opioid antagonist is naloxone, which is structurally related to morphine and oxymorphone, and is a pure antagonist at μ-, κ-, and δ-opioid receptors.[1] Naltrexone is a long-acting oral agent, which also has relatively pure antagonist activity. In some circumstances, naloxone can antagonize effects that appear to be mediated by endogenous opioids. For example, naloxone can reverse "stress analgesia" in animals and man, it can antagonize analgesia produced by low-frequency stimulation with acupuncture needles, and it can also reverse analgesia produced by placebo medications.[1]

In clinical anesthesia practice, naloxone is administered to antagonize opioid-induced respiratory depression and sedation. Because opioid antagonists will reverse all opioid effects, including analgesia, naloxone should be carefully titrated to avoid producing sudden, severe pain in postoperative patients. Sudden, complete antagonism of opioid effects with naloxone has been reported to cause severe hypertension, tachycardia, ventricular dysrhythmias, and acute, sometimes fatal, pulmonary edema.[270] Naloxone-induced pulmonary edema can occur even in healthy young patients who have received relatively small doses (80 to 500 μg) of naloxone.[271,272] The mechanism for this phenomenon is thought to be centrally mediated catecholamine release, which causes acute pulmonary hypertension. Because most patients with opioid-induced respiratory depression will often breathe on command, it is important to stimulate them in addition to administering carefully titrated naloxone doses in the immediate postoperative period. It is also essential to monitor vital signs and oxygenation closely after naloxone is administered to detect occurrence of any of these potentially serious complications.

Naloxone will precipitate opioid withdrawal symptoms in opioid-dependent individuals. Clinicians tend to be aware of

this risk when treating patients with known opioid addiction, but it is important to consider the potential for opioid withdrawal syndrome when treating nonaddicts who use opioids chronically,

such as cancer patients and severe burn and trauma patients with protracted recovery courses.

Naloxone has a very fast onset of action, and thus is easily titrated. Peak effects occur within 1 to 2 minutes, and duration is dose dependent, but total doses of 0.4 to 0.8 mg generally last 1 to 4 hours.[1] Suggested incremental doses for intravenous titration are 20 to 40 μg given every few minutes until the patient's ventilation improves, but analgesia is not completely reversed. Because naloxone has a short duration of action, respiratory depression may recur if large doses and/or long-acting opioid agonists have been administered. When prolonged ventilatory depression is anticipated, an initial loading dose followed by a naloxone infusion can be used. Infusion rates between 3 and 10 μg/h have been effective in antagonizing respiratory depression from systemic as well as epidural opioids.[273]

USE OF OPIOIDS IN CLINICAL ANESTHESIA

Opioids are used alone or in combination with other agents, such as sedatives or anticholinergic agents, as "premedications." For this purpose, longer acting opioids such as morphine are administered as single doses that are generally within the "analgesic" range. The goal of opioid premedication is to provide moderate sedation, anxiolysis, and analgesia while maintaining hemodynamic stability. Potential risks of opioid premedication include oversedation, respiratory depression, and nausea and vomiting. For induction of anesthesia, opioids are often used to blunt or prevent the hemodynamic responses to tracheal intubation. Opioids with rapid onset of action, such as fentanyl and its derivatives, are appropriate for this use.

Intraoperatively, opioids are administered as components of balanced anesthesia, or alone in high-dose opioid anesthesia. During maintenance of general anesthesia, opioid dosage is titrated to the desired effect based on the surgical stimulus as well as individual patient characteristics, such as age, volume status, neurologic status, liver dysfunction, or other systemic disease states. Plasma opioid concentrations required to blunt hemodynamic responses to laryngoscopy, tracheal intubation, and various surgical stimuli, as well as plasma opioid concentration associated with awakening from anesthesia, have been determined for several opioids. Titration to achieve these plasma concentrations (see Table 14-3), which reflect brain (effect site) concentrations, can be accomplished by administering repeated small bolus doses or by manual- or target-controlled infusion. Fentanyl and its derivatives sufentanil and alfentanil are the opioids most widely used as supplements to general anesthesia; remifentanil is a useful alternative when ultrashort duration is desirable. All of these opioids are more easily titrated than morphine because of their rapid onset of action. However, Shafer and Varvel[10] have emphasized that making a rational choice among these opioids requires an understanding of the relationships between their pharmacokinetics and pharmacodynamics. They have used elegant computer models to simulate the rate of decrease in plasma and effect site (brain) concentrations after various administration methods, including bolus doses, brief infusion, and prolonged infusion. Decreases in effect site concentration will determine time to recovery from various opioid effects. Comparable simulations have also been done for the newer opioid remifentanil.[218] Important pharmacokinetic differences among these opioids include volumes of distribution and intercompartmental (distributional) and central (elimination) clearances. A smaller distribution volume tends to shorten recovery time, and a reduction in clearance tends to increase recovery time.[10] The major pharmacodynamic differences among these opioids are potency and the equilibration times between the plasma and the site of drug effect. Equilibration half-times between plasma and effect site are 5 to 6 minutes for fentanyl and sufentanil and 1.3 to 1.5 minutes for alfentanil and remifentanil.[10,192] Computer simulations demonstrate that simply comparing elimination half-lives will not predict the relative rate of decline in drug concentration at the effect site after either bolus doses or continuous infusion of fentanyl, sufentanil, and alfentanil. The rate of recovery after a continuous infusion will depend on the duration of the infusion as well as the magnitude of decline that is required. Figure 14-12 demonstrates how the times required for 20, 50, and 80% decrements in effect site (i.e., brain)

concentrations vary with each opioid depending on infusion duration. If only a 20% drop in effect site concentration is required (upper panel), recovery from all three opioids will be rapid, although recovery time increases for fentanyl after 3 hours of drug infusion. However, if a 50% decrease is

required, recovery from sufentanil will be fastest for infusions less than 6 to 8 hours in duration, but more rapid for alfentanil if infusions are continued for more than 8 hours.

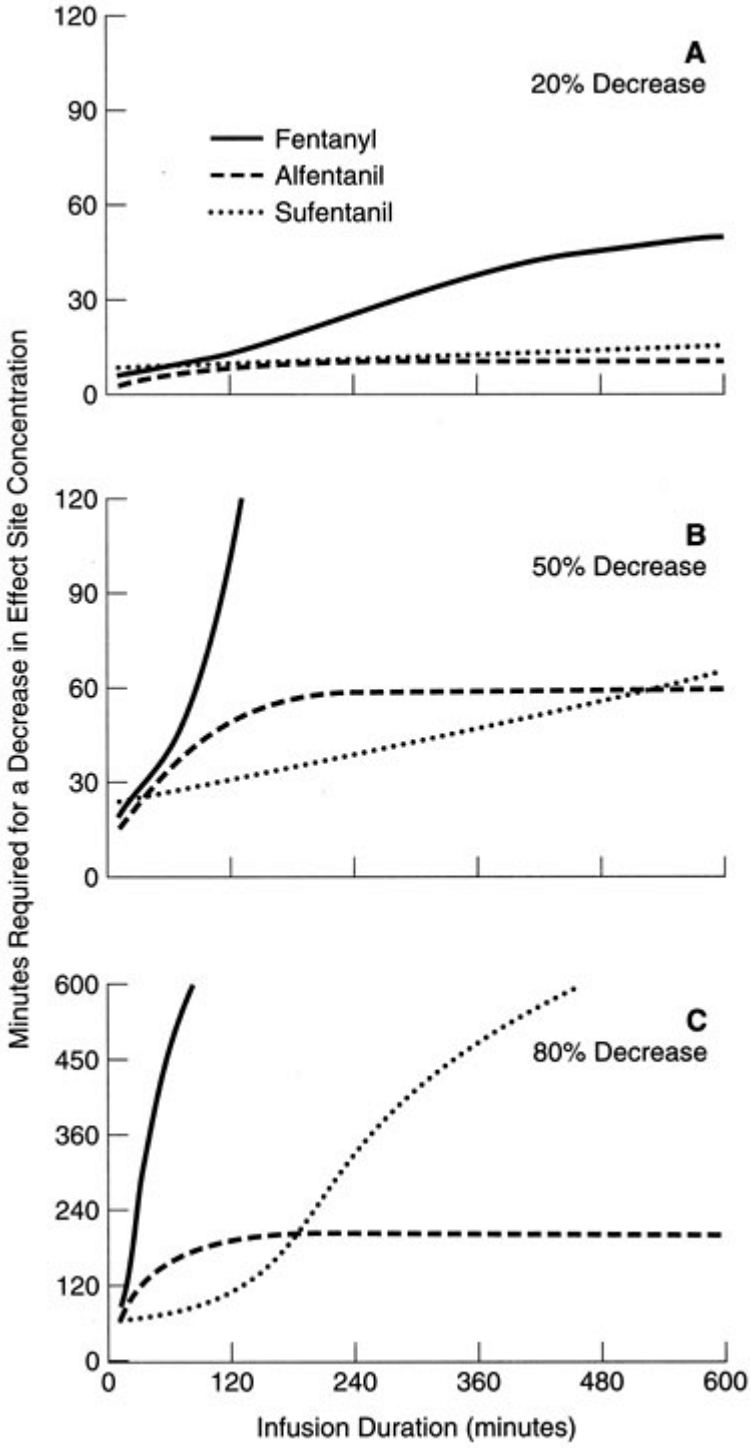

FIGURE 14-12. Recovery curves for fentanyl, sufentanil, and alfentanil showing the time required for decreases of 20% **(A)**, 50% **(B)**, and 80% **(C)** from maintained intraoperative effect site (brain) concentrations after termination of the infusion. (Reprinted with permission from Shafer SL, Varvel JR: Pharmacokinetics, pharmacodynamics, and rational opioid selection. Anesthesiology 74:53, 1991.)

Context-Sensitive Half-Time

Hughes et al[11] expanded the concepts of Shafer and Varvel to define the relative contributions of distribution compartments to central compartment (plasma) drug distribution. These relative

contributions vary according to infusion duration. Hughes devised the concept of "context-sensitive half-time," which is defined as the time required for the drug concentration in the central compartment to decrease by 50%, and demonstrated how this half-time changes as drug infusion duration increases. During an infusion, the peripheral (fast and slow) compartments begin to "fill up." After the infusion is stopped, drug will be eliminated, but will also continue to be redistributed as long as the concentration in a peripheral compartment is lower than that in the central compartment. This leads to a rapid drop in central compartment drug concentration. When central compartment (plasma) concentration drops below that of the peripheral compartment(s), the direction of drug redistribution will reverse and will slow the decline in plasma concentration. The degree to which redistribution will affect the rate of drug elimination depends on the ratio of the distributional to elimination time constants. Thus, a drug that can rapidly redistribute will have a correspondingly larger contribution from the peripheral compartment(s), and plasma concentration will drop progressively more slowly as infusion duration continues. Figure 14-13 illustrates the context-sensitive half-times for fentanyl, alfentanil, sufentanil, and remifentanil. This model predicts the time to a 50% concentration decrease in the plasma, which will reflect, but not be equal to, effect site concentrations depicted in Figure 14-12.

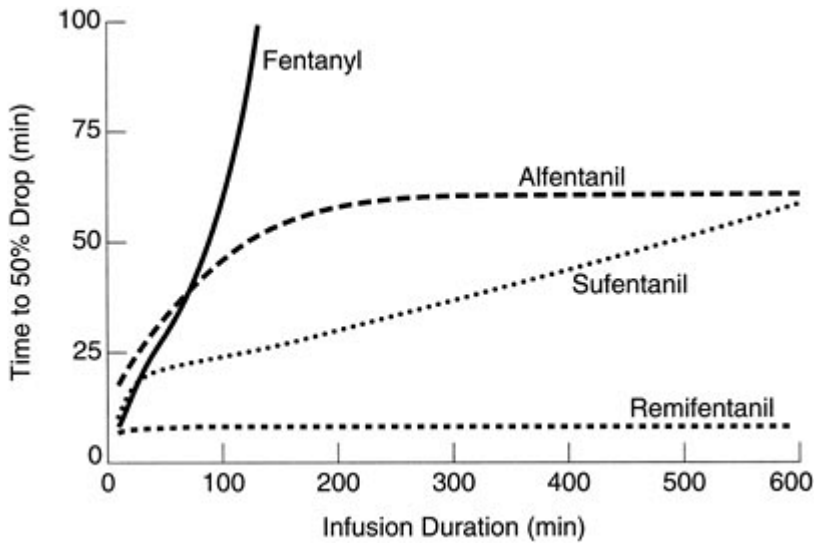

FIGURE 14-13. Context-sensitive half-times for fentanyl, sufentanil, alfentanil, and remifentanil. This computer simulation depicts the time necessary to achieve a 50% reduction in plasma opioid concentration as a function of infusion duration. (Reprinted with permission from Egan TD, Lemmens HJM, Fiset P *et al:* The pharmacokinetics of the new short-acting opioid remifentanil (GI87084B) in healthy adult male volunteers. Anesthesiology 79:881, 1993.)

Some testing of these computer models in humans has been done. Kapila et al[274] compared modeled context-sensitive half-times with measured decreases in drug concentration and drug effect (respiratory depression) in volunteers receiving remifentanil and alfentanil. After 3-hour opioid infusions, measured whole blood opioid concentrations and recovery of ventilatory drive corresponded closely to modeled values for both drugs. Although the concept of a context-sensitive half-time appears to be useful, Hughes et al[11] noted that it is unknown whether a decrement of 50% provides the most clinically useful description of the rate of offset of opioid effects. If one closely titrates infusions so that minimum effective concentrations are achieved, perhaps much smaller decrements will be necessary. For example, it can be seen in the upper panel of Figure 14-12 that if only a 20% decline in effect site concentration is needed, fentanyl, sufentanil, and alfentanil concentrations all drop rapidly if the infusion duration is 2 hours or less. This rapid resolution is seen for sufentanil and alfentanil even with prolonged (5- to 10-hour) administration if only a 20% decrement is required. In practice, it is relatively easy to administer higher than necessary doses of opioids, particularly to mechanically ventilated patients, because

hemodynamic consequences are minimal. Titrating against a quantifiable parameter, such as minute ventilation in a spontaneously breathing patient, may allow a tighter dose titration, but this may not be practical for many surgeries, for example, those requiring the use of muscle relaxants. It does seem clear, however, that some context-sensitive index is more useful than the elimination half-life. Understanding these concepts can be useful when deciding which opioid to use, as well as in adapting guidelines for opioid dosage and infusion rates depending on the duration of anesthesia.

Chapter 15

Inhalation Anesthesia

Thomas J. Ebert

KEY POINTS

1. Volatile anesthetics are relatively inexpensive, easily administered via inhalation, readily titrated, and have a high safety ratio in terms of preventing recall. Depth of anesthesia can be quickly adjusted in a predictable way while monitoring tissue levels via end-tidal concentrations. In addition they cause relaxation of skeletal muscle.

2. The inhaled anesthetics are among the most rapidly acting drugs in existence, and their pharmacokinetics are described in four phases: absorption, distribution, metabolism, and excretion. Anesthetic uptake is assessed with the ratio of the fractional concentration of alveolar anesthetic to inspired anesthetic (F_A/F_I), followed over time. The most important factor in the rate of rise of F_A/F_I is F_A because of the avid uptake of anesthetic from the alveoli into the bloodstream. The inhaled anesthetics with the lowest solubilities in blood show the fastest rise in F_A/F_I, and are eliminated most rapidly.

3. The pharmacodynamic effects of inhaled anesthetics is related to dose, described as the *minimum alveolar concentration* or *MAC*. MAC is the alveolar concentration of an anesthetic at one atmosphere that prevents movement in response to a surgical stimulus in 50% of patients.

4. All of the potent, volatile anesthetics depress cerebral metabolic rate and increase cerebral blood flow, varying as a function of dose. Increases in intracerebral pressure with sevoflurane, isoflurane, and possibly desflurane are minimal and far less than with halothane.

5. Sevoflurane has been associated with a lower heart rate compared to desflurane and does not increase sympathetic nervous system activity as does desflurane. Cardiac output is well preserved with sevoflurane, desflurane, and isoflurane, and all three have been associated with cellular protection from ischemia-induced myocardial injury.

6. In dehydrated carbon dioxide absorbents, degradation of desflurane, enflurane, isoflurane, and sevoflurane results in carbon monoxide formation. In rare instances, sevoflurane destruction has led to high heat and fires.

7 Halothane is 20% metabolized and an immune response to the metabolite trifluoroacetyl (TFA) has resulted in hepatitis. Based on % metabolized, halothane>enflurane>

P.385

isoflurane>desflurane in antigenic potential. Sevoflurane is not metabolized to a TFA halide; rather it is metabolized to hexafluoroisopropanol that does not serve as a neoantigen. Immunologic memory resulting in hepatitis has been reported years after an initial halothane exposure. In addition, cross-sensitivity has been reported in which exposure to one anesthetic can sensitize patients to a second but different anesthetic.

INTRODUCTION

1 Inhalation anesthetics are the most common drugs used for the provision of general anesthesia. Adding as little as 1% of a volatile anesthetic to the inspired oxygen results in a state of unconsciousness and amnesia, which are essential components of general anesthesia. When combined with intravenous adjuvants, such as opioids or benzodiazepines, a balanced technique is achieved that results in further sedation/hypnosis and analgesia. The popularity of the inhaled anesthetics for establishing general anesthesia is based on their ease of administration (i.e., via inhalation) and the ability to reliably monitor their effects with both clinical signs and end-tidal concentrations. In addition, the volatile anesthetic gases are relatively inexpensive in terms of the overall cost of the anesthesia care of the patient.

The most popular potent inhaled anesthetics used in adult surgical procedures are sevoflurane, desflurane, and isoflurane (Fig. 15-1). In pediatric cases, halothane and sevoflurane are most commonly employed. Although there are many similarities in terms of the overall effects of the volatile anesthetics (e.g., they all have a dose-dependent effect to decrease blood pressure), there are some unique differences that affect the clinician's selection for use. These differences are weighted against the patient's health and with the particular effects of the planned surgical procedure. Discussion of the four most popular inhaled anesthetics provides the major emphasis of this chapter. For the sake of completeness and for historical purposes related to metabolism and renal toxicity, comments on both enflurane and methoxyflurane also are included.

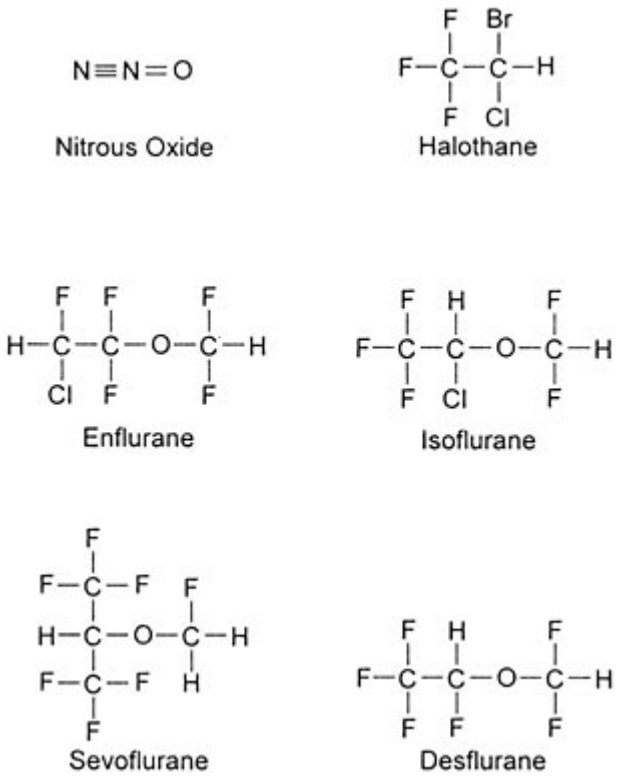

FIGURE 15-1. Chemical structure of inhaled anesthetics. Halothane is an alkane, a halogen-substituted ethane derivative. Isoflurane and enflurane are isomers that are methyl ethyl ethers. Desflurane differs from isoflurane in the substitution of a fluorine for a chlorine atom and sevoflurane is a methyl isopropyl ether.

HISTORY

The volatile anesthetics in early clinical use consisted of flammable gases, including diethyl ether, cyclopropane, and divinyl ether. Several nonflammable compounds were available, including chloroform and trichloroethylene, but these were associated with hepatic toxicity and neurotoxicity, and were only briefly in clinical use. In the early 1930s, studies on derivatives of the halogenated compound, chloroform, indicated that noncombustible anesthetic gases might be derived using organic fluoride compounds. Advances in fluorine chemistry in the 1940s allowed safe incorporation of fluorine into molecules at a reasonable expense. These advances proved to be pivotal to the development of modern-day anesthetics. Fluorine is the halogen with the lowest atomic weight (18.998; chlorine = 35.45; bromine = 79.90; iodine = 126.9). Fluorine substitutions for other halogens on the ether molecule lowered the boiling point, increased stability, and generally decreased toxicity. The fluoride ion also dampened the flammable hydrocarbon of the ether anesthetic framework.

In 1951, halothane was synthesized and extensively tested in animals by Suckling, working at ICI Laboratory in England. Halothane was introduced into clinical practice in 1956 and was rapidly embraced, owing in part to its nonflammability and in part to its lower tissue solubility. Halothane also had a relatively low pungency and a high potency; thus, it could be administered in high-inspired concentrations (relative to its potency) to induce anesthesia via inhalation. Halothane was associated with a lower incidence of nausea and vomiting.

Despite these desirable properties of halothane, some concerns and drawbacks remained. Most notable were the effects of halothane on sensitizing the myocardium to catecholamines and the later described role of its intermediate metabolite in hepatic necrosis. Thus, the search for better agents continued. Between the years of 1959 and 1966, Terrell and colleagues at Ohio Medical Products (subsequently called Anaquest, Ohmeda, and most currently, Baxter) synthesized more

than 700 compounds. The 347th and 469th compounds in the series were methyl ethyl ethers, enflurane and isoflurane, which were halogenated with fluorine and chlorine. Clinical trials of enflurane and isoflurane proceeded nearly in parallel, involving both human volunteer and patient studies. Years later, several compounds in Terrell's series were reexamined. One of these (the 653rd) was problematic because the compound had a vapor pressure close to 1 atmosphere, making it impossible to deliver with a standard wicked vaporizer. However, this particular compound was completely halogenated with fluorine and hence was predicted to have a very low solubility in blood. As synthesis and delivery problems were resolved, this compound, now known as desflurane, was introduced into clinical practice in 1993.

TABLE 15-1 Physiochemical Properties of Volatile Anesthetics

	·SEVO	·DES	·ISO	·ENFLUR	·HALO	·N_2O
Boiling point (°C)	59	24	49	57	50	-88
Vapor pressure at 20°C (mm Hg)	157	669	238	172	243	38,770
Molecular weight (g)	200	168	184	184	197	44
Oil:gas partition coefficient	47	19	91	97	224	1.4
Blood:gas partition coefficient	0.65	0.42	1.46	1.9	2.50	0.46
Brain:blood solubility	1.7	1.3	1.6	1.4	1.9	1.1
Fat:blood solubility	47.5	27.2	44.9	36	51.1	2.3
Muscle:blood solubility	3.1	2.0	2.9	1.7	3.4	1.2
MAC in O_2 30–60 yr, at 37°C P_B760 (%)	1.8	6.6	1.17	1.63	0.75	104
MAC in 60–70% N_2O (%)	0.66	2.38	0.56	0.57	0.29	
MAC, >65 yr (%)	1.45	5.17	1.0	1.55	0.64	-
Preservative	No	No	No	No	Thymol	No
Stable in moist CO_2 absorber	No	Yes	Yes	Yes	No	Yes

Flammability (%) (in 70% N_2O/30% O_2)	10	17	7	5.8	4.8	
Recovered as metabolites (%)	2–5	0.02	0.2	2.4	20	

Wallin and colleagues at Travenol Laboratories described other new compounds in the early 1970s, during the course of evaluating fluorinated isopropyl ethers. One of these proved to be a potent anesthetic agent and became known as sevoflurane. Like desflurane, it had a low solubility owing to fluorination of the ether molecule. It was noted that sevoflurane released organic and inorganic fluorides in both animals and humans; thus, the drug was not aggressively developed and marketed. When the patent rights were transferred to Ohio Medical Products, further testing revealed significant

breakdown of sevoflurane in the presence of soda lime, raising safety concerns that limited further evaluation. Maruishi Pharmaceutical in Japan undertook testing and development of sevoflurane, releasing the drug for general use in Japan in July 1990. Because of the rapid acceptance and safety record of sevoflurane in Japan, Abbott Laboratories began pursuing laboratory and clinical trials with sevoflurane in the United States. After its safety was established, sevoflurane was introduced in U.S. clinical practice in 1995.

The new inhaled anesthetics sevoflurane and desflurane differ from isoflurane most importantly in their kinetic behavior. They both have significantly lower solubility in blood, which increases their speed for washin and washout and their speed in adjustment of anesthetic depth (Table 15-1). These characteristics mesh well with the ambulatory anesthesia environment of modern day practice.

PHARMACOKINETIC PRINCIPLES

Pharmacokinetics as a discipline began with the study of noninhaled drugs before the concepts were applied to the inhaled anesthetics. Kety in 1950 was the first to examine the pharmacokinetics of inhaled agents in a systematic fashion.[1] Eger and colleagues accomplished much of the early research in the field leading to his landmark text on the subject in 1974.[2] The inhaled anesthetics differ substantially from nearly all other drugs because they are gases given via inhalation. This makes their pharmacokinetics unique as well, and most major textbooks of anesthesia continue to devote considerable space to pharmacokinetic principles of currently used agents.

Drug pharmacology is classically divided into two disciplines, pharmacodynamics and pharmacokinetics. *Pharmacodynamics* can be defined as what drugs do to the body. It describes the desired and undesired effects of drugs, as well as the cellular and molecular changes leading to these effects. *Pharmacokinetics* can be defined as what the body does to drugs. It describes where drugs go, how they are transformed, and the cellular and molecular mechanisms underlying these processes.

Systemic drug pharmacokinetics have four phases: absorption, distribution, metabolism, and excretion. *Absorption* is the phase in which drug is transferred from the administration site (e.g., digestive tract, lung, muscle) into the bloodstream. Intravenous drugs have no absorption phase

because they are delivered directly into the bloodstream. *Distribution* is the phase in which drug is transferred to tissue sites throughout the body. *Metabolism* refers to the physiochemical processes by which substances in a living organism are synthesized (anabolism) or altered (catabolism); but in the context of anesthetic drugs only drug alteration is pertinent. Finally, *excretion* is the phase in which changed or unchanged drug is transferred from tissues or blood into some vehicle (e.g., bile, exhaled air, urine) for removal from the body.

Tissues are often grouped into hypothetical *compartments* based on perfusion. An important implication of different compartments and perfusion rates is the concept of *redistribution*. After a given amount of drug is administered, it reaches highly perfused tissue compartments first where it can equilibrate rapidly and exert its effects. With time, however, compartments with lower perfusion rates receive the drug and additional equilibria are established between blood and these tissues. As the tissues with lower perfusion absorb drug, maintenance of equilibria throughout the body requires drug transfer from highly perfused compartments back into the bloodstream. This lowering of drug concentration in one compartment by delivery into another compartment is called redistribution.

In discussions of the inhaled anesthetics, the terminology just described is subject to some minor differences. The absorption phase is usually called *uptake*, the metabolic phase is usually called *biotransformation*, and the excretion phase is usually called *elimination*. The terms are completely interchangeable.

Unique Features of Inhaled Anesthetics

Speed, Gas State, and Route of Administration

2 The inhaled anesthetics are among the most rapidly acting drugs in existence, and when administering a general anesthetic, this speed provides a margin of safety. The ability to quickly increase or decrease anesthetic levels as necessary can mean the difference between an anesthetic state and an anesthetic misadventure. Speed also means efficiency. Rapid induction and recovery may lead to faster operating room turnover

times, shorter recovery room stays, and earlier discharges to home.

Technically, nitrous oxide is the only true gas, while the potent anesthetics are the vapors of volatile liquids. But for simplicity, all of them are called gases because they are all in the gas phase when administered via the lungs. As gases, none deviate significantly from ideal gas behavior. These agents are all nonionized and have low molecular weights. This allows them to diffuse rapidly without the need for facilitated diffusion or active transport from bloodstream to tissues. The other advantage of gases is that they can be delivered to the bloodstream via a unique route available in all patients: the lungs.

The lung route of administration is unique to the inhaled anesthetics, except for bronchodilators or endotracheal administration of cardiac resuscitation drugs. These exceptions are, however, a "one-way street" because their route of delivery is different from their elimination route. Inhaled anesthetics have a "two-way street" in the lungs; they are delivered and primarily eliminated via this route.

Speed, gaseous state, and the lung route of administration combine to form the major beneficial feature of the inhaled anesthetics—the ability to decrease plasma concentrations as easily and as rapidly as they are increased.

Physical Characteristics of Inhaled Anesthetics

The goal of delivering inhaled anesthetics is to produce the anesthetic state by establishing a specific concentration of anesthetic molecules in the central nervous system (CNS). This is done by establishing the specific partial pressure of the agent in the lungs, which ultimately equilibrates with the brain and spinal cord. Equilibration is a result of three factors:

1. Inhaled anesthetics are gases rapidly transferred bidirectionally via the lungs to and from the bloodstream and subsequently to and from CNS tissues as partial pressures equilibrate.
2. Plasma and tissues have a low capacity to absorb the inhaled anesthetics relative to the amount we can deliver to the lungs, allowing us to quickly establish or abolish anesthetizing concentrations of anesthetic in the bloodstream and ultimately the CNS.
3. Metabolism, excretion, and redistribution of the inhaled anesthetics are minimal relative to the rate at which they are delivered or removed from the lungs. This permits easy maintenance of blood and CNS concentrations.

At equilibrium, CNS partial pressure equals blood partial pressure, which in turn equals alveolar partial pressure:

$$P_{CNS} = P_{blood} = P_{alveoli} \qquad (15\text{-}1)$$

where *P* is partial pressure. The physical characteristics of inhaled anesthetics are shown in Table 15-1.

Inhaled anesthetics are delivered to the lung as gases and follow the ideal gas law, $PV = nRT$, where *P* is pressure, *V* is volume, *n* is number of moles of gas, *R* is the gas constant, and *T* is absolute temperature. If a gas is heated in a fixed volume, pressure will increase. If a gas is heated or if molecules of gas are added while keeping its pressure constant, its volume must increase. If the number of molecules of gas is increased into a fixed volume, pressure will increase.

The so-called *permanent gases*, such as oxygen and nitrogen, exist only as gases at ambient temperatures. Gases such as nitrous oxide can be compressed into liquids under high pressure at ambient temperature. Most *potent volatile anesthetics* are liquids at ambient temperature and pressure. Some molecules with sufficient energy escape the liquid and enter a gas phase above the surface of the liquid as a vapor. Pure gases always diffuse from an area of high pressure to an area of low pressure, because of their *chemical potential, μ*. Chemical potential, also called the escaping tendency, is a thermodynamic concept. It is similar to an electrical potential. In this case, however, it is gases that continue to seek equilibration until μ is equal throughout the system. Chemical potential depends on the substance and characteristics of the system in which it exists, such as temperature, pressure, and presence of other substances.

If the system in which the volatile liquid resides is a closed container, molecules of the substance will equilibrate between the liquid and gas phases (to equalize μ). At equilibrium the pressure exerted by molecular collisions of the gas against the container walls is the *vapor pressure*. One important property of vapor pressure is that as long as *any* liquid remains in the container, the vapor pressure is independent of the volume of that liquid. As with any gas, however, vapor pressure is proportional to temperature.

For all of the potent agents at 20°C the vapor pressure is below atmospheric pressure. If the temperature is raised the vapor pressure increases. The *boiling point* of a liquid is the temperature at which its vapor pressure exceeds atmospheric pressure in an open container. Desflurane is bottled in a special container because its boiling point of 23.5°C makes it boil at typical room temperatures. Boiling does not occur within the bottle because it is countered by buildup of vapor pressure within the bottle; but once opened to air, the desflurane would quickly boil away. The bottle is designed to allow transfer of desflurane from bottle to vaporizer without exposure to the atmosphere.

Gases in Mixtures

For any mixture of gases in a closed container, each gas exerts a pressure proportional to its *fractional mass* (or fractional *volume* according to $PV = nRT$, since "volume" is a more familiar term when dealing with gases). This is its *partial pressure*. The sum of the partial pressures of each gas in a mixture of gases equals the total pressure of the entire mixture (Dalton's law).

$$P_{total} = P_{gas1} + P_{gas2} + \cdots + P_{gasN} \qquad (15\text{-}2)$$

The entire mixture behaves just as if it were a single gas according to the ideal gas law.

Gases in Solution

Partial pressures of gases in solution are more complicated. Any gas/vapor dissolved in a liquid exerts a force to drive molecules out of solution and into the gas phase. Molecules in the gas phase counter this by exerting a force that drives them into the liquid phase. Only at a given concentration of molecules in the gas phase will the forces (hence chemical potentials) be equal and the system in equilibrium. This force is called the *tension*, and the concentration of molecules in the gas phase at equilibrium will determine the pressure of that phase according to the ideal gas law. Tension is conveniently described by the partial pressure of the gas in equilibrium with the liquid phase. The terms "tension" and "partial pressure" are used synonymously in this chapter.

The *concentration* of gas molecules in solution is more complicated still, owing to intermolecular interaction. Gas molecules within a liquid interact with solvent molecules to a much larger extent than do molecules in the gas phase. The gas molecules will be present in the liquid only to the extent that this equalizes the chemical potential between the liquid and gas phases. The chemical potential of the gas in a liquid

depends dramatically on the liquid itself and the energy-state of that liquid. "Solubility" is the term used to describe the tendency of a gas to equilibrate with a solution, hence determining its concentration in solution. The solubility coefficient, λ is an expression of this tendency:

$$\lambda = V_{\text{dissolved gas}}/V_{\text{liquid}} \text{ at } 37^{\circ}C \qquad (15\text{-}3)$$

where V = volume.

The principles of partial pressures and solubility apply in mixtures of gases in solution. That is, the concentration of any one gas in a mixture of gases in solution depends on two factors: (1) its partial pressure in the gas phase in equilibrium with the solution, and (2) its solubility within that solution. Thus, the partial pressure of a particular gas is proportional to its fractional volume in the gas phase, not the liquid phase.

The implications of these properties are that anesthetic gases administered via the lungs diffuse into blood until the partial pressures in alveoli and blood are equal. The concentration of anesthetic in the blood depends on the partial pressure at equilibrium and the blood solubility. Likewise, transfer of anesthetic from blood to target tissues also proceeds toward equalizing partial pressures. The concentration of anesthetic in target tissue depends on the partial pressure at equilibrium and the target tissue solubility. Because inhaled anesthetics are gases, and because partial pressures of gases equilibrate throughout a system, monitoring the alveolar concentration of inhaled anesthetics provides an index of their effects in the brain.

In summary:

1. Inhaled anesthetics equilibrate based on their partial pressures in each tissue (or tissue compartment), *not* based on their concentrations.
2. The partial pressure of a gas in solution is always defined by the partial pressure in the gas phase with which it is in equilibrium.
3. The concentration of anesthetic in a tissue depends on its partial pressure and tissue solubility.

Finally, the particular terminology used when referring to gases in the gas phase or absorbed in plasma or tissues is important. Inspired concentrations or fractional volumes of inhaled anesthetic are typically used rather than partial pressure. For most drugs, concentration is expressed as mass (mg) per volume (mL), but it can also be expressed in percent by weight or volume. Since

volume of a gas in the gas phase is directly proportional to mass according to the ideal gas law, it is easier to express this fractional concentration as a percent by volume. Tension and partial pressure, on the other hand, are expressed in mmHg, or torr (1 torr = 1 mmHg), or kPa (kilopascals). In the gas phase, fractional concentration is equal to the partial pressure (or tension) divided by ambient pressure, usually atmospheric, or:

$$\text{Fractional volume} = P_{\text{anesthetic}}/P_{\text{barometric}} \qquad (15\text{-}4)$$

Anesthetic Transfer: Machine to Central Nervous System

Anesthetics follow a multistep route from anesthesia machine to patient (and back). Each of these steps represents a transfer point or interface between hypothetical compartments. The compartments are organized by location or pharmacokinetic properties in an effort to simplify the concept of anesthetic flow. For example, one-way flow occurs from the fresh gas outlet to the anesthesia circuit and to the waste gas scavenging system. Equilibrium flow occurs between the anesthesia circuit and the airways (and alveoli) and between the alveoli and pulmonary blood. Bulk flow of blood accounts for anesthetic transfer to systemic blood and equilibrium flow occurs between systemic blood and tissues. The flow of anesthetic from compartment to compartment can be characterized by pharmacokinetics. Technically, the flow from fresh gas outlet (FGO) to circuit is not a pharmacokinetic concern because it does not characterize what the body does to the drug. But it is typically discussed as a pharmacokinetic parameter because it has important clinical implications.

TABLE 15-2

	▪% BODY MASS	▪% CARDIAC OUTPUT	▪PERFUSION mL/min/100 g
Vessel rich	10	75	75
Muscle	50	19	3
Fat	20	6	3

When the fresh gas flow and the vaporizer are turned on, fresh gas with a fixed fractional concentration of anesthetic leaves the FGO and mixes with the gas in the circuit—the bag, tubing, absorbent canister, and piping. It is immediately diluted to a lower fractional concentration, then slowly rises as this compartment equilibrates with the fresh gas flow. With spontaneous patient ventilation by mask, the anesthetic gas passes from circuit to airways. The fractional concentration of anesthetic leaving the circuit is designated as F_I (fraction inspired). In the lungs the gas comprising the dead space in the airways (trachea, bronchi) and the alveoli further dilutes the circuit gas. The fractional concentration of anesthetic present in the alveoli is F_A (fraction alveolar). The anesthetic then passes across the alveolar–capillary membrane and dissolves in pulmonary blood according to the partial pressure of the gas and its solubility. It is further diluted and travels via bulk blood flow throughout the vascular tree. The anesthetic then passes via simple diffusion from blood to tissues as well as between tissues.

The vascular system delivers blood to three physiologic tissue groups; the vessel-rich group (VRG), the muscle group, and the fat group. The VRG includes the brain, heart, kidney, liver, digestive tract, and glandular tissues. The percent body mass and perfusion of each are shown in Table 15-2. The CNS tissues of the VRG are referred to as *tissues of desired effect*. The other

tissues of the VRG comprise the compartment frequently referred to as *tissues of undesired effects*. The tissues of the muscle and fat groups comprise the *tissues of accumulation*.

Anesthetic is delivered most rapidly to the VRG because of high blood flow. Here it diffuses according to partial pressure gradients. CNS tissue takes in the anesthetic according to the tissue solubility, and at a high enough tissue concentration unconsciousness is achieved. Increasing CNS tissue concentrations causes progressively deeper stages of anesthesia. As this is occurring, anesthetic is also distributing to other VRG tissues. Also coincident with delivery to the CNS, anesthetic is being delivered—albeit more slowly because of lower perfusion—to muscle and fat where it accumulates and may affect the speed of emergence from the anesthetic. In reality, the fat solubilities provide little influence on emergence in cases lasting <4 hours since the delivery of anesthetic to fat tissue is extremely slow as a result of low blood flow. The concentration of inhaled anesthetic in a given tissue at a particular time during the

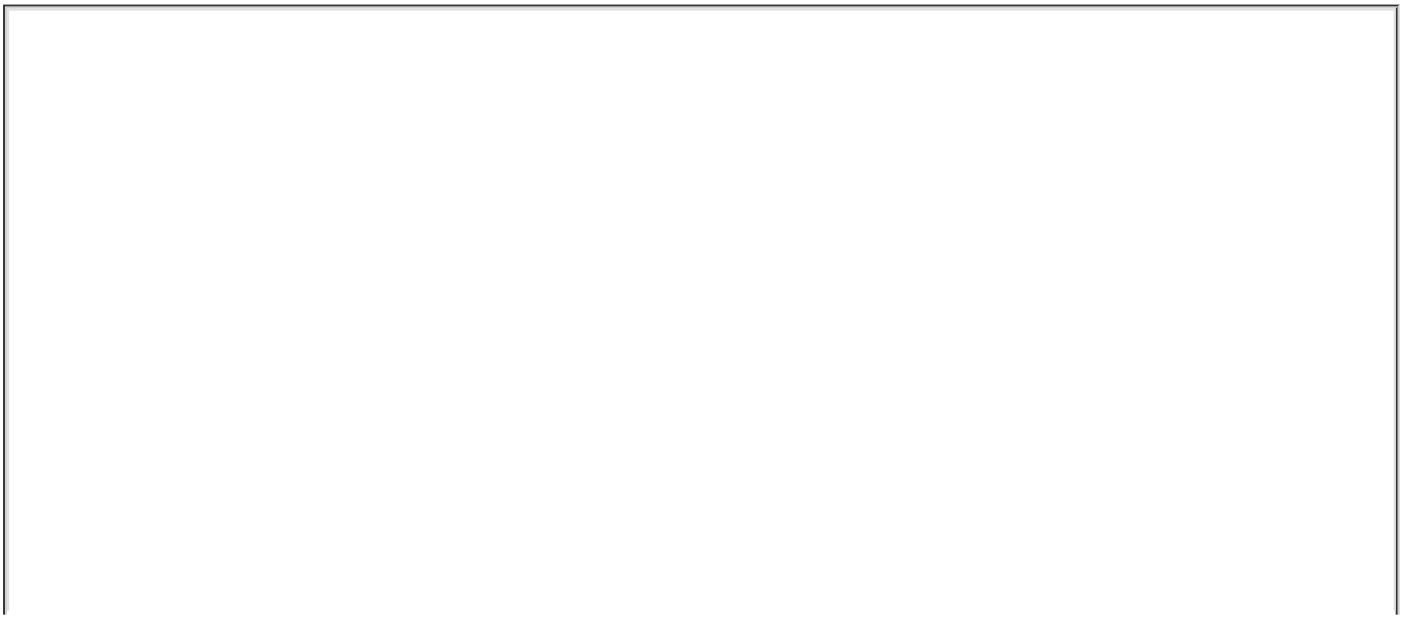
administration depends not only on tissue blood flow, but also on tissue solubility, which governs how the inhaled anesthetics partition themselves between blood and tissue. Partitioning depends on the relative solubilities of the anesthetic for each compartment. These relative solubilities are expressed by a partition coefficient, δ, which is the ratio of dissolved gas (by volume) in two-tissue compartments at equilibrium. Alternatively it is the ratio of tissue:gas solubilities in the two compartments. For a pure gas in the gas phase, λ equals 1, that is, $V_{\text{"dissolved" gas}}/V_{\text{gas}} = 1$. Thus blood:gas partition coefficient is the same as blood solubility:

$$\delta_{b/g} = \lambda_{blood}/\lambda_{gas} = \lambda_{blood}/1 = \lambda_{blood} \qquad (15\text{-}5)$$

where $\delta_{b/g}$ is the blood:gas partition coefficient.

For other partition coefficients such as brain:blood ($\delta_{br/bl}$), the volume of anesthetic dissolved in brain is divided by the volume of anesthetic dissolved in blood:

$$\delta_{br/bl} = \lambda_{brain}/\lambda_{blood} \qquad (15\text{-}6)$$



Some of the partition coefficients for the inhaled anesthetics are shown in Table 15-1.

As explained earlier, one of the reasons why inhaled anesthetics are rapidly titratable is that their tissue solubilities are low relative to delivery rate; thus delivery of a desired partial pressure to the CNS is possible despite redistribution and accumulation of anesthetic in other tissues.

Uptake and Distribution

F_A/F_I

A simple, common way to assess anesthetic uptake is to follow the ratio of fractional concentration of alveolar anesthetic to inspired anesthetic (F_A/F_I) over time. Experimentally derived data for F_A/F_I versus time during induction are shown in Figure 15-2.

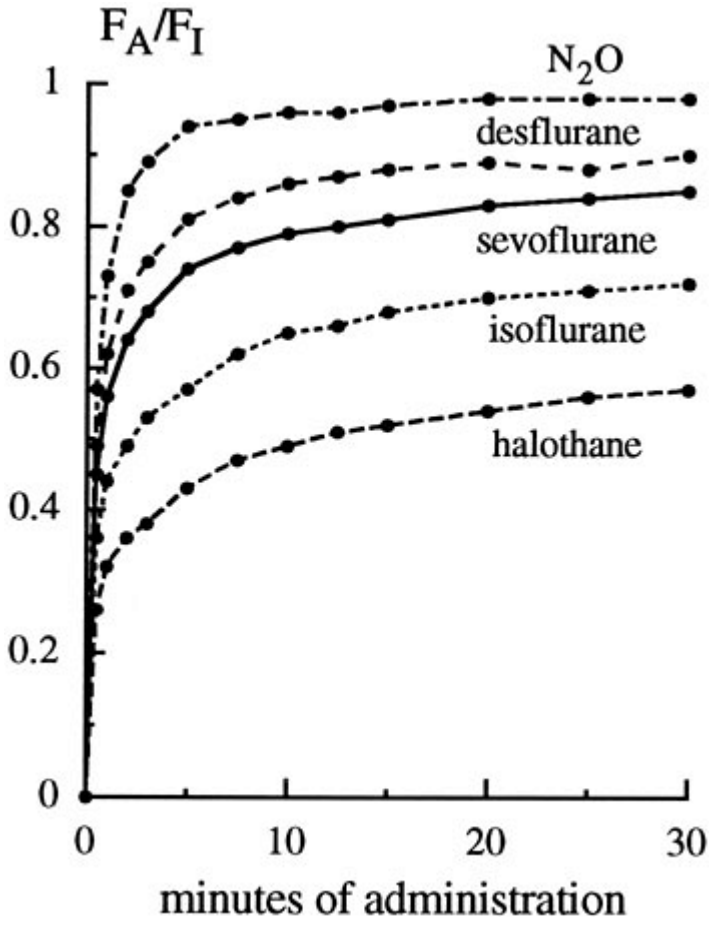


FIGURE 15-2. The rise in alveolar (F_A) anesthetic concentration toward the inspired (F_I) concentration is most rapid with the least soluble anesthetics, nitrous oxide, desflurane, and sevoflurane. It rises most slowly with the more soluble anesthetics, for example, halothane. All data are from human studies. (Adapted from Yasuda N, Lockhart SH, Eger EI II *et al*: Comparison of kinetics of sevoflurane and isoflurane in humans. Anesth Analg 72:316, 1991; and Yasuda N, Lockhart SH, Eger EI II *et al*: Kinetics of desflurane, isoflurane, and halothane in humans. Anesthesiology 74:489, 1991.)

The inhaled anesthetics with the lowest solubilities in blood show the fastest rise in F_A/F_I. The shape of these curves has several regions with different origins. As fresh gas carrying anesthetic begins to flow into the air-filled circuit (assuming complete mixing), the concentration in the circuit (F_I) will rise according to first-order kinetics:

$$F_I = F_{FGO}(1 - e^{-T/\tau}) \qquad (15\text{-}7)$$

F_{FGO} is the fraction of inspired anesthetic in the gas leaving the fresh gas outlet (i.e., the vaporizer setting), T is time, and τ is a time constant. Because all anesthetics in the circuit are in the gas phase, F (fractional volume or concentration) is also P (partial pressure) divided by P_B (barometric pressure), and inspired anesthetic can be expressed as either F_I or P_I. The time constant is simply the volume or "capacity" of the circuit (V_C) divided by the fresh gas flow (FGF) or $\tau = V_C/FGF$. For example, if the bag, tubing, absorbent canister, and piping comprise 8 L, and the fresh gas flow is 2 L, the time constant $\tau = 8/2 = 4$. One of the characteristics of first-order kinetics is that 95% of maximum is reached after 3 time constants—in this case, $3 \times 4 = 12$ minutes.

Because 12 minutes is relatively long, starting with a higher F_{FGO} can increase the rate of rise of F_I. Using the earlier example with $\tau = 4$, by first-order kinetics 63% of maximum is reached after one time constant, or 4 minutes. To attain an F_I of 2% at 4 instead of 12 minutes, the F_{FGO} can be set to 3.2% (2% divided by 0.63) and then lowered to 2% at the 4-minute mark.

Other ways to speed the increase in F_I include increasing the fresh gas flow, thus decreasing τ. Furthermore, the rebreathing bag can be collapsed prior to starting the fresh gas flow, such that the capacity in the circuit (V_C) is less, which also decreases τ. Finally, at high flows (>4 L/min) there is far less mixing because fresh gas pushes "old" gas out of the circuit via the pop-off valve before complete mixing occurs, causing F_I to increase at a greater rate.

One factor that delays the rate of rise of F_I arises from the fact that CO_2 absorbent can adsorb and decompose the inhaled anesthetics. From a practical standpoint, this does not affect the rate of rise in F_I to a significant extent compared to other factors. Another factor that delays the rate of rise of F_I is solubility of the inhaled anesthetics in some of the plastic and rubber parts of the anesthesia circuit. This absorption has been quantified, but plays only a small role in decreasing the rate of rise of F_I.

Rise in F_A in the Absence of Uptake

The rate of rise in F_I discussed earlier assumes that no anesthetic is mixing with gas in the patient's lungs. In reality, circuit gas mixes with exhaled gases from the lung with each breath. If extremely high fresh gas flows (producing a high volume of gas at the desired concentration) are used, little mixing with exhaled air occurs and F_I is relatively fixed. In this situation, circuit gas enters the lungs where it mixes with alveolar gas. If there were no blood flow to the lungs, F_A would rise in a fashion analogous to F_I; that is:

$$F_A = F_I(1 - e^{-T/\tau}) \qquad (15\text{-}8)$$

TABLE 15-3 Factors That Increase or Decrease the Rate of Rise of F_A/F_I

▪INCREASE	▪DECREASE	
Low λ_B	High λ_B	The lower the blood:gas solubility, the faster the rise in F_A/F_I
Low Q	High Q	The lower the cardiac output, the faster the rise in F_A/F_I
High $\dot{V}_A$	Low $\dot{V}_A$	The higher the minute ventilation, the faster the rise in F_A/F_I
High (P_A - P_v)	Low (P_A - P_v)	At the beginning of induction, P_v is zero but rises rapidly (thus [P_A-P_v] falls rapidly) and F_A/F_I increases rapidly. Later, during induction and maintenance, P_v rises more slowly so F_A/F_I rises more slowly.
Parameters as described in Equation 15–16: λ_B, blood solubility; Q, cardiac output; $\dot{V}$, minute ventilation; P_A, P_v, pulmonary arterial and venous blood partial pressure.		

In this equation, τ is the time constant for alveolar rise in anesthetic concentration and equals the functional residual capacity (FRC) of the patient's lungs divided by minute ventilation, $\dot{V}_A$. There are two ways to speed the equilibration of F_A with F_I, that is, to decrease τ. One way is to increase minute ventilation, and the other is to decrease FRC. Both of these methods can be used to speed induction by mask: the patient can exhale deeply before applying the mask (to decrease the initial FRC), and the patient can breathe deeply and rapidly (to increase

$\dot{V}_A$) after the mask is applied. One of the reasons that pediatric inductions by spontaneous breathing of inhaled anesthetics are so much quicker than adult inductions is that the low FRC relative to

$\dot{V}_A$ of children makes for a low time constant, and hence a rapid increase in F_A/F_I. One important caveat about the relationship of F_A to FRC is that FRC includes airway dead space; thus, in reality, F_A by Equation 15-8 is not just the concentration of inhaled anesthetic in the alveoli but also the concentration in the entire lung. However, it is simply called the alveolar concentration because the dead space in the airways is relatively insignificant and only the alveolar gas is exchanging anesthetic with the blood.

Rise in F_A in the Presence of Uptake

Because in reality there *is* pulmonary blood flow, the most important factor in the rate of rise of F_A/F_I is uptake of anesthetic from the alveoli into the bloodstream. The rate of rise of F_A/F_I (the slope of the curves seen in Fig. 15-2) reflects the speed at which alveolar anesthetic (F_A) equilibrates with that being delivered to the lungs (F_I). F_A is not solely a function of F_I and time. Inhaled anesthetics so avidly transfer into and are diluted by the bloodstream that uptake into blood is a primary determinant of F_A; that is, the greater the uptake, the slower the rate of rise of F_A/F_I. Uptake is proportional to tissue solubility. The less soluble the anesthetic (such as desflurane), the lesser its uptake and the faster it reaches equilibrium.

Consider a hypothetical example. Suppose that halothane and desflurane are soluble in blood, but insoluble in all other tissues. Suppose further that total lung capacity and blood volume were both 5 liters. If a fixed volume of anesthetic is delivered to the lungs (by asking the patient to take one deep breath and hold it), according to partition coefficients, 70.6% of the delivered halothane will be transferred to the blood while 29.4% remains in the alveoli (70.6/29.4 = 2.4). In contrast 29.6% of the desflurane will be transferred to the blood while 70.4% remains in the alveoli (29.6/70.4 = 0.42). Therefore, 2.4 times (70.6/29.6) more halothane than desflurane (by volume or number of molecules) will be transferred from alveoli to bloodstream before partial pressures equilibrate. At equilibrium, the partial pressures of halothane and desflurane are 29.4% and 70.4% of their inhaled values, respectively.

But anesthetics *are* soluble in tissues, and they are delivered *continuously* rather than in a "one-shot" fashion; thus they are again characterized by first-order kinetics:

$$P_{bl}(\text{blood}) = P_A(\text{alveoli}) \times (1 - e^{-T/\tau}),$$
$$\text{where } P_A = F_A \times P_B\,(\text{barometric}) \qquad (15\text{-}9)$$

where $P_A = F_A \times P_B$ (barometric)

Here, P_B is the barometric pressure, and the time constant, τ, equals "capacity" (volume of anesthetic dissolved in blood at the desired alveolar partial pressure) divided by flow (volume of anesthetic delivered per unit time). For any given flow of anesthetic into the system, this capacity for the more soluble halothane is greater than the capacity for the less soluble desflurane; thus, τ for halothane is greater than that for desflurane. The more soluble an inhaled anesthetic, the larger the capacity of the blood and tissues for that anesthetic, and the longer it takes to saturate at any given delivery rate.

Anesthetic flow can be described by a series of first-order rate equations: F_I as a function of F_{FGO}, F_A as a function of F_I, blood uptake as a function of F_A, and so on. These differential equations can then be solved to determine any value as a function of time. Relatively straightforward equations help describe which parameters determine the rate of rise of F_A/F_I.

During any given period of time, the alveolar anesthetic fraction, F_A, as a proportion of the inspired anesthetic fraction, F_I, will equal the ratio of

$\dot{V}_{expired}$ to

$\dot{V}$

$_{inspired}$; that is:

$$F_A/F_I = \dot{V}_{expired}/\dot{V}_{inspired} \qquad (15\text{-}10)$$

If F_A/F_I is zero and starts to increase as inhaled anesthetic reaches the alveoli from the circuit but uptake of anesthetic in the pulmonary blood nearly equals its delivery to the alveoli, then F_A/F_I will not rise. All of the anesthetic arriving at the alveoli is transferred immediately to the blood. Since blood capacity to absorb anesthetic is finite, F_A will eventually begin to rise relative to F_I. If, on the other hand, blood uptake is very small, F_A and F_I quickly become nearly equal.

Blood uptake of anesthetic is expressed by the equation:

$$\dot{V}_B = \delta_{b/g}{}^{*} Q \times ((P_A - P_v)/P_B) \qquad (15\text{-}11)$$

Where

$\dot{V}_B$ is blood uptake, $\delta_{b/g}$ is the blood:gas partition coefficient, Q is cardiac output, P_A is alveolar partial pressure of anesthetic, P_v is mixed venous partial pressure of anesthetic, and P_B is barometric pressure. This is the Fick equation applied to blood uptake of inhaled anesthetics. The parameters that increase or decrease the rate of rise in F_A/F_I during induction can be clearly defined and these important factors have been substantiated in experimental models (Table 15-3).

Before induction, P_v is zero because no anesthetic is present in the bloodstream. P_A is established with the first inspiration of anesthetic, and the alveolar to pulmonary blood partial pressure gradient, P_A-P_v, determines the rate of increase in F_A/F_I. Initially, P_A climbs at a much greater rate than P_v because circulation and dilution as well as tissue uptake together keep P_v low. As significant tissue concentrations of anesthetic start to accumulate, P_v rapidly climbs as the pulmonary blood, originally carrying no anesthetic, becomes saturated with anesthetic. This early rapid rise in F_A/F_I followed by slowing is seen in Figure 15-2.

Distribution (Tissue Uptake)

Until P_v starts to increase, the maximum F_A/F_I at a given inspired concentration of anesthetic, cardiac output, and minute ventilation are entirely dependent on the solubility of that drug in the blood as characterized by the blood:gas partition coefficient $\delta_{b/g}$. This can be seen in the time curves for the rise in F_A/F_I during induction for the various inhalation anesthetics shown in Figure 15-2. The first "knee" in each curve in Figure 15-2 represents the point at which the rapid rise in P_v begins to taper off, that is, when significant inhaled anesthetic concentrations begin to build up in the bloodstream because of distribution to and equilibration with the various tissue compartments.

Each of the three perfusion compartments—VRG, muscle, and fat—takes up anesthetic based on the Fick equation:

$$\dot{V}_{Compart.} = \lambda_{Compart.} \times Q_{Compart.} \times ((P_{aCompart.} - P_{vCompart.})/P_B) \qquad (15\text{-}12)$$

where $P_{aCompart.}$ and $P_{vCompart.}$ are arterial and venous partial pressures in the tissue compartment. Mixed venous partial pressure of anesthetic in the pulmonary outflow, P_v, depends on the relative uptake in each of these perfusion compartments. To the extent that the mass and blood flow to each of these compartments differs, anesthetic uptake will differ.

As blood is equilibrating with alveolar gas, it also begins to equilibrate with the VRG, muscle, and, more gradually, the fat compartments based on perfusion. Muscle is not that different from the VRG, having partition coefficients that range from 1.2 (nitrous oxide) to 3.4 (halothane), just under a 3-fold difference; and for each anesthetic except nitrous oxide, the muscle partition coefficient is approximately double that for the VRG. Although both VRG and muscle are lean tissues, the muscle compartment equilibrates far more slowly than the VRG. The explanation comes from Equation 15-12 and the mass of the compartments relative to perfusion. The perfusion of the VRG is about 75 mL/min/100 g of tissue, whereas it is only 3 mL/min/100 g of tissue in the muscle (see Table 15-2). This 25-fold difference in perfusion between VRG (especially brain) and

muscle means that even if the partition coefficients were equal, the muscle would still take 25 times longer to equilibrate with blood.

Fat is perfused to a lesser extent than muscle and its time for equilibration with blood is considerably slower because the partition coefficients are so much greater. All of the potent agents are highly lipid soluble. Partition coefficients range from 27 (desflurane) to 51 (halothane). On average, the solubility for these agents is about 25 times greater in fat than in the VRG group. Thus, fat equilibrates far more slowly with the blood and does not play a significant role in determining speed of induction. After long anesthetic exposures (>4 hours), the high saturation of fat tissue may play a role in delaying emergence.

Nitrous oxide represents an exception. Its partition coefficients are fairly similar in each tissue, it does not accumulate to any great extent and is not a very potent anesthetic. Its utility lies as an adjunct to the potent agents, and as a vehicle to speed induction.

Metabolism

Data suggest that enzymes responsible for biotransformation of inhaled anesthetics become saturated at less than anesthetizing doses of these drugs, such that metabolism plays little role in opposing induction. It may, however, have some significance to recovery from anesthesia as discussed later.

Overpressurization and the Concentration Effect

There are several ways to speed uptake and induction of anesthesia with the inhaled anesthetics. The first is *overpressurization*, which is analogous to an intravenous (IV) bolus. This is the administration of a higher partial pressure of anesthetic (F_I) than the alveolar concentration (F_A) actually desired for the patient.

Inspired anesthetic concentration (F_I) can influence both F_A and the *rate of rise* of F_A/F_I. The greater the inspired concentration of an inhaled anesthetic, the greater the rate of rise. This concentration effect has two components. The first is a concentrating effect, and the second is an augmented gas inflow effect.

For example, consider the administration of 10% anesthetic (10 parts anesthetic and 90 parts other gas) to a patient in which 50% of the anesthetic in the alveoli is absorbed by the blood. In this case 5 parts (0.5 × 10) anesthetic remain in the alveoli, 5 parts enter the blood, and 90 parts remain as other alveolar gas. The alveolar concentration is now 5/(90 + 5) = 5.3%. Consider next administering 50% anesthetic with the same 50% uptake. Now 25 parts anesthetic remain in alveoli, 25 parts pass into blood, and 50 parts remain as other alveolar gas. The alveolar concentration becomes 25/(50 + 25) = 33%. Giving five times as much anesthetic has led to a 33%/5.3% = 6.2 times greater alveolar concentration. The higher the F_I, the greater the effect. Thus nitrous oxide, typically given in concentrations of 50 to 70%, has the greatest concentrating effect. This is why the F_A/F_I versus time curve in Figure 15-2 rises the most quickly with nitrous oxide, even though desflurane has a slightly lower blood:gas solubility. The concentrating effect becomes most prominent with the most soluble anesthetic. Therefore, halothane and isoflurane *should* benefit most at any particular concentration of anesthetic, F_I. But because equipotent concentrations for halothane and isoflurane are lower than those of the less soluble anesthetics, sevoflurane and desflurane, these agents benefit from the concentration effect less than expected—that is, *concentration outweighs solubility*. The typical inspired concentrations of N_2O are so much greater than the potent anesthetics that its low tissue solubility is of no consequence.

This isn't the complete picture; there is yet another factor to consider. As gas is leaving the alveoli for the blood, new gas at the original F_I is entering to replace that which is lost. This other aspect of the concentration effect has been called *augmented gas inflow*. Again, take the example of 10% anesthetic delivered with 50% uptake into the bloodstream. The 5 parts anesthetic absorbed by the bloodstream are replaced by gas in the circuit that is still 10% anesthetic. The 5 parts anesthetic and 90 parts other gas left in the lungs mix with 5 parts replacement gas, or 5 × 0.10 = 0.5 parts anesthetic. Now the alveolar concentration is (5 + 0.5)/(100%) = 5.5% (as

anesthetic and 50% uptake, 25 parts of anesthetic removed from the alveoli are replaced with 25 parts of 50% anesthetic, giving a new alveolar concentration of (25 + 12.5)/(100%) = 37.5% (as compared to 50% without augmented inflow). Thus five times the F_I leads to 37.5/5.5 = 6.8 times greater F_A (compared to 6.2 times without augmented gas inflow). Of course, this cycle of absorbed gas being replaced by fresh gas inflow is continuous and has a finite rate so our example is a simplification.

Second Gas Effect

A special case of concentration effect applies to administration of a potent anesthetic with nitrous oxide—that is, two gases simultaneously. Along with the concentration of potent agent in the alveoli via its uptake, there is further concentration via the uptake of nitrous oxide, a process called the *second gas effect*. The second gas is the potent agent. The principle is simple (Figs. 15-3 and 15-4). Consider, for example, administering 2% of a potent anesthetic in 70% nitrous oxide and 28% oxygen. In this case, nitrous oxide, with its extremely high vapor pressure (despite low solubility), partitions into the blood more rapidly than the potent anesthetic, decreasing the alveolar N_2O concentration by some amount (e.g., by 50%). Ignoring uptake of the potent anesthetic, the uptake of N_2O is 35 parts, leaving 35 parts N_2O, 28 parts O_2, and 2 parts potent agent in the alveoli. The second gas is now present in the alveoli at a concentration of 2/(2 + 35 + 28) = 3.1%. The second gas has been concentrated.

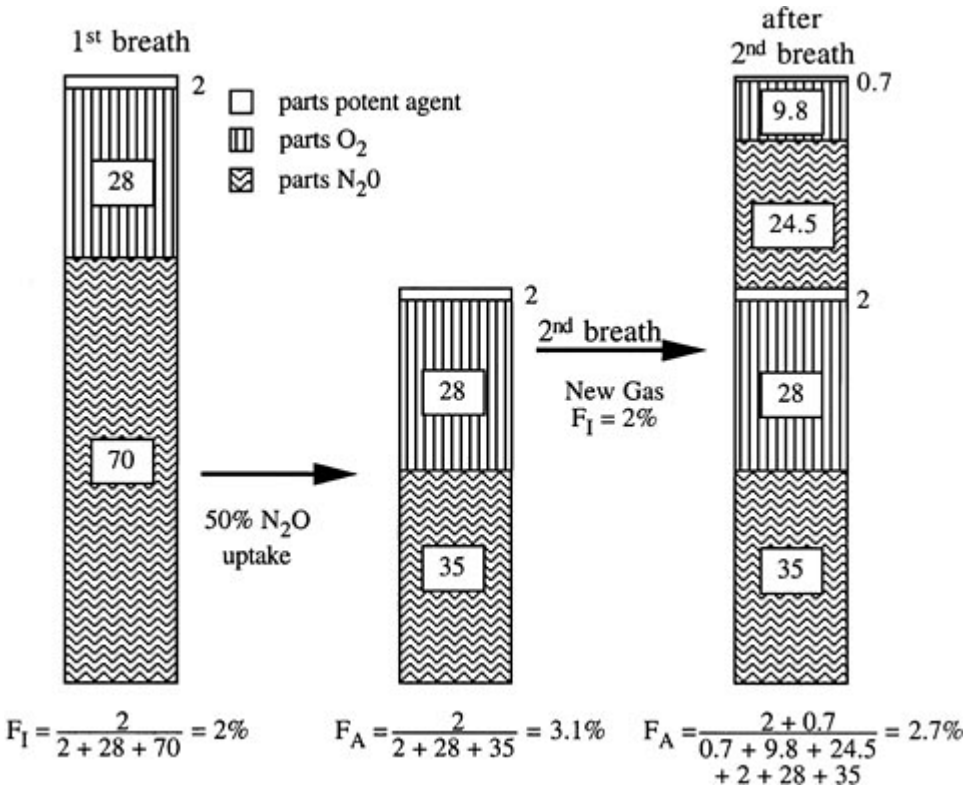

FIGURE 15-3. A graphic and the equations to demonstrate the second gas effect. In this hypothetical example, the second gas is set at 2% of a potent anesthetic and the model is set for 50% uptake of the first gas (nitrous oxide) in the first inspired breath. The second gas is concentrated because of the uptake of N_2O (**middle panel**). On replenishing the inspired second gas (F_I = 2%) in the next breath, the second gas has been concentrated to be 2.7% because of the uptake of N_2O in the previous breath.

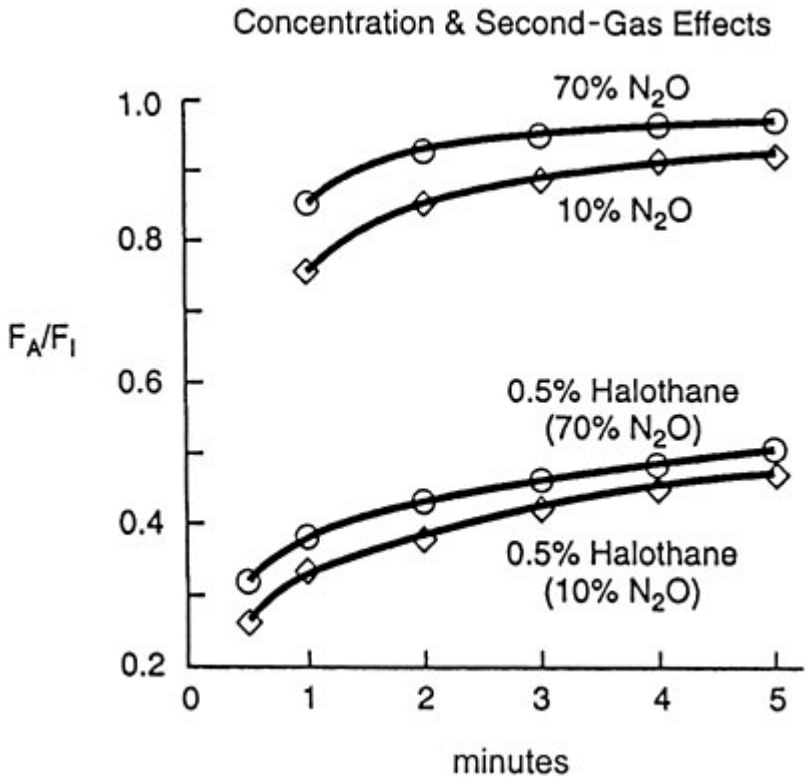

FIGURE 15-4. The concentration effect is demonstrated in the top half of the graph from dogs receiving nitrous oxide. Administration of 70% nitrous oxide produces a more rapid rise in the F_A/F_I ratio of nitrous oxide than administration of 10% nitrous oxide. The second gas effect is demonstrated in the lower graphs. The F_A/F_I ratio for 0.5% halothane rises more rapidly when given with 70% nitrous oxide than when given with 10% nitrous oxide. (Adapted from Epstein R, Rackow H, Salanitre E *et al*: Influence of the concentration effect on the uptake of anesthetic mixtures: The second gas effect. Anesthesiology 25:364, 1964.)

Ventilation Effects

As indicated by Figure 15-2 and Equation 15-3, inhaled anesthetics with very low tissue solubility have an extremely rapid rise in F_A/F_I with induction. This suggests that there is very little room to improve this rate by increasing or decreasing ventilation. This is consistent with the experimental evidence shown in Figure 15-5. The greater the solubility of an inhaled anesthetic, the more rapidly it is absorbed by the bloodstream, such that anesthetic delivery to the lungs may be rate limiting. Therefore, for more soluble anesthetics, augmentation of anesthetic delivery by increasing minute ventilation also increases the rate of rise in F_A/F_I.

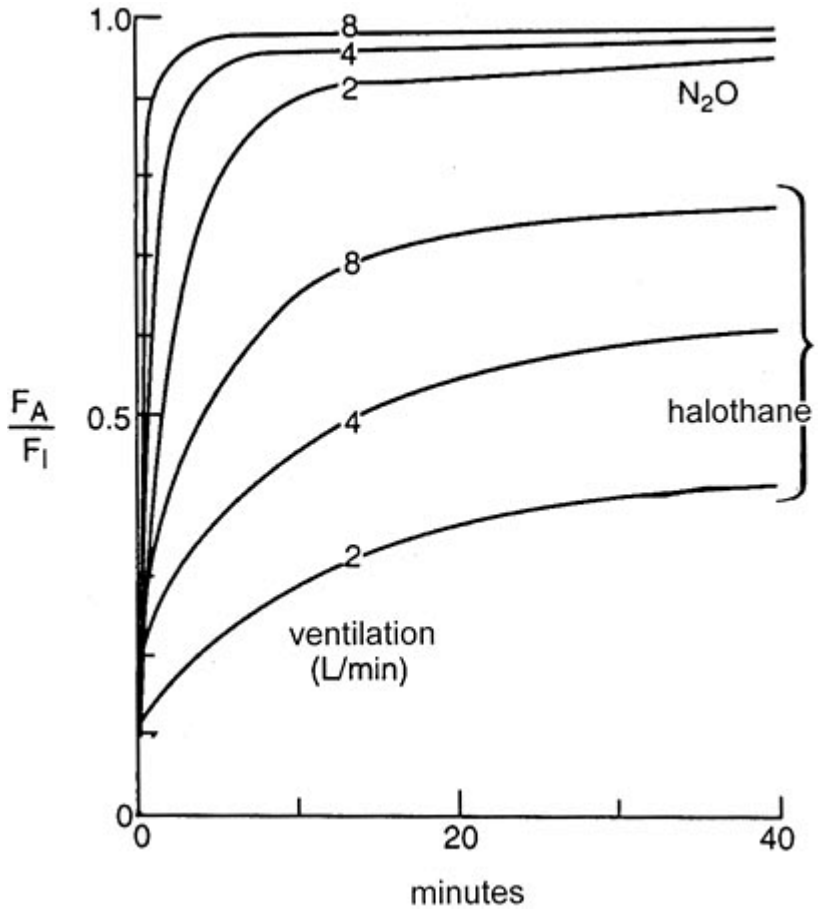

FIGURE 15-5. The F_A/F_I ratio rises more rapidly if ventilation is increased from 2 to 8 L/min. Solubility modifies this impact of ventilation; for example, the effect is greatest with the least soluble anesthetic, nitrous oxide (top 3 lines), and least with the more-soluble anesthetic, halothane. (Adapted from Eger EI II: Ventilation, circulation and uptake. In Eger EI II (ed): Anesthetic Uptake and Action, p 122. Baltimore, Williams & Wilkins, 1974.)

Spontaneous minute ventilation is not static, however, and to the extent that the inhaled anesthetics depress spontaneous ventilation with increasing inspired concentration, $\dot{V}_A$ will decrease and so will the rate of rise of F_A/F_I. This is demonstrated in Figure 15-5. This negative feedback should not be considered

a drawback of the inhaled anesthetics, because the respiratory depression produced at high anesthetic concentrations essentially slows the rise in F_A/F_I. This might arguably add a margin of safety in preventing an overdose.

Perfusion Effects

As with ventilation, cardiac output is not static during the course of induction. For the insoluble agents, changes in cardiac output do not affect the rate of rise of F_A/F_I to a great extent, but for the more soluble agents the effect is noticeable, as seen in Figure 15-6. However, as inspired concentration increases, greater cardiovascular depression reduces anesthetic uptake and actually increases the rate of rise of F_A/F_I. This positive feedback can rapidly lead to profound cardiovascular depression. Figure 15-6 presents experimental data in which lower cardiac outputs lead to a much more rapid rise in F_A/F_I when $\dot{V}_A$ is held constant. This more rapid rise is greater than can be accounted for just by concentration effect.

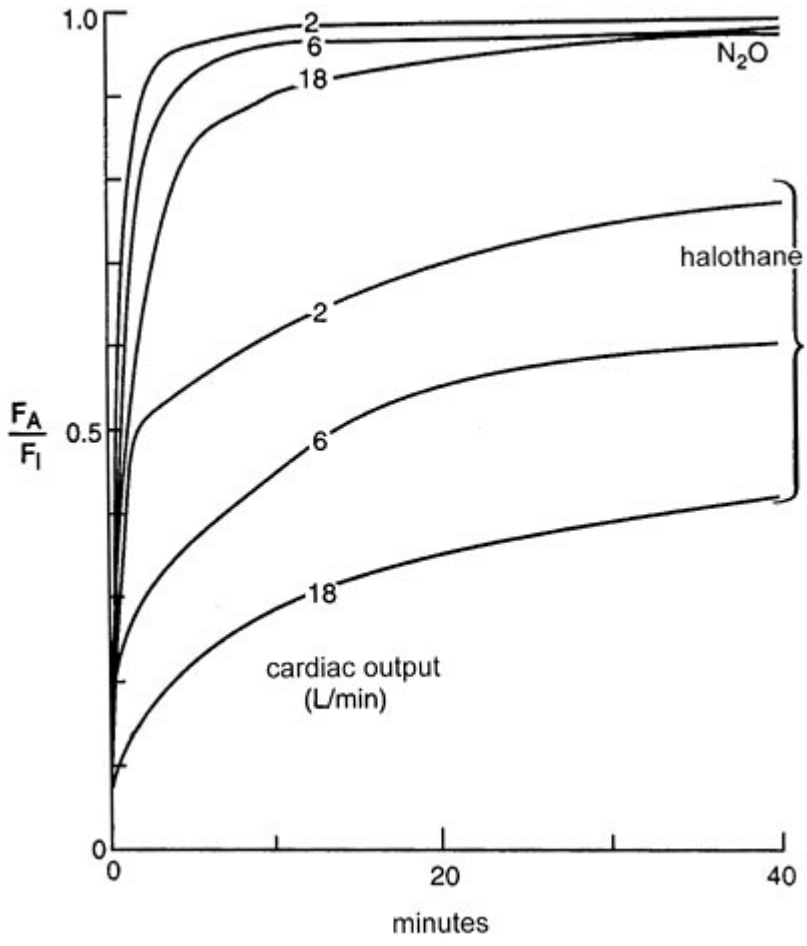

FIGURE 15-6. If ventilation is fixed, an increase in cardiac output from 2 to 18 L/min will decrease the alveolar anesthetic concentration by augmenting uptake, thereby slowing the rise of the F_A/F_I ratio. This effect is most prominent with the more-soluble anesthetics (halothane) than with the less-soluble anesthetics (nitrous oxide). (Adapted from Eger EI II: Ventilation, circulation and uptake. In Eger EI II (ed): Anesthetic Uptake and Action, p 131. Baltimore, Williams & Wilkins, 1974.)

Ventilation–Perfusion Mismatching

Ventilation and perfusion are normally fairly well matched in healthy patients such that P_A (alveolar partial pressure)/ P_I and P_a (arterial partial pressure)/ P_I are the same curve. If significant intrapulmonary shunt occurs, however, as in the case of inadvertent bronchial intubation, the rate of rise of alveolar and arterial anesthetic partial pressures can be affected. The effects, however, depend on the solubility of the anesthetic, as seen in Figure 15-7. Ventilation of the intubated lung is dramatically increased while perfusion increases slightly. The nonintubated lung receives no ventilation, while perfusion decreases slightly. For the less-soluble anesthetics, increased ventilation of the intubated lung cannot appreciably increase alveolar partial pressure relative to inspired concentration on that side, but alveolar partial pressure on the nonintubated side is essentially zero. Pulmonary mixed venous blood, therefore, comprises nearly equal parts blood containing normal amounts of anesthetic and blood containing no anesthetic, that is, diluted relative to normal. Thus the rate of rise in P_a relative to P_I is significantly reduced. There is less total anesthetic uptake, so the rate of rise of P_A relative to P_I increases even though induction of anesthesia is slowed because CNS partial pressure equilibrates with P_a. For the more soluble anesthetics, increased ventilation of the intubated lung *does* increase the alveolar partial pressure relative to inspired concentration on that side. Pulmonary venous blood from the intubated side contains a higher concentration of anesthetic that lessens the dilution by blood from the nonintubated side. Thus the rate of rise of P_a/P_I is not as depressed

as that for the less soluble anesthetics, and induction of anesthesia is less delayed.

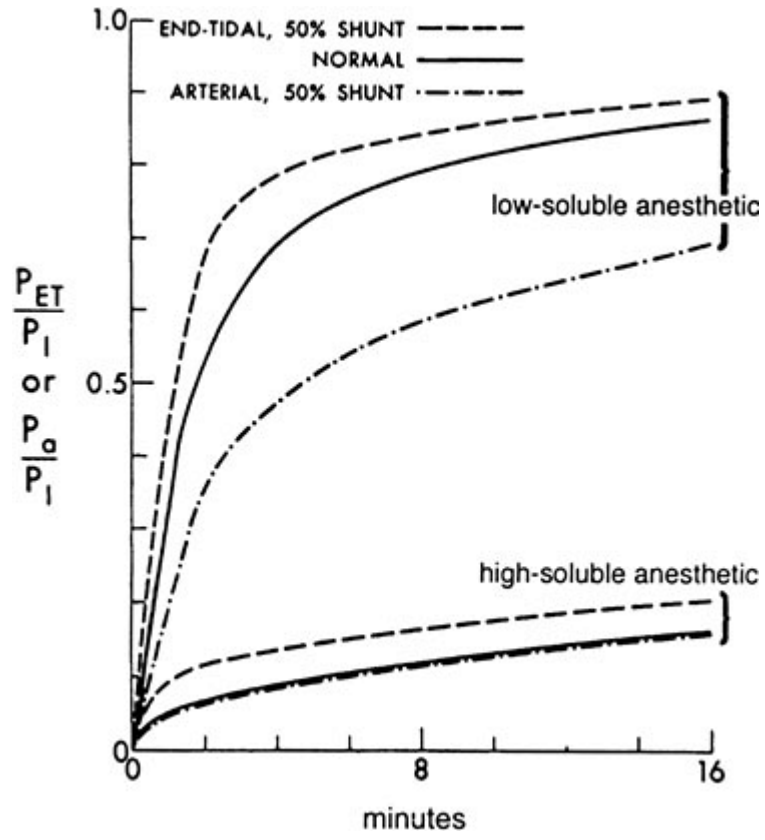

FIGURE 15-7. When no ventilation/perfusion abnormalities exist, the alveolar (P_A) or end-tidal (P_{ET}) and arterial (P_a) anesthetic partial pressures rise together (*continuous lines*) toward the inspired partial pressure (P_I). When 50% of the cardiac output is shunted through the lungs, the rate of rise of the end-tidal partial pressure (*dashed line*) is accelerated while the rate of rise of the arterial partial pressure (*dot-dashed line*) is slowed. The greatest effect of shunting is found with the least soluble anesthetics. (Adapted from Eger EI II, Severinghaus JW: Effect of uneven pulmonary distribution of blood and gas on induction with inhalation anesthetics. Anesthesiology 25:620, 1964.)

Elimination

Percutaneous and Visceral Loss

Although the loss of inhaled anesthetics via the skin is very small, it does occur and is the greatest for nitrous oxide. These anesthetics also pass across gastrointestinal viscera and the

pleura. During open abdominal or thoracic surgery there is some anesthetic loss via these routes. Relative to losses by all other routes, losses via percutaneous and visceral routes are insignificant.

Diffusion between Tissues

Using more elaborate mathematical modeling of inhaled anesthetic pharmacokinetics than presented here, several laboratories have derived a five-compartment model that best describes tissue compartments. These compartments are the alveoli, the VRG, the muscle, the fat, and one additional compartment. Current opinion is that this fifth compartment represents adipose tissue adjacent to lean tissue that receives anesthetic via intertissue diffusion. This transfer of anesthetic is not insignificant, and may account for up to one-third of uptake during long

administration.

Metabolism

Inhaled anesthetic biotransformation is discussed in more depth elsewhere in this chapter. Metabolism is greatest for halothane, up to 50% of loss. In fact, there is evidence that decreases in the alveolar concentrations of halothane during emergence outpace those for isoflurane, presumably because of this significant metabolism. Experimentally, it has been determined that metabolism does not significantly affect recovery from isoflurane.

Exhalation and Recovery

Recovery from anesthesia, like induction, depends on anesthetic solubility, cardiac output, and minute ventilation. Solubility is the primary determinant of the rate of fall of F_A (Fig. 15-8). The greater the solubility of inhaled anesthetic, the larger the capacity for absorption in the bloodstream and tissues. The "reservoir" of anesthetic in the body at the end of administration depends on tissue solubility (which determines the capacity) and the dose and duration of anesthetic (which determine how much of that capacity is filled). Recovery from anesthesia, or "washout," is usually expressed as the ratio of expired fractional concentration of anesthetic (F_E) to the expired concentration at time zero (F_{E0}) when the anesthetic was discontinued (or F_A/F_{A0}). Elimination curves of low and high soluble anesthetics are shown in Figure 15-9. The longer the duration of a highly soluble anesthetic, the greater the reservoir of anesthetic in the body, and the higher the curve seen in the right half of Figure 15-9. This effect is nearly absent with low soluble agents such as nitrous oxide, desflurane, and sevoflurane.[3]

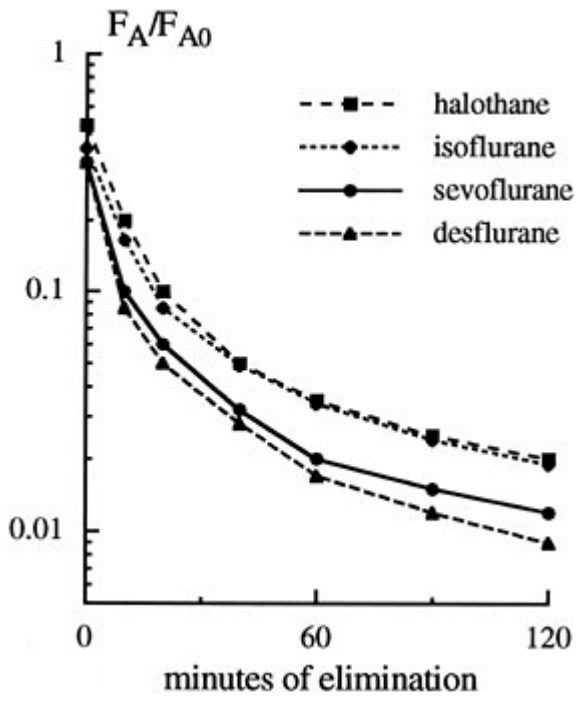

FIGURE 15-8. Elimination of anesthetic gases is defined as the ratio of end-tidal anesthetic concentration (F_A) to the last F_A during administration and immediately before the beginning of elimination (F_{AO}). During the 120-minute period after ending the anesthetic delivery, the elimination of sevoflurane and desflurane is 2 to 2.5 times faster than isoflurane or halothane (note logarithmic scale for the ordinate). (Adapted from Yasuda N, Lockhart SH, Eger EI II *et al*: Comparison of kinetics of sevoflurane and isoflurane in humans. Anesth Analg 72:316, 1991; and Yasuda N, Lockhart SH, Eger EI II *et al*: Kinetics of desflurane, isoflurane, and halothane in humans. Anesthesiology 74:489, 1991.)

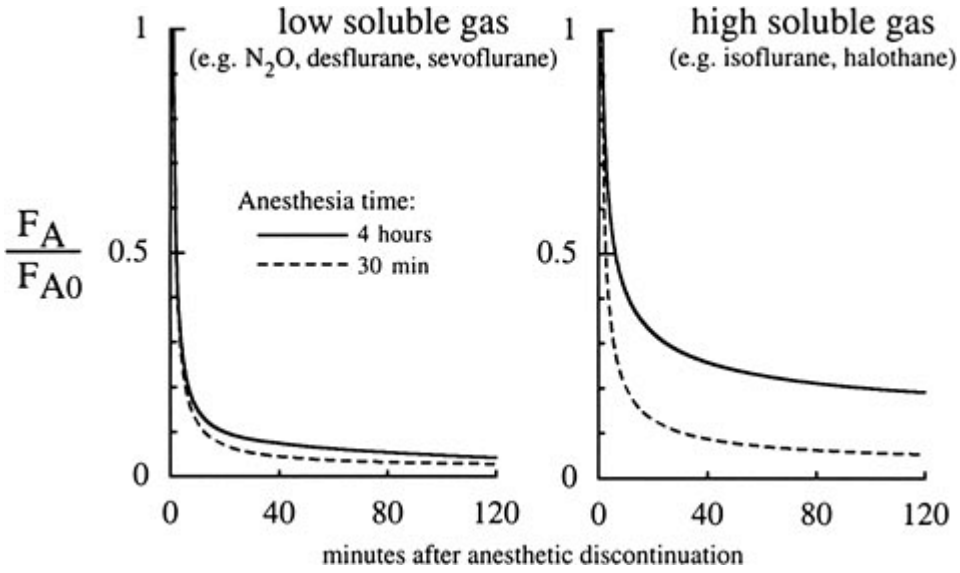

FIGURE 15-9. Both solubility and duration of anesthesia affect the decrease of the alveolar concentration (F_A) from its value immediately preceding the cessation of anesthetic administration (F_{AO}). A longer anesthetic time (from 15 minutes to 240 minutes) only slightly slows the decrease with low soluble anesthetics (**left graph**). An agent with a higher blood and tissue solubility (**right graph**) slows the elimination of the anesthetic and enhances the effect of duration. (Adapted from Stoelting RK, Eger EI II: The effects of ventilation and anesthetic solubility on recovery from anesthesia: An in vivo and analog analysis before and after equilibrium. Anesthesiology 30:290, 1969.)

There are two major pharmacokinetic differences between recovery and induction. First, whereas overpressurization can increase the speed of induction, there is no "under pressurization." Both induction and recovery rates depend on the P_A to P_v gradient, and P_A can never fall below zero. Second, whereas all tissues begin induction with zero anesthetic, each begins recovery with quite different anesthetic concentrations. The VRG tissues begin recovery with the same anesthetic partial pressure as that in alveoli, since $P_{CNS} = P_{blood} = P_{alveoli}$. The partial pressures in muscle and fat depend on the inspired concentration during anesthesia, the duration of administration, and the anesthetic tissue solubilities. As long as an arterial-to-tissue partial pressure gradient exists, these tissues will absorb anesthetic—especially fat, since it is a huge potential reservoir whose anesthetic partial pressures are typically low after hours of anesthesia. After discontinuation of anesthesia, muscle and fat may continue to absorb anesthetic, even hours later. The redistribution continues until blood/alveolar anesthetic partial

pressure falls below tissue partial pressure. This redistribution causes the early rate of decline in alveolar anesthetic concentration during recovery to exceed its increase during induction.

Because VRG tissues are highly perfused and washout of anesthetic is mostly via elimination from these tissues early in recovery, all anesthetics regardless of duration of administration, have approximately the same rate of elimination to 50% of F_{E0}. Unfortunately, halving the CNS concentration of anesthetic is rarely sufficient for waking the patient. More commonly, 80 to 90% of inhaled anesthetic must be eliminated before emergence. At these amounts of washout, the more soluble anesthetics are eliminated more slowly than less soluble agents.

Diffusion Hypoxia

During recovery from anesthesia, washout of high concentrations of nitrous oxide can lower alveolar concentrations of oxygen and carbon dioxide, a phenomenon called *diffusion hypoxia*. The resulting alveolar hypoxia can cause hypoxemia, and alveolar hypocarbia can depress respiratory

drive, which may exacerbate hypoxemia. It is therefore appropriate to initiate recovery from nitrous oxide anesthesia with 100% oxygen rather than less concentrated O_2/air mixtures.

CLINICAL OVERVIEW OF CURRENT INHALED ANESTHETICS

Halothane

Halothane, a relatively nonflammable liquid, is the most potent of the currently used volatile anesthetics. It is an alkane—a halogen-substituted ethane derivative (see Fig. 15-1)—that was placed into clinical use in 1956. The halogenated structure provided nonflammability. It has an intermediate blood solubility and is relatively nonpungent; hence, it can be inhaled via the face mask. The carbon–fluorine bond is important in providing nonflammability of halothane at room temperature and the trifluorocarbon group contributes to its molecular stability. Despite its chemical stability, halothane oxidizes spontaneously and is broken down by ultraviolet light. It decomposes to hydrochloric acid (HCL), hydrobromic acid (Hbr), chloride (CL^-), bromide (Br^-), and phosgene ($COCl_2$). To prevent this decomposition, halothane is stored in amber-colored bottles and 0.01% thymol is added as a preservative to prevent spontaneous oxidative decomposition. The thymol preservative can "gum up" vaporizers, mandating a more difficult and more frequent cleaning schedule than that for vaporizers specific to other volatile anesthetics. Halothane also is adsorbed by contact with dry soda lime and broken down to BCDFE (2-bromo-2-chloro-1,1-difluoroethene), which has organ toxicity in animal models. In humans, halothane has been associated with an immune-mediated hepatitis and a sensitization to epinephrine resulting in arrhythmias. It also has been associated with bradycardia when used in the pediatric population.

Enflurane

Enflurane, a halogenated methyl ethyl ether, is an isomer of isoflurane (see Fig. 15-1). It is a nonflammable liquid at room temperature and is pungent. Its use in high concentrations has been associated with seizure-like activity on the EEG. Its metabolism has resulted in an increase in blood fluoride concentration and, rarely, with a renal concentrating deficiency. Its popularity has generally been reserved owing to competition from isoflurane—the near-simultaneously introduced volatile anesthetic, which has few side effects—and more recently, the introduction of new anesthetics with lower solubilities.

Isoflurane

Isoflurane, a halogenated methyl ethyl ether, is a clear, nonflammable liquid at room temperature and has a high degree of pungency (see Fig. 15-1). The second most potent of the volatile anesthetics in clinical use, isoflurane has great physical stability and undergoes essentially no deterioration during storage for up to 5 years or on exposure to sunlight. It has become the gold standard anesthetic since its introduction in the 1970s. There has been a brief period of controversy concerning the use of isoflurane in patients with coronary disease because of the possibility for coronary "steal," arising from the potent effects of isoflurane on coronary vasodilation. In clinical use, however, this has been, at most, a rare occurrence.

Desflurane

Desflurane is a fluorinated methyl ethyl ether that differs from isoflurane by just one atom: a fluorine atom is substituted for a chlorine atom on the α-ethyl component of isoflurane (see Fig. 15-1). The process of completely fluorinating the ether molecule has several effects. It decreases blood and tissue solubility (the blood:gas solubility of desflurane equals that of

nitrous oxide), and it results in a loss of potency (the MAC of desflurane is five times higher than isoflurane). Moreover, the complete fluorination of the methyl ether molecule results in a high vapor pressure (owing to decreased intermolecular attraction). Thus, a new vaporizer technology has been developed to deliver a regulated concentration of desflurane as a gas. A heated, pressurized vaporizer requiring electrical power and more frequent servicing is required. One of

the advantages of desflurane is the near-absent metabolism to serum trifluoroacetate. This makes immune-mediated hepatitis extremely unlikely. Desflurane is the most pungent of the volatile anesthetics and cannot be administered via the face mask as it results in coughing, salivation, breath holding, and laryngospasm. In extremely dry CO_2 absorbers, desflurane (and to a lesser extent isoflurane, enflurane, and sevoflurane) degrades to form carbon monoxide. Desflurane has the lowest blood:gas solubility of the potent volatile anesthetics; moreover, its fat solubility is roughly half of that of the other volatile anesthetics. Thus, desflurane offers a theoretical advantage in long surgical procedures by virtue of decreased tissue saturation. Desflurane has been associated with tachycardia, hypertension, and, in select cases, myocardial ischemia when used in high concentrations or rapidly increasing the inspired concentration (without using opioid adjuvants to prevent such a response).

Sevoflurane

Sevoflurane is a sweet-smelling, completely fluorinated methyl isopropyl ether (see Fig. 15-1). Its vapor pressure is most similar to that of enflurane and it can be used in a conventional vaporizer. The blood:gas solubility of sevoflurane is second only to desflurane in terms of potent volatile anesthetics. Sevoflurane is approximately half as potent as isoflurane, and some of the preservation of potency, despite fluorination, is because of the bulky propyl side chain on the ether molecule. Sevoflurane has minimal odor, no pungency, and is a potent bronchodilator. These attributes make sevoflurane an excellent candidate for administration via the face mask on induction of anesthesia in both children and adults. Sevoflurane is half as potent a coronary vasodilator as isoflurane, but is 10 to 20 times more vulnerable to metabolism than isoflurane. Like that of enflurane and methoxyflurane, the metabolism of sevoflurane results in inorganic fluoride; the increase in plasma fluoride after sevoflurane administration has not been associated with renal concentrating defects, as is the case with methoxyflurane. Unlike other potent volatile anesthetics, sevoflurane is not metabolized to trifluoroacetate; rather, it is metabolized to an acyl halide (hexafluoroisopropanol). This does not stimulate formation of antibodies, and immune-mediated hepatitis has not been reported with sevoflurane. Sevoflurane can form carbon monoxide during exposure to dry CO_2 absorbents and an exothermic reaction in dry absorbent has resulted in canister fires. Sevoflurane breaks down in the presence of the carbon dioxide absorber to form a vinyl halide called compound A. Compound A has been shown to be a dose-dependent nephrotoxin in rats, but has not been associated with renal injury in human volunteers or patients, with or without renal impairment, even when fresh gas flows are 1 L/min or less.

Xenon

Xenon is an inert gas. Difficult to obtain, and hence extremely expensive, it has received considerable interest in the last few years because it has many characteristics approaching those of an "ideal" inhaled anesthetic.[5,6] Its blood:gas partition coefficient is 0.14, and unlike the other potent volatile anesthetics (except methoxyflurane), xenon provides some degree of analgesia. Unfortunately, the MAC in humans is 71%, which might prove to be a limitation. It is nonexplosive, nonpungent, and odorless, and thus can be inhaled with ease. In addition, it does not produce significant myocardial depression.[5] Because of its scarcity and high cost, new anesthetic systems need to be developed to provide for recycling of xenon. If this proves to be too difficult from either a technical or patient safety standpoint, it may be necessary to use it in a very low, or closed, fresh gas flow system to reduce wastage.

Nitrous Oxide

Nitrous oxide is a sweet-smelling, nonflammable gas of low potency (MAC = 104%) and is relatively insoluble in blood. It is most commonly administered as an anesthetic adjuvant in combination with opioids or volatile anesthetics during the conduct of general anesthesia. Although not flammable, nitrous oxide will support combustion. Unlike the potent volatile anesthetics in clinical use, nitrous oxide does not produce significant skeletal muscle relaxation, but it does have documented analgesic effects. Despite a long track record of use, controversy has surrounded nitrous oxide in four areas: its role in postoperative nausea and vomiting, its potential

toxic effects on cell function via inactivation of vitamin B_{12}, its adverse effects related to absorption and expansion into air-filled structures and bubbles, and last, its effect on embryonic development. The one concern that seems most valid and most clinically relevant is the ability of nitrous oxide to expand air-filled spaces because of its greater solubility in blood compared to nitrogen. Several closed gas spaces such as the bowel and middle ear exist in the body and other spaces may occur as a result of disease or surgery such as a pneumothorax. The nitrogen cannot be removed readily via the bloodstream. Unfortunately, nitrous oxide delivered to a patient diffuses from the blood into these closed gas spaces quite easily such that the spaces must increase pressure and potentially expand. Movement of nitrous oxide into these spaces continues until the partial pressure equals that of the blood and alveoli. Compliant spaces will continue to expand until sufficient pressure is generated to oppose further N_2O flow into the space. The higher the inspired concentration of nitrous oxide, the higher the partial pressure required for equilibration.

Seventy-five percent N_2O can expand a pneumothorax to double or triple its size in 10 and 30 minutes, respectively. Air-filled cuffs of pulmonary artery catheters and endotracheal tubes also expand with the use of N_2O, possibly causing tissue damage via increased pressure in the pulmonary artery or trachea, respectively.[6,7] In a rabbit model, the volume of an air embolus resulting in cardiovascular compromise is less during coadministration of nitrous oxide.[8] Accumulation of nitrous oxide in the middle ear can diminish hearing postoperatively[9] and is relatively contraindicated for tympanoplasty because the increased pressure can dislodge a tympanic graft.

NEUROPHARMACOLOGY OF INHALED ANESTHETICS

The inhaled anesthetics establish the anesthetic state by effects on spontaneous neuronal activity and metabolism. The exact anesthetic mechanisms of inhaled agents remain poorly understood and the associated nervous system effects may in part be mediated by these undetermined mechanisms. Therefore as a whole, the current understanding of inhaled anesthetic neuropharmacology tends to be more descriptive than mechanistic in nature.

The mechanisms of anesthesia are elusive partly because there is no uniform definition of when the brain is anesthetized;

however, a useful definition may be a brain that is incapable of self-awareness or subsequent recall. This definition is helpful conceptually, but from a practical standpoint it is difficult to know when the brain is no longer self-aware or will have no recall, and to know the dose of inhaled anesthetic at that point. The ability to determine, establish, and maintain this level of anesthesia is part of the art of anesthesia. It depends on the integration of knowledge of inhaled anesthetic pharmacokinetics and pharmacodynamics, direct observation of the patient, and interpretation of data from a complex array of monitors. With the recent advent of the processed electroencephalogram (EEG) monitor, the first, albeit crude, index of anesthetic "depth" via continuous real-time analysis of the patient's EEG might provide relevant information. The utility of this device remains controversial, and it is likely that relevant information might need tailoring to each anesthetic regimen.

TABLE 15-4 Factors That Increase MAC

- Increased central neurotransmitter levels (monoamine oxidase inhibitors, acute dextroamphetamine administration, cocaine, ephedrine, levodopa)
- Hyperthermia
- Chronic ethanol abuse (determined in humans)
- Hypernatremia

Minimum Alveolar Concentration

3 The pharmacodynamic effects of inhaled anesthetics must be based on a dose, and this dose is the *minimum alveolar concentration* or *MAC*. MAC is the alveolar concentration of an anesthetic at one atmosphere that prevents movement in response to a surgical stimulus in 50% of patients. It is analogous to the ED_{50} expressed for intravenous drugs. A variety of surgical stimuli have been used to establish the MAC for each inhaled anesthetic, but the classic, defining, noxious stimulus is incision of the abdomen. Likewise, skeletal muscle movement is the defining patient response, but other responses have been used to establish MAC as well. Experimentally determined MAC values for humans for the inhaled anesthetics are shown in Table 15-1.

The 95% confidence ranges for MAC are approximately ± 25% of the listed MAC values. Manufacturer's recommendations and clinical experience establish 1.2 to 1.3 times MAC as a dose that consistently prevents patient movement during surgical stimuli. Loss of consciousness typically precedes the absence of stimulus-induced movement by a wide margin. While 1.2 to 1.3 MAC values do not *absolutely* ensure the defining criteria for brain anesthesia (the absence of self-awareness and recall), vast clinical experience suggests it is extremely unlikely for a patient to be aware of, or to recall the surgical incision at these anesthetic concentrations unless other conditions exist such that MAC is increased in that patient (Table 15-4).

Concentrations of inhaled anesthetics that provide loss of self-awareness and recall are about 0.4 to 0.5 MAC. Several lines of reasoning lead to this conclusion. First, most patients receiving only 50% nitrous oxide (approximately 0.4 to 0.5 MAC) as in a typical dentist's office will have no recall of their procedure during N_2O administration. Second, various studies have shown that a shift in EEG dominance to the anterior leads, that is, the shift from self-aware to nonself-aware, accompanies loss of consciousness, and in primates, the EEG shift and loss of consciousness occur at 0.5 MAC.[10] Third, in dogs, loss of consciousness accompanies a sudden nonlinear fall in cerebral metabolic rate (CMR) at approximately 0.5 MAC (Fig. 15-10).

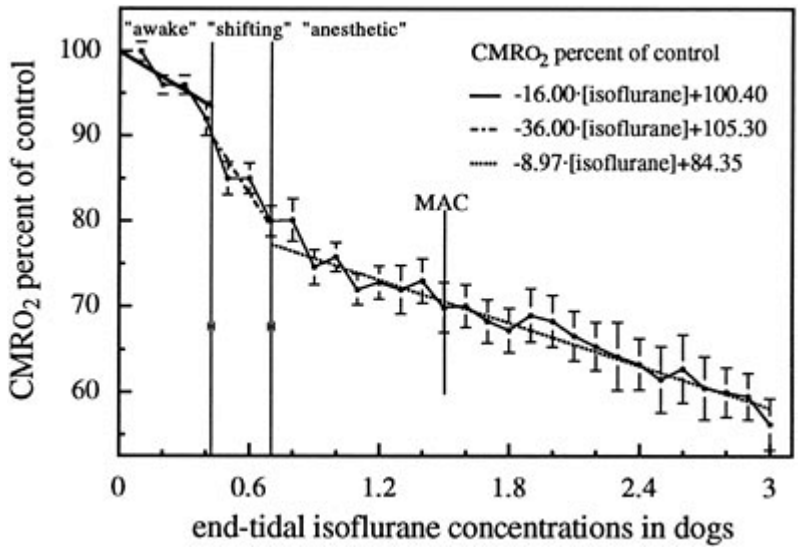

FIGURE 15-10. The effects of halothane on $CMRO_2$ as a percentage of control ("awake"). $CMRO_2$ is plotted versus end-tidal isoflurane concentration. Regression lines for changes in $CMRO_2$ are drawn for each EEG determined area. The pattern depicted here is characteristic of all of the anesthetics examined (enflurane, halothane, and isoflurane). (Adapted from Stullken EH Jr, Milde JH, Michenfelder JD *et al*: The non-linear responses of cerebral metabolism to low concentrations of halothane, enflurane, isoflurane and thiopental. Anesthesiology 46:28, 1977.)

MAC values can be established for any measurable response. MAC-awake, or the alveolar concentration of anesthetic at which a patient opens his or her eyes to command, varies from 0.15 to 0.5 MAC.[11] Interestingly, transition from awake to unconscious and back typically shows some hysteresis, in that it quite consistently takes 0.4 to 0.5 MAC to lose consciousness, but less than that (as low as 0.15 MAC) to regain consciousness. This may be because of the speed of alveolar washin versus washout.[12] MAC-BAR, or the alveolar concentration of anesthetic that blunts adrenergic responses to noxious stimuli, has likewise been established and is approximately 50% higher than standard MAC.[13] MAC also has been established for discreet levels of EEG activity, such as onset of burst suppression or isoelectricity.

Standard MAC values are roughly additive. Administering 0.5 MAC of a potent agent and 0.5 MAC of nitrous oxide is equivalent to 1 MAC of potent agent in terms of preventing *patient movement*, although this does not hold over the entire range of N_2O doses. MAC effects for other response parameters are not necessarily additive. Because MAC-movement probably differs from MAC for various secondary side effects (such hypothetical situations as "MAC-dysrhythmia," "MAC-hypotension," or "MAC-tachycardia," etc.), combinations of a potent agent and nitrous oxide may decrease or increase these secondary effects relative to potent agent alone. For example, combining 0.6 MAC of nitrous oxide with 0.6 MAC of isoflurane produces less hypotension than 1.2 MAC of isoflurane alone because isoflurane is a more potent vasodilator and myocardial depressant at equivalent MAC than N_2O.

TABLE 15-5 Factors That Decrease MAC

- Increasing age
- Metabolic acidosis
- Hypoxia (PaO_2, 38 mm Hg)

- Induced hypotension (MAP <50 mmHg)
- Decreased central neurotransmitter levels (alpha-methyldopa, reserpine, chronic dextroamphetamine administration, levodopa)
- Alpha-2 agonists
- Hypothermia
- Hyponatremia
- Lithium
- Hypoosmolality
- Pregnancy
- Acute ethanol administration[a]
- Ketamine
- Pancuronium[a]
- Physostigmine (10 times clinical dose)
- Neostigmine (10 times clinical dose)
- Lidocaine
- Opioids
- Opioid agonist–antagonist analgesics
- Barbiturates[a]
- Chlorpromazine[a]
- Diazepam[a]
- Hydroxyzine[a]
- Δ-9-Tetrahydrocannabinol
- Verapamil
- Anemia (<4.3 mL O_2/dL blood)

[a]Determined in humans.

Various factors increase (Table 15-4) or decrease (Table 15-5) MAC. Unfortunately, no single mechanism explains these alterations in MAC, supporting the view that anesthesia is the net result of numerous and widely varying physiologic alterations. In general, those factors that increase CNS metabolic activity and neurotransmission, increase CNS neurotransmitter levels, and upregulation of CNS responses to chronically depressed neurotransmitter levels (as in chronic alcoholism) also seem to increase MAC. Conversely, those factors that

decrease CNS metabolic activity and neurotransmission, decrease CNS neurotransmitter levels, and downregulation of CNS responses to chronically elevated neurotransmitter levels seem to decrease MAC. Many notable factors do not alter MAC, including duration of inhaled anesthetic administration, gender, type of surgical stimulation, thyroid function, hypo- or hypercarbia, metabolic alkalosis, hyperkalemia, and magnesium levels. However, there may be a genetic component influencing MAC. Redheaded females have a 19% increase in MAC compared to dark-haired females.[14] These data suggest involvement of mutations of the *MCIR* allele. Variants of the *MCIR* allele also have been implicated in altering analgesic responses to a κ opioid.[15] MAC also can vary in relationship to genotype and chromosomal substitutions as shown in rats.[16]

The Effect of Age on MAC

The MAC for each of the potent anesthetic gases shows a clear, age-related change (Fig. 15-11). MAC decreases with age and there are similarities between agents in the decline in MAC and age. Excluding data in patients less than 1 year of age (where MAC can be lower[17]), there is a linear model that describes the decrease in MAC with increasing age.[18] The slope of this model is: MAC = $a(10^{bx})$, where "x" is the difference in age in years from 40, "b" is –.00269, and "a" is the MAC at age 40. This equation defines a change in MAC of approximately 6% per decade, a 22% decrease

in MAC from age 40 to age 80, and a 27% decrease in MAC from age 1 to 40 years. MAC is typically expressed for an intermediate age (40 years), and these are:

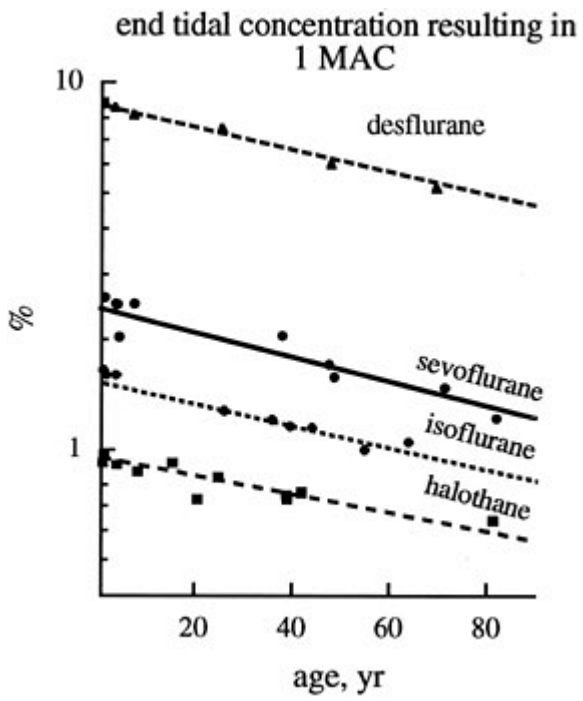

FIGURE 15-11. Effect of age on MAC. Regression lines are fitted to published values from separate studies. Data are from patients ages 1 to 80 years. (Adapted from Mapleson WW: Effect of age on MAC in humans: A meta-analysis. Br J Anaesth 76:179, 1996.)

Halothane 0.75%

Isoflurane 1.17%

Enflurane 1.63%

Sevoflurane 1.80%

Desflurane 6.60%

Nitrous Oxide 104.00%

Other Alterations in Neurophysiology

The four, current, widely used, potent agents, halothane, isoflurane, desflurane, and sevoflurane, all have reasonably similar effects on a wide range of parameters including cerebral metabolic rate, the EEG, cerebral blood flow (CBF), and flow–metabolism coupling. There are notable differences in effects on intracerebral pressure, cerebrospinal fluid production and resorption, CO_2 vasoreactivity, CBF autoregulation, and cerebral protection. Nitrous oxide departs from the potent agents in several important respects, and is therefore discussed separately.

Cerebral Metabolic Rate and Electroencephalogram

All of the potent agents depress cerebral metabolic rate (CMR) to varying degrees in a nonlinear fashion. In isoflurane-anesthetized dogs, there is a sudden decrease in $CMRO_2$ paralleling a change in the EEG from an awake to anesthetized pattern at about 0.4 to 0.6 MAC as seen in Figure 15-10.[19] For most of the potent agents, CMR is decreased only to the extent that spontaneous cortical neuronal activity (as reflected in the EEG) is decreased. Once spontaneous

cortical neuronal activity is absent (an isoelectric EEG), no further decreases in CMR are generated. Halothane is the exception. Halothane causes a 20 to 30% decrease in CMR at normal clinical concentrations, and at 4.5% produces an isoelectric EEG. Further increases in inspired concentration cause further decreases in $CMRO_2$. This further depression of $CMRO_2$ is because of toxic effects on oxidative phosphorylation. Toxic effects begin at concentrations as low as 2.3%, at which point brain lactate concentrations increase, but this dose is typically well above those used clinically for halothane.

Isoflurane causes a larger MAC-dependent depression of CMR than halothane, and does not depress $CMRO_2$ once an isoelectric EEG is produced.[20] Because of this greater depression in neuronal activity, isoflurane abolishes EEG activity at doses used clinically and can usually be tolerated from a hemodynamic standpoint.[38] Desflurane and sevoflurane both cause decreases in CMR similar to isoflurane.[21,22] Interestingly,

while both desflurane and sevoflurane depress the EEG and abolish activity at clinically tolerated doses of approximately 2 MAC,[21,22] in *dogs* desflurane-induced isoelectric EEG reverts to continuous activity with time despite an unchanging MAC, a property unique to desflurane.[21] Sevoflurane at isoelectric EEG concentrations in *cats* is not associated with a reversion to continuous EEG activity, although species differences could account for the differing results.[23] The reversion from an isoelectric to a continuous EEG does not occur in desflurane anesthetized swine[24] and there are no case reports of this phenomenon in humans.

Potential for cerebral toxicity has been studied for sevoflurane as compared to halothane. At normal CO_2 and blood pressure no evidence of sevoflurane toxicity exists.[25] With extreme hyperventilation to decrease cerebral blood flow by half, brain lactate levels increase, but significantly less than with halothane. There are conflicting data as to whether sevoflurane has a proconvulsant effect.[22,23,26] High, long-lasting concentrations of sevoflurane (1.5 to 2.0 MAC), a sudden increase in cerebral sevoflurane concentrations, and hypocapnia can trigger EEG abnormalities that often are associated with increases in heart rate in both adults and children.[27,28] This has raised the question as to the appropriateness of sevoflurane in patients with epilepsy.[29]

Cerebral Blood Flow, Flow–Metabolism Coupling, and Autoregulation

4 All of the potent agents increase CBF in a dose-dependent manner. Halothane is a very potent cerebral vasodilator[30] and causes the greatest increase in CBF per MAC-multiple. Because of this, halothane is rarely used in neurosurgery today, even though it was the dominant anesthetic for these cases until the early 1970s. Despite causing the greatest increase in CBF, the vasodilating effects of halothane are blunted by hyperventilating subjects to a $PaCO_2$ of 25 mm Hg prior to or simultaneous to the administration of halothane.[31]

Isoflurane, sevoflurane, and desflurane cause far less cerebral vasodilation per MAC-multiple than halothane (Fig. 15-12).[30,32,33] In human studies, isoflurane produces insignificant or no changes in CBF.[34] Desflurane and sevoflurane both influence CBF in a fashion similar to isoflurane.[21,22] All of these inhaled anesthetic agents affect CBF in a time-dependent as well as dose-dependent manner. In animals, an initial dose-dependent increase in CBF with halothane and isoflurane administration recovers to preinduction levels approximately 2 to 5 hours after induction. The mechanism of this recovery is unclear.

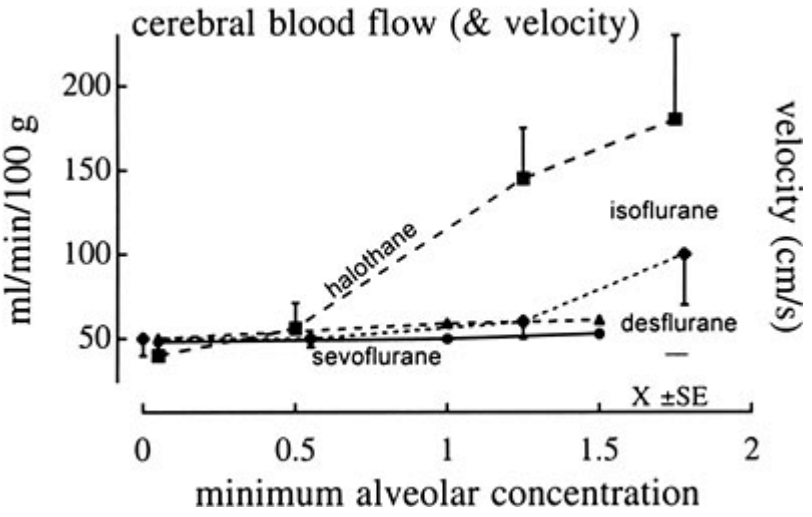

FIGURE 15-12. Cerebral blood flow (and velocity) measured in the presence of normocapnia and in the absence of surgical stimulation in volunteers receiving halothane or isoflurane. At light levels of anesthesia, halothane (but not isoflurane) increased cerebral blood flow. At 1.6 MAC isoflurane also increased cerebral blood flow. (Adapted from Eger, E. I. II. Isoflurane (Forane): A compendium and reference. Madison, Ohio Medical Products.) Cerebral blood flow velocity measured before and during sevoflurane and desflurane anesthesia up to 1.5 MAC showed no change in CBFV. (Adapted from Bedforth NM, Hardman JG, Nathanson MH: Cerebral hemodynamic response to the introduction of desflurane: A comparison with sevoflurane. Anesth Analg 91:152, 2000.)

The increase in CBF with increasing dose caused by the potent agents occurs despite decreases in CMR. This phenomenon has been called "uncoupling," but from a mechanistic standpoint, true uncoupling of flow from metabolism may not occur. That is, as CMR is depressed by the volatile anesthetics there still is a coupled decline in CBF opposed by a coincident direct vasodilatory effect on the cerebral blood vessels. The net effect on the cerebral vessels depends on the sum of indirect vasoconstricting and direct vasodilating influences.

This view is supported by several facts. First, at low doses, both halothane (<0.375%) and isoflurane (0.5%) can actually decrease CBF.[35,36] This likely reflects intact coupling of CBF to CMR with the depression in neuronal activity and metabolism causing a coupled decline in perfusion. At higher doses, increases in CBF occur presumably because direct vasodilation at these doses outweighs indirect vasoconstriction. Second, if CMR is maximally or near maximally depressed with a barbiturate, halothane and isoflurane produce similar increases in CBF.[37] This is consistent with the greater depression of CMR seen with isoflurane. From a starting point of normal CMR, isoflurane causes a greater dose-dependent decrease in CMR resulting in greater indirect vasoconstriction and less vasodilation. When CMR is maximally depressed prior to isoflurane or halothane administration, no further indirect vasoconstriction is possible, and the two agents dilate cerebral vessels to a similar extent. Third, CBF to $CMRO_2$ ratios are the same for many volatile anesthetics at equivalent MAC, and increase with increasing dose in a similar fashion.[38] Finally, regional CBF–CMR relationships are arguably a better indicator of coupling than the global CBF to CMR ratio, and both isoflurane and halothane show strong coupling between decreases in CMR and CBF in individual brain regions.[39]

Autoregulation is the intrinsic myogenic regulation of vascular tone. In normal brain, the mechanisms of autoregulation of CBF over a range of mean arterial pressures from 50 to 150 mm Hg are incompletely understood. Because the volatile anesthetics are direct vasodilators, all are considered to diminish autoregulation in a dose-dependent fashion such that at high anesthetic doses CBF is essentially pressure-passive. Sevoflurane preserves autoregulation up to approximately 1 MAC.[22] At 1.5 MAC, the dynamic rate of autoregulation (change in middle cerebral

artery blood flow to a rapid change in blood pressure [BP]) is better preserved with sevoflurane than isoflurane (Fig. 15-13). This may be a result of less of a direct vasodilator effect of sevoflurane, preserving the ability of the vessel to respond to changes in BP at 1.5 MAC. Based on a similar model but a separate study of dynamic autoregulation of cerebral blood flow, 0.5 MAC desflurane reduced autoregulation and isoflurane did not. At 1.5 MAC, both anesthetics substantially reduced autoregulation (see Fig. 15-13).

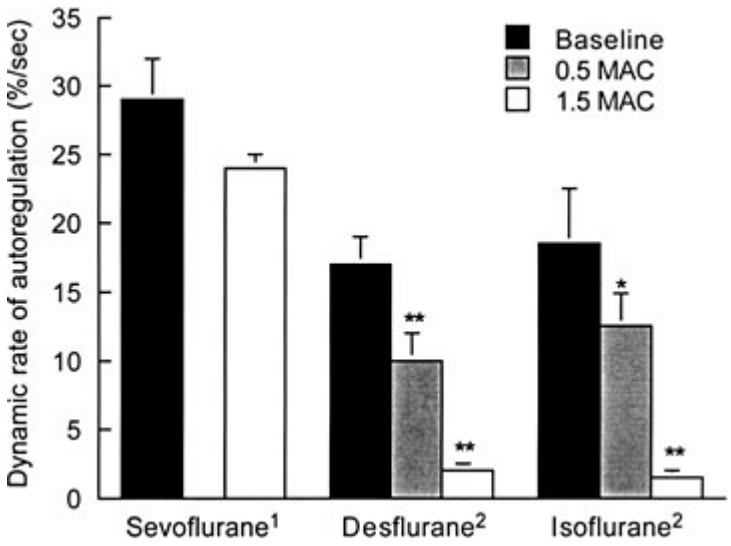

FIGURE 15-13. Dynamic rate of autoregulation (dRoR) during awake (or fentanyl and N_2O baseline), 0.5, and 1.5 minimum alveolar anesthetic concentration (MAC) anesthesia. Values are mean ± SD (SE for iso/des). * $p<0.05$ versus baseline, ** $p<0.001$ versus baseline and sevoflurane. (Data from Summors AC, Gupta AK, Matta BF: Dynamic cerebral autoregulation during sevoflurane anesthesia: A comparison with isoflurane. Anesth Analg 88:341, 1999; and Strebel S, Lam A, Matta B *et al*: Dynamic and static cerebral autoregulation during isoflurane, desflurane, and propofol anesthesia. Anesthesiology 83:66, 1995.)

Intracerebral Pressure

Probably the area of greatest clinical interest to the anesthesiologist is the effect of volatile anesthesia on intracerebral pressure (ICP). In general, ICP will increase or decrease in proportion to changes in CBF. Halothane increases ICP to the greatest extent, reflecting its effects on CBF that are the largest of the potent agents.[52] In fact, brain protrusion during craniotomy is greater with halothane than isoflurane, consistent with the greater increase in ICP by halothane.[40] At concentrations above 0.5 MAC, halothane has the propensity to increase

CBF and ICP. This effect, in association with a blood pressure decrease, may cause profound decreases in cerebral perfusion pressure. Preinduction hyperventilation and hyperventilation with induction blunt the increases in ICP seen with halothane administration.[52] Barbiturate coadministration likewise blunts or prevents halothane-induced increases in ICP.

In contrast to halothane, isoflurane increases ICP minimally in animals both with and without brain pathology, including those with an already elevated ICP.[51] In human studies there usually are mild increases in ICP with isoflurane administration that, as with halothane, are blocked or blunted by hyperventilation or barbiturate coadministration.[41] There are some contradictory data, however. In one human study, hypocapnia did not prevent elevations in ICP with isoflurane administration in patients with space-occupying brain lesions.[42] Nonetheless, the increase in ICP is far less for isoflurane than for halothane. Furthermore, any isoflurane-induced increases in ICP tend to be of short duration, in one study only 30 minutes,[43] as opposed to halothane in which ICP increases may last for hours.

Like isoflurane, both sevoflurane and desflurane above 1 MAC produce mild increases in ICP, paralleling their mild increases in CBF.[21,22,44,45] One potential advantage of sevoflurane is that its lower pungency and airway irritation may lessen the risk of coughing and bucking and the associated rise in ICP as compared to desflurane or isoflurane. In fact, introduction of desflurane after propofol induction of anesthesia has led to significant increases in HR, MAP, and middle cerebral artery blood flow velocity that were not noted in patients given sevoflurane.[54] This may relate to the airway irritant effects of desflurane rather than a specific alteration in neurophysiology. However, several studies in both children and adults suggest that increases in ICP from desflurane are slightly greater than from either isoflurane or sevoflurane.[46,47] The bottom line is that all four potent agents may be used at appropriate doses, especially with adjunctive and compensatory therapies, in just about any neurosurgical procedure. However, patients with traumatic head injuries, elevated ICP, or space-occupying brain lesions are probably better served with isoflurane, sevoflurane, and possibly desflurane than halothane.

Cerebrospinal Fluid Production and Resorption

Studies indicate that 1 MAC halothane decreases cerebrospinal fluid (CSF) production but increases resistance to resorption, the net effect being an increase in CSF volume.[63] Isoflurane does not appear to alter CSF production,[43] but may increase, decrease, or leave unchanged the resistance to resorption depending on dose. Sevoflurane at 1 MAC depresses CSF production up to 40%.[48] Desflurane at 1 MAC leaves CSF production unchanged or increased.[47,49] In general, anesthetic effects on ICP via changes in CSF dynamics are clinically far less important than anesthetic effects on CBF.

Cerebral Blood Flow Response to Hyper- and Hypocarbia

Significant hypercapnia is associated with dramatic increases in CBF whether volatile anesthetics are administered or not. As discussed earlier, hypocapnia can blunt or abolish volatile anesthetic-induced increases in CBF depending on when the hypocapnia is produced. This vasoreactivity to CO_2 may be somewhat altered by the volatile anesthetics as compared to normal. Neither isoflurane nor halothane abolish hypocapnic vasoconstriction, and at least two studies suggest that halothane actually enhances CO_2 reactivity.[32,50] CO_2 vasoreactivity under desflurane anesthesia is normal up to 1.5 MAC,[51] and CO_2 vasoreactivity for sevoflurane is preserved at 1 MAC.[52]

Cerebral Protection

Because all of the potent agents significantly depress CMR, one might reason that they all could offer some degree of neuroprotection. Unfortunately, this is not the case. In halothane anesthetized dogs, focal ischemia caused by middle cerebral artery occlusion led to larger infarct size and worse neurological outcome than for awake animals.[53] Fortunately the well-known neuroprotective effects of pentobarbital are preserved with halothane since pentobarbital coadministration minimized the pathological and functional damage.[54]

In comparison, isoflurane may provide neuroprotective effects in both mice and dogs during hypoxemia or ischemia.[55,56] In one study, cerebral hypoperfusion secondary to hypotension from isoflurane was associated with better tissue oxygen content than during hypotension by other means, consistent with the profound decrease in $CMRO_2$ seen with isoflurane.[57] The most compelling evidence for an advantage of isoflurane over halothane for neuroprotection was shown in two studies of human carotid endarterectomy surgery. In these patients, not only was the incidence of ischemic EEG changes less using isoflurane than halothane,[58] but ischemic EEG changes occurred at a lower CBF with isoflurane than with halothane.[59]

Both sevoflurane and desflurane have been shown to improve neurological outcome in comparison to N_2O-fentanyl after incomplete cerebral ischemia in a rat model.[60,61] In piglets undergoing low-flow cardiopulmonary bypass, desflurane improved neurologic outcome compared to a fentanyl/droperidol-based anesthetic.[62] In humans, desflurane has been shown to increase brain tissue PO_2 during administration, and to maintain PO_2 to a greater extent than thiopental during

temporary cerebral artery occlusion during cerebrovascular surgery.[63] Human neuroprotection outcome studies for sevoflurane and desflurane have not been published. Interpretation of the published data suggests that surgical cases in which temporary cerebral arterial occlusion is planned or probable would benefit more from isoflurane, sevoflurane, or desflurane than halothane anesthesia, but further studies are necessary.

Nitrous Oxide

The effects of nitrous oxide on cerebral physiology are not clear. Both the MAC for N_2O and its effects on CMR vary widely depending on species. The difference in CMR effects may in part be accounted for by differences in MAC, but MAC-equivalent effects on CMR also differ. In several studies in dogs, goats, and swine N_2O causes an increase in $CMRO_2$ and CBF, while in rodents no such increases or only slight increases occur. In human studies, N_2O administration preserved CBF but decreased $CMRO_2$.[38]

Another problem is the fact that N_2O is a coanesthetic used to supplement potent agents, not a complete anesthetic in itself, and CMR effects may differ depending on presence or absence of potent agent as well as the particular agent and dose. N_2O causes a greater increase in CBF and CMR in dogs at 0.2% halothane than at 0.8% halothane. In contrast, addition of N_2O to 1 or 2.2 MAC isoflurane does not alter $CMRO_2$, but does increase CBF at 1 MAC and not 2.2 MAC.

Barbiturates, narcotics, or a combination of the two appear to decrease or eliminate the increases in CMR and CBF produced by N_2O. The effect of pentobarbital/N_2O is dose dependent, with preserved increases in CMR by N_2O at low-dose pentobarbital, and no changes in CMR at high-dose pentobarbital.[64] N_2O and benzodiazepine coadministration is particularly confusing. Midazolam/N_2O in dogs increased CBF but did not alter $CMRO_2$[65] while the opposite was true in rats,[66] and both CBF and $CMRO_2$ declined in rats given diazepam/N_2O. N_2O administration increases ICP, but as is the case for CMR and CBF, changes in ICP are decreased or eliminated by a variety of co-anesthetics and more importantly by hypocapnia.

N_2O appears to have an antineuroprotective effect, as addition of N_2O to isoflurane during temporary ischemia is associated with greater tissue damage and worsened neurologic outcome.[66] In a study in mice, survival time after a hypoxic event was decreased by addition of N_2O.[68] Given the conflicting data on the effects of N_2O on CMR, CBF, ICP, and the apparent antineuroprotective effect of this agent, avoidance or discontinuation of its use should be considered in surgical cases with a high likelihood of elevated ICP or significant cerebral ischemia.

THE CIRCULATORY SYSTEM

Hemodynamics

The cardiac, vascular and autonomic effects of the volatile anesthetics have been carefully defined by a number of studies carried out in human volunteers not undergoing surgery.[69,70,71,72,73,74,75] In general, the information from these volunteer studies has translated well to the patient population commonly exposed to these anesthetics during elective and emergent surgeries. There are clearly factors such as interactions with anesthetic adjuvants and altered responses because of underlying disease that modify the circulatory effects of the volatile anesthetics.

A common effect of the potent volatile anesthetics has been a dose-related decrease in arterial blood pressure, with essentially no differences between the volatile anesthetics at steady-state, equi-anesthetic concentrations (Fig. 15-14). However, the mechanism by which they decrease arterial blood pressure is somewhat more specific for each anesthetic. Halothane is most noted for its decrease in cardiac output and this contributes importantly to its blood pressure lowering effect (Fig. 15-15).[76] The mechanism by which halothane decreases cardiac output is primarily a result of a profound depression of myocardial contractility and has been associated with an increase in right atrial pressure (see Fig. 15-15).[77] This contrasts to the newer volatile anesthetics, desflurane, sevoflurane, and isoflurane, which are known to maintain cardiac

output.[73,78] Their primary mechanism to decrease blood pressure with increasing dose is related to their potent effects on regional and systemic vascular resistance (see Fig. 15-15). Enflurane falls somewhere between halothane and the newer volatile anesthetics in terms of its effects on cardiac output and peripheral resistance.

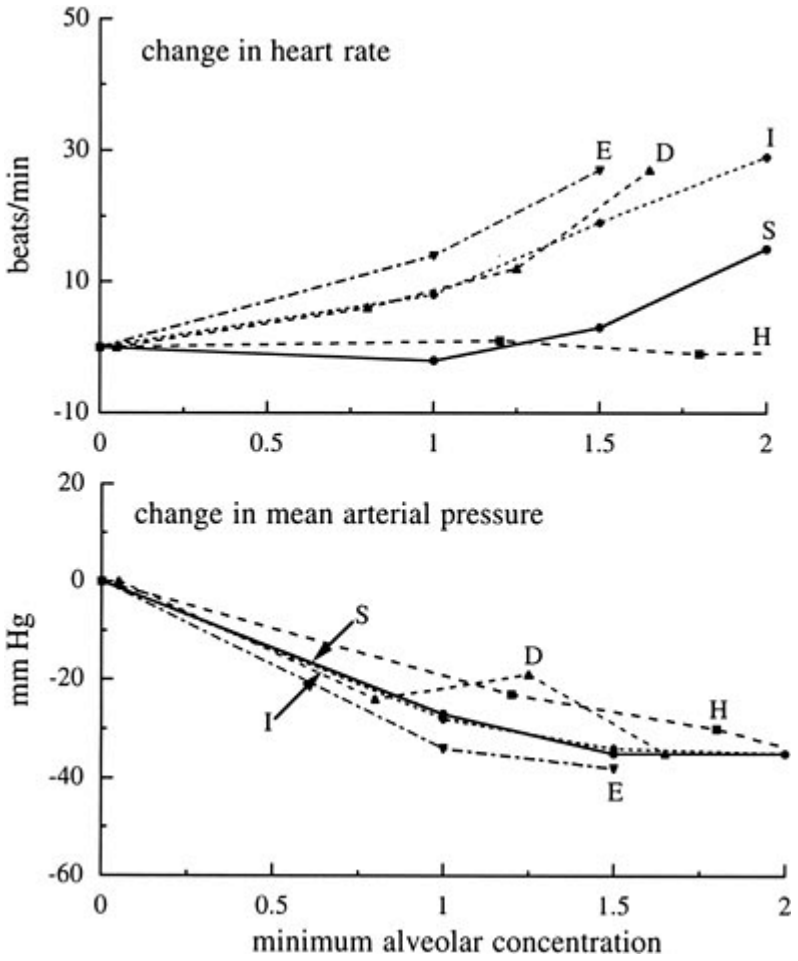

FIGURE 15-14. Heart rate and blood pressure changes (from awake baseline) in volunteers receiving general anesthesia with a potent anesthetic. Halothane and sevoflurane produced little change in heart rate at less than 1.5 MAC. All anesthetics caused similar decreases in blood pressure. (Adapted from Malan TP Jr, DiNardo JA, Isner RJ *et al*: Cardiovascular effects of sevoflurane compared with those of isoflurane in volunteers. Anesthesiology 83:918, 1995; Weiskopf RB, Cahalan MK, Eger EI II *et al*: Cardiovascular actions of desflurane in normocarbic volunteers. Anesth Analg 73:143, 1991; and Calverley RK, Smith NT, Prys-Roberts C *et al*: Cardiovascular effects of enflurane anesthesia during controlled ventilation in man. Anesth Analg 57:619, 1978.)

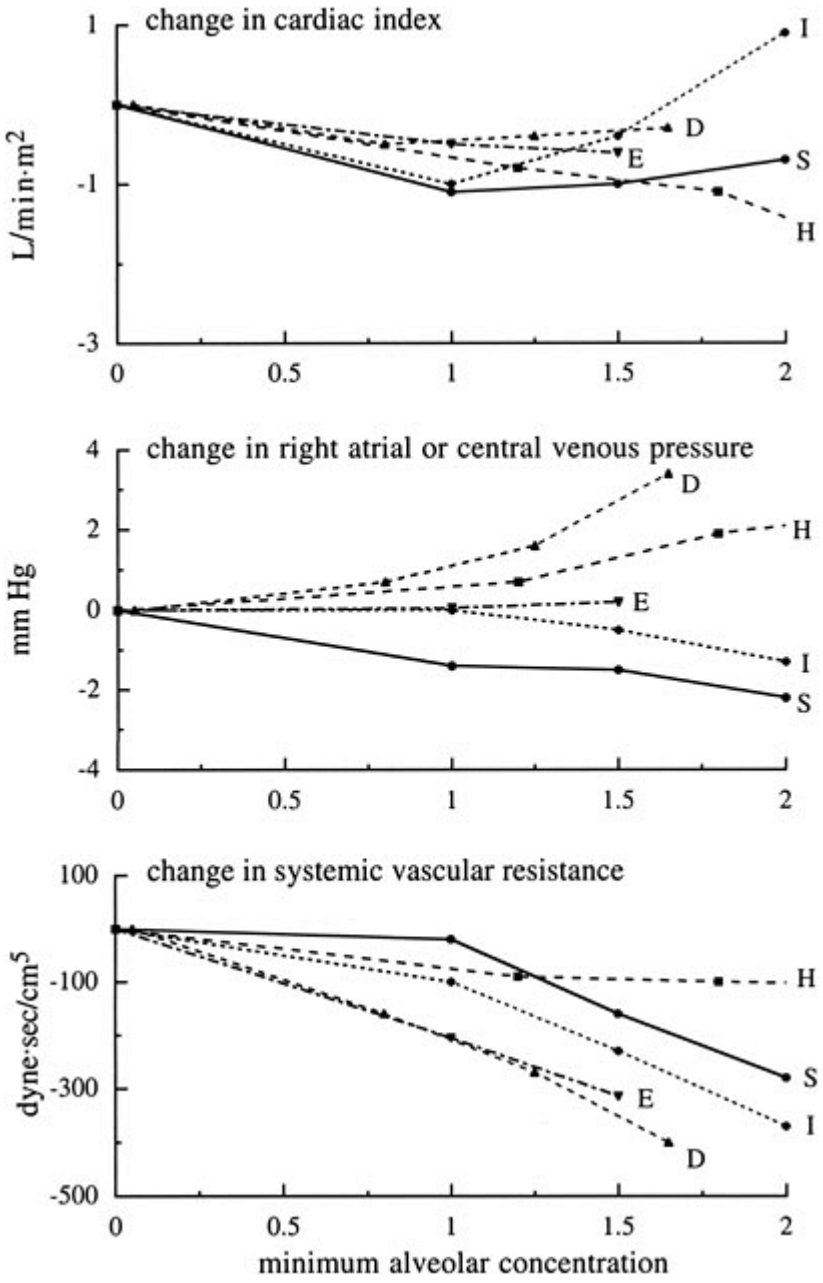

FIGURE 15-15. Cardiac index, systemic vascular resistance, and central venous pressure (or right atrial pressure) changes (from awake baseline) in volunteers receiving general anesthesia with a potent anesthetic. Increases in central venous pressure from halothane and desflurane might be because of different mechanisms. With halothane, the increase might be because of myocardial depression, whereas with desflurane, the increase is more likely because of venoconstriction. (Adapted from Malan TP Jr, DiNardo JA, Isner RJ, et al: Cardiovascular effects of sevoflurane compared with those of isoflurane in volunteers. Anesthesiology 83:918, 1995; Weiskopf RB, Cahalan MK, Eger EI II, et al: Cardiovascular actions of desflurane in nonmocarbic volunteers. Anesth Analg 73:143, 1991; and Calverley RK, Smith NT, Prys-Roberts C, et al: Cardiovascular effects of enflurane anesthesia during controlled ventilation in man. Anesth Analg 57:619, 1978.).

5 In terms of the effects of the volatile anesthetics on heart rate, data from animal studies indicate that desflurane consistently increases heart rate,[79,80] whereas sevoflurane provides a relatively stable heart rate.[81] In volunteers, sevoflurane and halothane up to about 1 MAC result in minimal, if any, changes in steady-state heart rate (see Fig. 15-14). This contrasts to both enflurane and isoflurane, which have been associated with an increase in heart rate of 10 to 20% at 1 MAC. At anesthetic levels greater than 1 MAC, desflurane has been associated with an

increase in heart rate to equal that of isoflurane.[82] This is generally reflected as a 10 to 15 beats/min increase in heart rate. Both desflurane and, to a lesser extent, isoflurane have been associated with transient and significant increases in heart rate during rapid increases in the inspired concentration of either anesthetic.[82] Although the mechanism(s) underlying these transient heart rate surges are not known, it is conjectured that the relative pungency of these anesthetics activates airway receptors leading to a reflex tachycardia.[83] This tachycardia can be lessened with fentanyl, alfentanil or clonidine pretreatment.[84,85,86]

Myocardial Contractility

Myocardial contractility indices have been directly evaluated in animals and indirectly evaluated in humans during the administration of each of the volatile anesthetics.[87] The older anesthetics, halothane and enflurane, have been studied in humans using a relatively imprecise technique called ballistocardiography, which permits an indirect measure of contractility (IJ amplitude). At 1 MAC, enflurane caused a 40% decrease in IJ amplitude, whereas halothane caused a 30% decrease in IJ amplitude.[69,70] At 1.5 MAC, greater depression of myocardial contractility was noted for both volatile anesthetics. These changes were noted in conjunction with approximately 20% decreases in cardiac output at 1 MAC halothane and enflurane. Animal and human studies indicate that the myocardial depression from halothane is greater than isoflurane and enflurane. In contrast, human studies with the newer volatile anesthetics, isoflurane, sevoflurane, and desflurane, have not demonstrated significant changes in echocardiographic-determined indices of myocardial function, including the more noteworthy measurement of the velocity of circumferential fiber shortening (Fig. 15-16). More precise indices of myocardial contractility have been obtained for sevoflurane, isoflurane, and desflurane in chronically instrumented dogs after autonomic innervation of the heart was pharmacologically blocked. These studies of the direct myocardial effects of the volatile anesthetics demonstrate that isoflurane, desflurane, and sevoflurane cause dose-dependent depression of myocardial function with no differences between the three anesthetics (Fig. 15-17). Thus, the direct effect of volatile anesthetics is a dose-dependent myocardial depression; however, halothane and enflurane have greater effects on myocardial contractility than do isoflurane, sevoflurane, and desflurane.

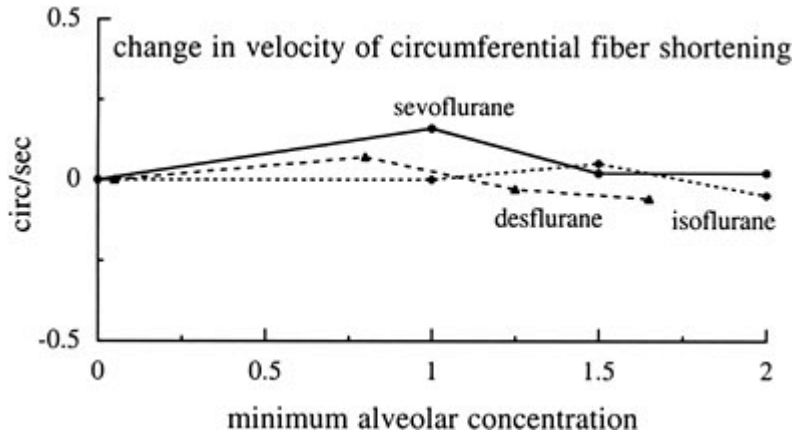

FIGURE 15-16. Noninvasive assessment of myocardial contractility with echocardiography during anesthesia in volunteers. Sevoflurane, desflurane, and isoflurane did not cause changes suggestive of myocardial depression. (Adapted from Malan TP Jr, DiNardo JA, Isner RJ, et al: Cardiovascular effects of sevoflurane compared with those of isoflurane in volunteers. Anesthesiology 83:918, 1995; Weiskopf RB, Cahalan MK, Eger EI II, et al: Cardiovascular actions of desflurane in normocarbic volunteers. Anesth Analg 73:143, 1991; and Calverley RK, Smith NT, Prys-Roberts C, et al: Cardiovascular effects of enflurane

anesthesia during controlled ventilation in man. Anesth Analg 57:619, 1978.)

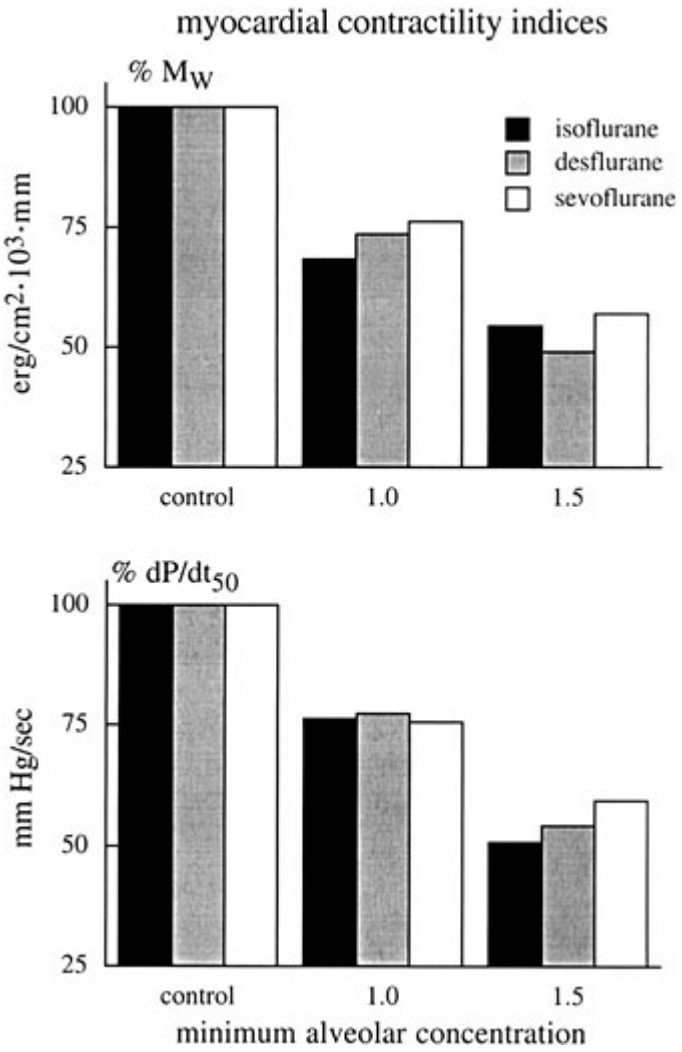

FIGURE 15-17. Myocardial contractility indices from chronically instrumented dogs. For these measurements, pharmacologic blockade of the autonomic nervous system was established to eliminate neural or circulating humoral influences on the inotropic state of the heart. The conscious control data were assigned 100%, and subsequent reductions in the inotropic state are depicted for both 1 and 1.5 minimum alveolar anesthetic concentrations of sevoflurane, desflurane, and isoflurane. There were no differences between these three volatile anesthetics. M_w, slope of the regional preload recruitable stroke work relationship; dP/dt_{50}, change in pressure per unit of time. (Adapted from Pagel PS, Kampine JP, Schmeling WT *et al*: Influence of volatile anesthetics on myocardial contractility in vivo: Desflurane versus isoflurane. Anesthesiology 74:900, 1991; and Harkin CP, Pagel PS, Kersten JR *et al*: Direct negative inotropic and lusitropic effects of sevoflurane. Anesthesiology 81:156, 1994.)

Other Circulatory Effects

The majority of the volatile anesthetics have been studied during both controlled and spontaneous ventilation.[71,73,88] The process of spontaneous ventilation reduces the high intrathoracic pressures from positive pressure ventilation. The negative intrathoracic pressure during the inspiratory phase of spontaneous ventilation augments venous return and cardiac filling and improves cardiac output and, hence, blood pressure. A second result of spontaneous ventilation is higher $PaCO_2$,

and this change causes cerebral and systemic vascular relaxation and further contributes to an improved cardiac output via afterload reduction. Thus, spontaneous ventilation decreases systemic vascular resistance and increases heart rate, cardiac output, and stroke volume as contrasted to positive pressure ventilation. It has been suggested that spontaneous ventilation might improve the safety of inhaled anesthetic administration, because the concentration of a volatile anesthetic that produces cardiovascular collapse exceeds the concentration resulting in apnea.

A curious observation with the potent volatile anesthetics has been an alteration in the cardiovascular effects during prolonged anesthetic exposures, noted as a small increase in heart rate and cardiac index, a gradual decrease in systemic vascular resistance, and no change in myocardial indices.[72,73] Activation

of beta-sympathetic receptors has been suggested as a mechanism contributing to the increased heart rate and cardiac output from prolonged anesthesia with halothane; however, this possibility has been questioned based on recent studies with prolonged exposure to desflurane anesthesia.[72]

Nitrous oxide is commonly combined with potent volatile anesthetics to maintain general anesthesia. Nitrous oxide has unique cardiovascular actions.[75,89] It increases sympathetic nervous system activity and vascular resistance when given in a 40% concentration.[89] When nitrous oxide is combined with volatile anesthetics and compared to equipotent concentrations of the volatile anesthetic without nitrous oxide, there still is evidence of sympathetic nervous system activation, with an increased systemic vascular resistance and an improved arterial pressure with little effect on cardiac output.[73] Part of these effects might not be because of the nitrous oxide per se, but may simply be attributed to a decrease in the concentration of the co-administered potent volatile anesthetic to achieve a MAC equivalent when using nitrous oxide.

Oxygen consumption is decreased approximately 10 to 15% during general anesthesia. The distribution of cardiac output also is altered by anesthesia. Blood flow to liver, kidneys, and gut is decreased, particularly at deep levels of anesthesia. In contrast, blood flow to the brain, muscle, and skin is increased or not changed during general anesthesia.[79,90] In humans, increases in muscle blood flow are noted with isoflurane, desflurane, and sevoflurane with very small differences between anesthetics at equipotent concentrations.[91]

In contrast to halothane, the ether-based anesthetics (isoflurane, enflurane, sevoflurane, and desflurane) have not predisposed patients to ventricular arrhythmias, nor sensitized the heart to the arrhythmogenic effects of epinephrine (Fig. 15-18). The use of IV lidocaine can lessen the epinephrine effect during halothane anesthesia. Some of the differences between volatile anesthetics in their ability to promote arrhythmias can be attributed to their direct effects on cardiac pacemaker cells and conduction pathways.[92] SA node discharge rate is slowed by the volatile anesthetics and conduction in the His-Purkinje system and conduction pathways in the ventricle are also prolonged by the volatile anesthetics.[92] A greater slowing by halothane over isoflurane in the His-Purkinje system might promote dysrhythmias via a reentry phenomena.

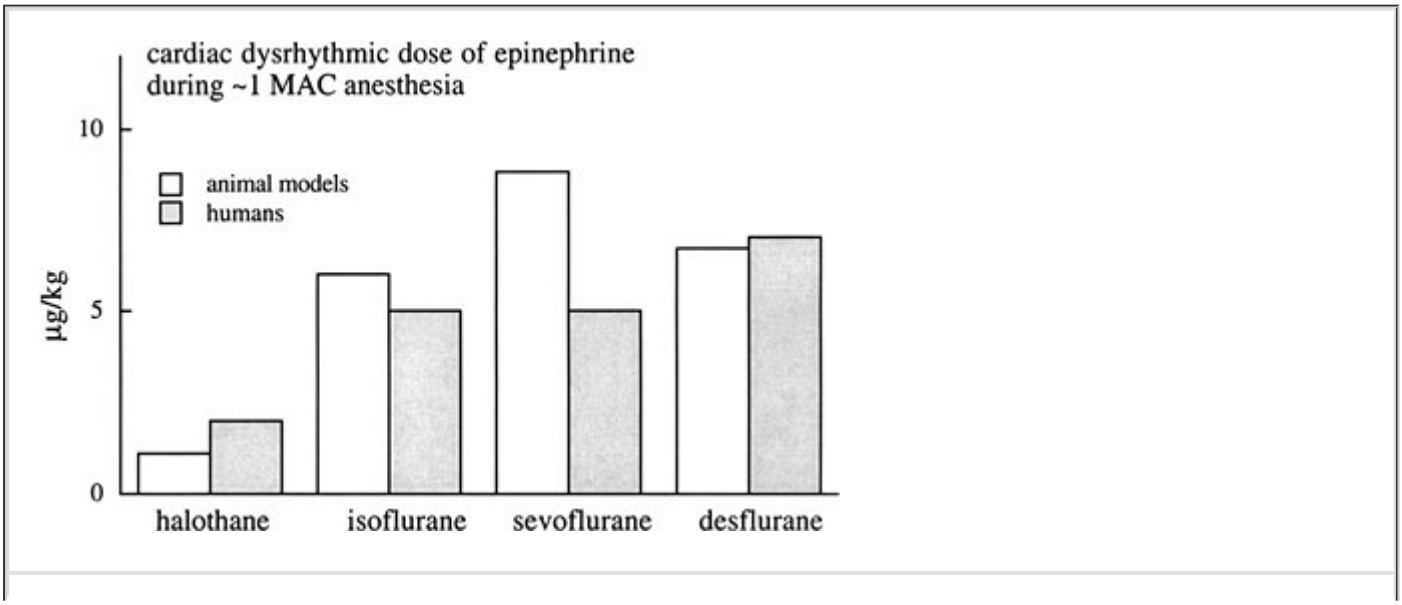

FIGURE 15-18. The dose of epinephrine associated with cardiac arrhythmias in animal and human models was least with halothane. The ether anesthetics, isoflurane, desflurane, and sevoflurane, required 3- to 6-fold greater doses of epinephrine to cause arrhythmias. (Adapted from Navarro R, Weiskopf RB, Moore MA, et al: Humans anesthetized with sevoflurane or isoflurane have similar arrhythmic response to epinephrine. Anesthesiology 80:545, 1994; Weiskopf RB, Eger EI II, Holmes MA, et al: Epinephrine-induced premature ventricular contractions and changes in arterial blood pressure and heart rate during I-653, isoflurane, and halothane anesthesia in swine. Anesthesiology 70:293, 1989; Hayashi Y, Sumikawa K, Tashiro C, et al: Arrhythmogenic threshold of epinephrine during sevoflurane, enflurane, and isoflurane anesthesia in dogs. Anesthesiology 69:145, 1988; and Moore MA, Weiskopf RB, Eger EI II, et al: Arrhythmogenic doses of epinephrine are similar during desflurane or isoflurane anesthesia in humans. Anesthesiology 79:943, 1993.)

Coronary Steal

Because the potent volatile anesthetics relax vascular smooth muscle and lead to vasodilation, there has been a concern related to abnormal distribution of blood flow in coronary blood vessels of patients with ischemic heart disease. This effect has been called coronary steal and became a concern with the introduction of isoflurane to clinical practice. Isoflurane (and most other potent volatile anesthetics) increases coronary blood flow many times beyond that of the myocardial oxygen demand, thereby creating potential for "steal." Steal is the diversion of blood from a myocardial bed with limited or inadequate perfusion to a bed with more adequate perfusion, especially one that has a remaining element of autoregulation. In instrumented animal models, the pronounced coronary vasodilation produced by isoflurane was shown to cause steal[93] and early

patient studies provided additional support.[94] However, more recent work in a chronically instrumented, canine model of multivessel coronary artery obstruction has shown that neither isoflurane, sevoflurane, nor desflurane at concentrations up to 1.5 MAC resulted in abnormal collateral coronary blood flow redistribution (steal), whereas adenosine, a potent coronary vasodilator, clearly resulted in abnormal flow distribution.[95,96,97] Interestingly, sevoflurane favorably increased (rather than decreased) collateral coronary blood flow in this instrumented animal model when aortic pressure was held constant (similar to what might be seen with systemic blood pressure support).[95]

Myocardial Ischemia and Cardiac Outcome

Not surprisingly, the clinical relevance of coronary steal with isoflurane has been debated and is generally thought to be minimal.[98] Outcome studies have failed to associate the use of isoflurane in patients undergoing coronary artery bypass operations with an increased incidence of myocardial infarction or perioperative death.[98,99] Most studies would suggest that determinants of myocardial oxygen supply and demand, rather than the anesthetic, are of far greater importance to patient outcomes.

Several studies have evaluated the two new anesthetics, sevoflurane and desflurane, to comparator anesthetics, in terms of myocardial ischemia and outcome in patients with coronary artery disease either undergoing noncardiac or coronary artery bypass graft (CABG) surgery.[100,101] In both populations, sevoflurane appears to be essentially equivalent to isoflurane in terms of the incidence of myocardial ischemia and adverse cardiac outcomes. Desflurane appears to result in similar outcome effects as isoflurane in cardiac patients having coronary artery bypass grafting,[102] with one exception. In a study where desflurane was given without opioids to patients with coronary artery disease requiring CABG surgery, significant ischemia mandating the use of beta-blockers was noted.[103] Desflurane has not been evaluated in terms of ischemia and outcome in a patient population with coronary disease undergoing noncardiac surgery.

Cardioprotection from Volatile Anesthetics

There is a new body of literature describing the potential for organ protective effects (particularly cardioprotective effects) of the potent inhaled agents.[104,105] Organ protection would be defined as "reducing tissue damage after hypoxic ischemia or toxic insult." A preconditioning stimulus of brief coronary occlusion and ischemia initiates a signaling cascade of intracellular events that reduces ischemia and reperfusion myocardial injury. There is a memory effect from an ischemic stimulus that offers 2 to 3 hours of protection. The volatile anesthetics mimic ischemic preconditioning and trigger a similar cascade of intracellular events resulting in myocardial protection that lasts beyond the elimination of the anesthetic. Numerous factors may be involved in preconditioning, including the sodium:hydrogen exchanger, the adenosine receptor (particularly a1 and a2 subtypes), inhibitory g proteins, protein kinase c, tyrosine kinase, and potassium (K_{ATP}) channel opening. Pharmacologic blockade of these factors, for example, with adenosine blockers, delta-1 opioids, pertussis toxin, or glibenclamide, reduces or eliminates the cardioprotective effect of ischemic preconditioning and of the volatile anesthetics.[106,107] Alternatively, administration of certain drugs can mimic ischemic or volatile anesthetic preconditioning. These include adenosine, opioid agonists, and K_{ATP} channel openers. In contrast to the inhalation of volatile anesthetics, these cardioprotective drugs must be given into a coronary artery because systemic administration has serious side effects.

Lipophilic volatile anesthetics diffuse through myocardial cell membranes and alter mitochondrial electron transport leading to reactive oxygen species formation.[107] This may be the trigger for preconditioning via protein kinase C activation of K_{ATP} channel opening.[108] Approximately 30 to 40% of the cardioprotection from the volatile anesthetics appears to be related to a reduced loading of calcium into the myocardial cells during ischemia.[105] Preconditioned hearts may tolerate ischemia for 10 minutes longer than nonconditioned hearts.[109] While these evolving data generally derive from animal models, there now is increasing evidence in cardiac patient populations that anesthetic cardioprotection lessens myocardial damage (based on troponin levels) during "on and off pump" cardiac surgery.[110] This effect seems to be common to all current-day potent volatile anesthetics and may favorably influence ICU length of stay after coronary surgery.[111]

Sulfonylurea oral hyperglycemic drugs close K_{ATP} channels abolishing anesthetic preconditioning. They should be discontinued 24 to 48 hours prior to elective surgery in high-risk patients.[106] But hyperglycemia also prevents preconditioning, so insulin therapy should be started when holding oral agents.[112]

Autonomic Nervous System

Studies that have focused on the efferent activity of the parasympathetic and sympathetic nervous systems indicate that the volatile anesthetics depress their activity in a dose-dependent fashion.[113,114] However, because the autonomic nervous system (ANS) is importantly modulated by baroreceptor reflex mechanisms, the effects of the anesthetic on the efferent system cannot be reported without taking into account their effects on different components of the baroreflex arc. Thus, although both limbs of the autonomic nervous system have been shown to be attenuated by the anesthetics, the afferent activity from the arterial baroreceptors has been found to be increased with some of the anesthetics, including halothane and isoflurane.[113,115,116] This increased discharge of the baroreceptors actually contributes to the depression of the entire baroreflex arc by tonically lowering the overall level of the outflow of the sympathetic nervous system. From the perspective of clinical relevance, studies have examined the behavior of arterial baroreflex system during a hypotensive or hypertensive stimulus by evaluating changes in heart rate and sympathetic nerve activity. The arterial baroreflex is the most rapid system responding to blood pressure perturbations. Early investigations focused primarily on the regulation of heart rate (and this reflects primarily a vagally mediated end point). Halothane, enflurane, and isoflurane[117,118] all depress, in a dose-dependent fashion, the arterial baroreflex control of heart rate, although there was a suggestion that isoflurane had less of a prominent effect than halothane or enflurane.[117] Similar effects on the reflex control of heart rate have recently been

demonstrated with sevoflurane and desflurane (Fig. 15-19).[119,120,121]

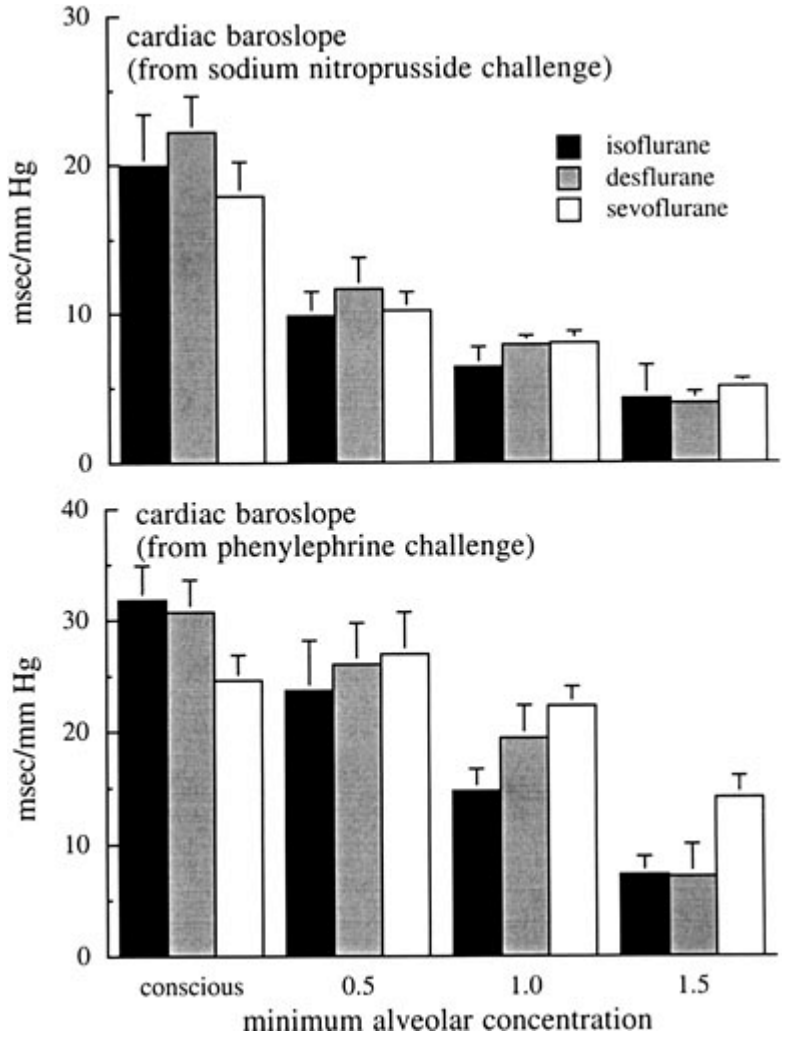

FIGURE 15-19. Summary data of the baroreflex regulation of heart rate (R-R interval) in response to a decreasing pressure stimulus (sodium nitroprusside) or in response to an increasing pressure stimulus (phenylephrine). These data were acquired in healthy volunteers who were randomized to receive isoflurane, desflurane, or sevoflurane. With increasing minimum alveolar anesthetic concentration (MAC), each of the volatile anesthetics led to a progressive reduction in the cardiac baroslope (an index of baroreflex sensitivity derived by relating changes in mean pressure to changes in R-R interval). There were no statistical differences between anesthetics. (Adapted from Ebert TJ, Harkin CP, Muzi M: Cardiovascular responses to sevoflurane: A review. Anesth Analg 81:S11, 1995.)

There is greater difficulty in evaluating the sympathetic component of the baroreflex arc in humans, but a technique called sympathetic microneurography has been utilized to directly record vasoconstrictor impulses directed to blood vessels in humans.[74,82] There is a dose-dependent depression of the reflex control of sympathetic outflow that appears to be relatively equivalent for isoflurane, sevoflurane, and desflurane (Fig. 15-20). Importantly, at low levels of anesthesia, for example, 0.5 MAC, there is little if any depression of reflex function and this might have important implications in the compromised patient population. Opioid and benzodiazepine adjuvants have only minimal effects on reflex function and combining these with low levels of potent anesthetics might preserve reflex function.[122,123] Another important observation has been the more rapid return of baroreflex function with the less-soluble anesthetic sevoflurane versus isoflurane.[124] This might add to hemodynamic stability in the postoperative period when tissue concentrations of the volatile anesthetics are declining.

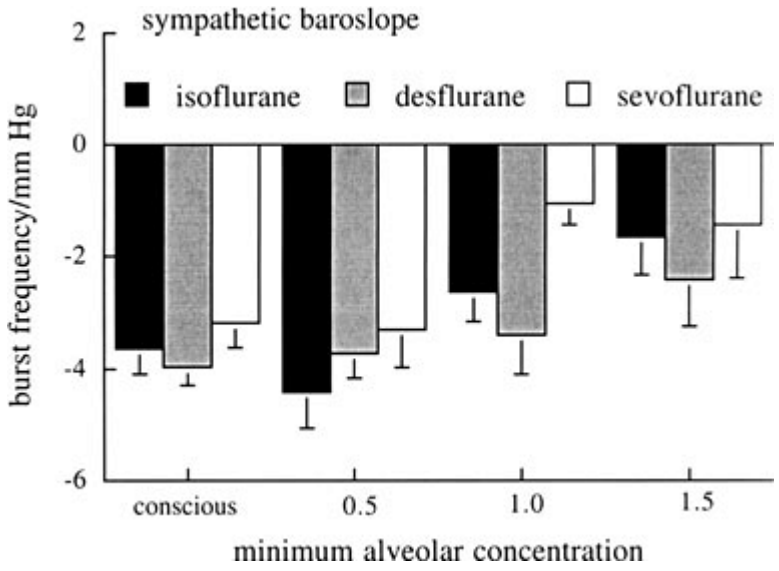

FIGURE 15-20. The sympathetic baroreflex function of healthy volunteers randomized to receive isoflurane, desflurane, or sevoflurane. The slope (sensitivity) is the relationship between decreasing diastolic pressure and increasing efferent sympathetic nerve activity. The reflex regulation of sympathetic outflow was fairly well preserved at 0.5 and 1.0 minimum alveolar anesthetic concentration (MAC) of anesthetic. At 1.5 MAC, there was a 50% decrease in the slope with all anesthetics. (Adapted from Ebert TJ, Harkin CP, Muzi M: Cardiovascular responses to sevoflurane: A review. Anesth Analg 81:S11, 1995.)

Desflurane has a unique and prominent effect on sympathetic outflow in humans, which is not apparent in animal models. With increasing steady-state concentrations of desflurane, there is a progressive increase in resting sympathetic nervous system activity and plasma norepinephrine levels.[74,82,125] Despite this increase in tonic sympathetic outflow, blood pressure decreases similarly to sevoflurane and isoflurane. This raises the question as to whether desflurane has the ability to uncouple neuroeffector responses. In addition, desflurane can cause marked activation of the sympathetic nervous system when the inspired concentration is increased, especially to concentrations above 5 to 6% (Fig. 15-21).[74,82,125] There is a transient surge in sympathetic outflow leading to both hypertension and tachycardia. In addition, the endocrine axis is activated as evidenced by 15- to 20-fold increases in plasma antidiuretic hormone and epinephrine (Fig. 15-22). The hemodynamic response persists for 4 to 5 minutes and the endocrine response persists for 15 to 25 minutes. Adequate concentrations of opioids or clonidine given prior to increasing the concentration of desflurane have been shown to attenuate these responses.[84,85,86] The source of the neuroendocrine activation has been actively sought, and it would appear that there are receptors in both the upper and the lower airways, and/or perhaps in a highly perfused tissue near the airways, that initiates the sympathetic activation.[83] The possibility that desflurane activates airway

irritant receptors is quite strong, since desflurane is the most pungent of the anesthetics available for clinical use.[126]

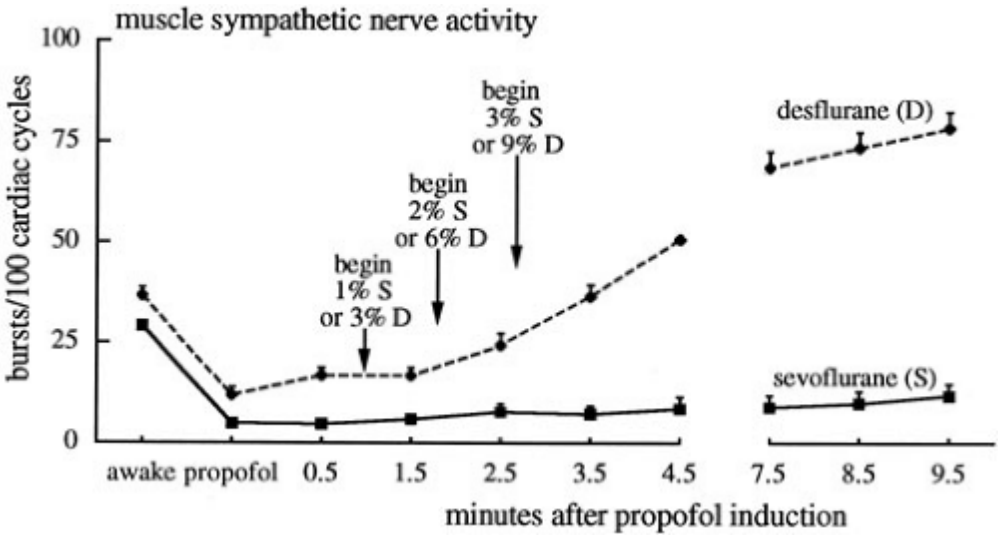

FIGURE 15-21. Consecutive measurements of sympathetic nerve activity (SNA)(mean ± SE) from human volunteers during induction of anesthesia with propofol and the subsequent mask administration of sevoflurane or desflurane for a 10-minute period. The inspired concentration of these anesthetics was increased at 1-minute intervals beginning precisely 2 minutes after propofol administration (0.41 MAC of sevoflurane and desflurane). In both groups, propofol reduced SNA and MAP. Desflurane resulted in significant increases in sympathetic nerve activity that persisted throughout the 10-minute mask administration period. (Adapted from Ebert TJ, Muzi M, Lopatka CW: Neurocirculatory responses to sevoflurane in humans. A comparison to desflurane. Anesthesiology 83:88, 1995.)

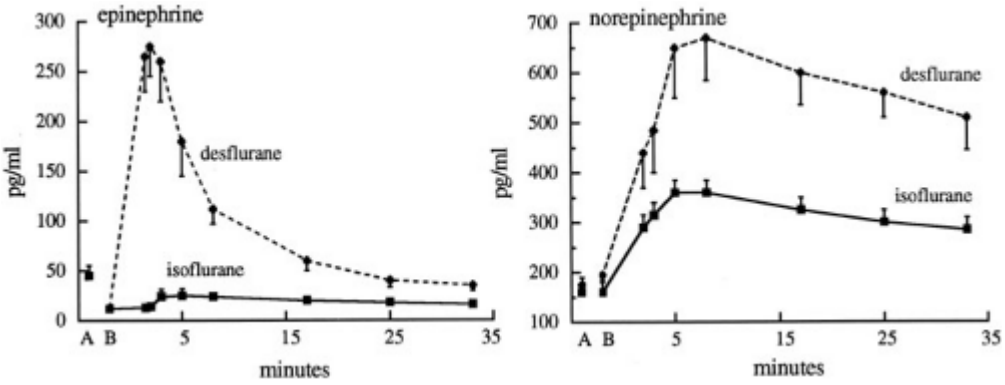

FIGURE 15-22. Stress hormone responses to a rapid increase in anesthetic concentration, from 4 to 12% inspired. Volunteers given desflurane showed a larger increase in plasma epinephrine and norepinephrine concentrations than when given isoflurane. Data are mean ± SE. A, awake value; B, value after 32 minutes of 0.55 MAC; time represents minutes after the first breath of increased anesthetic concentration. (Adapted from Weiskopf RB, Moore MA, Eger EI II *et al*: Rapid increase in desflurane concentration is associated with greater transient cardiovascular stimulation than with rapid increase in isoflurane concentration in humans. Anesthesiology 80:1035, 1994.)

THE PULMONARY SYSTEM

The volatile anesthetics have multiple and important effects on many aspects of pulmonary physiology, including respiratory rate and tidal volume, responses to CO_2 and hypoxia, effects on bronchiolar smooth muscle tone, and mucociliary function. Less pronounced, but still important effects of the volatile anesthetics have been observed on pulmonary vascular resistance and pulmonary blood flow.

General Ventilatory Effects

All volatile anesthetics decrease tidal volume but have lesser effects on decreasing minute ventilation because of an offsetting

response to increase respiratory rate (Fig. 15-23). These effects are dose dependent, with higher concentrations of volatile anesthetics, resulting in greater decreases in tidal volume and greater increases in respiratory rate. Their net effect of a gradual decrease in minute ventilation has been associated with increasing resting $PaCO_2$. The relative increases in $PaCO_2$ as an index of respiratory depression with volatile anesthetics evaluated at less than 1.24 MAC are as follows: enflurane > desflurane = isoflurane > sevoflurane = halothane. The respiratory depression can be partially antagonized during surgical stimulation where respiratory rate has been shown to increase, resulting in a decrease in the $PaCO_2$ (Fig. 15-24). In addition, resting $PaCO_2$ during desflurane or sevoflurane anesthesia is significantly decreased (returned toward normal) with the addition of nitrous oxide. This comparison (with and without nitrous oxide) requires a lessening of the potent volatile anesthetic to maintain an equi-MAC concentration when adding nitrous oxide to the inspired gas and this probably contributes to the return of $PaCO_2$ toward normal. The degree of respiratory depression from inhaled anesthetics may be lessened during prolonged administration of the anesthetic.[127]

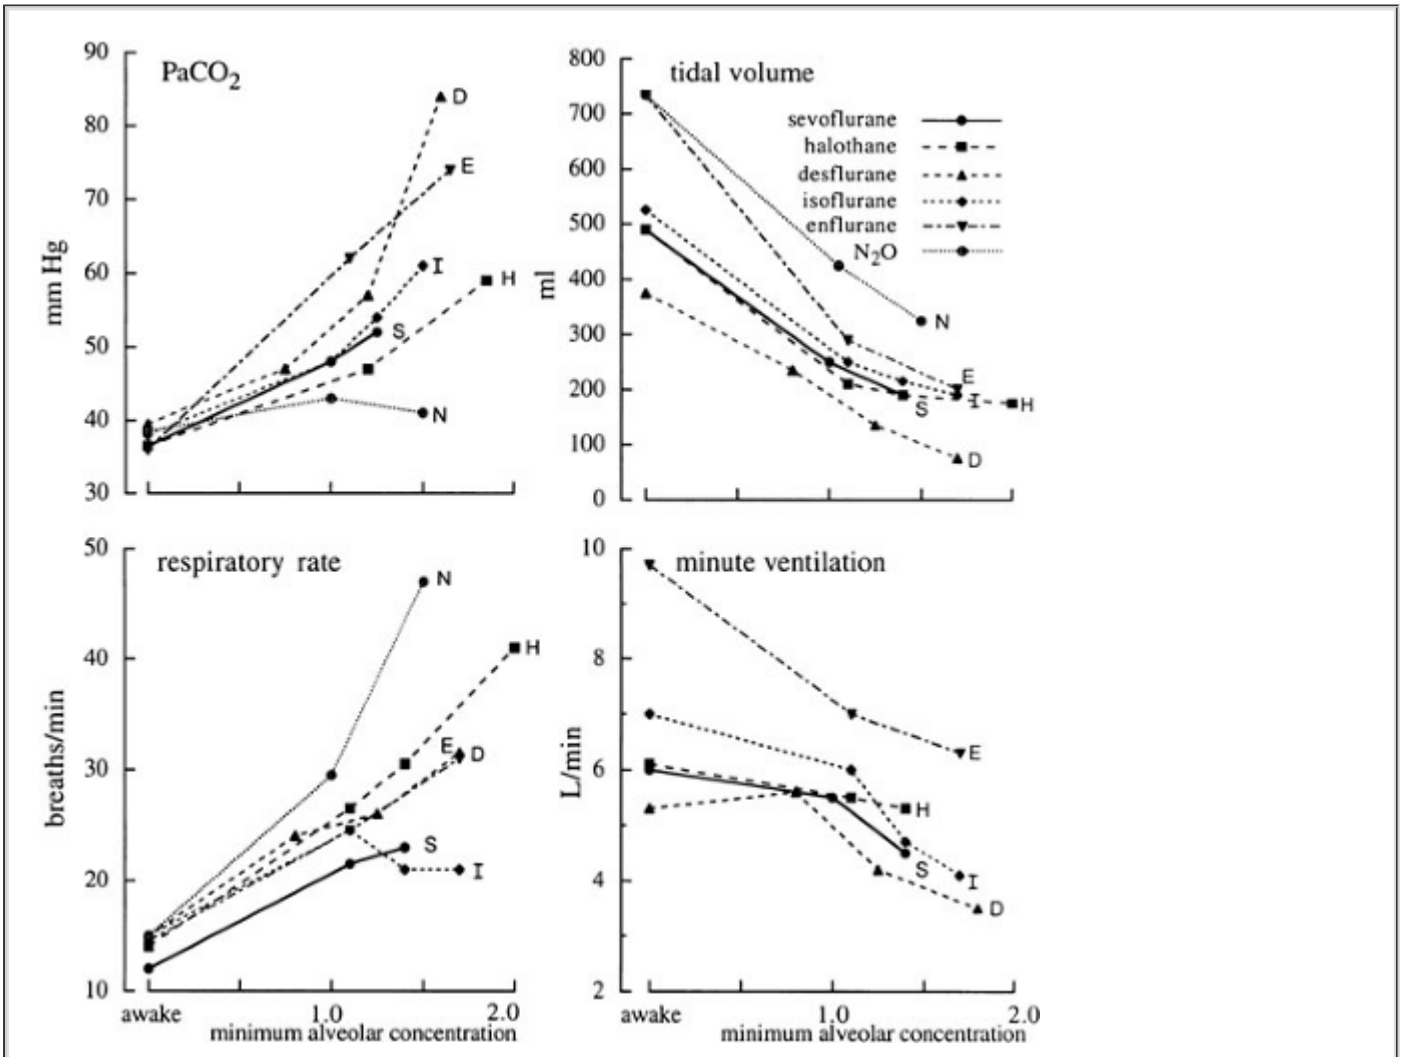

FIGURE 15-23. Comparison of mean changes in resting $PaCO_2$, tidal volume, respiratory rate, and minute ventilation in patients anesthetized with either halothane, isoflurane, enflurane, sevoflurane, desflurane, or nitrous oxide. Anesthetic-induced tachypnea compensates in part for the ventilatory depression caused by all volatile anesthetics (decrease in minute ventilation and tidal volume and concomitant increase in $PaCO_2$). Desflurane results in the greatest increase in $PaCO_2$ with corresponding reductions in tidal volume and minute ventilation. Isoflurane, like all other inhaled agents, increases respiratory rate, but does not result in dose-dependent tachypnea. (Adapted from Lockhart SH, Rampil IJ, Yasuda N, et al: Depression of ventilation by desflurane in humans. Anesthesiology 74:484, 1991; Doi M, Ikeda K: Respiratory effects of sevoflurane. Anesth Analg 66:241, 1987; Fourcade HE, Stevens WC, Larson CP Jr, et al: The ventilatory effects of Forane, a new inhaled anesthetic. Anesth Analg 57:610, 1978.)

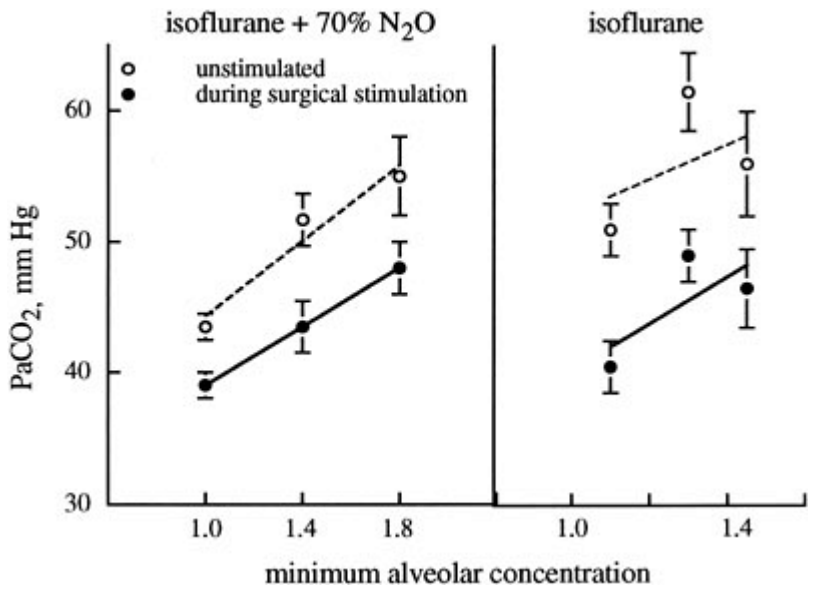

FIGURE 15-24. The effect of surgical stimulation on the ventilatory depression of inhaled anesthesia with isoflurane in the presence and absence of nitrous oxide. Surgical stimulation increased alveolar ventilation and decreased $PaCO_2$ at all depths of anesthesia examined. (Adapted from Eger EI II, Dolan WM, Stevens WC *et al*: Surgical stimulation antagonizes the respiratory depression produced by forane. Anesthesiology 36:544, 1972.)

Ventilatory Mechanics

Functional residual capacity is decreased during general anesthesia and this has been explained by a number of mechanisms, including a decrease in the intercostal muscle tone, alteration in diaphragm position, changes in thoracic blood volume, and the onset of phasic expiratory activity of respiratory muscles.[128,129,130] About 40% of the muscular work of breathing is via intercostal muscles and about 60% is from the diaphragm. The diaphragmatic muscle function is relatively spared when contrasted to the parasternal intercostal muscles.[128] However, inspiratory rib cage expansion is reasonably well maintained during anesthesia because of preserved activity of the scalene muscles.[128] Expiration is generally considered a passive function mediated by the elastic recoil of the lung. The process of applying a resistance or load to expiration typically results in a slowing of respiration but under anesthesia additional noted responses included a substantial

asynchrony of the thoracic movements with respiration.[131] This suggests that in patients with pulmonary disease associated with increased expiratory resistance, the act of spontaneous ventilation during general anesthesia might be associated with increased risk.

Response to Carbon Dioxide and Hypoxemia

In awake subjects a high sensitivity to CO_2 has been noted by increases in minute ventilation of approximately 3 L/min per 1 mm Hg increase in $PaCO_2$. It is mediated by central chemoreceptors and has been used as an index of ventilatory drive. All of the inhaled anesthetics produce a dose-dependent depression of the ventilatory response to hypercarbia (Fig. 15-25). Early studies suggested that the addition of nitrous oxide to halothane depressed ventilation less than an equi-MAC dose of halothane alone;[132] however, this does not appear to be the case for desflurane (see Fig. 15-25). During anesthesia with spontaneous ventilation, an apneic threshold can be determined that is generally 4 to 5 mm Hg below the prevailing resting $PaCO_2$, and this threshold is not related to the slope of the CO_2 response curves or to the level of the resting $PaCO_2$. The clinical relevance of this threshold may be important when assisting ventilation in an anesthetized patient who is breathing spontaneously. This only serves to lower the $PaCO_2$ to approach that of the apneic threshold, therefore mandating more control of ventilation.

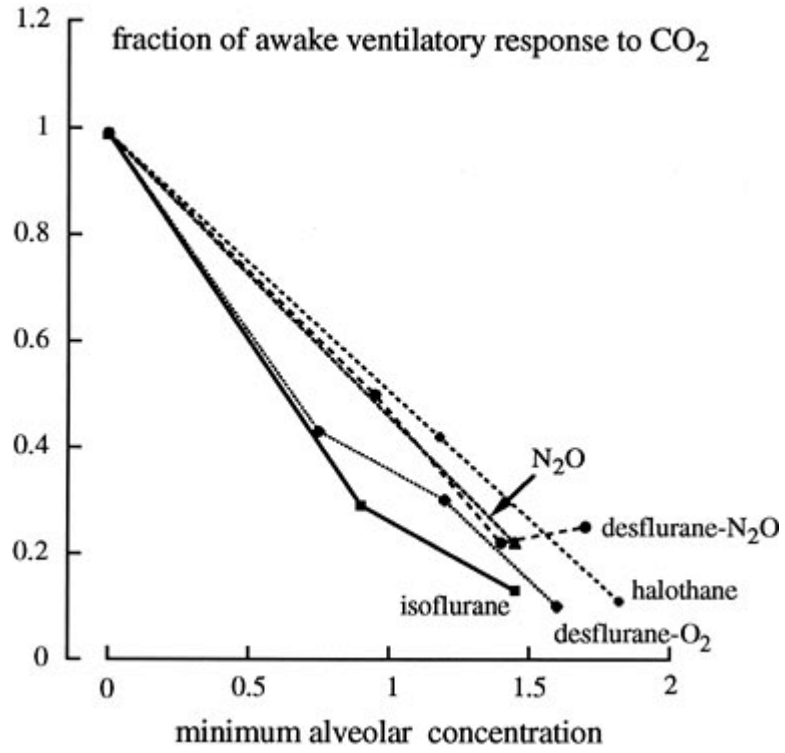

FIGURE 15-25. All inhaled anesthetics produce similar dose-dependent decreases in the ventilatory response to carbon dioxide. (Adapted from Eger EI II: Desflurane. Anesth Rev 20:87, 1993.)

Inhaled anesthetics, including nitrous oxide, also produce dose-dependent attenuation of the ventilatory response to hypoxia.[133,134] This action appears to be dependent on the peripheral chemoreceptors. In fact, even subanesthetic concentrations of volatile anesthetics (0.1 MAC) elicit anywhere from a 15 to 75% depression of the ventilatory drive to hypoxia (Fig. 15-26).[135] The mechanism of this depression still remains poorly understood. Studies have suggested that hypoxia may decrease the probability that potassium channels are open, thus causing membrane depolarization, influx of calcium ions, and release of neurotransmitters.[136] One theory is that the potassium channels are responding to reactive oxygen species, such as those formed as a result of halothane administration. In one study, the administration of antioxidants prior to the administration of halothane prevented the depression of the hypoxic

response.[137] The extreme sensitivity of the volatile anesthetics in terms of inhibiting hypoxic responsiveness has important clinical implications. Residual effects of volatile anesthetics may impair the ventilatory drive of patients in the recovery room. In this regard, the short-acting anesthetics (sevoflurane and desflurane) may prove advantageous because of their more rapid washout and their minimal effect on hypoxic sensitivity at subanesthetic concentrations (see Fig. 15-26). The effects of the volatile anesthetics on hypoxic drive may play an even more important role in patients who rely on hypoxic drive to set their level of ventilation, such as those with chronic respiratory failure.

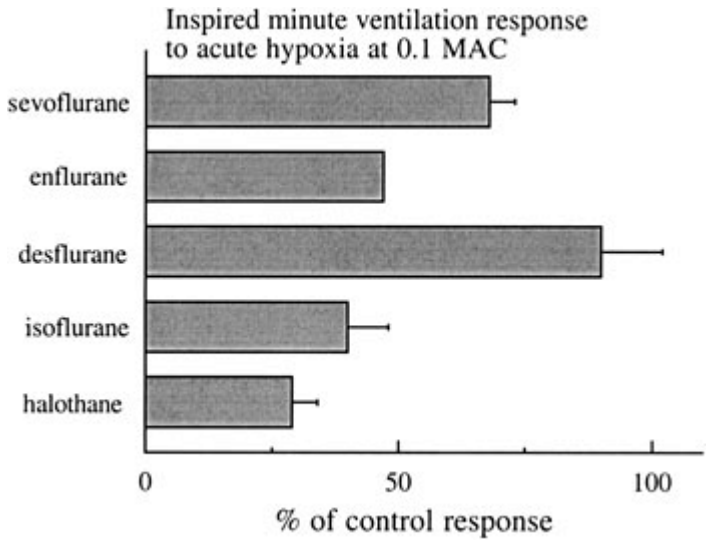

FIGURE 15-26. Influence of 0.1 MAC of five volatile anesthetic agents on the ventilatory response to a step decrease in end-tidal oxygen concentration. Values are mean ± SD. Subanesthetic concentrations of the volatile anesthetics, except desflurane and sevoflurane, profoundly depress the response to hypoxia. (Adapted from Sarton E, Dahan A, Teppema L *et al*: Acute pain and central nervous system arousal do not restore impaired hypoxic ventilatory responses during sevoflurane sedation. Anesthesiology 85:295, 1996.)

Bronchiolar Smooth Muscle Tone

Bronchoconstriction under anesthesia occurs because of direct stimulation of the laryngeal and tracheal areas and the administration of adjuvant drugs that cause histamine release, and from noxious stimuli especially in lightly anesthetized patients.[138] These responses are enhanced in patients with known reactive airway disease, (including those requiring bronchodilator therapy or those with chronic smoking histories). Airway smooth muscle, which extends as far distally as the terminal bronchioles, is under the influence of both parasympathetic and sympathetic nerves. The parasympathetic nerves mediate baseline airway tone and reflex bronchoconstriction, via an M3 muscarinic receptor on the airway smooth muscle that increases intracellular cyclic GMP. Adrenergic receptors also are located on bronchial smooth muscle with the beta-2 receptor subtype playing an important role in promoting bronchiolar muscle relaxation through an increase in intracellular cyclic-AMP. The volatile anesthetics relax airway smooth muscle by directly depressing smooth muscle contractility and indirectly by inhibiting the reflex neural pathways.[139] They also may have protective effects by acting on the bronchial epithelium via a nonadrenergic, noncholinergic mechanism, possibly involving the nitric oxide pathway.[140] A recent study in patients comparing isoflurane, halothane, and sevoflurane to a control group receiving thiopental indicated that sevoflurane may have a more rapid onset of bronchodilation than isoflurane or halothane.[141] Studies from our laboratory suggest that desflurane administration shortly after thiopental induction and tracheal intubation results in a transient increase in respiratory system resistance (bronchoconstriction), and we have attributed this to a direct effect from the pungency

and airway irritability of desflurane (Fig. 15-27). This effect is worsened in patients with an active smoking history. Volatile anesthetics have been used effectively to treat status asthmaticus when other conventional treatments have failed.[142] Although halothane has been successfully used in these situations, sevoflurane may be a better choice because of its quick onset, lack of pungency, lack of cardiovascular depression, and lower risk of cardiac arrhythmias compared to halothane.

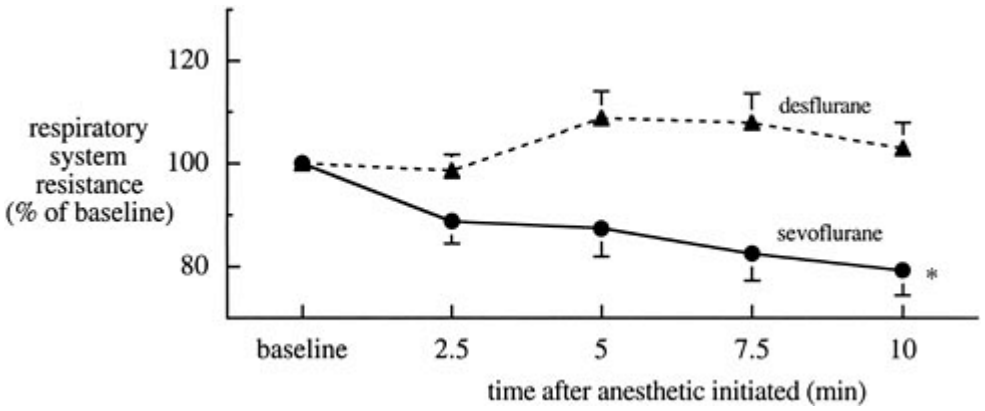

FIGURE 15-27. Changes in respiratory system resistance (*Rrs*) expressed as a percentage of the "thiopental" baseline recorded after tracheal intubation but prior to administration of sevoflurane or desflurane to the inspired gas mixture. Airway resistance responses to sevoflurane were significantly different from desflurane (*p<0.05). (Adapted from Goff MJ, Arain SR, Ficke DJ *et al*: Absence of bronchodilation during desflurane anesthesia: A comparison to sevoflurane and thiopental. Anesthesiology 93:404, 2000.)

Mucociliary Function

Adequate mucociliary function may be important in preventing postoperative atelectasis and hypoxemia. There are a number of factors involved in diminished mucociliary function, particularly in the mechanically ventilated patient. Anesthesia plays an as yet poorly defined role. Halothane, enflurane, and nitrous oxide with halothane have been shown to decrease, in a dose-dependent fashion, mucociliary movement. It also is known that smokers have impaired mucociliary function compared to nonsmokers, and the combination of a volatile anesthetic in a smoker who is mechanically ventilated sets up a scenario for inadequate clearing of secretions, mucous plugging, atelectasis, and hypoxemia.

Pulmonary Vascular Resistance

Although vascular smooth muscle is clearly affected by the volatile anesthetics, the pulmonary vasodilator action of the clinically relevant concentrations of inhaled anesthetics, including halothane, isoflurane, enflurane, sevoflurane, and desflurane, is minimal. In addition, any decrease in cardiac output that might occur from a volatile anesthetic tends to offset the direct vasodilator action of the anesthetic, resulting in little or no change in pulmonary artery pressures and pulmonary blood

flow. Even nitrous oxide, which has little effect on cardiac output and pulmonary blood flow, has at best a small effect to increase pulmonary vascular resistance. However, the effect of nitrous oxide may be magnified in patients with resting pulmonary hypertension.[143] Perhaps more important in terms of volatile anesthetics and pulmonary blood flow is their potential to attenuate hypoxic pulmonary vasoconstriction (HPV). During periods of hypoxemia, HPV reduces blood flow to underventilated areas of the lung, thereby diverting blood flow to areas of the lung with greater

ventilation. The net effect is to improve the V/Q matching, resulting in a reduced amount of venous admixture and improved arterial oxygenation. Although all of the inhaled anesthetics in high concentrations have been shown to attenuate HPV in animal models, the situation is less clear in patient studies. This may reflect the multifactorial effects of the volatile anesthetics on factors involved in pulmonary blood flow, including their cardiovascular, autonomic and humoral actions. Furthermore, nonpharmacologic variables impair HPV, including surgical trauma, temperature, pH, $PaCO_2$, size of the hypoxic segment, and intensity of the hypoxic stimulus. In patients undergoing one lung ventilation during thoracic surgery, PaO_2 and intrapulmonary shunt fraction (Qs/Qt) have been minimally affected when changing from two-lung to one-lung ventilation (OLV) during either halothane, isoflurane, enflurane, desflurane anesthesia (Fig. 15-28).[144] Isoflurane appears to be less inhibitory on HPV than halothane and, although this effect is subtle,[144] it might be attributed to the greater maintenance of cardiac output known to occur with isoflurane. Both sevoflurane and desflurane preserve cardiac output and should also help lessen shunt fraction during OLV. Propofol appears to be no more beneficial on shunt fraction during OLV compared to sevoflurane.[145] Finally, the addition of 4 cm positive end-expiratory pressure (PEEP) to the dependent lung may not impair cardiac output but reduces shunt fraction during OLV.[146]

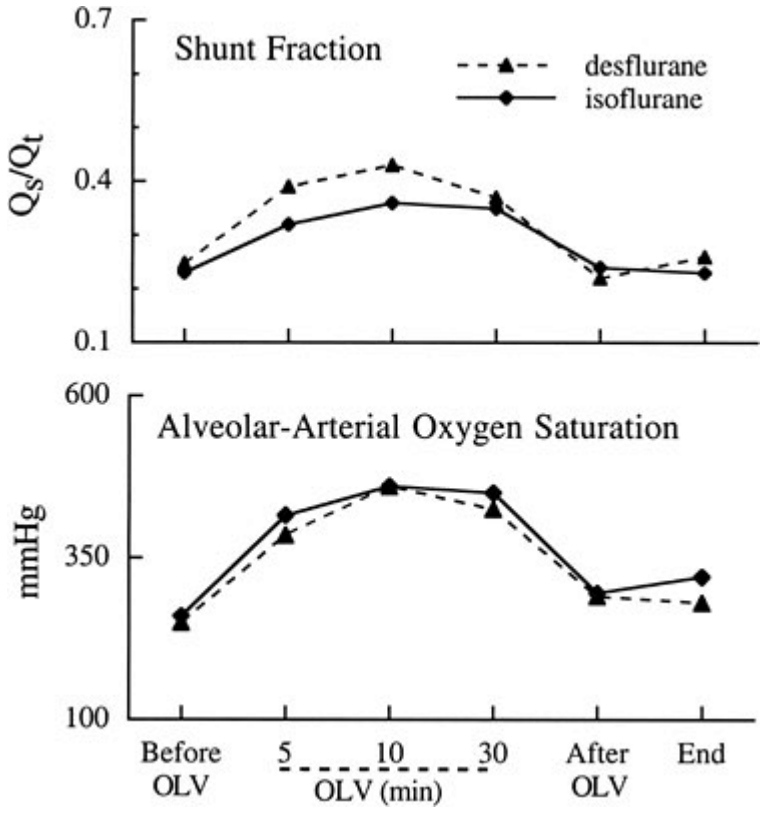

FIGURE 15-28. Shunt fraction (**top panel**) and the alveolar–arterial oxygen gradient (**bottom panel**) immediately before, during, and after one-lung ventilation (OLV) in patients anesthetized with desflurane or isoflurane. Data are means. (Adapted from Pagel PS, Fu JL, Damask MC *et al*: Desflurane and isoflurane produce similar alterations in systemic and pulmonary hemodynamics and arterial oxygenation in patients undergoing one-lung ventilation during thoracotomy. Anesth Analg 87:800, 1998.)

HEPATIC EFFECTS

Although postoperative liver dysfunction has been associated with many of the volatile anesthetics in current use, the most concern has been focused on halothane. There appears to be two distinct mechanisms by which halothane can cause hepatitis. One is more common but relatively mild, does not require a previous exposure, and has a low morbidity. The second is associated with repeat exposure and probably represents an immune reaction to oxidatively derived metabolites of

halothane and has been associated with severe liver damage and fulminant hepatic failure.

The liver has two blood supplies. One is the well-oxygenated blood from the hepatic artery and the second is the poorly oxygenated blood supply from the portal vein. Hepatocyte hypoxia is a significant contributor to postoperative hepatic injury. A pleasant attribute of the ether-based anesthetics (isoflurane, sevoflurane, and desflurane) is their ability to maintain or increase hepatic artery blood flow while decreasing (or not changing) portal vein blood flow.[79,147] This contrasts to halothane where decreases in portal vein blood flow are not compensated by increases in hepatic artery blood flow (Fig. 15-29). Rather, halothane causes selective hepatic artery vasoconstriction. It is estimated in animal models that there is a 65% reduction in oxygen availability during halothane anesthesia, while during isoflurane the reduction in availability is only 35%.[148]

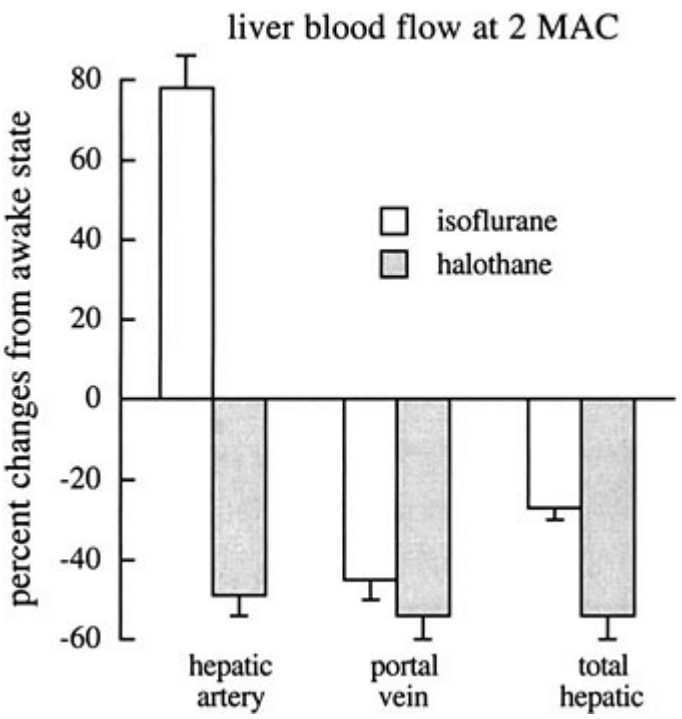

FIGURE 15-29. Changes (%, mean ± SE) in hepatic blood flow during administration of isoflurane or halothane. Decreases in portal vein blood flow produced by 2 MAC isoflurane are offset by increases in hepatic artery blood flow (autoregulation). Halothane resulted in decreases in both portal vein and hepatic artery blood flow, thereby significantly compromising total hepatic artery blood flow. (Adapted from Gelman, S, Fowler, KC, Smith, LR: Liver circulation and function during isoflurane and halothane anesthesia. Anesthesiology 61:726, 1984.)

Situations that decrease hepatic blood flow or increase hepatic oxygen demand make patients vulnerable to the unwanted effects of halothane on hepatic blood flow. For example, surgery in the area of the liver (or elsewhere in the abdominal cavity) that might compromise hepatic blood flow puts patients at risk for hepatic cell injury. In addition, enzyme induction, which increases oxygen demand, enhances the vulnerability of patients to the effects of halothane. Furthermore, patients who are critically dependent on oxygen supply for

survival of remaining liver tissue, such as the cirrhotic patient, are at a higher risk for further hepatic injury than noncirrhotic individuals.[149] Whether this injury can simply be explained by a direct effect of halothane during hypoxic conditions or be attributed to reductive metabolism of halothane that is enhanced under hypoxic conditions is not entirely clear.[150]

Changes in liver function tests have been used as an index of hepatic injury during anesthesia.

Transient increases in plasma alanine aminotransferase (ALT) activity followed the administration of enflurane, but not desflurane, isoflurane, or sevoflurane in human volunteers.[147,151,152] Although changes in the ALT or aspartate aminotransferase (AST) is an accepted index of liver cell damage, these measures may not accurately reflect the extent of hepatic injury and are not uniquely specific to the liver. Most cases of halothane hepatitis demonstrate lesions in the centrilobular area of the liver and not coincidentally, this area is most susceptible to hypoxia. Therefore, a more sensitive measure of injury may be glutathione-S-transferase (GST) since it is distributed primarily in the centrilobular hepatocytes. In patient studies comparing halothane anesthesia to isoflurane and enflurane,[153] significant increases in GST occurred after halothane (increases of 24 to 50%) and enflurane (20%), but not after isoflurane. There were two peaks in the GST responses; the first was 3 to 6 hours after halothane and the other was approximately 24 hours after halothane. It has been suggested that the early peak reflects direct damage or impaired liver blood flow and the second peak may be caused by metabolites or an immune response. The immune mechanism of hepatitis is considered later in this chapter in the section labeled "Anesthetic Metabolism."

NEUROMUSCULAR SYSTEM AND MALIGNANT HYPERTHERMIA

Compared to the alkane halothane, the ether-derived, fluorinated, volatile anesthetics produce about 2-fold greater skeletal muscle relaxation. Nitrous oxide does not relax skeletal muscles and in doses greater than 1 MAC may, in fact, result in skeletal muscle rigidity. Interestingly, the inhaled anesthetics, in addition to the direct effects of relaxing skeletal muscle, also potentiate the action of neuromuscular blocking drugs.[154,155] Although the mechanism of this potentiation is not entirely clear, it appears to be largely because of a postsynaptic effect at the nicotinic acetylcholine receptor located at the neuromuscular junction.[156] Specifically, at the receptor level, the volatile anesthetics act synergistically with the neuromuscular blocking drugs to enhance their action.[157] The degree of enhancement is related to their aqueous concentration so that at equi-MAC concentrations, the less potent anesthetics (e.g., desflurane and sevoflurane versus isoflurane) should have a greater inhibitory effect on neuromuscular transmission. Support for this concept comes from a clinical study demonstrating 20% lower requirement for vecuronium to maintain a stable twitch depression during 1.25% desflurane compared to 1.25% isoflurane.[158] In contrast, equipotent concentrations of desflurane, isoflurane, and sevoflurane acted similarly to enhance the effect of cisatracurium on neuromuscular function.[154] This may relate to major structural differences between neuromuscular blocking drugs.

All of the potent volatile anesthetics serve as triggers for malignant hyperthermia in genetically susceptible patients.[159,160,161] In contrast, nitrous oxide is only a weak trigger for malignant hyperthermia.[161] Studies evaluating the caffeine-induced contractures indicate the augmentation of the contractures by nitrous oxide is 1.3, whereas that for isoflurane is 3-fold, enflurane 4-fold, and halothane 11-fold.[161] Thus, halothane may be the most potent trigger of the volatile anesthetics for malignant hyperthermia. Although desflurane is a weak trigger for malignant hyperthermia, it has been associated with an unusual delayed onset of symptoms if succinylcholine was not used for neuromuscular blockade.[159,162]

GENETIC/CELLULAR EFFECTS

In tests employed to identify chemicals that cause a mutagenic or carcinogenic response, all of the volatile anesthetics, including nitrous oxide, have proven to be negative. The Ames test identifies chemicals that act as mutagens and carcinogens and has been shown to be negative for enflurane, isoflurane, desflurane, sevoflurane, and nitrous oxide.[149] Although halothane results in a negative Ames test, metabolites may be positive.

Virtually every volatile anesthetic agent has been shown to be teratogenic in animal studies, but none has been shown to be teratogenic in humans. Animal studies have indicated that nitrous oxide exposure in the early periods of gestation may result in adverse effects, including an increased incidence of fetal resorption.[163] The same vulnerability does not exist during the administration of the potent volatile anesthetics.[164]

However, learning function may be impaired in newborn animals exposed in utero to inhaled anesthetics.[165]

There has been an ongoing concern about the incidence of spontaneous abortions in operating room personnel chronically exposed to trace concentrations of inhaled anesthetics, especially nitrous oxide.[163] Animal studies using intermittent exposure to trace concentrations of nitrous oxide, halothane, enflurane, and isoflurane have not revealed harmful reproductive effects.[166] Methionine synthetase and thymidylate synthetase are vitamin B12–dependent enzymes that have been shown to decrease in activity during nitrous oxide exposure. The mechanism appears to be an irreversible oxidation of the cobalt atom of vitamin B12 by nitrous oxide. The half-time for inactivation of methionine synthetase is 46 minutes when 70% nitrous oxide is administered to patients (Fig. 15-30). Methionine synthetase and thymidylate synthetase are involved in the formation of myelin and the formation of DNA, respectively. Thus, the concern that these changes might have an effect on a rapidly developing embryo/fetus seems appropriate. Inhibition of these enzymes could also manifest as depression of bone marrow function and neurologic disturbances. In fact, megaloblastic changes in bone marrow are consistently observed in patients exposed to nitrous oxide for 24 hours,[239] and four days of exposure to nitrous oxide has resulted in agranulocytosis. Furthermore, animals exposed to 15% nitrous oxide for up to 15 days developed a neuropathy presented as ataxia and spinal cord and peripheral nerve degeneration. A sensory motor polyneuropathy that is often combined with signs of posterior lateral spinal cord degeneration resembling pernicious anemia has been described in humans who chronically inhale nitrous oxide for recreational use.[167] These effects have been attributed to reduced activity of the vitamin B12–dependent enzymes.

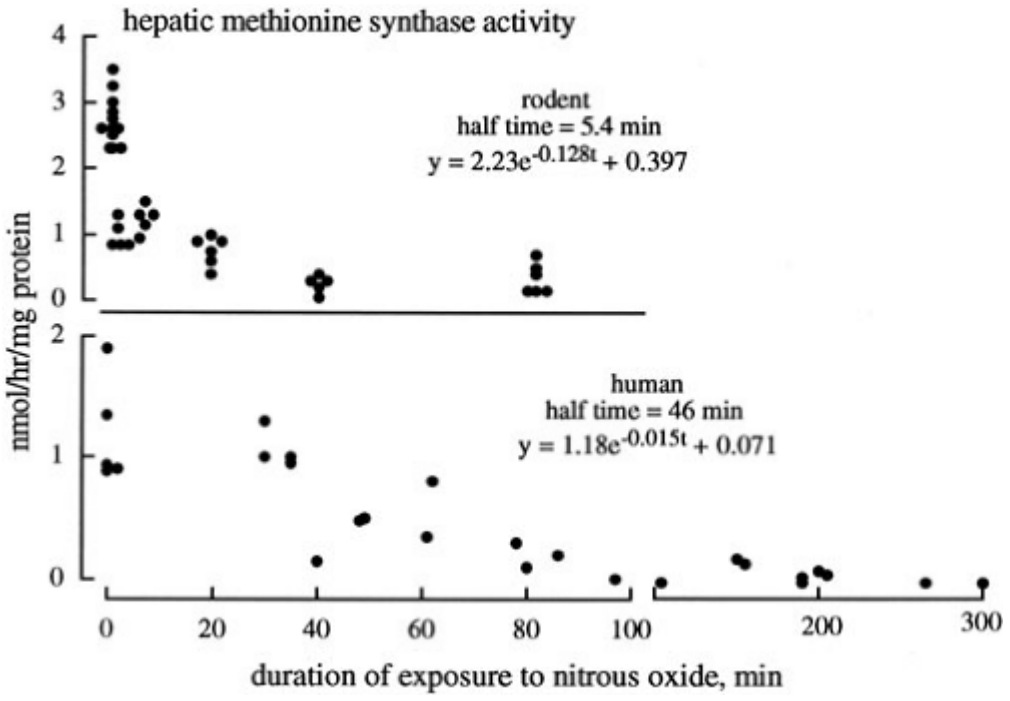

FIGURE 15-30. Time course of inactivation of hepatic methionine synthase (synthetase) activity during administration of 50% nitrous oxide to rats or 70% nitrous oxide to humans. The half-life was substantially less in rats. (Adapted from Royston BD, Nunn JF, Weinbren HK *et al*: Rate of inactivation of human and rodent hepatic methionine synthase by nitrous oxide. Anesthesiology 68:213, 1988.)

Despite the unproven influence of trace concentrations of the volatile anesthetics on congenital development and spontaneous abortions, these concerns have resulted in the use of scavenging systems to remove anesthetic gases from the operating room and the establishment of Occupational Saftey and Health Administration standards for waste gas exposure. The National

Institute for Occupational Safety and Health recommended exposure levels for nitrous oxide is 25 parts per million (ppm) as a time-weighted average over the time of exposure. The exposure limit for halogenated anesthetics (without nitrous oxide exposure) is 2 ppm.

OBSTETRIC EFFECTS

Similar to the effects of volatile anesthetics on vascular smooth muscle, a dose-dependent decrease in uterine smooth muscle contractility and blood flow occurs, and the response appears to be similar among the volatile anesthetics.[168,169] Consequently, a common technique used to provide general anesthesia for urgent Caesarean sections is to administer low concentrations of the volatile anesthetic, such as 0.5 MAC, combined with nitrous oxide. This decreases the likelihood of uterine atony and blood loss, especially at a time after delivery when uterine contraction is essential.[170] Uterine relaxation can become troubling at concentrations of volatile anesthesia greater than 1 MAC, and higher concentrations might delay the onset time of newborn respiration.[170] In some situations, uterine relaxation may be desirable, such as to remove a retained placenta. In this case, a brief, high concentration of a volatile anesthetic may be advantageous. In terms of neonatal effects of general anesthesia, APGAR scores and acid-base balance are not affected by anesthetic technique, such as spinal versus general.[171] More sensitive measures of neurologic and behavioral function, such as the Scanlon Early Neonatal Neurobehavioral Scale (ENNS) and the neurological and adaptive capacities score (NACS) indicate some transient depression of scores following general anesthesia that did not persist at 24 hours postdelivery measurements.[171,172] Fetal loss seems to increase following surgery in the first or second trimester, but the majority of these findings have been in patients following acute abdomen or trauma in emergency settings. Generally, elective surgeries are delayed until at least 6 weeks postpartum, or until the late second or early third trimester. Perhaps the most important factor in promoting good fetal outcome is maintaining good uterine blood flow during anesthesia and surgery.

ANESTHETIC DEGRADATION BY CARBON DIOXIDE ABSORBERS

The majority of adult general anesthesia is given through closed or semiclosed breathing circuits. This mandates the use of a carbon dioxide absorbent in the circuit. One of the problems with the CO_2 absorbents in use today is their chemical makeup, which consists of monovalent hydroxide bases (KOH and NaOH). These strong bases result in breakdown or degradation of all modern-day, potent anesthetics.[173] Degradation of the anesthetics is slightly greater with potassium hydroxide. Barium hydroxide lime, which contains potassium but not sodium hydroxide, causes more anesthetic degradation than soda lime (which contains less potassium hydroxide and more sodium hydroxide).[174] In the case of halothane and sevoflurane, the reaction with carbon dioxide absorbents results in degradation of these anesthetics to haloalkenes.[5] Halothane degrades to form trace amounts of BCDFE (2-bromo-2-chloro-1,1-difluoroethene) and sevoflurane degrades to form trace amounts of compound A (2,2-difluoro-1-[trifluoromethyl] vinyl ether). These haloalkenes have been shown to be nephrotoxic in rats,[175] although clinically significant renal effects of haloalkene formation in surgical patients have not been reported. In dehydrated carbon dioxide absorbents, degradation of desflurane, enflurane, isoflurane, and sevoflurane results in carbon monoxide formation [176,177,248]

Special mention of several novel carbon dioxide absorbents that have reduced or eliminated sodium and potassium hydroxide content is warranted prior to delving into the discussion of compound A, carbon monoxide, and fires. The new absorbents, called Amsorb Plus and DrägerSorb® Free, contain primarily calcium hydroxide. These new absorbents are chemically unreactive with sevoflurane, enflurane, isoflurane, and desflurane, and thus, they essentially eliminate the degradation of these anesthetics to carbon monoxide and compound A (Fig. 15-31).[178,179,180]

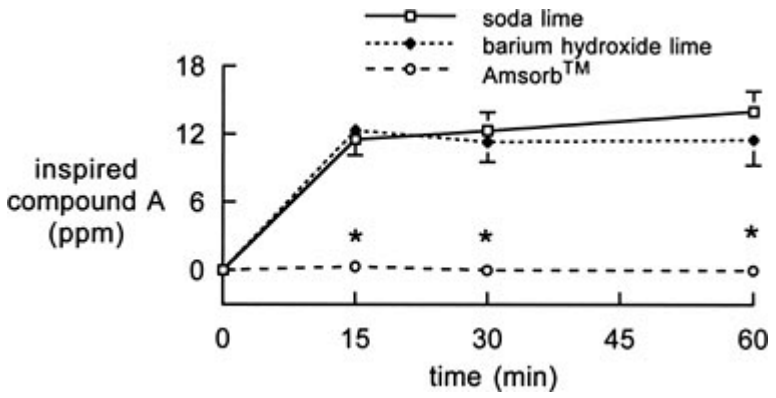

FIGURE 15-31. Compound A levels produced from three carbon dioxide absorbents during 1 MAC sevoflurane anesthesia delivered to volunteers at 1 lpm fresh gas flow (mean ± SE). Gas samples were taken from the inspired limb of the anesthesia circuit. *different from Baralyme® or soda lime ($p<0.05$). (Adapted from Mchaourab A, Arain SR, Ebert TJ: Lack of degradation of sevoflurane by a new carbon dioxide absorbent in humans. Anesthesiology 94:1007, 2001.)

Compound A

Sevoflurane undergoes base-catalyzed degradation in carbon dioxide absorbents to form a vinyl ether called "compound A." The production of compound A is enhanced in low-flow or closed-circuit breathing systems and by warm or very dry CO_2 absorbents. Barium hydroxide lime produces more compound A than soda lime and this can be attributed to slightly higher absorbent temperature during CO_2 extraction.[174]

Studies in rats where compound A has been administered in the inspired gas have identified a threshold for renal tubular necrosis between 290 and 340 parts per million (ppm) × hour (e.g., 50 ppm × 6 hr = 300 ppm·hr) (Fig. 15-32).[181,182] The nephrotoxicity is characterized by cell necrosis of the cortical medullary tubules located in the proximal tubules.[175] The associated biochemical markers include elevations of serum BUN and creatinine, glucosuria, and proteinuria.[175,181] In addition, several enzymes from the tubule cells have been used as markers of cell injury including increases in urinary excretion of n-acetyl-beta-D-glucosaminidase (NAG) and alpha-glutathione-S-transferase (αGST).[175,181]

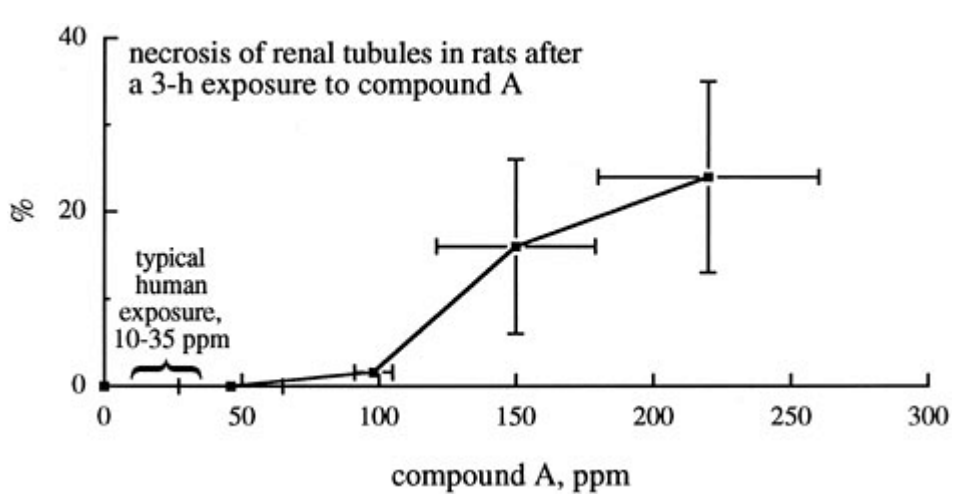

FIGURE 15-32. Renal biopsy results from rats inhaling different concentrations of compound A for 3 hours. The derived threshold to cause renal necrosis is around 100 ppm (300 ppm·hr). The typical human exposure during the administration of sevoflurane in a semiclosed circuit is between 10 and 35 ppm of compound A, which falls well below the threshold to cause renal injury in rats. (Adapted from Kharasch ED, Hoffman GM, Thorning D *et al*: Role of the renal cysteine conjugate β-lyase pathway in inhaled compound A nephrotoxicity in rats. Anesthesiology 88:1624, 1998.)

There are well-defined species differences in the threshold for compound A–induced nephrotoxicity. The threshold is approximately 300 ppm·hr in 250-gm rats,[181],[262] greater than 612 ppm·hr in pigs,[183] and between 600 and 800 ppm·hr in monkeys.[184] In patients and volunteers receiving sevoflurane in closed-circuit or low-flow delivery systems, inspired compound A concentrations averaged 8 to 24 and 20 to 32 ppm with soda lime and barium hydroxide lime, respectively.[185,186,187] Total exposures as high as 320 to 400 ppm·hr have had no clear effect on clinical markers of renal function.[188,189] In randomized and prospective volunteer and patient studies, no adverse renal effects from low-flow (0.5 to 1.0 L/min) or closed-circuit sevoflurane anesthesia were detected using both standard clinical markers of renal function (serum creatinine and BUN concentrations) and experimental markers of renal function and structural integrity (proteinuria, glucosuria, and enzymuria).[185,186,189,190,191,192] In fact, several new studies evaluated the renal effects of long duration, low-flow sevoflurane in patients with preexisting renal disease (plasma creatinine >1.5 mg/dL).[193,194] The fresh gas flow was 1 LPM, barium hydroxide absorbent was employed, and minimal anesthetic adjuvants were given to maximize the dose of sevoflurane and production of compound A. There were no adverse effects from sevoflurane determined with both standard clinical markers and biochemical markers of renal function. Recent evidence from patients undergoing elective surgery indicates that transient proteinuria, glucosuria, and enzymuria also occur after desflurane, isoflurane, and propofol anesthesia, without changes in serum BUN and creatinine.[186,187] Despite solid evidence for the renal safety of low-flow sevoflurane from randomized prospective studies, the renal safety of sevoflurane has been questioned and debated.[195,196]

Aside from the high probability that the absence of renal injury in patients is because of low compound A levels during the clinical use of sevoflurane in a low-flow system, another probable explanation must be considered. Compound A is not itself toxic to organs. Rather it is the biodegradation of compound A to cysteine conjugates and the further action of a renal enzyme called beta-lyase on the conjugates that can result in formation of a potentially toxic thiol (Fig. 15-33).[182,197] There is clear evidence for species differences in the biotransformation of compound A to cysteine-s conjugates.[198] Recent evidence suggests that the cysteine conjugates can be handled in one (or both) of two ways.[199] They can be acetylated to mercapturic acid through a detoxication pathway, which results in no organ toxicity, or acted on by an enzyme in the kidneys

called renal beta-lyase, to form reactive intermediates (toxification pathway). These reactive intermediates are responsible for the renal cell necrosis seen in rats. The beta-lyase-dependent metabolism pathway in humans is far less extensive than the beta-lyase pathway in rats (8 to 30 times less active).[198] Thus, compared with rats, humans receive markedly lower doses of compound A and metabolize a lower fraction of compound A via the renal beta-lyase pathway. This may account for the safety of sevoflurane in both human volunteers and patients when compared to rat models. Finally, pharmacovigilance suggests sevoflurane is not nephrotoxic. The anesthetic has been in clinical use for nearly a decade, and many countries outside the United States have no flow restrictions on sevoflurane, yet not a single case report of renal harm from sevoflurane has been presented in the literature.

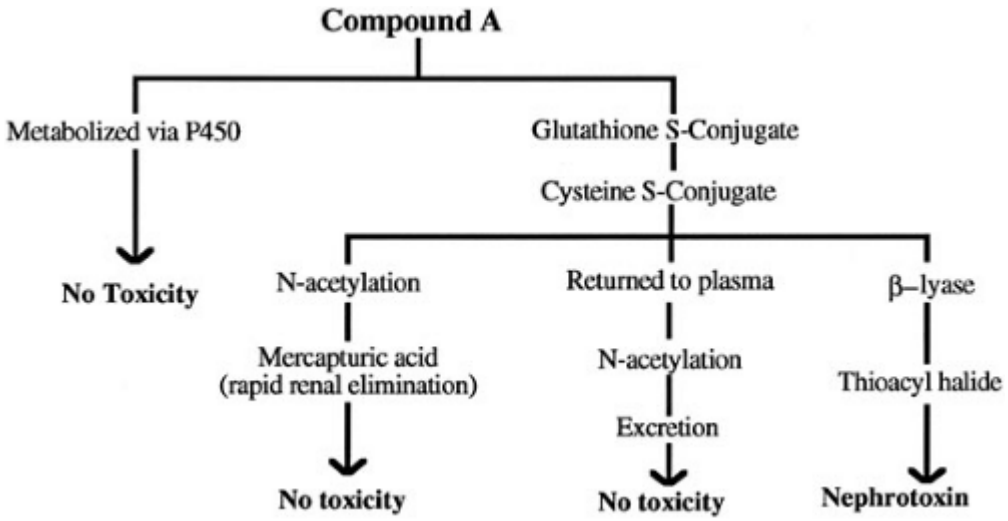

FIGURE 15-33. Known pathways for metabolism and elimination of compound A in humans. A potential toxin results only from the action of renal beta-lyase on cysteine-S-conjugates. The activity of this enzyme in humans is 8- to 30-fold less than in rats. Considerable handling of the cysteine-S-conjugates in humans is via N-acetylation to mercapturic acid. (Adapted from Kharasch ED, Jubert C: Compound A uptake and metabolism to mercapturic acids and 3,3,3-trifluoro-2-fluoromethoxypropanoic acid during low-flow sevoflurane anesthesia. Anesthesiology 91:1267, 1999.)

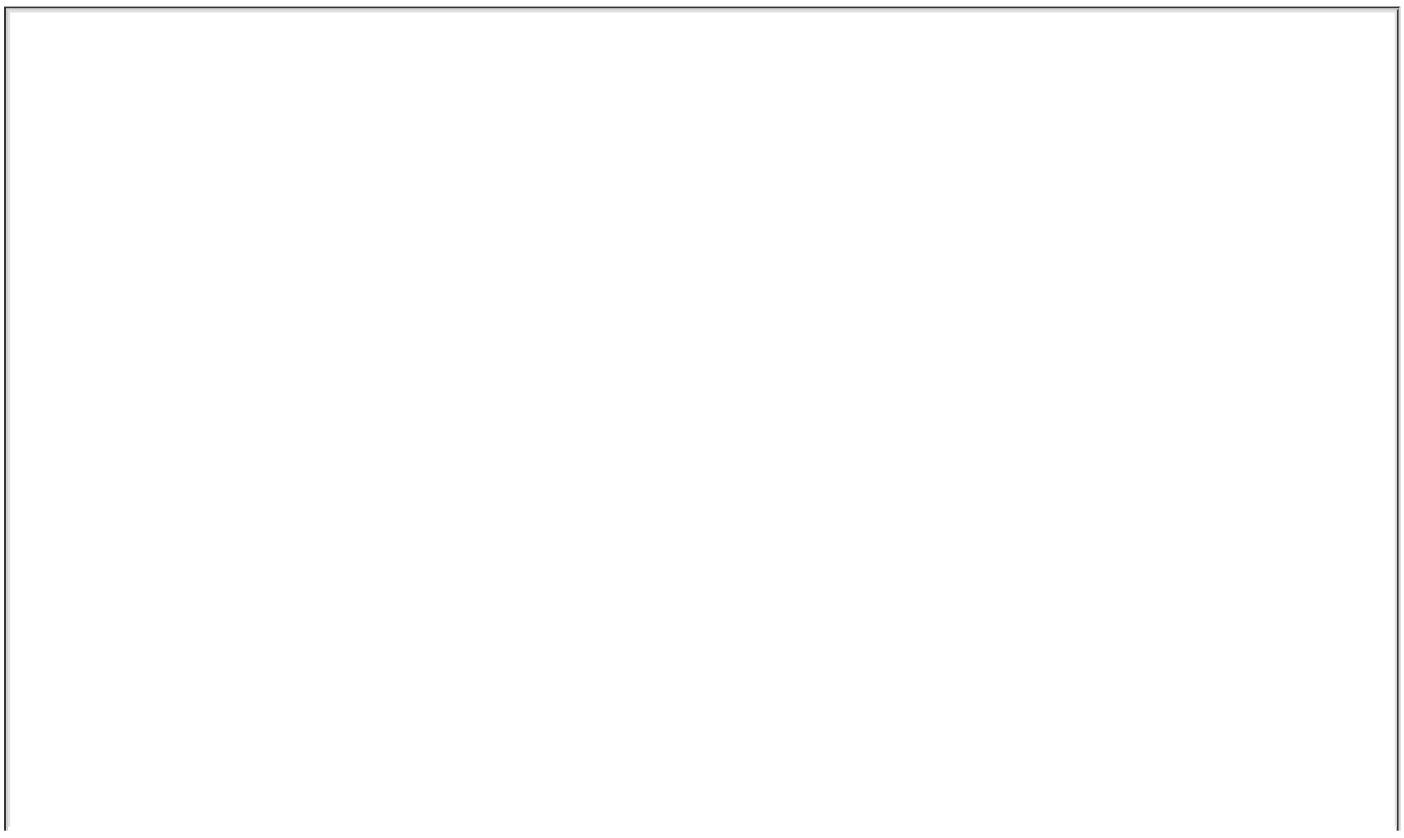
Carbon Monoxide and Heat

6 CO_2 absorbents degrade sevoflurane, desflurane, enflurane, and isoflurane to carbon monoxide when the normal water content of the absorbent (13 to 15%) is markedly decreased below 5%.[176,177,200] The degradation is the result of an exothermic reaction of the anesthetics with the absorbent. The anesthetic molecular structure and the presence of a strong base in the carbon dioxide absorbent are involved in the formation of CO. Desflurane, enflurane, and isoflurane contain a difluoromethoxy moiety that is essential for the formation of CO. When studies are conducted with CO_2 absorbents maintained at or just above room temperature, desflurane and enflurane given at just under 1 MAC produced up to 8,000 and 4,000 ppm of CO, respectively, versus 79 ppm with nearly 2 MAC sevoflurane.[176] In dehydrated barium hydroxide, CO production from desflurane was nearly 3-fold higher than with soda lime but was trivial with sevoflurane. In normal clinical use, CO_2 canister temperatures are 25 to 45°C, but can be higher when employing a very low fresh gas flow. In a laboratory setting, when CO_2 canister temperature is not controlled and sevoflurane is administered to desiccated barium hydroxide, the exothermic reaction can increase canister temperatures. If CO_2 canister temperature exceeds 80°C, significant CO production is noted with sevoflurane.[177] Instances of CO poisoning have been reported in situations where the CO_2 absorbent has been presumably dried (desiccated) because an anesthetic machine has been left on with a high fresh gas flow passing through the CO_2 absorbent over an extended period of time.[201,202,203,204] In an experimental setting, overnight drying of barium hydroxide for 14 hours at 10L/min fresh gas flow did not result in significant CO production from desflurane, whereas 24 to 66 hours of fresh gas flow drying produced significant CO production.[205]

Although desflurane produces the most CO with anhydrous CO_2 absorbers, the reaction with sevoflurane produces the most heat. The strong exothermic reaction has caused significant heat production, fires, and patient injuries.[206,207] Although sevoflurane is not flammable at less than 11%, formaldehyde, methanol, and formate have been identified and these alone or in combination with oxygen might be flammable at high canister temperatures. In experimental settings, long exposure of 1 MAC sevoflurane to desiccated absorbents resulted in canister temperatures in excess of 300°C and can be associated with smoldering, melting of plastic



components, explosions, and fires.[177]

There are newer CO_2 absorbents that do not degrade anesthetics (to either compound A or carbon monoxide) and they should reduce exothermic reactions. "From a patient safety perspective, widespread adoption of a nondestructive CO_2 absorbent should be axiomatic."[173] Although the cost of these new CO_2 absorbents (Amsorb® Plus and DrägerSorb® Free) is higher and the absorptive capacity may be lower than either barium hydroxide lime or soda lime, their benefit may be substantial. The use of a nondestructive absorbent eliminates all of the potential complications related to anesthetic breakdown and therefore minimizes the possibility of additional costs as a result of those complications, including additional lab tests, hospital days and medical/legal expenses. Adoption of these new absorbents into routine clinical practice is consistent with the patient safety goals of our anesthesia societies.

ANESTHETIC METABOLISM

Fluoride-Induced Nephrotoxicity

Metabolism (biotransformation) of halogenated anesthetics to free inorganic fluoride, resulting in nephrotoxicity, is now an accepted fact for the anesthetic methoxyflurane. The metabolism of methoxyflurane and, to a lesser extent, enflurane has resulted in a well-described injury to renal collecting tubules.[208,209] The nephrotoxicity associated with these anesthetics presents as a high output renal insufficiency that is unresponsive to vasopressin and is characterized by dilute polyuria, dehydration, serum hypernatremia, hyperosmolality, elevated BUN, and creatinine. An association between increased plasma fluoride concentrations and metabolism of these anesthetics led to a "fluoride hypothesis."[208] Nephrotoxicity is caused by metabolism of the volatile anesthetics to fluoride, and the inorganic fluoride is the ultimate substance producing the renal injury. This hypothesis has been reexamined recently in part because sevoflurane undergoes 5% metabolism that results in transient increases in serum fluoride concentrations but has not been associated with a renal concentrating defect.[209] The traditional hypothesis stated that both the duration of the high systemic fluoride concentrations (area under the fluoride time curve) and the peak fluoride concentration (peaks above 50 μM appear to represent the toxic threshold) were related to nephrotoxicity (Fig. 15-34).[208] The safety of sevoflurane and the relative safety of enflurane with regard to fluoride concentrations may be because of a rapid decline in plasma fluoride concentrations as a result of less availability of the anesthetic for metabolism from a faster washout compared to methoxyflurane.[210]

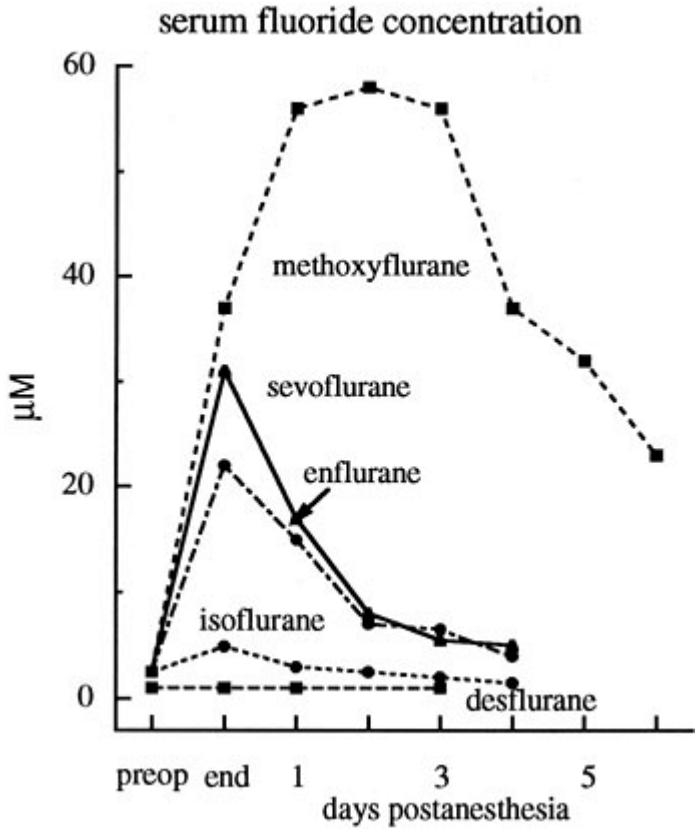


FIGURE 15-34. Plasma inorganic fluoride concentrations (mean ± SE) before and after 2 to 4 hours of methoxyflurane, enflurane, sevoflurane, isoflurane, and desflurane anesthesia. (Adapted from Kharasch ED, Armstrong AS, Gunn K, et al: Clinical sevoflurane metabolism and disposition. II. The role of cytochrome P450 2E1 in fluoride and hexafluoroisopropanol formation. Anesthesiology 82:1379, 1995; Mazze RI: Metabolism of the inhaled anaesthetics: Implications of enzyme induction. Br J Anaesth 56:27S, 1984; and Sutton TS, Koblin DD, Gruenke LD, et al: Fluoride metabolites after prolonged exposure of volunteers and patients to desflurane. Anesth Analg 73:180, 1991.)

A recent report further clarifies this issue and has led to a modification of the traditional fluoride hypothesis for renal toxicity.[211] That is, the site of metabolism is an important factor in toxicity (i.e., intrarenal metabolism contributes to nephrotoxicity). The metabolism of methoxyflurane to fluoride in the kidney is significantly greater than that of sevoflurane and enflurane. This may be related to the multiple cytochrome P450 enzymes in the kidney responsible for metabolism of methoxyflurane (P450-2A6, P450-3A, P450-2E1).[211] In contrast, sevoflurane and enflurane are primarily metabolized by the cytochrome P450-2E1. Thus, intrarenal fluoride generated from methoxyflurane metabolism and/or the multiple P450 isoenzymes involved in methoxyflurane metabolism may account for the nephrotoxicity from this anesthetic. Therefore, the potential for toxicity from relatively high plasma levels of fluoride following long exposure to sevoflurane and enflurane is offset by the minimal amount of renal defluorination and this may explain the relative absence of renal concentrating defects with these anesthetics.[209,211,273]

Factors such as total dose of anesthetic, enzyme induction, and obesity have been proven to enhance biotransformation. The activity of hepatic cytochrome P450 enzymes is increased by a variety of drugs, including phenobarbital, phenytoin, and isoniazid.[212] Obesity causes increased metabolism (defluorination) in halothane, enflurane, and isoflurane. However, the effects of obesity on the defluorination of sevoflurane are less clear.[213]

Hepatic Injury from Metabolism: Halothane Hepatitis

Although postoperative liver dysfunction has been associated with most of the volatile anesthetics in current use, the most focused attention has been directed to halothane. This is in part because of the relatively recent demonstration of binding of an oxidatively derived metabolite of halothane to liver cytochromes, which could then act as haptens and induce an immune reaction. This hypersensitivity reaction has been associated with severe liver damage and fulminant hepatic failure. There are many causes of postoperative jaundice and abnormal liver function tests, including viral hepatitis, coexisting liver disease (such as Gilbert's disease), blood transfusions, septicemia, drug reactions, intra- and postoperative hypoxia and hypotension, and direct tissue trauma as a result of the surgical procedure.[150] The diagnosis of halothane hepatitis is generally made based on "incomplete exclusion," defined as the appearance of liver damage within 28 days of halothane exposure in a person in whom other known causes of liver disease have been excluded.

Halothane was introduced into clinical practice in 1956, and case reports of unexplained jaundice following anesthesia with halothane began to appear in 1958. By 1963, at least 350 putative cases of "halothane hepatitis" had been reported. In 1967, it was identified that approximately 18% of halothane was metabolized in man.[214] The metabolites were oxidatively derived. It is now known that oxidative metabolism of halothane, catalyzed by hepatic cytochrome P450 2E1, produces a reactive intermediate, trifluoroacetyl (TFA) that can covalently modify liver microsomal proteins. This complex can produce an immune response in some individuals that is characterized by immunoglobulin G antibodies. However, halothane-associated hepatitis can present as one of two clinical syndromes and it is likely that only one syndrome can be explained by an immune mechanism.[150,215] Each syndrome may develop after an uneventful anesthesia and surgery with no apparent time-to-dose relationship. The most common syndrome, which occurs in close to 20% of the adult patients receiving halothane, is a mild, self-limited postoperative illness that has been attributed to *reductive* metabolism of halothane and this route of metabolism is enhanced under low oxygen or hypoxic conditions. Reductive metabolism of isoflurane, desflurane, sevoflurane, and enflurane does not occur. This may relate to the fact that halothane uniquely reduces hepatic blood flow (both portal vein and hepatic artery blood flow).[216,217] The typical presentation of hepatitis from reductive metabolism is a rapid (1 to 3 days) but mild, unprogressing pattern of liver injury characterized by nausea, lethargy, fever, moderately increased concentrations of liver transaminases, and, rarely, transient jaundice. It does not require a repeat exposure, as does the immune mechanism of hepatitis; it can occur on the first exposure to halothane.

Several more recent observations suggest that reductive metabolism is not an important mechanism in the evolution of the immune-mediated halothane hepatitis.[150] The possibility existed that binding of a metabolite of halothane to liver cytochromes could act as haptens and induce a hypersensitivity response.[218] Supporting this possibility were the clinical manifestations of hepatitis, including eosinophilia, fever, rash, arthralgia, and prior exposure to halothane. The possibility of a genetic susceptibility factor is suggested by case reports of halothane hepatitis in closely related patients.[215] The most compelling evidence for an immune-mediated mechanism is the presence of circulating immunoglobulin G (IgG) antibodies in up to 70% of patients with diagnosis of halothane hepatitis.[150,218] This antibody is not directed against the reductive metabolite of halothane, but against an oxidative compound, TFA halide, which is incorporated onto the surface of the hepatocyte (Fig. 15-35).[219] TFA proteins have been identified from the liver of rats after halothane exposure with enzyme-linked immunosorbent assays and immunoblotting techniques. These altered proteins can be seen by the immune

system as nonself (neoantigen), generating production of antibodies. These can now be identified from serum samples of humans by identifying anti-TFA albumin activity on an ELISA screening evaluation.[220]

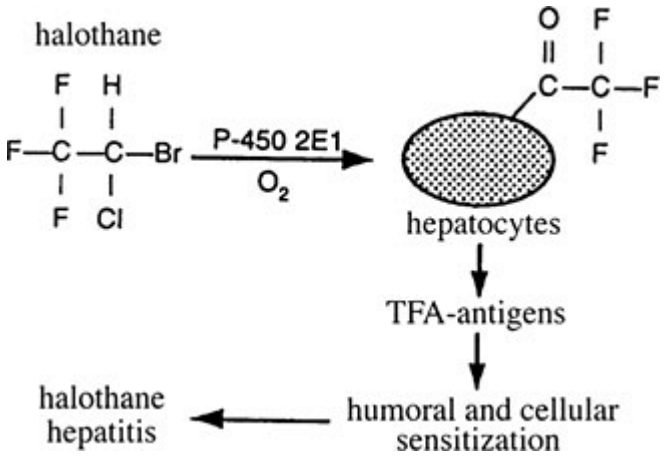

FIGURE 15-35. Halothane is metabolized to a trifluoroacetylated (TFA) adduct that binds to liver proteins. In susceptible patients, this adduct (altered protein) is seen as nonself (neoantigen), generating an immune response (production of antibodies). Subsequent exposure to halothane may result in hepatotoxicity. A similar process may occur in genetically susceptible individuals after anesthetic exposure to other fluorinated volatile anesthetics (enflurane, isoflurane, desflurane) that also generate a TFA adduct. (Adapted from Njoku D, Laster MJ, Gong DH *et al*: Biotransformation of halothane, enflurane, isoflurane, and desflurane to trifluoroacetylated liver proteins: Association between protein acylation and hepatic injury. Anesth Analg 84:173, 1997.)

This metabolic pathway involving the cytochrome P450 2E1 system during halothane exposure is identical to the metabolic pathway noted with enflurane, isoflurane, and desflurane. However, the expression of the neoantigens should be related to the amount of metabolism of each agent. This would suggest that halothane is > enflurane > isoflurane > desflurane in terms of antigenic load.[221] Indeed, case reports have appeared in the literature linking each of these anesthetics with immune-mediated hepatitis.[220,222,223,311] If the incidence of fulminant hepatic failure after halothane is 1 in 35,000,[224] hepatic failure caused by isoflurane may occur in only 1 in 3,500,000 isoflurane anesthetics, and a lower incidence would be expected with desflurane. There are no reports of fulminant hepatic necrosis associated with sevoflurane in humans. Sevoflurane is not metabolized to a TFA halide; rather it is metabolized to hexafluoroisopropanol, which does not serve as a neoantigen (Fig. 15-36).[147] Desflurane is the least metabolized of the volatile anesthetics, resulting in very small amounts of adduct, and only one case report of hepatotoxicity from desflurane has been described.[220] Sensitization of this patient by two exposures to halothane (18 years and 12 years previously) precipitated massive hepatotoxicity. Anti-TFA antibodies were identified in the serum.

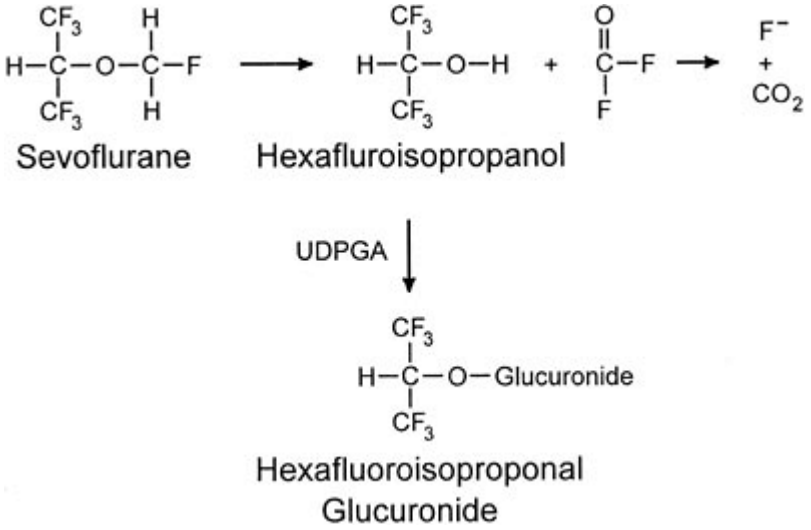

FIGURE 15-36. Pathway for oxidative metabolism of sevoflurane (UDPGA, uridine diphosphate glucuronic acid). Trifluoroacetylated (TFA) adducts are not formed from the metabolism of sevoflurane. (Adapted from Frink EJ Jr, Ghantous H, Malan TP *et al*: Plasma inorganic fluoride with sevoflurane anesthesia: Correlation with indices of hepatic and renal function. Anesth Analg 74:231, 1992.)

Herein lies another problem. Immunologic memory resulting in hepatitis has been reported 28 years after an initial halothane exposure.[225] In addition, cross-sensitivity has been reported in which exposure to one anesthetic can sensitize patients to a second but different anesthetic.[220,226] Recently these autoantibodies have been identified in 10% of health care workers (PACU nurses, nurse anesthetists, and anesthesiologists) chronically exposed to low levels of anesthetics.[221,227] Although this finding is intriguing if not alarming, the implication that anesthetics with the highest rates of metabolism (halothane, enflurane, and perhaps even isoflurane) should be removed from the OR setting requires further validation. It is worth recalling that despite case reports of hepatic damage associated with halothane, which appeared in the literature within 2 years of its introduction, it has taken some 35 years of research and debate to reach the current consensus on the mechanism of halothane-associated hepatitis and fulminant hepatic failure. It is the opinion of these authors that halothane should not be used in adult surgical cases and should be strongly discouraged in the pediatric population. Although the incidence of hepatitis appears to be much lower in the pediatric population, our concern is related to immunologic memory resulting in hepatitis later in life during a repeat exposure to anesthesia; additional concerns relate to health care workers who are chronically exposed to trace amounts of halothane. The new volatile anesthetics have an extremely low potential for hepatotoxicity and the possibility of avoiding even one case of fulminant hepatic failure from a volatile anesthetic is sufficiently compelling to discourage use of the older, more metabolized anesthetics including halothane and enflurane.

CLINICAL UTILITY OF VOLATILE ANESTHETICS

For Induction of Anesthesia

Although current-day practices for establishing the anesthetic state consist of initial administration of an IV sedative–hypnotic, there is an increasing interest in the use of volatile anesthetics via the face mask. This is commonplace in pediatric anesthesia but relatively rare in adult anesthesia. Historically, in the days of ether and cyclopropane, the standard induction technique was a mask induction. The renewed interest in this technique is attributed primarily to the newer potent and poorly soluble anesthetic, sevoflurane, which is nonpungent and, therefore, can easily be inhaled.[228] An important attribute of the gaseous induction technique is the ability to take the patient "deep" in a rapid fashion, thereby avoiding some of the unwanted side effects of

stage 2 of anesthesia (excitation, salivation, coughing, movement), noted historically with the use of the highly soluble anesthetic, ether. Induction of anesthesia with halothane in the pediatric population is quite common. The resurgence of interest in mask induction in the adult population centers on the potential safety and utility of this technique when using sevoflurane.[229,230,231,232] The safety issues consist primarily of the fact that spontaneous ventilation is preserved with a gas induction, and patients essentially regulate their own depth of anesthesia, as excessive sevoflurane would, in fact, suppress ventilation. Safety would be compromised if stage 2 excitation was problematic; however, clinical studies indicate that this is not the case. It is likely that the low blood:gas solubility of sevoflurane makes for a rapid induction. Typical times to loss of consciousness average approximately 1 minute when delivering 8% sevoflurane via the face mask. Sevoflurane also has been used in the approach to the difficult adult airway because of the preservation of spontaneous ventilation and absence of salivation with this technique.[233] The traditional "awake look" in the suspected difficult airway (where IV drugs are titrated to a level that allows direct laryngoscopy in the awake patient) has been modified to consist of spontaneous ventilation of high concentrations of sevoflurane until laryngoscopic evaluation is tolerated. Laryngeal mask placement can be successfully achieved 2 minutes after administering 7% sevoflurane via the face mask.[230] The addition of nitrous oxide to the inspired gas mixture does not add significantly to the induction sequence. The gas induction technique is promoted by pretreatment with benzodiazepines but complicated by apnea with opioid pretreatment.[231] Of course the utility of this technique is that clinicians simply need to pay attention to the airway during the induction sequence, rather than reaching for drugs and injecting them through an IV port. Importantly, patient acceptance of this technique has been relatively high, exceeding 90% of the cases.[232] There have been a number of techniques described to use sevoflurane for induction

of anesthesia via face mask. These include priming the circuit (emptying the rebreathing bag, opening the "pop-off" valve, dialing the vaporizer to 8% while using a fresh gas flow of 8 L/min, and maintaining this for 60 seconds prior to applying the face mask to the patient); a single-breath induction from end-expiratory volume to maximum inspired volume; and simply deep breathing. All seem to have the successful end result of loss of consciousness, generally within 1 minute.

For Maintenance of Anesthesia

The volatile anesthetics are clearly the most popular drug used to maintain anesthesia. They are easily administered via inhalation, they are readily titrated, they have a high safety ratio in terms of preventing recall, and the depth of anesthesia can be quickly adjusted in a predictable way while monitoring tissue levels via end-tidal concentrations. They are effective regardless of age or body habitus. They have some properties that prove beneficial in the operating room, including relaxation of skeletal muscle, in most cases preservation of cardiac output and cerebral blood flow, and relatively predictable recovery profiles. Some of the drawbacks to the use of the current volatile anesthetics are the absence of analgesic effects, their association with postoperative nausea and vomiting, and their potential for carbon monoxide poisoning and hepatitis.

PHARMACOECONOMICS AND VALUE-BASED DECISIONS

In the current environment of cost containment, clinicians are constantly being pressured to use less-expensive anesthetic agents, including antiemetics, neuromuscular blocking drugs, and volatile anesthetics. If succumbing to these pressures, the clinician must focus on providing value-based anesthesia. That is, to obtain the best results at the most practical cost. Factors involved in the value-based decision include the efficacy of the drug, the side effects, its direct costs, and its indirect effects. In terms of efficacy, all of the volatile anesthetics are reasonably similar, that is, they can be used to establish state of anesthesia for surgical interventions and can be easily reversed. In terms of side effects, the things to consider are serious side effects or toxicities versus manageable side effects, and to what extent these manageable side effects increase the cost. Regarding serious side effects, although halothane is the least expensive of the volatile anesthetics, it has definite life-threatening potential in terms of sensitization of the heart to arrhythmias and the development of an immune response that can cause fulminant hepatic

necrosis. One can make a strong argument that halothane does not belong in the operating room. A common side effect of the volatile anesthetics is nausea and vomiting. The need for rescue medications to treat nausea and vomiting after volatile anesthesia needs to be weighed into any legitimate cost analysis. Direct costs are not simply the cost/mL of liquid or cost/bottle of anesthetic. Rather, they reflect the combination of the potency of the drug to establish a MAC level, the fresh gas flow, and the cost of the anesthetic. At 2 L/min fresh gas flow, delivering 1 MAC, both desflurane and sevoflurane cost about $13.00 to $15.00/hr. This contrasts to generically priced isoflurane, which costs $1.00 to $2.00/MAC-hr when delivered at 2 L/min.[234] Simply reducing the fresh gas flow of sevoflurane and desflurane can halve the cost/MAC-hr of these more expensive anesthetics without compromising their speed and effectiveness. The indirect costs are probably the most difficult to pinpoint, but may be the most important to evaluating the cost of using the new volatile anesthetics. Examples of indirect costs include costs associated with OR time, time in the PACU versus bypassing the PACU to a step-down unit, and labor costs and outcome related costs, such as litigation to defend a bad outcome from an anesthetic drug.

One of the arguments for using the newer, more expensive volatile anesthetics, sevoflurane and desflurane, has been their relative speed in terms of emergence from anesthesia. It seems that this speed matches the ambulatory anesthesia environment in which we practice and the "move 'em in, move 'em out" approach to surgical patients. This argument has been tempered somewhat by the basic knowledge that one of the skills of the clinician is the titration of the volatile anesthetics. Even the more soluble drugs can be titrated based on clinical experience or with the aid of processed EEG monitors (such as the bispectral index system), permitting fast wake-ups regardless of the choice of anesthetic agent. However, there is strong evidence to support the use of the less-soluble (but most expensive) drugs in the longest surgical cases (Fig. 15-37).[3] In these cases the high direct cost of the anesthetic is balanced by the much improved recovery profile, including a more rapid time to emergence and a more rapid discharge from the recovery room. Curiously, the discharge advantage with the low soluble anesthetics has been difficult to show after shorter surgical procedures.

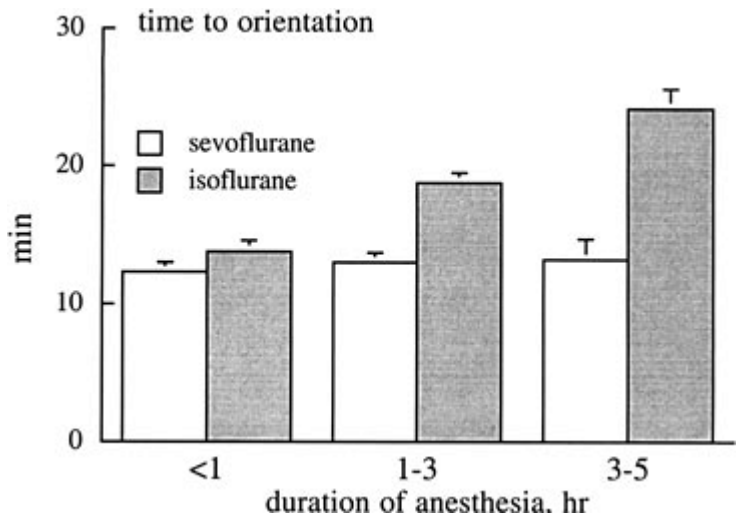

FIGURE 15-37. The recovery times to orientation after anesthesia of varying durations. With the less-soluble anesthetic sevoflurane, the time to orientation was independent of the anesthetic duration. In contrast, long anesthetic durations with isoflurane were associated with delayed times to orientation. (Adapted from Ebert TJ, Robinson BJ, Uhrich TD *et al*: Recovery from sevoflurane anesthesia: A comparison to isoflurane and propofol anesthesia. Anesthesiology 89:1524, 1998.)

Chapter 16

Neuromuscular Blocking Agents

Donati François

Bevan David R.

KEY POINTS

1	Neuromuscular blocking agents are used to improve conditions for tracheal intubation, to provide immobility during surgery, and to facilitate mechanical ventilation.
2	The main site of action of neuromuscular blocking agents (muscle relaxants) is on the nicotinic cholinergic receptor at the endplate of muscle. They also have effects at presynaptic receptors located on the nerve terminal.
3	Succinylcholine is a blocking agent that produces depolarization at the endplate and binds to extrajunctional receptors. In spite of many side effects, such as hyperkalemia, its rapid offset makes it the drug of choice for rapid sequence induction.
4	All other drugs available are nondepolarizing. They compete with acetylcholine for the same binding sites.
5	Fade-in response to high frequency stimulation (e.g. train-of-four, 2 Hz for 2 sec) is a characteristic of nondepolarizing blockade. Train-of-four fade is difficult to evaluate manually or visually during recovery when ratio is >0.4.
6	The upper airway is particularly sensitive to the effects of nondepolarizing blockade. Complete recovery does not occur until train-of-four ratio at the adductor pollicis >0.9.
7	Residual paralysis is more frequent with long-duration than intermediate-duration agents.
8	Reversal with anticholinesterases should be attempted when a certain degree of spontaneous recovery is manifest. Ideally, all four twitches in response to train-of-four stimulation should be visible before reversal is given.

It appears paradoxical that drugs having peripheral effects on neuromuscular transmission might have a role in anesthesia. If the patient is anesthetized, why provide agents to prevent movement? Yet, the introduction of muscle relaxants, more appropriately called neuromuscular blocking agents, into clinical practice more than 60 years ago is an important milestone in the history of anesthesia.[1] However, in 1954, in a paper on anesthetic mortality, Beecher and Todd claimed that mortality increased by sixfold when muscle relaxants were used.[2] This situation was probably because of the suboptimal use of mechanical ventilation and reversal drugs, but other controversies arose in recent years, for a variety of reasons.

For example, the incidence of awareness is greater when neuromuscular blocking agents are used,[3] and some authors recommend restricting the use of these drugs whenever possible, as patient movement might be an indicator of

consciousness. However, anesthetics act at the spinal cord level to produce immobility, and movement in response to a noxious stimulus indicates inadequate analgesia, not insufficient unconsciousness.[4] Therefore, awareness does not occur because too much of a neuromuscular blocking agent has been given, but because too little anesthetic is administered. This seems to be supported by an incident report review where an inadequate dose of anesthetic drugs was suspected in 68 of 81 cases of awareness.[3]

1 Complete paralysis is not required all the time for all surgical procedures. For example, anesthesiologists might tend to inject more mivacurium than really needed by surgeons. However, neuromuscular blocking agents were found to make a difference in lower abdominal surgery, where, in spite of generous doses of isoflurane, surgical conditions were better in patients receiving vecuronium (Fig. 16-1).[5] In addition to providing immobility and better surgical conditions, neuromuscular blocking agents improve intubating conditions. The doses of narcotics required for acceptable intubating conditions in the absence of muscle paralysis produce significant hypotension (Fig. 16-2).[6] Providing optimal intubating conditions is not a trivial objective. It has been demonstrated that poor intubating conditions are associated with an increased incidence of voice hoarseness and vocal cord damage (Fig. 16-3).[7] Furthermore, giving neuromuscular blocking agents improved the quality of intubating conditions.

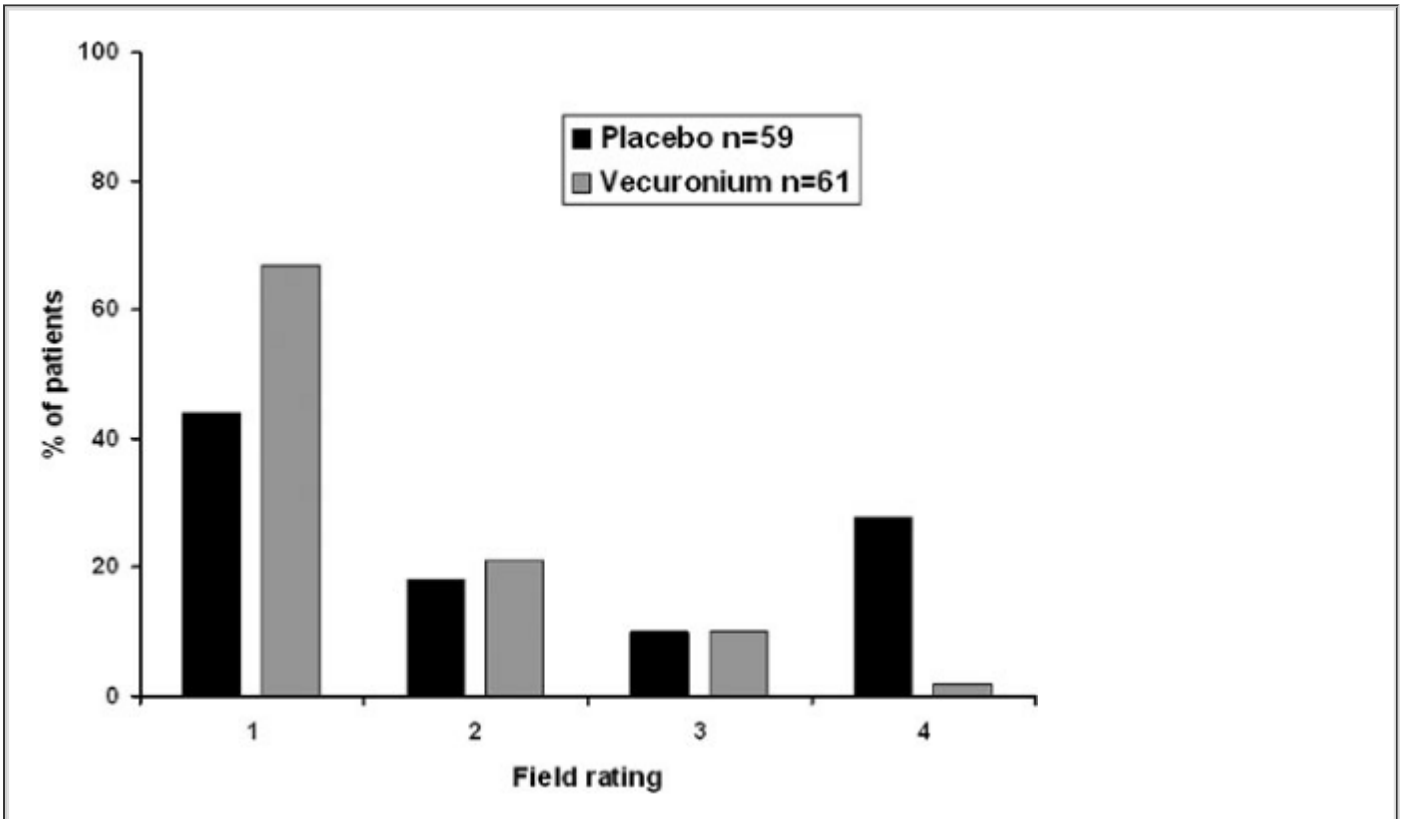

FIGURE 16-1. Surgeon's assessment of muscle relaxation during lower abdominal surgery. Rating goes from 1 (excellent) to 4 (poor). The incidence of poor rating was greater in

patients not given vecuronium (29%) compared with those who received the drug (2%). Redrawn from King et al.[5]

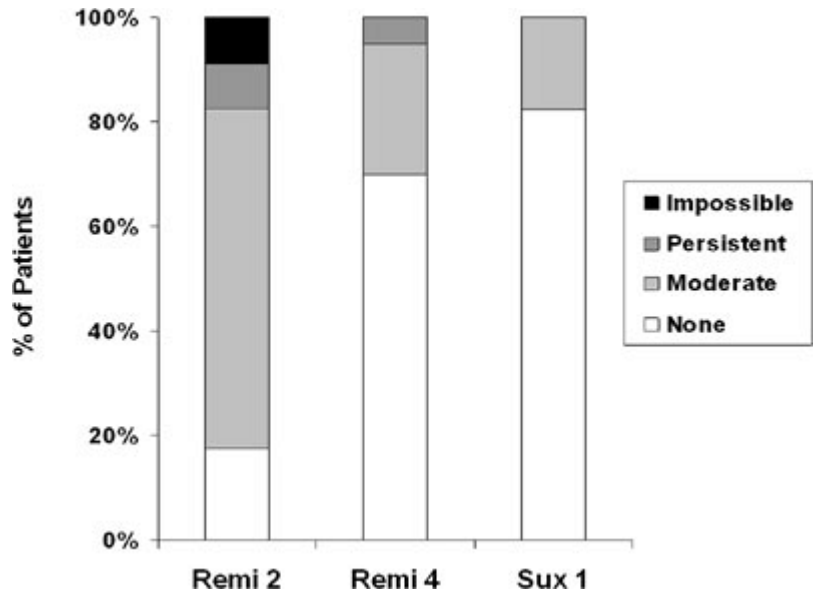

FIGURE 16-2. Neuromuscular blocking agents provide better intubating conditions than high doses of narcotics, without hypotension. In the study mentioned earlier, patients were randomized to remifentanil, 2 μg/kg (Remi 2), or 4 μg/kg (Remi 4), or succinylcholine 1 mg/kg (Sux 1). Mean arterial pressure decreased by a mean value of 21, 28, and 8%, respectively. Intubating conditions were rated as impossible or according to the degree of coughing produced (persistent, moderate, or none). Data from McNeil et al.[6]

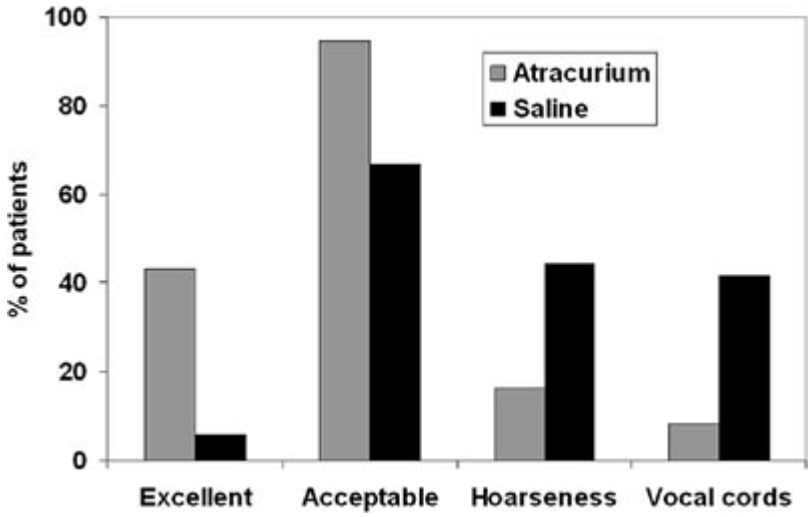

FIGURE 16-3. Neuromuscular blocking agents improve intubating conditions and reduce vocal cord sequelae. The graph depicts the incidence of excellent and acceptable (defined as good or excellent) intubating conditions after atracurium or saline. The percentage of patients who reported hoarseness and those with vocal cord lesions documented by stroboscopy is also shown. Data from Mencke et al.[7]

As it is important to provide adequate anesthesia while a patient is totally or partially paralyzed, it is also essential to make sure that the effects of neuromuscular blocking drugs have worn off or are reversed before the patient regains consciousness. With the introduction of shorter acting neuromuscular blocking agents, it was thought that reversal of blockade could be omitted. However, residual paralysis is still a problem, even 25 years after if was first described (Table 16-1).[8] In addition, the threshold for complete neuromuscular recovery is now considered to be a train-of-four (TOF) ratio of 0.9, instead of the traditional 0.7 (Fig. 16-4).[9] Thus, an understanding of the pharmacology of neuromuscular blocking agents and reversal drugs is essential.

AMG, acceleromyography; TOF, train-of-four ratio.

AMG, acceleromyography; TOF, train-of-four ratio.

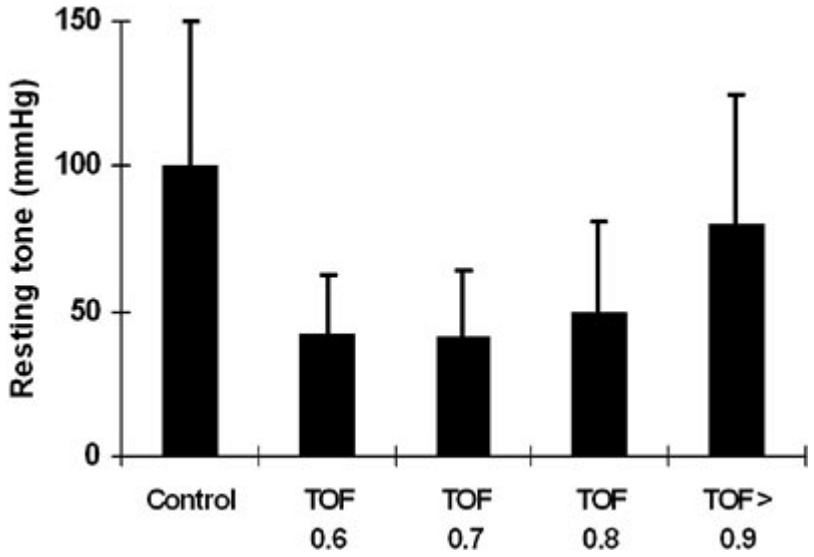

FIGURE 16-4. Upper esophageal resting tone in volunteers given vecuronium. Train-of-four ratio was measured at the adductor pollicis. Statistically significant decreases compared with control were found at all levels of paralysis until TOF >0.9. Redrawn from Eriksson et al.[146]

PHYSIOLOGY AND PHARMACOLOGY

Structure

The cell bodies of motor neurons supplying skeletal muscle lie in the spinal cord. They receive and integrate information from the central nervous system. This information is carried via an elongated structure, the axon, to distant parts of the body. Each nerve cell supplies many muscle cells (or fibers) a short distance after branching into nerve terminals. The terminal portion of the axon is a specialized structure, the synapse, designed for the production and release of acetylcholine. The synapse is separated from the endplate of the muscle fiber by a narrow gap, called the synaptic cleft, which is approximately 50 nm in width (0.05 μm) (Fig. 16-5).[10] The nerve terminal is surrounded by a Schwann cell, and the synaptic cleft has a basement membrane and contains filaments that anchor the nerve terminal to the muscle.

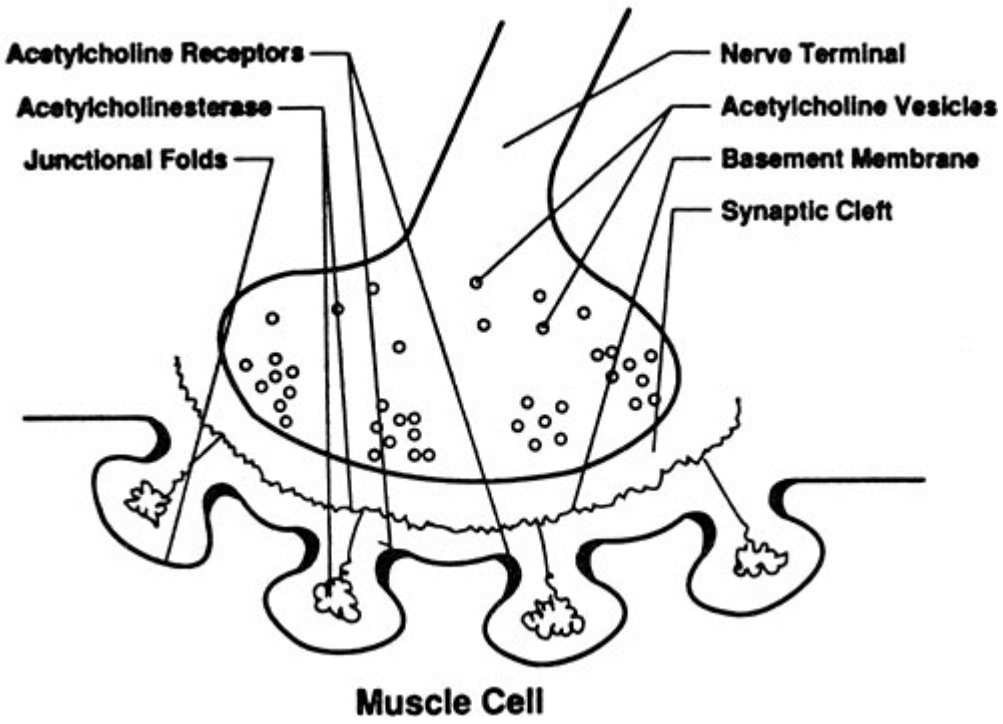

FIGURE 16-5. Schematic representation of the neuromuscular junction (not drawn to scale).

The endplate is a specialized portion of the membrane of the muscle fiber where nicotinic acetylcholine receptors are concentrated. During development, multiple connections are made

between nerve terminals and a single muscle fiber. However, as maturation continues, most of these connections atrophy and disappear, usually leaving only one connection per muscle fiber. This endplate continues to differentiate from the rest of the muscle fiber. The nerve terminal enlarges, and folds appear. The acetylcholine receptors cluster at the endplate, especially at the crests of the folds and their density decreases to almost zero in extrajunctional areas.[11,12] Mammalian endplates usually have an oval shape with the short axis perpendicular to the fiber. The width of the endplate is sometimes as large as the diameter of the fiber, but is usually smaller. However, its length is only a small fraction of that of the fiber.

Nerve Stimulation

Under resting conditions, the electrical potential of the inside of a nerve cell is negative with respect to the outside (typically –90 mV). If this potential is made less negative (depolarization), sodium channels open and allow sodium ions to enter the cell. This influx of positive ions makes the potential inside the membrane positive with respect to the outside. This potential change in turn causes depolarization of the next segment of membrane, causing more sodium channels to open, and an electrical impulse, or action potential, propagates. The duration of the action potential is brief (<1 msec), because of rapid inactivation of sodium channels and activation of potassium channels. An action potential also triggers the opening of calcium channels, allowing calcium ions to penetrate the cell. This entry of calcium facilitates release of the neurotransmitter at the nerve terminal.

The sodium channels in the axon may be activated in response to electrical depolarization provided by a nerve stimulator. A peripheral nerve is made up of a large number of axons, each of which axon responds in an all-or-none fashion to the stimulus applied. Thus, in the absence of neuromuscular blocking agents, the relationship between the amplitude of the muscle contraction and current applied is sigmoid.[13] At low currents, the depolarization is insufficient in all axons. As current increases, more and more axons are depolarized to threshold and the strength of the

muscle contraction increases. When the stimulating current reaches a certain level, all axons are depolarized to threshold and propagate an action potential. Increasing current beyond this point does not increase the amplitude of muscle contraction: the stimulation is supramaximal (Fig. 16-6). Most commercially available stimulators deliver impulses lasting 0.1 to 0.2 msec.

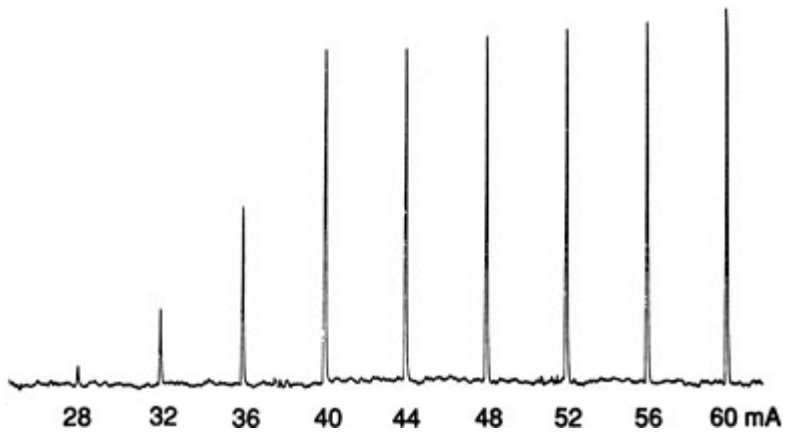

FIGURE 16-6. Example of increasing stimulating current in one patient. Current pulses, 0.2-msec duration, were delivered to the ulnar nerve at the wrist every 10 seconds. The force of contraction of the adductor pollicis was measured and appears as spikes. No twitch was seen if the current was <28 mA. At current strengths of ⩾40 mA, the current became supramaximal, increasing the current produced little change in force.

Release of Acetylcholine

Acetylcholine is synthesized from choline and acetate and packaged into 45-nm vesicles. Each vesicle contains 5,000 to 10,000 acetylcholine molecules. Some of these vesicles cluster near the cell membrane opposite the crests of the junctional folds of the endplate, in areas called active zones (see Fig. 16-5).[12]

Although there have been doubts regarding the vesicular hypothesis, it is now widely accepted that acetylcholine is released in packets, or quanta, and that a quantum represents the contents of one vesicle.[14] In the absence of nerve stimulation, quanta are released spontaneously, at random, and this is seen as small depolarizations of the endplate (miniature endplate potential; MEPP). When an action potential invades the nerve terminal, ~200 to 400 quanta are released simultaneously, unloading ~1 to 4 million acetylcholine molecules into the synaptic cleft.[10,14] Calcium, which enters the nerve terminal through channels that open in response to depolarization, is required for vesicle fusion and release. Calcium channels are located near docking proteins, and this special geometric

arrangement provides high intracellular concentrations of calcium to allow binding of specialized proteins on the vesicle membrane with docking proteins.[12] Binding produces fusion of the membranes and release of acetylcholine ensues. When the calcium concentration is decreased, or if the action of calcium is antagonized by magnesium, the release process is inhibited and transmission failure may occur. Other proteins regulate storage and mobilization of acetylcholine vesicles. It appears that a small proportion of vesicles is immediately releasable, while a much larger reserve pool can be mobilized more slowly. Each impulse releases 0.2 to 0.5% of the 75,000 to 100,000 vesicles in the nerve terminal.[14] With repetitive stimulation, the amount of acetylcholine released decreases rapidly because only a small fraction of the vesicles is in a position to be released immediately. To sustain release during high-frequency stimulation, vesicles

must be mobilized from the reserve pool, and this process requires calcium.[14]

Postsynaptic Events

The 1 to 10 million receptors located at the endplate are made up of five glycoprotein subunits arranged in the form of a rosette and lying across the whole cell membrane (Fig. 16-7). Two of these noncontiguous subunits, designated α, are identical. The other three units are called β, δ and γ or ε There are two acetylcholine binding sites, each located on the outside part of the α subunit. When two acetylcholine molecules bind simultaneously to each binding site, an opening is created in the center of the rosette, allowing sodium ions to enter the cell.[10,15] This depolarizes the endplate, that is, its inside becomes less negative. There is a high density of sodium channels in the folds of synaptic clefts and in the perijunctional area.[15] These channels open when the membrane is depolarized beyond a critical point, allowing more sodium to enter the cell, and producing further depolarization. This depolarization generates an action potential, which propagates by activation of sodium channels along the whole length of the muscle fiber. The muscle action potential has a duration 5 to 15 milliseconds and can be recorded as a electromyogram (EMG). It precedes the onset of contraction, or twitch, which lasts 100 to 200 milliseconds. With high-frequency (>10 Hz) stimulation, the muscle fiber does not have time to relax before the next impulse, so contractions fuse and add up, and a tetanus is obtained.

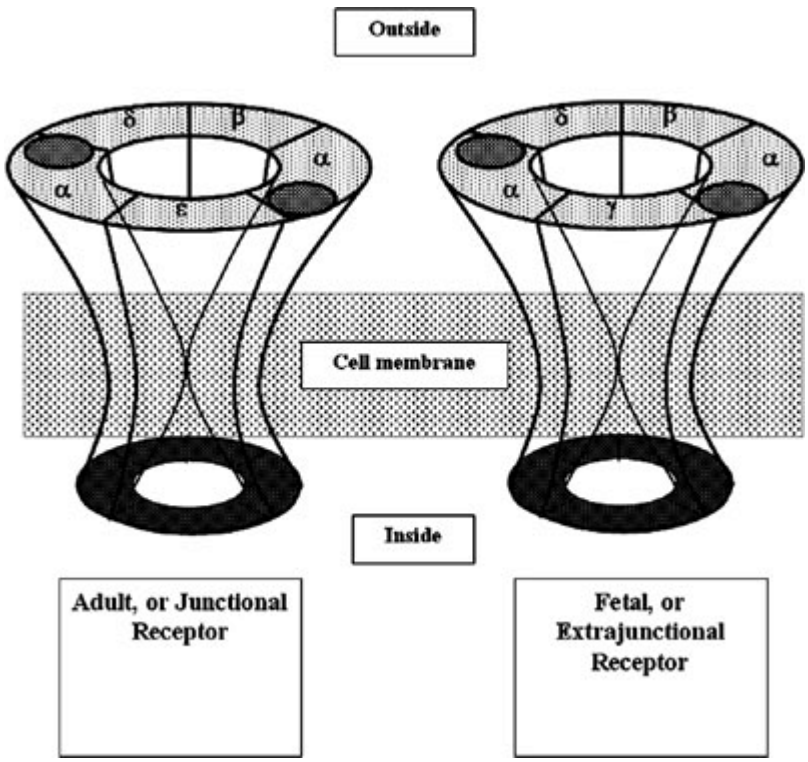

FIGURE 16-7. Two types of nicotinic receptors in muscle. Both have the same five subunits, except for a substitution of the ε for the γ subunits. The acetylcholine binding sites are represented by a shaded oval area. They are on the α subunit, at the δ and ε or γ interface, respectively. According to some authors, the order of the β and δ is inverted.

There are two types of nicotinic acetylcholine receptors. Early in development, receptors are evenly distributed along the whole length of the muscle fiber. These receptors, called fetal receptors, have a γ subunit (see Fig. 16-7). When the endplate develops, receptors tend to cluster at the neuromuscular junction and leave only few receptors in the extrajunctional areas. As maturation continues, the γ subunit is substituted by an ε subunit, which is characteristic of the adult-type, junctional receptor.[11,12] In humans, the switch occurs in the last weeks of pregnancy. Maintenance of adult receptors at the endplate depends on the integrity of nerve supply. A few γ-

type, extrajunctional receptors still persist in adults, but can proliferate in cases of denervation. Both types of receptor have slightly different sensitivities to agonist and antagonist drugs.[12] Both have two binding sites for acetylcholine, located on the subunit, at the interface between the δ and the ε or γ or subunits, respectively.[16]

2 The main action of nondepolarizing neuromuscular blocking drugs is to block the postsynaptic acetylcholine receptor by binding to at least one of the two α subunits, thus preventing access by acetylcholine. Under normal circumstances, only a small fraction of available receptors must bind to acetylcholine to produce sufficient depolarization to trigger a muscle contraction. In other words, there is a wide "margin of safety." This implies that neuromuscular blocking drugs must be bound to a large number of receptors before any blockade is detectable. Animal studies suggest that 75% of receptors must be occupied before twitch height decreases in the presence of *d*-tubocurarine, and blockade is complete when 92% of receptors are occupied.[17] The actual number depends on species and type of muscle, and humans might have a reduced margin of safety compared with other species.[18] So, it is futile to correlate receptor occupancy data obtained in cats with certain clinical tests in humans, such as hand grip and head lift, which involve different muscle groups. However, the general concept that a large proportion of receptors must be occupied before blockade becomes detectable, and that measurable blockade occurs over a narrow range of receptor occupancy, remains applicable to clinical practice. Because it must overcome the margin of safety, the initial dose of neuromuscular blocking agent is greater than maintenance doses.

Acetylcholine is hydrolyzed rapidly by the enzyme acetyl cholinesterase, which is present in the folds of the endplate as well as embedded in the basement membrane of the synaptic cleft. The presence of the enzyme in the synaptic cleft suggests that not all the acetylcholine released reaches the endplate; some is hydrolyzed en route.[14]

Presynaptic Events

The release of acetylcholine normally decreases during high-frequency stimulation because the pool of readily releasable acetylcholine becomes depleted faster than it can be replenished. Under normal circumstances, the reduced amount released is well above what is required to produce muscle contraction because of the high margin of safety at the neuromuscular junction. However, during partial nondepolarizing blockade this decrease in transmitter output produces fade—a progressive decrease in muscle response with each stimulus. Nondepolarizing neuromuscular blocking drugs probably accentuate the fade by blocking presynaptic nicotinic receptors, which differ structurally from postsynaptic receptors.[19] The function of the presynaptic receptors is to sustain acetylcholine mobilization

in the face of continuing stimulation, in other words to provide positive feedback. Nondepolarizing agents have a greater affinity for presynaptic than postsynaptic receptors. Only small doses of nondepolarizing relaxants are needed to block presynaptic receptors.[20] Whatever the exact mechanism of fade, it remains a key property of nondepolarizing neuromuscular blocking drugs and is useful for monitoring purposes.

NEUROMUSCULAR BLOCKING AGENTS

Neuromuscular blocking drugs interact with the acetylcholine receptor either by depolarizing the endplate or by competing with acetylcholine for binding sites. The former mechanism is characteristic of depolarizing drugs and the latter of nondepolarizing agents. The only depolarizing agent still in use is succinylcholine. All others are of the nondepolarizing type.

Pharmacological Characteristics of Neuromuscular Blocking Agents

The effect of neuromuscular blocking drugs is measured as the depression of adductor muscle contraction (twitch) following electrical stimulation of the ulnar nerve. The value is compared with a control value, obtained before injection of the drug. Each drug has onset, potency, and recovery

characteristics.

Potency of each drug is determined by constructing dose-response curves, which describe the relationship between twitch depression and dose (Fig. 16-8). Then, the effective dose 50, or ED_{50}, which is the median dose corresponding to 50% twitch depression, is obtained. A more clinically relevant value, the ED_{95}, corresponding to 95% block, is more commonly used. For example, the ED_{95} for vecuronium is 0.05 mg/kg, which means that half the patients will achieve at least 95% block of single twitch (compared with the prevecuronium value) with that dose, and half the subjects will reach less than 95% block. Rocuronium has an ED_{95} of 0.3 mg/kg. Therefore, it has one-sixth the potency of vecuronium because 6 times as much rocuronium has to be given to produce the same effect. The ED_{95} of known neuromuscular blocking agents vary over two orders of magnitude (Table 16-2).

TABLE 16-2 Potency, Onset Time, Duration, and Recovery Index of Neuromuscular Blocking Agents

▪AGENT	▪ED_{95} (mg/kg)	▪ONSET TIME (min)	▪DURATION TO 25% RECOVERY (min)	▪RECOVERY INDEX (25–75% RECOVERY) (min)
▪ULTRASHORT-DURATION AGENTS				
Succinylcholine	0.3	1–1.5	6–8	2–4
GW280430A[a]	0.19	1.7	6–8	2.5
▪SHORT-DURATION AGENTS				
Mivacurium	0.08	3–4	15–20	7–10
Rapacuronium[b]	0.75	1–1.5	15–25	5–7
▪INTERMEDIATE-DURATION AGENTS				
Atracurium	0.2–0.25	3–4	35–45	10–15
Cisatracurium	0.05	5–7	35–45	12–15
Rocuronium	0.3	1.5–3	30–40	8–12
Vecuronium	0.05	3–4	35–45	10–15
▪LONG-DURATION AGENTS				
Alcuronium[b]	0.25	3–5	60–90	30–40

Doxacurium	0.025	5–10	40–120	30–40
d-Tubocurarine[b]	0.5	2–4	60–120	30–45
Gallamine[b]	2	1.5–3	60–120	30–60
Metocurine[b]	0.3	3–5	60–150	40–60
Pancuronium	0.07	2–4	60–120	30–40
Pipecuronium[b]	0.05	3–5	90–130	35–45

Typical values for the average young adult patient. Onset and duration data depend on dose. The values presented are the best estimates available for twice the ED_{95} and are measured at the adductor pollicis. Actual values may vary markedly from one individual to the next, and may be affected by age, other medications, and/or disease states. The categories under which the drugs are classified are somewhat arbitrary.

[a]Being investigated at the time of writing.

[b]No longer used or very limited use in North America.

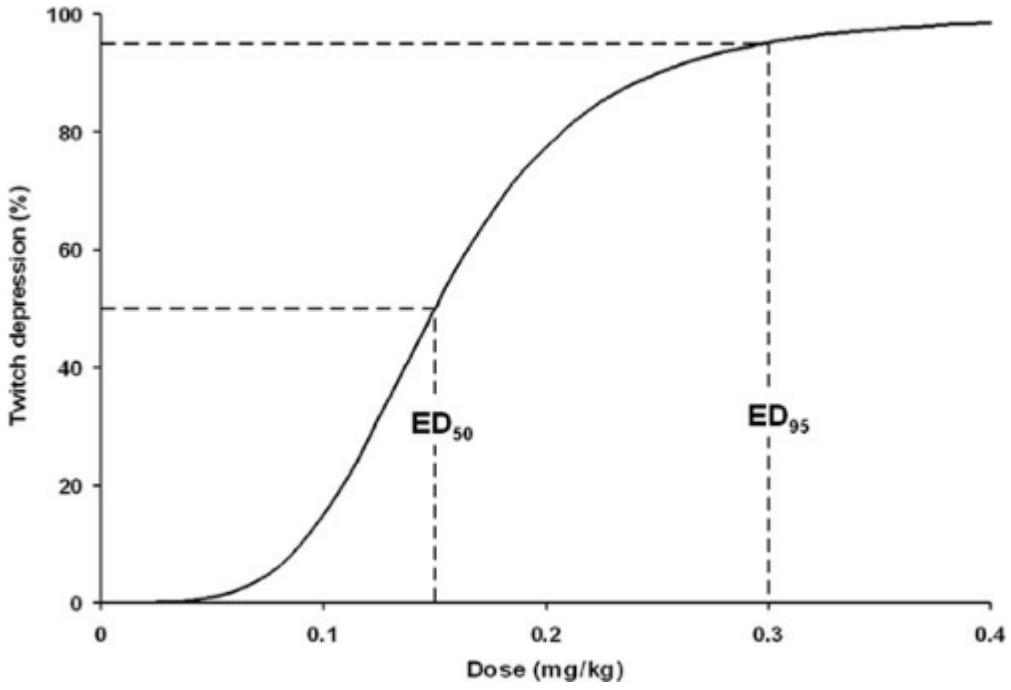

FIGURE 16-8. Example of a dose-response relationship. The actual numbers are approximately those for rocuronium. The ED_{50} is the dose corresponding to 50% blockade and ED_{95} the dose corresponding to 95% blockade.

Onset time, or time to maximum blockade, can be shortened if the dose is increased. When two or more drugs are compared, it is meaningful to compare only equipotent doses, and usually, clinically relevant doses ($2 \times ED_{95}$) are considered.

Duration of action is the time from injection of the neuromuscular blocking agent to return of 25% twitch height (compared with control). Duration increases with dose, so comparisons are normally made with $2 \times ED_{95}$ doses. The 25% twitch height figure was chosen because rapid reversal can normally be achieved at that level. Categories were proposed for neuromuscular blocking drugs according to their duration of action (see Table 16-2).[21] Same duration agents may have markedly different onsets.

Recovery index is the time interval between 25% and 75% twitch height. It provides information about the speed of recovery once return of twitch is manifest. It is sometimes preferred to duration of action, because it does not depend heavily on the dose given. The values for ED_{95}, onset time, duration of action, and recovery index depend on which muscle is used to make measurements. For consistency's sake, the adductor pollicis has been retained as the gold standard, not because of its physiological significance, but because it is most commonly monitored and data on it are most abundant.

The pharmacological characteristics of neuromuscular blocking agents are completed by an assessment of intubating conditions, which do not always parallel twitch height at the adductor pollicis. Intubating conditions depend on paralysis of centrally located muscles, but also on type and quantity of narcotic and hypnotic drug given for induction of anesthesia. To decrease variability between studies, criteria to grade intubating conditions as excellent, good, poor, or impossible in a scoring system were adopted by a group of experts who met in Copenhagen in 1994.[22]

DEPOLARIZING DRUGS: SUCCINYLCHOLINE

3 Among drugs that depolarize the endplate, only succinylcholine is still used clinically. Decamethonium, a depolarizing drug with a slow onset and intermediate duration, has been replaced by nondepolarizing alternatives. However, succinylcholine still

enjoys some popularity, despite a long list of undesired effects, because it is the only ultrarapid onset, ultrashort duration neuromuscular blocking drug available.

Neuromuscular Effects

The effects of succinylcholine at the neuromuscular junction are not completely understood. The drug depolarizes presynaptic, postsynaptic, and extrajunctional receptors. However, when the receptor is in contact with any agonist, including acetylcholine, for a prolonged time, it ceases to respond to the agonist. Normally, this desensitization process does not take place because of the rapid breakdown of acetylcholine (<1 msec). However, succinylcholine remains at the endplate for much longer, and desensitization can develop. Another possible mechanism is the inactivation of sodium channels in the junctional and perijunctional area, which occurs when the membrane remains depolarized. This inactivation prevents the propagation of the action potential.

Within 1 minute after succinylcholine injection and before paralysis is manifest, some disorganized muscular activity is observed frequently. This phenomenon is called “fasciculations” and is probably a result of depolarization of the nerve terminal produced by activation of presynaptic receptors. The effectiveness of small doses of nondepolarizing drugs in reducing the incidence of fasciculations suggests that the presynaptic receptors are relatively sensitive to these drugs.[20]

Succinylcholine has yet another neuromuscular effect. In some muscles, like the masseter and to a lesser extent the adductor pollicis, a sustained increase in tension that may last for several minutes can be observed. The mechanism of action of this tension change is uncertain but is most

likely mediated by acetylcholine receptors because it is blocked by large amounts of nondepolarizing drugs.[23] The increase in masseteric tone, which is probably always present to some degree but greater in some susceptive individuals, may lead to imperfect intubating conditions in a small proportion of patients. Masseter spasm may be an exaggerated form of this response.

Characteristics of Depolarizing Blockade

After injection of succinylcholine, single-twitch height is decreased. However, the response to high-frequency stimulation is sustained: minimal train-of-four and tetanic fade is observed. The block is antagonized by nondepolarizing agents so that the ED_{95} is increased by a factor two if a small dose of nondepolarizing drug is given before.[24] Succinylcholine blockade is potentiated by inhibitors of acetyl cholinesterase, such as neostigmine and edrophonium.[25]

Phase II Block

After administration of 7 to 10 mg/kg, or 30 to 60 minutes of exposure to succinylcholine, train-of-four and tetanic fade become apparent. Neostigmine or edrophonium can antagonize this block, which has been termed "nondepolarizing," "dual," or "Phase II block." The onset of Phase II block coincides with tachyphylaxis, as more succinylcholine is required for the same effect.[26]

Pharmacology of Succinylcholine

Succinylcholine is rapidly hydrolyzed by plasma cholinesterase (also called pseudocholinesterase), with an elimination half-life

of <1 minute in patients.[27] Because of the rapid disappearance of succinylcholine from plasma, the maximum effect is reached quickly. Subparalyzing doses (up to 0.3 to 0.5 mg/kg) reach their maximal effect within ~1.5 to 2 minutes at the adductor pollicis,[24] and within 1 minute at more central muscles, such as the masseter and the larynx. With larger doses (1 to 2 mg/kg), abolition of twitch response can be reached even more rapidly.

The mean dose producing 95% blockade (ED_{95}) at the adductor pollicis is 0.30 to 0.35 mg/kg with opioid–nitrous oxide anesthesia.[28] In the absence of nitrous oxide, the ED_{95} is increased to 0.5 mg/kg.[29] These values are doubled if *d*-tubocurarine, 0.05 mg/kg, is given as a defasciculating agent.[24] The time until full recovery is dose dependent and reaches 10 to 12 minutes after a dose of 1 mg/kg.[28]

Side Effects

Cardiovascular

Sinus bradycardia with nodal or ventricular escape beats (or both) may occur, especially in children, and asystole has been described after a second dose of succinylcholine in both pediatric and adult patients. These parasympathetic effects can be attenuated with atropine or glycopyrrolate.[30] Succinylcholine increases catecholamine release, and this effect may explain, in part, why bradycardia does not occur more frequently. The mechanism for the enhanced bradycardic effect of a second dose is not known.

Anaphylaxis

Succinylcholine has been incriminated as the trigger of allergic reactions more often than any other drug used in anesthesia. Successive studies conducted in France indicate that the number of reported events is decreasing, corresponding to the gradual replacement of succinylcholine by nondepolarizing drugs.[31] The incidence of anaphylactic reactions to succinylcholine is difficult to establish, but is probably of the order of 1:5,000 to 1:10,000.

Fasciculations

The prevalence of fasciculations is high (60 to 90%) after the rapid injection of succinylcholine, especially in muscular adults. Although this is a benign side effect of the drug, most clinicians prefer to prevent fasciculations. In this respect, a small dose of a nondepolarizing neuromuscular blocking drug is given 3 to 5 minutes before succinylcholine is effective. When the drug was available, *d*-tubocurarine 0.05 mg/kg was used for this purpose. Rocuronium is an acceptable alternative, as long as appropriate doses (0.03 to 0.04 mg/kg, that is, 10% of the ED_{95}) are given.[32] In one study, rocuronium, 0.03 mg/kg, decreased the incidence of fasciculations from 90 to 10%.[33] A dose of 0.06 mg/kg leads to an unacceptably high incidence of symptoms of neuromuscular weakness, such as blurred vision, heavy eyelids, voice changes, difficulty swallowing, or even dyspnea, in the awake patient.[34] Atracurium 0.02 mg/kg is also effective. Pancuronium, vecuronium, cisatracurium, and mivacurium are not as effective as defasciculants. After these nondepolarizing drugs, the dose of succinylcholine must be increased from 1 mg/kg to 1.5 or even 2 mg/kg because of the antagonism between depolarizing and nondepolarizing drugs.[24] Other drugs, such as diazepam, lidocaine, fentanyl, calcium, vitamin C, magnesium, and dantrolene, have all been used to prevent fasciculations. The results are no better than with nondepolarizing relaxants, and they may have undesirable effects of their own. "Self-taming," the administration of small (10-mg) doses of succinylcholine 1 minute before the intubating dose, does not appear to be effective[33] and has largely been abandoned.

Muscle Pains

Generalized aches and pains, similar to the myalgia that follows violent exercise, are common 24 to 48 hours after succinylcholine administration. They occur in 1.5 to 89% of patients receiving succinylcholine and are more common in young, ambulatory patients.[35] The intensity of muscle pains is not always correlated with the intensity of fasciculations, but the methods that have been shown effective to prevent fasciculations usually prevent muscle pains. For example, a precurarization dose of a nondepolarizing neuromuscular blocking agent is effective. Lidocaine (1 to 1.5 mg/kg), especially in conjunction with precurarization, has also been shown to be of value.[35] Calcium, vitamin C, benzodiazepines, magnesium, and dantrolene have been tried with inconclusive results.[35]

Intragastric Pressure

Succinylcholine increases intragastric pressure, and this effect is blocked by precurarization. However, succinylcholine causes even greater increases in lower esophageal sphincter pressure. Thus, succinylcholine does not appear to increase the risk of aspiration of gastric contents unless the lower esophageal sphincter is incompetent.

Intraocular Pressure

Intraocular pressure increases by 5 to 15 mm Hg after injection of succinylcholine. The mechanism is unknown but occurs after detachment of extraocular muscle, suggesting an intraocular etiology. Precurarization with a nondepolarizing blocker has little or no effect on this increase. This background information has led to the widespread recommendation to avoid succinylcholine in open eye injuries. However, it must be appreciated that other factors, such as inadequate anesthesia, elevated systemic blood pressure, and insufficient neuromuscular blockade during laryngoscopy and tracheal intubation, might increase intraocular pressure more than succinylcholine. In addition, there is little evidence that the use of succinylcholine has led to blindness or extrusion of eye content.[36]

Intracranial Pressure

Succinylcholine may increase intracranial pressure (ICP), and this response is probably diminished by precurarization.[37] Most of this change may be a result of an increase in PCO_2 produced by fasciculations. Again, laryngoscopy and tracheal intubation with inadequate anesthesia or muscle relaxation are likely to increase ICP even more than succinylcholine.

Hyperkalemia

Serum potassium increases by 0.5 to 1.0 mEq/L after injection of succinylcholine. This increase is not prevented completely by precurarization. In fact, only large doses of nondepolarizing blockers reliably abolish this effect.[38] Subjects with preexisting hyperkalemia, such as patients in renal failure, do not have a greater increase in potassium levels, but the absolute level might reach the toxic range. Succinylcholine is safe in normokalemic renal failure patients.[39] However, severe hyperkalemia, occasionally leading to cardiac arrest, has been described in patients after major denervation injuries, spinal cord transection, peripheral denervation, stroke, trauma, extensive burns, and prolonged immobility with disease, and may be related to potassium loss via a proliferation of extrajunctional receptors.[38] Hyperkalemia has been reported with myotonia and muscle dystrophies, and cardiac arrests have been reported in children before the diagnosis of the disease was made.[38]

Severe hyperkalemia after succinylcholine resulting in cardiac arrest has also been observed in acidotic hypovolemic patients.

Abnormal Plasma Cholinesterase

Plasma cholinesterase activity can be reduced by a number of endogenous and exogenous causes, such as pregnancy, liver disease, uremia, malnutrition, burns, plasmapheresis, and oral contraceptives. These conditions usually lead to a slight, clinically unimportant increase in the duration of action of succinylcholine.[40] Plasma cholinesterase activity is reduced by some anticholinesterases (e.g., neostigmine) so that the duration of succinylcholine given after neostigmine, but not after edrophonium, is increased.[25]

A small proportion of patients have a genetically determined inability to metabolize succinylcholine. Either plasma cholinesterase is absent or an abnormal form of the enzyme is present. Only patients homozygous for the condition (approximately 1:2,000 individuals) have prolonged paralysis (3 to 6 hours) after usual doses of succinylcholine (1 to 1.5 mg/kg). In heterozygous patients (1:30 cases), the duration of action is only slightly prolonged compared with normal individuals. Traditional methods for identifying plasma cholinesterase phenotype involve measurement of enzyme activity with a substrate and inhibition with dibucaine, fluoride, and chloride. These tests are only capable of identifying some enzyme variants. The complete amino acid sequence of plasma cholinesterase has now been determined using molecular genetics techniques. The cholinesterase gene is located on chromosome 3 at q26,[40] and 20 mutations in the coding region of the plasma cholinergic gene have been identified. Although whole blood or fresh frozen plasma (FFP) can be given to accelerate succinylcholine metabolism in patients with low or absent plasma cholinesterase, the best course of action is probably mechanical ventilation of the lungs until full recovery of neuromuscular function can be demonstrated. Neostigmine and edrophonium are unpredictable in the reversal of abnormally prolonged succinylcholine blockade and are best avoided.

Clinical Uses

The main indication for succinylcholine is to facilitate tracheal intubation. In adults, a dose of 1.0 mg/kg yields 75 to 80% excellent intubation conditions within 1 to 1.5 minutes after an induction sequence that includes a hypnotic (propofol or thiopental) and a moderate dose narcotic.[41] The dose must be increased to 1.5 to 2.0 mg/kg if a precurarizing dose of nondepolarizing blocker has been used.

Succinylcholine is especially indicated for the "rapid sequence induction," when a patient presents with a full stomach and the possibility of aspiration of gastric contents. In this situation, manual ventilation of the lung is avoided if possible to reduce the probability of aspiration because of excessive pressure in the stomach. Thus, the ideal neuromuscular blocking agent has both a fast onset, to reduce the time between induction and intubation of the airway, and a rapid recovery, to allow return of normal breathing before the patient becomes hypoxic. The duration of action of succinylcholine, given at a dose of 1 mg/kg, is short enough so that in the majority of properly

preoxygenated patients resume respiratory efforts (5 to 6 minutes) before hypoxia can be detected.[42] It has been argued that this is valid only in relatively healthy subjects and not in all cases. As a result, a lower dose has been suggested. However, a dose of 0.6 mg/kg results in substantially fewer patients with excellent intubating conditions, and the decrease in duration is modest.[41] For maintenance of relaxation, typical infusion rates are ~50 to 100 µg/kg/min.[26] However, the availability of short and intermediate nondepolarizing drugs makes succinylcholine infusions obsolete.

Children are slightly more resistant to succinylcholine than adults,[43] and doses of 1 to 2 mg/kg are required to facilitate intubation. In infants, 2 to 3 mg/kg may be required. Precurarization is not necessary in patients younger than 10 years because fasciculations are uncommon in this age group. Bradycardia is common in children unless atropine or glycopyrrolate is given.[30] Succinylcholine, at a dose of 4 mg/kg, is the only effective intramuscular neuromuscular blocking agent in children with difficult intravenous access and provides adequate intubating conditions in about 4 minutes. However, this route of administration should not be the method of choice.[44]

NONDEPOLARIZING DRUGS

4 Nondepolarizing neuromuscular blocking drugs bind to the postsynaptic receptor in a competitive fashion, by binding to one of the α subunits of the receptor (see Fig. 16-7).[12]

Characteristics of Nondepolarizing Blockade

The fade observed in response to high-frequency stimulation (>0.1 to 0.15 Hz) is characteristic of nondepolarizing blockade. With EMG recordings, fade is relatively constant in the range 2 to 50 Hz.[45] Mechanical fade is greater with 100 Hz than with 50 Hz.[46] Tetanic stimulation is followed by posttetanic facilitation, which is an increased response to any stimulation applied soon after the tetanus. The intensity and duration of this effect depend on the frequency and duration of the tetanic stimulation. With a 50-Hz tetanus of 5-second duration, twitch responses have been found to fall within 10% of their pretetanic values in 1 to 2 minutes, and in most cases in 1 minute (Fig. 16-9).

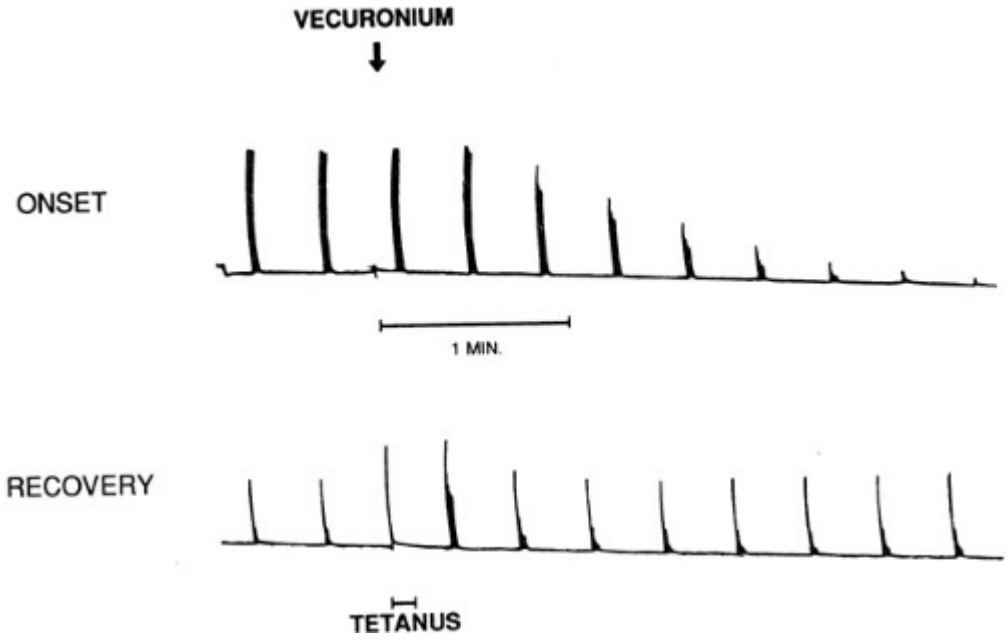

FIGURE 16-9. Characteristics of nondepolarizing blockade. Train-of-four responses are equal before administration of vecuronium (*arrow*). For a given twitch depression, fade is less during onset (*top trace*) than recovery (*bottom trace*). A 50 Hz- tetanus was applied during recovery. Tetanic fade is seen, with posttetanic facilitation, that is a greater train-of-four response after than before the train.

Finally, nondepolarizing blockade can be antagonized with anticholinesterase agents such as edrophonium, neostigmine, or pyridostigmine. It is also antagonized by depolarizing agents, such as succinylcholine, provided that the nondepolarizing blockade is intense and that the succinylcholine dose is too small to produce a block of its own.

Pharmacokinetics

As is the case for other drugs used in anesthesia, the elimination half-life of neuromuscular blocking agents does not always correlate with duration of action because termination of action sometimes depends on redistribution instead of elimination. However, knowledge of the kinetics of the drug helps us understand the behavior of the drug in special situations (prolonged administration, disease of the organs of elimination, and so on).

Several mechanisms can explain the various categories of durations of action listed in Table 16-3:

1. All long-acting drugs all have a long (1 to 2 hours) elimination half-life and depend on liver and/or kidney function for termination of action.
2. Intermediate-duration drugs either have an intermediate elimination half-life (atracurium and cisatracurium); or they have long elimination half-lives (1 to 2 hours) but depend on redistribution rather than elimination for termination of effect (vecuronium and rocuronium) (Fig. 16-10).
3. Short-duration drugs have either short elimination half-lives (the active isomers of mivacurium) or long

elimination half-life but extensive redistribution (rapacuronium).

4. Ultrashort-duration drugs have a very short elimination half-life (succinylcholine).

TABLE 16-3 Typical Pharmacokinetic Data for Neuromuscular Blocking Agents in Adults, Except where Stated

▪DRUG	▪VOLUME OF DISTRIBUTION (L/kg)	▪CLEARANCE (mL/kg/min)	▪ELIMINATION HALF-LIFE (min)
▪ULTRASHORT-DURATION AGENTS			
Succinylcholine	0.04	37	0.65
▪SHORT-DURATION AGENTS			
Mivacurium			
Trans–trans	0.05	29	2.4
Cis–trans	0.05	46	2.0
Cis–cis	0.18	7	30
Rapacuronium	0.2	7	100
▪INTERMEDIATE-DURATION AGENTS			
Atracurium	0.14	5.5	20
Cisatracurium			
Adults	0.12	5	23
Intensive care	0.26	6.5	25
Rocuronium			
Adults	0.3	3	90
Intensive care	0.7	3	330

Vecuronium	0.4	5	70
▪LONG-DURATION AGENTS			
Doxacurium	0.2	2.5	95
d-Tubocurarine			
Adults	0.3	1–3	90
Elderly	0.3	0.8	270
Neonates	0.7	1.1	300
Infants	0.5	1.0	300
Children	0.3	1.5	90
Pancuronium	0.3	1.8	140

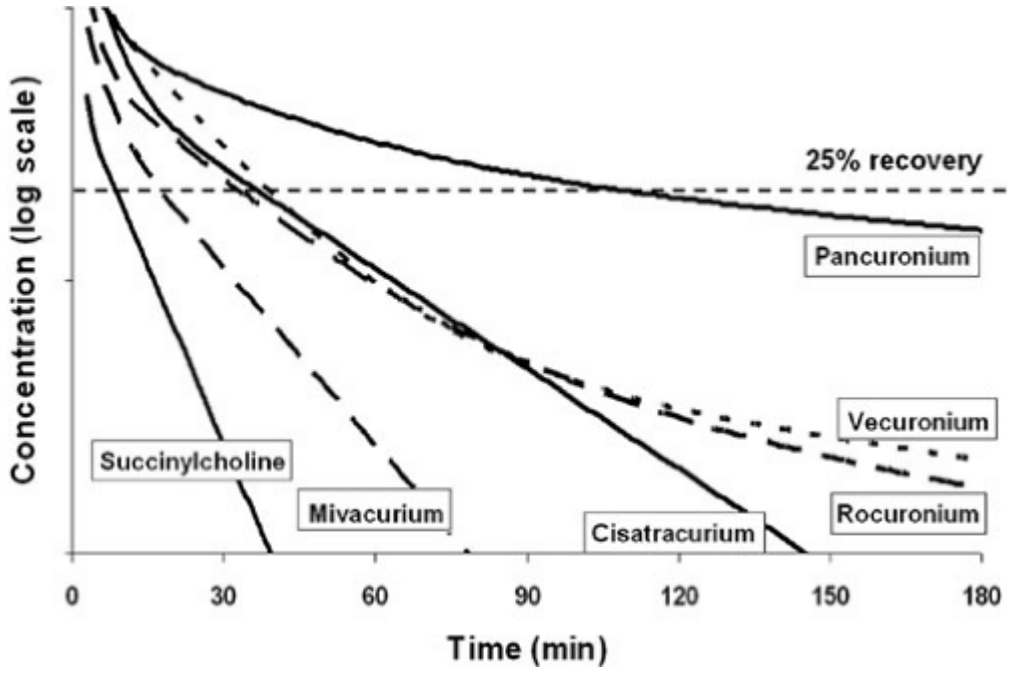

FIGURE 16-10. Representative concentrations at the neuromuscular junction for six representative drugs, after bolus doses of 2 × ED_{95}. Concentrations at the neuromuscular junction lag somewhat behind plasma concentrations. The level corresponding to 25% recovery is indicated. The curves were moved up or down so that the 25% level matched. Succinylcholine and the active mivacurium isomers have a rapid elimination. Pancuronium

has a long half-life and recovery occurs during the elimination phase. Cisatracurium has an intermediate terminal half-life, and recovery also occurs during the elimination phase. Rocuronium and vecuronium have an elimation half-life comparable to that of pancuronium. However, an important redistribution occurs before, and 25% recovery occurs during that redistribution process. As a result, both rocuronium and vecuronium have a duration of action comparable to that of cisatracurium.

The volume of distribution of all these agents is approximately equal to extracellular fluid (ECF) volume (0.2 to 0.4 L/kg) (see Table 16-3). Drugs with short elimination half-lives (succinylcholine and mivacurium) have even smaller volumes of distribution because they are degraded before distribution is complete. In infants, in whom the ECF volume, as a proportion of body weight, is increased, the volume of distribution parallels ECF volume closely.

Onset and Duration of Action

Onset and duration of action of neuromuscular blocking drugs are determined by the time required for drug concentrations at the site of action to reach, and return below, a critical level, respectively. For duration, this level is determined chiefly by plasma concentrations, at least for intermediate- and long-duration drugs. However, onset time (2 to 7 minutes) lags behind peak plasma concentrations (<1 minute). This delay reflects the time required for drug transfer between plasma and neuromuscular junction and is represented quantitatively by a rate constant (k_{eo}). This rate constant corresponds to half-times of 5 to 10 minutes for most nondepolarizing drugs and is determined by all the factors that modify access of the drug to, and its removal from, the neuromuscular junction. These include cardiac output, distance of the muscle from the heart, and muscle blood flow. Thus, onset times are not the same in all muscles because of different blood flows. If metabolism or redistribution is very rapid, the onset time is accelerated. This probably plays a role only for succinylcholine and mivacurium. Finally, potent drugs have a slower onset of action than less potent agents (Fig. 16-11).[47] This is because a large proportion of receptors must be occupied before blockade can be observed. Blockade of these receptors will occur faster, and onset will be more rapid, if more drug molecules are available, that is, if

potency is low. Table 16-2 shows that onset tends to be slower if a drug is potent, that is if ED_{95} is small.

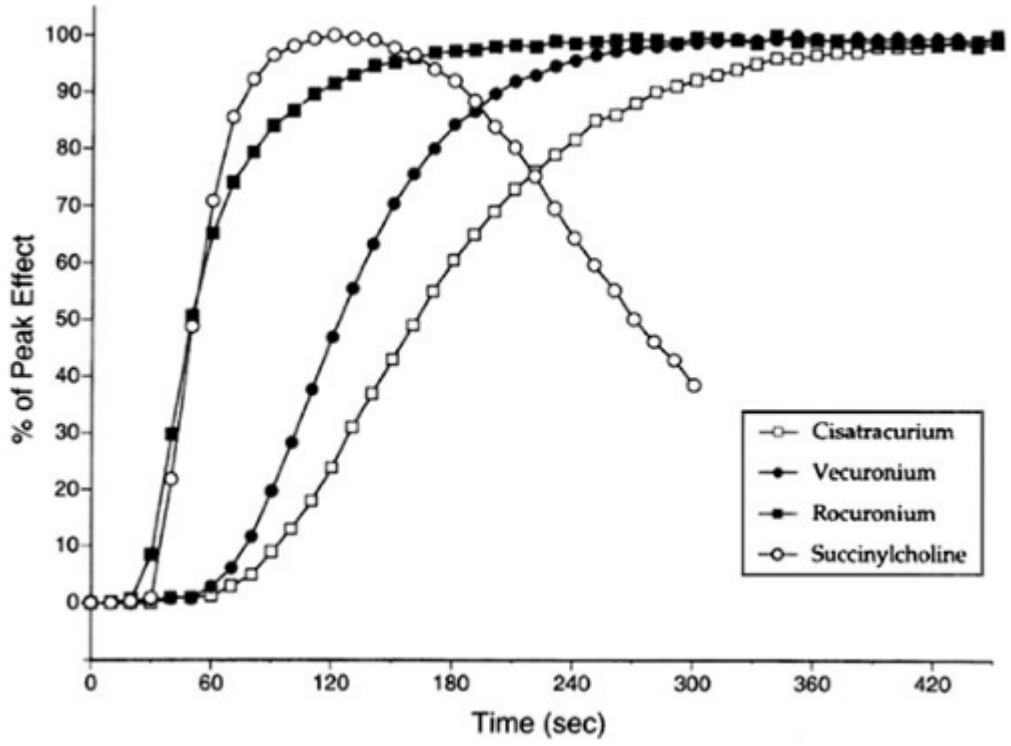

FIGURE 16-11. Neuromuscular blockade as a function of time for four neuromuscular blocking agents. Onset is faster for the less potent succinycholine and rocuronium than for the more potent vecuronium and cisatracurium. Reproduced from Kopman et al.[47]

Individual Nondepolarizing Agents

Since 1942, nearly 50 nondepolarizing neuromuscular blocking agents have been introduced into clinical anesthesia. This section covers only those drugs currently available in North America and Europe, plus a few others of historical interest. The first agent to undergo clinical investigation was Intocostrin, or *d*-tubocurarine, the purified and standardized product of curare obtained from the plant *Chondodendrum tomentosum*.[1] *d*-Tubocurarine has been almost completely replaced by more modern synthetic analogues.

d-Tubocurarine

The ED_{95} of *d*-tubocurarine is 0.5 mg/kg. At that dose, the duration of action is typical of a long-duration agent (see Table 16-2).[48]

Pharmacology. The molecule undergoes minimal metabolism so that 24 hours after its administration about 10% of the compound is found in the urine and 45% in the bile. Like most other neuromuscular blocking drugs, it is not extensively (30 to 50%) protein bound. Excretion is impaired in renal failure with an increase in elimination half-life.[49]

Cardiovascular Effects. Hypotension frequently accompanies the administration of *d*-tubocurarine even at doses less than ED_{95}. The mechanism involved is mainly histamine release, and skin flushing is frequently observed. Autonomic ganglionic blockade may also play a minor role in the production of hypotension.

Age. Pharmacokinetic studies have been performed in all age groups, and the results are helpful in understanding the behavior of all nondepolarizing agents in patients at the extremes of age. The potency of *d*-tubocurarine on a mg/kg basis does not vary greatly with age. Infants demonstrate greater blockade than older children or adults if the same concentration of *d*-tubocurarine is applied. However, this increased sensitivity of the neuromuscular junction in infants is concealed by the increased volume of distribution (see Table 16-3),[50] and this

phenomenon has also been observed with other neuromuscular blocking agents. The onset of action is more rapid in the young as a result of a more rapid circulation time. However, the decreased glomerular filtration rate (GFR) in the very young and the very old results in an increase in $T_{1/2}\beta$ and prolonged duration of action.[50]

Burns. Patients with massive burns demonstrate resistance to *d*-tubocurarine and other nondepolarizing drugs that is dependent on the size of the burn and the time since injury.[51] Resistance is associated with higher concentrations of the free drug to produce a given degree of twitch depression compared with nonthermally injured patients. As in denervation injury, there is an increase in the number of acetylcholine receptors in muscles close to the site of injury, and less so in more distant muscles.[52]

Clinical Use. The long duration and cardiovascular effects of *d*-tubocurarine have restricted its use and constituted a stimulus for the production of alternative agents. Initially, this led to the introduction of pancuronium, which replaced the hypotension of *d*-tubocurarine with hypertension and tachycardia. More recently, drugs of intermediate duration (atracurium, cisatracurium, vecuronium, and rocuronium) with virtually no cardiovascular effects have almost eliminated the use of *d*-tubocurarine. When available, *d*-tubocurarine has been mainly confined to be used as a "precurarization" (3 mg/70 kg) before succinylcholine to reduce fasciculations and muscle pains. Rocuronium has largely replaced *d*-tubocurarine for this indication.

Alcuronium

Although it has never been available in North America, alcuronium still enjoys limited use in some countries. The ED_{95} is approximately 0.2 to 0.25 mg/kg. Intubating doses are usually limited to 0.3 mg/kg because of the long duration of action. Although it was introduced as an intermediate-duration drug, its recovery index (37 minutes) makes it a long-acting neuromuscular blocking agent.[53]

Atracurium

Atracurium is a bisquaternary ammonium benzylisoquinoline compound. It was developed in an attempt to produce a short-acting muscle relaxant that was independent of the liver and the kidney for termination of its action. It is a mixture of 10 isomers of different potencies. In humans, atracurium is degraded via two metabolic pathways. One of these pathways is the Hofmann reaction, a nonenzymatic degradation the rate of which increases as temperature and/or pH increases. The second pathway is nonspecific ester hydrolysis. The enzymes involved in this metabolic pathway are a group of tissue esterases, which are distinct from plasma or acetyl cholinesterases. The same group of enzymes is involved in the degradation of esmolol and remifentanil. It has been estimated that two-thirds of atracurium is degraded by ester hydrolysis and one-third by Hofmann reaction.[54] Subjects with abnormal plasma cholinesterase have a normal response to atracurium.

The end products of the degradation of atracurium are laudanosine and acrylate fragments. Laudanosine has been reported as causing seizures in animals, but at doses largely exceeding the clinical range. No deleterious effect of laudanosine has been demonstrated conclusively in humans.[55] Laudanosine is excreted by the kidney. Acrylates have the potential to inhibit cell growth, and this has been demonstrated in vitro.[56] However, the concentrations and exposure times required to obtain this effect are much greater than what is obtained normally in clinical practice.

Pharmacology. Atracurium is an intermediate-duration drug, with a terminal half-life of approximately 20 minutes. Termination of effect occurs during the elimination phase of the drug. Because degradation does not depend on an end-organ function, duration of action is not dependent on renal or hepatic function. It does not increase with age.

The ED_{95} of atracurium is 0.2 to 0.25 mg/kg. The onset of action of equipotent doses is similar for atracurium, pancuronium, *d*-tubocurarine, and vecuronium. It is slower than succinylcholine. As with any neuromuscular blocking agent, onset time can be reduced if the dose is increased, but it

is not recommended to exceed 0.5 mg/kg, because of hypotension and histamine release. The duration of action is also dose related. The time to 25% first twitch recovery after 0.5 mg/kg is approximately 30 to 40 minutes.

Cardiovascular Effects. Atracurium releases histamine if large doses ($2 \times ED_{95}$ or greater) are administered, with hypotension and tachycardia as frequent manifestations. Similar changes occur after the use of *d*-tubocurarine or metocurine but at lower equipotent doses. The most obvious clinical manifestation of histamine release is skin flushing. Bronchospasm may also occur. These responses can be avoided by slow injection over 1 to 3 minutes or by pretreatment with H_1 and H_2 receptor blockade. Anaphylactic reactions to atracurium have been described, but they do not appear to be more frequent than after other neuromuscular blocking drugs.[31]

Special Situations. Dosage requirements are similar in the elderly, younger adults, and children, presumably reflecting the organ independence of atracurium's elimination. Similarly, no

dosage adjustment is required in individuals with renal or hepatic failure. As with other nondepolarizing agents, the dose must be increased in burn patients, partly because of increased protein binding, partly because of up-regulation of receptors, causing resistance at the endplate. In the obese patient, the dose of atracurium, as for all neuromuscular blocking agents, should be calculated based on lean body mass.

Clinical Uses. To obtain adequate intubating conditions, relatively large doses must be used (0.5 mg/kg), and laryngoscopy should be attempted only after 2 to 3 minutes. Cardiovascular manifestations of histamine release are often seen at that dose, and perfect intubating conditions are seen in only half the patients (see Fig. 16-3).[7] Increasing the dose may improve intubating conditions, but at the expense of greater cardiovascular effects. For intubation, there has been a tendency to replace atracurium by agents, such as rocuronium, with a shorter onset time and more cardiovascular stability. Atracurium is, however, convenient and versatile for maintenance of relaxation, either as a continuous infusion (5 to 10 μg/kg/min) or as intermittent injections (0.05 to 0.1 mg/kg every 10 to 15 minutes).

Cisatracurium

In an attempt to increase the margin of safety between the neuromuscular blocking dose and the histamine-releasing dose, a potent isomer of atracurium, cisatracurium, was identified. Like atracurium, its cardiovascular effects are manifest at doses exceeding 0.4 mg/kg, but its ED_{95} (0.05 mg/kg) is much lower. As a result, manifestations of histamine release are not seen in practice. The metabolism of cisatracurium is similar to that of atracurium, but it seems that the relative importance of Hofmann elimination is somewhat greater than for atracurium, and the role of ester hydrolysis is correspondingly less.[57] The end products of metabolism, laudanosine and acrylate fragments are the same as for atracurium.

Pharmacology. Because cisatracurium is a potent drug, its onset time is longer than that of atracurium and longer still than that of rocuronium. For example, equipotent doses of cisatracurium (0.092 mg/kg) and rocuronium (0.72 mg/kg) had onset times of 4 minutes and 1.7 minutes, respectively.[58] The elimination half-life (22 to 25 minutes) is similar to that of atracurium,[59] so that the duration of action for $2 \times ED_{95}$ doses (0.1 mg/kg) is 30 to 45 minutes. However, in an attempt to accelerate onset, the recommended dose was increased to 0.15 mg/kg. This is well below the threshold for histamine release, but the duration of action is prolonged to 45 to 60 minutes.

Because the doses required to obtain paralysis are considerably less for cisatracurium than for atracurium, less laudanosine and less acrylate byproducts are produced.[56] Peak concentrations of laudanosine have been found to be five times less with equipotent doses of cisatracurium. Thus, the concerns raised by the potential toxic effects of these metabolites are virtually eliminated.

Special Situations. As for atracurium, there is no need to adjust dosage in the elderly, children, or infants, when compared with young adults. The experience in burn and obese patients is limited, but the same principles that are valid for atracurium are expected to apply.

Side Effects. In contrast to atracurium, cisatracurium is devoid of histamine-releasing properties even at high doses (8 × ED_{95}). It is also devoid of cardiovascular effects. However, anaphylactic reactions have been described.[31]

Clinical Use. Cisatracurium may be used to facilitate tracheal intubation at doses equivalent to 3 to 4 times the ED_{95} (0.15 to 0.2 mg/kg) when manual ventilation is possible after induction of anesthesia and when the duration of the procedure is expected to exceed 1 hour. Duration is shorter with lower doses, but onset time is prolonged and intubating conditions are less ideal. Neuromuscular blockade is easily maintained at a stable level by continuous intravenous infusion of cisatracurium (1 to 2 μg/kg/min) at a constant rate and does not change with time, suggesting the lack of a significant cumulative drug effect and lack of dependence on renal and/or hepatic clearance mechanisms.[60] The rate of recovery is independent of the dose of cisatracurium and the duration of the administration.

Because cisatracurium does not depend on end-organ function for its elimination, the drug appears suitable for administration in the intensive care unit (ICU). The infusion rates to keep patients paralyzed is greater than in the operating room (typically 5 μg/kg/min), with wide interindividual variability.[61] It is likely that prolonged exposure of the receptors to a neuromuscular blocking agent causes some up-regulation, with a corresponding requirement for a higher dose.

Doxacurium

Doxacurium is a long-acting bisquaternary ammonium compound that is devoid of histamine-releasing or cardiovascular side effects. It has a prolonged elimination half-life (1 to 2 hours) and depends on the kidney and the liver for its disposition. Thus, duration of action is prolonged in the elderly and in subjects with impaired renal or hepatic function. Doxacurium is also a weak substrate for plasma cholinesterase. The ED_{95} for doxacurium is 25 μg/kg (see Table 16-2).[62] Doxacurium has a limited place in clinical practice because of its very slow onset and long duration of action. Nevertheless, it may be useful in patients with ischemic heart disease who are undergoing prolonged anesthesia or long-term mechanical ventilation of the lungs. The slow onset time, prolonged duration of action, and slow recovery make doxacurium unsuitable for facilitating tracheal intubation or for providing skeletal muscle relaxation during brief surgical procedures. When infused for several days to patients in the ICU, recovery after stopping the infusion exceeded 10 hours.

Gallamine

Gallamine was introduced in 1948 and has only historical interest. It is a low potency nondepolarizing drug (ED_{95} = 2 mg/kg) and it has a long duration of action. Gallamine produces significant tachycardia because of a vagolytic effect, even at doses associated with incomplete blockade at the adductor pollicis. It is effective when used to prevent succinylcholine-induced fasciculations.

GW280430A

The new compound called GW280430A is a nondepolarizing drug and belongs to the class of asymmetric mixed-onium chlorofumarates. Its main degradation pathway involves cysteine in the plasma and is independent of plasma cholinesterase. The ED_{95} in humans is 0.19 mg/kg.[63] Cardiovascular effects are observed at doses exceeding 3 × ED_{95}, and are most probably related to histamine release. At doses anticipated to be required for tracheal intubation (0.4 to 0.6 mg/kg), onset at the adductor pollicis is 1.5 minutes and duration to 25% T1 recovery is 8 to 10 minutes, making this drug comparable to succinylcholine in duration of action. At the time of writing, this compound was still an investigational drug.

Metocurine

Metocurine, produced by methylation of two hydroxy groups of *d*-tubocurarine, is twice as potent

as the parent compound and produces less histamine release. Its ED_{95} is approximately 0.3 mg/kg.[48] Its duration of action is comparable to that of *d*-tubocurarine, making it a long-acting agent.

Metocurine causes less histamine release and cardiovascular effects than equipotent doses of *d*-tubocurarine. Because of this, metocurine enjoyed a brief period of popularity before the introduction of atracurium and vecuronium. Metocurine and pancuronium combined were found to be synergistic with opposing cardiovascular effects, and the mixture was recommended for use in patients with severe cardiovascular disease.[64] However, the introduction of shorter duration alternatives without cardiovascular effects has made metocurine obsolete.

Mivacurium

Mivacurium is a benzylisoquinoline derivative with an intermediate onset and short duration of action that is hydrolyzed by plasma cholinesterase, like succinylcholine.[65] Contrary to succinylcholine, however, mivacurium produces nondepolarizing blockade. The drug is presented as a mixture of three isomers. Two, the cis–trans and trans–trans, have short half-lives, but the cis–cis isomer has a much longer half-life (see Table 16-3). The cis–cis isomer accounts for only 6% of the mixture, has less than one-tenth the potency of the other isomers and thus contributes little if anything to neuromuscular block during anesthesia. The pharmacology of mivacurium is governed largely by the behavior of the trans–trans and cis–trans isomers.

Pharmacology. Under steady-state nitrous oxide–narcotic anesthesia, the ED_{95} of mivacurium is 0.08 mg/kg (see Table 16-2). However, there is evidence that mivacurium is less effective when given at induction of anesthesia than during stable anesthesia.[66] This might be because cardiac output is decreased and/or peripheral blood flow might be increased after induction of anesthesia. Decreasing cardiac output tends to increase the effect of short-acting drugs because a bolus dose is diluted in a smaller volume, producing greater plasma concentrations. In any event, doses that are twice the ED_{95} mg/kg determined under steady-state anesthesia are associated with poor intubating conditions. In 9 out of 9 patients, a dose of 0.15 mg/kg provided unacceptable conditions.[67] These conditions are markedly improved if the dose is increased to 0.2 or 0.25 mg/kg but were not as good as with succinylcholine.[67] Onset time is surprisingly long for a drug whose active isomers have a terminal half-life of less than 2 minutes. At 2 to 3 × ED_{95}, twitch disappears in 2.5 to 4 minutes.[65] This long onset time is probably the result of the high potency of mivacurium. For all neuromuscular blocking agents, a direct relationship between onset time and potency has been demonstrated. Drugs with a low ED_{95}, expressed in μmoles/kg, have a longer onset time.[47] On the other hand, recovery to 25% does not depend heavily on dose, being in the range of 15 to 25 minutes for doses of 0.15 to 0.25 mg/kg. The infusion rate to maintain blockade constant does not vary with time, and recovery is as rapid after many hours of infusion than after a bolus dose, suggesting that the slowly eliminated cis–cis metabolite contributes very little to the overall neuromuscular effect.

Side Effects. Like atracurium, mivacurium releases histamine in a dose-related fashion. At doses of 0.15 mg/kg or less, the drug has virtually no cardiovascular effects. Hypotension and tachycardia are seen frequently when doses are increased to 0.2 mg/kg or more. Cutaneous signs, such as erythema and flushing, are also observed frequently with large doses. They can be seen in isolation or be accompanied by cardiovascular changes. These histamine-related effects are short lived (2 to 3 minutes) and should not normally be considered a manifestation of anaphylaxis, which is a rare event. Bronchospasm is rare, but may be seen more frequently with mivacurium than with other neuromuscular blocking agents.[68] Manifestations of histamine release may be decreased if the drug is either given slowly (in more than 30 seconds) or in divided doses (0.15 mg/kg followed 30 seconds later by 0.1 mg/kg).

Special Situations. In infants and children the ED_{95} is approximately the same as in adults, but onset of block and recovery are more rapid.[69] Cardiovascular effects are not as important as in adults, so doses up to 0.3 mg/kg have been used. Duration to 25% recovery is shorter (10 minutes) in infants and children than in adults.[69] The infusion rate required to maintain blockade is greater in children than in adults.[70] In the elderly, the ED_{95} is the same as in younger adults.

However, duration of action is prolonged by a few minutes and the infusion rate to maintain neuromuscular blockade is decreased.[71]

Burns. In burn patients, upregulation of the receptors, and to a lesser extent increased protein binding, causes a resistance to all nondepolarizing neuromuscular blocking agents. Thus, a larger dose of the drug is normally required. However, for mivacurium, the situation is different because plasma cholinesterase activity is decreased in burn patients. The net effect is either a normal or even an enhanced effect of usual doses.[72]

Reversal. Administration of anticholinesterase agents after mivacurium has been controversial for two main reasons. First, neostigmine, but not edrophonium, inhibits plasma cholinesterase. Therefore, the breakdown of mivacurium may be slower in the presence of neostigmine. In fact, neostigmine has been shown to delay recovery if given during intense neuromuscular block, presumably when high concentrations of mivacurium are still present.[73] However, if neostigmine is given when signs of spontaneous recovery are present (two twitches or more present), the rate of recovery is accelerated. Edrophonium does not interfere with plasma cholinesterase activity and was found to accelerate recovery, even when given when blockade is profound (one twitch in the train-of-four).[73] Also, mivacurium reversal has been suggested to be unnecessary because spontaneous recovery is rapid and its avoidance may reduce the incidence of side effects such as postoperative nausea and vomiting. However, this may result in residual block on arrival in the recovery room, particularly if large doses of mivacurium are used up to the end of anesthesia.

Plasma Cholinesterase. Mivacurium is metabolized by plasma cholinesterase somewhat more slowly than succinylcholine. The conditions associated with a decrease plasma cholinesterase activity known to affect succinylcholine metabolism also alter mivacurium duration of action. For example, a moderate increase in the duration of action of mivacurium can be seen in postpartum patients. Patients homozygous for atypical plasma cholinesterase may show very prolonged block.

Clinical Use. Mivacurium is well suited to surgical procedures requiring brief muscle relaxation, particularly those in which rapid recovery is required, such as ambulatory and laparoscopic surgery. However, it is not recommended for rapid sequence induction. Because of its slow onset, conditions for tracheal intubation are unsatisfactory unless large bolus doses, at least 0.2 mg/kg, are given and a delay of at least 2 minutes is allowed before intubation is attempted.[67] However, by using two doses of 0.15 and 0.1 mg/kg separated by 30 seconds, good to excellent intubating conditions have been achieved in almost 90% of patients, an onset similar to that of succinylcholine.[74] Small doses of mivacurium (0.04 to 0.08 mg/kg) have been suggested to facilitate insertion of a laryngeal mask airway.[75] Conditions and success rate are usually better than in the absence of neuromuscular blocking agent. The rapid recovery makes it necessary to monitor neuromuscular activity continuously during its administration, which is accomplished more easily by constant infusion (5 to 7 μg/kg/min in young and middle-aged adults) than by intermittent bolus injection. This infusion rate has to be increased in children and reduced in the elderly.[76] In children, mivacurium has a faster onset of action and more rapid

recovery than in adults, so the drug can be used for intubation and maintenance of relaxation for short procedures.[69,70]

Pancuronium

Pancuronium belongs to a series of bisquaternary aminosteroid compounds. It is metabolized to a 3-OH compound, which has one-half the neuromuscular blocking activity of the parent compound. The ED_{95} of pancuronium is 0.07 mg/kg. The duration of action is long, being 1.5 to 2 hours after a 0.15 mg/kg dose. Clearance is decreased in renal and hepatic failure, demonstrating that excretion is dependent on both organs. The onset of action is more rapid in infants and children than in adults and recovery is slower in the elderly.

Cardiovascular Effects. Pancuronium is associated with increases in heart rate, blood pressure, and cardiac output, particularly after large doses ($2 \times ED_{95}$). The cause is uncertain but includes a vagolytic effect at the postganglionic nerve terminal, a sympathomimetic effect as a result of blocking of muscarinic receptors that normally exert some braking on ganglionic transmission, and

an increase in catecholamine release. Pancuronium does not release histamine.

Clinical Use. The slow onset of action of pancuronium limits its usefulness in facilitating tracheal intubation. Administration in divided doses, with a small dose given 3 minutes before induction of anesthesia (priming principle), produces a small but measurable acceleration, but the intermediate- and short-acting compounds are more suitable when succinylcholine is contraindicated. In patients with myocardial ischemia, tachycardia should be avoided. However, pancuronium has enjoyed popularity in cardiac anesthesia because it counteracts the bradycardic effect of high doses of opioids. With the increased tendency toward early extubation in cardiac surgery, the appropriateness of pancuronium in this setting must be reevaluated. The use of pancuronium instead of rocuronium is associated with a greater incidence of muscular weakness in the recovery room after cardiac surgery,[77] and reversal should be considered seriously. The continued popularity of pancuronium is dependent on cost: generic pancuronium is cheaper than other nondepolarizing relaxants. Its use is associated with a high incidence of residual block in the postanesthesia care unit (PACU), at least in adults (see Table 16-1).[8,78] Pancuronium neuromuscular block is more difficult to reverse than that of the intermediate duration agents.[79]

Pipecuronium

In an effort to obtain a pancuronium without cardiovascular side effects, pipecuronium was developed. Its ED_{95} is slightly less (0.05 mg/kg) than that of pancuronium, and it is virtually without any cardiovascular effects. However, pipecuronium soon became obsolete because it had the drawbacks of long-acting agents (difficulty to reverse, residual paralysis, lack of versatility), and the absence of cardiovascular effects was also seen with the shorter acting vecuronium and rocuronium.

Rapacuronium

Rapacuronium is also an aminosteroid compound that was introduced for clinical use in 1999. It was withdrawn in 2001 because of rare, but severe cases of bronchospasm after intubation. Being less potent than rocuronium, it had a more rapid onset of action. Following 1.5 mg/kg, good to excellent intubation conditions were produced at 60 seconds, clinical duration (25% T_1 recovery) occurs in 17 minutes and spontaneous recovery to train-of-four ratio of 0.7 occurs in 35 minutes.[80] The intubating conditions were not as good as with succinylcholine and the duration of action was longer. Rapacuronium is metabolized to a 17-OH derivative (ORG 9488) that has twice the neuromuscular blocking activity of the parent compound and is excreted slowly via the kidneys.

Rapacuronium produces mild dose-related tachycardia and hypotension, and these cardiovascular changes do not appear to be because of histamine release. Mild to moderate increases in airway pressure and bronchospasm were observed in more patients given rapacuronium than succinylcholine.[80] The mechanism for this effect is not a hypersensitivity or allergic reaction, but is most likely related to the effect of rapacuronium on M2 and M3 muscarinic receptors in the lung. Activation of the postsynaptic M3 receptors by acetylcholine produces brochosconstriction in the lungs, and the effect is terminated by presynaptic M2 receptors that counteract this effect. Rapacuronium has the potential to block both receptors, but it has a greater affinity for the M2 receptor. The concentrations required for M2 blockade are well within the clinical range, while much more is required for M3 inhibition. The net effect is that if M2 receptors are blocked selectively, for example, in susceptible individuals, bronchoconstriction by activation of the M3 receptors is unopposed.[81] Other neuromuscular blocking agents, such as vecuronium and cisatracurium, have similar differential effects on the M2 and M3 receptors, but at concentrations higher than encountered clinically.[81]

Rocuronium

Rocuronium is an aminosteroid compound with structural similarity with vecuronium and pancuronium. Its duration of action is comparable to that of vecuronium, but onset is shorter.

Pharmacology. Plasma concentrations of rocuronium decrease rapidly after bolus injection

because of hepatic uptake.[82] Thus, the duration of action of the drug is determined chiefly by redistribution, rather than by its rather long terminal elimination half-life (1 to 2 hours) (see Fig. 16-10). Metabolism to 17-deacetylrocuronium is a very minor elimination pathway. Most of the drug is excreted unchanged in the urine, bile, or feces.[82]

With an ED_{95} of 0.3 mg/kg, rocuronium has one-sixth the potency of vecuronium, a more rapid onset, but a similar duration of action and similar pharmacokinetic behavior. With equipotent doses, rocuronium onset at the adductor pollicis was much faster than that of cisatracurium, atracurium, and vecuronium (see Fig. 16-11).[47] After doses of 0.6 mg/kg ($2 \times ED_{95}$) maximal block occurs in 1.5 to 2 minutes. In a multicenter study of 349 patients, intubating conditions at 60 seconds after 0.6 mg/kg rocuronium were good to excellent in 77% of cases. To obtain results similar to those after 1 mg/kg succinylcholine, the dose of rocuronium had to be increased to 1.0 mg/kg, which provided 92% good or excellent conditions.[83] However, the duration of action is longer than for succinylcholine, ranging between 30 to 40 minutes for a 0.6 mg/kg dose to approximately 60 minutes after 1 mg/kg in adults. Thus, rocuronium is an intermediate-duration drug.

As for other nondepolarizing agents the onset of action of rocuronium is more rapid at the diaphragm and adductor laryngeal muscles than at the adductor pollicis,[84] probably a result of a greater blood flow to centrally located muscles. Laryngeal adductor muscles are important in anesthesia because they close the vocal cords and insufficient relaxation prevents easy passage of the tracheal tube. Laryngeal adductor muscles are resistant to the effect of rocuronium, and the plasma concentration required for equivalent blockade is greater at the larynx than at the adductor pollicis.[85] The same is true of the diaphragm, which is resistant to the effect of rocuronium and other neuromuscular blocking agents. Recovery is faster at the diaphragm and larynx than at the adductor pollicis.[84]

Cardiovascular Effects. No hemodynamic changes (blood pressure, heart rate, or ECG) were seen in humans, and there were no increases in plasma histamine concentrations after doses of up to $4 \times ED_{95}$ (1.2 mg/kg).[86] Only slight hemodynamic changes are observed during coronary artery

bypass surgery. Anaphylactic reactions have been described, and it has been claimed that these events occur more frequently with rocuronium than with other neuromuscular blocking agents.[31] However, it now appears that many of these reports might not be a true anaphylactic reaction to rocuronium, because up to 50% of the general population show a positive intradermal or pick test to the drug.[87] Clearly, many patients who were investigated for a possible anaphylactic reaction were falsely labeled allergic to the drug, because of the high rate of false-positive tests. It is possible that overdiagnosis has played a role in the relatively high incidence of rocuronium anaphylaxis reported in Norway (29 cases in 150,000 administrations, or 1:5,000) [88] or in France, [31] while reports from other Nordic countries suggest a much lower incidence (7 cases in 800,000 administrations or less than 1:100,000).[88] Current evidence suggests that withholding rocuronium because of the fear of anaphylactic reactions is unjustified.

Special Situations. The potency of rocuronium has been reported to be slightly greater in women than in men, the ED_{95} being 0.27 and 0.39 mg/kg, respectively, with an increased duration in women.[89] Some ethnic groups are more sensitive to the drug. Chinese subjects living in Vancouver were found to be more sensitive than Caucasians.[90] Children (2 to 12 years old) require more rocuronium and duration of action is less. Onset of action is shorter in the pediatric than in the adult population. For example, a dose of 1.2 mg/kg provides an onset time (39 seconds) comparable to that of succinylcholine, 2 mg/kg, and mean duration of action is 41 minutes.[91] Thus, the recommended doses are 0.9 to 1.2 mg/kg in this age group. Rocuronium is more potent in infants than in older children.[92] Doses of 0.6 mg/kg have a longer duration in neonates (<1 month) than in infants (5 to 12 months), so a reduced dosage (0.45 mg/kg) is recommended.[93] Rocuronium may be used for rapid-sequence induction as succinylcholine is relatively contraindicated because of the possible presence of undiagnosed muscle dystrophy in pediatric patients, especially in boys.[38]

In elderly patients, the ED_{95} is similar to that found in younger adults, but the duration of action

is prolonged slightly.[94] Rocuronium has an increased terminal half-life in renal failure patients, probably because of its partial renal elimination, but this translates into very minor, if any, prolongation of block.[95] In hepatic disease, the slower uptake and elimination of rocuronium by the liver tends to prolong the duration of action of the drug, but this is compensated to some extent by the larger volume of distribution.[96]

Clinical Use. The rapid onset and intermediate duration of action makes this agent a potential replacement for succinylcholine in conditions where rapid tracheal intubation is indicated. However, large doses (>1 mg/kg) are required with a prolonged duration of action. Contrary to succinylcholine, the option to wait for spontaneous breathing to resume before hypoxia is manifest does not exist with rocuronium. To shorten the onset time, the "priming principle," which involves the administration of a small dose of rocuronium usually 3 minutes before induction, has been advocated. Unfortunately, the optimal priming dose, that is the largest dose that will not produce symptoms of weakness in the awake patient, is rather small. As with defasciculating doses before succinylcholine, it is not recommended to administer more than 0.1 × ED_{95},[32] which, in the case of rocuronium, amounts to 0.03 mg/kg. Such a small dose has minimal effects on onset times provided by much larger doses (0.6 to 1.0 mg/kg). However, priming might have an effect if the intubating dose is small (0.45 mg/kg). A "timing principle" has been described in which 0.6 mg/kg rocuronium is given *before* the induction agent, which is administered at the onset of ptosis. Considering that loss of consciousness does not occur immediately after injection of the induction agent, this technique is not recommended. Rocuronium and thiopental do not mix. They form a precipitate when they are in the same intravenous line. If thiopental is used for induction of anesthesia, the line must be flushed carefully before rocuronium is given.

Except in countries where it is not available, rocuronium has replaced vecuronium as an intermediate-duration relaxant because of its more rapid onset. Initial doses of 0.6 mg/kg iv will usually produce good intubating conditions within 90 seconds. Duration of action is 30 to 40 minutes. Smaller doses (typically 0.45 mg/kg) have a shorter duration of action, but time to intubation must be increased. Subsequent doses of 0.1 to 0.2 mg/kg will provide clinical relaxation for 10 to 20 minutes. Alternatively, rocuronium might be given by continued infusion, titrated with the help of a nerve stimulator. Infusion rates are in the range 5 to 10 μg/kg/min.[60] Recovery after infusions is slower than after bolus doses.[97]

Vecuronium

Vecuronium is an intermediate-duration aminosteroid neuromuscular relaxant without cardiovascular effects. Its ED_{95} is 0.04 to 0.05 mg/kg. Its duration and recovery characteristics are comparable to those of rocuronium. However, its onset of action is slower.

Pharmacology. Vecuronium is a monoquaternary ammonium compound produced by demethylation of the pancuronium molecule. The demethylation reduces the acetylcholine-like characteristics of the molecule and increases its lipophilicity, which encourages hepatic uptake. Vecuronium undergoes spontaneous deacetylation to produce 3-OH, 17-OH, and 3,17-$(OH)_2$ metabolites. The most potent of these metabolites, 3-OH vecuronium, about 60% of the activity of vecuronium, is excreted by the kidney, and may be responsible, in part, for prolonged paralysis in patients in the intensive care unit.[98] Like rocuronium, vecuronium has been found less potent and with a shorter duration of action in men than in women, probably because of a greater volume of distribution in men.

Duration of action of vecuronium, like that of rocuronium, is governed by redistribution, not by elimination (see Fig. 16-10). Attempts have been made to speed the onset of action by using the priming principle, that is by administering a small, subparalyzing dose several minutes before the principal dose is given. For vecuronium, the best results have been obtained with a priming dose of 0.01 mg/kg, followed 3 to 4 minutes later by 0.1 mg/kg. However, the introduction of rocuronium, which has a more rapid onset of action, is likely to make this practice obsolete.

Cardiovascular Effects. Vecuronium usually produces no cardiovascular effects with clinical doses. It does not induce histamine release. Bradycardia has been described with high-dose opioid anesthesia, and this might be the reflection of the opioid effect. Allergic reactions have been

described, but no more frequently than after the use of other neuromuscular blocking drugs.[31]

Clinical Use. The cardiovascular neutrality and intermediate duration of action make vecuronium a suitable agent for use in patients with ischemic heart disease or those undergoing short, ambulatory surgery. Care should be taken when vecuronium is administered immediately after thiopental because a precipitate of barbituric acid may be formed that may obstruct the intravenous cannula.

Large doses, 0.1 to 0.2 mg/kg, with or without priming, can be used to facilitate tracheal intubation instead of succinylcholine. For maintenance of relaxation, vecuronium may be given using intermittent boluses, 0.01 to 0.02 mg/kg, or by continuous infusion at a rate of 1 to 2 μg/kg/min. However, the rate of spontaneous recovery of neuromuscular function is slower after administration by infusion than by intermittent boluses.[99] Vecuronium has now largely been replaced by the more rapid rocuronium.

DRUG INTERACTIONS

Interactions between neuromuscular blocking drugs and several anesthetic and nonanesthetic drugs have been suggested. Although some interactions have been confirmed, many remain as isolated case reports or theoretical possibilities. Only some of these interactions will be discussed here.

Anesthetic Agents

Inhalational Agents

The anesthetic vapors potentiate neuromuscular blockade in a dose-related fashion. Studies attempting to quantify the magnitude of this effect have led to conflicting results, because the time factor is also important. The older halogenated agents halothane, enflurane, and isoflurane may take 2 hours or more to equilibrate with muscle, so in practice the potentiating effect of these vapors might not be immediately apparent. At similar MAC, enflurane appears to potentiate nondepolarizing blockade more than does isoflurane, which in turn potentiates to a greater extent than halothane. The newer agents sevoflurane and desflurane equilibrate more rapidly with muscle, but the effect may be measurable only after 30 minutes or more. For example, the duration of action of a bolus dose of mivacurium given at induction of anesthesia is not altered by the presence of sevoflurane (1 MAC). However, the infusion rate required to maintain block decreases by 75% over the next 1.5 hours, compared with no change under propofol anesthesia.[100] The degree of potentiation increases with the concentration of sevoflurane.[70] Recovery rate is longer in the presence of sevoflurane, even if the infusion rate of mivacurium was less.[70] There is evidence that desflurane might have a greater potentiating effect on the neuromuscular junction than sevoflurane.[101]

The mechanism of action of potentiation by halogenated agents is uncertain, but it appears that they produce their effects at the neuromuscular junction. Isoflurane and sevoflurane inhibit current through the nicotinic receptor at the neuromuscular junction, and this inhibition is dose dependent.[102]

Intravenous Anesthetics

Although some slight potentiation of neuromuscular blockade has been demonstrated with high doses of most iv induction agents in animals, clinical doses of drugs such as midazolam, thiopental, propofol, fentanyl, and ketamine have little or no neuromuscular effect in humans.

Local Anesthetics

Lidocaine, procaine, and other local anesthetic agents produce neuromuscular blockade in their own right as well as potentiating the effects of depolarizing and nondepolarizing neuromuscular blocking drugs. However, these data were obtained in vitro, with concentrations of local

anesthetics rarely obtained systemically in practice.

Interactions between Nondepolarizing Blocking Drugs

Combinations of two nondepolarizing neuromuscular blocking drugs are either additive or synergistic, depending on which two drugs are involved. Addition occurs when the total effect equals that of equipotent doses of each drug. For instance, pancuronium and vecuronium have an additive interaction.[103] An ED_{95} of either pancuronium (0.07 mg/kg) or vecuronium (0.05 mg/kg) yields 95% blockade. Half the ED_{95} of pancuronium (0.035 mg/kg) administered with half the ED_{95} of vecuronium (0.025 mg/kg) will also produce 95% block. However, some combinations are synergistic, that is their combined effect is greater than if an equipotent dose of either one of the constituents is given alone. For example, cisatracurium (ED_{95} = 0.05 mg/kg) and rocuronium (ED_{95} = 0.3 mg/kg) will produce a greater blockade than equipotent amounts of each drug given alone. To get 95% block, not one-half but approximately one-fourth the ED_{95} of each drug needs to be given together, that is cisatracurium, 0.0125 mg/kg with rocuronium, 0.075 mg/kg.[104] Generally, combinations of chemically similar drugs—for example, pancuronium–vecuronium, *d*-tubocurarine–metocurine, and atracurium–mivacurium—have additive effects. Combinations of dissimilar agents tend to show potentiation, but the rule is not always followed. For example, mivacurium and cisatracurium show synergism,[104] while vecuronium and atracurium show very little, if any. The first such synergism was demonstrated for pancuronium–metocurine combinations, and the mixture has less cardiovascular effects than either drug alone for the same neuromuscular block.[64] The use of combinations may be recommended to reduce cost, and this might be advocated for cisatracurium–rocuronium mixtures, which show synergism. Another reason to use mixtures of drugs is to take advantage of the properties of two drugs. For example, synergism occurs between mivacurium and rocuronium, and the mixture retains the fast onset of rocuronium, while having the short duration of action of mivacurium.[105]

The mechanism by which two drugs produce a greater effect than either one alone is unknown, except in rare cases. For example, synergism is expected between mivacurium and pancuronium, because of the inhibition of plasma cholinesterase that pancuronium produces, thus accentuating the effect of mivacurium. However, such a simple mechanism is absent in most cases. Administration of a combination of relaxants does not affect the degree of protein binding of either drug. Surprisingly, when drug mixtures are applied to receptors in vitro, no potentiation is observed.[106] Perhaps the interaction occurs via presynaptic receptors or some other, unknown, mechanism.

Interactions of a different nature occur when administration of a nondepolarizing agent is followed by injection of another nondepolarizing agent. Usually, the duration of action of the second agent is that of the first drug given. For example, if mivacurium, a short-acting agent, is given after mivacurium, it has a duration of action of 12 minutes. However, if the same dose of mivacurium, 0.05 mg/kg, is given after rocuronium, its duration of action is prolonged to 42 minutes.[107] On the contrary, if mivacurium is the first drug, rocuronium has a short duration of action. Thus, switching from a long- or intermediate-duration agent to a shorter duration drug to obtain paralysis of short duration at the end of a case will not provide paralysis of short duration. The reason why the characteristics of the first agent given are determinant is that the size of the loading dose is greater than that of the maintenance dose, so that even when the second dose is given, the majority of receptors is still occupied by the first drug.

Nondepolarizing–Depolarizing Interactions

Depolarizing and nondepolarizing relaxants are mutually antagonistic. When *d*-tubocurarine or other nondepolarizing agents are given before succinylcholine to prevent fasciculations and muscle pain, the succinylcholine is less potent and has a shorter duration of action.[24] The exception is with pancuronium, because it inhibits plasma cholinesterase. Mixtures of succinylcholine with mivacurium or atracurium demonstrate antagonism.[108] However, nondepolarizing drugs are somewhat more effective when administered after the effect of succinylcholine has worn off, compared with no prior succinylcholine. Finally, the response to a small dose of succinylcholine at the end of an anesthetic in which a nondepolarizing agent has been used is difficult to predict. It

potentiate the blockade, depending on the degree of nondepolarizing block. Antagonism is more likely if blockade is deep and potentiation if blockade is shallow. If an anticholinesterase agent has been given, then the effect of the succinylcholine is potentiated because of inhibition of plasma cholinesterase.

Antibiotics

Neomycin and streptomycin are the most potent of the aminoglycosides in depressing neuromuscular function.[109] The polymixins also depress neuromuscular transmission.[109] These antibiotics are not used frequently any more. Other aminoglycosides (e.g., gentamicin, netilmicin, tobramycin) also potentiate nondepolarizing neuromuscular blockade. They prolong the action of steroidal neuromuscular agents, but their effect on benzylisoquinoline compounds is less apparent.[110] The lincosamines clindamycin and lincomycin have prejunctional and postjunctional effects, but prolongation of blockade by clindamycin is unlikely to occur clinically unless large doses are used.[111] The penicillins, cephalosporins, tetracyclines, and erythromycin are devoid of neuromuscular effects at clinically relevant doses.[111] Metronidazole does not appear to have clinically significant effects at the neuromuscular junction.

Anticonvulsants

Acute administration of phenytoin produces augmentation of neuromuscular block.[112] Resistance to pancuronium, metocurine, vecuronium, and rocuronium, but not to atracurium or mivacurium, has been demonstrated in patients receiving chronic anticonvulsant therapy with carbamazepine or phenytoin.[113,114] A least part of the phenomenon has a pharmacokinetic origin. In patients with chronic carbamazepine therapy, the clearance of vecuronium was found to be increased and its terminal half-life decreased.[114]

Cardiovascular Drugs

Beta-blocking drugs and calcium channel antagonists have been found to have neuromuscular effects in vitro, but in practice, the duration of action of neuromuscular blocking agents is not altered in patients taking these drugs chronically.[115] Ephedrine given at induction of anesthesia has been found to accelerate onset of action of rocuronium while esmolol prolongs onset time.[116] The mechanism for this effect is probably by alteration of drug delivery to the site of action by changes in cardiac output. The acceleration of onset by ephedrine has not been found in all studies.

Miscellaneous

Metoclopramide inhibits plasma cholinesterase and thus prolongs the action of succinylcholine and mivacurium. Inconsistent interactions have been described for diuretics, digoxin, and corticosteroids, probably because these drugs induce chronic fluid and electrolyte shifts, the magnitude of which depends on the condition being treated. Magnesium at doses used for antiarrhythmic treatment or preeclampsia has profound potentiation effects on depolarizing and nondepolarizing blockade.[117]

ALTERED RESPONSES TO NEUROMUSCULAR BLOCKING AGENTS

Intensive Care Unit

Neuromuscular blocking agents are useful in the ICU to facilitate mechanical ventilation. It is essential to provide sedation to patients who receive paralyzing agents, to prevent discomfort associated with the inability to move. Enthusiasm for the liberal use of neuromuscular blocking agents in the ICU has waned considerably over the past decade or so, because of several reports of critically ill patients who demonstrated residual weakness for unexpectedly long periods after discontinuation of a neuromuscular blocking agent. In some, recovery took several months.

Pancuronium and vecuronium have been used most frequently, but recent descriptions of similar syndromes after atracurium and cisatracurium[118] suggest that the frequency of reports of weakness reflects the popularity of the drugs rather than a particular association with steroid-based compounds. Electromyographic (EMG) studies have shown variable lesions from myopathy to axonal degeneration of motor and sensory fibers. The picture is complicated by the syndrome of "critical illness neuropathy," which occurs in patients with sepsis and multiorgan failure, even in individuals not given neuromuscular blocking agents. Administration of corticosteroids is also considered a risk factor.[119] Symptoms include failure to wean from mechanical ventilation, limb weakness, and impaired deep tendon reflexes, but sensory function is usually not affected. There are no controlled clinical studies to allow the several initiating factors to be identified and matched with particular syndromes. In the absence of more definitive studies, it is recommended to administer neuromuscular blocking agents only to patients who cannot be managed otherwise, to limit the duration of administration to a few days or less, and to use only the dose that is necessary.[120]

Studies in ICU patients in whom the administration of relaxant was adjusted according to strict neuromuscular monitoring criteria have shown considerable variation in the requirement for neuromuscular blocking agent to maintain the same effect among patients and a wide within-patient pharmacokinetic variability.[121,122] Vecuronium and rocuronium have been associated with prolonged recovery times. For example, a mean of 3 hours was found between the end of rocuronium infusion and a train-of-four ratio of 0.7.[122] With cisatracurium, this interval was shorter (approximately 1 hour) and less variable.[121] Drug requirement is variable from patient to patient, is usually greater than in the operating room, and tends to increase with time. These reports suggest the need for more careful monitoring of neuromuscular block in ICU patients, although the optimal method and level of block to be achieved are uncertain. It is suggested to titrate neuromuscular blocking agents to the minimum infusion rate that will optimize oxygenation.

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease in which circulating antibodies produce a functional reduction in the number of acetylcholine receptors.[10,16] The lesion is postsynaptic: the number of acetylcholine quanta is normal and their content is either normal or increased.

Diagnosis and Management

The hallmark of myasthenia gravis is fatigue. Presentation is extremely varied, but typically, ocular symptoms, such as diplopia and ptosis, occur first. Bulbar involvement is usually seen next. Patients may go on to have extremity weakness and respiratory difficulties.[10] The characteristic EMG finding in myasthenia gravis is a voltage decrement to repeated stimulation at 2 to 5 Hz. This finding is also characteristic of nondepolarizing blockade in nonmyasthenic individuals. Edrophonium, 2 to 8 mg, produces brief recovery from myasthenia gravis and can be used as a diagnostic test. Finally, up to 80% of patients have an increased titer of the acetylcholine receptor antibody.[10]

Treatment is largely symptomatic. Anticholinesterase agents such as pyridostigmine are used to increase neurotransmission

at the neuromuscular junction. Corticosteroids and immunotherapy, with azathioprine, might produce long-term improvement. Plasmapharesis might be effective by eliminating the circulating antibody. Finally, many myasthenics have an associated thymoma, and surgical removal of the thymus may be indicated.[10]

Response to Neuromuscular Blocking Agents

Patients with myasthenia gravis are usually resistant to succinylcholine, with larger than usual doses required to produce complete blockade. This effect might be offset by the inhibition of plasma cholinesterase activity provided by pyridostigmine. Sensitivity to nondepolarizing

neuromuscular blocking drugs is increased to a variable extent, depending on the severity of the disease. The ED_{95} of vecuronium was found to be decreased by more than half in myasthenic patients, and the response of the orbicularis oculi is depressed even more than that of the adductor pollicis, reflecting some degree of ocular involvement.[123]

Management of Anesthesia

Traditionally, neuromuscular blocking drugs have been avoided in the patient with myasthenia gravis by the use of inhalational vapors with or without local anesthesia. More recently, there have been several reports of the successful use of small, titrated doses of atracurium, mivacurium, vecuronium, or rocuronium, administered under careful neuromuscular monitoring. Mivacurium might have a prolonged duration in myasthenic patients, especially those who have been treated with an anticholinesterase agent preoperatively, as plasma cholinesterase is inhibited by pyridostigmine. In addition, the effect of reversal drugs might be less than expected because myasthenic patients already receive drugs that produce cholinesterase inhibition. Thus, it is preferable to continue mechanical ventilation until spontaneous recovery is manifest.

Two problems remain after thymectomy: postoperative anticholinesterase therapy and predicting the need for mechanical support of ventilation. In most patients, the dose of anticholinesterases is reduced for 1 to 2 days after surgery. The need for mechanical ventilation of the lungs usually correlates with preoperative lung function tests.

Myotonia

Myotonia is characterized by an abnormal delay in muscle relaxation after contraction. Several forms have been described: myotonic dystrophy (dystrophia myotonica, myotonia atrophica, Steinert's disease), myotonia congenita (Thomsen's disease), hyperkalemic periodic paralysis, and paramyotonia congenita.

Diagnosis

Repeated nerve stimulation leads to a gradual but persistent increase in muscle tension. The EMG is pathognomonic; myotonic after-discharges are seen in peripheral muscle, consisting of rapid bursts of potential produced by tapping the muscle or moving the needle. They produce typical "dive-bomber" sounds on the loudspeaker.

Response to Neuromuscular Blocking Agents

The characteristic response to succinylcholine is a sustained, dose-related contracture that may make ventilation difficult for several minutes. Muscle membrane fragility may be responsible for the exaggerated hyperkalemia that is produced after succinylcholine.[38] Most case reports suggest that the response to nondepolarizing drugs is normal. However, myotonic responses have been observed after reversal with neostigmine.

Anesthesia

Succinylcholine is best avoided. Short- or intermediate-duration nondepolarizing agents may be used in usual doses with careful neuromuscular monitoring. Reversal agents are best avoided.

Muscular Dystrophy

The muscular dystrophies are a group of many diseases, with variability in presentation and typical age at onset of symptoms. The most common of these is the Duchenne-type muscular dystrophy (DMD), an X-linked hereditary disease that usually becomes apparent in childhood. Other types of muscular dystrophy include Becker, limb-girdle, fasciohumeral, Emery-Dreifuss, nemaline rod, and oculopharyngeal dystrophy. There have been several reports of cardiac arrest after administration of succinylcholine in children, often associated with hyperkalemia. Resuscitation was found to be difficult, and several of these cases were fatal.[38] The most likely explanation for these adverse events is previously undiagnosed, latent, muscular dystrophy. In

1993, the number of such reports encouraged Burroughs Wellcome, the manufacturer of Anectine (succinylcholine), to state that "succinylcholine [is] contraindicated in children and adolescents except when used for emergency tracheal intubation." After further discussion the recommendation was modified to a warning.

Response to Neuromuscular Blocking Agents

Most case reports describe a normal response to nondepolarizing agents, such as vecuronium, atracurium, and mivacurium, although there have been sporadic instances of increased sensitivity. There are little data on the response to anticholinesterases. There is considerable controversy over whether DMD patients are susceptible to malignant hyperthermia (MH).

Anesthesia

Succinylcholine should be avoided in patients with muscular dystrophy, especially if onset of symptoms occurred in childhood or adolescence. The possibility of latent or unrecognized DMD in young males (less than 10 years old) may be a reason to avoid succinylcholine in this patient population. Careful titration of short- or intermediate-duration nondepolarizing agents should be done. Reversal agents do not appear to be contraindicated.

Upper Motor Neuron Lesions

Patients with hemiplegia or quadriplegia as a result of central nervous system lesions show an abnormal response to both depolarizing and nondepolarizing agents. Hyperkalemia and cardiac arrest have been described after succinylcholine, probably as a result of extrajunctional receptor spread. Hyperkalemia is typically seen if the drug is given between from 1 week to 6 months after the lesion, but may be seen before and after that time period.[38] There is resistance to nondepolarizing neuromuscular blocking drugs below the level of the lesion. In hemiplegic patients, monitoring of the affected side shows that the block is less intense and recovery is more rapid than on the unaffected side. However, the apparently normal side also demonstrates some resistance to nondepolarizing drugs.

Similar findings have been reported after a stroke, with a greater resistance on the affected side.

Burns

As a result of the proliferation of extrajunctional receptors, succinylcholine produces severe hyperkalemia in patients with burns, and this may lead to cardiac arrest. The magnitude of the problem depends on the extent of the injury. It may appear as early as 24 to 48 hours after the burn injury and usually ends with healing.[38] Resistance to the effects of nondepolarizing neuromuscular blocking agents is manifest, even in muscles that are apparently not affected by the burn.[51,52] Mivacurium requirements may be decreased in burn patients, because of the lower plasma cholinesterase activity.[124]

Miscellaneous

Denervated muscle demonstrates potassium release after succinylcholine and resistance to nondepolarizing relaxants. Contractures in response to succinylcholine have also been observed in amyotrophic lateral sclerosis and multiple sclerosis. Succinylcholine is usually avoided in several neurologic diseases, including Friedrich's ataxia, polyneuritis, and Parkinson's disease, because of isolated reports of hyperkalemia.

MONITORING NEUROMUSCULAR BLOCKADE

Why Monitor?

Deep levels of paralysis are usually desired during anesthesia to facilitate tracheal intubation and to obtain an immobile surgical field. However, complete return of respiratory function must be

attained before the trachea is extubated. Administration of neuromuscular blocking drug must be individualized because blockade occurs over a narrow range of receptor occupancy,[18] and because there is considerable interindividual variability in response. Thus, it is important for the clinician to assess the effect of neuromuscular blocking drugs without the confounding influence of volatile agents, intravenous anesthetics, and opioids. To test the function of the neuromuscular junction, a peripheral nerve is stimulated electrically, and the response of the muscle is assessed.

Stimulator Characteristics

The response of the nerve to electrical stimulation depends on three factors: the current applied, the duration of the current, and the position of the electrodes. Stimulators should deliver a maximum current in the range of 60 to 80 mA. Most stimulators available for clinical use are designed to provide constant current, irrespective of impedance changes because of drying of the electrode gel, cooling, decreased sweat gland function, and so forth. However, this constant current feature does not hold for high impedances (>5 kΩ). Thus, electrodes should be firmly applied to the skin. A current display monitor on the stimulator is an asset, because accidental disconnection can be identified easily by a current approaching 0 mA. The duration of the current pulse should be long enough for all axons in the nerve to depolarize but short enough to avoid the possibility of exceeding the refractory period of the nerve. In practice, pulse durations of 0.1 to 0.2 msec are acceptable. At least one electrode should be on the skin overlying the nerve to be stimulated. If the negative electrode is used for this purpose, the threshold to supramaximal stimulation is less than for the positive electrode.[13] However, the difference is not large in practice. The position of the other electrode is not critical, but it should not be placed in the vicinity of other nerves. There is no need to use needle electrodes. Silver–silver chloride surface electrodes, used to monitor the electrocardiogram, are adequate for peripheral nerve stimulation, without the risk of bleeding, infection, and burns. In practice, applying these electrodes along the course of a nerve gives the best results (Fig. 16-12).

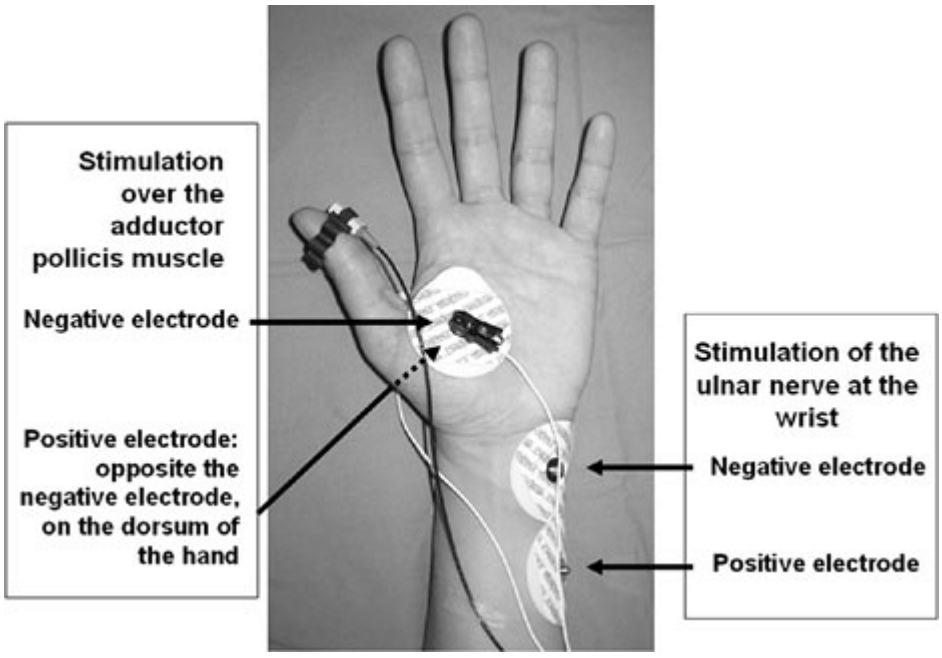

FIGURE 16-12. Electrode placement to obtain contraction of the adductor pollicis muscle. The traditional method is to stick the electrodes over the course of the ulnar nerve at the wrist, with the negative electrode distal (*right*). An alternate method is to position the electrodes over the adductor pollicis (*left*), the negative electrode on the palm of the hand, the positive in the same location, but on the dorsum of the hand. The device fixed to the thumb is an accelerometer.

Monitoring Modalities

Different stimulation modalities were introduced into clinical practice to take advantage of the characteristic features of nondepolarizing neuromuscular blockade: fade and posttetanic facilitation with high-frequency stimulation. Thus, the following discussion refers mostly to nondepolarizing block.

Single Twitch

The simplest way to stimulate a nerve is to apply a single stimulus, at intervals of >10 seconds. The amplitude of

response is compared with a control, preblockade twitch height. The single-twitch modality is useful to construct dose-response curves and to evaluate onset time. However, because a control value is required, the clinical usefulness of this mode of stimulation is limited.

Tetanus

When stimulation is applied at a frequency of ⩾30 Hz, the mechanical response of the muscle is fusion of individual twitch responses. In the absence of neuromuscular blocking drugs, no fade is present and the response is sustained. During nondepolarizing blockade, the mechanical response appears as a peak, followed by a fade (see Fig. 16-9). The sensitivity of tetanic stimulation in the detection of residual neuromuscular blockade is greater than that of single twitch, that is, tetanic fade might be present while twitch height is normal. Most nerve stimulators provide a 5-second train at a frequency of 50 Hz. This frequency was adopted because at >100 Hz, some fade may be seen even in the absence of neuromuscular blocking drugs. However, more fade is seen with 100-Hz than 50-Hz frequencies, and 100-Hz, 5-second trains are most useful in the detection of residual block.[46] With tetanic stimulation, no control prerelaxant response is required, as the degree of muscle paralysis can be assessed by the degree of fade following tetanic stimulation. However, the main disadvantage of this mode of stimulation is posttetanic facilitation (see Fig. 16-9), the extent of which depends on the frequency and duration of the tetanic stimulation. For a 50-Hz tetanus applied for 5 seconds, the duration of this interval appears to be at least 1 to 2 minutes.[125] If single-twitch stimulation is performed during that time, the response is spuriously exaggerated.

Train-of-Four

With 2-Hz stimulation, the mechanical or electrical response decreases little after the fourth stimulus, and the degree of fade is similar to that found at 50 Hz.[45] Thus, applying train-of-four stimulation at 2 Hz provides more sensitivity than single twitch and approximately the same sensitivity as tetanic stimulation at 50 Hz. In addition, this relatively low frequency allows the response to be evaluated manually or visually. Moreover, the presence of a small number of impulses (4) eliminates the problem of posttetanic facilitation. Train-of-four stimulation can be repeated every 12 to 15 seconds. There is a fairly close relationship between single-twitch depression and train-of-four response, and no control is required for the latter.[126] During recovery, the second twitch reappears at 80 to 90% single-twitch block, the third at 70 to 80%, and when blockade is 65 to 75%, all four twitches become visible.[127] Then, the train-of-four ratio, the height of the fourth twitch to that of the first twitch, is linearly related to first twitch height when blockade is <70%. When single-twitch height has recovered to 100%, the train-of-four ratio is ~70%.

Posttetanic Count

During profound neuromuscular blockade, there is no response to single-twitch, tetanic, or train-of-four stimulation. To estimate the time required before the return of a response, one may use a technique that depends on the principle of posttetanic facilitation. A 50-Hz tetanus is applied for 5 seconds, followed by a 3-second pause and by stimulation at 1 Hz. The train-of-four and tetanic

responses are undetectable, but facilitation produces a certain number of visible posttetanic twitches (Fig. 16-13). The number of visible twitches correlates inversely with the time required for a return of single-twitch or train-of-four responses.[128] For intermediate-duration drugs, the time from a posttetanic count of 1 to reappareance of twitch is 10 to 20 minutes.

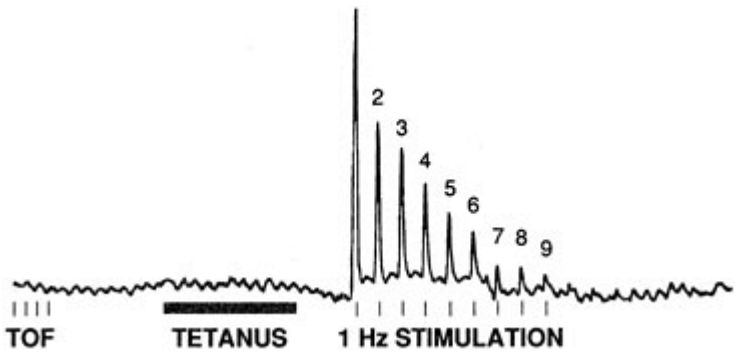

FIGURE 16-13. Posttetanic count (PTC). During profound blockade, no response is seen to train-of-four (TOF) or tetanus. However, because there is posttetanic facilitation, some twitches (in the case earlier, 9) can be seen after tetanic stimulation. In the example above, the PTC is 9.

Double-Burst Stimulation

Train-of-four fade may be difficult to evaluate by visual or tactile means during recovery from neuromuscular blockade. Irrespective of experience, it is difficult for anesthesiologists to detect train-of-four fade when actual train-of-four ratio is 0.4 or greater, meaning that residual paralysis can go undetected.[129] This shortcoming can be overcome, to a certain extent, by applying two short tetanic stimulations (three impulses at 50 Hz, separated by 750 msec), and by evaluating the ratio of the second to the first response. The double-burst stimulation ratio correlates closely with the train-of-four ratio, but is easier to detect manually.[129] At least 12 to 15 seconds must elapse between two consecutive double-burst stimulations.

Recording the Response

Visual and Tactile Evaluation

When electrical stimulation is applied to a nerve, the easiest and least expensive way to assess the response is to observe or feel the response of the muscle. This method is easily adaptable to any superficial muscle. However, serious errors in assessment can be made. In the case of evaluating the response of the adductor pollicis to ulnar nerve stimulation, the train-of-four count can be made reliably during a surgical procedure,[127] but the quantitative assessment of train-of-four ratio is difficult to make during recovery. Several investigations suggest that train-of-four ratios as low as 0.3[129] can remain undetected. The detection rate for tetanic fade (50 Hz) is no better.[130] With double-burst stimulation, fade can be detected reliably up to train-of-four ratios in the range of 0.5 to 0.6.[129] With 100-Hz tetanic stimulation, fade might be detected at train-of-four ratios of 0.8 to 1.0[46] and may be seen in individuals with no neuromuscular block.

Measurement of Force

A force transducer can overcome the shortcomings of one's senses. If applied correctly, the device

provides accurate and reliable responses, displayed as either a digital or an analog signal on a monitor. Force measurement can be measured after single-twitch, tetanus, train-of-four, double-burst, or posttetanic stimulation. However, the availability of tetanus and double-burst stimulation is superfluous if accurate recording of the train-of-four response can be made. Unfortunately, transducers are expensive, bulky, cumbersome, and can be applied to only one muscle, usually the adductor pollicis.

Electromyography

It is possible to measure the electrical instead of the mechanical response of the muscle. One electrode should be positioned over the neuromuscular junction, which is usually close to the midportion of the muscle, and the other near the insertion of the muscle. A third, neutral electrode can be located anywhere else. Theoretically, any superficial muscle can be used for EMG recordings. In practice, such recordings are limited to the hypothenar eminence, the first dorsal interosseous, and the adductor pollicis muscles, which are supplied by the ulnar nerve. Most EMG recording devices compute the area under the EMG curve during a specified time window (usually 3 to 18 msec) after the stimulus is applied.[131] This integrated EMG response is considered a better representation of the overall muscular activity than the measurement of peak response. There is usually good correlation between EMG and force of the adductor pollicis if the EMG signal is taken from the thenar eminence. The signal obtained from the hypothenar eminence is larger and less subject to movement artifacts, but it can underestimate the degree of paralysis when compared with the adductor pollicis.[132]

Accelerometry

According to Newton's law, acceleration is proportional to force if mass remains unchanged. The device is usually attached to the tip of the thumb (see Fig. 16-12) and a digital readout is obtained. The setup is sensitive to inadvertent displacement of the thumb and, in the absence of neuromuscular blocking drugs, train-of-four ratios >100% can be obtained.[133] In spite of these shortcomings, accelerometers have become increasingly popular because they are easy to use, are less cumbersome, can be used on muscles other than the adductor pollicis, and are relatively inexpensive. The use of accelerometry is helpful in the diagnosis of residual paralysis[134] and can reduce the incidence of the condition.[135]

Displacement

A variety of devices have been proposed that include a piezoelectric wafer that responds to motion or displacement. They are designed for the adductor pollicis. A thorough evaluation of these devices has not been made, but data indicate that there are slight, but clinically insignificant differences between the results such displacement trasnducers and mechanomyography provide.[136]

Phonomyography

A contracting muscle emits low frequency sounds. Train-of-four response and fade can be heard with a stethoscope placed over the adductor pollicis muscle. A quantitative response can be obtained with special microphones sensitive to frequencies (2 Hz) below the threshold of the human ear. An excellent correlation between phonomyography and force measurement has been found at several muscles, including the adductor pollicis and the corrugator supercilii.[84] At the time of writing, no commercial devices using phonomyography were available.

Choice of Muscle

Muscles do not respond in a uniform fashion to neuromuscular blocking drugs. After administration of a neuromuscular blocking agent, differences can be measured with respect to onset time, maximum blockade, and duration of action. It is not practical to monitor the muscles of physiological importance, for example, the abdominal muscles during surgery, or the respiratory and upper airway muscles postoperatively. A better approach is to choose a monitoring site that

has a response similar to the muscle of interest. For example, monitoring the response of the facial nerve around the eye is a good indicator of intubating conditions, and the use of the adductor pollicis during recovery reflects upper airway muscle function. Another strategy is to stick to one monitoring site, such as the adductor pollicis, and interpret the information provided from knowledge of the different responses between muscles (Fig. 16-14).

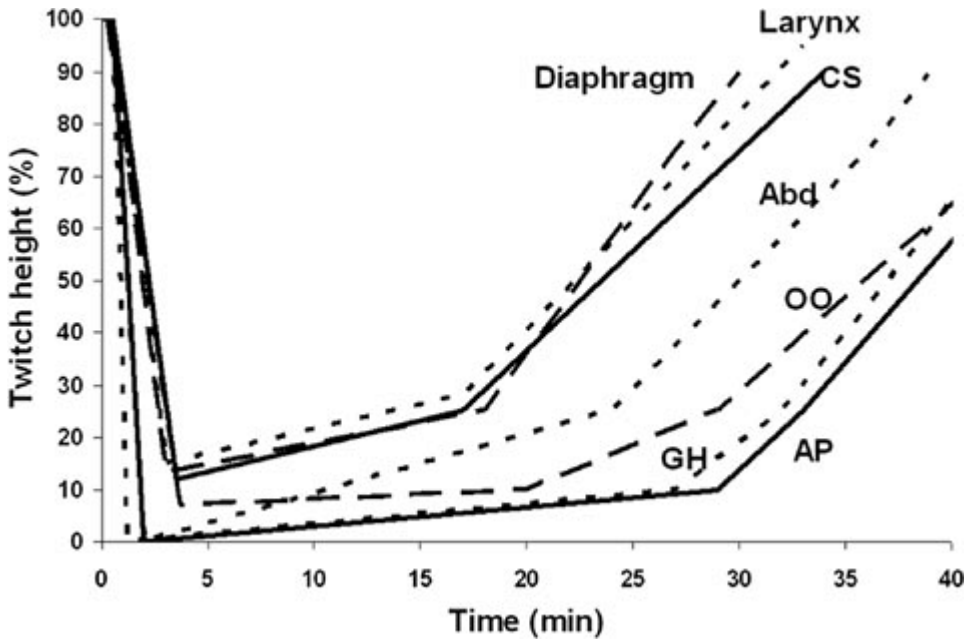

FIGURE 16-14. Approximate time course of twitch height after rocuronium, 0.6 mg/kg, at different muscles. Diaphragm: diaphragm; larynx: laryngeal adductors (vocal cords); CS: corrugator supercilii (eyebrow); abd: abdominal muscles; OO: orbicularis oculi (eyelid); GH: geniohyoid (upper airway); AP: adductor pollicis (thumb). The data are taken or inferred from Plaud et al,[142] Dhonneur et al,[166] Kirov et al,[139] and d'Honneur et al.[140]

Adductor Pollicis

The adductor pollicis is accessible during most surgical procedures. It is supplied by the ulnar nerve, which becomes superficial at the wrist where a negative electrode can be positioned. The positive electrode is applied a few centimeters proximally (see Fig. 16-12). The force of contraction of the adductor pollicis can be measured easily, and it has become a standard in research. After injection of a dose that produces less than 100% blockade, the time to maximal blockade is longer than in centrally located muscles.[137,138] The adductor pollicis is relatively sensitive to nondepolarizing neuromuscular blocking drugs, and during recovery it is blocked more than some respiratory muscles such as the diaphragm,[137] laryngeal adductors,[138] and abdominal muscles (see Fig. 16-14).[139] There

is evidence that recovery of the adductor pollicis and of upper airway muscles occurs more or less simultaneously (see Fig. 16-14).[140]

The adductor pollicis can also be stimulated by applying electrodes directly over it. This can be accomplished by placing the two electrodes in the space lying between the base of the first and second metacarpals, on the palmar and dorsal aspects on the hand, respectively (see Fig. 16-12). Such a stimulation avoids the confounding movement of hypothenar muscles. Direct muscle stimulation with this electrode position does not normally occur, because neuromuscular blocking agents abolish the response completely.[141]

Other Muscles of the Hand

Ulnar nerve stimulation also produces flexion and abduction of the fifth finger, which usually recovers before the adductor pollicis, the discrepancy in first twitch or train-of-four ratio being of the order of 15 to 20%.[132] Relying on the response of the fifth finger might overestimate recovery from blockade. Abduction of the index finger also results from stimulation of the ulnar nerve because of contraction of the first dorsal interosseous, the sensitivity of which is comparable to that of the adductor pollicis. The hypothenar eminence (near the fifth finger) and the first dorsal interosseous are particularly well suited for EMG recordings.[132] Stimulation in the hand (see Fig 16-12) eliminates contraction of the hypothenar muscles, but may evoke movement of the first dorsal interosseous.

Muscles Surrounding the Eye

There seem to be major differences in the response of muscles innervated by the facial nerve and located around the eye, and these differences have introduced some confusion in the literature. The orbicularis oculi essentially covers the eyelid, and its response to neuromuscular blocking agents is similar to that of the adductor pollicis.[142] However, it is customary to observe the movement of the eyebrow, and recordings at that site are similar to that of the laryngeal adductors (see Fig 16-14).[142] Onset of blockade is more rapid and recovery occurs sooner than at the adductor pollicis. Thus, facial nerve stimulation with inspection of the response of the eyebrow (which most likely represents the effect of the corrugator supercilii, not the orbicularis oculi) is indicated to predict intubating conditions and to monitor profound blockade. The facial nerve can be stimulated 2 to 3 cm posterior to the lateral border of the orbit. There is no need to use stimulating currents greater than 20 to 30 mA.

Muscles of the Foot

The posterior tibial nerve can be stimulated behind the internal malleolus to produce flexion of the big toe by contraction of the flexor hallucis. The response of this muscle is comparable to that of the adductor pollicis. Stimulation of the external peroneal nerve produces dorsiflexion, but the sensitivity of the muscles involved has not been measured.

Clinical Applications

Monitoring Onset

The quality of intubating conditions depends chiefly on the state of relaxation of muscles of the jaw, pharynx, larynx, and respiratory system. Onset of action is faster in all these muscles than in the hand or foot because they are closer to the central circulation and they receive a greater blood flow. Among these central muscles, the diaphragm and especially the laryngeal adductors are the most resistant to nondepolarizing agents. Data on laryngeal muscles are important not only because easy passage of the tracheal tube can be performed if vocal cords are relaxed, but also because all other muscles can be presumed to be blocked if the resistant laryngeal muscles are blocked. The relationship between onset time in laryngeal and hand muscles depends on dose. At relatively low doses (e.g., rocuronium, 0.3 to 0.4 mg/kg), onset time is slower at the adductor pollicis than at the laryngeal muscles. If the dose is increased (e.g., rocuronium, 0.6 to 1.0 mg/kg), onset is faster at the adductor pollicis because these doses produce 100% blockade at the adductor pollicis without blocking laryngeal muscles completely (see Fig. 16-14).[143] Onset time decreases considerably in any muscle if the dose given is sufficient to reach 100%. Finally, if the dose is large enough to block the laryngeal muscles completely, onset time again becomes shorter at the larynx. It is not surprising that monitoring the adductor pollicis muscle predicts intubating conditions poorly. Facial nerve stimulation with visual observation of the response over the eyebrow gives better results because the response of the corrugator supercilii is close to that of the vocal cords. Train-of-four fade takes longer to develop than single-twitch depression (see Fig. 16-9), and during onset, train-of-four stimulation does not have any advantages over single-twitch stimulation at 0.1 Hz.

Monitoring Surgical Relaxation

Adequate surgical relaxation is usually obtained when fewer than two or three visible twitches are observed at the adductor pollicis. However, this criterion might prove inadequate in certain circumstances when profound relaxation is required owing to the discrepancy between the adductor pollicis and other muscles. In this case, the posttetanic count can be used at the adductor pollicis,[128] provided that this type of stimulation is not repeated more often than every 2 to 3 minutes. A suitable alternative is stimulation of the facial nerve with observation of the response over the eyebrow, which recovers at the same rate as such resistant muscles as the diaphragm.[137,142]

Monitoring Recovery

Complete return of neuromuscular function should be achieved at the conclusion of surgery unless mechanical ventilation is planned. Thus, monitoring is useful in determining whether spontaneous recovery has progressed to a degree that allows reversal agents to be given and to assess the effect of these agents.

The effectiveness of anticholinesterase agents depends directly on the degree of recovery present when they are administered. Preferably, reversal agents should be given only when four twitches are visible,[144] which corresponds to a first-twitch recovery of >25%. For this assessment, using the adductor pollicis is preferable. The presence of spontaneous respiration is not a sign of adequate neuromuscular recovery. The diaphragm recovers earlier than the much more sensitive upper airway muscles, such as the geniohyoid, which recovers, on average, at the same time as the adductor pollicis.[140] To prevent upper airway obstruction after extubation, it is preferable to use the adductor pollicis to monitor recovery, instead of the more resistant muscles of the hypothenar eminence or those around the eye.

6 Finally, the adequacy of recovery should be assessed. Traditionally, a train-of-four ratio of 0.7 was considered to be the threshold below which residual weakness of the respiratory muscles could be present. There is abundant evidence that significant weakness may occur up to train-of-four values of 0.9. Awake volunteers given mivacurium failed to perform the head-lift test when the train-of-four ratio at the adductor pollicis decreased below 0.62, but needed a train-of-four ratio of

at least 0.86 to hold a tongue depressor between their teeth (Fig. 16-15).[145] This suggests that the head-lift test does not guarantee full recovery, and that the upper airway muscles used to retain a tongue depressor are very sensitive to the residual effects of neuromuscular blocking drugs. Furthermore, impairment in swallowing and laryngeal aspiration of a pharyngeal fluid was observed at train-of-four ratios as high as 0.9 in volunteers given vecuronium (see Fig. 16-4).[146]

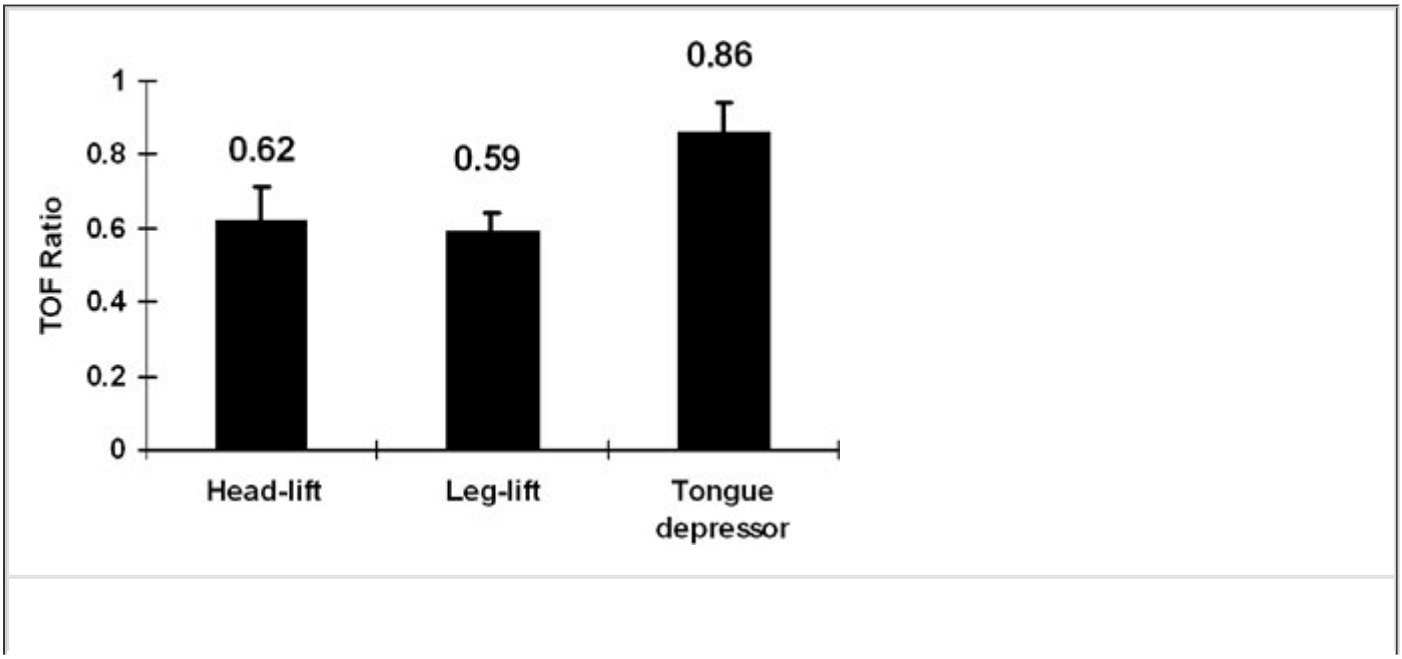

FIGURE 16-15. Correlation between train-of-four responses at the adductor pollicis and certain clinical tests of neuromuscular recovery. Volunteers were given mivacurium and were asked to lift their head for 5 seconds (head lift), lift their leg for 5 seconds (leg lift), or hold a tongue depressor between their teeth against force (tongue depressor). The minimum train-of-four ratio (and SD) when each of these tests was passed is indicated. Data from Kopman et al.[145]

Anesthetized patients appear considerably more sensitive to the ventilatory effects of neuromuscular blocking drugs than are awake patients. Whereas tidal volume and end-tidal CO_2 are preserved in awake patients receiving relatively high doses of neuromuscular blocking drugs,[147] anesthetized adults have a decreased tidal volume and increased PCO_2 with doses of pancuronium as low as 0.5 mg.[148] In conscious volunteers, administration of small doses of vecuronium to maintain train-of-four at less than 0.9 leads to severe impairment of the ventilatory response to hypoxia (Fig. 16-16).[149] The response to hypercapnia is maintained, and this indicates that the response to hypoxia is not a result of respiratory muscle weakness.[149]

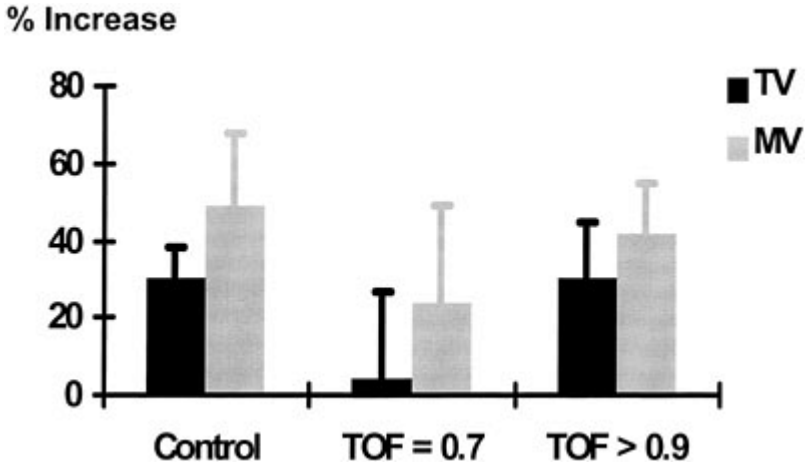

FIGURE 16-16. Response to hypoxia is impaired during recovery from vecuronium blockade. Normal response is an increase in minute volume (MV) or tidal volume (TV) (control). These increases are decreased significantly when vecuronium produces a train-of-four ratio of 0.7 at the adductor pollicis. They return to near normal values at a train-of-four ratio >0.9. Data from Eriksson et al.[149]

Taken together, the results of these investigations indicate that normal respiratory and upper airway function does not return to normal unless the train-of-four ratio at the adductor pollicis is 0.9 or more. However, it has become apparent that human senses fail to detect either a train-of-four or 50-Hz tetanic fade when the train-of-four ratio is as low as 0.3.[129,130] With double-burst stimulation, detection failures may occur at train-of-four ratios of 0.5 to 0.6.[129] Compared with the train-of-four, the ability to detect fade is not improved by using tetanic stimulation at 50 Hz for 5 seconds. However, in one study fade could be detected visually at train-of-four ratios of 0.8 to 0.9 by using 100-Hz tetanic stimulation.[46] It is unclear, however, whether fade induced by inhalational agents alone can be seen. Because of the presence of posttetanic facilitation, 50- or 100-Hz stimuli should not be applied more often than every 2 minutes. Because of the limitations of one's senses, it has been advocated that quantitative assessment of the train-of-four ratio be made routinely.[9] Mechanographic and EMG equipment give reliable values of train-of-four ratio, but the use of this equipment is limited by size, cost, and convenience. Accelerometers are less

bulky and cheaper, but they can overestimate the value of train-of-four ratio during recovery.[133] It has been suggested that a train-of-four ratio of 1.0 obtained by accelerometry must be obtained before neuromuscular function can be considered complete.[150] Monitoring devices based on the measurement of displacement or sound may prove to have more reliable train-of-four ratios than accelerometry. In one study, a transmission module sensitive to bending and deformation was found to yield train-of-four ratio values comparable to mechanomyography during the recovery period.[136]

In response to the shortcomings of visual or tactile evaluations, another approach to recovery is to wait until sufficient spontaneous recovery is present and give reversal agents systematically. Kopman et al[151] suggested that neostigmine be given at a train-of-four count of 2 or greater if the neuromuscular blocking agent is cisatracurium or rocuronim. Complete recovery took longer than expected, as some patients still had train-of-four ratios less than 0.9 after 30 minutes. In any event, clinicians must be aware of the limitations of the tests they are using and complete their evaluations with clinical tests.

Factors Affecting the Monitoring of Neuromuscular Blockade

Many drugs interfere with neuromuscular function and these are dealt with elsewhere. However, certain situations make the interpretation of data on neuromuscular function difficult. Central hypothermia may slow the metabolism of neuromuscular blocking agents and prolong blockade. If the extremity where monitoring is performed is cold, the degree of block will be accentuated. Thus, if only the monitored hand is cold, without central hypothermia, the degree of paralysis will appear to be increased. Resistance to nondepolarizing neuromuscular blocking drugs occurs with nerve damage, including peripheral nerve trauma, cord transection, and stroke. In this case, monitoring of the involved limb would tend to underestimate the degree of muscle paralysis. The level of paralysis should also be adjusted for the type of patient, as well as the type of surgery. For example, it is not necessary to paralyze frail individuals or patients at the extremes of age to the same extent as young muscular adults. The same applies to patients with debilitating muscular diseases.

Neuromuscular monitoring by itself does not guarantee adequate relaxation during surgery and complete recovery postoperatively. The surgical field may be poor in spite of full paralysis of the hand, because of difference in response between muscles.

Residual paralysis might occur because of excess neuromuscular blocking agents given, early administration of reversal, or an abnormal response of the patient. The effect of the neuromuscular blocking drug is the same whether or not monitoring is used. Neuromuscular monitoring can help in the diagnosis of inadequate skeletal muscle relaxation during surgery or insufficient recovery after surgery, but does not, in itself, treat these conditions.

ANTAGONISM OF NEUROMUSCULAR BLOCK

In most circumstances, all efforts should be made to ensure that the patient leaves the operating room with unimpaired muscle strength. Specifically, respiratory and upper airway muscles must function normally, so the patient can breathe, cough, swallow secretions, and keep his or her airway patent. Two strategies can be adopted to achieve this goal. The first is to titrate neuromuscular blocking agents carefully, so that no residual effect is manifest at the end of surgery. The second is to accelerate recovery by giving a reversal drug. This second option is probably safer, but both strategies require careful assessment of blockade.

Assessment of Neuromuscular Blockade

Spontaneous breathing can resume even if relatively deep degrees of paralysis are still present. Spontaneous ventilation, adequate to prevent hypercapnia, can be maintained despite considerable measurable skeletal muscle weakness if a patent airway is ensured. The ability to perform maneuvers such as vital capacity, maximum voluntary ventilation, and forced expiratory flow rate recovers at less intense levels of paralysis because it requires a greater strength.[147]

Such tests are, however, difficult to perform in everyday practice, particularly when the patient is recovering from general anesthesia. Moreover, the weakest point in the respiratory system is the upper airway. When given vecuronium, swallowing was impaired and laryngeal aspiration occurred when the TOF ratio was 0.9 or less.[146] These problems are difficult to diagnose when a tracheal tube is in place. Consequently, several indirect indices, which are easier to measure, have been correlated with the more specific tests of lung and upper airway function.

Clinical Evaluation

Several crude tests have been suggested, including head lift for 5 seconds, tongue protrusion, and the ability to lift the legs off the bed to determine recovery of neuromuscular function. Pavlin et al[147] correlated the maximum inspiratory pressure (MIP) with tests of skeletal muscle strength and of airway musculature in conscious volunteers receiving *d*-tubocurarine. As the dose was increased, head lift and leg raising were affected first. Then, the ability to swallow, touch teeth, and maintain a patent airway was impaired. Hand grip strength was decreased markedly by then. Nevertheless, as long as the mandible was elevated by an observer, the $PETCO_2$ was normal even when all the tests were failed. From these data, it was concluded that ability to maintain head lift for 5 seconds usually indicates sufficient strength to protect the airway and support ventilation.[147] However, Kopman et al have shown, in volunteers, that the most sensitive test is the ability to clamp the jaws shut and prevent removal of a wooden spatula.[145] This correlated with a TOF ratio measured at the adductor pollicis of >0.86, whereas head lift and leg lift could be performed at more intense levels of paralysis (TOF approximately 0.6) (see Fig. 16-15). All subjects complained of visual symptoms until TOF >0.9. Pressure measurements in the upper esophagus have been shown to be decreased (see Fig. 16-4) and laryngeal aspiration detected at a TOF ratio <0.9.[146,152] Thus, it appears that a normal head lift or leg lift is insufficient to guarantee normal upper airway function. The ability to resist removal of an object (such as a tongue depressor or a tracheal tube) from the mouth by closing the teeth probably correlates better with adequate upper airway function.

Evoked Responses to Nerve Stimulation

The clinical tests described above are usually unobtainable in the patient recovering from anesthesia. Furthermore, it is preferable to assess the degree of recovery before emergence. Evoked responses to nerve stimulation are then appropriate. The target is a TOF >0.9, considering that upper airway function does not recover completely until the train-of-four ratio at the adductor pollicis is at least 0.9. Even at that level, some subjects show some signs of weakness.[134]

With the introduction of short- and intermediate-duration nondepolarizing agents into clinical practice, the use of reversal agents has been considered by some as optional. The decision to omit pharmacological reversal of neuromuscular blockade must be made carefully, because the presence of residual paralysis may be missed. As mentioned earlier, manual and tactile evaluation of neuromuscular blockade by train-of-four or 50-Hz tetanic stimulation may fail to detect fade.[129,130] Double-burst stimulation is more sensitive, but becomes unreliable at train-of-four ratios in the 0.6 to 0.9.[129] The most sensitive test is the ability to maintain sustained contraction to 100-Hz tetanus for 5 seconds. Fade is detected when TOF ratio is as high as 0.8 to 0.9.[46] Tetanic stimulation at 100 Hz is painful and must be performed only in adequately anesthetized patients.

Because of the limitations of the visual and tactile estimate of the train-of-four response during recovery, objective measurement has been advocated.[9] Acceleromyographic recordings might be the most practical, because accelerometers are cheap and easy to use. However, it must be appreciated that the TOF ratio obtained with accelerometry is greater than that measured with mechanomyography and may exceed 1.0. An accelerographic TOF ratio of 1.0 has been proposed as the equivalent of a mechanomyographic TOF of 0.9.[150]

Residual Paralysis

7 Several studies have demonstrated that residual neuromuscular blockade is frequent in

patients in the recovery room after surgery. Viby-Mogensen et al found in 72 adult patients given long-acting agents that the train-of-four ratio was 0.7 in 30 (42%) patients, and that 16 of the 68 patients (24%) who were awake were unable to sustain head lift for 5 seconds.[8] In that study, the patients received appropriate doses of neostigmine. Similar results have been obtained in Sweden, Australia, Canada, and the United States (see Table 16-1).[153] The incidence of train-of-four ratio 0.7 is reduced from about 30% to less than 10% if the intermediate agents atracurium or vecuronium are substituted for the long-acting drugs and if reversal is given.[153] Recovery from mivacurium is even more rapid. However, the actual incidence of residual paralysis was certainly underestimated in these studies because of the criterion used (train-of-four ratio of 0.7). Recently, there has been a trend for a greater incidence of residual paralysis, even with intermediate-duration drugs. This can be explained by two factors. The threshold for residual paralysis has been raised from a train-of-four ratio of 0.7 to 0.8 and then to 0.9.[134] However, the most important reason for high incidence of residual paralysis seems to be omission of reversal. In one study, this incidence was 42% after vecuronium, using the 0.7 criterion.[154]

Clinical Importance

Residual paralysis in the recovery room has been shown to be associated with significant morbidity. In 1997, Berg et al studied nearly 700 general surgical patients who randomly received pancuronium, vecuronium, or atracurium to produce surgical relaxation.[155] In patients who had received pancuronium, the incidence of postoperative partial paralysis, defined by a train-of-four ratio <0.7, was five times that in patients receiving either of the two intermediate-acting drugs (26 versus 5%). In addition, the incidence of atelectasis demonstrated on chest radiographs taken 2 days later was greater in patients who had received pancuronium and who had not attained a train-of-four ratio of 0.7 (16%) than in those who exceeded this threshold (4.8%).[155] Intense residual block has been demonstrated in patients after cardiac surgery, and choosing rocuronium over pancuronium has been associated with fewer symptoms of weakness and a shorter time to extubation.[156]

Reversal Agents

So far, the only compounds that have been widely used to reverse the effect of neuromuscular blocking agents are the anticholinesterase drugs. The pharmacologic principle involved is inhibition of acetylcholine breakdown to increase its concentration of acetylcholine at the neuromuscular junction, thus tilting the competition for receptors in favor of the neurotransmitter. Other drugs such as suramin and 3–4 aminopyridine are not as effective, or more toxic, or both. At the time of writing, a chelating agent, ORG25696, designed to rid the organism of rocuronium, was investigated for its ability to reverse neuromuscular blockade.

Anticholinesterases: Mechanism of Action

Neostigmine, edrophonium, and pyridostigmine inhibit acetylcholinesterase, but this may not be the only mechanism by which blockade is antagonized. This inhibition is present at all cholinergic synapses in the peripheral nervous system. Thus, the anticholinesterases have potent parasympathomimetic activity, which is attenuated or abolished by the administration of an antimuscarinic agent, atropine or glycopyrrolate. Neostigmine, edrophonium, and pyridostigmine are quaternary ammonium compounds, which do not penetrate the blood-brain barrier well. Thus, although these agents have the ability to affect cholinergic function in the central nervous system, the concentrations in the brain are usually too small for such an effect. Physostigmine is an anticholinesterase that can cross the blood-brain barrier easily. For this reason, it is not used to reverse neuromuscular blockade. Neostigmine injected intrathecally is a good analgesic, but produces nausea and vomiting.

Neostigmine and pyridostigmine are attached to the anionic and esteratic sites of the acetylcholinesterase molecule and produce longer lasting inhibition than edrophonium. Neostigmine and pyridostigmine are inactivated by the interaction with the enzyme, whereas

edrophonium is unaffected.[153]

Inhibition of acetylcholinesterase results in an increased amount of acetylcholine reaching the receptor and in a longer time for acetylcholine to remain in the synaptic cleft. This causes an increase in the size and duration of the end plate potentials.[157] There is evidence that some of the effects of neostigmine are not the result of cholinesterase inhibition.[157] Anticholinesterases also have presynaptic effects. In the absence of neuromuscular blocking drugs, they potentiate the normal twitch response in a way similar to succinylcholine, probably as a result of the generation of action potentials that spread antidromically.[20] A ceiling effect, that is, the inability for large doses to produce an increasing effect, has been demonstrated in vitro.

Neostigmine Block

Large doses of anticholinesterases, greater than those used clinically, may produce neuromuscular blockade. Fade of both EMG and mechanical responses has been observed during tetanic stimulation after clinical doses of neostigmine but not edrophonium were given to reverse neuromuscular blockade.[158] Paradoxically, this neostigmine effect is antagonized with small doses of nondepolarizing blocking agents. The mechanism involved is uncertain. There are no clinical reports of postoperative weakness attributed to reversal agents, and this may be because all patients who received the anticholinesterase also had been given some neuromuscular blocking agent.

Potency

Dose-response curves have been constructed for edrophonium, neostigmine, and pyridostigmine. During a constant infusion of neuromuscular blocking drugs, the curves are obtained by plotting the peak effect versus the dose of reversal agent. In this situation, neostigmine was found to be approximately 12 times as potent as edrophonium.[159] However, the curves are not parallel, that of edrophonium being flatter. This indicates that edrophonium is effective over a narrower range of blockade and less effective against deep blockade. This was verified when neostigmine and edrophonium were used to reverse atracurium blockade. More neostigmine and edrophonium were required to reverse deep (99%) than moderate (90%) block, but the difference was greater for edrophonium.[160] There is no difference in the dose-response relationship of anticholinesterases if vecuronium is infused instead of pancuronium, but there is a marked shift to the left for the curves obtained during vecuronium block if the reversal agent is given during spontaneous recovery.[161] This indicates that anticholinesterase-assisted recovery is the sum of two components: (1) spontaneous recovery from the neuromuscular blocking agent itself, which depends on the pharmacokinetic characteristics of the drug, and (2) assisted recovery, which is a function of the dose and type of anticholinesterase agent given.

Pharmacokinetics

Following bolus iv injection, the plasma concentration of the anticholinesterases decreases rapidly during the first 5 to 10 minutes and then more slowly.[153] Volumes of distribution are in the range of 0.7 to 1.4 L/kg and the elimination half-life is 60 to 120 minutes. The drugs are water-soluble, ionized compounds so that their principal route of excretion is the kidney. Their clearances are in the range of 8 to 16 mL/kg/min, which is much greater than the GFR because they are actively secreted into the tubular lumen. Their clearance is reduced markedly in patients in renal failure.

Pharmacodynamics

The onset of action of edrophonium (1 to 2 minutes) to peak effect is much more rapid than that of neostigmine (7 to 11 minutes) or pyridostigmine (15 to 20 minutes) (Fig. 16-17).[159] The reason for the differences is uncertain, but may be related to the different rates of binding to the enzyme. The duration of action (1 to 2 hours) is similar to their elimination half-life. Even when used to reverse blockade produced by long-acting agents, duration of action of anticholinesterase agents is comparable to or most often exceeds that of the neuromuscular blocking drug. Well-documented recurarization has not been reported. In practice, cases of apparent reparalysis in the

recovery room are incomplete reversal that was initially thought to be complete. Either manual or visual assessment is performed using the train-of-four or tetanus mode, which can yield to gross underevaluation of residual paralysis, or respiratory function appeared adequate when the tracheal tube was in place, but once extubated, the patient cannot maintain a patent airway.

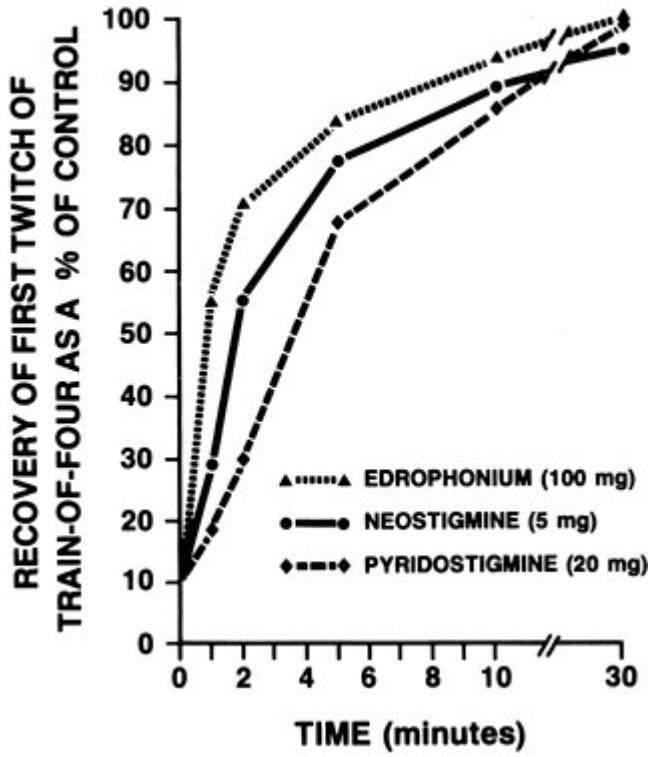

FIGURE 16-17. Reversal of pancuronium blockade at 10% twitch recovery. Reversal is given at time zero. Edrophonium is faster then neostigmine, which is faster than pyrodostigmine. Redrawn from Ferguson et al.[167]

Factors Affecting Reversal

Several factors modify the rate of recovery of neuromuscular activity after reversal.

Intensity of Block

8 The more intense the block at the time of reversal, the longer the recovery of neuromuscular activity (Fig. 16-18).[160] In addition, neostigmine is more effective than edrophonium or pyridostigmine in antagonizing intense (90%) blockade.[160] When reversal is administered after spontaneous recovery to $\geqslant$25% T_1 has occurred, recovery is rapid and the time from reversal to TOF 0.9 is usually only a few minutes, although recovery after

pancuronium may not be complete.[79] Thus, it has been recommended that reversal should not be attempted until $T_1 \geqslant$25% when four twitches to TOF stimulation are visible. Attempted reversal at only two twitches may take 30 minutes or more to reach TOF = 0.9.[151]

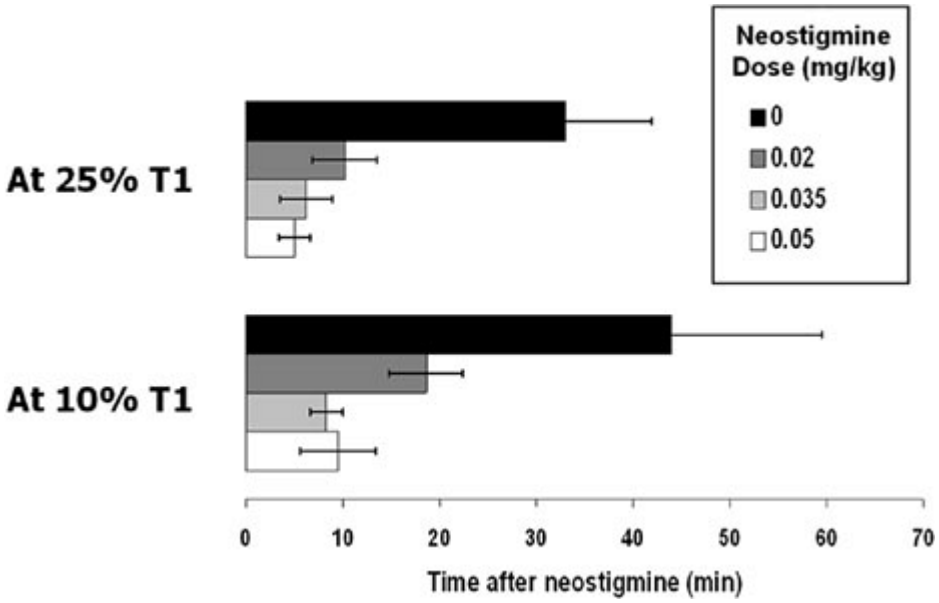

FIGURE 16-18. Neostigmine is more effective at greater degree of recovery from rocuronium blockade. Time to reach a train-of-four ratio of 0.8 after various doses of neostigmine. This time is less if neostigmine is given at 25% than at 10% first-twitch recovery. Notice a ceiling effect for neostigmine at doses greater than 0.035 mg/kg. A dose of 0 indicates no reversal given. Data from McCourt et al.[168]

It is sometimes argued that reversal can be attempted earlier, for instance when there is only one or no twitch visible following train-of-four stimulation, because time has to be spent anyway waiting for all four twitches to reappear. Several studies dealt with the problem of total time between injection of the neuromuscular blocking agent until complete recovery, with the reversal agent given at different levels of spontaneous recovery. Bevan et al[162] administered large doses of neostigmine (0.07 mg/kg) after rocuronium and vecuronium and measured time until train-of-four ratio was 0.9. Neostigmine decreased the time to recovery, no matter when it was given. However, time from injection to full reversal was not less when neostigmine was given 5 minutes after rocuronium (42.1 minutes) than at 25% recovery (28.2 minutes) (Fig. 16-19).[162] In addition, giving the reversal agent too early leads to a period of "blind paralysis," because neostigmine-assisted recovery is characterized by an early, rapid phase, followed by slower recovery. As a result, the interval between a train-of-four ratio of 0.4 to 0.9, that is, the time when fade is difficult to detect, is likely to be much longer with early neostigmine administration. Thus, there is little advantage in attempting early reversal.

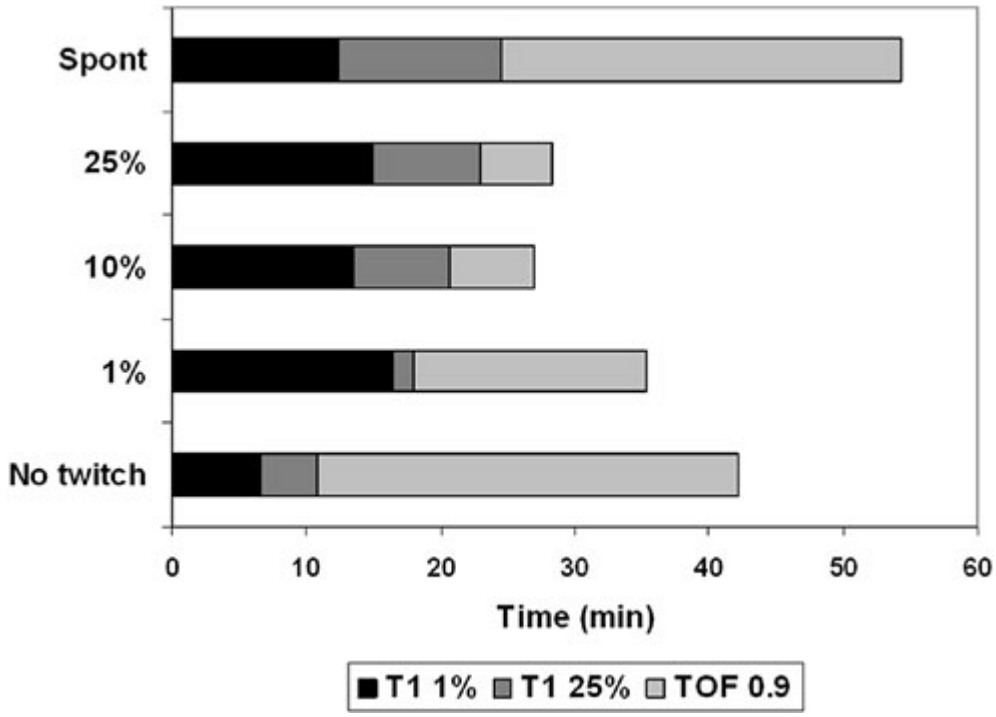

FIGURE 16-19. Time from injection of rocuronium until recovery to train-of-four ratio of 0.9 in adults. Reversal with neostigmine was either not given (spont), or given at 25, 10, or 1% twitch recovery, or given 5 minutes after rocuronium, when there was no twitch. Times from rocuronium injection to 1% first twitch, 25% first twitch and train-of-four ratio of 0.9 are indicated. Neostigmine was optimal when given at 10 to 25%. Giving it early had no advantage. Data from Bevan et al.[162]

Dose

Over a certain dose range, the degree and rate of reversal depends directly on dose.[163] However, all anticholinesterase agents demonstrate a ceiling effect (see Fig. 16-18). Usually, there is no added benefit in giving doses exceeding 0.07 mg/kg neostigmine, or 1.0 mg/kg edrophonium.

Choice of Neuromuscular Blocking Agent

Recovery of neuromuscular activity after reversal is dependent on the rate of spontaneous recovery as well as the acceleration induced by the reversal agent. Consequently, the overall recovery of intermediate-acting agents (atracurium, vecuronium, mivacurium, rocuronium) following the same dose of anticholinesterase is more rapid and more complete than after pancuronium, *d*-tubocurarine, or gallamine.[79] This is probably why residual paralysis is more frequent with longer acting neuromuscular blocking agents. After prolonged infusions, recovery is slower than after intermittent bolus administration.[97] This is especially true of drugs that depend on redistribution for termination of action, such as rocuronium and vecuronium.

Age

Recovery of neuromuscular activity occurs more rapidly with smaller doses of anticholinesterases in infants and children than in adults (Fig. 16-20).[162] Residual weakness in the recovery room is found less frequently in children than in adults. The effectiveness of reversal has not been studied extensively in the elderly. Although the elimination of anticholinesterases is reduced in this age group, this is counterbalanced by the tendency for neuromuscular blockade to wear off more slowly. This is especially true of steroid neuromuscular blocking agents, such as vecuronium and

rocuronium, which have a slower recovery index in the elderly.

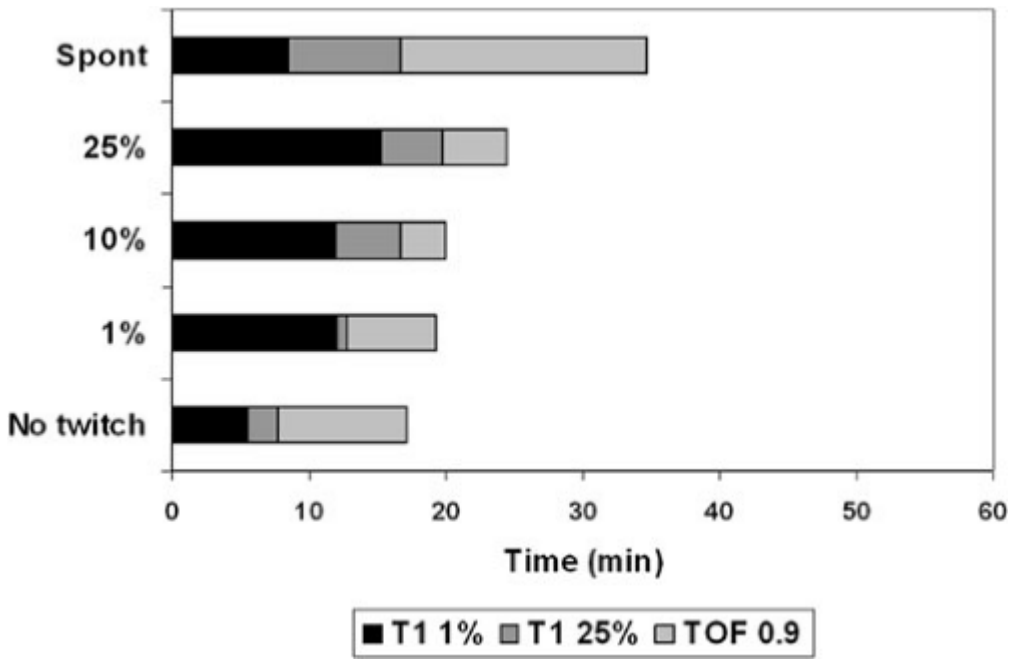

FIGURE 16-20. Same graph as in Figure 16-19, but in children 2 to 12 years old. Spontaneous recovery from rocuronium blockade is more rapid, as well as neostigmine-assisted recovery. Data from Bevan et al.[162]

Drug Interactions

Drugs that potentiate neuromuscular blockade can slow reversal or produce recurarization if given after anticholinesterase administration. Halogenated agents, when continued after neostigmine administration, prolong time to full reversal. Even when they are discontinued at the time of anticholinesterase drug administration, reversal time is not reduced significantly, probably because wash out of the vapor from muscle tissue takes time. Care must be taken if aminoglycoside antibiotics or magnesium must be given shortly after reversal agents.[117]

Renal Failure

Anticholinesterases are actively secreted into the tubular lumen so that their clearance is reduced in renal failure.[153] Thus, duration of action of neostigmine and edrophonium is increased in renal failure, at least to a comparable extent as duration of action of the neuromuscular blocking agent. No cases of recurarization have been reported.

Anticholinesterases: Other Effects

Cardiovascular

Anticholinesterases provoke profound vagal stimulation. The time course of the vagal effects parallels the reversal of block: rapid for edrophonium and slower for neostigmine. However, the bradycardia and bradyarrhythmias can be prevented with anticholinergic agents. Atropine has a rapid onset of action (1 minute), duration of 30 to 60 minutes, and crosses the

blood-brain barrier. Its time course makes it appropriate for use in combination with edrophonium,[159] whereas glycopyrrolate (onset 2 to 3 minutes) is more suitable with neostigmine or pyridostigmine. Because glycopyrrolate does not cross the blood-brain barrier, it is believed that the incidence of memory deficits after anesthesia is less than that after atropine. If atropine

is given with neostigmine, the dose is approximately half that of neostigmine (atropine 20 μg/kg for neostigmine 40 μg/kg). Such a combination leads to an initial tachycardia followed by a slight bradycardia. With glycopyrrolate, the dose is one-fourth to one-fifth that of neostigmine. Atropine requirements are less with edrophonium than with nesotigmine (atropine 7 to 10 μg/kg versus edrophonium 0.5 mg/kg).

Other Cholinergic Effects

Anticholinesterases produce increased salivation and bowel motility. Although atropine blocks the former, it appears to have little effect on peristalsis. Some reports claim an increase in bowel anastomotic leakage after the reversal of neuromuscular blockade. Others have held the use of anticholinesterases to be responsible for an increased incidence of vomiting after ambulatory surgery. In a recent meta-analysis, it was concluded that neostigmine (2.5 mg or more in adults) was associated with a higher incidence of nausea and vomiting than no reversal.[164] This conclusion is heavily affected by two studies showing a large effect, while all other studies showed no effect. The meta-analysis suggested that lower doses (1.5 mg or less) were not associated with a greater incidence of nausea and vomiting. Since then, two more studies failed to show any relationship between administration of neostigmine and an increased incidence of postoperative nausea and vomiting. This emetic effect has not been found for edrophonium. At any rate, possible nausea and vomiting is preferable to signs and symptoms of respiratory paralysis.

Respiratory Effects

Anticholinesterases may cause an increase in airway resistance, but anticholinergics reduce this effect. Several other factors, such as pain, the presence of an endotracheal tube, or light anesthesia, may predispose to bronchoconstriction at the end of surgery so that it is difficult to incriminate the reversal agents.

Clinical Use

Several reversal regimens have been proposed and are effective. In general, the more intense the block, the greater the dose of anticholinesterase that is required. However, there does not seem to be any advantage in giving more than the equivalent of neostigmine 0.07 mg/kg. Neostigmine is preferred to edrophonium for intense block, but the rapid action of edrophonium has the advantage of allowing the extent of reversal to be assessed in the operating room. Pyridostigmine has a slow onset of action, and does not appear to accelerate reversal of short- and intermediate-duration drugs to a great extent.

ORG 25969

A new method of reversing neuromuscular blockade has been advocated recently by the introduction of a cyclodextrin, ORG 25969, which, at the time of writing, was still in the investigational stage in humans.[165] The compound is made up of eight sugars arranged in a ring. It has a high affinity for rocuronium, with which it forms a complex, and the complex is excreted. ORG 25969 has less affinity for other steroidal neuromuscular blocking agents like vecuronium and pancuronium, and apparently no affinity for other endogenous steroidal compounds. It does not bind benzylisoquinoline-type neuromuscular blocking agents. The ability to produce a rapid return of twitch height even at deep levels of paralysis and the lack of side effects make this compound a promising new development in anesthesia.

Chapter 17

Local Anesthetics

Spencer S. Liu

Raymond S. Joseph Jr.

KEY POINTS

1	Local anesthetics block the generation, propagation, and oscillations of electrical impulses in electrically excitable tissue.
2	Molecular and genetic studies indicate that local anesthetics primarily work by binding to a modulated receptor located on the interior of the sodium channel.
3	In addition to sodium channel block, mechanisms of action of both peripheral and central neural block may involve decremental conduction, partial block of information carrying electrical oscillations, and interactions with other neurotransmitters such as GABA.
4	In general, the more potent and longer acting agents are more lipid soluble, have increased protein binding, less systemic absorption, but more potential for systemic toxicity.
5	All currently available local anesthetics are racemic mixtures with the exception of lidocaine (achiral), levobupivacaine (l = S), and ropivacaine (S). It appears that S isomers have nearly equal efficacy but less potential for systemic toxicity.
6	Efficacy for clinical use of local anesthetics may be increased by addition of epinephrine, opioids, and alpha-2 adrenergic agonists. The value of alkalinization of local anesthetics appears to be debatable as a clinically useful tool to improve anesthesia.
7	Systemic toxicity from the clinical use of local anesthetics for regional anesthesia appears to be an uncommon occurrence. Surveys from France and the United States approximate the seizure rate to be 1/10,000 for epidural injection and 7/10,000 for peripheral nerve block.
8	Nonetheless, systemic toxicity from local anesthetics should be promptly

treated. Patients with cardiovascular collapse from bupivacaine, ropivacaine, and levo-bupivacaine may be especially difficult to resuscitate.

INTRODUCTION

Local anesthetics block the generation, propagation, and oscillations of electrical impulses in electrically excitable tissue. Use of local anesthetics in clinical anesthesia is varied and includes direct injection into tissues, topical application, and intravenous administration to produce clinical effects at varied locations including the central neuraxis, peripheral nerves, mucosa, skin, heart, and airway. Detailed knowledge of pertinent anatomy and pharmacology will aid in optimal therapeutic use of local anesthetics. Care should be taken to avoid potential central nervous system (CNS) and cardiovascular toxicity from local anesthetics.

MECHANISMS OF ACTION OF LOCAL ANESTHETICS

Anatomy of Nerves

Local anesthetics are often used to block nerves either peripherally or centrally. Peripheral nerves are mixed nerves containing afferent and efferent fibers that may be myelinated or unmyelinated. Each axon within the nerve fiber is surrounded by endoneurium composed of nonneural glial cells. Individual nerve fibers are gathered into fascicles and surrounded by perineurium composed of connective tissue. Finally, the entire

peripheral nerve is encased by epineurium composed of dense connective tissue (Fig. 17-1). Thus, several layers of protective tissue surround individual axons, and these layers act as barriers to the penetration of local anesthetics.[1] In addition to the enveloping connective tissue, all mammalian nerves with a diameter greater than 1 μm are myelinated. Myelinated nerve fibers are segmentally enclosed by Schwann cells forming a bilayer lipid membrane that is wrapped several hundred times around each axon.[2] Thus, myelin accounts for over half the thickness of nerve fibers >1 μm (Fig. 17-2). Separating the myelinated regions are the nodes of Ranvier where structural elements for neuronal excitation are concentrated (Fig. 17-3).[3] The nodes are covered by interdigitations from nonmyelinating Schwann cells[4] and by negatively charged glycoproteins. Although axonal membranes are not freely in contact with their environment at the nodes, these areas do allow passage of drugs and ions.[5] Furthermore, the negatively charged proteins may bind basic local anesthetics and thus act as a depot. Unmyelinated nerve fibers (diameter <1 μm) are encased by a Schwann cell that simultaneously insulates several (5 to 10) axons (Fig. 17-2). These fibers are continuously encased by Schwann cells and do not possess interruptions (nodes of Ranvier). The existence of multiple protective layers around both myelinated and unmyelinated nerve fibers presents a substantial barrier to the entry of clinically used local anesthetics. For example, animal models suggest that only 1.6% of an injected dose of local anesthetic penetrates into the nerve following performance of peripheral nerve blocks.[6]

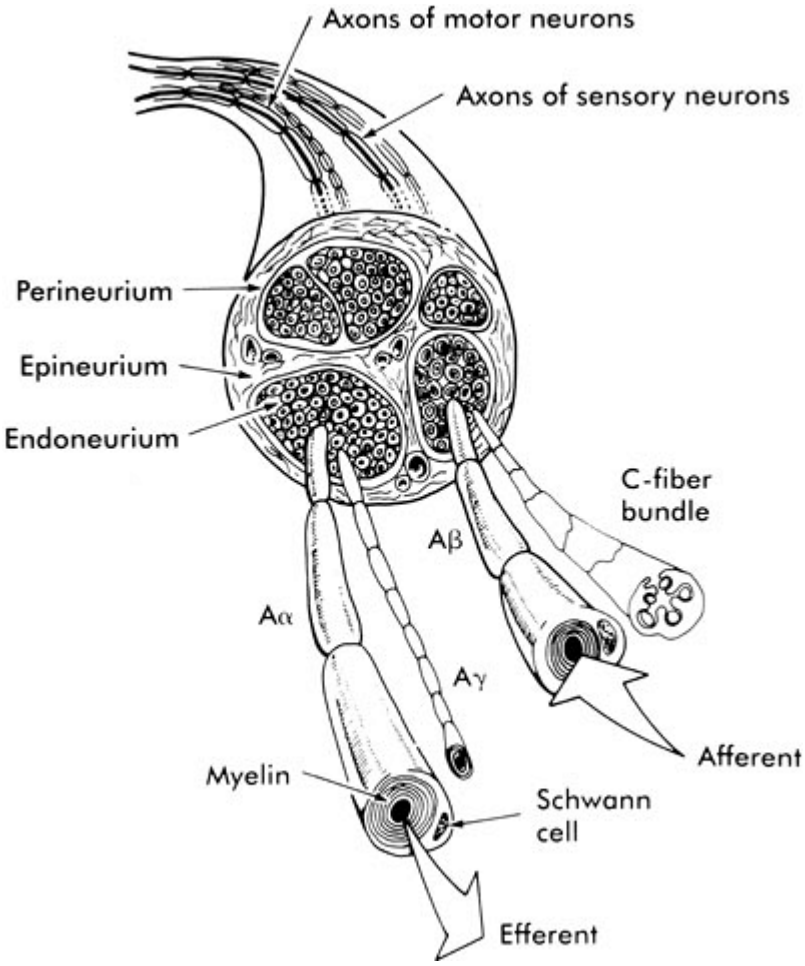

FIGURE 17-1. Schematic cross section of typical peripheral nerve. The epineurium, consisting of collagen fibers, is oriented along the long axis of the nerve. The perineurim is a discrete cell layer, whereas the endoneurium is a matrix of connective tissue. Both afferent and efferent axons are shown. Sympathetic axons (not shown) are also present in mixed peripheral nerves. (Adapted with permission from Strichartz GR: Neural physiology and local anesthetic action. St. Louis, Mosby Year Book, 1993.)

Nerve fibers are commonly classified by size, conduction velocity, and function (Table 17-1). In general, increasing myelination and nerve diameter lead to increased conduction velocity. The presence of myelin accelerates conduction velocity because of increased electrical insulation of nerve fibers and saltatory conduction. Increased nerve diameter accelerates conduction velocity both by increased myelination and by improved electrical cable conduction properties of the nerve. Myelinated and unmyelinated nerves carry out both afferent and efferent functions.

TABLE 17-1 Classification of Nerve Fibers

·CLASSIFICATION	·DIAMETER (µ)	·MYELIN	·CONDUCTION (m/sec)	·LOCATION	·FUNCTIO

Electrophysiology of Neural Conduction

Ionic disequilibria across semipermeable membranes form the basis for neuronal resting potentials and for the potential energy needed to initiate and maintain electrical impulses. The resting potential of neural membranes averages -60 to -70 mV, with the cell interior being negative to the cell exterior. This resting potential is predominantly maintained by a potassium gradient with a 10 times greater concentration of potassium within the cell. This gradient is maintained by an active protein pump that transports potassium into the cell and sodium out of the cell through voltage-gated potassium channels that are open at resting potentials.[7] Potassium equilibrium is not the only factor in resting potential, as a resting potential of approximately -90 mV is predicted by the Nernst equation if only potassium is considered. In addition to

potassium channels, voltage-independent channels that allow "leak" currents of sodium, chloride, and other ions affect the resting potential.

In contrast to the dependence of resting membrane potential on potassium disequilibria, generation of action potentials is primarily a result of activation of voltage-gated sodium channels.[7] These channels are protein structures spanning the bilayer lipid membrane composed of structural elements, an aqueous pore, and voltage-sensing elements that control passage of ions through the pore (Fig. 17-4).[8] Sodium channels exist in several conformations depending on membrane potential and time. At resting membrane potential, sodium channels predominantly exist in a resting (closed) conformation.[7,9] During membrane depolarization, channels open within a few hundred microseconds and allow passage of 10^7 ions/sec^{-1}. Sodium channels are relatively selective, but other monovalent ions can also gain passage through the channel. For example, lithium traverses about as well as sodium, whereas potassium only about one-tenth as well. Following activation (opening) of the sodium channel and depolarization, the channel will spontaneously close into an inactivated state in a time-dependent fashion to allow repolarization and then revert to a resting conformation.[10] Thus, a three-state kinetic scheme (Fig. 17-5) conceptualizes the changes in sodium channel conformation that account for changes in sodium conductance during depolarization and repolarization.

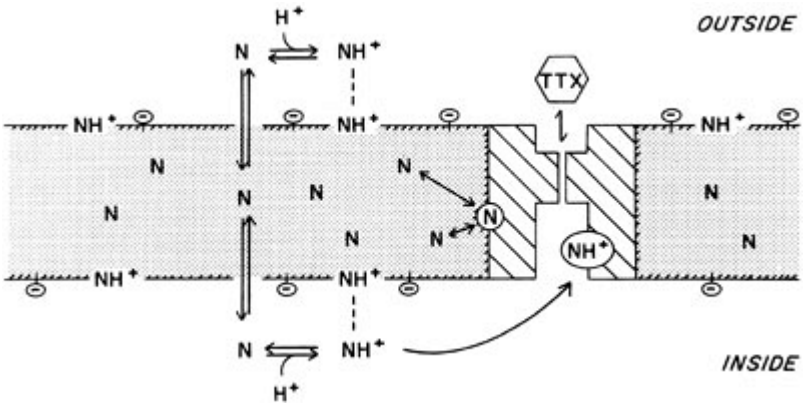

FIGURE 17-4. Diagram of bilayer lipid membrane of conductive tissue with sodium channel (*cross-hatching*) spanning the membrane. Tertiary amine local anesthetics exist as neutral base (N) and protonated, charged form (NH^+) in equilibrium. The neutral base (N) is more lipid soluble, preferentially partitions into the lipophilic membrane interior, and easily passes through the membrane. The charged form (NH^+) is more water soluble and binds to the sodium channel at the negatively charged membrane surface. Both forms can affect function of the sodium channel. The N form can cause membrane expansion and closure of the sodium channel. The NH^+ form will directly inhibit the sodium channel by binding with a local anesthetic receptor. The natural "local anesthetic" tetrodotoxin (TTX) binds at the external surface of the sodium channel and has no interaction with clinically used local anesthetics. (Adapted with permission from Strichartz GR: Neural physiology and local anesthetic action. In Cousins MJ, Bridenbaugh PO [eds]: Neural Blockade in Clinical Anesthesia and Management of Pain, p 35. Philadelphia, Lippincott–Raven, 1998.)

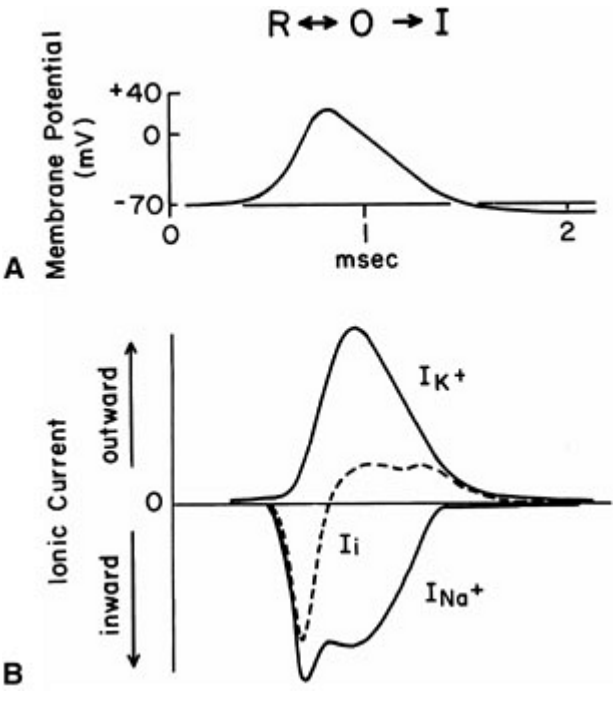

FIGURE 17-5. Illustration of dominant form of sodium channel during generation of an action potential. R = resting form, O = open form, I = inactive form. **Figure A** demonstrates

the concurrent generation of an action potential, as the membrane depolarizes from resting potential. **Figure B** demonstrates concurrent changes in ion flux, as inward sodium current (I_{Na^+}) and outward potassium current (I_{K^+}) together yield the net ionic current across the membrane (I_i). (Adapted with permission from Strichartz GR: Neural physiology and local anesthetic action. In Cousins MJ, Bridenbaugh PO [eds]: Neural Blockade in Clinical Anesthesia and Management of Pain, p 35. Philadelphia, Lippincott–Raven, 1998.)

An action potential will be generated by depolarization when the impulse-firing threshold of the axon is reached. That is the point at which no further depolarization is required for local processes to generate a complete action potential. This threshold is not an absolute voltage, but rather depends on the dynamics of the sodium and potassium channels. For example, a brief maximally depolarizing stimulus will not generate an

action potential because there is insufficient time for sodium channels to open. Nor will a depolarizing stimulus that increases too slowly create an action potential. As the stimulus slowly increases, initially activated sodium channels will spontaneously inactivate, so there will never be enough open channels at one time to generate an action potential. Furthermore, voltage-sensitive potassium channels would begin to increase potassium conductance that would further inhibit generation of an action potential. Thus, successful generation of an action potential requires a depolarizing stimulus of correct intensity and duration.

Once an action potential is generated, propagation of the potential along the nerve fiber is required for information to be transmitted. Both impulse generation and propagation are "all or nothing" phenomena. In the case of impulse propagation, either the locally generated action potential reaches the threshold potential of adjacent segments and causes propagation along the nerve, or the local depolarization ends. Nonmyelinated fibers require achievement of threshold potential at the immediately adjacent membrane, whereas myelinated fibers require generation of threshold potential at a subsequent node of Ranvier.

Repolarization after action potential generation and propagation rapidly follows owing to increasing equilibria of internal and external sodium ions, a time-controlled decrease in sodium conductance, and a voltage-controlled increase in potassium conductance.[11] In addition, active internal concentration of potassium occurs via the membrane-bound enzyme Na^+/K^+/ATPase that extrudes three sodium ions for every two potassium ions absorbed. Although many mammalian nonmyelinated nerve fibers develop a period of hyperpolarization after the action potential, myelinated nerve fibers return directly to resting membrane potential.[11]

Molecular Mechanisms of Action of Local Anesthetics

2 The sodium channel is the key target of local anesthetic activity. The wide variety of compounds that exhibit local anesthetic activity combined with the different effects of neutral and charged local anesthetics suggest that local anesthetics may act on the sodium channel either by modification of the lipid membrane surrounding it or by direct interaction with its protein structure.

Previous studies have demonstrated that anesthetics can reduce sodium conductance through sodium channels by interacting with the surrounding lipid membrane.[12] Alterations in neuronal membranes by local anesthetics can occur by altering the fluidity of the membrane that causes membrane expansion and subsequent closure of the sodium channel. Furthermore, alterations in membrane composition may lower the probability of occurrence of the open sodium channel state. Such observations can account for local anesthetic actions of neutral and lipophilic local anesthetics, but do not explain the different activity of clinically used, tertiary amine local anesthetics (e.g., lidocaine).

Instead, the mechanisms of action of these local anesthetics are best explained by direct

interaction with the sodium channel (modulated receptor theory).[13] The commonly used tertiary amine local anesthetics exist in free equilibrium as both a lipid-soluble neutral form and a hydrophilic, charged form depending on pK_a and environmental pH. Although the neutral form may exert anesthetic actions as described earlier, the cationic species is clearly the more potent form (see Fig. 17-4).[13] These tertiary amine local anesthetics also demonstrate greater sodium channel blockade when the neural membrane is repetitively depolarized (1 to 100 Hz),[14,15] whereas neutral local anesthetics exhibit little change in activity with increased frequency of stimulation (use-dependent block). Increasing frequency of stimulation increases the probability that sodium channels will exist in the open and inactive forms as compared to the unstimulated state. Thus, differences in activity of tertiary amine local anesthetics between use-dependent (repetitive stimulation) and tonic (unstimulated) block are well explained by the existence of a single local anesthetic receptor within the sodium channel that possesses different affinities during different channel conformations (resting, open, inactive). Specifically, higher affinities occur during the open and inactive phases. In support of this theory, when the affinity of inactive channels for local anesthetics is decreased through genetic manipulation, use-dependent block is reduced.[16,17]

Molecular manipulation of the sodium channel has revealed specifics of the local anesthetic receptor.[8] Binding sites to local anesthetics are located on the intracellular side of the sodium channel, may have different binding areas during the open and inactivated conformations of the sodium channel, and possess stereoselectivity with preference for the *R* isomers.[9,17,18]

Mechanism of Blockade of Peripheral Nerves

3 Local anesthetics may block function of peripheral nerves through several mechanisms. As discussed earlier, sodium channel blockade leads to attenuation of neural action potential formation and propagation. Although it remains unknown in humans by what percent the neural action potential must be decreased before functional block occurs, animal studies suggest that the action potential must be decreased by at least 50% before measurable loss of function is observed.[6] Previous studies have examined the differences in susceptibility of nerve fiber to local anesthetic blockade based on size, myelination, and length of fiber exposed to local anesthetic. Clinically, one can often discern a differential pattern of sensory block after application of local anesthetic to a peripheral nerve.[19] Classically, the sensation of temperature is lost, followed by sharp pain, then light touch. Thus, an initial assumption was that small, unmyelinated (C) fibers conducting temperature sensation were inherently more susceptible to local anesthetic blockade than large, myelinated (A) fibers conducting touch. However, experimental studies reveal a more complex picture. In vivo studies of sciatic nerve block in rats with lidocaine indicate that larger A fibers are more susceptible to tonic and phasic block than smaller C fibers.[15] Differential block of large and small nerve fibers is also affected by choice of local anesthetic. Those with an amide group, high pK_a, and lower lipid solubility are more potent blockers of C fibers. Thus, experimental studies indicate that local anesthetic block of nerve fibers will intrinsically depend on type (size) of fiber, frequency of membrane stimulation, and choice of local anesthetic.[14,20]

During clinical applications, the exposure length of the nerve fiber may explain differential block,[21,22] as small nerve fibers require a shorter length of fiber exposed to local anesthetic for block to occur than do large fibers. It is theorized that this observation is because of decremental conduction block of a "critical length" of nerve.[22] Decremental conduction describes the decreased ability of successive nodes of Ranvier to propagate an impulse in the presence of local anesthetic (Fig. 17-6). As internodal distances become greater with increasing nerve fiber size,[23] larger nerve fibers will demonstrate increasing resistance to local anesthetic block. Evidence for this mechanism is conflicting. Sciatic nerve blocks in rats demonstrate greater length of spread along the nerve and greater intraneural content of radiolabeled lidocaine with injections of high volume and low concentrations of lidocaine. However, the use of small volumes and greater concentrations of lidocaine produced more effective sensory and motor block despite lesser spread and intraneural penetration of lidocaine.[24] Further clinical studies on decremental conduction and role of "critical

length" will be needed, especially as nerve blocks in humans typically involve much greater

lengths of affected nerve than animal models. For example, sciatic nerve blocks in humans probably result in 5 to 10 cm of affected nerve length.[6]

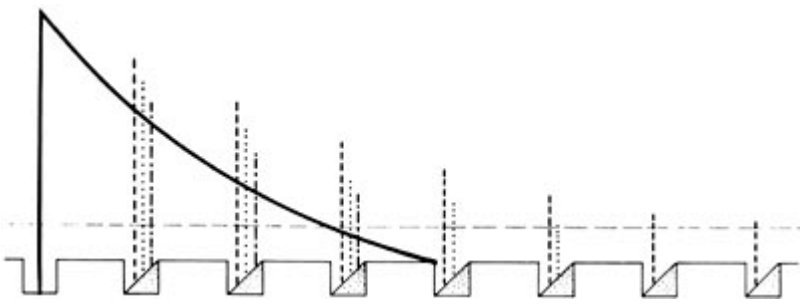

FIGURE 17-6. Diagram illustrating the principle of decremental conduction block by local anesthetic at a myelinated axon. The first node of Ranvier at left contains no local anesthetic and gives rise to a normal action potential (*solid curve*). If the nodes succeeding the first are occupied by a concentration of local anesthetic high enough to block 74 to 84% of the sodium conductance, then the action potential amplitudes decrease at successive nodes (amplitudes are indicated by interrupted bars representing three increasing concentration of local anesthetic). Eventually, the impulse decays to below threshold amplitude if the series of local anesthetic containing nodes is long enough. Propagation of the impulse has then been blocked by decremental conduction, even though none of the nodes are completely blocked. Concentrations of local anesthetic that block more than 84% of the sodium conductance at three successive nodes prevent any impulse propagation at all. (Adapted with permission from Fink BR: Mechanisms of differential axial blockade in epidural and spinal anesthesia. Anesthesiology 70:851, 1989.)

A final mechanism whereby local anesthetics may block peripheral nerve function is via degradation of transmitted electrical patterns. It is theorized that a large part of the sensory information transmitted via peripheral nerves is carried via coding of electrical signals in after-potentials and after-oscillations.[25] Evidence for this theory is found in studies demonstrating loss of sensory nerve function after incomplete local anesthetic blockade. For example, sensation of temperature of the skin can be lost despite unimpeded conduction of small fibers.[26] Furthermore, a surgical depth of epidural and peripheral nerve block anesthesia can be obtained with only minor changes in somatosensory evoked potentials from the anesthetized area.[27,28] Previous studies have demonstrated that application of sub-blocking concentrations of local anesthetic will suppress normally occurring after-potentials and after-oscillations without significantly affecting action potential conduction.[29] Thus, disruption of coding of electrical information by local anesthetics may be another mechanism for block of peripheral nerves.

Mechanism of Blockade of Central Neuraxis

Central neuraxial block via spinal or epidural administration of local anesthetics involves the same mechanisms at the level of spinal nerve roots, either intra- or extradural, as discussed earlier. In addition, central neuraxial administration of local anesthetics allows multiple potential actions of local anesthetics within the spinal cord at different sites. For example, within the dorsal horn, local anesthetics can exert familiar ion channel block of sodium and potassium channels in dorsal horn neurons and inhibit generation and propagation of nociceptive electrical activity.[30] Other spinal cord neuronal ion channels, such as calcium channels, are also important for afferent and

efferent electrical activity. Administration of calcium channel blockers to spinal cord N (neuronal) calcium channels results in hyperpolarization of cell membranes, resistance to electrical stimulation from nociceptive afferents, and intense analgesia.[31] Local anesthetics appear to have similar actions on calcium channels, which may contribute to analgesic actions of central neuraxially administered local anesthetics.[32]

In addition to ion channels, multiple neurotransmitters are involved in nociceptive transmission in the dorsal horn of the spinal cord.[33] For example, tachykinins (substance P) are important neurotransmitters modulating nociception from C fibers.[34] Administration of local anesthetics in concentrations that occur after spinal and epidural anesthesia inhibits postsynaptic depolarizations driven by substance P and may decrease nociception via this inhibitory mechanism.[35] Other neurotransmitters that are important for nociceptive processing in the spinal cord, such as acetylcholine, *γ*-aminobutyric acid (GABA), and N-methyl-D-aspartate (NMDA), can all be affected by local anesthetics either pre- or postsynaptically.[8,35] These studies suggest that antinociceptive effects of central neuraxial local anesthetic block may be mediated via complex interactions at neural synapses in addition to ion channel blockade.

PHARMACOLOGY AND PHARMACODYNAMICS

Chemical Properties and Relationship to Activity and Potency

The clinically used local anesthetics consist of a lipid-soluble, substituted benzene ring linked to an amine group (tertiary or quaternary depending on pK_a and pH) via an alkyl chain containing either an amide or ester linkage (Fig. 17-7). The type of linkage separates the local anesthetics into either *aminoamides*, metabolized in the liver, or *aminoesters*, metabolized by plasma cholinesterases. Several chemical properties of local anesthetics will affect their efficacy and potency.

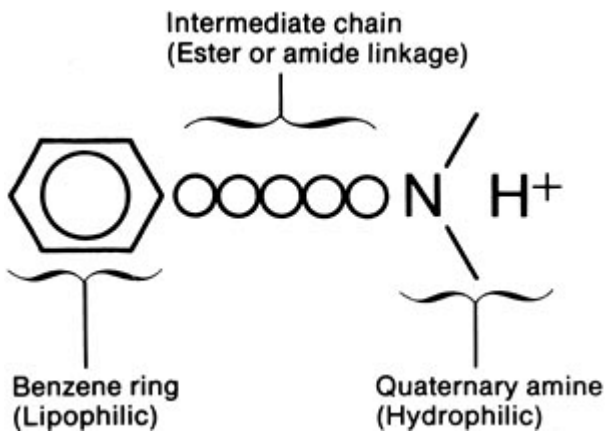

FIGURE 17-7. General struture of clinically used local anesthetics. (Adapted with permission from Carpenter RL, Mackey DC: Local anesthetics. In Barash PG, Cullen BF, Stoelting RF [eds]: Clinical Anesthesia, p 413. Philadelphia, Lippincott–Raven, 1996.)

All clinically used local anesthetics are weak bases that can exist as either the lipid-soluble, neutral form or as the charged, hydrophilic form. The combination of pH of the environment and pK_a, or dissociation constant, of a local anesthetic determines how much of the compound exists in each form (Table 17-2). As previously discussed, the primary site of action of local anesthetics appears to exist on the intracellular side of the sodium channel, and the charged form appears to be the predominantly active form.[13] Penetration of the lipid-soluble form through the lipid neural membrane appears to be the primary form of access of local anesthetic molecules, although some

access by the charged form can be gained via the aqueous sodium channel pore (see Fig. 17-4).[39] Thus, decreasing pK_a for a given environmental pH will increase the percentage of lipid-soluble forms in existence, hastening penetration of neural membranes and onset of action.

4 Lipid solubility is another important determinant of activity. Although increasing lipid solubility may hasten penetration of neural membranes, increasing solubility may also result in increased sequestration of local anesthetic in myelin and other lipid-soluble compartments. Thus, increasing lipid solubility usually slows the rate of onset of action.[40] Similarly, duration of

action is increased as absorption of local anesthetic molecules into myelin and surrounding neural compartments creates a depot for slow release of local anesthetics.[40] Finally, increased lipid solubility increases potency of the local anesthetic.[12,13] This observation may be explained by a correlation between lipid solubility and both sodium channel receptor affinity and ability to alter sodium channel conformation by direct effects on lipid cell membranes.

Degree of protein binding also affects activity of local anesthetics, as only the unbound form is free for pharmacologic activity. In general, the more lipid soluble and longer acting agents have increased protein binding.[41] Although the sodium channel is a protein structure, it does not appear that degree of local anesthetic protein binding correlates with binding to the local anesthetic receptor. Studies suggest that dissociation of local anesthetic molecules from the sodium channel occurs in a matter of seconds regardless of degree of protein binding of the local anesthetic.[42] Thus, prolongation in duration of action associated with an increased degree of protein binding must involve other extracellular or membranous proteins.

5 A final physical property of interest is stereoisomeric mixture of the commercially available local anesthetics. All currently available local anesthetics are racemic mixtures with the exception of lidocaine (achiral), ropivacaine (*S*), and levo-bupivacaine (*l* = *S*).[43,44] Stereoisomers of local anesthetics appear to have potentially different effects on anesthetic potency, pharmacokinetics, and systemic toxicity.[19,43,44] For example, *R* isomers appear to have greater in vitro potency for block of both neural and cardiac sodium channels and may thus have greater therapeutic efficacy and potential systemic toxicity.[18,43,44,45]

Relative in vitro potencies of the clinically used local anesthetics have been identified and vary depending on individual nerve fibers and frequency of stimulation, and overall increasing lipid solubility of local anesthetic correlates with increasing anesthetic potency (see Table 17-2).[46] However, clinical use of local anesthetics is complex and in vivo potencies often do not correlate with in vitro determinants.[47] Local factors affecting diffusion and spread of anesthetic will have great impact on clinical effects and will vary with different applications (e.g., peripheral nerve block vs. spinal injection). Furthermore, clinical use may not require absolute suppression of the compound action potential, but rather a disruption of information coding in the pattern of discharges. Few rigorous studies have been performed to evaluate relative clinical potencies of local anesthetics, and commonly accepted values are listed in Table 17-3.

Tachyphylaxis to Local Anesthetics

Tachyphylaxis to local anesthetics is a clinical phenomenon whereby repeated injection of the same dose of local anesthetic leads to decreasing efficacy. Tachyphylaxis has been described after central neuraxial blocks, peripheral nerve blocks, and for different local anesthetics.[48,49] An interesting clinical feature of tachyphylaxis to local anesthetics is dependence on dosing interval. If dosing intervals are short enough such that pain does not occur, tachyphylaxis does not develop. Conversely, longer periods of patient discomfort before redosing hasten development of tachyphylaxis.[48] Both pharmacokinetic and dynamic mechanisms may be involved. A study examining repeated sciatic nerve blocks and infiltration analgesia in rats noted tachyphylaxis accompanied by increased clearance of radiolabeled lidocaine out of nerves and skin.[50] Not all studies support a pharmacokinetic mechanism for tachyphylaxis. For example, with the development of clinical tachyphylaxis, there is no difference in local anesthetic spread within or clearance from the epidural space.[51]

The observation that pain is important for the development of tachyphylaxis has led to speculation that there is a pharmacodynamic mechanism for tachyphylaxis via spinal cord sensitization.[52] Rats receiving repeated sciatic nerve blocks failed to develop tachyphylaxis in the absence of noxious stimulation. Exposure of the rats to increasingly noxious degrees of thermal stimulation increasingly hastened development of tachyphylaxis, whereas pretreatment with an NMDA antagonist (MK-801) that prevents spinal cord sensitization also prevented development of tachyphylaxis. Second-messenger effects of nitric oxide for NMDA pathways may be especially important, as administration of nitric oxide synthetase inhibitors prevented development of tachyphylaxis in a

dose-dependent manner in the same model.[53] The clinical relevance of these findings needs to be explored, but the development of a mechanism for tachyphylaxis may lead to clinical means for its prevention.

Additives to Increase Local Anesthetic Activity

Epinephrine

Epinephrine has been added to local anesthetics since the early 1890s. Reported benefits of epinephrine include prolongation of local anesthetic block, increased intensity of block, and decreased systemic absorption of local anesthetic.[54] Epinephrine's vasoconstrictive effects augment local anesthetics by antagonizing inherent vasodilating effects of local anesthetics, decreasing systemic absorption and intraneural clearance, and perhaps by redistributing intraneural local anesthetic.[54,55]

Direct analgesic effects from epinephrine may also occur via interaction with α-2 adrenergic

receptors in the brain and spinal cord,[56] especially because local anesthetics increase the vascular uptake of epinephrine.[57] Clinical use of epinephrine is listed in Table 17-4. The smallest dose is suggested, as epinephrine combined with local anesthetics may have toxic effects on tissue,[58] the cardiovascular system,[59] peripheral nerves, and the spinal cord.[33,54]

Alkalinization of Local Anesthetic Solution

Since the late 1800s, local anesthetic solutions have been alkalinized in order to hasten onset of neural block.[60] The pH of commercial preparations of local anesthetics ranges from 3.9 to 6.47 and is especially acidic if prepackaged with epinephrine.[61]

As the pK_a of commonly used local anesthetics ranges from 7.6 to 8.9 (see Table 17-2), less than 3% of the commercially prepared local anesthetic exists as the lipid-soluble neutral form. As previously discussed, the neutral form is believed to be the most important for penetration into the neural cytoplasm, whereas the charged form primarily interacts with the local anesthetic receptor within the sodium channel. Therefore, the rationale for alkalinization was to increase the percentage of local anesthetic existing as the lipid-soluble neutral form. However, clinically used local anesthetics cannot be alkalinized beyond a pH of 6.05 to 8 before precipitation occurs,[61] and such pHs will only increase the neutral form to about 10%.

Clinical studies that have shown an association between alkalinization of local anesthetics and hastening of block onset have shown a decrease of less than 5 minutes when compared to commercial preparations.[60,62] In addition, a recent animal study suggests that alkalinization of lidocaine decreases the duration of peripheral nerve blocks if the solution does not also contain epinephrine.[63] Overall, the value of alkalinization of local anesthetics appears debatable as a clinically useful tool to improve anesthesia.

Opioids

Addition of opioids to local anesthetics has gained popularity. Opioids have multiple central neuraxial and peripheral mechanisms of analgesic action. Supraspinal administration of opioids results in analgesia via opiate receptors in multiple sites,[64] via activation of descending spinal pathways[65] and via activation of nonopioid analgesic pathways.[66] Spinal administration of opioids provides analgesia primarily by attenuating C fiber nociception[67] and is independent of supraspinal mechanisms.[68] Coadministration of opioids with central neuraxial local anesthetics results in synergistic analgesia.[69] An exception to this analgesic synergy is 2-chloroprocaine, which appears to decrease the effectiveness of epidural opioids when used for epidural anesthesia.[70] The mechanism for this action is unclear but does not appear to involve direct antagonism of opioid receptors.[71] Overall, clinical studies support the practice of central neuraxial coadministration of local anesthetics and opioids in humans for prolongation and intensification of analgesia and anesthesia.[69]

The discovery of peripheral opioid receptors offers yet another circumstance in which the coadministration of local anesthetics and opioids may be useful.[72] The most promising clinical results have been from intra-articular administration of local anesthetic and opioid for postoperative analgesia,[73] whereas combining local anesthetics and opioids for nerve blocks

appears to be ineffective.[74] There are several reasons for a predicted lack of effect of coadministration of local anesthetic and opioid for peripheral nerve blocks. Anatomically, peripheral opioid receptors are found primarily at the end terminals of afferent fibers.[75] However, peripheral nerves are commonly blocked by deposition of anesthetic proximal to the end terminals of nerve fibers. In addition, common sites for peripheral nerve blocks are encased in multiple layers of connective tissue that the anesthetics must traverse before gaining access to peripheral opioid receptors. Finally, previous studies have demonstrated the importance of concomitant local tissue inflammation for analgesic effectiveness of peripheral opioid receptors.[72] The mechanism for the underlying dependence on local inflammation is speculative and may involve upregulation or activation of peripheral opioid receptors or "loosening" of intercellular junctions to allow passage of opioids to receptors. Lack of inflammation at the site of a peripheral nerve block may also reduce the effects of coadministration of local anesthetic and opioid. All of these factors combine to decrease the theoretical effectiveness of combinations of local anesthetics and opioids for peripheral nerve blocks. In summary, coadministration of opioids and local anesthetic in the central neuraxis appears to be an effective, nontoxic[33] means to improve activity of local anesthetic, whereas there is little theoretical reason to expect the mixture to enhance peripheral nerve block.

α-2 Adrenergic Agonists

α-2 adrenergic agonists can be a useful adjuvant to local anesthetics. α-2 agonists, such as clonidine, produce analgesia via supraspinal and spinal adrenergic receptors.[76] Clonidine also has direct inhibitory effects on peripheral nerve conduction (A and C nerve fibers).[77] Thus, addition of clonidine may have multiple routes of action depending on type of application. Preliminary evidence suggests that coadministration of an α-2 agonist and local anesthetic results in central neuraxial and peripheral nerve analgesic synergy,[78] whereas systemic (supraspinal) effects are additive.[79] Overall, clinical trials indicate that clonidine enhances intrathecal and epidural anesthesia, peripheral nerve blocks,[80] and intravenous regional anesthesia[81] without evidence for neurotoxicity.[33]

PHARMACOKINETICS OF LOCAL ANESTHETICS

Clearance of local anesthetic from neural tissue and from the body governs both duration of effect and potential toxicity. Clinical effects of neural block from local anesthetics are primarily dependent on local factors as discussed in the Pharmacology section. However, systemic toxicity is primarily dependent on blood levels of local anesthetics. Resultant blood levels after administration of local anesthetics for neural blockade depend on absorption, distribution, and elimination of local anesthetics.

Systemic Absorption

In general, local anesthetics with decreased systemic absorption will have a greater margin of safety in clinical use. The rate and extent of absorption will depend on numerous factors, of which the most important are the site of injection, the dose of local anesthetic, the physicochemical properties of the local anesthetic, and the addition of epinephrine.

The relative amounts of fat and vasculature surrounding the site of local anesthetic injection will interact with the physicochemical properties of the local anesthetic to affect rate of systemic uptake. In general, areas with greater vascularity will have more rapid and complete uptake as compared to those with more fat, regardless of type of local anesthetic. Thus, rates of absorption from injection of local anesthetic into various sites generally decrease in the following order: intercostal > caudal > epidural > brachial plexus > sciatic/femoral (Table 17-5).[82,83]

TABLE 17-5 Typical C_{max} after Regional Anesthetics with Commonly Used Local Anesthetics

C_{max}, peak plasma levels; T_{max}, time until C_{max}.

Data from Liu SS. Local Anesthetics and Analgesia. In Ashburn MA, Rice LJ (eds): The Management of Pain. New York: Churchill Livingstone Inc., 1997:141–170, Berrisford RG. Plasma concentrations of bupivacaine and its enantiomers during continuous extrapleural intercostal nerve block. British Journal of Anaesthesia 70:201, 1993. Kopacz DJ. A comparison of epidural levobupivacaine 0.5% with or without epinephrine forlumbar spine surgery. Anesth Analg 2001 Sep:93:755, and Crews JC. Levobupivacaine for axillary brachial plexus block: a pharmacokinetic and clinical comparison in patients with normal renal function or renal disease. Anesth Analg 2002;95:219.

The greater the total dose of local anesthetic injected, the greater the systemic absorption and peak blood levels (C_{max}). This relationship is nearly linear (Fig. 17-8) and is relatively unaffected by anesthetic concentration[84] and speed of injection.[82,83]

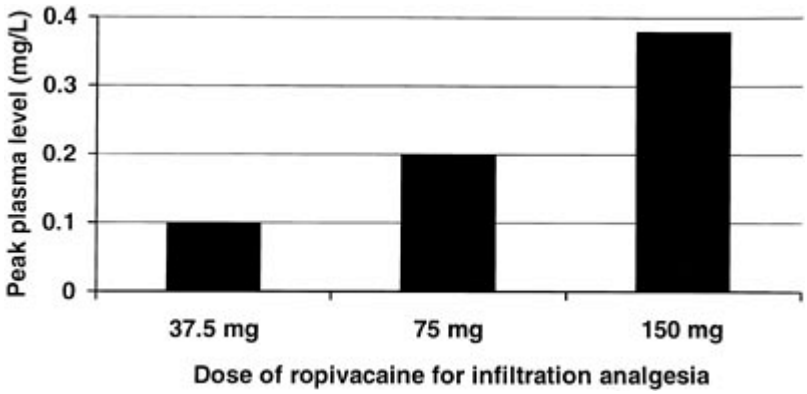

FIGURE 17-8. Increasing doses of ropivacaine used for wound infiltration result in linearly increasing maximal plasma concentrations (C_{max}). (Data from from Mulroy MF, Burgess FW, Emanuelsson B-M: Ropivacaine 0.25% and 0.5%, but not 0.125%, provide effective wound infiltration analgesia after outpatient hernia repair, but with sustained plasma drug levels. Reg Anesth Pain Med 24:136, 1999.)

Physicochemical properties of local anesthetics will affect systemic absorption. In general, the more potent agents with greater lipid solubility and protein binding will result in lower systemic absorption and C_{max} (Fig. 17-9).[83] Increased binding to neural and nonneural tissue probably explains this observation.

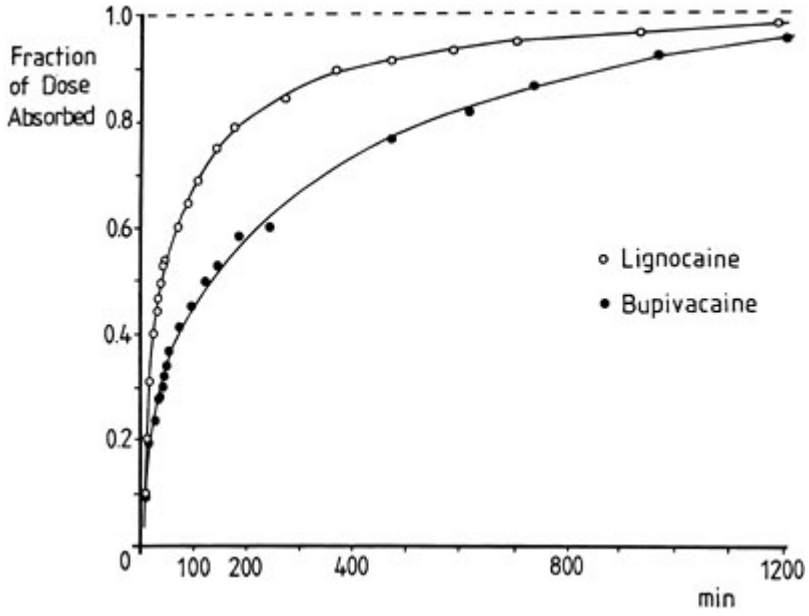

FIGURE 17-9. Fraction of dose absorbed into the systemic circulation over time from epidural injection of lidocaine or bupivacaine. Bupivacaine is a more lipid soluble, more potent agent with less systemic absorption over time. (Adapted with permission from Tucker GT, Mather LE: Properties, absorption, and disposition of local anesthetic agents. In Cousins MJ, Bridenbaugh PO [eds]: Neural Blockade in Clinical Anesthesia and Management of Pain, p 55. Philadelphia, Lippincott–Raven, 1998.)

The effects of epinephrine have been previously discussed. In brief, epinephrine can counteract the inherent vasodilating characteristics of most local anesthetics. The reduction in C_{max} with epinephrine is most effective for the less lipid-soluble,

less potent, shorter acting agents (see Table 17-4), as increased tissue binding rather than local blood flow may be a greater determinant of absorption for the long-acting agents.

Distribution

After systemic absorption, local anesthetics are rapidly distributed to the body. Regional distribution of local anesthetic will depend on organ blood flow, the partition coefficient of local anesthetic between compartments, and plasma protein binding. The end organs of main concern for toxicity are within the cardiovascular and the central nervous systems. Both are considered members of the "vessel-rich group" and will have local anesthetic rapidly distributed to them. Despite the high blood perfusion, regional blood and tissue levels of local anesthetics within these organs will not initially correlate with systemic blood levels because of hysteresis.[85] As regional, rather than systemic, pharmacokinetics govern subsequent pharmacodynamic effects, systemic blood levels may not correlate with effects of local anesthetics on end organs.[86] Regional pharmacokinetics of local anesthetics for the heart and brain have not been fully delineated; thus the volume of distribution at steady state (VDss) is often used to describe local anesthetic distribution (Table 17-6). However, VDss describes the extent of total body distribution and may be inaccurate for specific organ systems.

TABLE 17-6 Pharmacokinetic Parameters of Clinically Used Local Anesthetics

Br J Clin Pharmacol 38:125–129, 1994.

Elimination

Clearance (CL) of aminoester local anesthetics is primarily dependent on plasma clearance by cholinesterases,[87] whereas aminoamide local anesthetic clearance is dependent on clearance by the liver.[88] Thus, hepatic extraction, hepatic perfusion, hepatic metabolism, and protein binding (Table 17-2) will primarily determine the rate of clearance of aminoamide local anesthetics. In general, local anesthetics with higher rates of clearance will have a greater margin of safety.[83]

Clinical Pharmacokinetics

The primary benefit of knowledge of the systemic pharmacokinetics of local anesthetics is the ability to predict C_{max} after the agents are administered, thereby avoiding the administration of toxic doses (Tables 17-5, 17-7, and 17-8). However, pharmacokinetics are difficult to predict in any given circumstance as both physical and pathophysiologic characteristics will affect the individual pharmacokinetics. There is some evidence for increased systemic levels of local anesthetics in the very young and in the elderly owing to decreased clearance and increased absorption,[83] whereas correlation of resultant systemic blood levels between dose of local anesthetic and patient weight is often inconsistent (Figure 17-10).[89] Effects of gender on clinical pharmacokinetics of local anesthetics have not been well defined,[90] although pregnancy may decrease clearance.[83] Pathophysiologic states such as cardiac and hepatic disease will alter expected pharmacokinetic parameters (Table 17-9), and lower doses of local anesthetics should be

used for these patients. As expected, renal disease has little effect on pharmacokinetic parameters of local anesthetics (Table 17-9). Finally, the skill of the anesthesiologist should be considered, as a large dose of local anesthetic placed in the correct location may have much less potential for systemic toxicity than a small dose incorrectly injected intravascularly. All of these factors should be considered when utilizing local anesthetics and minimizing systemic toxicity, the commonly accepted maximal dosages (Table 17-8) notwithstanding.

CLINICAL USE OF LOCAL ANESTHETICS

Local anesthetics are used in a variety of ways in clinical anesthesia practice. Probably the most common clinical use of local anesthetics for anesthesiologists is for regional anesthesia and analgesia. Central neuraxial anesthesia and analgesia can be accomplished by epidural or spinal injections of local anesthetics. Placement of epidural and spinal catheters can allow continuous infusion of local anesthetics and other analgesics for extended durations. Intravenous regional anesthesia and peripheral nerve blocks allow for anesthesia of the head and neck including the airway, upper extremities, trunk, and lower extremities. Newly developed catheters for continuous peripheral nerve blocks can also be placed to allow continuous infusions of local anesthetics and other analgesics for prolonged analgesia in a fashion similar to continuous epidural analgesia. Topical application of local anesthetics to the airway, eye, and skin provides sufficient anesthesia for painless performance of minor anesthetic and surgical procedures such as tracheal intubation, intravenous catheter placement, or dural puncture.[91] Typical applications for each local anesthetic are listed in Table 17-8.[92]

Other common clinical uses for local anesthetics include administration of lidocaine to blunt

responses to tracheal instrumentation and to suppress cardiac dysrhythmias. Intravenous or topical administrations of lidocaine have been used with variable success to blunt hemodynamic response to tracheal intubation and extubation.[93,94] In addition to hemodynamic responses, instrumentation of the airway can result in coughing, bronchoconstriction, and other airway responses. Intravenous lidocaine can be effective for decreasing airway sensitivity to instrumentation by depressing airway reflexes and decreasing calcium flux in airway smooth muscle.[95,96] Doses of intravenous lidocaine from 2 to 2.5 mg/kg are needed to consistently blunt hemodynamic and airway responses to tracheal instrumentation.[95,96,97] Intravenous lidocaine is also effective for attenuating increases in intra-ocular pressure, intracranial pressure, and intra-abdominal pressure during

airway instrumentation.[98] Attenuation of all these responses may be beneficial in selected clinical situations (e.g., corneal laceration or increased intracranial pressure). Intravenous lidocaine has well-recognized cardiac antidysrhythmic effects.[99]

Finally, intravenous lidocaine (1 to 5 mg/kg) is an effective analgesic and has been used to treat postoperative[100] and chronic neuropathic pain.[101] Peripheral and central inhibition of generation and propagation of spontaneous electrical activity in injured C nerve fibers and Aδ nerve fibers are thought to be primary mechanisms as opposed to typical conduction block.[102,103,104] Positron emission tomography in patients with neuropathic pain suggests that altered activity in cerebral blood flow to the thalamus[105] may also contribute to systemic analgesic effects of local anesthetics. The ability of local anesthetics to provide systemic analgesic effects at central and peripheral sites may in part explain the ability of a single neural block to provide long-lasting analgesia from neuropathic pain. In addition, orally administered mexiletine (a Class I antidysrhythmic agent similar to lidocaine) has been successfully used to treat chronic pain conditions.[101]

TOXICITY OF LOCAL ANESTHETICS

Systemic Toxicity of Local Anesthetics

Central Nervous System Toxicity

Local anesthetics readily cross the blood-brain barrier, and generalized CNS toxicity may occur from systemic absorption or

direct vascular injection. Signs of generalized CNS toxicity because of local anesthetics are dose dependent (Table 17-10). Low doses produce CNS depression, and higher doses result in CNS excitation and seizures.[106] The rate of intravenous administration of local anesthetic will also affect signs of CNS toxicity, as higher rates of infusion of the same dose will lessen the appearance of CNS depression while leaving excitation intact.[107] This dichotomous reaction to local anesthetics may be a result of a greater sensitivity of cortical inhibitory neurons to the impulse blocking effects of local anesthetics.[106,108,109]

TABLE 17-10 Dose-Dependent Systemic Effects of Lidocaine

·PLASMA CONCENTRATION (mcg/mL)	·EFFECT
1–5	Analgesia
5–10	Lightheadedness Tinnitus Numbness of tongue

10–15	Seizures Unconsciousness
15–25	Coma Respiratory arrest
>25	Cardiovascular depression

Local anesthetic potency for generalized CNS toxicity approximately parallels action potential blocking potency (Tables 17-3 and 17-7).[106] In general, decreased local anesthetic protein binding and clearance will increase potential CNS toxicity. External factors can increase potency for CNS toxicity, such as acidosis and increased PCO_2, perhaps via increased cerebral perfusion or decreased protein binding of local anesthetic.[106] There are also external factors that can decrease local anesthetic potency for generalized CNS toxicity. For example, seizure thresholds of local anesthetics are increased by administration of barbiturates and benzodiazepines.[110]

Addition of vasoconstrictors such as epinephrine may reduce or promote the potential for generalized local anesthetic CNS toxicity. Addition of epinephrine to local anesthetics will decrease systemic absorption and peak blood levels and increase the safety margin. On the other hand, the convulsive threshold for intravenous administration of lidocaine in the rat is decreased by about 42% when epinephrine (1:100,000), norepinephrine, or phenylephrine is added to the plain solution.[111] The mechanisms of increased toxicity with addition of epinephrine are unclear but appear to depend on the development of hypertension from vasoconstriction. A hyperdynamic circulatory system may enhance the toxic effects of local anesthetics by causing increased cerebral blood flow and delivery of lidocaine to the brain[112,113] or through disruption of the blood-brain barrier.[114] In addition to enhancing distribution of local anesthetic to the brain, hyperdynamic circulatory changes can also decrease clearance of local anesthetic from the body because of changes in distribution of blood flow away from the liver. Changes in total body clearance from hyperdynamic circulatory changes induced by local anesthetic seizures have been studied in dogs.[115] Seizures significantly increased heart rate, blood pressure, and cardiac output while significantly decreasing total body clearance (29 to 68%) of lidocaine, mepivacaine, bupivacaine, and etidocaine.

7 Clinical reports suggest toxicity from local anesthetics used for regional anesthesia is uncommon. Surveys from France and the United States of over 280,000 cases of regional anesthesia report an incidence of seizures with epidural injection approximating 1/10,000 and an incidence of 7/10,000 with peripheral nerve blocks.[108,109] There appears to be a higher incidence of local anesthetic toxicity during peripheral nerve blocks, perhaps because of differences in practice or less clinical awareness. Nonetheless, epidural anesthesia (primarily obstetrical) constituted all the cases of death or brain damage resulting from unintentional intravenous injection of local anesthetic in an analysis of closed malpractice claims in the United States from 1980 to 1999.[116]

Cardiovascular Toxicity of Local Anesthetics

In general, much greater doses of local anesthetics are required to produce cardiovascular (CV) toxicity than CNS toxicity. Similar to CNS toxicity, potency for CV toxicity reflects the anesthetic potency of the agent (Tables 17-3 and 17-7). Attention has focused on the apparently exceptional cardiotoxicity of the more potent, more lipid-soluble agents (bupivacaine, levo-bupivacaine,

ropivacaine). These agents appear to have a different sequence of CV toxicity than less potent agents, with bupivacaine being the most cardiotoxic. For example, increasingly toxic doses of lidocaine lead to hypotension, bradycardia, and hypoxia, whereas toxic doses of bupivacaine, levo-bupivacaine, and ropivacaine often result in sudden cardiovascular collapse as a result of ventricular dysrhythmias that are resistant to resuscitation (Fig. 17-11).[106,110,117]

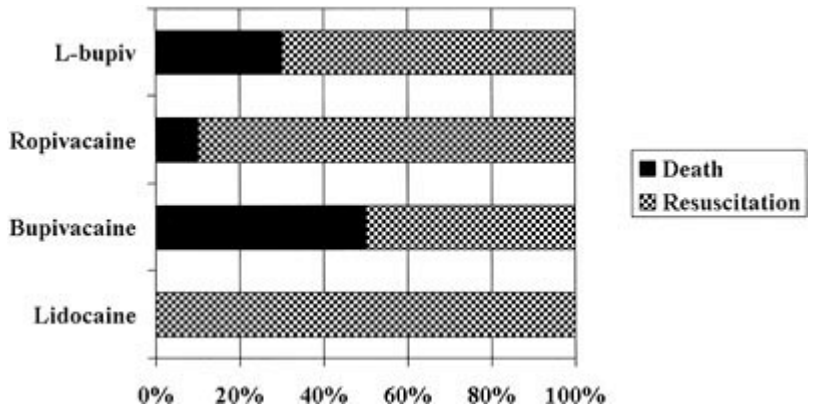

FIGURE 17-11. Success of resuscitation of dogs after cardiovascular collapse from intravenous infusions of lidocaine, bupivacaine, levo-bupivacaine, and ropivacaine. Success rates were greater for lidocaine (100%), than ropivacaine (90%), than levo-bupivacaine (70%), and than bupivacaine (50%). Required doses to induce cardiovascular collapse were greater for lidocaine (127 mg/kg), than ropivacaine (42 mg/kg), than levo-bupivacaine (27 mg/kg), and than bupivacaine (22 mg/kg). (Data from Groban L, Deal DD, Vernon JC, et al: Cardiac resuscitation after incremental overdosage with lidocaine, bupivacaine, levobupivacaine, and ropivacaine in anesthetized dogs. Anesth Analg 92:37, 2001.)

Use of the single–optical isomer (*S*/L) preparations of ropivacaine and levo-bupivacaine may improve the safety profile for long-lasting regional anesthesia. Both ropivacaine and

levo-bupivacaine appear to be approximately equipotent to racemic bupivacaine for epidural and plexus anesthesia (see Table 17-3).[118,119] Both ropivacaine and levo-bupivacaine have approximately 30 to 40% less systemic toxicity than bupivacaine on a mg:mg basis in animal studies[46,106] (Fig. 17-12), although human studies are less dramatic (Fig. 17-13).[120,121] Reduced potential for cardiotoxicity is likely because of reduced affinity for brain and myocardial tissue from their single isomer preparation.[18,45,106] In addition to stereoselectivity, the larger butyl side chain in bupivacaine may also have more of a cardiodepressant effect as opposed to the propyl-side chain of ropivacaine.[122]

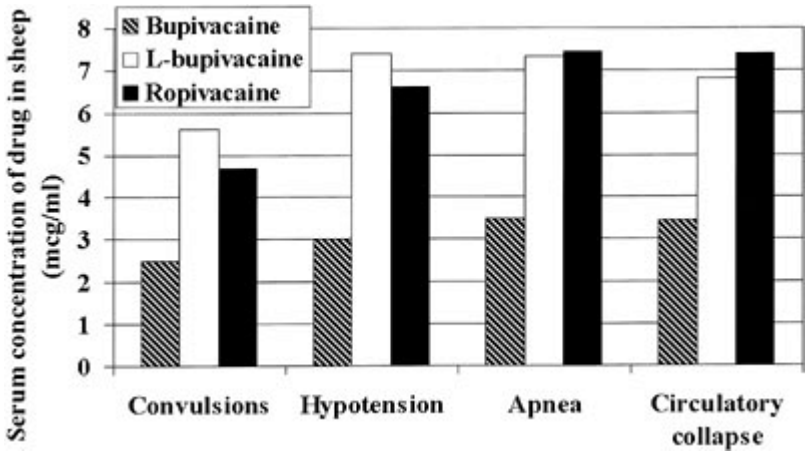

FIGURE 17-12. Serum concentrations in sheep at each toxic manifestation for bupivacaine, levo-bupivacaine, and ropivacaine in sheep. Both levo-bupivacaine and ropivacaine required significantly greater serum concentrations than bupivacaine. (Data from Santos AC, DeArmas PI: Systemic toxicity of levobupivacaine, bupivacaine, and ropivacaine during continuous intravenous infusion to nonpregnant and pregnant ewes. Anesthesiology 95:1256, 2001.)

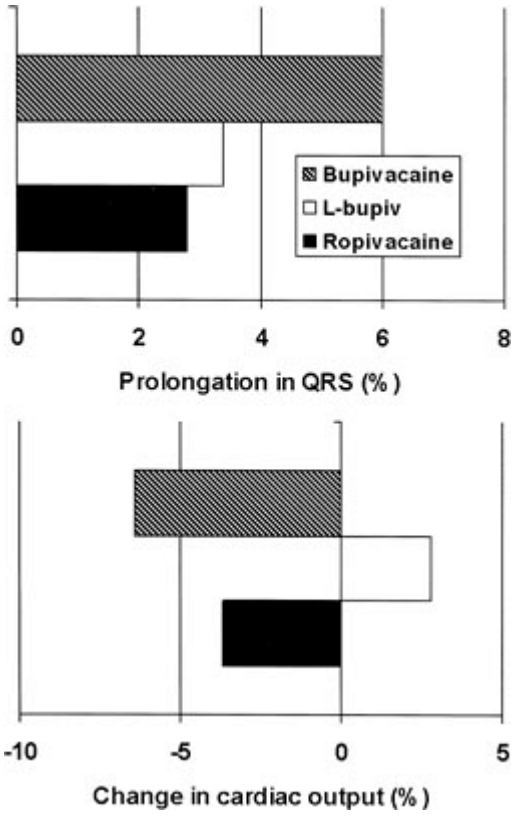

FIGURE 17-13. Mild prolongation in QRS interval and reduction in cardiac output are observed after intravenous infusions of bupivacaine (103 mg), levobupivacaine (37 mg), and ropivacaine (115 mg) in healthy volunteers. Data from: Knudsen K, Beckman Suurkula M, et al. Central nervous and cardiovascular effects of i.v. infusions of ropivacaine, bupivacaine and placebo in volunteers. Br Anaesth 1997:78:507. Stewart J, Kellett N, Castro D. The central nervous system and cardiovascular effects of levobupivacaine and ropivacaine in healthy volunteers. Anesth Analg 2003:97:412.

Cardiovascular Toxicity Mediated at the CNS. It has been demonstrated that the central and peripheral nervous systems may be involved in the increased cardiotoxicity with bupivacaine. The nucleus tractus solitarii in the medulla is an important region for autonomic control of the cardiovascular system. Neural activity in the nucleus tractus solitarii of rats is markedly diminished by intravenous doses of bupivacaine immediately prior to development of hypotension. Furthermore, direct intracerebral injection of bupivacaine can elicit sudden dysrhythmias and cardiovascular collapse.[123]

Peripheral effects of bupivacaine on the autonomic and vasomotor systems may also augment its CV toxicity. Bupivacaine possesses a potent peripheral inhibitory effect on sympathetic reflexes[123] that has been observed even at blood concentrations similar to those measured after uncomplicated regional anesthesia.[124] Finally, bupivacaine also has potent direct vasodilating properties, which may exacerbate cardiovascular collapse.[125]

Cardiovascular Toxicity Mediated at the Heart. The more potent local anesthetics appear to possess greater potential for direct cardiac electrophysiologic toxicity.[45,106] Although all local anesthetics block the cardiac conduction system via a dose-dependent block of sodium channels, two features of bupivacaine's sodium channel blocking abilities may enhance its cardiotoxicity. First, bupivacaine exhibits a much stronger binding affinity to resting and inactivated sodium channels than lidocaine.[126] Second, local anesthetics bind to sodium channels during systole and dissociate during diastole (Fig. 17-14). Bupivacaine dissociates from sodium channels during cardiac diastole much more slowly than lidocaine. Indeed, bupivacaine dissociates so slowly that the duration of diastole at physiologic heart rates (60 to 180 bpm) does not allow enough time for complete recovery of sodium channels and bupivacaine conduction block accumulates. In contrast, lidocaine fully dissociates from sodium channels during diastole and little accumulation of conduction block occurs (Fig. 17-15).[126,127] Thus, enhanced electrophysiologic effects of more potent local anesthetics on the cardiac conduction system may explain their increased potential to produce sudden cardiovascular collapse via cardiac dysrhythmias.

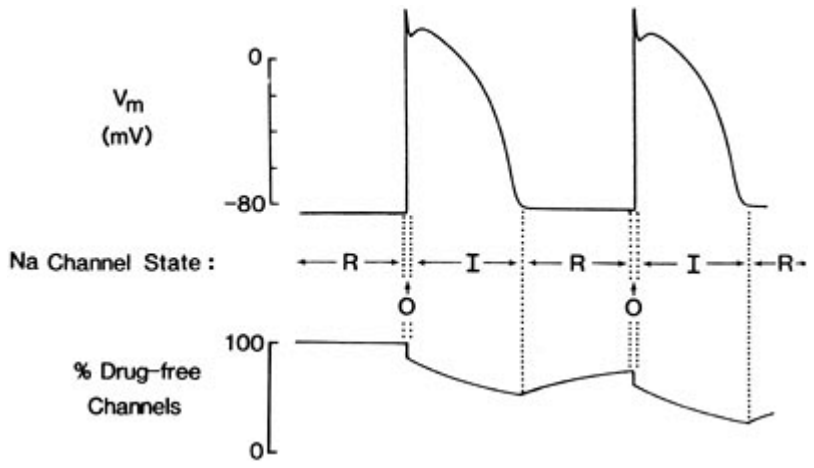

FIGURE 17-14. Diagram illustrating relationship between cardiac action potential **(top)**, sodium channel state **(middle)**, and block of sodium channels by bupivacaine **(bottom)**. R = resting, O = open, and I = inactive forms of the sodium channel. Sodium channels are predominantly in the resting form during diastole, open transiently during the action potential upstroke, and are in the inactive form during the action potential plateau. Block of sodium channels by bupivacaine accumulates during the action potential (systole) with recovery occurring during diastole. Recovery of sodium channels is from dissociation of bupivacaine and is time dependent. Recovery during each diastolic interval is incomplete and

results in accumulation of sodium channel block with successive heartbeats. (Adapted with permission from Clarkson CW, Hondegham LM: Mechanisms for bupivacaine depression of cardiac conduction: Fast block of sodium channels during the action potential with slow recovery from block during diastole. Anesthesiology 62:396, 1985.)

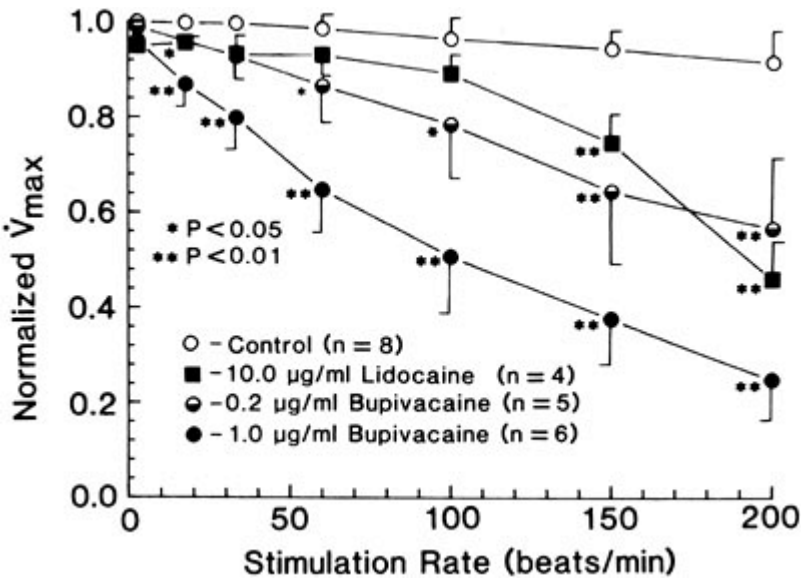

FIGURE 17-15. Heart rate dependent effects of lidocaine and bupivacaine on velocity of the cardiac action potential (V_{max}). Bupivacaine progressively decreases V_{max} at heart rates above 10 bpm because of accumulation of sodium channel block, whereas lidocaine does not decrease V_{max} until heart rate exceeds 150 bpm. (Adapted with permission from Clarkson CW, Hondegham LM: Mechanisms for bupivacaine depression of cardiac conduction: Fast block of sodium channels during the action potential with slow recovery from block during diastole. Anesthesiology 62:396, 1985.)

Increased potency for direct myocardial depression from the more potent local anesthetics is another contributing factor to increased cardiotoxicity (Fig. 17-16).[106,122] Again, multiple mechanisms may account for the increased potency for myocardial depression from more potent local anesthetics. Bupivacaine, the most completely studied potent local anesthetic, possesses a high affinity for sodium channels in the cardiac myocyte.[18,45,106] Furthermore, bupivacaine inhibits myocyte release and utilization of calcium[128] and reduces mitochondrial energy metabolism, especially during hypoxia.[129] Thus, multiple direct effects of bupivacaine on activity of the cardiac myocyte may explain the cardiotoxicity of bupivacaine and other potent local anesthetics.

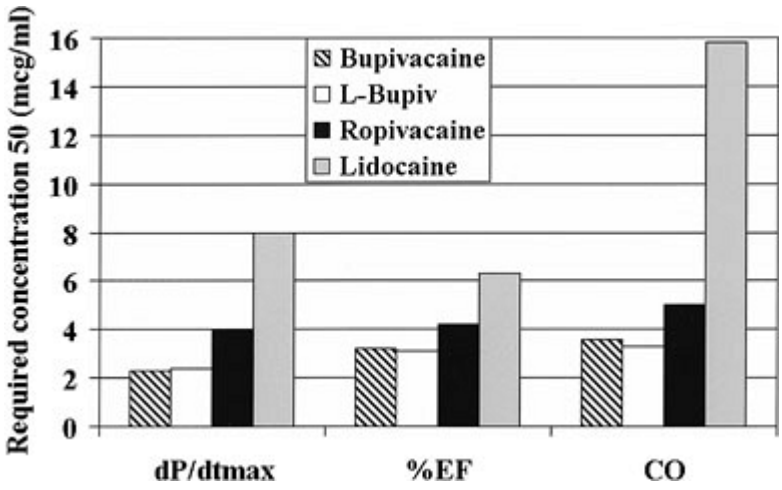

FIGURE 17-16. Plasma concentrations required to induce myocardial depression in dogs administered bupivacaine, levo-bupivacaine, ropivacaine, and lidocaine. dP/dtmax = 35% reduction of inotropy from baseline measure. %EF = 35% reduction in ejection fraction from baseline measure. CO = 25% reduction in cardiac output from baseline measure. (Data from Groban L, Deal DD, Vernon JC, et al: Does local anesthetic stereoselectivity or structure predict myocardial depression in anesthetized canines? Reg Anesth Pain Med 27:460, 2002.)

Treatment of Systemic Toxicity from Local Anesthetics

8 The best method for avoiding systemic toxicity from local anesthetics is through prevention. Toxic systemic levels can occur by unintentional intravenous or intra-arterial injection or by systemic absorption of excessive doses placed in the correct area. Unintentional intravascular and intra-arterial injections can be minimized by frequent syringe aspiration for blood, use of a small test dose of local anesthetic (~3 mL) to test for subjective systemic effects from the patient (e.g., tinnitus, circumoral numbness), and either slow injection or fractionation of the rest of the dose of local anesthetic.[110] Detailed knowledge of local anesthetic pharmacokinetics will also aid in reducing the administration of excessive doses of local anesthetics. Ideally, heart rate, blood pressure, and the electrocardiogram should be monitored during administration of large doses local anesthetics. Pretreatment with a benzodiazepine may also lower the probablility of seizure by raising the seizure threshhold.

Treatment of systemic toxicity is primarily supportive. Injection of local anesthetic should be stopped. Oxygenation and ventilation should be maintained, as systemic toxicity of local anesthetics is enhanced by hypoxemia, hypercarbia, and acidosis.[110] If needed, the patient's trachea should be intubated and positive pressure ventilation instituted. As previously discussed, signs of CNS toxicity will typically occur prior to CV events. Seizures can increase body metabolism and cause hypoxemia, hypercarbia, and acidosis. Pharmacologic treatment to terminate seizures may be needed if oxygenation and ventilation cannot be maintained. Intravenous administration of thiopental (50 to 100 mg), midazolam (2 to 5 mg), and propofol (1 mg/kg) can terminate seizures from systemic local anesthetic toxicity. Succinylcholine (50 mg) can terminate muscular activity from seizures and facilitate ventilation and oxygenation. However, succinylcholine will not terminate seizure

activity in the CNS, and increased cerebral metabolic demands will continue unabated.

Cardiovascular depression from less potent local anesthetics (e.g., lidocaine) is usually mild and caused by mild myocardial depression and vasodilation. Hypotension and bradycardia can usually be treated with ephedrine (10 to 30 mg) and atropine (0.4 mg). As previously discussed, potent local anesthetics (e.g., bupivacaine) can produce profound CV depression and malignant

dysrhythmias that should be promptly treated. Oxygenation and ventilation must be immediately instituted, with cardiopulmonary resuscitation if needed. Ventricular dysrhythmias may be difficult to treat and may need large and multiple doses of electrical cardioversion, epinephrine, vasopressin, and amiodarone. The use of calcium channel blockers in this setting is not recommended, as its cardiodepressant effect is exaggerated.[110] A novel and promising treatment for cardiac toxicity is the administration of intravenous lipid to theoretically remove bupivacaine from sites of action. Administration of a 20% lipid solution at a dose of 4 mL/kg followed by a 0.5 mL/kg/min infusion for 10 minutes allowed for the resuscitation of 100% of dogs with induced bupivacaine cardiotoxicity at a dose of 10mg/kg.[130] None of the dogs given an equivalent volume of crystalloid were rescuscitated in this study. These findings raise the question of whether propofol in a 10% lipid solution would be a preferred treatment for cardiac toxicity. Propofol has been reported to terminate bupivacaine-induced seizures and cardiac depression in patients.[130] However, the dose of lipid in a standard induction dose of propofol (2 mg/kg) would be only 3% of the dose used in the aforementioned animal experiment. As effects of lipid on cardiac toxicity are dose related, further information is needed prior to reaching conclusions on clinical use of propofol for local anesthetic–induced cardiac toxicity.

Neural Toxicity of Local Anesthetics

In addition to systemic toxicity, local anesthetics can cause injury to the central and peripheral nervous system from direct exposure. Mechanisms for local anesthetic neurotoxicity remain speculative, but previous studies have demonstrated local anesthetic–induced injury to Schwann cells, inhibition of fast axonal transport, disruption of the blood-nerve barrier, decreased neural blood flow with associated ischemia, and disruption of cell membrane integrity via a detergent property of local anesthetics.[131,132] Although all clinically used local anesthetics can cause concentration-dependent nerve fiber damage in peripheral nerves when used in high enough concentrations, previous studies have demonstrated that local anesthetics in clinically used concentrations are generally safe for peripheral nerves.[133] The spinal cord and the nerve roots, on the other hand, are more prone to injury.

Spinal cord toxicity of local anesthetics has been assessed by administration of local anesthetics to rabbits via intrathecal catheters. These studies suggest that bupivacaine (2%), lidocaine (8%), and tetracaine (1%) cause histopathologic changes and neurologic deficits. On the other hand, clinically relevant concentrations of these agents, chloroprocaine and ropivacaine (2%), did not disrupt spinal cord histology or cause nerurological deficits.[134] Desheathed peripheral nerve models, designed to mimic unprotected nerve roots in the cauda equina, have been used to further assess electrophysiologic neurotoxicity of local anesthetics.[135,136,137] Lidocaine 5% and tetracaine 0.5% caused irreversible conduction block in these models, whereas lidocaine 1.5%, bupivacaine 0.75%, and tetracaine 0.06% did not. Electrophysiologic toxicity of lidocaine in isolated nerve preparations represented by incomplete recovery of neuromuscular function occurs at 40 m*M* (~1%) (Fig. 17-17), with irreversible ablation of the compound action potential seen at 80 m*M* (~2%). Although such studies do not reflect in vivo conditions, they suggest that lidocaine and tetracaine may be especially neurotoxic in a concentration-dependent fashion and that neurotoxicity could theoretically occur with clinically used solutions. Local anesthetic effects on spinal cord blood flow, another possible etiology of neurotoxicity from direct drug exposure, appear benign. Spinal administration of bupivacaine, lidocaine, mepivacaine, and tetracaine cause vasodilation and increase spinal cord blood flow, whereas ropivacaine causes vasoconstriction and reduction in spinal cord blood flow in a concentration-dependent fashion.[138]

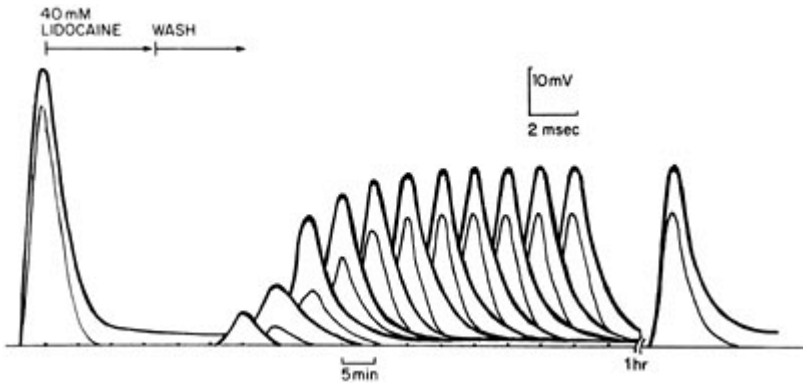

FIGURE 17-17. The nonreversible effect of 40 mM lidocaine on the compound action potential (CAP) of frog sciatic nerve. Lidocaine was applied to a stable nerve preparation for 15 minutes and then washed with frog Ringer's solution for 2 hours. Tracings represent CAPs in response to stimulus (1-Hz stimulus = heavy line; 40-Hz stimulus = thin line). 40 mM lidocaine completely ablated the CAP when applied to the nerve. The 1-Hz CAP response began to return after 10 to 15 minutes of washing and reached a new level in 45 minutes, where it was stable for the subsequent 2 hours of observation. The recovered 1-Hz CAP is only 65% of the original. (Adapted with permission from Bainton C: Concentration dependence of lidocaine-induced irreversible conduction loss frog nerve. Anesthesiology 81:657, 1994.)

Neurohistopathologic data in humans after intrathecal exposure to local anesthetics is not available. Electrophysiologic parameters such as somatosensory evoked potentials, monosynaptic H-reflex,[139] and cutaneous current perception thresholds[140] have been used to evaluate recovery after spinal anesthesia. These measurements have shown complete return to baseline activity after 5% lidocaine spinal anesthesia in very small study populations. Prospective surveys of over 80,000 spinal anesthetics report an incidence of 0 to 0.02% long-term neurologic injury in patients undergoing spinal anesthesia.[109] Thus, spinally administered local anesthetics have not notably manifested clinical neurotoxicity.

Transient Neurologic Symptoms after Spinal Anesthesia

Prospective, randomized studies reveal a 4 to 40% incidence of transient neurologic symptoms (TNS), including pain or sensory abnormalities in the lower back, buttocks, or lower extremities, after lidocaine spinal anesthesia.[139] These symptoms have been reported with other local anesthetics as well (Table 17-11). Increased risk of TNS is associated with lidocaine, the lithotomy position, and ambulatory anesthesia, but not with baricity of solution or dose of local anesthetic.[139] The potential neurological etiology of this syndrome coupled with known concentration-dependent toxicity of lidocaine led to concerns over a neurotoxic etiology for TNS from spinal lidocaine.

TABLE 17-11 Incidences of Transient Neurological Symptoms (TNS) Vary with Type of Spinal Local Anesthetic and Surgery

·LOCAL ANESTHETIC	·CONCENTRATION (%)	·TYPE OF SURGERY	·APPROXIMATE INCIDENCE OF TNS

			(%)
Lidocaine	2–5	Lithotomy position	30–36
	2–5	Knee arthroscopy	18–22
	0.5	Knee arthroscopy	17
	2–5	Mixed supine position	4–8
Mepivacaine	1.5–4	Mixed	23
Procaine	10	Knee arthroscopy	6
Bupivacaine	0.5–0.75	Mixed	1
Levo-bupivacaine	0.5	Mixed	1
Prilocaine	2–5	Mixed	1
Ropivacaine	0.5–0.75	Mixed	1

Data from: Pollock JE. Transient neurologic symptoms: etiology, risk factors, and management. Reg Anesth Pain Med 2002;27:581 and Breebaart MB. Urinary bladder scanning after day-case arthroscopy under spinal anaesthesia: comparison between lidocaine, ripovacaine, and levobupivacaine. Br J Anaesth 2003;90:309.

As previously discussed, laboratory work in both intrathecal and desheathed peripheral nerve models has proved that

the concentration of lidocaine is a critical factor in neurotoxicity. As concentrations of lidocaine below 40 m*M* (~1.0%) are not neurotoxic to desheathed peripheral nerve, such dilute concentrations of spinal lidocaine should not cause TNS if the syndrome is a result of subclinical concentration-dependent neurotoxicity. The dilution of lidocaine to as low as 0.5%, however, does not decrease the incidence of TNS.[141] The high incidence of TNS observed with lidocaine concentrations <1% despite further dilution in cerebrospinal fluid lessens the plausibility of a concentration-dependent neurotoxic etiology. Furthermore, a volunteer study comparing individuals with and without TNS symptoms after lidocaine spinal anesthesia showed no difference detected by electromyography, nerve conduction studies, or somatosensory evoked potentials.

Overall, there is little evidence to support a neurotoxic etiology for TNS.[139] Other potential etiologies for TNS include patient positioning, sciatic nerve stretch, muscle spasm, and myofascial strain.[139]

Interest in finding a short-acting spinal anesthetic with a lesser incidence of TNS has served as an impetus for investigations into the use of 2-chloroprocaine as a spinal anesthetic. Preliminary studies show that preservative-free 2-chloroprocaine provides an anesthetic profile similar to lidocaine without report of TNS, which would make 2-chloroprocaine potentially useful for outpatient procedures (Table 17-12). Enthusiasm for spinal 2-chloroprocaine should be tempered by the potential for neurotoxicity. In a laboratory study, 2-chloroprocaine (14 mg/kg) administered to rats via intrathecal catheter was noted to be histologically neurotoxic to the spinal cord to the same degree as 2.5% lidocaine. This finding calls into question the long held belief that the antioxidant sodium bisulfite is to blame for 2-chloroprocaine's clinical neurotoxicity.[142] The clinical applicability of this finding is uncertain, as the dose of chloroprocaine is far greater than the dose used for spinals in humans (0.6 mg/kg).

TABLE 17-12 Dose Range of Spinal 2-Chloroprocaine and Comparison to Lidocaine

·2-CHLOROPROCAINE	·30 MG	·45 MG	·60 MG	·LIDOCAINE 40 MG
Sensory Block Height				
Peak	T7	T5	T2	T8
Time to L1 regression (mins)	53±30	75±14	92±13	84±35
Thigh tourniquet tolerance (mins)	37±11	42±11	62±10	38±24
Complete regression (mins)	98±20	116±15	132±23	126±16
Time to ambulation (mins)	**100±20**	**119±15**	**133±20**	**134±14**
Time to bladder void (mins)	100±21	132±19	141±21	134±14

Myotoxicity of Local Anesthetics

Toxicity to skeletal muscle is an uncommon side effect of local anesthetic injection. Experimental

data suggests, however, that local anesthetics have the potential for myotoxicity in clinically applicable concentrations (Fig. 17-18). Histopathologic evidence shows that the injection of these agents causes diffuse myonecrosis, which is both reversible and clinically imperceptible. The reversible nature of this injury is possibly because of the relative resilience of myoblasts, which regenerate damaged tissue. Theoretical mechanisms of injury are numerous but dysregulation of intracellular calcium concentrations is the most likely culprit. One study shows that ropivacaine is less myotoxic than bupivacaine primarily because of the latter causing

apoptosis (programmed cell death).[143] Further investigation is needed to determine the clinical relevance of local or systemic myotoxicity following single injection or continuous infusion of local anesthetics.

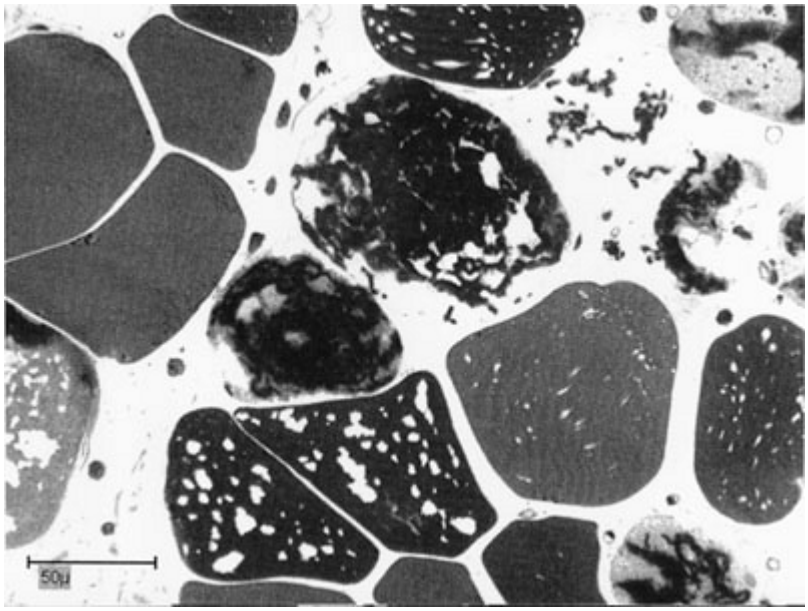

FIGURE 17-18. Skeletal muscle cross section with characteristic histologic changes after continuous exposure to bupivacaine for 6 hours. A whole spectrum of necrobiotic changes can be encountered, ranging from slightly damaged vacuolated fibers and fibers with condensed myofibrils to entirely disintegrated and necrotic cells. The majority of the myocytes are morphologically affected. Additionally, a marked interstitial and myoseptal edema appears within the sections. However, scattered fibers remain intact. (Reprinted with permission from Zink W, Graf B: Local anesthetic myotoxicity. Reg Anesth Pain Med 29(4):333–40, Jul–Aug 2004.)

Allergic Reactions to Local Anesthetics (see also Chapter 49)

True allergic reactions to local anesthetics are rare and usually involve Type I (IgE) or Type IV (cellular immunity) reactions.[144,145] Type I reactions are worrisome, as anaphylaxis may occur, and are more common with ester than amide local anesthetics. True Type I allergy to aminoamide agents is extremely rare.[145] Increased allergenic potential with esters may be a result of hydrolytic metabolism to para-aminobenzoic acid, which is a documented allergen. Added preservatives such as methylparaben and metabisulfite can also provoke an allergic response. Skin testing with intradermal injections of preservative-free local anesthetics has been advocated as a means to determine tolerance to local anesthetic. These tests should be undertaken with caution, as potentially severe and even fatal reactions can occur in truly allergic patients.[145]

Chapter 18

Preoperative Evaluation and Management

Hata Tara M.

Moyers John R.

KEY POINTS

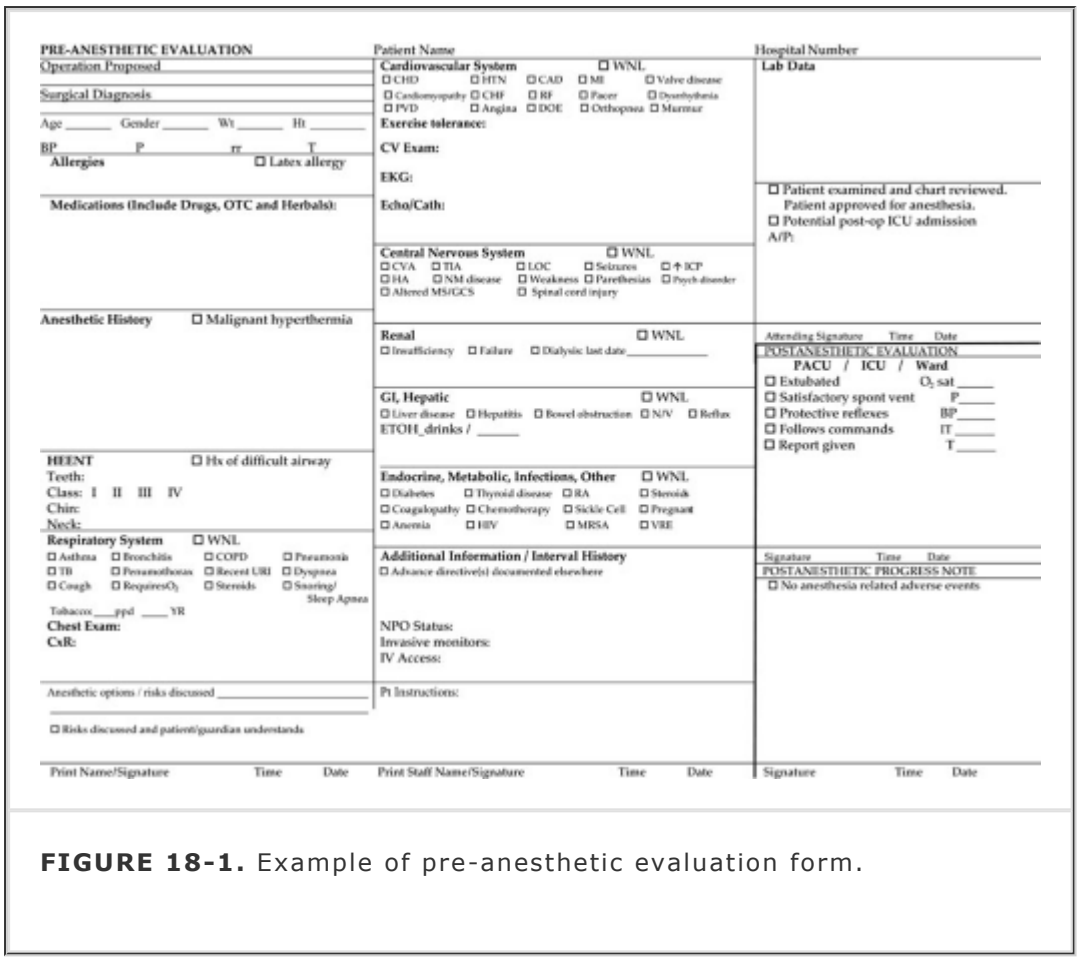
1	The Joint Commission for the Accreditation of Healthcare Organizations (JCAHO) requires that all patients receive a preoperative anesthetic evaluation and the American Society of Anesthesiologists (ASA) has approved Basic Standards for Preoperative Care.
2	When evaluating the patient with hypertension, it is important to determine the presence of end-organ damage (heart, lung, and cerebrovascular systems).
3	Exercise tolerance is a major determinant of cardiac risk and need for further testing.
4	The algorithm for preoperative evaluation of cardiac patients undergoing noncardiac surgery is very useful in guiding further testing and evaluation.
5	Preoperative laboratory tests should be ordered only based on defined indications such as positive findings on history and physical exam.
6	No best drug or combination of drugs exists for preoperative medication.
7	Psychological preparation is as important as pharmacologic preparation for anesthesia and surgery.
8	Timing of delivery is as important as drug selection with preoperative medication.
9	Age of the child is a major determinant of the approach to preoperative medication.

1 The goals of preoperative evaluation are to reduce patient risk and the morbidity of surgery, as well as to promote efficiency and reduce costs. The Joint Commission for the Accreditation

of Healthcare Organizations (JCAHO) requires that all patients receive a preoperative anesthetic evaluation. The American Society of Anesthesiologists (ASA) has approved Basic Standards for Preanesthetic Care, which outlines the minimum requirements for a preoperative evaluation. Conducting a preoperative evaluation is based on the premise that it will modify patient care and improve outcome. There is evidence, although not entirely convincing in all instances, that the preoperative evaluation will increase patient safety. That is, armed with knowledge preoperatively the anesthesiologist can formulate and conduct an anesthetic plan that avoids dangers inherent in patient disease states. Furthermore, preoperative evaluations may very well reduce costs and cancellation rates, increasing resource utilization in the operating room. This assumes that evaluations are done by anesthesiologists and others familiar with anesthetics, surgery, and perioperative events.

The preoperative evaluation has several components and goals. One should obtain a history and perform a physical exam pertinent to the patient and surgery contemplated. Based on the history and physical, the appropriate laboratory tests and preoperative consultations should be obtained. Through these one needs to determine whether the patient's preoperative condition may be improved prior to surgery. Guided by the above, the anesthesiologist should choose the appropriate anesthetic and care plan. Finally, the process should be used to educate the patient about anesthesia and the perioperative period, answer all questions, and obtain informed consent.

The first part of this chapter outlines clinical risk factors pertinent to patients scheduled for anesthesia and surgery and the use of tests to confirm diagnoses. The second part discusses preoperative medication. The chapter provides only an overview of the preoperative management process; for more details, the reader is referred to chapters focusing on specific organ systems.



CHANGING CONCEPTS IN PREOPERATIVE EVALUATION

In the past, patients were admitted to the hospital at least a day prior to surgery. Currently, more and more patients are admitted to the hospital on the day of surgery. Older patients are scheduled for more complex procedures, and there is more pressure on the anesthesiologist to reduce the time between cases. The first time the anesthesiologist performing the anesthetic sees the patient may be just prior to anesthesia and surgery. The patient has been seen previously by others in a preoperative evaluation clinic. Only a short time exists to engender trust and answer last-minute questions. It is often impossible to alter medical therapy at this juncture immediately preoperatively. However, preoperative screening clinics are becoming more effective and clinical practice guidelines becoming more prevalent. Information technology has helped the anesthesiologist in previewing the upcoming patients that will be anesthetized. Preoperative questionnaires and computer-driven programs have become alternatives to traditional information gathering. Finally, when anesthesiologists are responsible for ordering preoperative laboratory tests, cost saving occurs and cancellations of planned surgical procedures become less likely. In this setting it is important that communication between the preoperative evaluation clinic and the anesthesiologist performing the anesthetic occur through the patient record and in person.

APPROACH TO THE HEALTHY PATIENT

The preoperative evaluation form is the basis for formulating the best anesthetic plan tailored to the patient. It should aid the anesthesiologist in identifying potential complications, as well as serve as a medicolegal document. The importance of the design has increased because of the fact that it is more common today for the evaluation to be completed in a preop clinic by another physician or health professional who will not personally be performing the anesthetic, but also because regulatory agencies such as JCAHO demand better documentation. Therefore, the information obtained needs to be complete, concise, and legible. In those hospitals that have computerized patient forms, legibility is no longer an issue. A group from University of California, San Diego (UCSD) studied the quality of preoperative evaluation forms across the United States and rated them in three categories: informational content, ease of use, and ease of reading.[1] Their results revealed that a surprisingly high percentage of forms are missing important information. Figure 18-1 is an example of the preoperative evaluation form in use at the

University of Iowa Hospitals, which attempts to document all pertinent information.

PRE-ANESTHETIC EVALUATION

FIGURE 18-1. Example of pre-anesthetic evaluation form.

The approach to the patient should always begin with a thorough history and physical exam. This alone may be sufficient (without additional routine laboratory tests) prior to noninvasive procedures.

The indication for the surgical procedure is part of the preoperative history, because it will help determine the urgency of the surgery. True emergent procedures, which are associated with an accepted higher anesthetic morbidity and mortality, require a more abbreviated evaluation. A less-defined area is the approach to urgent procedures. For example, ischemic limbs require surgery soon after presentation, but can usually be delayed for 24 hours for further evaluation. The indication for the surgical procedure may also have implications on other aspects of perioperative management. For example, the presence of a small bowel obstruction has implications regarding the risk of aspiration and the need for a rapid sequence induction. The extent of a lung resection will dictate the need for further pulmonary testing and perioperative monitoring. Patients undergoing carotid endarterectomy may require a more extensive neurologic examination, as well as testing to rule out coronary artery disease (CAD). Frequently, further information will be required that necessitates contacting the surgeon. Perioperative care of the patient, as well as efficiency in the operating room, is always enhanced by close communication with the surgeons.

The ability to review previous anesthetic records is helpful in detecting the presence of a difficult airway, a history of malignant hyperthermia, and the individual's response to surgical stress and specific anesthetics. The patient should be questioned regarding any previous difficulty with anesthesia or other family members having difficulty with anesthesia. A patient history relating an "allergy" to anesthesia should make one suspicious for malignant hyperthermia.

The history should include a complete list of medications, including over-the-counter and herbal products, to define a preoperative medication regimen, anticipate potential drug interactions, and provide clues to underlying disease. A complete list of drug allergies, including previous reactions, should also be obtained.

The anesthesiologist should determine when the patient last ate, as well as note the sites of

preexisting intravenous cannulae and invasive monitors. Once the general issues are completed, the preoperative history and physical exam can focus on specific systems.

Systems Approach

Airway

A basic concern of the anesthesiologist is always the patient's airway. The ability to review previous anesthetic records is especially useful in uncovering unsuspected "difficult airways" or to confirm previous uneventful intubations, assuming the patient's body habitus has not changed in the interim. Evaluation of the airway involves determination of the thyromental distance, the ability to flex the base of the neck and extend the head, and examination of the oral cavity including dentition. The Mallampati classification has become the standard for assessing the relationship of the tongue size relative to the oral cavity (Table 18-1),[2] although **by itself** the Mallampati classification has a low positive predictive value in identifying patients who are difficult to intubate.[3,4] In trauma patients, as well as those with severe rheumatoid arthritis or Down

syndrome, assessment of the cervical spine is critical. In appropriate patients, the presence of pain or symptoms of cervical cord compression on movement should be assessed. In other instances, radiographic examination may be required.

TABLE 18-1 Airway Classification System

·CLASS	·DIRECT VISUALIZATION, PATIENT SEATED	·LARYNGOSCOPIC VIEW
I	Soft palate, fauces, uvula, pillars	Entire glottic
II	Soft palate, fauces, uvula	Posterior commissure
III	Soft palate, uvular base	Tip of epiglottis
IV	Hard palate only	No glottal structures

Pulmonary

A screening evaluation should include questions regarding the history of tobacco use, shortness of breath, cough, wheezing, stridor, and snoring or sleep apnea. The patient should also be questioned regarding the presence or recent history of an upper respiratory tract infection. Physical exam should assess the respiratory rate as well as the chest excursion, use of accessory muscles, nail color, and the patient's ability to carry on a conversation or to walk without dyspnea. Auscultation should be used to detect decreased breath sounds, wheezing, stridor, or rales. For the patient with positive findings, see preoperative evaluation of the pulmonary patient.

Cardiovascular System

When screening a patient for cardiovascular disease prior to surgery, the anesthesiologist is most

interested in recognizing signs and symptoms of uncontrolled hypertension and unstable cardiac disease such as myocardial ischemia, congestive heart failure, valvular heart disease, and significant cardiac dysrhythmias. Symptoms of cardiovascular disease should be carefully determined, especially the characteristics of chest pain, if present. Certain populations of patients, such as the elderly, women, or diabetics, may present with more atypical features. The presence of unstable angina has been associated with a high perioperative risk of myocardial infarction (MI).[5] The perioperative period is associated with a hypercoagulable state and surges in endogenous catecholamines, both of which may exacerbate the underlying process in unstable angina, increasing the risk of acute infarction.[6] The preoperative evaluation can affect both a patient's short- and long-term health by instituting treatment of unstable angina. Symptoms of clinically important valvular disease should be sought, such as angina,

syncope, or congestive heart failure from aortic stenosis that would require further evaluation. A history of other valvular disease such as mitral valve prolapse may simply dictate the need for SBE prophylaxis.

The exam of the cardiovascular system should include blood pressure, measuring both arms when appropriate. The anesthesiologist should take into account the effects of preoperative anxiety and may want a record of resting blood pressure measurements. However, Bedford and Feinstein reported that the admission blood pressure was the best predictor of response to laryngoscopy.[7] Auscultation of the heart is performed, specifically listening for a murmur radiating to the carotids suggestive of aortic stenosis or abnormal rhythms, or a gallop suggestive of heart failure. The presence of bruits over the carotid arteries would warrant further work-up to determine the risk of stroke. The extremities should also be examined for the presence of peripheral pulses to exclude peripheral vascular disease or congenital cardiovascular disease.

Neurologic System

A screening of the neurological system in the apparently healthy patient can mostly be accomplished through simple observation. The patient's ability to answer health history questions practically ensures a normal mental status. Questions can be directed to exclude the presence of increased intracranial pressure, cerebrovascular disease, seizure history, preexisting neuromuscular disease, or nerve injuries. The neurologic examination may be cursory in healthy patients, or extensive in patients with coexisting disease. Testing of strength, reflexes, and sensation may be important in patients if the anesthetic plan or surgical procedure may result in a change in the condition.

Endocrine System

Each patient should be screened for endocrine diseases that may affect the perioperative course: diabetes, thyroid disease, parathyroid disease, endocrine-secreting tumors, and adrenal cortical suppression.

Evaluation of the Patient with Known Systemic Disease

Cardiac Disease

The preoperative evaluation of the patient with suspected cardiovascular disease has been approached in two ways: clinical risk indices and preoperative cardiac testing. The goals are to define risk, determine which patients will benefit from further testing, form an appropriate anesthetic plan, and identify patients who will benefit from perioperative beta-blockade, intervention therapy, or even surgery. Clinical risk indices range from the physical status index of the American Society of Anesthesiologists (Table 18-2) to the Goldman Cardiac Risk Index, which has recently been updated.

TABLE 18-2 American Society of Anesthesiologists Physical Status Classification

·STATUS	·DISEASE STATE
ASA Class 1	No organic, physiologic, biochemical, or psychiatric disturbance
ASA Class 2	Mild to moderate systemic disturbance that may not be related to the reason for surgery
ASA Class 3	Severe systemic disturbance that may or may not be related to the reason for surgery
ASA Class 4	Severe systemic disturbance that is life threatening with or without surgery
ASA Class 5	Moribund patient who has little chance of survival but is submitted to surgery as a last resort (resuscitative effort)
Emergency operation (E)	Any patient in whom an emergency operation is required

From information in American Society of Anesthesiologists: New classification of physical status. Anesthesiology 24:111, 1963.

In an update of the Goldman Cardiac Risk Index, the investigators studied 4,315 patients aged 50 years and older who were undergoing elective, major noncardiac procedures.[8] Six independent predictors of complications were identified and included in a revised risk index: high-risk type of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative treatment with insulin, and preoperative serum creatinine >2.0 mg/dL. Cardiac complications rose with an increase in the number of risk factors present. Rates of major cardiac complications with 0, 1, 2, or 3 of these factors were 0.5, 1.3, 4, and 9%, respectively, in the derivation cohort and 0.4, 0.9, 7, and 11%, respectively, among 1,422 patients in the validation cohort (Fig. 18-2).

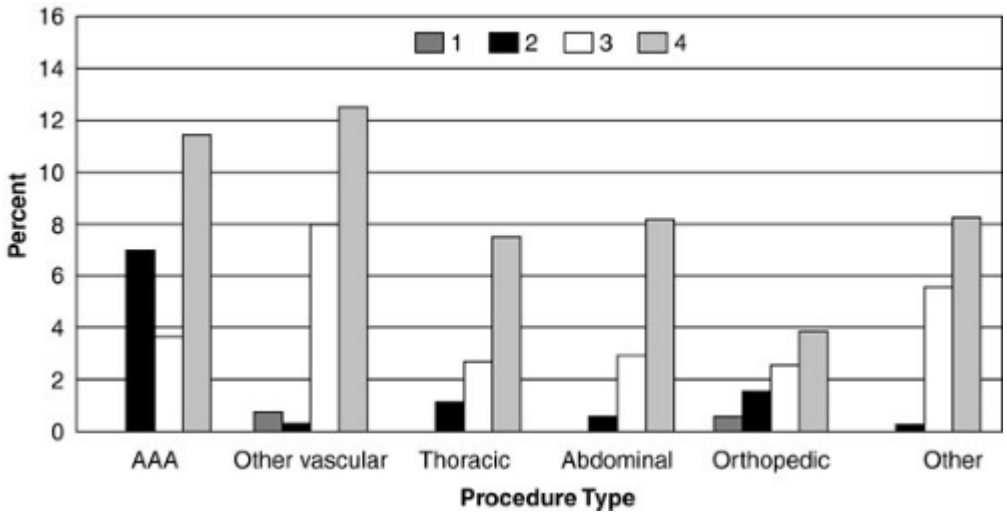

FIGURE 18-2. CRI cardiac risk index. Bars represent rate of major cardiac complications in entire patient population (both derivation and validation cohorts combined) for patients in revised CRI classes according to type of procedure performed. AAA, abdominal aortic aneurysm. Note that, by definition, patients undergoing AAA, thoracic, and abdominal procedures were excluded from Class I. In all subsets except patients undergoing AAA, there was a statistically significant trend toward greater risk with higher-risk class. See text for details. (Reproduced with permission from Lee TH, Marcantonio ER, Mangione CM *et al*: Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. Circulation 100:1043, 1999.)

While all of these indices provide information to assess the probability of complications and provide an estimate of risk, they do not prescribe perioperative management. In contrast,

the anesthesiologist is most concerned with forming an anesthetic plan after defining the cardiovascular risk factors.

In patients with symptomatic coronary disease, the preoperative evaluation may lead to the recognition of a change in the frequency or pattern of anginal symptoms. Certain populations of patients—for example, the elderly, women, or diabetics—may present with more atypical features. The presence of unstable angina has been associated with a high perioperative risk of MI.[5]

In virtually all studies, the presence of active congestive heart failure preoperatively has been associated with an increased incidence of perioperative cardiac morbidity.[9,10] Stabilization of ventricular function and treatment for pulmonary congestion are important prior to elective surgery. Because the type of perioperative monitoring and treatments would be different, clarifying the cause of heart failure is important. Congestive symptoms may be a result of nonischemic cardiomyopathy or cardiac valvular insufficiency and/or stenosis.

Adults with a prior MI almost always have coronary artery disease. Traditionally, risk assessment for noncardiac surgery was based on the time interval between the MI and surgery. Multiple studies have demonstrated an increased incidence of reinfarction if the MI was within 6 months of surgery.[11,12,13] With improvements in perioperative care, this difference has decreased. Therefore, the importance of the intervening time interval may no longer be valid in the current era of interventional therapy and risk stratification after an acute MI. Although many patients with an MI may continue to have myocardium at risk for subsequent ischemia and infarction, other patients may have their critical coronary stenoses either totally occluded or widely patent. For example, the use of percutaneous transluminal coronary angioplasty, thrombolysis, and early coronary artery bypass grafting (CABG) has changed the natural history of the disease.[14,15] Therefore, patients should be evaluated from the perspective of their risk for ongoing ischemia. The American Heart Association/American College of Cardiology Task Force on Perioperative Evaluation of the Cardiac Patient Undergoing Noncardiac Surgery has defined three risk groups—major, intermediate, and minor (Table 18-3). They indicate that recent MI (MI <30 days) places patients in the group at highest risk; after that period, a prior MI places the patient at intermediate risk.[16]

TABLE 18-3 Clinical Predictors of Increased Perioperative Cardiovascular Risk (Myocardial Infarction, Congestive Heart Failure, Death)

Major
Unstable coronary syndromes
• Recent myocardial infarction[a] with evidence of important ischemic risk by clinical

symptoms or noninvasive study
- Unstable or severe[b] angina (Canadian Class III or IV)[c]

Decompensated congestive heart failure
Significant arrhythmias

- High-grade atrioventricular block
- Symptomatic ventricular arrhythmias in the presence of underlying heart disease
- Supraventricular arrhythmias with uncontrolled ventricular rate

Severe valvular disease
Intermediate
Mild angina pectoris (Canadian Class I or II)
Prior myocardial infarction by history or pathological Q waves Compensated or prior congestive heart failure
Diabetes mellitus
Minor
Advanced age
Abnormal ECG (left ventricular hypertrophy, left bundle-branch block, ST-T abnormalities)
Rhythm other than sinus (e.g., atrial fibrillation)
Low functional capacity (e.g., inability to climb one flight of stairs with a bag of groceries)
History of stroke
Uncontrolled systemic hypertension

[a]The American College of Cardiology National Database Library defines recent MI as greater than 7 days but less than or equal to 1 month (30 days).

[b]May include "stable" angina in patients who are unusually sedentary.

[c]Campeau L: Grading of angina pectoris. Circulation 54:522, 1976.

Reproduced with permission from Eagle K, Brundage B, Chaitman B *et al*: Guidelines for perioperative cardiovascular evaluation of the noncardiac surgery. A report of the American Heart Association/American College of Cardiology Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures. Circulation 93:1278, 1996.

Patients with Coronary Artery Disease

For those patients without overt symptoms or history, the probability of CAD varies with the type and number of atherosclerotic risk factors present. Peripheral arterial disease has been shown to be associated with CAD in multiple studies.[17] Diabetes mellitus is a common disease in the elderly and represents a process that affects multiple organ systems. Complications of diabetes mellitus are frequently the cause of urgent or emergent surgery, especially in the elderly. Diabetes accelerates the progression of atherosclerosis, so it is not surprising that diabetics have a higher incidence of CAD than nondiabetics do. There is a high incidence of both silent myocardial infarction and myocardial ischemia.[18] Eagle et al demonstrated that diabetes is an independent risk factor for perioperative cardiac morbidity.[19] In attempting to determine the degree of this

increased probability, the length of the disease and other associated end-organ dysfunction should be taken into account. Autonomic neuropathy has been found to be the best predictor of silent coronary artery disease.[20] Because these patients are at very high risk for a silent MI, an electrocardiogram (ECG) should be obtained to examine for the presence of Q waves.

Hypertension has also been associated with an increased incidence of silent myocardial ischemia and infarction.[18] Hypertensive patients who have left ventricular hypertrophy and are undergoing noncardiac surgery are at a higher perioperative risk than nonhypertensive patients.[21] Investigators have suggested that the presence of a strain pattern on ECG suggests a chronic ischemic state.[22] Therefore, these patients should also be considered to have an increased probability of CAD and for perioperative morbidity.

2 There is controversy regarding a trigger to delay or cancel a surgical procedure in a patient with untreated or inadequately treated hypertension. Hypertension has been divided into three stages, with Stage 3 denoting that which might be used as a cutoff (Table 18-4).[23] Aggressive treatment of blood pressure is associated with increased reduction in long-term risk, although the effect diminishes in all but diabetic patients as diastolic blood pressure is reduced below 90 mmHg. Although there has been a suggestion in the literature that a case should be delayed if the diastolic pressure is greater than 110 mm Hg, the study often quoted as the basis for this determination demonstrated no major morbidity in that small group of patients.[24] Other authors state that there is little association between blood pressures of less than 180 mmHg systolic or 110 mm Hg diastolic and postoperative outcomes. However, such patients are prone to perioperative myocardial ischemia, ventricular dysrhythmias, and lability in blood pressure. It is less clear in patients with blood pressures above

180/100 mmHg, although no absolute evidence exists that postponing surgery will reduce risk.[25] In the absence of end-organ changes, such as renal insufficiency or left ventricular hypertrophy with strain, it would seem appropriate to proceed with surgery. In contrast, a patient with a markedly elevated blood pressure and new onset of a headache should have surgery delayed for further treatment.

TABLE 18-4 Blood Pressure (mmHg)

·CATEGORY	·SYSTOLIC		·DIASTOLIC
Optimal	<120	and	<80
Normal	<130	and	<85
High-normal	130–139	or	85–89
Hypertension			
Stage 1	140–159	or	90–99
Stage 2	160–179	or	100–109
Stage 3	⩾180	or	⩾110

Reproduced with permission from Sixth report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Arch Intern Med 157:2413, 1997.

Several other risk factors have been used to suggest an increased probability of CAD. These include the atherosclerotic processes associated with tobacco use and hypercholesterolemia. Although these risk factors increase the probability of developing coronary artery disease, they have not been shown to increase perioperative risk. When attempting to determine the overall probability of disease, the number of risk factors and severity of each are important.

Importance of Surgical Procedure

The surgical procedure influences the scope of preoperative evaluation required by determining the potential range of physiologic flux during the perioperative period. Few hard data exist defining the surgery-specific incidence of complications. It is known that peripheral procedures, such as those included in a study of ambulatory surgery completed at the Mayo Clinic, are associated with an extremely low incidence of morbidity and mortality,[26] while major vascular procedures are associated with the highest incidence of complications. Eagle et al published data on the incidence of perioperative myocardial infarction and mortality by procedure for patients enrolled in the Coronary Artery Surgery Study (CASS).[27] They determined the overall risk of perioperative morbidity in patients with known coronary artery disease treated medically compared to those patients who had prior coronary artery bypass grafting. High-risk procedures include major vascular, abdominal, thoracic, and orthopaedic surgery. The American Heart Association/American College of Cardiology Guidelines described a risk stratification for noncardiac surgery that is shown in Table 18-5.[16]

TABLE 18-5 Cardiac Risk[a] Stratification for Noncardiac Surgical Procedures

HIGH	(Reported cardiac risk often >5%) • Emergent major operations, particularly in the elderly • Aortic and other major vascular • Peripheral vascular • Anticipated prolonged surgical procedures associated with large fluid shifts and/or blood loss
INTERMEDIATE	(Reported cardiac risk generally <5%) • Carotid endarterectomy • Head and neck

	• Intraperitoneal and intrathoracic • Orthopaedic • Prostate
LOW[b]	(Reported cardiac risk generally <1%) • Endoscopic procedures • Superficial procedures • Cataract • Breast
[a]Combined incidence of cardiac death and nonfatal myocardial infarction.	
[b]Do not generally require further preoperative cardiac testing. Reproduced with permission from Eagle K, Brundage B, Chaitman B *et al*: Guidelines for perioperative cardiovascular evaluation of the noncardiac surgery. A report of the American Heart Association/American College of Cardiology Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures. Circulation 93:1278, 1996.	

Importance of Exercise Tolerance

3 Exercise tolerance is one of the most important determinants of perioperative risk and the need for further testing and invasive monitoring. An excellent exercise tolerance, even in patients with stable angina, suggests that the myocardium can be stressed without failing. If a patient can walk a mile without becoming short of breath, the probability of extensive coronary artery disease is small. Alternatively, if patients experience dyspnea associated with chest pain during minimal exertion, the probability of extensive coronary artery disease is high, which has been associated with greater perioperative risk. Additionally, these patients are at risk for developing hypotension with ischemia, and therefore may benefit from more extensive monitoring, coronary intervention therapy, or revascularization. Exercise tolerance can be assessed with formal treadmill testing or with a questionnaire that assesses activities of daily living (Table 18-6).[16]

TABLE 18-6 Estimated Energy Requirement for Various Activities[a]

1 MET	Can you take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2–3 mph or 3.2–4.8 km/hr? Do light work around the house like dusting or washing dishes?	4METs	Walk on level ground at 4 mph or 6.4 km/hr? Run a short distance Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football?

4 METs	Climb a flight of stairs or walk up a hill?	>10 METs	Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

MET = metabolic equivalent.

[a]Adapted from the Duke Activity Status Index and AHA Exercise Standards.

Reproduced with permission from Eagle K, Brundage B, Chitman B *et al*: Guidelines for perioperative cardiovascular evaluation of the noncardiac surgery. A report of the American Heart Association/American College of Cardiology Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures. Circulation 93:1278, 1996.

Reilly et al have evaluated the predictive value of self-reported exercise tolerance for serious perioperative complications and demonstrated that a poor exercise tolerance (could not walk four blocks and climb two flights of stairs) independently predicted a complication with an odds ratio of 1.94.[28] The likelihood of a serious adverse event was inversely related to the number of blocks that could be walked. Therefore, there is good evidence to suggest that minimal additional testing is necessary if the patient is able to describe a good exercise tolerance.

INDICATIONS FOR FURTHER CARDIAC TESTING

Multiple algorithms have been proposed to determine which patients require further testing. As described previously, the risk associated with the proposed surgical procedure influences the decision to perform further diagnostic testing and interventions. Guidelines must be tempered by recent studies in which perioperative cardiac morbidity was greatly reduced by perioperative β-adrenergic blockade administration.[29] With the reduction in perioperative morbidity, it has been suggested that extensive cardiovascular testing is not necessary. However,

until these findings can be confirmed, further testing may be warranted.

4 The algorithm to determine the need for testing proposed by the American College of Cardiology/American Heart Association Task Force and an update in 2002,[30] is based on the available evidence and expert opinion that integrates clinical history, surgery-specific risk, and exercise tolerance (Fig. 18-3).[16] In step one, the clinician evaluates the urgency of the surgery and the appropriateness of a formal preoperative assessment. Next, determine if the patient has undergone a recent revascularization procedure or coronary evaluation. Those patients with unstable coronary syndromes should be identified, and appropriate treatment instituted. Finally, the decision to undergo further testing depends on the interaction of the clinical risk factors, surgery-specific risk, and functional capacity. For patients at intermediate clinical risk, both exercise tolerance and the extent of the surgery are taken into account to determine the need for further testing. Importantly, no preoperative cardiovascular testing should be performed if the results will not change perioperative management.

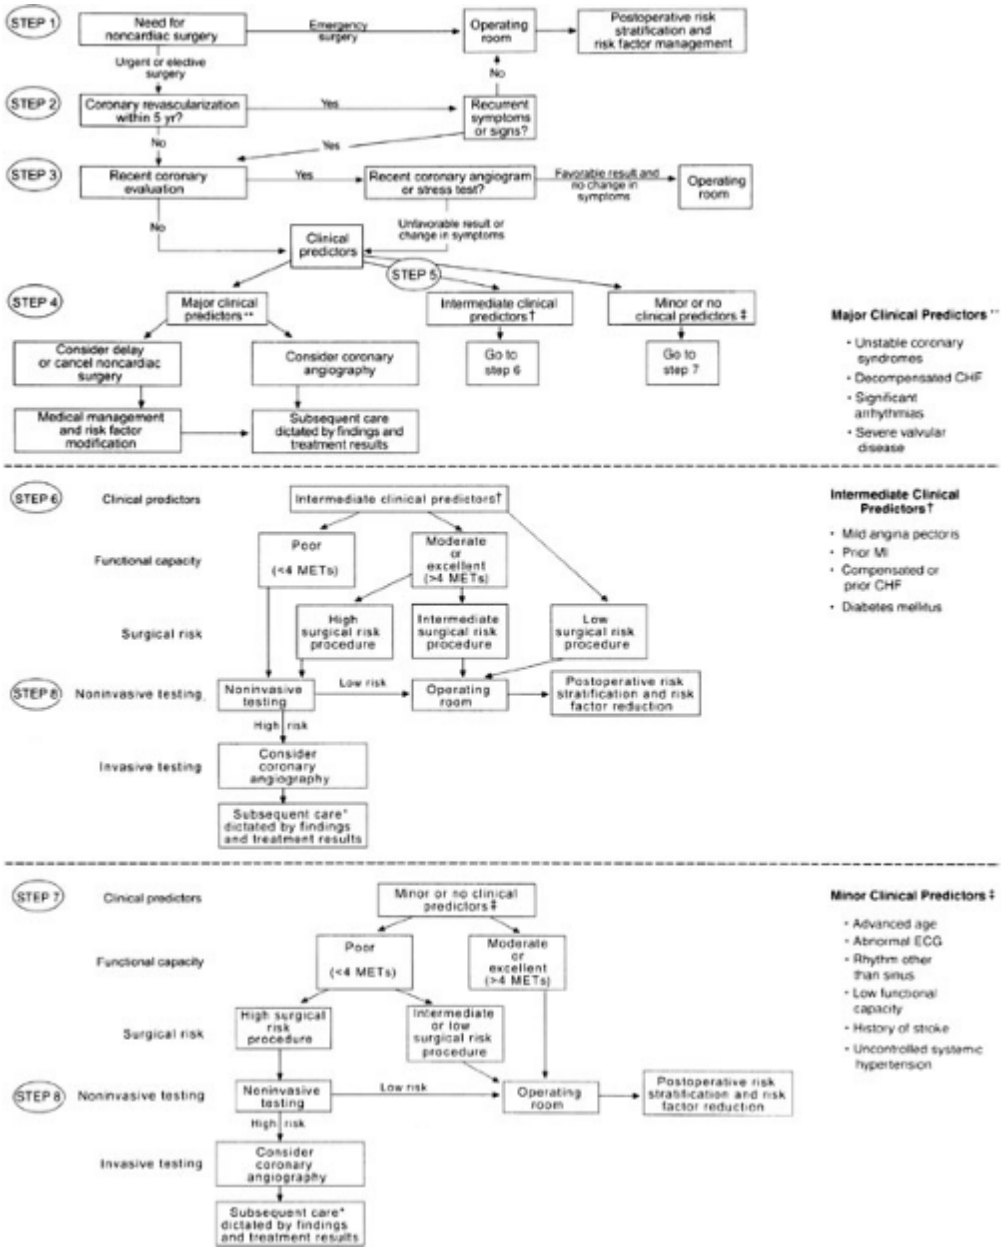

FIGURE 18-3. The American Heart Association/American College of Cardiology Task Force on Perioperative Evaluation of Cardiac Patients Undergoing Noncardiac Surgery has proposed an algorithm for decisions regarding the need for further evaluation. This represents one of multiple algorithms proposed in the literature. It is based on expert opinion and incorporates six steps. First, the clinician must evaluate the urgency of the surgery and the appropriateness of a formal preoperative assessment. Next, he or she must determine whether the patient has had a previous revascularization procedure or coronary evaluation. Those patients with unstable coronary syndromes should be identified, and appropriate treatment should be instituted. The decision to have further testing depends on the interaction of the clinical risk factors, surgery-specific risk, and functional capacity. (Adapted with permission from Eagle K, Brundage B, Chaitman B *et al*: Guidelines for perioperative cardiovascular evaluation of noncardiac surgery. A report of the American Heart Association/American College of Cardiology Task Force on Assessment of Diagnostic and Therapeutic Cardiovascular Procedures. Circulation 93:1278, 1996.)

Cardiovascular Tests

Electrocardiogram

Preoperative 12-lead electrocardiogram can provide important information on the state of the patient's myocardium and coronary circulation. Abnormal Q waves in high-risk patients are highly suggestive of a past myocardial infarction. Confirmation of active ischemia usually requires changes in at least two leads. It has been estimated that approximately 30% of myocardial infarctions occur without symptoms ("silent infarctions") and can only be detected on routine electrocardiograms, with the highest incidence occurring in patients with either diabetes or hypertension. The Framingham study showed that long-term prognosis is not improved by lack of symptoms.[18] The absence of Q waves on the electrocardiogram does not exclude the occurrence of a Q-wave myocardial infarction in the past. It has been shown that 5 to 27% of Q waves disappear over the 10-year period following an infarction.[32] Those patients in whom the electrocardiogram reverts to normal have improved survival compared with those with consistent abnormalities, with or without Q waves. The presence of Q waves on a preoperative electrocardiogram in a high-risk patient, regardless of symptoms, should alert the anesthesiologist to the increased perioperative risk and the possibility of active ischemia.

It has not been established that information obtained from the preoperative electrocardiogram affects clinical care. A review of clinical studies on the matter is inconclusive. In a retrospective review of adult patients undergoing ambulatory surgery, the preoperative electrocardiogram was not predictive of perioperative risk.[33] Although controversy exists, current recommendations include the need for a preoperative electrocardiogram in the presence of systemic vascular disease (for example, those patients with hypertension or peripheral vascular disease), for males over 40 years of age and for females over 50.

Noninvasive Cardiovascular Testing

The exercise electrocardiogram has been the traditional method in the past for evaluating patients with suspected coronary artery disease. It represents the most cost-effective and least invasive method for detecting ischemia, with a sensitivity of 70 to 80% and a specificity of 60 to 75% for identifying coronary artery disease. A positive exercise stress test alerts the anesthesiologist that the patient is at risk for ischemia over a wide range of heart rates, with the greatest risk in those who develop ischemia only after mild exercise. However, as discussed previously, the ability to exercise suggests that no further testing is necessary, and therefore stress electrocardiography is infrequently indicated.

A number of high-risk patients are either unable to exercise or have contraindications to exercise, for example, those with claudication. Therefore, pharmacologic stress testing and ambulatory electrocardiography have come into vogue, particularly as preoperative cardiovascular tests in patients scheduled for vascular surgery. Pharmacologic stress thallium imaging is useful in those patients who are unable to exercise. Dipyridamole or adenosine is administered as a coronary vasodilator to assess flow heterogeneity. The presence of a redistribution defect is predictive of postoperative cardiac events, especially in patients undergoing peripheral vascular surgery (Fig. 18-4). Similarly, dopamine can be used to increase myocardial oxygen demand, by increasing heart rate and blood pressure, in those patients who cannot exercise.

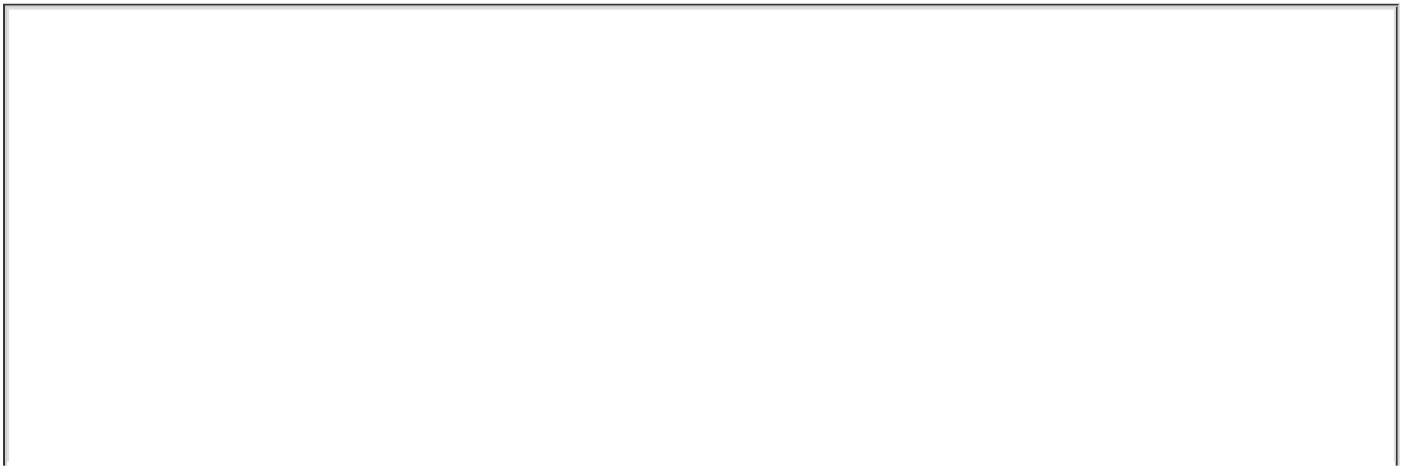

FIGURE 18-4. A dipyridamole-thallium SPECT image demonstrating a reversible defect. The top image demonstrates defects consistent with areas of low perfusion or ischemia, which fills in on subsequent imaging (*bottom*). (See upper left portion of image.)

The ambulatory ECG (Holter monitoring) provides a means of continuously monitoring the electrocardiogram for significant ST segment changes preoperatively. One study demonstrated that the presence of silent ischemia is a strong predictor of outcome, while its absence is associated with a favorable outcome in 99% of the patients studied.[34] Other investigators have demonstrated the value of ambulatory ECG monitoring, although the negative predictive values have not been as high as reported by some.

Stress echocardiography is another preoperative test that may be of value in evaluating patients with suspected coronary artery disease. The appearance of either new or more severe regional wall motion abnormalities with exercise is considered a positive test. Either represents areas at risk for myocardial ischemia. The advantage of the stress echocardiogram is that it is a dynamic assessment of ventricular function. Dobutamine echocardiography has also been studied and found to have among the best predictive values. It is generally accepted that the group at risk is comprised by those who demonstrate regional wall motion abnormalities at low heart rates.

Several groups have published meta-analyses of preoperative diagnostic tests. One group of

investigators demonstrated good predictive values using ambulatory ECG monitoring, radionuclide angiography, dipyridamole thallium imaging, or dobutamine stress echocardiography.[35] Shaw et al also demonstrated good predictive values of dipyridamole thallium imaging and dobutamine stress echocardiography.[36] Both of these studies demonstrated the superior value of dobutamine stress echocardiography; however, there was significant overlap of the confidence intervals with other tests. The most important determinant with respect to the choice of preoperative testing is the expertise of the local institution. The decision to perform further invasive testing should be based on the knowledge that the intervention will affect both short- and long-term outcomes.

Assessment of Ventricular and Valvular Function

Both echo and radionuclide angiography can assess cardiac ejection fraction at rest and under stress, but echo is less invasive and is also able to assess regional wall motion abnormalities, wall thickness, valvular function, and valve area. Pulse-wave Doppler can be used to determine the velocity time integral. Ejection fraction can then be calculated by determining the cross-sectional area of the ventricle. Conflicting results exist with regard to the predictive value of ejection fraction

using either echocardiographic or radionuclide measurements. Echocardiography can provide important information regarding valvular function, which may have important implications for either cardiac or noncardiac surgery, and is discussed more fully later in this text. Aortic stenosis has been associated with a poor prognosis in noncardiac surgical patients, and knowledge of valvular lesions may modify perioperative hemodynamic therapy.[9]

Coronary Angiography

Coronary angiography is currently the best method for defining coronary anatomy. In addition, information regarding ventricular and valvular function can also be assessed. Hemodynamic indices can be determined such as ventricular pressures and pressure gradients across valves. This information is routinely available in patients scheduled for coronary bypass grafting. Narrowing of the left main coronary artery and certain other lesions may be associated with a greater perioperative risk. Diffuse atherosclerosis in small vessels, as seen in diabetics, may lead to incomplete revascularization and a risk of developing ischemia despite coronary bypass grafting. Coronary angiography is used by cardiologists to determine whether coronary vascularization is an option.

Unlike the exercise or pharmacologic stress tests discussed earlier, coronary angiography provides anatomic, not functional, information. Although a critical coronary stenosis delineates an area of risk for developing myocardial ischemia, the functional response of that ischemia cannot be assessed by angiography alone. A critical stenosis may or may not be the underlying cause for a perioperative myocardial infarction that occurs. In the ambulatory population, many infarctions are the result of acute thrombosis of a noncritical stenosis. Therefore, the value of routine angiography prior to noncardiac surgery depends on the identification of lesions that will cause morbidity and mortality.

The American College of Physician Guidelines attempt to apply the evidence-based approach.[37] The initial decision point is the assessment of risk using the Detsky modification of the CRI.[10] If patients are Class II or III, they are considered high risk. If they are Class I, the presence of other clinical factors can be used to further stratify risk. Those who exhibit multiple markers for cardiovascular disease according to these risk indices and who are undergoing major vascular surgery are considered appropriate for further diagnostic testing, either by dipyridamole imaging or by dobutamine stress echocardiography. The Guidelines suggest that there is insufficient evidence to recommend diagnostic testing for nonvascular surgery patients.

Perioperative Coronary Interventions

The strategies to reduce the perioperative risk of noncardiac surgery have recently been studied. There are several large studies that suggest that in patients who survive CABG, the risk of

subsequent noncardiac surgery is low.[5,8] While there is little data to support the notion of coronary revascularization solely for the purpose of improving perioperative outcome, it is true that for some patients scheduled for high-risk surgery long-term survival may be enhanced by revascularization. Two studies utilized the Coronary Artery Surgery Study database and found that CABG significantly improved survival in those patients with both peripheral vascular disease and triple-vessel coronary disease, especially the group with depressed ventricular function.[6] After reviewing all available data, most clinicians believe the indication for CABG prior to noncardiac surgery remains the same as in other settings and is independent of the proposed noncardiac surgery.

The value of percutaneous translumimal coronary angioplasty (PTCA) is less well established. The current evidence does not support the use of PTCA beyond established indications for nonoperative patients.

Coronary stent placement may be a unique issue. In a case series of 39 patients who had undergone coronary stent placement within 1 month of noncardiac surgery there was a significant incidence of perioperative death and hemorrhage for patients who had surgery within 14 days of stent placement.[31] The authors of the ACC/AHA Guideline recommended waiting a minimum of 2 weeks, and preferably 4 weeks.

PULMONARY DISEASE

Introduction

Pulmonary complications remain a major cause of morbidity and mortality for patients undergoing surgery and anesthesia. They occur more frequently than cardiac complications, with an incidence of 5 to 10% in those having major noncardiac procedures. Perioperative pulmonary complications include atelectasis, pneumonia, bronchitis, bronchospasm, hypoxemia, and respiratory failure requiring mechanical ventilation.[38]

The site and type of surgery are the strongest predictors of complications. With regard to the surgical *site*, thoracic or

upper abdominal surgery is associated with the highest risk for postoperative pulmonary problems. Risk increases as the incision approaches the diaphragm.[38,39,40] Decreases in postoperative vital capacity and functional residual capacity, as well as diaphragmatic dysfunction, contribute to hypoxemia and atelectasis.[41] Functional residual capacity may take up to 2 weeks to return to baseline. Diaphragmatic dysfunction occurs despite adequate analgesia and is theorized to be because of phrenic nerve inhibition.[42] The *types* of surgery carrying the highest risks were AAA repair, thoracic, and upper abdominal surgery, followed by neck, peripheral vascular, and neurosurgery. Neurosurgery and neck surgery may be associated with perioperative aspiration pneumonia.

The need for emergency surgery and the need for general anesthesia are also associated with a slightly increased risk. Not only can the surgery affect pulmonary function, but general anesthesia also results in mechanical changes such as a decrease in the FRC and altered diaphragmatic motion leading to

$$\dot{V}/\dot{Q}$$

mismatch with shunting and dead space ventilation. General anesthesia also aggravates these changes by its effects at the microscopic level: inhibition of mucociliary clearance, increased alveolar-capillary permeability, inhibition of surfactant release, increased nitric oxide synthetase, and increased sensitivity of the pulmonary vasculature to neurohumoral mediators. Subanesthetic levels of intravenous or volatile agents have the ability to blunt the ventilatory response to hypoxemia and hypercarbia. Duration of anesthesia is a well-established risk factor for postoperative pulmonary complications, with morbidity rates increasing after 2 to 3 hours.[43] However, although laparoscopic surgery is often longer in duration, the decreased pulmonary

complications postoperatively compared to an open procedure usually outweigh the risks of increased anesthesia time.[44]

PATIENT-RELATED FACTORS (TABLE 18-7)

TABLE 18-7 Potential Patient-Related Risk Factors for Postoperative Pulmonary Complications

·POTENTIAL RISK FACTOR	·TYPE OF SURGERY	·UNADJUSTED RELATIVE RISK WITH ASSOCIATED FACTOR
Smoking	Coronary bypass	3.4
	Abdominal	1.4–4.3
ASA Class > II	Unselected	1.7
	Thoracic or abdominal	1.5–3.2
Age > 70 yr	Unselected	1.9–2.4
	Thoracic or abdominal	0.9–1.9
Obesity	Unselected	1.3
	Thoracic or abdominal	0.8–1.7
COPD	Unselected	2.7–3.6
	Thoracic or abdominal	4.7

ASA, American Society of Anesthesiologists; COPD, chronic obstructive pulmonary disease.

Adapted from Smetana GW: Preoperative pulmonary evaluation. N Engl J Med 340 (12):942, 1999.

Preoperative evaluation of patients with preexisting pulmonary disease should include assessment of the type and severity of disease, as well as its reversibility. Because clinical observations are often the best predictors for the development of postoperative pulmonary complications, a careful history and physical examination is imperative. The anesthesiologist should inquire about exercise

intolerance, chronic cough, or unexplained dyspnea. On physical exam, findings of wheezing, rhonchi, decreased breath sounds, dullness to percussion, and a prolonged expiratory phase are important. Preoperative pulmonary function testing is usually reserved for those scheduled for lung resection, or for those scheduled for major surgery who have unexplained pulmonary signs and symptoms after a careful history and physical examination. Early intervention helps to ensure that the patient's medical status is optimal prior to surgery.

Tobacco

The use of tobacco is an important risk factor, but one that usually cannot be influenced. Even among smokers who have not developed chronic lung disease, smoking is known to increase carboxyhemoglobin levels, decrease ciliary function and increase sputum production, as well as cause stimulation of the cardiovascular system secondary to the nicotine. While cessation of smoking for 2 days can decrease carboxyhemoglobin levels, abolish the nicotine effects, and improve mucous clearance, a prospective study by Warner showed that smoking cessation for at least 8 weeks was necessary to reduce the rate of postoperative pulmonary complications.[45] Because smokers often show increased airway reactivity under general anesthesia, it is useful to administer a bronchodilator such as albuterol preoperatively.

Asthma

Asthma is one of the most common coexisting diseases that confronts the anesthesiologist. During the patient interview it is important to elicit information regarding inciting factors, severity, reversibility, and current status. Frequent use of bronchodilators, hospitalizations for asthma, and the requirement for systemic steroids are all indicators of the severity of the disease. After an episode of asthma, airway hyperreactivity may persist for several weeks.[46] In addition to bronchodilators, perioperative steroids are worth considering as prophylaxis for the severe asthmatic; for example, hydrocortisone 100 mg intravenously every 8 hours on the day of surgery. The possibility of adrenal insufficiency is also a concern in those patients who have received more than a "burst and taper" of steroids in the previous 6 months. This group of patients should be administered "stress doses" of steroids perioperatively. Kabalin et al found there was a low complication rate for asthmatics treated with short-term steroids undergoing surgery.[47] Significantly, they found no association with impaired wound healing or infections. For patients using inhaled steroids, they should be administered regularly starting at least 48 hours prior to surgery for optimal effectiveness.

Endocrine Disease

Diabetes mellitus is the most common endocrinopathy and has acute and chronic disease manifestations. Because of this and other factors, diabetics are more likely to require surgery. Some recent studies in the critical care literature have sparked a trend toward tighter perioperative glucose control, especially in diabetics. Because the majority of diabetics develop disease in one or more systems, end-organ disease must be identified and managed carefully in the perioperative period. While long-term, close control of glucose may limit some of the microvascular effects of diabetes (retinopathy, neuropathy, and nephropathy), macrovascular events, such as myocardial infarctions or

stroke, may not be altered in incidence. Diabetics have an increased risk of coronary artery disease, perioperative myocardial infarction, hypertension, and congestive heart failure. In addition, they are more likely than the general population to have cerebral vascular, peripheral vascular, and renal vascular disease. Myocardial infarction or ischemia may be "silent" if diabetic autonomic neuropathy is present. A high index of suspicion for myocardial ischemia or past infarction should be maintained throughout the preoperative period. Administration of perioperative beta-blockers should be considered in diabetic patients with coronary artery disease to help limit perioperative myocardial ischemia. Some may have concerns regarding the use of beta-blockade in diabetics as a result of the fears of worsening glucose intolerance and masking hypoglycemic symptoms. Despite the controversy, many clinicians believe diabetics benefit at

least as much as the general population in receiving perioperative beta-blockers. Significant renal disease develops commonly in diabetics, many times necessitating chronic dialysis. Peripheral and autonomic neuropathies are common in diabetics. These deficits should be documented prior to anesthesia and surgery with the anesthetic plan adjusted accordingly. Joint rigidity (stiff joint syndrome) may significantly affect the temporomandibular, atlantooccipital, and cervical spine joints in patients with long-standing type 1 diabetes. The joint limitation may result in difficulty with intubation and should be identified prior to anesthesia and airway manipulation.

Thyroid and parathyroid disease have clinical manifestations that are important to the preoperative evaluation (Table 18-8). Thyroid disease is usually adequately evaluated by clinical history, although of course, the thyroid function tests are more sensitive. The preoperative evaluation should focus on evaluating the signs and symptoms of hyperthyroidism and hypothyroidism. Hypothyroidism can lead to the development of hypothermia, hypoglycemia, hypoventilation and hyponatremia, as well as a susceptibility to depressant drugs. Anesthesiologists should be alerted to the possibility of the hypermetabolic state of thyroid storm in patients with hyperthyroidism. A large thyroid mass may distort the upper airway, producing wheezing, especially evident in the supine position. In these cases, a chest x-ray should be obtained looking for evidence of tracheal deviation or narrowing. A computed tomography (CT) scan of the upper airway and trachea will provide better detail of any airway compromise. Patients with hyperparathyroidism often have hypercalcemia, indicating preoperative determination of a serum calcium level. The classic findings for pheochromocytoma include intermittent hypertension, headache, diaphoresis, and tachychardia. In patients with other endocrine tumors, a pheochromocytoma should be ruled out as the cause of unexplained hypertension as part of a multiple endocrine neoplasia syndrome. The preoperative preparation of a patient with a pheochromocytoma is fully discussed in Chapter 41. Over time the mortality for surgical resection of a pheochromocytoma has decreased because of improvements in perioperative therapy for patients with the syndrome. The important issue is to identify patients with a pheochromocytoma preoperatively before they are scheduled for other types of surgery. In patients on long-term corticosteroids, one should have a high index of suspicion for adrenal-cortical suppression and Cushing's syndrome. The hallmark symptoms found in Cushing's syndrome include moon facies, striations of the skin, trunk obesity, hypertension, easy bruisability, and hypovolemia. The preoperative preparation includes correction of the fluid and electrolyte abnormalities. There is consensus that for patients taking corticosteroids for long periods that perioperative steroid supplementation is indicated to cover the stresses of anesthesia and surgery. However, in patients who have had only a short course of steroids within the 12 months prior to surgery, the use of steroid supplementation is controversial, although most clinicians would favor their use preoperatively (Table 18-9).

TABLE 18-8 Clinical Manifestations of Thyroid and Parathyroid Diseases

	·HYPERTHYROIDISM	·HYPOTHYROIDISM	·HYPERPARATHYROIDISM
General	Weight loss; heat intolerance; warm, moist skin	Cold intolerance	Weight loss, polydipsia
Cardiovascular	Tachycardia, atrial fibrillation, congestive heart failure	Bradycardia, congestive heart failure, cardiomegaly, pericardial or pleural effusion	Hypertension, heart block

Neurologic	Nervousness, tremor, hyperactive reflexes	Slow mental function, minimal reflexes	Weakness, lethargy, headache, insomnia, apathy, depression
Musculoskeletal	Muscle weakness, bone resorption	Large tongue, amyloidosis	Bone pains, arthritis, pathologic fractures
Gastrointestinal	Diarrhea	Delayed gastric emptying	Anorexia, nausea, vomiting, constipation, epigastric pain
Hematologic	Anemia, thrombocytopenia		
Renal		Impaired free water clearance	Polyuria, hematuria

TABLE 18-9 Perioperative Corticosteroid Coverage

For minor surgery	The patient should take 1.5–2 times his or her usual prednisone dosage on the morning of surgery. The following day the patient should take his or her normal prednisone dose (or parenteral equivalent if gut cannot be used). The surgeon and anesthesiologist should be aware that the patient is glucocorticoid dependent and should be prepared to administer more "steroids" if the surgery becomes prolonged or more extensive.
For moderate surgery	The patient should be given 2 times his or her usual glucocorticoid dosage orally (if possible) on the morning of surgery and/or 25 mg hydrocortisone iv before the operation, then 75 mg hydrocortisone iv during the operation, and 50 mg hydrocortisone iv after the operation; then the dose should be rapidly tapered over 48 hr to the usual dose—if the postoperative course is uncomplicated.
For major surgery	The patient should be given 2 times his or her usual glucocorticoid dosage orally (if possible) on the morning of surgery and/or 50 mg hydrocortisone iv before the operation, then 100 mg hydrocortisone iv during the operation. After the operation, 100 mg iv q 8 hr × 24 hr should be administered and then rapidly tapered (over 48–72 hr) to the patient's usual glucocorticoid dosage—if the postoperative course is uncomplicated.

Other Organ Systems

Renal disease has important implications for fluid and electrolyte management, as well as metabolism of drugs (see Chapter 35). Liver disease is associated with altered protein binding and volume of distribution of drugs, as well as coagulation abnormalities (see Chapter 39). Coagulation disorders may influence the choice of regional anesthesia. The anesthesiologist should inquire about bruising, bleeding, and the use of medications that influence platelet function such as aspirin, other nonsteroidal anti-inflammatory drugs, and anticoagulants. The perioperative management of hemoglobinopathies is reviewed in Chapter 19. Musculoskeletal disorders have been associated with an increased risk of malignant hyperthermia. Osteoarthritis may result in difficulty exposing the glottic opening for tracheal intubation or difficulty in positioning for regional anesthetic. Because rheumatoid arthritis is a multisystem disease, it is important in such patients to perform a thorough review of systems. These patients may have restrictive lung disease, pleural effusions, pericarditis, anemia, and atlantooccipital instability. Finally, the anesthesiologist should inquire about

infectious diseases such as HIV or antibiotic-resistant infections.

PREOPERATIVE LABORATORY TESTING

The Value of Preoperative Testing: Normal Values

5 In attempting to determine the optimal choice of preoperative tests, it is important to understand the interpretation of the results. Ideally, tests would either confirm or exclude the presence of a disease; however, the vast majority of tests only increase or decrease the probability of disease. In determining reference ranges for diagnostic tests, values that fall outside of the 95% confidence intervals for normal individuals are considered abnormal. Therefore, up to 5% of normal individuals can have "abnormal" test results. To determine its clinical relevance, a test must be interpreted within the context of the clinical situation. Performing tests in patients with no risk for having the pathophysiologic process of interest can yield a high number of false-positive results. For example, a low potassium (3.0 mg/dL) in an otherwise healthy individual is most likely a normal result. Interpreting this test as abnormal, and initiating treatment, could lead to harm without any benefit.

THE VALUE OF PREOPERATIVE TESTING: BAYESIAN ANALYSIS

The use of noninvasive testing is another area in which the clinical situation significantly affects the interpretation. It is rare for a test result to be pathognomonic for a disease state; that is, no test is 100% sensitive and specific. For example, exercise or pharmacologic stress testing has sensitivities ranging from 60 to 90% and specificities ranging from 60 to 80% for a significant

coronary artery stenosis. To interpret the results of a noninvasive test, it is important to know the prevalence of disease in the population as well as the sensitivity and specificity of the test. If a test is used in a population with a very low prevalence of disease, a positive result is frequently a false-positive. Similarly, a negative result in a population with a very high prevalence of disease may be a false-negative. Bayes' theorem suggests a test is most useful in a population with a moderate probability of disease.[75]

RISKS AND COSTS VERSUS BENEFITS

The use of medical testing is associated with significant cost, both in real dollars and in potential harm. Routine preoperative testing has been estimated to cost $3 billion annually. An "abnormal" test that is later determined to be a false result can lead to significant cost and real harm. For example, a positive exercise electrocardiographic stress test in a healthy 40-year-old female may lead to coronary angiography. Coronary angiography is not a benign procedure, and can lead to vascular injuries. Based on Bayesian analysis, a positive test result in this patient is most likely a false-positive, and the test was inappropriately used. Therefore, the woman and her physician would gain no additional information, thousands of dollars in medical costs would accrue, and she would sustain morbidity.

Several studies have evaluated the implications of reduced testing. Golub et al retrospectively reviewed the records of 325 patients who had undergone pre-admission testing prior to ambulatory surgery.[48] Of these, 272 (84%) had at least one abnormal screening test result, while only 28 surgeries were delayed or canceled. The authors estimated that only three patients potentially benefited from pre-admission testing, including a new diagnosis of diabetes in one and nonspecific ECG changes in two, one of which had known ischemic heart disease.

In a study published in 1991, Narr and colleagues at the Mayo Clinic demonstrated minimal benefits from routine testing and proposed that routine laboratory screening tests were not required in healthy patients.[49] In a follow-up study published in 1997, a cohort of patients who had no preoperative testing during 1994 was reviewed and found to include no deaths or major perioperative morbidity.[50] They concluded that current anesthetic and medical practices rapidly identify indications for laboratory evaluation when necessary and therefore routine testing was not indicated in this healthy cohort.

Even if testing better defines a disease state, the risks of any intervention based upon the results may outweigh the benefit. Cardiovascular testing is a classic example (Fig. 18-5). If a noninvasive test is positive, coronary angiography may be performed. A positive angiogram may then result in coronary artery bypass grafting prior to the planned noncardiac surgery. Although cardiovascular morbidity and mortality may be reduced in patients with significant coronary artery disease who have undergone coronary revascularization, the morbidity associated with both the testing and revascularization procedure may be greater than any potential benefit.

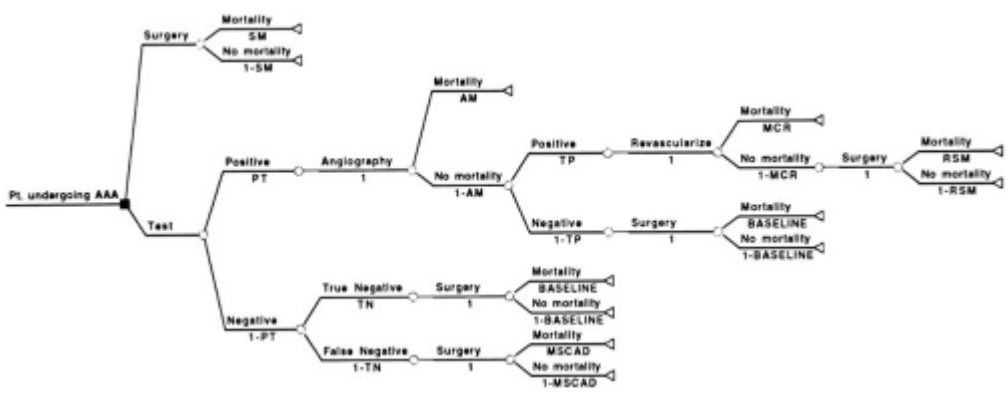

FIGURE 18-5. A decision algorithm evaluating the decision between vascular surgery alone or coronary artery revascularization before vascular surgery. There are currently no randomized trials to address the optimal strategy. By outlining the multiple decision points at which a patient can sustain mortality by choosing to undergo coronary revascularization first, the optimal strategy for preoperative evaluation can be demonstrated. Specifically, variation in mortalities at each decision point can change the optimal strategy. (Reproduced with permission from Fleisher LA, Skolnick ED, Holroyd KJ, Lehmann HP: Coronary artery revascularization before abdominal aortic aneurysm surgery: A decision analytic approach. Anesth Analg 79:661, 1994.)

Roizen and Cohn have suggested a protocol for screening tests based on the preoperative evaluation using a benefit–risk analysis.[51]

Complete Blood Count and Hemoglobin Concentration

The use of a preoperative hemoglobin has been suggested as the only test necessary in many patients prior to elective surgery; however, even this minimal standard has been questioned. Baron et al reviewed the records of 1,863 pediatric patients scheduled for elective outpatient procedures.[52] In only 1.1% of patients was the hematocrit abnormal, and in none of these patients was the procedure canceled or anesthetic plan

modified. However, a baseline hematocrit is still indicated in any procedure with a risk of blood loss.

The standard regarding the lowest acceptable perioperative hematocrit and indication for a preoperative transfusion has changed during the past decade. The current recommendations of the National Blood Resource Education Committee is that a hemoglobin of 7 g/dL is acceptable in patients without systemic disease. In patients with systemic disease, signs of inadequate systemic oxygen delivery (tachycardia, tachypnea) are an indication for transfusion.

Electrolytes

In the past, patients routinely received a chemistry panel prior to surgery. Because of technology issues, it may be cheaper to obtain a standard battery than to determine one particular test. However, testing rarely leads to any change in perioperative management.

There are numerous guidelines regarding the need for preoperative electrolytes. The only consensus is the lack of routine testing in asymptomatic adults, although a creatinine and glucose has been recommended in older patients. In patients with systemic diseases or on medications that affect the kidneys, a BUN and creatinine are indicated.

Coagulation Studies

Coagulation disorders can have significant impact on the surgical procedure and perioperative management. However, abnormal laboratory studies in the absence of clinical abnormalities will rarely lead to perioperative problems. Patients with known inherited coagulopathies, such as hemophilia or von Willebrand's disease, require preoperative preparation of the patient. It is important to identify such disorders from or history of bleeding problems. A prothrombin, partial thromboplastin time analysis is indicated in the presence of previous bleeding disorders such as following injuries; after tooth extraction or surgical procedures; and in patients with known or suspected liver disease, malabsorption or malnutrition, and on certain medications such as antibiotics and chemotherapeutic agents.

Bleeding time previously was advocated as a means of determining the presence of a qualitative platelet defect. However, recently clinicians have questioned the value of this test in clinical practice. The test is extremely operator dependent, and some authors have suggested that the test should be abandoned in favor of clinical history. In the absence of a clinical bleeding diathesis, complications are extremely rare. If such a history exists, it may be prudent to avoid regional anesthesia.

Pregnancy Testing

Routine pregnancy testing in women of child-bearing potential is a subject of considerable debate. The rationale is that specific agents may be avoided, or surgery may be delayed. Information regarding the last menstrual period can help define the potential, but does not eliminate the possibility. Roizen and Cohn suggest that pregnancy testing should be limited to females who believe they are pregnant or cannot tell if they are pregnant.[51] However, a number of studies have evaluated the validity of history as a means of assessing pregnancy status in adolescents with conflicting results. Current practice varies dramatically among centers and anesthesiologists and

may be a function of the population served with regard to the need to routinely test those women with a negative pregnancy history.

Chest X-Rays

A preoperative chest x-ray can identify abnormalities that may lead to either delay or cancellation of the planned surgical procedure or modification of perioperative care. For example, identification of pneumonia, pulmonary edema, pulmonary nodules, or a mediastinal mass could all lead to modification of care. However, routine testing in the population without risk factors can lead to more harm than benefit. Roizen and Cohn have demonstrated substantial harm from additional procedures based on shadows performed solely as a routine preoperative chest x-ray.[51]

The American College of Physicians suggests that a chest x-ray is indicated in the presence of active chest disease or an intrathoracic procedure, but not solely on the basis of advanced age alone.[53] Other guidelines suggest that a preoperative chest x-ray is reasonable in patients over the age of 60 years. In a meta-analysis, Archer et al reviewed the published reports from 1966 to 1992 in the English, French, and Spanish literature.[54] Twenty-one reports were identified with sufficient data to evaluate the use of testing. On average, abnormalities were reported in 10% of routine preoperative chest x-rays, of which only 1.3% were unexpected. These findings result in modification in management in only 0.1% of patients, with unknown influence on outcome. The authors estimated that each finding that influenced management would cost $23,000, concluding that routine chest x-rays without a clinical indication were not justified. Therefore, a preoperative chest x-ray is indicated in patients with a history or clinical evidence of active pulmonary disease, and *may* be indicated routinely only in patients with advanced age.

Pulmonary Function Tests

Pulmonary function tests can be generally divided into two categories, spirometry and an arterial blood gas. Spirometry can provide information on forced vital capacity (FVC), forced expiratory volume in 1 sec (FEV_1), ratio of FEV_1/FVC, and average forced expiratory flow from 25 to 75%. Although each of these measures has a sound physiologic basis, their practical assessment can vary greatly among healthy persons. Objective measures defining high risk for pulmonary resection have been proposed. For nonpulmonary surgery, they rarely provide additional information beyond that obtained from history. The one possible indication is the use of pulmonary function testing with bronchodilator therapy to assess responsiveness in a patient who is wheezing.

With the advent of the pulse oximeter, the use of preoperative arterial blood gas sampling has become less important. It may still be indicated, since determining the baseline CO_2 is useful in managing postoperative ventilation settings and resting hypercapnia is associated with increased perioperative risk. However, the physical act of obtaining an arterial blood gas can lead to hyperventilation and change the $PaCO_2$. One method of assessing the probability of CO_2 retention is evaluation of the serum bicarbonate. A normal serum bicarbonate will virtually exclude the diagnosis of CO_2 retention. If the serum bicarbonate is elevated, then an arterial blood gas either preoperatively or immediately prior to induction may be indicated.

Another indication for an arterial blood gas has been determination of oxygen concentration. With the advent and availability of pulse oximetry in the preoperative screening clinic, this is rarely an indication.

SUMMARY

The preoperative evaluation of the surgical patient continues to be an important component of the anesthesiologist's role. A thorough history and physical examination can be used to identify those medical conditions that might affect perioperative management and direct further laboratory testing. In the current era of capitated care and the desire to reduce inappropriate utilization of medical technology, the anesthesiologist can have a significant impact on health resource

utilization by performing appropriate laboratory tests. By combining data from the history, physical examination, exercise tolerance, and the stress of the surgical procedure, inappropriate testing can be reduced; but more importantly, appropriate screening tests will be performed.

PREOPERATIVE MEDICATION

6 Anesthetic management for patients begins with preoperative psychological preparation and, if necessary, preoperative medication. Specific pharmacologic actions should be kept in mind when these drugs are administered before operation, and they should be tailored to the needs of each patient. The anesthesiologist should assess the patient's mental and physical condition during the preoperative visit. Because it is part of and the beginning of the anesthetic, choice of preoperative medication is based on the same considerations as the choice of anesthesia, including the patient's medical problems, requirements of the surgery, and the anesthesiologist's skills. Satisfactory preoperative preparation and medication facilitate an uneventful perioperative course. Poor preparation may begin a series of problems and misadventures.

No consensus exists on the choice of preoperative medications. Their use has been dominated by tradition, which has been modified somewhat by the change in anesthetic agents and techniques over the years. Beecher stated that "empirical procedures firmly established in the habits of good doctors have a life, not to say, immortality of their own."[55] Similarly, "the emotional attachment of an anesthesiologist to his own regimen is often more obvious than his objective assessment of its effects."[56] Another reason for lack of consensus may be that several different drugs or combinations of drugs can accomplish the same goals. However, there is general agreement that most patients should enter the operating room after anxiety has been relieved and other specific goals have been met through preoperative preparation and medication. This should be accomplished without undue sedation, which can interfere with patient safety or, given the dramatic increase in the number of outpatient surgical procedures, prolong length of stay in the operating room.

PSYCHOLOGICAL PREPARATION

7 Psychological preparation of the patient involves the preoperative visit and interview with the patient and family members. The anesthesiologist should explain anticipated events and the proposed anesthetic management in an effort to reduce anxiety and allay apprehension. Patients may perceive the day of surgery as the biggest, most threatening day in their lives; they do not wish to be treated impersonally in the operating room. The anesthesiologist's first direct encounter with the patient may be in the immediate preoperative period. A growing number of patients receive their pre-anesthetic evaluations by others in preoperative evaluation clinics or just prior to surgery. Preoperative visits must be conducted efficiently, but they must also be informative and reassuring, answering all questions. Most of the anesthesiologist's time is spent with an unconscious or sedated patient; therefore, he or she must take time before the operation to earn the trust and confidence of that patient.

Most patients are anxious before surgery. Studies show that, depending on the intensity of inquiry, from 40 to 85% of patients are apprehensive before surgery. Preoperative anxiety states are at a high level, and most patients expect apprehension to be relieved before they arrive in the operating room. The classic study by Egbert et al showed that an average of 57% of patients felt anxious before operation.[57] An informative and comforting preoperative visit may replace many milligrams of depressant medication. For example, the study by Egbert and colleagues showed that more patients were adequately prepared for surgery after a preoperative interview than after 2 mg/kg of pentobarbital given intramuscularly 1 hour before surgery (see Table 18-10).[57] However, psychological preparation cannot accomplish everything and will not relieve all anxiety. Besides psychological preparation, there are other goals of preoperative medication. Control of pain and satisfactory levels of amnesia or sedation cannot be achieved with consistent success at the preoperative visit alone. In addition, emergency situations may provide little or no time for a preoperative interview. More seriously ill or elderly patients, conversely, may not tolerate the physiologic effects of sedative medications. Always remember that the substitution of preoperative

depressant drugs for a comforting and tactful preoperative visit may compromise patient safety.

PHARMACOLOGIC PREPARATION

The ideal drug or combination of drugs for preoperative pharmacologic preparation is as elusive as is the ideal anesthetic techniques and is not based on a large body of data that is either definitive or persuasive. Routine administration of the same drugs to all patients has fallen into disfavor as a selective approach has emerged. In selecting the appropriate drugs for preoperative medication, the patient's psychological condition, physical status, and age must be considered. The surgical procedure and its duration are important factors, as well. Is this an outpatient procedure? Is it elective surgery or emergency surgery? The anesthesiologist must know the patient's weight, prior response to depressant drugs, including unwanted side effects, and allergies. Finally, the anesthesiologist's experience and familiarity with certain preoperative medications more than others are determinants.

8 The goals to be achieved for each patient with preoperative medication are intimately involved in the selection process (Table 18-11). The desired goals may be multiple and should

be tailored to the needs of each patient. Some of the goals, such as relief of anxiety and production of sedation, apply to almost every patient, whereas others are important only occasionally. Prophylaxis against allergic reactions applies in just a few instances. Prevention of autonomic reflexes mediated through the vagus nerve or an antiemetic effect may be better attempted immediately before the anticipated need rather than achieved at the time of preoperative medication. Preoperative medication regimens do not produce sufficient obtundation to be clinically significant in reducing anesthetic requirement. Some patients should not receive depressant drugs before surgery. Patients with little physiologic reserve, at the extremes of age, with a head injury, or with hypovolemia may be harmed more than helped by many of the medications normally used before operation. In contrast, the conditions of others demand that attempts be made pharmacologically to reduce anxiety, provide analgesia, or dry secretions in the airway to produce a safer perioperative course. For elective surgery, the anesthesiologist will, in most instances, want the patient to enter the operating room free of anxiety and sedated, yet

easily arousable and cooperative. The patient should not be overly obtunded or display other unwanted side effects of the preoperative drugs. The patient who asks to be "asleep" before leaving the hospital room should be told that apprehension and sedation may be reduced but it would be unsafe to produce a comatose state. The time and route of administration of the preoperative medications are important. As a general rule, oral medications should be given to the patient 60 to 90 minutes before arrival in the operating room. It is acceptable to administer oral drugs with up to 150 mL of water.[58] Intravenous agents produce effects after a few circulation times, while for full effect, intramuscular medications should be given at least 20 minutes and preferably 30 to 60 minutes before the patient's arrival in the operating room. Every attempt should be made to have the preoperative medications achieve their full effect before the patient's arrival in the operating room rather than after induction of anesthesia. The drug(s), doses, route of administration, and effects should be recorded on the anesthetic record. A list of common preoperative medications is presented in Table 18-12.

TABLE 18-11 Various Goals for Preoperative Medicine

1. Relief of anxiety
2. Sedation
3. Amnesia
4. Analgesia
5. Drying of airway secretions
6. Prevention of autonomic reflex responses
7. Reduction of gastric fluid volume and increased pH
8. Antiemetic effects
9. Reduction of anesthetic requirements
10. Facilitation of smooth induction of anesthesia
11. Prophylaxis against allergic reactions

Sedative–Hypnotics and Tranquilizers

Benzodiazepines

Benzodiazepines are among the most popular drugs used for preoperative medication (Table 18-13). They are used to produce anxiolysis, amnesia, and sedation. Because the site of action of benzodiazepines is on specific receptors in the central nervous system (Fig. 18-6) there is relatively little depression of ventilation or of the cardiovascular system with premedicant doses. Benzodiazepines have a wide therapeutic index and a low incidence of toxicity. Other than central nervous

system depression, there are few side effects of this group of drugs. Specifically, nausea and vomiting are not usually associated with administration of benzodiazepines for preoperative medication.

TABLE 18-13 Comparison of Pharmacologic Variables of Benzodiazepines

	·DIAZEPAM	·LORAZEPAM	·MIDAZOLAM

Dose equivalent (mg)	10	1–2	3–5
Time to peak effect after oral dose (hr)	1–1.5	2–4	0.5–1
Elimination half-time (hr)	20–40	10–20	1–4
Clearance (mL/kg/min)	0.2–0.5	0.7–1.0	6.4–11.1
Volume of distribution (L/kg)	0.7–1.7	0.8–1.3	1.1–1.7

Adapted from Reves JG, Fragen RJ, Vinick HR *et al*: Midazolam: Pharmacology and uses. Anesthesiology 62:310, 1985; and Stoelting RK: Pharmacology and Physiology in Anesthetic Practice. Philadelphia, JB Lippincott, 1987.

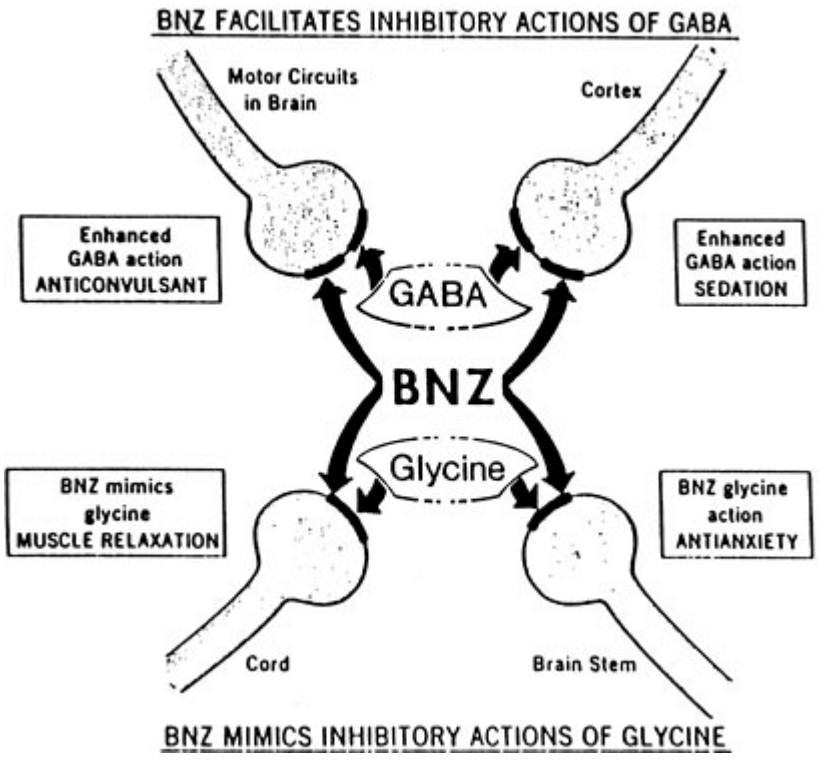

FIGURE 18-6. Schematic diagram of possible mechanisms for pharmacologic effects of benzodiazepines (BNZs). GABA, γ-aminobutyric acid. (Reprinted from Richter JJ: Current theories about the mechanisms of benzodiazepines and neuroleptic drugs. Anesthesiology 54:66, 1981.)

There are some hazards and unwanted side effects of the benzodiazepines. The central nervous system depression they cause is sometimes long and excessive, especially with use of lorazepam. There may be pain at the intramuscular or intravenous injection site with diazepam, as well as the

possibility of phlebitis. These drugs are not analgesic agents. Benzodiazepines may not always produce a calming effect but may cause agitation, as evidenced by restlessness and delirium.

Diazepam. While diazepam is often the standard against which other benzodiazepines are compared, it has largely been replaced. Because it is insoluble in water and must be dissolved in organic solvents, pain may occur on intramuscular or intravenous injection. Phlebitis is often a sequela of intravenous injection.

Lorazepam. Lorazepam resembles oxazepam structurally and is 5 to 10 times as potent as diazepam. Lorazepam can produce profound amnesia, relief of anxiety, and sedation (Fig. 18-7).[59] When lorazepam is compared with diazepam, their effects are very similar. Although it is insoluble in water and requires a solvent such as polyethylene glycol or propylene glycol, administration of lorazepam, unlike diazepam, is not associated with pain on injection or phlebitis. Prolonged sedation is more likely after lorazepam administration. Even though the elimination half-life of diazepam is longer than that of lorazepam (20 to 40 hours versus 10 to 20 hours), the effect of diazepam may be shorter because it more rapidly dissociates from the benzodiazepine receptor.[60]

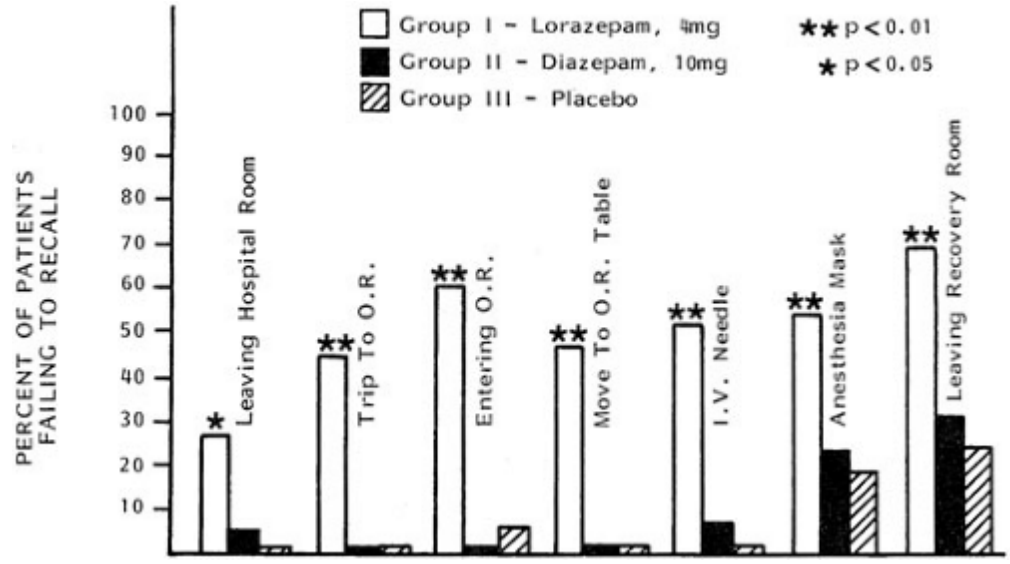

FIGURE 18-7. Percentage of patients in each group failing to recall specific events of the operative day. Medications were administered intramuscularly. (Reprinted with permission from Fragen RJ, Caldwell N: Lorazepam premedication: Lack of recall and relief of anxiety. Anesth Analg 55:792, 1976.)

Lorazepam is reliably absorbed both orally and intramuscularly. Maximal effect occurs 30 to 40 minutes after intravenous injection. Bradshaw et al demonstrated clinical effects 30 to 60 minutes after oral administration of lorazepam.[61] A study by Blitt et al demonstrated that lack of recall was not produced until 2 hours after intramuscular injection.[62] Peak plasma concentrations may not occur until 2 to 4 hours after oral administration. Therefore, lorazepam must be ordered well before surgery so that the drug has time to be effective before the patient arrives in the operating room. Lorazepam also may be given sublingually. As stated previously, the elimination half-life is 10 to 20 hours. The usual dose is about 25 to 50 μg/kg. The dose for an adult should usually not exceed 4.0 mg.[59,60] With recommended doses, anterograde amnesia may be produced for as long as 4 to 6 hours without excessive sedation. Higher doses lead to prolonged and excessive sedation without more amnesia. Because of its slow onset and length of action, lorazepam is not useful in instances in which rapid awakening is necessary, such as with outpatient anesthesia. There are no active metabolites of lorazepam; and because its metabolism is not dependent on microsomal enzymes, there is less influence on its effect from age or liver disease. As with diazepam, little cardiorespiratory depression occurs with lorazepam. However, there is the danger of unwanted

respiratory depression in those with lung disease.

Midazolam. Midazolam has predominantly replaced the use of diazepam for preoperative medication and conscious sedation. It is common to administer sedative doses intravenously just prior to the trip to the operating room. The physicochemical properties of the drug allow for its water solubility and rapid metabolism. As with other benzodiazepines, midazolam produces anxiolysis, sedation, and amnesia. It is two to three times as potent as diazepam because of its increased affinity for the benzodiazepine receptor. The usual intramuscular dose is 0.05 to 0.1 mg/kg and titration of 1.0 to 2.5 mg at a time intravenously. There is no irritation or phlebitis with injection of midazolam. The incidence of side effects after administration is low, although depression of ventilation and sedation may be greater than expected, especially in elderly patients or when the drug is combined with other central nervous system

depressants. There is more rapid onset of action and predictable absorption after intramuscular injection of midazolam than after diazepam. The time of onset after intramuscular injection is 5 to 10 minutes, with peak effect occurring after 30 to 60 minutes. The onset after intravenous administration of 5 mg would be expected to occur after 1 to 2 minutes. In addition to quicker onset, more rapid recovery occurs after midazolam administration compared with diazepam. This is probably the result of the lipid solubility of midazolam and its rapid distribution in the peripheral tissues and metabolic biotransformation. For these reasons, midazolam usually should be given within an hour of induction.[63] Midazolam is metabolized by hepatic microsomal enzymes to essentially inactive hydroxylated metabolites. H_2 receptor antagonists do not interfere with its metabolism. The elimination half-life of midazolam is approximately 1 to 4 hours and may be extended in the elderly. Tests show that mental function usually returns to normal within 4 hours of administration.[63] After administration of 5 mg, amnesia lasts from 20 to 30 minutes. Intramuscular administration may produce longer periods of amnesia. The lack of recall may be augmented by concomitant administration of scopolamine. The properties of midazolam make it ideal for shorter procedures.

Other Benzodiazepines. Oxazepam, another benzodiazepine that has been used for preoperative medication, is one of the pharmacologically active metabolites of diazepam. It is absorbed slowly after oral administration and has an elimination half-life of 5 to 15 hours. Temazepam has been given in oral doses of 20 to 30 mg before surgery. It must be given well before surgery because peak plasma levels do not occur until approximately 2 to 2.5 hours after administration. Triazolam is a short-acting benzodiazepine. The adult oral dose of the drug is 0.25 to 0.5 mg. Peak plasma concentrations occur in about 1 hour and its elimination half-life is 1.7 to 5.2 hours. The drug may become long-acting in the elderly. Similarly, a study by Pinnock et al did not show triazolam to be of short duration when compared with diazepam for premedication for minor gynecologic surgery.[64] Alprazolam (1 mg) given to adults has been shown to produce a modest reduction in anxiety before surgery.

Barbiturates

Use of barbiturates for preoperative medication is a time-tested practice with a long record of safety. These drugs are used primarily for their sedative effects. While barbiturate administration for pharmacologic preparation before surgery has been replaced in many instances by the use of benzodiazepines, they may be useful in certain settings. There is little cardiorespiratory depression associated with the usual preoperative doses. The barbiturates may be given orally as well as parenterally, and the drugs are relatively inexpensive. Barbiturates, however, are unlikely to produce sedation in the presence of pain. In fact, disorientation and paradoxical excitation may result. Low doses of barbiturates have been said to lower the pain threshold and be antianalgesic. The agents lack specificity of action on the central nervous system and have a lower therapeutic index than the benzodiazepines. Barbiturates should not be used in patients with certain kinds of porphyria.

Secobarbital. Secobarbital usually is administered to adults in oral doses of 50 to 200 mg when used for preoperative medication. Onset usually occurs 60 to 90 minutes after administration, and sedative effects last 4 hours or longer. Indeed, even though secobarbital traditionally has been

considered a "short-acting" barbiturate, it may impair performance for as long as 10 to 22 hours.[65]

Other Sedative Drugs

Hydroxyzine. Hydroxyzine is a nonphenothiazine tranquilizer. It is often given for its proposed additive effects to opioids and does not cause an increase in side effects. Hydroxyzine has sedative action and anxiolytic properties. It has limited analgesic properties and does not produce amnesia. It is an antihistamine and an antiemetic.

Diphenhydramine. Diphenhydramine is a histamine receptor antagonist with sedative and anticholinergic activity. It is also an antiemetic. A dose of 50 mg will last 3 to 6 hours in an adult. Diphenhydramine has been used recently in combination with cimetidine, steroids, and other drugs for prophylaxis in patients with chronic atopy and for prophylaxis before chemonucleolysis and dye studies. Diphenhydramine blocks the histamine receptor to prevent effects of histamine peripherally.

Phenothiazines. Promethazine, promazine, and perphenazine are often used in combination with opioids. Phenothiazines have sedative, anticholinergic, and antiemetic properties. These effects, added to the analgesic effects of the opioids, have been used for preoperative medication.

Opioids

Morphine and meperidine were historically the most frequently used opioids for intramuscular preoperative medication. Recently, the use of intravenous fentanyl just before surgery has become more popular. Opioids are used when analgesia is needed before operation. It has been stated in the strict sense that "unless there is pain, there is no need for narcotic in preanesthetic medication."[66] For the patient experiencing pain before operation, the opioids can produce good analgesia and even euphoria. Opioids have been ordered for patients before operation to ameliorate the discomfort that may occur during regional anesthesia or the insertion of invasive monitoring catheters or large intravenous lines. The dose of opioid may need to be reduced in the debilitated or elderly patient. The elderly patient often exhibits a reduced sensitivity to pain. Furthermore, elderly patients can have an increased analgesic response to opioids. Opioids also have been used before operation in the opioid-dependent patient.

Preoperative administration of opioids in other settings has been controversial. They have been given before surgery prior to a nitrous oxide–opioid anesthetic. This is done in an attempt to have a basal state of anesthesia on board when the patient arrives in the operating room and to get a preview of the patient's response to opioids. Opioids have been given to patients before operation to provide analgesia on their awakening in the recovery room. The other approach is to titrate the opioid intravenously during emergence or on the patient's arrival in the recovery room. Preoperative administration of opioids can lower anesthetic requirements. This may or may not be clinically significant for a specific patient receiving a particular anesthetic technique. Some anesthesiologists use opioids in combination with other drugs before operation to facilitate anesthetic induction by mask. It must be remembered that opioids decrease ventilation during spontaneous breathing and therefore decrease uptake of inhalation drugs. If necessary, the anesthesiologist may want to use assisted or controlled ventilation of the lungs to overcome the respiratory depressant effects of the opioids. Finally, opioids are not the best drugs to relieve apprehension, produce sedation, or prevent recall.

Administration of opioids has the potential for causing several side effects. Preoperatively, they usually exhibit no direct myocardial effects. However, opioids do interfere with the compensatory constriction of smooth muscles of the peripheral vasculature. This may lead to orthostatic hypotension. Histamine release after injection of morphine may compound these circulatory effects. As with most preoperative medications, it is probably safest to have the patient remain at bed rest after opioid premedication. The analgesic properties and respiratory

depressant effects of opioids usually go hand in hand. The decrease in the carbon dioxide drive at the medullary respiratory center may be prolonged. Furthermore, there is a decrease in the

responsiveness to hypoxia at the carotid body after injection of only low doses of opioids.[67] The anesthesiologist may wish to consider supplemental oxygen for the patient receiving opioid premedication. In general, the opioid agonist–antagonists produce less respiratory depression, but they also produce less analgesia. Rather than euphoria, the opioids may produce dysphoria. When this side effect does occur, it is most commonly seen in a patient who does not have pain before operation and has received the opioid premedication. Nausea and vomiting may result from opioid administration. The effect of opioids on the vestibular apparatus leading to motion sickness or stimulation of the medullary chemoreceptor trigger zone is a postulated reason for nausea and vomiting. Choledochoduodenal sphincter (sphincter of Oddi) spasm has occasionally been noted subsequent to injection of opioids. The opioid produces smooth muscle constriction, which leads to right upper quadrant pain. Pain relief may be achieved with naloxone or possibly glucagon. Occasionally, the pain from biliary tract spasm is difficult to differentiate from the pain of angina pectoris. The administration of nitroglycerin should relieve angina pectoris and pain resulting from biliary tract spasm; an opioid antagonist should relieve only pain resulting from biliary tract spasm. Some question the use of opioid premedication in patients with biliary tract disease. All opioids have the potential to induce choledochoduodenal sphincter spasm. Meperidine is less likely than morphine to produce this side effect. Opioids may produce pruritus. Morphine, possibly through histamine release, often produces itching, especially around the nose. Opioids also may cause flushing, dizziness, and miosis.

Other drugs are often combined with opioids for their additive effects or to overcome the disadvantages of opioid side effects. The sedative–hypnotics and scopolamine are often used with opioids to produce sedation, anxiolysis, and amnesia in addition to analgesia. In selected patients, the combination of morphine and a benzodiazepine or scopolamine may be useful for pharmacologic preoperative preparation.

Morphine

Morphine is well absorbed after intramuscular injection. The onset of effect should occur within 15 to 30 minutes. The peak effect occurs in 45 to 90 minutes and lasts as long as 4 hours. After intravenous administration, the peak effect usually occurs within 20 minutes. Morphine is not reliably absorbed after oral administration. As with the other opioids, depression of ventilation and orthostatic hypotension may occur after injection of morphine. The effect of morphine on the chemoreceptive trigger zone may produce nausea and vomiting. Nausea and vomiting may also occur owing to a vestibular component.

Meperidine

Meperidine is about one-tenth as potent as morphine. It may be given orally or parenterally. A single dose of meperidine usually lasts 2 to 4 hours. The onset after intramuscular injection is unpredictable, and a great deal of variability in time to peak effect exists.

Fentanyl

Fentanyl is a synthetic opioid agonist structurally similar to meperidine. It is 75 to 125 times more potent than morphine in its analgesic characteristics. The lipid solubility of fentanyl is greater than that of morphine, which contributes to its rapid onset of action. Peak plasma concentrations occur within 6 to 7 minutes following intravenous administration and its elimination half-time is 3 to 6 hours. The drug's short duration of action is attributed to redistribution to inactive tissues, such as the lungs, fat, and skeletal muscle. Metabolism occurs primarily by *N*-demethylation to norfentanyl, which is a less potent analgesic. A decreased clearance rate in the elderly may prolong elimination.

In doses of 1 to 2 μg/kg intravenously, fentanyl may be used to provide preoperative analgesia. Oral transmucosal fentanyl preparations of fentanyl are available, delivering 5 to 20 μg/kg of the drug. This form has been examined as a premedicant in both adults and children to relieve anxiety and pain. Because of a high incidence of preoperative nausea and vomiting, oral transmucosal fentanyl (in doses greater than 15 μg/kg) is not recommended in children younger than six years

of age.[68] Fentanyl causes neither myocardial depression nor histamine release, but may be associated with ventilatory depression and profound bradycardia. Synergistic effects with benzodiazepines warrant close observation when this combination is given in the preoperative period.

Opioid Agonist–Antagonists

Opioid agonist-antagonists have been chosen for preoperative medication in an attempt to reduce the ventilatory side effects of pure opioid agonists. However, there is a ceiling on the analgesia that can be produced by agonist–antagonist drugs. They are similar to the pure opioids with regard to side effects. In addition, dysphoria may be even more likely to occur after their administration. Another issue to remember is that the agonist–antagonist drug can reduce the effectiveness of a pure opioid agonist needed to control postoperative pain. The most commonly used opioid agonist–antagonists are pentazocine, butorphanol, and nalbuphine.

Gastric Fluid pH and Volume

Many patients who come to the operating room are at risk for aspiration pneumonitis. The classic example is the patient with acute pain and a "full stomach" who must have emergency surgery. The pregnant patient, the obese patient, the diabetic, the patient with hiatal hernia or gastroesophageal reflux, all may be at risk for aspiration of gastric contents and subsequent chemical pneumonitis. Although it is not certain, it is believed that in adults aspiration of more than 25 mL of gastric fluid with a pH lower than 2.5 will cause pulmonary sequelae. This has not been, and probably never will be, proved in humans. However, using these guidelines, some have estimated that 40 to 80% of patients scheduled for elective surgery may be at risk.[69,70] However, clinically significant pulmonary aspiration of gastric contents is very rare in healthy patients having elective surgical procedures, and few anesthesiologists advocate routine prophylaxis.[71]

The necessity of prolonged fasting (nothing by mouth after midnight) before induction of anesthesia for elective surgery has been challenged.[72] Some institutions allow ingestion of clear liquids until 3 or even 2 hours before surgery in selected patients. Indeed, gastric fluid volume immediately after induction of anesthesia is not increased by ingestion of 150 mL of water, coffee, or orange juice 2 to 3 hours earlier. A study by Shevde and Trivedi described the administration of 240 mL of water, coffee, or pulp-free orange juice to healthy volunteers. All had gastric volumes of less than 25 mL with a slight decrease in pH within 2 hours of taking one of the three liquids.[73] There is concern about comfort, hypovolemia, and hypoglycemia in the pediatric age group perioperatively after prolonged fasting. An investigation by Splinter and associates concluded that drinking clear fluid up to 3 hours before scheduled surgery does not have a measurable effect on gastric volume and pH of healthy children aged 2 to 12 years.[74] Other studies in infants,

children, and healthy adults scheduled for elective surgery have found similar results. Therefore, fears that ingestion of oral fluid on the morning of surgery will invariably result in a predictable increase in gastric fluid volume are unfounded. It must be appreciated, however, that these data are from healthy patients not "at risk" for aspiration and apply only to ingestion of clear liquids. The American Society of Anesthesiologists has defined and summarized preoperative fasting practices through guidelines adapted in 1998 (Table 18-14).[71]

TABLE 18-14 Summary of Fasting Recommendations to Reduce the Risk of Pulmonary Aspiration[a]

▪INGESTED MATERIAL	▪MINIMUM FASTING PERIOD (APPLIED TO ALL AGES)
Clear liquids[b]	2 hours

Breast milk	4 hours
Infant formula	6 hours
Nonhuman milk	6 hours
Light meal (toast and clear liquids)	6 hours

[a]Applies only to healthy patients who are undergoing elective procedures and are not intended for women in labor. Following the guidelines does not guarantee complete gastric emptying.

[b]Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

Adapted from Practice Guidelines for Preoperative Fasting and the Use of Pharmacologic Agents to Reduce the Risk of Pulmonary Aspiration: Application to Healthy Patients Undergoing Elective Procedures. A Report by the American Society of Anesthesiologists Task Force on Preoperative Fasting. Anesthesiology 90:896, 1999.

Many different kinds of drugs have been used to alter gastric fluid volume and increase the pH of gastric fluid. Anticholinergics, H_2 receptor antagonists, antacids, and gastrokinetic agents have all been used to reduce the possibility of aspiration pneumonitis.

Anticholinergics

Neither atropine nor glycopyrrolate has been shown to be very effective in increasing gastric fluid pH or reducing gastric fluid volume.[69,70] Furthermore, intravenous doses of anticholinergics may cause relaxation of the gastroesophageal junction (Fig. 18-8). Therefore, the risk of aspiration pneumonitis may be increased, but this specific effect of intramuscular administration of anticholinergics for preoperative use has not been proved.

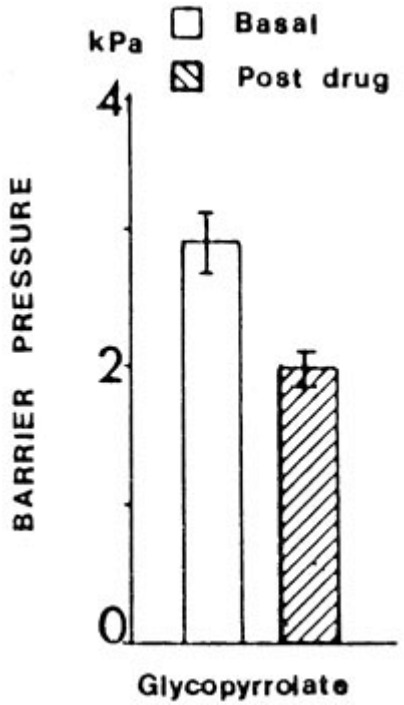

FIGURE 18-8. Barrier pressure (esophageal sphincter pressure minus gastric pressure) before and after intravenous administration of glycopyrrolate, 0.3 mg, to adult patients. Mean ± SE. (Reprinted with permission from Brock-Utne JG, Welman RS, Moshal MG *et al*: The effect of glycopyrrolate [Robinul] on the lower esophageal sphincter. Can Anaesth Soc J 25:144, 1978.)

Histamine Receptor Antagonists

The H_2 receptor antagonists cimetidine, ranitidine, famotidine, and nizatidine reduce gastric acid secretion. They block the ability of histamine to induce secretion of gastric fluid with a high hydrogen ion concentration. Therefore, the H_2 receptor antagonists increase gastric fluid pH. Their antagonism of the histamine receptor occurs in a selective and competitive manner. It is important to remember that these drugs cannot be expected reliably to affect gastric fluid volume or gastric emptying time. Compared with other premedicants, they have relatively few side effects. Because there are few side effects, many anesthesiologists have advocated the liberal preoperative use of H_2 receptor antagonists. Multiple-dose regimens may be more effective in increasing gastric pH than a single dose before operation on the day of surgery. An H_2 antagonist also may be used for the allergic patient or in preparing a patient for exposure to a trigger of the allergic response, such as radiologic dye.

Cimetidine. Cimetidine usually is administered in 150 to 300 mg doses orally or parenterally. Administration of 300 mg of cimetidine orally 1 to 1.5 hours before surgery has been shown to increase the gastric fluid pH above 2.5 in 80% of patients.[75,76] Cimetidine can be given intravenously for those unable to take oral medications. Cimetidine can cross the placenta, but adverse fetal effects are unproved. The gastric effects of cimetidine last as long as 3 or 4 hours, and therefore this drug is suitable for operations of that duration.

Cimetidine has few side effects, but there are some of note. It inhibits the hepatic mixed-function oxidase enzyme system; therefore, it can prolong the half-life of many drugs, including diazepam, chlordiazepoxide, theophylline, propranolol, and lidocaine. The clinical significance of this after one or two preoperative doses of cimetidine is uncertain. Life-threatening cardiac dysrhythmias, hypotension, cardiac arrest, and central nervous system depression have been reported after cimetidine administration. These side effects may be especially likely to occur in critically ill patients after rapid intravenous administration. As discussed previously, cimetidine does not affect

gastric fluid already present.

Ranitidine. Ranitidine is more potent, specific, and longer acting than cimetidine. The usual oral dose is 50 to 200 mg. Ranitidine, 50 to 100 mg, given parenterally will decrease gastric fluid pH within 1 hour. It is as effective in reducing the number of patients at risk for gastric aspiration as cimetidine and produces fewer cardiovascular or central nervous system side effects. The effects of ranitidine last up to 9 hours. Thus, it may be superior to cimetidine at the conclusion of lengthy procedures in reducing the risk of aspiration pneumonitis during emergence from anesthesia and extubation of the trachea.

Other Histamine Receptor Antagonists. Famotidine is a third H_2 receptor blocker that has been given preoperatively to raise gastric fluid pH. Its pharmacokinetics are similar to those of cimetidine and ranitidine, with the exception of having a longer serum elimination half-life than the other two drugs. Famotidine in a dose of 40 mg orally 1.5 to 3 hours preoperatively

has been shown to be effective in increasing gastric pH. Nizatidine 150 to 300 mg orally 2 hours before surgery will similarly decrease preoperative gastric acidity.[77,78,79]

Antacids

Antacids are used to neutralize the acid in gastric contents. A single dose of antacid given 15 to 30 minutes before induction of anesthesia is almost 100% effective in increasing gastric fluid pH above 2.5. The nonparticulate antacid, 0.3 *M* sodium citrate, is commonly given before operation when an increase in gastric fluid pH is desired. The nonparticulate antacids do not produce pulmonary damage themselves if aspiration of gastric fluid containing these antacids should occur. Colloid antacid suspension may be more effective than the nonparticulate antacids in increasing gastric fluid pH. However, aspiration of gastric fluid containing particulate antacids may cause significant and persistent pulmonary damage, despite the increase in gastric fluid pH. The serious pulmonary sequelae have been manifested in the form of pulmonary edema and arterial hypoxemia.

Antacids work at the time given. There is no "lag time," as with the H_2 receptor blockers. Antacids are effective on the fluid already present in the stomach. This makes them especially attractive in emergency situations for those patients who are able to take medications orally.

However, antacids do increase gastric fluid volume, unlike H_2 receptor blockers.[75] The risk of aspiration depends on both the pH and the volume of gastric content. The increase in gastric fluid volume from antacid administration may become readily apparent after repeated doses, such as during labor, during which opioid administration may also contribute to delayed gastric emptying. Withholding antacids because of concern about increasing gastric volume is not warranted, considering animal evidence documenting increased mortality after aspiration of low volumes of acidic gastric fluid (0.3 mL/kg, pH 1) compared with aspiration of large volumes of buffered gastric fluid (1 to 2 mL/kg, pH 1.8).[80] Antacids may slow gastric emptying, and complete mixing with all gastric contents may be questionable in the immobile patient. The effect of antacids on food particles within the stomach is unknown.

Omeprazole

Omeprazole suppresses gastric acid secretion in a dose-dependent manner by binding to the proton pump of the parietal cell. For an adult patient intravenous doses of 40 mg 30 minutes before induction have been used. Oral doses of 40 to 80 mg must be given 2 to 4 hours before surgery to be effective. Effect on gastric pH may last as long as 24 hours. Much like the other H_2 receptor antagonists, investigators have found increases in gastric pH and inconsistent effects on gastric volume with administration of omeprazole.[81,82,83]

Gastrokinetic Agents

Gastrokinetic agents are useful because of their effectiveness in reducing gastric fluid volume.

Metoclopramide is an example of a gastrokinetic agent that may be administered before operation.

Metoclopramide. Metoclopramide is a dopamine antagonist that stimulates upper gastrointestinal motility, increases gastroesophageal sphincter tone, and relaxes the pylorus and duodenum. It also has antiemetic properties. Metoclopramide speeds gastric emptying but has no known effect on acid secretion and gastric fluid pH. It may be administered orally or parenterally. A parenteral dose of 5 to 20 mg is usually given 15 to 30 minutes before induction. When the drug is administered intravenously over 3 to 5 minutes, it usually prevents the abdominal cramping that can occur from more rapid administration. An oral dose of 10 mg achieves onset within 30 to 60 minutes. The elimination half-life of metoclopramide is approximately 2 to 4 hours.

The clinical usefulness of the gastrokinetic agents is found in those patients who are likely to have large gastric fluid volumes, such as parturients, patients scheduled for emergency surgery who have just eaten, obese patients, patients with trauma, outpatients, and those with gastroparesis secondary to diabetes mellitus.

However, the administration of metoclopramide does not guarantee gastric emptying. Significant gastric fluid volume may still be present despite its administration. The effect of metoclopramide on the upper gastrointestinal tract may be offset by concomitant atropine administration or prior injection of opioids. It will not further reduce gastric volume in patients undergoing elective surgery with already small gastric volumes. It may not be effective after administration of sodium citrate. In contrast, metoclopramide may be especially effective in reducing the risk of aspiration pneumonitis when combined with an H_2 receptor antagonist (for example, ranitidine) before elective surgery.

As mentioned previously, the drugs used to alter gastric fluid pH and volume are relatively free of side effects. The risk–benefit ratio for these drugs in reducing the risk of pulmonary sequelae from aspiration is often very favorable. Indeed, the drugs do decrease the number of patients at risk. However, none of the drugs or combinations of drugs is absolutely reliable in preventing the risk of aspiration pneumonitis in all patients all of the time. Therefore, their use does not eliminate the need for careful anesthetic techniques to protect the airway during induction, maintenance, and emergence from anesthesia.

Antiemetics

There are several groups of patients in whom the antiemetic effects of drugs may be helpful in reducing nausea and vomiting. Droperidol, metoclopramide, ondansetron, and dexamethasone, singly or in combination, are agents in common usage.[84] These are patients scheduled for ophthalmologic surgery, patients with a prior history of nausea and vomiting or motion sickness, patients scheduled for laparoscopic surgery or gynecologic procedures, and patients who are obese. A risk score for predicting postoperative nausea and vomiting after inhalation anesthesia identified four risk factors: female gender, prior history of motion sickness or postoperative nausea, nonsmoking, and the use of postoperative opioids. The investigators suggested prophylactic antiemetic therapy when two or more of the risk factors were present when using volatile anesthetics.[85] Many anesthesiologists prefer not to administer antiemetics as part of a preoperative regimen, but believe that antiemetics should be administered intravenously just before they are needed at the conclusion of surgery.

Anticholinergics

Previously, anticholinergic drugs were widely used when inhalation anesthetics produced copious respiratory tract secretions and intraoperative bradycardia was a frequent danger. The advent of newer inhalation agents has almost completely dispelled the routine use of anticholinergic drugs for preoperative medication. Their routine use has been questioned by several authors, who believe that the same care in selection of anticholinergics should be exhibited as in the choice of other drugs. Specific indications for an anticholinergic before surgery are (1) antisialagogue effect and (2) sedation and amnesia (Table 18-15). Uses that are less firmly established and not universally agreed on include the preoperative prescription of

anticholinergics for their vagolytic action or in an attempt to decrease gastric acid secretion.

TABLE 18-15 Comparison of Some of the Effects of Anticholinergic Drugs

	·ATROPINE	·GLYCOPYRROLATE	·SCOPOLAMINE
Increased heart rate	+++	++	+
Antisialagogue	+	++	+++
Sedation	+	0	+++
0, no effect; +, small effect; ++, moderate effect; +++, large effect.			
Adapted from Stoelting RK: Pharmacology and Physiology in Anesthetic Practice. Philadelphia, JB Lippincott, 1991.			

Antisialagogue Effect

Anticholinergics have been prescribed in a selective fashion when drying of the upper airway is desirable. For example, when endotracheal intubation is contemplated, an anesthesiologist may want to reduce secretions. In the study by Falick and Smiler, conditions were more often rated as satisfactory after endotracheal intubation when an anticholinergic drug had been administered.[86] The antisialagogue effect may be important for intraoral operations and instrumentations of the airway such as bronchoscopic examination. Administration of anticholinergics may be desirable before the use of topical anesthesia for the airway to prevent a dilutional effect of secretions and to allow contact of the local anesthetic with the mucosa.

Scopolamine is a more potent drying agent than atropine. It is less likely to increase heart rate and more likely to produce sedation and amnesia. Glycopyrrolate is a more potent and longer acting antisialagogue than atropine, with less likelihood of increasing heart rate. Because glycopyrrolate is a quaternary amine, it does not easily cross the blood-brain barrier and does not produce sedation. Anticholinergics are not the only drugs that can dry secretions. As demonstrated by the study of Forrest et al, several other drugs and placebo (presumably a reflection of apprehension) can cause a patient to have a dry mouth before operation[87] (Table 18-16).

TABLE 18-16 Incidence of Side-Effects 1 Hour After Preoperative Medication (Percentage of Patients)

·MEDICATION	·DRY MOUTH	·SLURRED SPEECH	·DIZZY	·NAUSEATED	·RELAXED
Pentobarbital (50–150 mg)	29	27	10	7	2
Secobarbital (50–	41	32	8	9	4

150 mg)					
Diazepam (5–15 mg)	35	20	10	3	12
Hydroxyzine (50–150 mg)	45	31	6	2	9
Morphine (5–10 mg)	80	33	15	7	20
Meperidine (50–100 mg)	85	45	20	12	25
Placebo	34	21	7	12	4

Modified from Forrest WH, Brown CR, Brown BW *et al*: Subjective responses to six common preoperative medications. Anesthesiology 47:241, 1977.

Sedation and Amnesia

When sedation and amnesia are desired before operation, scopolamine is frequently the anticholinergic chosen, especially in combination with morphine. Scopolamine and atropine both cross the blood-brain barrier. Scopolamine is a much more potent sedative and amnestic drug than atropine. In a study of patient acceptance of preoperative medication, the combination of morphine and scopolamine was superior to that of morphine and atropine.[88] Scopolamine does not produce amnesia in all patients. It may not be as effective as lorazepam or diazepam in preventing recall. Scopolamine has an additive amnestic effect when combined with benzodiazepines. The study by Frumin et al showed that the combination of diazepam and scopolamine produced amnesia more often than did diazepam alone.[89]

Vagolytic Action

Vagolytic action of the anticholinergic drugs is produced through the blockade of effects of acetylcholine on the sinoatrial node. Atropine given intravenously is more potent than glycopyrrolate and scopolamine in increasing heart rate. The vagolytic action of the anticholinergic drugs is useful in the prevention of reflex bradycardia during surgery. Bradycardia may result from traction on extraocular muscles or abdominal viscera, from carotid sinus stimulation, or after the administration of repeated doses of intravenous succinylcholine. The prevention of reflex bradycardia with intramuscular doses of the anticholinergics is unreliable, given the drug dosages and timing usually involved with preoperative medication administered on the unit. Many anesthesiologists prefer to give atropine or glycopyrrolate intravenously just before surgery and the anticipated bradycardic stimulus. Atropine and glycopyrrolate given intravenously immediately before surgery have been equally effective in preventing bradycardia resulting from repeated doses of succinylcholine.

Elevation of Gastric Fluid pH Level

High doses of anticholinergics often are needed to alter gastric fluid pH. Even then, when given in

gastric hydrogen ion secretion.[70] This function has largely been replaced by the use of H_2 receptor antagonists (see Gastric Fluid pH and Volume section).

Side Effects in Anticholinergic Drugs

Scopolamine and atropine may cause central nervous system toxicity, the so-called central anticholinergic syndrome. This is most likely to occur after the administration of scopolamine, but can be seen after high doses of atropine. The symptoms of central nervous system toxicity resulting from anticholinergic drugs include delirium, restlessness, confusion, and obtundation. Elderly patients and patients with pain appear to be particularly susceptible. The central nervous system toxic effect of anticholinergics has been noted to be potentiated by inhalation anesthetics. Some clinicians have successfully treated the syndrome after it occurred with 1 to 2 mg of physostigmine intravenously.

The anticholinergics relax the lower esophageal sphincter. In theory, after parenteral administration of an anticholinergic drug, the risk of pulmonary aspiration of gastric contents is increased. This has yet to be proved as an important clinical issue.

Mydriasis and cycloplegia from anticholinergic drugs could be unwanted in patients with glaucoma because of resulting increased intraocular pressure. This seems unlikely with the doses used for preoperative medication. Atropine and glycopyrrolate may be less likely to increase intraocular pressure than scopolamine. In patients with glaucoma, most anesthesiologists feel safe in continuing medications for glaucoma up until the time of surgery and using atropine or glycopyrrolate when necessary (see Chapter 33).

Because anticholinergic drugs block vagal activity, relaxation of bronchial smooth muscle occurs and respiratory dead space increases. The magnitude of the increase in dead space depends on prior bronchomotor tone, but increases as large as 25 to 33% have been reported. Anticholinergic drugs cause secretions to dry and thicken. In theory, a dose of anticholinergic drug given before operation could lead to inspissation of secretions and an increase in airway resistance. This may develop into more than a theoretical issue when patients with diseases such as cystic fibrosis are being considered.

Sweat glands of the body are innervated by the sympathetic nervous system and use cholinergic transmission. Therefore, administration of anticholinergic agents interferes with the sweating mechanism, which may cause body temperature to increase. This side effect of anticholinergic medication must be considered carefully in a child with a fever.

Atropine is more likely than glycopyrrolate or scopolamine to cause an increase in heart rate. Unwanted increases in heart rate are much more likely after intravenous administration than after intramuscular administration. In fact, heart rate may transiently decrease after intramuscular administration as a result of a peripheral agonist effect of the anticholinergic agent.

Adrenergic Agonists

Alpha-2 adrenergic agonists have been used as premedicants.[90,91] Clonidine in doses of 2.5 to 5 μg/kg has been administered preoperatively to produce sedation, reduce maximum allowable concentration, and prevent hypertension and tachycardia from endotracheal intubation and surgical stimulation. It has even been used as part of anesthetic technique to produce induced hypotension. Dexmedetomidine is another alpha-2 adrenergic agonist studied for preoperative use to attenuate intraoperative sympathoadrenal responses.[90] After the administration of clonidine preoperatively, one is more likely to see episodes of hypotension and bradycardia during anesthesia when there are periods of little surgical stimulation. Furthermore, some anesthesiologists ask if preoperative alpha-2 adrenergic agonists are a substitute for a properly conducted anesthetic if appropriate attention is given to depth of anesthesia.

Other Drugs Given with Preoperative Medications

Although they are not preoperative medications in the strict sense, other drugs are often given at the time of preoperative medication. Examples of such drugs are insulin, steroids, antibiotics, and methadone for patients who are addicted to opioids. They may be prescribed by either the anesthesiologist or the surgeon to be given on the ward or in the operating room immediately prior to surgery. Regardless of these factors, their actions may affect the anesthetic, and the anesthesiologist must be knowledgeable about their administration and actions.

Beta-Blockers

For patients with known or suspected coronary artery disease, preoperative beta-blockers may add to safety in the perioperative period. Clinical studies have shown that beta-blockers in this setting have reduced mortality and the incidence of nonfatal myocardial infarction after surgery. Because benefit has been shown with several different beta-blockers, it is probably a drug class effect or hemodynamic effect rather than the result of employing a specific beta-blocker. Contraindications to preoperative beta-blocker therapy include known allergy to beta-blockers, second- or third-degree heart block, congestive heart failure, acute bronchospasm, low systolic blood pressure (less than 100 mm Hg), slow heart rate (less than 60 beats per minute), and other hemodynamic instability. Many clinicians use either atenolol (50 to 100 milligrams po daily) or metoprolol (25 to 50 milligrams po twice daily). They are chosen because of their long action and relative beta-1 selectivity. The goals are to achieve a heart rate near 50 to 70 beats per minute, while maintaining a systolic blood pressure greater than 110 mm Hg. The beta-blockade is usually maintained throughout the perioperative period to achieve maximum effect. Intravenous metoprolol may be given just prior to surgery if inadequate blockade has been achieved with the oral medications. The oral beta-blockers may be started several days prior to surgery.

Antibiotics

Antibiotics are often administered immediately before operation for contaminated, potentially contaminated, or dirty surgical wounds. Prophylactic antibiotics may be warranted for "clean" surgical procedures when infection would be catastrophic. Other instances for the use of prophylactic antibiotics include in the immunosuppressed patient, in the aged, or in patients taking steroids. Antibiotics given immediately before surgery are also used for the prevention of endocarditis.[92] Antibiotic administration comes under the anesthesiologist's purview because of the desire to have such agents given immediately before exposure to pathogens, which is just before the beginning of surgery.

It has been estimated that 60 to 70% of surgical patients receive antibiotics just before surgery or intraoperatively. Cephalosporins are the most popular. However, no drug or combination of drugs may be relied on to protect against all potential pathogens in all patients for all types of surgery. As with any other medication, the anesthesiologist must know the side effects and complications of the antibiotics to be administered. Some are associated with allergic reactions, hypotension,

and bronchospasm (e.g., penicillin and vancomycin). Allergic reactions from cephalosporin administration have been estimated to occur in about 5% of patients. Cross-reactivity of the cephalosporins in patients with a known penicillin allergy has been estimated at anywhere from 5 to 20%. The aminoglycosides, vancomycin, and the polymyxins have been implicated in nephrotoxicity. In addition, ototoxicity has resulted from aminoglycoside and vancomycin administration. Pseudomembranous colitis is a known complication of clindamycin administration. Finally, the aminoglycosides are known to extend the neuromuscular blocking effects of muscle relaxants.

Steroids

Steroid administration may be necessary immediately before surgery in the patient treated for hypoadrenocorticism or in the patient with suppression of the pituitary-adrenal axis owing to

present or previous administration of corticosteroids. It is impossible to identify the specific duration of therapy or dose of steroids that produces pituitary and adrenal suppression. Marked variability among patients exists. Certainly, more suppression may be expected the higher the dose and the longer the duration of therapy. A conservative estimate is to consider treatment in any patient who has received corticosteroid therapy for at least 1 month in the past 6 to 12 months.

Because of disease states of the pituitary-adrenal axis or its suppression from steroid therapy, patients may not be able to respond to the stress of surgery. The dose and duration of supplemental steroid administration depend on an estimate of the stress of the surgical procedure in the perioperative period. One regimen is to administer 25 mg of cortisol preoperatively and then give an intravenous infusion of 100 mg of cortisol over the next 12 to 24 hours for adult patients. Another method is to administer 100 mg of hydrocortisone intravenously before, during, and after surgery. This dose is meant to equal the estimated maximum amount of steroid that stress could produce in patients perioperatively. When considering whether to administer steroids or a higher dose of steroids, the anesthesiologist should keep in mind that the risk–benefit ratio is usually very small.

Insulin

Anesthesia and surgery may interrupt the regular meal schedule and insulin administration of diabetics (see Chapter 41). Perioperative stress may increase serum glucose concentrations. A plan for perioperative insulin and glucose management must be agreed on among the anesthesiologist, the surgeon, and the endocrinologist involved in the diabetic patient's care. There are several methods of doing this, none of which has proved superior to the others. One method is to administer one-fourth to one-half of the usual daily dose of intermediate-acting insulin preoperatively in the morning of surgery and begin an infusion of glucose-containing fluid. A second way is to administer no insulin or no glucose preoperatively and to measure serum glucose levels frequently during anesthesia. Regular insulin or glucose is then administered intraoperatively and postoperatively as needed. A third method is to begin an infusion of insulin and glucose immediately preoperatively and to check serum glucose levels frequently.

Opioid Dependency

Withdrawal produced by drug cessation is a preoperative issue in the patient who is taking methadone or is dependent on other opioids. There should be an attempt to maintain opioid use at the usual level by continuing methadone or substituting other appropriate agents for methodone. The anesthesiologist should be cautioned about using agonist-antagonist drugs in these patients in the preoperative period for fear of producing withdrawal.

DIFFERENCES IN PREOPERATIVE MEDICATION BETWEEN PEDIATRIC AND ADULT PATIENTS

Differences between children and adults with regard to preoperative medication include aspects of psychological preparation, the emphasis on oral medications when pharmacologic preparation is desired, and more frequent use of anticholinergics for their vagolytic activity. What remains the same is the need to assess the needs of each child individually and to tailor the psychological preparation and preoperative medication accordingly (see Chapter 44).

Psychological Factors in Pediatric Patients

Hospital admission and major surgery can produce long-lasting psychological effects in some children. The hospital stay is stressful and full of apprehension over the short term for almost all children. The demeanor and communicative efforts of the anesthesiologist can make a difference to the child and family who are getting ready for a trip to the operating room, anesthesia, and surgery.

Age is probably the most important aspect when psychological preparation of the pediatric patient

is considered.[93] A baby younger than 6 to 8 months of age is not emotionally upset when separated from his or her mother. Others in the health care team can substitute very easily. Preoperative preparation in this age group is often directed toward other goals, for example, obtundation of vagal reflex responses. However, preschool children are upset when separated from their mothers and fear the operating room. This is an age when hospitalization may be the most upsetting. It is difficult to explain the forthcoming events to children in this age group. It is easier to communicate with patients from age 5 years to adolescence. The anesthesiologist can explain and offer reassurance about such issues as separation from parents and the home, operating room events, and any of the patient's perceived fears of surgery and anesthesia. Adolescent patients may already be anxious and apprehensive. They may also be worried about loss of consciousness, have a fear of death, or be apprehensive about what they will do or say after preoperative sedation or during anesthesia. The more fearful child may be difficult to identify. This is usually the child who is quiet during the preoperative interview and appears nonchalant or even detached. If these patients can be identified before operation, they are often candidates for heavy pharmacologic preparation.

Psychological Preparation

For the above reasons, a good preoperative visit and proper psychological preparation may be even more important in children than adults. This is an art that is acquired by the anesthesiologist. The preoperative visit is a time of reassurance and explanation. It is an opportunity to gain the child's trust. Most anesthesiologists will want to involve the parents when possible. Some hospitals have found brochures, motion pictures, and slide shows to be helpful in preparing pediatric patients for the operating room. The child may want to bring a personal belonging, such as a stuffed animal or blanket, to the operating room for security. Some children wish to take an active role by doing such things as holding the face mask during inhalation induction of anesthesia. It may be helpful in a case with supportive parents to have them accompany the child to the

operating room suite after an explanation of events that may occur during induction. It is common in many hospitals for a parent to go into the operating room and stay until induction is complete.

Differences in Pharmacologic Preparation

The discussion of pharmacologic preparation for the pediatric patient presumes proper psychological preparation, a satisfactory operating room environment, and preparation for an efficient and timely induction of anesthesia (see Chapter 44).

Sedative–Hypnotics

As in adults, the sedative–hypnotic medications are used to reduce apprehension, produce sedation and amnesia, and to facilitate smooth induction of anesthesia when an inhalation method is to be used. The use of preoperative medication is controversial in pediatric patients and may not be completely successful in as many as 20% of instances. It has not been proved to reduce unwanted psychological outcome after surgery and anesthesia. Neither has it been shown that the uneventful induction of anesthesia is less likely to produce long-lasting psychological problems in children. After 6 months to 1 year of age, the child scheduled for a surgical procedure may benefit from a sedative–hypnotic drug before surgery. There is some emphasis on avoiding intramuscular injections in children. The oral route is often used for preoperative medication in the older child, whereas in preschool children drugs may also be given rectally. Many different sedative–hypnotic drugs via different routes (oral, intranasal, and rectal) have been prescribed for children before operation. Midazolam can be given intramuscularly (0.05 to 0.2 mg/kg). However, the most effective and acceptable route for midazolam is the oral route, achieved by mixing 0.5 to 0.75 mg/kg with flavored syrup, apple juice, or cola because of its bitter taste.[94] It is effective in producing sedation and compliance, but not usually sleep, in about 15 minutes and lasts for 30 to 60 minutes. Oral ketamine 5 to 10 mg has been prescribed 20 to 30 minutes before induction. Although often allowing smooth separation from parents, oral secretions and preoperative or

postoperative delirium can be problems. Both ketamine (3 to 8 mg/kg) and midazolam (0.2 mg/kg) can be given using a nasal atomizer, with the caveat that nasal drug administration and bitter aftertaste are disadvantageous. Ketamine (5 mg/kg) and midazolam (0.3 to 1.0 mg/kg) have also been given rectally before induction of anesthesia. A further option in the pharmacologic preparation of children is the rectal administration of methohexital (Fig. 18-9). Methohexital (20 to 30 mg/kg) may be given immediately before operation, using pulse oximetry and while the child is still in the parent's arms. The intramuscular route is also possible.

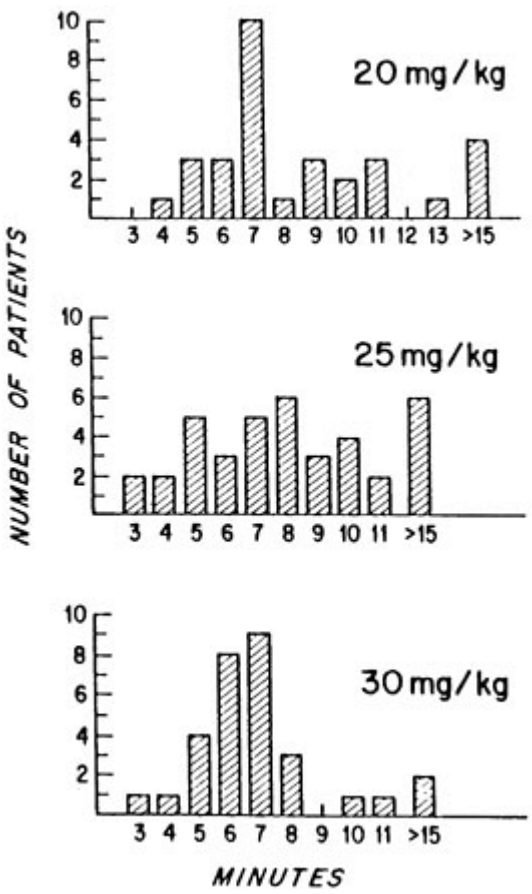

FIGURE 18-9. Frequency distribution of sleep induction times after rectal instillation of methohexital. Patients averaged 3.3 years in age and 15 kg in body weight. (Reprinted from Liu LMP, Goudsouzian NG, Liu PL: Rectal methohexital premedication in children, a dose-comparison study. Anesthesiology 53:343, 1980.)

Opioids

There is the occasional need for opioid premedication in children. Methadone has the advantage of oral administration, usually prescribed in the 0.1 to 0.2 mg/kg dose range. Intramuscular morphine and meperidine are used, often in combination with other premedications. Intramuscular morphine is often seen as part of the pharmacologic preparation for the child with congenital heart disease. In many hospitals, opioids have been combined with sedative–hypnotic and anticholinergic drugs to make a "cocktail" that may be given orally for preoperative medication. Transmucosal administration of fentanyl (5 to 20 μg/kg) appears to be effective in producing sedation preoperatively. However, transmucosal fentanyl may increase gastric fluid volume and also increase the incidence of rigidity, respiratory depression, pruritus, nausea, and vomiting.[68] Fentanyl (2 μg/kg) and sufentanil (3.0 μg/kg) given by the intranasal route have been shown to calm pediatric patients preoperatively. Again, postoperative nausea and vomiting, in addition to respiratory complications, have resulted in lack of enthusiasm for this technique.

Anticholinergics

Easily induced vagal reflexes make anticholinergics especially important in children. Bradycardia may result from airway manipulation, surgical manipulation, or anesthetic drugs such as halothane or succinylcholine. Also, the child's cardiac output is more dependent on heart rate than is the adult's. If no contraindication exists, most pediatric patients receive atropine intravenously immediately after induction of anesthesia and placement of an intravenous catheter. If the intramuscular route has been used for atropine, it will often be administered immediately after the patient becomes unconscious during induction of anesthesia. Glycopyrrolate also has been used in children in this setting. Scopolamine has a place in premedication of the pediatric patient to produce sedation, amnesia, and drying of the airways. One must be aware of the hazards of administering an anticholinergic to a child with a fever or when inspissation of secretions is not wanted. Finally, it has been noted that patients with Down syndrome appear to be sensitive to atropine. This is especially evident with the effect on heart rate and mydriasis.

Chapter 19

Anesthesia for Patients with Rare and Coexisting Diseases

Stephen F. Dierdorf

J. Scott Walton

KEY POINTS

1	The muscle membrane in patients with muscular dystrophy has an abnormal structure and is susceptible to damage from succinylcholine. Massive release of intracellular contents, especially potassium, may occur.
2	Myotonic dystrophy produces cardiac conduction delay that can manifest as first-, second-, or third-degree atrioventricular heart block.
3	Patients with myasthenia gravis are exquisitely sensitive to nondepolarizing muscle relaxants. Short-acting muscle relaxants and careful objective and clinical monitoring of neuromuscular function are indicated.
4	Many types of cancer in addition to small cell lung carcinoma can produce myasthenic syndrome.
5	Patients with multiple sclerosis should be advised that they may have an exacerbation of neurologic symptoms during the perioperative period.
6	Repeated episodes of sickling in patients with sickle cell disease cause pulmonary hypertension. Pulmonary hypertension in sickle cell patients is associated with increased mortality.
7	Rheumatoid arthritis is a multisystem disease that causes subclinical cardiac and pulmonary dysfunction.
8	Many patients with rheumatoid arthritis have significant degeneration of the cervical spine with few neurologic symptoms. Cervical manipulation during laryngoscopy and intubation requires special precautions.
9	Esophageal dysfunction in patients with scleroderma or dermatomyositis

	increases the risk of aspiration pneumonitis.
10	Patients with epidermolysis bullosa can have undiagnosed myocardial dysfunction.

Knowledge of the pathophysiology of coexisting diseases and an understanding of the implications of concomitant drug therapy are essential for the optimal management of anesthesia for an individual patient. In many instances, the nature of the coexisting disease has more impact on the management of anesthesia than does the actual surgical procedure. A variety of rare disorders may influence the selection and conduct of anesthesia (Table 19-1). Recent advances in molecular genetics and biology have clarified the pathophysiology of many uncommon diseases. These discoveries have radically altered the treatment of some disorders. Consequently, anesthesiologists must periodically update their diagnostic skills and clinical knowledge to recognize when additional evaluation or treatment may be required.

MUSCULOSKELETAL DISEASES

Muscular Dystrophy

The cytoskeleton of the muscle cell is composed of different proteins such as dystrophin, merosin, utrophin, syntrophin, dystrobrevin, and sarcoglycans. Abnormal muscle proteins or

insufficient quantities of normal proteins diminish the integrity of the muscle membrane, making it more susceptible to damage (Fig. 19-1). The muscular dystrophies are diseases associated with abnormalities of the muscle membrane (Table 19-2).[1]

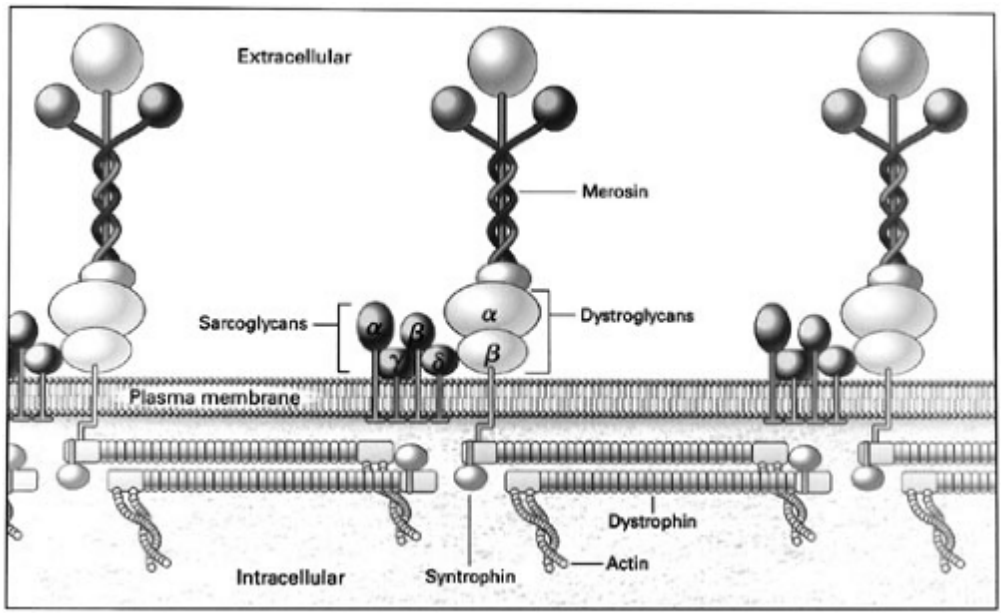

FIGURE 19-1. Muscle cell cytoskeleton. (Reprinted with permission from Duggan DJ, Gorospe JR, Fanin M *et al*: Mutations in the sarcoglycan genes in patients with myopathy. N Engl J Med 336:618, 1997.)

TABLE 19-2 Types of Muscular Dystrophy

Duchenne
Becker
Emery-Dreifuss

Oculopharyngeal
Fascioscapulohumeral
Congenital muscular dystrophy

Muscular dystrophies are characterized by a progressive, but variable loss of skeletal muscle function. Although many of the presenting signs and symptoms of muscular dystrophy are a result of skeletal muscle weakness, cardiac and smooth muscle are also affected. In many types of muscular dystrophy, cardiac muscle dysfunction may be more significant than skeletal muscle dysfunction, and preoperative evaluation of cardiac function can influence perioperative management.

Recent research has revealed a wide variety of unrelated genetic defects that produce clinically similar muscle diseases. It is still, however, more clinically useful to classify muscle diseases by clinical expression rather than genetic origin (Fig. 19-2).

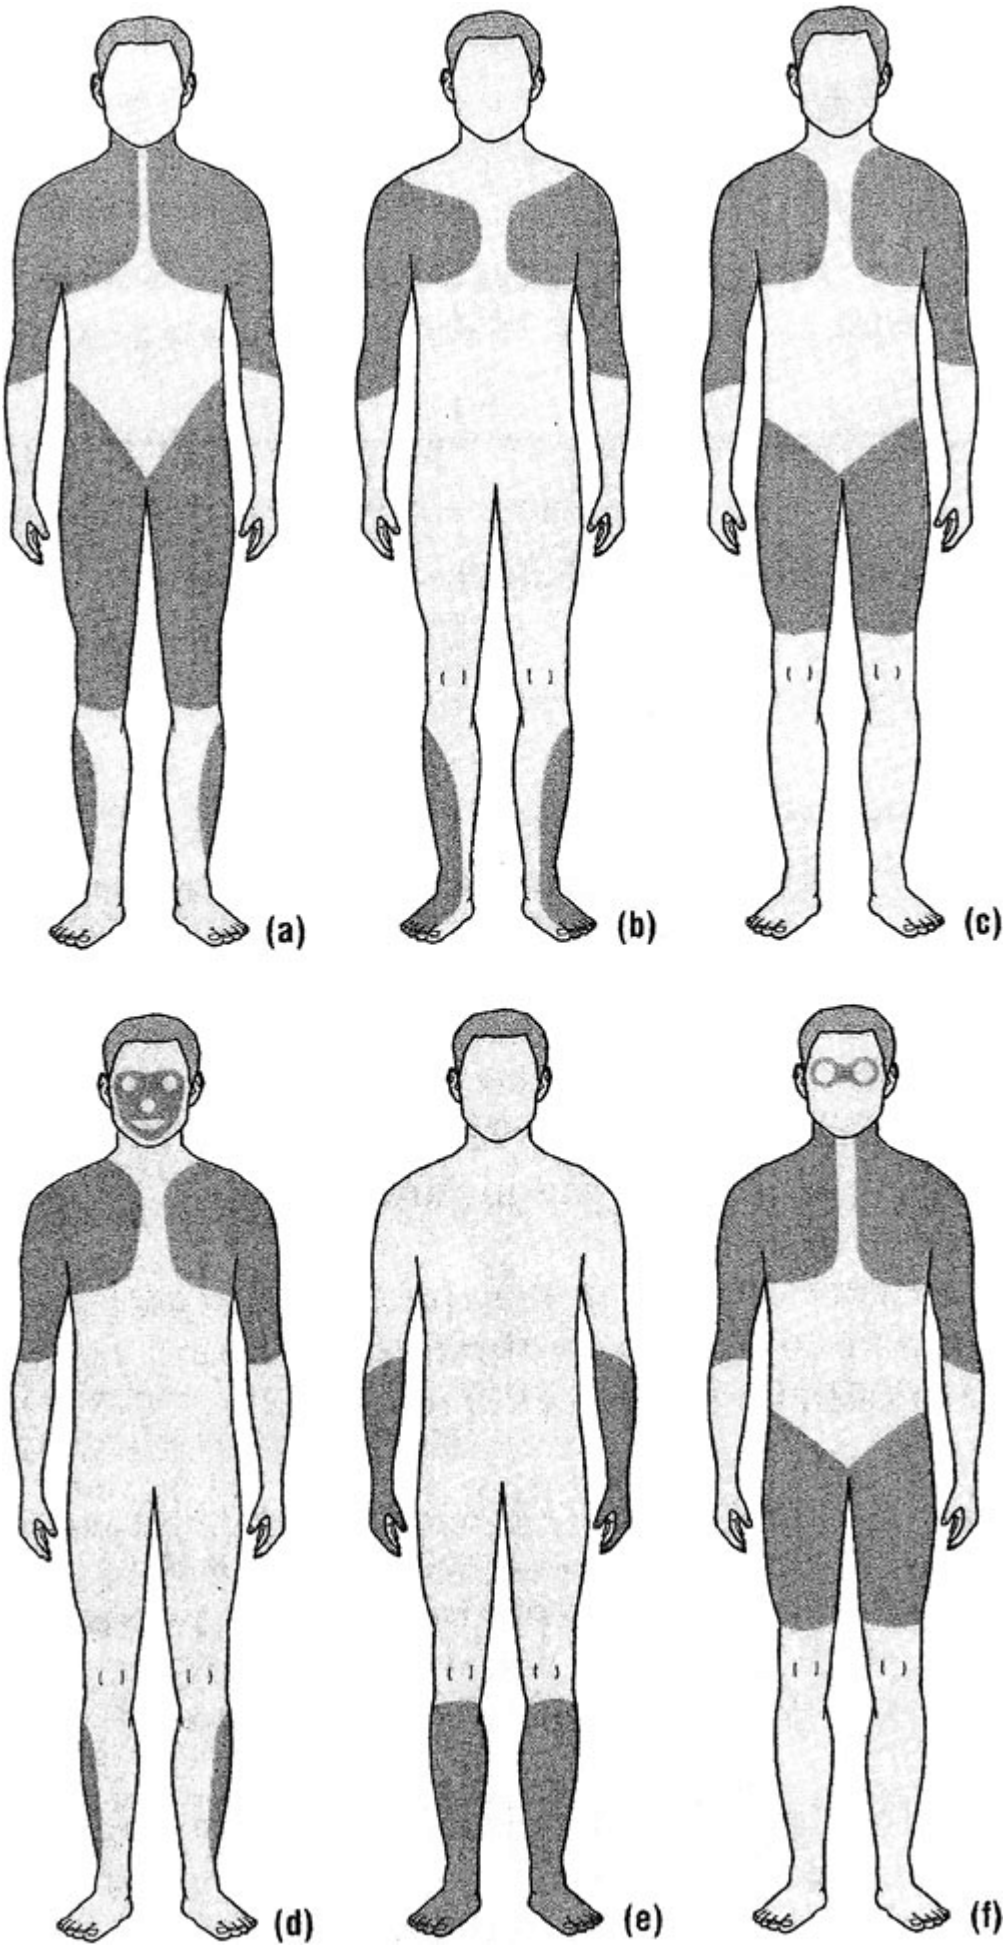

FIGURE 19-2. Distribution of predominant muscle weakness in different types of muscular

dystrophy. **A.** Duchenne-type and Becker-type. **B.** Emery-Dreifuss. **C.** Limb-girdle. **D.** Fascioscapulohumeral. **E.** Distal. **F.** Oculopharyngeal. (Reproduced with permission from the BMJ Publishing Group Emery AEH: BMJ 317:991, 1998.)

Duchenne's Muscular Dystrophy

Duchenne's muscular dystrophy is produced by a genetic abnormality resulting in a lack of production of dystrophin, a major component of the skeleton of the muscle membrane. Duchenne's dystrophy is characterized by painless degeneration and atrophy of skeletal muscle. This disorder is a sex-linked recessive trait clinically evident in boys, although sensitive testing may reveal subclinical abnormalities in carrier females. Progressive muscle weakness produces symptoms between the ages of 2 and 5 years and limitation of movement usually confines the patient to a wheelchair by 12 years of age. Axial skeletal muscle imbalance produces kyphoscoliosis that often requires operative instrumentation for stabilization. Death is usually secondary to congestive heart failure or pneumonia. Aggressive treatment of cardiopulmonary dysfunction has improved survival for many patients until the age of 30 years. Serum creatine kinase levels reflect the progression of the disease. Early in the patient's life the creatine kinase level is increased. Later, as significant amounts of muscle have degenerated, the creatine kinase level decreases.

Involvement of cardiac muscle is reflected by a progressive loss of R-wave amplitude in the lateral precordial leads of the

electrocardiogram as the patient ages. Routine echocardiography can provide important information about cardiac function and is indicated at regular intervals. Progressive loss of myocardial tissue results in cardiomyopathy, ventricular dysrhythmias, and mitral regurgitation. Treatment of cardiac dysfunction may include angiotensin-converting enzyme (ACE) inhibitors and beta-adrenergic blockers.[2]

Degeneration of respiratory muscles can be measured with pulmonary function testing (spirometry), which reveals a restrictive pulmonary disease pattern. Diminished muscle strength produces an ineffective cough resulting in retention of pulmonary secretions, pneumonia, and death. Smooth muscle involvement causes intestinal tract hypomotility, delayed gastric emptying, and gastroparesis.

Although the genetic defect that causes Duchenne's dystrophy is known, specific genetic therapy remains elusive. Current treatment is supportive and directed at better nutrition and improvement of cardiorespiratory function.

Emery-Dreifuss Muscular Dystrophy

Emery-Dreifuss muscular dystrophy is characterized by contractures of the elbows, ankles, and spine as well as humeropectoral muscle weakness. There are two types of Emery-Dreifuss dystrophy. The autosomal dominant type is caused by a defect in the cell nuclear protein lamin, while the X-linked recessive type is caused by a defect in the nuclear protein emerin. The skeletal muscle manifestations are usually mild, whereas cardiac conduction defects can be fatal.[3] Implantable defibrillating pacemakers are often indicated for patients with Emery-Dreifuss muscular dystrophy.

Limb-Girdle Muscular Dystrophy

Patients with limb-girdle dystrophy exhibit weakness of the muscles of the shoulder and pelvic girdles. Cardiomyopathy and atrioventricular conduction defects can occur in patients with limb-girdle dystrophy. Although most cases of limb-girdle dystrophy are inherited as an autosomal recessive trait, some forms are inherited as autosomal dominant traits. Fifteen different genetic

defects have been discovered and most cause an abnormality in the sarcoglycan proteins.

Fascioscapulohumeral Muscular Dystrophy

Fascioscapulohumeral muscular dystrophy is inherited as an autosomal dominant trait. Patients with this disease have diverse clinical manifestations. Weakness of the facial, scapulohumeral, anterior tibial, and pelvic-girdle muscles is prominent. Other abnormalities include retinal vascular disease, deafness, and neurologic dysfunction. Cardiac conduction defects and dysrhythmias may occur.

Oculopharyngeal Muscular Dystrophy

Oculopharyngeal muscular dystrophy typically presents in late adulthood. The primary clinical manifestations are ptosis and dysphagia. Dysphagia is secondary to pharyngeal skeletal muscle weakness and esophageal smooth muscle dysfunction. Weakness of the muscles of the head, neck and arms may also develop.

Congenital Muscular Dystrophy

Congenital muscular dystrophy is characterized by early onset (infancy, in utero) of muscle weakness, mental retardation, feeding difficulties, and respiratory dysfunction. Included in this group of muscular dystrophies are merosin-deficient muscular dystrophy, Fukuyama muscular dystrophy, Walker-Warburg syndrome, Ulrich's disease, muscle-eye-brain (MEB) disease, rigid spine muscular dystrophy, central core disease, myotubular myopathy, and nemaline myopathy.[4]

Management of Anesthesia

1 Most of the significant complications from anesthesia in patients with muscular dystrophy are secondary to the effects of anesthetic drugs on myocardial and skeletal muscle. Myocardial dysfunction makes patients with muscular dystrophy more susceptible to the myocardial depressant effects of potent inhaled anesthetics. There are numerous case reports of cardiac arrest occurring during the induction of anesthesia. These reports are associated with rhabdomyolysis and hyperkalemia and have occurred with volatile anesthetics alone or in combination with succinylcholine. In view of the weakened muscle structure of patients with muscular dystrophy, succinylcholine may damage the muscle membrane and release intracellular contents. Succinylcholine is best avoided in patients with muscular dystrophy. The effect of volatile anesthetics on abnormal skeletal muscle is not known. It could be speculated that volatile anesthetics, by releasing calcium from the sarcoplasmic reticulum, could damage the muscle membrane and cause rhabdomyolysis. Sevoflurane is a less-potent stimulus for release of calcium from the sarcoplasmic reticulum and may be the preferred volatile agent for patients with muscular dystrophy.[5] Some patients with muscular dystrophy may be susceptible to malignant hyperthermia, but this is unpredictable.

Nondepolarizing muscle relaxants can be used although patients with Duchenne's muscular dystrophy may have prolonged recovery. The response to mivacurium is, however, normal.[6] The response of patients with other forms of muscular dystrophy to nondepolarizing muscle relaxants is variable and close monitoring of neuromuscular function is indicated.

Degeneration of gastrointestinal smooth muscle with hypomotility of the intestinal tract and delayed gastric emptying in conjunction with impaired swallowing increases the risk of perioperative aspiration of gastric contents. After surgery, the patient with muscular dystrophy must be closely monitored for evidence of pulmonary dysfunction and retention of pulmonary secretions. Vigorous respiratory therapy and mechanical ventilation may be required.

The Myotonias

The myotonias are a diverse group of diseases that share a common pathologic feature: myotonia. Myotonia is the delayed relaxation of skeletal muscle after voluntary contraction. Typically, muscle relaxants and regional anesthesia will not prevent or treat myotonia. Drugs that alter ion channel

activity and skeletal muscle membrane excitability such as mexilitene, tocainide, and quinine may relax a myotonic contracture. Recent research has identified a wide variety of genetic defects that produce abnormalities in ion channels in the muscle membrane (Table 19-3). These defects can occur in the sodium, chloride, and calcium ion channels.

TABLE 19-3 Classification of Myotonic Dystrophy

Recessive myotonia
Unknown defect
Proximal myotonic dystrophy

Myotonic Dystrophy (Steinert's Disease)

Myotonic dystrophy is the most common of the myotonic disorders. Myotonic dystrophy is an autosomally dominant inherited disorder with symptoms occurring during the second and third decades of life. In addition to myotonia, other clinical features of myotonic dystrophy include muscle degeneration, cataracts, premature balding, diabetes mellitus, thyroid dysfunction, adrenal insufficiency, gonadal dystrophy, and

cardiac conduction abnormalities. Myotonic dystrophy is the result of an enlarged trinucleotide repeat of cytosine, thymine, and guanine (CTG) on chromosome 19. This defect produces a decrease in protein kinase that causes a degeneration of the sarcoplasmic reticulum.

2 Cardiac abnormalities have been well described in patients with myotonic dystrophy. The most prominent cardiac disorders include atrioventricualr conduction delays (A-V block), atrial flutter and fibrillation, and ventricular dysrhythmias. First-degree A-V block may actually precede the onset of skeletal muscle symptoms. Sudden death may be a result of the abrupt onset of third-degree A-V block. Other cardiac abnormalities associated with myotonic dystrophy include mitral valve prolapse, left ventricular diastolic dysfunction, and cardiac failure.[7]

Pulmonary function studies demonstrate a restrictive lung disease pattern, mild arterial hypoxemia, and diminished ventilatory responses to hypoxia and hypercapnia. Brainstem respiratory control mechanisms may also be defective. Weakness of the respiratory muscles diminishes the effectiveness of cough and may lead to pneumonia. Myotonia of the respiratory muscles can produce intense dyspnea requiring treatment with procainamide. Alteration of smooth muscle function produces gastric atony and intestinal hypomotility. Pharyngeal muscle weakness in conjunction with delayed gastric emptying increases the risk of aspiration of gastric contents.

Pregnancy often produces an exacerbation of myotonic dystrophy that may be secondary to increased levels of progesterone. Congestive heart failure is also more likely to occur during pregnancy. Cesarean section must often be performed because of uterine smooth muscle dysfunction. Some infants of mothers with myotonic dystrophy may develop congenital myotonic dystrophy. Congenital myotonic dystrophy is characterized by hypotonia, respiratory insufficiency, and difficulty with feeding. Mental retardation is common in patients with the congenital form of

myotonic dystrophy.

Therapy for myotonic dystrophy is directed at treatment of cardiac dysrhythmias (pacemaker implantation) and surgical therapy for cataracts and gallbladder disease. Mexilitene is effective for the treatment of myotonia. Treatment with growth hormone, selenium, vitamin E, coenzyme Q, and dehydroepiandrosterone may be effective but are as yet unproven.

Other Myotonias

Other forms of myotonic dystrophy include proximal myotonic myopathy, myotonic dystrophy type 2, and proximal myotonic dystrophy.

Patients with proximal myotonic myopathy have myotonia, proximal muscle weakness, and cataracts, but no facial muscle weakness. Cardiac dysrhythmias occur less frequently than in patients with myotonic dystrophy.

Myotonic dystrophy type 2 patients have clinical manifestations similar to myotonic type 1 patients but have a different mode of inheritance.

Proximal myotonic dystrophy produces clinical manifestations similar to proximal myotonic myopathy but with more severe muscle degeneration.[8]

Management of Anesthesia

Considerations for anesthesia for patients with myotonic dystrophy include the presence of cardiac and respiratory muscle disease and the abnormal responses to drugs used during anesthesia. Succinylcholine produces an exaggerated contracture and its use should be avoided (Fig. 19-3). The myotonic response to succinylcholine can be so severe that ventilation and tracheal intubation are difficult or impossible. Most patients with myotonic dystrophy develop a chronic myopathy and the response to nondepolarizing muscle relaxants may be enhanced. It would be prudent to use short-acting muscle relaxants such as mivacurium or cis-atracurium with close monitoring of the response. Reversal with neostigmine may provoke myotonia. The response to the peripheral nerve stimulator must be carefully interpreted because muscle stimulation may produce myotonia. The myotonic response may be misinterpreted as sustained tetanus when significant neuromuscular blockade still exists.

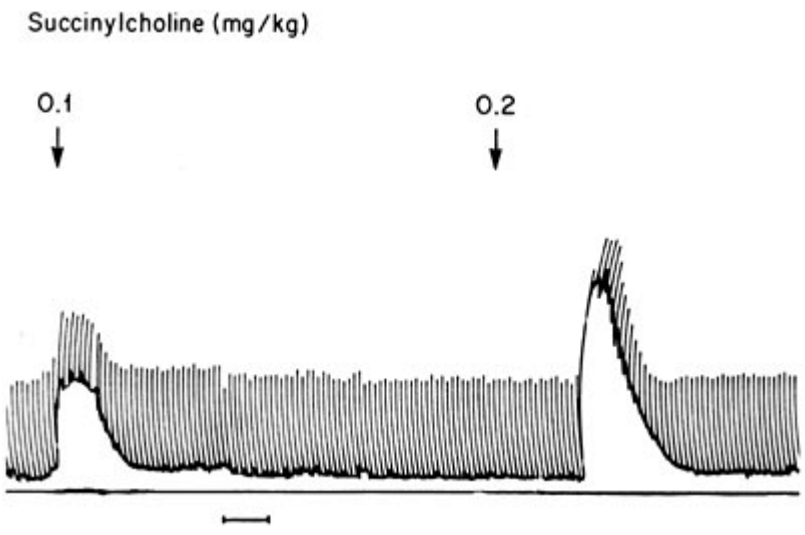

FIGURE 19-3. Administration of low does of succinylcholine to a patient with myotonic dystrophy produces an exaggerated contraction of skeletal muscle. (Reprinted with permission from Mitchell MM, Ali HH, Savarese JJ: Myotonia and neuromuscular blocking drugs. Anesthesia 49:44, 1978.)

Patients with myotonic dystrophy are sensitive to the respiratory depressant effects of opioids (systemic and neuraxial), barbiturates, benzodiazepines, and inhaled anesthetics. The severity of the respiratory depression parallels the progression of the disease and may be the result of depression of central respiratory centers as well as peripheral muscle effects. In a study of more than 200 patients with myotonic dystrophy undergoing surgery, respiratory complications were more likely to occur in the early postoperative period after upper abdominal surgery or in those patients in whom preoperative upper extremity weakness was clinically evident.[9]

No specific anesthetic technique has been shown to be superior for patients with myotonic dystrophy. Higher doses of propofol have been associated with prolonged recovery. Carefully controlled propofol infusions have been successfully used for patients with myotonic dystrophy. Inhaled anesthetics may be used but close monitoring of cardiac rhythm and cardiovascular function is indicated. Postoperative mechanical ventilation should be employed until muscle strength and function return.[10] Successful regional anesthesia has been described for both children and adults with myotonic dystrophy.[11]

Skeletal muscle weakness and myotonia are exacerbated during pregnancy. Labor is typically prolonged and there is an increased incidence of postpartum hemorrhage (placenta accreta). Spinal and epidural anesthesia have been successfully used for pregnant patients.

Familial Periodic Paralysis

Genetic research required a reclassification of the periodic paralyses and some types of myotonias. These diseases have been reclassified as the skeletal muscle channelopathies.[12] The skeletal muscle channelopathies include hyperkalemic and hypokalemic periodic paralysis, paramyotonia congenita, and potassium aggravated myotonia.

Hyperkalemic Periodic Paralysis

Hyperkalemic periodic paralysis is inherited as an autosomal dominant trait that causes a mutation in the sodium ion channel. Hyperkalemic periodic paralysis is characterized by episodes of myotonia and muscle weakness that may last several hours after exposure to a trigger. Weakness can occur during rest after strenuous exercise, infusions of potassium, metabolic acidosis, or hypothermia. The weakness may be so severe that ventilatory support is required. The hyperkalemia is often transient, occurring only at the onset of weakness and potassium levels measured during the attack may be normal or decreased. Treatment consists of a low-potassium diet and the administration of thiazide diuretics (Table 19-4).

TABLE 19-4 Clinical Features of Familial Periodic Paralysis

- **HYPOKALEMIC**
  - Calcium channel defect
  - Potassium level <3 mEq/L during symptoms
  - Precipitating factors
    - High glucose meals
    - Strenuous exercise
    - Glucose-insulin infusions
    - Stress
    - Hypothermia
  - Other features
    - Chronic myopathy with aging
- **HYPERKALEMIC**
  - Sodium channel defect

Potassium level normal or >5.5 mEq/L during symptoms
Precipitating factors
  Rest after exercise
  Potassium infusions
  Metabolic acidosis
  Hypothermia
Other features
  Skeletal muscle weakness may be localized to tongue and eyelids

Hypokalemic Periodic Paralysis

Hypokalemic periodic paralysis is inherited as an autosomal dominant trait that produces a defect in the calcium ion channel. Paralysis may be produced by the ingestion of carbohydrates, strenuous exercise, and the infusion of glucose and insulin. Paralysis is usually incomplete, affecting the limbs and trunk, but sparing the diaphragm. Vocal cord paralysis can cause respiratory distress. Low potassium levels during acute episodes can cause cardiac dysrhythmias. Treatment consists of potassium infusion and the administration of acetazolamide and dichlorphenamide. Chronic muscle weakness occurs in most patients with hypokalemic periodic paralysis as they age.

Management of Anesthesia

The primary goal of the perioperative management of patients with both forms of periodic paralysis is the maintenance of normal potassium levels and avoidance of events that precipitate weakness. If possible, any electrolyte abnormality should be corrected prior to surgery. These patients may be sensitive to nondepolarizing muscle relaxants. Short-acting muscle relaxants are preferred and the response should be monitored with a peripheral nerve stimulator. Succinylcholine is best avoided as its administration may alter serum potassium levels. Metabolic changes (acidosis and alkalosis) or medications (glucose and insulin, diuretics) that reduce potassium levels may initiate an episode of paralysis. Since changes in the potassium level may precede the onset of weakness, serial measurement of potassium levels during prolonged surgical procedures and the early postoperative period should be considered. The electrocardiogram (ECG) should be continuously monitored for evidence of potassium-related dysrhythmias. Other recommendations include the avoidance of carbohydrate loads, hypothermia, and excessive hyperventilation. Any cause of potassium depletion can produce muscle weakness in patients with hypokalemic periodic paralysis. Halogenated inhaled anesthetics have been administered without complication. Regional anesthesia has also been successfully used.[13] Malignant hyperthermia has been associated with both forms of periodic paralysis.

After surgery, adequate muscle strength must be assured before mechanical ventilation of the lungs is discontinued.

Myasthenia Gravis

Myasthenia gravis is an autoimmune disease with antibodies directed against the nicotinic acetylcholine receptor or other muscle membrane proteins. Eighty-five percent of patients with myasthenia gravis have identifiable antiacetylcholine receptor antibodies. The majority of previously described "seronegative" patients have been found to have antibodies to muscle-specific receptor tyrosine kinase (MuSK).[14] Antiacetylcholine receptor antibodies damage the postsynaptic muscle membrane via a complement-mediated reaction causing an increased

degradation and decreased formation of acetylcholine receptors. The thymus may play a central role in the pathogenesis of myasthenia gravis as 90% of patients have histologic abnormalities such as thymoma, thymic hyperplasia, or thymic atrophy. Many myasthenic patients also have antinuclear and antithyroid antibodies and other autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, pernicious anemia, and thyroiditis is associated with myasthenia gravis.

The clinical hallmark of myasthenia gravis is skeletal muscle weakness. Typically, the weakness is aggravated by repetitive muscle use and there are periods of exacerbation alternating with remission. Any skeletal muscle may be affected, although there is a predilection for muscles innervated by cranial nerves. Initial symptoms include diplopia, dysarthria, dysphagia, or limb-muscle weakness. Although respiratory insufficiency is not a common presenting symptom, undiagnosed myasthenia gravis should be included in the differential diagnosis of respiratory failure.[15] A myasthenic crisis will occur in 15 to 20% of patients during the course of their disease. Myasthenic crises are often precipitated by pulmonary infections and result in respiratory failure requiring mechanical ventilation. Potential cardiac manifestations of myasthenia gravis include focal myocarditis, atrial fibrillation, atrioventricular conduction delay, and left ventricular diastolic dysfunction.

Many conditions such as viral infection, pregnancy, extreme heat, stress, and surgery may initiate or exacerbate the symptoms of myasthenia, but the response to such stressors is unpredictable. Some pregnant patients have a remission during pregnancy while others (20 to 40%) have increased symptoms during gestation. Postpartum respiratory failure can occur. Fifteen to 20% of neonates born to myasthenic mothers have transient myasthenia from passive placental transfer of antiacetylcholine receptor antibodies. Signs and symptoms of neonatal myasthenia begin 12 to 48 hours after birth and may persist for several weeks.

There are several types of myasthenia gravis. Disease classification is based on skeletal muscle groups affected as well as the age of onset (Table 19-5). The Osserman staging system is based on the severity of the disease. Type I: ocular signs and symptoms only; type IIA: generalized muscle weakness;

type IIB: generalized moderate weakness and/or bulbar dysfunction; type III: acute fulminant presentation and/or respiratory dysfunction; and type IV: severe, generalized myasthenia.

TABLE 19-5 Different Presentations of Myasthenia Gravis

	·ETIOLOGY	·ONSET	·SEX	·THYMUS	·COURSE
Neonatal myasthenia	Passage of antibodies from myasthenic mothers across the placenta	Neonatal	Both sexes	Normal	Transient
Congenital myasthenia	Congenital end-plate pathology, genetic, autosomal recessive	0–2 yr	Male > female	Normal	Nonfluctuating, compatible with long survival

	pattern of inheritance				
Juvenile myasthenia	Autoimmune disorder	2–20 yr	Female > male (4:1)	Hyperplasia	Slowly progressive, tendency to relapse and remission
Adult myasthenia	Autoimmune disorder	20–40 yr	Female > male	Hyperplasia > thymoma	Maximum severity within 3–5 yr
Elderly myasthenia	Autoimmune disorder	>40 yr	Male > Female	Thymoma (benign or locally invasive)	Rapid progress, higher mortality

Reproduced with permission from Barka A: Anesthesia and myasthenia gravis. Can J Anaesth 39:476, 1992.

The diagnosis of myasthenia gravis is based on the clinical history, the edrophonium test, electromyography, and the detection of circulating antiacetylcholine receptor antibodies. No single test, however, is definitive. The administration of edrophonium, for example, can improve muscle strength in myasthenic patients and in patients with other neuromuscular disorders.

Treatment modalities include the administration of cholinesterase inhibitors, corticosteroids, immunosuppressants, plasmapharesis, and thymectomy. The mainstay of medical therapy is the cholinesterase inhibitor pyridostigmine. Cholinesterase inhibitors function by effectively increasing the concentration of acetylcholine at the nicotinic postsynaptic membrane. Consistent control of myasthenia with cholinesterase inhibitors can be quite challenging. Underdosing will result in increased muscle weakness, whereas overdosing will produce a "cholinergic crisis." Excessive amounts of cholinesterase inhibitors produce abdominal cramping, salivation, bradycardia, and skeletal muscle weakness that mimics the weakness of myasthenia.

The immunosuppressive effects of corticosteroids produce an improvement in muscle strength in myasthenic patients although the precise mechanism is unknown. High-dose corticosteroids may, however, cause a transient increase in muscle weakness. Other immunosuppresants used for the treatment of myasthenia include azathioprine, cyclosporine, cyclophosphamide, tacrolimus, rituximab, and mycophenolate mofetil. Plasmapharesis removes antiacetylcholine receptor antibodies from the circulation and is effective treatment for patients in myasthenic crisis. Intravenous immunoglobulin may also be effective for the treatment of myasthenic crisis.

The association between the thymus and myasthenia gravis has been known for decades. The role of thymectomy for the treatment of myasthenia gravis is, however, not clearly established. Although a thymoma is a clear indication for thymectomy, thymectomy for other myasthenic patients is controversial. Thymectomy may be more effective if performed in the early stages of the disease. Should thymectomy be recommended, the surgical approach is also controversial. It is not clear whether wide surgical exposure through a sternal splitting approach is better than a transcervical or a video-assisted thorascopic (VATS) approach. The less-invasive approaches offer

fewer postoperative complications, but may result in an incomplete resection of the thymus.[16]

Management of Anesthesia

3 The primary concern in anesthesia for the patient with myasthenia gravis is the potential interaction between the disease, treatment of the disease, and neuromuscular blocking drugs. The uncontrolled or poorly controlled myasthenic patient is exquisitely sensitive to nondepolarizing muscle relaxants. Small defasiculating doses of nondepolarizers can produce significant respiratory muscle weakness and respiratory distress. It should be anticipated that any patient with myasthenia, no matter how localized, will have increased sensitivity to nondepolarizing muscle relaxants (Fig. 19-4). An anesthetic technique that avoids the use of a muscle relaxant may be

preferred for patients with myasthenia gravis.[17] Conditions suitable for tracheal intubation can be obtained with a standard induction technique (thiopental, propofol) and the inhalation of volatile halogenated agents. Isoflurane, sevoflurane, and desflurane depress neuromuscular transmission and may provide enough muscle relaxation so that tracheal intubation can be performed without neuromuscular blocking drugs after an adequate depth of anesthesia has been attained. Adjuvant drugs such as propofol, opioids, and lidocaine that blunt responses to laryngosocpy may be useful.

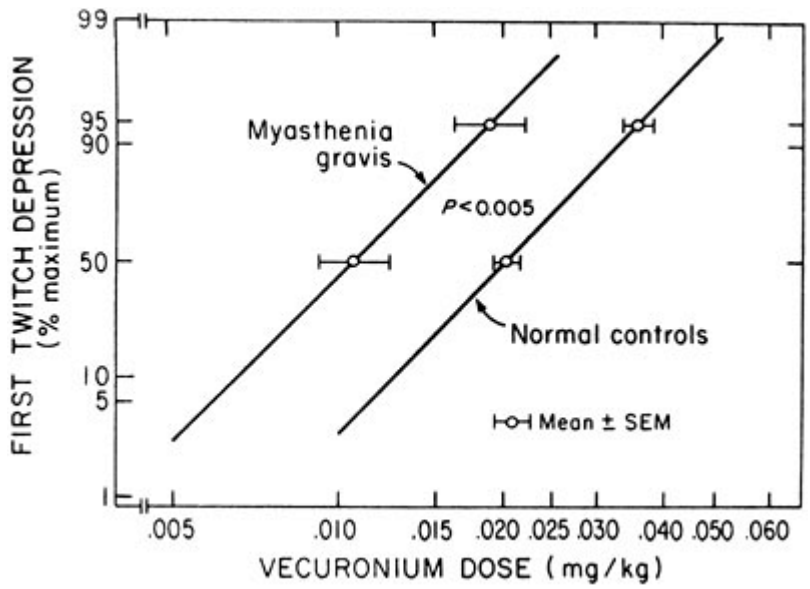

FIGURE 19-4. Dose-response for vecuronium in normal patients and patients with myasthenia gravis. (Reprinted with permission from Eisenkraft JB, Book WJ, Paparestas AE: Sensitivity to vecuronium in myasthenia gravis: A dose-responsive study. Can J Anaesth 37;301, 1990.)

Myasthenia and the cholinesterase inhibitor drugs used to treat myasthenia will influence the response to both depolarizing and nondepolarizing muscle relaxants. Certain recommendations are indicated. Pretreatment doses of nondepolarizers and long-acting nondepolarizing muscle relaxants (pancuronium) should not be used in myasthenic patients. If additional muscle relaxation is required for the procedure, short-acting nondepolarizers in small doses should be used for myasthenic patients. Close, objective monitoring of neuromuscular transmission and clinical effect is necessary. Atracurium, cisatracurium, mivacurium, vecuronium, and rocuronium have been used. The response of the myasthenic patients to these drugs varies greatly. Although patients with myasthenia have a resistance to succinylcholine, a dose of 1.5 to 2 mg/kg will be adequate for rapid tracheal intubation. Preoperative administration of pyridostigmine, however, may prolong the action of succinylcholine and mivacurium.[18]

Adjuvant drugs that may exacerbate muscle weakness in myasthenic patients include aminoglycoside antibiotics, polymyxins, beta-adrenergic blockers, procainamide, corticosteroids, and phenytoin. Patients with myasthenia gravis may have central respiratory depression and the respiratory depressant effects of barbiturates, benzodiazepines, opioids, and propofol may be accentuated. Vigilant monitoring of respiratory function is required.

Most modern anesthetic techniques permit weaning from mechanical ventilation and tracheal extubation of myasthenic patients soon after surgery.[19] Less-invasive surgical techniques for thymectomy, such as a transcervical approach or video-assisted thoracoscopic thymectomy, produce less disruption of respiratory function than transsternal thymectomy. Because of the unpredictability of postoperative recovery, however, it would be prudent to make preoperative arrangements for postoperative ventilation. Risk factors that increase the likelihood of postoperative insufficiency include a long duration of myasthenia, chronic respiratory disease, and treatment requiring high doses of pyridostigmine. The patient with myasthenia gravis can be quite challenging to wean from ventilatory support. Skeletal muscle strength can vary greatly during a short period of time.

Epidural analgesia and anesthesia can be used for labor and delivery. Muscle relaxation induced by regional anesthesia may, however, compound the weakness caused by myasthenia. This potential synergism necessitates careful monitoring of the patient's muscle strength. Amide local anesthetics may be better than ester local anesthetics as the metabolism of amides is not affected by cholinesterase activity. Exacerbations of myasthenia must be anticipated during pregnancy.

Myasthenic Syndrome (Lambert-Eaton Syndrome)

The Lambert-Eaton myasthenic syndrome (LEMS) is a disorder of neuromuscular transmission associated with carcinomas, particularly small cell carcinoma of the lung and lymphoproliferative diseases (Table 19-6). The onset of the myasthenic syndrome may actually precede the discovery of the malignancy by as much as 5 years. LEMS is an autoimmune disease in which immunoglobulin G (IgG) antibodies against voltage-gated calcium channels (presynaptic) are produced. In those cases associated with carcinoma, the autoantibodies are directed at calcium channels in the tumor. These autoantibodies, however, cross-react with calcium channels at the neuromuscular junction. The result is a decreased release of acetylcholine in response to nerve stimulation. Typically, the patient is a man, 50 to 70 years of age, complaining of proximal extremity weakness (hip, shoulder) that markedly affects gait and the ability to stand and climb stairs. Rarely, the clinical presentation may be respiratory failure. Autonomic dysfunction, such as xerostomia, impotence, orthostatic hypotension, constipation, and altered sweating responses may also develop.[20]

TABLE 19-6 Comparison of Myasthenic Syndrome and Myasthenia Gravis

	·MYASTHENIC SYNDROME	·MYASTHENIA GRAVIS
Manifestations	Proximal limb weakness (arms > legs)	Extraocular, bulbar, and facial muscle weakness
	Exercise improves with strength	Fatigue with exercise
	Muscle pain common	Muscle pain uncommon
	Reflexes absent or decreased	Reflexes normal

Gender	Male > female	Female > male
Coexisting pathology	Small cell carcinoma of the lung	Thymoma
Response to muscle relaxants	Sensitive to succinylcholine and nondepolarizing muscle relaxants	Resistant to succinylcholine Sensitive to nondepolarizing muscle relaxants
	Poor response to anticholinesterases	Poor response to anticholinesterases

Treatment of the underlying neoplasm may improve the neurologic condition. The most effective drug for the treatment of myasthenic syndrome is 3,4-diaminopyridine. 3,4-diaminopyridine improves synaptic transmission by opening voltage-gated potassium channels, which prolongs the action potential and increases release of acetylcholine. Side effects of 3,4-diaminopyridine include perioral and digital paresthesias and seizures. Immunosuppression with corticosteroids, azathioprine, and cyclosporine may also be effective.

Plasmapharesis and intravenous immunoglobulin may produce short-term improvement.[21]

Management of Anesthesia

Patients with myasthenic syndrome are sensitive to the effects of both depolarizing and nondepolarizing muscle relaxants. Consequently, doses of these drugs should be reduced and neuromuscular function should be monitored carefully. The administration of 3,4-diaminopyridine should be continued up to the time of surgery.

4 Because the myasthenic syndrome is difficult to diagnose, a high index of suspicion should be maintained if unexpected muscle weakness occurs in patients with malignant tumors. Although myasthenic syndrome is most frequently associated with small cell carcinoma of the lung, muscle weakness can occur with other malignancies as well.

Guillain-Barré Syndrome (Polyradiculoneuritis)

Guillain-Barré syndrome is the most common cause of acute, flaccid paralysis. Guillain-Barré syndrome is an autoimmune disease triggered by a bacterial or viral infection. The list of infectious triggers is long and includes Epstein-Barr virus, hemophilus parainfluenza, influenza, adenovirus, herpes simplex, varicella, human immunodeficiency virus, mycoplasma, and campylobacter. The infection triggers an immune response that produces antibodies to an antigen of the infectious agent. The antigen mimics an epitope of the Schwann cell and the antibodies damage myelin nerve sheaths.

Most patients have a history of a respiratory or gastrointestinal infection within 4 weeks of the onset of neurologic symptoms. Guillain-Barré syndrome is characterized by the acute or subacute onset of skeletal muscle weakness or paralysis of the legs. Sensory disturbances such as paresthesias often precede the paralysis. The paralysis typically progresses cephalad to include

the muscles of the trunk and arms. Difficulty in swallowing and impaired ventilation secondary to intercostal muscle paralysis can occur. Progression occurs over 10 to 12 days, followed by gradual recovery. The most serious immediate problem is ventilatory insufficiency. The vital capacity should be measured frequently. If the vital capacity decreases to less than 15 to 20 mL/kg, mechanical ventilation of the lungs is indicated. The more rapid the onset of quadriplegia, the more likely the need for ventilatory support. Although 85% of patients with this syndrome achieve a good or full recovery, chronic recurrent neuropathy develops in 3 to 5% of patients. Subtypes of Guillain-Barré syndrome include acute inflammatory demyelinating polyneuropathy (AIDP), acute motor axonal neuropathy (AMAN), acute motor-sensory axonal neuropathy (AMSAN), and Miller-Fisher syndrome (MFS).

The primary therapy for Guillain-Barré syndrome is intensive respiratory care and management of autonomic dysfunction. Intensive critical care has reduced mortality from Guillain-Barré syndrome to less than 5%. Plasmapharesis and the administration of intravenous immunoglobulin may help alleviate the harmful effects of the disordered immune response.[22]

Autonomic nervous system dysfunction occurs in many patients with Guillain-Barré syndrome. This dysfunction can produce wide fluctuations in cardiovascular parameters. In a manner similar to autonomic hyperreflexia, physical stimulation can precipitate hypertension, tachycardia, and cardiac dysrhythmias. Appropriate alpha- and beta-adrenergic blockade may be required. Mild hepatic dysfunction may also develop in patients with Guillain-Barré syndrome.

Management of Anesthesia

Autonomic nervous system dysfunction indicates that compensatory cardiovascular responses may be absent, resulting in significant hypotension secondary to postural changes, blood loss, or positive airway pressure. On the other hand, noxious stimuli such as laryngoscopy and tracheal intubation may produce exaggerated increases in heart rate and blood pressure. Direct-acting vasopressors may be required to control blood pressure. Cardiovascular function should be carefully monitored in the perioperative period.

The administration of succinylcholine should be avoided because of the danger of drug-induced potassium release and hyperkalemia. This risk may actually persist after clinical recovery from the disorder.[23] A nondepolarizing muscle relaxant with minimal cardiovascular effects such as cisatracurium, vecuronium, or rocuronium would be a useful choice. The sensitivity of patients with Guillain-Barré syndrome to nondepolarizing muscle relaxants, however, may vary from extreme sensitivity to resistance, depending on the phase of the disease.[24] It is likely that mechanical ventilation will be required during the immediate postoperative period. Patients with Guillain-Barré syndrome that have pronounced sensory disturbances may benefit from the administration of epidural opioids.

It should be remembered that it can be very difficult to differentiate Guillain-Barré syndrome from other neurologic disorders such as anterior spinal syndrome or chronic inflammatory demyelinating polyneuropathy. Guillain-Barré syndrome can occur after surgery.

CENTRAL NERVOUS SYSTEM DISEASES

Multiple Sclerosis

Multiple sclerosis is an acquired disease of the central nervous system (CNS) characterized by central nervous system inflammation and multiple sites of demyelination in the brain and spinal cord. The cause of multiple sclerosis is multifactorial and involves a complex series of immunologic events occurring in genetically susceptible individuals. Initially, a virus or other agent (? ischemia) triggers an inflammatory reaction that causes a T-cell–mediated autoimmune response to myelin. Demyelination exposes the axon to harmful factors and interferes with neural transmission. The nerve's ability to repair itself during the early phases of the process explains the relapsing nature of the disease.[25]

The symptoms of multiple sclerosis depend on the sites of demyelination in the brain and spinal

cord. Demyelination of the optic tracts produces visual disturbances, whereas demyelination of the oculomotor pathways results in nystagmus. Lesions of the spinal cord produce limb weakness and paresthesias. The legs are affected more than the arms. Bowel retention and urinary incontinence are frequent complaints. Brainstem involvement can produce diplopia, trigeminal neuralgia, cardiac dysrhythmias, and autonomic dysfunction, while alterations in ventilation can lead to hypoxemia, apnea, and respiratory failure. The course of multiple sclerosis is characterized by exacerbation of symptoms at unpredictable intervals over a period of years. Residual symptoms eventually persist and may lead to severe disability. Three clinical courses are recognized: relapsing-remitting MS (RR-MS), primary-progressive MS (PP-MS), and secondary-progressive MS (SP-MS). Ten to 20% of patients with multiple sclerosis have a relatively benign course with little disability. Pregnancy is associated with an improvement in symptoms, but relapse frequently occurs in the first three postpartum months.

The diagnosis of multiple sclerosis is based primarily on clinical determinants. Clinical criteria include age of onset between 10 and 50 years, neurologic signs and symptoms of CNS white matter disease, two or more attacks separated by a month or more, and involvement of two or more noncontiguous anatomic areas. Laboratory confirmation of the diagnosis can be made by chemical analysis of the cerebrospinal fluid and cranial magnetic resonance imaging (MRI). Seventy percent of patients with multiple sclerosis have elevated levels of IgG in the CSF. An elevated level of albumin in the CSF is indicative of blood-brain barrier dysfunction. MRI is a sensitive diagnostic tool for multiple sclerosis and provides direct evidence of the location of demyelinated plaques in the central nervous system. MRI can also be used as a measure of the effectiveness of treatment.

Current therapy for multiple sclerosis is directed at modulating the immunologic and inflammatory responses that damage myelin. Corticosteroids (methylprednisolone) are the primary agents for treatment of an acute exacerbation of multiple sclerosis. Corticosteroids have diverse effects that suppress cellular immune responses. Interferon (IFN) alters the inflammatory response and augments natural disease suppression and has been shown to reduce the relapse rate. Side effects of interferon therapy include aggravation of spasticity, development of autoantibodies, and flu-like symptoms. Glatiramer is a mixture of polypeptides that mimics the structure of myelin and serves as a decoy for autoantibodies. A number of immunosuppressants have been studied but patient response has been variable. Mitoxantrone can be used to treat aggressive multiple sclerosis. Mitoxantrone, however, is cardiotoxic. Currently under investigation are therapies directed at remyelination such as Schwann cell transplantation.[26] Symptomatic therapy for some of the complications of multiple sclerosis include diazepam, dantrolene, and baclofen for spasticity. Painful dysesthesias, tonic seizures, dysarthria, and ataxia may be treated with carbamazepine. Nonspecific measures include the avoidance of excessive fatigue, emotional stress, and hyperthermia. Demyelinated nerve fibers are extremely sensitive to increases in temperature. A temperature increase of 0.5 degrees C can block impulse conduction in demyelinated fibers.

Management of Anesthesia

5 The effect of surgery and anesthesia on the course of multiple sclerosis is controversial. Regional and general anesthesia have been reported to exacerbate multiple sclerosis, while other reports have found no correlation between anesthesia and the course of the disease. Factors other than anesthesia such as infection, emotional stress, and hyperpyrexia may contribute to an increased risk of a perioperative exacerbation. Preoperatively, the patient should be advised that surgery and anesthesia could produce a relapse despite a well-managed anesthetic. Ideally, the patient should have a thorough neurologic examination before the operation to document coexisting neurologic deficits. After surgery, the examination can be repeated so that pre- and postoperative findings can be compared.

Although the mechanism is not known, spinal anesthesia has been associated with an exacerbation of the disease. It could be speculated that demyelinated areas of the spinal cord are more sensitive to the effects of the local anesthetic causing a relative neurotoxicity. Further evidence for this theory is found by the observation that higher concentrations of bupivacaine (0.25%) used

for labor epidural analgesia were more likely to produce relapse than lower concentrations.[27] With such a precaution in mind, epidural analgesia can be safely provided for women during labor. Neuraxial local anesthetics and opioids may also be indicated for the treatment of chronic, refractory pain syndromes in patients with multiple sclerosis.

Selection of agents for general anesthesia should take into consideration potential interactions with medications the patient is receiving. Patients being treated with corticosteroids may require intravenous corticosteroid supplementation during the perioperative period. Immunosuppressants can produce cardiotoxicity and subclinical cardiac dysfunction. Baclofen can produce an increase sensitivity to nondepolarizing muscle relaxants, while anticonvulsants produce resistance to nondepolarizers. In theory, succinylcholine could produce an exaggerated release of potassium, although this has not been reported. Autonomic dysfunction caused by multiple sclerosis may exaggerate the hypotensive effects of volatile anesthetics. Careful monitoring of cardiovascular function is indicated. Respiratory muscle weakness and respiratory control dysfunction increase the likelihood of the need for supplemental oxygen and/or mechanical ventilation during the immediate postoperative period.[28]

Epilepsy

A seizure is a common manifestation of many types of CNS diseases. A seizure results from an excessive discharge of large numbers of neurons that become depolarized in a synchronous fashion. Idiopathic seizures usually begin during childhood. The sudden onset of seizures in a young or middle-aged adult should arouse suspicion of focal brain disease, particularly a tumor. The onset of seizures after 60 years of age is usually secondary to cerebrovascular disease but can be a result of head injury, tumor, metabolic disturbances, or central nervous system infection. The onset of seizures mandates a thorough neurologic evaluation to determine the etiology. Advanced neuroimaging techniques provide powerful diagnostic tools for the determination of structural causes of epilepsy. Research in molecular biology and genetics has revealed that some forms of epilepsy are caused by mutations in ion channels. The availability of new antiseizure drugs has increased the therapeutic options for patients with epilepsy. Selecting the right drug or drugs for the treatment of epilepsy may require trial and error to balance efficacy with side effects.[29]

There are more than 40 types of epilepsy based on several clinical features. The most common classification is the International Classification of Epileptic Seizures (Table 19-7). A description of the most frequently encountered types of seizures follows.

TABLE 19-7 Classification of Seizures

▪LOCALIZATION-RELATED EPILEPSIES AND SEIZURES
Idiopathic
  Benign childhood epilepsy
  Childhood epilepsy with occipital paroxysms
▪GENERALIZED EPILEPSIES
Idiopathic
  Absence epilepsy
    Childhood
    Juvenile
  Benign neonatal convulsions
  Myoclonic epilepsy
    Neonatal
    Juvenile
  Grand mal seizures on awakening
Idiopathic and/or symptomatic

West's syndrome
Lennox-Gestaut syndrome
Myoclonic–astatic seizures
Myoclonic absences
Symptomatic
Nonspecific etiology
▪UNDETERMINED EPILEPSIES AND SYNDROMES
With both generalized and focal seizures
Neonatal seizures
Severe myoclonic epilepsy of infancy
Acquired epileptic aphasia
▪SPECIAL SYNDROMES
Febrile seizures
Alcohol-related seizures

Modified with permission from Riela AR: Management of seizures. Crit Care Clin 5:863, 1989.

1. Grand Mal Seizures

   A grand mal seizure is characterized by generalized tonic-clonic activity. All respiratory activity is arrested and a period of arterial hypoxemia ensues. The tonic phase lasts for 20 to 40 seconds and is followed by the clonic phase. In the postictal period, the patient is lethargic and confused. Initial therapy is directed toward maintaining arterial oxygenation and stopping the seizure activity. Diazepam and thiopental are effective for the treatment of acute, generalized seizures. Antiseizure drugs effective for seizure control and prevention are valproate, phenytoin, felbamate, carbamazepine, and lamotrigine (Table 19-8). Epileptic patients resistant to drug therapy may benefit from surgical resection of a seizure focus or vagal nerve stimulator implantation.[30]

2. Focal Cortical Seizure

   Focal cortical seizure, also known as Jacksonian epilepsy, may be sensory or motor, depending on the site of neuronal discharge. There is usually no loss of consciousness, although the seizure activity may spread to produce a grand mal seizure.

3. Absence Seizure (Petit Mal)

   Absence seizures, previously called petit mal seizures, are characterized by a brief loss of awareness lasting 30 seconds. Additional manifestations include staring, blinking, and rolling of the eyes. There is an immediate resumption of consciousness. Absence seizures typically occur in children and young adults. Absence seizures without other seizure activity are best treated with ethosuximide. Valproate is the drug of choice for absence seizures associated with other seizure activity.

4. Akinetic Seizure

   Akinetic seizures are characterized by a sudden, brief loss of consciousness and loss of postural tone. These types of seizures usually occur in children and can produce severe head injury from a fall.

5. Myoclonic Seizure

   Myoclonic seizures occur as isolated clonic jerks in response to a sensory stimulus. In most

cases a single group of muscles is involved. Myoclonic seizures are often associated with degenerative and metabolic brain diseases.

6. Psychomotor Seizure

   Psychomotor seizures are seen as an impairment of consciousness, inappropriate motor acts, hallucinations, amnesia, and unusual visceral symptoms. This type of seizure is preceded by an aura.

7. Status Epilepticus

   Status epilepticus is defined as two consecutive tonic-clonic seizures without regaining consciousness, or seizure activity that is unabated for 30 minutes or more. Status epilepticus can include all types of seizure activity. Grand mal status epilepticus is of the greatest concern because mortality can be as high as 20%. Grand mal status epilepticus typically lasts for 48 hours with a seizure frequency of four to five per hour. As the seizure progresses, skeletal muscle activity diminishes and seizure activity may be evident only on the electroencephalogram (EEG). Respiratory effects of status epilepticus include inhibition of the respiratory centers, uncoordinated skeletal muscle activity that impairs ventilation, and abnormal autonomic activity that produces bronchoconstriction. In addition to the danger of arterial hypoxemia, there is a high likelihood of permanent neuronal damage from continued seizures. Diazepam or lorazepam are considered the drugs of choice for treatment of status epilepticus. Because the effects of the benzodiazepines are transient, a longer acting anticonvulsant such as phenytoin or phenobarbital must also be administered. Thiopental is quite effective for the initial treatment of status epilepticus, but the effect is transient. Muscle relaxants may be required to facilitate tracheal intubation if a secured airway is necessary. Although muscle relaxants will terminate the skeletal muscle manifestations of a seizure, there is no effect on seizure activity in the brain. On rare occasions, general anesthesia with isoflurane or barbiturates may be required for treatment of status epilepticus.

TABLE 19-8 Anticonvulsant Drugs

·DRUG	·SEIZURE TYPE	·THERAPEUTIC BLOOD LEVELS (µg/mL)	·SIDE EFFECTS
Phenobarbital	Generalized	15–35	Sedation, increased drug metabolism
Valproate	Generalized	50–100	Pancreatitis, hepatic
	Absence		dysfunction
Felbamate	Generalized	20–140	Insomnia, ataxia, nausea
	Partial		
Phenytoin	Generalized	10–20	Gingival hyperplasia

	Partial		Dermatitis
			Resistance to NM blockers
Fosphenytoin	Generalized		Paresthesias
	Partial		Hypotension
Carbamazepine	Generalized	6–12	Cardiotoxic, hepatitis
	Partial		Resistance to NM blockers
Lamotrigine	Generalized	2–16	Rash
	Partial		Stevens-Johnson syndrome
Topiramate	Generalized	4–10	
	Partial		
Gabapentin	Generalized	4–16	Fatigue, somnolence
	Partial		
Primidone	Generalized	6–12	Nausea, ataxia
	Partial		
Clonazepam	Absence	0.01–0.07	Ataxia
Ethosuximide	Absence	40–100	Leuopenia
			Erythema multiforme
Levetiracetam	Generalized	5–45	Dizziness, headache
	Partial		Somnolence

Oxycarbazepine	Partial	10–35	Hyponatremia, diplopia
			Somnolence
Tiagabine	Partial		Tremor, depression
Zonisamide	Generalized	10–40	Anorexia
	Partial		Decreased cognition

Management of Anesthesia

Patients receiving antiseizure medications should be maintained on their normal medication regimen until the time of surgery. After surgery, medications should be given parenterally until oral intake can be resumed. A decline in blood levels of anticonvulsant drugs will increase the likelihood of postoperative seizures.

In the management of anesthesia for the patient with a seizure disorder, the potential influence of anticonvulsants on the response to anesthesia must be considered. Conversely, an anesthesia technique should be used that will not increase the likelihood of seizure activity. Because anticonvulsant drugs affect the liver and neuromuscular systems, the potential for significant drug interactions certainly exists. Stimulation of the hepatic microsomal enzymes by anticonvulsants may increase the magnitude of biotransformation of anesthetic drugs. Increased biotransformation of volatile halogenated anesthetics may increase the risk of organ toxicity. Other known side effects of anticonvulsants include leukopenia, anemia, and hepatitis from phenytoin; pancreatitis, hepatic failure, and coagulopathy from valproate; aplastic anemia, cardiotoxicity, and hypothyroidism from carbamazepine; leukopenia from felbamate; and rash and hypersensitivity from lamotrigine.[31]

Although most inhaled anesthetics, including nitrous oxide, have been reported to produce seizure activity, such activity during the administration of isoflurane, sevoflurane, and desflurane is extremely rare. In general, these anesthetics produce a dose-dependent depression of EEG activity. The use of ketamine is controversial. Ketamine has been shown to produce seizure activity in patients with known seizure disorders. Similarly, methohexital may produce seizure activity. It would seem reasonable to avoid the use of ketamine and methohexital for patients with seizure disorders when alternative drugs such as thiopental, propofol, and benzodiazepines are available. Propofol has a more depressant effect on the EEG than thiopental and has been shown to increase the seizure threshold in patients receiving electroconvulsive therapy.

Potent opioids such as fentanyl, sufentanil, and alfentanil may produce myoclonic activity or chest wall rigidity that can be confused with seizure activity. In clinical doses, opioid induced seizures are unlikely. Prolonged administration of

large doses of fentanyl (200 to 400 µg/kg) or sufentanil (40 to 160 µg/kg) may produce seizures and should be used with caution in patients with seizure disorders.

Patients receiving phenytoin or carbamazepine exhibit resistance to nondepolarizing muscle relaxants.

Parkinson's Disease

Parkinson's disease, one of the most common disabling neurologic diseases, affects 1% of the

population over 60 years of age. Parkinson's disease is a degenerative disease of the central nervous system caused by loss of dopaminergic fibers in the basal ganglia of the brain. The characteristic pathologic feature is destruction of dopamine-containing nerve cells in the substantia nigra of the basal ganglia. Lewy bodies, a hallmark of the pathology of Parkinson's disease, are proteinaceous cytoplasmic cell inclusions. Theories of the etiology of Parkinson's disease include mitochondrial dysfunction with disordered oxidative metabolism, excitotoxicity (persistent activation of glutamatergic receptors), inadequate neurotrophic support, and exposure to toxins (pesticides, herbicides, industrial chemicals, or viral infection).[32] Other than the well-known postencephalitic Parkinson's disease, however, there is little evidence that Parkinson's disease is caused by a virus.

The clinical effects of Parkinson's disease are caused by dopamine deficiency. Dopamine deficiency increases activity of gamma-aminobutyric acid (GABA). GABA inhibits thalamic and brainstem nuclei, which suppress cortical motor activity, thereby causing tremor, akinesia, and gait and posture abnormalities. The most characteristic clinical features of Parkinson's disease are resting tremor, cogwheel rigidity of the extremities, bradykinesia, shuffling gait, stooped posture, and facial immobility. These features are all secondary to diminished inhibition of the extrapyramidal motor system as a result of depletion of dopamine from the basal ganglia. Other features that occur in patients with Parkinson's disease are seborrhea, sialorrhea, orthostatic hypotension, bladder dysfunction, pupillary abnormalities, diaphragmatic spasm, oculogyric crises, dementia, and mental depression.

The treatment of Parkinson's disease is directed toward increasing dopamine levels in the brain but preventing the adverse peripheral effects of dopamine. Levodopa is the single most effective therapy for patients with Parkinson's disease. When administered orally, however, levodopa is converted to dopamine and causes side effects such as nausea, vomiting, and hypotension. To avoid such side effects, levodopa is administered in combination with a peripheral decarboxylase inhibitor (carbidopa). Cardiovascular side effects of levodopa include depletion of myocardial norepinephrine stores, peripheral vasoconstriction, hypovolemia, and orthostatic hypotension. Although levodopa has significantly reduced morbidity and mortality from Parkinson's disease, motor fluctuations causing significant disability occur in levodopa treated patients. There is also some evidence that levodopa may accelerate the pathologic process that causes Parkinson's disease. In an effort to delay the use of levodopa, other drugs such as selegiline, dopamine agonists, amantadine, COMT inhibitors, and apomorphine have been used as initial treatment drugs.[33] Anticholinergic

drugs (trihexyphenidyl, benztropine) are effective because they counteract loss of inhibition of cholinergic neurons. Anticholinergics can worsen dementia and are reserved for younger patients in the early phases of Parkinson's disease. Amantadine is a glutamate receptor antagonist and may exert a neuroprotective effect on neurons in the basal ganglia. Dopamine receptor agonists (bromocriptine, pergolide, pramipexole, ropinirole) exert their effect on dopamine receptors in the brain. Side effects of dopamine agonists include pulmonary and retroperitoneal fibrosis, erythromelalgia, and Raynaud's phenomenon. Selegiline is a selective MAO-B inhibitor that decreases the metabolism of dopamine. COMT inhibitors (entacapone, tolcapone) prevent the degradation of levodopa. Many of the aforementioned types of drugs, although not entirely successful as sole agents for the treatment of Parkinson's disease, are effective in combination with levodopa. Therapies directed at neuroprotection with a variety of agents (coenzyme Q10, creatine, vitamin E) are under study. Patients with advanced drug-resistant Parkinson's disease may benefit from surgical implantation of deep brain stimulators.[34]

Management of Anesthesia

Management of anesthesia is usually determined by potential interaction between anesthesia drugs and anti-Parkinson medications and the severity of neurologic impairment. The patient's medications should be administered on the morning of surgery. The half-life of levodopa is short and interruption of therapy for more than 6 to 12 hours can result in severe skeletal muscle rigidity that interferes with ventilation. Dopamine antagonists such as phenothiazines, droperidol,

and metoclopramide should be avoided. Alfentanil and fentanyl may produce acute dystonic reactions in patients with Parkinson' disease. Although ketamine could produce an exaggerated sympathetic nervous system response with resultant tachycardia and hypertension, it has been used without difficulty in patients with Parkinson's disease. The likelihood of coexisting heart disease in elderly patients with Parkinson's disease, however, makes the use of ketamine less attractive. There are no reports of adverse responses to isoflurane, sevoflurane, or desflurane in patients with Parkinson's disease. Although definitive studies of anesthesia for patients receiving selegiline have not been performed, clinical experience indicates that anesthesia is usually uneventful. There have been reports of agitation, muscle rigidity, and hyperthermia in patients receiving meperidine and selegiline. Patients with Parkinson's disease who are being treated with dopamine agonists may be at risk for neuroleptic malignant syndrome. Apomorphine is a dopamine agonist that can be administered subcutaneously or intravenously in the perioperative period if oral levodopa cannot be administered.

Autonomic dysfunction is common in patients with Parkinson's disease. Gastrointestinal dysfunction is manifested by excessive salivation, dysphagia, and esophageal dysfunction. Consequently, the patient with Parkinson's disease should be considered to be at risk for aspiration pneumonitis. The most consistent cardiovascular abnormality is orthostatic hypotension. The disease process undoubtedly contributes to hypotension, which is further compounded by the tendency for anti-Parkinson drugs to cause peripheral vasodilation. Patients with Parkinson's disease would be more likely to develop exaggerated decreases in blood pressure in response to inhaled halogenated anesthetics.

Perioperative respiratory complications are common in patients with Parkinson's disease.[35] Upper airway obstruction may occur as a result of poor coordination of upper airway muscles secondary to neurotransmitter imbalance caused by the disease process or induced by the administration of antidopaminergic drugs. Some Parkinson's patients with upper airway obstruction may respond to the administration of anti-Parkinson drugs.

In the postoperative period, patients with Parkinson's disease are susceptible to mental confusion and even hallucinations. These alterations in mental function may not appear until the day after surgery. The patient and the patient's caregiver should be advised of this possibility.

Huntington's Disease

Huntington's disease is a neurodegenerative disease caused by severe neuronal atrophy in the corpus striatum and later the cortex. Huntington's disease is one of the trinucleotide repeat disorders. An increase in cytosine, adenine, and guanine (CAG) repeat sequences on chromosome 4 causes the genetic defect that causes Huntington's disease. This gene encodes for the huntingtin protein. Although the function of the huntingtin protein is not known, intranuclear inclusions of huntingtin and ubiquitin are found in neurons that eventually die. Huntington's disease is a heritable disorder that is transmitted as an autosomal dominant trait. Identification of the Huntington's gene provides a reliable technique for predictive testing; however, the delayed nature of the clinical manifestations of the disease presents legal and ethical concerns about early predictive testing.[36]

The hallmark clinical features are choreiform movements and dementia. Onset is typically between the ages of 35 and 40 years, although a juvenile form may develop as early as 5 years of age. Although chorea is the most common movement disorder, athetosis and dystonia also occur. Movement abnormalities can involve the extremities, trunk, face, eyes, oropharynx, and respiratory muscles. The disease progresses for several years and mental depression makes suicide a frequent occurrence. Death usually results from malnutrition and aspiration pneumonitis. The duration of Huntington's disease averages 17 years from the time of diagnosis to death.

There is no specific therapy for Huntington's disease. Pharmacotherapy is directed at relief of mental depression and control of movement disorders. Drugs that reduce dopaminergic transmission such as phenothiazines, butyrophenones, and thioxanthines or drugs that deplete dopamine such as tetrabenzamine and reserpine reduce the severity of chorea. Selective serotonin reuptake inhibitors (SSRIs) such as fluoxitene, sertraline, and paroxitene are the primary drugs

for treatment of depression.[37]

Management of Anesthesia

Many of the manifestations of Huntington's disease are typical of patients with neurodegenerative disorders. As the disease progresses, the pharyngeal muscles become dysfunctional and the risk of aspiration pneumonitis increases. Appropriate antiaspiration maneuvers should be used.

If preoperative and postoperative sedation are necessary, the butyrophenones or phenothiazines are logical choices. Cases of neuroleptic malignant syndrome in patients with Huntington's disease are most likely secondary to the administration of neuroleptic drugs rather than intrinsic effects of Huntington's disease. Although there are no specific contraindications to the use of inhaled or intravenous anesthetics, recovery from propofol may be faster than from other intravenous hypnotics. Short-acting neuromuscular blocking drugs would be preferable to longer acting relaxants. Decreased plasma cholinesterase activity may prolong the relaxant effects of succinylcholine and mivacurium. Although reported experience with regional anesthesia is sparse, spinal anesthesia has been successfully administered.

As for any patient with a progressive neurologic disease, delayed emergence and an increased likelihood of respiratory complications must be anticipated in the immediate postoperative period.

Alzheimer's Disease

Alzheimer's disease is the major cause of dementia in the United States and the major reason that patients are admitted to nursing homes. The incidence of Alzheimer's disease is 1% in 60 year olds and 30% in 85 year olds. Although dementia is caused by more than 60 disorders, Alzheimer's disease is responsible for 50 to 60% of the cases. Dementia is characterized by intellectual and cognitive deterioration that impairs social function. Memory impairment and language deterioration occur early in the disease process. Motor and sensory abnormalities, gait disturbances, seizures, agitation, and psychosis are later features of the disease. Any systemic cause of dementia must be eliminated before the diagnosis of Alzheimer's is made. Laboratory testing for thyroid dysfunction, infection, and heavy metal exposure may be indicated. Computed tomography (CT), MRI, and positron emission tomography (PET) are helpful in differentiating Alzheimer's from other causes of dementia.

The deposition of beta-amyloid peptide appears to be central to the process of degeneration and neuronal death. The pathologic features of Alzheimer's such as neurofibrillary tangles and neuritic plaques are secondary to beta-amyloid deposition. Different genetic patterns may explain variations in clinical presentation and age of onset. To date, no effective antiamyloid therapies are available.

Treatment of Alzheimer's disease is directed in four areas: neuroprotection, cholinesterase inhibitors, psychopharmacologic agents to improve behavior, and health maintenance.[38] Neuroprotective therapies under investigation include vitamin E, selegiline, memantine, and anti-inflammatory agents. The administration of cholinesterase inhibitors is now considered standard of care treatment for patients with Alzheimer's disease. The three most commonly used cholinesterase inhibitors are donepezil, rivastigmine, and galantamine. Cholinesterase inhibitors improve the patient's ability to perform daily living activities and may improve cognition. Side effects of cholinesterase inhibitors include nausea, vomiting, bradycardia, syncope, and fatigue. Appropriate psychotropic drugs can be used to treat psychosis and depression. Treatment of the medical and nutritional problems of a neurodegenerative disease and the elderly patient are indicated to reduce morbidity and mortality.

Management of Anesthesia

Selection of anesthetic drugs and techniques for patients with Alzheimer's disease is guided by the patient's general physiologic condition, the degree of neurologic deterioration, and the potential for interaction between anesthetics and medications the patient is receiving. Because of dementia,

these patients are likely to be disoriented and uncooperative preoperatively. Sedative preoperative drugs are rarely indicated as further mental confusion could result. Anesthetics known to result in rapid recovery, such as propofol, desflurane, and sevoflurane are advantageous because they permit a rapid return to the patient's preoperative state. If an anticholinergic is required, glycopyrrolate, which does not cross the blood-brain barrier, is preferable to atropine or scopolamine. An anticholinergic drug that crosses the blood-brain barrier could exacerbate the dementia. Patients receiving cholinesterase inhibitors may have a prolonged response to succinylcholine and mivacurium. The patient's preoperative drug list should be reviewed for the possibility of interactions with anesthetics.

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a degenerative disease of motor cells (anterior horn cells) throughout the central nervous system. Progression of the disease is relentless and death usually follows within 3 to 5 years of diagnosis. Ten percent of ALS patients, however, survive for 10 years. Upper and lower motor neurons are involved, although lower motor neurons are affected first. The cause of ALS is unknown, but proposed causes include glutamate excitotoxicity, free radical stress, impaired neural protein repair, viral or prion infections, heavy metal exposures, or an autoimmune response. Although the similarity between ALS and poliomyelitis is striking, there is no increase in the incidence of ALS in postpolio patients. Five to 10% of the cases of ALS are hereditary.[39]

The signs and symptoms of ALS reflect the upper and lower motor neuron dysfunction. Initial symptoms are weakness, atrophy, and skeletal muscle fasciculation, often beginning in the intrinsic muscles of the hand. Deep tendon reflexes are inappropriately brisk. As the disease progresses, the atrophy and weakness involve most skeletal muscles, including those of the tongue, pharynx, larynx, and chest. Dysarthria and dysphagia are a result of bulbar involvement. Pulmonary function tests demonstrate a decrease in vital capacity, maximal voluntary ventilation, and diminished expiratory muscle function. In rare instances, the initial presentation of ALS may be respiratory failure. Eventually, respiratory failure develops in all patients with ALS and ventilatory support is required. Although mechanical ventilation can prolong life, many patients with ALS do not opt for aggressive ventilatory management because of the futility of life-prolonging measures. Intellectual and cognitive function is preserved.[40] Patients with ALS have evidence of autonomic dysfunction as evidenced by an increased resting heart rate, orthostatic hypotension, and elevated levels of epinephrine and norepinephrine. There may be a decreased R-R interval variation on the ECG and a decreased heart rate response to atropine. The cause of death for patients with ALS is usually respiratory failure. Sudden death from circulatory collapse frequently occurs in ventilator-dependent patients with ALS.

Riluzole, an antiglutamate drug, is the only specific drug approved for the treatment of ALS. Although not curative, riluzole may modestly prolong survival and delay the need for tracheostomy. Side effects of riluzole include dizziness and hepatic dysfunction. Investigations of other drug therapies have been unproductive.[41] Creatine therapy has been shown to produce some benefit in a mouse model of ALS. Although similar efficacy has not yet been shown in humans, many ALS patients take creatine supplements. Palliative care may include ventilatory and nutritional support and medications for the relief of muscle cramps and fasiculations.

Management of Anesthesia

Neuromuscular transmission is markedly abnormal in patients with ALS and these patients can be very sensitive to nondepolarizing muscle relaxants. As with other patients with lower motor neuron disease, ALS patients should be considered vulnerable to hyperkalemia in response to succinylcholine. Bulbar involvement with dysfunction of pharyngeal muscles predisposes patients with ALS to pulmonary aspiration. The need for postoperative ventilatory support is highly likely for these patients. There is no evidence that a specific anesthetic drug or combination of drugs is best for patients with ALS. Subclinical autonomic dysfunction can produce very

exaggerated decreases in cardiovascular function in response to anesthesia.[42]

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease (CJD) is one of three disorders that constitute the class of diseases known as the human spongiform encephalopathies. The other two diseases in this group are kuru and Gerstmann-Straussler syndrome. Pathologically these diseases are characterized by vacuolation of brain tissue and neuronal loss. Creutzfeldt-Jakob disease is caused by a prion. A prion is a small proteinaceous infectious agent that modifies nucleic acids. Most cases of CJD are sporadic although some are hereditary. Iatrogenic transmission of CJD has been linked to contaminated dural graft material, the use of contaminated surgical instruments, corneal transplants, and pooled human growth hormone. Although CJD was previously considered to be a rare form of dementia, the discovery of transmission of another prion disease (bovine spongiform encephalopathy, mad cow disease) from cows to humans in the mid 1990s catapulted CJD to media prominence. This disease is termed variant CJD (vCJD) and it differs clinically from classic CJD.[43] The typical clinical characteristics of classic CJD are subacute dementia, myoclonus, and EEG changes. The EEG pattern is relatively characteristic with diffuse, slow activity, and periodic complexes. Progressive loss of cognitive and neurologic function occurs. Patients with vCJD present at an earlier age with psychiatric features such as dysphoria, withdrawal, anxiety, and insomnia. Neurologic features develop 1 to 2 months after the psychiatric changes commence.[44] Presumably, transmission of vCJD is by the ingestion of contaminated animal products. Accurate epidemiologic studies are difficult because the incubation period is several years. Scrapie and chronic wasting disease (mule and elk) are other animal forms of spongiform encephalopathy. The risk of transmission of these diseases to humans is unknown.

Management of Anesthesia

Creutzfeldt-Jakob is a transmissible disease and appropriate precautions must be observed when administering anesthesia. High-risk patient tissues include brain, spinal cord, cerebrospinal fluid, and lymphoid tissue. Human to human transmission via blood transfusion has occurred. Single-use anesthesia supplies, including facemasks, breathing circuits, laryngoscopes, and tracheal tubes, should be employed.[45]

Patients with degenerative neurologic diseases are prone to aspirate gastric contents because they have impaired swallowing function and decreased activity of laryngeal reflexes. Appropriate anti-aspiration precautions are indicated during anesthesia. Because lower motor neuron dysfunction occurs in CJD patients, the use of succinylcholine should be avoided. The autonomic and peripheral nervous systems may be adversely affected, which may result in abnormal cardiovascular responses to anesthesia and vasoactive drugs.

ANEMIAS

Anemia is defined as an absolute or relative deficiency in the concentration of circulating functional red blood cells. Anemias can be classified as nutritional, hemolytic, and genetic (hemoglobinopathies, thalassemias) (Table 19-9).

TABLE 19-9 Types of Anemia

·NUTRITIONAL
Iron deficiency
Vitamin B12 deficiency
Folic acid deficiency
Chronic illness
·HEMOLYTIC

Spherocytosis
Glucose-6-phosphate dehydrogenase deficiency
Immune-mediated
Drug-induced ABO incompatibility
▪GENETIC
Hemoglobin S (sickle cell)
▪THALASSEMIAS
Thalassemia major (Cooley's anemia)
Thalassemia intermedia
Thalassemia minor

Regardless of the cause of the anemia, compensatory physiologic mechanisms develop to offset the decreased oxygen carrying capacity of the blood. In a healthy person, symptoms do not develop until the hemoglobin level decreases below 7 g/dL. Symptoms are variable and depend on other concurrent disease processes. Physiologic compensation includes increased plasma volume, increased cardiac output, and increased levels of red blood cell 2,3-diphosphoglycerate (Table 19-10). Because elderly patients with chronic anemia have an increased plasma volume, transfusion of whole blood in these patients may result in congestive heart failure. Similarly, the myocardial depressant effects of anesthetics may be exaggerated for patients with increased cardiac output at rest as compensation for anemia.

TABLE 19-10 Compensatory Mechanisms to Increase Oxygen Delivery with Chronic Anemia

Increased cardiac output
Increased red blood cell 2,3-diphosphoglycerate
Increased P-50
Increased plasma volume
Decreased blood viscosity

Concern about the transmission of blood-borne infections has greatly influenced the perioperative use of blood products. Traditional hematocrit levels that have triggered the need for blood transfusion have been radically altered and there is no universally accepted hematocrit level that demands transfusion. The patient's physiologic status and coexisting diseases must be factored into a subjective decision.

Nutritional Deficiency Anemias

The three primary causes of nutritional deficiency anemia are iron deficiency, vitamin B_{12} deficiency, and folic acid deficiency. Chronic illness, as well as poor dietary intake, can result in nutritional deficiency anemia.

Iron deficiency anemia produces the typical microcytic, hypochromic red blood cell. Iron deficiency anemia may be an absolute deficiency secondary to decreased oral intake or a relative deficiency caused by a rapid turnover of red

blood cells (e.g., chronic blood loss, hemolysis). Measuring the hemoglobin and serum ferritin levels is a rapid and effective method for differentiating true iron deficiency anemia from other causes. Severe iron deficiency anemia can result in respiratory distress, congestive heart failure, thrombocytopenia, and neurologic abnormalities.

Megaloblastic anemia can be caused by vitamin B_{12} (cobalamin) deficiency, folate deficiency, or refractory bone marrow disease. Absorption of vitamin B_{12} by the gastrointestinal tract depends on production of intrinsic factor, a glycoprotein produced by gastric parietal cells. Atrophy of the gastric mucosa causes vitamin B_{12} deficiency and megaloblastic anemia. Chronic gastritis and gastric atrophy may be caused by autoantibodies to gastric parietal cells. In addition to megaloblastic anemia, vitamin B_{12} deficiency can interfere with myelination and produce nervous system dysfunction. In adults, this is manifested by a peripheral neuropathy secondary to degeneration of the lateral and posterior spinal cord columns. The neuropathy is evidenced by symmetric loss of proprioception and vibratory sensation, especially in the lower extremities. Administration of parenteral vitamin B_{12} reverses both the hematologic and neurologic changes in adults. Congenital vitamin B_{12} deficiency, however, produces severe neurologic changes that can only be partially reversed with therapy. The coexisting neuropathy of vitamin B_{12} deficiency must be considered when regional anesthesia or peripheral nerve blocks might be used. The clinical significance of the effects of nitrous oxide on vitamin B_{12} metabolism is controversial. Nitrous oxide inactivates the vitamin B_{12} component of methionine synthetase and prolonged exposure to nitrous oxide results in megaloblastic anemia and neurologic changes similar to those that occur with pernicious anemia. Relatively short exposures to nitrous oxide have also been reported to produce megaloblastic changes. Whether the duration of exposure to nitrous oxide obtained during the course of a normal anesthetic produces such changes in humans has not been established. The issue of nitrous oxide causing postoperative neurologic dysfunction is very controversial and case reports of neuropathy linked to intraoperative nitrous oxide exposure have increased. Whether these reports influence the future use of nitrous oxide is not clear.

Folic acid deficiency also produces megaloblastic anemia. Although peripheral neuropathy may occur, it is not as common as with vitamin B_{12} deficiency. The administration of folic acid during early pregnancy markedly reduces the risk of neural tube defects in infants. Causes of folic acid deficiency include alcoholism, pregnancy, and malabsorption syndromes. Methotrexate, phenytoin, and ethanol are among the drugs known to interfere with folic acid absorption.

Hemolytic Anemias

The normal life span of an erythrocyte is 120 days. Abnormalities in the erythrocyte may result in the premature destruction of the cell (hemolysis). Causes of hemolytic anemia include structural erythrocyte abnormalities, enzyme deficiencies, and immune hemolytic anemias.

Hereditary Spherocytosis

Spherocytosis, elliptocytosis, pyropoikilocytosis, and stomatocytosis are the four types of hereditary red cell membrane defects resulting in abnormally shaped red blood cells.

Hereditary spherocytosis is the most common of the red blood cell membrane defects producing hemolysis. Spherocytosis is a disorder of the proteins (spectrin) of the red blood cell cytoskeleton in which the red blood cell is more rounded, more fragile, and more susceptible to hemolysis than the normal, biconcave red blood cell. As a result of this increased fragility, the spleen destroys the abnormal red blood cells and a chronic anemia ensues. Cholelithiasis from chronic hemolysis and elevation of the serum bilirubin occur frequently in patients with hereditary spherocytosis. Patients with hereditary spherocytosis may have hemolytic crises accompanied by anemia, vomiting, and abdominal pain. These crises may be triggered by infection or folic acid deficiency.

Hereditary spherocytosis is treated by splenectomy, which is usually delayed until the patient is 6

years of age or older. Splenectomy before that age is associated with a high incidence of bacterial infections, especially those secondary to pneumococcus. Before splenectomy, most patients require a folic acid supplement owing to excessive utilization of folic acid for red blood cell production. Transfusion is rarely necessary because adequate compensatory mechanisms for chronic anemia have developed in these patients.

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is the most common enzymopathy in humans and afflicts 400 million people worldwide. G6PD deficiency may confer malarial resistance and the distribution of this variant parallels the geographic distribution of malaria. African Americans, Africans, Asians, and Mediterranean populations are susceptible to the abnormality. In patients with G6PD deficiency, G6PD activity decreases by 50% during the 120 day life span of the red blood cell. G6PD initiates the hexose monophosphate shunt. This shunt produces nicotinamide-adenine dinucleotide phosphate (NADPH). Without NADPH, the red blood cell is susceptible to damage by oxidation. A deficiency of G6PD results in decreased levels of glutathione when the red blood cell is exposed to oxidants. This increases the rigidity of the red blood cell membrane and accelerates clearance of the cell from the circulation. In severe forms of G6PD deficiency, oxidation produces denaturation of globin chains and causes intravascular hemolysis. Glutathione synthetase is another enzyme of the hexose monophosphate shunt, and deficiency of this enzyme may also produce anemia.

There are a number of drugs that accentuate the destruction of erythrocytes in patients with G6PD deficiency, including analgesics, antibiotics, sulfonamides, and antimalarials (Table 19-11). There is considerable variability in the hemolytic response to drugs; many drugs (e.g., aspirin) cause hemolysis only in very high doses. Patients with G6PD deficiency are unable to reduce the methemoglobin produced by sodium nitrate; therefore sodium nitroprusside and prilocaine should not be administered. Characteristically, the crisis begins 2 to 5 days

after drug administration. The hemolytic episode is usually self-limited because only the older red blood cells are affected. Bacterial infections can also trigger hemolytic episodes. Presumably, the oxidants produced by active white blood cells may hemolyze susceptible red blood cells. Anesthetic drugs have not been implicated as hemolytic agents; however, early postoperative evidence of hemolysis might indicate a G6PD deficiency.

TABLE 19-11 Drugs that Produce Hemolysis in Patients with Glucose-6-Phosphate Dehydrogenase Deficiency

Phenacetin	Nalidixic acid
Aspirin (high doses)	Isoniazid
Penicillin	Primaquine
Streptomycin	Quinine
Chloramphenical	Quinidine
Sulfacetamide	Doxorubicin

Sulfanilimide	Methylene blue
Sulfapyridine	Nitrofurantoin

Pyruvate Kinase Deficiency

Pyruvate kinase is a glycolytic enzyme of the Embden-Meyerhof pathway. This pathway converts glucose to lactate and is the primary pathway for adenosine triphosphate synthesis in the red blood cell. A deficiency of pyruvate kinase produces a potassium leak from red blood cells, increasing their rigidity and accelerating destruction in the spleen. Pyruvate kinase deficiency is responsible for 95% of the deficiency syndromes in the Embden-Meyerhof pathway, whereas deficiency of glucose phosphate isomerase accounts for 4%.

Clinically, these patients exhibit anemia, premature cholelithiasis, and splenomegaly. The degree of anemia varies from a very mild anemia to a severe, transfusion dependent anemia. The clinical features resemble those for patients with spherocytosis. There are no special considerations for anesthesia other than those for any patient with chronic anemia.

Immune Hemolytic Anemia

The immune hemolytic anemias are characterized by immunologic alterations in the red blood cell membrane and are caused by drugs, disease, or erythrocyte sensitization. There are three types of immune hemolytic anemia: autoimmune hemolysis, drug-induced immune hemolysis, and alloimmune hemolysis (erythrocyte sensitization).[46] Autoimmune hemolytic anemia includes warm and cold antibody hemolytic anemia. Cold autoimmune hemolytic anemia is of special concern to the anesthesiologist because of the likelihood that the cold operating room environment and hypothermia during cardiopulmonary bypass may initiate a hemolytic crisis. Cold hemagglutinin disease is caused by IgM autoantibodies that react with the I antigen of red blood cells. Maintaining a warm environment is essential for prevention of hemolysis. Plasmapheresis to reduce the titer of cold antibody is recommended before hypothermic procedures such as cardiopulmonary bypass. Collagen vascular diseases, neoplasia, and infections produce immune hemolytic anemias by a variety of mechanisms including warm and cold antibody-mediated hemolysis.

There are three types of drug-induced immune hemolysis: autoantibody type, hapten-induced type, and immune complex type. Hemolysis induced by alpha-methyldopa is of the autoimmune type mediated by an IgG antibody that does not fix complement. The hapten-induced type is characteristic of the response to penicillin and other antibiotics. The immune complex type of reaction can occur after the administration of quinidine, quinine, sulfonamides, isoniazid, phenacetin, acetaminophen, cephalosporins, tetracycline, hydralazine, and hydrochlorothiazide.

The classic example of alloimmune hemolysis (erythrocyte sensitization) is hemolytic disease of the newborn produced by Rh sensitization. An Rh-negative mother with Rh antibodies produces hemolysis in an Rh-positive fetus. Differences in fetal and maternal ABO groups may also cause hemolysis. This is, however, unusual because A and B antibodies are of the IgM class and do not

readily cross the placenta.

Hemoglobinopathies

There are more than 300 different hemoglobinopthies described in the literature. Most are quite rare and may never be encountered by an anesthesiologist during his or her career. Sickle cell diseases are the most common hemoglobinopathies in the United States. An estimated 8 to 10% of African Americans have the sickle cell trait, and 1 in 400 has sickle cell anemia.

Sickle Cell Disease

Normal hemoglobin is composed of four globin polypeptide units arranged in a tetramer. There are four globin proteins in normal human hemoglobin designated: alpha (α), beta (β), delta (δ), gamma (γ). In adult hemoglobin the tetramer $\alpha_2\beta_2$ predominates and is called hemoglobin A. Hemoglobin F (tetramer $\alpha_2\gamma_2$) predominates in fetal and neonatal life. In sickle cell disease an abnormal globin is produced and is designated β^s and the tetramer $\alpha_2\beta_2{}^s$ is hemoglobin S. The β^s globin is abnormal in that valine is substituted for glutamic acid in the sixth amino acid position. This abnormality causes the hemoglobin to aggregate and form a polymer when exposed to low concentrations of oxygen. The formation of polymeric hemoglobin strands within the erythrocyte causes the red blood cell to sickle. As the sickle prone cell passes through the microcirculation, the cell is exposed to progressively lower oxygen tensions. The deformed sickle cells can occlude small vessels causing reduced blood flow and stasis. The sickled erythrocyte may return to a normal shape when reexposed to higher oxygen tensions. Permanent alterations to the cell membrane do occur and worsen with each cycle of sickling, resulting in early removal of the red blood cell from the circulation. Erythrocyte life span is only 12 to 17 days in sickle cell disease compared to the normal 120 days. The altered red blood cell membrane increases the adhesion of sickle cells to the vascular endothelium. This adhesion activates coagulation and releases inflammatory mediators. Hemolysis of altered erythrocytes with release of free hemoglobin causes oxidant injury to tissues and decreases nitric oxide levels. The basis of multiple organ system damage in sickle cell disease is vascular occlusion, tissue ischemia, infarction, hypercoagulability, thrombosis, and inflammation.

The definitive diagnosis of sickle cell disease is made with hemoglobin electrophoresis. This test not only detects hemoglobin S but also reveals any other types of hemoglobin present.

Clinical Manifestations. The clinical manifestations of sickle cell disease can develop in any organ system (Table 19-12). The most frequent manifestation is pain. A "painful episode" is thought to be because of tissue ischemia and usually affects the back, chest, extremities, and abdomen. The severity of painful events may range from annoying to severe and disabling. Parenteral narcotic analgesics are the mainstay of therapy but may be supplemented with non-steroidal anti-inflammatory drugs (NSAIDs). Supplemental oxygen and intravenous fluids are administered to maximize tissue oxygenation. The term "crisis" is used to describe painful episodes that coincide with life-threatening events. Crises that may be seen in sickle cell disease are: splenic sequestration, aplastic anemia, right upper quadrant syndrome, and acute chest syndrome. The concentration of hemoglobin F may be predictive of clinical manifestations as increased levels of hemoglobin F decrease the likelihood of clinical events.

Splenic sequestration occurs when there is a dramatic acceleration of erythrocyte trapping in an enlarged spleen. The removal of large numbers of erythrocytes causes the hematocrit to fall precipitously. Hypovolemia and shock may develop. Left upper quadrant pain is a prominent symptom. Infusion of fluids and red blood cells must be performed to restore the intravascular volume and hematocrit. Splenectomy is often performed following the acute episode to prevent recurrence.

An *aplastic crisis* occurs when there is a failure of reticulocyte formation. The high turnover rate

of erythrocytes in sickle cell disease results in a rapid worsening of anemia when erythrocyte formation is interrupted. Symptoms of an aplastic crisis are nonspecific and are related to severe anemia. Transfusion is performed to maintain an adequate hematocrit until reticulocyte formation returns to normal.

Right upper quadrant syndrome is heralded by pain in the right upper quadrant. Fever, jaundice, and liver failure follow. The right upper quadrant pain may represent hepatic ischemia, cholecystitis, cholangitis, or ischemia of other visceral organs. Transfusion will reduce the concentration of hemoglobin S and optimize the hematocrit. Intravenous fluids, analgesics, antibiotics, and supplemental oxygen are usually required.

Acute chest syndrome (ACS) is characterized by chest pain, dyspnea, fever, and acute pulmonary hypertension. ACS may be fatal. Transfusion or exchange transfusion is performed to maintain the hematocrit at 30%. Supplemental oxygen, antibiotics, and inhaled bronchodilators are administered as required.

6 Sickle cell disease also produces chronic cardiac, pulmonary, and renal dysfunction. Cor pulmonale may result from chronic hypoxemia, pulmonary fibrosis, and pulmonary hypertension. Cardiac dysfunction is characterized by systolic and diastolic dysfunction. The renal medulla is vulnerable to infarction and there may be an inability to concentrate the urine. Other systemic effects of sickle cell disease include cholelithiasis (chronic hemolysis), cerebral infarction, and priapism.[47,48]

There are at least 40 variants of S hemoglobinopathy. Patients with SA hemoglobin (sickle cell trait) usually have a normal life expectancy and few complications. Hemoglobin levels are normal and sickling occurs only under extreme physiologic conditions. Although the risk of anesthesia is small, there have been some reports of death in the perioperative period in patients with sickle cell trait. Hemoglobin C also results from a mutation of the β globin at the 6th amino acid position. Lysine is substituted for glutamic acid. Some patients have both the sickle cell gene and the hemoglobin C gene (hemoglobin SC). Hemoglobin S may also be combined with thalassemia trait resulting in hemoglobin S-thalassemia trait. The severity of sickle cell disease from worst to least is: SS > S-thalassemia > SC > CC > SA (Table 19-13).

TABLE 19-13 Common Hemoglobin S Variants

	·HEMOGLOBIN SS	·HEMOGLOBIN SC	·HEMOGLOBIN SA
Hemoglobin level (g/dL)	7–8	9–12	13–15
Life expectancy (years)	30	Slightly reduced	Normal
Propensity for sickling	++++	++	+
Clinical features	Vaso-occlusive crises	Vaso-occlusive crises	Few, under physiologic conditions
	Splenic infarction	Retinal thrombosis	

	Hepatomegaly	Femoral head necrosis	
	Skin ulceration		

Treatment. Although the exact molecular defect of S hemoglobin has been known for over 50 years, there is no specific corrective therapy. Supportive therapy has improved, increasing survival, so that many patients with SS disease live more than 50 years. In some cases bone marrow transplantation may be curative, especially when performed in early childhood. Because of the risks of bone marrow transplantation, this therapy is reserved for very severe cases.[49] An unaffected sibling is usually required for donor matching.

Preventive treatment is begun as soon as the diagnosis is made. Patients should be referred to centers that provide a multidisciplinary approach for routine and urgent care. Daily oral penicillin is begun in infancy as prophylaxis against pneumococcal sepsis. Patients receiving frequent transfusions should be monitored for iron overload. Liver biopsy is the most common method of monitoring the effects of excessive iron. If iron overload occurs, chelation therapy must be instituted to prevent cardiomyopathy and cirrhosis. Hydroxyurea is often administered to increase production of hemoglobin F and reduce the likelihood of sickling.

Management of Anesthesia. Surgery is frequently required for patients with sickle cell disease. Operations commonly performed on these patients include cholecystectomy, liver biopsy, splenectomy, tonsillectomy, hip replacement, and obstetric procedures. It is ideal for the anesthesiologist, hematologist, and

surgeon to interact closely when sickle cell patients require surgery. Prevention of conditions that favor sickling is the basis for recommendations regarding perioperative management. Adequate oxygenation, avoidance of excessive oxygen consumption, assurance of adequate oxygen-carrying capacity, and avoidance of vascular stasis are imperative. Normothermia should be achieved as this minimizes oxygen consumption. Hypothermia may cause peripheral vasoconstriction and vascular stasis; whereas hyperthermia accelerates hemoglobin S polymerization. A warm ambient temperature supplemented with forced air warming is desired. Vascular stasis is minimized with adequate hydration and anticipation of intraoperative volume loss. Use of the tourniquet should be reserved for those operations where its use is essential for the success of the surgery.

The hemoglobin and hematocrit should be measured preoperatively. Adequate oxygen carrying capacity is maintained by transfusion to keep the hematocrit at 30%. Exchange transfusion may be used to keep the hematocrit at 30% and reduce the concentration of hemoglobin S to 30 to 40%. Exchange transfusion is the preferred method for patient preparation for cardiopulmonary bypass (Table 19-14).

Drugs commonly used for anesthesia do not have any significant direct effects on the sickling process. The anesthetic technique may influence outcome if it produces hypoxemia, vascular stasis, and reduced cardiac output. Regional anesthesia has been successfully employed for surgery, labor and delivery, and pain management. Pain management of patients with sickle cell disease in the postoperative period can be quite challenging. A variety of techniques, including opioids (morphine), nonnarcotic analgesics, and regional anesthesia have been used.

Close monitoring of the sickle cell patient during the postoperative period for pulmonary complications and aggressive treatment with supplemental oxygen is necessary as hypoxemia may be the primary trigger of acute chest syndrome. Acute chest syndrome during the early postoperative period produces significant morbidity and mortality.[50,51]

Thalassemia

The thalassemias are a group of genetically transmitted (autosomal recessive) anemias caused by insufficient production of one of the globin polypeptide components of hemoglobin. Although there are four globin chains (α, β, γ, δ), α and β thalassemias are the most common. Thalassemia genes are most prevalent in the Mediterranean region, the Middle East, India, Southeast Asia, and malarial zones. The carrier incidence in these areas is 2.4 to 15%.

There are three prominent clinical features of thalassemia: anemia, hemolysis, and marked hyperplasia of the bone marrow. The anemia is microcytic and hypochromic and can be profound. In addition to anemia, there is unbalanced production of globin pairs. In β thalassemia, there is inadequate production of β globin, but normal production of α globin. The excess α globins are poorly soluble and precipitate to form inclusion bodies in erythroid precursor cells. The excess globins are highly reactive and cause free radical cellular injury. Many erythrocytes fail to mature and others are destroyed by the spleen and reticuloendothelial system. Splenomegaly, hepatomegaly, cholelithiasis, and jaundice are common. Anemia causes a vigorous secretion of erythropoietin that produces bone marrow hyperplasia. Bone marrow hyperplasia causes skeletal abnormalities such as retarded growth, fractures, and facial dysmorphism. Extramedullary marrow develops in the pleura, sinuses, epidural space, and pleural cavities. Spontaneous bleeding from extramedullary marrow is common and can cause hemothorax, epidural hematoma, and epistaxis.[52]

A wide variety of clinical phenotypes are manifest, from very mild anemia to very severe anemia. The anemia in thalassemia major (Cooley's anemia) is severe and often life threatening. β thalassemia minor produces a mild anemia of iron deficiency. β thalassemia intermedia is an intermediate form of thalassemia that usually does not require transfusion. α thalassemia produces a mild hemolytic anemia (Table 19-15).

TABLE 19-15 Thalassemic Syndromes

Note: ^{0} indicates none of that type of globin is produced.
$^+$ indicates a subnormal amount of that globin is produced.

Treatment of thalassemia is based on the severity of the anemia. Thalassemia major must be treated aggressively to reduce

complications and prolong life. Bone marrow transplantation may cure thalassemia and can be undertaken after 2 years of age if the illness is likely to be severe. Thalassemia major patients who do not qualify for or fail bone marrow transplantation will require transfusion therapy. Three transfusion protocols are employed: palliative transfusion, hypertransfusion, and supertransfusion. Palliative transfusion is used to treat only severe complications of anemia. Extramedullary erythropoiesis is not suppressed by palliative transfusion. Palliative transfusion is generally practiced in areas where there is poor access to medical care. The goal of hypertransfusion is to maintain a hemoglobin level of 9 to 10 grams/dL. Transfusion is required every 3 to 4 weeks. Extramedullary erythropoiesis is substantially reduced. Supertransfusion is used to maintain a hemoglobin level greater that 12 grams/dL in an effort to suppress all erythropoiesis. Frequent blood transfusion predictably causes hemosiderosis. Chelation therapy with deferoxamine or deferiprone is required to reduce the likelihood of cardiac and hepatic iron toxicity (cirrhosis).

Management of Anesthesia. Anesthetic considerations depend on the severity of the anemia. Hemosiderosis is likely in patients receiving regular transfusion therapy. A preoperative echocardiogram may be indicated if there is any suggestion of cardiac dysfunction. Extramedullary erythropoiesis can produce hyperplasia of the facial bones and narrowing of the nasal passages and make direct laryngoscopy and tracheal intubation difficult. Epidural, spinal, and intrapleural

anesthesia are relatively contraindicated as the presence of extramedullary bone marrow in these sites increases the likelihood of bleeding and hematoma formation. Massive bleeding into the epidural and pleural spaces can occur. Patients receiving palliative transfusion therapy are at greater risk for extramedullary erythropoiesis than those receiving hyper-transfusion therapy.

COLLAGEN VASCULAR DISEASES

A number of diseases are classified as the collagen vascular diseases or connective tissue diseases (Table 19-16). The four most common disorders of this group are rheumatoid arthritis, systemic lupus erythematosus, scleroderma, and dermatomyositis/polymyositis. Although many such patients can be categorized as having discrete disease syndromes, many others with collagen vascular diseases are considered to have overlap syndromes (also termed mixed connective tissue diseases) with features of different collagen vascular diseases, and cannot be conveniently classified. The etiology of the collagen vascular diseases is unknown, although the immune system is clearly involved in the cascade of pathologic events that cause clinical manifestations of the diseases. Although all of these diseases have effects on joints, each has diffuse systemic effects as well. The alterations in joint function and systemic effects will both have significant impact on the management of anesthesia.

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic inflammatory disease characterized by a symmetric polyarthropathy and significant systemic involvement. Although the etiology of rheumatoid arthritis is not known, the pathogenesis has been delineated. An as yet unknown antigen provokes a cellular immune response in which monocytes, macrophages, and fibroblasts release cytokines (TNF-tumor necrosis factor and interleukin-1). These cytokines initiate an inflammatory cascade that damages synovial and joint tissue. B lymphocyte dysregulation causes additional damage via complement fixation.[53] The presence of rheumatoid factor (IgM) in 75% of patients with rheumatoid arthritis supports the concept of rheumatoid arthritis as an autoimmune disease. The pathologic changes of rheumatoid arthritis begin with cellular hyperplasia of the synovium followed by invasion of the synovium by lymphocytes, plasma cells, and fibroblasts. Ultimately, the cartilage and articular surfaces are destroyed.

The hands and wrists are involved first, particularly the metacarpophalangeal and interphalangeal joints. In the lower extremity, the knee is involved most frequently. Compression of lower extremity peripheral nerves by the deformed knee can produce paresis and sensory loss over the lower leg. The upper cervical spine is affected in nearly 80% of patients with rheumatoid arthritis. Instability of the upper cervical spine can manifest as atlantoaxial instability, cranial settling, and

subaxial instability. Plain radiography and CT of the cervical spine will demonstrate the bony changes of rheumatoid arthritis. MRI is better suited to the study of the bony and soft tissue changes on the spinal cord. The degree of cord compression, however, may not correlate with the patient's symptoms. Although a very rare event, spinal cord damage after laryngoscopy and tracheal intubation has been reported.[54] Intradural cord compression secondary to rheumatoid nodules or pannus formation can also occur. Rheumatoid arthritis commonly affects the joints of the larynx, resulting in limitation of vocal cord movement and generalized erythema and edema of the laryngeal mucosa that may progress to airway obstruction. Arthritic changes in the temporomandibular joints also occur. All of these abnormalities can complicate laryngoscopy and tracheal intubation.

Extra-articular and systemic manifestations of rheumatoid arthritis are diverse (Table 19-17). Pericarditis occurs in nearly one-third of patients with rheumatoid arthritis and can produce constrictive pericarditis or cardiac tamponade. Although cardiac tamponade develops in only a small proportion of patients with rheumatoid arthritis, rheumatoid arthritis is more likely to cause tamponade than systemic lupus erythematosus. Cardiovascular disease is a common cause of mortality in patients with rheumatoid arthritis and there is a high incidence of subclinical cardiac dysfunction.[55] Cardiovascular effects include myocarditis, coronary arteritis, pulmonary hypertension, diastolic dysfunction, dysrhythmias, and aortitis (aortic root dilation, aortic insufficiency). Pulmonary changes are common and include pleural effusions, pulmonary nodules, interstitial lung disease, obstructive lung disease, and restrictive lung disease. Several of the antirheumatic drugs can cause or accentuate pulmonary dysfunction. Renal failure is a common cause of death in patients with rheumatoid arthritis. Renal dysfunction may be secondary to vasculitis, amyloidosis, and anti-rheumatic drugs.

Blood
Anemia
Leukopenia

Mild anemia is present in almost all patients with rheumatoid arthritis. The anemia may be secondary to a cytokine-induced decrease in erythropoiesis or may result from side effects of drug therapy. Felty's syndrome is the clinical complex of rheumatoid arthritis, leukopenia, and hepatosplenomegaly.

Neurologic complications of rheumatoid arthritis include peripheral nerve compression (carpal tunnel syndrome) and cervical nerve root compression. Mononeuritis multiplex is presumed to be caused by deposition of immune complexes in blood vessels supplying the affected nerves. Rheumatoid vasculitis may affect cerebral blood vessels, producing a cerebral necrotizing vasculitis.

There is no treatment that cures rheumatoid arthritis. The goals for therapy are induction of a remission, improved function, and maintenance of a remission. There are three groups of drugs used to treat rheumatoid arthritis: NSAIDs, corticosteroids, and disease-modifying antirheumatic drugs (DMARDs). Since NSAIDs do not affect the course of the disease, they are used in conjunction with DMARDs. Corticosteroids are potent anti-inflammatory and anti-immune drugs, but the side effects associated with long-term treatment limit their usefulness. DMARDS are now the first line of therapy for the early treatment of rheumatoid arthritis. Methotrexate has proven to be very effective and is often the initial drug of choice. Other synthetic DMARDs include leflunomide, cyclosporine, azathioprine, gold, sulfasalazine, minocycline, and hydroxychloroquine. Biologic DMARDs that inhibit TNF-alpha include infliximab, etanercept, and adalimumab. Anakinra inhibits interleukin-1. The primary side effect of the biologic DMARDs is an increased susceptibility to infection.[56] Most of the drugs used for the treatment of rheumatoid arthritis have significant side effects that may limit their use (Table 19-18). Surgical procedures such as synovectomy, tenolysis, and joint replacement are performed to relieve pain and restore joint function.

TABLE 19-18 Adverse Effects of Drugs Used to Treat Collagen Vascular Diseases

·DRUG	·EFFECT
Immunosuppressants	
Methotrexate	Hepatotoxicity, anemia, leukopenia
Azathioprine	Biliary stasis, leukopenia

Cyclosporine	Renal dysfunction, hypertension
	Hypomagnesemia
Cyclophosphamide	Leukopenia, hemorrhagic cystitis
	Inhibition of pseudocholinesterase
Leflunomide	Hepatoxicity, weight loss, hypertension
TNF Antagonists	
Etanercept	Bacterial infections, tuberculosis
Infliximab	Lymphoma, heart failure
Adalimumab	
Interleukin-1 Antagonists	
Anakinra	Infection, skin irritation
Corticosteroids	Hypertension, fluid retention
	Osteoporosis, infection
Aspirin	Platelet dysfunction, peptic ulcer
	Hepatic dysfunction, hypersensitivity
NSAIDs	Peptic ulcer, hypertension, hyperglycemia, leukopenia
COX-2 inhibitors	Renal dysfunction
Gold	Aplastic anemia, dermatitis, nephritis
Antimalarials	Myopathy, retinopathy
Penicillamine	Glomerulonephritis, myasthenia, aplastic anemia

Management of Anesthesia

7 Because rheumatoid arthritis is a multisystem disease and the clinical manifestations are so diverse, individualized preoperative evaluation is important in the identification of systemic effects.

8 The joint effects of rheumatoid arthritis, including arthritic changes in the temporomandibular joints, cricoarytenoid joints, and cervical spine, can render rigid, direct laryngoscopy and tracheal intubation very difficult. The mobility of these joints should be evaluated before surgery so that a plan for airway management can be formulated. If atlantoaxial instability exists, flexion of the neck may compress the spinal cord. Neck pain radiating to the occiput may be the first sign of cervical spine involvement. Patients with symptoms or evidence of cervical cord compression can be fitted with a cervical collar preoperatively to minimize the risk of overmanipulation of the neck during surgery. Many patients with rheumatoid arthritis, however, are asymptomatic with respect to cervical spine disease (Fig. 19-5). Preoperative imaging (radiography, CT, MRI) may be indicated if the degree of cervical involvement is unknown. Although there have been no documented reports of spinal cord damage in patients with rheumatoid arthritis undergoing tracheal intubation for elective surgery, alleged neurologic damage after laryngoscopy has been the source of litigation against anesthesiologists. Any preoperative evidence of neurologic function should be documented before surgery. To minimize the risk of neurologic damage during tracheal intubation, awake, fiberoptic laryngoscopy may be the best means of performing tracheal intubation in patients with significant cervical spine involvement. Because patients with rheumatoid arthritis undergo repeated anesthetics, it is quite helpful if the technique of airway management is clearly documented in the patient's medical record. Progression of the rheumatoid

process may, however, alter joint function to the extent that neck motion may diminish with time and render a previously successful intubation technique useless. Criocoarytenoid arthritis produces erythema and edema of the vocal cords. Involvement of the cricoarytenoid joints reduces the size of the glottic inlet and necessitates the use of a smaller than predicted tracheal tube. Exaggerated postextubation edema and stridor may occur.

FIGURE 19-5. Magnetic resonance imaging of a cervical spine in a patient with rheumatoid arthritis. Although the patient had no neurologic symptoms, there is severe spinal stenosis in the upper cervical spine.

The degree of cardiopulmonary involvement by the rheumatoid process influences the selection of the type of anesthesia. Functional evaluation of the heart and lungs is necessary if the clinical history suggests dysfunction. It may be difficult to determine if the dysfunction is secondary to rheumatoid arthritis or other common causes of cardiopulmonary disease such as arteriosclerosis or smoking. The need for postoperative ventilatory support should be anticipated if severe pulmonary disease is present.

Medications that the patient is receiving influence the management of anesthesia. Corticosteroid supplementation may be necessary during the perioperative period. Aspirin and other anti-inflammatory drugs interfere with platelet function and clotting may be abnormal. Many rheumatoid medications suppress red blood cell formation and anemia is common. Drug induced hepatic and renal dysfunction may be present.

Restriction of joint mobility necessitates careful positioning of the patient during the operation. The extremities should be positioned to minimize the risk of neurovascular compression and further joint injury. Preoperative evaluation of joint motion will help determine how the extremities should be positioned.

Rheumatoid arthritis is a multisystem disease. Potential joint disabilities have been well documented in the medical literature and are often obvious. More significant and less evident are the effects on the spinal cord, heart, lungs, kidneys, and liver. The type and severity of systemic dysfunction must be considered when planning an anesthetic for patients with rheumatoid arthritis.[57,58]

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is an autoimmune disease with diverse clinical and immunologic manifestations. The etiology of SLE is unknown, but appears to be a complex interaction between genetic susceptibility and hormonal and environmental factors. Patients with SLE produce autoantibodies primarily to DNA, but also RNA polymerase, cardiolipin, and ribosomal phosphoproteins. Some of the clinical manifestations of SLE may be the result of the production of an autoantibody highly specific for a single protein within an organ.[59]

The clinical manifestations of SLE are diverse. The most common presenting features are polyarthritis and dermatitis. The arthritis is oligoarticular and migratory. Any joint may be involved including the cervical spine. The classic malar rash is present in only one-third of SLE patients. Renal disease is a common cause of morbidity and mortality in patients with SLE. Proteinuria, hypertension, and decreased creatinine clearance are the usual manifestations of SLE nephritis. Of patients with SLE, 10 to 20% develop end-stage renal disease and require dialysis or transplantation. Central nervous system involvement occurs in 50% of patients with SLE and is a result of vasculopathy. CNS manifestations include seizures, stroke, dementia, psychosis, myelitis, and peripheral neuropathy. The cranial MRI may demonstrate vascular lesions, but is not adequate for patients with diffuse cerebral disease.[60]

SLE produces a diffuse serositis that manifests as pleuritis and pericarditis. Although 60% of SLE patients have a pericardial effusion, cardiac tamponade is uncommon. In rare cases, cardiac tamponade may be the presenting sign of SLE. Myocarditis, cardiac conduction abnormalities, ventricular dysfunction, and coronary arteritis can occur in patients with SLE.[61] A noninfectious endocarditis (Libman-Sacks endocarditis) often affects the mitral valve and can produce mitral insufficiency. Effective treatment of SLE has improved survival, but has increased the likelihood of ischemic heart disease. Pulmonary effects of SLE include pleural effusion, pneumonitis, pulmonary hypertension, and alveolar hemorrhage. There is a high incidence of pulmonary hypertension in

SLE patients who have Raynaud's phenomenon. Patients with SLE are susceptible to infection that may present as pneumonia or adult respiratory distress syndrome. Pulmonary function studies typically demonstrate a restrictive lung disease pattern and a decreased diffusing capacity. Patients with SLE may have cricoarytenoid arthritis that can manifest as hoarseness, stridor, or airway obstruction.

Nearly one-third of patients with SLE have detectable antiphospholipid antibodies and may have thromboembolic complications. Lupoid hepatitis typically occurs in young women with SLE. Other potentially serious manifestations of SLE include peritonitis, pancreatitis, bowel ischemia, and protein-losing enteropathy.

There is no specific etiologic therapy for SLE. Despite the diverse effects of SLE and the lack of specific therapy, current regimens have improved survival. NSAIDs are used for mild arthritis. Antimalarials (hydroxychloroquine) control arthritis and exert antithrombotic effects. Corticosteroids are effective for moderate and severe SLE, but toxicity limits the dose. Immunosuppressants such as methotrexate, azathioprine, cyclophosphamide, and mycophenolate mofetil are effective and permit lower dosages of corticosteroids. The potential for side effects from any of the drugs used to treat SLE is significant and can result in morbidity.[62]

Drug-induced lupus may be caused by procainamide, quinidine, hydralazine, methyldopa, enalapril, captopril, clonidine, isoniazid, or minocycline. Drug-induced lupus may be caused by reactive drug metabolites and reactive T cells. The clinical manifestations of drug-induced lupus are generally mild and

include arthralgia, fever, anemia, and leukopenia. These effects typically resolve within 4 weeks of discontinuation of the drug.

Management of Anesthesia

Careful preoperative evaluation of the patient with SLE is necessary because of the diverse systemic effects of the disease. Preoperative chest radiography, echocardiography, or pulmonary function testing may be necessary if the clinical history suggests dysfunction. Anesthesia management is influenced not only by the degree of organ dysfunction, but also by the drugs used to treat SLE. Although there are no specific contraindications to a particular type of anesthetic, myocardial dysfunction will certainly influence the choice of anesthetic and the type of intraoperative monitors. Because renal dysfunction is so common, renal function should be quantified preoperatively if there is any suggestion of a recent change in renal function. Although minor abnormalities in hepatic function are present in many patients with SLE, these changes are not usually significant. Patients with SLE are at increased risk for postoperative infections.

Arthritic involvement of the cervical spine is unusual in patients with SLE and tracheal intubation is not generally difficult. The potential for laryngeal involvement and upper airway obstruction does, however, require clinical evaluation of laryngeal function. Should postextubation laryngeal edema or stridor occur, intravenous administration of corticosteroids is effective for alleviation of symptoms.

Drugs administered to the patient for treatment of SLE may also influence the management of anesthesia. Patients receiving corticosteroids may require intraoperative administration of corticosteroids. Cyclophosphamide inhibits plasma cholinesterase and may prolong the response to succinylcholine and mivacurium.

Scleroderma

Scleroderma (systemic sclerosis) is characterized by excessive deposition of collagen and fibrosis in the skin and internal organs. The etiology of scleroderma is unknown. Infectious or environmental trigger agents have been proposed. Alterations in the function of fibroblasts, endothelial cells, and T and B lymphocytes result in exaggerated deposition of collagen, inflammation, obliteration of small arteries and arterioles, and ultimately fibrosis and atrophy of organs. Endothelial cell injury may be the earliest manifestation of scleroderma. The endothelial

cells appear to be deficient in intrinsic vasodilators while having increased levels of the potent vasoconstrictor endothelin-1. Increased activity of connective tissue growth factor (CTGF) and transforming growth factor-beta (TGF-β) may be responsible for the deposition of large amounts of collagen.[63]

The manifestations of scleroderma are most evident in the skin, which becomes thickened and swollen. Eventually, the skin becomes atrophic and small arteries are obliterated. The skin becomes fibrotic and taut and produces severe restriction of joint mobility. Raynaud's phenomenon is present in 85% of patients with scleroderma and is often the presenting symptom.

The same pathologic process that affects the vascular system in the skin affects small blood vessels in other organs as well. Lung involvement occurs in 80% of patients with scleroderma and is characterized by interstitial fibrosis, pulmonary hypertension, and an impaired diffusing capacity. These changes in conjunction with the effects of chronic aspiration pneumonitis produce a restrictive lung disease. The onset of pulmonary hypertension is an ominous prognostic sign.[64] Myocardial fibrosis occurs in 70 to 80% of patients with scleroderma, although only 25% have clinical symptoms. Echocardiography may reveal a decreased ejection fraction and impaired left ventricular filling. Degeneration of cardiac conducting tissue may cause conduction defects and cardiac dysrhythmias. Pericarditis with effusion is very common.

Renal dysfunction is relatively common in patients with scleroderma. This dysfunction is secondary to pathologic changes in the renal vasculature similar to the changes in the digital arteries that produce Raynaud's phenomenon. Renal dysfunction can be so severe that a scleroderma renal crisis develops with hypertension, retinopathy, and a rapid deterioration in renal function.

9 Gastrointestinal motility is decreased and is very pronounced in the esophagus. The frequent episodes of gastroesophageal reflux and aspiration pneumonitis exacerbate pulmonary dysfunction. Involvement of the colon and small intestine may result in pseudoobstruction.

Currently, the therapy for scleroderma is limited to the treatment of specific organ dysfunction, immunosuppressants (corticosteroids, methotrexate, cyclophosphamide, antithymocyte globulin), and decreasing collagen production (penicillamine). Vasodilators such as calcium channel blockers, ACE inhibitors, and prostacyclin analogs are frequently used for the treatment of cardiac dysfunction, pulmonary hypertension, and Raynaud's phenomenon.[65]

Management of Anesthesia

Scleroderma, like other collagen vascular diseases, is a multiorgan disease with many systemic manifestations. The altered organ systems must be thoroughly evaluated so that a logical plan for anesthesia can be selected. There are no specific contraindications to the use of any type of anesthesia, although the selection must be guided by the degree of organ dysfunction.

Tracheal intubation can be quite difficult. Fibrotic and taut facial skin can markedly hinder active and passive mobility of the temporomandibular joints. Awake fiberoptic-assisted laryngoscopy and tracheal intubation may be required; tracheostomy may be necessary in severely affected patients. Orotracheal intubation is preferred as the fragility of the nasal mucosa increases the risk of severe nasal hemorrhage from nasotracheal intubation.

The patient with scleroderma is at risk for aspiration pneumonitis during the induction of anesthesia owing to the high incidence of esophageal dysmotility and gastroesophageal reflux. Appropriate measures to minimize the risk of acid aspiration, such as the use of histamine-2 blockers and oral antacids, may be indicated.

Chronic arterial hypoxemia is often present because of restriction of lung expansion and impaired oxygen diffusion. Controlled ventilation with an increased oxygen concentration is usually necessary. Compromised myocardial function and decreased coronary vascular reserve often necessitate the use of invasive cardiovascular monitoring because the response to inhaled anesthetics may be exaggerated. Transesophageal echocardiography can provide valuable information about cardiac function, although passage of the probe may be difficult because of esophageal stricture. Venous access can be difficult and a venous cutdown or central venous

catheterization may be required. Muscle involvement may increase the sensitivity to muscle relaxants and short-acting neuromuscular blockers should be used.

Regional anesthesia may be administered to patients with scleroderma, although the response to local anesthetics may be prolonged. The anesthesiologist is often consulted as to the efficacy of sympathetic blockade for the treatment of vasospasm secondary to Raynaud's phenomenon. Stellate ganglion

blockade, however, may produce deleterious effects on contralateral blood flow in patients with scleroderma. Intractable ischemic limb pain may necessitate long-term pain management.

Polymyositis/Dermatomyositis

Three diseases comprise the inflammatory myopathies: polymyositis, dermatomyositis, and inclusion-body myositis. Clinical features common to these three diseases are severe muscle weakness, and noninfectious muscle inflammation. The etiology of these diseases is unknown; however, many of the processes that cause the inflammation have been delineated. Dermatomyositis is the result of an antibody induced complement activation that lyses muscle capillaries and causes muscle necrosis. Muscle fiber necrosis in polymyositis and inclusion-body myositis is caused by cytotoxic T cells.[66]

Common presenting symptoms of polymyositis are muscle pain, tenderness, and proximal muscle weakness. Patients with dermatomyosisits have skin manifestations that may precede the muscle weakness. The skin rash of dermatomyositis is characterized by a purplish discoloration of the eyelids (heliotrope rash), periorbital edema, erythematous lesions on the knuckles and a sun-sensitive rash on the face, neck, and chest. Inclusion-body myositis typically presents with weakness of the quadriceps and ankle dorsiflexors in men over 50 years of age. Although the pathogenic processes of these diseases are different, the effects on the heart and lungs are similar. Of patients with polymyositis and dermatomyositis, 50% have evidence of pulmonary disease. Pulmonary manifestations include interstitial lung disease, bronchopneumonia, and alveolitis. Aspiration is one of the most common complications of polymyositis. Intrinsic lung disease and thoracic muscle weakness produce a restrictive lung disease and decreased diffusing capacity. Myocardial fibrosis can result in congestive heart failure and cardiac dysrhythmias.

The most effective treatment for the inflammatory myopathies are corticosteroids (prednisone). Patients that do not respond to corticosteroids are treated with immunosuppressants such as azathioprine, methotrexate, cyclophosphamide, cyclosporine, and mycophenolate mofetil. Intravenous immunoglobulin and total body lymphocyte irradiation have been recommended for patients resistant to other forms of therapy.[67]

Management of Anesthesia

Mobility of the temporomandibular joints and cervical spine is usually adequate in patients with polymyositis. Some patients, however, have restricted mobility that can make direct laryngoscopy difficult. Adequate mouth and neck mobility must be ascertained before induction of anesthesia. Awake flexible fiberoptic laryngoscopy and tracheal intubation may be required for those patients with restricted neck mobility and inadequate mouth opening.

Dysphagia and gastroesophageal reflux are very common and there is an increased likelihood of aspiration pneumonitis. Appropriate precautions to minimize the risk of aspiration of gastric contents should be taken during the perioperative period. Gastrointestinal perforations that necessitate surgical intervention are relatively common in patients with polymyositis.

Although the typical electromyographic changes of polymyositis suggest the potential for hyperkalemia after succinylcholine, succinylcholine has been administered to patients with polymyositis without complication.[68] Prolonged neuromuscular blockade may occur after the administration of nondepolarizing muscle relaxants. This prolonged response may be secondary to the myopathy or an interaction between the muscle relaxant and immunosuppressants. The reported experience with anesthesia for patients with inflammatory myopathies is very limited and

generalizations from a few case reports must be interpreted with caution. It should be anticipated that considerable variation in response to muscle relaxants will occur. It would seem to be prudent to avoid the administration of succinylcholine and to use short-acting nondepolarizing muscle relaxants such as mivacurium, cisatracurium, and rocuronium.

The degree of cardiopulmonary dysfunction influences the choice of anesthesia and selection of intraoperative monitors. Further preoperative evaluation of cardiopulmonary function may be required if the clinical history suggests deterioration in cardiac or pulmonary function. Because of the preoperative muscle weakness, postoperative ventilatory support may be necessary.

SKIN DISORDERS

Most primary diseases of the skin are localized and cause few systemic effects or complications during the administration of anesthesia. Two blistering skin disorders, however, can result in complications during anesthesia: epidermolysis bullosa and pemphigus.

Epidermolysis Bullosa

Epidermolysis is a rare skin disorder that can be inherited or acquired. Patients with heritable forms have abnormalities that cause defects in the anchoring systems of skin layers. The acquired forms are autoimmune disorders in which autoantibodies are produced that destroy the basement membrane of the skin and mucosa. The end result is the loss or absence of normal intercellular bridges and separation of skin layers (Fig. 19-6). The separation of the skin layers results in intradermal fluid accumulation and bullae formation. Even minor skin trauma produces skin blisters. Lateral shearing forces applied to the skin are especially damaging. Pressure applied perpendicular to the skin is not as hazardous. Although there are 25 subtypes of epidermolysis bullosa, these disorders can be categorized into three groups depending on where the actual skin separation occurs: epidermolytic (epidermolysis simplex), junctional, and dermolytic (epidermolysis bullosa dystrophica). Although serious complications from skin and mucosal loss can occur with any form of epidermolysis, the simplex form is generally benign. Patients with the junctional form rarely survive beyond early childhood. Laryngeal involvement is unusual, but is most likely to occur with the junctional type.

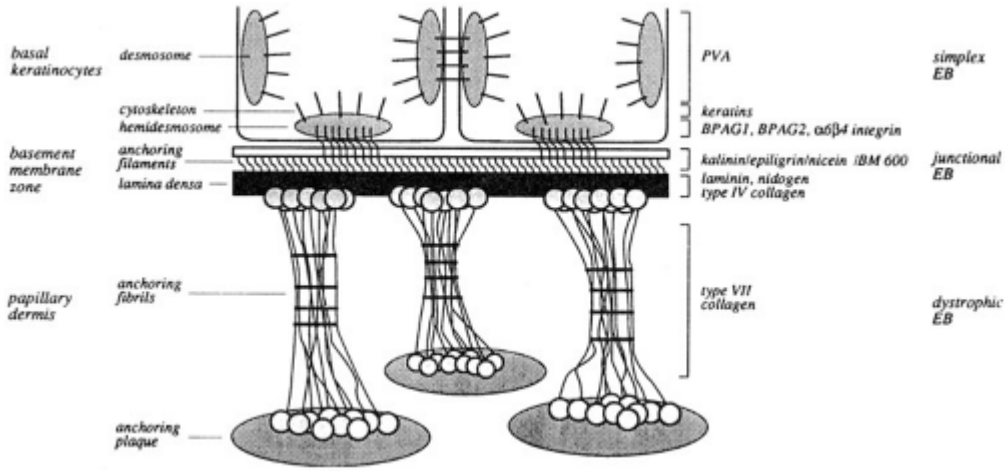

FIGURE 19-6. The ultrastructure for the zones of the skin. The diagram demonstrates where skin separation occurs in the different types of epidermolysis bullosa. (Reproduced with permission from Uitto J, Christiano AM: Molecular genetics of the cutaneous basement membrane zone. J Clin Invest 90;687, 1992; copyright of the American Society for Clinical Investigation.)

10 Epidermolysis dystrophica is caused by a defect in type VII collagen. This form produces

severe scarring of the fingers and toes with pseudosyndactyly formation and ankylosis of the interphalangeal joints and resorption of the metacarpals and metatarsals (Fig. 19-7). Malignant degeneration of the skin is common. Involvement of the esophageal mucosa is present in most patients, resulting in dysphagia and esophageal strictures that contribute to poor nutrition.[69] Secondary infection of bullae with staphylococcus aureus or beta hemolytic streptococcus is frequent. Glomerulonephritis may be secondary to streptococcal infection. Hypoalbuminemia, secondary to nephritis, protein loss into bullae, and poor nutrition, is usual. Other consequences of chronic infection and malnutrition are anemia and cardiomyopathy. Mitral valve prolapse may occur. Hypoplasia of tooth enamel results in carious degeneration of the teeth and the need for extensive dental restorations. Diseases associated with epidermolysis bullosa include porphyria

cutanea tarda, amyloidosis, multiple myeloma, diabetes mellitus, and hypercoagulation. Patients with epidermolysis bullosa dystrophica rarely survive beyond the third decade of life.

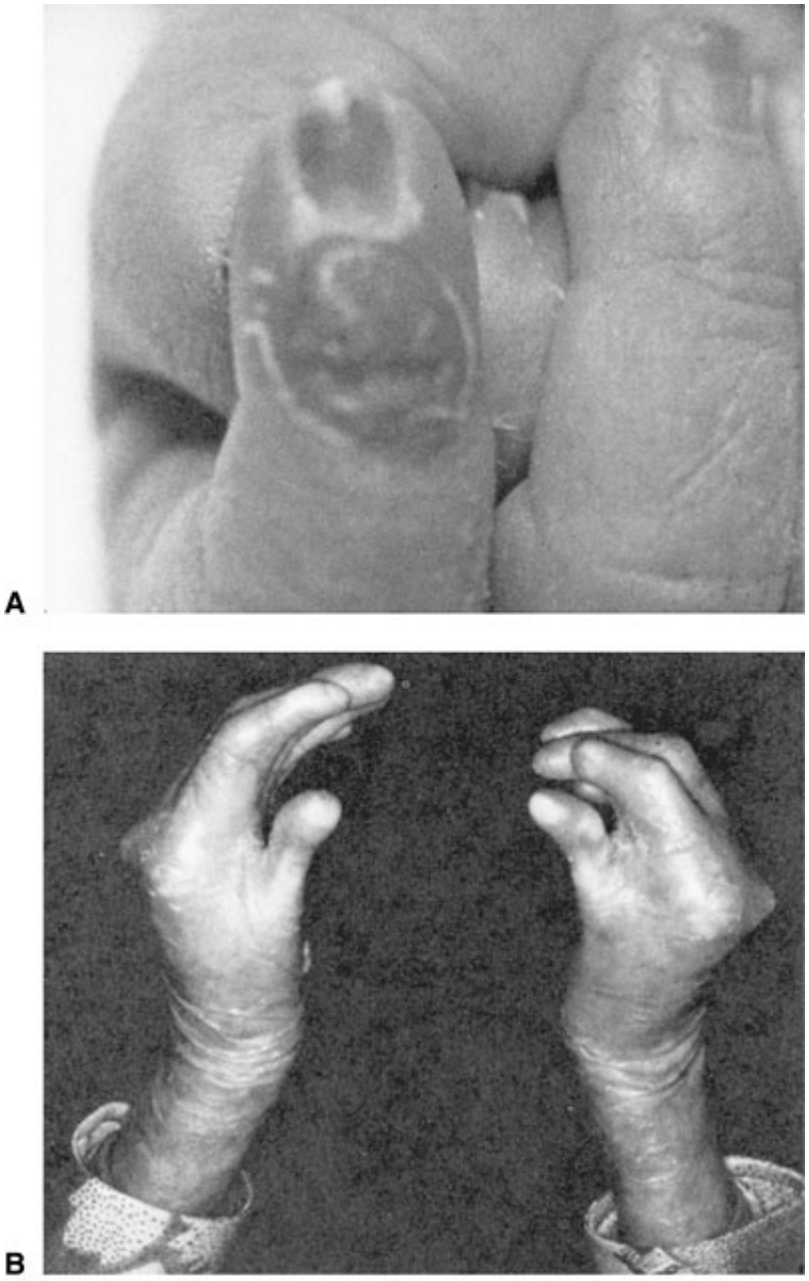

FIGURE 19-7. Epidermolysis bullosa. **A:** Bullous lesion of the finger of a neonate with epidermolysis. **B:** Hands of an older child with epidermolysis progression to produce severe scarring and pseudosyndactyly. (Courtesy of James E. Bennett, MD, Division of Plastic Surgery, Indiana University School of Medicine, Indianapolis, IN.)

Medical therapy for epidermolysis bullosa has not been very successful. Phenytoin, a collagenase inhibitor, may produce short-term improvement. Corticosteroids are not effective. Coverage of denuded skin with cultured human skin preparations may be effective. Surgical therapy is directed at preservation and improvement of hand function.

Management of Anesthesia

It is critical that trauma to the skin and mucous membranes be avoided or minimized during the intraoperative period. Trauma from adhesive tape, blood pressure cuffs, and adhesive ECG electrodes can cause bullae formation. The blood pressure cuff should be padded with loose cotton dressing. Intravascular catheters should be anchored with sutures or a gauze dressing rather than adhesive tape. Trauma from a facemask may be reduced by lubrication of the mask and the patient's face. Use of upper airway instruments, including oropharyngeal and nasopharyngeal

airways, should be kept to a minimum because the squamous epithelial lining of the oropharynx and esophagus is susceptible to bullous formation. Frictional trauma to the oropharynx may result in the formation of large intraoral bullae, airway obstruction, and extensive hemorrhage from denuded mucosa. For similar reasons, insertion of an esophageal stethoscope should be avoided. Laryngeal involvement in patients with epidermolysis bullosa dystrophica is rare. If tracheal intubation is required, the laryngoscope and tracheal tube should be well lubricated to reduce friction against the oropharyngeal mucosa. Scarring of the oral cavity can cause microstomia and immobility of the tongue, which increases the difficulty of tracheal intubation. Fiberoptic-assisted tracheal intubation may be required. Although the safety of tracheal intubation has been established for patients with epidermolysis bullosa dystrophica, similar safety has not been established for patients with the junctional form. The junctional form affects all mucosa, including the respiratory epithelium. The types of surgical procedures (intra-abdominal) required in infants with the junctional type, however, usually mandate tracheal intubation.

Surgical procedures for patients with epidermolysis are usually peripheral and involve the hands. Ketamine is very useful for such superficial procedures because it provides good analgesia and usually does not require supplemental inhalation anesthesia. There are, however, no contraindications to inhaled anesthetics. Porphyria cutanea tarda, often associated with epidermolysis bullosa, does not have the same implications for anesthesia as acute intermittent porphyria. Regional anesthesia, including spinal, epidural, and brachial plexus anesthesia, has been used successfully for patients with epidermolysis bullosa.

Despite all the potential complications with anesthesia for patients with epidermolysis bullosa, appropriate intraoperative management is associated with surprisingly few complications. This is especially true when care is provided at a center experienced with the management of patients with epidermolysis bullosa.[70,71]

Pemphigus

Pemphigus is a vesiculobullous disease that may involve extensive areas of the skin and mucous membranes. Pemphigus is an autoimmune disease in which IgG antibodies attack the desmosomal proteins desmoglein 3 and desmoglein 1, leading to disruption of cell adhesion and separation of epithelial layers. A growing number of drugs have been implicated in the cause or exacerbation of pemphigus. These drugs include penicillamine, cephalosporins, ACE inhibitors, phenobarbital, propranolol, levodopa, piroxicam, and nifedipine.

There are several types of pemphigus including pemphigus vulgaris, pemphigus foliaceus, pemphigus vegetans, pemphigus erythematosus, and paraneoplastic pemphigus.[72] Pemphigus vulgaris is the most common type and the most clinically significant for the anesthesiologist because of the occurrence of oral lesions. Oral lesions develop in 50 to 70% of patients with pemphigus vulgaris and usually precede the cutaneous lesions. Lesions of the pharynx, larynx, esophagus, conjunctiva, urethra, cervix, and anus can develop. Extensive

oropharyngeal lesions may make eating painful to the extent that malnutrition occurs. Skin denudation and bullae formation can result in significant fluid and protein losses and the risk of secondary bacterial infection is great. As with epidermolysis bullosa, lateral shearing force is more likely to produce bullae than pressure exerted perpendicular to the skin surface. Systemic corticosteroids are the most effective therapy for pemphigus vulgaris. Improvement may be seen within days of corticosteroid therapy with full healing in 6 to 8 weeks. Adjuvant immunosuppressants such as azathioprine, cyclophosphamide, methotrexate, and mycophenolate mofetil can be used to reduce corticosteroid doses and side effects.[73]

Paraneoplastic pemphigus is an autoimmune disease associated with a number of malignant tumors, especially lymphomas and leukemias. IgG antibodies are produced that react to desmoglein 3 and 1. Oral and cutaneous lesions occur in most patients. Obstructive respiratory failure may result from inflammation and sloughing of the tracheobronchial mucosa.[74]

Pemphigus foliaceus (superficial pemphigus) is a less-severe form of pemphigus in which skin separation occurs near the epithelial surface; the oral mucosa is not affected. Pemphigus foliaceus

can, however, be fatal if not treated. Pemphigus erythematosus (Senear-Usher syndrome) is a superficial form of pemphigus with erythematous hyperkeratotic lesions over the nose and malar areas; the oral cavity is not involved.

Management of Anesthesia

Preoperative drug therapy and the extreme fragility of the mucous membranes are the primary concerns for the management of anesthesia for patients with pemphigus. Corticosteroid supplementation will be necessary during the perioperative period. Management of the airway and tracheal intubation should be performed as described for patients with epidermolysis bullosa. Ketamine and regional anesthesia have been used successfully for patients with pemphigus.[75]

There are no specific contraindications to the use of any inhaled or intravenous anesthetics; however, potential side effects of treatment drugs and interactions with anesthetics must be considered. Methotrexate produces hepatorenal dysfunction and bone marrow suppression, and cyclophosphamide may prolong the action of succinylcholine and mivacurium by inhibiting cholinesterase activity.

Malignant Hyperthermia and Other Pharmacogenetic Disorders

Henry Rosenberg

Barbara W. Brandom

Nyamkhishig Sambuughin

Jeffrey E. Fletcher

KEY POINTS

1	Malignant hyperthermia syndrome (MH) is an uncommon pharmacogenetic disorder of skeletal muscle. This means several things: (a) MH is inherited. (b) The syndrome is induced by pharmacologic agents in almost all cases. A few cases have been documented to result from exercise and heat exposure. (c) The pathophysiology involves biochemical changes in skeletal muscle physiology resulting in hypermetabolism. (d) The incidence is approximately one in 10,000 general anesthetics in the general population.
2	Unexpected elevation of end-tidal carbon dioxide in the absence of equipment malfunction is the most sensitive and specific sign of MH. Other signs of MH include tachycardia, tachypnea, acidosis, muscle rigidity, and rhabdomyolysis. MH may occur at any time in the course of an anesthetic from induction to emergence.
3	Masseter muscle rigidity after succinylcholine is more common in children than adults. It is predictive of MH susceptibility in up to 25% of cases and is associated with myoglobinuria. Trigger agents should be discontinued after masseter muscle rigidity.
4	Sudden cardiac arrest in a young male during general anesthesia, with or without succinylcholine, is likely a result of hyperkalemia in a patient with an occult myopathy, especially Duchenne muscular dystrophy.
5	Disorders that predispose patients to MH include central core disease and rarer forms of myotonia (e.g., hypokalemic periodic paralysis).
6	Trigger agents for MH include all potent inhalation agents and succinylcholine.

7	The gold standard test for diagnostic testing is the caffeine halothane contracture test (of freshly biopsied muscle) wherein muscle is exposed to incremental doses of caffeine or to halothane.
8	The essential points in treatment are the immediate discontinuation of trigger agents, hyperventilation, administration of dantrolene in doses of 2.5 mg/kg, repeated prn to signs of MH, and cooling by all routes available (especially nasogastric lavage, treatment of hyperkalemia in a standard fashion). Following an MH episode the patient should be treated with dantrolene for at least 36 hours.
9	Prevention of MH and avoidance of medicolegal action consists of obtaining a thorough history related to anesthetic complications, avoiding MH trigger agents in susceptibles and their relatives, having dantrolene immediately available, and monitoring body temperature during general anesthesia.
10	MH susceptibility is inherited in an autosomal dominant pattern in humans. Administration of triggering agents such as all halogenated an aesthetic agents and/or succinylcholine leads to an uncontrolled release of free calcium from the sarcoplasmic reticulum of skeletal muscle. Several genes have been linked to MH, with mutations found in three, the ryanodine receptor gene, the dihydropyridine receptor gene, and the gene that elaborates the sodium channel of muscle. In humans, over 18 mutations have been found to be causal for MH. Mutations in these genes alter the function of the calcium channel leading to increased calcium release from the sarcoplasmic reticulum. There are many other DNA variants whose significance is yet to be determined.

Many inherited disorders have significant implications for anesthetic management. In this chapter we discuss those disorders that are precipitated by drugs often administered by anesthesiologists. In some cases, such as the porphyrias, the illness may be induced by agents other than anesthetics. In other enzymatic disorders, such as pseudocholinesterase abnormalities, it would be unlikely for a patient to have any problems until he or she is exposed to the depolarizing neuromuscular blocking agent succinylcholine. Malignant hyperthermia (MH) or malignant hyperpyrexia is perhaps the most significant inherited disorder triggered by exposure to anesthetic drugs.

MALIGNANT HYPERTHERMIA

Malignant hyperthermia was first formally described in 1960 in Lancet[1] by Denborough and Lovell and subsequently in *The British Journal of Anaesthesia*.[2] That first case report laid the foundation for much of our understanding of the clinical presentations of MH. The patient was a young man who claimed that several of his relatives died without apparent cause during anesthesia. He was anesthetized with halothane and developed tachycardia, hot sweaty skin, peripheral mottling, and cyanosis. Early recognition and symptomatic treatment saved him. It became apparent that this new syndrome had the following elements: patients were otherwise healthy unless exposed to an anesthetic agent, temperature elevation was a hallmark, a heritable or genetic component was present, and a high mortality rate was likely. In addition, with early recognition and treatment it was possible to abort the malignant effects of the syndrome.

The association between porcine stress syndrome (PSS) or "pale soft exudative porksyndrome" and MH was described in the early 1970s, thus providing an animal model for MH.[3] Porcine breeds such as the Landrace, Poland China, and Pietrain show the classic presentations of MH when potent inhalation agents and/or succinylcholine are administered. During the 1970s, many more clinical presentations of MH were reported. The development of an in vitro diagnostic test was suggested by Kalow et al based on exposure of a skeletal muscle biopsy specimen to caffeine and then halothane.[4] In 1975, Harrison reported that dantrolene could be effective in treating and preventing MH in pigs.[5] By 1979, a sufficient number of cases were described showing that intravenous dantrolene could successfully reverse the human form of MH, and the drug was approved for use by the U.S. Food and Drug Administration (FDA). In the 1980s, lay organizations in the United States, Canada, and Great Britain were formed to disseminate information to patients affected by MH as well as to enhance awareness of the syndrome among physicians. Application of the muscle biopsy diagnostic halothane–caffeine contracture test was standardized and a registry for MH was created in the United States in the late 1980s. In addition, a variety of other tests for diagnosing MH were introduced, many of which subsequently were found to be of little or no validity.

A major step forward occurred in 1985, when Lopez and colleagues directly demonstrated an increased intracellular concentration of calcium ion in muscle from MH-susceptible pigs and humans.[6] The intracellular calcium concentration dramatically increased during an MH crisis and was reversed by the administration of dantrolene.

In the 1990s molecular biologic techniques were applied to identify the genes associated with MH susceptibility. It is anticipated that better understanding of the genetic substrate of the pathophysiology of MH will result in a less invasive diagnostic test than the contracture tests used at present. In the 1990s epidemiologic information helped to differentiate MH from other life-threatening anesthetic complications. It was appreciated that some deaths in children formerly attributed to MH were really the result of destruction of muscle cells that occurred during anesthesia with volatile agents and succinylcholine in patients with unrecognized myopathies, specifically the dystrophinopathies, Duchenne and Becker muscular dystrophy.[7]

Clinical Presentations

1 As our knowledge of MH has grown, the definition of MH has changed. At first, MH was thought in all cases to be a heritable syndrome consisting of an extremely elevated body temperature, skeletal muscle rigidity, and acidosis associated with a high mortality rate. However, MH should be thought of in terms of its underlying pathophysiologic characteristics. MH is a hypermetabolic disorder of skeletal muscle with varied presentations, depending on species, breed, and triggering agents. An important pathophysiologic process in this disorder is intracellular hypercalcemia in skeletal muscle. Intracellular hypercalcemia activates metabolic pathways that result in adenosine triphosphate depletion, acidosis, membrane destruction, and cell death. Although a heritable component is present in many cases, it is not invariably apparent from patient family history. In addition, disorders that may have symptoms and signs similar to those of MH, such as neuroleptic malignant syndrome (NMS), and heat stroke may not have an inherited basis.

Classic Malignant Hyperthermia

2 Malignant hyperthermia may present in several ways. In almost all cases, the first manifestations of the syndrome occur in the operating room. However, MH also may occur in the recovery room or (rarely) even later. In the classic case, the initial signs of tachycardia and tachypnea result from sympathetic nervous system stimulation secondary to underlying hypermetabolism and hypercarbia derived primarily from the skeletal muscle. Because many patients receive neuromuscular blockers and controlled ventilation during general anesthesia, tachypnea usually is not recognized. Shortly after the increase in heart rate, an increase in blood pressure occurs, often associated with ventricular dysrhythmias induced by sympathetic nervous system stimulation resulting from hypercarbia or caused by hyperkalemia or catecholamine release. Thereafter, muscle rigidity or an increase in muscle tone may become apparent. Increase

in body temperature, at a rate of 1 to 2°C every 5 minutes, follows. With the increase in metabolism, the patient may "break through" the neuromuscular blockade. At the same time, the CO_2

absorbent becomes activated and warm to the touch (because the reaction with CO_2 is exothermic). The patient will display peripheral mottling and, on occasion, sweating and cyanosis. Blood gas analysis usually reveals hypercarbia with respiratory and metabolic acidosis without marked oxygen desaturation. Elevation of end-tidal CO_2 is one of the earliest most sensitive and specific signs of MH. However, vigorous hyperventilation may mask such hypercarbia and delay the diagnosis.[8] A mixed venous blood sample will show even more dramatic evidence of CO_2 retention and metabolic acidosis.[9] Hyperkalemia, hypercalcemia, lactacidemia, and myoglobinuria are characteristic. An increase in creatine kinase (CK) levels is dramatic, often exceeding 20,000 units in the first 12 to 24 hours. Death results unless the syndrome is promptly treated. Even with treatment and survival, the patient is at risk for life-threatening myoglobinuric renal failure and disseminated intravascular coagulation. Another significant clinical problem is recrudescence of the syndrome within the first 24 to 36 hours.[10,11] If succinylcholine is used during induction of anesthesia, an acceleration of the manifestations of MH may occur such that tachycardia, hypertension, marked temperature elevation, and dysrhythmias are seen over the course of 5 to 10 minutes. However, a completely normal response to succinylcholine does not rule out the subsequent development of MH when potent volatile agents are used.

Masseter Muscle Rigidity

3 Rigidity of the jaw muscles after administration of succinylcholine is referred to as *masseter muscle rigidity* (MMR) or *masseter spasm.* The association of this phenomenon with MH was underlined by many case reports of MMR preceding MH.[12,13] Although MMR probably occurs in patients of all ages, it is distinctly most common in children and young adults. MMR occurs in about 1% of children induced with halothane prior to administration of succinylcholine. Several studies have shown a peak age incidence at 8 to 12 years of age. Characteristically, anesthesia is induced by inhalation of halothane or sevoflurane, after which succinylcholine is administered. Snapping of the jaw or rigidity on opening of the jaw is seen. Although less common MMR may follow induction with thiopental or propofol prior to succinylcholine administration. However, this rigidity can be overcome with effort and usually abates within 2 to 3 minutes. Repeat doses of succinylcholine do not relieve the problem nor do non-depolarizing relaxants. A peripheral nerve stimulator usually reveals flaccid paralysis. However, increased tone of other muscles also may be noted. Tachycardia and dysrhythmias are not infrequent. Only in rare cases does frank MH supervene immediately after MMR. More commonly (if the anesthetic is continued with a triggering agent), the initial signs of MH appear in 20 minutes or more. If the anesthetic is discontinued, the patient usually recovers uneventfully. However, within 4 to 12 hours, myoglobinuria occurs and CK elevation is detected.

Muscle biopsy with caffeine–halothane contracture testing has shown that approximately 25% of patients who experience MMR are also susceptible to MH.[14,15] Therefore, one may elect to discontinue anesthesia and postpone surgery after an episode of MMR. If surgery must be continued, it should be with nontriggering anesthetics and the use of end-tidal CO_2 and core temperature monitoring. The issue of whether to give dantrolene after an episode of MMR is unresolved. Dantrolene is most useful only when there is a clear diagnosis of MH. When MMR is accompanied by rigidity of chest or limb, MH is more likely to follow than after isolated jaw rigidity.[16,17]

The differential diagnosis of MMR consists of the following: (1) myotonic syndrome, (2) temporomandibular joint dysfunction, (3) underdosing with succinylcholine, (4) not allowing sufficient time for succinylcholine to act before intubation, (5) increased resting tension after succinylcholine in the presence of fever or elevated plasma epinephrine. A variety of reports have shown that succinylcholine increases jaw muscle tone in patients with normal muscle.[18] This normal agonistic effect of succinylcholine, further increased by temperature[19] and epinephrine in the presence of halothane, may account for some cases of MMR. Signs of temporomandibular

dysfunction as well as myotonia should be sought following the MMR episode. If rigidity precluding laryngoscopy occurred without temporomandibular joint dysfunction, the patient should be evaluated by a neurologist for the presence of occult myopathy and counseled regarding the need for a muscle biopsy and diagnostic contracture test to evaluate MH susceptibility. It is incumbent on the anesthesiologist to alert the patient to the possibility that MH may follow in subsequent procedures.

MMR has been shown in both retrospective as well as prospective studies to occur in as many as 1 in 100 children anesthetized with halothane and given succinylcholine. A retrospective study based on the information supplied to the Danish Malignant Hyperthermia Registry found that the incidence of MMR was 1 in 12,000 (including adults and children).[20] A prospective study found MMR in 1 of 500 children who received halothane and then intravenous succinylcholine.[21]

Our advice regarding MMR is as follows:

1. When it occurs, the anesthesiologist should, if at all possible, discontinue the anesthetic and postpone surgery. If end-tidal CO_2 monitoring and dantrolene are available and the anesthesiologist is experienced in managing MH, he or she may elect to continue with a nontriggering anesthetic.
2. After episodes of MMR, the patient should be observed carefully for a period of 12 to 24 hours for myoglobinuria and signs of MH. Administration of 1 to 2 mg/kg of dantrolene should be considered.
3. The family should be informed of the episode of MMR and its implications.
4. Creatine kinase levels should be checked 6, 12, and 24 hours after the episode. If the CK level is still grossly elevated at 12 hours, additional samples should be drawn until it begins to return to normal.
5. If the CK level is greater than 20,000 IU in the perioperative period and a concomitant myopathy is not present, the diagnosis of MH is very likely.[22] If contracture test results are within normal limits after an episode of MMR, we currently do not recommend that other family members undergo testing, but advise that succinylcholine be avoided in future anesthetics for that patient.

A study by Littleford et al[23] has shown that acidosis and rhabdomyolysis occur when anesthesia is continued with a volatile inhalation agent after MMR, although fulminant MH may not occur. MMR has been documented most frequently in association with succinylcholine, although it may occur after induction with any anesthetic agent, intravenous or inhalation, before succinylcholine administration.[24] Hence, pediatric anesthesiologists avoid the use of succinylcholine except on specific indication. (See also Myodystrophies Exacerbated by Anesthesia section.)

Late Onset of MH and Myoglobinuria

Malignant hyperthermia may occur in the postoperative period, usually within the first few hours of recovery from anesthesia. The characteristic tachycardia, tachypnea, hypertension, and dysrhythmias indicate that an episode of MH may be about to follow. Myoglobinuria may occur without an

obvious increase in metabolism.[25] Succinylcholine may cause rhabdomyolysis in patients who have other muscle disorders that may not be clinically obvious on cursory examination.[7,26,27] Myoglobinuria may result from interactions with other drugs such as inhibitors of cholesterol formation.[28] The presence of myoglobinuria mandates that the patient be referred to a neurologist for further investigation.

Myodystrophies Exacerbated by Anesthesia: Relation to

Malignant Hyperthermia

4 Patients suffering from *muscular dystrophy*, Duchenne or Becker's, are at risk to develop hyperkalemic cardiac arrest after administration of succinylcholine. The same may occur following administration of volatile anesthetic agents only. These adverse events were first believed to represent a form of MH.[29,30] It now appears that the pathophysiology of the hyperkalemic episodes and MH is different. Case reports collected by the Malignant Hyperthermia Association of the United States (MHAUS) and the North American MH Registry indicate that when an apparently healthy child experiences a sudden unexpected cardiac arrest on induction of anesthesia, once hypoxemia and ventilatory problems are ruled out, hyperkalemia should be considered. Of 29 patients with such a presentation, 60% died. In 50% there was evidence of undiagnosed myopathy (usually muscular dystrophy).[7] The treatment of hyperkalemic arrests includes administration of calcium chloride, glucose, insulin, bicarbonate, and hyperventilation.

In 1993 and in 1994 the package insert for succinylcholine was modified to warn against routine use of succinylcholine in children. Of course, in special circumstances, such as airway emergencies and the presence of a "full stomach," succinylcholine may still be appropriate. However, administration of rapid-acting nondepolarizing neuromuscular blockers in these situations may be an appropriate alternative to use of succinylcholine.

5 *Central core disease* (CCD) is a congenital myopathy characterized by muscle weakness. CCD is generally inherited in an autosomal dominant manner, although a few families with autosomal recessive inheritance and many sporadic cases have been reported.[31] Mutations that predispose to central core disease, similar to MH, are usually associated with the ryanodine receptor gene. Many cases of MH have been reported in patients with CCD. Therefore, precautions regarding MH must be taken for all patients with central core disease.[32]

The *myotonias* are a varied set of disorders resulting from abnormalities in either the sodium or chloride channel of muscle. The common pathophysiologic process is prolonged depolarization of the muscle membrane following activation. Patients with any of these disorders will display muscle contractures after succinylcholine. Hypokalemic periodic paralysis and a rare form of myotonia, myotonia fluctuans, have been linked to MH susceptibility by the halothane–caffeine contracture test.[33,34]

King or *King-Denborough* syndrome is a rare myopathy characterized by cryptorchidism, markedly slanted eyes, low-set ears, pectus deformity, scoliosis, small stature, and hypotonia. Several patients with this disorder have been diagnosed as MH susceptible both clinically and by muscle biopsy.[35,36] Skeletal abnormalities such as osteogenesis imperfecta[37] and the Schwartz-Jampel[38] syndrome *myotonia* have been associated with signs of MH. Metabolism is increased in patients with osteogenesis imperfecta because of the bone disease. Fever during anesthesia is common in these patients. The Schwartz-Jampel syndrome is an autosomal recessive myotonic-like condition with osteoarticular deformities. Fever is common in these patients because of continuous muscle activity. In both these conditions, association with MH is sporadic. Despite a few well-documented cases of MH in patients with osteogenesis imperfecta, we (and others[39]) have not confirmed MH susceptibility in three cases of osteogenesis imperfecta tested with the halothane–caffeine contracture test. Inhalation anesthetics have been administered without complication to many patients with osteogenesis imperfecta. But we have found typical contractures in one other muscle biopsy from a patient with osteogenesis imperfecta.

Syndromes with a Clinical Resemblance to MH

Pheochromocytoma may be mistaken for MH because it presents with tachycardia, hypertension, and fever during anesthesia. However, pheochromocytoma does not predispose to MH.[40] Thyrotoxicosis could also be mistaken for MH. Carbon dioxide production is lower in these endocrine disorders than in MH. Hypertension is greater in pheochromocytoma than in thyrotoxicosis, and even less in MH. Neither endocrine crisis is associated with muscle rigidity as in MH. Metabolic acidosis is generally not present during thyrotoxicosis and not as great during pheochromocytoma as during MH. Thyroid crisis did not trigger MH even in susceptible pigs.[41]

Sepsis is most often confused with MH. Patients undergoing urinary tract surgery; ear, nose, and throat surgery; or appendectomy for appendicitis can and will develop fever and sometimes acidosis in the PACU. Hyperkalemia may also appear during episodes of sepsis. Unlike MH, however, muscle rigidity is uncommon, although rigors may be mistaken for rigidity. In addition, signs of sepsis are treated effectively with nonsteroidal anti-inflammatory agents and antibiotics. MH will not respond to such nonspecific therapy. Dantrolene may often be associated with acute reduction of fever. This, however, is also nonspecific. Differentiating sepsis from MH is often not possible clinically.

Hypoxic encephalopathy is characterized by failure to awaken from anesthesia, posturing and opisthotonus, and hyperthermia. It has been mistaken for MH. The diagnosis is based on the clinical presentation.

Mitochondrial myopathies resemble MH. Defects within the mitochondrial genome affect oxidative phosphorylation and result in impaired production of ATP. These disorders have many manifestations, usually presenting at an early age with central nervous system (CNS) and muscle pathology. Failure to thrive, developmental delays, muscle weakness, and cardiomyopathy may be present. Elevated serum lactate and pyruvate are found on laboratory examination. There does not appear to be a relation between the mitochondrial myopathies and MH. However, respiratory depression is often seen following anesthesia. Succinylcholine is best avoided in these patients because of the potential for hyperkalemia. There is insufficient evidence in the literature to characterize the response to potent volatile agents.[42]

Periodic paralyses are inherited disorders characterized by marked muscle weakness and paralysis resulting from small deviations in potassium concentrations. The disorders are inherited and result from mutations in the gene that elaborates the sodium channel or the calcium channel of skeletal muscle.

In *hypokalemic periodic paralysis*, the patient is exquisitely sensitive to lowered potassium as may occur with administration of a glucose load or fasting. As mentioned earlier, there has been a relation to MH described in some patients.[33]

In *hyperkalemic periodic paralysis* small increases in potassium will lead to muscle weakness and paralysis. A relation to MH susceptibility has not been described. In almost all cases

the patient will relate a family history of muscle weakness and paralysis under conditions where there is a change in serum potassium.

Malignant Hyperthermia Outside the Operating Room

The often-repeated observation that an MH-like syndrome can occur in certain pig breeds in response to stressful situations supports the suggestion that MH may occur outside the operating room in humans. Gronert et al have described a patient who had episodic fevers and whose muscle produced a contracture consistent with MH susceptibility.[43] The fevers were controlled by dantrolene. A minority of exercise-induced rhabdomyolysis and heat stroke cases are also related to MH. Mutations in the RYR1 receptor gene, known to be causative of MH, have been found in a patient who died of heat stroke[44] and in some patients with exercise-induced rhabdomyolysis.[45]

In 1997 Tobin and associates documented an apparent awake episode of fatal MH in a 12-year-old-boy. The child had recovered from an episode of clinical MH during anesthesia several months prior to the episode. Following soccer practice on a day that was not overly hot and humid, he complained of muscle discomfort and rapidly developed ventricular fibrillation. His CK rose to 9,000 IU. Genetic investigation revealed the presence of a ryanodine receptor mutation known to be causal for MH. Other family members also harbor the mutation.

A few other cases of apparent awake episodes of fatal MH have been reported from other countries.

Neuroleptic Malignant Syndrome and Other Drug-Induced

Hyperthermic Reactions

The symptoms and signs of the NMS include fever, rhabdomyolysis, tachycardia, hypertension, agitation, muscle rigidity, and acidosis.[46] The mortality rate is unknown, but is significant. Dantrolene is an effective therapeutic modality in many cases of NMS. Therefore, it is not unusual for an anesthesiologist to be consulted in the management of patients with this disorder.

Although the resemblance of NMS to MH is striking, there are significant differences between the two. MH is acute, whereas NMS often occurs after longer term drug exposure. Phenothiazines and haloperidol or any of the newer potent antipsychotic agents alone or in combination are usually triggering agents for NMS. Sudden withdrawal of drugs used to treat Parkinson's disease may also trigger NMS. Electroconvulsive therapy (ECT) with succinylcholine does not appear to trigger the syndrome.[47] Also, NMS does not seem to be inherited, and there are no case reports of it in family members who have had an episode of MH.

Many believe that the changes in NMS are a reflection of dopamine depletion in the central nervous system by psychoactive agents. In support of this theory, therapy with bromocriptine, a dopamine agonist, is often useful in treatment of NMS. Therefore, although there appear to be similarities between MH and NMS,[46] a common pathophysiology is not readily apparent. From an anesthesiologist's viewpoint, it is best to monitor patients with NMS as though they were susceptible to MH. However, drugs such as succinylcholine have been used for ECT without problems in MH patients.

A similar set of signs may be observed in some patients taking serotonin uptake inhibitors. Much less is known regarding this syndrome.

Other drugs known to induce a hypermetabolic syndrome and rhabdomyolysis, probably through mechanisms not related to those of MH, are cocaine, amphetamines, and MDMA. Dantrolene has been used sporadically as an adjunct to treatment of marked hyperthermia with promising results. Treatment, however, is usually symptomatic.

Drugs That Trigger Malignant Hyperthermia

6 It is clearly established that the potent inhalation agents, including sevoflurane, desflurane, isoflurane, halothane, methoxyflurane, cyclopropane, and ether, may trigger MH. Succinylcholine and decamethonium are also triggers. Other anesthetic drugs and adjuvants are not MH triggers. Table 20-1 indicates the drugs believed to be safe and those that are unsafe.

TABLE 20-1 Safe Versus Unsafe Drugs in Malignant Hyperthermia

·SAFE DRUGS	·UNSAFE DRUGS
Antibiotics Antithistamines Barbiturates Benzodiazepines Droperidol Ketamine Local anesthetics Nitrous oxide Nondepolarizing neuromuscular blockers Opioids Propofol Propranolol Vasoactive drugs	All inhalation agents (except nitrous oxide) Succinylcholine

Local Anesthetics

All local anesthetics are safe for MH-susceptible patients.[48] Preliminary studies of local anesthetics during an MH crisis (e.g., for dysrhythmia control) do not show an exacerbation of MH by amide local anesthetics.

Catecholamines

Although plasma catecholamines increase during an MH crisis, such an elevation is usually secondary to metabolic and cardiovascular changes. Vasopressors and other catecholamines are not involved in triggering MH.[49] Therefore, these drugs should be used as necessary but only with simultaneous treatment of the MH crisis.

Nondepolarizing Relaxants and Anticholinesterases

Vecuronium, rocuronium, atracurium, pancuronium, and all other nondepolarizing drugs are considered safe to use in patients with MH. Clinical studies have shown that anticholinesterase–anticholinergic combinations are safe for reversal of nondepolarizing relaxants in MH-susceptible patients.[50]

Phenothiazines and Drugs Used to Treat Psychoses

Phenothiazines increase intracellular calcium ion concentration and may cause contractures in vitro in muscle from MH-susceptible patients.[51] Phenothiazines also induce the related neuroleptic malignant syndrome. Therefore, although there have been several reports that phenothiazines are effective in managing temperature fluctuations during recovery from MH,

these compounds should be used cautiously in MH-susceptible patients. Medications used in the treatment of psychiatric conditions such as haloperidol, atypical antipsychotics may induce NMS. Since NMS and MH are dissimilar, there is no evidence that these agents are precipitants of MH.

Other Drugs

Digoxin, quinidine, and calcium salts do not induce MH in the swine.[52] Therefore, it is reasonable to assume that they are safe to use in clinical situations. Neither ketamine nor propofol are MH triggers.[53]

Incidence and Epidemiology

Although the incidence of reported episodes of MH has increased, the mortality rate from MH has declined. In part, these two trends reflect a greater awareness of the syndrome, earlier diagnosis, and better therapy. The incidence of MH varies from country to country, based on differences in gene pools. In the upper midwest of the United States, for example, there are many families containing large numbers of MH-susceptible people. In contrast, other areas of the country and parts of the world have rarely reported MH. For example, Bachand and colleagues examined the incidence of MH in the province of Quebec, Canada, where many families had been biopsied. They traced the pedigrees of the patients to the original immigrants from France and found an incidence of MH susceptibility of 0.2% in this province. However, that represented only five extended families.[54] A study in Great Britain revealed 3 cases of MH in 100,000 administered anesthetics.[55] The best epidemiologic study of MH was done in the mid 1980s by Ording.[20] Based on information supplied to the Danish Malignant Hyperthermia Registry comprising the reported incidence of MH in Denmark (population approximately 5 million), this study revealed fulminant MH in approximately 1 in 250,000 administered anesthetics. However, if the definition of MH is expanded to include abortive cases of MH and is further refined to include only cases in which inhalation anesthetics and succinylcholine were used, the incidence was as high as 1 in 4,000 anesthetic administrations![20]

A better understanding of the prevalence of MH is likely to emerge from the widespread use of

molecular genetics for the diagnosis of MH susceptibility. For example, Monnier and colleagues estimate that one in 2,000 to 3,000 persons in France harbor one of the known MH causative mutations.[56] Currently, the consensus is that mortality from MH is under 5% in Western countries. However, the epidemiologic characteristics of MH are very difficult to define for the following reasons:

1. Widespread diagnostic testing for MH is difficult to apply.
2. The clinical diagnosis of MH is often questionable.
3. Triggering of MH even in susceptible patients may not occur on each anesthetic exposure. In some cases, susceptible patients have received triggering agents for up to 13 anesthetics without any problems, only to have MH triggered on the subsequent anesthetic. Investigation of the Danish Malignant Hyperthermia Registry found the MH genotype to be expressed in only 34 to 54% of anesthetic exposures.[57]
4. Registries of MH cases do not capture all data. There is a paucity of data concerning the frequency of use of anesthesia in the general population.

Inheritance of Malignant Hyperthermia

Many of the difficulties that limit an understanding of the epidemiologic characteristics of MH also limit accurate assessment of its inheritance. The animal model does not clarify the issue of inheritance in humans. MH in most pig breeds is inherited in an autosomal recessive fashion.[58] Variability in clinical presentation and the fact that MH is not regularly apparent on exposure to triggering agents, even in those who are susceptible, result in great difficulty in assessing the inheritance of MH in affected families. Nevertheless, it is generally accepted that MH in humans is inherited as an autosomal dominant trait with variable penetrance.[59] This implies that children of MHS patients have a 50% chance of being MHS themselves.

Diagnostic Tests for Malignant Hyperthermia

Development of the In Vitro Contracture Test

In 1970, Kalow et al demonstrated that isolated muscle from MH-susceptible patients was unusually sensitive to caffeine when exposed in vitro.[4] Shortly thereafter, Ellis and co-investigators demonstrated that muscle from MH-susceptible patients also had a more sensitive than normal contracture response to halothane. The European MH Group (EMHG)[60,61] and North American MH Group (NAMHG)[62,63,64] separately have standardized protocols for contracture testing. Treatment of muscle biopsy specimens in a tissue bath with either halothane or caffeine has come to be the standard test for diagnosing MH susceptibility.

Other tests have been proposed to differentiate patients with MH from those who are normal. None of these tests distinguished MHS patients from normals with accuracy. However, several newer approaches suggest that nonmuscle biopsy tests might be valuable as an initial estimation of likelihood of MH susceptibility and are discussed later in the chapter.

Halothane–Caffeine Contracture Test

Although some procedures and interpretations differ between the EMHG and NAMHG protocols, the following steps are similar. Skeletal muscle (1 to 3 g) is usually biopsied from the vastus lateralis muscle. Strips of muscle weighing 100 to 200 mg and measuring 15 to 30 mm ($\geqslant$25 mm preferred) in length by 2 to 3 mm in width by 2 to 3 mm in thickness are carefully isolated and mounted in a standard muscle bath apparatus (Fig. 20-1). The tissue bath contains a modified Krebs solution at 37°C bubbled with O_2 and CO_2 (95%/5%), and the resting tension is adjusted to the optimum length for maximal twitch tension (usually about 2 g). The bundles are stimulated supramaximally with pulses of frequency 0.1 to 0.2 Hz with 2 msec pulses to verify

viability. After a 15- to 60-minute equilibration in which the preparation is oxygenated with O_2/CO_2 (95/5%), halothane is added to the gas phase, either as a bolus dose or in incrementally increasing concentrations (Fig. 20-2). The concentration of halothane is verified by gas chromatography. A second set of muscle strips is equilibrated and subsequently exposed to incrementally increasing concentrations of caffeine-free base (see Fig. 20-2). It is recommended that the caffeine strips be tested early in the procedure because they tend to be more sensitive to instability over time. Testing is usually completed within about 5 hours of biopsy to ensure adequate viability of the muscle preparations. Owing to time constraints, it is essential that the biopsy be performed at or within about 1 hour of the testing laboratory. Usually, a histologic evaluation accompanies the contracture test to examine whether the subject has a muscle disorder other than MH.

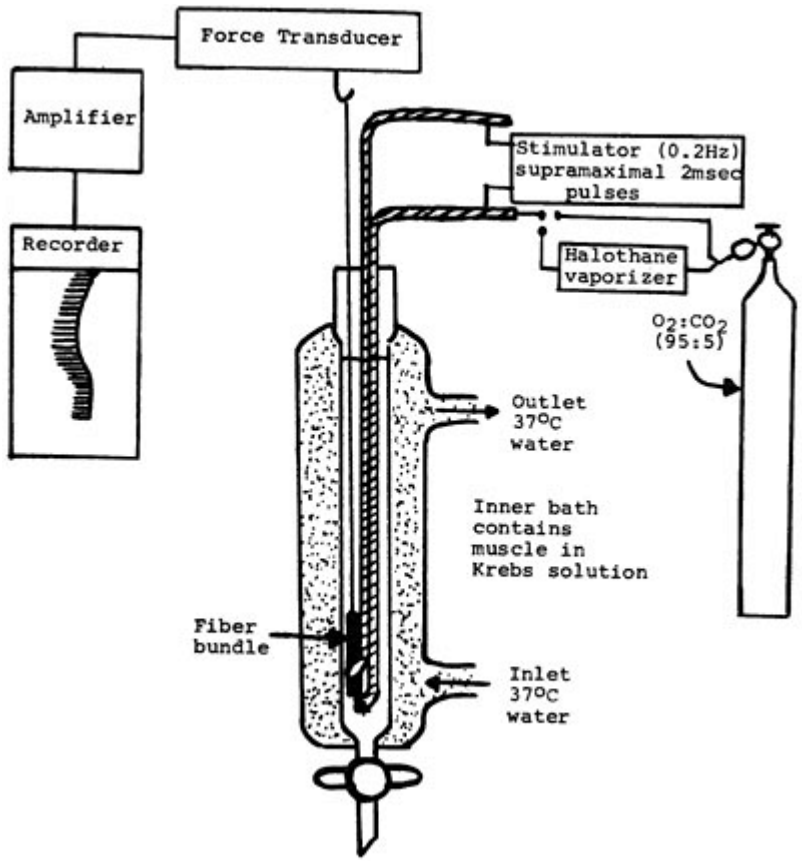

FIGURE 20-1. Diagram of the muscle bath apparatus used for contracture testing for diagnosing MH susceptibility.

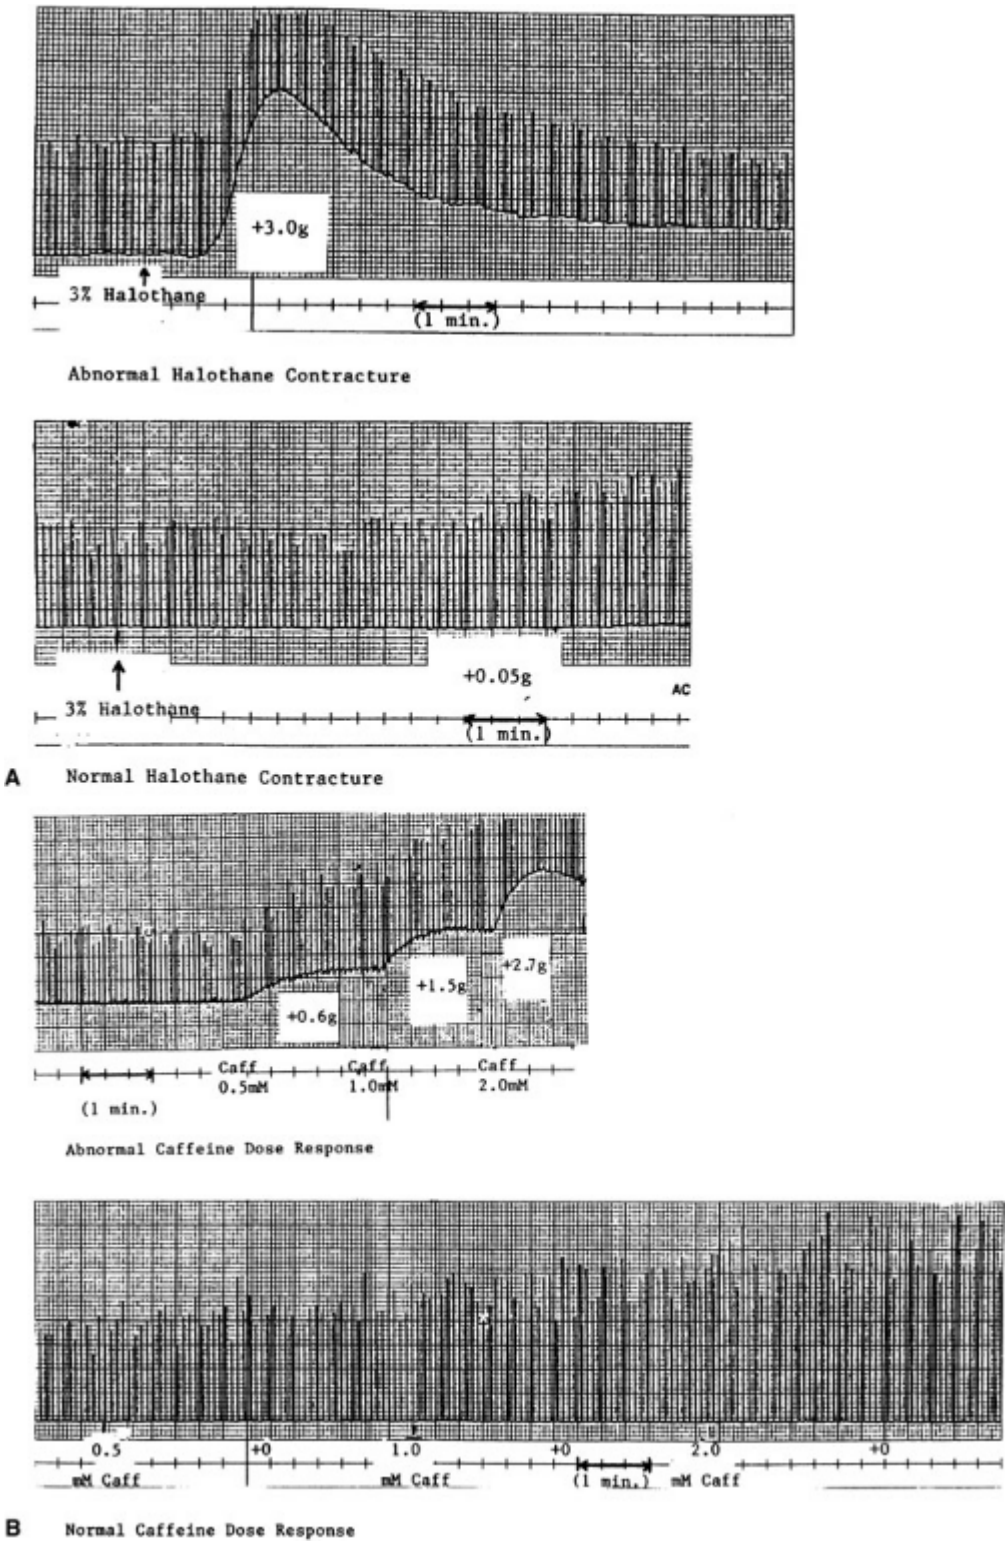

FIGURE 20-2. Muscle strips weighing approximately 150 mg and stimulated supramaximally are exposed to 3% halothane or incremental doses of caffeine. **A.** A 3-g contracture is recorded from this strip from an MHS patient after exposure of the muscle to 3% halothane (*top*); a normal response to 3% halothane (*bottom*). **B.** Contractures noted after exposure to 0.5, 1, and 2 m*M* caffeine in MHS muscle (*top*); no contracture response to the same caffeine concentrations. Twitch height augmentation is normal following caffeine addition (*bottom*).

Interpretation of the Halothane–Caffeine Contracture Test. Two protocols have been adopted for use over the past decade. These protocols were initiated to standardize procedures so that the results from groups of laboratories could be pooled for analysis. A uniform approach was necessary to standardize the phenotype derived from the contracture test for use in genetic

analysis.

In the EMHG protocol, also known as the IVCT for In Vitro Contracture Test,[60,61] halothane is added incrementally (0.5, 1.0, 2.0%) with the preparation exposed to each concentration for 3 minutes. A response indicative of MH susceptibility is based on a contracture threshold (>0.2 g) at a halothane concentration ⩽2% in either of the two muscle strips tested. Caffeine is also added incrementally in concentrations of 0.25, 0.5, 1.0, 1.5, 2.0, 3.0, and 4.0 m*M.* Each caffeine concentration is maintained until the contracture plateau is reached, or for 3 minutes, whichever is sooner. A positive response is a contracture threshold (>0.2 g) at a concentration of caffeine of 2 m*M* or less in either of two strips tested.

In the NAMHG protocol,[62] also known as the Caffeine Halothane Contracture Test (CHCT), a bolus dose of halothane 3% is added to the gas phase for each of three muscle strips and the maximum contracture within 10 minutes is recorded. A positive response is a contracture >0.7 g tension to halothane 3% and a negative response is <0.5 g. An equivocal response to halothane (MH-equivocal, or MHE) is between 0.5 and 0.7 g.[63] As in the EMHG protocol, caffeine is added incrementally, but the concentrations are 0.5, 1.0, 2.0, 4.0, 8.0, and 32 m*M*. A positive response is a contracture >0.3 g (determined by the specific laboratory) to 2 m*M* caffeine. The interpretations of the outcomes of the halothane and caffeine tests differ between the EMHG and NAMHG protocols. The EMHG protocol requires a positive response to halothane and a positive response to caffeine for a diagnosis of MH-susceptible (MHS). If the outcomes of both tests are negative, then the subject is diagnosed as MH-normal (MHN). If only the caffeine test is abnormal, the patient is considered MHE to caffeine (MHEc). If only the halothane test is abnormal, the patient is considered MHE to halothane (MHEh). The NAMHG protocol differs in that the subject is considered MH positive (MH+ or MHS) if either the response to halothane or the response to caffeine is abnormal. The patient is diagnosed as normal (MH- or MHN) if neither test is positive. As in the EMHG protocol, MHE subjects are treated clinically as MH susceptible.

Sensitivity and Specificity of the Halothane–Caffeine Contracture Test. The sensitivity of the NAMHG protocol (CHCT) is 100% with specificity 78% (false-negatives are to be avoided).[64] The EMHG test (IVCT) has sensitivity of 98% with specificity of 93%. It is difficult to be certain of the sensitivity and specificity of the contracture test because although one can be fairly certain of the clinical phenotype of MHS based on anesthetic exposures, it is almost impossible to be assured that control subjects do not harbor a causative mutation. Determination of the sensitivity and specificity is based on contracture studies of patients with no known MH history undergoing routine surgery (controls) compared to contracture studies from patients who experienced a clinical episode of MH. When the genetic characterization of MH is more complete, the sensitivity and specificity of the contracture test may be clarified.

Other Contracture Tests

In an attempt to further improve the specificity and sensitivity of the contracture test, other agents have been tested for their effect on skeletal muscle.

Ryanodine. An additional contracture test using the plant alkaloid ryanodine was proposed for inclusion in the EMHG protocol. Ryanodine binds to and activates the calcium release channel of the sarcoplasmic reticulum. It was reasoned that this test would afford maximum specificity for MH, and early studies supported this concept.[65,66,67,68]

The basic testing conditions for ryanodine are similar to those described for halothane and caffeine testing. High-purity ryanodine is employed. A bolus of ryanodine (1 μM) is added to the bath and the time to onset of contracture, time to 0.2-g contracture, time to 1-g contracture, and the time and amplitude of maximum contracture are recorded. Discrimination was improved by using the time to initial contracture and time to development of a 10-m*N* (1 g) contracture.[69]

4-Chloro-*m*-cresol. 4-Chloro-*m*-cresol (4-CmC) is a potent activator of ryanodine receptor–mediated Ca^{2+} release. Cumulative administration of 25, 50, 75, 100, 150, and 200 μmol/L 4-CmC produced concentration-dependent contractures. Contractures developed earlier and to a greater

magnitude in muscle from patients identified as MHS by the EMHG protocol than in normal muscle.[70] The addition of testing with this compound has been approved by the EMHG.

Pitfalls in the Contracture Test

Ideally, each laboratory should derive specimens from patients who are clearly and unequivocally normal and those who are clearly and unequivocally MH susceptible to verify that cutpoints for MH susceptibility are diagnostic within the laboratory. Unfortunately, because of the variation in presentation of MH and the confusion with signs associated with non-MH causes, it is not always possible to have complete agreement on the MH status of a patient based on a clinical history, even among experts in the field. This problem has made estimates of sensitivity and specificity difficult.

A clinical grading scale has been developed to address concerns for objectively evaluating the clinical episode.[71] This scale lacks sensitivity, because incomplete recording of necessary data or early termination of the crisis would not yield scores indicative of MH, even if an episode had occurred. The scoring system also is designed to avoid overweighting duplicative indicators representing the same processes. The value of the grading scale is mainly in identifying those subjects with the most convincing episodes of MH for subsequent evaluation of the sensitivity and specificity of the diagnostic tests. The clinical grading scale (Table 20-2) is useful in evaluating clinical episodes in those cases in which the subject is rated a D6 (Diagnostic rank 6, almost certainly MH), but lower scores should not be considered for actual diagnosis. We would even encourage the practice of sending patients rated D6 for diagnostic muscle contracture testing, because these individuals are rare

and essential for the continuing evaluation of the sensitivity and specificity of the contracture test and for study of the genetics of MH.

TABLE 20-2 Criteria Used in the MH Clinical Grading Scale

Process I: Muscle Rigidity	
Generalized Rigidity	15
Masseter Rigidity	15
Process II: Myonecrosis	
Elevated CK>20,000 (+Succ.)	15
Elevated CK>10,000 (No Succ.)	15
Cola Colored Urine	10
Myoglobin in urine >60 ug/L	5
Blood/plasma/serum K>6 mEg/L	3

Process III: Respiratory Acidosis	
$PetCO_2$>55 with CV	15
$PaCO_2$>60 with CV	15
$PetCO_2$>60 with SV	15
Inappropriate hypercarbia	15
Inappropriate tachypnea	10
Process IV: Temperature Increase	
Rapid increase in temperature	15
Inappropriate temperature >38.8 in perioperative period	10
Process V: Cardiac Involvement	
Inappropriate tachycardria	3
V. tach or V. fib	3
See Larach et al[71] for full details of this scoring system. Briefly, a case may receive 15 points for the worst presentation in five of the first six categories. A sum of more than 50 points is termed "D6," almost certainly a case of MH. A sum of 35 to 49 points is "D5," very likely to be a case of MH.	

There have been a few reports describing patients who were diagnosed as nonsusceptible by contracture testing subsequently experiencing clinical episodes highly suggestive of MH; and in one case, the estimated false-negative rate was 4 out of 171 subjects (2%).[72,73] MH experts are not convinced that these are valid cases of MH. A mimic of MH such as sepsis may explain the clinical problem.[73] In contrast, studies have reported 16 MHN patients receiving triggering agents on 23 occasions[74] and 13 MHN patients receiving triggering agents on 26 occasions,[75] all without complications. Unfortunately, studies like these are difficult to conduct because they require large patient populations and tracking of subjects diagnosed several years before the actual study. Until more data are gathered, it is difficult to put the occasional false-negative diagnosis into proper perspective.

Variability seems to exist between families in the magnitude of contracture.[76] This may be because of the inheritance of different genetic defects. Until such time as all the basic biochemical defects of MH are uncovered, the contracture test will be subject to some differences in interpretation. However, the halothane–caffeine contracture test is currently the only method of MH diagnosis

that has been standardized and has had sensitivity and specificity confirmed in any manner by multiple centers throughout the world. When a patient is diagnosed as MHS by the contracture test, then MH trigger agents are to be avoided. IF the patient is MHN, then volatile agents may be used.

Tests with More Limited Usefulness in Malignant Hyperthermia Diagnosis

Alternative tests that have not gained acceptance within the EMHG or NAMHG have been reviewed elsewhere.[77,78] These tests include lymphocyte tests, platelet aggregation, skinned fiber tests, adenosine triphosphate depletion, erythrocyte osmotic fragility, and others. The tests discussed later have at least some usefulness in some cases of MH.

Elevated resting CK values are associated with MH susceptibility in a few families. However, many subjects susceptible to MH do not have elevated CK values, making this method of diagnosis relatively insensitive.[78] Also, several muscle disorders are associated with elevated resting CK values, making this test nonspecific.[78] We caution that this method of diagnosis is only tentative and should be confirmed by contracture testing. Elevated CK values also may be useful in preliminarily identifying key family members to be referred for contracture testing and in identifying MH in children too young to undergo contracture testing.

The use of resting CK values for general screening for MH is neither sensitive nor specific, but there is a relationship between high postoperative CK values associated with masseter muscle rigidity (MMR) and the probability for diagnosis as MH susceptible by the contracture test.[15,22] Although it is not a perfect indicator of MH susceptibility,[79] the chances are about 80% that a CK value >20,000 after MMR will yield a positive diagnosis by contracture testing.[15,22] A relatively normal CK postoperatively does not rule out the possibility of an acute MH reaction during that anesthetic.[80]

A variety of minimally invasive diagnostic tests are in development at present. One utilizes nuclear magnetic resonance spectroscopy to evaluate ATP depletion during graded exercise in vivo. MH patients have a greater breakdown of ATP and creatine phosphate as well as an increase in acid content compared to normals.[81] Utilizing cultured muscle cells[82] or B lymphocytes,[83] it has been shown that agents such as caffeine and chlorocresol will raise intracellular calcium ion concentrations to a greater extent in tissue derived from MHS individuals than normals. Injection of a small amount of caffeine through a microdialysis catheter inserted into muscle will elicit an enhanced release of carbon dioxide locally. Metabolic changes are measured through the catheter.[84,85] Repetitive nerve stimulation produces a different pattern of contraction and relaxation in MHS muscle than in normal muscle.[86,87] All of these tests are still in the developmental stage.

Molecular Genetic Testing for MH Susceptibility

The discovery of multiple MH causing mutations in the RYR1 gene[31,59] has led to the introduction of genetic testing of MH susceptibility on a limited basis in Europe and the US. The guidelines published by the European Malignant Hyperthermia Group suggest that for clinical diagnosis a panel of 23 of the more common RYR1 mutations should be examined. <http://www.emhg.org> A limitation of genetic testing in the United States is the sensitivity of about 23% when testing for 21 mutations.[87a] Screening of the entire coding region of the RYR1 identifies sequence variants in more than 50% of patients.[87b] Therefore sensitivity of genetic tests will improve as more mutations are identified as causative of MH.

Patients should consider genetic testing if:

1. They have had a positive contracture test.
2. A family member has had a positive contracture test.

3. They have suffered a very likely MH episode but have not had a contracture test.
4. A family member has been found to have a causal mutation.

When a mutation known to be causative for MH is identified in a family member who has had an abnormal contracture response to halothane or caffeine, it is possible to determine MH susceptibility in other members of that family by examination of their RYR1 DNA for that mutation. Those with the mutation are MH susceptible (with high specificity) but those

without the mutation cannot be considered MH negative as they may harbor another mutation. The patient cannot be presumed to be MH-negative without negative results on muscle contracture testing.[88] The decision to undergo genetic testing is complex. The pros and cons of testing should be discussed with either an MH expert or a genetic counselor.

Treatment of Malignant Hyperthermia

8 Malignant hyperthermia is a treatable disorder. All institutions in which anesthetic agents are administered should have dantrolene available (36 ampules [720 mg] is recommended) and a management plan.

The Acute Episode

The following steps should be taken immediately when MH is diagnosed:

1. Administration of all inhalation agents and succinylcholine should be discontinued and assistance should be secured. (It is helpful to have a dedicated cart available containing the agents for treatment of MH.)
2. Hyperventilation with 100% oxygen should be instituted at >10 L/min. Oxygen flow should be 10 L/min to hasten purging of residual anesthetic gases. Time should not be wasted in securing another anesthetic machine, but an ambu bag and E-cylinder of oxygen can be used.
3. Assistance should be obtained in mixing dantrolene. The present preparation of dantrolene is poorly soluble. Each vial containing 20 mg should be mixed with 50 mL of bacteriostatic sterile distilled water (not saline solution). It is important to store sterile water in clearly labeled containers of a different size from that used for routine intravenous solutions. It may be helpful to keep a mixing system adjacent. Dantrolene will dissolve faster as temperature of the diluent increases from 20 to 40°C.[89] Intravenous therapy should be started with 2.5 mg/kg with repeat doses as needed. More than 10 mg/kg of dantrolene may be given as dictated by clinical circumstances, however many acute episodes are controlled with 2 to 3 mg/kg. There is 300 mg mannitol with each 20 mg dantrolene. Therefore a bladder catheter should be inserted to facilitate monitoring urine output.
4. Titration of dantrolene and bicarbonate to heart rate, body temperature, and $PaCO_2$ is the best clinical guideline of therapy.
5. In fulminant cases in which significant metabolic acidosis is present, 2 to 4 mEq/kg bicarbonate should be given. Large volumes of fluid may be needed to replace loss into edematous tissues and into the urine.
6. If it is not already available, a capnometer should be obtained so that CO_2 excretion can be documented.
7. Dysrhythmia control usually follows hyperventilation, dantrolene therapy, and correction of acidosis. Calcium channel blockers should not be used in the acute treatment of MH. Verapamil can interact with dantrolene to produce hyperkalemia and myocardial depression.[90,91] Lidocaine can be given safely during an MH crisis.

8. Body temperature elevation should be managed by placing ice packs on the groin and in the axillae and by use of gastric, wound, and rectal lavage. Gastric lavage is the quickest, most practical means for rapid temperature control. Some have recommended peritoneal dialysis and others, cardiopulmonary bypass. Cooling should be stopped when core temperature reaches 38°C to avoid hypothermia.
9. Although arterial blood is useful for assessing acidosis, central mixed venous blood gas determinations (or, if not available, femoral venous blood gas readings) serve as a better guideline for therapy.
10. Hyperkalemia should be managed in the usual fashion with glucose, insulin, bicarbonate, and hyperventilation. If hyperkalemia is associated with significant cardiac effects, calcium chloride, one gram or 10 mg/kg, should be given. During therapy of MH, hypokalemia frequently results. However, potassium replacement should be undertaken very cautiously, if at all, because potassium may retrigger an MH episode.
11. Baseline laboratory tests should include creatinine, coagulation profile, and creatine kinase (CK). CK elevations may not occur for 6 to 12 hours after an MH episode and should be followed as a rough guide to therapy. These tests will serve as a baseline for management of subsequent complications.

Management After the Acute Episode

After the acute episode, the clinician should be concerned about three complications of MH:

1. Recrudescence of MH. As many as 25% of patients may experience acute recrudescence, a relapse, within hours of the first episode.[92,93,94,95]
2. Disseminated intravascular coagulation (DIC).[94] DIC has often been described in cases of MH, probably resulting from release of thromboplastins secondary to shock and core temperature >41°C [95] and/or release of cellular contents on membrane destruction. The usual regimen for treatment of DIC should be followed.
3. Myoglobinuric renal failure. Myoglobinuria may occur within hours after the episode begins. If analysis shows that there is blood in the urine, urine should be sent to measure RBCs and myoglobin. If there are no RBCs, myoglobinuria is presumed present. If the urine is acid, bicarbonate should be given to decrease the chance that myoglobin will injure renal tubules.

The guidelines for the dose and duration of dantrolene therapy after resolution of acute MH are empirical. It would seem prudent to continue dantrolene, 1 mg/kg every 6 hours intravenously (iv), for at least 24 to 36 hours but more may be given if signs of MH reappear. Some recommend conversion of dantrolene therapy from iv to oral form (4 mg/kg per day or more) with continuation for several days.

Significant muscle weakness and pain may follow MH, resulting from muscle destruction along with dantrolene administration; this should be managed symptomatically. Recovery of strength may require weeks to months.

A variety of other electrolyte changes may occur, such as hypocalcemia and hyperphosphatemia. Sodium and chloride changes may occur secondary to fluid shifts during the acute episode. All these changes usually respond to control of the acute episode.

Dantrolene

Dantrolene sodium is a hydantoin derivative (1-[[[5-(4-nitrophenyl)-2-furanyl]methylene]imino]-2,4-imidazolidinedione). In 1979, iv dantrolene was approved for treatment of MH. Until that time, the primary use of dantrolene was in the management of spasticity. Dantrolene is a unique muscle relaxant. Unlike neuromuscular blocking agents (whose site of action is at the nicotinic receptor of

the neuromuscular junction) or the nonspecific relaxants (which modulate spinal cord synaptic reflexes), dantrolene acts within the muscle cell itself by reducing calcium release by the sarcoplasmic reticulum. [^{3}H]azidodantrolene, a pharmacologically active, photoaffinity analog of dantrolene, specifically binds to a site on the ryandodine receptor.[96,97] During an MH episode,

dantrolene reduces intracellular calcium levels. Therefore, dantrolene is a specific and effective agent in the treatment of MH. In the usual clinical doses, dantrolene has little effect on myocardial contractility.[98]

Studies have also indicated that doses of neuromuscular blocking agents need not be changed significantly after dantrolene administration. However, the drug should be used cautiously in patients with neuromuscular disease.[99]

The serum level of dantrolene required for prophylaxis against MH is about 2.5 μg/mL. The half-life of iv dantrolene, the only form recommended, is approximately 12 hours. However, the therapeutic level of dantrolene usually persists for 4 to 6 hours after a usual iv dose of 2.5 mg/kg.[100] Therefore, dantrolene should be supplemented at least every 6 hours after a clinical episode. Muscle weakness may persist for 24 hours after dantrolene therapy is discontinued. Nausea and phlebitis are other complications of acute dantrolene administration. Hepatotoxicity has been demonstrated only with long-term use of oral dantrolene. Prophylaxis for MH should be carried out with iv or oral dantrolene (5 mg/kg per 24 hours) in those *rare* situations where prophylaxis is desired.[101]

Management of the Patient Susceptible to Malignant Hyperthermia

Because of an increasing awareness of MH and more widespread use of diagnostic tests, it is not unusual for an anesthesiologist to be confronted with a MH-susceptible patient or a patient who has a family history of MH. The management of such patients should be carefully planned.

In the preoperative interview, the anesthesiologist should try to obtain sufficient information regarding previous episodes of MH and their documentation. If the family has participated in the North American Malignant Hyperthermia Registry, the Registry may be able to give details to the anesthesia provider. The anesthesiologist should allow adequate time to reassure patients and their families that he or she is familiar with MH and its implications and that appropriate monitoring and therapy will be instituted as necessary. It may be worth mentioning that there have been no deaths from MH in previously diagnosed MH-susceptible patients when the anesthesia team was aware of the problem. Anesthesia and premedication should be designed to produce a low normal heart rate. Standard premedicant drugs such as opioids, benzodiazepines, ataractics, barbiturates, antihistamines, and anticholinergics do not cause problems in MH-susceptible patients when administered in appropriate doses; however, phenothiazines are not recommended. Dantrolene need not be given preoperatively if nontriggering agents are used and end-tidal CO_2 and core temperature are monitored. Dantrolene must be immediately available in the operating room, and equipment for rapid measurement of blood gases and electrolytes should be available.

The anesthesia machine is prepared by draining, removing, or disabling anesthetic vaporizers, and changing tubing and CO_2 absorbent and flowing oxygen at 10 L/min for 20 minutes.[102] The modern anesthesia workstation is larger than older anesthesia machines and requires 30 minutes to flush out with 10 L/min at 1 L tidal volume, if new breathing hoses, bag, and soda lime cartridge have been placed.[103] Obviously, iced solutions and adequate supplies of dantrolene must be available in the vicinity of the operating room when MH-susceptible patients are anesthetized.

Exhaled CO_2 should be monitored because the earliest sign of MH is an increase in CO_2 production and excretion.[104] Arterial and central venous monitoring is recommended for MH-susceptible patients, as dictated by the surgical procedure. Body core temperature should be monitored by nasopharyngeal, rectal, or esophageal routes in all patients for all surgical procedures. Skin temperature, although acceptable, is not as desirable because it may not reflect core temperature.[105]

If possible, a regional, local, or major conduction anesthetic should be used with either amide or ester local anesthetics. If not possible, iv induction of anesthesia followed by nitrous oxide, oxygen, and a nondepolarizing relaxant with opioid supplementation is recommended. Induction agents that have not been implicated in MH are midazolam, diazepam, droperidol, and propofol.

Neuromuscular blocking agents such as pancuronium, vecuronium, atracurium, cisatracurium, rocuronium, and mivacurium are safe. Routine reversal of nondepolarizing relaxants with anticholinesterase and anticholinergic agents is recommended.

Many thousands of safe anesthetics have been administered with nitrous oxide in MH-susceptible patients. Two cases have been reported in which early signs of MH have been documented despite the use of a safe anesthetic technique.[106] Therefore, even under the most controlled circumstances, the anesthesiologist should be alert to the early signs of MH.

Administration of dantrolene after surgery is not recommended if there are no signs of MH. However, the patient must be observed closely for 4 to 6 hours. If there is no sign of MH in the first hour postoperatively after safe anesthetic techniques were used, it is very unlikely that MH will occur later. The patient may be discharged on the same day as surgery.[107,108] Complete rehydration with iv fluid and adequate oral intake decreases the chance that fever will occur postdischarge as a result of dehydration.

The same precautions should be taken for the obstetric patient as for the routine surgical patient. Evidence that the stress of labor may precipitate MH is not convincing, and well-conducted epidural anesthesia for labor and delivery without dantrolene pretreatment but with careful monitoring of vital signs is recommended. If an emergency cesarean section with general anesthesia is necessary, alternatives to succinylcholine should be used. The maternal:fetal partition ratio for dantrolene is probably 0.4.[109] Dantrolene has not been reported to produce significant problems for the fetus or newborn, but existing data are very scanty.

Malignant Hyperthermia in Species Other Than Pigs and People

Malignant hyperthermia has been reported sporadically in many species. Clinical episodes have been documented in cats, dogs, and horses.[110] Capture myopathy is a syndrome characterized by temperature elevation, rhabdomyolysis, acidosis, and death in wild animals (e.g., zebra, elk).[111] This also has been suggested to be an MH variant.

Medicolegal Aspects

In this era of malpractice actions, it is not surprising that MH cases have been the subject of malpractice suits. Because MH may be considered an inborn genetic problem with a relatively fixed associated mortality that may go unrecognized before a patient's exposure to triggering agents, it may be used as a "cover" for other problems.

Fever, opisthotonic posturing, and neurologic abnormalities may accompany hypoxic brain injury, and because of their similarity to MH, MH may be incorrectly implicated in the differential diagnosis. Furthermore, after cardiac arrest from any cause, CK and potassium levels may be significantly elevated. The incidence of litigation after the occurrence of MH is unknown.

Some have stated that, with the advent of dantrolene, there should be no deaths from MH. This is unrealistic because the syndrome may be truly explosive in some cases and impossible to control with current therapy. Also, all the factors that lead to MH are not known. The dose of dantrolene needed to prevent recrudescence cannot be determined with certainty. Nevertheless, certain common themes underlie the basis for litigation in MH:

9. Failure to obtain a thorough personal history in regard to anesthetic problems and a family history of any unexplained perioperative problems.

2. Failure to monitor core temperature continuously with an electronic temperature monitoring device. Several jury trial cases have been lost by the defense because the patient's temperature was not monitored. Intraoperative temperature monitoring is now considered a "standard of care" in the United States by the legal profession, despite the failure of the American Society of Anesthesiologists to recommend routine temperature monitoring during administration of all general anesthetics.
3. Failure to have adequate supplies of dantrolene on hand with a plan of management of MH.
4. Failure to investigate unexplained increases in body temperature and increased skeletal muscle tone (especially after succinylcholine administration) when associated with increased heart rate and dysrhythmias.

Several examples of medicolegal cases involving these principles are described below:

1. A young female patient had shoulder surgery with isoflurane–nitrous oxide–oxygen. Temperature was not monitored continuously. At the end of the procedure, premature ventricular beats and increasing end-tidal carbon dioxide were noted. The patient had a cardiac arrest as the dysrhythmia was being treated. As the drapes were being removed, the patient felt warm. A temperature probe revealed a reading of nearly 42°C. The patient was diagnosed as having an acute episode of MH. Dantrolene was administered an hour later. The patient developed DIC over the next day and died. The case was settled out of court.
2. A 26-year-old woman was undergoing a breast augmentation in a plastic surgeon's office using general anesthesia with isoflurane. Toward the end of the procedure, her heart rate increased as did end-tidal carbon dioxide and skin temperature. Dantrolene was not available and the patient was sent to a nearby emergency room. By the time dantrolene was given, her temperature was about 43°C. She developed DIC and died. The case was settled without jury trial. The company providing insurance for the physician now mandates that dantrolene be immediately available wherever general anesthesia is administered.
3. Symptoms of bowel obstruction developed in a middle-aged man. He was taken to a local hospital, and anesthesia was administered with nitrous oxide–oxygen–halothane and succinylcholine. His temperature was not monitored, but an unexplained tachycardia (140 to 160 beats/min) was present throughout the 2-hour procedure. On arrival in the intensive care unit after the operation, the patient was slightly hypotensive. Invasive monitoring was started. Despite marked metabolic and respiratory acidosis, a Pa_{CO_2} of 100 mm Hg, and a recorded temperature of nearly 42°C, MH was not diagnosed. A cooling blanket and antibiotics failed to arrest the decrease in the patient's blood pressure, which eventually led to cardiac arrest. A judgment against the physicians and hospital of $4.5 million was reached.

There have been several malpractice cases filed against anesthesiologists in which cardiac arrest and death occurred after succinylcholine was used in patients with an undiagnosed myopathy. The usual outcome is an out-of-court settlement.

The message is clear. All facilities where general anesthesia is administered (including hospitals, outpatient surgery centers, physician offices, and dental offices) should have a full supply of dantrolene available. All patients undergoing general anesthesia should have standard monitoring, including end-tidal carbon dioxide and, except for brief cases, body temperature.

Patient Support Services

To answer the needs of patients and families who wished to learn more about MH and of those families whose relatives have died from MH, support groups were founded in several countries (e.g., the Malignant Hyperthermia Association [of Canada] and the Malignant Hyperthermia Association of the United States [MHAUS]). Both groups serve as a repository of information about

MH, provide names of physicians knowledgeable about MH and the location of MH diagnostic centers, and simply lend an ear to those with MH who have questions. Both organizations have an advisory committee of physicians. The Malignant Hyperthermia Association of the United States publishes a quarterly newsletter, *The Communicator*, with excerpts from the medical literature, explanatory articles, questions and answers, and related information. In addition MHAUS organized two hotlines so that a health care provider with an urgent question about MH or NMS can be placed in contact with a knowledgeable volunteer specialist. Approximately 30 to 40 calls a month are handled by the MH Hotline, 1-800-644-9737, and a smaller number by the Neurolept Malignant Syndrome Information Service (NMSIS).

The address of the Malignant Hyperthermia Association of the United States is 11E State Street, Box 1069, Sherburne, New York, 13460-1069, FAX 607-674-7910. The phone number is 1-800-98MHAUS. The hotline number is 1-800-MHHyper. The Web site address is http://www.mhaus.org.

In 1989, the North American MH Registry was formed. Now based in Pittsburgh, Pennsylvania (Children's Hospital of Pittsburgh, 412-692-5464), the Registry is the repository for patient and family specific information for MH-susceptible patients. MH susceptible patients are invited to contact the Registry. If an MHS individual wishes to join the Registry, he or she must complete a questionnaire and sign a consent form. The Registry was merged with MHAUS in 1995. A description of the Registry is available at http://www.anesth.upmc.edu. The forms used in the Registry can be reviewed at http://www.mhreg.org.

Pathogenesis and Etiology

Several major developments have contributed to the present understanding of the complex pathophysiology of MH. The first was the recognition that the syndrome is genetically transmitted.[2] This finding is significant because it suggests that a rigorous application of modern molecular genetics will lead to the identification of mutations in specific proteins causing the disorder. A second finding was a greater sensitivity of biopsied skeletal muscle from MH-susceptible patients to halothane or caffeine. This was the basis for an in vitro diagnostic test and studies of the mechanisms underlying MH. The third was the recognition of similarities between human MH and porcine stress syndrome. This animal model was used to elucidate the role of altered Ca^{2+} regulation in MH and led to the finding that a mutation in the ryanodine receptor may be a causative factor in many families with MH.[112] Fourth, MH has

been identified as a heterogeneous disorder.[31,59] Heterogeneity may account for some variability in presentation and forces investigators to consider the role of a final common pathway resulting from a mutation in any one of several different proteins. Fifth, the finding that pigs or human subjects with MH do not always trigger in response to adequate triggering agents, has suggested that modulators influence the expression of the syndrome.[113,114]

Experimental Models for Malignant Hyperthermia

Although MH is rare in humans, breeding pigs for leaner meat and better musculature has resulted in the appearance of the MH gene in a relatively high frequency in a number of herds (e.g., Poland, China, Landrace, Pietrain). A syndrome in pigs undergoing anesthesia is similar to the MH syndrome in humans. However, the porcine syndrome can also be elicited in the absence of anesthetics, by factors such as heat and stress. Although pigs administered MH-triggering anesthetics have provided a model for human MH, there is little evidence that a human stress syndrome analogous to PSS exists in the majority of patients. However, there is a weak association between exertional heat stroke and MH.[115,116,117] A single genetic defect in the ryanodine receptor has been associated with porcine MH, and this specific mutation is found in some humans with MH. The mode of inheritance in swine (autosomal recessive) is different from that in humans (autosomal dominant). The porcine model has been extensively exploited in studies of MH. Reports of MH exist, but are rare, in horses, dogs, and cats. Of these, only the dog has been proposed as a model of human MH.[118] The pattern of inheritance in the dog appears to be autosomal dominant, yet there are some differences between the anesthesia-elicited canine and

human MH syndromes.

Understanding the Malignant Hyperthermia Defect: Necessary Concepts

A hypothesis explaining MH must account for the puzzling clinical observations surrounding this disorder. Most importantly, the large majority of these patients function normally in the absence of anesthetics. Therefore, the defect should not significantly interfere with normal muscle physiology. The defect, at least in humans, appears to be expressed significantly only in skeletal muscle. The expression of the syndrome shows a large variability among individuals. For example, 30% of patients have had up to three uneventful anesthetics.[57,119] A spectrum of presentations can occur, ranging from relatively minor intraoperative complications to rapid temperature rise, muscle rigidity, acidosis, dysrhythmias, and death. Some cases have a greater latency to onset and are not made manifest until several hours postoperatively. MH does not always occur in response to triggering agents. This is a well-established observation in human MH and similar observations have been reported in swine. Also, while most investigators would agree that PSS is a more consistently triggered syndrome than the human MH syndrome, even adult swine occasionally do not respond to adequate triggering agents in either a barnyard challenge with halothane alone[120] or prolonged halothane,[121] or halothane and succinylcholine challenge.[11] The term "MH" may, in fact, be a misnomer, as sometimes patients show no signs of temperature elevation. Finally, many cases do not exhibit rigidity. The large variability among individuals may be explained by different genes causing MH in different families or by other predisposing factors being expressed differently in different patients or families.[76] The function of many different proteins has been reported to be altered in MH skeletal muscle. Thus, it is reasonable to assume that systems other than those directly involved in Ca^{2+} regulation are secondarily altered in MH and these may play a crucial role in modifying the response to triggering agents. The involvement of secondary systems would explain the high variability in the phenotype.

Skeletal Muscle: Site of the Malignant Hyperthermia Defect

The MH and PSS defects are expressed in skeletal muscle, as evidenced by the in vitro contracture test for MH susceptibility. Results regarding other tissues are more controversial, especially in humans, and are not considered in detail in this chapter. The defects are expressed in type I and type II fibers.[122] While the distributions and amounts of protein in whole skeletal muscle and in isolated sarcoplasmic reticulum appear to be normal by electrophoretic analysis, downregulation of specific proteins, including the ryanodine receptor[123] and dihydropyridine receptor,[124] has been reported. Additionally, the expression of subtypes of the sodium channel is altered in MH muscle.[125,126,127]

Altered Calcium Regulation: The Common Final Pathway

Ultimately, the main problem in skeletal muscle is a lack of control of myoplasmic Ca^{2+} concentration during anesthesia,[6,128] which may be manifest clinically as muscle rigidity. Ca^{2+} levels are controlled by a complex interaction of Ca^{2+} release from the terminal cisternae, the adenosine triphosphate–driven Ca^{2+} pumps at the sarcoplasmic reticulum and sarcolemma, Na^{+}/Ca^{2+} exchange, several Ca^{2+} buffering proteins (calsequestrin, parvalbumin), and mitochondrial Ca^{2+} regulation (Fig. 20-3). Although several of these systems may become involved as the MH syndrome progresses, the difficulty in Ca^{2+} regulation appears to originate in the Ca^{2+} release mechanism in the terminal cisternae. The Ca^{2+} release mechanism could be made sensitive to anesthetics by any of several possibilities, including a mutation in the skeletal muscle calcium release channel, termed the ryanodine receptor (*RYR*1); a protein directly coupled to *RYR*1 (e.g., dihydropyridine receptor); or an altered modulator of *RYR*1 function (e.g., fatty acids). Succinylcholine opens the acetylcholine receptor and depolarizes the muscle membrane by opening the voltage dependent sodium channels, which may have altered function in MH. Depolarization leads to Ca^{2+} release from the sarcoplasmic reticulum. Dantrolene antagonizes Ca^{2+} release from the sarcoplasmic reticulum, lowers elevated intracellular Ca^{2+} levels, and reverses an episode of MH.[6]

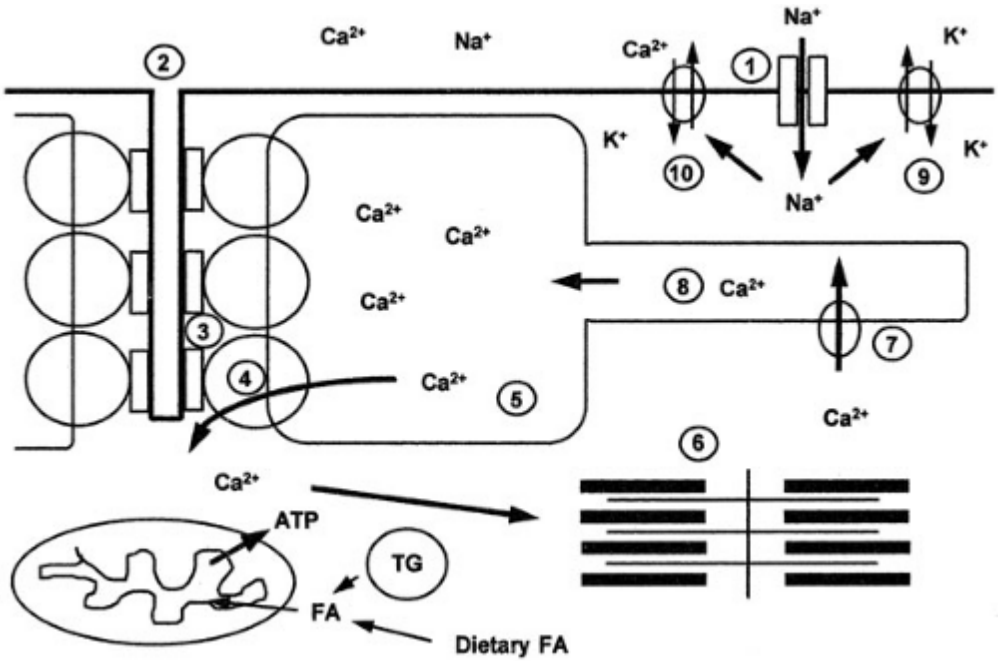

FIGURE 20-3. Excitation–contraction coupling and MH. The action potential generated at the endplate region of the neuromuscular junction is propagated down the sarcolemma (muscle plasma membrane) by the opening of voltage-dependent Na^+ channels (*1*). The action potential continues down into the t-tubules (*2*) to the dihydropyridine receptors (*3*). The dihydropyridine receptors in skeletal muscle function as voltage sensors and are coupled to the Ca^{2+} release channels (*4*). Through this coupled signaling process, the Ca^{2+} release channels are opened, some of the available terminal cisternae Ca^{2+} stores (*5*) are released, and the levels of myoplasmic Ca^{2+} are elevated. The Ca^{2+} then diffuses to the myofibrils (*6*) and interacts with the troponin/tropomyosin complex associated with actin (*thin lines*) and allows interaction of actin with myosin (*thick lines*) for mechanical movement. The Ca^{2+} diffuses away from the myofibrils and this Ca^{2+} signal is terminated by an ATP-driven Ca^{2+} pump (*7*), which pumps Ca^{2+} into the longitudinal sarcoplasmic reticulum (*8*). The Ca^{2+} diffuses from the longitudinal sarcoplasmic reticulum to the terminal cisternae, where it is concentrated for release by Ca^{2+} binding proteins. Na^+ entering during the action potential is subsequently extruded from the cell by the Na^+/K^+-ATPase (*9*) and possibly through Na^+/Ca^{2+} exchange (*10*). This latter process would elevate intracellular Ca^{2+} and could result from delayed inactivation of Na^+ currents. A major form of energy for supplying cellular ATP for the ion pumps and numerous other energy consuming processes is fatty acids (FA) derived from the serum (dietary FA), or from intramuscular triglyceride (TG) stores. Therefore, a defect in the intracellular Ca^{2+} regulating processes (increased Ca^{2+} release or decreased Ca^{2+} uptake), or a defect in the sarcolemma could account for an increase in myoplasmic Ca^{2+}.

Presence or Absence of a Malignant Hyperthermia-Associated Defect Within Skeletal Muscle Organelles: Sarcolemma

The sarcolemma (see Fig. 20-3) maintains the membrane potential of the muscle cell and acts as a permeability barrier to ions, including Na^+, K^+, Cl^-, and Ca^{2+}. Skeletal muscle, in most cases, does not require extracellular Ca^{2+} for nerve or electrically evoked contractility. In contrast, halothane-induced contractures[128,129] and, to a lesser extent (depending on the species), caffeine-induced contractures[128] require extracellular Ca^{2+}. A loss of integrity in the sarcolemma could cause a large influx of Ca^{2+} from the extracellular medium. Also, opening specific Ca^{2+} channels (e.g., dihydropyridine receptors) in the sarcolemma would allow the entry of extracellular Ca^{2+}.

Terminal Cisternae: Ca^{2+} Release. The terminal cisternae of the sarcoplasmic reticulum are the sites of Ca^{2+} sequestration. They are coupled to the t-tubules through the ryanodine receptor and the dihydropyridine receptor (Fig. 20-4; see Fig. 20-3). Several investigators have reported a hypersensitive Ca^{2+}-induced Ca^{2+} release in terminal cisternae preparations from porcine MH muscle.[130,131,132] Also observed for PSS

Ca^{2+}-induced Ca^{2+} release are an enhanced rate of release from skinned fibers[133] and terminal cisternae preparations.[134,135]

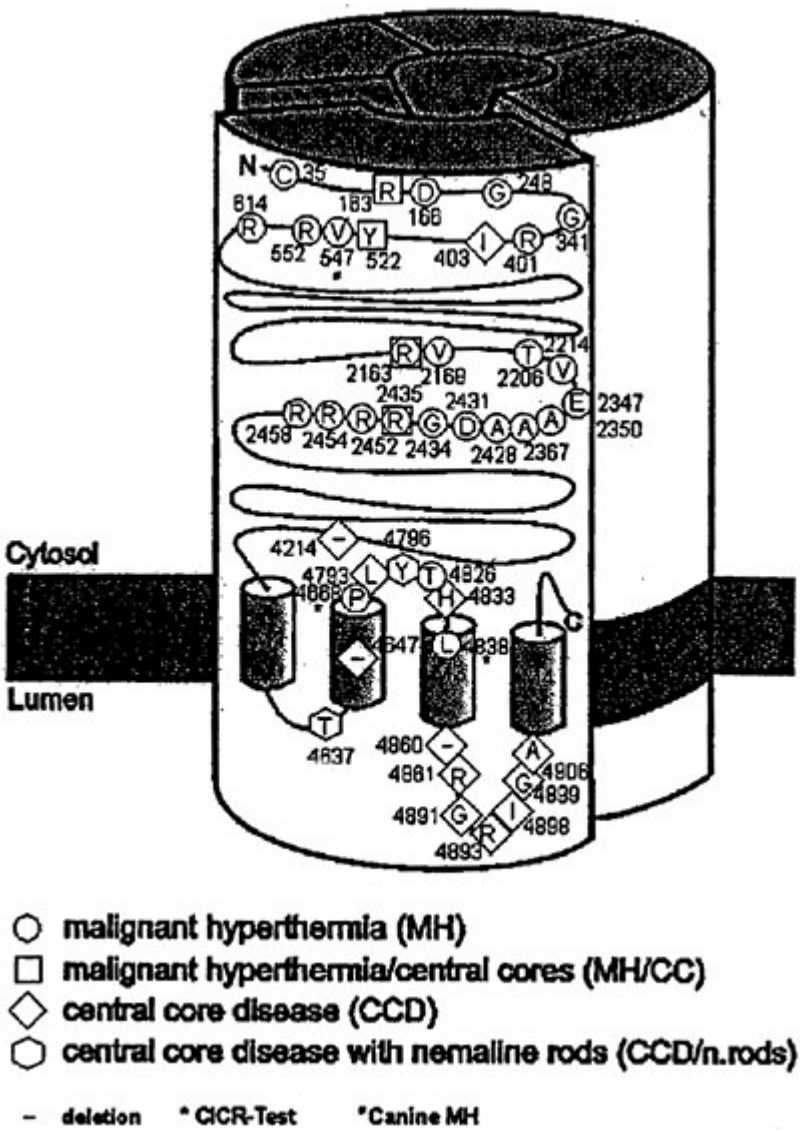

FIGURE 20-4. Schematic illustration of the homotetrameric ryanodine receptor, the calcium release channel situated in the membrane of the sarcoplasmic reticulum (SR). The cytosolic part of the protein complex, the so-called foot, bridges the gap between the transverse tubular system and the SR. Mutations have been described for the skeletal muscle ryanodine receptor (RYR1), which cause susceptibility to malignant hyperthermia (MHS) and central core disease (CCD). (From Lehmann-Horn F, Lerche H, Jurkat-Rott K: Skeletal muscle channelopathies: Myotonias, periodic paralyses and malignant hyperthermia. In Stahlberg E (ed): Clinical Neurophyisology of Disorders of Muscle and Neuromuscular Junction. Handbook of Clinical Neurophysiology, vol 2. Elsevier BV, 2003:476.)

The maximum amount of Ca^{2+} released is normal for PSS vesicles.[136] In the human MH population, the Ca^{2+} release process appears to be less dramatically affected than that in PSS muscle. For example, the threshold of Ca^{2+}-induced Ca^{2+} release in terminal cisternae–containing fractions is

not altered in a human MH population.[131,137] Although the alterations in Ca^{2+} release reported in swine cannot be observed in isolated heavy sarcoplasmic reticulum preparations from humans, abnormalities in Ca^{2+} release are observed when preparations containing additional cellular components are examined, such as skinned fiber preparations (Fig. 20-5). MH subjects have a greater than normal rate and hypersensitivity of Ca^{2+}-induced Ca^{2+} release[138] and Ca^{2+} release is hypersensitive to caffeine using the skinned fiber preparation.[139]

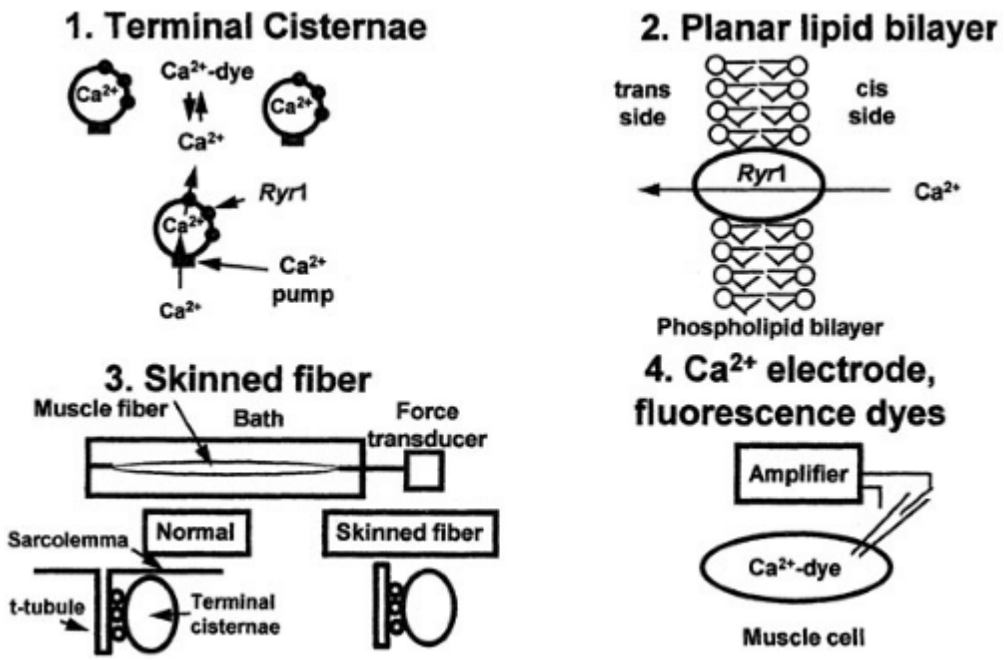

FIGURE 20-5. Methods to examine Ca^{2+} regulation. (*1*) *Terminal cisternae.* Skeletal muscle can be homogenized and resealed portions of the terminal cisternae containing the Ca^{2+} release channel (*RYR*1) can be recovered by a series of centrifugation steps. These vesicles can take up Ca^{2+} from the bathing medium by means of the ATP-driven Ca^{2+} pump and can subsequently release Ca^{2+} by opening of *RYR*1. Ca^{2+} levels in the extravesicular medium can be monitored spectrophotometrically by a number of dyes (usually metalochrome indicators such as arsenazo III or antipyrylazo III). Alternatively, $^{45}Ca^{2+}$ and filtration of the vesicles can be used. The amount of calcium released is usually determined by the decrease in radioactivity retained on the filters that contain the vesicles. Both the spectrophotometric and radioisotopic approaches allow monitoring of Ca^{2+} uptake and Ca^{2+} release, and these processes can be dissociated pharmacologically with the *RYR*1 blocker, ruthenium red. The terminal cisternae method allows the overall response of a large population of channels to be examined and may best reflect the overall responsiveness of the muscle. (*2*) *Planar lipid bilayers.* It is possible to incorporate *RYR*1 into artificial lipid bilayers (i.e., planar lipid bilayer) and monitor the Ca^{2+} current as electrical charge movement through one to several channels at a time. Although this method can provide very useful, detailed information on the opening and closing of individual *RYR*1s, it does not provide an indication of the overall responsiveness of the muscle in which both Ca^{2+} uptake and Ca^{2+} release are participating and in which many modulating substances are present. (*3*) *Skinned fibers.* A third approach involves skinned fiber preparations in which the sarcolemma is either removed mechanically or made permeable chemically, and the function of the sarcoplasmic reticulum (Ca^{2+} uptake and release) and myofibrils (actin and myosin) monitored by the contractile response of the fiber. This preparation has an interesting advantage in that type I and type II fibers can be distinguished. Also, the t-tubules seal completely, allowing the function of the dihydropyridine receptors and Na^{+} channels to be examined. This method only examines one muscle fiber at a time, which might be a slight disadvantage in MH or PSS skeletal muscle, because the defect is not uniformly expressed throughout the tissue. (*4*) *C*a^{2+} *electrodes and fluorescence dyes.* The cytoplasmic Ca^{2+} levels can be monitored in intact muscle either with fluorescence dyes or Ca^{2+} electrodes. The former can monitor a muscle mass, while the latter

examines individual fibers. Both approaches can be used with muscle fibers or cell culture systems.

With respect to anesthetic action, the rate of halothane induced Ca^{2+} release is abnormally high in PSS susceptibles.[132,140] In contrast, in human MH muscle[141] and PSS muscle,[142] the dose-response curves for halothane-induced Ca^{2+} release are normal when the amount of Ca^{2+} release is monitored. Free calcium was determined (with fura-2) in voltage-clamped human muscle fibers.[143] The kinetics and voltage dependence of calcium release for MH muscle was normal; however, the maximal peak rate of Ca^{2+} release increased about 3-fold. Although resting Ca^{2+} concentrations are normal, human skeletal muscle cell cultures have a 2-fold greater than normal sensitivity to halothane.[144] There is no effect of temperature on the rate of halothane-induced Ca^{2+} release.[140,145]

In heavy sarcoplasmic reticulum preparations (containing triads and sarcoplasmic reticulum), halothane at clinically relevant concentrations cannot induce a sustained net Ca^{2+} release if physiologic levels of adenosine triphosphate and Mg^{2+} are included. This ability to overcome the effects of halothane under approximate physiologic conditions is because of the enormous capacity of the Ca^{2+} pumping system.[137] The addition of fatty acids, even to vesicles isolated from normal muscle, markedly (~20- to 30-fold) decreases the concentration of halothane required for the sustained opening of the Ca^{2+} release channel in the presence of adenosine triphosphate and Mg^{2+}.[137] Under these conditions, fatty acids can cause a sustained Ca^{2+} release at clinical concentrations of halothane. Unlike studies of Ca^{2+} release in the absence of fatty acids,[145] there is an absolute temperature dependence (occurs at 37°C, not at 25°C) of the fatty acid enhancement of halothane-induced Ca^{2+} release, which is consistent with the temperature dependence of halothane-induced contractures of MH muscle.[146]

Mitochondria. Mitochondria oxidize a variety of substrates to generate the form of energy (adenosine triphosphate) most useful for driving cellular reactions. Defects in mitochondrial function do not appear to initiate the MH syndrome. The uncoupling of Ca^{2+}-stimulated, but not adenosine diphosphate-stimulated, mitochondrial succinate

oxidation has been demonstrated in muscle from pigs and humans[147] susceptible to MH.

Longitudinal Sarcoplasmic Reticulum: Ca^{2+} Uptake. The longitudinal sarcoplasmic reticulum (see Fig. 20-3) is primarily involved in removing Ca^{2+} from the myoplasm through the adenosine triphosphate–driven Ca^{2+} pump. While earlier studies had suggested a defect in Ca^{2+} uptake might cause the loss of Ca^{2+} regulation associated with MH, subsequent studies have ruled out a role for the Ca^{2+} pump in causing MH.[140]

Myofibrils. Relatively few studies have been conducted on myofibrils in MH. However, there is apparently no defect in the Ca^{2+} sensitivity of the fast or slow fibers of the contractile system from MH skeletal muscle.

Proteins or Systems Reported Altered in Malignant Hyperthermia Muscle

Calcium Release Channel of Skeletal Muscle

The human skeletal muscle calcium release channel is encoded by a ryanodine receptor type 1 (*RYR*1) gene located on chromosome 19q13.1.[148] There are other types of RYR that exist in cardiac muscle (type 2) and brain (type 3) tissues, respectively. *RYR*1 is the primary conduit through which the sarcoplasmic reticulum stores of Ca^{2+} are released to the sarcoplasm.[112] *RYR*1 is an extremely large homotetramer, having subunits of about 560,000 MW each. *RYR*1 has binding sites for the contracture-inducing plant alkaloid ryanodine[149] and the preservative 4-chloro-*m*-cresol.[150]

In about 50% of MH susceptible families, susceptibility to MH is linked to chromosome 19 and a

mutation in *ryr*1.[31,59,151] The hypothesis that mutation in *RYR*1 causes MH susceptibility is supported by physiologic studies showing subtle effects of halothane on isolated *RYR*1 currents in human MH muscle.[152] Halothane can open a hypersensitive *RYR*1, leading to an uncontrolled release of Ca^{2+} into the myoplasm and the MH syndrome. However, the buffering capacity of the Ca^{2+} pump in the presence of adenosine triphosphate is able to sustain normal Ca^{2+} regulation in the presence of halothane in terminal cisternae preparations isolated from MH muscle.[114] These observations are consistent with the observed interindividual variability in human MH and the occurrence of nonrigid MH. When ATP is low the syndrome occurs and the lower the energy stores are, the worse the MH sysndrome is. Unlike the hypersensitive Ca^{2+} release in porcine muscle,[130] Ca^{2+} regulation in human MH heavy sarcoplasmic reticulum fractions appeared to be normal.[131] However, using planar bilayer approaches capable of monitoring single *RYR*1 channels, subtle changes in the function of *RYR*1 have been observed in human MH muscle,[152,153] similar in some respects to those in PSS muscle in planar bilayers.[154] These differences relate primarily to an increased probability of the MH *RYR*1 being in an open state. While differences between normal and PSS susceptibles have been reported in the absence of halothane or caffeine,[154] human MH muscle requires the presence of caffeine[153] or halothane[152] to detect differences in *RYR*1 function. In human MH muscle two populations of ion channels appear to be present: one halothane-insensitive and the other halothane-sensitive.[152] The halothane-sensitive channels have an increased probability of opening in the presence of clinically relevant concentrations of halothane. The halothane-sensitive channels do not occur in muscle from all MH patients, and both types (or states) of channels can coexist in the same muscle biopsy. Whether these subtle differences in *RYR*1 function in planar bilayers, or the differences in K_d of ryanodine binding,[149] in human muscle reflect a different acylation or phosphorylation state of *RYR*1 is not known. Consistent with the altered function of the PSS *RYR*1, there has been a specific mutation identified (Arg^{615} to Cys^{615}) in *RYR*1 in PSS.[155] The mutation is on the cytoplasmic surface of *RYR*1.[156] This mutation accounts for the altered functional states of *RYR*1 and ryanodine binding in PSS swine. However, the porcine mutation does not appear to account directly for the caffeine sensitivity of PSS muscle.[157] In between 2 and 11% of MH families the human equivalent (Arg^{614} to Cys^{614}) to the PSS *RYR*1 mutation has been identified. However, there may be discordance between the presence of this mutation and the outcome of the diagnostic contracture test.[158,159,160] A major reason for the attenuated effects of the *RYR*1 mutation in human muscle is likely the dominant mode of inheritance with reduced penetrance and genetic heterogeneity of MH versus recessive mutation in the pig. Thus, normal copies of *RYR*1 are expressed in human MH muscle, but not PSS muscle. The number of sequence variants in *RYR*1 reported at scientific meetings to date is more than 200, including Arg614Cys, and this number is constantly rising. The majority of these are usually found in only one or two families.

There is a 2-fold greater than normal sensitivity to halothane in cell cultures from MH muscle.[144] However, a 2-fold increase in sensitivity to triggering agents in cell culture does not equate to the much greater sensitivity of MH muscle to halothane observed in vivo. Transfection of human MH skeletal

muscle cell cultures with normal (wild-type) *RYR*1 does not result in the MH-negative phenotype (judged by sensitivity of Ca^{2+} transients to halothane), whereas expression of a mutated *ryr*1 (Arg^{163} to Cys^{163}) in normal muscle cells causes hypersensitivity to halothane.[144] Transfection of nonmuscle cell lines with any one of 19 *RYR*1 mutations increased the sensitivity of the cells to relatively high concentrations of halothane and caffeine.[161,162] Therefore, cell cultures can be useful models for elucidating the mechanisms by which MH mutations enhance the sensitivity of muscle to triggering agents.

In summary, there are physiologic, biochemical, pharmacologic, and molecular genetic data supporting a mutation in *RYR*1 as an important factor, and perhaps an initiating factor, in about 50% of the families with MH. The effects of the altered *RYR*1 function on Ca^{2+} regulation determined in vitro are not as pronounced in humans as in swine, possibly owing to the dominant mode of inheritance and genetic heterogeneity of MH in humans. It is highly probable that other systems come into play as modulators of the MH response. This may better explain the extreme intra- and interindividual variability in the human MH syndrome, which is in contrast to the more

consistent response in MH swine.

Sodium Channel

Skeletal and cardiac muscle sodium channels are composed of two subunits (α, 220,000 MW; *β*, 40,000 MW). The α subunit forms the ion pore, allowing Na^+ to enter the cell, and the smaller *β* subunit can modify the kinetics of the ion flux.[163,164] Sodium channels in skeletal muscle are of two, and possibly three,[127] subtypes. These subtypes can be differentiated by their sensitivity to tetrodotoxin (TTX), a toxin from the puffer fish that blocks the channel pore. The adult sodium channel (SKM1) is 90% blocked by a 100 n*M* concentration of TTX. The "embryonic" sodium channel (SKM2) in skeletal muscle is identical to the cardiac sodium channel, and is blocked by a 10-*μ*M concentration of TTX in cell culture. A third channel is expressed following denervation,

and this subtype is not antagonized by TTX, even at a 100-*μ*M concentration. The adult sodium channel α subunit, encoded on chromosome [17,163,164] was formerly believed to be the only subtype expressed in normal, mature skeletal muscle. The embryonic sodium channel α subunit appears early in muscle differentiation and is encoded on chromosome 3. Each of the α subunits interacts with the same *β* subunit (β_1), encoded on chromosome 19.[165] The sodium channels of normal human skeletal muscle (vastus lateralis) are composed of approximately 50% SkM1 and 50% SkM2.[127] Specific mutations in the α subunit of SkM1 have been implicated as the cause of other disorders of skeletal muscle, including the myotonic form of hyperkalemic periodic paralysis,[164,166] paramyotonia congenita,[167] and myotonia fluctuans.[168] These disorders are well known to exhibit masseter muscle rigidity and whole body rigidity to agents associated with the MH syndrome,[169] although they lack the signs of acidosis characteristic of MH.

Altered sodium channel function may play a role in the expression of MH. The function of the sodium channel is abnormal in primary cultures of human MH skeletal muscle.[170] There are two populations of sodium currents separated by their kinetics of inactivation (i.e., closing of the channel). These are the normally inactivating and delayed inactivating fast sodium currents. There is a greater proportion of the slow inactivation of the Na^+ current in cultured human MH muscle[125] that would keep the sodium current active for a longer time (delayed inactivation). The consequence of this prolonged sodium current in MH muscle is a longer membrane depolarization and increased period of Ca^{2+} release from the terminal cisternae. A toxin from the sea anemone (ATX II) causing delayed inactivation of the sodium current, as found in human MH muscle cultures, enhances the response of normal muscle to halothane, caffeine, and ryanodine.[171] This finding supports a role for altered Na^+ channel currents in the response of MH muscle to triggering agents. Veratridine, also a sodium channel inhibitor, enhances the response of MH muscle to halothane.[173] Therefore, altered Na^+ currents may be important for at least some of the signs associated with MH. Those patients expressing sodium channel abnormalities may be more likely to exhibit certain signs, such as muscle rigidity.

The expression of sodium channel subtypes is also altered in MH skeletal muscle. SkM2 (embryonic form) appears to be downregulated in MH, in cell culture systems, or in biopsies of vastus lateralis muscle.[126] This would lead to a predominance of SkM1 in MH muscle. SkM1 is more sensitive to halothane than SkM2.[173] There also is evidence for linkage of MH to chromosome 17[174,175] at or near the locus encoding the Na^+ channel α subunit.[176] In one family, a Gly1306Ala mutation in the sodium channel known to cause myotonia fluctuans cosegregated with MH susceptibility, as determined by contracture testing.[34] Two of these patients had whole body rigidity and/or masseter muscle rigidity to succinylcholine, although without metabolic acidosis. As with *RYR*1, it is not clear in most cases if the altered function reflects a primary defect in the Na^+ channel protein, or if the function is altered indirectly by processes such as phosphorylation or acylation.[177]

In summary, changes in sodium channel expression or function could be the result of mutations within a sodium channel subtype, or a secondary effect of a primary mutation in another protein (e.g., *RYR*1). Also, second-messenger systems, such as fatty acids, may play a role in altered sodium channel function and expression. These changes in sodium channel function may be essential for the phenotypic expression of certain aspects of the MH syndrome, such as muscle

rigidity.

Elevated Fatty Acid Production

Lipids are an important component of a cell, as they provide energy and structure (e.g., membranes) and participate in function. Several lipid metabolites, including fatty acids, serve second-messenger functions.[178] Fatty acids are the major source of energy in the resting state of skeletal muscle and can also contribute up to 65% of the energy during exercise.[179] Fatty acids provide about 70% of the energy in resting muscle. Therefore, fatty acid utilization is likely upregulated in MH muscle to compensate for the energy consumed by the adenosine triphosphatases attempting to maintain Na^+ and Ca^{2+} homeostasis.

In addition to existing in a free form, fatty acids are esterified to phospholipids, triacylglycerides, diacylglycerides, monoacylglycerides, cholesterol esters, and many proteins. Free fatty acids are maintained at very low levels in a cell (since they are not only essential, but very toxic) and most of the "free" fatty acids actually are bound to fatty acid–binding proteins.[180]

Fatty acid production is elevated in mitochondrial fractions[147] and whole muscle homogenates from PSS and MH susceptibles. There is an age-related increase in fatty acid production in skeletal muscle that parallels an age-related increase in susceptibility to the PSS. [181] When only static levels of free fatty acids are examined, they are at normal levels in human MH and PSS muscle. However, the flux of fatty acids through β-oxidation can still be increased to a large extent in MH muscle without increasing the levels of free fatty acids. The fatty acid flux is derived from triacylglycerides, and this likely accounts for the low levels of triacylglycerides (or total neutral lipid) in biopsied MH or PSS skeletal muscle.[138] The effects of fatty acids on Ca^{2+} release from skeletal muscle sarcoplasmic reticulum are significant, but not dramatic, in the absence of anesthetics,[182,183] and they are not mediated through *RYR*1.[184] However, the fatty acids act in synergy with halothane and decrease the amount of halothane required for sustained Ca^{2+} release by 20- to 30-fold![114,131] This fatty acid enhancement of halothane-induced Ca^{2+} release, in contrast with all other studies of Ca^{2+} release, exhibits the same temperature dependence (i.e., it occurs only at 37°C, not at 25°C) as halothane-induced contractures of skeletal muscle and is mediated through *RYR*1.[114] While the concentration of fatty acid required for this effect exceeds that of the normal unbound form, halothane can displace fatty acids from fatty acid–binding proteins.[185] Therefore, it is highly likely that sufficient concentrations of fatty acids could be achieved at the site of halothane action. If the production of free fatty acids is sustained by accelerated triacylglyceride breakdown and the fatty acids are shunted toward acylation of *RYR*1 and the sodium channel, then this could lead to greatly elevated myoplasmic Ca^{2+} levels. In the case of *RYR*1, this would lead to a greater sensitivity to halothane.

Phospholipase C and Inositol 1,4,5-Trisphosphate

One specific metabolite of phospholipase C action, IP_3, has been demonstrated to be elevated in human MH[186] and PSS[187] muscle, but not in MH human blood specimens.[186] This product of the hydrolysis of the phospholipid, phosphatidylinositol 4,5-bisphosphate, causes Ca^{2+} release from intracellular stores.[188] The elevation of all products of phosphatidylinositol hydrolysis is observed,[188] and this suggests that phospholipase C activity may be elevated in MH. Activation of phospholipase C in skeletal muscle also elevates diacylglycerol and indirectly elevates free fatty acids by deacylation of the diacylglycerol. Diacylglycerol and fatty acids have diverse cell signaling effects.[178,189] In addition to elevated IP_3 production, MH muscle is also hypersensitive to IP_3.[190] Therefore, secondary involvement of this system could have multiple effects that together increase the sensitivity of Ca^{2+} release.

Molecular Biology of Malignant Hyperthermia

The identification of the porcine mutation causing PSS and the location of the human RYR1 gene on chromosome 19q13.1 has helped to establish a direct link of this gene to MH.[148,191] RYR1 was proposed as a candidate gene for MH and the "pig" mutation Arg614Cys was identified in an MH

family subsequently.[155] Further genetic linkage studies and research on mutations in RYR1 have revealed that MH is characterized by genetic heterogeneity. About 50% of MH families are linked to RYR1. RYR1 is one of the largest human genes. It contains 106 exons that are transcribed into a 15,364 nucleotide mRNA. Transcription occurs practically only in skeletal muscle level. More than 200 different sequence variants have been identified in the RYR1 gene. The majority are clustered in three regions: the N-terminal region between codons 34 and 614, the central region between codons 2163 and 2458 and the C-terminal region between codons 4136 and 4973.[31,59,192,193] This preferential localization raised speculations concerning the specific role of these regions. The central region is close to the region where the protein would interact with the regulatory protein, FKBP12, and the dihydropyridine receptor, a voltage sensor of RYR1. The C-terminal region that corresponds to the transmembrane domain of the protein.[192] The pathogenic character of many RYR1 gene mutations has been studied by kinetic measures of intracellular calcium release in response to caffeine or halothane with use of different cell lines.[161,162,194,195] Sei and colleagues have demonstrated the presence of calcium channels similar to those found in skeletal muscle in the B lymphocyte. Enhanced intracellular calcium levels are found in lymphocytes from cell lines with mutated ryanodine genes upon exposure to caffeine or chlorocresol.[196,197]

The phenotype and genotype correlation studies are very limited in MH because it is difficult to establish correlation between the mutation and contractile data because of variables among diagnostic laboratories and because of the fact that clinical episodes of MHS that fulfill all criteria are rare as a result of successful intervention during anesthetic complications. Nevertheless, the most severe phenotype as a result of RYR1 mutation is central core disease (CCD), characterized by marked hypotonia and muscle weakness. Interestingly, the majority of RYR1 mutations causing CCD are located in the transmembrane region of the protein, suggesting a critical role of this region in Ca^{+} regulation. In addition, the mutations causing both MH and CCD (R163C, R2163H, and R2435H) exhibit more severe caffeine and halothane responses than those associated with MH alone.[198]

Genetic studies have identified linkage of five other chromosomal regions to MH, suggesting genetic heterogeneity of the disorder. However, only a single gene has been identified to date. The Arg1086His mutation was identified in the CACNL1A3 gene of a large French MH family. CACNL1A3 codes for the skeletal muscle L-type calcium channel's alpha1 subunit.[199] This voltage-dependant channel is also called the dihydropyridine receptor (DHPR) and serves as a voltage sensor for RYR1. Mutational screening studies, however, indicate that only 1% of MHS families exhibit mutations in the DHPR.

There have been several reports of discordance between segregation of mutations identified in *RYR*1 and the outcome of the in vitro contracture test for MH.[158,159,200] This discordance is relatively rare and the reason for it is unknown. However, a study in swine has demonstrated that there is an excellent correlation between the contracture test outcome and the genetic susceptibility for MH. In human families, specific ryanodine mutations usually correlate extremely well with the in vitro contracture test result. Hence, in a particular family the presence of the familial MH mutation predicts MH susceptibility.[201]

The Future of Research in Malignant Hyperthermia

While molecular genetics has dominated the research in MH in recent years, a deeper understanding of the physiology and biochemistry of the interplay among *RYR*1, the Na^{+} channel, and fatty acid metabolism still is needed. DNA-based linkage analyses are no longer pursued to the same extent as in the early 1990s. Instead, the focus of recent molecular genetic studies has been on identifying new mutations in *RYR*1. Further linkage studies are necessary to identify other chromosomes linked to MH. Molecular genetic approaches may be the only hope for a diagnostic blood test. However, at present molecular genetic testing will be most useful for the 50% of MH susceptible families in which a specific proven causative mutation is known to exist.

Summary

Mutations associated with skeletal muscle control of intracellular calcium concentration are causal for most cases of classic MH. Any one of at least six different genes may cause MH, although the exact proteins remain to be identified in some cases. Mutations have been identified in *RYR*1 and in the dihydropyridine receptor gene. A variety of poorly understood biochemical and/or gene expression factors influence the clinical manifestations of MH. For example, mutations in a sodium channel subunit may be associated with some signs of MH, but this clinical MH requires the expression of other factors also. A disturbance in fatty acid metabolism, as a secondary effect, alters the function of several organelles and can lead to a hypersensitive *RYR*1 response to halothane and altered Na^+ channel subunit expression in skeletal muscle. The MH syndrome is the result of a complex and poorly understood interaction among several systems in skeletal muscle.

OTHER INHERITED DISORDERS

Inherited diseases affect every bodily organ and every physiologic and biochemical process. Some are mild and allow a relatively normal life span, whereas others are incompatible with extrauterine existence even for a few days. Adding to the complexity is a natural variability of genetic penetrance and expressivity even in a single family. All of these disorders have as a common feature an abnormality in one or more genes that affects the function of one or more enzymes. The metabolic basis of inherited diseases is the subject of several well-known books,[202] which may be consulted for an in-depth appreciation of our state of knowledge of many of these disorders.

DISORDERS OF PLASMA CHOLINESTERASE

Plasma cholinesterase, pseudocholinesterase, or nonspecific cholinesterase is an enzyme with a molecular weight of 320,000 and a tetrahedral structure. It is found in plasma and most tissue but not in red blood cells. Pseudocholinesterase degrades acetylcholine released at the neuromuscular junction, as well as other choline and aliphatic esters.[203] The half-life of pseudocholinesterase has been estimated to be 8 to

16 hours. It is very stable in serum samples and can be stored for long periods of time at –20°C with little or no activity loss. Cholinesterase is synthesized in the liver. Therefore, decreased plasma cholinesterase activity occurs in advanced cases of hepatocellular dysfunction.

Inherited variants of pseudocholinesterase are of interest to the anesthesiologist because the duration of action of succinylcholine, mivacurium, and (in some cases) ester-linked local anesthetics, as well as the toxicity of cocaine,[204] is a function of the activity of this enzyme system. Prolonged apnea after succinylcholine, or mivacurium, administration occurs in patients who have very low absolute activity of pseudocholinesterase or have enzyme variants.[205,206] These patients otherwise have no symptoms.

Many physiologic, pharmacologic, and pathologic factors can either increase or decrease the activity of this enzyme to a significant extent. However, it is only when there is a >75% decrease in the levels of the normal pseudocholinesterase that there is clinically evident prolongation of succinylcholine activity (see later). Table 20-3 lists some of the causes for variation in plasma cholinesterase activity.

TABLE 20-3 Some Causes of Changes in Cholinesterase Activity

- **INHERITED**
  Cholinesterase variants that may lead to decreased or increased activity (e.g., silent gene or C5 variant)
- **PHYSIOLOGIC**
  Decreases in last trimester of pregnancy
  Reduced activity of the newborn

▪ACQUIRED DECREASES

Succinylcholine-Related Apnea

Succinylcholine is hydrolyzed by a two-step process, first to succinylmonocholine and then to succinic acid. It has been estimated that only about 5% of the injected drug reaches the end-plate region because of a combination of both hydrolysis and diffusion from the plasma. Urinary excretion and protein binding play unimportant roles in the disposition of the drug when plasma cholinesterase activity is normal. The rate of metabolism determines the duration of action of succinylcholine.

A variety of assay procedures are available for pseudocholinesterase activity. However, most involve the reaction of a thiocholine (e.g., butyrylthiocholine) with serum or plasma containing cholinesterase. The reaction product is coupled with 5,5′-dithiobis(2-nitrobenzoic acid) and forms

a colored product that can be followed spectrophotometrically. The use of benzoylcholine, a specific substrate for plasma cholinesterase, avoids contamination of the assay for plasma cholinesterase by the esterase in red blood cells that is released when hemolysis occurs.

Kalow and Genest were the first to show that qualitative as well as quantitative differences in the pseudocholinesterase enzyme determine the duration of succinylcholine apnea.[207] Kalow found that in certain persons displaying succinylcholine sensitivity, the local anesthetic dibucaine (Nupercaine) inhibited the hydrolysis of a benzylcholine substrate less than it inhibited the reaction in those displaying a normal response to succinylcholine. Thus, this atypical phenotype may be referred to as dibucaine-resistant. The percentage inhibition of the reaction was termed the *dibucaine number.* It was found to be constant for a person and did not depend on the concentration of the enzyme.

A discontinuous distribution of dibucaine numbers suggested an inheritance pattern based on alteration at a single gene locus (Table 20-4). Those with dibucaine numbers in the range of 80 would be homozygous normal with a normal response to succinylcholine, those with dibucaine numbers of 20 would be homozygous atypical with a marked prolongation of succinylcholine activity, and those with dibucaine numbers in the 60 range would be heterozygous and, in general, have a normal response to succinylcholine.

TABLE 20-4 Biochemical Characteristics of Some Cholinesterase Variants

·GENOTYPE	·ACTIVITY	·DIBUCAINE #	·FLUORIDE#	·CHLORIDE#	·SUCCINYLCHOLINE#
EuEu	677–1860	78–86	55–65	1–12	89–98
EaEa	140–525	18–26	16–32	46–58	4–19
EuEa	285–1008	51–70	38–55	15–34	51–78
EuEf	579–900	74–80	47–48	14–30	87–91
EfEa	475–661	49–59	25–33	31–36	56–59
EfEs	351	63	26	25	81

Eu = normal enzyme gene; Ea = atypical enzyme gene; Ef = fluoride-resistant gene; Es = silent gene.

Reproduced with permission from Viby-Mogensen J: Succinylcholine neuromuscular blockade in subjects homozygous for atypical plasma cholinesterase. Anesthesiology 55:429, 1981.

Over the years, two other major allelic variants were discovered. In one case, the silent gene, the enzyme is not produced. In the other, there is a differential inhibition of cholinesterase activity by fluoride.[208] In those with prolonged duration of succinylcholine activity with this genotype, fluoride ion inhibits the in vitro hydrolysis of substrate by the enzyme less than it does in normals. Thus

the phenotype may be referred to as fluoride resistant. A *fluoride number*, similar to a dibucaine number, is thereby created. Other variants exist, including the K variant, which can be identified only by genetic analysis, not by the current tests of substrate degradation.

When there is a question of succinylcholine sensitivity, the absolute activity of pseudocholinesterase should be determined as well as the dibucaine and fluoride numbers. In some cases, because of biologic variability or unusual combinations of genotype (e.g., combination of atypical and fluoride genes), it is helpful to use other inhibitors of the cholinesterase reaction in genotyping the patient. Bromide, urea, sodium chloride, and succinylcholine have been used to distinguish the various genotypes (see Table 20-4).

Molecular genetic techniques have been successfully applied to pseudocholinesterase variants. La Du's laboratory

has identified a point mutation in the gene for human serum cholinesterase in which a nucleotide change leads to an alteration of a single amino acid (adenine to guanine) in the protein.[209] This change apparently alters the affinity of atypical cholinesterase for choline esters. Other base pair alterations account for other atypical variants, including the K and J silent gene variants, which, while common, produce little to no clinical prolongation of succinylcholine action (Table 20-5).[210]

TABLE 20-5 Structural Changes of BCHE Variants

Fluoride-2	117 GLY→Frame shift
Atypical	70ASP→GLY
Silent	117 GLY→Frame shift
Fluoride-1	243 THR→MET
Fluoride-2	390 GLY→VAL
K Variant	539 ALA→THR
H Variant	142 VAL→MET
J Variant	497 GLU→VAL

The identification of causative mutations offers the prospect that more accurate and precise diagnostic tests for atypical pseudocholinesterase variants will exist in the future.

The frequencies of occurrence of the various genes vary to some extent with ethnic background. For example, South African blacks[211] and Eskimo populations have the silent gene much more frequently, patients with Huntington's chorea are more likely to have an Ef gene (fluoride-resistant) than are normal controls, and Israelis have a higher chance of having an atypical genotype than Americans. In European studies, the approximate percentages in the population of the genotypes are as follows: EuEu (96%), EuEa (2.5%), EuEf or EuEs (0.3%), EaEf (0.005%), EaEa (0.05%), and EfEf or EfEs (0.006%).[212]

Patients homozygous for atypical, fluoride, or silent genes as well as those with the combination

of atypical with fluoride, atypical with silent genes, or fluoride with silent genes should wear safety identification bracelets indicating that succinylcholine administration will lead to prolonged apnea. Relatives should be tested as well. There are only a few cholinesterase research units that investigate families and interpret results: Whittaker's in Great Britain, Hanel and Viby-Mogensen's in Denmark, and La Du's in the United States (University of Michigan, Department of Anesthesiology).

Clinical Implications of Pseudocholinesterase Abnormalities

Important questions for the anesthesiologist are: Which patients are at risk for development of an abnormal response to succinylcholine? What are the clinical characteristics of this response? and What are the treatment options?

Significant prolongation of succinylcholine's effects occurs in the following genotypes: EaEa, EfEf, EaEs, EfEa, and EsEs. The more common situations in which homozygote normals and heterozygotes are at risk are as follows: patients who have been receiving echothiophate eyedrops (up to 2 weeks after therapy is discontinued), patients who are undergoing plasmapheresis patients with severe liver disease, and patients (particularly heterozygotes) who have received succinylcholine after reversal of nondepolarizing blockade with neostigmine.

Viby-Mogensen[205,206] has studied the question of plasma cholinesterase apnea in detail. His cholinesterase unit found that 6.2% of patients who displayed apnea for 50 to 250 minutes after a "usual" dose of succinylcholine had an acquired deficiency of plasma cholinesterase. He then studied 70 patients who were genotypically normal for pseudocholinesterase and administered 1.0 mg/kg of succinylcholine during a 50% nitrous oxide–oxygen–1% halothane anesthetic and followed the depression and return of thumb twitch. He found that there was indeed a relationship between the duration of apnea, the return of a full twitch response, and plasma cholinesterase activity. However, only moderate prolongation of apnea was found when cholinesterase was depressed by as much as 70%. Apnea is significantly prolonged only with extreme depression of cholinesterase activity.

In a second study with a similar protocol, he found that heterozygotes having one normal gene (e.g., EuEa, EuEf) had a normal response to succinylcholine, including typical fasciculations and a depolarizing type of block with train-of-four stimulations.[205] However, heterozygotes without the usual gene (e.g., EaEf) had a prolonged response to succinylcholine, with apnea lasting as long as 24 minutes. Most showed typical fasciculations. Fade with train-of-four stimulations was the rule. It should be noted that others have found that heterozygotes with one normal gene display a prolonged response to succinylcholine under certain conditions. About 1 in 500 heterozygotes is prone to such a response.

Apnea lasts from 120 minutes to more than 300 minutes in homozygous atypical patients (EaEa) when they are given succinylcholine.[206] The other class of patients who regularly display prolonged apnea after succinylcholine administration comprises patients who are homozygous for the silent gene.

Treatment of Succinylcholine Apnea

The safest course of treatment after the patient fails to breathe within 10 to 15 minutes after succinylcholine administration is to continue mechanical ventilation until adequate muscle tone has returned. Two units of blood may contain adequate amounts of pseudocholinesterase to hydrolyze

the succinylcholine,[213] although blood transfusion is not recommended for routine treatment of succinylcholine-induced apnea.

The use of cholinesterase inhibitors in treating succinylcholine apnea is controversial. When given along with blood or plasma, the improvement is rapid and lasting. If they are administered alone before there is evidence of fade with train-of-four stimulation, there may be a transient improvement followed by intensification of the neuromuscular block. Remember that neostigmine

inhibits the degradation of succinylcholine by plasma cholinesterase. The best chance for reversal of succinylcholine-related apnea in these situations occurs when no more than 0.03 mg/kg of neostigmine is given 90 to 120 minutes after succinylcholine when a nondepolarizing type of blockade is present.

C5 Variant

An isoenzyme of pseudocholinesterase has been demonstrated whereby the hydrolysis of succinylcholine is increased, and therefore the duration of apnea is decreased after succinylcholine administration. The gene does not appear to be an allele of the Eu and Ea gene and is found infrequently in the population.[214]

Plasma Cholinesterase Abnormalities and the Metabolism of Local Anesthetics

Although the ester-linked local anesthetics (e.g., procaine, tetracaine, 2-chloroprocaine) are metabolized by pseudocholinesterase, prolongation of block and/or clinical toxicity of these local anesthetics in homozygous atypical patients has rarely been documented.[215,216] Jatlow et al have shown delayed hydrolysis of cocaine in vitro with plasma from homozygote atypicals.[217] They theorized that such persons may be at risk for toxic reaction from normal doses of cocaine.

Mivacurium Disposition and Plasma Cholinesterase. The short duration of action of mivacurium is because of its degradation by pseudocholinesterase. Although it is theoretically possible to reverse neuromuscular block in patients with atypical pseudocholinesterase who receive mivacurium, the few cases so far reported indicate that anticholinesterase agents may not be effective under such situations. These individuals should be managed in a manner similar to patients with the atypical enzyme who received succinylcholine.[218] When abnormal plasma cholinesterase does not metabolize mivacurium as rapidly as expected, the neuromuscular blocker is cleared by the kidneys as is curare. The most rapid adequate recovery from mivacurium-induced block will be obtained when the plasma concentration of mivacurium has decreased to the level at which three to four responses to a train-of-four stimulation to the ulnar nerve are palpable. Then neostigmine should induce recovery as it would from blocker that was expected to be long acting.

THE PORPHYRIAS

All the porphyrias result from a defect in heme synthesis. The heme pigments are tetrapyrroles that are the essential elements in hemoglobin, myoglobin, and the cytochromes, that is, compounds that are involved in the transport of oxygen, activation of oxygen, and the electron transport chain. Cytochrome P-450 is a hemoprotein intimately involved in the conversion of lipid-soluble nonpolar drugs to soluble polar compounds that may be excreted in the urine.

A complete deficiency of enzymes that are involved in heme synthesis is incompatible with life. However, a partial deficiency may lead to the accumulation of one or more of the molecular intermediates in heme production. Such an accumulation of precursors is responsible for the clinical manifestations of the porphyrias (in an as-yet unexplained manner).

The rate-limiting step in heme synthesis is the conjugation of succinyl-CoA with glycine to form D-aminolevulinic acid (the enzyme is aminolevulinic acid synthetase). In the porphyrias, there is a partial deficiency of enzymes subsequent to this initial step, which results in a stimulation of this reaction to form aminolevulinic acid. The result is overproduction of intermediate products before the deficient step (Figs. 20-6 and 20-7).

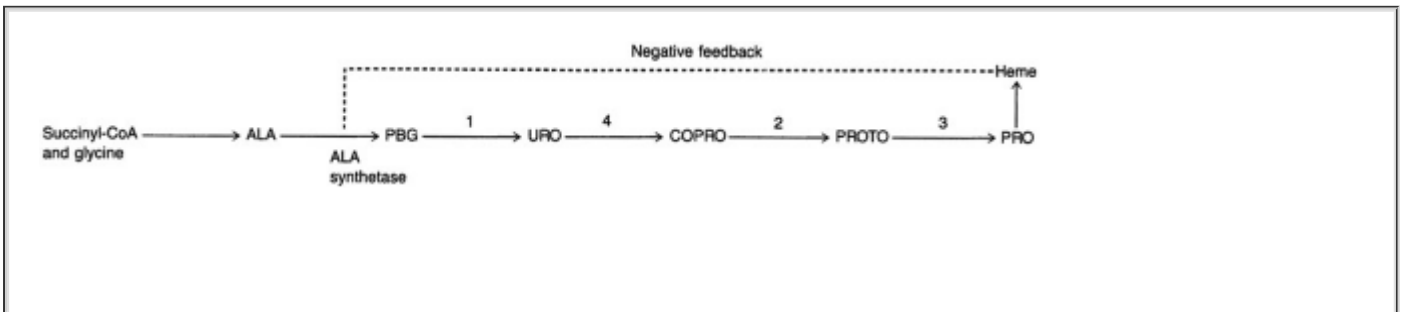

FIGURE 20-6. Biosynthesis of heme and sites of defects in certain porphyrias. (ALA = aminolevulinic acid; PBG = porphobilinogen; URO = uroporphyrinogen; COPRO = coproporphyrinogen; PROTO = protoporphyrinogen; PRO = protoporphyrin.) In intermittent acute porphyria, there is a partial deficiency of the enzyme at site 1. In hereditary coproporphyria, there is an enzyme deficiency at site 2. In variegate porphyria, the enzyme problem is at site 3. In porphyria cutanea tarda, there is a deficiency at site 4. (Reprinted with permission from Mees DL, Frederickson EL: Anesthesia and the porphyrias. South Med J 68:29, 1975.)

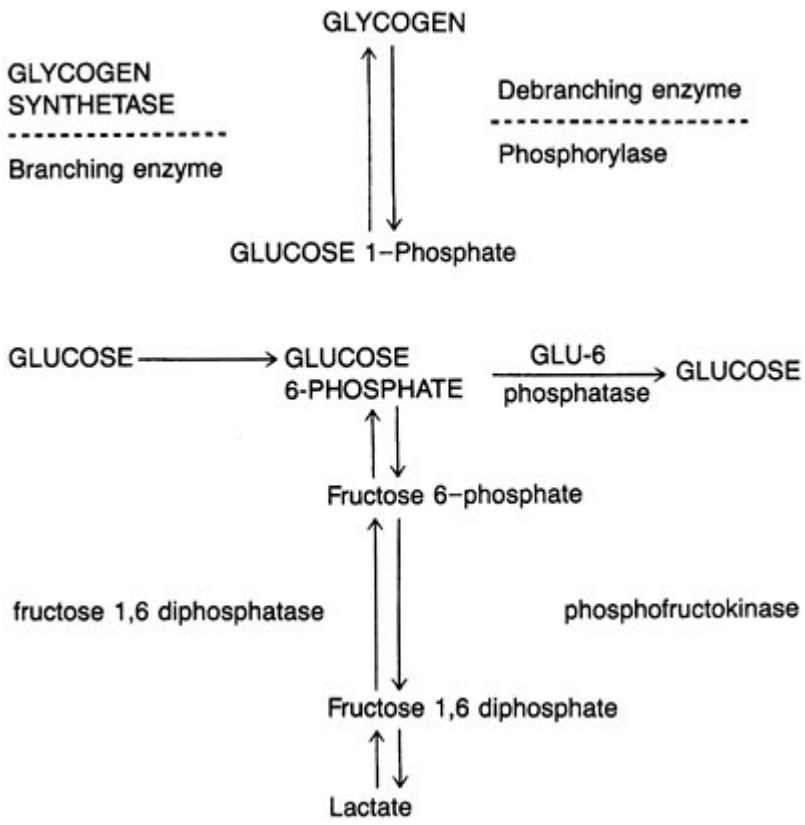

FIGURE 20-7. The glycogen–glucose–lactate pathway.

The porphyrias generally manifest after puberty. Inheritance is through an autosomal dominant pattern, but congenital erythropoietic porphyria is inherited as an autosomal recessive pattern.

A functional classification for the anesthesiologist is based on a division of the porphyrias into inducible and noninducible forms. The inducible porphyrias are those in which the acute symptoms are precipitated on drug exposure (Table 20-6).[219] These forms are acute intermittent porphyria, variegate porphyria, and hereditary coproporphyria. These porphyrias cause an acute neurologic syndrome and are therefore of interest to the anesthesiologist. Cutaneous manifestations, with particular sensitivity to ultraviolet light exhibited by skin fragility and bleeding, are the chief features of the other porphyrias. About 80% of patients with variegate porphyria are photosensitive. Some patients with hereditary coproporphyria also may have skin lesions. The porphyrias are very difficult to diagnose in the latent phase of the disorder. Direct assay of the intermediates themselves may be used in the acute state to measure the elevated levels of the heme intermediates. The inducible porphyrias are seen as a neurologic syndrome with a variety of presentations.

TABLE 20-6 Drugs Known to Precipitate Porphyria

▪SEDATIVES
Barbiturates
Hypnotics such as chlordiazepoxide, glutethimide, diazepam
▪ANALGESICS
Pentazocaine, antipyrine, aminopyridine
Lidocaine
▪ANTICONVULSANTS
Phenytoin, methsuximide
▪ANTIBIOTICS
Sulfonamides, chloramphenicol
▪STEROIDS
Estrogens, progesterones
▪HYPOGLYCEMIC SULFONYLUREAS
Tolbutamide, chlorpropramide
▪TOXINS
Lead, ethanol
▪MISCELLANEOUS
Ergot preparations
Amphetamines
Methyldopa

The central, peripheral, and autonomic nervous systems may be involved in the porphyrias. A frequent manifestation

is colicky abdominal pain, often with nausea and vomiting, which may suggest the diagnosis of acute abdomen, leading to exploratory laparotomy. Other symptoms are psychiatric disturbance, quadriplegia, hemiplegia, alterations of consciousness, and pain. Hyponatremia and hypokalemia may result from vomiting during the acute attack or may be related to hypothalamic disturbance. Death may result from paralysis of the respiratory muscles. The cause of these changes is unknown; they may be related to metabolites of the intermediates or result from deficiency of the heme pigment in the nerve cell itself.

Because the porphyrias are unusual disorders, there is limited experience with the clinical use of many anesthetic drugs. In vitro studies suggest that certain anesthetics or anesthetic adjuvants may be contraindicated, but sufficient clinical experience is lacking (see later).[220]

Management of Patients with Porphyria

It is important to recognize porphyria in patients who are scheduled for surgery. It may become apparent through a careful family history and personal history related to anesthesia. A careful history in the patient with porphyria should concentrate on neurologic background. Laboratory work should include electrolyte and blood urea nitrogen levels. Physical examination includes inspection of cutaneous lesions over the body.

In the anesthetic management of patients with porphyria, the chief concern is to avoid the administration of drugs that can induce a crisis; the drugs that induce cytochrome enzyme production can trigger the syndrome. Chief among those are the barbiturates; therefore, all barbiturates are contraindicated in porphyria. Ethyl alcohol, nonbarbiturate sedatives, hydantoin anticonvulsants, and a variety of other drugs also can induce a crisis (see Table 20-5). Other factors, such as fasting, infection, and estrogens, may also precipitate porphyria. Diagnosis can be especially difficult because attacks may occur at a variable time period after drug administration

or they may not occur at all despite administration of inducing drugs.

Propofol appears to be a safe induction agent.[221] Nitrous oxide, muscle relaxants, and opioids are unequivocally safe drugs. Experience with other inhalation agents and reversal agents has been favorable, but in vitro studies suggest that they might exacerbate a crisis.

Most experts have advised that regional techniques be avoided to prevent confusion should neurologic signs develop after operation. However, reports of uneventful epidural anesthesia in the parturient with acute intermittent porphyria may indicate that this technique can be safely performed in these patients.[222] Blistered or fragile skin areas should be padded and given special attention. Glucose infusion should be started because starvation may induce an attack.

The acute attack should be treated with glucose infusion, and correction of hyponatremia, hypokalemia, and hypomagnesemia. Pyridoxine and hematin also have been valuable in some cases. Supportive therapy for respiratory insufficiency and treatment of pain is also suggested.

GLYCOGEN STORAGE DISEASES

The metabolic pathways involving glucose degradation to lactate, glucose conversion to glycogen, and the breakdown of glycogen to glucose are important to the whole body biochemistry as well as to cellular physiology in general. The enzymatic steps involved in glucose metabolism have been studied intensively since the earliest days of modern biochemistry. The glycogen storage diseases are inherited and are characterized by dysfunction of one of the many enzymes involved in glucose metabolism. To date, several different glycogen storage disorders, each based on the deficiency of an enzyme involved in glucose metabolism, have been identified. Some of the glycogen storage diseases are incompatible with life past infancy, whereas others are not. Anesthetic experience with these diseases is limited, but several particular problems have been identified.[223]

Hypoglycemia. Hypoglycemia is a constant risk in these patients. It results from failure to metabolize stored glycogen to glucose.

Acidosis. This is related to fat and protein metabolism because glycogen stores are not metabolically available.

Cardiac and Hepatic Dysfunction. This is secondary to destruction and displacement of normal tissue by the accumulated glycogen.

Detailed descriptions of glucose metabolism are given elsewhere. Figure 20-7 outlines the glycogen–glucose–lactate pathway. There are, of course, multiple enzymatic steps to reach each of the end points.

Defects in Glucose Metabolism

Type I (Von Gierke's Disease; Glucose-6-phosphate Deficiency). Inheritance is autosomal recessive. The prognosis is moderately good, with many patients surviving into adulthood. Short stature and liver enlargement are characteristic. These patients tolerate fasting very poorly. Hypoglycemia, acidosis, and convulsions may be a problem. Prolonged bleeding has been described. Often, preoperative hyperalimentation is used to reduce liver glycogen stores. Portacaval shunt has been performed with limited success in these patients.

Type II (Pompe's Disease). Inheritance of this disease is considered to be autosomal recessive. This is a devastating disease with a very poor prognosis. There is a deficiency of lysosomal acid maltase with an accumulation of glycogen in the lysosomes, especially in the heart, liver, muscle, and central nervous system. Cardiac compromise resulting from outflow obstruction of hypertrophied muscle occurs, as does congestive heart failure secondary to myocardial disruption by glycogen stores. A case report has been described in which halothane was used without incident.[224] In another case, halothane led to prompt

hypotension and intractable cardiac failure.[225] A late-onset form with a better prognosis has been described as well.

Type III (Forbes' Disease; Debranching Enzyme Deficiency). Inheritance of this disease is autosomal recessive.

Type IV (Andersen's Disease; Branching Enzyme Deficiency). This is a very rare disorder, characterized by a defect in the synthesis of normal glycogen. Cirrhosis of the liver and death are characteristic before a patient reaches age 2 years.

Type V (McArdle's Disease; Muscle Phosphorylase Deficiency). An autosomal recessive inheritance pattern and cramping with exercise are characteristic of this disorder. Skeletal muscle is not able to mobilize glycogen stores, the usual fuel in muscle, for sustained exercise. Myoglobinuria occurs with overexertion in these patients and may occur after succinylcholine administration as well. Muscle atrophy occurs in adulthood. Tourniquets should not be used in these patients, and frequent automated blood pressure readings should be done with caution. Severe rhabdomyolysis has been observed after bypass for cardiac surgery.[226]

Type VI (Hers' Disease; Reduced Hepatic Phosphorylase). A decreased ability to mobilize hepatic glycogen occurs in this disorder, with normal muscle and cardiac physiology.

Type VII (Muscle Phosphofructokinase Deficiency). This disorder is similar to McArdle's disease and is characterized by muscle cramping. The same enzymatic defect in erythrocytes leads to chronic hemolysis.

Type VIII (Deficient Hepatic Phosphorylase Kinase). This results from a deficiency in the regulatory enzyme controlling the phosphorylase enzyme. A case report has described fever and acidosis during succinylcholine, halothane, and ketamine anesthesia.[227] Liver transplantation has been used with success in the more severe forms of the glycogen storage diseases.

Defects of Fructose Metabolism

Fructose-6-phosphate is converted to fructose-1,6-diphosphate during glucose breakdown to lactate. Conversely, fructose-1,6-diphosphate is converted to fructose-6-phosphate by the enzyme fructose-1,6-diphosphatase during gluconeogenesis.

In fructose-1,6-diphosphatase deficiency, there is an inability to produce glycogen from lactate. Hypoglycemia may result. Acidosis has been reported because lactate is formed preferentially. In errors of fructose metabolism, like those of glucose metabolism, hypoglycemia and acidosis pose the greatest threats to the patient.[228]

THE MUCOPOLYSACCHARIDOSES

The mucopolysaccharides are polysaccharides that yield mixtures of monosaccharides and derived products after hydrolysis. The mucopolysaccharides contain *N*-acetylated hexosamine in a characteristic repeating unit. For example, chondroitin sulfate A is a monosaccharide of *d*-glucuronic acid and *N*-acetyl *d*-galactosamine 4-sulfate. Monopolysaccharides are found in all cells.

The mucopolysaccharidoses are genetically determined diseases in which mucopolysaccharides are stored in tissues in abnormal quantities and excreted in large amounts in the urine. The disorders result from a deficiency of a specific lysosomal enzyme that is required to break down these compounds. As a result, mucopolysaccharides accumulate in tissues, producing specific clinical manifestations. There are seven basic forms of mucopolysaccharidoses and several subgroups. Most of the mucopolysaccharidoses are inherited as autosomal recessive traits. All the mucopolysaccharidoses are progressive, and patients characteristically are marked by coarse facial features (gargoylism); associated skeletal abnormalities such as lumbar lordosis, stiff joints,

chest deformity, dwarfing, and hypoplasia of the odontoid process (Morquio's syndrome); corneal opacities; limitation of joint motion; and heart, liver, and spleen enlargement resulting from mucopolysaccharide accumulation. Mental deterioration also occurs frequently. Some cases have been successfully treated by bone marrow transplantation at a young age.

The Hunter and Hurler syndromes are the best known variants of the mucopolysaccharidoses. The Hunter syndrome is an X-linked recessive disease.[229] Respiratory infection and heart disease, both valvular and ischemic, often lead to death when patients are young. Patients may commonly present for repair of inguinal hernia or ear, nose, and throat or orthopaedic procedures. The thick, soft tissues and the copious, thick secretions make perioperative and intraoperative airway management a particular problem. In Leroy and Crocker's series, minor difficulties occurred with anesthesia in patients in more than one-third of 60 operations.[229] The use of a laryngeal mask airway may not be successful.[230] Postoperative respiratory obstruction was noted in several cases. Because of the underlying heart disease, these patients should have electrocardiograms and echocardiographic tests performed before surgery.

Mucopolysaccharidosis IV (Morquio's syndrome) is associated with perhaps the most significant skeletal deformities. In addition to cardiovascular disorders and respiratory insufficiency from marked chest wall deformity, acute, subacute, or chronic myelopathy is extremely common. This is secondary to severe hypoplasia or absence of the odontoid process of the

second cervical vertebra. In anesthesia care, the head should be positioned carefully and precautions, such as avoidance of succinylcholine, should be taken with patients with spinal cord compromise.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta is seen in approximately 1 of 50,000 births. Most cases are autosomal dominant; some are autosomal recessive. The pathophysiologic characteristics include decreased collagen synthesis, which leads to osteoporosis, joint laxity, and tendon weakness. The manifestations of osteogenesis imperfecta are small bowed limbs, large head, short neck, blue sclerae, otosclerosis, joint laxity, brittle teeth, and a tendency to fractures. An increased bleeding tendency is also seen resulting from abnormal platelet function, and aortic and mitral valve dysfunction resulting from dilation of the valve ring. Temperature elevation is common, possibly because of elevated basal metabolic rate.

The patient should be handled carefully because minor trauma may lead to fractures. Airway management may also be difficult because of cervical spine involvement with this disorder. Patients have short necks, and mandibular fractures frequently occur. The patient's cardiovascular status should be evaluated, especially mitral and aortic valve function. Kyphoscoliosis may also occur, with pulmonary compromise. Care should be taken to pad the pressure areas, particularly for long procedures. One should be prepared to obtain platelet transfusions. The patient's core temperature should be monitored because hyperthermia (possibly resulting from central nervous system dysfunction or excessive metabolism in bone) has been reported.[231] Signs consistent with MH have been observed, but contracture tests for MH susceptibility have not confirmed a constant association between osteogenesis imperfecta and MH.[39]

RILEY-DAY SYNDROME (FAMILIAL DYSAUTONOMIA)

A deficiency of dopamine β-hydroxylase that leads to decreased norepinephrine at the nerve endings is thought to be the cause of Riley-Day syndrome.[232] This syndrome is inherited in an autosomal recessive fashion. Patients with Riley-Day syndrome exhibit copious pulmonary secretions, dysphagia, denervation supersensitivity, no sensitivity to pain, no response to histamine, and impairment of temperature control. The impairment of temperature control leads to intermittent fevers.

There are numerous problems related to anesthesia. These include corneal abrasions, excess secretions, pneumonia, labile blood pressure secondary to baroreceptor insensitivity, a decreased vascular volume, possible decreased response to hypoxia and hypercarbia, increased potential for

aspiration because of swallowing problems, postural hypotension, and sensitivity to vasopressors.

Anesthesia management is well summarized by Axelrod et al.[233] Perioperative management should include diazepam (0.1 to 0.2 mg/kg po) without an opioid. Antacid may be given on call. Intraoperative management should include temperature monitoring and careful blood pressure monitoring. Application of regional techniques may result in more stable cardiovascular function. Fresh gases should be humidified. Vasopressors need to be titrated carefully because of the hypersensitivity response. After operation secretions can be managed with chest percussion therapy. Postoperatively, opioids should be used only with great care to minimize the risk of apnea.[234]

Chapter 21

Delivery Systems for Inhaled Anesthetics

Russell C. Brockwell

J. Jeffrey Andrews

KEY POINTS

1	The low-pressure circuit (LPC) is the “vulnerable area” of the anesthesia workstation because it is most subject to breakage and leaks. The LPC is located downstream from all anesthesia machine safety features except the oxygen analyzer, and it is the portion of the machine that is missed if an inappropriate LPC leak test is performed. Leaks in the LPC can cause delivery of a hypoxic mixture and/or patient awareness during anesthesia.
2	Because most Ohmeda anesthesia machines have a one-way check valve in the LPC, a negative leak test is required to detect leaks in the LPC. A positive pressure leak test will not detect leaks in the LPC of most Datex-Ohmeda products.
3	Internal vaporizer leaks can only be detected with the vaporizer turned “on.”
4	Prior to an anesthetic, the circle system must be checked for leaks and for flow. To test for leaks, the circle system is pressurized to 30-cm water pressure, and the circle system airway pressure gauge is observed (static test). To check for appropriate flow to rule out obstructions and faulty valves, the ventilator and a test lung (breathing bag) are used (dynamic test).
5	Some new anesthesia workstation self-tests do not detect internal vaporizer leaks unless each vaporizer is individually turned on during the self-test.
6	In the event of a pipeline crossover, two actions must be taken. The backup oxygen cylinder must be “on,” and the wall supply sources must be disconnected.
7	Fail-safe valves and proportioning systems help minimize delivery of a hypoxic mixture, but they are not foolproof. Delivery of a hypoxic mixture can result from (1) the wrong supply gas, (2) a defective or broken safety device, (3)

	leaks downstream from the safety devices, (4) inert gas administration, and (5) dilution of the inspired oxygen concentration by high concentrations of inhaled anesthetics.
8	Because of desflurane's low boiling point and high vapor pressure, controlled vaporization of desflurane requires special sophisticated vaporizers such as the Datex-Ohmeda Tec 6 and the Aladin cassette vaporizer.
9	Misfiling an empty variable bypass vaporizer with desflurane could theoretically be catastrophic, resulting in delivery of a hypoxic mixture and a massive overdose of inhaled desflurane anesthetic.
10	Inhaled anesthetics can interact with CO_2 absorbents and produce toxic compounds. During sevoflurane anesthesia, compound A can be formed, particularly at low fresh gas flow rates, and during desflurane anesthesia, carbon monoxide can be produced, particularly with desiccated absorbents.
11	Desiccated strong base absorbents (particularly Baralyme) can react with sevoflurane, producing extremely high absorber temperatures and combustible decomposition products. These in combination with the oxygen or nitrous oxide–enriched environment of the circle system can produce fires within the breathing system.
12	Anesthesia ventilators with ascending bellows (bellows that ascend during the expiratory phase) are safer than descending bellows because disconnections will readily manifest with ascending bellows.
13	Use of the oxygen flush valve during the inspiratory phase of mechanical ventilation can cause barotrauma, particularly in pediatric patients.
14	Ventilators that use fresh gas decoupling technology virtually eliminate the possibility of barotrauma by oxygen flushing during the inspiratory phase because fresh gas flow and oxygen flush flow is diverted to the reservoir breathing bag. However, if the breathing bag has a leak or is absent, patient awareness under anesthesia and delivery of a lower than expected oxygen concentration could occur because of entrainment of room air.
15	With newer Ohmeda anesthetic ventilators such as the 7100 and 7900 Smart Vent, both the patient gas and the drive gas are scavenged resulting in substantially increased volumes of scavenged gas. Thus, the scavenging systems must be set appropriately to accommodate the increased volume or pollution of the operating room environment could result.

INTRODUCTION

The anesthesia delivery system has evolved from a simple pneumatic device to a complex integrated computer-controlled multisystem workstation (Figs. 21-1 and 21-2). The subsystems within the anesthesia workstation function in harmony to safely deliver the inhaled anesthetic to the patient. These component systems include what was formerly referred to as the anesthesia

machine-proper (i.e., the pressure-regulating and gas-mixing components), the vaporizers, the anesthesia breathing circuit, the ventilator, the scavenging system, and respiratory and physiologic monitoring systems.

For anesthesia providers to safely use the many features of the anesthesia workstation, a thorough understanding of its operation is essential. Because of large-scale education efforts, in addition to improvements in the engineering and design of the anesthesia workstation, malpractice claims associated with gas-delivery equipment are becoming less frequent. On the other hand, because of the continual development of new volatile anesthetics, aftermarket add-on devices, and even new anesthesia workstation features, claims are not likely to go away completely. In fact, in a review of the American Society of Anesthesiologists (ASA) “Closed Claim” database, Caplan found that although claims related to the medical gas-delivery system were rare, when they occurred, they were usually severe, often resulting in death or permanent brain injury.[1]

In this chapter the anesthesia workstation is examined piece by piece. The normal operation, function, and integration of major anesthesia workstation subsystems are described. More importantly, the potential problems and hazards associated with the various components of the anesthesia delivery system, and the appropriate preoperative checks that may help to detect and prevent such problems, are illustrated.

ANESTHESIA WORKSTATION STANDARDS AND PRE-USE PROCEDURES

A few years ago, a fundamental knowledge of the basic anesthesia machine pneumatics would suffice for most anesthesia providers. Today, a detailed understanding of pneumatics, electronics, and even computer science is necessary to fully understand the capabilities and complexities of the anesthesia workstation. Along with the changes in the composition of the anesthesia workstation to include more complex ventilation systems and integrated monitoring, recently there has also been increasing divergence between anesthesia workstation designs from different manufacturers. In 1993, a joint effort between the ASA and the U.S. Food and Drug Administration (FDA) produced the 1993 FDA Anesthesia Apparatus Pre-use Checkout Recommendations (Appendix A). This pre-use checklist was versatile and could be applied to most commonly available anesthesia machines equally well and did not require users to vary the pre-use procedure significantly from machine to machine.

Today, because of increasing fundamental anesthesia workstation design variations, the 1993 FDA pre-use checklist may

no longer be applicable to certain anesthesia workstations. In such cases, anesthesia providers must be aware of this, and the original equipment manufacturer's recommended pre-use checklist should be followed. Some of the newer workstations even have computer-assisted self-tests that automatically perform all or a part of the pre-use machine checkout procedure. The availability of such automated checkout features further adds to the complexity of constructing a standardized pre-use anesthesia machine checklist such as the one utilized in the recent past. Ultimately, the responsibility of performing adequate pre-use testing of the anesthesia workstation falls to the individual user. That anesthesia provider of record must be aware of which anesthesia workstation components are tested by these automated self-tests and which ones are not. Because of the number of machines available and the variability among their self-testing procedures, the following discussion will be limited to general topics related to these systems.

STANDARDS FOR ANESTHESIA MACHINES AND WORKSTATIONS

Standards for anesthesia machines and workstations provide guidelines to manufacturers regarding their minimum performance, design characteristics, and safety requirements. During the past two decades, the progression of anesthesia machine standards has been as follows:

1979: American National Standards Institute (ANSI) Z79.8-1979,[2]

1988: American Society for Testing and Materials (ASTM) F1161-88,[3]

1994: ASTM F1161-94[4] (reapproved in 1994 and discontinued in 2000),

2000: ASTM F1850-00[5]

To comply with the 2000 ASTM F1850-00 standard, newly manufactured workstations must have monitors that measure the following parameters: continuous breathing system pressure, exhaled tidal volume, ventilatory CO_2 concentration, anesthetic vapor concentration, inspired oxygen concentration, oxygen supply pressure, arterial hemoglobin oxygen saturation, arterial blood pressure, and continuous electrocardiogram. The anesthesia workstation must have a prioritized alarm system that groups the alarms into three categories: high, medium, and low priority. These monitors and alarms may be automatically enabled and made to function by turning on the anesthesia workstation, or the monitors and alarms can be manually enabled and made functional by following a pre-use checklist.[5]

CHECKING THE ANESTHESIA WORKSTATION

A complete anesthesia apparatus checkout procedure must be performed each day prior to the first use of the anesthesia workstation. An abbreviated version should be performed before each subsequent case. Several checkout procedures exist, but the 1993 FDA Anesthesia Apparatus Checkout Recommendations reproduced in Appendix A are the most popular and remain applicable to the majority of anesthesia machines in use worldwide.[6,7,8,9,10] It should be noted that many machines have been modified in the field. The addition of aftermarket products may mandate modification of the pre-use checklist. The user must refer to the operator's manual for special procedures or precautions.

The three most important preoperative checks are (1) oxygen analyzer calibration, (2) the low-pressure circuit leak test, and (3) the circle system test. Each is discussed in the following sections. Additional details regarding these systems will be presented in subsequent sections describing the anatomy of the anesthesia workstation. For a simplified diagram of a two-gas anesthesia machine and the components described in the following discussion, please refer to Figure 21-3. A comprehensive discussion of Figure 21-3 can also be found in the Anesthesia Workstation Pneumatics section.

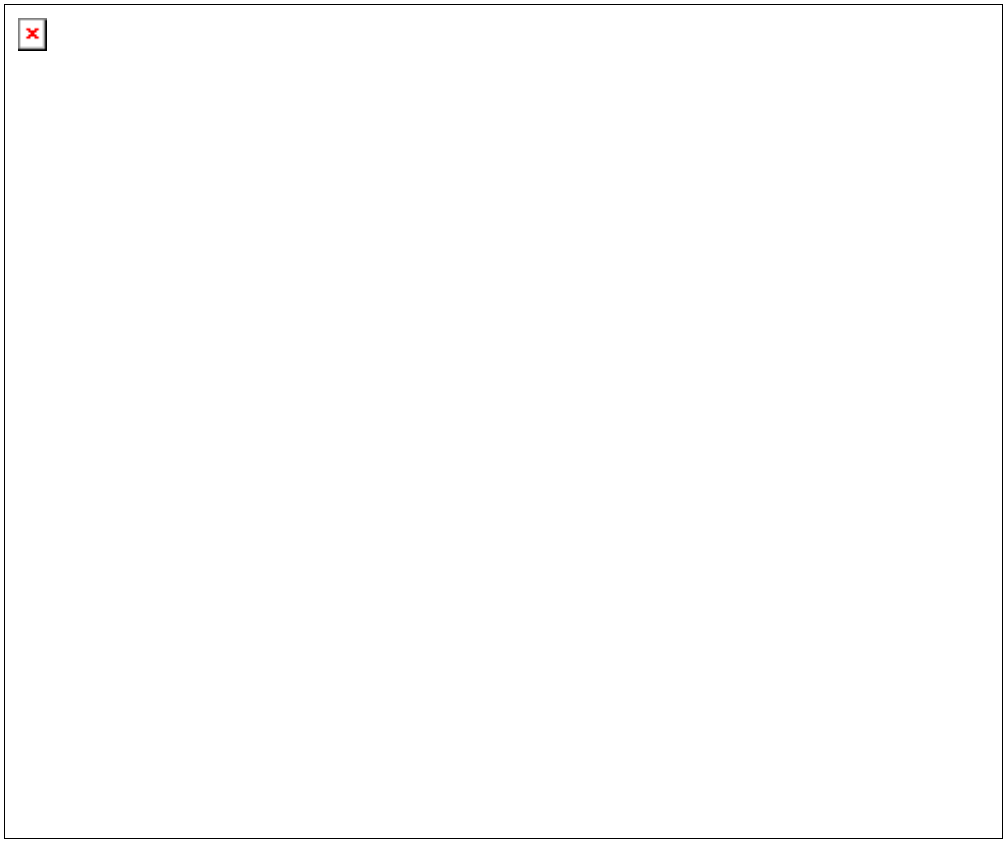

FIGURE 21-3. Diagram of a generic two-gas anesthesia machine. (Modified with permission from Check-Out, A Guide for Preoperative Inspection of an Anesthesia Machine. Park Ridge, Illinois, American Society of Anesthesiologists, 1987.)

Oxygen Analyzer Calibration

The oxygen analyzer is one of the most important monitors on the anesthesia workstation. It is the only machine safety device that evaluates the integrity of the low-pressure circuit in an ongoing fashion. Other machine safety devices, such as the fail-safe valve, the oxygen supply failure alarm, and the proportioning system, are all upstream from the flow control valves. The only machine monitor that detects problems downstream from the flow control valves is the oxygen analyzer. Calibration of this monitor is described in Appendix A (Anesthesia Apparatus Checkout Recommendations, 1993, #9). The actual procedure for calibrating the oxygen analyzer has remained reasonably similar over the recent generations of the anesthesia workstations. Generally, the oxygen concentration sensing element must be exposed to room air for calibration to 21%. This may require manually setting a dial on older machines, but on newer ones, it usually only involves temporary removal of the sensor, selecting and then confirming that the oxygen calibration is to be performed from a set of menus on the workstation's display screen, and finally reinstalling the sensor.

Low-Pressure Circuit Leak Test

1 The low-pressure leak test checks the integrity of the anesthesia machine from the flow control valves to the common outlet. It evaluates the portion of the machine that is downstream from all safety devices except the oxygen analyzer. The components located within this area are *precisely* the ones most subject to breakage and leaks. Leaks in the low-pressure circuit can cause hypoxia or patient awareness.[11,12] Flow tubes, the most delicate pneumatic component of the machine, can crack or break. A typical three-gas anesthesia machine has 16 O-rings in the low-pressure circuit. Leaks can occur at the interface between the glass flow tubes

and the manifold, and at the O-ring junctions between the vaporizer and its manifold. Loose filler caps on vaporizers are a common source of leaks, and these leaks can cause patient awareness under anesthesia.[11,13]

Several different methods have been used to check the low-pressure circuit for leaks. They include the oxygen flush test, the common gas outlet occlusion test, the traditional positive pressure leak test, the North American Dräger positive pressure leak test, the Ohmeda 8000 internal positive pressure leak test, the Ohmeda negative pressure leak test, the 1993 FDA universal negative pressure leak test, and others. One reason for the large number of methods is that the internal design of various machines differs considerably. The most notable example is that most GE Healthcare/Datex-Ohmeda (hereafter referred to as Datex-Ohmeda) workstations have a check valve near the common gas outlet, whereas Dräger medical workstations do not. The presence or absence of the check valve profoundly influences which preoperative check is indicated.

Several mishaps have resulted from application of the wrong leak test to the wrong machine.[14,15,16,17] Therefore, it is mandatory to perform the appropriate low-pressure leak test each day. To do this, it is essential to understand the exact location and operating principles of the Datex-Ohmeda check valve. Many Datex-Ohmeda anesthesia workstations have a machine outlet check valve located in the low-pressure circuit (Table 21-1). The check valve is located downstream from the vaporizers and upstream from the oxygen flush valve (see Fig. 21-3). It is open (Fig. 21-4, left) in the absence of back pressure. Gas flow from the manifold moves the rubber flapper valve off its seat and allows gas to proceed freely to the common outlet. The

valve closes (Fig. 21-4, right) when back pressure is exerted on it.[8] Back pressure sufficient to close the check valve may occur with the following conditions: oxygen flushing, peak breathing circuit pressures generated during positive pressure ventilation, or use of a positive pressure leak test.

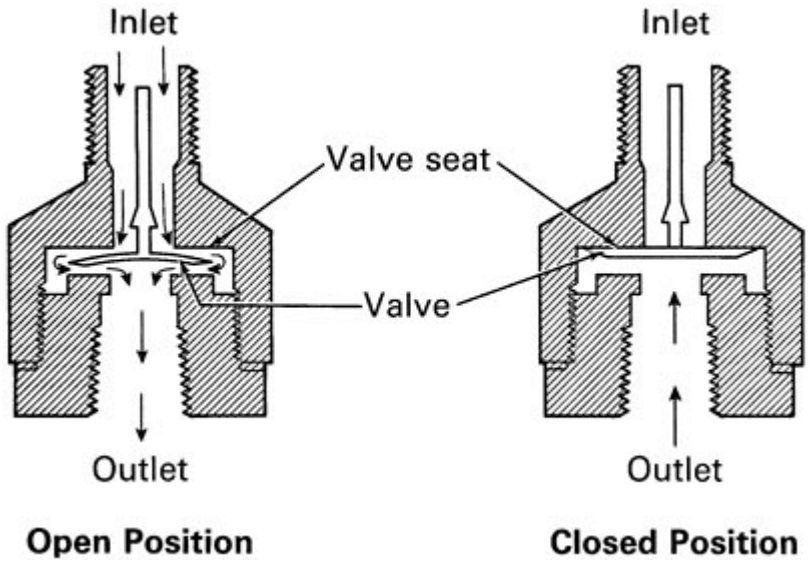

FIGURE 21-4. Machine outlet check valve. See text for details. (Reproduced with permission from Bowie E, Huffman LM: The Anesthesia Machine: Essentials for Understanding. Madison, Ohmeda, Inc., a Division of BOC Health Care, 1985.)

Generally speaking, the low-pressure circuit of anesthesia workstations without an outlet check

valve can be tested using a positive pressure leak test, and machines with check valves must be tested using a negative pressure leak test. When performing a positive pressure leak test, the operator generates positive pressure in the low-pressure circuit using flow from the anesthesia machine or from a positive pressure bulb to detect a leak. When performing a negative pressure leak test, the operator creates negative pressure in the low-pressure circuit using a suction bulb to detect leaks. Two different low-pressure circuit leak tests are described below.

Oxygen Flush Positive-Pressure Leak Test

2 Historically, older anesthesia machines did not have check valves in the low-pressure circuit. Therefore, it was common practice to pressurize the breathing circuit and the low-pressure circuit with the oxygen flush valve to test for internal anesthesia machine leaks. Because many modern Datex-Ohmeda machines now have check valves in the low-pressure circuit, application of a positive-pressure leak test to these machines can be misleading or even dangerous (Fig. 21-5). Inappropriate use of the oxygen flush valve or the presence of a leaking flush valve may lead to inadequate evaluation of the low-pressure circuit for leaks. In turn, this can lead the workstation user into a false sense of security despite the presence of large leaks.[15,16,17,18,19] Positive pressure from the breathing circuit results in closure of the outlet check valve, and the value on the airway pressure gauge will fail to decline. The system appears to be tight, but in actuality, only the circuitry downstream from the check valve is leak free.[20] Thus, a vulnerable area exists from the check valve back to the flow control valves because this area is not tested by a positive pressure leak test.

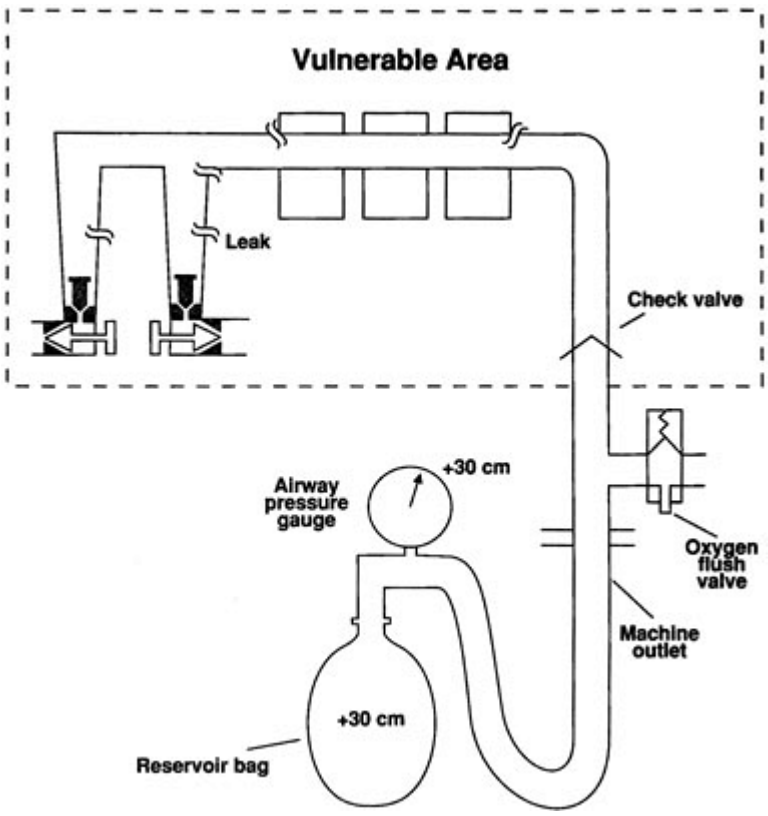

FIGURE 21-5. Inappropriate use of the oxygen flush valve to check the low-pressure circuit of an Ohmeda machine equipped with a check valve. The area within the rectangle is not checked by the inappropriate use of the oxygen flush valve. The components located within this area are *precisely* the ones most subject to breakage and leaks. Positive pressure within the patient circuit closes the check valve, and the value on the airway pressure gauge does not decline despite leaks in the low-pressure circuit.

1993 FDA Negative-Pressure Leak Test

The 1993 FDA Universal negative pressure leak test[10] (Appendix A, #5) was so named “universal” because at that time it could be used to check all contemporary anesthesia machines regardless of the presence or absence of check valves in the low-pressure circuit. It remains effective for many anesthesia workstations and can be applied to many Datex-Ohmeda machines, Dräger Medical machines, and others. Unfortunately, some newer machines are no longer compatible with this test. The ASA Committee on Equipment and Facilities in conjunction with the FDA is expected to update the 1993 Anesthesia Apparatus Pre-Use Checkout Recommendations as this chapter comes to press. Until the new recommendations become available, the 1993 guidelines should continue to be followed as closely as possible, since they remain applicable to the vast majority of anesthesia workstations in use worldwide.

The 1993 FDA check is based on the Datex-Ohmeda negative-pressure leak test (Fig. 21-6). It is performed using a negative-pressure leak testing device, which is a simple suction bulb. The machine master switch, the flow control valves, and vaporizers are turned off. The suction bulb is attached to the common fresh gas outlet and squeezed repeatedly until it is fully collapsed. This action creates a vacuum in the low-pressure circuitry. The machine is leak free if the hand bulb remains collapsed for at least 10 seconds. A leak is present if the bulb reinflates during this period. The test is repeated with each vaporizer individually turned to the on position because internal vaporizer leaks can be detected only with the vaporizer turned on.

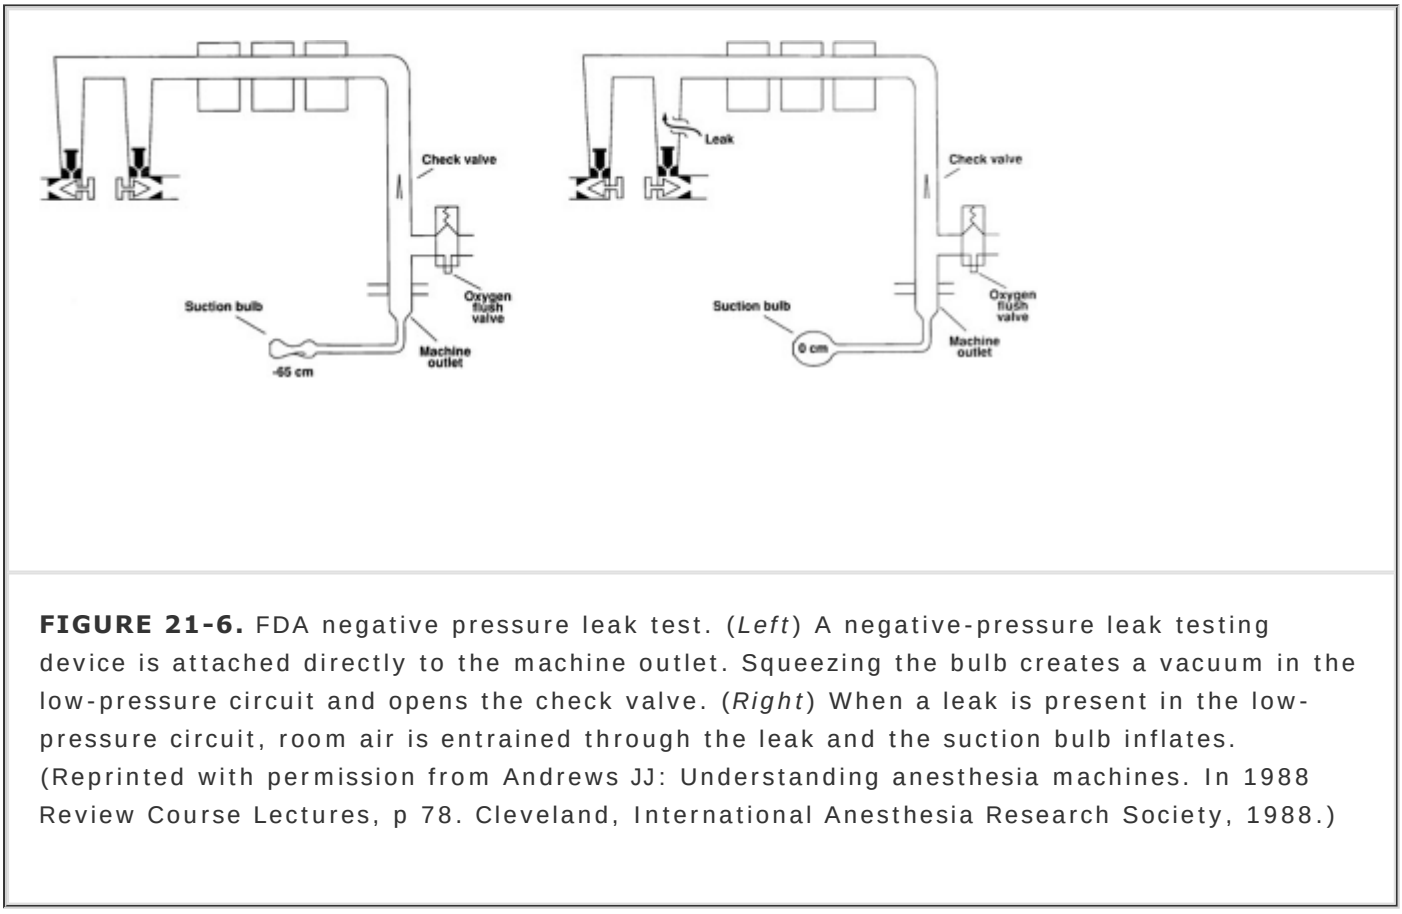

FIGURE 21-6. FDA negative pressure leak test. (*Left*) A negative-pressure leak testing device is attached directly to the machine outlet. Squeezing the bulb creates a vacuum in the low-pressure circuit and opens the check valve. (*Right*) When a leak is present in the low-pressure circuit, room air is entrained through the leak and the suction bulb inflates. (Reprinted with permission from Andrews JJ: Understanding anesthesia machines. In 1988 Review Course Lectures, p 78. Cleveland, International Anesthesia Research Society, 1988.)

3 The FDA “universal” negative-pressure low-pressure circuit leak test has several advantages.[21] The universal test is quick and simple to perform. It has an obvious end point, and it may help isolate the problem. For example, if the bulb reinflates in less than 10 seconds, a leak is present somewhere in the low-pressure circuit. Therefore, it differentiates between breathing-circuit leaks and leaks in the low-pressure circuit. The universal negative-pressure leak test is the most sensitive of all contemporary leak tests because it is not volume dependent. That is, it does not involve the use of a breathing bag or corrugated hoses whose compliance could mask a significant leak. It can detect leaks as small as 30 mL/min. Finally, the operator does not need a detailed or in-depth knowledge of proprietary design differences. If the operator performs

the universal test correctly, the leak will be detected.

Circle System Tests

4 The circle system tests (Appendix A, #11–12) evaluate the integrity of the circle breathing system, which spans from the common gas outlet to the Y-piece (Fig. 21-7). It has two parts—the *leak test* and the *flow test*. To thoroughly check the circle system for leaks, valve integrity, and obstruction, both tests must be performed preoperatively. The *leak test* is performed by closing the pop-off valve, occluding the Y-piece, and pressurizing the circuit to 30 cm water pressure using the oxygen flush valve. The value on the pressure gauge will not decline if the circle system is leak free, but this does not assure valve integrity. The value on the gauge will read 30 cm water even if the unidirectional valves are stuck shut or if the valves are incompetent.

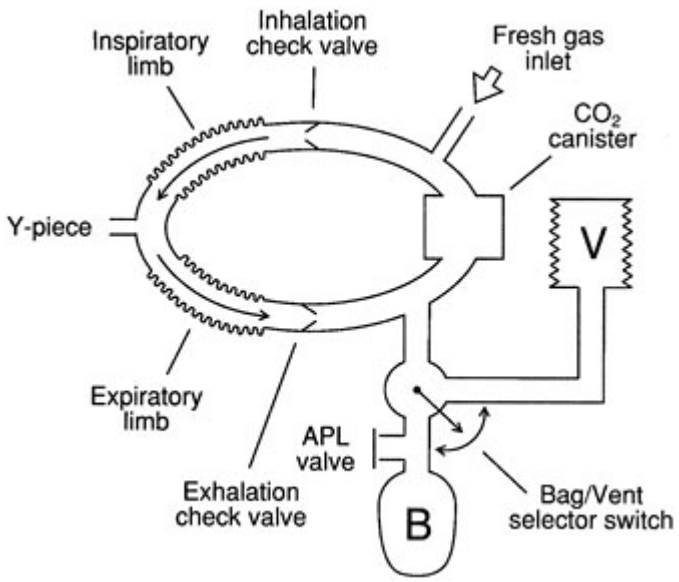

FIGURE 21-7. Components of the circle system. *B* = Reservoir Bag; *V* = ventilator; APL = Adjustable Pressure Limiting. (Reproduced with permission from Brockwell RC: Inhaled Anesthetic Delivery Systems. In Miller RD (ed): Anesthesia, 6th ed, p 295. Philadelphia, Churchill Livingstone, 2004.)

The *flow test* checks the integrity of the unidirectional valves, and it detects obstruction in the circle system. It can be performed by removing the Y-piece from the circle system and breathing through the two corrugated hoses individually. The valves should be present, and they should move appropriately.

The operator should be able to inhale but not be able to exhale through the inspiratory limb. The operator should be able to exhale but not inhale through the expiratory limb. The flow test can also be performed by using the ventilator and a breathing bag attached to the “Y” piece as described in the 1993 FDA Anesthesia Apparatus Checkout Recommendations (Appendix A, #12).[10]

Workstation Self-Tests

As previously mentioned, many new anesthesia workstations now incorporate technology that allows the machine to either automatically or manually walk the user through a series of self-tests to check for functionality of electronic, mechanical, and pneumatic components. Tested components commonly include the gas supply system, flow control valves, the circle system, ventilator, and in the case of the Datex-Ohmeda ADU, even the Aladin cassette vaporizer. The comprehensiveness of these self-diagnostic tests varies from one model and manufacturer to

another. If these tests are to be employed, users must be sure to read and strictly follow all manufacturer recommendations. Although a thorough understanding what the particular workstation's self-tests include is very helpful, this information is often difficult to obtain and may vary greatly between devices.

5 One particularly important point of caution with self-tests should be noted on systems with manifold mounted vaporizers such as the Dräger Medical Fabius GS and Narkomed 6000 series. A manifold mounted vaporizer does not become a part of an anesthesia workstation's gas flow stream until its concentration control dial is turned to the on position. Therefore, to detect internal vaporizer leaks on this type of a system, the “leak test” portion of the self-diagnostic must be repeated separately with each individual vaporizer turned to the on position. If this precaution is not taken, large leaks that could potentially result in patient awareness, such those from a loose filler cap or cracked fill indicator, could go undetected.

Anesthesia Workstation Pneumatics

The Anatomy of an Anesthesia Workstation

A simplified diagram of a generic two-gas anesthesia machine is shown in Figure 21-3. The pressures within the anesthesia workstation can be divided into three circuits: a high-pressure, an intermediate-pressure, and a low-pressure circuit (see Fig. 21-3). The ***high-pressure circuit*** is confined to the cylinders and the cylinder primary pressure regulators. For oxygen, the pressure range of the high-pressure circuit extends from a high of 2,200 pounds per square inch gauge (psig) to 45 psig, which is the regulated cylinder pressure. For nitrous oxide in the high-pressure circuit, pressures range from a high of 750 psig in the cylinder to a low of 45 psig. The ***intermediate-pressure circuit*** begins at the regulated cylinder supply sources at 45 psig and it includes the pipeline sources at 50 to 55 psig and extends to the flow control valves. Depending on the manufacturer and specific machine design, second-stage pressure regulators may be used to decrease the pipeline supply pressures to the flow control valves to even lower pressures such as 14 psig or 26 psig within the intermediate pressure circuit.[22,23] Finally, the ***low-pressure circuit*** extends from the flow control valves to the common gas outlet. Therefore, the low-pressure circuit

includes the flow tubes, vaporizer manifold, vaporizers, and the one-way check valve on most Datex-Ohmeda machines.[22]

Both oxygen and nitrous oxide have two supply sources. These consist of a pipeline supply source and a cylinder supply source. The pipeline supply source is the primary gas source for the anesthesia machine. The hospital pipeline supply system provides gases to the machine at approximately 50 psig, which is the normal working pressure of most machines. The cylinder supply source serves as a back-up if the pipeline supply fails or the primary supply if the anesthesia workstation is being used in a location without the availability of pipeline supplied gases. As previously described, the oxygen cylinder source is regulated from 2,200 to approximately 45 psig, and the nitrous oxide cylinder source is regulated from 745 to approximately 45 psig.[22,23,24]

A safety device traditionally referred to as the **fail-safe** valve is located downstream from the nitrous oxide supply source. It serves as an interface between the oxygen and nitrous oxide supply sources. This valve shuts off or proportionally decreases the supply of nitrous oxide (and other gases) if the oxygen supply pressure decreases. To meet ASTM standards, contemporary machines have an alarm device to monitor the oxygen supply pressure. A high-priority alarm is actuated as declining oxygen supply pressure reaches a predetermined threshold, such as 30 psig.[22,23,24]

Many Datex-Ohmeda machines have a second-stage oxygen regulator located downstream from the oxygen supply source in the intermediate pressure circuit. It is adjusted to a precise pressure level, such as 14 psig.[23] This regulator supplies a constant pressure to the oxygen flow control valve regardless of fluctuating oxygen pipeline pressures. For example, the flow from the oxygen

flow control valve will be constant if the oxygen supply pressure is greater than 14 psig.

The flow control valves represent an important anatomic landmark within the anesthesia workstation because they separate the intermediate-pressure circuit from the low-pressure circuit. The low-pressure circuit is that part of the machine that lies downstream from the flow control valves. The operator regulates flow entering the low-pressure circuit by adjusting the flow control valves. The oxygen and nitrous oxide flow control valves are linked mechanically or pneumatically by a proportioning system to help prevent inadvertent delivery of a hypoxic mixture. After leaving the flow tubes, the mixture of gases travels through a common manifold and may be directed to a calibrated vaporizer. Precise amounts of inhaled anesthetic can be added, depending on vaporizer control dial setting. The total fresh gas flow plus the anesthetic vapor then travel toward the common gas outlet.[22,23]

Many Datex-Ohmeda anesthesia machines have a one-way check valve located between the vaporizers and the common gas outlet in the mixed-gas pipeline. Its purpose is to prevent back flow into the vaporizer during positive pressure ventilation, therefore minimizing the effects of downstream intermittent pressure fluctuations on inhaled anesthetic concentration (see Vaporizers: Intermittent Back Pressure section). The presence or absence of this check valve ***profoundly*** influences which preoperative leak test is indicated (see Checking Your Anesthesia Workstation). The oxygen flush connection joins the mixed-gas pipeline between the one-way check valve (when present) and the machine outlet. Thus, when oxygen flush valve is activated the pipeline oxygen pressure has a “straight shot” to the common gas outlet.[22,23]

Pipeline Supply Source

Under normal conditions, the pipeline supply serves as the primary gas source for the anesthesia machine. Most hospitals today have a central piping system to deliver medical gases such as oxygen, nitrous oxide, and air to the operating room. The central piping system must supply the correct gases at the appropriate pressure for the anesthesia workstation to function properly. Unfortunately, this does not always occur. Proven as recently as 2002, even large medical centers with huge cryogenic bulk oxygen storage systems are not immune to component failures that may contribute to critical oxygen pipeline supply failures.[25] In this case, a faulty joint ruptured at the bottom of the primary cryogenic oxygen storage tank, releasing 8,000 gallons of liquid oxygen to flood the streets in the surrounding area. This mishap suddenly compromised the oxygen delivery to a major medical center.

In a survey of approximately 200 hospitals in 1976, 31% reported difficulties with pipeline systems.[26] The most common problem was inadequate oxygen pressure, followed by excessive pipeline pressures. The most devastating reported hazard, however, was accidental crossing of oxygen and nitrous oxide pipelines, which has led to many deaths. This problem caused 23 deaths in a newly constructed wing of a general hospital in Sudbury, Ontario, during a 5-month period.[26,27] More recently, in 2002, two additional hypoxic deaths were reported in New Haven, Connecticut. These resulted from a medical gas system failure in which an altered oxygen flowmeter was inadvertently connected to a wall supply source for nitrous oxide.[28]

6 In the event a pipeline crossover is ever suspected, the workstation user must immediately make **two** corrective actions. First, the back-up oxygen cylinder should be turned on. Then, the pipeline supply must be disconnected. This second step is mandatory because the machine will preferentially use the inappropriate 50 psig pipeline supply source instead of the lower-pressure (45 psig) oxygen cylinder source if the wall supply is not disconnected.

Gas enters the anesthesia machine through the pipeline inlet connections (see Fig. 21-3; see arrows). The pipeline inlet fittings are gas-specific Diameter Index Safety (DISS) threaded body fittings. The DISS provides threaded noninterchangeable connections for medical gas lines, which minimize the risk of misconnection. A check valve is located downstream from the inlet. It prevents reverse flow of gases from the machine to the pipeline or the atmosphere.

Cylinder Supply Source

Anesthesia workstations have E cylinders for use when a pipeline supply source is not available or if the pipeline system fails. Anesthesia providers can easily become complacent and falsely assume that back-up gas cylinders are in fact present on the back of the anesthesia workstation, and further, that if they are present, that they contain an adequate supply of compressed gas. The pre-use checklist should contain steps that confirm both.

Medical gases supplied in E cylinders are attached to the anesthesia machine via the hanger yoke assembly. The hanger yoke assembly orients and supports the cylinder, provides a gas-tight seal, and ensures a unidirectional flow of gases into the machine.[30] Each hanger yoke is equipped with the Pin Index Safety System (PISS). The PISS is a safeguard introduced to eliminate cylinder interchanging and the possibility of accidentally placing the incorrect gas on a yoke designed to accommodate another gas. Two metal pins on the yoke assembly are arranged so that that they project into corresponding holes on the cylinder valve. Each gas or combination of gases has a specific pin arrangement.[31]

Once the cylinders are turned on, compressed gases may pass from their respective high-pressure cylinder sources into the anesthesia machine (see Fig. 21-3). A check valve is located downstream from each cylinder if a double-yoke assembly is used. This check valve serves several functions. First, it

minimizes gas transfer from a cylinder at high pressure to one with lower pressure. Second, it allows an empty cylinder to be exchanged for a full one while gas flow continues from the other cylinder into the machine with minimal loss of gas or supply pressure. Third, it minimizes leakage from an open cylinder to the atmosphere if one cylinder is absent.[23,30] A cylinder supply pressure gauge is located downstream from the check valves. The gauge will indicate the pressure in the cylinder having the higher pressure when two reserve cylinders of the same gas are opened at the same time.

Each cylinder supply source has a pressure-reducing valve known as the cylinder pressure regulator. It reduces the high and variable storage pressure present in a cylinder to a lower, more constant pressure suitable for use in the anesthesia machine. The oxygen cylinder pressure regulator reduces the oxygen cylinder pressure from a high of 2,200 psig to approximately 45 psig. The nitrous oxide cylinder pressure regulator receives pressure of up to 745 psig and reduces it to approximately 45 psig.[22,23]

The gas supply cylinder valves should be turned off when not in use, except during the preoperative machine checking period. If the cylinder supply valves are left on, the reserve cylinder supply can be silently depleted whenever the pressure inside the machine decreases to a value lower than the regulated cylinder pressure. For example, oxygen pressure within the machine can decrease below 45 psig with oxygen flushing or possibly even during use of a pneumatically driven ventilator, particularly at high inspiratory flow rates. Additionally, the pipeline supply pressures of all gases can fall to less than 45 psig if problems exist in the central piping system. If the cylinders are left on when this occurs, they will eventually become depleted and no reserve supply may be available if a pipeline failure occurs.[20,23]

The amount of time that an anesthesia machine can operate from the E-cylinder supplies is important knowledge. This is particularly true now that anesthesia is being provided more frequently in office-based and in remote (outside the OR) hospital settings. For oxygen, the volume of gas remaining in the cylinder is proportional to the cylinder pressure. One author has proposed the following equation to help estimate the remaining time.[32]

$$\text{Approx. Remaining Time (Hrs)} \approx \frac{\text{Oxygen cylinder pressure (psig)}}{200 \times \text{oxygen flow rate (L/Min)}}$$

It should be noted that this calculation will provide only a gross estimate of remaining time and may not be exact. Furthermore, users should be cautioned that use of a pneumatically driven mechanical ventilator will dramatically increase oxygen utilization rates and decrease the

remaining time until cylinder depletion. Hand ventilating with low fresh gas flow rates may consume <5% the amount of oxygen as compared to intermediate flowmeter settings coupled with the use of pneumatically powered mechanical ventilation.[25] Because piston type anesthesia ventilators such as found in the Dräger Medical Fabius GS and Narkomed 6000 series do not impact oxygen consumption rates, they may be preferable to conventional gas-driven ventilators in practice settings that are dependent on the use of compressed gas cylinders as the primary gas sources.

Oxygen Supply Pressure Failure Safety Devices

Oxygen and nitrous oxide supply sources existed as independent entities in older models of anesthesia machines, and they were not pneumatically or mechanically interfaced. Therefore, abrupt or insidious oxygen pressure failure had the potential to lead to the delivery of a hypoxic mixture. The 2000 ASTM F1850-00 standard states that, “The anesthesia gas supply device shall be designed so that whenever oxygen supply pressure is reduced to below the manufacturer specified minimum, the delivered oxygen concentration shall not decrease below 19% at the common gas outlet.”[5] Contemporary anesthesia machines have a number of safety devices that act together in a cascade manner to minimize the risk of delivery of a hypoxic gas mixture as oxygen pressure decreases. Several of these devices are described in the following sections.

Pneumatic and Electronic Alarm Devices

Many older anesthesia machines have a pneumatic alarm device that sounds a warning when the oxygen supply pressure decreases to a predetermined threshold value such as 30 psig. The 2000 ASTM F1850-00 standard mandates that a medium priority alarm shall be activated within 5 seconds when the oxygen pressure decreases below a manufacturer-specific pressure threshold.[5] Electronic alarm devices are now used to meet this guideline.

Fail-Safe Valves

7 A fail-safe valve is present in the gas line supplying each of the flowmeters except oxygen. Controlled by oxygen supply pressure, the valve shuts off or proportionally decreases the supply pressure of all other gases (nitrous oxide, air, CO_2, helium, nitrogen) as the oxygen supply pressure decreases. Unfortunately, the misnomer “fail-safe” has led to the misconception that the valve prevents administration of a hypoxic mixture. This is not the case. Machines that are either not equipped with a flow proportioning system (see Proportioning Systems section) or ones whose system may be disabled by the user can deliver a hypoxic mixture under normal working conditions. On such a system, the oxygen flow control valve can be closed intentionally or accidentally. Normal oxygen pressure will keep other gas lines open so that a hypoxic mixture can result.[22,23]

Many Datex-Ohmeda machines are equipped with a fail-safe valve known as the pressure-sensor shutoff valve (Fig. 21-8). This valve operates in a threshold manner and is either open or closed. Oxygen supply pressure opens the valve, and the valve return spring closes the valve. Figure 21-8 shows a nitrous oxide pressure-sensor shutoff valve with a threshold pressure of 20 psig. In Figure 21-8A, an oxygen supply pressure greater than 20 psig is exerted on the mobile diaphragm. This pressure moves the piston and pin upward and the valve opens. Nitrous oxide flows freely to the nitrous oxide flow control valve. In Figure 21-8B, the oxygen supply pressure is less than 20 psig, and the force of the valve return spring completely closes the valve.[23] Nitrous oxide flow stops at the closed

fail-safe valve, and it does not advance to the nitrous oxide flow control valve.

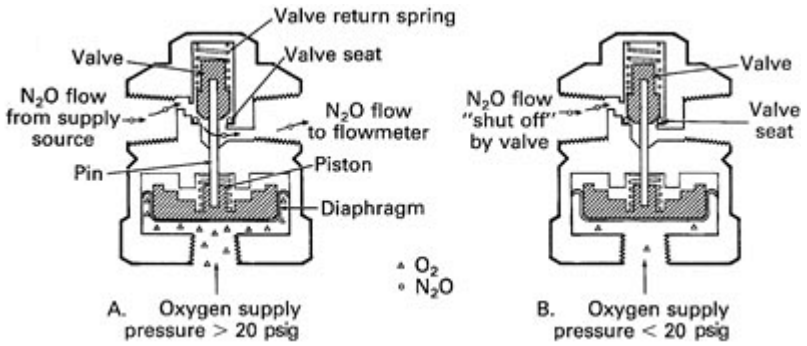

FIGURE 21-8. Pressure-sensor shutoff valve. The valve is open in *A* because the oxygen supply pressure is greater than the threshold value of 20 psig. The valve is closed in *B* because of inadequate oxygen pressure. (Redrawn with permission from Bowie E, Huffman LM: The Anesthesia Machine: Essentials for Understanding. Madison, Wisconsin, Ohmeda, a Division of BOC Health Care, Inc, 1985.)

North American Dräger uses a different fail-safe valve known as the Oxygen Failure Protection Device (OFPD) to interface the oxygen pressure with that of other gases, such as nitrous oxide or other inert gases. This is in contrast to Datex-Ohmeda's oxygen pressure-sensor shutoff valve, because the OFPD is based on a proportioning principle rather than a threshold principle. The pressure of all gases controlled by the OFPD will decrease proportionally with the oxygen pressure. The OFPD consists of a seat-nozzle assembly connected to a spring-loaded piston (Fig. 21-9). The oxygen supply pressure in the left panel of Figure 21-9 is 50 psig. This pressure pushes the piston upward, forcing the nozzle away from the valve seat. Nitrous oxide and/or other gases advance toward the flow control valve at 50 psig. The oxygen pressure in the right panel is zero psig. The spring is expanded and forces the nozzle against the seat, preventing flow through the device. Finally, the center panel shows an intermediate oxygen pressure of 25 psig. The force of the spring partially closes the valve. The nitrous oxide pressure delivered to the flow control valve is 25 psig. There is a continuum of intermediate configurations between the extremes (0 to 50 psig) of oxygen supply pressure. These intermediate valve configurations are responsible for the proportional nature of the OFPD. An important concept to be understood with these particular fail-safe devices is that the Datex-Ohmeda Pressure Sensor Shutoff Valve is threshold in nature (all-or-nothing), whereas the Dräger Oxygen Failure Protection Device is a variable flow type proportioning system.

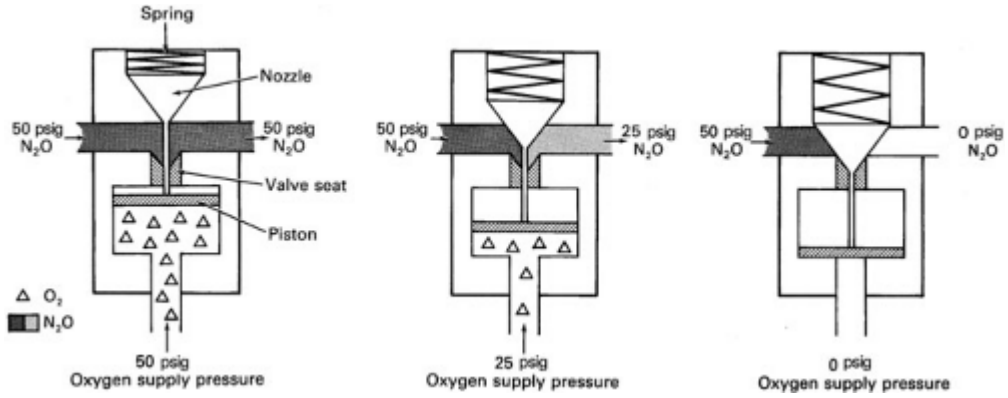

FIGURE 21-9. Oxygen Failure Protection Device/Sensitive Oxygen Ratio Controller (OFPD/S-ORC), which responds proportionally to changes in oxygen supply pressure. (Redrawn with permission from Narkomed 2A Anesthesia System: Technical Service Manual, 6th ed. Telford, PA, North American Dräger, June 1985.)

Second-Stage Oxygen Pressure Regulator

Most contemporary Datex-Ohmeda workstations have a second-stage oxygen pressure regulator set at a specific value ranging from 12 to 19 psig. Output from the oxygen flowmeter is constant when the oxygen supply pressure exceeds the threshold (minimal) value. The pressure-sensor shutoff valve of Datex-Ohmeda is set at a higher threshold value (20 to 30 psig) to ensure that oxygen is the last gas flowing if oxygen pressure failure occurs.

Flowmeter Assemblies

The flowmeter assembly (Fig. 21-10) precisely controls and measures gas flow to the common gas outlet. With traditional glass flowmeter assemblies, the flow control valve regulates the amount of flow that enters a tapered, transparent flow tube known as a Thorpe tube. A mobile indicator float inside the flow tube indicates the amount of flow passing through the associated flow control valve. The quantity of flow is indicated on a scale associated with the flow tube.[22,23] Some newer

anesthesia workstations have now replaced the conventional glass flow tubes with electronic flow sensors that measure the flows of the individual gases. These flow rate data are then presented in either numerical format, graphical format, or a combination of the two. The integration of these “electronic flowmeters” is an essential step in the evolution of the anesthesia workstation if it is to become fully integrated with anesthesia data-capturing systems such as computerized anesthesia record keepers.

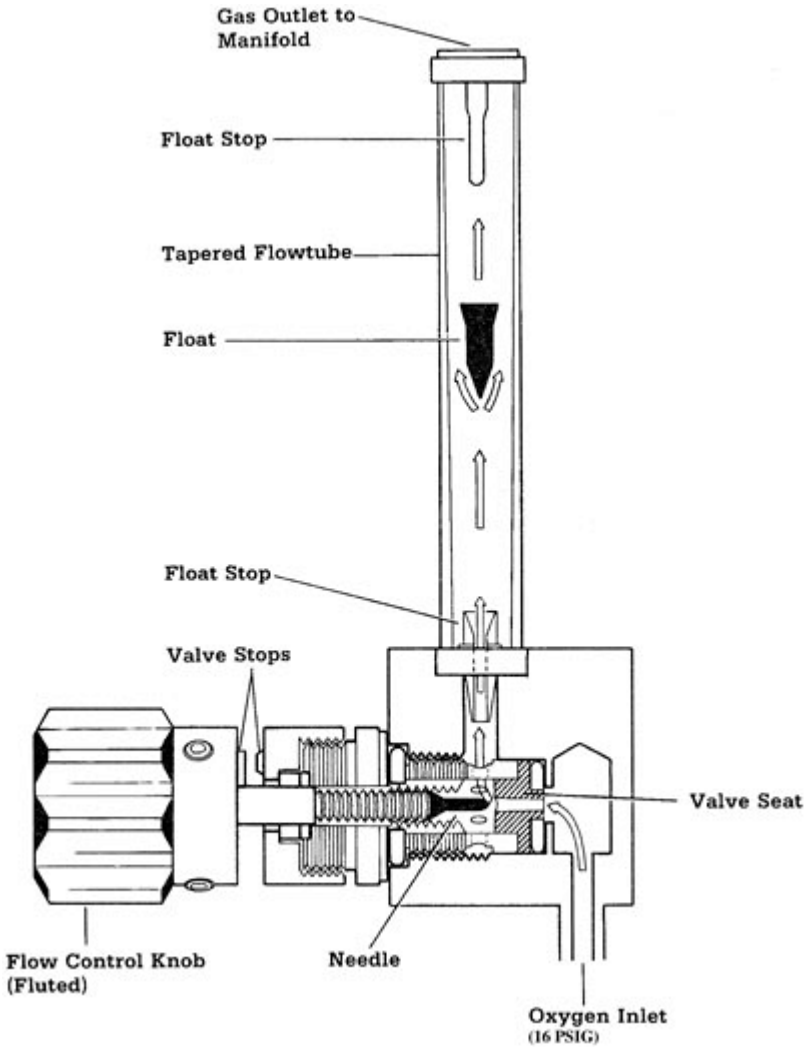

FIGURE 21-10. Oxygen flowmeter assembly. The oxygen flowmeter assembly is composed of the flow control valve assembly plus the flowmeter subassembly. (Reproduced with permission from Bowie E, Huffman LM: The Anesthesia Machine: Essentials for Understanding. Madison, Wisconsin, Ohmeda, a Division of BOC Health Care, Inc, 1985.)

Operating Principles of Conventional Flowmeters

Opening the flow control valve allows gas to travel through the space between the float and the flow tube. This space is known as the annular space (Fig. 21-11). The indicator float hovers freely in an equilibrium position where the upward force resulting from gas flow equals the downward force on the float resulting from gravity at a given flow rate. The float moves to a new equilibrium position in the tube when flow is changed. These flowmeters are commonly referred to as *constant pressure* flowmeters because the pressure decrease across the float remains constant for all positions in the tube.[22,31,33]

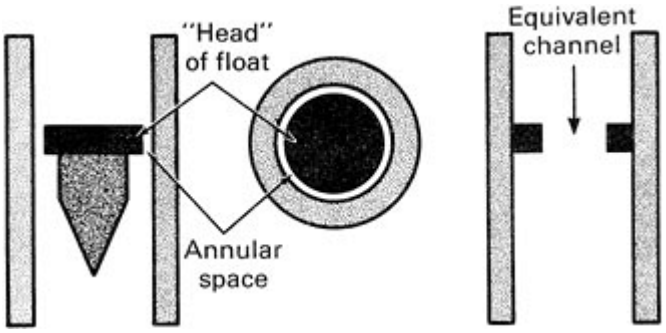

FIGURE 21-11. The annular space. The clearance between the head of the float and the flow tube is known as the annular space. It can be considered an equivalent to a circular channel of the same cross-sectional area. (Redrawn with permission from Macintosh R, Mushin WW, Epstein HG: Physics for the Anaesthetist, 3rd ed. Oxford, England, Blackwell Scientific Publications, 1963.)

Flow tubes are tapered, with the smallest diameter at the bottom of the tube and the largest diameter at the top. The term *variable orifice* designates this type of unit because the annular space between the float and the inner wall of the flow tube varies with the position of the float. Flow through the constriction created by the float can be laminar or turbulent, depending on the flow rate (Fig. 21-12). The characteristics of a gas that influence its flow rate through a given constriction are viscosity (laminar flow) and density (turbulent flow). Because the annular space is tubular, at low flow rates laminar flow is present and *viscosity* determines the gas flow rate. The annular space simulates an orifice at high flow rates, and turbulent gas flow then depends predominantly on the *density* of the gas.[22,33]

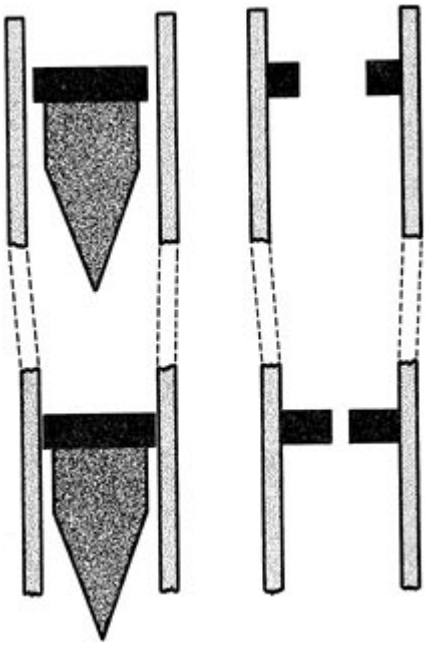

FIGURE 21-12. Flow tube constriction. The lower pair of illustrations represents the lower portion of a flow tube. The clearance between the head of the float and the flow tube is

narrow. The equivalent channel is tubular because its diameter is less than its length. Viscosity is dominant in determining gas flow rate through this tubular constriction. The upper pair of illustrations represents the upper portion of a flow tube. The equivalent channel is orificial because its length is less than its width. Density is dominant in determining gas flow rate through this orificial constriction. (Redrawn with permission from Macintosh R, Mushin WW, Epstein HG: Physics for the Anaesthetist, 3rd ed. Oxford, England, Blackwell Scientific Publications, 1963.)

Components of the Flowmeter Assembly

Flow Control Valve Assembly. The flow control valve (see Fig. 21-10) assembly is composed of a flow control knob, a needle valve, a valve seat, and a pair of valve stops.[22] The assembly can receive its pneumatic input either directly from the pipeline source (50 psig) or from a second-stage pressure regulator. The location of the needle valve in the valve seat changes to establish different orifices when the flow control valve is adjusted. Gas flow increases when the flow control valve is turned counterclockwise, and it decreases when the valve is turned clockwise. Extreme clockwise rotation may result in damage to the needle valve and valve seat. Therefore, flow control valves are equipped with valve "stops" to prevent this occurrence.[23]

Safety features. Contemporary flow control valve assemblies have numerous safety features. The oxygen flow control knob is physically distinguishable from other gas knobs. It is distinctively fluted, projects beyond the control knobs of the other gases, and is larger in diameter than the flow control knobs of other gases. All knobs are color-coded for the appropriate gas, and the chemical formula or name of the gas is permanently marked on each. Flow control knobs are recessed or protected with a shield or barrier to minimize inadvertent change from a preset position. If a single gas has two flow tubes, the tubes are arranged in series and are controlled by a single flow control valve.[5]

Flowmeter Subassembly. The flowmeter subassembly (see Fig. 21-10) consists of the flow tube, the indicator float with float stops, and the indicator scale.[22]

Flow tubes. Contemporary flow tubes are made of glass. Most have a single taper in which the inner diameter of the flow tube increases uniformly from bottom to top. Manufacturers provide double flow tubes for oxygen and nitrous oxide to provide better visual discrimination at low flow rates. A fine flow tube indicates flow from approximately 200 mL/min to 1 mL/min, and a coarse flow tube indicates flow from approximately 1 mL/min to 10 to 12 mL/min. The two tubes are connected in series and supplied by a single flow control valve. The total gas flow is that shown on the higher flowmeter.

Indicator floats and float stops. Contemporary anesthesia machines use several different types of bobbins or floats, including plumb-bob floats, rotating skirted floats, and ball floats. Flow is read at the top of plumb-bob and skirted floats and at the center of the ball on the ball-type floats.[22] Flow tubes are equipped with float stops at the top and bottom of the tube. The upper stop prevents the float from ascending to the top of the tube and plugging the outlet. It also ensures that the float will be visible at maximum flows instead of being hidden in the manifold. The bottom float stop provides a central foundation for the indicator when the flow control valve is turned off.[22,23]

Scale. The flowmeter scale can be marked directly on the flow tube or located to the right of the tube.[5] Gradations corresponding to equal increments in flow rate are closer together at the top of the scale because the annular space increases more rapidly than does the internal diameter from bottom to top of the tube. Rib guides are used in some flow tubes with ball-type indicators to minimize this compression effect. They are tapered glass ridges that run the length of the tube. There are usually three rib guides that are equally spaced around the inner circumference of the

tube. In the presence of rib guides, the annular space from the bottom to the top of the tube increases almost proportionally with the internal diameter. This results in a nearly linear scale.[22] Rib guides are employed on many Dräger Medical flow tubes.

Safety features. The flowmeter subassemblies for each gas on the Datex-Ohmeda Modulus I, Modulus II, Modulus II Plus, CD, and Aestiva are housed in independent, color-coded, pin-specific modules. The flow tubes are adjacent to a gas-specific, color-coded backing. The flow scale and the chemical formula (or name of the gas) are permanently etched on the backing to the right of the flow tube. Flowmeter scales are individually hand-calibrated using the specific float to provide a high degree of accuracy. The tube, float, and scale make an inseparable unit. The entire set must be replaced if any component is damaged.

Dräger Medical does not use a modular system for the flowmeter subassembly. The flow scale, the chemical symbol, and the gas-specific color codes are etched directly onto the flow tube. The scale in use is obvious when two flow tubes for the same gas are used.

Problems with Flowmeters

Leaks. Flowmeter leaks are a substantial hazard because the flowmeters are located downstream from all machine safety devices except the oxygen analyzer.[34] Leaks can occur at the O-ring junctions between the glass flow tubes and the metal manifold or in cracked or broken glass flow tubes, the most fragile pneumatic component of the anesthesia machine. Even though gross damage to conventional glass flow tubes is usually apparent, subtle cracks and chips may be overlooked, resulting in errors of delivered flows.[35] The use of electronic flowmeters and the removal of conventional glass flow tubes from some newer anesthesia workstations (Datex-Ohmeda S/5 ADU and the Dräger Fabius) may help to eliminate these potential sources of leaks (see Electronic Flowmeters section).

Eger et al in 1963[36] demonstrated that, in the presence of a flowmeter leak, a hypoxic mixture is less likely to occur if the oxygen flowmeter is located downstream from all other flowmeters. Figure 21-13 is a more contemporary version of the figure in Eger's original publication. The unused air flow tube has a large leak. Nitrous oxide and oxygen flow rates are set at a ratio of 3:1. A potentially dangerous arrangement is shown in Figure 21-13A and 21-13B because the nitrous oxide flowmeter is located in the downstream position. A hypoxic mixture can result because a substantial portion of oxygen flow passes through the leak, and all nitrous oxide is directed to the common gas outlet. A safer configuration is shown in Figure 21-13C and 21-13D. The oxygen flowmeter is located in the downstream position. A portion of the nitrous oxide flow escapes through the leak, and the remainder goes toward the common gas outlet. A hypoxic mixture is less likely because all the oxygen flow is advanced by the nitrous oxide.[36] North American Dräger flowmeters are arranged as in Figure 21-13C, and Datex-Ohmeda flowmeters are as in Figure 21-13D.

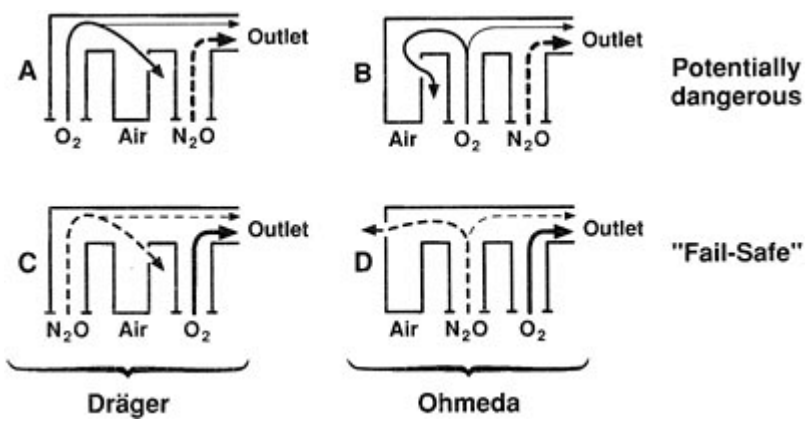

FIGURE 21-13. Flowmeter sequence—a potential cause of hypoxia. In the event of a flowmeter leak, a potentially dangerous arrangement exists when nitrous oxide is located in the downstream position (*A* and *B).* The safest configuration exists when oxygen is located in the downstream position (*C* and *D).* See text for details. (Modified with permission from Eger EI II, Hylton RR, Irwin RH *et al*: Anesthetic flowmeter sequence—a cause for hypoxia. Anesthesiology 24:396, 1963.)

A leak in the oxygen flow tube may result in creation of a hypoxic mixture even when oxygen is located in the downstream position (Fig. 21-14).[34,35] Oxygen escapes through the leak and nitrous oxide continues to flow toward the common outlet, particularly at high ratios of nitrous oxide to oxygen flow.

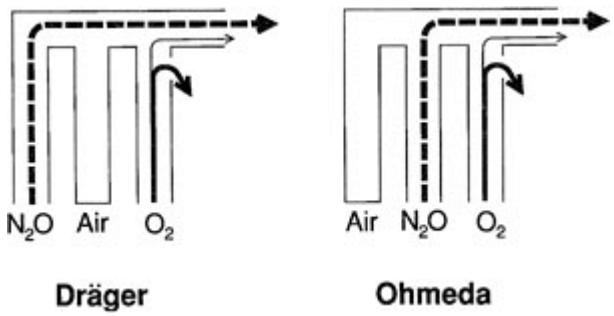

FIGURE 21-14. Oxygen flow tube leak. An oxygen flow tube leak can produce a hypoxic mixture regardless of flow tube arrangement. (Reproduced with permission from Brockwell RC: Inhaled Anesthetic Delivery Systems. In Miller RD (ed): Anesthesia, 6th ed, p 281. Philadelphia, Churchill Livingstone, 2004.)

Inaccuracy. Flow measurement error can occur even when flowmeters are assembled properly with appropriate components. Dirt or static electricity can cause a float to stick, and the actual flow may be higher or lower than that indicated. Sticking of indicator float is more common in the low flow ranges because the annular space is smaller. A damaged float can cause inaccurate readings because the precise relationship between the float and the flow tube is altered. Back pressure from the breathing circuit can cause a float to drop so that it reads less than the actual flow. Finally, if flowmeters are not aligned properly in the vertical position (plumb), readings can be inaccurate because tilting distorts the annular space.[17,22,35]

Ambiguous Scale. Before the standardization of flowmeter scales and the widespread use of oxygen analyzers, at least two deaths resulted from confusion created by ambiguous scales.[17,35,37] The operator read the float position beside an adjacent but erroneous scale in both cases. Today this error is less likely to occur because contemporary flowmeter scales are marked either directly onto the flow tube or immediately to the right of it.[5] The possibility of confusion is minimized when the scale is etched directly onto the tube.

Electronic Flowmeters

As mentioned earlier, some newer anesthesia workstations such as the Datex-Ohmeda S/5 ADU

knobs and flow control valves, but have electronic flow sensors and digital displays rather than glass flow tubes. The output from the flow control valve is represented graphically and/or numerically in liters per minute on the workstation's integrated user interface. These systems are dependent on electrical power to provide a precise display of gas flow. However, even when electrical power is totally interrupted, since the flow control valves themselves are nonelectronic, oxygen should continue to flow. Since these machines do not have individual flow tubes that physically quantitate flow of each gas, electronic flow sensors and often a small conventional pneumatic “fresh gas” or “total flow” indicators are provided that give the user an estimate of the total quantity fresh gas flowing from all flow control valves. This miniature flow tube indicator serves to inform the user of the approximate quantity of gas that is leaving the anesthesia workstation's common gas outlet, and is functional even in the event of a total power failure.

Proportioning Systems

Manufacturers equip anesthesia workstations with proportioning systems in an attempt to prevent creation and delivery of a hypoxic mixture. Nitrous oxide and oxygen are interfaced mechanically and/or pneumatically so that the minimum oxygen concentration at the common gas outlet is between 23 to 25% depending on manufacturer.

Datex-Ohmeda Link-25 Proportion Limiting Control System

Conventional Datex-Ohmeda machines use the Link-25 System. The heart of the system is the mechanical integration of the nitrous oxide and oxygen flow control valves. It allows independent adjustment of either valve, yet automatically intercedes to maintain a minimum 25% oxygen concentration with a maximum nitrous oxide–oxygen flow ratio of 3:1. The Link-25 automatically increases oxygen flow to prevent delivery of a hypoxic mixture.

Figure 21-15 illustrates the Datex-Ohmeda Link-25 System. The nitrous oxide and oxygen flow control valves are identical. A 14-tooth sprocket is attached to the nitrous oxide flow control valve, and a 28-tooth sprocket is attached to the oxygen flow control valve. A chain physically links the sprockets. When the nitrous oxide flow control valve is turned through two revolutions, or 28 teeth, the oxygen flow control valve will revolve once because of the 2:1 gear ratio. The final 3:1 flow ratio results because the nitrous oxide flow control valve is supplied by approximately 26 psig, whereas the oxygen flow control valve is supplied by 14 psig. Thus, the combination of the mechanical and pneumatic aspects of the system yields the final oxygen concentration. The Datex-Ohmeda Link-25 proportioning system can be thought of as a system which *increases oxygen flow* when necessary to prevent delivery of a fresh gas mixture with oxygen concentration of less than 25%.

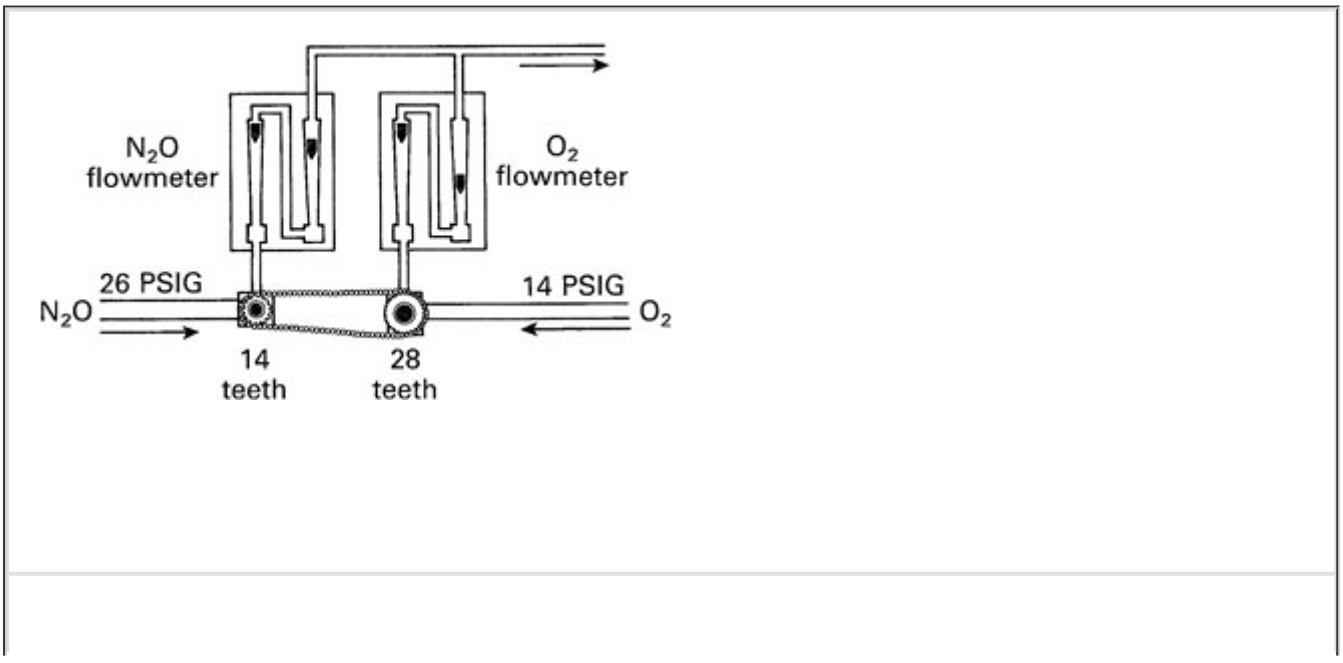

FIGURE 21-15. Ohmeda Link-25 Proportion Limiting Control system. See text for details.

A few reports have described failures of the Datex-Ohmeda Link-25 system.[37,38,39,40,41] The authors of these reports describe failures that resulted in either inability to administer oxygen without nitrous oxide or that allowed creation of a hypoxic mixture.

North American Dräger Oxygen Ratio Monitor Controller/Sensitive Oxygen Ratio Controller System

North American Dräger's proportioning system, the Oxygen Ratio Monitor Controller (ORMC), is used on the North American Dräger Narkomed 2A, 2B, 3, and 4. An equivalent system is known as the Sensitive Oxygen Ratio Controller (S-ORC) on some newer Dräger anesthesia workstations such as the Dräger Fabius GS and Narkomed 6000 series. The ORMC and the S-ORC are pneumatic oxygen–nitrous oxide interlock systems designed to maintain a fresh gas oxygen concentration of at least 25 ± 3%. They control the fresh gas oxygen concentration to levels substantially higher than 25% at oxygen flow rates less than 1 L/min. The ORMC and S-ORC limit nitrous oxide flow to prevent delivery of a hypoxic mixture. This is unlike the Datex-Ohmeda Link-25, which actively increases oxygen flow.

A schematic of the ORMC is shown in Figure 21-16. It is composed of an oxygen chamber, a nitrous oxide chamber, and a nitrous oxide slave control valve. All are interconnected by a mobile horizontal shaft. The pneumatic input into the device is from the oxygen and the nitrous oxide flowmeters. These flowmeters are unique because they have specific resistors located downstream from the flow control valves. These resistors create back pressures directed to the oxygen and nitrous oxide chambers. The value of the oxygen flow tube resistor is three to four times that of the nitrous oxide flow tube resistor, and the relative value of these resistors determines the value of the controlled fresh gas oxygen concentration. The back pressure in the oxygen and nitrous oxide chambers pushes against rubber diaphragms attached to the mobile horizontal shaft. Movement of the shaft regulates the nitrous oxide slave control valve, which feeds the nitrous oxide flow control valve.

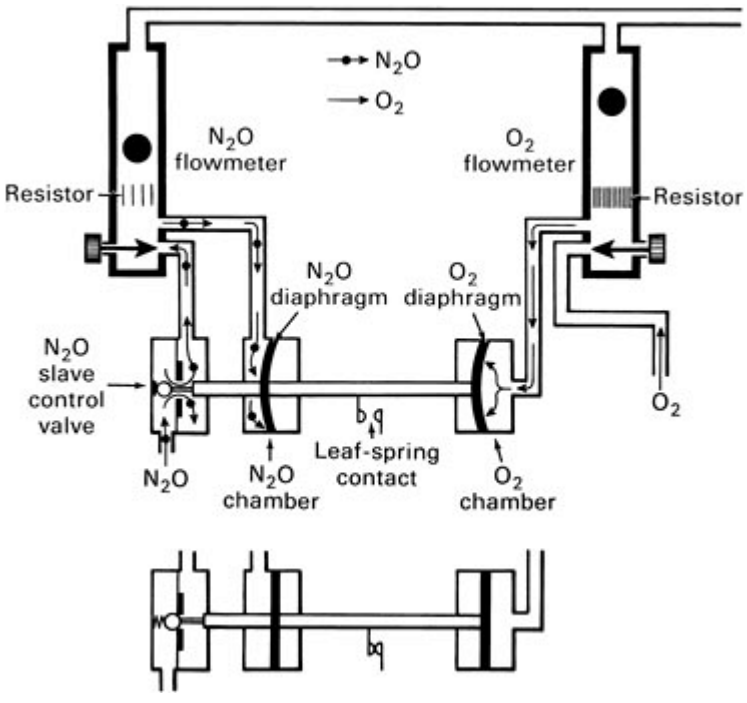

FIGURE 21-16. North American Dräger Oxygen Ratio Monitor Controller. See text for details. (Redrawn with permission from Schreiber P: Safety Guidelines for Anesthesia Systems.

Telford, Pennsylvania, North American Dräger, 1984.)

If the oxygen pressure is proportionally higher than the nitrous oxide pressure, the nitrous oxide slave control valve opens more widely, allowing more nitrous oxide to flow. As the nitrous oxide flow is increased manually, the nitrous oxide pressure forces the shaft toward the oxygen chamber. The valve opening becomes more restrictive and limits the nitrous oxide flow to the flowmeter.

Figure 21-16 illustrates the action of a single ORMC/S-ORC under different sets of circumstances. The back pressure exerted on the oxygen diaphragm, in the upper configuration is greater than that exerted on the nitrous oxide diaphragm. This causes the horizontal shaft to move to the left, opening the nitrous oxide slave control valve. Nitrous oxide is then able to proceed to its flow control valve and out through the flowmeter. In the bottom configuration, the nitrous oxide slave control valve is closed because of inadequate oxygen back pressure.[24] To summarize, in contrast to the Datex-Ohmeda Link-25 system that actively increases oxygen flow to maintain a fresh gas oxygen concentration greater than 25%, the Dräger ORMC and S-ORC are systems that limit nitrous oxide flow to prevent delivery of a fresh gas mixture with an oxygen concentration of less than 25%.

Limitations

Proportioning systems are not foolproof. Workstations equipped with proportioning systems can still deliver a hypoxic mixture under certain conditions. Following is a description of some of the situations in which this may occur.

Wrong Supply Gas. Both the Datex-Ohmeda Link-25 and the Dräger ORMC/S-ORC will be fooled if a gas other than oxygen is present in the oxygen pipeline. In the Link-25 System, the nitrous oxide and oxygen flow control valves will continue to be mechanically linked. Nevertheless, a hypoxic mixture can proceed to the common gas outlet. In the case of the Dräger ORMC or S-ORC, the rubber diaphragm for oxygen will reflect adequate supply pressure on the oxygen side even though the incorrect gas is present, and flow of both the wrong gas plus nitrous oxide will result. The oxygen analyzer is the only workstation monitor besides an integrated multigas analyzer that would detect this condition in either system.

Defective Pneumatics or Mechanics. Normal operation of the Datex-Ohmeda Link-25 and the North American Dräger ORMC/S-ORC is contingent on pneumatic and mechanical integrity.[42] Pneumatic integrity in the Datex-Ohmeda System requires properly functioning second-stage regulators. A nitrous oxide–oxygen ratio other than 3:1 will result if the regulators are not precise. The chain connecting the two sprockets must be intact. A 97% nitrous oxide concentration can occur if the chain is cut or broken.[43] In the North American Dräger System, a functional Oxygen Failure Protection Device (OFPD) is necessary to supply appropriate pressure to the ORMC. The mechanical aspects of the ORMC/S-ORC, such as the rubber diaphragms, the flow tube resistors, and the nitrous oxide slave control valve, must likewise be intact.

Leaks Downstream. The ORMC/S-ORC and the Link-25 function at the level of the flow control valves. A leak downstream from these devices, such as a broken oxygen flow tube (see Fig. 21-14), can result in delivery of a hypoxic mixture to the common gas outlet. In this situation, oxygen escapes through the leak, and the predominant gas delivered is nitrous oxide. The oxygen monitor and/or integrated multigas analyzer are the only machine safety devices that can detect this problem.[34] For the majority of its products, Dräger Medical recommends a preoperative positive pressure leak test to detect such a leak. However, in addition to this test, for many North American Dräger products, application of the negative-pressure leak test as well may provide a more sensitive way to detect such a leak. Datex-Ohmeda almost universally recommends a preoperative negative pressure leak test for its workstations, because of the frequently present

check valve located at the common gas outlet (see Checking Your Anesthesia Workstation section).

Inert Gas Administration. Administration of a third inert gas, such as helium, nitrogen, or CO_2, can cause a hypoxic mixture because contemporary proportioning systems link only nitrous oxide and oxygen.[44] Use of an oxygen analyzer is mandatory (or preferentially a multigas analyzer when available) if the operator uses a third gas.

Dilution of Inspired Oxygen Concentration by Volatile Inhaled Anesthetics. Volatile inhaled anesthetics, like inert gases, are added to the mixed gases downstream from both the flowmeters and the proportioning system. Concentrations of less-potent inhaled anesthetics such as desflurane may account for a larger percentage of the total fresh gas composition than more potent agents. This can be seen when the maximum vaporizer dial settings of the various volatile agents are examined (e.g., desflurane maximum dial setting 18% versus isoflurane maximum dial setting of 5%). Since significant percentages of these inhaled anesthetics may be added downstream of the proportioning system, the resulting gas/vapor mixture may contain an inspired oxygen concentration that is less than 21% oxygen despite a functional proportioning system. The anesthesia provider must be aware of this possibility, particularly when high concentrations of less potent volatile inhaled anesthetics are used.

Oxygen Flush Valve

The oxygen flush valve allows direct communication between the oxygen high-pressure circuit and the low-pressure circuit (see Fig. 21-3). Flow from the oxygen flush valve enters the low-pressure circuit downstream from the vaporizers and most importantly downstream from the Datex-Ohmeda machine outlet check valve. The spring-loaded oxygen flush valve stays closed until the operator opens it by depressing the oxygen flush button. Actuation of the valve delivers 100% oxygen at 35 to 75 L/min to the breathing circuit.[23]

The oxygen flush valve can provide a high pressure oxygen source suitable for jet ventilation under the following circumstances: (1) the anesthesia machine is equipped with a one-way check valve positioned between the vaporizers and the oxygen flush valve; and (2) when a positive pressure relief valve exists downstream of the vaporizers, this pressure relief valve must be upstream of the outlet check valve. Because the Ohmeda Modulus II has such a one-way check valve and its positive pressure relief valve is upstream from the check valve, the entire oxygen flow of 35 to 75 L/min is delivered to the common gas outlet at a high pressure of 50 psig. On the other hand, the Ohmeda Modulus II Plus and some Ohmeda Excel machines are not capable of functioning as an appropriate oxygen source for jet ventilation. The Ohmeda Modulus II plus, which does not have the check valve, provides only 7 psig at the common gas outlet because some oxygen flow travels retrograde through an internal relief valve located upstream from the oxygen flush valve. The Ohmeda Excel 210, which does have a one-way check valve, also has a positive pressure relief valve downstream from the check valve and therefore is unsuitable for jet ventilation. Older North American Dräger machines such as the Narkomed 2A (which also does not have the outlet check valve) provide an intermediate pressure of 18 psig to the common gas outlet because some pressure is vented retrograde through a pressure relief valve located in the vaporizers.[45]

Several hazards have been reported with the oxygen flush valve. A defective or damaged valve can stick in the fully open position, resulting in barotrauma.[46] A valve sticking in a partially open position can result in patient awareness because the

oxygen flow from the incompetent valve dilutes the inhaled anesthetic.[19,47] Improper use of normally functioning oxygen flush valves also can result in problems. Overzealous intraoperative oxygen flushing can dilute inhaled anesthetics. Oxygen flushing during the inspiratory phase of positive pressure ventilation can produce barotrauma in patients if the anesthesia machine does not incorporate fresh gas decoupling or an appropriately adjusted inspiratory pressure limiter. Anesthesia systems (Dräger Narkomed 6000 series, Julian, Fabius GS and Datascope Anestar) with fresh gas decoupling are inherently safer from the standpoint of minimizing the chance of producing barotrauma from inappropriate oxygen flush valve use. These systems physically

divorce the fresh gas inflow from either the flowmeters or the oxygen flush valve from the delivered tidal volume presented to the patient's lungs (see Fresh Gas Decoupling section). With traditional anesthesia breathing circuits, excess volume cannot be vented during the inspiratory phase of mechanical ventilation because the ventilator relief valve is closed and the Adjustable Pressure Limiting (APL) valve is either out-of-circuit or closed.[48] An alternative way to manage this problem can be seen on the Datex-Ohmeda S/5 ADU and Aestiva. These circle systems utilize an integrated adjustable pressure limiter. If this device is properly adjusted, it functions like the APL valve to limit the maximum airway pressure to a safe level, thereby reducing the possibility of barotrauma.

Some very old anesthesia systems made use of a freestanding vaporizer downstream from the common gas outlet; on these systems, oxygen flushing could rapidly deliver large quantities of inhaled anesthetic to the patient. Finally, inappropriate preoperative use of the oxygen flush to evaluate the low-pressure circuit for leaks can be misleading, particularly on Datex-Ohmeda machines with a one-way check valve at the common outlet.[18] Since back pressure from the breathing circuit closes the one-way check valve air-tight, major low-pressure circuit leaks can go undetected with this leak test (see Checking Your Anesthesia Workstation section).

VAPORIZERS

As dramatically as the evolution of the anesthesia workstation has been in recent years, vaporizers have also changed from rudimentary ether inhalers and copper kettles to the present temperature compensated, computer-controlled, and flow-sensing devices we use today. In 1993, with the introduction of desflurane to the clinical setting, an even more sophisticated vaporizer was introduced to handle the unique physical properties of this agent. Now, a new generation of anesthesia vaporizers blending both “old” copper kettle-like technology and “new” computerized control technology has emerged in the Datex-Ohmeda Aladin cassette vaporizer system. Before the discussion of variable bypass vaporizers, the Datex-Ohmeda Tec 6 desflurane vaporizer, and the Datex-Ohmeda Aladin cassette vaporizer, certain physical principles will be reviewed briefly to facilitate understanding of the operating principles, construction, and design of contemporary volatile anesthetic vaporizers.

Physics

Vapor Pressure

Contemporary inhaled volatile anesthetics exist in the liquid state at temperatures below 20°C. When a volatile liquid is in a closed container, molecules escape from the liquid phase to the vapor phase until the number of molecules in the vapor phase is constant. These molecules in the vapor phase bombard the wall of the container and create a pressure known as the *saturated vapor pressure*. As the temperature increases, more molecules enter the vapor phase, and the vapor pressure increases (Fig. 21-17). Vapor pressure is independent of atmospheric pressure and is contingent only on the temperature and physical characteristics of the liquid. The *boiling point* of a liquid is defined as that temperature at which the vapor pressure equals atmospheric pressure.[49,50,51] At 760 mm Hg, the boiling points for desflurane, isoflurane, halothane, enflurane, and sevoflurane are approximately 22.8, 48.5, 50.2, 56.5, and 58.5°C, respectively. Unlike other contemporary inhaled anesthetics, desflurane boils at temperatures that may be encountered in clinical settings such as pediatric and burn operating rooms. This unique physical characteristic alone mandates a special vaporizer design to control the delivery of desflurane. If agent-specific vaporizers are inadvertently misfilled with incorrect liquid anesthetic agents, the resulting mixtures of volatile agents may demonstrate unique properties from those of the individual component agents. The altered vapor pressure and other physical properties of the resulting azeotropic mixtures that result from the mixing of various agents may alter the output of the anesthetic vaporizer (see Variable Bypass Vaporizers: Misfilling section).[52]

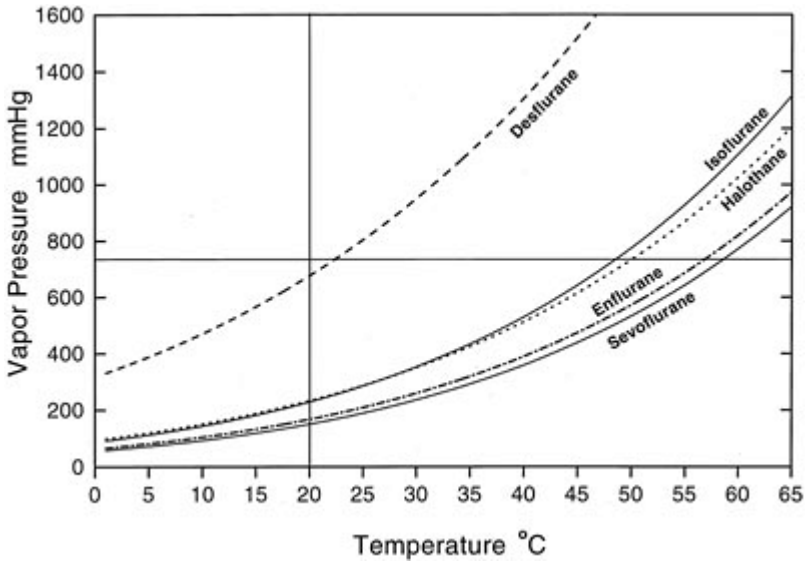

FIGURE 21-17. Vapor pressure versus temperature curves for desflurane, isoflurane, halothane, enflurane, and sevoflurane. The vapor pressure curve for desflurane is both steeper and shifted to higher vapor pressures when compared with the curves for other contemporary inhaled anesthetics. (From inhaled anesthetic package insert equations and from Susay SR, Smith MA, Lockwood GG: The saturated vapor pressure of desflurane at various temperatures. Anesth Analg 83:864, 1996.)

Latent Heat of Vaporization

When a molecule is converted from a liquid to the gaseous phase, energy is consumed because the molecules of a liquid tend to cohere. The amount of energy that is consumed for a given liquid as it is converted to a vapor is referred to as the *latent heat of vaporization.* It is more precisely defined as the number of calories required to change 1 g of liquid into vapor without a temperature change. The energy for vaporization must either come from the liquid itself or from an outside source. The temperature of the liquid itself will decrease during vaporization in the absence of an outside energy source. This energy loss can lead to significant decreases in temperature of the remaining liquid, and can greatly decrease subsequent vaporization.[49,51,53]

Specific Heat

The *specific heat* of a substance is the number of calories required to increase the temperature of 1 g of a substance by

1°C.[21,49,51] The substance can be a solid, liquid, or gas. The concept of specific heat is important to the design, operation, and construction of vaporizers because it is applicable in two ways. First, the specific heat value for an inhaled anesthetic is important because it indicates how much heat must be supplied to the liquid to maintain a constant temperature when heat is being lost during vaporization. Second, manufacturers select vaporizer component materials that have a high specific heat to minimize temperature changes associated with vaporization.

Thermal Conductivity

Thermal conductivity is a measure of the speed with which heat flows through a substance. The higher the thermal conductivity, the better the substance conducts heat.[49] Vaporizers are constructed of metals that have relatively high thermal conductivity, these help to maintain a uniform internal temperature.

Ambient Pressure Effects

See Datex-Ohmeda Tec-6 Vaporizer for Desflurane: Factors that Influence Vaporizer Output: Varied Altitudes.

Variable Bypass Vaporizers

The Datex-Ohmeda Tec 4, Tec 5, and Tec 7, as well as the North American Dräger Vapor 19.n and 20.n vaporizers are classified as variable bypass, flow-over, temperature-compensated, agent-specific, out of breathing circuit vaporizers.[49] *Variable bypass* refers to the method for regulating the anesthetic agent concentration output from the vaporizer. The concentration control dial setting determines the ratio of flow that goes through the bypass chamber and through the vaporizing chamber as fresh gas from the flowmeters enters the vaporizer inlet. The gas channeled through the vaporizing chamber flows over a wick system saturated with the liquid anesthetic and subsequently also becomes saturated with vapor. Thus, *flow-over* refers to the method of vaporization and is in contrast to a bubble-through system that may be seen in some copper kettle type vaporizers of old. The Tec 4, Tec 5, and Tec 7, and the DrägerVapor 19.n and 20.n are further classified as *temperature compensated.* Each of these is equipped with an automatic temperature-compensating device that helps maintain a constant vaporizer output over a wide range of operating temperatures. These vaporizers are *agent specific* and *out-of-circuit* because each is designed to accommodate a single anesthetic agent and to be physically located outside of the breathing circuit. Variable bypass vaporizers are used to deliver halothane, enflurane, isoflurane, and sevoflurane, but not desflurane.

Basic Operating Principles

A diagram of a generic, variable bypass vaporizer is shown in Figure 21-18. Vaporizer components include the concentration control dial, the bypass chamber, the vaporizing chamber, the filler port, and the filler cap. Using the filler port, the operator fills the vaporizing chamber with liquid anesthetic. The maximum safe fill level is predetermined by the position of the filler port, which is positioned to minimize the chance of overfilling. If a vaporizer is overfilled or tilted, liquid anesthetic can spill into the bypass chamber. If this were to happen, both the vaporizing chamber flow and the bypass chamber flow could potentially be carrying saturated anesthetic vapor, and an overdose would result. The concentration control dial is a variable restrictor, and it can be located either in the bypass chamber or the outlet of the vaporizing chamber. The function of the concentration control dial is to regulate the relative flow rates through the bypass and vaporizing chambers.

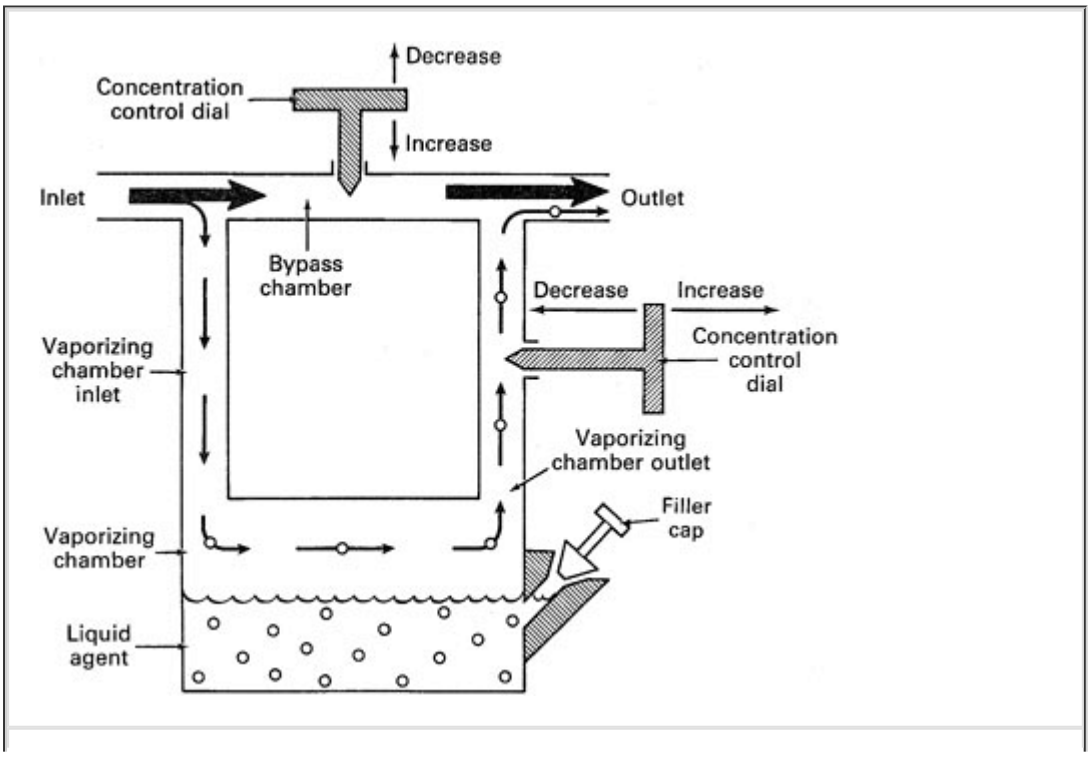

FIGURE 21-18. Generic variable bypass vaporizer. See text for details.

Flow from the flowmeters enters the inlet of the vaporizer. More than 80% of the flow passes straight through the bypass chamber to the vaporizer outlet, and this accounts for the name “bypass chamber.” Less than 20% of the flow from the flowmeters is diverted through the vaporizing chamber. Depending on the temperature and vapor pressure of the particular inhaled anesthetic, the fresh gases entering the vaporizing chamber entrain a specific flow of the inhaled anesthetic agent. The mixture that exits the vaporizer is the combination of flow through the bypass chamber, flow through the vaporizing chamber, and flow of entrained anesthetic vapor. The final concentration of inhaled anesthetic is the ratio of the flow of the inhaled anesthetic to the total gas flow.[49,54]

The vapor pressure of an inhaled anesthetic depends on the ambient temperature (see Fig. 21-17). For example, at 20°C the vapor pressure of isoflurane is 238 mm Hg, whereas at 35°C the vapor pressure almost doubles (450 mm Hg). Variable bypass vaporizers have an internal mechanism to compensate for variations in ambient temperature. The temperature-compensating valve of the Datex-Ohmeda Tec 4 is shown in Figure 21-19. At relatively high ambient temperatures, such as those commonly seen in operating rooms designated for the care of pediatric or burn patients, the vapor pressure inside

the vaporizing chamber is high. To compensate for this increased vapor pressure, the bimetallic strip of the temperature-compensating valve leans to the right, decreasing the resistance to flow through the bypass chamber. This allows more flow to pass through the bypass chamber and less flow to pass through the vaporizing chamber. In contrast, in a cold operating room environment, the vapor pressure inside the vaporizing chamber is reduced. To compensate for this decrease in vapor pressure, the bimetallic strip leans to the left. This increases the resistance to flow through the bypass chamber, causing more flow to pass through the vaporizing chamber and less to pass through the bypass chamber. The net effect in both situations is maintenance of relatively constant vaporizer output.

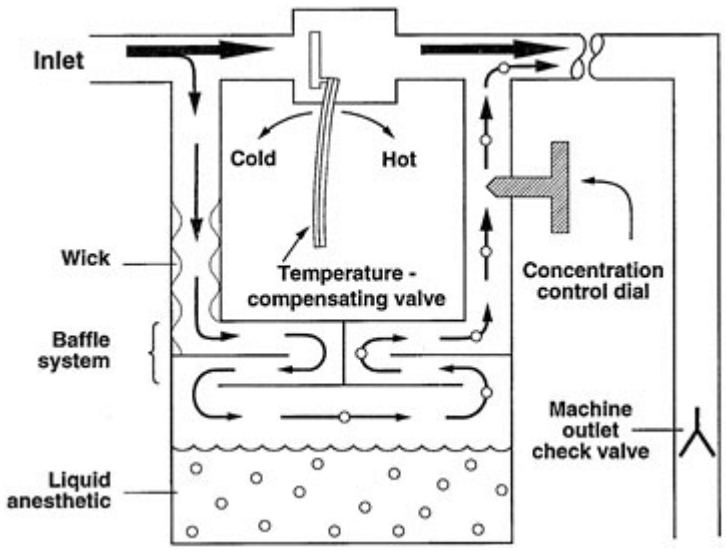

FIGURE 21-19. Simplified schematic of the Ohmeda Tec Type Vaporizer. See text for details.

Factors That Influence Vaporizer Output

If an ideal vaporizer existed, with a fixed dial setting, its output would be constant regardless of

varied flow rates, temperatures, back pressures, and carrier gases. Designing such a vaporizer is difficult because as ambient conditions change, the physical properties of gases and of vaporizers themselves can change.[54] Contemporary vaporizers approach ideal but still have some limitations. Even though some of the most sophisticated vaporizer systems now available use computer-controlled components and multiple sensors, they have yet to become significantly more accurate than conventional vaporizers. Several factors that affect vaporizer performance in general are described below.

Flow Rate. With a fixed dial setting, vaporizer output can vary with the rate of gas flowing through the vaporizer. This variation is particularly notable at extremes of flow rates. The output of all variable bypass vaporizers is less than the dial setting at low flow rates (less than 250 mL/min). This results from the relatively high density of volatile inhaled anesthetics. Insufficient turbulence is generated at low flow rates in the vaporizing chamber to upwardly advance the vapor molecules. At extremely high flow rates, such as 15 L/min, the output of most variable bypass vaporizers is less than the dial setting. This discrepancy is attributed to incomplete mixing and failure to saturate the carrier gas in the vaporizing chamber. Also, the resistance characteristics of the bypass chamber and the vaporizing chamber can vary as flow increases. These variations can result in decreased output concentration.[54]

Temperature. Because of improvements in design, the output of contemporary temperature-compensated vaporizers is almost linear over a wide range of temperatures. Automatic temperature-compensating mechanisms in the bypass chamber maintain a constant vaporizer output with varying temperatures.[23] As previously described, a bimetallic strip (see Fig. 21-19) or an expansion element (Fig. 21-20) directs a greater proportion of gas flow through the bypass chamber as temperatures increase.[54] Additionally, the wick systems are placed in direct contact with the metal wall of the vaporizer to help replace energy (heat) consumed during vaporization. The materials vaporizers are constructed from are chosen because they have a relatively high specific heat and high thermal conductivity. These factors help minimize the effect of cooling during vaporization.

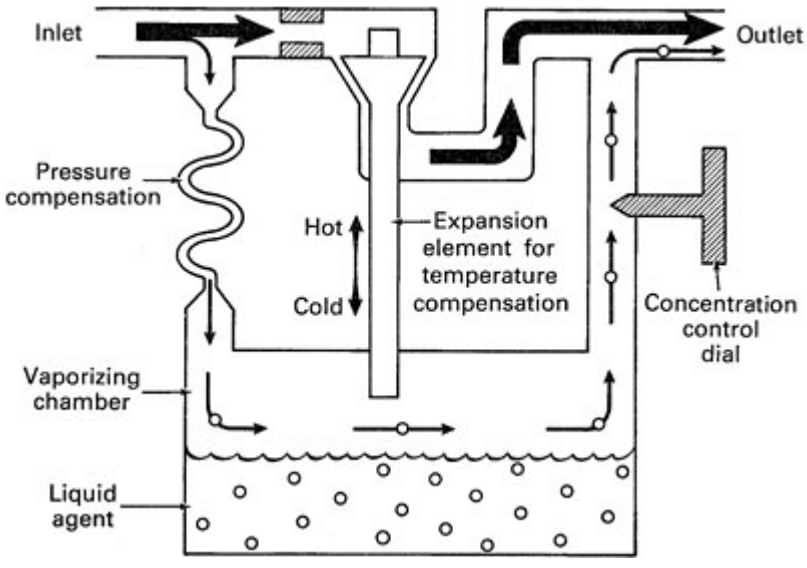

FIGURE 21-20. Simplified schematic of the North American Dräger Vapor 19.1 vaporizer. See text for details.

Intermittent Back Pressure. Intermittent back pressure that results from either positive pressure ventilation or use of the oxygen flush valve may result in higher than expected vaporizer output. This phenomenon, known as the *pumping effect*, is more pronounced at low flow rates, low dial settings, and low levels of liquid anesthetic in the vaporizing chamber.[49,54,55,56,57] Additionally, the pumping effect is increased by rapid respiratory rates, high peak inspired

pressures, and rapid drops in pressure during expiration.[47,48,49,50,51] Newer variable bypass vaporizers such as the Datex-Ohmeda Tec 4, Tec 5, and Tec 7, and North American Dräger Vapor 19.n and 20.n are relatively immune from the pumping effect. One proposed mechanism for the pumping effect is dependent on retrograde pressure transmission from the patient circuit to the vaporizer during the inspiratory phase of positive pressure ventilation. Gas molecules are compressed in both the bypass and vaporizing chambers. When the back pressure is suddenly released during the expiratory phase of positive-pressure ventilation, vapor exits the vaporizing chamber via both the vaporizing chamber outlet and retrograde through the vaporizing chamber inlet. This occurs because the output resistance of the bypass chamber is lower than that of the vaporizing chamber, particularly at low dial settings. The enhanced output concentration results from the increment of vapor that travels in the retrograde direction to the bypass chamber.[54,55,56,57]

To decrease the pumping effect, the vaporizing chambers of newer systems are smaller than those of early variable bypass vaporizers such as the Fluotec Mark II (750 mL).[56] Therefore, no substantial volumes of vapor can be discharged from the vaporizing chamber into the bypass chamber during the expiratory phase. The North American Dräger Vapor 19.1 and 20.n (see Fig. 21-20) have a long spiral tube that serves as the inlet to the vaporizing chamber.[56] When the pressure in the vaporizing chamber is released, some of the vapor enters this tube but does not enter the bypass chamber because of tube length.[50] The Tec 4 (see Fig. 21-19) has an extensive baffle system in the vaporizing chamber, and a one-way check valve has been inserted at the common gas outlet to minimize the pumping effect. This check valve attenuates but does not eliminate the pressure increase because gas still flows from the flowmeters to the vaporizer during the inspiratory phase of positive pressure ventilation.[49,58]

Carrier Gas Composition. Vaporizer output is influenced by the composition of the carrier gas that flows through the vaporizer.[59,60,61,62,63,64,65,66] During experimental conditions, when the carrier gas is rapidly changed from 100% oxygen to 100% nitrous oxide, a sudden transient decrease in vaporizer output occurs, followed by a slow increase to a new steady-state value (Fig. 21-21B).[64,65] Because nitrous oxide is more soluble than oxygen in the halogenated liquid within the vaporizer sump, when this switch occurs the output from the vaporizing chamber is transiently reduced.[64] Once the anesthetic liquid is totally saturated with nitrous oxide, vaporizing chamber output increases somewhat, and a new steady state is established.

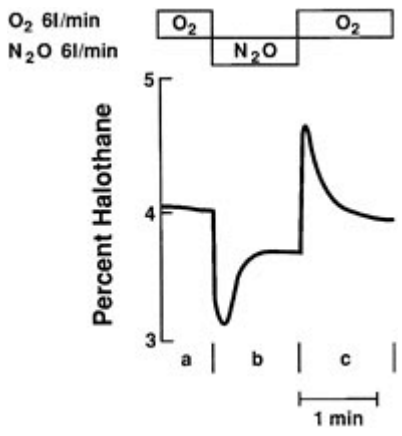

FIGURE 21-21. Halothane output of a North American Dräger Vapor 19.1 vaporizer with different carrier gases. The initial output concentration is approximately 4% halothane when oxygen is the carrier gas at flows of 6 L/min **(A)**. When the carrier gas is quickly switched to 100% nitrous oxide **(B)**, the halothane concentration decreases to 3% within 8 to 10 seconds. Then, a new steady-state concentration of approximately 3.5% is attained within 1 minute. See text for details. (Modified with permission from Gould DB, Lampert BA, MacKrell

TN: Effect of nitrous oxide solubility on vaporizer aberrance. Anesth Analg 61:939, 1982.)

The explanation for the new steady-state output value is less well understood.[66] With contemporary vaporizers such as the North American Dräger Vapor 19.n and 20.n and the Ohmeda Tec–type conventional vaporizers, the steady-state output value

is less when nitrous oxide rather than oxygen is the carrier gas (see Fig. 21-21B). Conversely, the output of some older vaporizers is enhanced when nitrous oxide is the carrier gas instead of oxygen.[59,61] The steady-state plateau is achieved more rapidly with increased flow rates, regardless of the ultimate output value.[65] Factors that contribute to the characteristic steady-state response resulting when various carrier gases are used include the viscosity and density of the carrier gas, the relative solubilities of the carrier gas in the anesthetic liquid, the flow-splitting characteristics of the specific vaporizer, and the concentration control dial setting.[61,64,65,66]

Safety Features

Newer generations of anesthesia vaporizers including the North American Dräger 19.n and 20.n, and the Datex-Ohmeda Tec 4, Tec 5, and Tec 7 now have built-in safety features that have minimized or eliminated many hazards once associated with variable bypass vaporizers. Agent-specific, keyed filling devices help prevent filling a vaporizer with the wrong agent. Overfilling of these vaporizers is minimized because the filler port is located at the maximum safe liquid level. Finally, today's vaporizers are firmly secured to a vaporizer manifold on the anesthesia workstation. Thus, problems associated with vaporizer tipping have become much less frequent. Contemporary interlock systems prevent administration of more than one inhaled anesthetic.

Hazards

Despite many safety features, some hazards are still associated with contemporary variable bypass vaporizers.

Misfilling. Vaporizers not equipped with keyed fillers have been occasionally misfilled with the wrong anesthetic liquid.[67] A potential for misfilling exists even on contemporary vaporizers equipped with keyed fillers.[68,69,70] When a vaporizer misfilling occurs, patients can inadvertently be rendered inadequately, or excessively, anesthetized depending on which drug is placed in the vaporizer. The use of a multigas analyzer may alert the user to such a problem.

Contamination. Contamination of anesthetic vaporizer contents has occurred by filling an isoflurane vaporizer with a contaminated bottle of isoflurane. A potentially serious incident was avoided because the operator detected an abnormal acrid odor.[71]

Tipping. Tipping of a vaporizer can occur when they are incorrectly “switched out” or moved. However, tipping is unlikely when a vaporizer is attached to the anesthesia workstation manifold short of the entire machine being turned over. Excessive tipping can cause the liquid agent to enter the bypass chamber and can cause output with extremely high agent concentration.[72] The Tec 4 is slightly more immune to tipping than the North American Dräger Vapor 19.n because of its extensive baffle system. However, if either vaporizer is tipped, it should not be used until it has been flushed for 20 to 30 minutes at high fresh gas flow rates. During this procedure, having the vaporizer concentration control dial set at a low concentration maximizes bypass chamber flow and will aid in removal of any residual liquid anesthetic in that area.[49] After following this procedure, the use of a multigas analyzer is strongly recommended. The Dräger Vapor 20.n series vaporizers now have a transport (“T”) dial setting that helps prevent tipping-related problems. When the dial is placed in this position, the vaporizer sump is isolated from the bypass chamber, thereby reducing the likelihood of tipping and a resulting accidental overdose. Therefore, any time one of these vaporizers is moved separate from the anesthesia workstation, the control dial should be placed in the “T” position.

The design of the Tec-6 and the Aladin cassette vaporizer systems, both from Datex-Ohmeda, has practically eliminated the possibility of tipping from these products. Since the Aladin cassette vaporizer's bypass chamber is physically separated from the “cassette,” and permanently resides in the anesthesia workstation, the possibility of tipping is virtually eliminated. Tipping of the Aladin cassettes themselves when they are not installed in the vaporizer is not problematic.

Overfilling. Improper filling procedures combined with failure of the vaporizer sight glass can cause overfilling and patient overdose. Liquid anesthetic enters the bypass chamber, and up to 10 times the intended vapor concentration can be delivered to the common gas outlet.[73] Most modern vaporizers are now relatively immune to overfilling because of side-fill rather than top-fill designs. Side-fill systems largely prevent overfilling.

Underfilling. Just as with overfilling, underfilling of anesthetic vaporizers may also be problematic. When a Tec 5 sevoflurane vaporizer is in a low-fill state and used under conditions of high fresh gas flow rates (>7.5 L/min) and high dial setting (such as seen during inhalational inductions), the vaporizer output may abruptly decrease to less than 2%. The causes of this problem are most likely multifactorial. However, the combination of low vaporizer fill state (<25% full) in combination with the high vaporizing chamber flow, can result in a clinically significant and reproducible fall in vaporizer output.[74]

Simultaneous Inhaled Anesthetic Administration. On some older anesthesia machines from Datex-Ohmeda that are equipped with the Select-a-Tec® three-vaporizer manifold that does not utilize a vapor-interlock system, two inhaled anesthetics can be administered simultaneously when the center vaporizer is removed. On such machines, the left or right vaporizer should be moved to the central position if the central vaporizer is removed (as indicated by the manifold warning label). Once this is done, the vaporizer's interlock system will allow only one agent to be administered at a time. More contemporary Select-a-Tec vaporizer manifolds have a built-in vapor-interlock or vapor-exclusion device that prevents this problem. On these newer three-vaporizer systems, a U-shaped plastic device links the vaporizer extension rods even when the vaporizers are not adjacent to one another on the manifold. On such a system, the manifold plus the vaporizers themselves comprise the vapor-interlock or vapor-exclusion system.

Leaks. Vaporizer leaks occur frequently, and can potentially result in patient awareness during anesthesia.[11,15,55,75] A loose filler cap is the most common source of vaporizer leaks. With

some key-filled Penlon and Dräger vaporizers, a loose filler screw clamp allows escape of saturated anesthetic vapor.[11] Leaks can occur at the O-ring junctions between the vaporizer and its manifold. To detect a leak within a vaporizer, the concentration control dial must be in the on position. Even though vaporizer leaks in Dräger Systems can potentially be detected with a conventional positive-pressure leak test (because of the absence of an outlet check valve), a negative-pressure leak test is more sensitive and allows the user to detect even small leaks. Datex-Ohmeda recommends a negative-pressure leak testing device (suction bulb) to detect vaporizer leaks in the Modulus I, Modulus II, Excel, and the Aestiva workstations because of the check valve located just upstream of each machine's fresh gas outlet (see Checking Your Anesthesia Workstation section).

Many newer anesthesia workstations are capable of performing self-testing procedures that, in some cases, may eliminate the need for the conventional negative-pressure leak testing. However, it is of vital importance that anesthesia providers understand that these self-tests may not detect internal vaporizer leaks on systems with add-on vaporizers. For the self-tests to determine if an internal vaporizer leak is present, the leak test must be repeated with each vaporizer sequentially while its concentration control dial is turned to the on position. Recall that when a vaporizer's concentration control dial is set in the off position, it may not be possible to detect even major internal leaks such as an absent or loose filler cap.

Anesthesia Vaporizers and Environmental Considerations. Today, more than ever, anesthetics are being administered to patients outside the operating room. One such location that has proved sometimes difficult to work in is the MRI suite. The presence of a powerful magnet field, the significant noise pollution, and limited access to the patient during the procedure all

complicate care in this setting. It is imperative that only nonferrous (MRI compatible) equipment be used in these settings. Some anesthesia vaporizers, although they may appear nonferrous by testing with a horseshoe magnet, may indeed contain substantial internal ferrous components. Inappropriate use of such a device in an MRI suite may potentially turn them into a dangerous missile if left unsecured.[76]

The Datex-Ohmeda Tec 6 Vaporizer for Desflurane

8 Because of its unique physical characteristics, the controlled vaporization of desflurane required a novel approach to vaporizer design. Datex-Ohmeda developed the Tec 6 vaporizer, the first such system, and released it into clinical use in the early 1990s. The Tec 6 vaporizer is an electrically heated, pressurized device specifically designed to deliver desflurane.[77,78] The vapor pressure of desflurane is three to four times that of other contemporary inhaled anesthetics, and it boils at 22.8°C,[79] which is near room temperature (see Fig. 21-17). Desflurane has a minimum alveolar anesthetic concentration (MAC) value of 6 to 7%.[79] Desflurane is valuable because it has a low blood gas solubility coefficient of 0.45 at 37°C, and recovery from anesthesia is more rapid than with many other potent inhaled anesthetics.[79] In 2004, Dräger Medical received FDA approval for its own version of the Tec 6 desflurane vaporizer. The operating principles described in the following discussion are applicable to either system, even though we refer to the Tec 6 specifically.

Unsuitability of Contemporary Variable Bypass Vaporizers for Controlled Vaporization of Desflurane

9 Desflurane's high volatility and moderate potency preclude its use with contemporary variable bypass vaporizers such as Datex-Ohmeda Tec 4, Tec 5, and Tec 7, or the North American Dräger Vapor 19.n or 20.n for two primary reasons:[77]

1. At 20°C the vapor pressure of desflurane is near one atmosphere.

   The vapor pressures of enflurane, isoflurane, halothane, and desflurane at 20°C are 172, 240, 244, and 669 mm Hg, respectively (see Fig. 21-17).[79] Equal amounts of flow through a traditional vaporizer would vaporize many more volumes of desflurane than any other of these agents. For example, at one atmosphere and 20°C, 100 mL/min passing through the vaporizing chamber would entrain 735 mL/min desflurane versus 29, 46, and 47 mL/min of enflurane, isoflurane, and halothane, respectively.[77] Under these same conditions, to produce 1% desflurane output the amount of bypass flow necessary to achieve sufficient dilution of the large volume of desflurane saturated anesthetic vapor would be approximately 73 L/min, compared to 5 L/min or less for the other three anesthetics. Additionally, above 22.8°C at one atmosphere, desflurane will boil. The amount of vapor produced would be limited only by the heat energy available from the vaporizer owing to its specific heat.[77]

2. Contemporary vaporizers lack an external heat source.

   The latent heat of vaporization for desflurane is approximately equal to that of enflurane, isoflurane, and halothane; however its MAC is 4 to 9 times higher than those of the other three inhaled anesthetics. Thus, the absolute amount of desflurane vaporized over a given time period is considerably greater than the other anesthetic drugs. Supplying desflurane via a conventional vaporizer in higher (equivalent MAC) concentrations would lead to excessive cooling of the vaporizer and would significantly reduce its output. In the absence of an external heat source, temperature compensation using traditional mechanical devices would be almost impossible. Because of the broad range of temperatures seen in the clinical setting, and because of desflurane's steep vapor pressure versus temperature curve (see Fig. 21-17), the delivery of desflurane in a conventional anesthetic vaporizer would be at best unpredictable.[77]

Operating Principles of the Tec 6 and Tec 6 Plus

To achieve controlled vaporization of desflurane, Datex-Ohmeda introduced the Tec 6 vaporizer to widespread clinical practice in 1993. This was the first clinically available vaporizer ever to be electrically heated and pressurized. The physical appearance and operation of the Tec 6 are similar to contemporary vaporizers, but some aspects of the internal design and operating principles are radically different. The Tec 6 Plus represents a later version of the original Tec 6. The Tec 6 Plus has the same basic Tec 6 design, but also incorporates an enhanced audible alarm system not previously available on the Tec 6.

Functionally, the Tec 6's operation is more accurately described as a dual-gas blender than as a vaporizer. A simplified schematic of the Tec 6 is shown in Figure 21-22. The vaporizer has two independent gas circuits arranged in parallel. The fresh gas circuit is shown in gray, and the vapor circuit is shown in white. The fresh gas from the flowmeters enters at the fresh gas inlet, passes through a fixed restrictor (R1), and exits at the vaporizer gas outlet. The vapor circuit originates at the desflurane sump, which is electrically heated and thermostatically controlled to 39°C, a temperature well above desflurane's boiling point. The heated sump assembly serves as a reservoir of desflurane vapor. At 39°C, the vapor pressure in the sump is approximately 1,300 mm Hg absolute,[80] or approximately 2 atmospheres absolute (see Fig. 21-17). Just downstream from the sump is the shutoff valve. After the vaporizer warms up, the shutoff valve fully opens when the concentration control valve is turned to the on position. A pressure-regulating valve located

downstream from the shutoff valve downregulates the pressure to approximately 1.1 atmospheres absolute (74 mm Hg gauge) at a fresh gas flow rate of 10 L/min. The operator controls desflurane output by adjusting the concentration control valve (R2), which is a variable restrictor.[77]

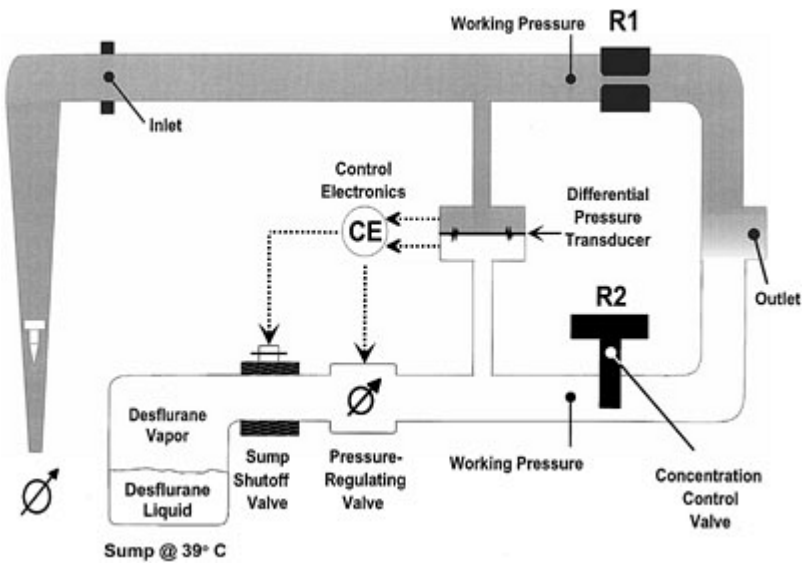

FIGURE 21-22. Simplified schematic of the Tec 6 desflurane vaporizer. (From Andrews JJ: Operating Principles of the Ohmeda Tec 6 Desflurane Vaporizer: A Collection of Twelve Color Illustrations. Washington, DC, Library of Congress, Copyright 1996, with permission.)

The vapor flow through R2 joins the fresh gas flow through R1 at a point downstream from the restrictors. Until this point, the two circuits are physically divorced. They are interfaced pneumatically and electronically, however, through differential pressure transducers, a control electronics system, and a pressure-regulating valve. When a constant fresh gas flow rate encounters the fixed restrictor, R1, a specific back pressure, proportional to the fresh gas flow rate, pushes against the diaphragm of the control differential pressure transducer. The differential pressure transducer conveys the pressure difference between the fresh gas circuit and the vapor

circuit to the control electronics system. The control electronics system regulates the pressure-regulating valve so that the pressure in the vapor circuit equals the pressure in the fresh gas circuit. This equalized pressure supplying R1 and R2 is the working pressure, and the working pressure is constant at a fixed fresh gas flow rate. If the operator increases the fresh gas flow rate, more back pressure is exerted upon the diaphragm of the control pressure transducer, and the working pressure of the vaporizer increases.[77]

Table 21-2 shows the approximate correlation between fresh gas flow rate and working pressure for a typical vaporizer. At a fresh gas flow rate of 1 L/min, the working pressure is 10 millibars, or 7.4 mm Hg gauge. At a fresh gas flow rate of 10 L/min, the working pressure is 100 millibars, or 74 mm Hg gauge. Therefore, there is a linear relationship between fresh gas flow rate and working pressure. When the fresh gas flow rate is increased 10-fold, the working pressure increases 10-fold.[77]

TABLE 21-2 Fresh Gas Flow Rate Versus Working Pressure

▪FRESH GAS FLOW RATE (L/min)	▪WORKING PRESSURE AT R1 AND R2 (GAUGE)(GAS INLET PRESSURE)

Listed below are two specific examples to demonstrate the operating principles of the Tec 6.[77]

Example A: Constant fresh gas flow rate of 1 L/min, with an increase in the dial setting.

With a fresh gas flow rate of 1 L/min, the working pressure of the vaporizer is 7.4 mm Hg. That is, the pressure supplying R1 and R2 is 7.4 mm Hg. As the operator increases the dial setting, the opening at R2 becomes larger, allowing more vapor to pass through R2. Specific vapor flow values at different dial settings are shown in Table 21-3.

Example B: Constant dial setting with an increase in fresh gas flow from 1 to 10 L/min.

At a fresh gas flow rate of 1 L/min, the working pressure is 7.4 mm Hg, and at a dial setting of 6% the vapor flow rate through R2 is 64 mL/min (see Tables 21-2 and 21-3). With a 10-fold increase in the fresh gas flow rate, there is a concomitant 10-fold increase in the working pressure to 74 mm Hg. The ratio of resistances of R2 to R1 is constant at a fixed dial setting of 6%. Because R2 is supplied by 10 times more pressure, the vapor flow rate through R2 increases 10-fold to 640 mL/min. Vaporizer output is constant because both the fresh gas flow and the vapor flow increase proportionally.

TABLE 21-3 Dial Setting Versus Flow Through Restrictor R2

Factors that Influence Vaporizer Output

Varied altitude and carrier gas composition influence Tec 6 output. Each is discussed in the following sections.

Varied Altitudes. Although ambient pressure changes affect conventional vaporizer output significantly in terms of volumes percent (%v/v, i.e. concentration), their effect on anesthetic potency (i.e. partial pressure) is minimal. This effect is illustrated using the example of isoflurane shown in Table 21-4. With a constant dial setting of 0.89%, at 1 atm (760 mm Hg), if perfectly calibrated, the %v/v delivered would be 0.89% and the partial pressure of isoflurane would be 6.8 mm Hg. Maintaining the same dial setting and lowering ambient pressure to 0.66 atm or 502 mm Hg (roughly equivalent to 10,000 ft elevation) would result in an increase in the concentration output to 1.75% (almost double), but the partial pressure only increases to 8.77 mm Hg (only a 29% increase) because of the proportionate decline in ambient pressure.

TABLE 21-4 Performance of Tec Type Vaporizers vs. the Tec 6 Desflurane Vaporizer at Varying Ambient Pressures

	·ISOFLURANE VAPORIZER WITH A DIAL SETTING OF 0.89%			·TEC 6 DESFLURANE VAPORIZER WITH A DIAL SETTING OF 6%
·AMBIENT PRESSURE	·cc ISOFLURANE VAPOR ENTRAINED	·OUTPUT CONCENTRATION IN PERCENT	·PARTIAL PRESSURE OUTPUT (mm Hg)	·Partial PRESSURE OUTPUT OF DESFLURANE

·ATMOSPHERES	(mm Hg)	BY 100 cc O_2			(mm Hg)
0.66 (2/3)	500 (10,000 feet)	91	1.753%	8.77	30
0.74	560	74	1.429%	8.0	33.6
0.80	608 (6,564 feet)	64.32	1.25%	7.6	36.5
1.0	760	46	0.89%	6.8	45.6
1.5	1,140	26.4	0.515%	5.87	68.4
2	1,520	19	0.36%	5.5	91.2
3	2,280	11.65	0.228%	5.198	136
(The following were assumed: 5,000 cc bypass chamber flow, 100 cc vaporizing chamber flow - Equivalent to an isoflurane dial setting of 0.89%)					

It is generally considered that the partial pressure of the anesthetic agent in the central nervous system, not its concentration, is responsible for the anesthetic effect. To obtain a consistent depth of anesthesia when gross changes in barometric pressure occur, the %v/v must be changed in inverse

proportion to the barometric pressure. For the most part, traditional variable bypass vaporizers automatically compensate for this change and for practical purposes the effect of barometric pressure can generally be ignored.

This should be considered in stark contrast to the response of the Tec-6 desflurane vaporizer at varied altitudes (Table 21-4). One must remember this device is more accurately described as a dual gas “blender” than a vaporizer. Regardless of the ambient pressure, the Tec-6 will maintain a constant concentration of vapor output (%v/v), not a constant partial pressure. This means that at high altitudes, the partial pressure of desflurane for any given dial setting will be decreased in proportion to the atmospheric pressure divided by the calibration pressure (normally 760 mm Hg) per the following formula.

$$\text{Required Dial Setting} = \frac{\text{Normal Dial Setting (\%v/v)} \times 760 \text{ mm Hg}}{\text{Ambient Pressure (mm Hg)}}$$

For example at an altitude of 2000 m (6564 ft) where the ambient pressure is 608 mm Hg, the Tec-6 dial setting must be advanced from 10%v/v to 12.5%v/v to avoid underdosing that could potentially result in patient awareness. Conversely, the Tec-6's maintenance of a constant %v/v in hyperbaric conditions could produce significant increases in partial pressure output, and if not accounted for, the potential for anesthetic overdose. Therefore, in hyperbaric settings the Tec-6 dial setting would need to be reduced to maintain the desired partial pressure output of

desflurane.

Carrier Gas Composition. Vaporizer output approximates the dial setting when oxygen is the carrier gas because the Tec 6 vaporizer is calibrated using 100% oxygen. At low flow rates when a carrier gas other than 100% oxygen is used, however, a clear trend toward reduction in vaporizer output emerges. This reduction parallels the proportional decrease in viscosity of the carrier gas. Nitrous oxide has a lower viscosity than oxygen, so the back pressure generated by resistor R1 (see Fig. 21-22) is less when nitrous oxide is the carrier gas, and the working pressure is reduced. At low flow rates using nitrous oxide as the carrier gas, vaporizer output is approximately 20% less than the dial setting. This suggests that, at clinically useful fresh gas flow rates, the gas flow across resistor R1 is laminar, and the working pressure is proportional to both the fresh gas flow rate and the viscosity of the carrier gas.[81]

Safety Features

Because desflurane's vapor pressure is near one atmosphere, misfilling contemporary vaporizers with desflurane could theoretically result in both desflurane overdose and creation

of a hypoxic gas mixture.[82] Datex-Ohmeda has introduced a unique, anesthetic-specific filling system to minimize occurrence of this potential hazard. The agent-specific filler of the desflurane bottle known as the “Saf-T-Fill” adapter is intended to prevent its use with traditional vaporizers. The filling system also minimizes spillage of liquid or vapor anesthetic by maintaining a “closed system” during the filling process. Each desflurane bottle has a spring-loaded filler cap with an O-ring on the tip. The spring seals the bottle until it is engaged in the filler port of the vaporizer. Thus, this anesthetic-specific filling system interlocks the vaporizer and the dispensing bottle, preventing loss of anesthetic to the atmosphere. A case report described the misfilling of a Tec 6 desflurane vaporizer with sevoflurane. This error was possible because of similarities between a new type of keyed filler for sevoflurane and the desflurane Saf-T-fill adapter. In this case, the desflurane vaporizer detected this error and automatically shut itself off.[70]

Major vaporizer faults cause the shutoff valve located just downstream from the desflurane sump (see Fig. 21-22) to close, producing a no-output situation. The valve is closed and a “no-output” alarm is activated immediately if any of the following conditions occur: (1) the anesthetic level decreases to below 20 mL; (2) the vaporizer is tilted; (3) a power failure occurs; or (4) there is a disparity between the pressure in the vapor circuit versus the pressure in the fresh gas circuit exceeding a specified tolerance.

Summary

The Tec 6 vaporizer is an electrically heated, thermostatically controlled, constant-temperature, pressurized, electromechanically coupled dual circuit, gas-vapor blender. The pressure in the vapor circuit is electronically regulated to equal the pressure in the fresh gas circuit. At a constant fresh gas flow rate, the operator regulates vapor flow using a conventional concentration control dial. When the fresh gas flow rate increases, the working pressure increases proportionally. For a given concentration setting even when varying the fresh gas flow rate, the vaporizer output is constant because the amount of flow through each circuit remains proportional.[77]

The Datex-Ohmeda Aladin Cassette Vaporizer

The vaporizer system used in the Datex-Ohmeda S5/Anesthesia Delivery Unit (ADU) is unique in that the single electronically controlled vaporizer is designed to deliver five different inhaled anesthetics including halothane, isoflurane, enflurane, sevoflurane, and desflurane. The vaporizer consists of a permanent internal control unit housed within the ADU and an interchangeable Aladin agent cassette that contains anesthetic liquid. The Aladin agent cassettes are color coded for each anesthetic agent, and they are also magnetically coded so that the Datex-Ohmeda ADU can identify which anesthetic cassette has been inserted. The cassettes are filled using agent-specific fillers.[49]

Though very different in external appearance, the functional anatomy of the S/5 ADU cassette vaporizer (Fig. 21-23) is very similar to that of the Dräger vapor 19.1 and 20.n and the Datex-Ohmeda Tec 4, Tec 5, and Tec 7 vaporizers. The Aladin system is functionally similar to these conventional vaporizers because it is also made up of a bypass chamber and vaporizing chamber. A fixed restrictor is located in the bypass chamber, and flow measurement sensors are located both in the bypass chamber and in the outlet of the vaporizing chamber. The heart of the S/5 ADU cassette vaporizer is the electronically regulated flow control valve located in the vaporizing chamber outlet. This valve is controlled by a central processing unit (CPU). The CPU receives input from multiple sources including the concentration control dial, a pressure sensor located inside the vaporizing chamber, a temperature sensor located inside the vaporizing chamber, a flow measurement unit located in the bypass chamber, and a flow measurement unit located in the outlet of the vaporizing chamber. The CPU also receives input from the flowmeters regarding the composition of the carrier gas. Using data from these multiple sources, the CPU is able to precisely regulate the flow control valve to attain the desired vapor concentration output. Appropriate electronic control of the flow control valve is essential to the proper function of this vaporizer.[49,84]

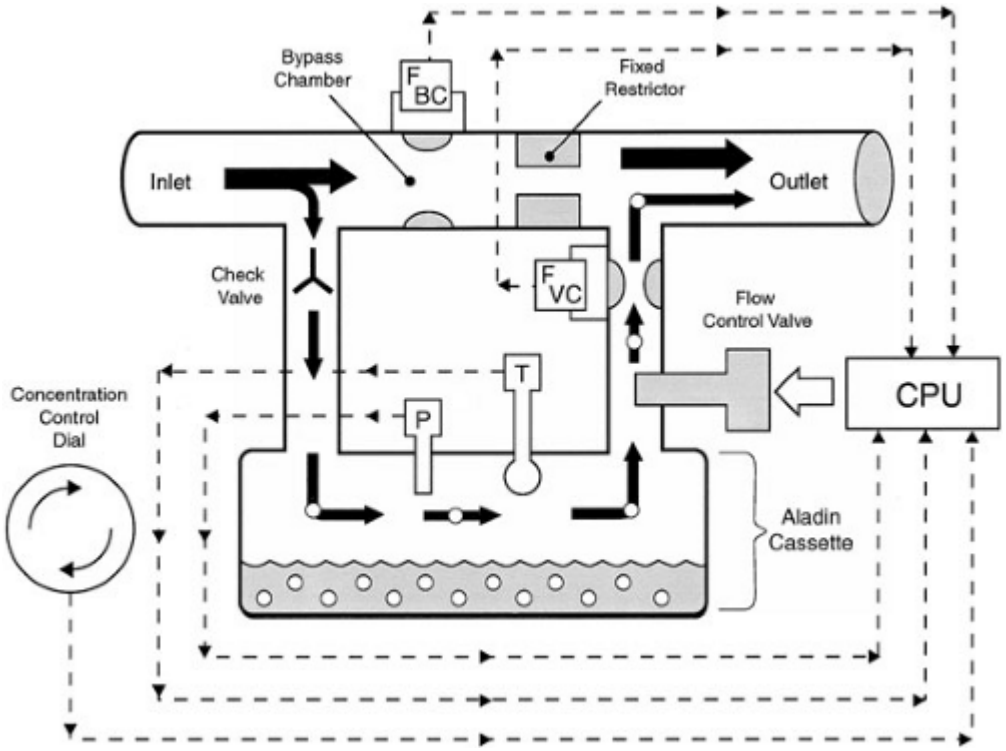

FIGURE 21-23. Simplified schematic of Datex-Ohmeda Aladin Cassette Vaporizer. The *black arrows* represent flow from the flowmeters, and the *white circles* represent anesthetic vapor. The heart of the vaporizer is the electronically controlled flow control valve located in the outlet of the vaporizing chamber. CPU, central processing unit; F_{BC}, flow measurement unit, which measures flow through the bypass chamber; F_{VC} = flow measurement unit, which measures flow through the vaporizing chamber; P, pressure sensor; T, temperature sensor. (Modified from Andrews JJ: Operating Principles of the Datex-Ohmeda Aladin Cassette Vaporizer: A Collection of Color Illustrations. Washington, DC, Library of Congress, 2000.)

A fixed restrictor is located in the bypass chamber, and it causes flow from the vaporizer inlet to split into two flow streams (see Fig. 21-23). One stream passes through the

bypass chamber, and the other portion enters the inlet of the vaporizing chamber and passes through a one-way check valve. The presence of this check valve is unique to the Aladin system. This one-way valve prevents retrograde flow of the anesthetic vapor back into the bypass

chamber, and its presence is crucial when delivering desflurane if the room temperature is greater than the boiling point for Desflurane (22.8°C).[49] A precise amount of vapor-saturated carrier gas passes through the flow control valve, which is regulated by the CPU. This flow then joins the bypass flow and is directed to the outlet of the vaporizer.[49]

As mentioned during the discussion of the Tec 6, the controlled vaporization of desflurane presents a unique challenge, particularly when the room temperature is greater than the boiling point of desflurane (22.8°C). At higher temperatures, the pressure inside the vaporizer sump increases, and the sump becomes pressurized. When the sump pressure exceeds the pressure in the bypass chamber, the one-way check valve located in the vaporizing chamber inlet closes preventing carrier gas from entering the vaporizing chamber. At this point, the carrier gas passes straight through the bypass chamber and its flow sensor. Under these conditions, the electronically regulated flow control valve simply meters in the appropriate flow of pure desflurane vapor needed to achieve the desired final concentration selected by the user. At least one case report has described a failure of the vaporizing chamber inlet check valve to function as designed. In this case, an anesthetic overdose occurred as a result of regurgitation of desflurane from the vaporizing chamber in a retrograde fashion back into the bypass chamber. This report merits ADU users to be cautious of this potential problem, especially when desflurane is used.[84]

During operating conditions in which high fresh gas flow rates and/or high dial settings are used, large quantities of anesthetic liquid are rapidly vaporized. As a result, the temperature of the remaining liquid anesthetic and the vaporizer itself decrease as a result of energy consumption of the latent heat of vaporization. To offset this cooling effect, the S/5 ADU is equipped with a fan that forces warmed air from an “agent heating resistor” across the cassette (vaporizer sump) to raise its temperature when necessary. The fan is activated during two common clinical scenarios: (1) desflurane induction and maintenance, and (2) sevoflurane induction.

ANESTHETIC BREATHING CIRCUITS

As the prescribed mixture of gases from the flowmeters and vaporizer exits the anesthesia workstation at the common gas outlet, it then enters an anesthetic breathing circuit. The function of the anesthesia breathing circuit is not only to deliver oxygen and anesthetic gases to the patient, but also to eliminate CO_2. CO_2 can be removed either by washout with adequate fresh gas inflow or by the use of CO_2 absorbent media (e.g., soda lime absorption). The following discussion focuses on the semiclosed rebreathing circuits and the circle system.

Mapleson Systems

In 1954 Mapleson described and analyzed five different semiclosed anesthetic systems, and they are now classically referred to as the Mapleson Systems and are designated with letters A through E (Fig. 21-24).[85] Subsequently in 1975, Willis et al described the F system that was added to the original five.[86] The Mapleson Systems consist of several common components. Theses components commonly include a facemask, a spring-loaded pop-off valve, reservoir tubing, fresh gas inflow tubing, and a reservoir bag. Within the Mapleson Systems, three distinct functional groups can be seen. They include the A, the BC, and DEF groups. The Mapleson A, also known as the Magill Circuit, has a spring-loaded pop-off valve located near the facemask, and the fresh gas flow enters the opposite end of the circuit near the reservoir bag. In the B and C systems, the spring-loaded pop-off valve is located near the facemask, but the fresh gas inlet tubing is located near the patient. The reservoir tubing and breathing bag serve as a blind limb where fresh gas, dead space gas, and alveolar gas can collect. Finally, in the Mapleson D, E, F group or “T-piece” group, the fresh gas enters near the patient, and excess gas is popped off at the opposite end of the circuit.

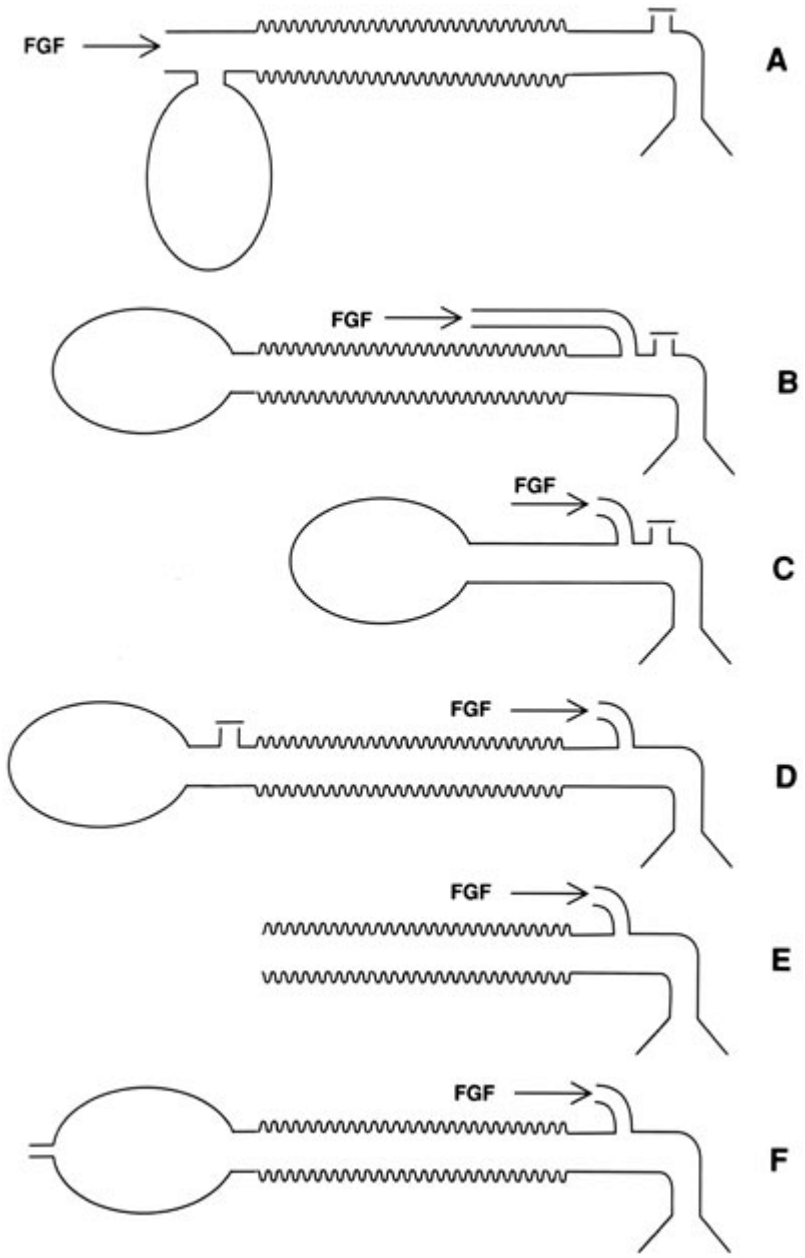

FIGURE 21-24. Mapleson Breathing Systems **A-F.** (Redrawn with permission. Willis BA, Pender JW, Mapleson WW: Rebreathing in a T-piece: Volunteer and Theoretical Studies of the Jackson-Rees Modification of Ayre's T-piece during spontaneous respiration. Br J Anaesth 47:1239, 1975.)

Even though the components and component arrangement are simple, functional analysis of the Mapleson Systems can be complex.[87,88] The amount of CO_2 rebreathing associated with each system is multifactorial, and variables which dictate the ultimate CO_2 concentration include the following: (1) the fresh gas inflow rate, (2) the minute ventilation, (3) the mode of ventilation (spontaneous or controlled), (4) the tidal volume, (5) the respiratory rate, (6) the I:E ratio, (7) the duration of the expiratory pause, (8) the peak inspiratory flow rate, (9) the volume of the reservoir tube, (10) the volume of the breathing

bag, (11) ventilation by mask, (12) ventilation through an endotracheal tube, and (13) the CO_2 sampling site.

The performance of the Mapleson Systems is best understood by studying the expiratory phase of the respiratory cycle.[89] Illustrations of the various Mapleson System component arrangements may be found in Figure 21-24. During spontaneous ventilation, the Mapleson A has the best efficiency

of the six systems requiring a fresh gas inflow rate of only one times the minute ventilation to prevent rebreathing of CO_2. But it has the worst efficiency during controlled ventilation, requiring a minute ventilation as high as 20 L/min to prevent rebreathing. Systems DEF are slightly more efficient than systems BC. To prevent rebreathing CO_2, the DEF systems require a fresh gas inflow rate of approximately 2.5 times the minute ventilation, whereas the fresh gas inflow rates required for BC systems are somewhat higher.[88]

The following summarizes the relative efficiency of different Mapleson Systems with respect to prevention of rebreathing, during spontaneous ventilation: A > DFE > CB. During controlled ventilation, DFE > BC > A.[85,88] The Mapleson A, B, and C systems are rarely used today, but the D, E, F systems are commonly employed. In the United States, the most popular representative from the D, E, F group is the Bain Circuit, and it will be discussed in the next section.

Bain Circuit

The Bain circuit is a coaxial circuit and a modification of the Mapleson D system. The fresh gas flows through a narrow inner tube within the outer corrugated tubing.[91] The central fresh gas tubing enters the outer corrugated hose near the reservoir bag, but the fresh gas actually empties into the circuit at the patient end (Fig. 21-25). Exhaled gases enter the corrugated tubing and are vented through the expiratory valve near the reservoir bag. The Bain circuit may be used for both spontaneous and controlled ventilation. The fresh gas inflow rate necessary to prevent rebreathing is 2.5 the minute ventilation.

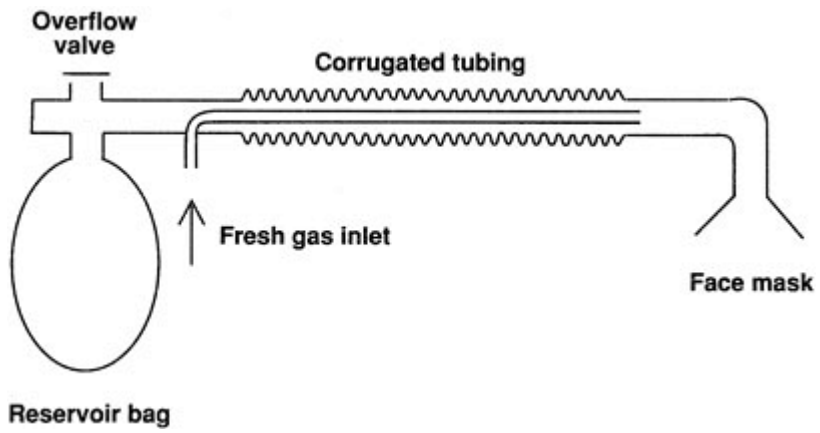

FIGURE 21-25. The Bain Circuit. (Redrawn with permission from Bain JA, Spoerel WE: A streamlined anaesthetic system. Can Anaesth Soc J 19:426, 1972.)

The Bain circuit has many advantages over other systems. It is lightweight, convenient, easily sterilized, and may be reusable. Scavenging of the gases from the expiratory valve is facilitated because the valve is located away from the patient. Exhaled gases in the outer reservoir tubing add warmth by countercurrent heat exchange to inspired fresh gases. The main hazards related to the use of the Bain circuit are either an unrecognized disconnection or kinking of the inner fresh gas hose. These problems can cause hypercarbia from inadequate gas flow or increased respiratory resistance. As with other circuits, an obstructed antimicrobial filter positioned between the Bain circuit and the endotracheal tube can result in increased resistance in the circuit. This may produce hypoventilation and hypoxemia, and may even mimic the signs and symptoms of severe bronchospasm.[92]

The outer corrugated tube should be transparent to allow ongoing inspection of the inner tube. The integrity of the inner tube can be assessed as described by Pethick.[93] With his technique, high-flow oxygen is fed into the circuit while the patient end is occluded until the reservoir bag is

filled. The patient end is opened, and oxygen is flushed into the circuit. If the inner tube is intact, the venturi effect occurs at the patient end. This causes a decrease in pressure within the circuit, and as a result, the reservoir bag deflates. Conversely, a leak in the inner tube allows the fresh gas to escape into the expiratory limb, and the reservoir bag will remain inflated. This test is recommended as a part of the pre-anesthesia check if a Bain circuit is used.

Circle Breathing Systems

For many years, the overall design of the circle breathing system has changed very little from one anesthesia workstation manufacturer to the next. Both the individual components and the order in which they appeared in the circle system were consistent across major platforms. More recently, however, with the increasing technological complexity of the anesthesia workstation, the circle system has gone through some major changes as well. These changes have resulted in part from an effort to improve patient safety (as in the integration of Fresh Gas Decoupling and Inspiratory Pressure Limiters), but have also allowed the deployment of new technological advances. Examples of major new technologies include (1) a return to the application of single-circuit piston-type ventilators and (2) use of new spirometry devices that are located at the Y-connector instead of at the traditional location on the expiratory circuit limb. The following discussion first focuses on the traditional circle breathing system, and then is followed by a brief discussion of some variations in the designs of newer circle systems.

The Traditional Circle Breathing System

The circle system remains the most popular breathing system in the United States. It is so named because its components are arranged in a circular manner (see Fig. 21-7). One version of the traditional circle system, referred to as either a “Universal F” or “single limb circuit,” has increased in popularity over recent years. Though these systems appear very different externally, they have the same overall functional layout as the traditional circle system and the following discussion is applicable to both the traditional circle system and the “Universal F” system.

The circle system prevents rebreathing of CO_2 by use of CO_2 absorbents but allows partial rebreathing of other exhaled gases. The extent of rebreathing of the other exhaled gases depends on breathing circuit component arrangement and the fresh gas flow rate. A circle system can be semiopen, semiclosed, or closed, depending on the amount of fresh gas inflow.[94] A semiopen system has no rebreathing and requires a very high flow of fresh gas. A semiclosed system is associated with some rebreathing of exhaled gases and is the most commonly used application in the United States. A closed system is one in which the inflow gas exactly matches that being taken up, or consumed, by the patient. In a closed system, there is complete rebreathing of exhaled gases after absorption of CO_2, and the overflow (pop-off or APL) valve or ventilator relief valve remains closed.

The circle system (see Fig. 21-7) consists of seven primary components, including the following: (1) a fresh gas inflow source; (2) inspiratory and expiratory unidirectional valves; (3) inspiratory and expiratory corrugated tubes; (4) a Y-piece connector; (5) an overflow or pop-off valve, referred to as the Adjustable Pressure-Limiting (APL) valve; (6) a reservoir bag;

and (7) a canister containing a CO_2 absorbent. The inspiratory and expiratory valves are placed in the system to ensure gas flow through the corrugated hoses remains unidirectional. The fresh gas inflow enters the circle by a connection from the common gas outlet of the anesthesia machine.

Numerous variations of the circle arrangement are possible, depending on the relative positions of the unidirectional valves, the pop-off valve, the reservoir bag, the CO_2 absorber, and the site of fresh gas entry. However, to prevent rebreathing of CO_2 *in a traditional circle system*, three rules must be followed: (1) a unidirectional valve must be located between the patient and the reservoir bag on both the inspiratory and expiratory limbs of the circuit; (2) the fresh gas inflow cannot enter the circuit between the expiratory valve and the patient; and (3) the overflow (pop-off) valve cannot be located between the patient and the inspiratory valve. If these rules are followed, any arrangement of the other components will prevent rebreathing of CO_2.[90] Some newer

anesthesia workstations now employ less traditional circle breathing systems. Two of these systems are discussed in detail below (see Anesthesia Workstation Variations section).

The most efficient circle system arrangement with the highest conservation of fresh gases is one in which the unidirectional valves are near the patient and the pop-off valve is located just downstream from the expiratory valve. This arrangement minimizes dead space gas and preferentially eliminates exhaled alveolar gases. A more practical arrangement, the one used on most conventional anesthesia machines (see Fig. 21-7), is somewhat less efficient because it allows alveolar and dead space gases to mix before they are vented.[95,96]

The main advantages of the circle system over other breathing systems include its (1) maintenance of relatively stabil inspired gas concentrations, (2) conservation of respiratory moisture and heat, and (3) prevention of operating room pollution. Additionally, the circle system can be used for closed system anesthesia or semiclosed with very low fresh gas flows. The major disadvantage of the circle system stems from its complex design. Commonly, the circle system may have 10 or more different connections. These multiple connection sites set the stage for misconnections, disconnections, obstructions, and leaks. In an ASA “closed claim” analysis of adverse anesthetic outcomes arising from gas delivery equipment, over one-third (25/72) of malpractice claims resulted from breathing circuit misconnections or disconnections.[1] Malfunction of the circle system's unidirectional valves can result in life-threatening problems. Rebreathing can occur if the valves stick in the open position, and total occlusion of the circuit can occur if they are stuck shut. If the expiratory valve is stuck in the closed position, breath-stacking and barotrauma or volutrauma can result. Obstructed filters located in the expiratory limb of the circle breathing system have caused increased airway pressures, hemodynamic collapse, and bilateral tension pneumothorax. Causes of circle system obstruction and failure include manufacturing defects, debris, patient secretions, and particulate obstruction from other odd sources such as albuterol nebulization.[97,98,99,100] Some systems, such as the Datex-Ohmeda 7900 SmartVent, use flow transducers located on both the inspiratory and expiratory limbs of the circle system. In one report cracks in the flow transducer tubing used by this system produced a leak in the circle system that was difficult to detect.[101]

CO_2 ABSORBENTS

In the early 2000s, there were several reports of adverse chemical reactions between CO_2 absorbent materials and anesthetic agents. Some of these undesirable interactions are quite dramatic such as sevoflurane interacting with desiccated Baralyme®, resulting in fires within the breathing system and severe patient injury.[102,103] Although other sources of ignition and fire in the breathing system continue to be described,[104] the Baralyme®-sevoflurane problem is somewhat unique in that nothing “unusual” is added to or removed from the breathing system for this to occur. Other reactions such as desflurane or sevoflurane with desiccated strong base absorbents can produce more insidious patient morbidity and even death from the release of byproducts such as carbon monoxide or compound A.[105] Although absorbent materials may be problematic, they still represent an important component of the circle breathing system. Different anesthesia breathing systems eliminate CO_2 with varying degrees of efficiency. The closed and semiclosed circle system both **require** that CO_2 be absorbed from the exhaled gases to avoid hypercapnea. If one could design an ideal CO_2 absorbent, its characteristics would include lack of reactivity with common anesthetics, lack of toxicity, low resistance to air flow, low cost, ease of handling, and efficiency in CO_2 absorption.

The Absorber Canister

On modern anesthesia machines, the absorber canister (see Fig. 21-7) is composed of two clear plastic canisters arranged in series. The canisters can be filled with either loose bulk absorbent or with absorbent supplied by the factory in prefilled plastic disposable cartridges called prepacks. Free granules from bulk absorbent can create a clinically significant leak if they lodge between the clear plastic canister and the O-ring gasket of the absorber. Leaks have also been caused by defective prepacks, which were larger than factory specifications.[106] Prepacks can also cause total obstruction of the circle system if the clear plastic shipping wrapper is not removed prior to

use.[107]

Chemistry of Absorbents

Three formulations of CO_2 absorbents are commonly available today: soda lime, Baralyme®, and calcium hydroxide lime (Amsorb®). Of these agents, the most commonly used is soda lime. All serve to eliminate CO_2 from the breathing circuit with varying degrees of efficiency.

By weight the approximate composition of "high moisture" soda lime is 80% calcium hydroxide, 15% water, 4% sodium hydroxide, and 1% potassium hydroxide (an activator). Small amounts of silica are added to produce calcium and sodium silicate. This addition produces a harder more stable pellet and thereby reduces dust formation. The efficiency of the soda lime absorption varies inversely with the hardness; therefore, little silicate is used in contemporary soda lime. Sodium hydroxide is the catalyst for the CO_2 absorptive properties of soda lime.[108,109] Baralyme® is a mixture of approximately 20% barium hydroxide and 80% calcium hydroxide. It may also contain some potassium hydroxide. Baralyme® is the primary CO_2 absorbent implicated as an agent that may produce fires in the breathing system when used with sevoflurane. Calcium hydroxide lime is one of the newest clinically available CO_2 absorbents. It consists primarily of calcium hydroxide and calcium chloride and contains two setting agents: calcium sulfate and polyvinylpyrrolidine. The latter two agents serve to enhance the hardness and porosity of the agent.[110] The most significant advantage of calcium hydroxide lime over other agents is its lack of the strong bases, sodium and potassium hydroxide. The absence of these chemicals eliminates the undesirable production of carbon monoxide, the nephrotoxic substance known as compound A, and may reduce or eliminate the possibility of a fire in the breathing circuit.[111] The most significant disadvantages of calcium hydroxide lime are (1) less absorptive capacity—about 50% less than strong-base containing

absorbents, and (2) generally higher cost per unit than other absorbents.[112,113]

The size of the actual absorptive granules has been determined over time by trial and error. The current size particles represent a compromise between resistance to air flow and absorptive efficiency.[114] The smaller the granule size, the greater the surface area that is available for absorption. However, as particle size decreases, air flow resistance increases. The granular size of soda lime and Baralyme® used in clinical practice is between 4 and 8 mesh, a size at which absorptive surface area and resistance to flow are optimized. Mesh size refers to the number of openings per linear inch in a sieve through which the granular particles can pass. A 4-mesh screen means that there are four quarter-inch openings per linear inch. Likewise, an 8-mesh screen has eight per linear inch.[108]

The absorption of CO_2 by absorbents such as soda lime occurs by a series of chemical reactions; it is not a physical process like soaking water into a sponge. CO_2 combines with water to form carbonic acid. Carbonic acid reacts with the hydroxides to form sodium (or potassium) carbonate and water. Calcium hydroxide accepts the carbonate to form calcium carbonate and sodium (or potassium) hydroxide. The equations are as follows:

1. $CO_2 + H_2O \Leftrightarrow H_2CO_3$
2. $H_2CO_3 + 2NaOH\ (KOH) \Leftrightarrow Na_2CO_3\ (K_2CO_3) + 2H_2O + Heat$
3. $Na_2CO_3\ (K_2CO_3) + Ca(OH)_2 \Leftrightarrow CaCO_3 + 2NaOH\ (KOH)$

Some CO_2 may react directly with $Ca(OH)_2$, but this reaction is much slower.

The reaction with Baralyme® differs from that of soda lime because more water is liberated by a direct reaction of barium hydroxide and CO_2.

1. $Ba(OH)_2 + 8H_2O + CO_2 \Leftrightarrow BaCO_3 + 9H_2O + Heat$

2. $9H_2O + 9CO_2 \Leftrightarrow 9H_2CO_3$

   Then by direct reactions and by KOH and NaOH,

3. $9H_2CO_3 + 9Ca(OH)_2 \Leftrightarrow CaCO_3 + 18H_2O + Heat$

Absorptive Capacity

The maximum amount of CO_2 that can be absorbed by soda lime is 26 L of CO_2 per 100 g of absorbent. The absorptive capacity of calcium hydroxide lime is significantly less, and has been reported at 10.2 L per 100 g of absorbent.[110,113] However, as previously mentioned, absorptive capacity is the product of both available chemical reactivity and physical (granule) availability. As the absorbent granules stack up in the absorber canisters, small passageways inevitably form. These small passages channel gases preferentially through low resistance areas. Because of this phenomenon, functional absorptive capacity of either soda lime or calcium hydroxide lime may be substantially decreased. In practice, because of channeling, the efficiency of soda lime may be reduced to allow only 10 to 20 L or less of CO_2 to actually be absorbed per 100 g of absorbent.[115]

Indicators

Ethyl violet is the pH indicator added to both soda lime and Baralyme to help assess the functional integrity of the absorbent. This compound is a substituted triphenylmethane dye with a critical pH of 10.3.[109] Ethyl violet changes from colorless to violet in color when the pH of the absorbent decreases as a result of CO_2 absorption. When the absorbent is fresh, the pH exceeds the critical pH of the indicator dye, and it exists in its colorless form (Fig. 21-26, A). However, as absorbent becomes exhausted, the pH decreases below 10.3, and ethyl violet changes to its violet form (Fig. 21-26, B) because of alcohol dehydration. This change in color indicates the absorptive capacity of the material has been consumed. Unfortunately, in some circumstances ethyl violet may not always be a reliable indicator of the functional status of absorbent. For example, prolonged exposure of ethyl violet to fluorescent lights can produce photodeactivation of this dye. When this occurs, the absorbent appears white even though it may have a reduced pH and its absorptive capacity has been exhausted.[116]

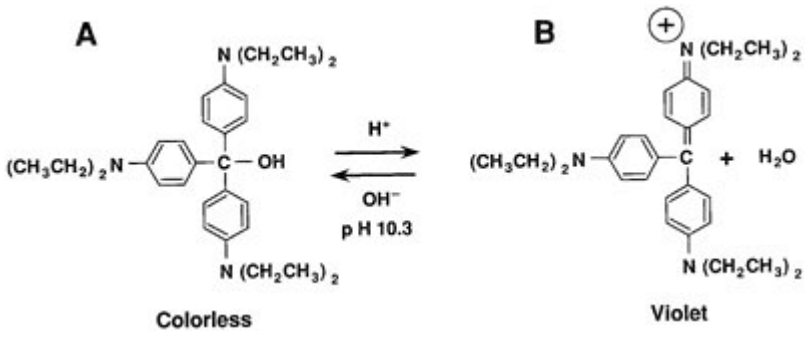

FIGURE 21-26**A and B.** Ethyl Violet. See text for details. (Reprinted with permission from Andrews JJ, Johnston RV Jr, Bee DE, Arens JF: Photodeactivation of ethyl violet: A potential hazard of sodasorb. Anesthesiology 72:59, 1990.)

Interactions of Inhaled Anesthetics with Absorbents

It is important and desirable to have CO_2 absorbents that neither release toxic particles or fumes nor produce toxic compounds when exposed to common anesthetics. Soda lime and Baralyme generally fit this description, but inhaled anesthetics do interact with absorbents to some extent. Historically speaking, an uncommon anesthetic, trichloroethylene, reacts with soda lime to produce toxic compounds. In the presence of alkali and heat, trichloroethylene degrades into the cerebral neurotoxin dichloroacetylene, which can cause cranial nerve lesions and encephalitis. Phosgene, a potent pulmonary irritant, is also produced and phosgene can cause adult respiratory distress syndrome (ARDS).[117]

Sevoflurane has been shown to produce degradation products upon interaction with CO_2 absorbents.[105,118,119] The major degradation product produced is an olefin compound known as fluoromethyl-2, 2-difluoro-1-(trifluoromethyl) vinyl ether, or compound A. During sevoflurane anesthesia, factors apparently leading to an increase in the concentration of compound A include: (1) low flow or closed circuit anesthetic techniques; (2) the use of Baralyme® rather than soda lime; (3) higher concentrations of sevoflurane in the anesthetic circuit; (4) higher absorbent temperatures; and (5) fresh absorbent.[118,119,120,121] Interestingly, the dehydration of Baralyme increases the concentration of compound A, but the dehydration of soda lime decreases the concentration of compound A.[122,123] Apparently, the degradation products released during clinical conditions do not commonly result in adverse effects in humans even during low flow anesthesia,[120] but further studies are needed to verify this.[124,125,126]

10 Desiccated strong-base absorbents can also degrade contemporary inhaled anesthetics to clinically significant concentrations of carbon monoxide (CO) as well as trifluoromethane, which can interfere with anesthetic gas monitoring.[105] Under certain conditions, this process can produce very high carboxyhemoglobin concentrations, reaching 35% or more.[127] Higher levels of carbon monoxide are more likely after prolonged contact between absorbent and anesthetics, and

after disuse of an absorber for at least 2 days, especially over a weekend. Thus, case reports describing carbon monoxide poisoning have been most common in patients anesthetized on Monday morning, presumably because continuous flow from the anesthesia machine dehydrated the absorbents over the weekend.[128,129] Fresh gas flow rates of 5 liters per minute or more through the breathing system and absorbent (without a patient connected) are sufficient to cause critical drying of the absorbent material. This is even worse when the breathing bag is left off the breathing circuit. Absence of the reservoir bag facilitates retrograde flow through the circle system (Fig. 21-27).[127] Because the inspiratory valve leaflet produces some resistance to flow, the fresh gas flow takes the retrograde path of least resistance through the absorbent and out the 22 mm breathing bag mount.

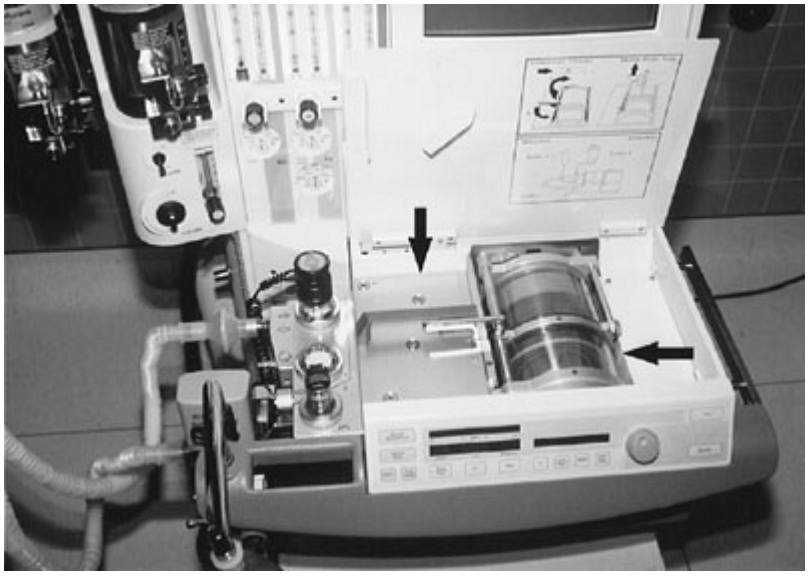

FIGURE 21-27. The Dräger Medical Narkomed 6000 with its single-circuit ventilator. The

horizontal arrow indicates the piston cylinder unit of the Divan Ventilator. The *vertical arrow* indicates the rectangular valve manifold for fresh gas decoupling.

Several factors appear to increase the production of carbon monoxide and resulting elevated carboxyhemoglobin levels. Those factors include (1) the inhaled anesthetic used (for a given MAC multiple, the magnitude of CO production from greatest to least is desflurane ⩾ enflurane >isoflurane >> halothane = sevoflurane); (2) the absorbent dryness (completely dry absorbent produces more CO than hydrated absorbent); (3) the type of absorbent (at a given water content, Baralyme® produces more CO than does soda lime); (4) the temperature (an increased temperature increases CO production); (5) the anesthetic concentration (more CO is produced from higher anesthetic concentrations);[130] (6) low fresh gas flow rates; and (7) reduced experimental animal (patient) size[105,131] per 100 g of absorbent.

Several interventions have been suggested to reduce the incidence of carbon monoxide exposure in humans undergoing general anesthesia.[129] These interventions include (1) educating anesthesia personnel regarding the etiology of CO production; (2) turning off the anesthesia machine at the conclusion of the last case of the day to eliminate fresh gas flow that dries the absorbent; (3) changing CO_2 absorbent if fresh gas was found flowing during the morning machine check; (4) rehydrating desiccated absorbent by adding water to the absorbent;[113] (5) changing the chemical composition of soda lime to reduce or eliminate potassium hydroxide (such products now available include Dragersorb® 800 plus, Sofnolime®, and Spherasorb®); and (6) using absorbent materials such as calcium hydroxide lime that are free of both sodium and postassium hydroxides. The elimination of sodium and potassium hydroxides from desiccated soda lime diminishes or eliminates degradation of desflurane to carbon monoxide and sevoflurane to compound A, but does not compromise CO_2 absorption.[111,132]

11 One extremely rare, but potentially life-threatening complication related to CO_2 absorbent use is the development of fires within the breathing system. Specifically, this can occur as the result of interactions between the strong-base absorbents (particularly Baralyme®) and the inhaled anesthetic, sevoflurane. In August 2003, Abbott Laboratories changed the package insert for sevoflurane to describe this rare phenomenon and the conditions under which it could occur. Almost 1 year later, in the fall of 2004, several case reports describing patient injuries related to this problem were published (all involving Baralyme®). It seems that when desiccated strong-base absorbents are exposed to sevoflurane, absorber temperatures of several hundred degrees may result from their interaction.[103] The build-up of very high temperatures, the formation of combustible degradation byproducts (formaldehyde, methanol, and formic acid), plus the oxygen- or nitrous oxide–enriched environment provide all the substrates necessary for a fire to occur.[105] Avoidance of the use of the combination of sevoflurane with strong-base absorbents, particularly Baralyme®, especially if it has become desiccated is the best way to prevent this unusual potentially life-threatening complication.

ANESTHESIA VENTILATORS

The ventilator on the modern anesthesia workstation serves as a mechanized substitute for the manual squeezing of the reservoir bag of the circle system, the Bain circuit, or another breathing system. As recently as the late 1980s, anesthesia ventilators were mere adjuncts to the anesthesia machine. Today, in newer anesthesia workstations, they have attained a prominent central role. In addition to the near ubiquitous role of the anesthesia ventilator in today's anesthesia workstation, many advanced ICU-style ventilation features have also been integrated into anesthesia ventilators (see Fig. 21-27). Although many similarities exist between today's anesthesia ventilator and ICU ventilator, some fundamental differences in ventilation parameters and control systems still remain. This discussion focuses on the classification, operating principles, and hazards associated with contemporary anesthesia ventilators.

Classification

Ventilators can be classified according to their power source, drive mechanism, cycling mechanism, and bellows type.[133,134]

Power Source

The power source required to operate a mechanical ventilator is provided by compressed gas, electricity, or both. Older pneumatic ventilators required only a pneumatic power source to function properly. Contemporary electronic ventilators from Dräger Medical, Datex-Ohmeda, and others require either an electrical only or both an electrical and a pneumatic power source.

Drive Mechanism and Circuit Designation

Double-circuit ventilators are most commonly used on modern anesthesia workstations. Generally, these conventional ventilators are pneumatically driven. In a double-circuit ventilator, a driving force such as pressurized gas compresses a component analogous to the reservoir bag known as the ventilator bellows. The bellows then in turn delivers ventilation to the patient. The driving gas in the Datex-Ohmeda 7000, 7810, 7100, and 7900 is 100% oxygen. In the North American Dräger AV-E

and AV-2+, a venturi device mixes oxygen and air. Some newer pneumatic anesthesia workstations have the ability for the user to select whether compressed air or oxygen is used as the driving gas.

In recent years, with the introduction of circle breathing systems that integrate fresh gas decoupling, resurgence has been seen in the utilization of mechanically driven anesthesia ventilators. These “piston”-type ventilators utilize a computer-controlled stepper motor instead of compressed drive gas to actuate gas movement in the breathing system. In these systems, rather than having dual circuits with patient gas in one and drive gas in another, a single patient gas circuit is present. Thus, they are classified as piston-driven single-circuit ventilators. The piston operates much like the plunger of a syringe to deliver the desired tidal volume or airway pressure to the patient. Sophisticated computerized controls are able to provide advanced types of ventilatory support such as synchronized intermittent mandatory ventilation (S-IMV), pressure-controlled ventilation (PCV), and pressure support–assisted ventilation, in addition to the conventional control mode ventilation. Since the patient's mechanical breath is delivered without the use of compressed gas to actuate a bellows, these systems consume dramatically less compressed gas during ventilator operation than traditional pneumatic ventilators. This improvement in efficiency may have clinical significance when the anesthesia workstation is used in a setting where no pipeline gas supply is available (e.g., remote locations or office-based anesthesia practices).

Cycling Mechanism

Most anesthesia machine ventilators are time cycled and provide ventilator support in the control mode. Inspiratory phase is initiated by a timing device. Older pneumatic ventilators use a fluidic timing device. Contemporary electronic ventilators use a solid-state electronic timing device and are thus classified as time cycled and electronically controlled. More advanced ventilation modes such as S-IMV, PCV, and modes that utilize a pressure-support option may have an adjustable threshold pressure trigger as well. In these modes, pressure sensors provide feedback to the ventilator control system to allow it to determine when to initiate and/or terminate the respiratory cycle.

Bellows Classification

12 The direction of bellows movement during the expiratory phase determines the bellows classification. *Ascending (standing) bellows* ascend during the expiratory phase (Fig. 21-28B, right), whereas *descending (hanging) bellows* descend during the expiratory phase. Older

pneumatic ventilators and some new anesthesia workstations use weighted descending bellows, while most contemporary electronic ventilators have an ascending bellows design. Of the two configurations, the ascending bellows is generally safer. An ascending bellows will not fill if a total disconnection occurs. However, the bellows of a descending bellows ventilator will continue its upward and downward movement despite a patient disconnection. The driving gas pushes the bellows upward during the inspiratory phase. During the expiratory phase, room air is entrained into the breathing system at the site of the disconnection because gravity acts on the weighted bellows. The disconnection pressure monitor and the volume monitor may be fooled even if a disconnection is complete (see Breathing Circuit Problems section).[34] Some contemporary anesthesia workstation designs have returned to the descending bellows to integrate fresh gas decoupling (Dräger Medical Julian and Datascope Anestar). An essential safety feature on any anesthesia workstation that utilizes a descending bellows is an integrated CO_2 apnea alarm that cannot be disabled while the ventilator is in use.

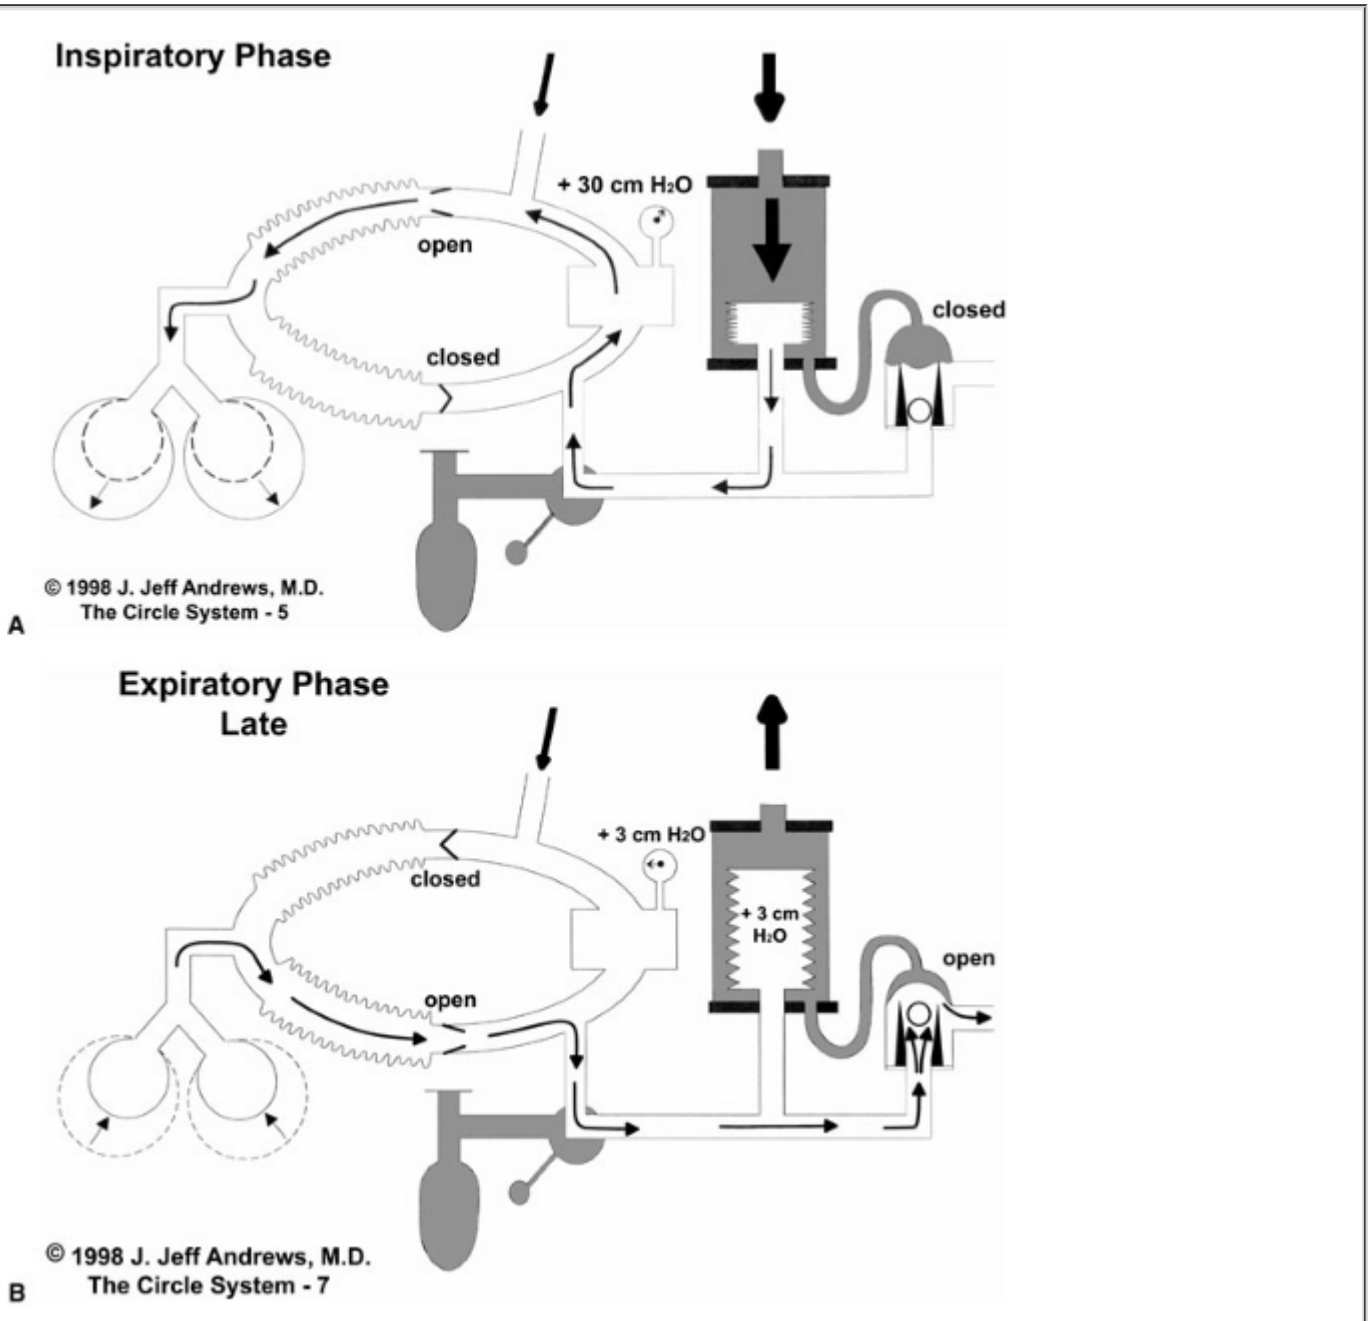

FIGURE 21-28**A and B.** Inspiratory **(A)** and expiratory **(B)** phases of gas flow in a traditional circle system with an ascending bellows ventilator. The bellows physically separates the driving-gas circuit from the patient gas circuit. The driving-gas circuit is located outside the bellows, and the patient gas circuit is inside the bellows. During inspiratory phase **(A)**, the driving gas enters the bellows chamber, causing the pressure within it to increase. This

causes the ventilator relief valve to close, preventing anesthetic gas from escaping into the scavenging system, and the bellows to compress, delivering anesthetic gas within the bellows to the patient's lungs. During expiratory phase **(B)**, pressure within the bellows chamber and the pilot line decreases to zero, causing the mushroom portion of the ventilator relief valve to open. Gas exhaled by the patient refills the bellows before any scavenging occurs, because a weighted ball is incorporated into the base of the ventilator relief valve. Scavenging occurs only during the expiratory phase, because the ventilator relief valve is only open during expiration. (Reprinted with permission from Andrews JJ: The Circle System. A Collection of 30 Color Illustrations. Washington, DC, Library of Congress, 1998.)

Operating Principles of Ascending Bellows Ventilators

Contemporary examples of ascending bellows, double-circuit, electronic ventilators include the Dräger Medical AV-E, AV-2+, the Datex-Ohmeda 7000, 7800, and 7900 series. A generic ascending bellows ventilator is illustrated in Figure 21-26. It may be viewed as a breathing bag (bellows) located within a clear plastic box. The bellows physically separates the driving gas circuit from the patient gas circuit. The driving gas circuit is located outside the bellows, and the patient gas circuit is inside the bellows. During the inspiratory phase (Fig. 21-28A, left) the driving gas enters the bellows chamber, causing the pressure within it to increase. This increase in pressure is responsible for two events. First, the ventilator relief valve closes, preventing anesthetic gas from escaping into the scavenging system. Second, the bellows is compressed, and the anesthetic gas within the bellows is delivered to the patient's lungs. This compression action is analogous to the hand of the anesthesiologist squeezing the breathing bag.[48]

During the expiratory phase (see Fig. 21-28B), the driving gas exits the bellows housing. This produces a drop to atmospheric pressure within both the bellows housing and the pilot line to the ventilator relief valve. The decrease in pressure to the ventilator relief valve causes the “mushroom valve” portion of the assembly to open. Exhaled patient gases refill the bellows before any scavenging can begin. The bellows refill first because a weighted ball [like those used in ball-type positive end-expiratory pressure (PEEP) valves] or similar device is incorporated into the base of the ventilator relief valve. This ball produces 2 to 3 cm water of back pressure; therefore, scavenging occurs only after the bellows fills completely and the pressure inside the bellows exceeds the pressure threshold of the “ball valve.” This design causes all ascending bellows ventilators to produce 2 to 3 cm water pressure of PEEP within the breathing circuit when the ventilator is in use. Scavenging occurs only during the expiratory phase, as the ventilator relief valve is open only during expiration.[48]

It is important to understand that on most anesthesia workstations, gas flow from the anesthesia machine into the breathing circuit is continuous and independent of ventilator activity. During the inspiratory phase of mechanical ventilation, the ventilator relief valve is closed (see Fig. 21-28A), and the breathing system's Adjustable Pressure Limiting Valve (“pop-off” valve) is most commonly out of circuit. Therefore, the patient's lungs receive the volume from the bellows plus that from the flowmeters during the inspiratory phase. Factors that influence the correlation between set tidal volume and exhaled tidal volume include the flowmeter settings, the inspiratory time, the compliance of the breathing circuit, external leakage, and the location of the tidal volume sensor. Usually, the volume gained from the flowmeters during inspiration is counteracted by the volume lost to compliance of the breathing circuit, and set tidal volume generally approximates the exhaled tidal volume. However, certain conditions such as inappropriate activation of the oxygen flush valve during the inspiratory phase can result in barotrauma and/or volutrauma because excess pressure and volume may not be able to be vented from the circle system.[48]

Problems and Hazards

Numerous hazards are associated with anesthesia ventilators. These include problems with the

breathing circuit, the bellows assembly, and the control assembly.

Traditional Circle System Problems

Breathing circuit misconnections and disconnection are a leading cause of critical incidents in anesthesia.[1,135] The most common disconnection site is at the Y-piece. Disconnections can be complete or partial (leaks). In the past, a common source of leaks with older absorbers was failure to close the Adjustable Pressure Limiting Valve (APL or pop-off valve) upon initiation of mechanical ventilation. On today's anesthesia workstations, the bag/ventilator selector switch has virtually eliminated this problem, as the APL valve is usually out of circuit when the ventilator mode is selected. Preexisting undetected leaks can exist in compressed, corrugated, disposable anesthetic circuits. To detect such a leak preoperatively, the circuit must be fully expanded before the circuit is checked for leaks.[136] As previously mentioned, disconnections and leaks manifest more readily with the ascending bellows ventilator systems because they result in a situation in which the bellows will not refill.[34]

Several disconnection monitors exist, although none should replace vigilance. Monitoring of breath sounds and observation of chest wall excursion should continue despite use of both mechanical (spirometers and pressure sensors) and physiologic monitors.

Pneumatic and electronic pressure monitors are helpful in diagnosing disconnections. Factors that influence monitor effectiveness include the disconnection site, the pressure sensor location, the threshold pressure alarm limit, the inspiratory flow rate, and the resistance of the disconnected breathing circuit.[137,138] Various anesthesia workstations and ventilators have different locations for the airway pressure sensor and different values for the threshold pressure alarm limit. The threshold pressure alarm limit may be preset at the factory or adjustable. An audible or visual alarm is actuated if the peak inspiratory pressure of the breathing circuit does not exceed the threshold pressure alarm limit. When an adjustable threshold pressure alarm limit is available, such as on many workstations from Dräger Medical, the operator should set the pressure alarm limit to within 5 cm water of the peak inspiratory pressure. On systems that have an “autoset” feature, when activated, the threshold limit is automatically set at 3 to 5 cm water

pressure below the current peak inspiratory pressure. On such systems, failure to reset the threshold pressure alarm limit may result in either an “Apnea Pressure” or “Threshold Low” alert. Figure 21-29 illustrates how a partial disconnection (leak) may be unrecognized by the low-pressure monitor if the threshold pressure alarm limit is set too low or if the factory preset value is relatively low.

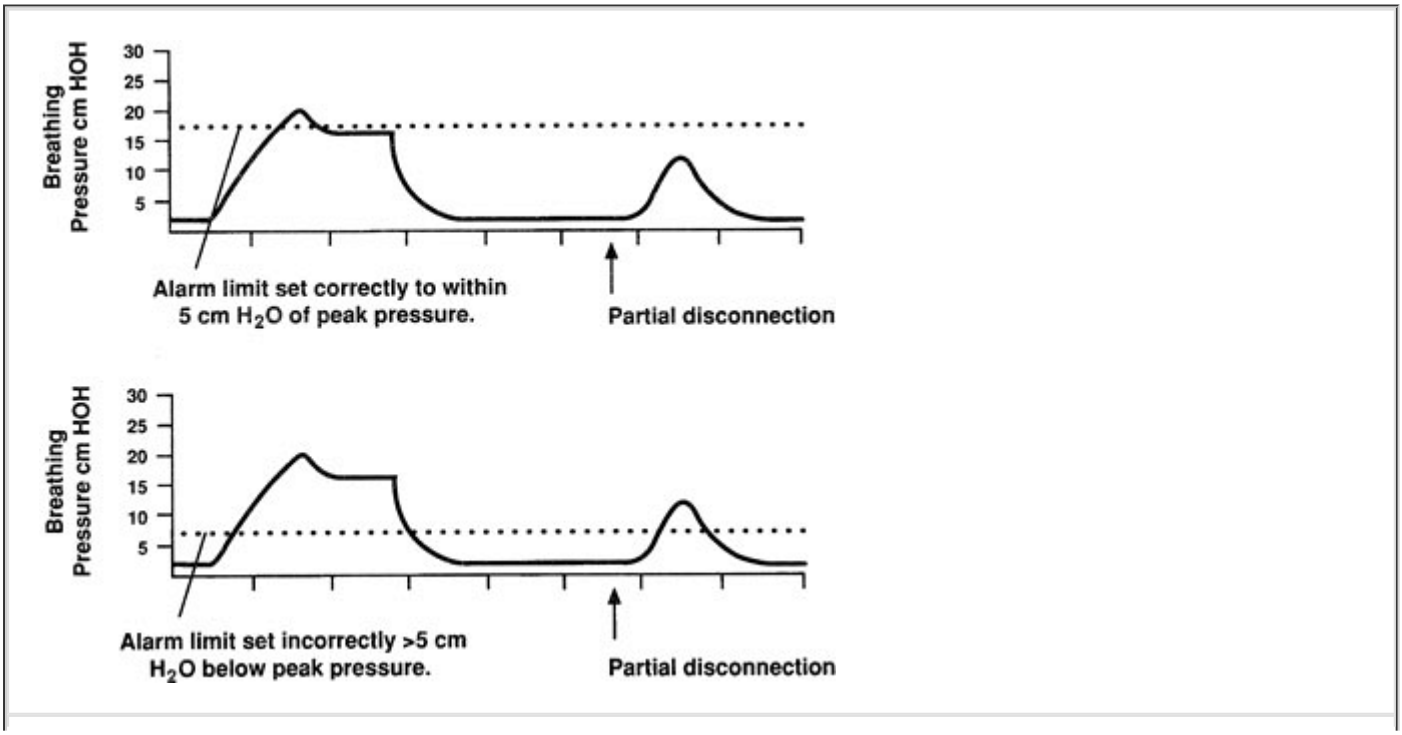

FIGURE 21-29. Threshold pressure alarm limit. (*Top*) The threshold pressure alarm limit (*dotted line*) has been set appropriately. An alarm is actuated when a partial disconnection occurs (*arrow*) because the threshold pressure alarm limit is not exceeded by the breathing circuit pressure. (*Bottom*) A partial disconnection is unrecognized by the pressure monitor because the threshold pressure alarm limit has been set too low. (Redrawn with permission from Baromed Breathing Pressure Monitor: Operator's Instruction Manual. Telford, Pennsylvania, North American Dräger, August 1986.)

Respiratory volume monitors are useful in detecting disconnections. Volume monitors may sense exhaled tidal volume, inhaled tidal volume, minute volume, or all three. The user should bracket the high and low threshold volumes slightly above and below the exhaled volumes. For example, if the exhaled minute volume of a patient is 10 L/min, reasonable alarm limits would be 8 to 12 L/min. Many Datex-Ohmeda ventilators are equipped with volume monitor sensors that use infrared light/turbine technology. These volume sensors are usually located in the expiratory limb of the breathing circuit and thus measure exhaled tidal volume. In the case of the Datex-Ohmeda S/5 ADU, a special attachment known as the D-Lite® spirometry connector is placed in the breathing circuit. This device is actually placed at or near the level of the patient connection and permits measurement of both inhaled and exhaled volumes and pressures (see Anesthesia Workstation Variations section). With the older infrared type sensors, exposure to a direct beam of light from the overhead surgical lighting could cause erroneous volume readings as the surgical beam interfered with the infrared sensor.[139] Other types of expiratory volume sensors can be seen in systems such as the Datex-Ohmeda Aestiva, Aespire, and other workstations that incorporate the 7100 ventilator or 7900 SmartVent. These systems generally utilize differential pressure transduction technology to determine inhaled and exhaled volumes as well as to measure airway pressures. The Dräger Medical Narkomed 6000 series, 2B and GS workstations commonly use an ultrasonic flow sensor located on the expiratory limb. Still other systems from Dräger measure exhaled volume using “hot wire” sensor technology. With this type of sensor, a tiny array of two platinum wires is electrically heated to a high temperature. As gas flows past the heated wires, they tend to be cooled. The amount of energy required to maintain the temperature of the wire is proportional to the volume of gas flowing past it. This system has been associated in at least one report with accidental development of a fire in the breathing circuit.[104]

CO_2 monitors are probably the best devices for revealing patient disconnections. CO_2 concentration is measured near the Y-piece either directly (mainstream) or by aspiration of a gas sample to the instrument (sidestream). Either a sudden change in the differences between the inspiratory and end-tidal CO_2 concentrations or the acute absence of measured CO_2 indicates a disconnection, a nonventilated patient, or other problems.[34] Importantly, an absence of exhaled CO_2 can be an indication of absent cardiac output rather than a mechanical equipment problem.

Misconnections of the breathing system are unfortunately, relatively common. Despite the efforts of standards committees to eliminate this problem by assigning different diameters to various hoses and hose terminals, they continue to occur. Anesthesia workstations, breathing systems, ventilators, and scavenging systems incorporate many of these diameter-specific connections. The “ability” of anesthesia providers to outwit these “fool-proof” systems has led to various hoses being cleverly adapted or forcefully fitted to inappropriate terminals and even to various other solid cylindrically shaped protrusions of the anesthesia machine.[34]

Occlusion (obstruction) of the breathing circuit may occur. Tracheal tubes can become kinked. Hoses throughout the breathing circuit are subject to occlusion by internal obstruction or external mechanical forces, which can impinge on flow and have severe consequences. For example, blockage of a bacterial filter in the expiratory limb of the circle system has resulted in bilateral tension pneumothorax.[98] Incorrect insertion of flow direction–sensitive components can result in a no-flow state.[34] Examples of these components include some PEEP valves and cascade humidifiers. Depending on the location of the occlusion relative to the pressure sensor, a high-pressure alarm

may alert practitioners to the problem.

Excess inflow to the breathing circuit from the anesthesia machine during the inspiratory phase can cause barotrauma. The best example of this phenomenon is oxygen flushing. Excess volume cannot be vented from the system during inspiration because the ventilator relief valve is closed and the APL valve is out of circuit.[48] A high-pressure alarm, if present, may be activated when the pressure becomes excessive. With many Dräger Medical systems, both audible and visual alarms are actuated when the high-pressure threshold is exceeded. In the Modulus II Plus System, the Datex-Ohmeda 7810 ventilator automatically switches from the inspiratory to the expiratory phase when the adjustable peak pressure threshold is exceeded.

On workstations equipped with adjustable inspiratory pressure limiters such as the Datex-Ohmeda S/5 ADU, Aestiva, Dräger Medical's Narkomed 6000 series, 2B, 2C, GS and Fabius GS, maximal inspiratory pressure may be set by the user to a desired peak airway pressure. An adjustable pressure relief valve will open when the predetermined user-selected pressure is reached. This theoretically prevents generation of excessive airway pressure. Unfortunately, this feature is dependent on the user having preset the appropriate “pop-off” pressure. If the setting is too low, insufficient pressure for ventilation may be generated, resulting in inadequate minute ventilation; if set too high, the excessive airway pressure may still occur, resulting in barotrauma. The piston-driven Fabius GS, as well as others may also include a factory preset inspiratory pressure safety valve that opens at a preset airway pressure such as 75 cm of water pressure to minimize the risk of barotrauma. These strategies may reduce the risk of barotrauma and volutrauma; however, they are no substitute for vigilance.

Bellows Assembly Problems

Leaks can occur in the bellows assembly. Improper seating of the plastic bellows housing can result in inadequate ventilation because a portion of the driving gas is vented to the atmosphere. A hole in the bellows can lead to alveolar hyperinflation and possibly barotrauma in some ventilators because high-pressure driving gas can enter the patient circuit. The oxygen concentration of the patient gas may increase when the driving gas is 100% oxygen, or it may decrease if the driving gas is composed of an air–oxygen mixture.[140]

The ventilator relief valve can cause problems. Hypoventilation occurs if the valve is incompetent because anesthetic gas is delivered to the scavenging system during the inspiratory phase instead of to the patient. Gas molecules preferentially exit into the scavenging system because it represents the path of least resistance, and the pressure within the scavenging system can be subatmospheric. Ventilator relief valve incompetency can result from a disconnected pilot line, a ruptured valve, or from a damaged flapper valve.[141,142] A ventilator relief valve stuck in the closed or partially closed position can produce either barotrauma or undesired PEEP.[143] Excessive suction from the scavenging system can draw the ventilator relief valve to its seat and close the valve during both the inspiratory and expiratory phases.[34] In this case, breathing circuit pressure escalates because excess anesthetic gas cannot be vented. It is worthwhile to note that during expiratory phase, some newer machines from Datex-Ohmeda (S/5 ADU, 7100 and 7900 SmartVent) scavenge both excess patient gases and the exhausted ventilator drive gas. That is, when the ventilator relief valve opens, and waste anesthetic gases are vented from the breathing circuit, the drive gas from the bellows housing joins with it to enter the scavenging system. Under certain conditions, the large volume of exhausted gases could overwhelm the scavenging system, resulting in pollution of the operating room with waste anesthetic gases (see Scavenging Systems section). Other mechanical problems that can occur include leaks within the system, faulty pressure regulators, and faulty valves. Unlikely problems such as an occluded muffler on the Dräger AV-E ventilator can result in barotrauma. In this case, obstruction of driving gas outflow closes the ventilator relief valve, and excess patient gas cannot be vented.[144]

Control Assembly and Power Supply Problems

The control assembly can be the source of both electrical and mechanical problems. Electrical

failure can be total or partial; the former is the more obvious. As anesthesia workstations are becoming more dependent on integrated computer-controlled systems, power interruptions become more significant. Battery back-up systems are designed to continue operation of essential electronics during brief (up to several hours') outages. However, even with these systems, in the event of a failure, some time may be required to reboot after an electrical outage has occurred. During this time the availability of certain workstation features such as manual or mechanical ventilation can be variable. One cluster of electrical failures that could have potentially resulted in operating room fires was reported early on after the release of the Dräger Medical Narkomed 6000. Problems with the workstation's power supply printed circuit boards prompted a corrective recall action in November 2002.[145]

ANESTHESIA WORKSTATION VARIATIONS

With the introduction of new technology, often comes the need for adaptation of current technology to successfully allow its integration into existing systems. Otherwise, a more comprehensive redesign of an entire anesthesia system “from the ground up” could be necessary. One such example of adaptation in the anesthesia workstation can be seen with two new design variations of the circle breathing system. The first of these is found on the Datex-Ohmeda S/5 ADU (Fig. 21-1), and the second is incorporated into the Dräger Narkomed 6000 series (Fig. 21-2) and Fabius GS workstations. Since use of the circle system is fundamental to the day-to-day practice for most anesthesiologists, a comprehensive understanding of these new systems is crucial for their safe use.

THE DATEX-OHMEDA S/5 ADU (FIG. 21-1)

The Datex-Ohmeda S/5 ADU debuted as the AS/3 ADU in 1998. Along with its more comprehensive safety features and integrated design that eliminated glass flow tubes and conventional anesthesia vaporizers in exchange for a computer screen with digital fresh gas flow scales and the built-in Aladin Cassette vaporizer system, the machine had a radically different appearance in general. It is not until closer inspection that the other unique properties of the ADU begin to stand out. The principal difference in the ADU's circle system lies in the incorporation of the specialized “D-lite” flow and pressure transducer fitting into the circle at the level of the Y-connector. On most traditional circle systems, exhaled tidal volume is measured by a spirometry sensor located in proximity to the expiratory valve. The placement of the D-lite fitting at the Y-connector provides a better location to perform exhaled volume measurement; allows airway gas composition and pressure monitoring to be done with a single adapter instead of with multiple fittings added to the breathing circuit; and it provides the ability to assess both inspiratory and expiratory gas flow and therefore generation of complete flow-volume spirometry. The relocation of the spirometer sensor to the Y-connector also makes it possible to move the location of the fresh gas inlet to the “patient” side of the inspiratory valve without adversely affecting accuracy of exhaled tidal volume measurement.

This atypical circle system arrangement with the fresh gas entering on the patient side of the inspiratory valve is advantageous for several reasons. It is likely to be more efficient in delivering fresh gas to the patient, while preferentially eliminating exhaled gases. Importantly, it is also less likely to cause desiccation of the CO_2 absorbent (see Interactions of Inhaled Anesthetics with Absorbents section). Other notable changes on the S/5 ADU circle system include a compact proprietary CO_2 absorbent canister design that can be changed during ventilation without loss of circle system integrity, and the relocation of the inspiratory and expiratory unidirectional valves from a horizontal position to a vertical position on the “compact block” assembly just below the absorbent canister. The reorientation of the unidirectional valves reduces the breathing circuit resistance encountered by a spontaneously ventilated patient. The vertically oriented unidirectional valves only have to be tipped away from the vertical position to be opened, unlike conventional horizontal valve discs, which have to be physically lifted off of the valve seat against gravity to be opened.

THE DRÄGER MEDICAL NARKOMED 6000 SERIES (FIG. 21-2)

AND FABIUS GS

Several important differences exist between the traditional circle breathing systems of the newest Dräger products. At first glance, the most notable difference lies in the appearance and design of the ventilators used with these systems. From the inconspicuous horizontally mounted Divan piston ventilator

of the Narkomed 6000 to the vertically mounted and visible piston ventilator of the Fabius GS with its absent flow tubes and glowing electronic fresh gas flow indicators, these systems appear drastically different from traditional anesthesia systems. The piston ventilators of the Dräger Narkomed 6000 and Fabius Series anesthesia systems are classified as electrically powered, piston driven, single circuit, electronically controlled with fresh gas decoupling."

The circle breathing systems utilized by these Dräger workstations incorporate a feature known as Fresh Gas Decoupling (FGD). The incorporation of this patient safety enhancing technology has required a significant redesign of the traditional circle system. A functional schematic of a circle system similar to the one used by the Dräger Narkomed 6000 series during both inspiratory and expiratory phase of mechanical ventilation can be seen in Figure 21-30A and 21-30B. To understand the operating principles of FGD, it is important to have a good understanding of gas flows in a traditional circle system both during inspiratory and expiratory phases of mechanical ventilation. A complete discussion of this was presented earlier in the section entitled Operating Principles of Ascending Bellows Ventilators.

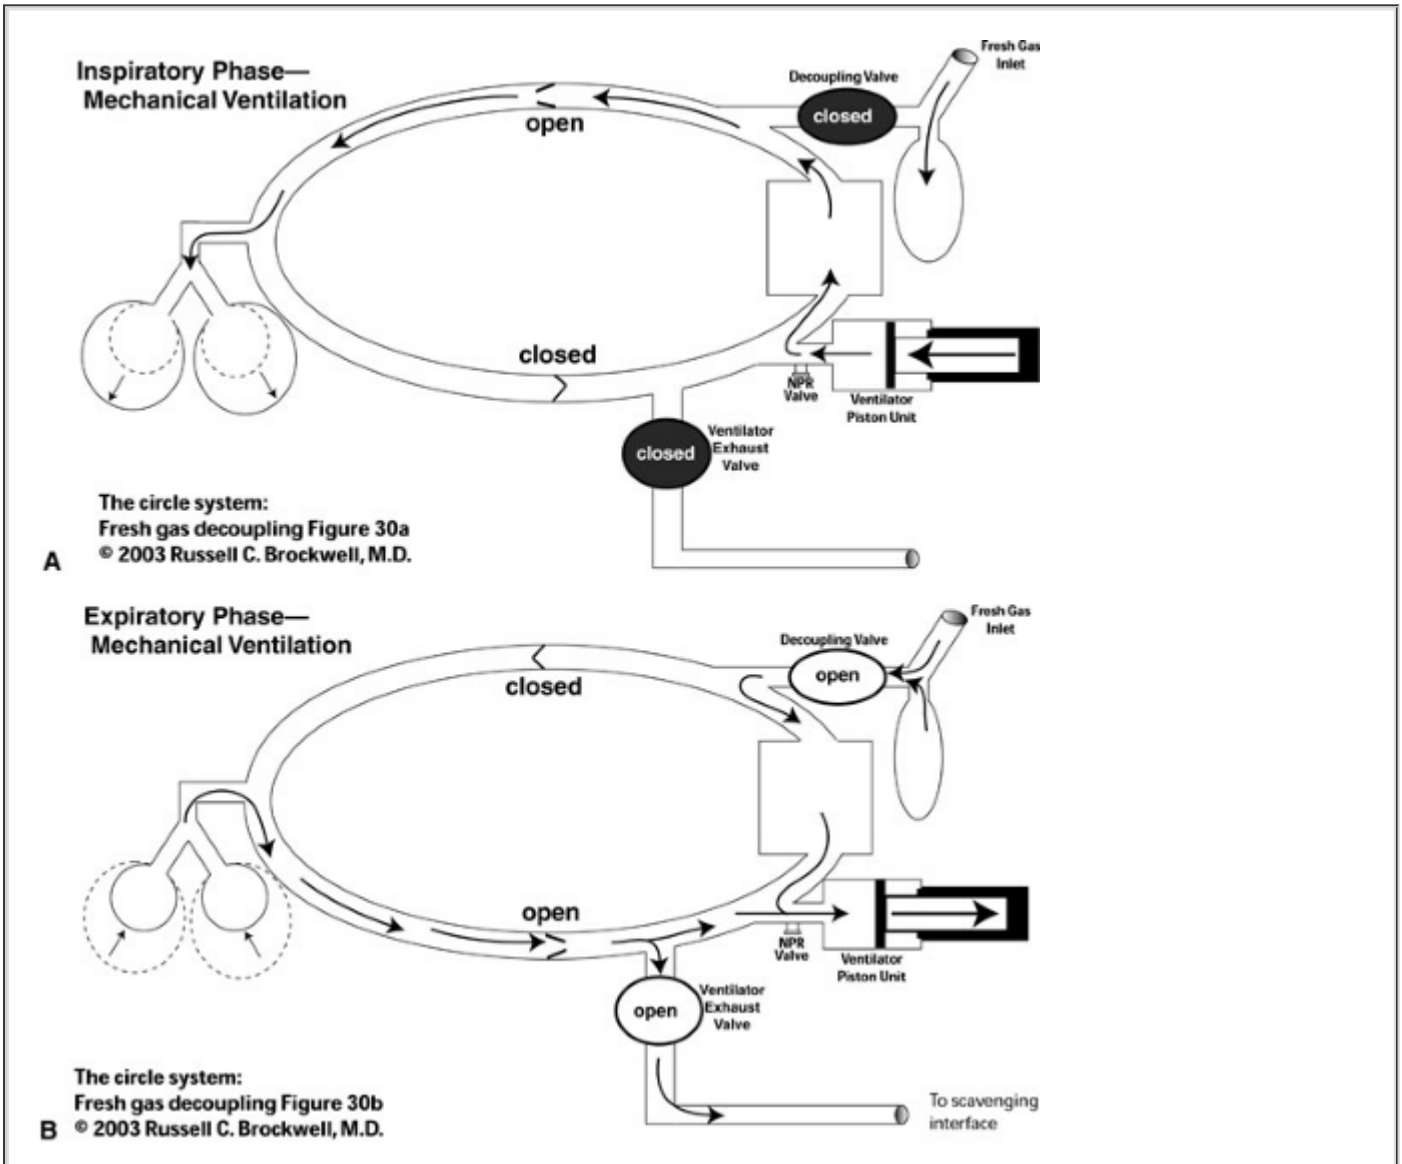

FIGURE 21-30**A and B.** Inspiratory and expiratory phase gas flows of a Dräger Narkomed 6000–type circle system with piston ventilator and fresh gas decoupling. NPR valve =

Negative Pressure Relief Valve. See text for details. (Reprinted with permission from Brockwell RC: New Circle System Designs: A Collection of figures privately published in Birmingham, AL 2003.)

The key concept of the fresh gas decoupled breathing system can be illustrated during the inspiratory phase of mechanical ventilation. With the traditional circle system, several events are occurring (see Fig. 21-28A): (1) continuous fresh gas flow from the flowmeters and/or the oxygen flush valve is entering the circle system at the fresh gas inlet; (2) the ventilator is delivering the prescribed tidal volume to the patient's lungs; and (3) the ventilator relief valve (ventilator exhaust valve) is closed, so no gas is escaping the circle system except into the patient's lungs.[146] In a traditional circle system, when these events coincide and fresh gas inflow is coupled directly into the circle system, the total volume delivered to the patient's lungs is the sum of the volume from the ventilator plus the volume of gas that enters the circle via the fresh gas inlet. In contrast, when FGD is used, during the inspiratory phase (see Fig. 21-30A) the fresh gas coming from the anesthesia workstation via the fresh gas inlet is diverted into the reservoir bag by a decoupling valve that is located between the fresh gas source and the ventilator circuit. The reservoir (breathing) bag serves as an accumulator for fresh gas until the expiratory phase begins. During expiratory phase (see Fig. 21-30B), the decoupling valve opens, allowing the accumulated fresh gas in the reservoir bag to be drawn into the circle system to refill the piston ventilator chamber or descending bellows. Since the ventilator exhaust valve also opens during expiratory phase, excess fresh gas and exhaled patient gases are allowed to escape to the scavenging system.

Current fresh gas decoupled systems are designed with either piston-type or descending bellows–type ventilators. Since the bellows in either of these type of systems refills under slight negative pressure, it allows the accumulated fresh gas from the reservoir bag to be drawn into the ventilator for delivery to the patient during the next ventilator cycle. Because of this design requirement, it is unlikely that fresh gas decoupling, as

described here, can be used with conventional ascending bellows ventilators, which refill under slight positive pressure.

14 The most significant advantage of circle systems using FGD is decreased risk of barotrauma and volutrauma. With a traditional circle system, increases in fresh gas flow from the flowmeters or from inappropriate use of the oxygen flush valve may contribute directly to tidal volume, which if excessive, may result in pneumothorax or other injury. Since systems with FGD isolate fresh gas coming into the system from the patient while the ventilator exhaust valve is closed, the risk of barotrauma is greatly reduced.

Possibly the greatest disadvantage to the new anesthesia circle systems that utilize FGD is the possibility of entraining room air into the patient gas circuit. As previously discussed, in a fresh gas decoupled system the bellows or piston refills under slight negative pressure. If the volume of gas contained in the reservoir bag volume plus the returning volume of gas exhaled from the patient's lungs is inadequate to refill the bellows or piston, negative patient airway pressures could develop. To prevent this, a negative pressure relief valve is placed in the breathing system (see Fig. 21-30A and 21-30B). If breathing system pressure falls below a preset value such as -2 cm H_2O pressure, then the relief valve opens and ambient air is entrained into the patient gas circuit. If this goes undetected, the entrained atmospheric gases could lead to dilution of either or both the inhaled anesthetic agents or an enriched oxygen mixture (lowering an enriched oxygen concentration toward 21%). If unchecked, this could lead to either intraoperative awareness or hypoxia. High-priority alarms with both audible and visual alerts should notify the user that fresh gas flow is inadequate and room air is being entrained.

Another potential problem with an FGD system such as seen on the Narkomed 6000 series lies in its reliance on the reservoir bag to accumulate the incoming fresh gas. If the reservoir bag is

removed during mechanical ventilation, or if it has a significant leak from poor fit on the bag mount or a perforation, room air may enter the breathing circuit as the ventilator piston unit refills during expiratory phase. This may also result in dilution of either or both the inhaled anesthetic agents or an enriched oxygen mixture, potentially resulting in awareness during anesthesia or hypoxia. Furthermore, this type of a disruption could lead to significant pollution of the operating room with anesthetic gases as fresh gases would be allowed to escape into the atmosphere. Other FGD designs, such as those seen in the Dräger Medical Fabius GS and the recently released Apollo anesthesia systems do not use the breathing bag as the fresh gas reservoir, but instead have an alternate location for fresh gas accumulation during inspiratory phase.

SCAVENGING SYSTEMS

Scavenging is the collection and the subsequent removal of waste anesthetic gases from the operating room.[147] In most cases, the amount of gas used to anesthetize a patient for a given anesthetic far exceeds the minimal amount needed. Therefore, scavenging minimizes operating room pollution by removing this excess of gases. In 1977, the National Institute for Occupational Safety and Health (NIOSH) prepared a document entitled “Criteria for a Recommended Standard: Occupational Exposure to Waste Anesthetic Gases and Vapors.”[148] Although it was maintained that a minimal safe level of exposure could not be defined, the NIOSH proceeded to issue the recommendations shown in Table 21-5.[148] In 1991 the American Society for Testing and Materials (ASTM) released the ASTM F1343-91 standard entitled “Standard Specification for Anesthetic Equipment—Scavenging Systems for Anesthetic Gases.”[149] The document provided guidelines for devices that safely and effectively scavenge waste anesthetic gases to reduce contamination in anesthetizing areas.[149] In 1999, the ASA Task Force on Trace Anesthetic Gases developed a booklet entitled “Waste Anesthetic Gases: Information for Management in Anesthetizing Areas and the Postanesthesia Care Unit.” This publication addresses analysis of the literature, the role of regulatory agencies, scavenging and monitoring equipment, and recommendations.[150]

TABLE 21-5 Niosh Recommendations for Trace Gas Level

·ANESTHETIC GAS	·MAXIMUM TWA[a] CONCENTRATION(ppm)
Halogenated agent alone	2
Nitrous oxide	25
Combination of halogenated agent plus nitrous oxide:	
Halogenated agent	0.5
Nitrous oxide	25
Dental facilities (nitrous oxide alone)	50

[a] TWA, time-weighted average. Time-weighted average sampling, also known as time-integrated sampling, is a sampling method that evaluates the average concentration of anesthetic gas over a prolonged period of time, such as 1 to 8 hours.

Reprinted with permission from US Department of Health, Education, and Welfare: Criteria for a recommended standard: Occupational exposure to waste anesthetic gases and vapors. March ed, Washington DC, 1977.

The two major causes of waste gas contamination in the operating room are the anesthetic technique employed and equipment issues.[150,151] Regarding the anesthetic technique, the following factors cause operating room contamination: (1) failure to turn off gas flow control valves at the end of an anesthetic, (2) poorly fitting masks, flushing the circuit, (3) filling anesthetic vaporizers, (4) use of uncuffed endotracheal tubes, and (5) use of breathing circuits such as the Jackson-Rees, which are difficult to scavenge. Equipment failure or lack of understanding of proper equipment use can also contribute to operating room contamination. Leaks can occur in the high-pressure hoses, the nitrous oxide tank mounting, the high-pressure circuit and low-pressure circuit of the anesthesia machine, or in the circle system, particularly at the CO_2 absorber assembly. The anesthesia provider must be certain that the scavenging system is operational and adjusted properly to ensure adequate scavenging. If side stream CO_2 or multigas analyzers are used, the analyzed gas (50 to 250 cc/min) must be directed to the scavenging system or returned to the breathing system to prevent pollution of the operating room.[150,151]

Components

Scavenging systems generally have five components (Fig. 21-31): (1) the gas-collecting assembly, (2) the transfer means, (3) the scavenging interface, (4) the gas-disposal assembly tubing, and (5) an active or passive gas-disposal assembly.[149] An “active system” uses a central evacuation system to eliminate waste gases. The “weight” or pressure of the waste gas itself produces flow through a “passive system.”

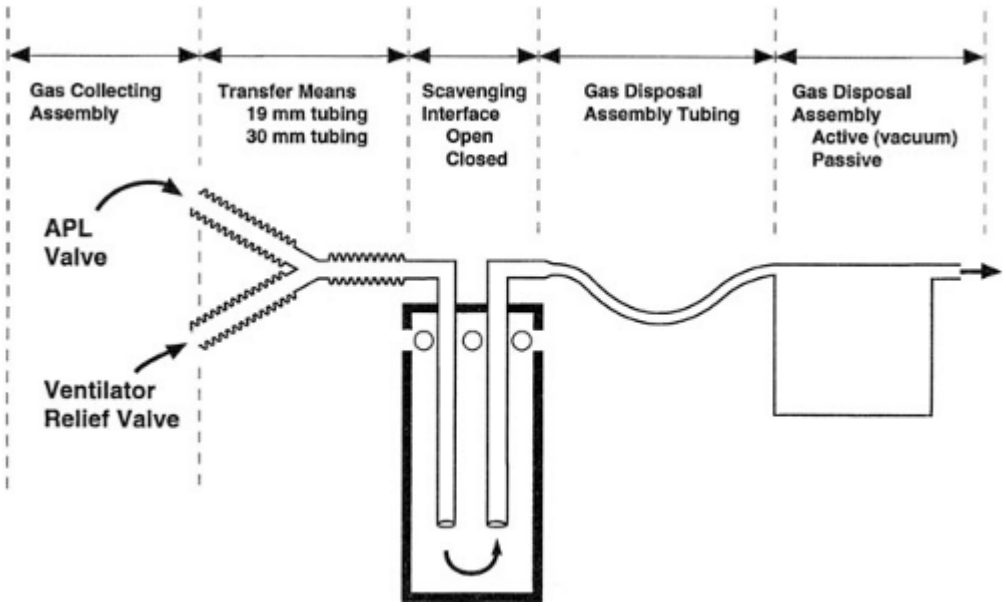

FIGURE 21-31. Components of a scavenging system. APL = adjustable pressure limiting valve.

Gas-Collecting Assembly

The gas-collecting assembly captures excess anesthetic gas and delivers it to the transfer tubing.[134] Waste anesthetic gases are

vented from the anesthesia system either through the APL valve or through the ventilator relief valve. All excess patient gas is either vented into the room (e.g., from a poor facemask fit or endotracheal tube leak) or exits the breathing system through one of these valves. Gas passing through these valves accumulates in the gas-collecting assembly, and is directed to the transfer means. In some newer Datex-Ohmeda systems such as the S5/ADU and others that incorporate either the 7100 or 7900 ventilators, the ventilator drive gas is also exhausted into the scavenging system. This is significant, because under conditions of high fresh gas flows and high minute ventilation, the gases flowing into the scavenging interface may overwhelm the evacuation system. If this occurs, waste anesthetic gases may overflow the system via the positive-pressure relief valve (closed systems) or through the atmospheric vents (open systems) polluting the operating room. In contrast, most other pneumatic ventilators from both Datex-Ohmeda and Dräger exhaust their drive gas (100% oxygen or oxygen/air mixture) into the operating room through a small vent on the back of the ventilator control housing.

Transfer Means

The transfer means carries excess gas from the gas-collecting assembly to the scavenging interface. The tubing must be either 19 or 30 mm, as specified by the ASTM F1343-91 standard.[149] The tubing should be sufficiently rigid to prevent kinking, and as short as possible to minimize the chance of occlusion. Some manufacturers color code the transfer tubing with yellow bands to distinguish it from 22-mm breathing system tubing. Many machines have separate transfer tubes for the APL valve and for the ventilator relief valve. The two tubes frequently merge into a single hose before they enter the scavenging interface. Occlusion of the transfer means can be particularly problematic since it is upstream from the pressure-buffering features of the scavenging interface. If the transfer means is occluded, baseline breathing circuit pressure will increase, and barotrauma can occur.

Scavenging Interface

The scavenging interface is the most important component of the system because it protects the breathing circuit or ventilator from excessive positive or negative pressure.[147] The interface should limit the pressures immediately downstream from the gas collecting assembly to between -0.5 and +10 cm water with normal working conditions.[149] Positive pressure relief is mandatory, irrespective of the type of disposal system used, to vent excess gas in case of occlusion downstream from the interface. If the disposal system is an “active system,” negative pressure relief is necessary to protect the breathing circuit or ventilator from excessive subatmospheric pressure. A reservoir is highly desirable with active systems, since it stores waste gases until the evacuation system can remove them. Interfaces can be open or closed, depending on the method used to provide positive and negative pressure relief.[147]

Open Interfaces. An open interface contains no valves and is open to the atmosphere, allowing both positive and negative pressure relief. Open interfaces should be used only with active disposal systems that use a central evacuation system. Open interfaces require a reservoir because waste gases are intermittently discharged in surges, whereas flow from the evacuation system is continuous.[147]

Many contemporary anesthesia machines are equipped with open interfaces like those in Figure

21-32A and 21-32B.[152] An open canister provides reservoir capacity. The canister volume should be large enough to accommodate a variety of waste gas flow rates. Gas enters the system at the top of the canister and travels through a narrow inner tube to the canister base. Gases are stored in the reservoir between breaths. Positive and negative pressure relief is provided by holes in the top of the canister. The open interface shown in Figure 21-32A differs somewhat from the one shown in Figure 21-32B. The operator can regulate the vacuum by adjusting the vacuum control valve shown in Figure 21-32B. [152]

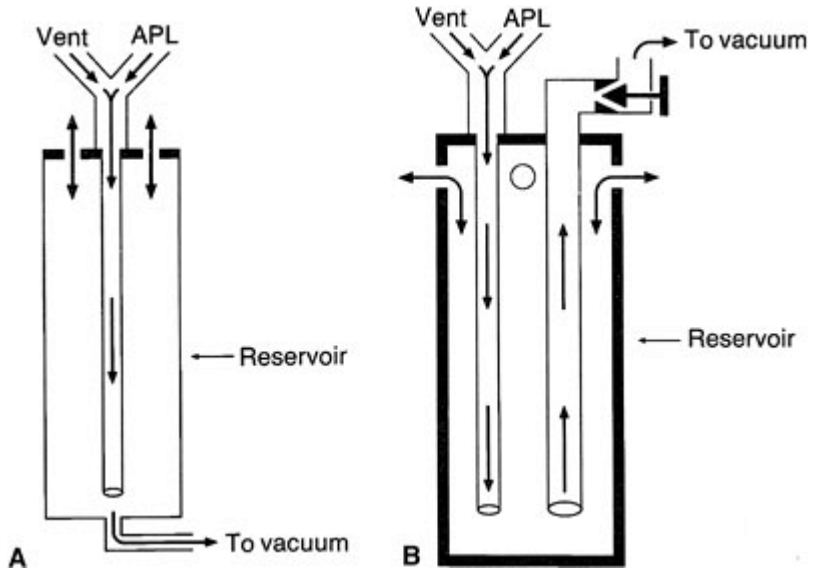

FIGURE 21-32**A and B.** Two open scavenging interfaces. Each requires an active disposal system. APL, adjustable pressure limiting valve. See text for details. (Modified with permission from Dorsch JA, Dorsch SE: Controlling trace gas levels. In Dorsch JA, Dorsch SE (eds): Understanding Anesthesia Equipment, 4th ed, p 355. Baltimore, Williams & Wilkins, 1999.)

The efficiency of an open interface depends on several factors. The vacuum flow rate per minute must equal or exceed the minute volume of excess gases to prevent spillage. The volume of the reservoir and the flow characteristics within the interface are important. Spillage will occur if the volume of a single exhaled breath exceeds the capacity of the reservoir. The flow characteristics of the system are important because gas leakage can occur long before the volume of waste gas equals the reservoir volume if significant turbulence occurs within the interface.[153]

Closed Interfaces. A closed interface communicates with the atmosphere through valves. All closed interfaces must have a positive-pressure relief valve to vent excess system pressure if obstruction occurs downstream from the interface. A negative-pressure relief valve is mandatory to protect the breathing system from subatmospheric pressure if an active disposal system is used.[147] Two types of closed interfaces are commercially available. One has positive pressure relief only; the other has both positive and negative pressure relief. Each type is discussed in the following sections.

Positive pressure relief only. This interface (Fig. 21-33, left) has a single positive-pressure relief valve and is designed to be used only with passive disposal systems. Waste gas enters the interface at the waste gas inlets. Transfer of the waste gas from the interface to the disposal system relies on the “weight” or pressure of the waste gas itself since a negative pressure evacuation system is not used. The positive-pressure relief valve opens at a preset value such as 5 cm water if an obstruction between the interface and the disposal system occurs.[154] On this type of system, a reservoir bag is not required.

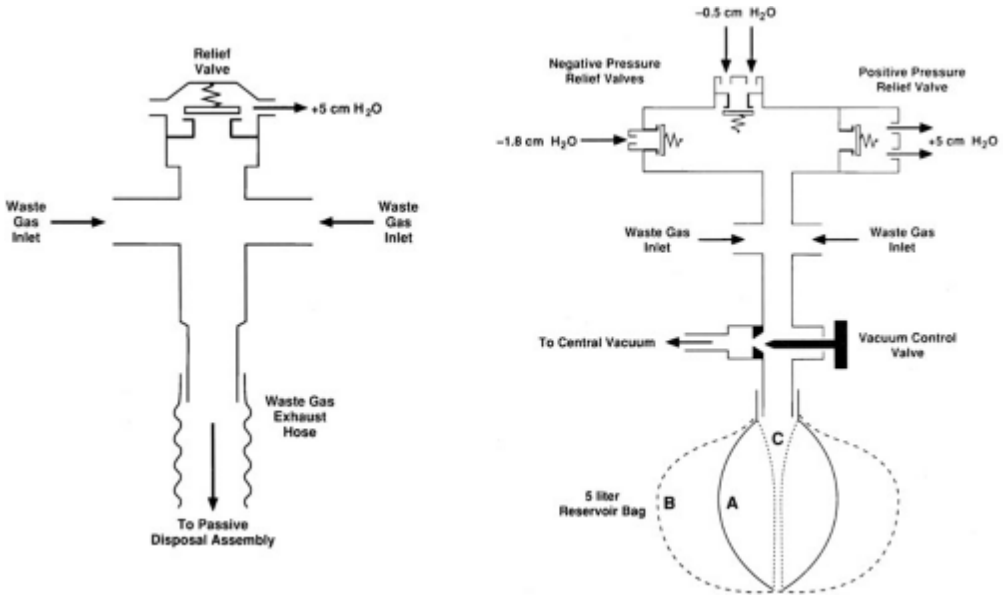

FIGURE 21-33. Closed scavenging interfaces. (*Left*) Interface used with a passive disposal system. (*Right*) Interface used with an active system. See text for details. (Modified with permission (*left*) from Scavenger Interface for Air Conditioning: Instruction Manual. Telford, Pennsylvania, North American Dräger, October 1984; (*right*) from Narkomed 2A Anesthesia System: Technical Service Manual. Telford, Pennsylvania. North American Dräger, 1985.)

Positive and negative pressure relief. This interface has a positive-pressure relief valve, and at least one negative-pressure relief valve, in addition to a reservoir bag. It is used with active disposal systems. Figure 21-33 (right) is a schematic of Dräger Medical's closed interface for suction systems. A variable volume of waste gas intermittently enters the interface through the waste gas inlets. The reservoir intermittently accumulates excess gas until the evacuation system eliminates it. The operator should adjust the vacuum control valve so that the reservoir bag is properly inflated **(A)**, not over distended **(B)**, or completely deflated **(C)**. Gas is vented to the atmosphere through the positive-pressure relief valve if the system pressure exceeds +5 cm water. Room air is entrained through the negative-pressure relief valve if the system pressure is more negative than -0.5 cm water. On some systems, a back-up negative-pressure relief valve opens at -1.8 cm water if the primary negative-pressure relief valve becomes occluded.

15 The effectiveness of a closed system in preventing spillage depends on the rate of waste gas inflow, the evacuation flow rate, and the size of the reservoir. Leakage of waste gases into the atmosphere occurs only when the reservoir bag becomes fully inflated and the pressure increases sufficiently to open the positive pressure relief valve. In contrast, the effectiveness of an open system to prevent spillage depends not only on the volume of the reservoir but also on the flow characteristics within the interface.[153]

Gas-Disposal Assembly Conduit

The gas-disposal assembly conduit (see Fig. 21-31) conducts waste gas from the scavenging interface to the gas-disposal assembly. It should be collapse proof and should run overhead, if possible, to minimize the chances of accidental occlusion.[149]

Gas-Disposal Assembly

The gas-disposal assembly ultimately eliminates excess waste gas (see Fig. 21-31). There are two types of disposal systems: active and passive.

The most common method of gas disposal is the active assembly, which uses a central evacuation system. A vacuum pump serves as the mechanical flow-inducing device that removes the waste gases usually to the outside of the building. An interface with a negative-pressure relief valve is mandatory because the pressure within the system is negative. A reservoir is very desirable, and the larger the reservoir, the lower the suction flow rate needed.[147,153]

A passive disposal system does not use a mechanical flow-inducing device. Instead, the “weight” or pressure from the heavier-than-air anesthetic gases produces flow through the system. Positive pressure relief is mandatory, but negative pressure relief and a reservoir are unnecessary. Excess waste gases can be eliminated from the surgical suite in a number of ways. Some include venting through the wall, ceiling, floor, or to the room exhaust grill of a nonrecirculating air conditioning system.[147,153]

Hazards

Scavenging systems minimize operating room pollution, yet they add complexity to the anesthesia system. A scavenging system functionally extends the anesthesia circuit all the way from the anesthesia machine to the ultimate disposal site. This extension increases the potential for problems. Obstruction of scavenging pathways can cause excessive positive pressure in the breathing circuit, and barotrauma can occur. Excessive vacuum applied to a scavenging system can result in undesirable negative pressures within the breathing system. Finally, in 2004, another unusual problem that resulted from waste gas scavenging was reported by Lees et al.[155] They reported cases of fires in engineering equipment rooms that house the vacuum pumps used for waste anesthetic gas evacuation. It seems that in some hospitals, waste gases are not directly vented outside, but may be vented into machine rooms that have vents that open to the outside. Since some new anesthesia machines such as the Datex-Ohmeda S5/ADU and Aestiva, among others, now also scavenge ventilator drive gas (which is 100% oxygen in most cases) in addition to gas from the breathing system, the environments in these machine rooms may become highly enriched with oxygen gas. The result of this has been the production of fires in these spaces outside the operating room. These sites may contain equipment or materials such as petroleum distillates (pumps/oil/grease) that in the presence of an oxygen-enriched atmosphere could be excessively combustible and a severe fire hazard.

Anesthesia Apparatus Checkout Recommendations

This checkout, or a reasonable equivalent, should be conducted before administration of anesthesia. These recommendations are only valid for an anesthesia system that conforms to current and relevant standards and includes an ascending bellows ventilator and at least the following monitors: Capnograph, pulse oximeter, oxygen analyzer, respiratory volume monitor (spirometer), and breathing system pressure monitor with high- and low-pressure alarms. This is a guideline that users are encouraged to modify to accommodate differences in equipment design and variations in local clinical practice. Such local modifications should have appropriate peer review. Users should refer to the operator's manual for the manufacturer's specific procedures and precautions, especially the manufacturer's low-pressure leak test (step #5).

Emergency Ventilation Equipment

1. *__Verify Back-up Ventilation Equipment is Available & Functioning__

   High-Pressure System

2. *__Check Oxygen Cylinder Supply__
   a. Open O_2 cylinder and verify at least half full (about 1,000 psi).
   b. Close cylinder.

3. *__Check Central Pipeline Supplies__
   a. Check that hoses are connected and pipeline gauges read about 50 psi.

      Low-Pressure System

4. *Check Initial Status of Low-Pressure System
   a. Close flow control valves and turn vaporizers off.
   b. Check fill level and tighten vaporizers' filler caps.
5. *Perform Leak Check of Machine Low-Pressure System
   a. Verify that the machine master switch and flow control valves are OFF.
   b. Attach “Suction Bulb” to common (fresh) gas outlet.
   c. Squeeze bulb repeatedly until fully collapsed.
   d. Verify bulb stays *fully* collapsed for at least 10 seconds.

e. Open one vaporizer at a time and repeat “c” and “d” as above.

f. Remove suction bulb, and reconnect fresh gas hose.

6. *__Turn on Machine Master Switch__ and all other necessary electrical equipment.

7. *__Test Flowmeters__

   a. Adjust flow of all gases through their full range, checking for smooth operation of floats and undamaged flow tubes.

   b. Attempt to create a hypoxic O_2/N_2O mixture and verify correct changes in flow and/or alarm.

Scavenging System

8. *__Adjust and Check Scavenging System__

   a. Ensure proper connections between the scavenging system and both APL (pop-off) valve and ventilator relief valve.

   b. Adjust waste gas vacuum (if possible).

   c. Fully open APL valve and occlude Y-piece.

   d. With minimum O_2 flow, allow scavenger reservoir bag to collapse completely and verify that absorber pressure gauge reads about zero.

   e. With the O_2 flush activated, allow the scavenger reservoir bag to distend fully, and then verify that absorber pressure gauge reads < 10 cm H_2O.

Breathing System

9. *__Calibrate O_2 Monitor__

   a. Ensure monitor reads 21% in room air.

   b. Verify low O_2 alarm is enabled and functioning.

   c. Reinstall sensor in circuit and flush breathing system with O_2.

   d. Verify that monitor now reads greater than 90%.

10. __Check Initial Status of Breathing System__

   a. Set selector switch to “Bag” mode.

   b. Check that breathing circuit is complete, undamaged, and unobstructed.

   c. Verify that CO_2 absorbent is adequate.

   d. Install breathing circuit accessory equipment (e.g., humidifier, PEEP valve) to be used during the case.

11. __Perform Leak Check of the Breathing System__

   a. Set all gas flows to zero (or minimum).

   b. Close APL (pop-off) valve and occlude Y-piece.

   c. Pressurize breathing system to about 30 cm H_2O with O_2 flush.

   d. Ensure that pressure remains fixed for at least 10 seconds.

   e. Open APL (pop-off) valve and ensure that pressure decreases.

Manual and Automatic Ventilation Systems

12. __Test Ventilation Systems and Unidirectional Valves__

a. Place a second breathing bag on Y-piece.

b. Set appropriate ventilator parameters for next patient.

c. Switch to automatic ventilation (Ventilator) mode.

d. Turn ventilator ON and fill bellows and breathing bag with O_2 flush.

e. Set O_2 flow to minimum, other gas flows to zero.

f. Verify that during inspiration bellows delivers appropriate tidal volume and that during expiration bellows fills completely.

g. Set fresh gas flow to about 5 L/min.

h. Verify that the ventilator bellows and simulated lungs fill *and empty* appropriately without sustained pressure at end expiration.

i. *Check for proper action of unidirectional valves.*

j. Exercise breathing circuit accessories to ensure proper function.

k. Turn ventilator OFF and switch to manual ventilation (bag/APL) mode.

l. Ventilate manually and assure inflation and deflation of artificial lungs and appropriate feel of system resistance and compliance.

m. Remove second breathing bag from Y-piece.

Monitors

13. **Check, Calibrate, and/or Set Alarm Limits of all Monitors**

Capnometer

Oxygen Analyzer

Pressure monitor with High- and Low-Airway Pressure Alarms

Pulse Oximeter

Respiratory Volume Monitor (Spirometer)

Final Position

14. **Check Final Status of Machine**

a. Vaporizers off.

b. APL valve open.

c. Selector switch to “Bag.”

d. All flowmeters to zero (or minimum).

e. Patient suction level adequate.

f. Breathing system ready to use.

Chapter 22

Airway Management

William H. Rosenblatt

KEY POINTS

1	Three mechanisms account for 75% of airway management injuries: inadequate ventilation, esophageal intubation, and difficult tracheal intubation.
2	Several physical evaluation measures of the difficult airway have become popularized, though their reproducibility and predictability are disputed.
3	Multivariate composite indexes of airway exam findings have improved positive predicted value and specificity.
4	Tracheal intubation should be considered nonroutine under the following conditions: (1) the presence of equally important priorities to the management of the airway ("full stomach," "open globe," etc.), (2) abnormal airway anatomy, (3) an emergency, or (4) direct injury to the larynx and/or trachea.
5	It must be noted that the patient with normal lung compliance should require no more than 20 to 25 cm H_2O pressure to inflate the lungs.
6	Laryngeal mask airway (LMA) size selection is critical to its successful use, and to the avoidance of minor as well as more significant complications.
7	Timing of the removal of the LMA at the end of surgery is critical to avoid complications.
8	It is important to assure that the first attempt at laryngoscopy is a "best attempt."
9	The Functional Airway Assessment (FAA) places an emphasis on the interdependence of anatomic characteristics rather than on their individual size or functional integrity.
10	If, during the laryngoscopy, a satisfactory laryngeal view is not achieved, the backward-upward-rightward pressure (BURP) maneuver may aid in improving

	the view.
11	Extubation of the trachea must not be considered a benign procedure. Most adult patients are extubated after the return of consciousness and spontaneous respiration, the resolution of neuromuscular block, and the ability to follow simple commands.
12	The LMA had been "repositioned" from the emergency to the routine management pathway of the American Society of Anesthesiologists (ASA) Difficult Airway Algorithm.
13	The ASA defines the difficult airway as the situation in which the conventionally trained anesthesiologist experiences difficulty with mask ventilation or both. Entry into the algorithm begins with the evaluation of the airway.
14	Awake airway management remains a mainstay of the ASA's Difficult Airway Algorithm.
15	There is no true or firm indication for fiberoptic bronchoscope (FOB)–aided intubation, as there might be with direct laryngoscopy.
16	Retrograde wire intubation (RWI) can be a primary intubation technique (elective or urgent) and also employed after failed attempts at direct laryngoscopy, fiberoptic-aided intubation, and LMA-guided intubation.
17	The ASA Difficult Airway Algorithm lists transtracheal jet ventilation as an option in the cannot-mask ventilate, cannot-intubate situation.

PERSPECTIVES ON AIRWAY MANAGEMENT

The airway manager of the twenty-first century is faced with a mind-boggling choice of devices and techniques. The penultimate decade of the last century reintroduced the concept of supralaryngeal ventilation for a large number of surgical procedures. This was followed in the late 1990s by a proliferation of capable supraglottic airways (SGA). Two prominent movements in medicine fueled this movement: evidence-based analysis of medical therapies and a trend toward reduced invasiveness in instrumentation. Techniques of difficult airway management are influenced by both the expanded clinical applications and clinician comfort with SGA ventilation, and new, nonirritating inhalation agents.

1 Techniques and practices in airway management have long been an important concern of the American Society of Anesthesiologists (ASA). In 1991, Caplan et al reported that 24% of 1,541 liability claims in the ASA closed claims database were related to adverse respiratory events.[1] Three mechanisms accounted for 75% of these injuries: inadequate ventilation, esophageal intubation, and difficult tracheal intubation. A more recent analysis of the closed claims data examined

airway injuries (6% of 4,460 claims as of 1996). Interestingly, most injuries to the larynx occurred

during routine tracheal intubations.[2]

Airway management remains as much art as science. "Experience matters" holds as much truth for airway management as "vigilance" does for the entire field of anesthesiology. In part, this is because of the lack of adequate means of preoperatively detecting the patient who is difficult to tracheally intubate by direct laryngoscopy (DL). More information has surfaced showing that routine patient evaluation fails to detect a major source of these failures.[3] Fortunately, this has become a less significant problem as SGA use proliferates and new means of intubation are adopted.[4] Still DL remains the fastest means of achieving tracheal intubation across all operators.

It is clear that management of the airway is paramount to safe perioperative care and the following steps become necessary to favorably affect outcome: (1) a thorough airway history and physical examination; (2) consideration of management plans for use of a supraglottic means of ventilation (e.g., facemask, Laryngeal Mask Airway [LMA]); (3) a management plan for intubation and extubation techniques; and (4) an alternative plan of action should difficulties arise.

Review of Airway Anatomy

The term "airway," refers to the upper airway—consisting of the nasal and oral cavities, pharynx, larynx, trachea, and principal bronchi. The airway in humans is primarily a conducting pathway. Because the oroesophageal and nasotracheal passages cross each other, anatomic and functional complexities have evolved for protection of the sublaryngeal airway against aspiration of food that passes through the pharynx. Anatomically complex, the airway undergoes growth and development and significant changes in its size, shape, and relation to cervical spine between infancy and childhood.[5] Similar to other systems in the body, it is not immune from the influence of genetic, nutritional, and hormonal factors. Table 22-1 illustrates the anatomic differences in the larynx between the infant and adult.

TABLE 22-1 Anatomic Differences Between The Pediatric and Adult Airways

Proportionately smaller infant/child larynx
Narrowest portion: cricoid cartilage in infant/child; vocal folds in adult
Relative vertical location: C3, C4, C5 in infant/child; C4, C5, C6 in adult
Epiglottis: longer, narrower, and stiffer in infant/child
Aryepiglottic folds closer to midline in infant/child
Vocal folds: anterior angle with respect to perpendicular axis of larynx in infant/child
Pliable laryngeal cartilage in infant/child
Mucosa more vulnerable to trauma in infant/child

The laryngeal skeleton consists of nine cartilages (three paired and three unpaired); together, these house the vocal folds, which extend in an anterior–posterior plane from the thyroid cartilage to the arytenoid cartilages. The shield-shaped thyroid cartilage acts as the anterior "protective housing" of the vocal mechanism (Fig. 22-1). Movements of the laryngeal structures are controlled by two groups of muscles: the extrinsic muscles, which move the larynx as a whole, and the intrinsic muscles, which move the various cartilages in relation to one another. The larynx is innervated bilaterally by two branches of each vagus nerve: the superior laryngeal nerve and the recurrent laryngeal nerve. Because the recurrent laryngeal nerves supply all of the intrinsic muscles of the larynx (with the exception of cricothyroid), trauma to these nerves can result in vocal cord dysfunction. As a result of unilateral nerve injury, airway function is usually unimpaired, but the protective role of larynx in preventing aspiration may be compromised.

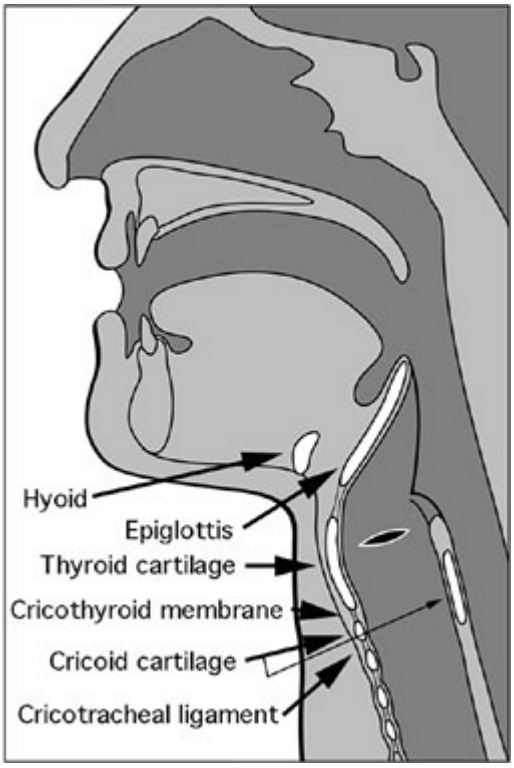

FIGURE 22-1. The major landmarks of the airway mechanism. Note that the cricoid cartilage is less than 1 cm in height in its anterior aspect, but may be 2 cm in height posteriorly (*small arrow*).

The cricothyroid membrane (CTM) provides coverage to the cricothyroid space. The membrane, which is typically 9 mm in height and 3 cm in width, is composed of a yellow elastic tissue that lies directly beneath to the skin and a thin facial layer. It is located in the anterior neck between the thyroid cartilage superiorly and the cricoid cartilage inferiorly. It can be identified 1 to 1.5 fingerbreadths below the laryngeal prominence (thyroid notch, or Adam's apple). It is often crossed horizontally in its upper third by the anastomosis of the left and right superior cricothyroid arteries. The membrane has a central portion known as the conus elasticus and two lateral portions, which are thinner and located directly over the laryngeal mucosa. Because of anatomic variability in the course of veins and arteries and its proximity to the vocal folds (which are 0.9 cm above the ligaments' upper border), it is suggested that any incisions or needle punctures to the cricothyroid membrane be made in its inferior third and be directed posteriorly.

At the base of the larynx, suspended by the underside of the cricothyroid membrane, is the signet ring–shaped cricoid cartilage. This cartilage is approximately 1 cm in height anteriorly, but almost 2 cm in height in its posterior aspect as it extends in a cephalad direction, behind the cricothyroid membrane and the thyroid cartilage (see Fig. 22-1). The trachea is suspended from the cricoid cartilage by the cricotracheal ligament (CTL). The trachea measures ~15 cm in adults and is circumferentially supported by 17 to 18 C-shaped cartilages, with a posterior membranous aspect overlying the esophagus (Fig. 22-2).

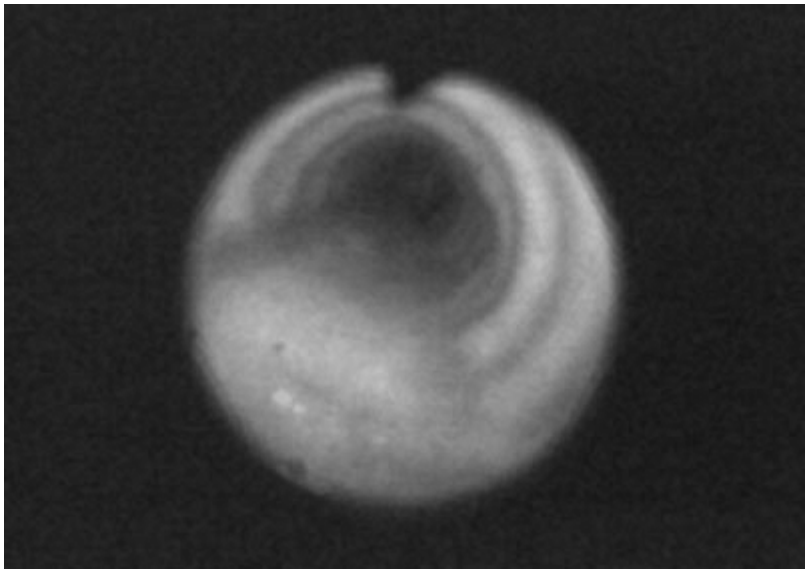

FIGURE 22-2. Bronchoscopic view of the adult trachea. The cartilaginous, C-shaped tracheal rings are seen anteriorly, and the membranous portion, overlying the esophagus, is posterior.

The first tracheal ring is anterior to the sixth cervical vertebrae. The tracheal cartilages are interconnected by fibroelastic tissue, which allows for expansion of the trachea both in length

and diameter with inspiration/expiration and flexion/extension of the thoracocervical spine. The trachea ends at the carina at the level of the fifth thoracic vertebra, where it bifurcates into the principal bronchi (Fig. 22-3). The right principal bronchus is larger in diameter than the left, and deviates from the plane of the trachea at a less acute angle. Aspirated materials, as well as a deeply inserted tracheal tube, tend to gain entry into the right principal bronchus though left sided position should be excluded. Cartilaginous rings support the first seven generations of the bronchi.

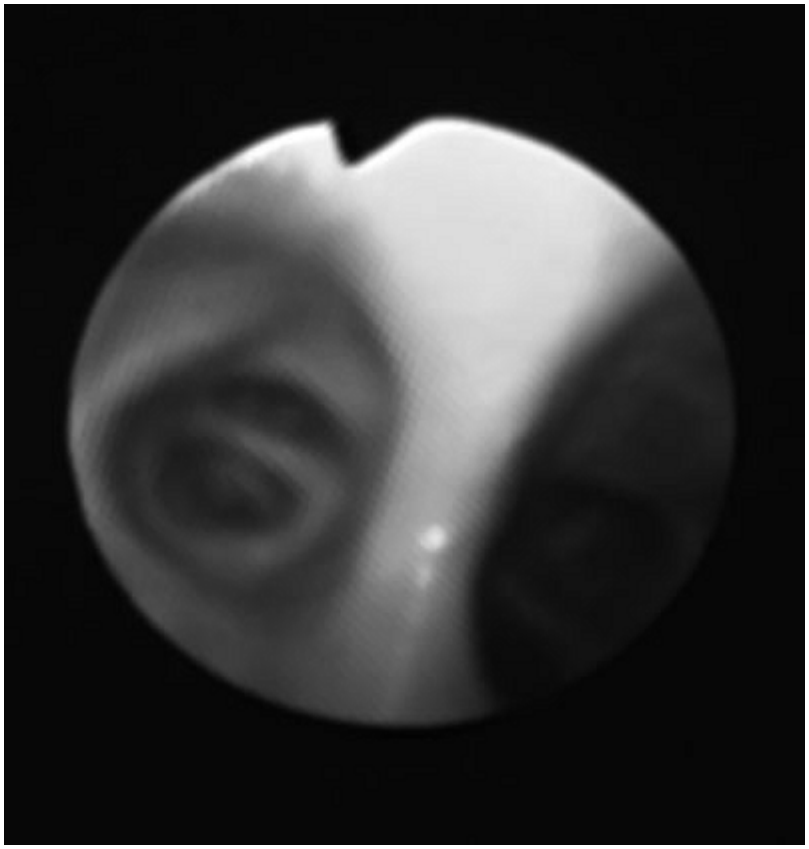

FIGURE 22-3. The adult tracheal carina. The cartilaginous rings of the principal bronchi are easily visualized beyond the carina.

Patient History and Physical Exam

Preoperative evaluation of the patient should elicit a thorough history of airway-related untoward events as well as related symptoms. A search for documentation to confirm or elucidate these problems should be conducted. Signs and symptoms related to the airway should be elicited, such as snoring (e.g., obstructive sleep apnea), chipped teeth, changes in voice, dysphagia, stridor, bleeding, cervical spine pain or limited range of motion, upper extremity neuropathy, temporomandibular joint pain or dysfunction, and significant or prolonged sore throat/mandible after a previous anesthetic. Many congenital and acquired syndromes are associated with difficult airway management (Table 22-2).

TABLE 22-2 Syndromes Associated with Difficult Airway Management

▪Pathologic Condition	▪Principal Pathologic Clinical Features Pertaining to Airway
▪CONGENITAL	
Pierre Robin syndrome	Micrognathia, macroglossia, glossoptosis, cleft soft palate

Treacher Collins syndrome (mandibulofacial dysostosis)	Auricular and ocular defects; malar and mandibular hypoplasia, microstomia, choanal atresia
Goldenhar's syndrome (oculo–auriculo–vertebral syndrome)	Auricular and ocular defects; malar and mandibular hypoplasia; occipitalization of atlas
Down's syndrome (mongolism)	Poorly developed or absent bridge of the nose; macroglossia, microcephaly, cervical spine abnormalities
Klippel-Feil syndrome	Congenital fusion of a variable number of cervical vertebrae; restriction of neck movement
Alpert's syndrome (acrocephalosyndactyly)	Maxillary hypoplasia, prognathism, cleft soft palate, tracheobronchial cartilaginous anomalies
Beckwith's syndrome (infantile gigantism)	Macroglossia
Cherubism	Tumorous lesion of mandibles and maxillae with intraoral masses
Cretinism (congenital hypothyroidism)	Absent thyroid tissue or defective synthesis of thyroxine; macroglossia, goiter, compression of trachea, deviation of larynx/trachea
Cri du chat syndrome	Chromosome 5-P abnormal; microcephaly, micrognathia, laryngomalacia, stridor
Meckel's syndrome	Microcephaly, micrognathia, cleft epiglottis
von Recklinghausen disease (neurofibromatosis)	Increased incidence of pheochromocytoma; tumors may occur in the larynx and right ventricle outflow tract
Hurler's syndrome (mucopolysaccharidosis I)	Stiff joints, upper airway obstruction because of infiltration of lymphoid tissue; abnormal tracheobronchial cartilages
Hunter's syndrome (mucopolysaccharidosis II)	Same as in Hurler's syndrome, but less severe; pneumonias

Pompe's disease (glycogen storage II)	Muscle deposits, macroglossia
▪ACQUIRED	
Infections	
Supraglottitis	Laryngeal edema
Croup	Laryngeal edema
Abscess (intraoral, retropharyngeal)	Distortion and stenosis of the airway and trismus
Papillomatosis	Chronic viral infection forming obstructive papillomas, primarily supraglottic
Ludwig's angina	Distortion and stenosis of the airway and trismus
Arthritis	
Rheumatoid arthritis	Temporomandibular joint ankylosis, cricoarytenoid arthritis, deviation of larynx, restricted mobility of cervical spine
Ankylosing spondylitis	Ankylosis of cervical spine; less commonly ankylosis of temporomandibular joints; lack of mobility of cervical spine
Benign Tumors	
Cystic hygroma, lipoma, adenoma, goiter	
Stenosis or distortion of the airway	
Malignant Tumors	
Carcinoma of tongue, carcinoma of larynx, carcinoma of thyroid	Stenosis or distortion of the airway; fixation of larynx or adjacent tissues (e.g., infiltration or fibrosis from irradiation)

Trauma	
Head injury, facial injury, cervical spine injury	Cerebrospinal rhinorrhea, edema of the airway; hemorrhage; unstable fracture(s) of the maxillae and mandible; intralaryngeal damage
Miscellaneous Conditions	
Morbid obesity	Short, thick neck and large tongue are likely to be present
Acromegaly	Macroglossia; prognathism
Acute burns	Edema of airway

2 Over the last two decades, several physical evaluation measures have become popularized, though their reproducibility and predictability are disputed.[6] The difficulty in developing the perfect airway evaluation tool lies in two interrelated areas: simplicity and interdependency. Though simple bedside evaluation tools are useful, adequate evaluation may require endoscopic, radiologic, or other uncommon examinations.[3] Interdependency refers to the predictive value of one airway exam measure based on the findings of another. This is discussed under the topic of functional airway assessment (FAA) in a later section.

El-Ganzouri et al designed a model for stratifying risk of difficult direct laryngoscopy using a large population.[7] This group examined five common indices individually and in a multivariate model to assess predictive power. As can be seen in Table 22-3, no individual measure proved both sensitive and specific. Though the Mallampati classification (Fig. 22-4) was the most sensitive index, it had low specificity (many false-positives), and low-positive predictive value (4% for a grade IV laryngeal view).[8] Positive predictive values were low for all the commonly used indices.

TABLE 22-3 Statistical Accuracy of Commonly Applied Physical Airway Indexes[7,8,9]

	·SENSITIVITY[a]%	·SPECIFICITY[a]%	·POSITIVE PREDICTIVE VALUE[a]
Mouth opening (<4 cm)	26.3	94.8	25
Thyromental distance (<6 cm)	7	99.2	38.5
Mallampati Class III	44.7	89.0	21
Neck movement <80	10.4	98.4	29.5

Inability to prognath	16.5	95.8	20.6
Body weight >110	11.1	94.6	11.8
History of difficult intubation	4.5	99.8	69.0

[a]For finding of grade III/IV view on direct laryngoscopy.

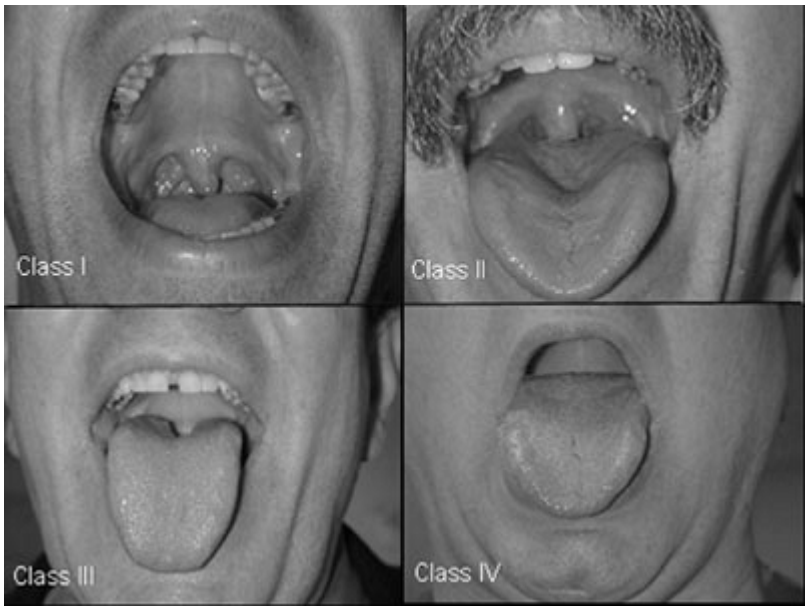

FIGURE 22-4. Mallampati/Samsoon–Young classification of the oropharyngeal view.[10] *Class I:* uvula, faucial pillars, soft palate visible; *Class II:* faucial pillars, soft palate visible; *Class III:* soft and hard palate visible; *Class IV:* hard palate visible only (added by Samsoon and Young).

3 This multivariate index (MI) assigned relative weights to each exam finding based on the odds of a high-grade laryngeal view on DL with increasing exam score. The scoring of each of these physical exams is listed in Table 22-4. The authors noted that at increasing MI scores, positive predictive value increased, but sensitivity decreased (i.e., higher MI scores occur when there are more positive physical findings, but not all difficult laryngoscopy patients will manifest multiple findings). Compared to the Mallampati classification alone, the multivariate composite index had an improved positive predictive and specificity value at equal sensitivity. Of course, some pathology will only present on the induction of anesthesia and/or attempts at laryngoscopy (Fig. 22-5).[10]

TABLE 22-4 Techniques of Common Airway Indexes Measurement

Thyromental distance: measured along a straight line from tip of mentum to thyroid notch in neck-extended position
Mouth opening: interincisor distance (or inter-alveolus distance when edentulous) with the mouth fully opened[7]
Mallampati score (see legend, Fig. 22-4)
Head and neck movement: the range of motion from full extension to full flexion[9]
Ability to prognath: capacity to bring the lower incisors in front of the upper incisors[7]

FIGURE 22-5. A 40-year-old male whose epiglottic cyst was discovered at laryngoscopy.

Few studies have objectively determined those findings that identify the difficult-to-mask ventilate patient. This basic airway maneuver was examined in a control study by Langeron et al.[11] Of 1,502 patients (excluding planned rapid-sequence induction or emergency cases), 5% were characterized as difficult mask ventilation (DMV). Only one patient in the series was impossible to ventilate by face mask. Table 22-5 describes the criteria for defining a DMV and the five independent clinical predictors. The presence of two predictors indicted a high likelihood of DMV.

TABLE 22-5 Assessment and Predictability of Difficult Mask ventilation[11]

Criteria for difficult mask ventilation
Inability for one anesthesiologist to maintain oxygen saturation >92%

Significant gas leak around face mask	
Need for ⩾IS 4 min gas flow (or use of fresh gas flow button more than twice)	
No chest movement	
Two-handed mask ventilation needed	
Change of operator required	

Independent risk factors for difficult mask ventilation

	Odds ratio
Presence of a beard	3.18
Body mass index >26 ng/m^2	2.75
Lack of teeth	2.28
Age >55	2.26
History of snoring	1.84

4 In general, tracheal intubation should be considered nonroutine under the following conditions: (1) the presence of equally important priorities to the management of the airway ("full stomach," "open globe," etc.), (2) abnormal airway anatomy, (3) an emergency, or (4) direct injury to the larynx and/or trachea. Although the finding of abnormal anatomy is not necessarily synonymous with the difficult airway, it should kindle a heightened level of suspicion. Several investigators have identified anatomic features as having unfavorable influences on the mechanics of direct laryngoscopy; these are explainable on the basis of inability to create a line of sight from the operator's eye to the aperture of the larynx. In the earliest attempt to describe anatomic correlates of difficult intubation, Cass et al placed emphasis on a short muscular neck with a

full dentition, a receding mandible with obtuse mandibular angles, protruding maxillary incisor teeth, decreased mobility at temporomandibular joints, a long high arched palate, and increased alveolar–mental distance.[12] Early radiographic studies showed that the posterior depth of the mandible (the distance between the bony alveolus immediately behind the third molar tooth and the lower border of mandible) was an important factor in determining the ease or difficulty of laryngoscopy.[13] As is discussed later, this anatomic feature is receiving renewed interest.

CLINICAL MANAGEMENT OF THE AIRWAY

Preoxygenation

Preoxygenation (also commonly termed "denitrogenation") should be practiced in all cases when time permits.[14] This procedure entails the replacement of the nitrogen volume of the lung (upwards of 69% of the functional residual capacity [FRC]) with oxygen to provide a reservoir for diffusion into the alveolar capillary blood after the onset of apnea.[15] Preoxygenation with 100% O_2 via a tight-fitting facemask for 5 minutes in a spontaneously breathing patient can furnish up to 10 minutes of oxygen reserve following apnea (in a patient without significant cardiopulmonary disease and a normal oxygen consumption).[16] In one study of healthy, nonobese patients who were allowed to breathe 100% O_2 preoperatively, subjects sustained an oxygen saturation of greater than 90% for 6 ± 0.5 min, whereas obese patients experienced oxyhemoglobin desaturation to under 90% in 2.7 ± 0.25 min.[17] The patient breathing room air (21% O_2) will experience oxyhemoglobin desaturation to a level of under 90% after approximately 2 minutes under ideal conditions. Patients in respiratory failure, or with conditions affecting metabolism or lung volumes, frequently evidence desaturation sooner owing to increased O_2 extraction, decreased FRC, or right-to-left transpulmonary shunting. The most common reason for not achieving a maximum alveolar FIO_2 during preoxygenation is a loose-fitting mask, allowing the entrainment of room air.[14] Less time-consuming methods of preoxygenation have also been described. Using a series of four vital capacity breaths of 100% O_2 over a 30-second period, a high arterial PaO_2 (339 mm Hg) can be achieved, but the time to desaturation is consistently shorter as compared to techniques of breathing 100% O_2 for 5 minutes.[18] A modified vital capacity technique, wherein the patient is asked to take eight deep breaths in a 60-second period, shows promise in terms of prolonging the time to desaturation.[14,19] I prefer the technique of applying a tight-fitting mask for 5 minutes or more of tidal volume breathing; the mask is placed immediately after the patient has been made comfortable on the operating room table and remains in place during intravenous catheter insertion and application of monitors. Pharyngeal insufflation of oxygen is a technique that has been described to prolong the duration that an apneic patient sustains an oxyhemoglobin saturation of >90%. In this technique, oxygen is insufflated at a rate of 3 L/min via a catheter passed through the nares. This technique relies on the phenomenon of apneic oxygenation, a process by which gases are entrained into the alveolar space during apnea, as long as there is a patent airway.[20] This entrainment can provide enough oxygen to sustain hemoglobin saturation for prolonged periods. It is based on the decrease in intrathoracic pressure, relative to atmospheric pressure, produced as approximately 210 cm^3 of oxygen diffuses into the alveolar capillary bed each minute while as little as 12 cm^3 of carbon dioxide diffuses into

the alveolar space (the remainder of the carbon dioxide being buffered in the blood or tissues). The alveolar carbon dioxide is not removed in this situation, limiting the duration of this technique of oxygenation.

Support of the Airway with the Induction of Anesthesia

With the induction of anesthesia and the onset of apnea, ventilation and oxygenation are supported by the anesthesiologist. Traditional methods include the anesthesia facemask and the tracheal tube. During the last decade several SGA devices have been introduced into worldwide clinical practice. Of these, the LMA has gained significant acceptance among anesthesiologists in the United States, with use rates as high as 35% of all general anesthesia cases, in some settings.[21] The use of the LMA in routine surgery, including cases traditionally managed with tracheal intubation, has been previously discussed.[58]

The Anesthesia FaceMask

The anesthesia facemask is the device most commonly used to deliver anesthetic gases and oxygen, as well as to ventilate the patient who has been made apneic.

The skillful use of a facemask may be challenging and, despite the many advances in airway management, remains a mainstay in the delivery of anesthesia and resuscitation. When the induction of anesthesia is initiated, the patient's level of consciousness changes from the awake

state, with a competent and protected airway, to the unconscious state, with an unprotected and potentially obstructed airway. This drug-induced central ventilatory drive depression with a relaxation of the musculature of the upper airway can rapidly lead to hypercapnea and hypoxia. Facemask ventilation is minimally invasive and virtually universal and requires the least sophisticated equipment, thus making it critical to management of the airway.

Appropriate positioning of the patient is paramount to successful mask ventilation. With the patient in the supine position, the head and neck are placed in the *sniffing* position, which is discussed extensively later in the chapter. This position improves mask ventilation by anteriorizing the base of the tongue and the epiglottis.

The mask is gently held over the patient's face with the left hand, leaving the right hand free for other uses (Fig. 22-6).

Elastic "mask straps" may be used to help secure the mask in the awake or anesthetized patient who is breathing spontaneously and without obstruction, or to complement the left-hand grip. The mask straps can be particularly helpful for the clinician with short fingers. However, prolonged use of tight-fitting mask straps has been associated with motor and sensory neuropraxias.

FIGURE 22-6. Holding the anesthesia mask on the face. The thumb and the first finger grip the mask in such a fashion that the anesthesia circuit (or ambu bag) connection abuts the web between these digits. This allows the palm of the hand to apply pressure to the left side of the mask, while the tips of these three digits apply pressure over the right. The third finger helps to secure under the mentum, while the fourth finger is under the angle of the mandible or along the lower mandibular ridge. Mask straps (on pillow) may be used to

complement the hand grip by securing the right side of the mask.

After induction of anesthesia, a tight fit of the facemask is achieved by downward displacement of the mask between the thumb and first/second fingers with concurrent upward displacement of the mandible with the remaining fingers. This latter maneuver, commonly known as a *jaw thrust*, raises the soft tissues of the anterior airway off of the pharyngeal wall and allows for improved ventilation. In those patients who are obese, edentulous, or bearded, two hands or a mask strap may be required to ensure a tight-fitting mask seal. When two hands are required for holding the facemask, a second operator will obviously be required to ventilate the patient (Fig. 22-7). If need be, the second operator can lend a third hand to the mask fitting, providing for both jaw thrust and chin lift.

FIGURE 22-7. When mask ventilation is difficult owing to upper airway obstruction, a second operator may be required so that **(A)** two or **(B)** three hands can be used in a jaw-thrust maneuver.

5 It must be noted that the patient with normal lung compliance should require no more than 20 to 25 cm H_2O pressure to inflate the lungs. If more pressure than this is required, the clinician should reevaluate the adequacy of the airway, then adjust the mask fit, seek the aid of a second operator to perform two- or three-handed mask holds, and/or consider other devices that aid in the creation of an open passage for airflow through the upper airway. Both rigid oral airways and soft nasal airways create an artificial passage between the roof of the mouth, tongue, and the posterior pharyngeal wall (Fig. 22-8).

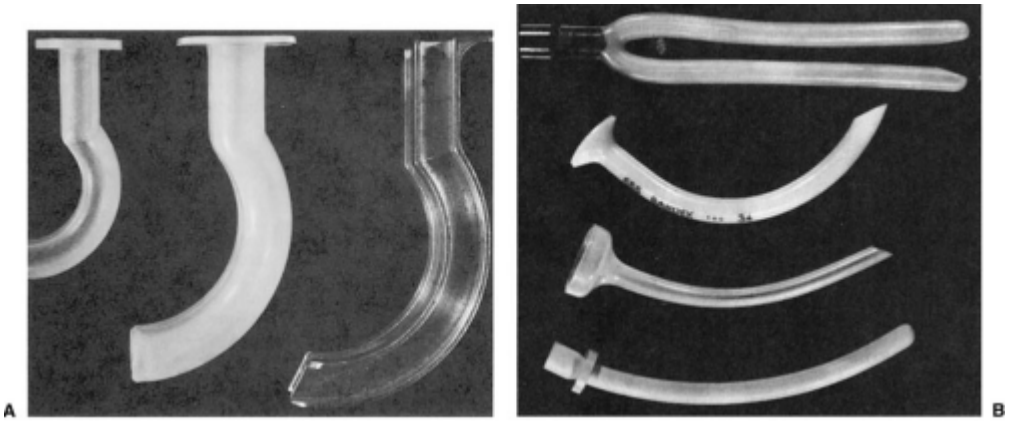

FIGURE 22-8. A variety of oral **(A)** and nasal **(B)** airways are available. The goal of these devices is to hold the base of the tongue forward to create an air passage.

Oral airways, which come in a wide variety of sizes, can stimulate the semiconscious patient and provoke coughing, vomiting, and/or laryngospasm. The level of anesthesia must be assessed before they are inserted. Likewise, an SGA may be used at this juncture if the anesthetic is adequate. Nasal airways, less stimulating to the patient, can cause significant nasal trauma

and bleeding and should be used with extreme caution in patients with known coagulopathy or nasal deformities. These devices are contraindicated in the patient with a basilar skull fracture.

Obstruction to mask ventilation may be caused by laryngospasm, a reflex closure of the vocal folds. Laryngospasm occurs as a result of foreign body (e.g., oral or nasal airway); saliva, blood, or vomitus touching the glottis; or even a light plane of anesthesia. Hypoxia as well as noncardiogenic pulmonary edema can result if there is continued spontaneous ventilation against closed vocal cords. Treatment of laryngospasm includes removal of an offending stimulus (if it can be identified), continuous positive airway pressure, deepening of the anesthetic state, and the use of a rapid-acting muscle relaxant.

If there are no contraindications (e.g., a "full stomach" or other aspiration risk), mask ventilation can be the technique employed for the duration of anesthesia maintenance. Otherwise, it is commonly used to administer anesthetic gases until the anesthetic state is adequate for use of another means of airway support (e.g., SGA, tracheal tube). This decision is made after careful consideration of the patient's coexisting diseases and surgical requirements.

Supraglottic Airways

The LMA ushered in the first major use of SGAs in the United States. But, by the time of its initial introduction in 1989 and approval by the U.S. Federal Drug Administration (FDA) in 1991, it was being used in more than 500 hospitals in the United Kingdom. Though initially approved for use as a substitute for facemask ventilation and when tracheal intubation was not achievable, it soon enjoyed wide use in surgical cases traditionally managed with tracheal intubation.[21]

Though other SGAs were available in the early 1990s (e.g., COPA J. Mallinkroft Medical, Athlone, Ireland), it was not until the patent of original LMA design, the LMA-Classic®, expired in 2002 that there was a proliferation of similar devices. A wealth of information exists on the LMA and its subsequent iterations (all by the original inventor, Dr. Archie Brain). Much of this knowledge may apply to newer SGAs but studies on those devices are few at the time of this writing. This chapter devotes considerable text to the family of LMAs. This is not meant to infer preference, but rather a

relative availability of information.

The advent of the LMA as well as other supralaryngeal airways have led some to question the relative safety of tracheal intubation.[22] A recent study by Tanaka et al demonstrated vocal cord edema and increased airflow resistance in patients undergoing minor surgery with a tracheal tube.[23] These changes were not seen with LMA use. This, along with ASA closed claim database information, lends support to the search for safe alternatives to tracheal intubation whenever possible.[24]

LMA Design. The LMA is composed of a small "mask" designed to sit in the hypopharynx, with an anterior surface aperture overlying the laryngeal inlet (Fig. 22-9). The rim of the mask is composed of an inflatable silicone cuff that fills the hypopharyngeal space, creating a seal that allows positive-pressure ventilation with up to 20 cm H_2O pressure.[25] The adequacy of the seal is dependent on correct placement and appropriate size. It is less dependent on the cuff filling pressure or volume. Attached to the posterior surface of the mask is a barrel (airway tube) that extends from the mask's central aperture through the mouth and can be connected to an ambu bag or anesthesia circuit.

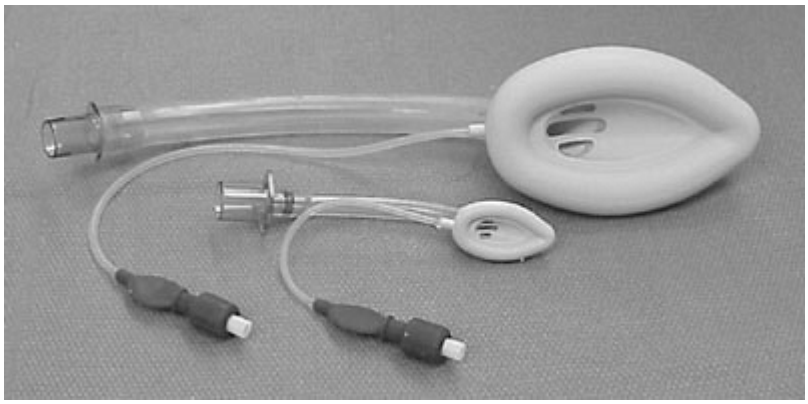

FIGURE 22-9. The original LMA design: a size 1 and size 6 LMA-Classic. The two bars over the airway aperture prevent the epiglottis from obstructing the LMA barrel.

6 LMA size selection is critical to its successful use, and to the avoidance of minor as well as more significant complications. Neonatal to large adult sizes are available. Table 22-6 gives the recommended size for patient weight and the maximum inflation volumes. The manufacturer recommends that the clinician choose the largest size that will comfortably fit in the oral cavity, then inflate to the minimum pressure that allows ventilation to 20 cm H_2O without an air leak. The intracuff pressure should never exceed 60 cm H_2O (and should be periodically monitored if nitrous oxide is used as part of the anesthetic). When an adequate seal cannot be obtained with 60 cm H_2O cuff pressure, the LMA may be malpositioned and/or sizing should be reevaluated. Light anesthesia may also contribute to poor seal or partial or complete laryngospasm.

TABLE 22-6 LMA Sizing and Inflation Volumes

·LMA SIZE	·PATIENT WEIGHT	·INCREASE IN SIZE (%)	·MAXIMUM INFLATION VOLUME (mL)	·TEST INFLATION VOLUME (mL)

1	Neonates/infants up to 5 kg	—	4	6
1.5	5–10 kg	21	7	10
2	10–20 kg	21	10	15
2.5	20–30 kg	18	14	21
3	>30 kg	15.7	20	30
4	Small adults	14.4	30	45
5	Normal adults	13.8	40	60
6	Large adults	8.1	50	80

LMA Insertion. The insertion of the LMA as described by its inventor, Dr. Archie J. I. Brain, has been modified by a number of writers. Discussion of these various alternatives is beyond the scope of this text. Dr. Brain's initial contemplations

of this unique airway considered routine and natural placement of a "foreign body" in the hypopharynx—food. It was Dr. Brain's intent to mimic the placement of food into the hypopharynx and thereby establish the placement of a device, which could then serve as an airway. All varieties of the LMA (with the exception of the LMA-Fastrach) follow the same insertion technique.

To understand the insertion technique, we must therefore review the processes of deglutination: lubrication with saliva; formation of a flat oval food bolus by the tongue; initiation of the swallowing reflex by stimulation of the palate; upward pressure by the tongue flattening the food bolus against the palate; directing of the food bolus toward the posterior pharyngeal wall and into the hypopharynx by the shape of the palate and pharyngeal wall; head extension and neck flexion opening the space behind the larynx to allow passage of the food bolus into the hypopharynx; and finally, opening of the upper esophageal sphincter to allow esophageal entry of the food bolus. These functions allow the food bolus to reach its mark blindly, while avoiding the anterior pharyngeal structures and avoiding reflex responses meant to protect the airway.

Prototype insertion methods involved rotation through 180° and the early use of an introducer to prevent down-folding of the epiglottis. The currently recommended technique, illustrated in Figure 22-10, has been found to be less traumatic and has a 98% success rate. In this technique the mask is lubricated with a nonsilicone, nonlocal anesthetic–containing lubricant (simulating the saliva) and is fully deflated to form a thin, flat wedge shape (masticated food bolus). The operator's nondominant hand is placed under the occiput to flex the neck on the thorax and extend the head at the atlanto-occipital joint (creating a space behind the larynx; this action also tends to open the mouth).[26] The index finger of the dominant hand is placed in the cleft between the mask and barrel. The hard palate is visualized and the superior (nonaperture) surface of the mask is placed against it. Force is applied by the index finger in an upward direction toward the top of the patient's head. This will cause the mask to flatten out against the palate and follow the shape of the palate as it slides into the pharynx and hypopharynx. The index finger continues

along this arc, always applying an outward pressure until the resistance of the upper esophageal sphincter is met. The most common error made by clinicians is applying pressure with a posterior vector. This tends to catch the tip of the LMA on the posterior pharyngeal wall, causing folding with resultant misplacement and trauma.

FIGURE 22-10. Insertion of the LMA. The LMA is inserted with the index finger of the dominant hand pressing with a force vector against the hard palate (**A** and **B**). The outward force vector is continued from the hard palate to the pharynx and hypopharynx **(C)** until the index finger meets resistance against the upper esophageal sphincter **(D)**.

Once insertion is complete, removal of the inserting hand is facilitated by gentle stabilization of the LMA barrel with the nondominant hand. Prior to attachment of the anesthesia circuit, the LMA is inflated with the minimum amount of gas to form an effective seal. Though it is difficult to suggest a particular volume of gas to be used, the operator should be

accustomed to the feel of the pilot bulb when it is inflated to 60 cm H_2O pressure, the maximum suggested seal pressure. Accompanying the inflation, one should be able to observe a rising of the cricoid and thyroid cartilage and lifting of the barrel out of the mouth by approximately 1 cm as the mask is lifted off the upper esophageal sphincter. The mask is fixed in position by bringing the barrel down against the chin and taping in the midline while a gentle upward pressure is exerted against the hard palate. If a midline position is not possible owing to the nature of the patient position or surgical procedure, a flexible LMA (discussed later) should be considered. A bite block is recommend to prevent biting and occlusion of the LMA barrel.

The LMA and Gastroesophageal Reflux. Although the distal tip of the LMA's mask sits in the esophageal inlet, it does not reliably seal it. A predominant clinical perception is that the LMA does not protect the trachea from regurgitated gastric contents. As of 2004, just 23 cases of suspected pulmonary aspiration have been reported (with an estimated 200,000,000 uses of the LMA worldwide). Of these, only 13 were verified as true aspiration events and none resulted in death, though five patients required positive-pressure ventilation. There were predisposing factors in most of the cases, including obesity, dementia, emergency surgery, upper abdominal surgery, Trendelenburg position, intraperitoneal insufflation, or a difficult airway.[27,28,29,30,31,32,33,34,35,36,37,38,39,40] Indeed, when used in patients at low risk for regurgitation,

the rate of aspiration during LMA use is similar to that in all non-LMA general anesthetics (~2 in 10,000 cases), though the incidence of gastroesophageal reflux may be increased when compared to use of the facemask.[41,42,43,44,45]

Some evidence suggests that there may be more gastroesophageal reflux during LMA use with a patient in the Trendelenburg or lithotomy position.[43,45] If regurgitated gastric contents are noted in the LMA barrel, maneuvers similar to those applied when using an ETT should be instituted: Trendelenburg position, administer 100% oxygen, leave the LMA in place and use a flexible suction device down the barrel, deepen anesthetic if necessary.

When populations of patients considered to have a full stomach are studied (in controlled trials, prospective series, or anecdotally), there is a very low incidence of aspiration noted with elective or emergency LMA use. Reports have included patients who are morbidly obese or experience frequent gastroesophageal reflux and those undergoing elective cesarean section or airway rescue during labor and those presenting to emergency departments or paramedic crews.[46,47,48,49,50,51,52,53,54,55,56] During cardiopulmonary resuscitation, the incidence of gastroesophageal regurgitation is four times greater with a bag-valve mask than with the LMA.[57]

Unconventional Use of the LMA. Since its introduction, a wealth of clinical data has indicated that the LMA can be safely used in the operating room in a variety of clinical situations. A large number of clinical situations traditionally managed with tracheal intubation and mechanical ventilation have been performed with the LMA.[58]

LMA and Positive-Pressure Ventilation. Though first introduced for use with spontaneous ventilation, the LMA has proved useful for cases in which positive-pressure ventilation is either desired or preferred.[59,60] Contrary to initial impression, positive-pressure ventilation can be safely accomplished with the LMA.[61,62,63,64] There is no difference found in gastric inflation with positive pressure (<17 cm H_2O) when comparing the LMA and the ETT.[65,66] When using the LMA, one should limit tidal volumes to 8 mL/kg and airway pressure to 20 cm H_2O since this is the sealing pressure of the device under normal circumstances. LMA use has been described with the supine, prone, lateral, oblique, Trendelenburg, and lithotomy positions.[67] Though the manufacturer recommends use for a maximum of 2 to 3 hours, reports of use lasting more than 24 hours can be found.[68]

The LMA-Flexible. The advent of the LMA-flexible (Fig. 22-11) has permitted extension of LMA use to a variety of cases in which the airway is shared with the surgical team (e.g., otolaryngologic surgery).[69] The LMA-flexible differs from the original design by virtue of a thin-walled, small-diameter, wire-reinforced (kink-resistant) barrel, which can be positioned out of the midline without affecting the hypopharyngeal position of the mask. It was designed to be used with a tonsillar mouth gag, as employed in surgery on the mouth and pharynx.[70,71] The LMA-flexible has also proved useful when heavy drapes are placed over the head and airway (e.g., mastoidectomy), when there is movement of the head position during surgery (e.g., typanostomy tubes), or when the LMA barrel cannot be secured in the midline (e.g., mid or lateral facial surgery). The use of this mask in surgery above the level of the hypopharynx, including tonsillectomy, affords a number of clinically important advantages over tracheal intubation (Table 22-7).

TABLE 22-7 Advantages of the LMA in Supraglottic Surgery

Improved protection of the airway from blood and surgical debris
Reduced cardiovascular responses
Reduced coughing on emergence
Reduced laryngospasm after airway device removal
Improved oxygen saturation after airway device removal
Ability to administer oxygen until complete restoration of airway reflexes

FIGURE 22-11. An LMA-flexible in place with a Crow-Davis mouth gag during a tonsillectomy and uvulopharyngopalatoplasty. The uvula has been removed. The LMA mask is not visible to the surgeon when correctly placed.

When correctly placed, the LMA mask serves to block the airway from blood, secretions, and

surgical debris above the level of the mask, as compared to the tracheal tube, which is known not to protect the trachea from liquids instilled into the pharynx[72,73,74,75] (Fig. 22-12).

FIGURE 22-12. Following endoscopic sinus surgery, **(A)** the superior, pharyngeal surface of the LMA is blood-stained, whereas **(B)** the laryngeal surface remains clean.

The LMA and Bronchospasm. As a supraglottic airway, the LMA appears to be well suited to the patient with a history of extrinsic asthma. The LMA presents a unique opportunity for the clinician to conveniently and effectively control the airway without having to introduce a foreign body into the trachea. Thus, it may be an ideal airway tool in the asthmatic patient who is not at risk for reflux and aspiration.[76,77,78] Because the halogenated inhaled anesthetics are potent bronchodilators, it is at the time of emergence (when the anesthetic is discontinued)

that the patient at risk for bronchospasm is most likely to wheeze. In the patient managed with the LMA, there is no foreign body in the sensitive bronchorespiratory tree and the patient can be fully emerged prior to removal of the device. In the event that uncontrollable bronchospasm does occur intraoperatively (e.g., from vagal stimuli such as traction on the peritoneum), intubation can be performed through the LMA or after its removal.[79]

7 **LMA Removal.** Timing of the removal of the LMA at the end of surgery is critical.[80,81] The LMA should be removed either when the patient is deeply anesthetized or after protective reflexes have returned and the patient is able to open the mouth on command. Removal during excitation stages of emergence can be accompanied by coughing and/or laryngospasm. Many clinicians remove the LMA fully inflated; thus, it acts as a "scoop" for secretions above the mask, bringing them out of the airway.[82] This has been particularly useful in otolaryngologic surgery (see Fig. 22-12).

Contraindications to LMA Use. The primary contraindication to elective use of the LMA is a risk of gastric-contents aspiration (e.g., full stomach, hiatus hernia with significant gastroesophageal reflux, morbid obesity, intestinal obstruction, delayed gastric emptying, poor history). Other contraindications include poor lung compliance or high airway resistance, glottic or subglottic airway obstruction, and limited mouth opening (<1.5 mm).[67]

LMA Use Complications. Apart from gastroesophageal reflux and aspiration, reported complications have included laryngospasm, coughing, gagging, retching, bronchospasm, and other events characteristic of airway manipulation. The incidence of sore throat is approximately 10%, as compared to 30% with tracheal intubation, but has been reported as 0 to 70%.[67] Also reported are hoarseness (4 to 47%) and dysphagia (4 to 24%). The LMA may cause transient changes in vocal cord function.[80] This is possibly related to cuff overinflation during prolonged procedures.

There have been few reports of nerve injury associated with LMA use. As of March 2004, 14 cases of nerve palsy have been reported: recurrent (7), hypoglossal (5), and lingual (2).[84,85] All but one of these resolved spontaneously. In all cases, size 3 and 4 LMAs were in use and, in all but one case, nitrous oxide was one of the inhalation agents (which can increase cuff pressures by 9 to 38%).[86] Cuff pressures were not monitored in any of the cases. It is hypothesized that lingual nerve injuries occur as the nerve is trapped between the mandible and the LMA barrel lying lateral to the tongue. The hypoglossal nerve runs rostral and lateral to the hyoid bone and may be trapped against it. The recurrent nerve may be compressed between the LMA cuff and the cricoid or thyroid cartilage. Unmonitored increases in pressure as a result of N_2O diffusion, light anesthesia with constriction of pharyngeal musculature, tissue edema and venous engorgement from a head-down position, and lidocaine gel lubricant have been blamed for nerve injury.[87] To prevent such injury, the cuff of the LMA should be inflated to no more than 60 cm H_2O and should be monitored if N_2O is in use. The use of a larger LMA, with less pressure, has also been recommended.[88] Lidocaine should not be present in cuff lubricants.

One death has been associated with an LMA device. An elderly woman suffered a tear of her esophagus after use of the intubating LMA (LMA-Fastrach®), dying 9 weeks later from septic shock after a series of related complications.[89] Interestingly, the actual complication was most likely a small esophageal tear from an inadvertent esophageal intubation. Therefore, this complication was more of a misadventure of "blind intubation" not inherently attributable to the LMA-Fastrach itself. No other deaths because of complication of LMA use have been reported in the literature. It has been estimated, though, that 600 deaths occur each year in the developed world because of complications of difficult tracheal intubation.[90]

The LMA-Proseal®. Although the original LMA and the LMA-flexible have been used successfully for positive-pressure ventilation, they are not ideally suited to this task for two reasons: first, if poorly seated in the hypopharynx, gastric inflation may occur; second, the seal pressure is limited to approximately 20 cm H_2O. In 1994, an LMA prototype that included a gastric drain was described.[91] The LMA-Proseal® was introduced to clinical practice in 2001 (Fig. 22-13). It was believed that such a design would reduce both the risk of gastric inflation (by providing a low-resistance pathway for pressure transmitted to the esophagus) and the risk of aspiration of refluxed gastric contents. Subsequently, it was found that the design, which also incorporates a second, posterior cuff, could reliably allow positive-pressure ventilation with 40 cm H_2O pressure. It is inserted in an identical manner as describe previously for the LMA-classic. A metallic insertion device is available from the manufacturer. Table 22-8 lists the unique features of the LMA-Proseal and the resultant clinical advantage.

TABLE 22-8 Features of the LMA-Proseal

·FEATURE	·CLINICAL IMPACT
Gastric drain	• Position confirmation
	• Active gastric emptying
	• Passive gastric emptying
	• Protection from gastric content aspiration[92]
Posterior cuff	• Increased seal pressure

Bite block	• Prevents patient biting obstruction
Wire-reinforced airway barrel	• Reduced overall size
	• Decreased ability to tracheally intubate
Large barrel/bite block configuration	• First attempt insertion less successful than LMA-classic
	• Confers rotational stability
	• Size choice—size down from LMA-classic

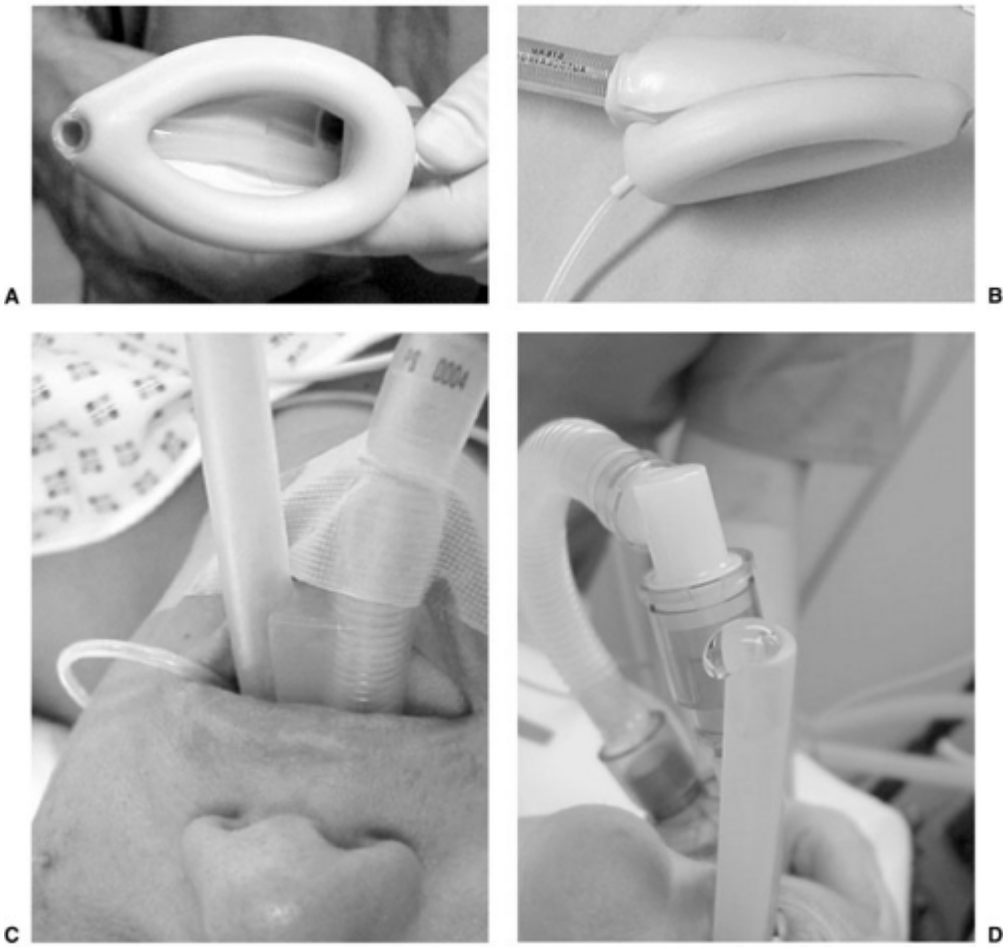

FIGURE 22-13. The LMA-Proseal: **A.** Anterior view showing gastric drain passing through the bowl. **B.** Lateral view showing the circumferential and posterior mask cuffs. (In the photograph, the view of the esophageal lumen is obscured by the airway lumen.) **C.** The airway lumen and gastric drain, separated by an integral bite block, emerge from the patient. **D.** A drop of water-soluble lubricant has been placed in the proximal aperture of the esophageal lumen to monitor for gas leak, which should not be present.

The LMA-Proseal has been shown to achieve a higher effective seal than the LMA-classic (40 to 45 cm H_2O) and allow easier and quicker gastric tube placement.[93,94] A wide variety of surgical cases have been performed with the LMA-Proseal. Many of these have previously been considered contraindicated for supraglottic airway use.[93] Maltby et al have pioneered the use of the LMA-Proseal laparoscopic cholecystectomy in obsess patients.[93] This surgical procedure has long been considered the prototypical case for contraindicated LMA use because of high intraperitoneal pressures, as well as intraoperative stomach manipulation. Laparoscopic cholecystectomy was performed in 46 patients, 12 of whom had a body mass index of greater than 30 kg/m^2. The median airway pressure at which a gas leak occurred was 34 cm H_2O (range 18 to 45). Four obese patients crossed over to a control, tracheal tube group. Stomach size (e.g., distension) was equal between groups.

Apart from being successfully used as a positive pressure as well as spontaneous ventilation airway, the LMA-Proseal has a distinct advantage over all currently available supraglottic airways. The presence of the gastric drain allows position diagnosis.[95] This facility, originally intended by Dr. Brain, has been extensively researched by Drs. M. Stix and C. O'Connor. These authors have developed a protocol for

judging LMA-Proseal position, a task typically difficult for the less experienced LMA user. The protocol of Stix and O'Connor follows a simple logic based on the observations of Dr. Brain and

their own observations.

Bite block depth. Based on the successful use of the LMA-Proseal in 147 women and 127 men, a first approximation of insertion adequacy can be made from observation of the integral bite block. The midway point of the bite block was found to be proximal to the incisors (e.g., within the oral cavity) in 78% of women and 92% of men.[96] Though mid (or greater) bite block advancement into the esophagus indicated good placement, a normal distribution of depths indicate that the bite block test affords a "first approximation" of LMA-Proseal position adequacy.

Suprasternal notch test (SSN). When correctly positioned, the proximal orifice of the gastric drain tube should be within the boundaries of the upper esophagus, making it contiguous with the esophageal lumen.[95] Gentle percussion over the suprasternal notch results in a brief pressure increase in the lumen of the gastric drain. This can be demonstrated with the placement of a seal of surgical jelly, or preferably, nontoxic soap (e.g., children's bubble-making soap) over the distal end of gastric drain (Fig. 22-13D).[97] Inadequate insertion depth and glottic or folded positions will result in a negative SSN test.[98]

Airway seal test. Once the insertion depth and esophageal position of the proximal gastric drain orifice is assured, positive-pressure breaths are given. If an adequate separation of the alimentary and airway tracks has been achieved, no insufflated gas should emerge from the distal gastric drain.[95] The surgical jelly-soap or bubble seal of the distal gastric drain will aid in detection of escaping gas.[99]

Gastric drain patency. Posterior folding of the distal aspect of the LMA-Proseal mask has been described.[100] Folding of the mask in the hypopharynx may not be detected during routine ventilation. Dr. Brimacombe and colleagues have stated that one or more of the above-mentioned tests may give a false-positive results.[101] These authors suggest supplementing the LMA-Proseal position testing with the insertion of a gastric tube, thereby assuring gastric drain patency.

The importance of position testing was highlighted in a report of pulmonary aspiration of gastric contents during a cholecystectomy with an LMA-Proseal.[102] No position testing had been performed, and though adequate ventilation was achieved and with airway pressures of 27 cm H_2O, the LMA-Proseal had been unknowingly placed in a folded position. This case illustrates the importance of the LMA-Proseal in modern clinical practice: as of this writing more than 10 supraglottic airways are in use in clinical practice. Because many are recent arrivals to the clinical arena, there is little or no information available regarding gastric insufflation with positive-pressure ventilation and protection from gastric content aspiration. The LMA-Proseal remains the only device where these questions have been repeatedly investigated, and position testing is a possibility.

Similarly, little is known of the resuscitation utility of new SGAs. The LMA-Proseal would be expected to function similarly to the LMA-Classic in a cannot intubate/cannot ventilate situation, and adds gastric emptying as a resuscitative maneuver.[103,104]

Esophageal and gastric insufflation have been noted with some proseal LMA placements.[105] The incidence and clinical signature of this air trapping are unknown.

The LMA and the Difficult Airway. Apart from its role as a routine anesthetic airway device, the LMA has a history of being a valuable tool in the care of the patient with the anticipated, or the unanticipated, difficult airway. This will be considered later in this chapter.

The Laryngeal Tube. The laryngeal tube (LT) (VBM Modizintechnile, GmbH, Sulz aN, Germany) consists of a single lumen tube with an approximately 130 degree midshaft angle and two (distal and proximal) low pressure cuffs (Fig. 22-14A). An oval aperture between the cuffs serves as a ventilation artifice. The distal end of the tube is scaled around the distal cuff. When inserted correctly, the distal cuff seals the oral and nasal pharynx. Ventilation (spontaneous or positive pressure) occurs via the midcuff orifice. The cuffs are inflated via a common pilot valve. The LT is reusable, requires a mouth opening of at least 2.3 cm and is inserted either blindly or with the aid of a laryngoscope. Six sizes (0 through 5) are suitable for neonates to large adults. Several studies have examined the use of the LT in spontaneous and controlled ventilation, and in

comparison to the LMA classic and the LMA-proseal. Gaitini et al used the LT in 175 patients presenting for elective surgery.[106] Positive-pressure ventilation was successful in 96.6% of cases.

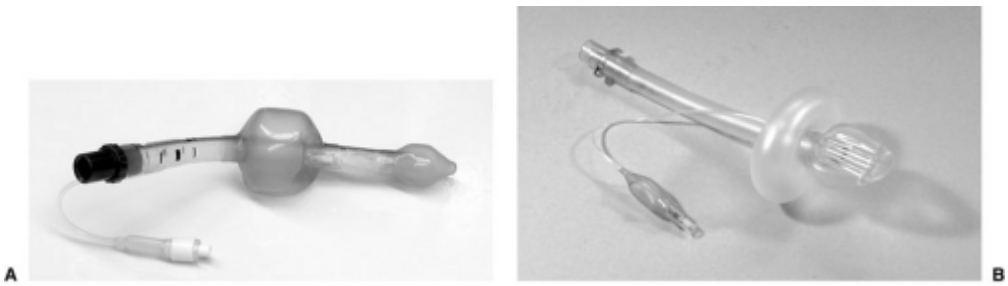

FIGURE 22-14. A. The Laryngeal Tube. **B.** The Cobra Pharyngeal Laryngeal Airway.

Ocker et al compared the LT to the LMA classic in 50 patients undergoing routine surgery. Time of insertion and adequacy of ventilation were similar for both devices.[107] Peak airway pressure and airway leak pressure were higher with the LT (leak pressures LT 36 ±3 cm H_2O, LMA 22 ± 3 cm H_2O).

The Cobra Pharyngeal. Laryngeal Airway (Engineered Medical Systems, Indianapolis, IN, USA) is a disposable supralaryngeal airway device. It has a single lumen that terminates in a widened distal end (Fig. 22-14B). A pharyngeal cuff serves to occlude the upper airway from the oral cavity. A series of

slots in the widened end serve to hold the epiglottis out of the barrel. A fiberscope and/or ETT may be passed through the barrel and the slots. Reports have demonstrated the use of the cobra in airway rescue, as well as routine anesthetic care with spontaneous as well as positive-pressure ventilation.[108,109]

Tracheal Intubation

Routine Laryngoscopy

8 *Preparing for laryngoscopy and the "best attempt."* Whether laryngoscopy is undertaken with the patient in an awake or unconscious state, repeated attempts often result in edema and bleeding of the anterior upper airway structures (e.g., tongue, vallecula, epiglottis, laryngeal structures), hindering subsequent attempts at visualization and causing increased airway obstruction. It is therefore important to assure that the first attempt at laryngoscopy is a "best attempt."

First, when faced with the critically ill patient, the most skilled laryngoscopist available should be positioned to perform the laryngoscopy. In less acute situations, it is not inappropriate for a trainee, clinician extender, or other skilled personnel to assume this role. Second, the availability of all the materials needed to perform laryngoscopy and intubation should be assured, as should the availability of materials needed to manage a failed intubation. When devices are available in a variety of sizes (e.g., tracheal tubes, LMAs), the operator should have at hand the presumed correct size, as well as one size smaller and one size larger of each item (Table 22-9).

TABLE 22-9 Equipment for Laryngoscopy[a]

Oxygen source and self-inflating ventilation bag (e.g., ambu bag) Face mask[b] Oropharyngeal and nasopharyngeal airways[b] Tracheal tubes[b] Tracheal tube stylet Syringe for tracheal tube cuff inflation Suction apparatus Laryngoscope handle (2), tested for working order and battery freshness Laryngoscope blades: Common blades include the curved (Macintosh) and straight (Miller)[b] Pillow, towel, blanket, or foam for head positioning Stethoscope
[a]Equipment that should be immediately available in the ideal clinical setting.
[b]Presumed size as well as one larger and one smaller should be immediately available.

Other devices that complete the equipment list, but may not be uniformly available, include: end-tidal CO_2 monitoring (e.g., capnography or colorimetric device [e.g., Easy Cap II, Mallinckrodt]), pulse oximetry, transtracheal jet ventilation catheter, and a high-pressure oxygen source.

The height of the supine patient surface should be at the level of the laryngoscopist's xyphoid cartilage, with the bed or operating room table in a non-movable mode (e.g., wheels locked). The clinician performing the intubation must have unobstructed access to the head.

Direct laryngoscopy. Successful laryngoscopy involves the distortion of the normal anatomic planes of the supralaryngeal airway to produce a line of direct visualization from the operator's eye to the larynx: this requires the creation of a new (nonintrinsic) visual axis, through maximal alignment of the axes of the oral and pharyngeal cavities, and displacement of the tongue. Unanticipated failure of direct laryngoscopy is primarily a problem of tongue displacement (inability to align the axes can be anticipated by physical exam).[3] Some investigators have focused the search for the cause of difficult direct laryngoscopy on the relative position of the tongue. Chow et al have found that a hypopharyngeal tongue (e.g., the greater mass of the tongue is within the hypopharynx) is accompanied by a caudad larynx, which is in turn determined by measurement of the mandibular hyoid distance (a measure of the cephalocaudad separation of the mandible and hyoid during fetal development).[110]

Benumof eloquently explains this finding in terms of ontogeny and the descent of the larynx to create the phonics of the human pharyngeal space (antagony recapitulates phylongony). A long descent of the larynx results in a large part of the tongue to be in the hypopharynx.[111] Poor descent of the larynx results in a small thyromental distance (TMD) and can indicate a difficult intubation. Chow et al also noted that the long mandibularhyoid distance can be in part because of a shortened mandibular ranus. A short ranus results in the floor of the mouth being more rostrad and less compliant, and therefore displacement of the tongue is more difficult.[112] If both a small TMD as well as a large TMD can both predict difficult laryngoscopy, then how can this measure be useful to the airway evaluator? As pointed out by the ASA Difficult Airway Algorithm, no one measure may be adequate to determine difficulty of DL, and multiple measures must be integrated to make sensible airway management decisions.[113]

Another mandibular dimension that has been examined is the mandibular depth index (the posterior depth of the mandible/mandibular length).[114] Kikkawa et al have noted that a deep or

short mandible (higher index) indicates a large hypopharyngeal tongue and difficulty with displacement. Though

the mandibular hyoid distance and the mandibular depth index are distinct measures, they approach the problem of difficulty with DL similarly: anatomic relationships of the mandible may predict a difficult to displace hypopharyngeal tongue. They also highlight that a single measure (e.g., thyromental distance) does not yield enough information to be predictive.

Though congenital, anatomic variation may occur, pathologic variations may mimic the same problem of hypopharyngeal tongue mass: Ovassapian et al have identified hyperplasia of the lymphoid tissue at the base of the tongue as the principle cause of unanticipated difficult laryngoscopy.[3] Visualization of this tissue is currently the only method of diagnosis. It is therefore typically discovered during a failed DL.

9 Direct laryngoscopy requires the creation of a line of sight from the operator's eye to the aperture of the larynx. Bannister and MacBeth proposed a three-axis model to explain the anatomic relationships involved in this operation.[115] Recently, this explanation has been challenged.[116] Work by Adnet et al noted that whereas extension at the atlanto-occipital joint maximally facilitated an oral cavity/pharyngeal alignment, no significant improvement was achieved with flexion of the cervical spine on the thorax. Chow and Wu refined this approach by noting that laryngeal axis alignment is unnecessary.[117] The end point of the effort to create an in-line space for tracheal intubation is the glottic aperture: alignment of the entire larynx is therefore unnecessary. These authors propose a two-axes/tongue-displacement model. This model does not depend on the alignment of all axes to create an in-line view of the larynx, but rather maximizes the spaces between the alveolar ridge and laryngeal aperture through oral-pharyngeal alignment and tongue displacement. This concept can be used to understand not only the problems that may hinder direct laryngoscopy, but also why common indexes of airway assessment fail in their predictive power. This concept has been described previously and can be viewed as functional airway assessment (FAA).[118] FAA is a method of examining the functional nature of each of the anatomic correlates of the commonly used assessment indices. FAA places an emphasis on the interdependence of these anatomic characteristics rather than on their individual size or functional integrity. As explained by Chow and Wu, when the head and neck are in the neutral position, the oral and pharyngeal axis are perpendicular to each other.[117] With maximal extension of a normal atlanto-occipital joint, 35 degree of motion is attained Fig. 22-15. This brings the angle between the oral and pharyngeal axis to 125 degree. Though an improvement, certainly not the 180 degree required for creation of a line of sight to the glottis. A different space must be created. This space is created by displacement of the tongue with the laryngoscope. Though atlanto-occipital extension cannot by itself allow direct laryngeal vision, it does provide anterior displacement of the mass of the tongue and brings upper the alveolar ridge into improved position relative to the tongue and larynx. The extension of the atlanto-occipital point also provides an advantage in mouth opening.[26] Calder et al has shown that the maximal mouth opening is 50% greater in full atlanto-occipital extension as compared to the neutral head position. Temporal-mandibular jaw (TMJ) function also contributes to the displacement of the tongue away from the required visual axis. Rotation and translation of the TMJ result in a relaxation of the tongue insertion, as well as creation of the aperture width needed for instrumentation.

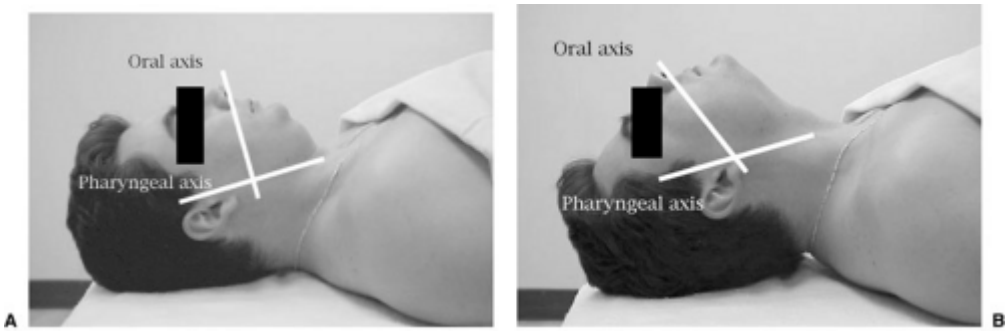

FIGURE 22-15. A. With the patient supine, the oral and pharyngeal axes do not overlap. **B.** Extenstion at the atlanto-occipital joint maximally overlaps the oral and pharyngeal axes.

Using the FAA approach to airway evaluation also helps to explain the value of the popular yet highly criticized Mallampati and Thyromental distance indices. These two measures have historically been considered important because they approximate the relative mass of the tongue (Mallampati) and the anterior-posterior borders of space in which it will be displaced (TMD) by the laryngoscope. As noted elsewhere, these indices have shown to have poor and/or variable predictive power. Two groups have considered the interrelated nature of these measures in a way which reveals why they perform poorly when considered individually: Ayoub et al found a high Mallampati score to be predictive of a difficult DL when the TMD was less than 4 cm.[119] When the TMD was greater than 4 cm, relative tongue size (as determined by the Mallampati) was not predictive: Iohon et al found similar results using a TMD cutoff of 6 cm.[120] The finding that the predictive power of the Mallampati improves when the mandible is short is consistent with the concept of FAA: When the mandibular space is restricted, tongue size is important. When the space is large, a tongue of any nonpathologic size should be accommodated. An exception to this may be hypopharyngeal tongue as described by Chow and Wu, though according to those authors, measurement of the mandibular hyoid distance should help in diagnosing this.[110]

An unforeseen cause of difficulty in direct laryngoscopy is a pathologic increase in tongue size. Ovassapian et al have identified lingual tonsil hyperplasia (LTH) as the most commonly undiagnosed cause of unanticipated difficult direct laryngoscopy.[3,121] Ovassapian et al reviewed the cases of unanticipated difficult direct laryngoscopy in their institution from 1989 to 2000. Thirty-three patients were identified. All patients were found to have LTH on fiberoptic exam.

Devices that aid in positioning the patient in a sniff position pillow have become available. These include the Sniff position pillow (AliMed, Inc. of Dedham, MA) developed by Michael

Popitz, and Pi's pillow (Dupaco, Oceanside, CA), which is comfortable for the awake patient but easily reconfigured after anesthetic induction to provide an ideal position, has been developed by Dr. Kaiduan Pi (Fig. 22-16).

FIGURE 22-16. A Pi's pillow (Dupaco, Oceanside, CA) places the patient in a comfortable position prior to the induction of anesthesia and **(B)** in an ideal "sniff" position during airway management. **C** The Popitz sniff position pillow.

The obese patient may need further positioning to move the mass of the chest away from the plane across which the laryngoscope handle will sweep as it is manipulated into the mouth. This may require placing a wedge-shaped lift (e.g., blankets, pillows) under the scapula, shoulders, and nape of neck, raising the head and neck above the thorax and providing a grade to allow gravity to take the mass away from the airway (Fig. 22-17).

FIGURE 22-17. A. With the morbidly obese patient, a 10-cm pillow may not provide a position adequate for laryngoscopy. **B.** A wedge-shaped lift is used to move the mass of the morbidly obese patient's chest away from the area of laryngoscopy and to improve the compliance of the thoracic cavity.

10 If, during the laryngoscopy, a satisfactory laryngeal view is not achieved, the backward-upward-rightward pressure (BURP) maneuver may aid in improving the view. In this maneuver, a second operator displaces the larynx (*B*) backward against the cervical vertebrae, (*U*) superiorly as possible, and (*R*) slightly laterally to the right, using external pressure over the cricoid cartilage. The BURP maneuver has been shown to improve the laryngeal view, decreasing the rate of difficult intubation in 1,993 patients from 4.7 to 1.8%.[122,123] When a left-handed operator is using a left-handed laryngoscope blade, the lateral external pressure should displace the larynx to the left. Similarly, Benumof describes "optimal external laryngeal manipulation," which consists of pressing posteriorly and cephalad over the thyroid, hyoid, and cricoid, as improving laryngeal view by at least one Cormack and Lehane grade.[124,125]

Once alignment has been achieved, the mouth is opened by one of two techniques (Fig. 22-18). The first accomplishes hyperextension of the atlanto-occipital joint by the use of the dominant hand under the occiput. This maneuver tends to open the mouth, and can be accentuated by using the fifth finger of the nondominant hand (holding the laryngoscope) to apply pressure over the chin in a caudad direction (Fig. 22-18A). In the second technique, which tends to be more effective but requires contact of the (gloved) hand with the teeth and/or gum, caudad pressure is applied with the thumb of the dominant hand on the mandibular molars on the patient's same side while the first finger, crossed above or below the thumb, applies cephalad pressure to the ipsilateral maxillary molars (Fig. 22-18B). The ultimate goal of both techniques is rotation and translation of the temporomandibular joint to achieve the widest interincisor gap. The patient,

whether conscious or not, is now ready for laryngoscopy.

FIGURE 22-18. Techniques of opening the mouth in preparation for laryngoscopy. **A.** Hyperextension of the atlanto-occipital joint and use of the fifth finger of the dominant hand. **B.** The thumb–first finger "scissors" technique.

Though direct laryngoscopy remains the most utilized method for tracheal intubation,[126] it is far from successful in all cases nor always benign when successful. DL may be difficult or impossible 8.5% and 1.8%, respectively, of the time.[126] Domino et al's analysis of the ASA closed claims database reveals that laryngeal injury during DL occurs more often in "easy" as opposed to difficult laryngoscopies.[24] Among the 4,460 cases in the ASA closed claim database, 87 instances of laryngeal trauma were recorded. Of these, 80% occurred during routine (non-difficult) tracheal intubation, where no injury was suspected. This has led some to question whether routine tracheal intubation is as safe as assumed.[22]

Use of the laryngoscope blade. Proper use of the laryngoscope blade is vital to the success of this basic airway management technique. Two blade types are commonly available and each is applied in a unique manner (Fig. 22-19). The curved (Macintosh) blade is used to pull the epiglottis out of the line of sight by tensing the glossoepiglottic ligament, whereas the straight blade (Miller) compresses the epiglottis against the base of the tongue. Both blades include a flange along the left

side of their length, which is used to sweep the tongue to the left side of the mouth. Blades with a right-side flange are available for the left-handed practitioner, but they are not commonly found in practice.

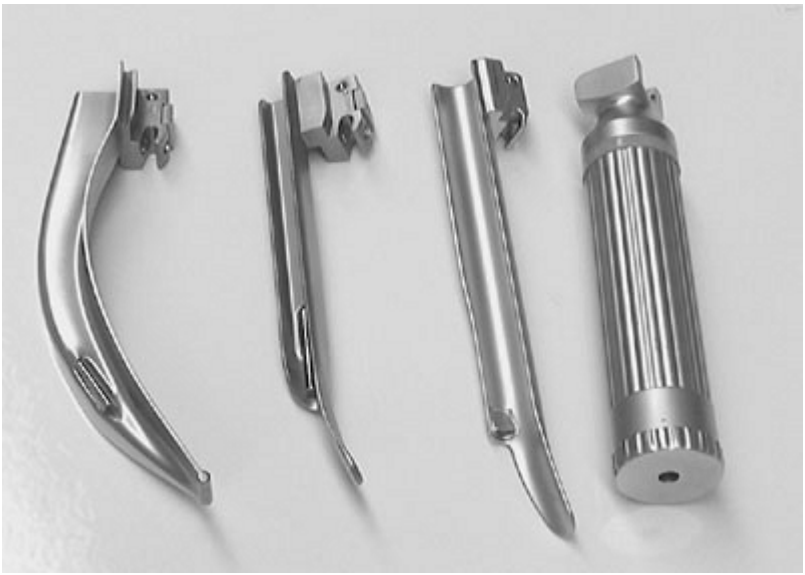

FIGURE 22-19. Macintosh, Miller, and Henderson laryngoscope blades with small and regular-sized handles.

Historically, choice of laryngoscopic blade had a theoretical bases in airway innervation. The internal branch of the superior laryngeal nerve (a branch of the vagus) provides sensory innervation from the level of the vocal cords to the underside of the epiglottis. Stimulation of these structures (with the Miller blade) was believed to cause more vagally related reactions (laryngospasm, bradycardia, hypertension.) The vallecula, stimulated by the curved, Macintosh blade, is innervated by the glossopharyngeal nerve.

In most available systems the flange incorporates the light source, either a bulb placed near the distal blade aspect or a rigid fiberoptic cable that transmits light produced within the handle. In either case, these blades must be long enough to achieve their respective applications. Therefore, blade size needs to be chosen appropriately and, on occasion, exchanged after a failed attempt. As a generalization, the Macintosh blade is regarded as advantageous whenever there is little room to pass an endotracheal tube (e.g., small mouth), whereas the Miller blade is considered better in the patient who has a small mandibular space, large incisor teeth or a large epiglottis.[127] The straight-against-the tongue nature of the Miller blade affords maximal transfer of effort from the operator's elbow and shoulder to the displacement of the tongue into a small mandibular space.

With the left hand holding the laryngoscope handle, the blade is inserted into the right side of the mouth, with care taken not to compress the upper lip against the teeth. As the blade is advanced toward the epiglottis, it is swept leftward, using the flange to displace the tongue to the left as the blade compresses it into the mandibular space. Once reaching the base of the tongue (the Macintosh blade tip in the vallecula, or the Miller blade compressing the epiglottis against the base of

the tongue), the operator's arm and shoulder lift in an anterior and caudad direction (Fig. 22-20).

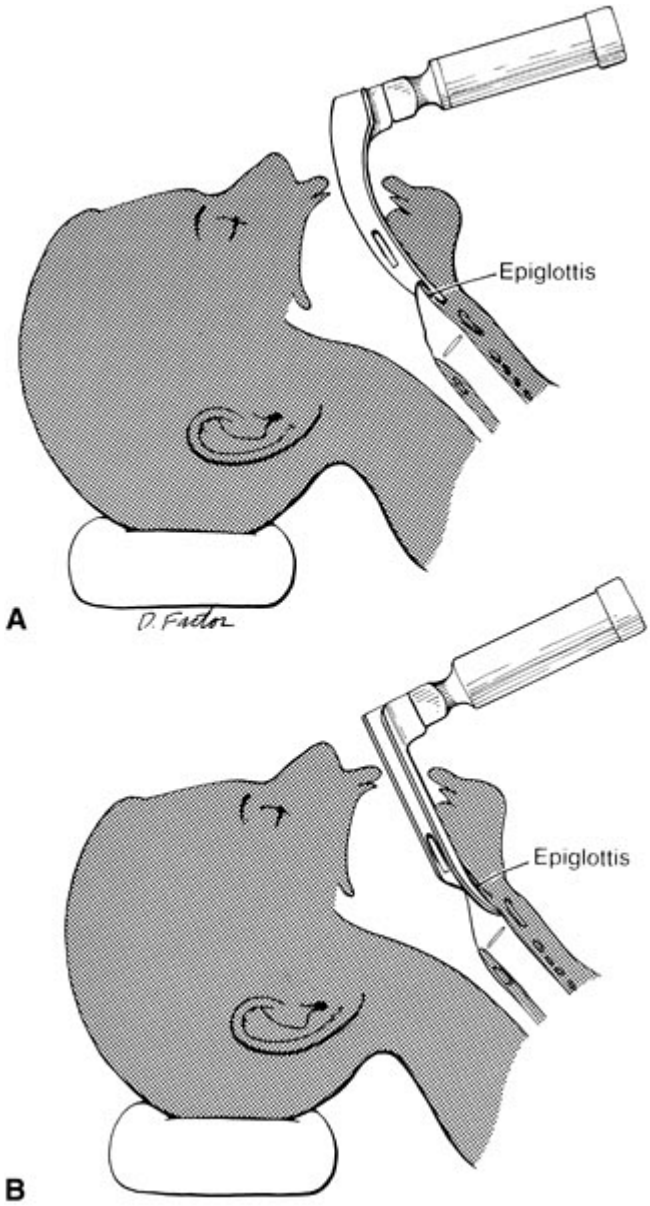

FIGURE 22-20. A. When a curved laryngoscope blade is used, the tip of the blade is placed in the vallecula, the space between the base of the tongue and the pharyngeal surface of the epiglottis. **B.** The tip of a straight blade is advanced beneath the epiglottis.

Importantly, the laryngoscopist must strive to avoid rotating the wrist and laryngoscope handle in a cephalad direction, bringing the blade against the upper incisor teeth. Extending either blade style too deeply can bring the tip of the blade to rest under the larynx itself, so that forward pressure lifts the entire airway from view (Fig. 22-21).

FIGURE 22-21. The sequence of routine laryngoscopy. **A.** With the mouth maximally opened, the laryngoscope is held in the left hand and the blade inserted on the right side of the mouth. Using the blade flange, the tongue is swept to the left as the wrist pulls in a caudad direction. **B.** While visualizing the laryngeal inlet, the tracheal tube is inserted.

Special considerations apply to the technique of laryngoscopy and intubation in the infant and child. Because of the relatively larger size of the occiput in children, producing an anatomic sniffing position, elevation of the head (as done in the adult) is not needed.[128] On occasion, one may need to elevate the thorax instead. The relatively short neck gives the impression of an anterior position of the larynx. Posterior cricoid pressure is often required to place the laryngeal inlet into view. A straight blade is more helpful in displacing the stiff, omega-shaped, and high epiglottis. Since the cricoid cartilage is the narrowest aspect of the airway until 6 to 8 years of age, the intubator must be sensitive to resistance to advancement of the ETT that has easily passed the vocal folds. Hyperextension at the atlanto-occipital joint, as done in adult, may cause airway obstruction because of the relative pliability of the trachea. In the child, there is a higher risk of endobronchial intubation or extubation with head movement owing to the short length of the trachea.

With laryngoscopy, the view of the larynx may be complete, partial, or impossible. A laryngeal view scoring system that has won general acceptance was developed by Cormack and Lehane, who described four grades of laryngeal view.[125] Grade 1 includes visualization of the entire glottic aperture; Grade 2 includes visualization of only the posterior aspects of the glottic aperture; Grade 3 is visualization of the tip of the epiglottis; Grade 4 is visualization of no more than the soft palate (Fig. 22-22). A Cormach–Lehane Grade 3 or 4 is expected in 1.5 to 8.5% of adult laryngoscopies.[129]

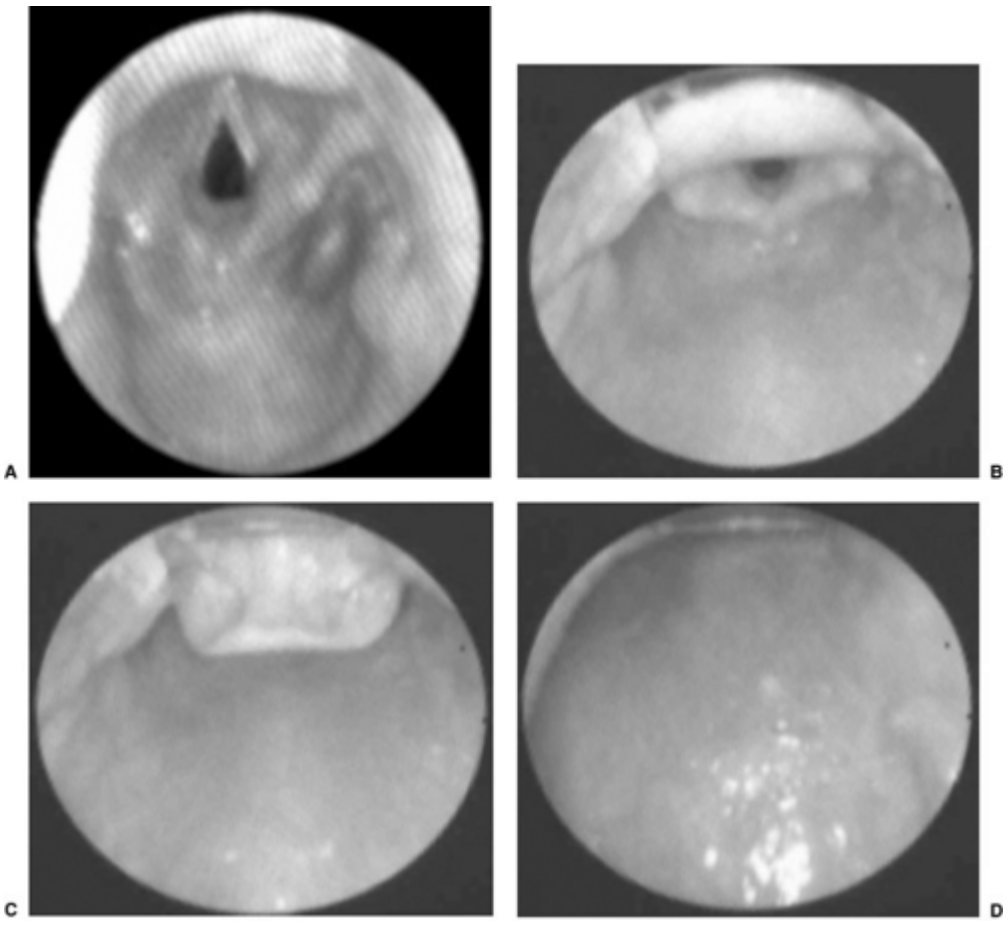

FIGURE 22-22. The Cormack–Lehane laryngeal view scoring system: **(A)** Grade 1, **(B)** Grade 2, **(C)** Grade 3, **(D)** Grade 4.

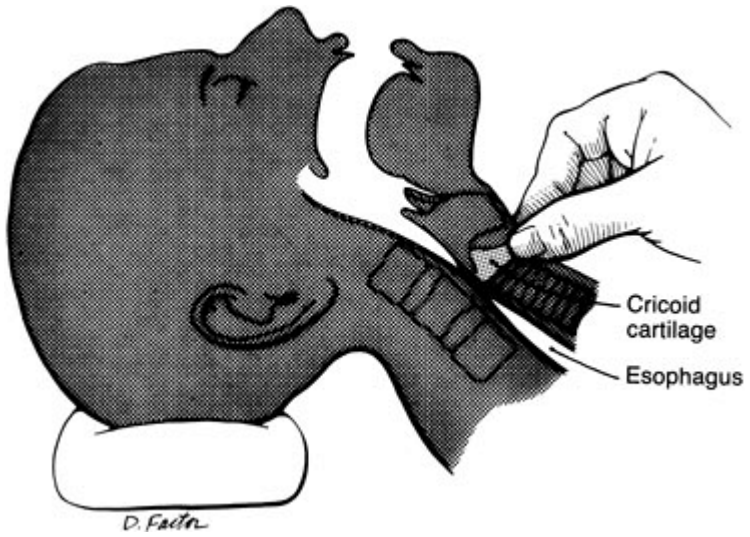

FIGURE 22-23. Cricoid pressure (Sellick's maneuver) is applied to occlude the esophagus and prevent aspiration of gastric contents.

This system has proved useful not only as a means of recording the laryngeal view on individual patients, but also as a clinical end point in the evaluation of preoperative airway assessment tools. A modification of the Cormack and Lehane score (MCLS) has been proposed by Koh et al, who noted that partial vocal cord view (MCLS 2A) was significantly easier to intubate than when only the artynoids and epiglottis were seen (MCLS 2B).[130]

Once the larynx is visualized with a left side–flanged blade, the tracheal tube is inserted from the right-hand side, care being taken not to obstruct the view of the vocal folds. Whenever possible, the action of the endotracheal tube passing through the vocal folds should be witnessed by the laryngoscopist. The tracheal tube should be inserted to a depth of at least 2 cm after the disappearance of the tracheal tube cuff past the vocal folds to approximate placement in the midtrachea. This should present the 21-cm and 23-cm external markings at the teeth for the typical adult female and male, respectively.[131] Choice of adult tracheal tube size may be made by the generalization that for women, size 7 to 8 id (internal diameter) may be used, and for a man, size 8 to 9 id. The larger tracheal tubes may be desirable if pulmonary toilet or diagnostic or therapeutic bronchoscopy is to be part of the clinical course. Pediatric laryngoscope blades and tracheal tube sizes are discussed in detail elsewhere in this chapter (Table 22-10).

TABLE 22-10 Size and Length of Tracheal Tubes Relative To Airway Anatomy

·AGE	·INTERNAL DIAMETER (mm)	·DISTANCE FROM LIPS TO MIDTRACHEA[a] (cm)	·DIAMETER OF TRACHEA (mm)	·LENGTH OF TRACHEA (cm)	·DISTANCE FROM LIPS TO CARINA (cm)
Premature	2.5	8			

Full term	3.0	10			
1–6 mo	3.5	11	5	6	13
6–12 mo	4.0	12			
2 yr	4.5	13			
4 yr	5.0	14			
6 yr	5.5	15			
8 yr	6.5	16	8	8	18
10 yr	7.0	17–18			
12 yr	7.5	18–20			
14 yr	8.0–9.0	20–22	20[b] 15[c]	14[b] 12[c]	28[b] 24[c]

An alternative approach to direct laryngoscopy has been described by Henderson.[132] In this approach to tongue displacement, a straight-bladed laryngoscope is introduced into the right side of the mouth. The blade is advanced between the tongue and palastine tonsil. The blade passes below the epiglottis, which is then elevated. This approach subjects the tongue to less compressive forces. It has been suggested that this technique may improve the view of the larynx in the presence of linguar tonsil hyperplasia (see Fig. 22-19).

Verification of successful tracheal tube placement is made by a variety of methods. The gold standard for confirmation

uof placement includes visualization of placement through the vocal folds and sustained detection of exhaled carbon dioxide as measured with capnography or a disposable chemical colorimetric device such as the Easy Cap II (Mallinckrodt). Other portable techniques include auscultation over the chest and abdomen, visualization of the chest excursion, observation of condensation in the ETT, use of a self-inflating bulb (Tubechek-B, Ambu, Linthicum, MD), lighted stylets (Trachlight, Laerdal Medical, Armonk, NY; SURCH-LITE, Aaron Medical Industries, St. Petersburg, FL), fiberoptic bronchoscope (FOB) identification of the tracheal rings, or chest x-ray.[132,133]

NPO Status and the Rapid-Sequence Induction. Induction of anesthesia in patients who have

"full stomachs" or incompetent gastroesophageal sphincters can result in regurgitation and pulmonary aspiration. Individuals at risk include the morbidly obese, pregnant women, diabetics with gastroparesis, those who require emergency operations, patients with gastroesophageal reflux disease, and patients who have recently eaten. Individuals experiencing emotional stress have increased gastric acid secretions and are also at an increased risk for aspiration.[134] A complete discussion of the pharmacologic therapy for aspiration prophylaxis is available elsewhere in this text.

The technique of rapid-sequence induction is performed to gain control of the airway in the least amount of time after the ablation of protective airway reflexes with the induction of anesthesia. In the rapid-sequence technique, the administration of an intravenous anesthetic induction agent is immediately followed by a rapidly acting neuromuscular blocking drug. Direct laryngoscopy and intubation are performed as soon as muscle relaxation is confirmed. Cricoid pressure (Sellick's maneuver) is applied by an assistant from the beginning of induction until confirmation of endotracheal tube placement. Cricoid pressure entails the downward displacement of the cricoid cartilage against the vertebral bodies (Fig. 22-22). In this manner, the lumen of the esophagus is ablated, while the completely circular nature of the cricoid cartilage maintains the tracheal lumen. Early cadaveric studies showed that correctly applied cricoid pressure was effective in preventing gastric fluids, under 100 cm H_2O pressure, from leaking into the pharynx. Unfortunately, the esophagus is laterally displaced in a majority of normal patients.[135] Because cricoid pressure further lateralizes the esophagus, the adequacy of esophageal abalation has been questioned. Cricoid pressure is contraindicated with active vomiting (risk of esophageal rupture), cervical spine fracture, and laryngeal fracture. Historically, facemask ventilation is not undertaken for the 40 to 90 seconds of time required to achieve adequate neuromuscular relaxation. This practice is based on minimal data and has recently been questioned.

If during rapid-sequence induction there are difficulties in securing the airway and oxyhemoglobin desaturation occurs, gentle positive-pressure ventilation may be used while maintaining cricoid pressure. This positive pressure should require <25 cm H_2O pressure. If more positive pressure is used, there is a risk of gastric distention and regurgitation.

The Intubating Laryngeal Mask Airway (LMA-Fastrach). Blind, fiberoptic aided, stylet-guided, and laryngoscopy-directed intubation via the LMA has been widely reported in adults and children.[79,136,137,138,139,140,141,142] There are several limitations to this procedure including the maximal size ETT that can be used, the minimal length of the ETT required to ensure that its cuff is within the larynx and not wedged between or above the vocal folds, and the difficulty in removing the LMA after intubation.[79,143] In an effort to overcome these limitations, Brain introduced a version of the LMA with a large-diameter (13 mm id), short-length (14 cm) rigid stainless steel barrel curved to align the mask aperture to the glottic vestibule (Fig. 22-24).[144,145,146]

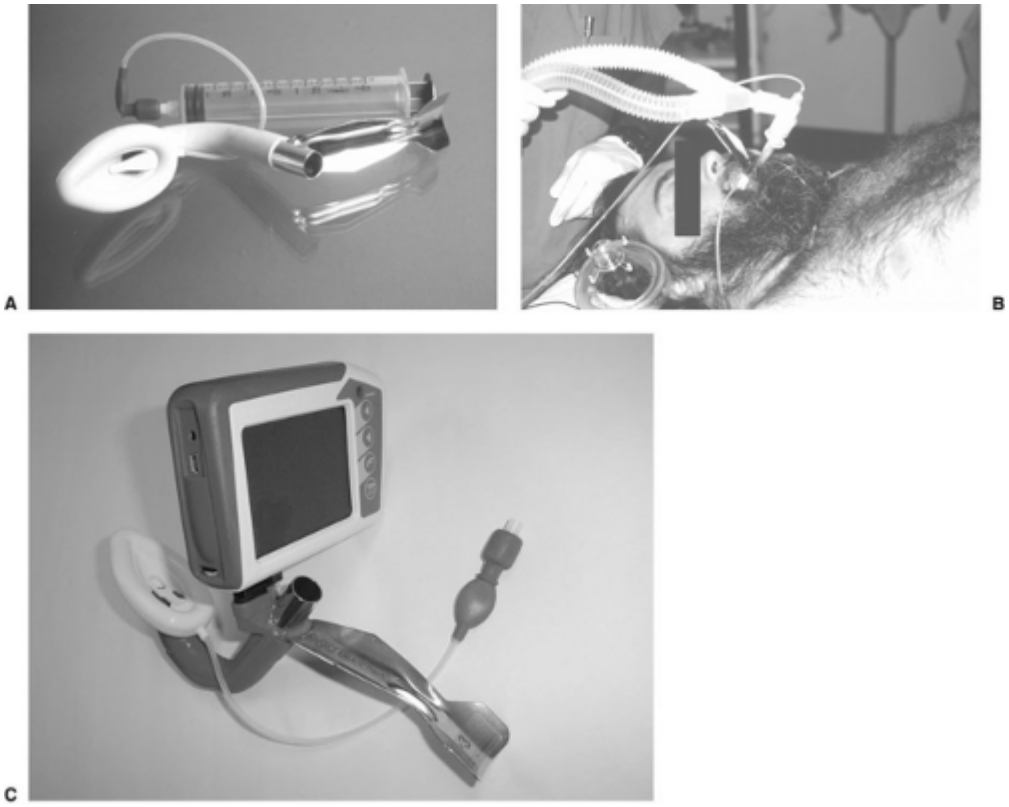

FIGURE 22-24. A. The LMA-Fastrach. **B.** The LMA-Fastrach used for intubation in a patient outside the operating room. **C.** The LMA C-Trach.

The mask incorporates a vertically oriented semirigid bar, fixed at the proximal end of the bowl aperture and positioned to sit beneath the epiglottis in the average adult. A handle at the proximal end of the barrel is used for insertion, repositioning, and removal. A secondary advantage of the handle is that the operator need never place fingers into the patient's mouth. This device, the LMA-Fastrach, can accommodate up to an 8.0-mm id cuffed ETT, which can be inserted blindly or over a fiberscope or other stylet device. The LMA-Fastrach is designed to be used with a straight, armored, silicone tracheal tube (Euromedics, Malaysia), although standard or Parker Flex-tip (Parker Medical, Englewood, Colorado) polyvinyl chloride tracheal tubes have been used.[147] To date, the LMA-Fastrach has been distributed in adult sizes with cuffs equivalent to the size 3, 4, and 5 LMAs. Experience has suggested that most adults between 40 and 70 kg are best managed with a size 4 LMA-Fastrach, larger persons requiring the size 5. Pediatric sizes are not yet available.

The LMA-Fastrach is indicated for routine, elective intubation and for anticipated and unanticipated difficult intubation.

Since it was designed to facilitate blind tracheal intubation, the presence of airway secretions, blood, or edema (e.g., from previous intubation attempts or trauma) does not interfere with its use. Because the design of the barrel is based on the normal adult palate-to-glottis relationship, patients who are evaluated as being manageable with tracheal intubation based on external exam, but subsequently are found to have a high Cormack–Lehane score (because of lingual tonsil hyperplasia or cervical spine immobility, for example) should be successfully managed with the LMA-Fastrach.[125] In the largest trial of the LMA-Fastrach to date, ventilation was satisfactory in 95% and unsatisfactory in 1% of 500 uses, and 96% were intubated within three attempts (79.8% on first, 12.4% on second, 4% on third).[148] Patients who are assessed as grossly abnormal on preoperative airway exam may often still be managed with the LMA-Fastrach.[149] The LMA-Fastrach has been demonstrated to be useful as a ventilatory and intubating device after failed rapid

sequence intubation.[147]

A large study has shown the utility of the LMA-Fastrach in anticipated as well as unanticipated difficult to intubate patients. Ferson et al successfully intubated 234 patients over a 3-year period using the LMA-Fastrach.[150] Studied patients included those with normal-appearing airways on routine exam who were unexpectedly difficult to manage, patients with a Cormack and Lehane laryngeal view grade 4 on laryngoscopy, patients with immobilized or traumatized cervical spines and patients with airway tumors, prior airway surgery, or radiation. Successful blind intubation via the LMA-Fastrach occurred in 96.99%, the remaining ones facilitated with supplemental use of a fiberoptic intubation scope. [A new design of the LMA-Fastrach, the C-Trach, introduced in 2004 incorporates a fiberoptic cable and miniaturized monitor into the LMA-Fastrach design (Fig 22-24C)].

Notably in this series all patients who presented with a cannot intubate/cannot ventilate situation were successfully ventilated and intubated with the LMA-Fastrach, emphasizing its

importance in the cannot intubate/cannot mask ventilate and emergency pathways of the ASA Difficult Airway Algorithm.[113]

Contraindications to the LMA-Fastrach are similar to those of the LMA. Since the end point of LMA-Fastrach procedure is tracheal intubation, it may prove useful for the management of patients at moderate risk for gastroesophageal regurgitation and aspiration, or for high-risk patients on whom other techniques have failed.

The LMA-Fastrach is inserted with the head in a neutral position. It can be used in the unconscious or awake patient (with the use of topical anesthetics). The mask of the LMA-Fastrach is tested, deflated, and lubricated as described for the LMA. It is inserted into the mouth, with the handle held parallel to the chest, so the mask lies flat against the palate. Gentle pressure on the handle and barrel, toward the chin, reproduces the palatal pressure described for insertion of the LMA. A smooth backward rotation of the handle toward the top of the head seats the tip of the mask in the hypopharynx, posterior to the cricoid cartilage. Once seated, the LMA-Fastrach's mask is inflated via the pilot cuff. An ambu bag or anesthesia circuit is attached to the proximal end of the LMA-Fastrach barrel and ventilation is attempted. By using the LMA-Fastrach handle, the position of the device can be optimized by lateral and anterior–posterior manipulation. This is termed the Chandy Maneuver (after Dr. Chandy Verghese, United Kingdom). A seemingly common cause of airway obstruction is the down-folding of the epiglottis. This can be relieved with a smooth rotational movement of the inflated LMA-Fastrach out of the airway (6 cm along the axis of the insertion) while the cuff remains inflated, and immediate re-placement (the "up-down" maneuver).

After adequate ventilation is achieved, the ETT is advanced through the barrel. As the ETT exits the bowl aperture of the LMA-Fastrach, the semirigid elevating bar is pushed anteriorly, carrying the epiglottis out of the way of the airway. If positioned correctly, the ETT can freely enter the glottis.

The second part of the Chandy Maneuver may facilitate blind tracheal intubation. In this maneuver the handle is used to gently lift (without rotation) the LMA-Fastrach anteriorly, sealing the bowl against the larynx.

When blind intubation fails (esophageal insertion or obstruction) several maneuvers are undertaken.[150] Early obstruction is typically a result of a down-folded epiglottis. An up-down maneuver, as described earlier, can be employed and tracheal intubation attempts repeated. Early resistance (within 1 cm of the Euromedics ETT exit mark) may also signify vallecular entrapment secondary to too large an LMA-Fastrach. The operator may remove the LMA-Fastrach and place a smaller size. Obstruction at 3 cm past the exit mark may signify entrapment or too small a device, and again, a change is indicated.

When intubation fails despite the Chandy or up-down maneuvers, or a change in the ILM size, the clinician should recall that the LMA-Fastrach is a ventilation device first! Typically ventilation will be adequate despite failure to intubate. At this juncture the clinician can (1) continue with short surgical procedures using the LMA-Fastrach as a simple SGA (procedures longer than 15 minutes

may be ill advised because of the pressure excited by the LMA-Fastrach on tissues), (2) change to another LMA device, (3) diagnose the intubation impediment with the aid of another device (e.g., fiberoptic bronchoscope or FAST (Clarus Medical), (4) remove the LMA-Fastrach and continue with DL, or an another technique of tracheal intubation, or (5) in the resuscitative situation, perform a surgical airway while continuing ventilation with the LMA-Fastrach.

This last procedure may be an underappreciated facility of all LMAs and the SGAs. These devices may serve as a bridge while invasive airway procedures are performed.

Once intubation is achieved and confirmed (e.g., by auscultation or capnography), the ETT circuit adapter is removed and the LMA-Fastrach is withdrawn over the ETT. During this removal procedure, the ETT is stabilized by one of two methods. A silicone stabilizing rod (supplied by the manufacturer) can be held against the ETT as the LMA-Fastrach is retreated out of the mouth. The advantage of this technique is that the operator's hands do not have to enter the oral cavity. The disadvantage is that in the midremoval position, the operator loses direct contact with the ETT. In the second technique, described by Rosenblatt and Murphy, a Magill forceps is used to hold the proximal tip of the ETT while the LMA-Fastrach is removed.[147] In the midremoval position, a finger is placed in the mouth to identify and stabilize the ETT, while the Magill forceps is removed and the LMA-Fastrach is fully retreated. This technique requires the hand to be placed in the mouth, but allows improved control of the ETT.

Extubation of the Trachea

Though a wealth of literature is focused on the field of tracheal intubation, few reviews have well contemplated the area of extubation after completion of surgery, or prolonged ventilatory support.[151] Indeed, the period of extubation may be far more treacherous than that of intubation (Table 22-11 [see section A]).

TABLE 22-11 Tracheal Extubation

A. Causes of Ventilatory Compromise during Tracheal Extubation

- Residual anesthetic
- Poor central respiratory effort
- Decreased respiratory rate
- Decreased respiratory drive in response to CO_2
- Decreased respiratory drive in response to O_2
- Reduced tone of upper airway musculature
- Reduced gag and swallow reflex
- Decreased threshold to laryngospasm
- Surgical airway compromise
- Surgical airway edema
- Vocal cord paralysis
- Arytenoid cartilage dislocation
- Supraglottic edema with airway obstruction by the epiglottis
- Retroarytenoid edema with limited vocal fold abduction
- Subglottic edema
- Tracheomalacia (from long-standing tracheal intubation)
- Bronchospasm

B. Complications of Tracheal Extubation

- Respiratory drive failure
- Hypoxia (e.g., atelectasis)
- Upper airway obstruction (e.g., edema, residual anesthetic)
- Vocal fold–related obstruction (e.g., vocal cord paralysis)
- Tracheal obstruction (e.g., subglottic edema)

Bronchospasm
Aspiration
Hypertension
Increased intracranial pressure
Increased pulmonary artery pressure
Increased bronchial stump pressure (e.g., after pulmonary resection)
Increased ocular pressure
Increased abdominal wall pressure (e.g., risk of wound dehiscence)

Routine Extubation. Extubation of the trachea must not be considered a benign procedure. It is not simply the elimination or reversal of tracheal intubation. Extubation is fraught with its own set of potential complications (Table 22-11 [see section B]). Appropriately trained personnel and equipment should be immediately available at the time of extubation. This may range from a postanesthetic care unit nurse or respiratory therapist with a set of laryngoscopes to a surgeon prepared to perform an emergency tracheostomy.

Most adult patients are extubated after the return of consciousness and spontaneous respiration, the resolution of neuromuscular block, and the ability to follow simple commands (Table 22-12). The patient is asked to open the mouth and a suction catheter is used to remove excessive secretions and/or blood. The airway pressure is allowed to rise to 5 to 15 cm of H_2O to allow for a "passive cough," and the endotracheal tube is removed after the cuff (if present) is deflated.[151] If coughing or straining is contraindicated or hazardous (e.g., increased intracranial pressure), extubation may be performed while the patient is in a surgical plane of anesthesia. In patients at risk for gastric contents aspiration (e.g., full stomach) or upper

airway obstruction, the clinician needs to assess the relative risk of each potential morbidity. For the latter risk, and possibly the former, a maneuver has been described in which an LMA is placed posterior to the ETT, which is then removed. This obviates the problem of upper airway obstruction, and may offer some protection against regurgitation and aspiration.[152,153,154] Because of the risks of atelectasis and diffusion hypoxia, the ability to administer oxygen should be available at the time of extubation.

TABLE 22-12 Criteria For Routine "Awake" Extubation

Subjective Clinical Criteria:
Follows commands
Clear oropharynx/hypopharynx (e.g., no active bleeding, secretions cleared)
Intact gag reflex
Sustained head lift for 5 seconds, sustained hand grasp
Adequate pain control
Minimal end-expiratory concentration of inhaled anesthetics

Objective Criteria:
Vital capacity: ⩾10 mL/kg
Peak voluntary negative inspiratory pressure: >20 cm H_2O
Tidal volume >6 cc/kg
Sustained tetanic contraction (5 sec)

T_1/T_4 ratio >0.7 Alveolar-Arterial Pao_2 gradient (on FIO_2 of 1.0): <350 mm Hg[a] Dead space to tidal volume ratio: ⩽0.6[a]
[a] Used during weaning from mechanical ventilation in the intensive care setting.

Difficult Extubation. The patient who presented as a difficult airway at the time of anesthetic induction must be considered a difficult airway at the time of extubation, even when corrective surgery was performed in the interim (e.g., uvulopharyngoplasty in the obstructive sleep apnea patient).

As a cause of ventilatory compromise, laryngospasm deserves special attention because of it prevalence in children and because it accounts for 23% of all critical postoperative respiratory events in adults.[151] Laryngospasm may be triggered by respiratory secretions, vomitus, or blood in the airway; pain in any part of the body; and pelvic or abdominal visceral stimulation. The cause of airway obstruction during laryngospasm is the contraction of the lateral cricoarytenoids, the thyroarytenoid, and the cricothyroid muscles. Management of laryngospasm consists of the immediate removal of the offending stimulus (if identifiable), administration of oxygen with continuous positive airway pressure, and, if other maneuvers are unsuccessful, the use of a small dose of short-acting muscle relaxants.[151]

Negative-pressure pulmonary edema may result from any airway obstruction in a patient who continues to have a voluntary respiratory effort. Negative intrathoracic pressure is transmitted to the alveoli, which are unable to expand owing to the more proximal obstruction. Fluid is entrained from the pulmonary capillary bed. Negative-pressure pulmonary edema is treated as any other form of noncardiogenic edema.

Identification of patients at risk at extubation. A number of well known clinical situations may place patients at increased risk for complication at the time of extubation. Table 22-13 lists the risk factors for extubation complications. However, the clinician should evaluate every patient in terms of potential problems, in the same manner that they are prepared for the unanticipated difficult intubation.

TABLE 22-13 Clinical Situations Presenting Increased Risk For Complications at Extubation[151]

Paradoxical vocal cord motion (preexisting)	Poorly understood mechanism
Thyroid surgery	4.3% recurrent laryngeal nerve injury
	Local edema

	Tracheomalacia (from long-standing goiter)
Laryngoscopy (diagnostic)	Edema, laryngospasm, especially with biopsy
Uvulopalatoplasty	Palatal and oropharyngeal edema
Obstructive sleep apnea syndrome (uncorrected)	
Carotid endarterectomy	Wound hematoma, glottic edema, nerve palsies
Maxillofacial trauma	Laryngeal fracture
	Reduced level of consciousness
	Requirements for mandibular/maxillary wires
Cervical vertebrae decompression	Supraglottic and hypopharyngeal edema
Parkinson's disease	
Rheumatoid arthritis	
Generalized edema	Laryngotracheal narrowing
Angioneurotic edema	Laryngotracheal narrowing
Anaphylaxis	Laryngotracheal narrowing
Hypopharyngeal infections	Laryngotracheal narrowing
Hypoventilation syndromes[a]	
Hypoxemic syndromes[b]	
Inadequate airway protective reflexes	Aspiration risk
[a]Residual anesthetic or preoperative medications (including alcohol and illicit drugs), central sleep apnea, carotid endarterectomy, poliomyelitis, Guillain-Barré syndrome, myasthenia gravis, botulism, thoracic skeletal deformity, severe pain (with	

	diaphragmatic splinting), morbid obesity, severe chronic obstructive pulmonary disease.
	[b]Hypoventilation, ventilation–perfusion mismatch, intracardiac or intrapulmonary shunting, increased oxygen consumption, severe anemia, impaired alveolar oxygen diffusion.

Approach to the difficult extubation. When there is a suspicion that a patient may have difficulty with oxygenation or ventilation after tracheal extubation, the clinician may choose from a number of management strategies. These may range from the preparation of standby reintubation equipment to the active establishment of a route or guide for reintubation and/or oxygenation. When the patient's intubation is without difficulty and there is no substantial reason to believe that an interim insult to the airway has occurred, extubation may be accomplished in a routine fashion, with a heightened state of readiness for reintubation. When there has been difficulty with intubation or there is a clinical suspicion that reintubation will be difficult, extubation over a guiding stylet may be a successful technique. Any number of devices can be used as a stylet (Table 22-14).

TABLE 22-14 Devices Used as Extubating Stylets

·DEVICE	·ADVANTAGE	·DISADVANTAGE
Fiberoptic bronchoscope	Visualize structures Oxygen can be insufflated through working channel	ETT cannot be exchanged
Eschmann catheter or similar device	Inexpensive, semirigid	Cannot visualize or oxygenate
Exchange/ventilatory catheter	Oxygen can be insufflated through central lumen	Cannot visualize, may be too flexible

A popular test to predict airway patency after extubation is the detection of a leak on deflation of the ETT cuff. A recent investigation has cast doubt on the reliability of this test as a predictor of airway incompetence: though the absence of an airway leak on cuff deflation was not predictive of subsequent ventilatory failure after extubation, no patient with a positive leak test (leak around the ETT cuff) developed problems after extubation.[155]

Another technique may be the use of an FOB to view the tracheal structures during the removal of the ETT. If extubation is tolerated, the FOB can be slowly withdrawn into the subglottic region. If secretions do not obstruct the objective lens, the vocal folds and other structures may be visualized and evaluated.

A number of obturators are available for use in trial extubation (where they may be left in place in the airway for extended periods) or endotracheal tube exchange (e.g., failure of the ETT cuff).[156] It is beyond the scope of this text to

describe all the commercially available catheters. The Cook Airway Exchange Catheters (Cook Critical Care, Bloomington, IN) are manufactured with external diameters of 2.7, 3.7, 4.7, and 6.33 mm (Fig. 22-25A). The smallest diameter catheter (which can fit within a 3.0-mm id ETT) is 45 cm long, whereas the others are 83 cm in length. They all have a central lumen and rounded, atraumatic ends. The catheters are graduated from the distal end. The proximal end is fitted with either a 15-mm or a Luer-lock Rapi-Fit adapter, which can be quickly removed and replaced for ETT removal or change. With these adapters an oxygen source can be used to provide insufflated or jet-ventilated oxygen if the patient fails extubation and/or if reintubation over the catheter fails.

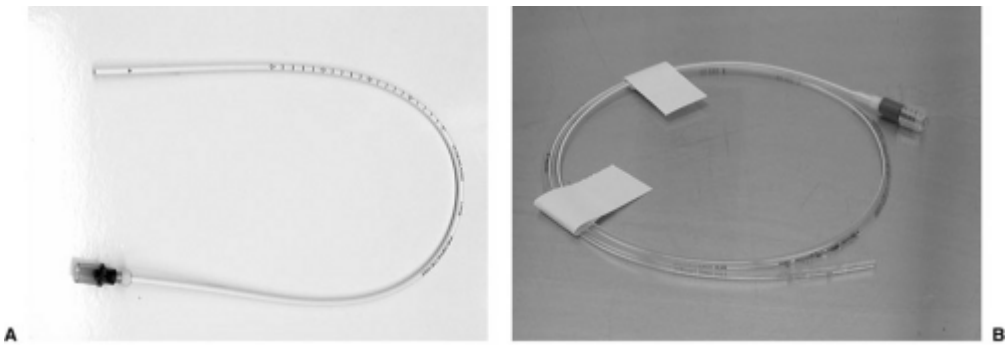

FIGURE 22-25. A. The Cook airway exchange catheter fitted with a Rapifit Luer-lock adapter (Cook Critical Care, Bloomington, IN). A 15-mm Rapifit adapter for attachment to an anesthesia circuit or ambu bag is also available. **B.** The Cardiomed endotracheal ventilation catheter.

The Cardiomed endotracheal ventilation catheter (Gromley, Ontario, Canada) designed by Richard Cooper, MD, a Canadian anesthesiologist, is 85 cm in length, and has inner and outer diameters of 3 and 4 mm, respectively. An integral Luer-lock fitting adapter is found at the proximal end, whereas the blunted distal end incorporates eight helically arranged side holes in addition to the distal end hole (Fig. 22-25B). The arrangement of these holes is meant to center the catheter during oxygen insufflation, and prevent traumatic "whipping" within the trachea. The use of this catheter for ETT exchange, tracheal reintubation, oxygen insufflation, jet ventilation, and end-tidal CO_2 detection after extubation has been documented by the inventor.[151]

THE DIFFICULT AIRWAY

The Difficult Airway Algorithm

12 In 1993, the ASA's Task Force on the Difficult Airway first published an algorithm that has become a staple of management for clinicians. This algorithm was reissued in 2003.[113,157]

13 The

most dramatic change in the ASA Difficult Airway Algorithm (ASA-DAA) was the repositioning of the LMA from the emergency to the routine management pathway (Fig. 22-26). The ASA defines

the difficult airway as the situation in which the "conventionally trained anesthesiologist experiences difficulty with mask ventilation or both." Based on available data, the incidence of failed intubation is 0.05 to 0.35%, whereas the incidence of failed intubation/inability to perform mask ventilation is 0.01 to 0.03%.[158,159]

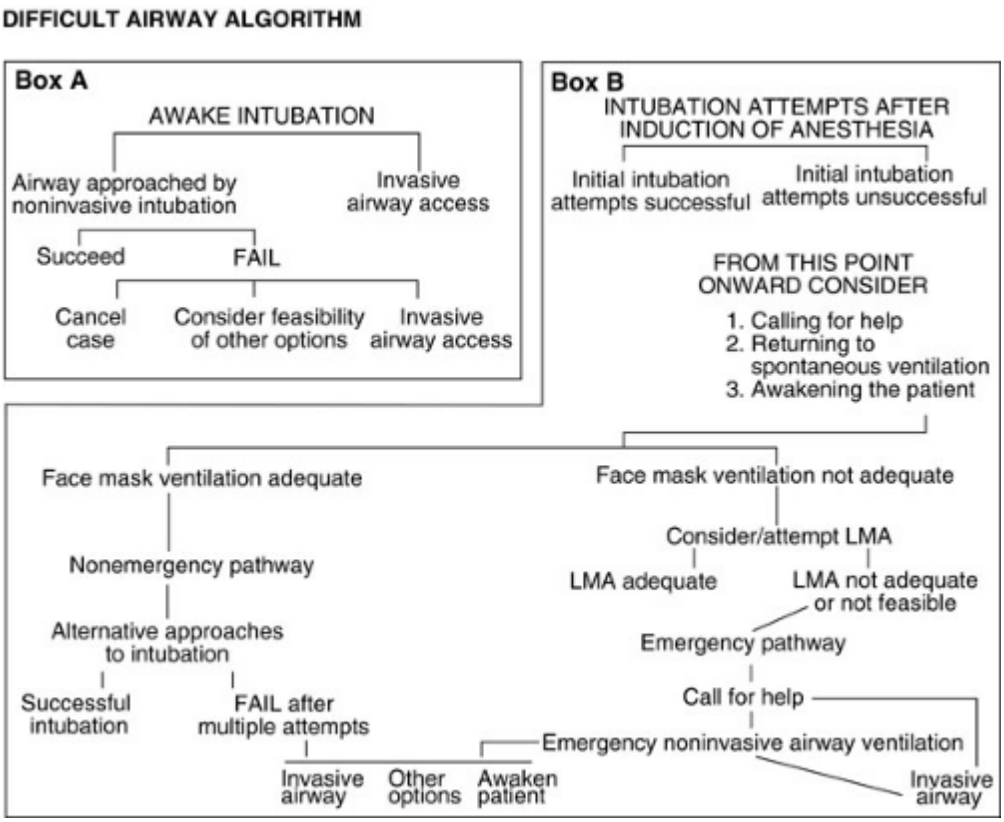

FIGURE 22-26. The American Society of Anesthesiologists Difficult Airway Algorithm. (Adapted from Practice guidelines for the management of the difficult airway: An updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Anesthesiology 98:1269, 2003.)

The ASA algorithm stands as a model for the approach to the difficult airway for nurse anesthetists, emergency medicine physicians, and prehospital personnel, as well as for anesthesiologists. Although the algorithm largely speaks for itself, its salient features are discussed here. One statement in this document summarizes the difficulty of writing and recommending practices in the difficult airway management: "The difficult airway represents a complex interaction between patient factors, the clinical setting and the skills of the practitioner."[113]

Entry into the algorithm begins with the evaluation of the airway. Although there is some debate as to the value of particular evaluation methods and indices, clinicians must use all available data and their own clinical experience to reach a general impression as to the difficulty of the patient's airway in terms of laryngoscopy and intubation, supraglottic ventilation techniques, aspiration risk, or apnea tolerance.

This evaluation should direct the clinician to enter the ASA algorithm at one of its two root points: A—awake intubation, or B—intubation attempts after the induction of general anesthesia (see Fig. 22-26). This highlights the misnomer of the algorithm: it is not only for difficult airways, but is relevant to

all instances where the airway is managed. Box B describes the approach taken in the majority of tracheal intubations (and is applicable to facemask– and SGA-managed patients). The decision to

enter the algorithm via box A or B is a premanagement one. Box A is chosen when difficulty is anticipated, while box B is for the situation when no difficulty is anticipated. This decision can be refined in light of the proliferation of SGAs. Takenaka et al, have questioned the need to enter the ASA-DAA box A when SGAs are deemed usable despite an anticipated difficult tracheal intubation by DL.[160] This has been further delineated into a preoperative decision tree by Rosenblatt.[161] Figure 22-27 outlines the Airway Approach Algorithm (AAA), which is a simple, one-pathway algorithm for entering into the ASA-DAA. Branch choice, like the earlier-noted statement from the ASA practice guidelines, is highly dependent on the clinician's skill and experience. Details of the AAA can be found elsewhere and are summarized here:[161]

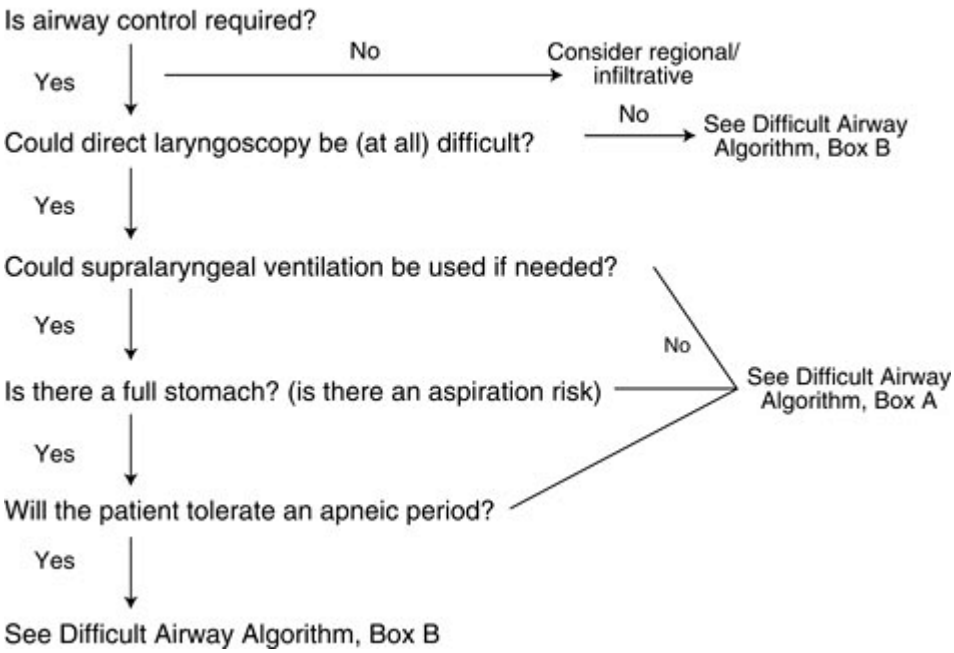

FIGURE 22-27. The Airway Approach Algorithm: A decision tree approach to entry into the American Society of Anesthesiologists Difficult Airway Algorithm (see Fig. 22-26). (From Rosenblatt W. The airway approach algorithm. J Clin Anesthesia 16:312, 2004.)

1. Is airway control necessary? No matter how routine sedation or general anesthesia become to potentially make a patient apneic, should always be considered seriously and alternatives should be considered.
2. Will DL be (at all) difficult? If there is no indication that DL will be difficult (based on physical exam and history), the clinician may proceed with any technique (induction, DL, LMA, etc.) as clinically appropriate. This is the essence of box B of the ASA-DAA.
3. Can SGA ventilation be used? If the clinician feels that there is a physical reason that SGA ventilation (by facemask, LMA, or other device) will be difficult, the juncture of possible "cannot intubate/cannot ventilate" (CNI/CNV) has been reached. Because this is a preoperative algorithm, box A of the ASA-DAA may be the root entry point.
4. Is there an aspiration risk? As discussed earlier, the patient at risk for aspiration is not a candidate for elective SGA use. A juncture of "cannot intubate/should not ventilate" has been reached and box A of the ASA-DAA is chosen.
5. Will the patient tolerate an apneic period? Question 3 from this list is difficult to answer and is highly dependent on the skills and experience of the clinician. Should intubation fail, and SGA ventilation not be adequate, the patient's ability to sustain oxygen saturation will

dictate their ability to tolerate an apneic period. Factors such as age, obesity, pulmonary status, abnormal oxygen consumption (e.g., fever), and choice of induction agents will influence this. These factors have been discussed in detail elsewhere.[161] To illustrate the clinical application of the AAA, the path through this algorithm will be traced for the clinical scenarios at the end of this chapter.

The exception to the AAA is the patient who is unable to cooperate owing to mental retardation, intoxication, anxiety, depressed level of consciousness, or age. This patient may still enter box A, but awake intubation may need to be modified in favor of techniques which maintain spontaneous ventilation (e.g., inhalation induction).

Preparation of the patient for awake intubation is discussed later. In most instances, awake intubation is successful if approached with care and patience. When awake intubation fails, the clinician has a number of options. First, one can consider cancellation of the surgical case. In this situation, specialized equipment or personnel can be assembled for a return to the operating room. Where cancellation is not an option, regional anesthetic techniques can be considered, or, if demanded by the situation, a surgical airway (e.g., tracheostomy) may be called for.

The decision to proceed with regional anesthesia because the airway has been assessed or proven to be difficult to manage must be considered in terms of risks and benefits (Table 22-15). The ASA-DAA truly becomes useful in the unanticipated difficult airway (box B, unable to intubate by DL after the induction of anesthesia). When induction agents (with or without muscle relaxants) have been administered and the airway cannot be controlled, vital management decisions must be made rapidly. Typically, the clinician has attempted direct laryngoscopy and intubation after successful or failed anesthesia mask ventilation (unless a rapid-sequence induction is being performed). Even if the patient's oxygen saturation remains adequate throughout these efforts, the number of laryngoscopy attempts should be limited to three. As discussed earlier, significant soft tissue trauma can result from multiple laryngoscopies, thereby worsening the situation. First, mask ventilation should be instituted. If facemask ventilation is adequate, the ASA-DAA nonemergency pathway is entered. The clinician may then turn to the most convenient and/or appropriate technique for establishing tracheal intubation, if needed. This might include, but is not limited to, blind oral or nasal intubation; intubation facilitated by a fiberoptic bronchoscope, LMA, LMA-Fastrach, bougie, lighted stylet, or a retrograde wire; or a surgical airway. (The most widely applied of these procedures, as well as new techniques, is discussed within the clinical scenarios in a later section of this chapter.) When mask ventilation fails, the algorithm suggests supraglottic ventilation via any LMA. If successful, the nonemergency pathway of the ASA-DAA has again been entered and alternative techniques of tracheal intubation may be utilized, if needed (e.g., perhaps LMA ventilation is adequate for the clinical situation).

TABLE 22-15 Factors To Consider in Proceeding With Regional Anesthesia (RA) After The Patient Has Been Judged To Have a Difficult Airway

▪MAY CONSIDER RA	▪SHOULD NOT CONSIDER RA
Superficial surgery	Cavity-invading surgery
Minimal sedation needed	Significant sedation needed
Anesthetic may be provided with local infiltration	Extensive neuroaxial local anesthetic administration will be required, or risk of intravascular injection/absorption is high

Access to the airway is good	Access to the airway is poor
Surgery can be halted at any time	Surgery cannot be stopped once started

Should LMA ventilation fail to sustain the patient, the emergency pathway is entered. The ASA-DAA suggests use of an Esophageal-Tracheal Combitube, rigid bronchoscopy, transtracheal oxygenation, or a surgical airway.

At any juncture, the decision to awaken the patient should be considered based on the adequacy of ventilation, the risk of aspiration, and the risk of proceeding with intubation attempts or the surgical procedure.

The repositioning of the LMA within the algorithm (in its 2003 republication) was based on more than 12 years of clinical use in the United States (and more than 20 years' experience worldwide). Relatively few cases of LMA failure in the face of the CNI/CNV situation have been reported.[10,162,163,164,165,166,167,168] Three broad categories account for these failures: acute oral–pharyngeal angle, obstruction at the level of the hypopharynx, obstruction below the vocal folds. Conversely many cases of LMA rescue of the failed airway have been reported. Though control studies are lacking, Parmet et al noted that all cases of CNI/CNV (with the exception of an iatrogenic subglottic obstruction) occurring in a 2-year period in a single hospital were rescued with an LMA.[162]

Awake Airway Management

14 Awake airway management remains a mainstay of the ASA's Difficult Airway Algorithm. Awake intubation provides many advantages over the anesthetic state, including maintenance of spontaneous ventilation in the event that the airway cannot be secured rapidly, increased size and patency of the pharynx, relative forward placement of the base of the tongue, posterior placement of the larynx, and patency of the retropalatal space.[169,170] The effect of sedatives and general anesthetics on airway patency may be secondary to direct effects on motoneurons and on the reticular activating system.[171] The sleep apnea patient may be particularly prone to obstruction with minimal sedation. Additionally, the awake state confers some maintenance of upper and lower esophageal sphincter tone, thus reducing the risk of reflux. In the event that reflux occurs, the patient can close the glottis and/or expel aspirated foreign bodies by cough to the extent that these reflexes have not been obtunded by local anesthesia.[172] Lastly, patients at risk for neurologic sequelae (e.g., patients with unstable cervical spine pathology) may undergo sensory-motor monitoring after tracheal intubation. In an emergent situation, there may be cautions (e.g., cardiovascular stimulation in the presence of cardiac ischemia or ischemic risk, bronchospasm, increased intraocular pressure, increased intracranial pressure) but no absolute contraindications to awake intubation.[173] Contraindications to elective awake intubation include patient refusal or inability to cooperate (e.g., child, profound mental retardation, dementia, intoxication) or allergy to local anesthetics.

Once the clinician has decided to proceed with awake airway management, the patient must be prepared both physically and psychologically. Most adult patients will appreciate an explanation of

the need for an awake airway exam and will be more cooperative once they realize the importance of, and rationale for any uncomfortable procedures. Once the airway has been prepared, patients will realize that they should experience no further discomfort during the intubation.

Apart from appropriate explanation, medication can also be used to allay anxiety. If sedatives are to be used, the clinician must keep in mind that producing obstruction or apnea in the difficult airway patient can be devastating and an overly sedated patient may not be able to protect the airway from regurgitated gastric contents, or cooperate with procedures. Small doses of benzodiazepines (diazepam, midazolam, lorazapam) are commonly used to alleviate anxiety without producing significant respiratory depression. These drugs may be given in iv or oral forms (when available) and may be reversed with specific antagonists (e.g., flumazenil). Opioid receptor agonists (e.g., fentanyl, alfentanil, remifentanil) can also be used in small, titrated doses for their sedative and antitussive effects, although caution must be exercised. A specific antagonist (e.g., naloxone) should always be immediately available. Ketamine and droperidol and the new agent, dexmetomodine, have also been popular among clinicians.

Administration of antisialagogues is important to the success of awake intubation techniques. As will be discussed below, clearing of airway secretions is essential to the use of indirect optical instruments (e.g., fiberoptic bronchoscope, rigid fiberoptic laryngoscope) because small amounts of any liquid can obscure the objective lens. The commonly used drugs atropine (0.5 to 1 mg im or iv) and glycopyrrolate (0.2 to 0.4 mg im or iv) have other significant effects: by reducing saliva production, these drugs increase the effectiveness of topically applied local anesthetics by removing a barrier to mucosal contact and reducing drug dilution. Vasoconstriction of the nasal passages is needed if there is to be instrumentation of this part of the airway. If the patient is at risk for gastric regurgitation and aspiration, prophylactic measures should be undertaken. It is also prudent to supply supplemental oxygen to the patient by nasal cannula (which can be placed over the nose or mouth).

Local anesthetics are a cornerstone of awake airway control techniques. The airway, from the base of the tongue to the bronchi, comprises an undeniably sensitive series of tissues. Topical anesthesia and injected nerve block techniques have been developed to blunt the protective airway reflexes as well as to provide analgesia. As is well known to the anesthetic practitioner, local anesthetics are both effective and potentially dangerous drugs. The clinician should have a thorough understanding of the mechanism of action, metabolism, toxicities, and acceptable cumulative doses of the drugs that he or she chooses to employ in the airway. Because much of the agent used will be within the tracheal–bronchial tree and will travel to the alveoli, there will be significant and rapid intravascular absorption.

Despite the availability of myriad local anesthetics, only those most commonly used in airway preparation will be discussed here.

Among otolaryngologists, cocaine is a popular topical agent. Not only is it a highly effective local anesthetic, but also it is the only local anesthetic that is a potent vasoconstrictor. It is commonly available in a 4% solution. The total dose applied to the mucosa should not exceed 200 mg in the adult. Cocaine should not be used in patients with a known cocaine hypersensitivity, hypertension, ischemic heart disease, preeclampsia, or those taking monoamine oxidase inhibitors.[174] Since cocaine is metabolized by pseudocholinesterase, it is contraindicated in patients deficient in this enzyme.

Lidocaine, an amide local anesthetic, is available in a wide variety of preparations and doses (Table 22-16). Topically applied, peak onset is within 15 minutes. Toxic plasma levels are not impossible to achieve but are not commonly reported in airway management.

TABLE 22-16 Available Lidocaine Preparations

·PREPARATION	·DOSES

Injectable/topical solution	1%, 2%, 4%
Viscous solution	1%, 2%
Ointment	1%, 5%
Aerosol	10%

Tetracaine is an amide local anesthetic with a longer duration of action than either cocaine or lidocaine. Solutions of 0.5%, 1%, and 2% are available. Absorption of this drug from the respiratory and GI tracts is rapid, and toxicity after nebulized application has been reported with doses as low as 40 mg, although the acceptable safe dose in adults is 100 mg.[175]

Benzocaine is popular among some clinicians because of its very rapid onset (<1 minute) and short duration (~10 minutes). It is available in 10%, 15%, and 20% solutions. It has been combined with tetracaine (Hurricaine®, Beutlich Pharmaceuticals) to prolong the duration of action. A 0.5-second aerosol administration of Hurricaine delivers 30 mg of benzocaine, the toxic dose being 100 mg. Another common preparation is Cetacaine spray, which combines benzocaine with tetracaine, butyl aminobenzoate, benzalkonium chloride, and cetyldimethylethyl ammonium bromide. Benzocaine may produce methemoglobinemia, which is treated by the administration of methylene blue.

There are three anatomic areas to which the clinician directs local anesthetic therapy: the nasal cavity/nasopharynx, the pharynx/base of tongue, and the hypopharynx/larynx/trachea. The nasal cavity is innervated by the greater and lesser palantine nerves (innervating the nasal turbinates and most of the nasal septum) and the anterior ethmoid nerve (innervating the nares and anterior third of the nasal septum). The two palantine nerves arise from the sphenopalantine ganglion, located posterior to the middle turbinate. Two techniques for nerve block have been described. The ganglion can be approached through a noninvasive nasal approach: cotton-tipped applicators soaked in local anesthetic are passed along the upper border of the middle turbinate until the posterior wall of the nasopharynx is reached. They are left in place for 5 to 10 minutes. In the oral approach, a needle is introduced into the greater palantine foramen, which can be palpated in the posterior lateral aspect of the hard palate, 1 cm medial to the second and third maxillary molars. Anesthetic solution (1 to 2 mL) is injected with a spinal needle inserted in a superior/posterior direction at a depth of 2 to 3 cm. Care must be taken not to inject into the sphenopalantine artery. The anterior ethmoid nerve can be blocked by cotton-tipped applicators soaked in local anesthetic placed along the dorsal surface of the nose until the anterior cribriform plate is reached. The applicator is left in place for 5 to 10 minutes.

The oropharynx is innervated by branches of the vagus, facial, and glossopharyngeal nerves. The glossopharyngeal nerve (GPN) travels anteriorly along the lateral surface of the pharynx, its three branches supplying sensory innervation to the posterior third of the tongue, the vallecula, the anterior surface of the epiglottis (lingual branch), the walls of the pharynx (pharyngeal branch), and the tonsils (tonsillar branch). A wide variety of techniques may be used to anesthetize this part of the airway. The simplest techniques involve aerosolized local anesthetic solution, or a voluntary "swish and swallow." As long as the clinician has developed a plan to anesthetize all relevant structures, has allowed enough time for drying agents to work, and remains continually cognizant of the total dose of local anesthetics administered, most patients will be adequately

anesthetized in this way.

Some patients may require a GPN block, especially when topical techniques do not adequately block the gag reflex. The branches of this nerve are most easily accessed as they transverse the palatoglossal folds. These folds are seen as soft tissue ridges, which extend from the posterior aspect of the soft palate to the base of the tongue, bilaterally (Fig. 22-28).

FIGURE 22-28. The palatoglossal arch (*arrow*) is a soft tissue fold that is a continuation of the posterior edge of the soft palate to the base of the tongue. A local anesthetic–soaked swab placed in the gutter along the base of the tongue is left in contact with the fold for 5 to 10 minutes.

A noninvasive technique employs anesthetic-soaked cotton-tip applicators, which are positioned against the inferior-most aspect of the folds and left in place for 5 to 10 minutes. When the noninvasive technique proves inadequate, local anesthetic can be injected. Standing on the side contralateral to the nerve to be blocked, the operator displaces the extended tongue to

the contralateral side and a 25-G spinal needle is inserted into the membrane near the floor of the mouth. An aspiration test is performed. If air is aspirated, the needle has passed through-and-through the membrane. If blood is aspirated, the needle is redirected more medially. The lingual branch is most readily blocked in this manner, but retrograde tracking of the injectate has also been demonstrated.[172] Though providing a reliable block, this technique is reported to be painful and may result in a bothersome and persistent hematoma.[176] A posterior approach to the GPN has been described in the otolaryngologic literature (for tonsillectomy). It may be difficult to visualize the site of needle insertion, which is behind the palatopharyngeal arch where the nerve is in close proximity to the carotid artery. Because of the risk for arterial injection and bleeding, the technique will not be described here; however, the reader is referred to a more authoritative text.[177]

The internal branch of the superior laryngeal nerve (SLN), which is a branch of the vagus nerve, provides sensory innervation to the base of the tongue, epiglottis, aryepiglottic folds, and arytenoids. The branch originates from the SLN lateral to the cornu of the hyoid bone. It then pierces the thyrohyoid membrane and travels under the mucosa in the pyriform recess. The remaining portion of the SLN, the external branch, supplies motor innervation to the cricothyroid muscle. Several blocks of this nerve have been described. In many instances topical application of anesthetics in the oral cavity will provide adequate analgesia. An external block is performed with the patient supine with the head extended and the clinician standing on the side ipsilateral to the

nerve to be blocked. Beneath the angle of the mandible the clinician identifies the superior cornu of the hyoid bone (Fig. 22-29). Using one hand, medially directed pressure is applied to the contralateral hyoid cornu, displacing the ipsilateral hyoid cornu toward the clinician. Caution must be taken to locate the carotid artery and displace it if necessary. The needle can be inserted directly over the hyoid cornu and then "walked" off the cartilage in an anterior-caudad direction until it can be passed through the membrane to a depth of 1 to 2 cm (Fig. 22-29A). Before the injection of local anesthetic, an aspiration test should be performed to ensure that one has not entered the pharynx or a vascular structure. Local anesthetic with epinephrine (1.5 to 2 mL) is injected in the space between the thyrohyoid membrane and the pharyngeal mucosa. The superior laryngeal nerve can also be blocked with a noninvasive block internal technique. The patient is asked to open the mouth widely, and the tongue is grasped using a gauze pad or tongue blade. A right-angle forceps (e.g., Jackson-Krause forceps) with anesthetic-soaked cotton swabs is slid over the lateral tongue and into the pyriform sinuses bilaterally. The cotton swabs are held in place for 5 minutes.

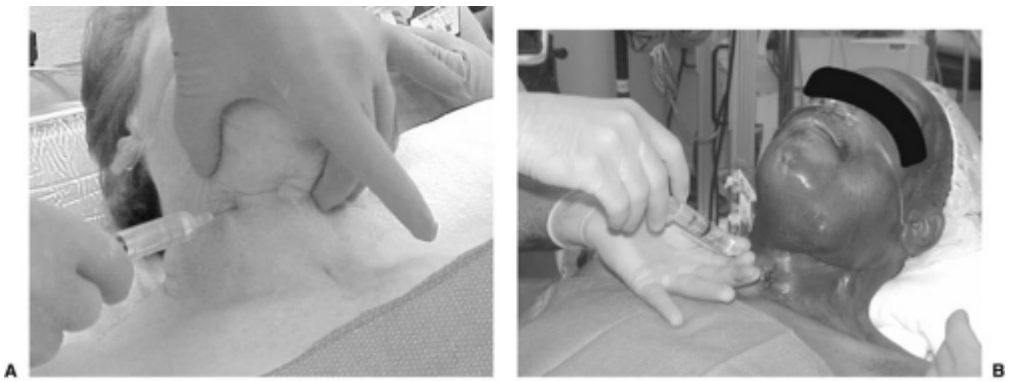

FIGURE 22-29. When a superior laryngeal nerve block is performed, pressure is applied to the contralateral greater cornu of the hyoid to facilitate identification of anatomic landmarks. The needle is inserted at the level of the thyrohyoid membrane just inferior to the greater cornu of the thyroid cartilage. **A.** Superior laryngeal nerve block. **B.** Transtracheal aspiration and injection of local anesthetic (note bubble of aspirated tracheal air).

Sensory innervation of the vocal folds and the trachea is provided by the recurrent laryngeal nerve. Transtracheal injection of local anesthetic can easily be performed to produce adequate analgesia, and the technique is described in detail below (see Retrograde Intubation section, Case 2) (Fig. 22-29B). Lidocaine, 4 mL of 2% or 4% solution, is injected.

An effective and noninvasive technique of tracheal and vocal cord topical analgesia utilizes the working channel of the fiberoptic bronchoscope. A disadvantage of this technique is that solutions leaving the working channel can obscure the objective lens. This can be overcome by use of an epidural catheter, inserted through the working channel, as described by Ovassapian.[178] Not only does this prevent the obscuring of the view, but also it allows specific "aiming" of the anesthetic stream.

Clinical Difficult Airway Scenarios

The clinician approaching the patient with a difficult airway has a vast armamentarium of techniques and instruments that can be applied to securing and maintaining oxygenation and ventilation.[179] Although this array can be confusing, textbook authors cannot dictate specific approaches in every situation; moreover, the variability of patient presentation makes specific

recommendations difficult. Thus, to discuss management, the following section presents a number of brief clinical scenarios and the author's own approach. The major alternative airway management techniques are discussed in this manner. All of the clinical cases described herein have been managed by the author or a colleague. Other techniques that might be applied in each situation are also discussed, together with the author's own "decision tree" regarding their applicability. In these cases, as in actual practice, the first technique applied may not have

been the best one. The principle of flexibility (and a keen eye to the need to change course quickly) is emphasized repeatedly. In view of the critical importance of the act of airway control, the clinician must be prepared to alter his or her approach as the situation demands. Table 22-17 shows the author's route through the AAA (Figure 22-27) with each case.

TABLE 22-17 The Airway Approach Algorithm as Applied to the Clinical Cases Presented in This Chapter

·CASE[a]	·REQUIRE CONTROL?[b]	·DL Difficult?[b]	·SGA POSSIBLE?[b]	·ASPIRATION RISK?[b]	·APNEA[b]	·BOX[b]
1	Yes	Yes	Yes	Yes		A
2	Yes	Yes	?	—		A

4	Yes	No	—	—		B
5	Yes	Yes	Yes	No		B

[a]Refer to clinical cases.

[b]Refer to Figure 22-7.

When DL and tracheal intubation fail, the clinician has a large armamentarium of tools to turn to. Because successful DL is dependent on sufficient tissue distortion (to create a line of sight), techniques that do not require similar anatomic alignment may be successful after failed DL. Fiberoptic, SGA, stylet-assisted (e.g., lighted stylet) and retrograde techniques may provide a successful alternative. But these techniques also call on alternative skill sets. In a difficult or even critical situation it is unlikely that turning to an unpracticed technique will be helpful.[180]

Unfortunately, clinicians rarely employ alternative techniques until a difficult situation arises. Heidegger et al introduced a simple algorithm for incorporating flexible fiberoptic-aided tracheal intubation into daily practice as a routine alternative to DL.[180] Their incidence of difficult intubation was 6 in 1,324 cases, or 0.049%, markedly lower than the 0.3% reported previously.[181]

Case 1: Flexible Fiberoptic-Aided Intubation

A 50-year-old man with symptomatic cervical vertebrae disk herniation presents for disk resection and spinal fixation. He has a history of tobacco use, alcohol consumption, and gastroesophageal

reflux. In the preoperative holding area 0.4 mg of glycopyrrolate is administered. Fifteen minutes later, when the patient states that his oral secretions are minimized, topical anesthesia is administered to the airway. The patient receives 4 mg of intravenous midazolam. An intubating oral airway is placed without eliciting a gag reflex and a flexible fiberoptic bronchoscope is advanced into the airway. The vocal ligaments are visualized, and 4 mL of 4% lidocaine solution are injected through the fiberscope's working channel, being seen to bathe the laryngeal and sublaryngeal structures. The distal end of the fiberscope is advanced into the larynx, and a 7.0-id endotracheal tube, which had been threaded onto the fiberscope's insertion shaft, is advanced into the trachea. The fiberscope is removed while the structures of the carina, trachea, and, finally, the tracheal tube are observed. The anesthesia circuit is attached to the tracheal tube and a steady output of carbon dioxide is detected by capnography. A brief sensory and motor neurologic exam is performed by the attending surgeon and general anesthesia is induced.

Use of the Fiberoptic Bronchoscope in Airway Management. The FOB is a ubiquitous instrument in anesthesia, being available to 99% of surveyed active ASA members.[179] The technique of fiberoptic-aided intubation was first performed using a choledochoscope in a patient with Still's disease (idiopathic, adult onset arthritis).[182] By the late 1980s it was recognized that the use of the flexible FOB represented such a significant advancement in the management of the patient with a difficult airway that experts stated that no anesthesiologist could afford not to be facile with this technique.[183] It is now generally accepted that for a variety of clinical situations, the FOB is a critical tool in the armamentarium of the anesthesiologist dealing with the awake or unconscious patient who is, or appears to be, difficult to intubate.[184] The FOB has proven to be the most versatile tool available in this regard.[178]

15 There is no true or firm indication for FOB-aided intubation, as there might be with direct laryngoscopy (e.g., rapid-sequence induction for the full-stomach patient). There are, however, many clinical situations where the FOB can be of unparalleled aid in securing the airway, especially if the clinician has made an effort to master the necessary skills by using it in routine intubations.[178,180] These include anticipated difficult intubation because of historical or physical exam findings, unanticipated difficult intubation (where other techniques have failed), lower and upper airway obstruction, unstable or fixed cervical spine disease, mass effect in the upper or lower airways, dental risk or damage, and awake intubation.[178] Unlike the other devices used to intubate the trachea, the FOB can also serve to visualize structures below the level of the vocal folds. For example, it can identify the placement of the tracheal tube or aid in placement of a double lumen tracheal tube. It may be helpful in diagnosis within the trachea and bronchial tree, or in pulmonary toilet (Fig. 22-30).

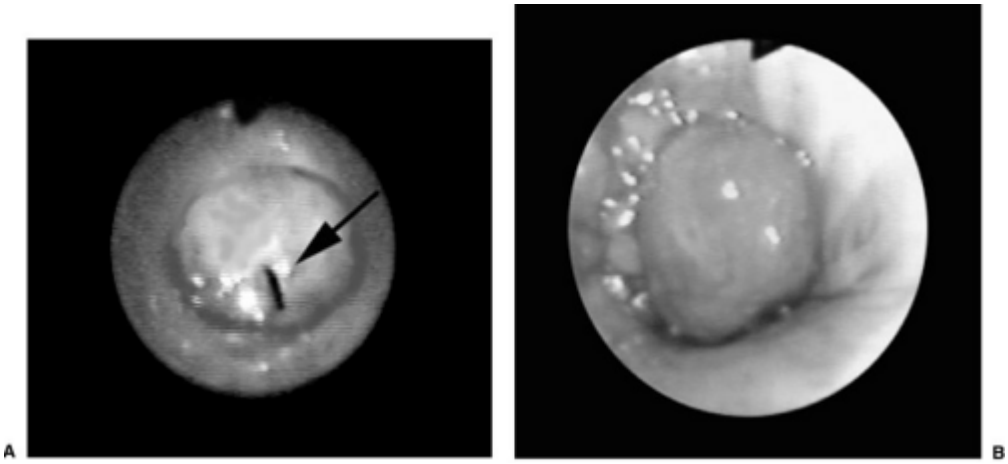

FIGURE 22-30. The fiberoptic bronchoscope may be useful for diagnosis and therapy below the level of the vocal ligaments including bronchial segments exam and toilet (see Fig. 22-30). **A.** Laryngeal web. **B.** Bronchial tumor.

Contraindications to FOB-aided intubation are relative and revolve about the limitations of the device (Table 22-18).

TABLE 22-18 Contraindications To Fiberoptic Bronchoscopy

Hypoxia
Heavy airway secretions not relieved with suction or antisialagogues
Bleeding from the upper or lower airway not relieved with suction
Local anesthetic allergy (for awake attempts)
Inability to cooperate (for awake attempts)

Because the optical elements are small (the objective lens is typically 2 mm in diameter or smaller), minute amounts of airway secretions, blood, or traumatic debris can hinder visualization. Care must be taken to remove these obstacles from the airway beforehand: application of intramuscular or intravenous antisialagogues (e.g., glycopyrrolate, 0.2 to 0.4 mg; atropine, 0.5 to 1 mg) will produce a drying effect within 15 minutes, but caution should be taken in patients who may not be able to tolerate an increase in heart rate. Vasoconstriction of the nose using topical oxymetazoline, phenylephrine, or cocaine reduces the chances of bleeding should this route be chosen. If an awake intubation is planned using the FOB, the patient must be able to cooperate—a "quiet" airway, with little motion of the head, neck, tongue, and larynx, is vital to success. Finally, because FOB-aided intubation of the trachea can require significant time, especially if the clinician is not facile with the device, hypoxia or impending hypoxia is a contraindication, and a more rapid method of securing an airway (e.g., LMA or surgical airway) should be considered.

Elements of the Fiberoptic Bronchoscope. The FOB is a fragile device with optical and nonoptical elements. The

fundamental element consists of a glass-fiber bundle. Each fiber is 8 to 12 microns in diameter and is coated with a secondary glass layer, turned the cladding. The cladding aids in maintaining the image within each fiber as the light is reflected off the sidewall 10,000 times per meter as it moves from the objective lens to the eyepiece lens in the operator's handle. The typical intubating FOB has 10,000 to 30,000 such fibers encased in a 60-cm, water-impermeable insertion cord, with graduation marks every 10 cm. Though the fibers are allowed to rotate over each other throughout the length of the cord, they are fused together at the two ends in a coherent pattern; that is, the arrangement of the fibers at the eyepiece end is identical to the arrangement at the objective lens, where a diopter ring allows focusing. Therefore, one might envision that the image before the objective lens (i.e., the objective) is divided into 10,000 individual and unique pictures, which independently travel down an unwieldy cord, to be reassembled in front of the eyepiece lens. Broken fibers, which may occur because of bending of the insertion cord, entrapping the cord in other equipment, and dropping the FOB, are readily apparent and are generally no more than a nuisance until the number of broken fibers interferes with the visual field.

The insertion cord also contains a *working channel*: a lumen, up to 2 mm in diameter, which travels from the distal tip to the handle. It can be used for applying suction, or oxygen, and

instilling lavaging fluids or drugs (e.g., local anesthetics). There is one report of gastric rupture attributed to the insufflation of oxygen through the working channel when the FOB was within the esophagus.[185] In general, FOBs <2 mm in external diameter (e.g., pediatric) do not have a working channel.

Two wires traveling from a lever in the handle down the length of the insertion cord control movement of the distal tip in the sagittal plane. The entire insertion cord is protected by a metal "wrap" until the level of the distal tip, which is hinged for movement. Coronal plane movement is accomplished by a combined use of the control lever and rotation of the entire FOB from handle to distal end. Because the fibers are able to move over one another, except for where they are fused at the extreme ends of the optic cord, rotational control is maximized by reducing any curves in the FOB shaft (Fig. 22-31).

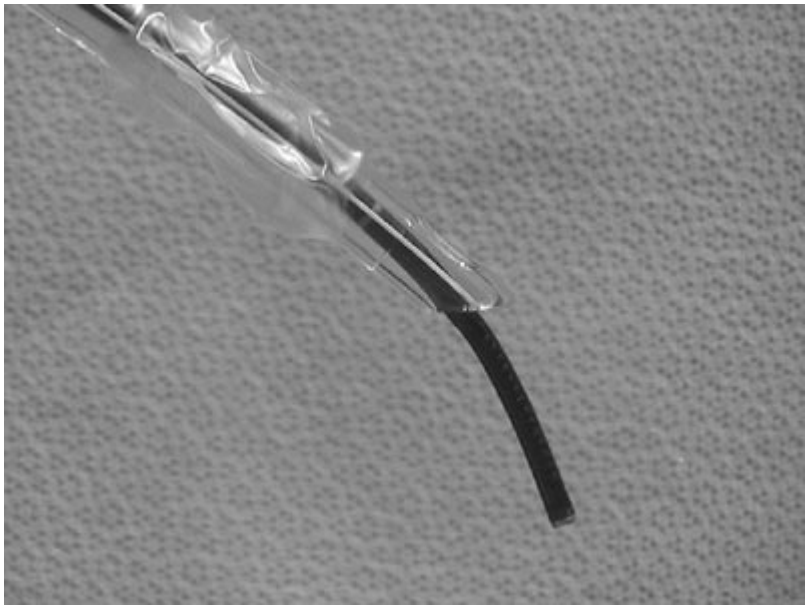

FIGURE 22-31. Handling of the fiberoptic bronchoscope. **A.** The handle is held in the nondominant hand with the tip of thumb over the sagittal plane control lever. The index finger can be used to control the working channel (e.g., suction, oxygen insufflation). The dominant hand is used for fine manipulation at the distal end. **B.** The operator's two hands should be kept maximally apart so as to keep the insertion shaft as straight as possible, maximizing coronal plane rotational control. **C.** Curves introduced along the shaft reduce coronal plane rotational control.

The final element of the FOB is the light source. Illumination of the objective is provided by one or two noncoherent bundles of glass fibers that transmit light from the handle to the distal tip. The light is provided either by a "universal" cord that emerges from the handle and is inserted into a medical-grade endoscopic light source, or may be provided by a battery-operated light source on the handle.

Preparation of the Fiberoptic Bronchoscope. When approaching the FOB-aided intubation, one must ensure that the device is in working order. A series of inspections are made, as listed in Table 22-19.

TABLE 22-19 Preparation of the Fiberoptic Bronchoscope

·PROCEDURE	·FINDING	·SIGNIFICANCE AND ACTION

Inspect passive angulation:		
Allow FOB to hang from the hand.	Observer deviations from "plum."	Angulation may signify damage to the insertion shaft. If lever controls are operative, the FOB may be usable. Excessive angulation or curvature may make manipulation difficult, disorienting the operator, so the scope should not be used.
Active angulation: The control lever is used to manipulate the distal tip	Does the lever control move the tip in the sagittal plane smoothly and to the extent stated by the manufacturer?	There may be a damaged or entrapped control wire. The device should be repaired by the manufacturer.
Apply suction to the working channel.	No or minimal suction at distal aperture.	Caking of secretions within channel may require cleaning by the manufacturer. Crimping of insertion cord requires repair.
Picture clarity: Observe printed writing a few millimeters in front of the objective lens.	Foggy or dirty picture.	The objective lens and eyepiece lens can be cleaned with a lint-free cloth. Use a commercial defogger. Prior to placing in the patient, warm water may prevent further fogging by equalizing the lens and patient temperatures. Suction or oxygen insufflation. If these are unsuccessful, the FOB may need cleaning by the manufacturer.

Use of the Fiberoptic Bronchoscope. The FOB is held in the nondominant hand, the thumb over the control lever and the index finger poised over the working channel valve (see Fig. 22-31). The dominant hand will be used to steady and hold the insertion cord as it is manipulated in the patient. Many operators are tempted to "switch" hands, but the thumb of the nondominant hand should be capable of controlling the gross movement of the control lever. Any experienced endoscopist will recognize that the fine control required to hold the shaft of the endoscope steady, advance the objective end into the airway, and make directional adjustments is where the art of endoscopy lies.

The insertion shaft is lubricated with a water-soluble lubricant, and it is threaded through the lumen of an ETT, the objective end emerging from the main ETT orifice. A clinically appropriate ETT should be chosen, but the larger the ratio between the internal diameter of the ETT and the external diameter of the insertion shaft, the greater the risk of "hangup" on airway structures, as occurs in 20 to 30% of attempts (Fig. 22-32).[178]

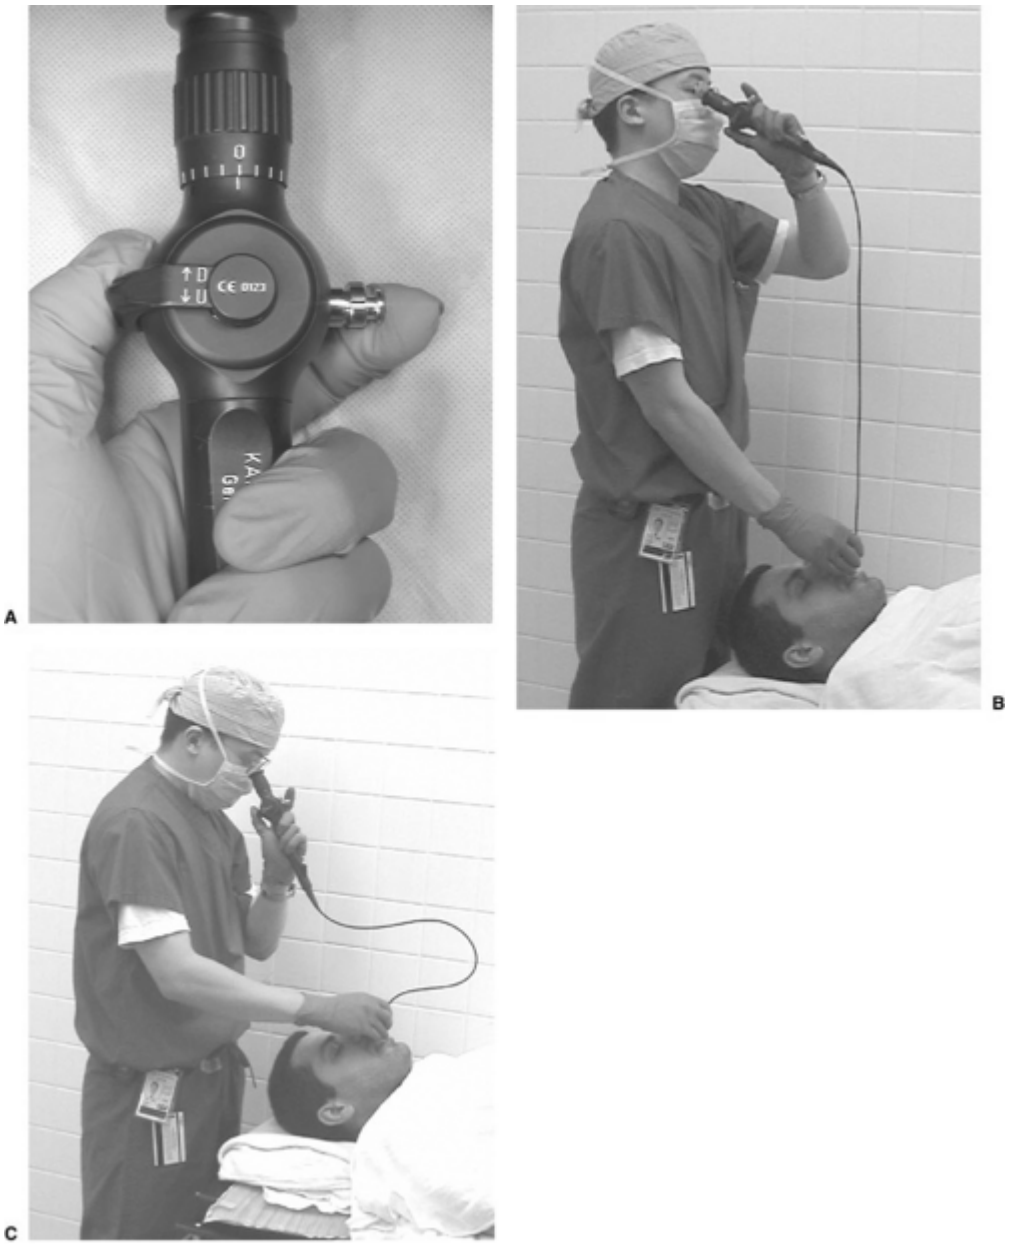

FIGURE 22-32. The size discrepancy between the fiberoptic bronchoscope and the tracheal tube that has been threaded onto it can create a cleft that can entrap anterior anatomic structures, hindering advancement of the tracheal tube into the larynx (hangup).

Hangup occurs when a cleft exists between these two devices because of the differential sizes. Hangup may involve entrapment of the epiglottis, corniculate/arytenoid cartilages, the aryepiglottic folds, or the vocal folds, and can occur with any number of stylet-guided techniques (e.g., fiberoptic, retrograde wire, lighted stylet) though it is most thoroughly described with fiberoptic aided intubation.[186,187] The orientation of the tracheal tube bevel is important in this regard. In orotracheal intubation, the bevel cleft is likely to entrap the right arytenoid cartilage when the ETT is in its typical concavity anterior position. Rotation of the ETT counterclockwise 90°

places the bevel facing positively and improves passage. During nasotraceheal intubation, the epiglottis may be entrapped, and a bevel-up position (rotation of the ETT 90° clockwise) may facilitate passage. [188]

The type of tracheal tube may also affect passage. It has been suggested that the Parker Flex-tip (Parker Medical, Cincinnati, OH) may pass the airway structures more easily than a standard ETT bevel.[189] The use of soft-tipped ETTs, asking the patient to inspire deeply during the ETT advancement, and the "double setup" ETT, which uses a small ETT (e.g., 5.0 id) within a clinically adequate ETT (e.g., 7.5 id) to overcome the clefts caused by size differentials have been described.[186,190]

The clinician chooses the route of intubation, either oral or nasal, based on clinical requirements, surgical needs, operator experience, and other intubation techniques available should FOB-aided intubation fail. This last factor is important because should an attempt at nasal intubation fail, there may be significant bleeding hindering other indirect visualization techniques. The nasal route is considered easier by many clinicians. The differences between oral and nasal FOB-aided intubation are discussed in Table 22-20.

TABLE 22-20 Techniques of Nasal and Oral Fob-Aided Intubation

	▪NASAL	▪ORAL
Preparation	Antisialagogues, topical decongestant, serial dilations with soft and lubricated nasal trumpets[a]	Antisialagogue, intubating oral airway (IOA)
ETT	Softened by placing in warm water. May be kept either on proximal insertion cord (near handle) or inserted[b] into the nose so that it is felt to turn the bend from the nasal cavity into the nasopharynx	Kept either on proximal insertion cord (near handle) or inserted 4-5 cm into the IOA
Structures seen	Floor of nose, nasal turbinates, superior aspect of the soft palate, nasopharyngeal posterior wall, base of tongue, epiglottis (distal tip),[c] arytenoid cartilages, vocal folds, tracheal rings, carina	IOA (anterior or anterior/posterior depending on IOA) Soft palate/uvula Epiglottis (distal tip),[c] arytenoid cartilages, vocal folds, tracheal rings, carina

[a]Although phenylephrine and cocaine have been used to decongest the nose, evidence suggests that oxymetazoline may be the best agent.

[b]The bevel of the ETT should follow along the nasal septum, away from the turbinates. If the ETT will not turn into the nasopharynx, it may be rotated 90° in a clockwise or counterclockwise direction and readvanced.

[c]An obstructing base of tongue or epiglottis can be moved by extension at the atlanto-occipital joint, jaw thrust, chin lift, or having an assistant pull the tongue forward.

A variety of intubating oral airways (IOA) are commercially available. Their chief function is to provide a clear visual path from the oral aperture to the pharynx, keep the bronchoscope in the midline, prevent the patient from biting the insertion cord, and provide a clear airway for the spontaneously or mask-ventilated patient. The common characteristic of all IOAs is a channel along the length of the airway large enough to allow the passage of the endotracheal tube. The Ovassapian airway (Fig. 22-33) provides two sets of semicircular, incomplete flexible flanges that stabilize the ETT (up to size 9.0 id) in the midline but allow its removal from the airway after intubation has been accomplished so that the IOA can be removed from

the mouth. The flat lingual surface of the airway gives it good lateral and rotational stability. The Patil-Syracuse endoscopic airway and the Luomanen oral airway (see Fig. 22-33) were also designed for fiberoptic-aided intubation. Each has a central groove, open at the lingual (Patil-Syracuse) or palatal (Luomanen) aspect, which allows easy removal of the ETT. The flat lingual surface provides good stability. Though this style of IOA provides superb access to the pharynx, it is larger than other airways and is often uncomfortable for the patient. The Williams airway (see Fig. 22-33) and the Berman airway were both designed for blind oral intubation. It is often

difficult to manipulate the tip of the fiberscope when it is within these narrow airways. Both are molded plastic with a complete circular internal lumen which guides the ETT toward the larynx. These airways have a small profile and are often better tolerated by the awake patient, but tend to be less stable on the tongue. Because the internal lumen is a complete circle, the Williams airway must be retreated off the ETT if it is going to be removed after intubation. This may pose difficulty if the ETT in use has a fused circuit adapter. The Berman airway solves this problem by being split along the length of one side. The plastic of the opposite side is thin and malleable. If the interincisor gap is adequate, the airway can be opened laterally to allow removal from the ETT.

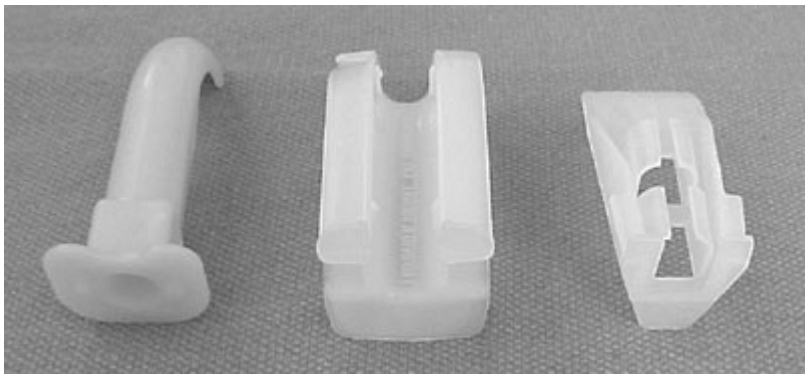

FIGURE 22-33. Left. Williams airway. **Middle.** Luomanen airway.**Right.** Ovassapian fiberoptic intubating airway.

After successful navigation through the supraglottic airway, the endoscopist visualizes the vocal folds. If glottic closure, gag, or coughing occur as the FOB distal tip stimulates the structures of the larynx, the operator can choose to apply local anesthetic through the working channel, administer more sedation, or withdraw the scope and reinforce preparatory procedures. The clinician might also decide to advance the FOB into the larynx without further preparation. The actions taken must be dictated by the individual clinical situation; in the elective scenario, for example, there may be time for reinforced airway analgesia, whereas in the face of impending respiratory arrest patient discomfort may need to be tolerated. Once the larynx is entered, the operator may choose a structure, such as the tracheal carina, to serve as an identifying landmark as the ETT is advanced. Simply because the FOB has entered the trachea, there is no guarantee that the intubation will be successful. As noted earlier, 20 to 30% of ETT advancements are accompanied by hangup. Therefore, a patient with a critical airway should not be induced with a general anesthetic with the assumption that the ETT will be easy to pass.

Once the ETT enters the trachea, the clinician may choose to view the ETT and a chosen anatomic landmark simultaneously (e.g., the tracheal carina) to assure correct ETT placement before the FOB is withdrawn.

There have been a number of variations and adjuncts to FOB-aided intubation. The reader is referred to the primary literature listed in Table 22-21, which is not meant to be exhaustive.

TABLE 22-21 Aids to Fiberoptic-Aided Intubation

▪TECHNIQUE	▪ADVANTAGE

Endoscopy mask	Control ventilation maintained during or between attempts at FOB-aided intubation
Laryngeal mask	Excellent view of the larynx and ability to ventilate during or between attempts at FOB-aided intubation
Fiberoptic-aided retrograde intubation	Guiding of the FOB with a wire known to be entering the trachea
Retrograde fiberoptic intubation	Changing a tracheostomy to an oral or nasal tracheal tube when antegrade intubation is difficult or impossible
FOB-aided intubation with the aid of a rigid laryngoscope	Helpful with an obstructing mass or large epiglottis

Although FOB-aided intubation is a versatile and vital technique, there are several pitfalls, most of which have been discussed. Table 22-22 lists the most common reasons for failure of FOB-aided intubation.

TABLE 22-22 Common Reasons For Failure During Fiberoptic-Aided Intubation

Lack of experience: Not practicing on routine intubations
Failure to adequately dry the airway: Underdose or rushed technique
Failure to adequately anesthetize the airway of the awake patient: Secretions not dried; rushed technique
Nasal cavity bleeding: Inadequate vasoconstriction; rushed technique; forcible ETT insertion
Obstructing base of tongue or epiglottis: Poor choice of intubating airway; require chin lift/jaw thrust
Inadequate sedation of the awake patient
Hangup: ETT too large
Fogging of the FOB: Suction or oxygen not attached to working channel; cold bronchoscope

Flexible fiberoptic-aided intubation is a technology-intense technique. Apart from the delicate fiberoptic device, there are cameras, recorders, light sources, and a variety of disposable adjuncts that are typically required. Dedicated wheeled carts, designed carry required as well as optional equipment in a functional arrangement, are available (Fig. 22-34). The clinician called to manage the patient outside the operating theater may benefit from portable arrangements (Fig. 22-35).

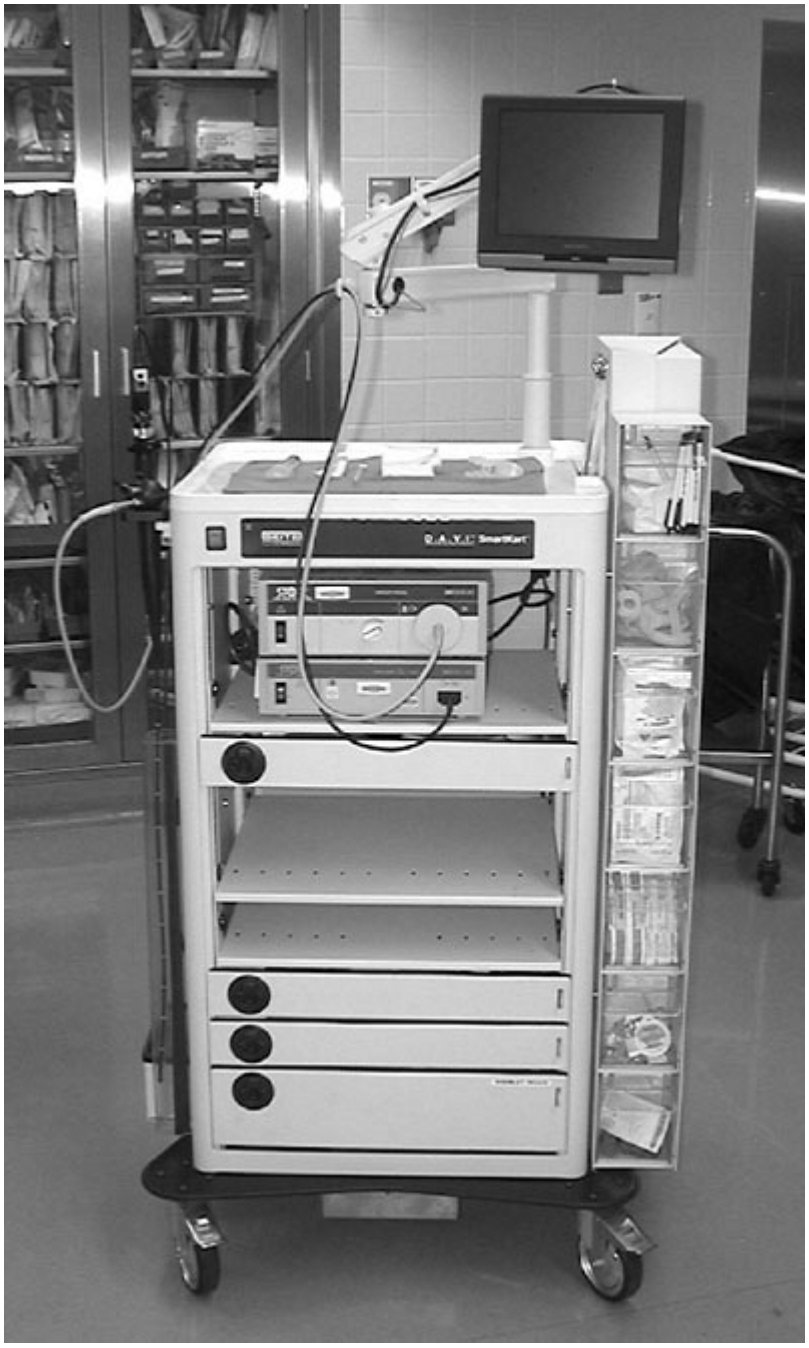

FIGURE 22-34. The Difficult Airway SmartKart (Seitz Technical Products, Avondale, PA) is designed to transport several fiberscopes as well as other difficult airway equipment, accessories, and the electronics required for video viewing through indirect optical devices.

FIGURE 22-35. The Medipack (Karl Storz Endoscopy, Culver City, CA) incorporates a light source, fiberscope camera receiver, and video screen in one package.

Rigid Fiberoptic Intubation Devices. Rigid fiberoptic devices allow indirect views of the larynx and act as an ETT guide for intubation. More than one-third of all anesthesiologists have access to these devices.[179] The most commonly available of these devices include the Bullard (ACMI, Santa

Barbara, CA, USA) and WuScope (Pentax Precision Instruments, Orangeburg, NY) laryngoscopes (Fig. 22-36). Although these laryngoscopes may be used in routine clinical situations, they are particularly useful when movement of the patient's head and neck is impossible or contraindicated (e.g., atlanto-occipital joint disease and the spine-injured patient). They are also applicable when there is a limited oral aperture (0.64 cm in the case of the Bullard). These devices consist of a rigid, stainless-steel laryngoscope-like blade that encases a fiberoptic cable with a proximal eyepiece and distal objective lens. The blades have an anatomic curve to match the neutral position of the human oral cavity-pharynx-hypopharynx relationship. Alignment of the oral, pharyngeal, and tracheal axes is not required. Illumination is provided by a second fiberoptic cable transmitting light from a battery or free-standing light source.

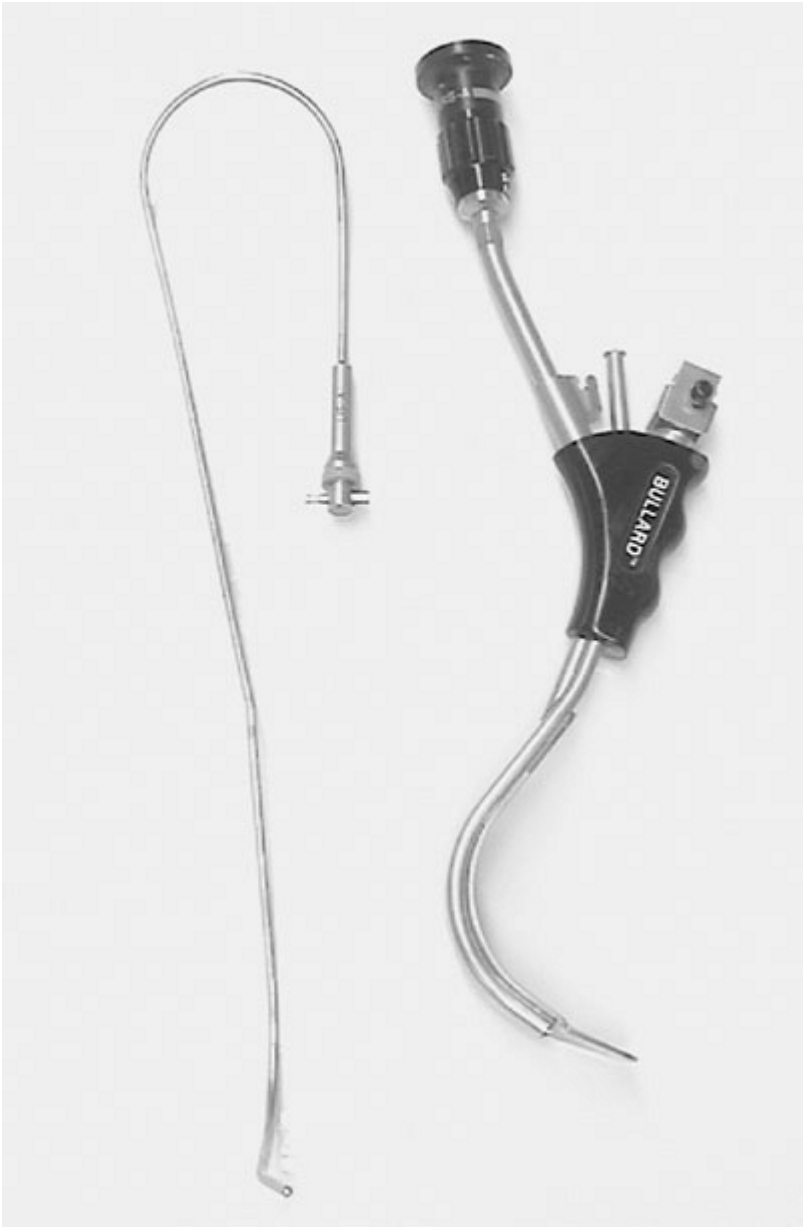

FIGURE 22-36. The Bullard laryngoscope, battery handle, and stylet.

The Bullard scope, which comes in adult and pediatric sizes, has been the best investigated. It features a fixed fiberoptic cable located on the posterior aspect of the blade. The eyepiece lens has an adjustable diopter. A working channel also runs the length of the blade. Once the larynx is visualized, the ETT is advanced using a detachable stylet, although other techniques have been described.[191] The advantages of the Bullard scope over traditional laryngoscope blades in managing the spine-injured patient and the obese patient have been investigated.[192,193,194]

Adequate exposure with the Bullard laryngoscope may be achieved after failed DL.[195]

The Upsher scope is available in an adult size as of this writing. Instead of a stylet, the ETT is held and advanced through a C-shaped lumen in the blade. There is no working channel in this scope. The eyepiece is focusable.

The Wu scope differs from the other devices in that a flexible fiberoptic endoscope is fitted into a passage within a three-part stainless steel handle and blade. A second, larger lumen accepts the ETT. A working channel is positioned alongside the endoscope lumen. Two adult sizes are manufactured. Once the larynx is visualized and the ETT advanced into the trachea, the two stainless-steel pieces of the laryngoscope blade are disassembled and removed from the mouth.

Unlike the other two devices, the Wu scope can also be used for nasal intubation by assembling only the anterior blade portion and the handle. An ETT, previously placed in the pharynx via the nares, can be fitted into the anterior portion of the blade.

A new generation of fiberoptic devices is focused on simplicity and portability, by incorporating optical and light source elements into a single stylet-like stainless steel sheath. The lack of a tongue displacing blade and a suction/oxygen channel are potential disadvantages. The Bonfils Intubation Fiberscope (Karl Storz Endoscopy, Tuttingen, Germany) (Fig. 22-37A) is a long, rigid tubular device with conventional optical and light transmitting fiberoptic elements.[196] A proximal end eyepiece (with adjustable diopter) can be used with the naked eye or fitted with a standard endoscopy camera. A cable (or battery powered attachment) brings illumination from an external light source. The distal end has a 40° angulation. Suction may be applied through a working channel. The technique of use replicates the paraglossal approach of laryngoscopy discussed previously in this chapter. The Shikani Seeing Optical Stylet (Clarus Medical, LLC, Minneapolis, MN) (SOS) has a similar configuration to the Bonfils with the exception that the distal one-half of the stylet is malleable (Fig. 22-37B). The light source may be self-contained (a proprietary powered handle or a green line

[Rusch Medical, Duluth, Georgia] laryngoscope handle) or cabled. Unlike the Bofils, a midline approach is recommended. Studies have investigated the use of the SOS as a substitute for the laryngoscope in routine anesthetic cases.[197] The hypothetical benefit of this practice is the reduction of unanticipated difficult intubations and the maintenance of alternative technique skills by incorporating this or similar devices into daily practice.[180]

Glidescope© (Fig. 22-38)

New innovations in video delivery have given rise to the next generation of video-assisted laryngoscopy tools. The Glidescope (Saturn Biomedical Systems, Burnaby, BC, Canada) provides an electronically projected image on a video monitor emanating from a video chip set at the distal end of a conventional-like laryngoscope blade, but with a more acute (60°) angulation.[198] Illumination is likewise generated at the distal aspect. This configuration affords several advantages: (1) It may be handled with a skill set similar to that used with conventional DL. (2) The operator's point of sight (e.g., the video apparatus) is positioned close to the distal blade aspect (thereby eliminating fragile fiberoptic elements). The operator therefore "sees" at a position behind the tongue, and displacement as with conventional DL, is not necessary in most cases. Similarly, lingual tonsil hyperplasia should not affect the visual axis as it does with

conventional DL.[3] (3) The video image of the airway is displayed on a lightweight portable screen. The video display allows for visualization by more than one individual (e.g., aid, mentor, student). (4) Less stress is imposed on the airway by virtue of reduced compressive force directed to the tongue. (5) An external light source is not needed. At the time of this writing, no controlled trial information is available on this device.

Video-Macintosh Laryngoscope (Fig. 22-39)

The Video-Macintosh (VM) (Karl-Storz Endovision, Culver City, California) consists of a conventional-appearing laryngoscope handle and blade. A stainless-steel shaft built into the blade flange accepts a short, fiberoptic cable containing both light source and optical cables. This fiberoptic cable enters the handle where the camera elements are housed. Two larger (and less fragile) cables exit proximal handle and connect to standard light- and video-processing devices from the same manufacturer. The video image is displayed on a standard NTSC monitor. Though the image projected from the VM closely resembles that seen with the naked eye (1) ETT placement is facilitated because the operator need not maintain an unobstructed line of sight (his eye using the video monitor), (2) external laryngeal manipulation can be observed by a second operator, and (3) use of the VM is identical standard DL, making the

video facility uniquely valuable during supervised instruction. Though large controlled trials have not been published at the time of this writing, the VM will likely have a significant advantage in teaching and some difficult laryngoscopies.

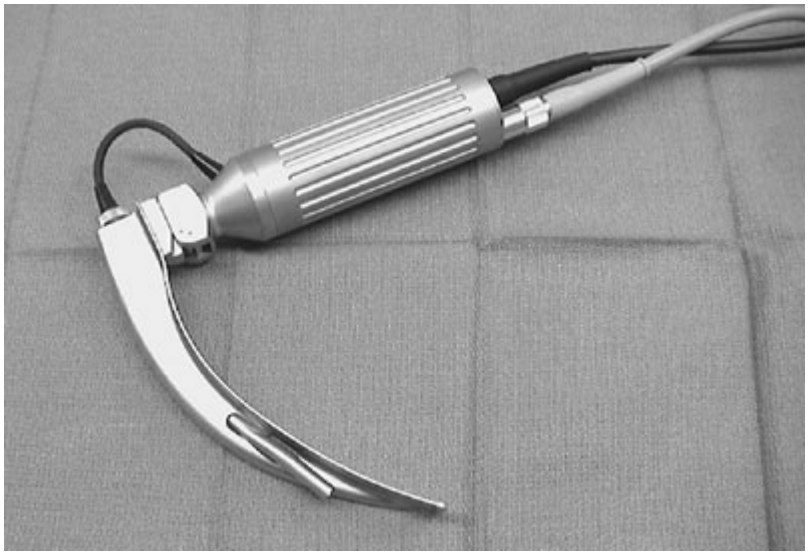

FIGURE 22-39. The Video Macintosh (Karl Storz Endoscopy, Culver City, CA).

Case 2: Retrograde Wire Intubation

A 65-year-old female with a 60-pack/year history of smoking and advanced rheumatoid arthritis presents to the emergency department (ED) in respiratory distress. Her oxygen saturation with a nonrebreather oxygen mask is 85%. She has a limited oral aperture (~2.5 cm) and a thyromental distance of 6 cm. Although the cricothyroid membrane can be palpated, there is limited access to it and the tracheal rings owing to a significant cervical kyphosis. The sputum is noted to be blood-tinged and contains thickened bronchial secretions. Awake blind nasal intubation is attempted twice by the emergency medicine physicians, is unsuccessful, and results in epistaxis. Retrograde intubation of the airway is performed with the patient in a sitting position. After initial local anesthetic infiltration of the skin over the membrane, on 18 G angiocatheter is advanced over the mid-cricothyroid membrane at an angle of 45° to the chest. After the free aspiration of air is noted, the Teflon sheath of the catheter is advanced into the trachea. A 0.035-inch radiologic guidewire 110 inches in length is advanced via the catheter until the proximal end emerges from the mouth. A 7.0 ETT is placed over the wire and is guided into the trachea. The wire is removed by pushing it into the percutaneous puncture site and retrieving it from the proximal end of the tracheal tube. Breath sounds are auscultated over the lung fields as ventilation is assisted with positive pressure. Once improved oxygen saturation is noted, the patient receives sedation with intravenous midazolam (in divided doses, titrating to the sedative effect).

Use of the Retrograde Wire Intubation in Airway Management. Retrograde wire intubation (RWI) involves the antegrade pulling or guiding of an ETT into the trachea using a wire or catheter, which has been passed into the trachea via a percutaneous puncture through the cricothyroid membrane or the cricotracheal membrane and blindly passed retrograde into the larynx, hypopharynx, pharynx and out of the mouth or nose. Retrograde intubation was first described in 1960 by Butler and Cirillo, with the placement a red rubber urethral catheter via a previous tracheostomy up through the larynx and out of the mouth.[199] The percutaneous technique used today was first described by Waters in 1963, using an epidural catheter.[200] In 1993 the technique was included in the ASA's Difficult Airway Algorithm.[157] The basic equipment used in the retrograde intubation technique is listed in Table 22-23.

TABLE 22-23 Equipment for Retrograde Wire Intubation

18 G or larger angiocatheter
Luer-lock syringe, 3 mL or larger
Guidewire:

- Preferably J-type end
- Length: at least 2.5 times the length of a standard ETT (typically 110 to 120 cm)
- Diameter: capable of passing via angiocatheter being chosen

Other: Scalpel blade, nerve hook, Magill forceps, 30″″ silk suture, epidural catheter

16 Retrograde wire intubation has been described in a number of clinical situations as a primary intubation technique (elective or urgent) and after failed attempts at direct laryngoscopy, fiberoptic-aided intubation, and LMA-guided intubation.[201] The most common indications are inability to visualize the vocal folds owing to blood, secretions, or anatomic variations; unstable cervical spine, upper airway malignancy; and mandibular fracture. Contraindications include lack of access to the cricothyroid membrane or the cricotracheal ligament

(because of severe neck deformity, obesity, mass), laryngotracheal disease (stenosis, malignancy, infection), coagulopathy, and skin infection.

The anatomic relationships to be considered in RWI have been described elsewhere in this chapter. Typically, the procedure requires 5 minutes to perform.[202] Because most clinicians are not facile with the technique, it may take several minutes in inexperienced hands; therefore, RWI is relatively contraindicated in the hypoxic patient. RWI has been used in elective and emergent situations, in adults and infants, in the operating room, ED, and the prehospital environment. Complications reported with RWI are listed in Table 22-24.

TABLE 22-24 Complications Associated with Retrograde Wire Intubation[201]

Bleeding (11)
Subcutaneous emphysema (4)
Pneumomediastinum (1)
Breath-holding (1)
Catheter traveling caudad (2)
Trigeminal nerve trauma (1)
Pneumothorax (1)

In the current patient (as in Case 1), RWI was chosen in a setting where the patient was not apneic and was therefore supporting her own ventilation and oxygenation, albeit poorly. The two cases differ in impending respiratory failure (Case 2) versus FOB-aided intubation undertaken in an stable situation (Case 1). In many situations, where awake intubation is an obvious initial approach to securing the airway, there is little time for patient preparation (e.g., the

administration of antisialagogues, topical anesthetics, and/or sedation). In this regard, RWI does not require a clear visual field or significant patient cooperation and can often be performed with little analgesia of the airway. The technique of RWI differs greatly from other methods of tracheal intubation familiar to the anesthesiologist. Preferably RWI should be learned on a simulator/mannequin model before being attempted in a patient. In addition, unless RWI is practiced often, it may be time-consuming. For this reason, RWI may be a poor choice for rescue of an acutely compromised airway.

Performing Retrograde Wire Intubation (Fig. 22-40). RWI is generally performed with the patient in a supine position, although the sitting position is often used for patients in respiratory distress. Extension of the head or the neck displaces the cricoid and tracheal cartilages anteriorly and displaces the sternocleidomastoid muscles laterally, though, as in Case 2, this may not always be possible. The skin should be prepared. If the patient is conscious, a local anesthetic skin wheel is made over the puncture site. Local anesthesia of the airway should be administered to prevent discomfort and airway reflexes as time permits. In general, topical anesthesia of the trachea, larynx, pharynx, and nasal passages is desirable. Translaryngeal anesthesia is a particularly convenient technique since a percutaneous entry of the trachea is required during the RWI. Structures above and below the vocal folds are anesthetized during the ensuing patient cough if a local anesthetic–filled syringe is used to facilitate the recognition of appropriate placement

(with tracheal air bubbles) and then is injected to provide airway anesthesia (see Fig. 22-29B).[203]

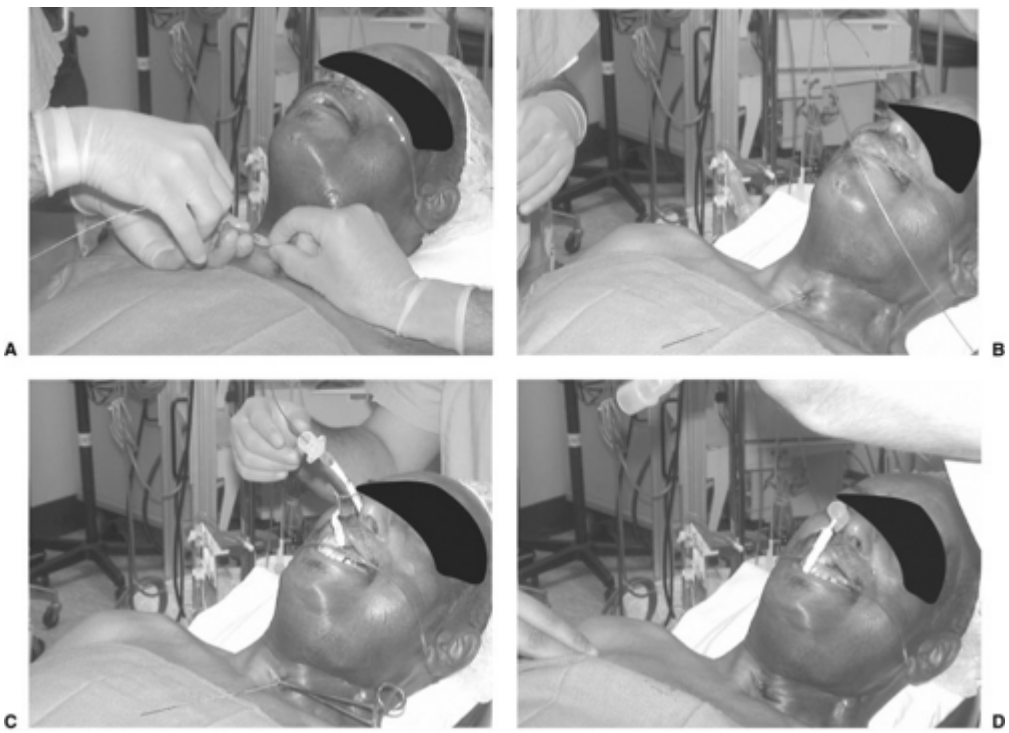

FIGURE 22-40. The sequence of retrograde wire intubation after the cricothyroid or cricotracheal ligament is identified and a percutaneous puncture is performed with air aspiration (see Fig. 22-29B). **(A)** The retrograde device (twisted wire, Cook Critical Care) is advanced until **(B)** it emerges from the mouth or nose. **(C)** The wire is clamped at the entrance site and the endotracheal tube is advanced over the wire in an antegrade fashion. **(D)** The wire is removed, leaving the tracheal tube in place.

As noted earlier, the CTM and CTL are both potential sites for translaryngeal puncture. Although the CTM has the advantage of being directly anterior to the large posterior surface of the cricoid cartilage, thereby protecting the esophagus from a puncturing needle, it places the needle in close proximity (0.9 to 1.5 cm) to the vocal folds and hence allows for a somewhat smaller margin of

error at the time of the intubation.

Although classically performed with a Tuohy needle and epidural catheter, the advent of smaller diameter, stiffer wires with atraumatic "J" tips has made the guidewire modification popular. These guidewires are typically 0.032 to 0.038 inches in diameter, being able to pass through an 18-G intravenous catheter. The typical length is between 110 and 120 cm. The only requirement for length is that the wire be more than twice as long as the tracheal tube to be used, so that no matter where in its course along the wire the tracheal tube should be, both ends of the wire are always accessible to the operator. Kits that conveniently incorporate all the necessary equipment are available (Cook Critical Care, Bloomington, IN).

The needle/catheter approaches the trachea at 90° to the coronal and sagittal planes if possible (as it was not in Case 2). In this orientation, the needle is likely to impact the posterior aspect of the cricoid cartilage if advanced too far, and not puncture the esophagus. Additionally, this angle will help to avoid trauma to the near-lying vocal folds.

After the percutaneous puncture is made and the trachea identified by free air aspiration, the catheter is angled cephalad and the wire is advanced (J-tip) into the trachea until it emerges from the mouth or nose. The wire may need to be retrieved from the mouth with a "sweeping" finger, Magill forceps, or nerve hook. Any obstruction to advancement of the wire should prompt re-evaluation of the angle of the catheter

and the position of the head and neck (e.g., catheter directed posterior and/or caudad, neck flexed). Coughing typically heralds caudad traveling of the wire. If the wire is retracted and found to be bent, it is prudent to procure a new one. When complaints of pain are encountered above the level of the larynx, it is typically a result of the wire passing into an inadequately prepared nasal cavity. Options include retracting the wire modestly and asking the patient to open the mouth and maximally protrude the tongue during the readvancement, reaching into the oropharynx to retrieve the wire, or patiently repreparing the nasal passages. Once the wire is satisfactorily retrieved, placement of the tracheal tube may be performed using the wire in a number of fashions, depending on the operator's preference and previous experience. Table 22-25 lists common techniques, together with their advantages and disadvantages. Details of these techniques have been described elsewhere.[204]

TABLE 22-25 Techniques of ETT Advancement Over a Retrograde Wire

·TECHNIQUE	·ADVANTAGE	·DISADVANTAGE
Wire travels through entire main lumen of the ETT	Standard technique	Margin of error[a] equals distance from vocal folds to puncture site No stylet after removal of wire "Railroading"[b] can occur
Wire placed into ETT lumen via Murphy eye	Increased margin of error	Cannot use stylet (below)
	Decreased railroading	
Wire enters distal end of ETT and exits via Murphy eye	Decreased railroading	Margin of error equals distance from vocal folds to puncture site

		Cannot use stylet (below)
ETT "exchange" stylet is placed over wire, prior to placement of ETT	Decreased railroading	Cost
	Can use stylet to vastly increase margin of error once wire is removed	
Fiberoptic bronchoscope is placed over wire prior to placement of ETT	Decreased railroading	Cost
	Can use stylet to vastly increase margin of error once wire is removed	
	Visualization	
Silk suture	No railroading	May be difficult to place silk suture
	Margin of error issues reduced	
Small ETT	Reduced railroading	May not be clinically adequate
[a]*Margin of error* refers to the distance below the vocal folds that the endotracheal tube extends at the time that the guidewire is removed. If this distance is not adequate, there is a risk of immediate extubation.		
[b]*Railroading* refers to the differential size of the guidewire and the tracheal tube. A large discrepancy in size allows for a cleft, which may entrap the epiglottis, arytenoid cartilages, aryepiglottic folds, or vocal folds, hindering intubation attempts.		

In the case reported, other techniques may have been considered. Although indirect visual devices (flexible fiberoptic bronchoscope, rigid fiberoptic laryngoscope) may have also been helpful in this case, three elements worked against their use: (1) tissue trauma from repeated attempts at blind nasal intubation produced a bloody airway, frustrating the use of these devices; (2) the patient was unable to cooperate owing to her respiratory distress; (3) because of the impending respiratory failure, there was little time for adequate airway analgesia. A coughing, gagging, conscious patient makes fiberoptic techniques nearly impossible. Straining and coughing during fiberoptic intubation attempts have resulted in Mallory-Weiss tears of the esophagus, resulting in significant hemorrhage.

Blind nasal intubation was the first technique attempted in this patient. Until recently, blind nasal intubation has been a staple of airway control, especially in the emergency department, where it has been largely supplanted by rapid-sequence intubation.[205] This technique requires significant analgesia of the nasal passages in the awake patient. Success is far more likely in the

spontaneously breathing patient. With the head in the Magill position, the ETT is advanced into the nares, nasal passage (keeping the ETT bevel alongside the nasal septum), and into the pharynx. Breath sounds are auscultated from the ETT, and its position adjusted to keep them maximized. The patient's head and larynx can be manipulated externally as necessary.

Case 3: Esophageal Tracheal Combitube

A 55-year-old male with a history of cirrhosis and esophageal varices requires airway control as a result of acute, recurrent upper gastrointestinal bleeding. Apart from fresh blood in the airway, physical exam of his external airway is consistent with a routine laryngoscopy. Furthermore, he had been intubated for similar events in the past. After a rapid-sequence induction, the larynx cannot be visualized on three laryngoscopies owing to fresh blood emanating from the esophagus. On all three attempts, the ETT is advanced blindly, and the absence of breath sounds over the thorax together with the presence of copious blood in the ETT leads to the diagnosis of esophageal intubation. A large adult-sized esophageal tracheal Combitube (Tyco Healthcare, Mansfield, NY) is requested, blindly inserted into the airway, and the pharyngeal and distal cuffs are inflated. Ventilation through the pharyngeal perforations lumen (blue) produces bilateral breath sounds to auscultation, and the oxygen saturation increases to >90%. Copious blood is suctioned from the esophageal lumen. The patient is transported to the angiography suite where his esophageal varices are embolized. The esophageal tracheal Combitube is removed and the patient is intubated with direct laryngoscopy.

History of the Tracheal Esophageal Combitube. The tracheal esophageal Combitube was developed from the concept of the esophageal obturator (ESO) airway, which was introduced in 1968.[206] The ESO consisted of a tracheal-like tube,

34 cm in length, with an inflatable cuff at its sealed, distal end. It was inserted blindly into the esophagus, so that the cuff lay at a level caudad and posterior to the tracheal carina. Sixteen holes communicating with the central lumen were positioned so as to be in the hypopharynx when inserted to the proper depth. A facemask at the proximal end was used to "seal" the airway. Ventilation was achieved by applying positive pressure to the proximal open aperture, where it emerged from the facemask. Unfortunately, significant problems/complications became apparent as the ESO came into common practice.

These shortcomings of the ESO were addressed by Dr. Michael Frass, a critical care physician in Vienna, Austria, in 1986.[207] The facemask of the ESO was replaced by an oropharyngeal balloon, sealing the upper airway and anchoring the device against the hard palate. As with the ESO, perforations at the hypopharyngeal level allowed egress of air near the level of the larynx. A second lumen, patent from proximal to distal end, without perforations was substituted for the blind esophageal tube of the ESO. As with the ESO, a cuff at the distal aspect of the esophageal lumen occludes the esophagus. This design, named the Tracheal Esophageal Combitube, is functional if introduced into the esophagus (ventilation being achieved through the esophageal lumen, via the hypopharyngeal perforations) or in the trachea (ventilation being achieved through the tracheal lumen, via the distal aperture). In either case, the proximal balloon seals both the oral and nasal passages, and the distal conventional tracheal tube cuff isolates the respiratory system from the gastrointestinal system. The device is available in two sizes: the 41Fr size is used for larger adults (height >5.5 feet) and the 37Fr size is used for adults 4 to 6 feet tall (Fig. 22-41). Though a single-use device, Combitube reprocessing and reuse has been reported.[208]

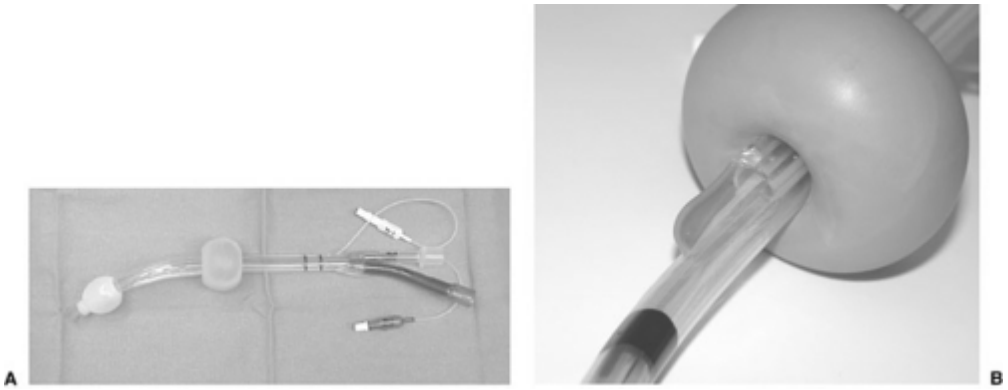

FIGURE 22-41. A. The esophageal tracheal Combitube. **B.** The fiberoptic port of the Easy Tube.

Use of the Esophageal Tracheal Combitube. The esophageal tracheal Combitube is inserted "blindly." The operator lifts the lower jaw and tongue anteriorly with one hand, and the esophageal tracheal Combitube is inserted with a downward, caudad-curved motion until the proximal depth indicator (two black rings printed on the double lumen tube) come to rest at the level of the teeth. The oropharyngeal balloon is inflated with 100 mL of air through a blue plastic pilot balloon (85 mL in the small adult size) while the distal cuff is inflated with 5 to 15 mL (via a white pilot balloon). An ambu bag or anesthesia circuit is attached to the proximal end of the esophageal lumen (constructed of blue polyvinyl chloride), and ventilation is confirmed by auscultation or other means. Because 90% of esophageal tracheal Combitube placements result in an esophageal position, ventilation occurs via this lumen's hypopharyngeal perforations. If no breath sounds are auscultated and/or gastric inflation is noted, the esophageal tracheal Combitube has been positioned in the trachea. Without repositioning, ventilation is changed to the distal end of tracheal lumen (clear polyvinyl chloride). If no maneuver improves ventilation, the device is most likely in the esophagus, but has been advanced too deeply, with the oropharyngeal cuff obstructing the airway.[209] In this case, the cuffs should be deflated, the device withdrawn 2 cm, and the ventilation sequence repeated.

Advantages of the esophageal tracheal Combitube include rapid airway control, airway protection from regurgitation, ease of use by the inexperienced operator, no requirement to visualize the larynx, and being able to maintain the neck in a neutral position, though cervical spine movement may be greater than that seen with the LMA, LMA-Fastrach, and flexible fiberscope.[210] It has been shown to be useful in the patient with massive upper gastrointestinal bleeding or vomiting, and as a rescue device in failed rapid-sequence induction or unanticipated difficult intubation. It is also useful in the morbidly obese, in acute bronchospasm, during cardiopulmonary resuscitation, and for prolonged ventilation after airway rescue.[129,163,164,165,166,167,168,169,170,171,172,173,174,211,212,213,214,215,216,217] Several series have demonstrated the effectiveness esophageal tracheal Combitube in prehospital management of the airway.[218,219,220] Urtubia et al have used the esophageal tracheal Combitube for elective surgery with a high success and low complication rate.[221]

Techniques for exchange of the esophageal tracheal Combitube (after patient stabilization) for an endotracheal tube have been described.[222]

Contraindications to use of the esophageal tracheal Combitube use include esophageal obstruction or other abnormality, ingestion of caustic agents, upper airway foreign body or mass, lower airway obstruction, height less than 4 feet, and an intact gag reflex. Since the esophageal tracheal

Combitube includes latex in its construction, it should not be used in patients with latex allergy.

Complications associated with the esophageal tracheal Combitube have included lacerations to the pyriform sinus and esophageal wall resulting in subcutaneous emphysema, pneumomediastinum, pneumoperitoneum, and esophageal rupture.[223,224,225]

A device similar to the esophageal tracheal Combitube has been available in many parts of the world since 2003.[226] The Easy Tube (EzT) (Rusch International, Kernen, German) is distributed in two sizes, 41ch for patients above 130 cm in height and 28ch for patients 90 to 130 cm in height. Unlike the Combitube, the distal lumen of the EzT is designed to resemble an ETT (including a Murphy eye). The pharyngeal aperture is designed to allow easy passage of a fiberscope (or suction catheter) (Fig. 22-41B). The EzT was designed for routine anesthetics as well as emergency and cannot intubate/cannot ventilate situations. Contraindications to EzT use are identical to those for the Combitube. Though it may be inserted blindly, it is designed to be used with a laryngoscope (much like a standard ETT). Unlike the Combitube, it is latex free.

Case 4: Failed Rapid-Sequence Induction and the LMA

A 39-year-old male presents for elective uvulopharyngopalatoplasty. He has no previous surgical history. His maximal incisor gap is 5 cm, thyromental distance is 7 cm, and his oropharyngeal view is a Samsoon–Young Class 2. There is no limitation in head and neck flexion and extension. During a sleep apnea study, he had 15 apneic events each hour. The patient has a significant history of gastroesophageal reflux, and rapid-sequence induction is planned. After the administration of pentothal, succinylcholine, and cricoid pressure (Sellick maneuver), direct laryngoscopy with a Macintosh number 3 laryngoscope blade reveals a large epiglottis obscuring the view of the vocal folds (Cormack–Lehane Grade 3).[125] Significant hyperplasia of the base of the tongue, which prevents its full displacement, is also noted. The BURP maneuver does not improve the view.[122] A Macintosh 4 and Miller 3 blades are used and do not improve the view. Oxygen saturation, which was 100% prior to induction, is now 92%, and facemask ventilation is initiated with the Sellick maneuver in place. Complete obstruction to ventilation is encountered, despite chin and/or jaw lift, two-person ventilation, and a reduction in the degree of cricoid pressure. The oxygen saturation falls to 85% and a size 5 LMA (which had been prepared prior to the induction of anesthesia) is inserted with the technique as described by the inventor. Immediately, a clear airway is established, and the Sellick pressure remains in place. A second dose of pentothal is administered, and the patient is intubated by the blind passage of a 7.0-id ETT via the LMA. The LMA is then removed using a Cook airway exchange catheter (Cook Critical Care, Bloomington, IN) as a stylet, and the surgical case proceeds.

The LMA in the Failed Airway. One clear advantage of LMA use is in the failed airway. There have been many reported (and unreported) cases of failed intubation and failure to ventilate by facemask in which the airway was rescued with an LMA.[227,228] Parmet et al estimate that 1:800,000 failed airway patients cannot be managed with an LMA, providing an 80-fold increase in margin of safety over the oft-noted 1:10,000 patients who cannot be ventilated by mask nor intubated by traditional means.[162] Likewise, a wealth of literature describes the use of the LMA in elective difficult airway management in awake and unconscious patients, in anticipated and unanticipated situations, in cervical spine injury, and in pediatric dysmorphic syndromes.[103,104,162,229,230] The characteristics of the LMA that underlie its superiority as a tool in the difficult airway armamentarium are that it is well tolerated by the patient, simulating the natural distension of the hypopharyngeal tissues by food, and that its insertion follows an intrinsic pathway, requiring no tissue distortion (as with laryngoscopy), which may not be possible in all patients. Finally, it is a blind technique not hindered by blood, secretions, debris, and edema from previous attempts at laryngoscopy.[229] Because the LMA's ease of insertion is not dependent on anatomy that can be assessed on routine physical exam, typical airway assessment measures do not apply to its application.[230] The major disadvantage of the LMA in resuscitation is the lack of mechanical protection from regurgitation and aspiration. Lower rates of regurgitation during CPR (3.5%) than with the bag-valve mask ventilation (12.4%) have been shown.[52,231,232,233] Even in the face of regurgitation, pulmonary aspiration is a rare event with the LMA.[234] Unfortunately, the

use of the Sellick maneuver may prevent proper seating of the LMA in a minority of instances.[235,236,237] This may require the brief removal of the cricoid pressure until the LMA has been properly seated. Cricoid pressure is effective with an LMA in situ. Had it been available, the Fastrack-LMA would also have been an ideal device in this case scenario.

Case 5: Deviation from the Difficult Airway Algorithm

Thirteen hours after admission to the intensive care unit, a 76-year-old female who had sustained trauma to the face, head, and neck in a motor vehicle accident is noted to have progressive decline in her level of consciousness and respiratory effort. On examination, there appears to be an adequate interincisor gap and thyromental distance. The oropharyngeal view and range of motion of the head and neck cannot be evaluated. Owing to the inability to fully evaluate the airway with respect to ease of intubation, an awake procedure is chosen. Fiberoptic devices are not considered usable because of the presence of fresh and clotted blood in the mouth as a result of continued epistaxis. Other airway techniques that require significant patient preparation are not considered because of the rapid progression of the patient's respiratory failure. Additionally, the presence of fresh blood in the oral and pharyngeal cavities will hinder adequate drying and analgesia. Blind nasal intubation is considered contraindicated based upon the obvious facial trauma and the risk of cribriform plate disruption. Neither equipment for retrograde intubation nor the tracheal esophageal Combitube is readily available. A lighted stylet intubation guide is available, but no clinician present is experienced with this technique. Although the mental status change is believed to reflect an intracranial process (e.g., intracranial hypertension), the risk of complete loss of the airway is judged to be the primary clinical hazard. Awake direct laryngoscopy is attempted with manual in-line stabilization of the neck. After clearing fresh blood from the pharynx with a Yankauer suction catheter, a Cormack–Lehane Grade 3 laryngeal view is obtained; but because of patient resistance (biting on the laryngoscope and movement), tracheal intubation is not achieved. The decision is made to proceed with rapid-sequence induction and intubation, with preparations made for an emergency tracheostomy. After surgical preparation of the neck and preoxygenation, intravenous succinylcholine and etomidate are administered, direct laryngoscopy is undertaken, the larynx is easily visualized, and the trachea is intubated.

Muscle Relaxants and Direct Laryngoscopy. In the case described, the use of muscle relaxants significantly improved the ability to visualize the larynx.[238,239,240] In a recent study, the use of muscle relaxants during a direct laryngoscopy increased the success rate of intubation and was associated with fewer incidents of airway trauma, intubation attempts, esophageal intubations, aspiration, and even death.[241] Intubating conditions with and without muscle relaxation have been investigated in few well-controlled trials because the superior intubating conditions achieved with muscle relaxants has discouraged inclusion of control groups.[242] The effects of muscle relaxation actions that improve laryngoscopic view include allowing complete temporomandibular joint relaxation and opening, anterior movement of the epiglottis, and widening of the laryngeal vestibule and laryngeal sinus.[243,244] In addition, the finding that laryngoscopic stimulation of the pharyngeal

musculature causes the upper airway lumen to appear small is offset by the use of relaxants.

Leaving the Algorithm. The situation described in Case 5 is unusual in that rapid-sequence induction was attempted because the clinical situation had deviated from the ASA Difficult Airway Algorithm owing to the progressive nature of the airway compromise. The situation was more akin to the "crash" airway described by Walls et al.[205] In this case, the institution of muscle relaxation, which might be considered contraindicated in the apparently difficult-to-intubate patient, allowed for full visualization of the larynx. Knowing that failure to intubate in this case would result in probable loss of the airway, the clinician was prepared for cricothyroidotomy. Although the ASA's Difficult Airway Algorithm is a valuable tool in the process of approaching the difficult airway, the clinician must always be prepared for the case that does not fit the mold. As stated earlier, adaptability in a rapidly changing clinical situation is critical to the success of airway management. Also of interest in this case was the availability of a lighted stylet for use in similar difficult airway scenarios. Although this device may have been useful in the current case, no

clinician present was familiar with its operation. A critical situation is not an occasion for trying an unfamiliar technology.

Other Devices

An ever-increasing number of airway management devices are commercially available. Although encyclopedic coverage of these tools is beyond the scope of this chapter, a review of the more established equipment follows.

Lighted Stylets

These devices rely on transillumination of the airway. A light source introduced into the trachea will produce a well-circumscribed glow of the tissues over the larynx and trachea. The same light placed in the esophagus will produce no or a diffuse light. A number of devices have become available, including disposable, partly disposable, and fully reusable systems. Although there are many reports of successful intubation using these devices, some common problems have been noted: In general, the operating theater lights must be dimmed to best appreciate the circumscribed glow; a stylet tip successfully placed in the trachea, but not pointing in an anterior direction, may give a false-negative impression; it is often difficult to remove the semirigid stylet from the ETT after intubation.

Airway Bougie

These encompass a series of solid or hollow, semimalleable stylets that may be blindly manipulated in to the trachea. An ETT is then "threaded" over the bougie and into the trachea. These bougies are generally low in cost and highly portable. The Eschmann introducer (Eschmann Health Care, Kent, England) was introduced in 1949. It is 60 cm long, 15Fr-gauge, and angled 40 degrees 3.5 cm from its distal end (Fig. 22-42). It is constructed from a woven polyester base, which is malleable. It can be very helpful when the larynx cannot be visualized with laryngoscopy. The introducer (also known as the gum elastic bougie) can be manipulated under the epiglottis, its angled segment directed anteriorly toward the larynx. Once it has entered the larynx and trachea, a distinctive "clicking" feel is elicited as the tip passes over the cartilaginous structures. A similar device, the Frova Intubating Introducer (Cook Critical Care, Bloomington, IN), is a disposable device, with an optional "stiffening" stylet and a hollow bore. The internal lumen allows for the insufflation of oxygen, the detection of carbon dioxide, and the use of a self-inflating bulb to detect inadvertent esophageal placement.[245]
