When access to the airway from the mouth or nose fails or is unavailable (e.g., maxillofacial, pharyngeal, or laryngeal trauma, pathology, or deformity), emergency access via the extrathoracic trachea is a feasible route to the airway. The clinician must be familiar with these alternative techniques of oxygenation and ventilation. The decision to proceed with an invasive procedure can be difficult, and most clinicians will hesitate at potentially grave risk to the patient. One should consider becoming facile with at least one of these techniques in elective situations (such as transtracheal aspiration for airway analgesia or elective retrograde intubation or, consider, for example, assisting a surgical colleague on a tracheostomy). Although tracheostomy and cricothyroidotomy are beyond the scope of this chapter, percutaneous techniques will be considered.

Cricothyroidotomy, cricothyrotomy, coniotomy, and minitracheostomy are synonyms for establishing an air passage through the cricothyroid membrane. The anatomy of this structure and those surrounding it was discussed earlier in this chapter. Although cricothyrotomy is the procedure of choice in an emergency situation, it may also apply to an elective situation when there is limited access to the trachea (e.g., severe cervical kyphoscoliosis). Cricothyrotomy is contraindicated in neonates and children under 6 years of age, and in patients with laryngeal fractures.

Percutaneous Transtracheal Jet Ventilation

17 Percutaneous transtracheal jet ventilation (TTJV), as a form of cricothyroidotomy, is the most familiar to anesthesiologists.[246] The ASA Difficult Airway Algorithm lists transtracheal jet ventilation as an option in the cannot mask ventilate/cannot intubate situation. TTJV is a simple and relatively safe means to sustain the patient's life in this critical situation.[247] An intravenous catheter of 12-, 14-, or 16-gauge, attached to a 5-mL or larger empty or partially fluid-filled (saline or local anesthetic) syringe should be used to enter the airway. The patient is positioned supine, with the head midline or extended on the neck and thorax (if not contraindicated by the clinical situation). After aseptic preparation, local anesthetic is injected over the cricothyroid membrane (if the patient is awake and time permits). The right-handed clinician stands on the right side of the patient, facing the head. The clinician can use his or her nondominant hand to stabilize the larynx. The catheter-needle is advanced at right angles to all planes in the caudad third of the membrane. From the moment of skin puncture there should be constant aspiration on the syringe plunger. Free aspiration of

air confirms entrance into the trachea. Unless there is significant pulmonary fluid (e.g., blood, aspirated gastric contents, or water from drowning), the aspiration of tracheal air should be incontrovertible. The needle-catheter assembly should be advanced slightly, and subsequently the catheter advanced fully into the airway alone. Although this technique has been described with common angiocatheters, dedicated devices made of kink-resistant materials and with accessory ports are available (Fig. 22-43).

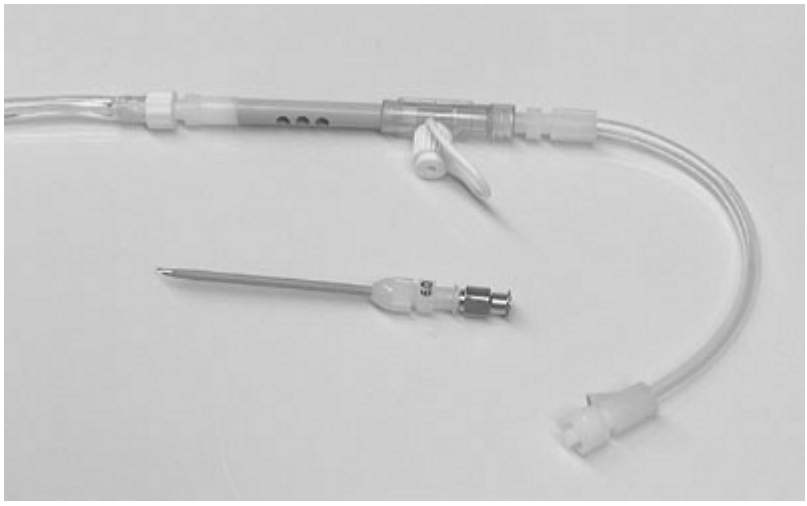

FIGURE 22-43. The Cook Critical Care transtracheal ventilation catheter and Enk Flow Modulator (Cook Critical Care, Bloomington, IN).

Once the catheter has been successfully placed in the airway, an oxygen source is attached. The clinician may have several options in this regard. If a high-pressure system is available—for example, a metered and adjustable oxygen source with a hand-controlled valve (Fig. 22-44) and a Luer-lock connector—25 to 30 psi of oxygen (central hospital supply or regulated cylinder) can be delivered directly through the catheter, with insufflations of 1 to 1.5 seconds at a rate of 12 insufflations per minute. If a 16-gauge catheter has been placed, this system will deliver a tidal volume of 400 to 700 mL. Low-pressure systems cannot provide enough flow to expand the chest adequately for oxygenation and ventilation (e.g., ambu bag: 6 psi, common gas outlet: 20 psi).

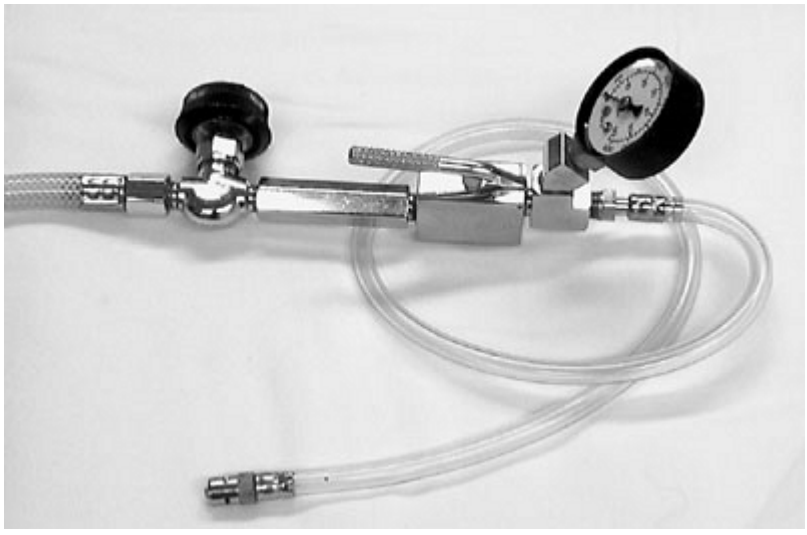

FIGURE 22-44. System for regulation of a high-pressure oxygen source for transtracheal jet ventilation.

Low-pressure oxygen flow meters can be used for TTJV. These systems are capable of delivering a brief (0.5 second) 30 psi burst pressure, which quickly decays to 5 psi or less.[248] If this oxygen source is to be used an I:E ratio of 1:1 with a rate of 30 to 60 breaths per minute should be used to assure adequate burst pressures.

The Muallem Jet Ventilator (Dr. Muallem Lebanon) automates respiratory cycles during jet ventilation. This device was developed primarily for use during bronchoscopy but could be applicable to TTJV.[249]

Specialized percutaneous cricothyroidotomy systems have been developed that improve the ease of this technique. These devices generally provide a large-bore access that is adequate for oxygenation and ventilation with low-pressure systems. The Melker emergency cricothyroidotomy catheter set (Cook Critical Care, Bloomington, IN) uses a Seldinger—catheter-over-a-wire—technique familiar to most anesthesia practitioners (Fig. 22-45). The set comes in a variety of cannula sizes (3.5-, 4-, and 6-mm internal diameter cuffed and uncuffed). Preparation and positioning of the patient are the same as with needle cricothyroidotomy. A 1- to 1.5-cm vertical incision of the skin only is made over the lower third of the cricothyroid membrane. Aiming 45° caudad, a percutaneous puncture of the subcutaneous tissue and cricothyroid membrane is made with the provided 18-gauge needle-catheter assembly and syringe. After air is aspirated, the catheter is advanced into the trachea. The provided guidewire is inserted through the catheter and into the trachea. The catheter is removed and the tracheal cannula, fitted internally with a curved dilator, is threaded onto the wire. The dilator is advanced through the membrane using firm pressure. Significant resistance to its advancement may indicate that the skin incision needs to be extended. Once the cannula-dilator has been fully inserted, the dilator and wire are removed. The 15-mm circuit adapter end of the cannula is now attached to an ambu bag or anesthesia circuit.

FIGURE 22-45. The Melker cricothyroidotomy cannula and curved dialator (Cook Critical Care, Bloomington, IN). The guidewire is not shown.

Other percutaneous systems include Nu-Trake (Weiss Emergency Airway System; International Medical Devices) and the QuickTrach® transtracheal catheter (VBM Medizintechnik GMBH). Nonneedle puncture techniques are beyond the current discussion.

CONCLUSION

Apart from monitoring, the management of the "routine" patient airway is the most common task of the anesthesiologist—even during the administration of regional anesthesia, the airway must be monitored and possibly supported. Unfortunately, routine tasks often become neglected tasks in terms of the care and vigilance that is afforded each event. But the consequences

of a lost airway are so devastating that the clinician can never afford a lackadaisical approach.

Although the ASA's Task Force on the Difficult Airway has given the medical community an immensely valuable tool in the approach to the patient with the difficult airway, the Task Force's

algorithm must be viewed as a starting point only. Judgment, experience, the clinical situation, and available resources all affect the appropriateness of the chosen pathway through, or divergence from, the algorithm. The clinician need not be expert in all the equipment and techniques currently available. Rather, a broad range of approaches should be mastered, so that the failure of one does not present a road block to success.

Similarly, the medical manufacturing community, and the far-sighted clinicians who supply it with concepts for airway management products, has supplied a vast array of devices. Many represent redundancy in concept, and each has its supporters and detractors. No one device can be considered superior to another when considered in isolation. It is the clinician and his or her resources (both equipment and personnel) and judgment that determine the effectiveness of any technique. In the management of the difficult airway, flexibility, and not rigidity, prevails.[250,251]

Chapter 23

Patient Positioning

Mark A. Warner

KEY POINTS

1	Sedated or anesthetized patients should not be placed in positions that are not comfortable while they are awake.
2	Elevated lower-extremity positions (e.g., lithotomy) may reduce perfusion pressure in the elevated extremities and increase the opportunity for developing compartment syndromes, especially when the extremities are elevated for prolonged periods.
3	Padding provided by any number of different materials (e.g., gel or foam pads, blankets) should be used to widely disperse point pressure on body parts or tissues.
4	Brachial plexus neuropathy associated with sternotomy in anesthetized patients undergoing cardiac procedures may mimic as peripheral ulnar neuropathy.
5	The etiology of ulnar neuropathy is not always clear. Most commonly it develops postoperatively in men 40 to 70 years of age who undergo abdominal or pelvic procedures. There are anatomic and neurophysiologic reasons for men compared to women to develop this problem.
6	Excessive flexion or extension of the spine in anesthetized patients who are placed in unique surgical positions may contribute to spinal cord ischemia and catastrophic neurologic damage.
7	Perioperative vision loss occurs most frequently in anesthetized patients undergoing cardiac surgical procedures. Patients undergoing extensive spine procedures while positioned prone also have a high frequency of vision loss, primarily from posterior ischemic optic neuropathy.
8	Neuropathies that result in motor function loss as well as sensory loss compared to those with isolated sensory loss generally are associated with more prolonged or permanent nerve dysfunction.

Positioning a patient for a surgical procedure is frequently a compromise between what the anesthetized patient can tolerate, both structurally and physiologically, and what the surgical team requires for access to their anatomic targets.[1,2] Physiologic instability resulting from disease or injury may be magnified by rapidly moving a seriously ill patient from bed to transport cart, through corridors and elevators, and onto the operating table. Induction of anesthesia and positioning may need to be delayed until that patient is hemodynamically stable, or establishment of the intended surgical posture may need to be modified to match the patient's tolerance. This chapter presents the physiologic significance of various positions in which a patient may be placed during an operation, briefly describes the techniques of establishing the positions, and discusses the potential complications of each posture.

It is very important for clinicians to understand the physiologic and potential pathologic consequences of patient positioning. Although considerable information is available on the physiologic effects of various positions, there is a paucity of information on the complications of positioning. Until recently, there have been few studies, either retrospective or prospective, that provided epidemiologic evidence of the frequency and natural history of many of the perioperative positioning complications. Why? In decades preceding the 1990s, catastrophic perioperative outcomes, such as death or hypoxic brain injury from either the delivery of inadequate oxygen or failure adequately to ventilate patients, were infrequent but potentially avoidable consequences of the delivery of anesthesia. The development of pulse oximetry and end-tidal respiratory monitoring in the 1980s, the subsequent acceptance of monitoring standards of care by the anesthesia community, the introduction of improved drugs, and improved physician education contributed to a dramatic decline in the frequency of these major events. Less catastrophic, yet still disabling, perioperative complications, such as those possibly related to positioning, consequently became a higher priority for study.

In the 1990s and more recently, a number of studies of large surgical populations provided new information on the frequency and natural history of rare perioperative events such as neuropathies and vision loss. These studies occasionally provided sufficient data to allow speculation on potential mechanisms of injury. Based on the findings of these studies, investigators are seeking to confirm mechanisms of injury and the efficacy of novel interventions to decrease the frequency of, or to prevent, these perioperative events. For now, however, the mechanism and even the onset of many potential positioning-related complications often are unknown.

The lack of solid scientific information on basic mechanisms of positioning-related complications often leads to medicolegal entanglements. Attempts to determine the etiology of complications alleged to be caused by patient positioning are often unconscionably biased. Notations on anesthesia and operating room records may be absent or uninformative. On some occasions, medicolegal conclusions have been shaped by assumptions and assertions made by people having no understanding of the case in question and no personal familiarity with proceedings in an operating room. Careful, but laconic, descriptive notations about positions used during anesthesia and surgery, as well as brief comments about special protective measures such as eye care and pressure-point padding, are useful information to include on the anesthesia record. In potentially complicated or contentious circumstances, a brief resume in the progress notes is advisable. Only in this manner can subsequent inquiries be properly answered on behalf of either the patient or the anesthesiologist. When credible, expanded knowledge that further delineates mechanisms of positioning-related complications is available, these issues and the care of patients will be improved.

DORSAL DECUBITUS POSITIONS

Physiology

Circulatory

In the horizontal supine position (Fig. 23-1A), the influence of gravity on the vascular system is minimal. Intravascular pressures from head to foot vary little from mean pressures at the level of

the heart; therefore, almost no perfusion gradient exists between the heart and arteries in either the head or the lower extremities. Similarly, venous gradients from the periphery to the right atrium consist principally of the cyclic intrathoracic pressure changes that occur with respiration.

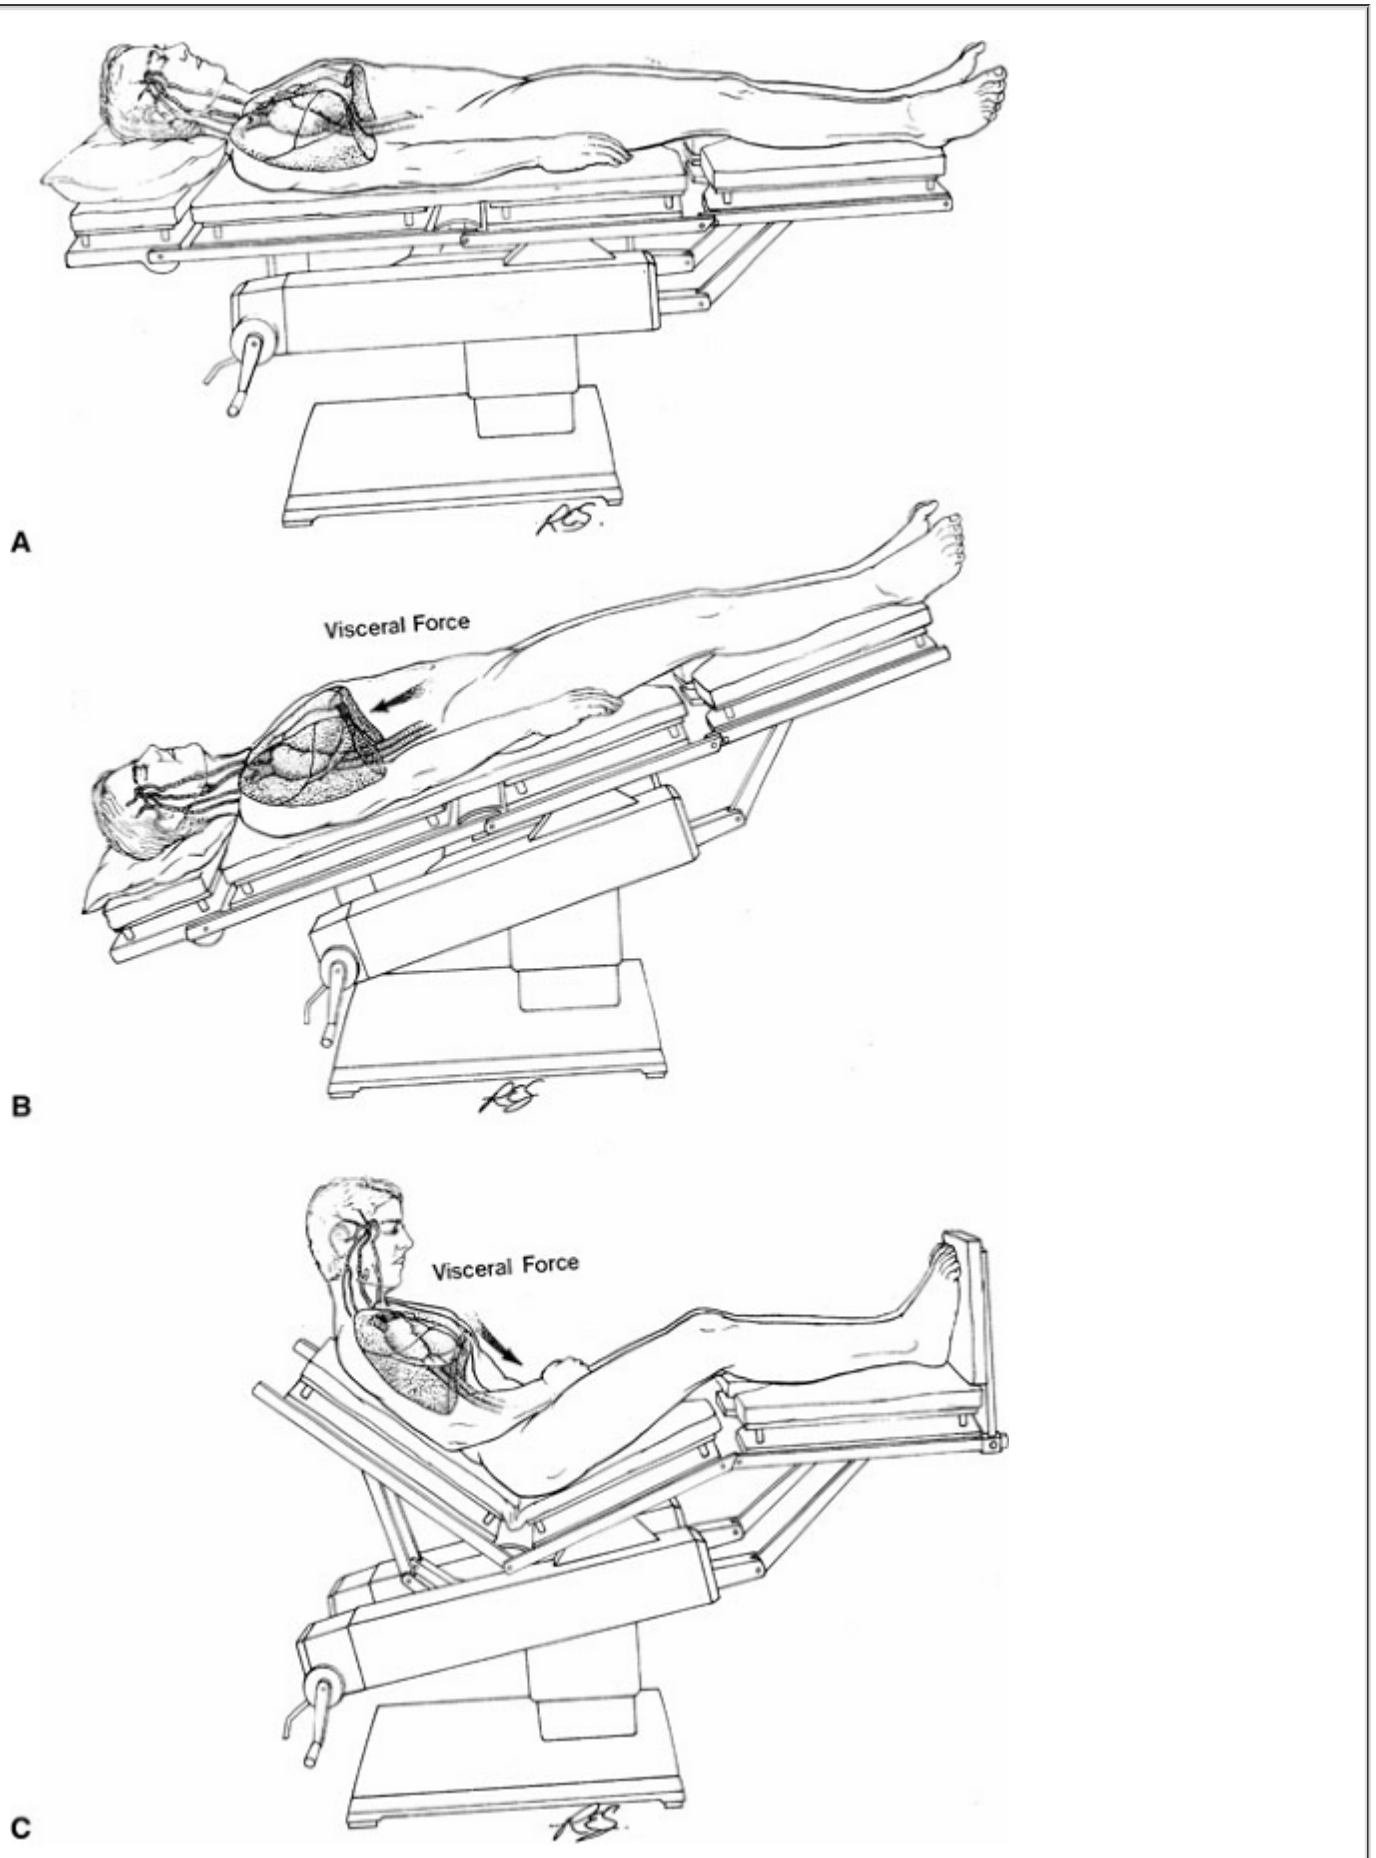

FIGURE 23-1. A. Supine adult with minimal gradients in the horizontal vascular axis.

Pulmonary blood volume is greatest dorsally. Viscera displace the dorsal diaphragm cephalad. Cerebral circulation is slightly above heart level if the head is on a small pillow. **B.** Head-down tilt aids blood return from lower extremities but encourages reflex vasodilation, congests vessels in the poorly ventilated lung apices, and increases intracranial blood volume. **C.** Elevation of the head shifts abdominal viscera away from the diaphragm and improves ventilation of the lung bases. According to the gradient above the heart, pressure in arteries of the head and neck decreases; pressure in accompanying veins may become subatmospheric.

If the patient in the dorsal decubitus position is tilted head high or head low, the effects of gravity on blood flow in the head or the feet can become quite significant as the gradient to or from the heart increases. Pressures have been shown to change by 2 mm Hg for each 2.5 cm that a given point varies in vertical height above or below the reference point at the heart.[3]

When the lower extremities are below the level of the heart, blood pools in distensible dependent vessels, causing a reduction in effective circulating volume, cardiac output, and systemic perfusion. If the head is high and blood pressure measured at the level of the heart is low, the blood pressure in the brain is decreased further according to the magnitude of the head elevation.

If the head is tilted down (Fig. 23-1B), pressure in the cerebral veins increases in proportion to the gradient upward to the heart. Many alert patients so positioned complain of a rapidly occurring, pounding vascular headache. Congestion develops in the nasal mucosa and conjunctivae. In the presence of an intracranial pathologic process, such as a head injury or a stroke, elevations of cerebral venous pressure resulting from head-down tilt can provoke or intensify cerebral edema and dangerously raise intracranial pressure. Head-down tilt also increases cerebrospinal fluid pressure in the cranial vault, adding its effect to the total intracranial pressure elevation. Finally, venous congestion and resultant edema may cause a “compartment syndrome” in areas within the head as vessels and nerves are squeezed as they traverse small bony spaces.

West et al[4] have identified three separate perfusion zones in the pulmonary circulation, based on the interrelationship among pressures in the alveoli, arterioles, and venules.

In zone 1, alveolar pressure exceeds either arterial or venous pressure and perfusion of the lung unit is prevented. Although it is rarely present in a normal lung, zone 1 can be produced by pulmonary hypotension, excessive positive end-expiratory pressure (PEEP), or overdistention of alveolar units from large tidal volumes during positive-pressure ventilation.

In zone 2, arterial pressure exceeds alveolar pressure, whereas alveolar pressure remains higher than venous pressure. This relationship is found in nondependent portions of the lung, and perfusion is the result of a fluctuating balance between arterial and alveolar pressures.

In zone 3, hydrostatic forces in the dependent portion of the lung produce venous congestion, and perfusion is determined by the difference between arterial pressure and venous pressure.

In the dorsal recumbent positions, the pulmonary circulation tends to be most congested along the dorsal body wall and least congested substernally. When the patient is tilted head high, zone 3 moves toward the lung bases as better ventilatory mechanics improve gas exchange. If the tilt is head down, zone 3 shifts cephalad into the poorly ventilated lung apices, and abnormal ventilation–perfusion ratios can be expected to intensify.

Respiratory

In the supine position, mobile abdominal viscera gravitate toward the dorsal body wall and press the dorsal parts of the diaphragm cephalad. The displacement lengthens muscle fibers in that portion of the diaphragm and increases the strength and effectiveness of its contractions during spontaneous ventilation. The benefit is improved aeration of the congested, compacted, and less

compliant lung bases. With head-up tilt (Fig. 23-1C), the visceral weight shifts away from the diaphragm and ventilation is enhanced. In the head-down position, the visceral mass, its weight potentially increased by the presence of abdominal fat, fluid, or tumors, can cause significant respiratory embarrassment by impeding caudad excursions of the contracting diaphragm and preventing adequate expansion of the lung bases.

In the supine position, gravity-induced vascular congestion forces the dorsal portions of the lung to function as a zone 3.[4] Consequently, the compliance of the area is reduced, and passive ventilation tends to distribute gas preferentially to more easily distensible substernal units where pulmonary blood volume is less. To prevent development of a clinically significant ventilation–perfusion imbalance during use of controlled ventilation, tidal volumes must be used that are greater than the average amount that is sufficient for the spontaneously breathing, conscious patient.[5]

Variations of the Dorsal Decubitus Position

Supine

Horizontal. In the traditional horizontal supine position (dubbed “lying at attention”), the patient lies on his or her back with a small pillow beneath the head (see Fig. 23-1A). The arms are either comfortably padded and restrained

alongside the trunk or abducted on well padded arm boards. Either arm (or both) may be extended ventrally and the flexed forearm secured to an elevated frame in such a way that perfusion of the hand is not compromised, no skin-to-metal contact exists to cause electrical burns if a cautery is used, and the brachial neurovascular bundle is neither stretched nor compressed at the axilla (see the left arm arrangement in Fig. 23-13). The lumbar spine may need padded support to prevent a postoperative backache (see Complications of the Dorsal Decubitus Positions section). Bony contact points at the occiput, elbows, and heels should be padded.

Although the horizontal supine posture has a long history of widespread use, it does not place hip and knee joints in neutral positions and is poorly tolerated for any length of time by an immobilized, awake patient.

Contoured. A contoured supine posture (Fig. 23-2C) has been termed the *lawn chair position*.[6] It is established by arranging the surface of the operating table so that the

trunk–thigh hinge is angulated approximately 15 degrees and the thigh–knee hinge is angulated a similar amount in the opposite direction. Alternatively, a rolled towel or blanket can be placed beneath the patient's knees to keep them flexed. The patient of average height then lies comfortably with hips and knees flexed gently. Quite often a person who has been required to lie motionless on a rigid horizontal table and then is changed to the contoured supine position offers an almost involuntary expression of relief and appreciation.

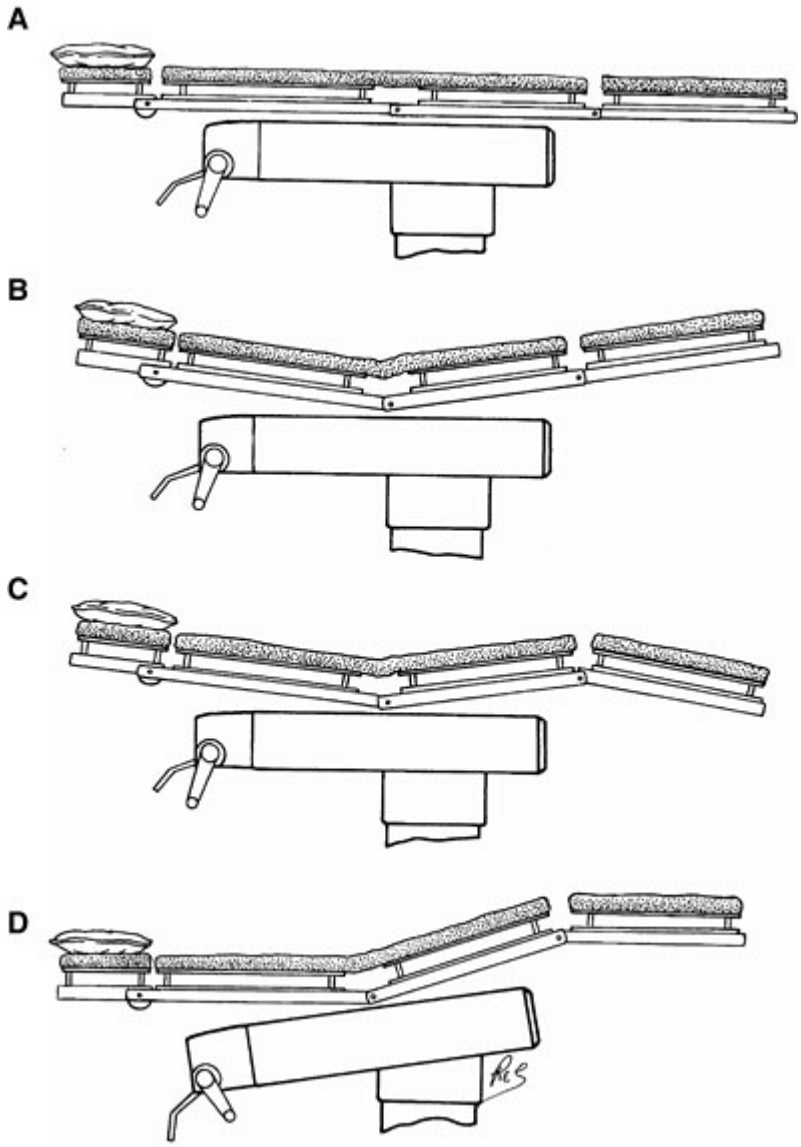

FIGURE 23-2. Establishment of the contoured supine (“lawn chair”) position. **A.** Traditional flat supine table top. **B.** Thighs flexed on trunk. **C.** Knees gently flexed in final body position. **D.** Trunk section leveled to stabilize floor-supported arm board. (Reproduced with permission from Figure 5-3 (p. 42) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

As in the horizontal supine position, the patient should have a pad or pillow beneath the occiput, elbows, and heels. Arms can be positioned as described for the horizontal supine posture.

Frog-Leg. On occasion, a surgeon may wish to have access to the perineum. Placing the patient supine with the knees bent and the soles of the feet together separates the thighs sufficiently to permit access to the perineum and vagina for the surgeon standing at the patient's flank. If the patient's skeleton is stiff, lateral spread of the knees may seriously stress the hips or stretch branches of the obturator nerves;[7] a pad of sufficient size should be used to support each knee (1) to minimize the opportunity for postoperative hip and back pain and (2) to prevent a dislocated hip or fracture of an osteoporotic femur during the operation.

Lateral Uterine or Abdominal Mass Displacement. With a patient in the supine position, a mobile abdominal mass, such as a very large tumor or a pregnant uterus, can rest on the great vessels of the abdomen and compromise circulation. This is known as the *aortocaval syndrome* or the *supine hypotensive syndrome.* A significant degree of perfusion can be restored if the compressive mass is rolled toward the left hemiabdomen by leftward tilt of the table top or by a

wedge under the right hip.[8]

Lithotomy

Standard. In the standard lithotomy position (Fig. 23-3), the patient lies supine with arms crossed on the trunk or with one or both arms extended laterally to less than 90 degrees on arm boards. Each lower extremity is flexed at the hip and knee, and both limbs are simultaneously elevated and separated so that the perineum becomes accessible to the surgeon. For many gynecologic and urologic procedures, the patient's thighs are flexed approximately 90 degrees on the trunk and the knees are bent sufficiently to maintain the lower legs nearly parallel to the floor. More acute flexion of the knees or hips can threaten to angulate and compress major vessels at either joint. In addition, hip flexion to greater than 90 degrees on the trunk has been shown to increase stretch of the inguinal ligaments.[7] Branches of the lateral femoral cutaneous nerves often pass directly through these ligaments and can be impinged and become ischemic within the stretched ligament.

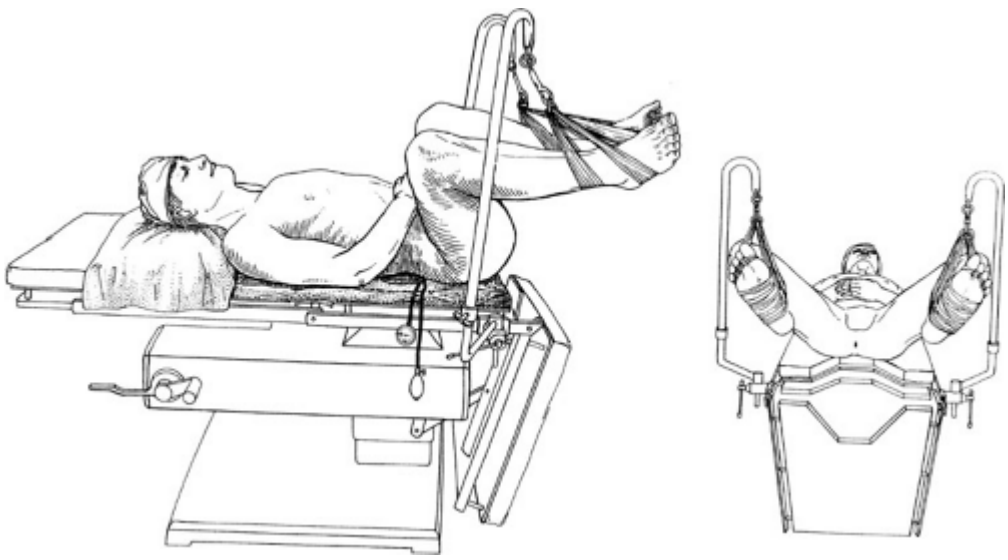

FIGURE 23-3. Standard lithotomy position with “candy cane” extremity support. Thighs are flexed approximately 90 degrees on abdomen; knees are flexed enough to bring lower legs grossly parallel to the torso section of the table top. Arms are retained on boards, crossed on the abdomen, or snugged at the sides of patient. (Modified with permission from Figures 6-5 and 6-14 of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Numerous devices are available to hold legs that are elevated during delivery or operation. Each should be fitted to the stature of the individual patient. Care should be taken to ensure that angulations or edges of the padded holder do not compress the popliteal space or the upper dorsal thigh. Compartment syndromes of one or both lower extremities have resulted from prolonged use of the lithotomy position with some types of support devices.[9]

When the legs are to be lowered to the original supine position at the end of the procedure, they should first be brought together at the knees and ankles in the sagittal plane and then lowered slowly together to the table top. This minimizes torsion stress on the lumbar spine that would occur if each leg were lowered independently. It also permits gradual accommodation to the increase in circulatory capacitance, thereby avoiding sudden hypotension.[10]

Low. For most urologic procedures and for many procedures that require simultaneous access to the abdomen and perineum, the degree of thigh elevation in the lithotomy position is only approximately 30 to 45 degrees (Fig. 23-4). This reduces perfusion gradients to and from the lower extremities and improves access to a perineal surgical site for members of the operating

team who may need to stand at the lateral aspect of either leg.

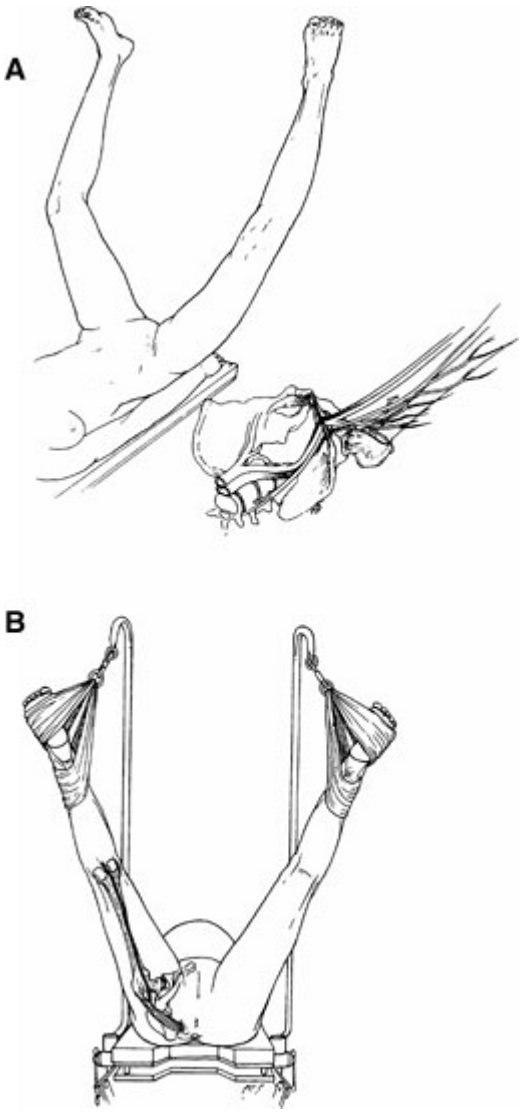

FIGURE 23-4. Low lithotomy position for perineal access, transurethral instrumentation, or combined abdominoperineal procedures. (Modified with permission from Figure 8-4, (p. 99) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

High. Some surgeons prefer to improve access to the perineum by suspending the patient's feet from high poles. The effect is to have the patient's legs almost fully extended on the thighs (Fig. 23-5) and the thighs flexed 90 degrees or more on the trunk. The posture produces a significant uphill gradient for arterial perfusion into the feet, requiring careful avoidance of systemic hypotension. Less mobile patients may tolerate this posture poorly because of angulation and compression of the contents of the femoral canal by the inguinal ligament (see Fig. 23-5A), or stretch of the sciatic nerve (see Fig. 23-5B), or both.

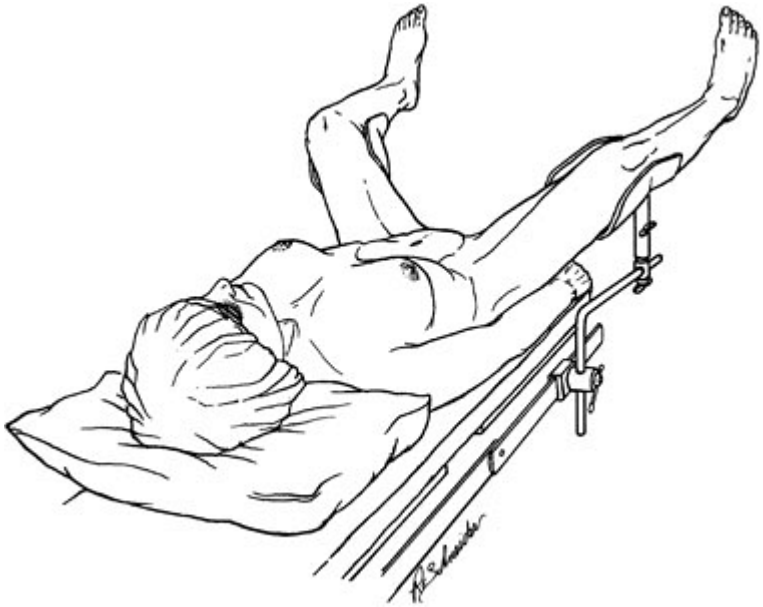

FIGURE 23-5. High lithotomy position. Note potential for angulation and compression/obstruction of contents of femoral canal **A**, *insert*) or stretch of sciatic nerve **(B).** (**A** reproduced with permission from McLeskey CH [ed]: Geriatric Anesthesiology. Baltimore, Williams & Wilkins, 1997. **B** reproduced with permission from Figure 6-11 and 6-12, (pp. 61 & 63) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

2 **Exaggerated.** Transperineal access to the retropubic area requires that the patient's pelvis be flexed ventrally on the spine, the thighs almost forcibly flexed on the trunk, and the lower legs aimed skyward so as to be out of the way (Fig. 23-6). The result places the long axis of the symphysis pubis almost parallel to the floor. This exaggerated lithotomy position stresses the lumbar spine, produces a significant uphill gradient for perfusion of the feet, and may restrict ventilation because of abdominal compression by bulky thighs. It can be tolerated under anesthesia but can rarely be assumed by an awake patient.

Control of ventilation is usually necessary. If painful lumbar spine disease exists, an alternative surgical position may need to be chosen beforehand to avoid severely accentuating the lumbar distress after surgery. This position has been associated with a very high frequency of lower extremity compartment syndrome.[11] Maintenance of adequate perfusion pressure in the legs is important.

FIGURE 23-6. The exaggerated lithotomy position. Shoulder braces, usually needed to stabilize the torso, are placed over the acromioclavicular area to minimize compression of the brachial plexus and adjacent vessels. (Reprinted with permission from Figure 6-7 (p. 54) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Tilted. Frequently, some degree of head-down tilt is added to one of the lithotomy positions. If the tilt is great enough, and particularly in the instance of the exaggerated lithotomy position, the patient may slide cephalad. Care must be taken to avoid this situation; there are several anecdotes from medicolegal actions involving patients who slid off operating tables with resulting head injuries.

Depending on the degree of head depression, the addition of tilt to the lithotomy position combines the worst features of both the lithotomy and the head-down postures. The weight of abdominal viscera on the diaphragm adds to whatever abdominal compression is produced by the flexed thighs of an obese patient or of one placed in an exaggerated lithotomy position. Ventilation should be assisted or controlled. Because elevation of the lower extremities above the heart produces an uphill perfusion gradient, systemic hypotension and compressive leg wrapping may limit perfusion to the periphery, a factor in the development of compartment syndromes in the legs of lithotomized patients.[9] This perfusion gradient often is unpredictable and exaggerated, potentially increasing the risk of compartment syndrome.[12,13]

Head-Down Tilt. Sometime during the mid 1800s, Bardenhauer, an innovative German surgeon in Cologne, began to elevate the hips of patients to gravitate the viscera cephalad and help expose lesions deep within the pelvis.[14] Others may have used the posture at about the same time. That unique maneuver, tilting a patient 30 to 45 degrees head down (Fig. 23-7), was adopted and popularized by Friedrich Trendelenburg of Bonn and Leipzig before 1870 (thus the often-used term “Trendelenburg position”). However, its publication apparently awaited an article by Meyer, an

American pupil of Trendelenburg, in 1885.[15]

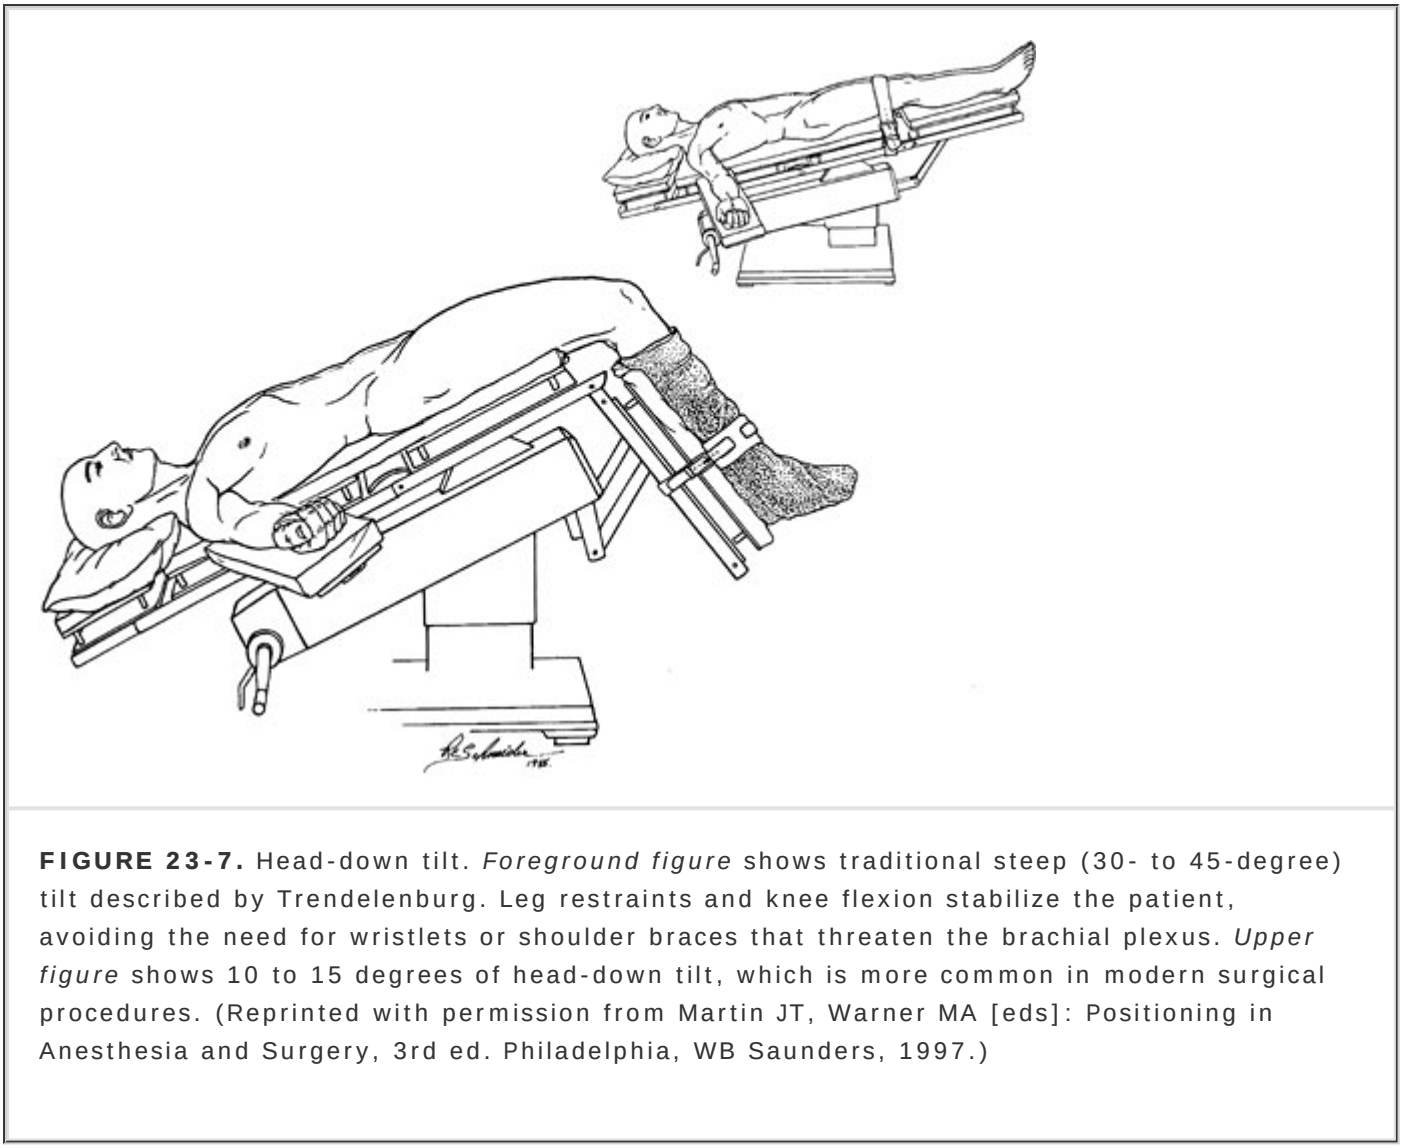

FIGURE 23-7. Head-down tilt. *Foreground figure* shows traditional steep (30- to 45-degree) tilt described by Trendelenburg. Leg restraints and knee flexion stabilize the patient, avoiding the need for wristlets or shoulder braces that threaten the brachial plexus. *Upper figure* shows 10 to 15 degrees of head-down tilt, which is more common in modern surgical procedures. (Reprinted with permission from Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Reich and associates,[16] studying well-instrumented, anesthetized patients, have compared circulatory variables in the level supine position with those recorded after 3 minutes of marked (60-degree) elevation of the lower extremities or after 3 minutes of 20 degrees of head-down tilt. They found that head-down tilt only minimally increased cardiac output and mean arterial pressure, whereas leg raising slightly increased

mean arterial pressure without affecting cardiac output. In each posture, there was evidence of deteriorating pulmonary function and right ventricular stress. They urged caution in the use of either maneuver in patients with pulmonary disease or right ventricular compromise.

Cephalad displacement of the diaphragm and obstruction of its caudad inspiratory stroke accompany a head-down position because of gravity-shifted abdominal viscera. Consequently, the work of spontaneous ventilation is increased for an anesthetized patient in a posture that already worsens the ventilation–perfusion ratio by gravitational accumulation of blood in the poorly ventilated lung apices. During controlled ventilation, higher inspiratory pressures are needed to expand the lung.

Intracranial vascular congestion and increased intracranial pressure can be expected to result from head-down tilt. For patients with known or suspected intracranial disease, the position should be used only in those rare instances in which a surgically useful alternate posture cannot be found. Maintenance of the position should then be as brief as possible, and the need for postoperative neurologic intensive care should be anticipated.

Steep head-down tilt positions (e.g., 30 to 45 degrees of head-down tilt) may require some means of preventing the patient from sliding cephalad out of position. The use of anklets and bent knees

is a satisfactory method of retaining the tilted patient in position (see Fig. 23-7) if the anklets are not excessively tight and if the flexed knee joints are placed sufficiently caudad of the leg–thigh hinge of the table top so that the adjacent firm edge of the depressed leg section of the table cannot indent either proximal calf. Should indentation occur, compressive ischemia and phlebitis or a compartment syndrome may result.

Historically, shoulder braces also have been used to prevent cephalad sliding in steep head-down tilt positions. These braces are best tolerated if placed over the acromioclavicular joints, but care must be taken to see that the shoulder is not forced sufficiently caudad to trap and compress the subclavian neurovascular bundle between the clavicle and the first rib. If the braces are placed medially against the root of the neck, they may easily compress neurovascular structures that emerge from the area of the scalene musculature. For these and other reasons, the use of shoulder braces has waned in popularity.

Complications of the Dorsal Decubitus Positions

Postural Hypotension

Depending on the resilience of the patient's vasocompensatory mechanisms, postural hypotension may be seen when a head-elevated position is being established. If mean arterial pressure at the circle of Willis remains within the range of cerebral blood flow autoregulation in a patient who is not hypertensive, the postural hypotension may require little treatment other than

to appropriately decrease the concentration of anesthetic drugs to preserve compensatory reflexes. If the degree of hypotension encountered is more severe, further head elevation should be delayed until the level of anesthetic is decreased; in addition, judicious use of fluids and vasopressors can reestablish effective perfusion.

Postural hypotension may also appear in the presence of inadequately replaced blood loss when the intravascular space has been functionally increased either by lowering the legs to horizontal at the termination of the lithotomy position or by returning a head-down tilt to horizontal. Volume repletion is the indicated therapy, although judiciously small doses of vasopressors may sometimes be needed initially.

Pressure Alopecia

Prolonged compression of hair follicles can produce hair loss. Abel and Lewis[17] described patients who had pain, swelling, and exudation where the occiput had been supporting the weight of the head for long periods in the Trendelenburg position. Alopecia occurred between the 3rd and 28th postoperative day; regrowth was complete within 3 months. Use of tight head straps to hold anesthetic face masks and prolonged hypotension and hypothermia have also been associated with compression alopecia.[18] Frequently turning the patient's head during long operations[19] and use of padded, soft head supports are recommended to reduce the risks of this complication.

Pressure-Point Reactions

3 Weight-bearing bony prominences can produce ischemic necrosis of overlying tissue unless proper padding is applied. Hypothermia and vasoconstrictive hypotension may enhance the process. The heels, the elbows, and the sacrum are particularly vulnerable. The use of a variety of pads (e.g., foam or gel) may disperse point pressure if used for protection. While their use may protect against skin and soft tissue compression and ischemia, there are no studies that have proven their use to be beneficial in reducing peripheral neuropathies in the perioperative period.

BRACHIAL PLEXUS AND UPPER EXTREMITY INJURIES

Brachial Plexus Neuropathy

Root Injuries

Shoulder braces placed tight against the base of the neck can compress and injure the roots of the brachial plexus. Braces, if needed at all, are considered less harmful when placed more laterally over the acromioclavicular joint.

The dorsal decubitus positions do not usually threaten structures in the patient's neck unless considerable lateral displacement of the head occurs. In that position, the roots of the brachial plexus on the side of the obtuse head–shoulder angle can be stretched and damaged. If the upper extremity is fixed at the wrist, the stretch injury of the plexus can be accentuated as the head moves laterally away from the anchoring point of the wrist. Similarly, exaggerated rotation of the head away from an extended arm can be associated with a brachial plexus injury.

Sternal Retraction

4 Frequently, the patient undergoing a median sternotomy has both arms padded and secured alongside the torso. An alternative is to have both arms abducted.[20] Vander Salm et al[21,22] described first rib fractures and brachial plexus injuries associated with median sternotomies. They related the extent of the injury to the amount of retractor displacement of the rib, with the most severe injury being caused by displacement sufficient to produce a first rib fracture. Roy and associates,[23] in a study of 200 consecutive adults scheduled for cardiac surgery via a median sternotomy, positioned the left arm either abducted and padded on an arm board with the palm supinated or secured by a draw sheet alongside the trunk; the right arm was always placed alongside the trunk. They found a 10% incidence of upper extremity nerve injury that was not influenced by internal mammary artery harvest, internal jugular vein catheterization, or left arm position. Surgical manipulation was more contributory than extremity positioning in producing trauma to the

brachial plexus. Jellish et al[20] reported that there is less slowing of somatosensory evoked potentials (SSEPs) of the ulnar nerve during sternotomy when both arms are abducted instead of tucked at the sides. However, they found no differences in perioperative symptoms between patients in the arm-abducted versus arm-at-side groups.

Long Thoracic Nerve Dysfunction

Several lawsuits have centered on postoperative serratus anterior muscle dysfunction and winging of the scapula (Fig. 23-8) alleged to be the result of position-related injuries to the long thoracic nerve of Bell, which arises from nerve roots C5, C6, and C7. Because C5 and C6 fibers of the nerve course through the middle scalene muscle and emerge from its lateral border to join the fibers from C7, it has been proposed that neuropathies of the long thoracic nerve are traumatic in origin.[24] Johnson and Kendall[25] described the widely variable etiology of serratus anterior muscle paralysis in a review of 111 cases and found only 13% occurring after either a surgical procedure or an obstetric delivery. Because the nerve is not routinely involved in a stretch injury of the brachial plexus and because the plexus is not routinely involved when long thoracic nerve dysfunction occurs, the relationship between postoperative long thoracic nerve palsy and patient positioning remains speculative. Based on evidence of Foo and Swann[26] plus data from litigations, Martin[27] concluded that in the absence of demonstrable trauma, postoperative dysfunctions of the long thoracic nerve were quite likely the result of coincidental neuropathies, possibly of viral origin.

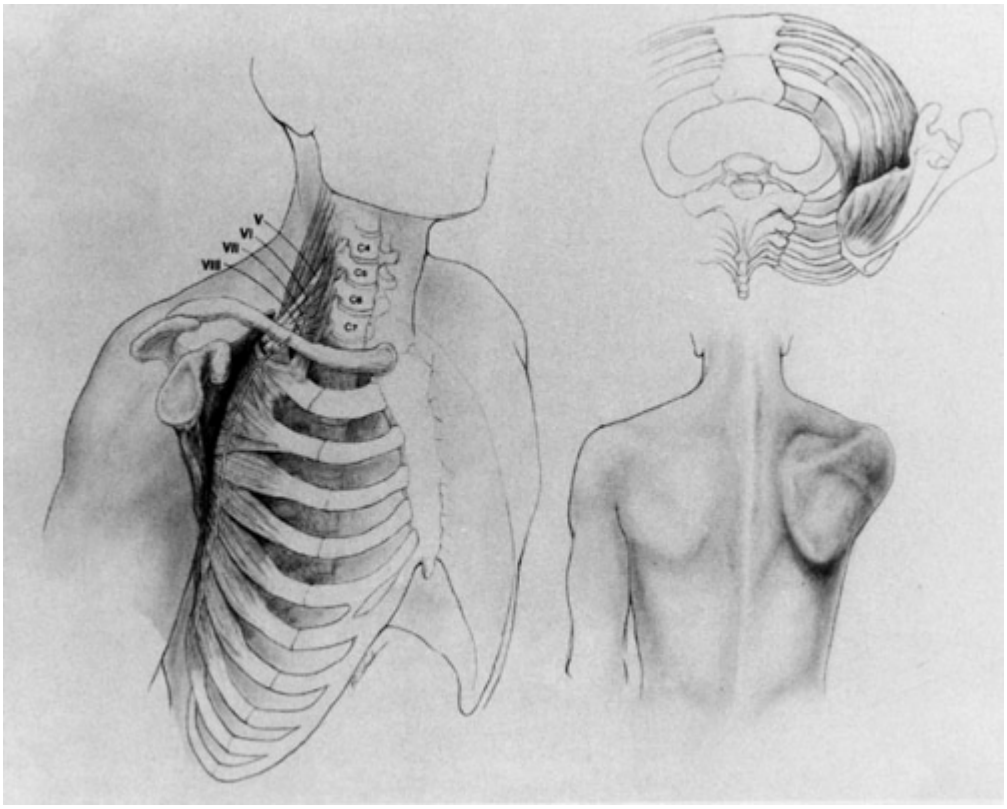

FIGURE 23-8. Scapular winging. The serratus anterior muscle (*upper right*) is supplied solely by the long thoracic nerve that branches immediately from C5, C6, C7, and sometimes C8 (*left figure*). Arising on the lateral ribs and inserting on the deep surface of the scapula, the muscle keeps the shoulder girdle approximated to the dorsal rib cage. Long thoracic nerve palsy allows dorsal protrusion of the scapula (*lower right*). See text. (Reproduced with permission from Martin JT: Postoperative isolated dysfunction of the long thoracic nerve: A rare entity of uncertain etiology. Anesth Analg 69:614, 1989.)

Axillary Trauma from the Humeral Head

Excessive abduction of the arm on an arm board may thrust the head of the humerus into the axillary neurovascular bundle. The bundle is stretched at that point and its neural structures may be damaged. In the same manner, vessels can be compressed or occluded and perfusion of the extremity can be jeopardized.

Radial Nerve Compression

The radial nerve, arising from roots C6-8 and T1, passes dorsolaterally around the middle and lower portions of the humerus in its musculospiral groove. At a point on the lateral aspect of the arm, approximately three fingerbreadths proximal to the lateral epicondyle of the humerus, the nerve can be compressed against the underlying bone and injured. Pressure from the vertical bar of an anesthesia screen or a similar device against the lateral aspect of the arm[28] and excessive cycling of an automatic blood pressure cuff[29] have been implicated in causing damage to the radial nerve. Postoperative radial nerve dysfunction is a relatively rare reason for malpractice litigation.[30,31]

Clinical manifestations of a radial nerve lesion include wrist drop, weakness of abduction of the thumb, inability to extend the metacarpophalangeal joints, and loss of sensation in the web space between the thumb and index finger.[32] Radial nerve function can be rapidly assessed by noting the patient's ability actively to extend the distal phalanx of the thumb.

Median Nerve Dysfunction

Isolated perioperative injuries to the median nerve are uncommon and the mechanism is obscure.[30,31] A potential source of injury is iatrogenic trauma to the nerve during access to vessels in the antecubital fossa, as might occur during venipuncture. Anecdotally, this problem appears to occur primarily in men 20 to 40 years of age who cannot easily extend their

elbows completely. Forced elbow extension after administration of muscle relaxants and while positioning the arms, with resultant stretch of the median nerve, has been suggested as one potential mechanism for this problem. A quick check of sensation over the dorsal and palmar surfaces of the distal phalanges of the first and second fingers identifies an acute injury.

Ulnar Neuropathy

Improper anesthetic care and patient malpositioning have been implicated as causative factors in the development of ulnar neuropathies since reports by Büdinger[33] and Garriques[34] in the 1890s. These factors likely play an etiologic role for this problem in some surgical patients. Other factors, however, may contribute to the development of postoperative ulnar neuropathies. In a series of 12 inpatients with newly acquired ulnar neuropathy, Wadsworth and Williams[35] determined that external compression of an ulnar nerve during surgery was a factor in only two patients. Ulnar neuropathies develop in medical as well as surgical patients.[36] The mechanisms of ulnar neuropathy are unclear.

5 Typically, anesthesia-related ulnar nerve injury is thought to be associated with external nerve compression or stretch caused by malpositioning during the intraoperative period. Although this implication may be true for some patients, three findings suggest that other factors may contribute. First, patient characteristics (e.g., male sex, high body mass index [⩾38], and prolonged postoperative bed rest) are associated with these ulnar neuropathies.[37] Various reports suggest that 70 to 90% of patients who have this problem are men.[30,31,35,36,37] Second, many patients with perioperative ulnar neuropathies have a high frequency of contralateral ulnar nerve conduction dysfunction.[38] This finding suggests that many of these patients likely have asymptomatic but abnormal ulnar nerves before their anesthetics, and these abnormal nerves may become symptomatic during the perioperative period. Finally, many patients do not notice or complain of ulnar nerve symptoms until more than 48 hours after their surgical procedures.[37,38] A prospective study of ulnar neuropathy in 1,502 surgical patients found that none of the patients had symptoms of the neuropathy during the first 2 postoperative days.[39] It is not clear whether onset of symptoms indicates the time that an injury has occurred to the nerve. Prielipp et al[40] found that 8 of 15 awake volunteers who had notable alterations in their ulnar nerve SSEP signals from direct ulnar nerve pressure did not perceive a paresthesia, even when the SSEP waveforms decreased as much as 72%.

Elbow flexion can cause ulnar nerve damage by several mechanisms. In some patients, the ulnar nerve is compressed by the aponeurosis of the flexor carpi ulnaris muscle and cubital tunnel retinaculum when the elbow is flexed by more than 110 degrees[41,42] (Fig. 23-9). In other patients, this fibrotendinous roof of the cubital tunnel is poorly formed and can lead to anterior subluxation or dislocation of the ulnar nerve over the medial epicondyle of the humerus during elbow flexion. This displacement has been observed in approximately 16% of cadavers in whom the flexor muscle aponeurosis and supporting tissues have not been dissected.[43,44] Ashenhurst[44] has speculated that the ulnar nerve may be chronically damaged by recurrent mechanical trauma as the nerve subluxates over the medial epicondyle.

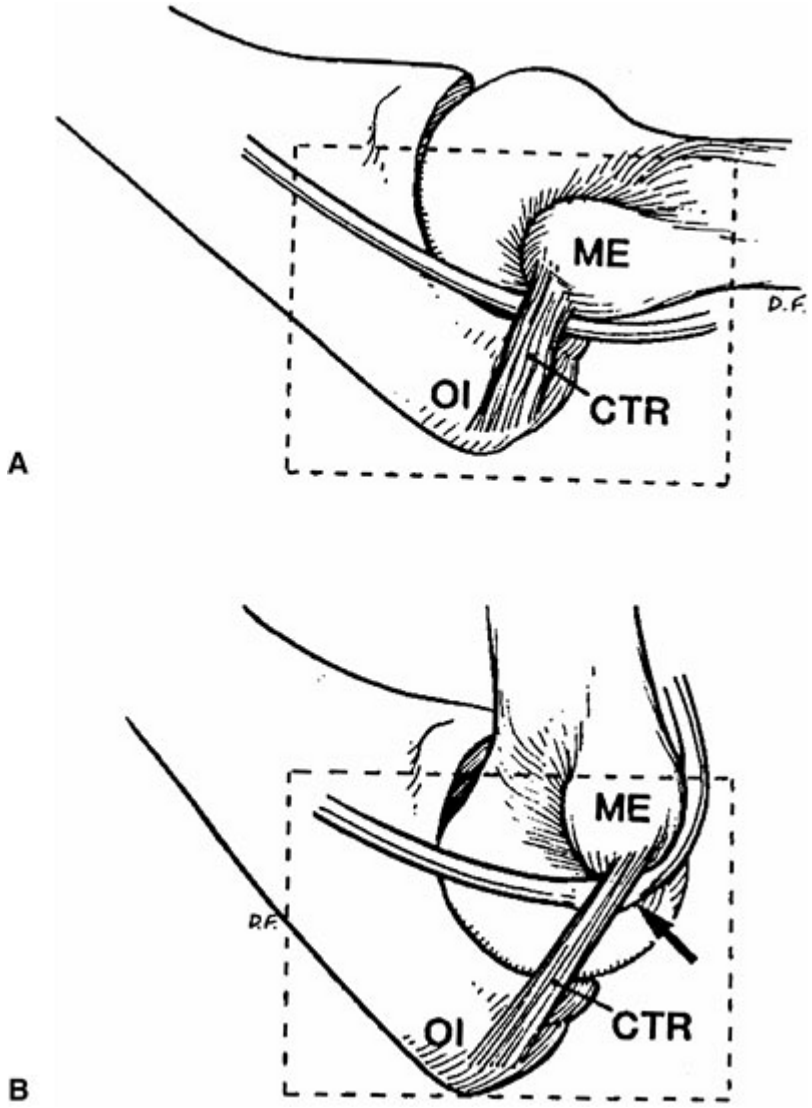

FIGURE 23-9. Medial-to-lateral view of right elbow. The cubital tunnel retinaculum (CTR) is lax in extension **(A)** as it stretches from the medial epicondyle (ME) to the olecranon (OI). The retinaculum tightens in flexion **(B)** and can compress the ulnar nerve (*arrow*). (Reprinted with permission from O'Driscoll SW, Horii E, Carmichael SW *et al:* The cubital tunnel and ulnar neuropathy. J Bone Joint Surg Am 73:613, 1991.)

External compression in the absence of elbow flexion also may damage the ulnar nerve.[45,46] Although compression within the medial epicondylar groove may be possible if the groove is shallower than normal, the bony groove usually is deep and the nerve is well protected from external compression.[47] External compression may occur distal to the medial epicondyle, where the nerve and its associated artery are relatively superficial. In an anatomic study, Contreras et al[48] observed that the ulnar nerve and posterior recurrent ulnar artery pass posteromedially to the tubercle of the coronoid process, where they are covered only by skin, subcutaneous fat, and a thin distal band of the aponeurosis of the flexor carpi ulnaris.

Why are men more likely to have this complication? There are several anatomic differences between men and women that may increase the likelihood of perioperative ulnar neuropathy developing in men. First, two anatomic differences may increase the chance of ulnar nerve compression in the region of the elbow. The tubercle of the coronoid process is approximately 1.5 times larger in men than women.[48] In addition, there is less adipose tissue over the medial aspect of the elbow of men compared with women of similar body fat composition.[48-50] Second, men may be more likely to have a well-developed cubital tunnel retinaculum than women, and the retinaculum, if present, is thicker. A thicker cubital tunnel retinaculum may increase the risk of

ulnar nerve compression in the cubital tunnel when the elbow is flexed.

Clinical manifestations of ulnar nerve dysfunction vary with the location and extent of the lesion.[51] Nearly all patients

have numbness, tingling, or pain in the sensory distribution of the ulnar nerves once they become symptomatic. However, there can be considerable ulnar nerve dysfunction before symptoms appear. Prielipp et al[40] found that only 8 of 15 male volunteers with significant ulnar nerve conduction slowing noted any symptoms. More studies are needed to understand better the mechanism and natural history of ulnar neuropathy.

Ulnar nerve injury is relatively common.[30,31,39] Also, a significant proportion of patients have symptoms of bilateral ulnar nerve dysfunctions both before and after surgery.[38] Therefore, some have speculated it might be helpful during the preanesthetic interview to inquire about a history of ulnar neuropathies (“crazy bone” problems) or previous surgery at the elbow. If such a history is indicated, the finding must be recorded and a discussion with the patient or family should present the possibility of a postoperative recurrence despite special precautions of padding and positioning.

The time of recognition of digital anesthesia associated with ulnar nerve dysfunction may be quite important in establishing the origin of the postoperative syndrome. If ulnar hypesthesia or anesthesia is noted promptly after the end of anesthesia, as in the recovery facility, the condition is likely to be associated with events that occurred during anesthesia or surgery. If the recognition is delayed for many hours, the likelihood of cause shifts from the intra-anesthetic period to postoperative events. In a review of closed claims, Kroll and associates[30] commented that postoperative ulnar dysfunction can occur as a result of events in the postanesthetic period and that nerve injury may develop in certain susceptible patients “despite conventionally accepted methods of positioning and padding.”

Opioids may mask postoperative dysesthesias and pain, but even strong analgesics cannot mask a loss of sensation as a result of nerve dysfunction. It may be helpful to assess ulnar nerve function and record these observations before discharging the patient from the recovery room.

Arm Complications

An arm that is hyperabducted can force the head of the humerus into the axillary neurovascular bundle and damage nerves and vessels to the arm. Abduction of the arm to more than 90 degrees from the trunk should be avoided. An arm board should be securely attached to the operating table to prevent its accidental release. An arm that is not properly secured can slip over the edge of the table or arm board, resulting in injury to the capsule of the shoulder joint by excessive dorsal extension of the humerus, fracture of the neck of an osteoporotic humerus, or injury to the ulnar nerve at the elbow. Conversely, in the unlikely event that the retaining strap is excessively tight across the supinated forearm (Fig. 23-10), the potential exists for pressure to compress the anterior interosseous nerve, a branch of the median nerve in the upper forearm that courses with its artery along the volar surface of the tough interosseous membrane. The result is an ischemic injury to the distribution of the nerve and artery that resembles a compartment syndrome in the lower extremity and may require prompt surgical decompression.[52-54]

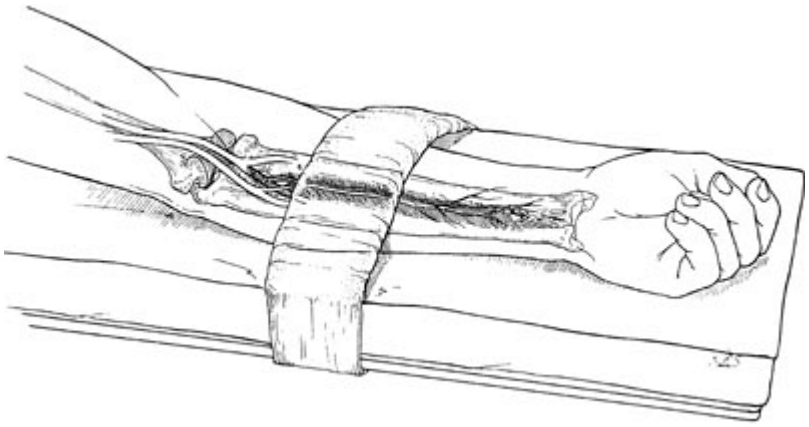

FIGURE 23-10. Arm restraint, if excessively tight, can compress the anterior interosseous nerve and vessel against the interosseous membrane in the volar forearm to produce an ischemic neuropathy. Backache

6 Lumbar backache can be worsened by the ligamentous relaxation that occurs with general, spinal, or epidural anesthesia. Loss of normal lumbar curvature in the supine position is apparently the issue. Padding (see Fig. 23-3) placed under the lumbar spine before the induction of anesthesia may help retain lordosis and make a patient with known lumbar distress more comfortable. Hyperlordosis should be avoided, however. Hyperextension of the lumbar spine, especially to an angulation of more than 10 degrees at the L2-3 apex of the lumbar spine, may result in ischemia of the spinal nerves.[55]

Elevation of the legs can worsen the pain of a herniated nucleus pulposus. When the lithotomy position is contemplated for a patient with a history of low back pain or a herniated lumbar disk, gentle passive attempts to have the patient assume the posture before anesthesia may be helpful in determining whether the position can be tolerated.

Perineal Crush Injury

The supine patient who is placed on a fracture table for repair of a fractured femur usually has the pelvis retained in place by a vertical pole at the perineum (Fig. 23-11), with the foot of the injured extremity fixed to a mobile rest. A worm gear on the rest lengthens the distance between the foot and the pelvis so that the bone fragments can be distracted and realigned. Unless the pole is well padded, severe pressure can be exerted on the pelvis, and damage can occur to the genitalia and the pudendal nerves. Complete loss of penile sensation has been reported after use of the fracture table.[56,57] The correct position for the pole is against the pelvis between the genitalia and the uninjured limb.[56]

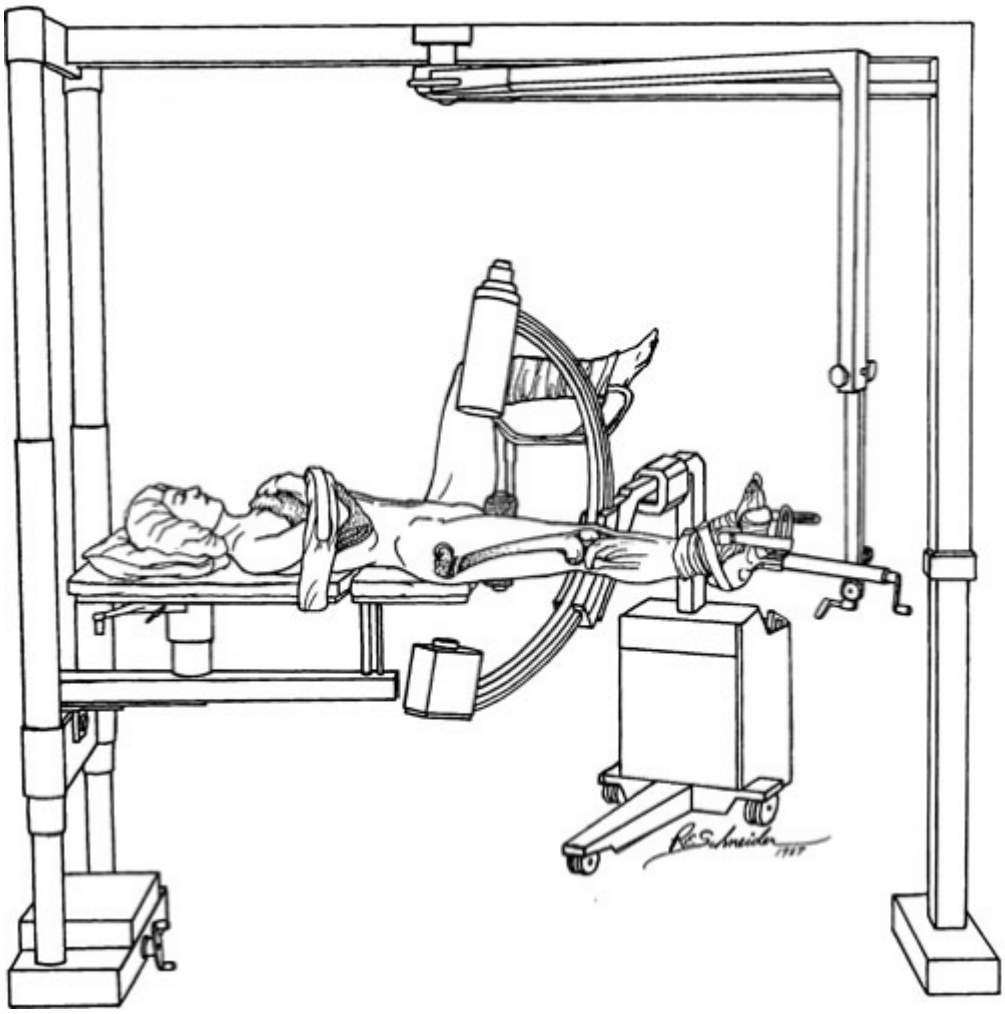

FIGURE 23-11. Traction table with perineal post stabilizing patient while leg is elongated to reposition bone ends. Elevated leg risks hypoperfusion; pelvic post threatens genitalia. (Reproduced with permission from Figure 6-6, (p. 54) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Compartment Syndrome

If, for whatever reason, perfusion to an extremity is inadequate, a compartment syndrome may develop. Characterized by ischemia, hypoxic edema, elevated tissue pressure within fascial compartments of the leg, and extensive rhabdomyolysis, the syndrome produces extensive and potentially lasting damage to the muscles and nerves in the compartment. Because the pathologic process is at tissue level, distal pulses and capillary refill may remain intact while a compartment syndrome is developing in an extremity; thus, they are not useful indicators of the ongoing process. Ferrihemate, resulting from myoglobin destruction, exerts a direct toxic effect on renal tubular epithelium, and renal failure is likely.[58] Circulating debris from infections in the involved extremities is apt to be filtered by pulmonary microvasculature with injurious consequences for the lung.

Causes of a compartment syndrome while a patient is in any of the dorsal decubitus positions include (1) systemic hypotension and loss of driving pressure to the extremity (augmented by elevation of the extremity); (2) vascular obstruction of major leg vessels by intrapelvic retractors, by excessive flexion

of knees or hips, or by undue popliteal pressure from a knee crutch; and (3) external compression of the elevated extremity by straps or leg wrappings that are too tight, by the inadvertent

pressure of the arm of a surgical assistant, or by the weight of the extremity against a poorly supportive leg holder.[9,59] A tight strap on an arm as well as tight “drawsheets” for maintaining arms at the patient's sides may compress the anterior interosseous neurovascular bundle and may be associated with an anterior interosseous neuropathy or a forearm or a hand compartment syndrome.[53,54]

Several clinical characteristics seem to be associated with perioperative compartment syndrome. Prolonged lithotomy posture in excess of 5 hours has been a common factor in literature anecdotes of postlithotomy compartment syndromes. For lengthy procedures in the lithotomy position, well-padded holders that immobilize the limb by supporting the foot without compressing the calf or popliteal fossa seem to be the least threatening choice. There is considerable variability in the perfusion pressure of the lower extremity in elevated legs. Halliwill et al[12] and Pfeffer et al[13] found significant blood pressure variation at the ankle in volunteers placed in various lithotomy positions. Several volunteers had mean pressures of less than 20 mm Hg when positioned in the high lithotomy position. This pressure is less than intracompartment pressures commonly measured in many lithotomy positions.

Warner et al[60] have shown that perioperative compartment syndromes occur in patients in positions other than lithotomy. In fact, the frequency of this problem occurs as often (approximately 1:9,000 patients) in anesthetized patients who are positioned laterally as in similar patients who are positioned in lithotomy. The difference between compartment syndromes in these two groups is that patients in a lateral decubitus position tend to have compartment syndromes of either arm, while those in a lithotomy position have compartment syndromes of the lower extremities.[60]

Finger Injury

In 1968, Courington and Little[61] described the amputation of a young woman's fingers that were caught between the leg and thigh sections of the operating table as the leg section was returned to the horizontal position at the termination of an operation during which the patient was in the lithotomy position. A towel used to create a boxing glove–like wrap on the hands of lithotomized patients or carefully removing the patient's hands from the risk position before raising the foot of the table may prevent such a tragic misadventure.[62]

LATERAL DECUBITUS POSITIONS

Physiology

Circulatory

In the lateral decubitus position, the patient is turned onto one side of the trunk and stabilized to prevent accidental rolling toward either the supine or the prone posture. It is of practical and legal importance to note that the side of the body that rests on the table is the side that determines the name of the position (left side down = left lateral decubitus position).

If the legs are maintained in the long axis of the body, almost no pressure gradients exist along the great vessels from head to foot. Small hydrostatic differences are detected between the values when blood pressure is recorded simultaneously on the two arms.

If the lower extremities are positioned below the level of the heart, blood pools in the distensible vessels of the dangling legs because of gravity-induced increases in venous pressure and resultant venous stasis. Wrapping the legs and thighs in compressive bandages has been commonly used to combat

venous pooling. Marked flexion of the lower extremities at knees and hips can partially or completely obstruct venous return to the inferior vena cava either by angulation of vessels at the popliteal space and inguinal ligament or by thigh compression against an obese abdomen. A small support placed just caudad of the down-side axilla can be used to lift the thorax enough to relieve

pressure on the axillary neurovascular bundle and prevent disturbed blood flow to the arm and hand. However, this chest support (inappropriately called an *axillary roll* by some) has not been proven to reduce the frequency of ischemia, nerve damage, or compartment syndrome to the down-side upper extremity. It may, however, decrease shoulder discomfort postoperatively. Any padding should support only the chest wall and it should be periodically observed to ensure that it doesn't impinge on the neurovascular structures of the axilla.

In the low-pressure pulmonary circuit, hydrostatic gradients occur between the two hemithoraces. Although the degree of gravity-induced lateral displacement of the heart is different in the two lateral decubitus positions, it is generally true that most of the down-side lung lies below the level of the atrium and that the up-side lung lies above it. Vascular congestion of the down-side lung resembles a zone 3 of West et al,[4] whereas the relative hypoperfusion of the up-side lung resembles a zone 2. Kaneko et al[63] found that the transition between zone 3 and zone 2 occurred at approximately 18 cm above the most dependent part of the lung.

If the cervical spine of the patient who is placed in a horizontal lateral decubitus position is carefully maintained in alignment with the thoracolumbar spine, almost no gradient occurs between pressures in the mediastinum and those in the head. However, if the head is not supported and sufficient lateral angulation of the neck occurs in either direction, obstruction of jugular flow may occur.

Respiratory

In the presence of a supple chest, the lateral decubitus position can decrease the volume of the down-side hemithorax. The weight of the chest may force the down-side rib cage into a less expanded conformation. Gravity-induced shifts of mediastinal structures toward the down-side chest wall tend further to reduce the volume of the dependent lung. Abdominal viscera force the down-side diaphragm cephalad if the long axis of the trunk is horizontal or head down.

Spontaneous ventilation can partially compensate for the diaphragmatic stretching in the dependent hemithorax because the contractile efficiency of the elongated diaphragmatic muscle fibers is increased. The compacted lung base and zone 3 vascular congestion decrease compliance and interfere with the distribution of gas during positive-pressure ventilation. An elevated kidney rest placed against either the down-side rib margin or flank, or that migrates into that position as the patient shifts on it, further interferes with movement of the down-side hemidiaphragm and passive ventilation of the dependent lung.

The up-side hemithorax is much less compressed than the dependent side, and because the lung lies above the level of the atria, it has less vascular congestion than the down-side lung. As a result, unless contralateral flexion has stretched the up-side flank muscles to the point of rigidity and limited excursions of the costal margin, positive-pressure ventilation is directed preferentially to the more compliant up-side lung. The result can easily be excessive ventilation of the underperfused up-side lung and hypoventilation of the congested down-side lung. The potential for a clinically significant ventilation–perfusion mismatch is obvious, particularly in the presence of pulmonary disease.

Variations of the Lateral Decubitus Positions

Standard (Horizontal) Lateral Position

In the horizontal lateral decubitus position (Fig. 23-12), the patient is rolled onto one side on a flat table surface and stabilized in that posture by flexing the down-side thigh. The down-side knee is bent to retain the leg on the table and improve stabilization of the trunk. The common peroneal nerve of that side is padded to minimize compression damage caused by the weight of the legs. The up-side thigh and leg are extended comfortably, and pillows are placed between the lower extremities. The head is supported by pillows or a head rest so that the cervical and thoracic spines are properly aligned. A small pad, thick enough to raise the chest wall and prevent excessive compression of the shoulder or entrapment/compression of the neurovasclar structures of the axilla, is placed just caudad to the down-side axilla. This padding may support adequate

perfusion of the down-side hand and minimize circumduction of the dependent shoulder, which might stretch its suprascapular nerve.

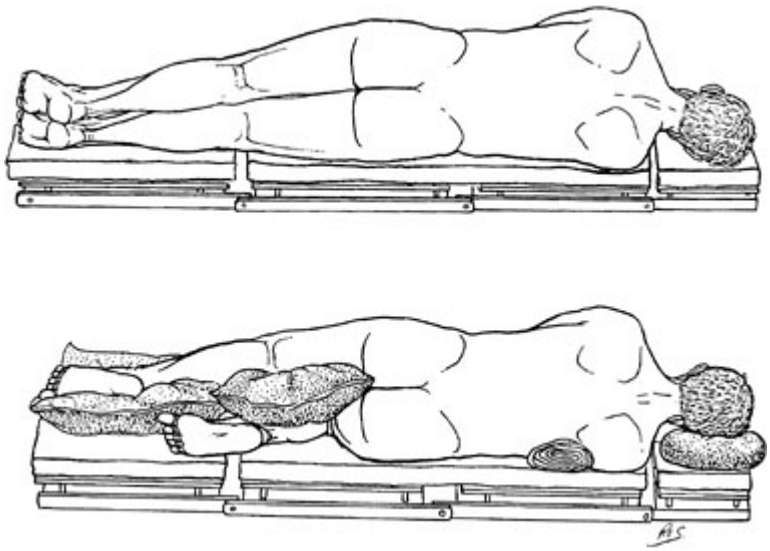

FIGURE 23-12. The standard lateral decubitus position. Proper head support, axillary roll, and leg pillow arrangement are shown on *lower figure*. Down-side leg is flexed at hip and knee to stabilize torso. Retaining straps and pad for down-side peroneal nerve are not shown. (Reproduced with permission from Figure 9-1, (p. 127) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Arms may be extended ventrally and retained on a single arm board with suitable padding between them, or they may be individually retained on a padded two-level arm support that can also help to stabilize the thorax. An alternate method of arm arrangement is to flex each elbow and place the arms on suitable padding on the table in front of the patient's face.

The patient is stabilized in the lateral position by the use of one or more retaining tapes or straps stretched across the hip and fixed to the underside of the table top. Care must be taken to see that the hip tapes or straps lie safely between the iliac crest and the head of the femur rather than over the head of the femur. An additional restraining tape or strap may be used across the thorax or shoulders if needed.

Semisupine and Semiprone

The semilateral postures are designed to allow the surgeon to reach anterolateral (semisupine) and posterolateral (semiprone) structures of the trunk. In the semisupine position, the up-side arm must be carefully supported so that it

is not hyperextended and no traction or compression is applied to the brachial and axillary neurovascular bundles (Fig. 23-13). The supporting bar should be well wrapped to prevent electrical grounding contact (see Fig. 23-13A). Sufficient noncompressible padding should be placed under the dorsal torso (see Fig. 23-13, *large figure*) and hip to prevent the patient from rolling supine and stretching the anchored extremity. The pulse of the restrained wrist should be checked to ensure adequate circulation in the elevated arm and hand (Fig. 23-13B).

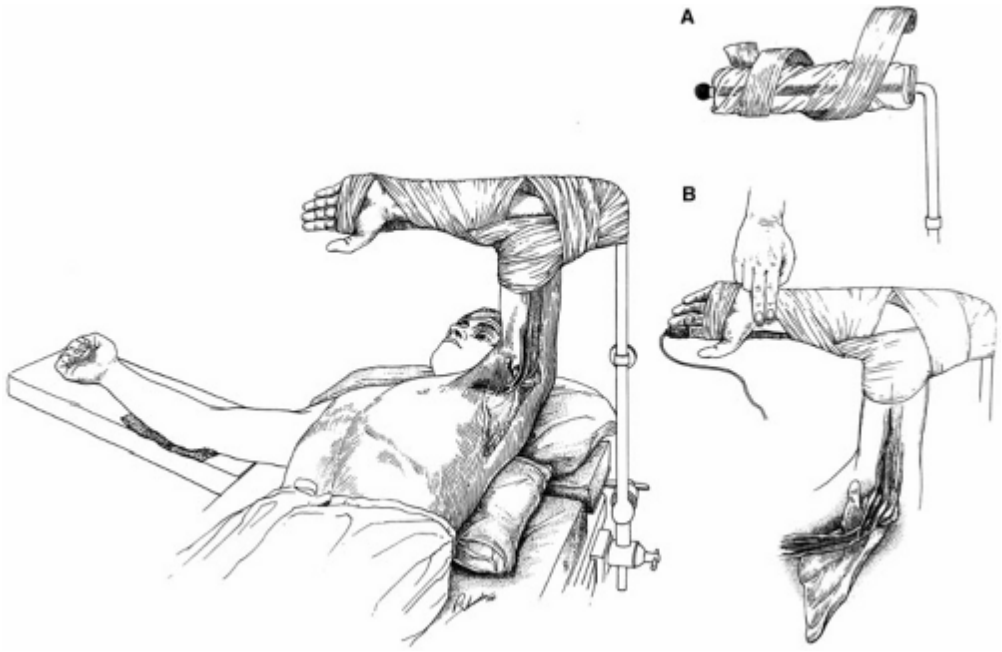

FIGURE 23-13. The semisupine position with dorsal pads supporting the torso, the extended arm padded at the elbow, and the elevated arm restrained on a well cushioned, adjustable overhead bar **(A).** Axillary contents **(B)** are not under tension and are not compressed by the head of the humerus, and a pulse oximeter ensures that the digital circulation is not compromised. The position is safe only if the arm does not become a hanging mechanism to support the torso. (Reproduced with permission from Figure 7-2, (p. 176) of Collins VJ [ed]: Principles of Anesthesiology, 3rd ed. Philadelphia, Lea & Febiger, 1993.)

Flexed Lateral Positions

Lateral Jackknife. The lateral jackknife position places the down-side iliac crest over the hinge between the back and thigh sections of the table (Fig. 23-14). The table top is angulated at that point to flex the thighs on the trunk laterally. After the patient has been suitably positioned and restrained, the chassis of the table is tipped so that the uppermost surface of the patient's flank and thorax becomes essentially horizontal. As a result, the feet are below the level of the atria, and significant amounts of blood may pool in distensible vessels in each leg.

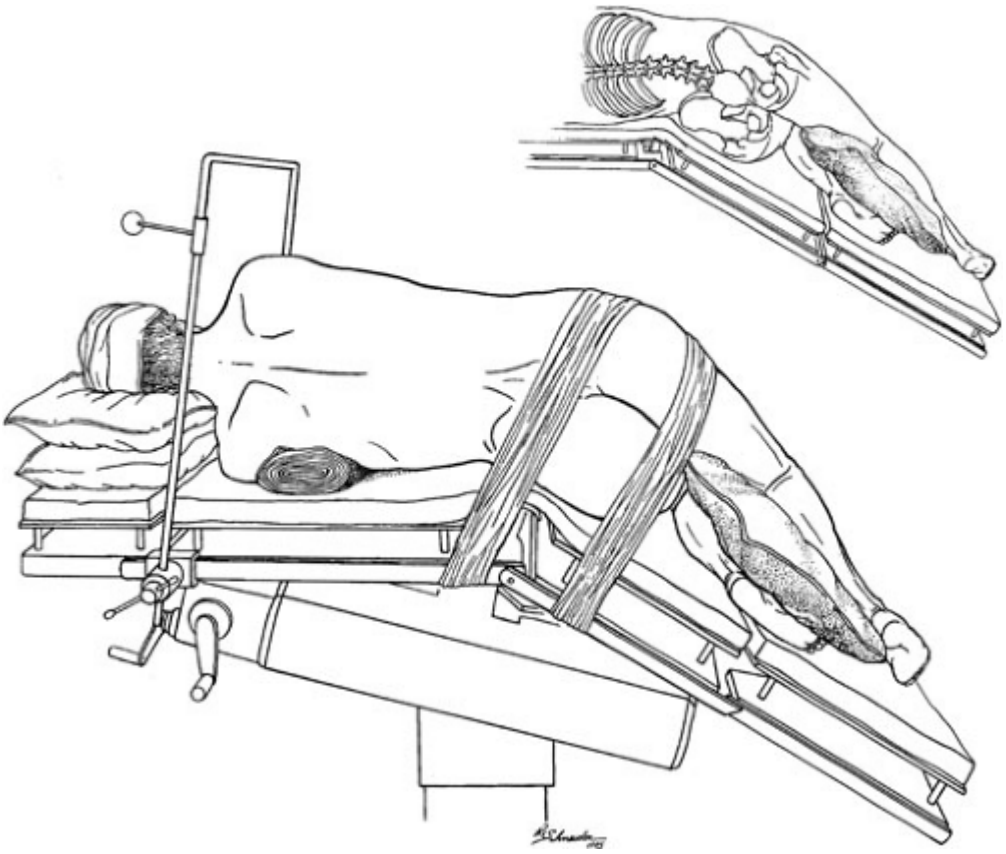

FIGURE 23-14. The lateral jackknife position, intended to open intercostal spaces. Note the properly placed restraining tapes (*large figure*) thrusting cephalad to retain the iliac crest at the flexion point of the table and prevent caudad slippage, which compresses the down-side flank (*insert*). (Reproduced with permission from Figure 9-4, (p. 130) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

The lateral jackknife position is usually intended to stretch the up-side flank and widen intercostal spaces as an asset to a thoracotomy incision. However, in terms of lumbar stress, restriction by the taut flank of up-side costal margin motion, and pooling of blood in depressed lower extremities, the position imposes a significant physiologic insult. Actually, its usefulness to the surgeon is brief, and its use should be limited. Once the rib-spreading retractor is placed in the incision, the position has reduced value for the rest of the operation.[64]

Kidney. The kidney position (Fig. 23-15) resembles the lateral jackknife position, but it adds the use of an elevated rest (the *kidney rest*) under the down-side iliac crest to increase the amount of lateral flexion and improve access to the up-side kidney under the overhanging costal margin. Unlike the lateral jackknife position, the kidney position does not have a useful alternative for a flank approach to the kidney. Thus, the physiologic insults associated with the posture need to be limited by vigilant anesthesia and rapid surgery. Strict stabilizing precautions should be taken to prevent the patient from subsequently shifting caudad on the table in such a manner that the elevated rest relocates into the down-side flank and becomes a severe impediment to ventilation of the dependent lung.

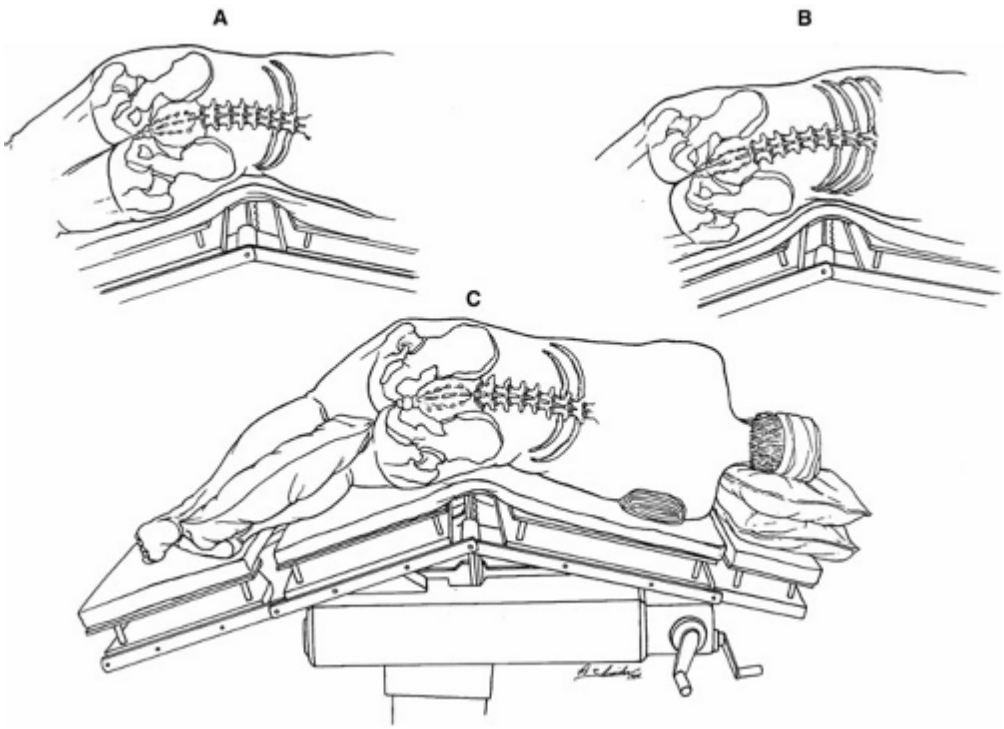

FIGURE 23-15. The flexed lateral (kidney) position. Upper panels show improper locations of the elevated transverse rest, the flexion point of the table, in the flank **(A)** or at the lower costal margin **(B)** to impede ventilation of the down-side lung. The iliac crest at the proper flexion point **(C)**, allowing the best possible expansion of the down-side lung. Restraining tapes deleted for clarity. (Reproduced with permission from Figure 9-6, (p. 132) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Complications of the Lateral Decubitus Positions

Eyes and Ears

Injuries to the dependent eye are unlikely if the head is properly supported during and after the turn from the supine to the lateral position. If the patient's face turns toward the mattress, however, and the lids are not closed or the eyes otherwise protected, abrasions of the ocular surface can occur. Direct pressure on the globe can displace the crystalline lens, increase intraocular pressure or, particularly if systemic hypotension is present, cause ischemia.

In the lateral position, the weight of the head can press the down-side ear against a rough or wrinkled supporting surface. Careful padding with a pillow or a foam sponge is usually sufficient protection against contusion of the ear. The external ear should also be palpated to ensure that it has not been folded over in the process of placing support beneath the head.

Neck

Lateral flexion of the neck is possible when the head of a patient in the lateral position is inadequately supported. If the cervical spine is arthritic, postoperative neck pain can be troublesome. Pain from a symptomatic protrusion of a cervical disk can be intensified unless the head is carefully positioned so that lateral or ventral flexion, extension, or rotation is avoided. Patients with unstable cervical spines can be intubated while awake and turned gently into the operative position while repeated neurologic checks, with which the patient cooperates and

responds, are accomplished to detect the development of a positioning injury.[65]

Suprascapular Nerve

Ventral circumduction of the dependent shoulder can rotate the suprascapular notch away from the root of the neck (Fig. 23-16). Because the suprascapular nerve is fixed both paravertebrally and at the notch, circumduction can stretch the nerve and produce troublesome, diffuse, dull shoulder pain. The diagnosis is established by blocking the nerve at the notch and producing pain relief. Treatment may require resecting the ligament over the notch to decompress the nerve. A supporting pad placed under the thorax just caudad of the axilla and thick enough to raise the chest off the shoulder should prevent a circumduction stretch injury to the nerve.

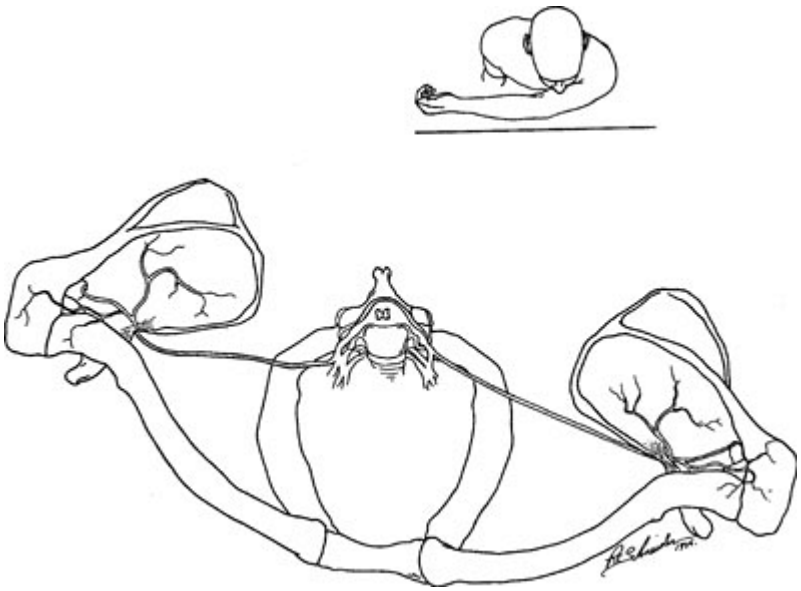

FIGURE 23-16. Circumduction of the arm displacing the scapula and stretching the suprascapular nerve between its anchoring points at the cervical spine and the suprascapular notch. (Reproduced with permission from Figure 9-14, (p. 147) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Long Thoracic Nerve

Instances of postoperative winging of the scapula (see Fig. 23-8) have followed use of the lateral decubitus position.[27] Although coincidental viral neuropathies of the long thoracic nerve may play a major etiologic role in postoperative appearances of scapular winging in patients for whom only a dorsal decubitus position was used, the possibility of trauma to the nerve while establishing the lateral position is difficult to refute. Lateral flexion of the neck may stretch the long thoracic nerve in the obtuse angle of the neck.

VENTRAL DECUBITUS (PRONE) POSITIONS

Physiology

Circulatory

In the *prone position*, the circulatory dynamics vary according to the postural modification in use. If the legs remain essentially horizontal, pressure gradients in the blood vessels are minimal. If the patient is kneeling, or if the table chassis is rotated head high, significant pooling of venous blood in distensible dependent vessels is likely to occur.

With the patient lying on the soft abdominal wall, pressure of compressed viscera is transmitted to

the dorsal surface of the abdominal cavity. Mesenteric and paravertebral vessels are compressed, causing engorgement of veins within the spinal canal. Obstruction of the inferior vena cava can produce immediate, visible distention of vertebral veins. Because bleeding from incised vessels about the spine is increased under these circumstances, numerous modifications of the prone position have been created to free the abdomen from pressure, reduce the congestion of intraspinal veins, and facilitate surgical hemostasis.[66]

If the head of a prone patient is below the level of the heart, venous congestion of the face and neck becomes evident. Turning the patient's head can alter arterial perfusion and venous drainage in both extracranial and intracranial vessels. Conjunctival edema is usual and reflects the influence of gravity on accumulation of extravascular fluid (see Complications of the Ventral Decubitus Positions: Blindness section).

If the head is above the level of the heart, mean vascular pressures are decreased according to the distance above the heart and conjunctival edema is less evident or absent, but air entrainment in open veins is possible.

Kaneko et al[63] described the perfusion of the entire lung of prone subjects in terms that subsequently fit the zone 3 of West et al.[4] Backofen and Schauble[67] found that even the carefully established and supported prone position caused a significant fall in stroke volume and cardiac index, despite the development of increased vascular resistance in both the systemic and pulmonary circuits. No significant changes were detected in mean arterial pressure, right atrial pressure, or pulmonary artery occlusion pressure. On the basis of these observations, they recommend that, in patients whose cardiovascular status is precarious, invasive hemodynamic monitors be introduced to detect otherwise unrecognizable deterioration of cardiac function caused by positioning.

Respiratory

Using computed tomography, Gattinoni's group[68] found a dramatic redistribution of densities from the dorsal (paravertebral supine) to the ventral (substernal) portions of the lungs when subjects in respiratory failure were turned from the supine to the prone position. The original areas of compression atelectasis reopened when those parts of the lung became nondependent, whereas fresh areas of compression atelectasis formed rather promptly in newly dependent areas of the lung. In their study group, they found no change in oxygenation or shunting when pronation occurred.

If the thorax is supple or compliant, the body weight of an anesthetized, prone patient compresses the anteroposterior

diameter of the relaxed chest to a degree that is real but poorly defined. If the particular prone posture in use allows the pressure of the abdominal viscera to be sufficient to force the diaphragm cephalad, the lung is shortened along its long axis. With both the dorsoventral and the cephalocaudad dimensions of the lung decreased, and in the presence of the relative vascular congestion of a zone 3 of West et al,[4] the compliance of the compacted prone lung can be anticipated to decrease. The result of decreased pulmonary compliance in a poorly positioned, prone, anesthetized patient is either an increased work of spontaneous ventilation or the need for higher inflation pressures during positive-pressure ventilation.

Proper positioning can retain more nearly normal pulmonary compliance by minimizing the cephalad shift of the diaphragm caused by compressed abdominal viscera. If the patient is arranged so that the abdomen hangs free, the loss of functional residual capacity is less in the prone position than in either the supine or the lateral position.[69] Rehder et al[70] noted that the weight of the freed abdominal contents had an “inspiratory effect on the diaphragm” when the pronated patient was properly supported by pads under the shoulder girdle and pelvis.

Variations of the Ventral Decubitus Position

Full (Horizontal) Prone

In the so-called *full* or *horizontal prone position* (Fig. 23-17), the requirement to elevate the trunk off the supporting surface so that the ventral abdominal wall is freed of compression almost always results in the head and lower extremities being below the level of the spine. If the table top is angulated at the trunk–thigh hinge to remove the lumbar lordosis and separate the lumbar spinous processes, and if the chassis is then rotated head-up sufficiently to level the patient's back, a significant perfusion gradient may develop between the legs and the heart. Wrapping the legs in compressive bandages, or the use of full-length elastic hosiery, minimizes pooling of blood in distensible vessels and supports venous return.

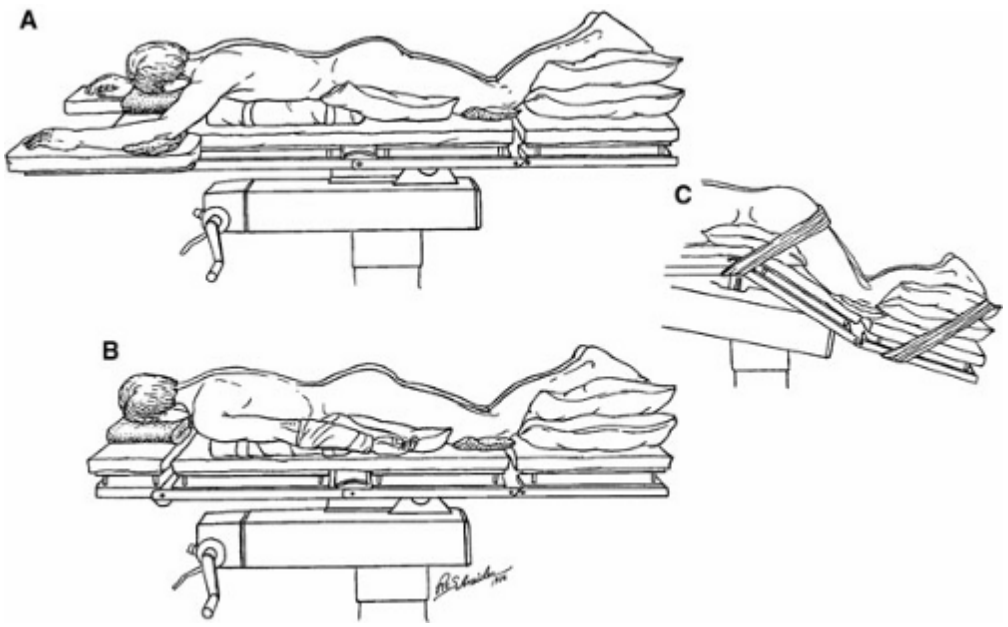

FIGURE 23-17. The classic prone position. **A.** Flat table with relaxed arms extended alongside patient's head. Parallel chest rolls extended from just caudad of clavicle to just beyond inguinal area, with pillow over pelvic end. Elbows and knees are padded, and legs are bent at the knees. Head is turned onto a C-shaped foam sponge that frees the down-side eye and ear from compression. **B.** Same posture with arms snugly retained alongside torso. **C.** Table flexed to reduce lumbar lordosis; subgluteal area straps placed after the legs are lowered to provide cephalad thrust and prevent caudad slippage. (Reproduced with permission from Figure 10-1, (p. 156) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Various ventral supports, including parallel rolls of tightly packed sheets, padded and adjustable metal frames, and four-pillar frames, have been devised to free the abdomen from compression.[66,71] Each has merit, and no specific unit has been shown to be better than the others for hemodynamic or respiratory maintenance or patient safety. The choice is based on the physique of the patient, the requirements of the surgical procedure, and the available equipment.

Pronated patients with limited mobility of the neck, a history of postural neck pain, or a history suggesting a symptomatic cervical disk should have their heads retained in the sagittal plane, either with a skull-pin head clamp[72] or with a face rest. If the neck is pain free and its mobility is satisfactory, the head can be turned laterally and supported to prevent pressure on the down-side eye and ear.[73] However, forced rotation of the pronated head should be carefully avoided lest it induce postoperative neck pain or cervical nerve root or vascular compression.

When a patient is scheduled to be pronated after induction of anesthesia, it is worthwhile during the preanesthetic interview to obtain and record information about any limitations that may exist

in his or her ability to raise the arms overhead during work or sleep.[66] If the patient is symptomatic, it may be prudent to place the arms alongside the torso after pronation (see the discussion of the Thoracic Outlet Syndrome, later). If the arms are placed alongside the head (i.e., extended ventrally at the shoulder, flexed at the elbow, and abducted onto arm boards; the "surrender" position), the musculature about the shoulders should be under no tension, neither humeral head should stretch or compress its axillary neurovascular bundle (i.e., shoulders should be abducted less than 90 degrees), ulnar nerves at the elbow should be padded, and the pulses at the wrists should remain full. Anterior (forward) flexion of the shoulders may reduce tension on the neurovascular structures of the axilla.

Prone Jackknife

The prone jackknife posture is used to provide access to the sacral, perianal, and perineal areas as well as to the lower alimentary canal (Fig. 23-18). The thighs are flexed on the trunk more than is usual in the full prone position, with the table surface hinges determining the degree of flexion achievable.[66]

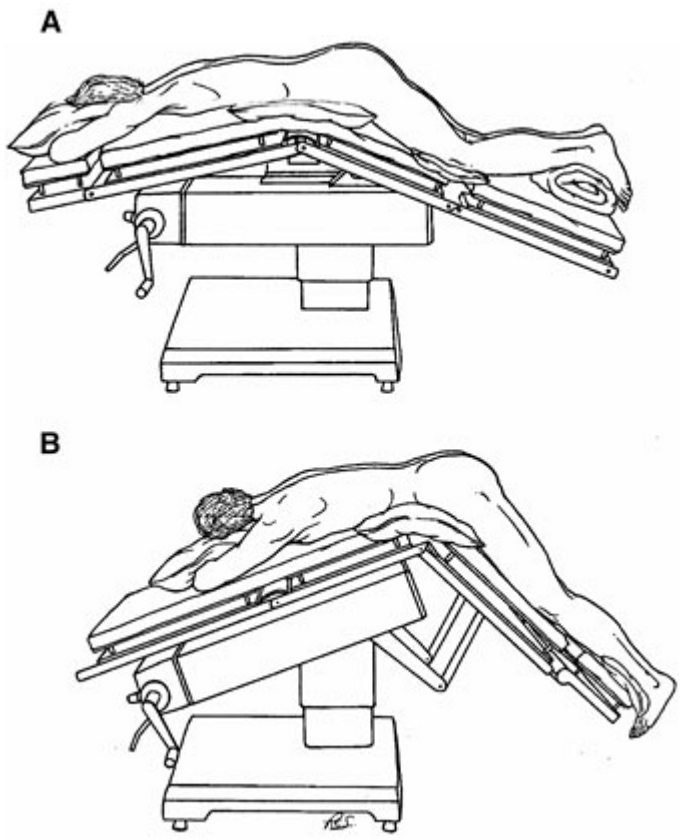

FIGURE 23-18. The prone jackknife positions. **A.** Low jackknife position with the trunk–thigh hinge of the table used as the flexion position and augmented by a pillow under the pelvis. **B.** Full jackknife position with the thigh–leg hinge of the table used as the flexion point to achieve more acute angulation of the hips on the torso. (Reproduced with permission from Figure 10-14 & 10-15, (p. 163 & 164) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Prone Kneeling

Kneeling positions have been used to improve operative conditions in the lumbar and cervicooccipital areas (Fig. 23-19).

Numerous frames have been constructed to support the weight of a kneeling patient, and their

usefulness again depends on local use and the physique of the patient. If the vertebral column is unstable, kneeling frames are not as useful as parallel longitudinal supports because kneeling risks application of shearing forces at the fracture site, with the potential for damage of the contents of the spinal canal. In massively obese patients who must be operated on in the prone position, kneeling frames tend to prevent pressure on the abdomen more successfully than longitudinal frames.

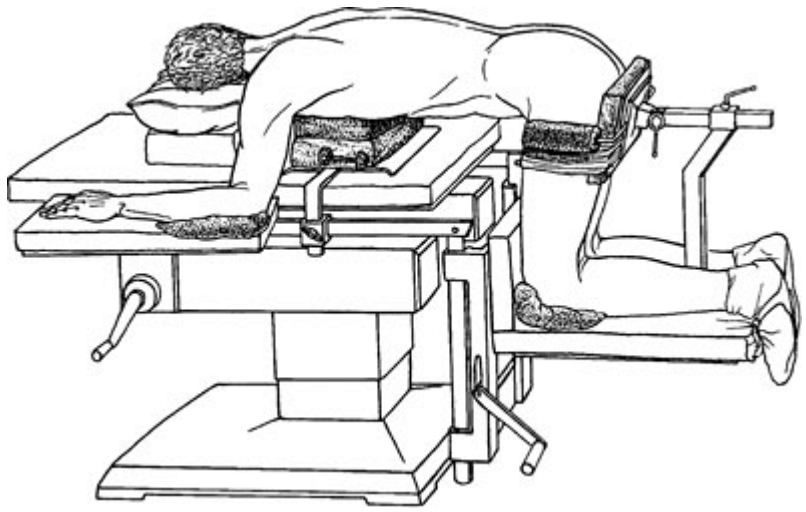

FIGURE 23-19. The Andrews kneeling frame with Wiltse's thoracic jack in use. (Reproduced with permission from Figure 10-9, (p. 161) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Complications of the Ventral Decubitus Positions

Eyes and Ears

The eyes and ears may sustain injury in the prone position. The eyelids should be closed, and each eye should be protected in some manner so that the lids cannot be accidentally separated and the cornea scratched. Instillation of lubrication in the eyes should be considered, although the value of this treatment is debated. The eyes should also be protected against the head turning medially after positioning as well as against pressure being exerted on the globe. Monitoring wires and intravenous tubing should be checked after pronation to see that none has migrated beneath the head. If the head is retained in the sagittal plane, the eyes should be checked after positioning to ensure that they are safe from compression by any head rest.

Conjunctival edema usually occurs in the eyes of the pronated patient if the head is at or below the level of the heart. It is usually transient, inconsequential, and requires only reestablishment of the normal tissue perfusion gradients of the supine position, or of a slight amount of head-up tilt, to be redistributed.

7 **Blindness.** Permanent loss of vision can occur after nonocular surgical procedures, especially those performed in a ventral decubitus position.[74-89] The occurrence of this devastating complication is particularly associated with extensive surgical procedures done in the prone position, such as reconstructive spine surgery, where there is associated blood loss, anemia, and hypotension. Visual loss after neurovascular and cardiopulmonary bypass procedures is well recognized and may be related to embolic events produced by the surgical intervention itself, hypoperfusion, or other nonpositioning causes.[90-93] Visual loss after noncardiac, nonneurovascular procedures may initially be noticed by a loss of acuity, a loss of visual field, or both.

Speculated causes of significant permanent postoperative visual loss usually involve compromise of oxygen delivery to elements of the visual pathway and include ischemic optic neuropathy

(anterior or posterior), retinal artery occlusion (central or branch), and cortical blindness.[94] No case series exist to provide information regarding the frequency of these events after nonocular, noncardiac surgery in a general surgical population. Roth et al[76] surveyed approximately 61,000 patients undergoing nonocular surgery (including cardiac surgery) over a 4-year period and identified 34 ocular injuries (mostly corneal abrasions), including one case of permanent postoperative visual loss from ischemic optic neuropathy after lumbar spinal fusion. In a review of 3,450 spinal surgeries, Stevens et al[82] identified three patients who had permanent postoperative visual loss. Brown et al[95] identified three patients in whom postoperative ischemic optic neuropathy developed after noncardiac surgery over a 10-year period in one institution. Warner et al[96] noted none of nearly 11,000 prone-positioned patients developed perioperative vision loss. However, these authors subsequently have experienced several patients who have developed complete blindness after spinal surgery performed with patients positioned prone. Reflecting concern about the apparent increased incidence of perioperative blindness, the American Society of Anesthesiologists, Committee on Professional Liability, has created a formal registry to monitor and document the incidence of this complication (see http://www.asahq.org).

Positioning appears to be a risk factor for some of these events. Studies noting a relative high frequency of postoperative visual loss in spinal surgery patients have implicated positioning as one causative factor.[77,78,79,80,83,92] Use of the knee–chest position,[77] the prone position,[78,83,97] and the horseshoe head rest[79] have been cited as potential causes of visual loss, perhaps

by direct pressure on the globe increasing the intraocular pressure beyond the perfusion pressure of the retina. Other reports, including those of spinal surgery patients, describe visual loss after prolonged procedures, intraoperative hypotension, and massive blood loss,[74,75,76,81,82] which may prevent adequate oxygen delivery to the visual apparatus. For example, all patients with ischemic optic neuropathy in the series of Brown et al[95] experienced periods of significant anemia (hemoglobin concentration <8 g/dL) and intraoperative hypotension. It is possible that venous congestion and edema in the head associated with the prone position may be a contributing factor.

Neck Problems

Anesthesia impairs reflex muscle spasm that protects the skeleton against motion that would be painful if the patient were alert. Lateral rotation of the head and neck of an anesthetized, pronated patient, particularly one with an arthritic cervical spine, can stretch relaxed skeletal muscles and ligaments and injure articulations of cervical vertebrae. Postoperative neck pain and limitation of motion can result. The arthritic neck is usually best managed by keeping the head in the sagittal plane when the patient is prone.

Extremes of head and neck rotation can also interfere with flow in either the ipsilateral or contralateral vessels to and from the head. Excessive head rotation can reduce flow in both the carotid[98] and vertebral systems.[99] Impaired cerebral perfusion is the obvious consequence.

Brachial Plexus Injuries

Stretch injuries to the roots of the brachial plexus (Fig. 23-20A) on the side contralateral to the turned face are possible if the contralateral shoulder is held firmly caudad by a wrist restraint. If an arm is placed on an arm board alongside the head, care must be taken to ensure that the head of the humerus is not stretching and compressing the axillary neurovascular bundle (see Fig. 23-20B,C).

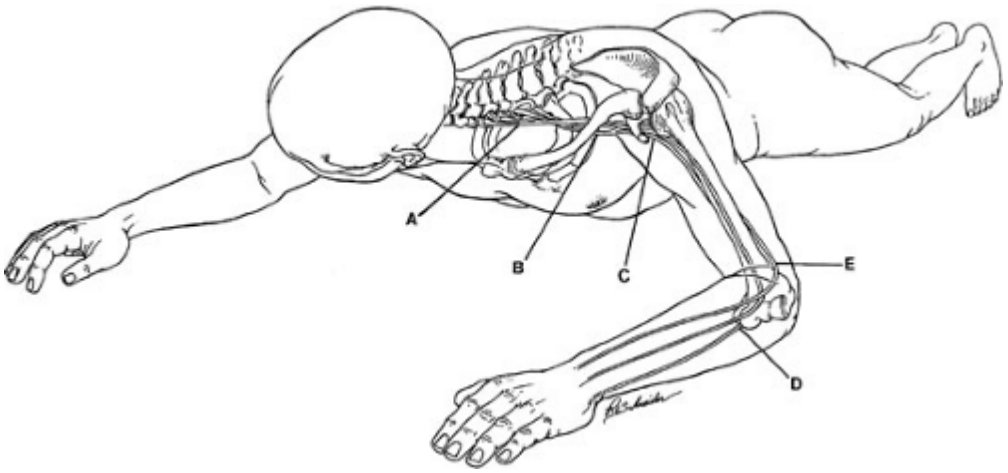

FIGURE 23-20. Sources of potential injury to the brachial plexus and its peripheral components when the patient is in the prone position. **A.** Neck rotation, stretching roots of the plexus. **B.** Compression of the plexus and vessels between the clavicle and first rib. **C.** Injury to the axillary neurovascular bundle from the head of the humerus. **D.** Compression of the ulnar nerve before, beyond, and within the cubital tunnel. **E.** Area of vulnerability of the radial nerve to lateral compression proximal to the elbow. (Reproduced with permission from Figure 10-29, (p. 185) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

When an arm is placed on an arm board alongside the head, the forearm naturally pronates. As a result, the ulnar nerve, lying in the cubital tunnel (the groove between the olecranon process and the medial epicondyle of the humerus), is vulnerable to being compressed by the weight of the elbow (see Fig. 23-20D). Consequently, the medial aspect of the elbow must be well padded and its weight borne principally on the medial epicondyle.

Asking patients about their ability to work or sleep with arms elevated overhead may identify patients with *thoracic outlet obstruction*.[66] A useful preoperative test if the history is in question is to have the patient clasp hands behind the occiput during the interview (Fig. 23-21). If the patient describes dysesthesias, it may be prudent to keep the arms alongside the trunk in the prone position. Agonizing, debilitating, and unremitting postoperative pain has been known to follow overhead arm placement in pronated patients who have had prior discomfort in their arms in that position.[66]

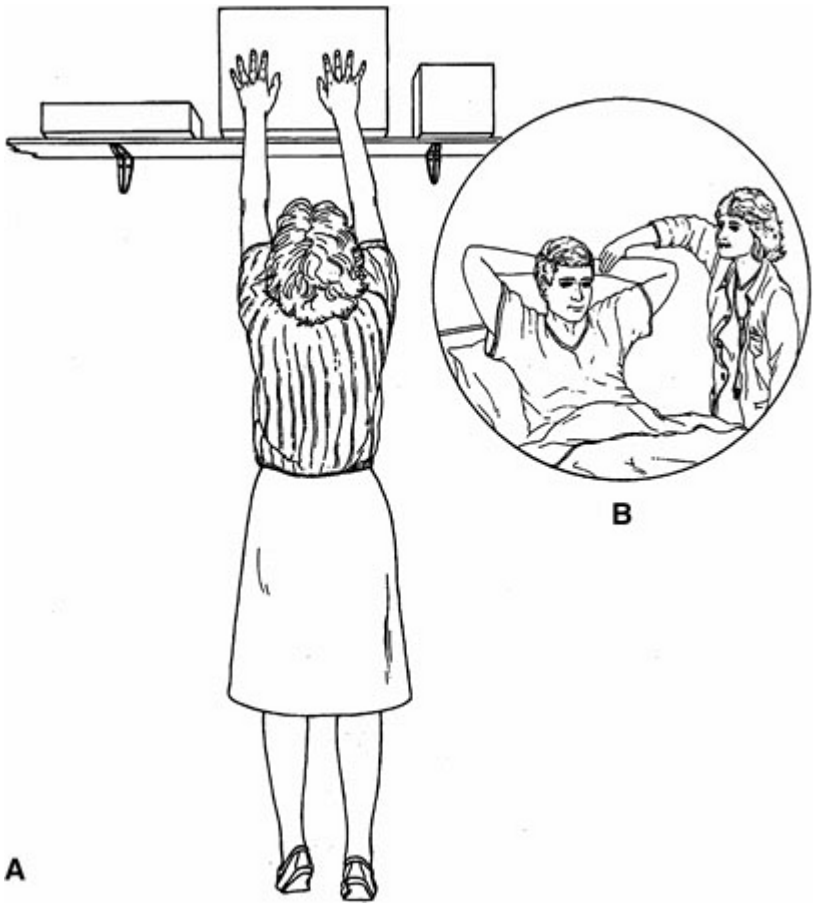

FIGURE 23-21. Assessment of a potential thoracic outlet syndrome. **A.** The patient has a history of distress when trying to work or sleep with arms over head. **B.** Interview was carried out with patient's hands clasped on occiput and radial pulses checked for damping. (Reproduced with permission from Figure 10-30, (p. 186) of McLeskey CH [ed]: Geriatric Anesthesiology. Baltimore, Williams & Wilkins, 1997.)

Breast Injuries

The breasts of a pronated woman, if forced laterally by ventral chest supports, can be stretched and injured along their sternal borders. Medial and cephalad displacement seems better

tolerated. Direct pressure on breasts (particularly if breast prostheses are present) can cause ischemia to breast tissue and should be avoided.

Abdominal Compression

Compression of the abdomen by the weight of the prone patient's trunk can cause viscera to force the diaphragm cephalad enough to impair ventilation. If intra-abdominal pressure approaches or exceeds venous pressure, return of blood from the pelvis and lower extremities is reduced or obstructed. Because the vertebral venous plexuses communicate directly with the abdominal veins, increased intra-abdominal pressure is transmitted to the perivertebral and intraspinal surgical field in the form of venous distention and increased difficulty with hemostasis. All of the various supportive pads and frames, when properly used, are designed to remove pressure from the abdomen and avoid these problems.[66]

Viscerocutaneous Stomata

Stomata that drain visceral contents into containers affixed to the abdominal wall are at risk in

the prone position if they lie against a part of the ventral supporting frame or pad (Fig. 23-22). Compressive ischemia of the stomal orifice can cause it to slough.

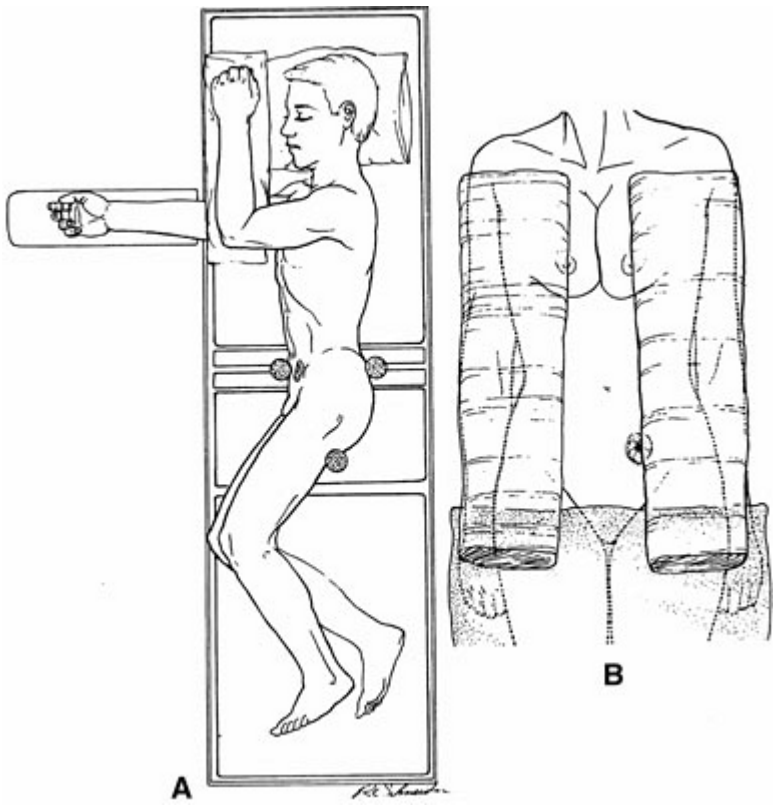

FIGURE 23-22. Postural supports compromising visceral stoma. Both the vertical abdominal support of a device designed to maintain a patient in the lateral position **(A)** and the longitudinal chest rolls supporting a pronated patient **(B)** can cause ischemic compression of a viscerocutaneous anastomosis and subsequent necrosis. Surgical repair of the stoma may be needed. (Modified with permission from Figure 22-18, (p. 340) of McLeskey CH [ed]: Geriatric Anesthesiology. Baltimore, Williams & Wilkins, 1997.)

Knee Injuries

Obese patients, or those who have pathologic conditions of the knees, can have their knee joints injured in the kneeling position if the supportive ledges are not heavily padded (see Fig. 23-19). Often there is no suitable alternative position for these patients, and the possibility of postoperative knee problems caused by the kneeling prone position should be carefully discussed in the preanesthetic interview.

HEAD-ELEVATED POSITIONS

Physiology

Circulatory

Coonan and Hope[100] have reviewed circulatory changes that occur in alert humans with the change from the supine to the erect position. As the head is raised above the level of the heart, pressure gradients develop and increase with the degree of elevation. Blood shifts from the upper body toward the feet. Atrial filling pressures decrease, sympathetic tone increases, parasympathetic tone decreases, the renin-angiotensin-aldosterone system is activated, and fluid and electrolytes are retained by the kidneys.[101,102] Albin et al[103,104] and Dalrymple[105] noted similar alterations in cardiovascular parameters when the head-elevated position was established after patients were

anesthetized. Although significant changes were not encountered with less than 60 degrees of head-up tilt, the magnitude of changes in anesthetized patients was often greater than in the awake patients.

The presence of an intracranial pathologic process can be expected to exacerbate potentially harmful reductions in cerebral blood flow associated with head elevation.[106] In the anesthetized, seated patient, mean arterial pressure should be measured at the level of the circle of Willis because that site is more reliable as an indicator of cerebral perfusion pressure in the head-elevated posture than is measurement at the level of the arm or wrist.[100] Additional information regarding the neurosurgical implications of the head-elevated (sitting) position appear in Chapter 27.

Respiratory

As the patient becomes more upright in the head-elevated dorsal decubitus position, the inspiratory stroke of the diaphragm becomes less impeded by the bulk of abdominal viscera. Spontaneous chest wall motion requires less effort, and less pressure is needed to inflate the lungs during passive inspiration. Functional residual capacity increases in the head-elevated positions.[107]

Variations of the Head-Elevated Positions

Sitting

The classic *sitting position* for surgery places the patient in a semireclining posture on an operating table, with the legs elevated to approximately the level of the heart and the head flexed ventrally on the neck (Fig. 23-23). Head flexion should not be sufficient to force the chin into the suprasternal notch (see Midcervical Tetraplegia section). Elastic stockings or compressive wraps around the legs reduce pooling of blood in the lower extremities. The head often is held in place by some type of a face rest or by a three-pin skull fixation frame.

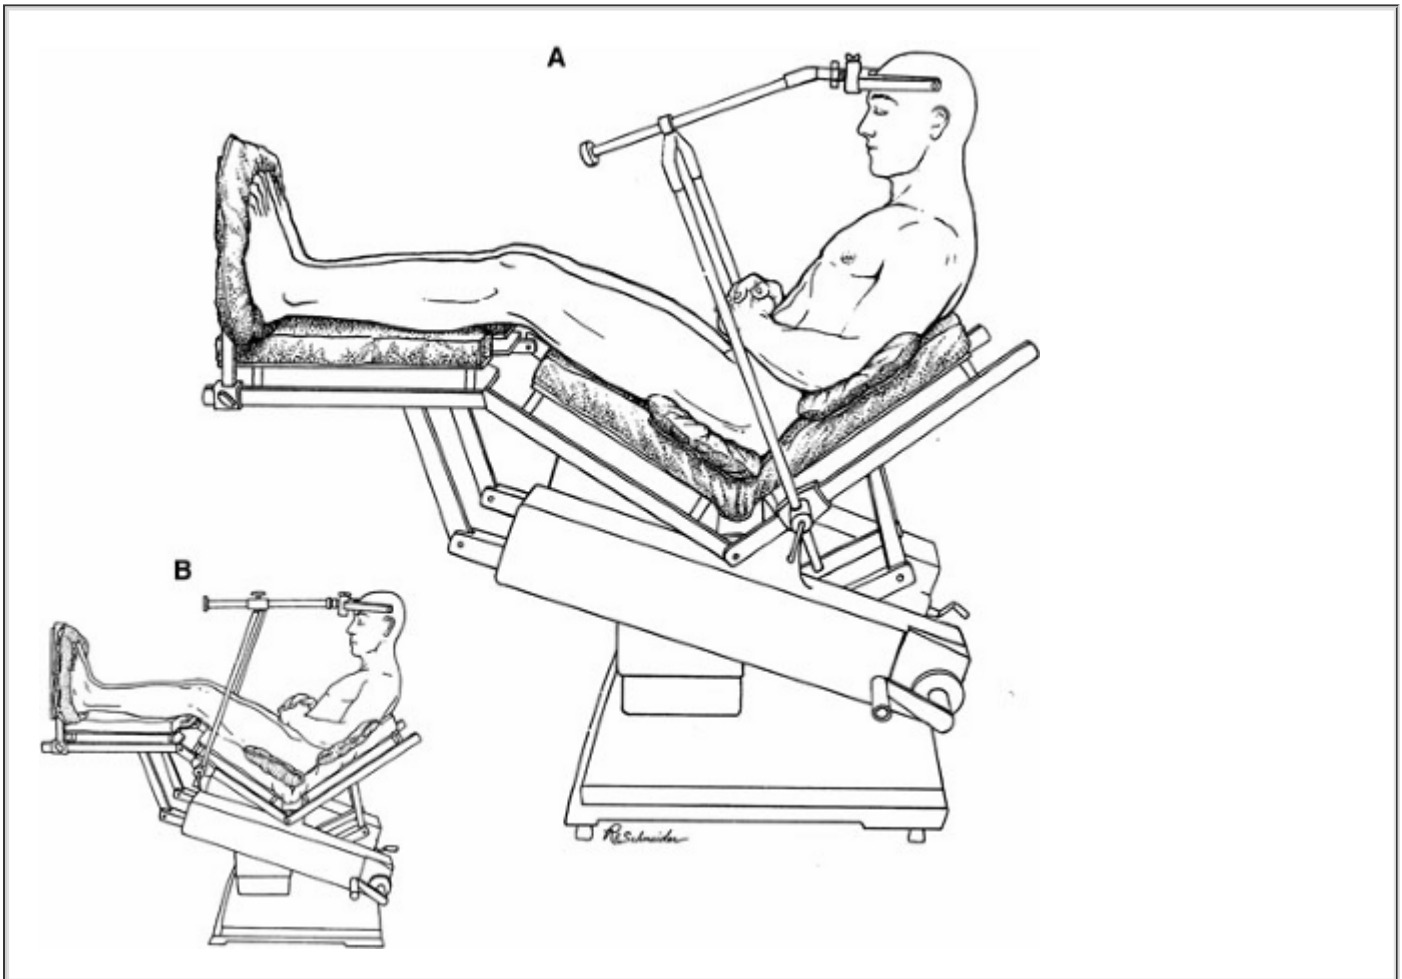

FIGURE 23-23. A. Conventional neurosurgical sitting position. The legs are at approximately the level of the heart and gently flexed on the thighs; the feet are supported at right angles to the legs; subgluteal padding protects the sciatic nerve. The frame of the head holder is *properly* clamped to the side rails of the back section in the event of hemodynamically significant air embolism. **B.** *Improper* attachment of the head frame to the table side rails at the thigh section. In this position, the patient's head could not be quickly lowered because it would require disengaging the skull clamp. (Reproduced with permission from Figure 7-1, (p. 72) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Supine—Tilted Head Up

A dorsal recumbent position with the head of the patient elevated is used for many operations involving the ventral and lateral aspects of the head (Fig. 23-24) and neck, and occasionally with the neck flexed, for transcranial access to the top of the brain. Its purpose is to improve access to the surgical target

for the operating team as well as to drain blood and irrigation solutions away from the wound. The back section of the surgical table can be elevated as needed to produce a low sitting position (see Fig. 23-24A), or the entire table can be rotated head-high with the patient's extended legs supported by a foot rest (see Fig. 23-24B). Although the degree of tilt typically is not great, small pressure gradients are created along the vascular axis that can pool blood in the lower extremities or entrain air in patulous vessels that are incised above the level of the heart.

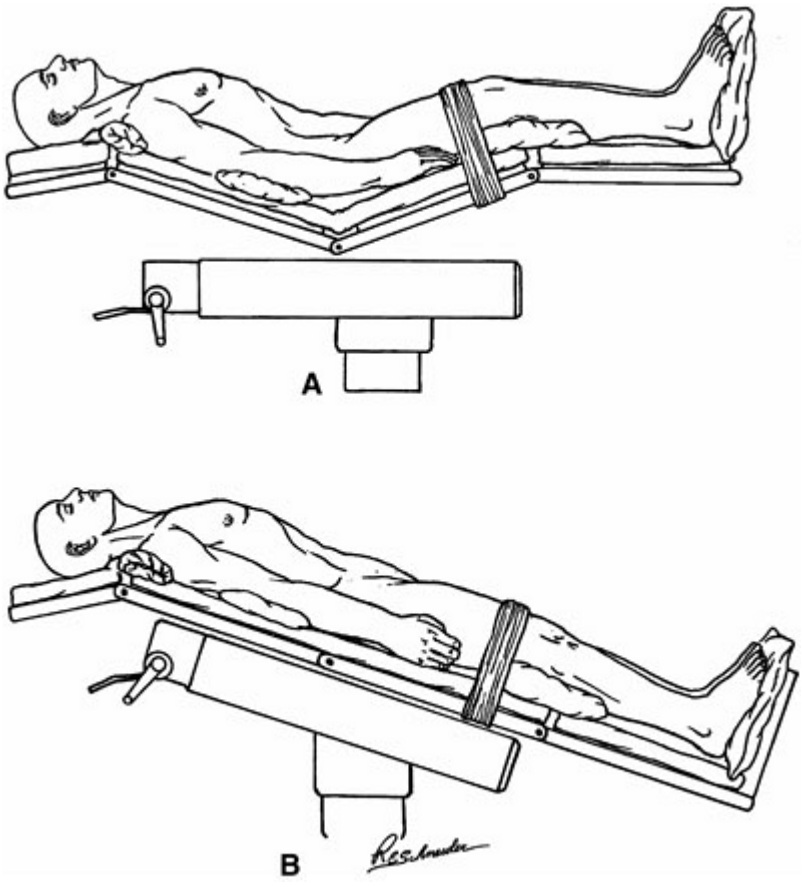

FIGURE 23-24. Head-elevated positions often used for operations about the ventral and ventrolateral aspects of the head, face, neck, and cervical spine. **A.** The legs are at approximately heart level and the gradient into the head is appreciable but slight. **B.** The flat

table and foot rest are useful when a thyroidectomy is planned under regional anesthesia. (Reproduced with permission from Figure 7-7, (p. 89) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

For operations around the shoulder joint, the patient may be placed in a head-elevated semisupine position, with the upper torso rotated toward the nonsurgical shoulder and supported by a firm roll or pad (Fig. 23-25). The upper trunk is moved laterally until the raised surgical shoulder extends beyond the edge of the operating table. The torso is supported so that the hips are on the table, the surgical shoulder is off and above the table edge, and the head rests on either a pillow (see Fig. 23-25A) or a horseshoe head rest (see Fig. 23-25B). Access is thereby provided to both the dorsal and ventral aspects of the shoulder girdle. The surgical arm remains on the ventral torso and is prepared and draped to be mobile in the surgical field.

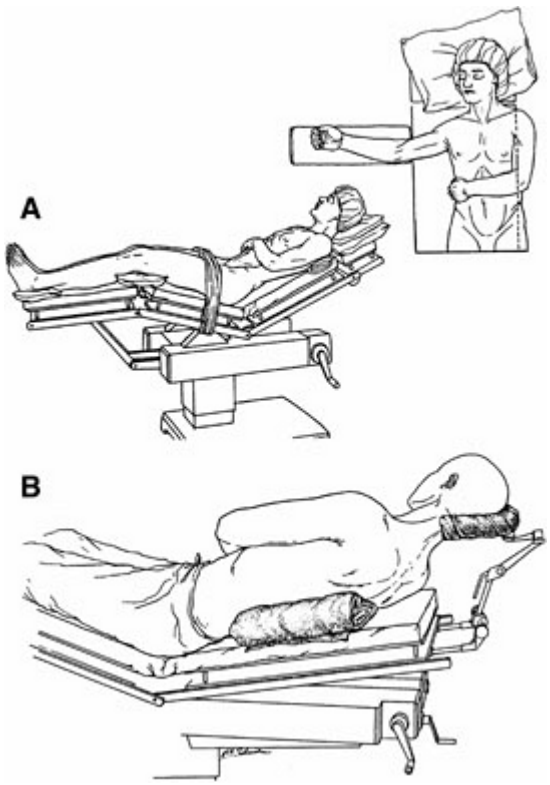

FIGURE 23-25. A. The barber chair position for surgery around the shoulder joint. **B.** The upper torso is rotated toward the nonsurgical shoulder and supported with a firm roll or pad.

Lateral—Tilted Head Up

The lateral decubitus position with the head somewhat elevated, a means of access to occipitocervical lesions, has also been referred to as the *park bench position*.[108] All the stabilizing requirements needed for the usual lateral decubitus position apply. The head may be held firmly in a three-pin skull fixation holder, which can be readjusted as needed during surgery, or supported by pillows or padding. Although the degree of head elevation used typically is less than 15 degrees, the position does not completely remove the threat of air embolization. The anesthesiologist has good access to the patient's face and ventral thorax for purposes of monitoring, manipulation,

and resuscitation. Considerable attention should be directed to avoiding compression of neck

veins, which can lead to an increase in intracranial pressure and to edema of the tongue.

Prone—Tilted Head Up

The ventral decubitus posture with the table rotated head high (Fig. 23-26) can be used to access dorsal structures of the head and neck. Usually the perceived advantage of this position compared to a sitting position is the avoidance of air embolization. Although the pressure gradients for air entrainment into patulous veins are less than in the full sitting position, the hazard is not eliminated. As a result of the positive-pressure inflation cycle of passive ventilation, a bothersome recurrent flux of cerebrospinal fluid into and out of the exposed wound may be encountered. The posture also restricts resuscitative access to the ventral thorax.

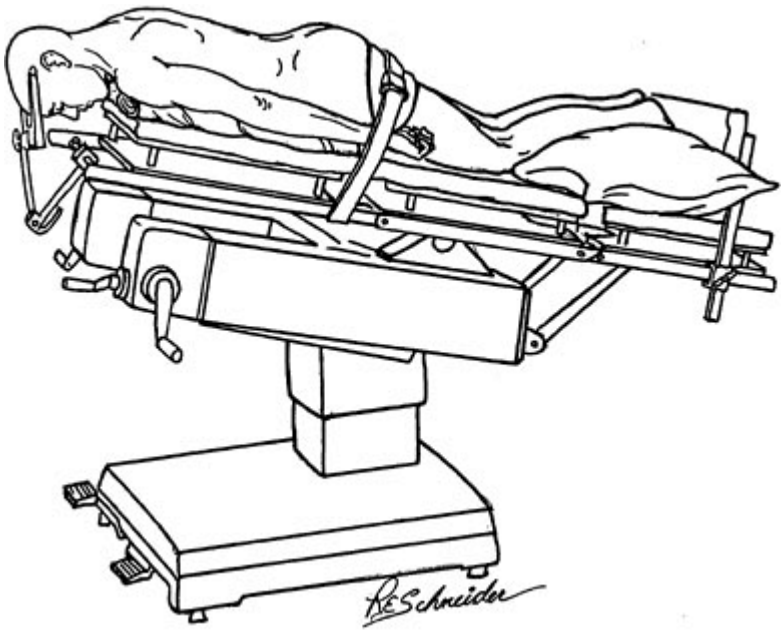

FIGURE 23-26. The skull-pin head rest used to stabilize a patient in the head-elevated prone position. Note the chest rolls used to free the abdomen from compression and the gluteal strap to minimize caudad slippage after head-up tilt. (Reproduced with permission from Figure 7-6, (p. 88) of Martin JT, Warner MA [eds]: Positioning in Anesthesia and Surgery, 3rd ed. Philadelphia, WB Saunders, 1997.)

Complications of the Head-Elevated Positions

Postural Hypotension

In the anesthetized patient, establishing any of the head-elevated positions is frequently accompanied by some degree of reduction in systemic blood pressure. The normal protective reflexes are inhibited by drugs used during anesthesia. Measuring mean arterial pressures at the level of the circle of Willis is recommended to assess cerebral perfusion pressures more accurately.

Air Embolus

Air embolization is potentially lethal. In the bloodstream, air migrates to the heart, where it creates a compressible foam that destroys the propulsive efficiency of ventricular contraction and irritates the conduction system. Air can also move into the pulmonary vasculature, where bubbles obstruct small vessels and compromise gas exchange, or it can cross through a patent foramen ovale to the left side of the heart and the systemic circulation.

The potential for venous air embolization increases with the degree of elevation of the operative site above the heart. Although the occurrence of air emboli is a relatively frequent phenomenon in head-elevated positions, most of the emboli are small in volume, clinically silent, and recognizable only by sophisticated Doppler detection techniques. Nevertheless, the potential for continuing, dangerous accumulations of entrained air requires immediate detection of the embolization, a careful search for its portal of entry, and prompt treatment of its clinical effects.

Pneumocephalus

In the usual craniotomy, most of the brain lies subjacent to the incision. After the dura is incised, cerebrospinal fluid is removed to improve working conditions, and the surgical field is open to the air. During closure of the craniotomy, most of the intracranial air escapes from the wound and any residual pneumocephalus is of little consequence. However, when an incision is made through the dura in the posterior fossa or cervical spine of a seated patient, the bulk of the brain lies above the incision. Cerebrospinal fluid drains downward out of the wound, and tissue retraction can allow air to bubble up over the surfaces of the brain to become trapped in the upper reaches of the cranium.[109] When brain mass is decreased by ventricular drainage, steroids, and diuresis, the space available to a pneumocephalus is enlarged. Diffusion of nitrous oxide into the accumulated air, or the warming of trapped gas, can produce a tension pneumocephalus with signs of increased intracranial pressure and delayed awakening from anesthesia.

Toung et al[110] found postoperative pneumocephalus in all of a group of seated patients and in most of those who had been in the prone or the park bench position. Intraventricular air was present in most of the seated patients and was rare in those in the other positions. None of their group of 100 patients had neurologic changes attributable to the trapped intracranial air. Standefer et al[111] reported a 3% incidence of symptomatic (tension) pneumocephalus in seated, anesthetized patients whose duras were opened.

TABLE 23-1 Summary of Task Force Consensus

Preoperative assessment: When judged appropriate, it is helpful to ascertain that patients can comfortably tolerate the anticipated operative position.
Upper Extremity Positioning:
• Arm abduction should be limited to 90 degrees or less in supine patients. Patients who are positioned prone may comfortably tolerate arm abduction of 90 degrees or more. • Arms should be positioned to decrease pressure on the postcondylar groove of the humerus (ulnar groove). When arms are tucked at the side, a neutral forearm position is recommended. When arms are abducted on arm boards, either supination or a neutral forearm position is acceptable. • Prolonged pressure on the radial nerve in the spiral groove of the humerus should be avoided. • Extension of the elbow beyond a comfortable range may stretch the median nerve.
Lower Extremity Positioning:
• Lithotomy positions that stretch the hamstring muscle group beyond a comfortable range may stretch the sciatic nerve.

- Prolonged pressure on the peroneal nerve at the fibular head should be avoided.
- Neither extension nor flexion of the hip increases the risk of femoral neuropathy.

Protective Padding:

- Padded armboards may decrease the risk of upper extremity neuropathy.
- The use of chest rolls in laterally positioned patients may decrease the risk of upper extremity neuropathies.
- Padding at the elbow and at the fibular head may decrease the risk of upper and lower extremity neuropathies, respectively.

Equipment:

- Properly functioning automated blood pressure cuffs on the upper arms do not affect the risk of upper extremity neuropathies.
- Shoulder braces in steep head-down positions may increase the risk of brachial plexus neuropathies.

Postoperative Assessment: A simple postoperative assessment of extremity nerve function may lead to early recognition of peripheral neuropathies.

Documentation: Charting specific positioning actions during the care of patients may result in improvements of care by (1) helping practitioners focus attention on relevant aspects of patient positioning and (2) providing information that continuous improvement processes can use to lead to refinements in patient care.

Ocular Compression

Pressure from a padded head rest on the eyes of a patient who has been placed in a head-elevated position can dislocate a crystalline lens or render the globe ischemic. Unilateral blindness has been reported as a result (see Blindness section).[112] Modern skull-pin head clamps that grip firmly when properly applied have made ocular compression in the sitting position a rarity. In the head-elevated lateral decubitus or prone position, the threats to the eyes are those described in the preceding discussions of those nonelevated postures.

Edema of the Face, Tongue, and Neck

Severe postoperative macroglossia, apparently because of venous and lymphatic obstruction, can be caused by prolonged, marked neck flexion.[113] Try to avoid placing the patient's chin firmly against the chest and use of an oral airway to protect the endotracheal tube. Ellis et al[114] reported a patient who needed a tracheostomy because of massive swelling of the tongue, lips, pharynx, and epiglottis occurring shortly after extubation at the end of a lengthy anesthetic in the sitting position that involved deliberate hypotension. Extremes of neck flexion, with or without head rotation, have been widely used to gain access to structures in the posterior fossa and cervical spine, but their potential for damage should be understood and excessive flexion–rotation avoided if possible. Moore and associates[115] have described five cases of macroglossia in patients with posterior fossa disease and have suggested that the primary mechanism is neurologically determined rather than being the result of either vascular obstruction or local trauma. This

problem also has been described with the use of transesophogeal echocardiography probes.

Midcervical Tetraplegia

This devastating injury occurs after hyperflexion of the neck, with or without rotation of the head, and is attributed to stretching of the spinal cord with resulting compromise of its vasculature in the midcervical area. An element of spondylosis or a spondylotic bar may be involved.[116,117] The result is paralysis below the general level of the fifth cervical vertebra. Although most reports in the literature have described the condition as occurring after the use of the sitting position, midcervical tetraplegia has also occurred after prolonged, nonforced head flexion for intracranial surgery in the supine position.

Sciatic Nerve

Stretch injuries of the sciatic nerve can occur in some seated patients if the hips are markedly flexed without bending the knees. Prolonged compression of the sciatic nerve as it emerges from the pelvis is possible in a thin, seated patient if the buttocks are not suitably padded. Foot drop may be the result of injuries to either the sciatic nerve or the common peroneal nerve and can be bilateral.

PERIOPERATIVE PERIPHERAL NEUROPATHIES

Prevention

The American Society of Anesthesiologists approved an advisory on peripheral neuropathies in 1999.[118] This advisory includes pertinent literature and a summary of the opinions of anesthesia providers on a variety of positioning and

peripheral neuropathy issues. The paucity of literature related to these issues limited the advisory to recommendations based on opinions and current practices of a broadly representative group of anesthesia providers from around the United States. Additional input and opinions were obtained from consultants from around the world. A summary of the findings of the advisory is shown in Table 23-1.

Practical Considerations

Efforts to prevent perioperative neuropathies are frequently debated, and there often is confusion over how to manage a neuropathy once it has occurred. In general, there are no data to support recommendations on any of these issues. Therefore, the following opinions have been formulated by personal experience, guided by advice from neurologists who primarily care for patients with peripheral neuropathies, and seasoned or supported by speculation derived from anecdotal case reports.

Padding-Exposed Peripheral Nerves

Many types of padding materials are advocated to protect exposed peripheral nerves. They often consist of cloth (e.g., blankets and towels), foam sponges (e.g., “eggcrate” foam), and gel pads. There are no data to suggest that any of these materials is more effective than any other, or that any is better than no padding at all. A good rule of thumb would be to position and pad exposed peripheral nerves to (1) prevent their stretch beyond normally tolerated limits while awake; (2) avoid their direct compression, if possible; and (3) distribute over as large an area as possible any compressive forces that must be placed on them.

Prolonged Duration in One Position

Prolonged duration in one position appears to increase the risk of neuropathy and other integumentary damage. For example, prolonged duration in lithotomy positions greatly increases the risk of lower extremity neuropathy.[119,120] When possible, it would appear prudent to limit as

much as practical the time any patient spends in one position. However, intermittent movement of the limbs or head during the intraoperative period may increase the opportunity for a number of different problems, including but not limited to dislodging an endotracheal tube, abrading a cornea, or moving an extremity into a suboptimal position. Practitioners must judge the benefits versus risks of any intraoperative changes in a patient's position.

Course of Action for the Patient with a Neuropathy

Although each situation is unique and requires careful assessment, the following guidelines may suggest a basic course of action that will lead to appropriate care: [121]

8 Is the neuropathy sensory or motor? Sensory lesions are more frequently transient than motor lesions. If the symptoms are numbness or tingling only, it may be appropriate to inform the patient that many of these neuropathies can be expected to resolve during the first 5 days.[39] The patient should be instructed to avoid postures that might compress or stretch the involved nerve. Arrangements should be made for frequent contact with the patient. A call to alert a neurologist is appropriate, and if the symptoms still persist on postoperative day 5, the neurologist should be consulted.

- If the neuropathy has a motor component, a neurologist should be consulted immediately. Electromyographic studies may be needed to assess the location of any acute lesion. This knowledge may direct an appropriate treatment plan. The studies may also demonstrate chronic abnormalities of the nerve or, if applicable, the contralateral nerve.

Chapter 24

Monitoring the Anesthetized Patient

Glenn S. Murphy

Jeffery S. Vender

KEY POINTS

1	Effective monitoring reduces the potential for adverse outcomes in the perioperative setting by identifying derangements before they result in serious injury.
2	Alterations in ventilation, cardiac output, distribution of pulmonary blood flow, and metabolic activity can all influence the capnograph display during carbon dioxide gas analysis.
3	During direct invasive arterial pressure monitoring, systemic fidelity is optimized when the catheter and tubing are stiff, the mass of the fluid is small, and the length of the connecting tubing is not excessive.
4	On the basis of available evidence, it is difficult to draw meaningful conclusions regarding the effectiveness of pulmonary artery catheter monitoring in reducing morbidity and mortality in critically ill patients. Expert opinion suggests that perioperative complications may be reduced if pulmonary artery catheters (PACs) are used in the appropriate patients and settings, and if clinicians interpret and apply the data provided by the PAC correctly.
5	Transesophageal echocardiography provides a more accurate estimation of ventricular preload than pulmonary artery catheterization. Transesophageal echocardiography also allows the clinician to rapidly assess patients for evidence of myocardial ischemia, cardiac valvular dysfunction, and causes of perioperative hemodynamic instability.

Monitoring represents the process by which anesthesiologists recognize and evaluate potential physiologic problems in a timely manner. The term is derived from *monere*, which in Latin means to warn, remind, or admonish. In perioperative care, monitoring implies the following four essential features: observation and vigilance, instrumentation, interpretation of data, and initiation of corrective therapy when indicated.

1 Monitoring is an essential aspect of anesthesia care. Patient safety is enhanced when appropriate monitoring is operational and clinical judgments are proper. Effective monitoring reduces the potential for poor outcomes that may follow anesthesia by identifying derangements

before they result in serious or irreversible injury. Electronic monitors improve a physician's ability to respond because they are able to make repetitive measurements at higher frequencies than humans and do not fatigue or become distracted. Monitoring devices increase the specificity and precision of clinical judgments. At no time in the history of anesthesia have practitioners had the capability routinely to monitor so many diverse physiologic variables in real time, often noninvasively, as they do today. Our understanding of the physiologic effects of anesthesia and its inherent risks is enhanced by using appropriate intraoperative physiologic monitoring.

This chapter discusses the methods by which anesthesiologists monitor organ function during anesthesia care. The descriptions of the technologic and scientific principles used in monitoring devices have been simplified for clarity.

Cost containment has been raised as a reason to discourage the use of expensive, technologically advanced monitoring systems. The value of a given monitor depends on the clinical expertise of the anesthesiologist, the clinical setting, the anesthetic technique, and the performance of the specific equipment in question. Monitoring devices should not be denied solely on the basis of expense.[1] Although it is appropriate for society to demand cost containment, anesthesiologists have a responsibility to assess how monitoring should be used. Professional societies, regulatory agencies, and the legal profession have played important roles in establishing current monitoring practices.

Standards for basic anesthetic monitoring have been established by the American Society of Anesthesiologists (ASA).

Since 1986, these standards have emphasized the evolution of technology and practice. Today's standards (last affirmed on October 15, 2003) emphasize the importance of regular and frequent measurements, integration of clinical judgment and experience, and the potential for extenuating circumstances that can influence the applicability or accuracy of monitoring systems.[2]

Standard I requires qualified personnel to be present in the operating room, to monitor the patient continuously and modify anesthesia care based on clinical observations and the responses of the patient to dynamic changes resulting from surgery or drug therapy. Standard II focuses attention on continually evaluating the patient's oxygenation, ventilation, circulation, and temperature. Standard II specifically mandates the following:

1. Using an oxygen analyzer with a low concentration limit alarm during general anesthesia.
2. Quantitatively assessing blood oxygenation during any anesthesia care.
3. Continuously ensuring the adequacy of ventilation by physical diagnostic techniques during all anesthesia care. Quantitative monitoring of tidal volume and capnography are encouraged in patients undergoing general anesthesia.
4. Ensuring the adequacy of circulation by the continuous display of the electrocardiogram (ECG), and determining the arterial blood pressure at least at 5-minute intervals. During general anesthesia, circulatory function is to be continually evaluated by assessing the quality of the pulse, either electronically or by palpation or auscultation.
5. Endotracheal intubation or laryngeal mask airway insertion requires qualitative identification of carbon dioxide in the expired gas. During general anesthesia, capnography and end-tidal carbon dioxide analysis are encouraged.
6. During all anesthetics, the means for continuously measuring the patient's temperature must be available. When changes in body temperature are intended or anticipated, temperature should be continuously measured and recorded on the anesthesia record.

The ASA standards emphasize the melding of physical signs with instrumentation. Electronic monitoring, no matter how sophisticated or comprehensive, does not necessarily reduce the need for clinical skills such as inspection, palpation, and auscultation. Although the authors believe that

electronic monitors augment clinical judgments when properly used, there is little evidence that electronic monitors, by themselves, reduce mortality or morbidity. Moreover, there is considerable controversy regarding the need to apply specific monitors in unique clinical situations, particularly those that may add significant cost. Monitoring can be classified as invasive, minimally invasive, or noninvasive. Invasive monitors place patients at risk for complications related to their application and use. Anesthesiologists must balance the potential risk of instituting invasive monitoring with the presumed benefits derived from its application.

The variety of devices available for patient monitoring is expansive and changing as advances in biomedical engineering find their way into the marketplace. The Association for the Advancement of Medical Instrumentation has been effective in promoting design guidelines to ensure patient and operator safety and reduce stress and distractions often associated with medical monitoring.[3]

The proliferation of alarm tones during anesthesia care can be disturbing and may paradoxically impair clinical vigilance. Monitoring systems may be insufficiently sensitive to reject errors. During routine anesthesia care, a minimum of five alarms (inspired oxygen, airway pressure, oximetry, blood pressure, and heart rate) should be operational. Unfortunately, spurious warnings occur with high frequency during routine anesthesia monitoring. The integration of alarm signals is an important area in need of continuing evaluation. Loeb[4] reported that anesthesia providers have difficulty in accurately recognizing the source of an alarm tone. Alarm annunciators using unique sound and visual prompts are incorporated into anesthesia equipment. Warning signals for ventilation, oxygenation, drug administration, temperature, and cardiovascular parameters need to be designed so that problem identification is fast, simple, and relevant.

INSPIRATORY AND EXPIRED GAS MONITORING: OXYGEN

The concentration of oxygen in the anesthetic circuit must be measured. Measuring inspired oxygen does not guarantee the adequacy of arterial oxygenation.[5] Gas machine manufacturers place oxygen sensors on the inspired limb of the anesthesia circuit to ensure that hypoxic gas mixtures are never delivered to patients. Oxygen monitors require a fast response time (2 to 10 seconds), accuracy (± pm2%), and stability when exposed to humidity and inhalation agents.

Paramagnetic Oxygen Analysis

Oxygen is a highly paramagnetic gas. Paramagnetic gases are attracted to magnetic energy because of unpaired electrons in their outer shell orbits. Differential paramagnetic oximetry has been incorporated into a variety of operating room monitors. These instruments detect the change in sample line pressure resulting from the attraction of oxygen by switched magnetic fields. Signal changes during electromagnetic switching correlate with the oxygen concentration in the sample line.

Galvanic Cell Analyzers

Galvanic cell analyzers meet the performance criteria necessary for operative monitoring. These analyzers measure the current produced when oxygen diffuses across a membrane and is reduced to molecular oxygen at the anode of an electrical circuit. The electron flow (current) is proportional to the partial pressure of oxygen in the fuel cell. Galvanic cell analyzers require regular replacement of the galvanic sensor capsule. In the sensor, the electric potential for the reduction of oxygen results from a chemical reaction. Over time, the reactants require replenishment.[6]

Polarographic Oxygen Analyzers

Polarographic oxygen analyzers are commonly used in anesthesia monitoring. In this electrochemical system, oxygen diffuses through an oxygen-permeable polymeric membrane and participates in the following reaction: $O_2 + 2H_2O + 4e \rightarrow 4\ OH^-$. The current change is proportional to the number of oxygen molecules surrounding the electrode. Polarographic oxygen sensors are versatile and are important components of gas machine oxygen analyzers, blood gas analyzers,

MONITORING OF EXPIRED GASES

Carbon Dioxide

2 Expiratory CO_2 monitoring ($PECO_2$) has evolved as an important physiologic and safety monitor. CO_2 is usually sampled near the endotracheal–gas delivery interface. Alterations in ventilation, cardiac output (CO), distribution of pulmonary blood flow, and metabolic activity influence $PECO_2$ and the capnograph display obtained during quantitative expired gas analysis.

Capnometry is the measurement and numeric representation of the CO_2 concentration during inspiration and expiration. A *capnogram* is a continuous concentration–time display of the CO_2 concentration sampled at a patient's airway during ventilation. *Capnography* is the continuous monitoring of a patient's capnogram. The capnogram is divided into four distinct phases (Fig. 24-1). The first phase (A–B) represents the initial stage of expiration. Gas sampled during this phase occupies the anatomic dead space and is normally devoid of CO_2. At point B, CO_2-containing gas presents itself at the sampling site, and a sharp upstroke (B–C) is seen in the capnogram. The slope of this upstroke is determined by the evenness of ventilation and alveolar emptying. Phase C–D represents the alveolar or expiratory plateau. At this phase of the capnogram, alveolar gas is being sampled. Normally, this part of the waveform is almost horizontal. Point D is the highest CO_2 value and is called the *end-tidal* CO_2 ($ETCO_2$). $ETCO_2$ is the best reflection of the alveolar CO_2 ($PACO_2$). As the patient begins to inspire, fresh gas is entrained and there is a steep downstroke (D–E) back to baseline. Unless rebreathing of CO_2 occurs, the baseline approaches zero.

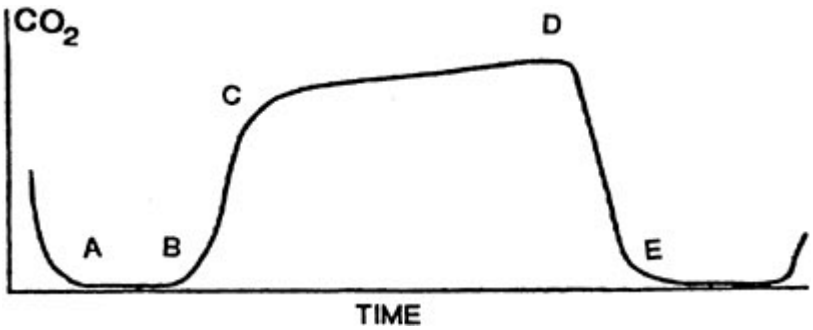

FIGURE 24-1. The normal capnogram. *Point D* delineates the end-tidal CO_2. $ETCO_2$ is the best reflection of the alveolar CO_2 tension.

The utility of capnography depends on an understanding of the relationship between arterial CO_2 ($PaCO_2$), alveolar CO_2 ($PACO_2$), and $ETCO_2$. This concept assumes that ventilation and perfusion are appropriately matched, that CO_2 is easily diffusible across the capillary–alveolar membrane, and that no sampling errors occur during measurement. If these conditions are met, changes in $ETCO_2$ reflect changes in $PaCO_2$ even if it is assumed that all alveoli do not empty at the same time. If one assumes an idealized mathematical model of ventilation–perfusion, $ETCO_2 \approx PACO_2 \approx PaCO_2$. If the $PaCO_2$–$PACO_2$ gradient is constant and small, capnography provides a noninvasive, continuous, real-time reflection of ventilation. During general anesthesia, the $ETCO_2$–$PaCO_2$ gradient typically is 5 to 10 mm Hg. A maldistribution of ventilation and perfusion ($\dot{V}$

/
$\dot{Q}$
) or problems in gas sampling may result in a widening of the $ETCO_2$–$PaCO_2$ gradient.
/
$\dot{V}$
/
$\dot{Q}$
maldistribution is a common cause of an increased $PaCO_2$–$PACO_2$ gradient. Other patient factors that may influence the accuracy of $ETCO_2$ monitoring by widening the $PaCO_2$–$ETCO_2$ gradient include shallow tidal breaths, prolongation of the expiratory phase of ventilation, or uneven alveolar emptying.

Dead space (wasted) ventilation is the extreme example of
/
$\dot{V}$
/
$\dot{Q}$
mismatch, where a complete absence of perfusion in the presence of adequate alveolar ventilation occurs. Because only perfused alveoli can participate in gas exchange, the nonperfused alveoli have a $PaCO_2$ of zero. The ventilation-weighted average of the perfused and nonperfused alveoli determines the $ETCO_2$. Therefore, conditions resulting in an increase of dead space ventilation lower the $ETCO_2$ measurement and increase the $PaCO_2$–$ETCO_2$ gradient. The common clinical causes associated with a widened $PaCO_2$–$ETCO_2$ gradient include embolic phenomena (thrombus, fat, air, amniotic fluid), hypoperfusion states with reduced pulmonary blood flow, and chronic obstructive pulmonary disease. In contrast, conditions that increase pulmonary shunt (perfusion in the absence of ventilation) result in minimal changes in the $PaCO_2$–$ETCO_2$ gradient.

Capnography is an essential element in determining the appropriate placement of endotracheal tubes. The presence of a stable $ETCO_2$ for three successive breaths indicates that the tube is not in the esophagus. A continuous, stable CO_2 waveform ensures the presence of alveolar ventilation but does not necessarily indicate that the endotracheal tube is properly positioned in the trachea. For example, the tip of the tube could be located in a main-stem bronchus. Capnography is also a monitor of potential changes in perfusion or dead space, is a very sensitive indicator of anesthetic circuit disconnects and gas circuit leaks, and is a method to detect the quality of CO_2 absorption. Increases in $ETCO_2$ can be expected when CO_2 production exceeds ventilation, such as in hyperthermia or when an exogenous source of CO_2 is present. Table 24-1 summarizes the common elements that may be reflected by changes in $ETCO_2$ during anesthesia care.

TABLE 24-1 Factors That May Change End-Tidal Co_2 ($ETCO_2$) During Anesthesia

Increases in $ETCO_2$	Decreases in $ETCO_2$
·ELEMENTS THAT CHANGE CO_2 PRODUCTION	
Increases in metabolic rate	**Decreases in metabolic rate**
Hyperthermia	Hypothermia
Sepsis	Hypothyroidism
Malignant hyperthermia	
Shivering	

Hyperthyroidism	
·ELEMENTS THAT CHANGE CO_2 ELIMINATION	
Hypoventilation	Hyperventilation
Rebreathing	Hypoperfusion
	Pulmonary embolism

A sudden drop in $ETCO_2$ to near zero followed by the absence of a CO_2 waveform is a potentially life-threatening problem that could indicate malposition of an endotracheal tube into the pharynx or esophagus, sudden severe hypotension, pulmonary embolism, a cardiac arrest, or an artifact resulting from disruption of sampling lines. When a sudden drop of the $ETCO_2$ occurs, it is essential to quickly verify that there is pulmonary ventilation and to identify physiologic and mechanical factors that might account for a zero-line capnogram. During life-saving cardiopulmonary resuscitation, the generation of adequate perfusion can be assessed by the restoration of the CO_2 waveform.

Whereas abrupt decreases in the $ETCO_2$ are often associated with an altered cardiopulmonary status (e.g., embolism or hypoperfusion), gradual reductions in $ETCO_2$ more often

reflect decreases in $PaCO_2$ that occur after increases in minute ventilation where ventilation overmatches CO_2 production.

The size and shape of the capnogram waveform can be informative.[7] A slow rate of rise of the second phase (B–C, see Fig. 24-1) is suggestive of either chronic obstructive pulmonary disease or acute airway obstruction as from bronchoconstriction (asthma). A normally shaped capnogram with an increase in $ETCO_2$ suggests alveolar hypoventilation or an increase in CO_2 production. Transient increases in $ETCO_2$ are often observed during tourniquet release, aortic unclamping, or the administration of bicarbonate.

Several methods for the quantification of CO_2 have been applied to patient monitoring systems. One of the most commonly used methods is based on infrared absorption spectrophotometry (IRAS).

Infrared Absorption Spectrophotometry

Asymmetric, polyatomic molecules like CO_2 absorb infrared light at specific wavelengths. Operating room IRAS devices can detect CO_2, N_2O, and the potent inhaled anesthetic agents. Operating room instruments are designed to measure the unique energy absorbed by the gases and vapors of interest when a sample of the inspired and expired gas is placed into the optical path of an infrared beam.[8] The mixtures complicate the analysis because of interactions between the gases and vapors and the closeness of absorption spectra for the gases of interest. All anesthetic vapors absorb infrared light at 3.6 μm. Therefore, manufacturers using this signature cannot display with certainty the concentration of a specific anesthetic agent of interest. Optical filters and unique detection systems enhance the sensitivity of IRAS monitoring and permit estimation of CO_2, N_2O, and the specific potent inhalational agent present in the measurement chamber. IRAS devices have five components: an infrared light source, a gas sampler, an optical path, a detection system, and a signal processor. The light source produces the infrared energy. The light is focused and filtered so that the quality of the photons with respect to the energy and

frequency is stable over time. Narrow wavelengths are then presented to the gas stream. Once the sample has entered the measurement chamber, a detection system calibrated to determine the concentration of a specific gas or agent over time is activated. Changes in temperature, pressure, and acoustic characteristics in the detection chamber can be used to determine the concentration of the gas or agents of interest. Signal detectors create electrical currents analyzed by the signal processor, which transforms the current change to a measurement. The capnogram or agent waveform is an oscilloscopic representation of the electrical current changes over time. The signal-processing section of an IRAS instrument has a memory section that correlates the absorbed energy with a concentration as predicted by the Lambert-Beer law.

Multiple Expired Gas Analysis

Most operating room gas analyzers incorporate methods so that they can monitor concentrations of at least O_2, CO_2, and the inhaled anesthetic agents. *Mass spectrometry systems* bombard the gas mixture with electrons, creating ion fragments of a predictable mass and charge. These fragments are accelerated in a vacuum. A sample of this mixture enters a measurement chamber, where the fragment stream is subjected to a high magnetic field. The magnetic field separates the fragments by their mass and charge. The fragments are deflected onto a detector plate, and each gas has a specific landing site on the detector plate. The ion impacts are proportional to the concentration of the parent gas or vapor. The processor section of the mass spectrometer system calculates the concentration of the gases of interest.

Another unique approach to monitor respiratory gases is based on *Raman scattering.* Raman scattering results when photons generated by a high-intensity argon laser collide with gas molecules. After impact, the gases are momentarily excited to unstable vibrational and rotatory states. When the gases return to their normal state, photons of a characteristic frequency are emitted. The scattered photons are measured as peaks in a spectrum that determine the concentration and composition of respiratory gases and inhaled vapors. Advances in laser technology have made Raman spectroscopic monitors available for clinical use. The instrument is fast and easy to calibrate. O_2, N_2, N_2O, CO_2, and H_2O vapor are all measurable using Raman scattering technology.

The clinical indications for routine CO_2 and O_2 gas monitoring are well documented. Monitors equipped to measure anesthetic gases are also prevalent and desirable. Nitrogen monitoring provides quantification of washout during preoxygenation. A sudden rise in N_2 in the exhaled gas indicates either introduction of air from leaks in the anesthesia delivery system or venous air embolism. Critical events that can be detected by the analysis of respiratory gases and anesthetic vapors are listed in Table 24-2.

TABLE 24-2 Detection of Critical Events by Implementing Gas Analysis

▪EVENT	▪MONITORING MODALITY
Error in gas delivery	O_2, N_2, CO_2, agent analysis
Anesthesia machine malfunction	O_2, N_2, CO_2, agent
Disconnection	CO_2, O_2, agent analysis
Vaporizer malfunction or contamination	Agent analysis

Anesthesia circuit leaks	N_2, CO_2 analysis
Endotracheal cuff leaks	N_2, CO_2
Poor mask or LMA fit	N_2, CO_2
Hypoventilation	CO_2 analysis
Malignant hyperthermia	CO_2
Airway obstruction	CO_2
Air embolism	CO_2, N_2
Circuit hypoxia	O_2 analysis
Vaporizer overdose	Agent analysis
LMA, laryngeal mask airway.

OXYGENATION MONITORING

The assessment of oxygenation is an integral part of anesthesia practice. Early detection and prompt intervention may limit serious sequelae of hypoxemia. The clinical signs associated with hypoxemia (e.g., tachycardia, altered mental status, cyanosis) are often masked or difficult to appreciate during anesthesia. The mechanisms responsible for hypoxemia are multifactorial. Oxygen analyzers assess oxygen delivery to the patient. Other noninvasive technologies detect the presence of arterial hypoxemia. Arterial oxygen monitors do not ensure adequacy of oxygen delivery to, or utilization by, the tissues and should not be considered a replacement for arterial blood gas measurements when more definitive information regarding oxygenation is desired.

Pulse Oximetry

Pulse oximetry is the standard of care for monitoring oxygenation during anesthesia. Pulse oximeters measure pulse rate and oxygen saturation of hemoglobin (Hb) (SpO_2) on a noninvasive, continuous basis. Figure 24-2 displays the oxyhemoglobin dissociation curve that defines the relationship of hemoglobin saturation and oxygen tension. On the steep part of the curve, a predictable correlation exists between SaO_2 and PO_2. In this range, the SaO_2 is a good reflection of the extent of hypoxemia and the changing status of arterial oxygenation. Shifts in the oxyhemoglobin dissociation curve to the right or to the left define changes in the affinity of Hb for oxygen. At a PO_2 of >75 mm Hg, the SaO_2 plateaus and loses its ability to reflect changes in PaO_2.

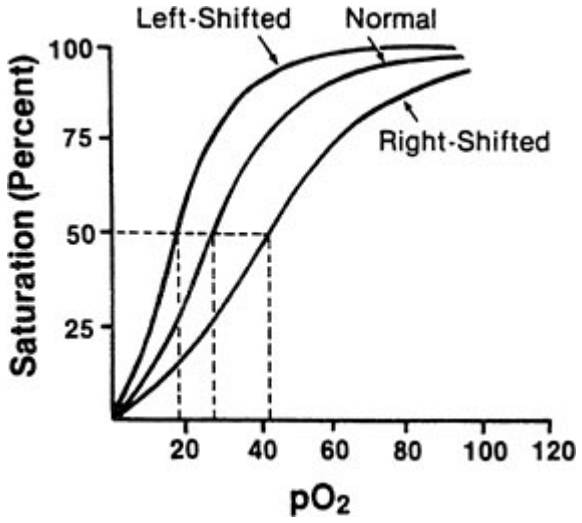

FIGURE 24-2. The oxyhemoglobin dissociation curve. The relationship between arterial saturation of hemoglobin and oxygen tension is represented by the sigmoid-shaped oxyhemoglobin dissociation curve. When the curve is left-shifted, the hemoglobin molecule binds oxygen more tightly. (Reproduced with permission from Brown M, Vender JS: Non-invasive oxygen monitoring. Crit Care Clin 4:493, 1988.)

Pulse oximetry is based on several premises:

1. The color of blood is a function of oxygen saturation.
2. The change in color results from the optical properties of Hb and its interaction with oxygen.
3. The ratio of O_2Hb and reduced Hb can be determined by absorption spectrophotometry.

Pulse oximetry combines the technology of plethysmography and spectrophotometry. Plethysmography produces a pulse trace that is helpful in tracking circulation. Oxygen saturation is determined by spectrophotometry, which is based on the Beer-Lambert law. At a constant light intensity and Hb concentration, the intensity of light transmitted through a tissue is a logarithmic function of the oxygen saturation of Hb. Two wavelengths of light are required to distinguish O_2Hb from reduced Hb. Light-emitting diodes in the pulse sensor emit red (660 nm) and near infrared (940 nm) light. The percentage of O_2Hb and reduced Hb is determined by measuring the ratio of infrared and red light sensed by a photodetector. Pulse oximeters perform a plethysmographic analysis to differentiate the pulsatile "arterial" Hb saturation from the nonpulsatile signal resulting from "venous" absorption and other tissues such as skin, muscle, and bone. The absence of a pulsatile waveform during extreme hypothermia or hypoperfusion limits the ability of a pulse oximeter to calculate the SpO_2.

The SpO_2 measured by pulse oximetry is not the same as the arterial saturation (SaO_2) measured by a laboratory co-oximeter. Pulse oximetry measures the "functional" saturation, which is defined by the following equation:

$$\text{Functional } SaO_2 = O_2Hb/(O_2Hb + \text{reduced Hb}) \times 100$$

Laboratory co-oximeters use multiple wavelengths to distinguish other types of Hb by their characteristic absorption. Co-oximeters measure the "fractional" saturation, which is defined by the following equation:

$$\text{Fractional } SaO_2 = O_2Hb/(O_2Hb + \text{reduced Hb} + COHb + MetHb) \times 100$$

In clinical circumstances where other Hb moieties are present, the SpO_2 measurement is higher

than the SaO_2 reported by the blood gas laboratory. In most patients, MetHb and COHb are present in low concentrations so that the functional saturation approximates the fractional value.

Pulse oximetry has been used in all patient age groups to detect and prevent hypoxemia. The clinical benefits of pulse oximetry are enhanced by its simplicity. Modern pulse oximeters are noninvasive, continuous, and autocalibrating. They have quick response times and their battery backup provides monitoring during transport. The clinical accuracy is typically reported to be ±pm 2 to 3% at 70 to 100% saturation and ± 3% at 50 to 70% saturation. Published data from numerous investigations support accuracy and precision reported by instrument manufacturers.

The appropriate use of pulse oximetry necessitates an appreciation of both physiologic and technical limitations. Despite the numerous clinical benefits of pulse oximetry, other factors affect its accuracy and reliability. Factors that may be present during anesthesia care and that affect the accuracy and reliability of pulse oximetry include dyshemoglobins, vital dyes, nail polish, ambient light, light-emitting diode variability, motion artifact, and background noise. Electrocautery can interfere with pulse oximetry if the radiofrequency emissions are sensed by the photodetector. Reports of burns or pressure necrosis exist but are infrequent. These complications can be reduced by inspecting the digits during monitoring.

Recent developments in pulse oximetry technology permit more accurate measurements of SpO_2 during patient movement or low-perfusion conditions. These instruments use complex signal processing of the two wavelengths of light to improve the signal-to-noise ratio and reject artifact. Studies in volunteers suggest that the performance of pulse oximeters incorporating this technology is superior to conventional oximetry during motion of the hand.[9]

There is overwhelming evidence supporting the capability of pulse oximetry for detecting desaturation before it is clinically apparent. Pulse oximetry has wide applicability in many hospital and nonhospital settings. However, there are no definitive data demonstrating a reduction in morbidity or mortality associated with the advent of pulse oximetry. An older large, randomized trial did not detect a significant difference in postoperative complications when routine pulse oximetry was used.[10] However, there was a sense that use of SpO_2 provided early warning of hypoxemia, and anesthesiologists using SpO_2 felt a greater level of comfort than those who did not use SpO_2. A reduction of anesthesia mortality, as well as fewer malpractice claims for respiratory events, coincident with the introduction of pulse oximeters suggests that the routine use of these devices may have been a contributing factor. Pulse oximetry is an inexpensive, essential tool for anesthesia care.

BLOOD PRESSURE MONITORING

Perioperative measurement of arterial blood pressure is an important indicator of the adequacy of circulation. Systemic blood pressure monitoring is commonly performed indirectly

using extremity-encircling cuffs or directly by inserting a catheter into an artery and transducing the arterial pressure trace. Today, anesthesiologists have a variety of techniques available for measuring changes in systolic, diastolic, and mean arterial pressure (MAP).

Indirect Measurement of Arterial Blood Pressure

The simplest method of blood pressure determination estimates systolic blood pressure by palpating the return of the arterial pulse while an occluding cuff is deflated. Modifications of this technique include the observance of the return of Doppler sounds, the transduced arterial pressure trace, or a photoplethysmographic pulse wave as produced by a pulse oximeter.

Auscultation of the Korotkoff sounds permit estimation of both systolic (SP) and diastolic (DP) blood pressures. MAP can be calculated using an estimating equation (MAP = DP + 1/3 [SP-DP]). Korotkoff sounds result from turbulent flow within an artery created by the mechanical deformation from the blood pressure cuff. Systolic blood pressure is signaled by the appearance of the first Korotkoff sound. Disappearance of the sound or a muffled tone signals the diastolic blood

pressure.

The detection of sound changes is subjective and prone to errors based on deficiencies in sound transmission or hearing. Cuff deflation rate also influences accuracy. Quick deflations underestimate blood pressure. Palpation and auscultatory techniques require pulsatile blood flow and are unreliable during conditions of low flow. These techniques are reasonably accurate when aneroid gauges are within calibration, the encircling cuff is appropriately sized and positioned, the inflation is above the true systolic pressure, and the Korotkoff sounds or pulse is properly identified.

The American Heart Association recommends that the bladder width for indirect blood pressure monitoring should approximate 40% of the circumference of the extremity. Bladder length should be sufficient to encircle at least 60% of the extremity. Falsely high estimates result when cuffs are too small, when cuffs are applied too loosely, or when the extremity is below heart level. Falsely low estimates result when cuffs are too large, when the extremity is above heart level, or after quick deflations.

Since 1976, microprocessor-controlled oscillotonometers have replaced auscultatory and palpatory techniques for routine perioperative blood pressure monitoring. Standard oscillometry measures mean blood pressure by sensing the point of maximal fluctuations in cuff pressure produced while deflating a blood pressure cuff. Most current instruments use oscillometric techniques to measure systolic, diastolic, and mean blood pressures by determining parameter identification points during cuff deflation.

In a generic noninvasive oscillometric monitor (*noninvasive blood pressure*, or NIBP), cuff pressure is sensed by a pressure transducer whose output is digitized for processing. After the cuff is inflated by an air pump, cuff pressure is held constant while oscillations are sampled. If no oscillations are sensed by the pressure transducer, the microprocessor switches open a deflation valve, and the next lower pressure level is sampled for the presence of oscillations. The microprocessor controlling the operation of the NIBP compares the amplitude of oscillation pairs and numerically displays the blood pressure estimate. Figure 24-3 depicts how a typical NIBP is obtained. In this example, the effect of respiratory variation, a premature ventricular complex, and cuff movement are demonstrated.

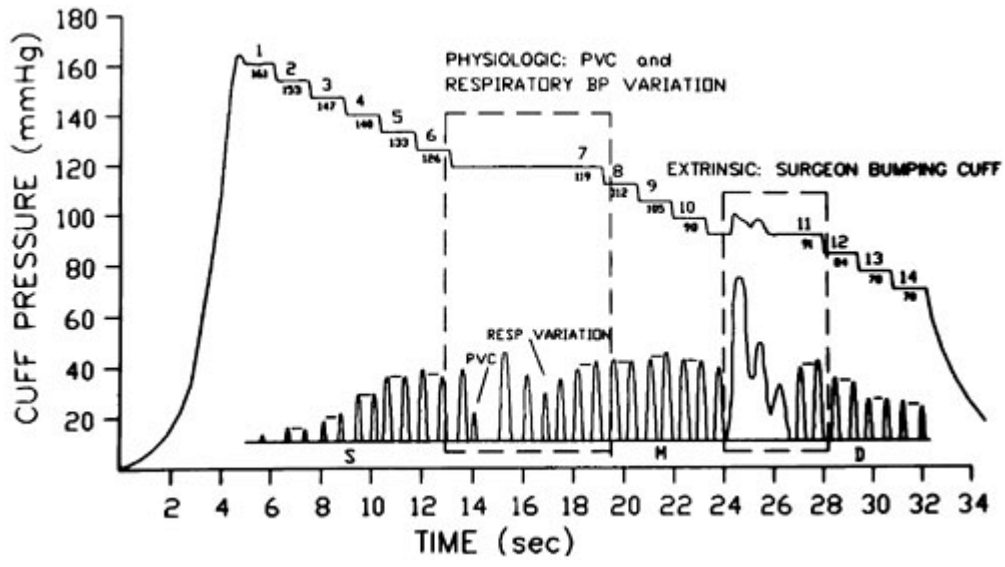

FIGURE 24-3. Diagram illustrating motion artifact, a premature ventricular contraction, and respiratory artifact as sensed by a Dinamap noninvasive blood pressure monitor. (Reproduced with permission from Ramsey M: Blood pressure monitoring: Automated oscillometric devices. J Clin Monit 7:56, 1991.)

Automated oscillometry has been demonstrated to correlate well with direct intra-arterial measurement of MAP and diastolic blood pressure. Automated oscillometry may underestimate systolic blood pressure, with mean errors reported from -6.9 to -8.6 mm Hg compared with direct radial artery pressure measurements.

Oscillometry requires the careful evaluation of several cardiac cycles at each increment of deflation to smooth out pronounced respiratory variations or motion artifacts. Cuff movement or erratic pulse transmission influences accuracy. In the anesthetized patient, automated oscillometry is usually accurate and versatile. A variety of cuff sizes makes it possible to use oscillometry in all age groups.

Problems With Noninvasive Blood Pressure Monitoring

Cuff-based pressure monitoring continues to be the standard method used in the perioperative period. When clinical circumstances require frequent blood pressure readings for a prolonged period, it is advisable periodically to move the cuff to alternative sites. Failure to deflate the cuff increases venous pressure. Hematomas have been described both beneath and distal to the cuff. Tremors or shivering can delay cuff deflation and prolong the deflation cycle. A compartment syndrome attributed to a prolonged inflation cycle has been described. Ulnar neuropathy has been reported after the use of automated cycled blood pressure cuffs. Compression of the ulnar nerve can be avoided by applying the encircling cuff proximal to the ulnar groove. Automated sequencing may alter the timing of intravenous drug administration when the access site is located in the same extremity. Hydrostatic errors result when blood pressure cuffs are placed on extremities that are above or below the level of the right atrium. The hydrostatic offset can be

mathematically corrected by adding or subtracting 0.7 mm Hg for each centimeter that the cuff is off the horizontal plane of the heart.

Indirect Continuous Noninvasive Techniques

Several methods for monitoring blood pressure continuously and noninvasively have been designed and evaluated for intraoperative blood pressure surveillance. These techniques provide clinicians with a continuous blood pressure estimate and an accurate display of the arterial blood pressure trace. *Indirect continuous noninvasive techniques* (ICNTs) continue to be evaluated because it is desirable to enhance beat-to-beat blood pressure monitoring while reducing the inherent risks and costs of direct intra-arterial monitoring. Clinical studies suggest that accuracy and precision of ICNTs are satisfactory, even under conditions of rapidly changing hemodynamics.[11,12,13] At present, however, ICNTs are not considered substitutes for direct arterial pressure monitoring in critically ill patients in the operating room.

Invasive Measurement of Vascular (Arterial Blood) Pressure

Indwelling arterial cannulation permits the opportunity to monitor arterial blood pressure continuously and to have vascular access for arterial blood sampling. Intra-arterial blood pressure monitoring uses saline-filled tubing to transmit the force of the pressure pulse wave to a pressure transducer that converts the displacement of a silicon crystal into voltage changes. These electrical signals are amplified, filtered, and displayed as the arterial pressure trace. Intra-arterial pressure transducing systems are subject to many potential errors based on the physical properties of fluid motion and the performance of the catheter-transducer-amplification system used to sense, process, and display the pressure pulse wave.

3 The behavior of transducers, fluid couplings, signal amplification, and display systems can be described by a complex second-order differential equation. Solving the equation predicts the output and characterizes the fidelity of the system's ability faithfully to display and estimate the arterial pressure over time. The fidelity of fluid-coupled transducing systems is constrained by two properties: *damping* (ζ) and *natural frequency* (Fo). Zeta (ζ) describes the tendency for saline in the measuring system to extinguish motion. Fo describes the tendency for the measuring system to resonate. The fidelity of the transduced pressure depends on optimizing ζ and Fo so that the

system can respond appropriately to the range of frequencies contained in the pressure pulse wave. Analysis of high-fidelity recordings of arterial blood pressure indicates that the pressure trace contains frequencies from 1 to 30 Hz.

The performance of a transducing system is often described by its *bandwidth*. The bandwidth contains the frequencies in which the transducing system faithfully reproduces the frequencies contained in the pulse pressure wave. Conventional disposable, saline-coupled transducers with 60 in of pressure tubing have an acceptable bandwidth and commonly have frequency responses approaching 30 Hz. If the system begins to resonate (ringing) or becomes damp (inertia), the fidelity of the system is impaired and estimates of blood pressure become less accurate. Measuring the bandwidth of transducer systems requires complicated equipment. Estimates of ζ and Fo can be obtained at the bedside.

Studies have demonstrated that system fidelity is optimized when catheters and tubing are stiff, the mass of the fluid is small, the number of stopcocks is limited, and the connecting tubing is not excessive. Damping lowers the effective bandwidth of the transducer system, which promotes the potential for resonance. Figure 24-4 demonstrates the effect of damping on the character of the arterial pressure trace. In clinical practice, underdamped catheter–transducer systems tend to overestimate systolic pressure by 15 to 30 mm Hg and amplify artifact (catheter whip). Likewise, excessive increases in Z reduce fidelity and underestimate systolic pressure. The presence of air bubbles in the coupling fluid reduces the natural frequency of the transducing system. For clinical use, it is sufficient to place the transducer at the level of the right atrium, open the stopcock to atmosphere, and balance the electronic amplifying system to display "zero." Periodic checks of the zero reference point ensures that transducer drift is eliminated.

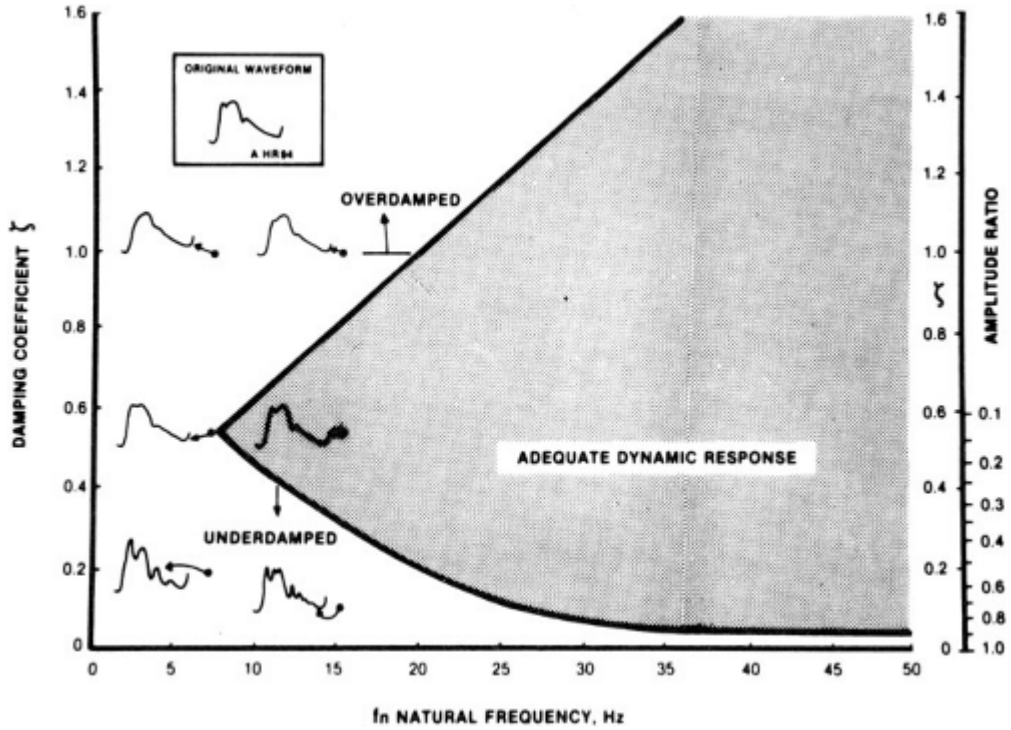

FIGURE 24-4. The relationship between the frequency of fluid-filled transducing systems and damping. The *shaded area* represents the appropriate range of damping for a given natural frequency (Fn). The size of the wedge also depends on the steepness of the arterial pressure trace and heart rate. (Reproduced with permission from Gardner RM: Direct blood pressure measurement: Dynamic response requirements. Anesthesiology 54:231, 1981.)

Gardner[14] suggested using the "fast flush" test to determine the natural frequency and damping characteristics of the transducing system. This test examines the characteristics of the resonant waves recorded after the release of a flush. Damping is estimated by the amplitude ratio of the

first pair of resonant waves and the natural frequency is estimated by dividing the paper speed by the interval cycle. Kleinman et al[15] have confirmed the utility of the fast flush test. Because many therapeutic decisions are based on changes in arterial blood pressure, it is imperative that anesthesiologists understand the physical limitation imposed by fluid-filled pressure transducer systems. Significant exaggeration of pressure measurements occur when the transducer system has a resonant frequency in the range of the pressure wave frequencies. Systolic pressure is underestimated when measured with overdamping systems and overestimated by underdamping or resonating systems. Mean pressure estimates are typically less affected even when damping and resonance are not optimal.

Arterial Cannulation

Multiple arteries can be used for direct measurement of blood pressure, including the radial, brachial, axillary, femoral, and dorsalis pedis arteries. The radial artery remains the most popular site for cannulation because of its accessibility and the presence of a collateral blood supply. In the past, assessment of the patency of the ulnar circulation by performance of an *Allen's test* has been recommended before cannulation. Allen's test is performed by compressing both radial and ulnar arteries while the patient tightens his or her fist. Releasing pressure on each respective artery determines the dominant vessel supplying blood to the hand. The prognostic value of the Allen's test in assessing the adequacy of the collateral circulation has not been confirmed.[16,17]

Radial artery cannulation and blood pressure monitoring have been associated with several problems. The radial artery pulse pressure wave is subject to inaccuracies inherent to its distal location. After separation from cardiopulmonary bypass, large pressure gradients between aortic and radial arteries have been described.

Complications of Invasive Arterial Monitoring

Traumatic cannulation has been associated with hematoma formation, thrombosis, and damage to adjacent nerves. Abnormal radial artery blood flow after catheter removal occurs frequently. Studies suggest that blood flow normalizes in 3 to 70 days. Radial artery thrombosis can be minimized by using small catheters, avoiding polypropylene-tapered catheters, and reducing the duration of arterial cannulation. Flexible guidewires may reduce the potential trauma associated with catheters negotiating tortuous vessels. During cannula removal, the potential for thromboembolism may be diminished by compressing the proximal and distal arterial segment while aspirating the cannula during withdrawal.

Many cannulation sites have been used for direct arterial blood pressure monitoring (Table 24-3). Three techniques for cannulation are common: direct arterial puncture,

guidewire-assisted cannulation (Seldinger's technique), and the transfixion–withdrawal method. A necessary condition for percutaneous placement is identification of the arterial pulse, which may require a Doppler flow detection device in patients with poor peripheral pulses.

TABLE 24-3 Arterial Cannulation and Direct Blood Pressure Monitoring

·ARTERIAL CANNULATION SITE	·CLINICAL POINTS OF INTEREST
Radial artery	Preferred site for monitoring
	Nontapered catheters preferred

Ulnar artery	Complication similar to radial
	Primary source of hand blood flow
Brachial artery	Insertion site medial to biceps tendon
	Median nerve damage is potential hazard
	Can accommodate 18-gauge cannula
Axillary artery	Insertion site at junction of pectoralis and deltoid muscle
	Specialized kits available
Femoral artery	Easy access in low flow states
	Potential for local and retroperitoneal hemorrhage
	Longer catheters preferred
Dorsalis pedis artery	Collateral circulation = posterior tibial artery
	Higher systolic pressure estimates

Arterial cannulation is regarded as an invasive procedure with a documented morbidity. Ischemia after radial artery cannulation resulting from thrombosis, proximal emboli, or prolonged shock has been described.[18] Contributing factors include severe atherosclerosis, diabetes, low cardiac output, and intense peripheral vasoconstriction. Ischemia, hemorrhage, thrombosis, embolism, cerebral air embolism (retrograde flow associated with flushing), aneurysm formation, arteriovenous fistula formation, skin necrosis, and infection have occurred as the direct result of arterial cannulation, arterial blood sampling, or high-pressure flushing.

Continuous-flush devices are incorporated into disposable transducer kits and infuse at 3 to 6 mL/h. In neonates, the infusion volume may contribute to fluid overload. Continuous-flush devices have little effect on the blood pressure measurement. However, pressurized flush systems may serve as a source of an air embolism. Removing air from the pressurized infusion bag, stopcocks, and tubing minimizes the potential for air embolism.

Direct arterial pressure monitoring requires constant vigilance. The data displayed must correlate with clinical conditions before therapeutic interventions are initiated. Sudden increases in the transduced blood pressure may represent a hydrostatic error because the position of the transducer was not adjusted after change in the operating room table's height. Sudden decreases often result from kinking of the catheter or

tubing. Before initiating therapy, the transducer system should be “rezeroed” and the patency of

the arterial cannula verified. This ensures the accuracy of the measurement and avoids a potentially dangerous medication error.

Central Venous and Pulmonary Artery Monitoring

Central venous cannulas are important portals for intraoperative vascular access and for the assessment of changes in vascular volume. Central venous cannulas permit the rapid administration of fluids, insertion of PACs, insertion of transvenous electrodes, monitoring of central venous pressure (CVP), and a site for observation and treatment of venous air embolism.

The right internal jugular vein is the preferred site for cannulation because it is accessible from the head of the operating table, has a predictable anatomy, and has a high success rate in both adults and children.[19] The left-sided internal jugular vein is also available but is less desirable because of the potential for damaging the thoracic duct or difficulty in maneuvering catheters through the jugular–subclavian junction. Accidental carotid artery puncture is a potential problem with either location.

Three techniques (posterior, central, and anterior) have been described for internal jugular cannulation. Each insertion point is referenced to the triangle formed by the sternal and clavicular heads of the sternocleidomastoid muscle and the clavicle. Venipuncture using a 22-gauge "seeker" needle minimizes trauma to adjacent structures. When the location of the internal jugular vein is difficult to ascertain, ultrasonography can assist in identifying the proximity of internal jugular vein and the carotid artery. Alternatives to the internal jugular vein include the external jugular, subclavian, antecubital, and femoral veins.

Central Venous Pressure Monitoring

The benefit of CVP monitoring has been the subject of considerable debate. Proponents of CVP monitoring believe that CVP pressures are essentially equivalent to right atrial pressures and serve as a reflection of right ventricular preload.[20] Conditions that affect right atrial pressure also influence the CVP pressure trace. The normal CVP waveform consists of three peaks (a, c, and v waves) and two descents (x, y), each resulting from the ebb and flow of blood in the right atrium (Fig. 24-5). Corresponding events occur in the left atrium and similar pressure contours are observed during monitoring of pulmonary artery pressure when the PAC is placed in the occluded position.

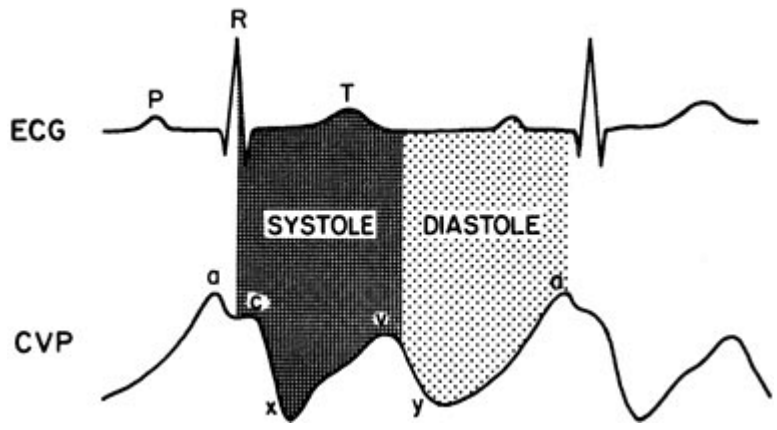

FIGURE 24-5. The normal central venous pressure trace. (Redrawn with permission from Mark JB: Central venous pressure monitoring: Clinical insights beyond the numbers. J Cardiothorac Vasc Anesth 5:163, 1991.)

The character of the CVP trace depends on many factors, including heart rate, conduction disturbances, tricuspid valve function, normal or abnormal intrathoracic pressure changes, and changes in right ventricular compliance. In patients with atrial fibrillation, a waves are absent. When resistance to the emptying of the right atrium is present, large a waves are often observed. Examples include tricuspid stenosis, right ventricular hypertrophy as a result of pulmonic stenosis, or acute or chronic lung disease associated with pulmonary hypertension. Large a waves may also be observed when right ventricular compliance is impaired.

Tricuspid regurgitation typically produces giant v waves that begin immediately after the QRS complex. Large v waves are often observed when right ventricular ischemia or failure is present or when ventricular compliance is impaired by constrictive pericarditis or cardiac tamponade. A prominent v wave during CVP monitoring may suggest right ventricular papillary muscle ischemia and tricuspid regurgitation. When right ventricular compliance decreases, the CVP often increases with prominent a and v waves fusing to form an *m* or *w* configuration.

Central venous pressure monitoring is often unreliable for estimating left ventricular filling pressures, especially when cardiopulmonary disease processes alter the normal cardiovascular pressure–volume relationships. CVP monitoring is less invasive and less costly than pulmonary artery monitoring and offers unique understanding of right-sided hemodynamic events and the status of vascular volume.

Pulmonary Artery Monitoring

The development of the flow-directed, balloon flotation PAC was a major advance in hemodynamic monitoring, and it has become an important tool in the quantitative assessment of cardiopulmonary function. Numerous articles have reviewed the various applications and benefits of pulmonary artery monitoring.[21] Use should be guided by the information needed for enhanced diagnosis and therapy.[22] Today, PAC monitoring is commonly used in surgical patients to help evaluate and treat hemodynamic alterations, which contribute significantly to the morbidity and mortality inherent to the surgical care of high-risk patients.

4 In 1993, the ASA published practice guidelines that examined the evidence supporting the clinical effectiveness of PAC monitoring. These guidelines were updated in 2003.[23] Issues such as the timing of PAC monitoring, its effect on treatment decisions, patient selection and case mix, and evidence regarding PAC monitoring contribution to positive or negative outcomes were evaluated using stringent evidence-based methodology. This effort identified many flaws in the body of evidence, which made it difficult to draw meaningful conclusions regarding the effectiveness of PAC monitoring to reduce morbidity or mortality. The consensus opinion implies that PAC monitoring may reduce perioperative complications if critical hemodynamic data obtained during appropriate PAC monitoring are accurately interpreted and appropriate treatment is tailored to the conditions as they change over time.[23] Monitoring the hemodynamic status of high-risk patients may reduce cardiac complications (e.g., myocardial ischemia, congestive heart failure, dysrhythmias), renal insufficiency, brain injury, and pulmonary complications.

Pulmonary artery catheters permit the measurement of intracardiac pressures, thermodilution CO (TCO), mixed venous oxygen saturation, intracavitary electrograms, and lung water. This information can help define clinical problems, monitor the progression of hemodynamic dysfunctions, and guide the response of corrective therapy.

The measurement of intracardiac pressures can indirectly assess left ventricular preload, diagnose the existence of pulmonary hypertension, or differentiate cardiac and noncardiac causes of pulmonary edema. PACs allow for the rapid and reproducible measurements of TCO, calculation of oxygen delivery (CO × arterial O_2 content), and assessment of cardiac work. Hemodynamic measurements are often predicated on the manipulation of preload, afterload, and contractility. Several derived indices of hemodynamic function necessitate measurements commonly obtained from PAC monitoring (Table 24-4).

TABLE 24-4 Derived Hemodynamic Variables

·NAME	·ABBREVIATION	·CALCULATION	·UNITS
Cardiac index	CI	CO/BSA	1 min/m^2
Systemic vascular resistance	SVR	(MAP-CVP/CO) × 80	dyne-cm/s
Pulmonary vascular resistance	PVR	(MPAP-PCWP/CO) × 80	dyne-cm/s
Stroke index	SI	CI/heart rate	mL/beat/m^2
Left ventricular stroke work index	LVSWI	SI × (MAP-PCWP) × 0.0136	gm/beat/m^2
Right ventricular stroke work index	RVSWI	SI × (MPAP-CVP) × 0.0136	gm/beat/m^2
BSA, body surface area; MAP, mean arterial pressure; CVP, central venous pressure; MPAP, mean			
pulmonary arterial pressure; PCWP, pulmonary capillary wedge pressure.			

Access to mixed venous blood from the pulmonary artery port provides an indirect assessment of the balance between O_2 delivery and O_2 utilization. Mixed venous oxygen saturation ($S\bar{v}O_2$) measurements are needed to calculate mixed venous oxygen content ($C\bar{v}O_2$). $C\bar{v}O_2$ is an important variable used for calculating intrapulmonary (Eq. 24-1) or intracardiac shunts (Eq. 24-2).

$$\frac{Cco_2 - Cao_2}{Cco_2 - C\bar{v}o_2} = \frac{\dot{Q}s}{\dot{Q}t} \qquad (24\text{-}1)$$

$$\frac{Sao_2 - SRAo_2}{Sao_2 - S\bar{v}o_2} = \frac{\dot{Q}p}{\dot{Q}s} \qquad (24\text{-}2)$$

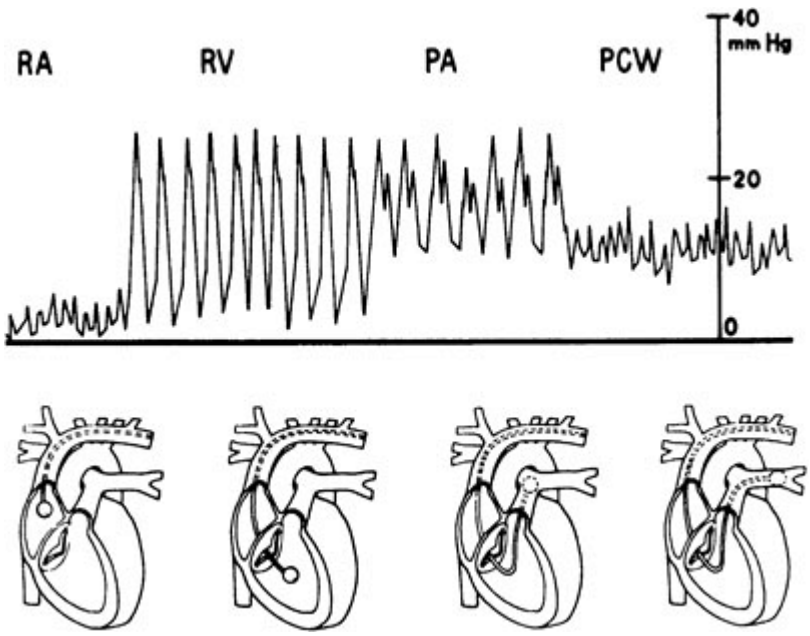
Where CCO_2 = capillary O_2 content, CaO_2 = arterial O_2 content, $C\bar{v}O_2$ = mixed venous O_2 content, $\dot{Q}s/\dot{Q}t$ = shunt fraction, SaO_2 = arterial O_2 saturation, $SRAO_2$ = right atrial O_2 saturation, $S\bar{v}O_2$ = mixed venous O_2 saturation, and

p/

$\dot{Q}$

s = pulmonary-to-systemic shunt.

The validity of PAC monitoring depends on a properly functioning pressure monitoring system, correctly identifying the "true" *pulmonary capillary wedge pressure* (PCWP), and integration of the various factors that affect the relationship of PCWP, and the other cardiac pressures and volumes that are determinants of ventricular function. Figure 24-6 depicts the transduced pressure waves observed as a PAC is floated to the wedged position. Catheter placement is most commonly performed by observing the pressure waves as the catheter is floated from the CVP position through the right heart chambers into the pulmonary artery.



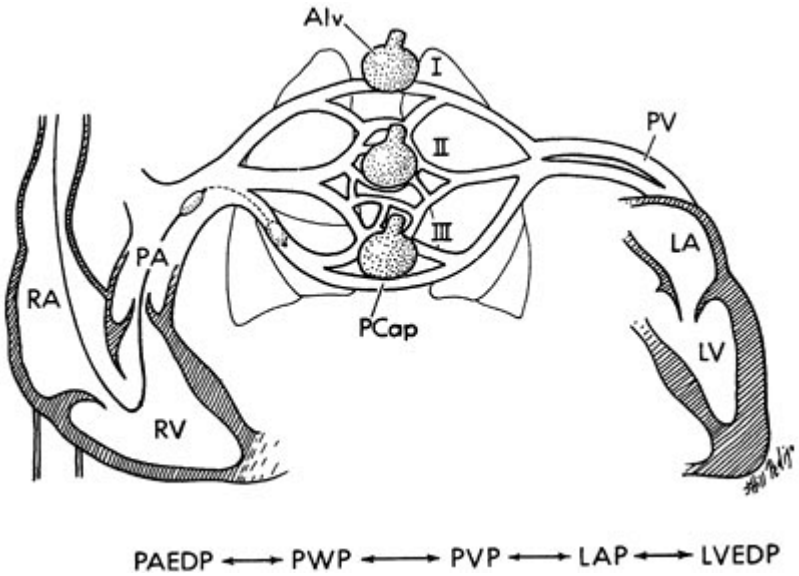


FIGURE 24-6. Pressure tracing observed during the flotation of a pulmonary artery catheter. (Reproduced with permission from Dizon CT, Barash PG: The value of monitoring pulmonary artery pressure in clinical practice. Conn Med 41:622, 1979.)

Pulmonary artery catheter monitoring necessitates an appreciation of the various physiologic determinants of CO and oxygen delivery. The PAC is used to continuously monitor the pulmonary artery pressure and intermittently monitor pulmonary wedge pressure. PCWP is used to assess left ventricular preload indirectly by reflecting changes in left ventricular end-diastolic pressure (LVEDP). Figure 24-7 depicts the relationship between the various pressures in the cardiopulmonary system.

PAEDP ⟷ PWP ⟷ PVP ⟷ LAP ⟷ LVEDP

FIGURE 24-7. The anatomic position of a pulmonary artery catheter in the pulmonary artery. The *dashed line* positions the inflated balloon in the "wedged" position. (RA, right atrium; RV, right ventricle; PA, pulmonary artery; Alv, alveolus; Pcap, pulmonary capillary; PV, pulmonary vein; LA, left atrium; LV, left ventricle.) I, II, and III characterize the relationship of $P_{aveolar}$, $P_{arterial}$, and P_{venous} as described by West. The bottom of the figure shows a progressive correlation of vascular pressures. (Reproduced with permission from Vender JS: Invasive cardiac monitoring. Crit Care Clin 4:455, 1988.)

It has been well demonstrated that right-sided pressures in the heart often are poor indicators of left ventricular filling, either as absolute numbers or in terms of the direction of change in response to therapy. The correlation of these pressures as estimates of LVEDP (or left ventricular end-diastolic volume [LVEDV]) is directly related to their proximity to the left ventricle and the status of ventricular compliance. Assuming an open conduit from the catheter tip to the left ventricle, when the PAC is occluded ("wedged"), the right-sided heart chambers and valves are bypassed. During end-diastole, there is cessation of forward blood flow, and a static fluid column is presumed to exist from the left ventricle to the PAC tip. Ideally, changes in LVEDP are reflected by all proximal pressures (left atrial, pulmonary venous, pulmonary artery end-diastolic pressure [PAEDP], and PCWP). Alterations of internal or external forces applied to the open conduit during PCWP measurements may invalidate the PCWP-LVEDP-LVEDV relationship.

Factors Affecting the Accuracy of Pulmonary Artery Catheter Data

Pulmonary Vascular Resistance. Any disease process or condition that increases pulmonary vascular resistance has the

potential to reduce pulmonary blood flow and alter the relationship between PCWP and PAEDP. Pathologic conditions such as acute or chronic lung disease, pulmonary emboli, alveolar hypoxia, acidosis, and hypoxemia, and many vasoactive drugs increase pulmonary vascular resistance and have the potential to modify the PCWP–PAEDP relationship. Tachycardia shortens ventricular diastole and also increases pulmonary vascular resistance.

Alveolar–Pulmonary Artery Pressure Relationships. West et al[25] described a gravity-dependent difference between ventilation and perfusion in the lung. The variability in pulmonary blood flow is a result of differences in pulmonary artery (PA), alveolar (Palv), and venous pressures (PV) and is categorized into three distinct zones. Only Zone III (PA > PV > Palv) meets the criteria for uninterrupted blood flow and a continuous communication with distal intracardiac pressures. Increases in alveolar pressure, decreases in perfusion, or changes in positioning can

convert areas of Zone III into either Zone II or I. Flow-directed PACs usually advance to gravity-dependent areas of highest blood flow.

The location of a PAC can be confirmed by a lateral chest film to ascertain that the catheter tip is below the level of the left atrium. The following characteristics suggest that the PAC tip is not in Zone III: PCWP > PAEDP, nonphasic PCWP tracing, and inability to aspirate blood from the distal port when the catheter is wedged.

Respiratory Pattern and Airway Pressure. Changes in intrathoracic and intrapleural pressure affect transmural cardiac pressures. Transmural pressure is defined as the net distending pressure of the left ventricle. Changes in intrathoracic pressure affect the PCWP–LVEDP relationship. Positive end–expiratory pressure (PEEP) therapy can induce changes in both intravascular and intrapleural pressures. PEEP increases alveolar pressure, potentially converting Zone III areas to Zone II. If PEEP is transmitted across the alveoli, intrapleural pressure increases. Pulmonary compliance determines the extent of this effect. PEEP alters ventricular distensibility and decreases venous return. This causes a disproportionate increase in PCWP (and LVEDP) compared with changes in LVEDV.

The effect of PEEP therapy is minimal if the levels of PEEP are low ($\leqslant$10 cm) and the PAC is located in Zone III. Higher levels of PEEP influence the PCWP–LVEDP relationship. During high PEEP therapy, esophageal pressure measurements can be made to determine intrapleural pressure. Alternatively, subtracting 1 to 2 mm Hg from the displayed "wedge" pressure for each 5 cm H_2O of PEEP therapy gives an estimate when PEEP is above 10 cm H_2O.

Intracardiac Factors. Pathologic obstruction at the mitral valve secondary to mitral stenosis, atrial myxoma, or clot can interfere with the ability of left atrial pressure to reflect LVEDP. Similarly, mitral regurgitation, a noncompliant left atrium, or left-to-right intracardiac shunting often is associated with large v waves.

Decreases in left ventricular compliance, aortic regurgitation, or premature closure of the mitral valve may reverse the left atrial pressure–LVEDP pressure gradient. When this occurs, PCWP is not a valid reflection of LVEDV.

Figure 24-8 graphically depicts the relationship between LVEDP and LVEDV. The LVEDP–LVEDV relationship is not linear. A family of LVEDP–LVEDV compliance curves characterizes the effect of changing the stiffness of the left ventricle. Ventricular compliance is a dynamic factor influenced by many physiologic and pathologic variables. The LVEDP–LVEDV compliance curves suggest that at low preloads, larger increases in LVEDV produce smaller changes in LVEDP. Conversely, at higher preloads, a similar change in LVEDV produces a greater pressure change. For a given LVEDV, any decrease in ventricular compliance results in an increase in LVEDP. This explains the development of hydrostatic pulmonary edema at normal LVEDV. Factors that are associated with changes in ventricular compliance are listed in Table 24-5.

TABLE 24-5 Decreased Left Ventricular Compliance: Common Etiologies

Myocardial ischemia	Cardiac tamponade
Restrictive myopathies	Myocardial fibrosis
Right-to-left intraventricular shunts	Inotropic drugs
Aortic stenosis	Hypertension

Complications of Pulmonary Catheter Monitoring

Adverse effects from PAC monitoring can result during central venous access, the catheterization procedure, or any time after

PAC placement. Central venous access represents an invasive process with inherent risks, some of which are potentially life threatening.

Unintentional puncture of nearby arteries, bleeding, neuropathy, and pneumothorax may result from needle insertion into adjacent structures. Air embolism may occur if a cannula is open to the atmosphere and air is entrained during or after CVP placement. Dysrhythmias are common during the catheterization procedure, with a reported incidence of 4.7 to 68.9%. Ventricular tachycardia or fibrillation may be induced during catheter advancement. Catheter advancement has been associated with right bundle-branch block and, in patients with preexisting left bundle-branch block, may precipitate complete heart block. Table 24-6 summarizes the adverse effects as reported by the ASA task force on pulmonary artery catheterization.[23]

TABLE 24-6 Adverse Effects Associated with Pulmonary Artery Monitoring

·COMPLICATION	·REPORTED INCIDENCE(%)
Central venous access	
Arterial puncture	1.1–13
Postoperative neuropathy	5.3
Pneumothorax	0.3–1.1
Air embolism	0.3–4.5
Flotation of pulmonary artery catheter	
Minor dysrhythmias	4–68.9
Ventricular tachycardia or fibrillation	0.3–62.7
Right bundle-branch block	0.1–4.3
Complete heart block (prior left bundle-branch block)	0–8.5
Complications associated with catheter residence	
Pulmonary artery rupture	0.1–1.5
Positive cultures from catheter tip	1.4–34.8
Sepsis secondary to catheter resistance	0.7–11.4
Thrombophlebitis	6.5
Venous thrombosis	0.5–66.7
Pulmonary infarction	0.1–5.6
Mural thrombus	28–61

Valvular or endocardial vegetations	2.2–100
Deaths attributed to pulmonary artery catheter	0.02–1.5

ASA Task Force on Pulmonary Artery Catherization. Practice Guidelines for Pulmonary Artery Catherization: an updated report by The American Society of Anesthesiologists Task Force on Pulmonary Catherization. Anesthesiology 99:988–1014, 2003.

The rate of iatrogenic deaths associated with PAC monitoring is uncertain. The most dreaded complication associated with PAC monitoring is pulmonary artery rupture. Pulmonary hypertension, coagulopathy, and heparinization are often present in patients who have died of pulmonary artery rupture. Perforations and subsequent hemorrhage can be avoided by restricting "overwedging," minimizing the number of balloon inflations, and using proper technique during balloon inflations.

Infection is a potential complication of the continued use of CVP and PAC catheters. Guidelines for the prevention of intravascular catheter-related infections have recently been published by the Centers for Disease Control and Prevention (CDC).[24] Methods recommended to reduce the incidence of local and bloodstream infections include (1) education and training of clinicians who insert and maintain central catheters;

(2) use of maximal sterile barrier precautions (mask, cap, sterile gloves and gown, and large sterile drape); (3) use of 2% chlorhexidine for skin preparation; and (4) avoidance of routine replacement of CVP and PAC catheters solely for the purpose of reducing the risk of infection.

Since the advent of PACs, several modifications have been integrated into the design that enhance their monitoring capabilities. The first significant design modification incorporated a thermistor at the tip, permitting the measurement of CO. Other features have been introduced for clinical use or evaluation. These include mixed venous oximetry, measurement of right ventricular ejection fraction, pacing options, and continuous CO monitoring (CCOM).

Mixed Venous Oximetry

Continuous estimates of S$\bar{v}O_2$ provide a reflection of total tissue oxygen balance. Oxygen delivery ($\dot{D}O_2$) equals the arterial oxygen content multiplied by the CO ($\dot{D}O_2 = [Hb \times 13.8] \times CO$), where 13.8 represents the volume of oxygen carried by Hb converted to grams per liter. Oxygen consumption ($\dot{V}O_2$) is determined by the difference between arterial and venous oxygen delivery. The relationship between S$\bar{v}O_2$, $\dot{V}O_2$, and $\dot{D}O_2$ is demonstrated in the following equation derived from the Fick relationship:

$$S\bar{v}O_2 = SaO_2 - \frac{\dot{V}O_2}{Hb \times 13.8} \times CO$$

This equation indicates that changes in S$\bar{v}O_2$ vary directly with changes in CO, Hb, and SaO_2 and inversely with $\dot{V}O_2$. The normal S$\bar{v}O_2$ is 75%, which denotes tissue oxygen extraction = 25%.

The oximetric PAC uses reflectance spectrophotometry and technology similar to pulse oximetry. Several wavelengths are transmitted through optical fibers embedded in the pulmonary artery. The reflected intensity of light identifies the saturation of blood surrounding the tip of the PAC. Three-wavelength in vivo systems correlate well with simultaneous samples measured by co-oximetry.[26,27] An example of the utility of mixed venous oximetry is depicted in Figure 24-9.

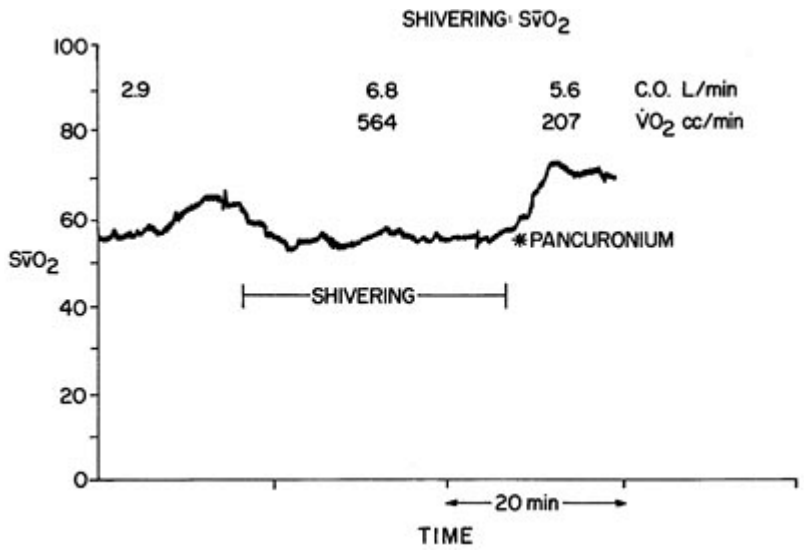

FIGURE 24-9. This S$\bar{v}O_2$ recording in a postcoronary artery bypass patient demonstrates the effects of shivering and its treatment, and the relationship between S$\bar{v}O_2$, cardiac output (CO), and metabolic rate ($\dot{V}O_2$). Indicator Dilution Applications

Indicator dilution determination of CO is based on a concept proposed by Stewart and tested by Hamilton and colleagues. TCO determination is the most widely used adaptation of the indicator dilution principle, which was first described by Fegler in 1954.[28] Today, 5% dextrose or 0.9% saline is used as the indicator. A thermistor located at the PAC tip records the decrease in temperature as the bolus of cooled injectate passes through the pulmonary artery. Computers contend with the complexity of the TCO equation, which includes the following factors: specific heat of the blood and the indicator fluid, the volume of injectate, catheter size, specific gravity of the blood and indicator, the volume of the injectate, and the area of the blood temperature curve. Comparison studies suggest that using either room-temperature or iced injectates provides accurate estimates of CO. Iced injectate is preferred because it produces a more exacting curve with a better signal-to-noise ratio.[29]

When properly performed, TCO measurements correlate well with direct Fick or dye dilution estimates of CO. In clinical practice, triplicate determinations are averaged to increase precision. Differences in values of 12 to 15% are not of clinical significance. TCO estimates vary with the respiratory cycle. This variability can be reduced by performing measurements at peak inspiration or end expiration. Precision is enhanced by ensuring that the rate of injection and the volume are constant. Most CO computers delay the repeat measurement 30 to 90 seconds to stabilize the thermal environment of the pulmonary thermistor.

Adaptations for Continuous Cardiac Output Monitoring

Continuous CO monitoring offers the potential to identify acute changes in ventricular performance as they occur. A properly positioned PAC provides access to the right atrium, right ventricle, and pulmonary artery outflow tract. These locations provide many options for assessment of CCOM. Several thermal techniques are currently used. Pulsed thermodilution uses a coiled right ventricular filament that is randomly heated. A thermistor at the tip of the PAC detects changes in blood temperature and sends the temperature information to a microcomputer that uses stochastic analysis to create a thermodilution curve. CO is computed continuously from a conservation of heat equation.[30]

Another technique applies heat to a thermistor located at the tip of a PAC. The right ventricular outflow subsequently cools the tip. The temperature changes registered are proportional to the decreased temperature produced by right ventricular blood flow. Both of these systems require calibration using standard thermodilution before initiating the CCOM mode. CCOM compares favorably with bolus CO measurements, even under conditions of varying patient temperature and CO.[31]

Right Ventricular Ejection Fraction

Calculation of right ventricular ejection fraction and end-diastolic volume may be performed with a special PAC that uses a rapid response thermistor and a sophisticated computer system. This system analyzes the exponential decay of the pulmonary artery temperature over several cardiac cycles and calculates the ejection fraction by subtracting the mean residual fraction from the CO. Studies have demonstrated good correlation with in vitro techniques and clinical utility for detecting intraoperative right ventricular ischemia.[32,33,34] Right ventricular ejection fraction monitoring has been recommended when impairment of right ventricular function is suspect. Accuracy requires proper placement. Atrial fibrillation and tricuspid regurgitation can affect the accuracy of the thermal decay methodology.

Clinical Benefits of Pulmonary Artery Monitoring

The debate regarding the clinical benefit of PAC monitoring has persisted since the mid 1980s. Perioperative outcomes have been reported to be improved, worsened, or unchanged by PAC use. At the present time, assessment of the benefits of PAC monitoring is hampered by the lack of well-designed outcome trials. Interpretation of most clinical trials is significantly limited by important flaws in study design, which include inadequate sample size to detect meaningful outcomes, lack of randomization, and lack of standardization of treatments based on PAC data.[24] A study by Sandham et al. was designed to address many of the methodologic limitations present in previous PAC outcome trials.[35] This large-scale, randomized, controlled, single-blind study examined the impact of PAC monitoring in high-risk patients undergoing major surgical procedures. Patients were randomized to a protocol group (PACs used to achieve specific targeted hemodynamic treatment goals) or a standard care group (no PAC use). No differences in major morbidity or mortality were observed between the two groups. Additional well-designed studies are needed to determine the benefits and risks of invasive right-heart catheterization.

Inadequate understanding and application by physician users have been implicated as conditions that limit the benefit of PAC monitoring. To optimize clinical outcome and reduce complications, the care provider must be able to interpret and use the data provided by the PAC. A questionnaire that measured physician knowledge of the technical and theoretical aspects of PAC monitoring was

administered to critical care specialists in the United States and Europe. These surveys revealed knowledge of pulmonary artery catheterization is not uniformly good among intensive care unit physicians, with only half of respondents able to read the PCWP correctly from a clearly marked tracking.[36,37] Changes in training and credentialing have been proposed to improve these deficiencies in knowledge.[38,39] In experienced and knowledgeable hands, the PAC can add valuable information with limited risk.

NONINVASIVE TECHNIQUES FOR CARDIAC OUTPUT

The quest for technically simple, noninvasive methods for accurately estimating CO continues. Three methods are available for clinical use.

Impedance Plethysmography

Impedance plethysmography is based on determining the pulsatile changes in resistance occurring during ventricular ejection. Four electrodes are applied to the neck and thorax and a small electric current is applied. Impedance measurements (dZ/dT) are made using two thoracic electrode pairs. Changes in impedance correlate with stroke volume. CO is estimated by determining stroke volume and ventricular ejection time.[40] Electrode placement is an important source of error. Other factors influencing bioimpedance measurements include intrathoracic fluid shifts and changes in hematocrit. More than 150 validation studies have been published, and both poor and good correlations between impedance plethysmography and a reference method have been reported.[41] Although impedance plethysmography has not gained wide acceptance, the technique offers clinicians a simple, quick method to determine CO with minimal direct patient risk.

Doppler Ultrasonography

Doppler ultrasonography can measure the velocity of blood in the ascending or descending aorta or outflow tract of the pulmonary artery. CO is calculated by multiplying the time-weighted average velocity of blood flow by an estimate of aortic or pulmonary artery cross-sectional area that can be directly measured or predicted from a nomogram. Accuracy and precision depend on the estimate of the vessel diameter and the alignment of the Doppler probe. Velocity measurements are most accurate when the Doppler probe and the blood flow are parallel. If the alignment exceeds 25 degrees, velocity measurements lose precision. Suprasternal, transtracheal, and transesophageal probes have been designed for clinical use.[42,43] The development of esophageal Doppler probes allows for continuous, minimally invasive estimation of CO, and may allow for optimization of intravascular volume status without the use of a CVP or PAC.[44]

Arterial Pulse Contour Analysis

Pulse contour analysis of the arterial pressure waveform allows clinicians to determine beat-to-beat measurements of left ventricular output. Computer algorithms are used to calculate the area under the systolic portion of the arterial pulse waveform (from the end of diastole to the end of the ejection phase). Stroke volume is determined by dividing the resulting area by the aortic impedance. A limitation of arterial pulse contour analysis is that the technique requires calibration with another method of measuring cardiac output. Reference cardiac output determinations for calibration can be obtained using moderately invasive (thermodilution CO using a PAC or transpulmonary themodilution using a central venous and arterial line) or minimally invasive (lithium dilution using a peripheral venous and arterial catheter) technology. A number of clinical studies have demonstrated that the precision and accuracy of arterial pulse contour analysis is acceptable when compared with thermodilution CO measurements obtained by PACs.[45,46]

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

The use of transesophageal echocardiography (TEE) in the perioperative period has increased significantly since its first application in humans was reported by Frazen in 1976. (See also Chapter 3) Rapid technological advances have occurred since then, including a reduction in

transducer size, the development of multiplane probes, and the use of pulsed-wave, continuous-wave, and color flow Doppler. Improvements in computer design and image acquisition have allowed for a more comprehensive examination of the heart and surrounding structures. TEE appears to offer distinct advantages over other monitors of cardiovascular function and can provide the anesthesiologist with unique diagnostic information in the operating room.

Modern TEE machines offer a number of imaging techniques. In *M-mode*, or motion mode, all of the structures along a narrow ultrasound beam are plotted on the *x*-axis versus time on the *y*-axis. M-mode allows only a few millimeters of the heart to be visualized at any one time. *Two-dimensional (2-D) mode* uses multiple scanning lines to create a two-dimensional image of a cross section of the heart. This image is updated 30 to 60 times per second, which produces a real-time display of cardiac motion.

Doppler technology provides information about blood flow in the heart and major vessels. The *Doppler effect* is based on the principle that moving objects (red blood cells) change the frequency of the emitted ultrasound beam. If an object is moving toward the transducer, the ultrasound beam is compressed, which increases the frequency of the transmitted signal. An object moving away from the transducer lowers the frequency of the transmitted ultrasound beam. This information allows the calculation of blood flow velocity within the cardiovascular system. Current TEE machines use three Doppler systems: pulsed-wave, continuous-wave, and color flow Doppler. *Pulsed-wave Doppler* uses a single crystal to emit and receive short bursts of ultrasound at a known frequency (pulse repetition frequency). By measuring the time required for the transmitted ultrasound bursts to return to the transducer, the velocity of blood flow at precise locations in the heart can be measured. A major limitation of pulsed-wave Doppler is that high-velocity flows cannot be accurately quantified. The maximal velocity that can be measured is limited to one half of the pulse repetition frequency; this is known as the Nyquist limit. *Continuous-wave Doppler* uses two crystals (one to transmit, one to receive) to measure blood flow velocity continuously. This allows for accurate measurement of high-velocity flows, but does not permit precise localization. *Color flow Doppler* uses pulsed-wave technology to measure blood flow velocity at multiple sites. Blood flow toward the transducer is coded red and flow away from the transducer is coded blue. Rapidly accelerating or turbulent flow is coded green. By superimposing this color map on a 2-D image of the heart, the direction and velocity of blood flow in the heart can be easily imaged.

Monitoring Applications

There are a number of important monitoring applications for TEE in the perioperative period. In 1996, the ASA and the Society of Cardiovascular Anesthesiologists published practice guidelines to define the proper indications for performing TEE in the operative setting.[47] Indications were divided into three categories.

Category I indications are supported by the strongest evidence or expert opinion; TEE frequently is useful in improving clinical outcomes and is often indicated, depending on patient risk and practice setting. Category II indications are supported by weaker evidence and expert consensus; TEE may be useful in improving clinical outcomes, depending on individual circumstances. Category III indications have little current scientific or expert support, and TEE is infrequently useful in improving clinical outcomes. These indications are summarized in Table 24-7.

TABLE 24-7 Indications for Perioperative Transesophageal Echocardiography

Category I indications: Supported by the strongest evidence or expert opinion; TEE is frequently useful in improving clinical outcomes in these settings and is often indicated, depending on individual circumstances (e.g., patient risk and practice setting).

Intraoperative evaluation of acute, persistent, and life-threatening hemodynamic disturbances in which ventricular function and its determinants are uncertain and have

not responded to treatment

Intraoperative use in valve repair

Intraoperative use in congenital heart surgery for most lesions requiring cardiopulmonary bypass

Intraoperative use in repair of hypertrophic obstructive cardiomyopathy

Intraoperative use for endocarditis when preoperative testing was inadequate or extension of infection to perivalvular tissue is suspected

Preoperative use in unstable patients with suspected thoracic aortic aneurysms, dissection, or disruption who need to be evaluated quickly

Intraoperative assessment of aortic valve function in repair of aortic dissections with possible aortic valve involvement

Intraoperative evaluation of pericardial window procedures

Use in intensive care unit for unstable patients with unexplained hemodynamic disturbances, suspected valve disease, or thromboembolic problems (if other tests or monitoring techniques have not confirmed the diagnosis or patients are too unstable to undergo other tests)

Category II indications: Supported by weaker evidence and expert consensus; TEE may be useful in improving clinical outcomes in these settings, depending on individual circumstances, but appropriate indications are less certain.

Perioperative use in patients with increased risk of myocardial ischemia or infarction

Perioperative use in patients with increased risk of hemodynamic disturbances

Intraoperative assessment of valve replacement

Intraoperative assessment of repair of cardiac aneurysms

Intraoperative evaluation of removal of cardiac tumors

Intraoperative detection of foreign bodies

Intraoperative detection of air emboli during cardiotomy, heart transplantation operations, and upright neurosurgical procedures

Intraoperative use during intracardiac thrombectomy

Intraoperative use during pulmonary embolectomy

Intraoperative use for suspected cardiac trauma

Preoperative assessment of patients with suspected acute thoracic aortic dissections, aneurysms, or disruption

Intraoperative use during repair of thoracic aortic dissections without suspected aortic valve involvement

Intraoperative detection of aortic atheromatous disease or other sources of aortic emboli

Intraoperative evaluation of pericardectomy or pericardial effusions, or evaluation of pericardial surgery

Intraoperative evaluation of anastomotic sites during heart or lung transplantation

Monitoring placement and function of assist devices

Category III indications: Little current scientific or expert support; TEE is infrequently useful in improving clinical outcomes in these settings, and appropriate indications are uncertain.

Intraoperative evaluation of myocardial perfusion, coronary artery anatomy, or graft patency

Intraoperative use during repair of cardiomyopathies other than hypertrophic obstructive cardiomyopathy

Intraoperative use for uncomplicated endocarditis during noncardiac surgery

Intraoperative monitoring for emboli during orthopaedic procedures

Intraoperative assessment of repair of thoracic aortic injuries

Intraoperative use for uncomplicated pericarditis

Intraoperative evaluation of pleuropulmonary diseases

Monitoring placement of intra-aortic balloon pumps, automatic implantable cardiac defibrillators, or pulmonary artery catheters Intraoperative monitoring of cardioplegia administration
TEE, transesophageal echocardiography.
Reproduced with permission from American Society of Anesthesiologists and Society of Cardiovascular Anesthesiologists Task Force on Transesophageal Echocardiography: Practice guidelines for perioperative transesophageal echocardiography. Anesthesiology 84:96, 1996.

5 Transesophageal echocardiography is used extensively as a monitor of ventricular function. TEE appears to provide more accurate estimates of left ventricular preload than pulmonary artery catheterization. In echocardiography, preload is determined by measuring end-diastolic area. Studies in patients undergoing cardiac or vascular surgery revealed that end-diastolic area calculated by TEE correlated well with left ventricular preload, whereas pulmonary artery diastolic pressure correlated poorly with left ventricular preload.[48,49] Left atrial and left ventricular pressures may also be calculated using Doppler measurements of flow across the mitral valve, or from the pulmonary veins into the left atrium. TEE estimates of intracardiac filling pressures correlate well with data obtained from PACs.[50] Left ventricular contractility can be estimated using a variety of techniques. Ejection fraction can be determined by measuring left ventricular end-diastolic area (EDA) and end-systolic area (ESA):

$$\text{ejection fraction area} = \frac{\text{EDA} - \text{ESA}}{\text{EDA}} \times 100$$

Stroke volume can be calculated by measuring the Doppler velocity of flow across an area of the heart (aortic valve, pulmonary artery, left ventricular outflow tract) and multiplying this value times the area through which the flow occurs. The stroke volume times heart rate yields CO. The use of biplane or multiplane probes appears to increase the accuracy of CO measurements.[51]

Transesophageal echocardiography may provide a more meaningful reference standard for myocardial ischemia than ECG. Within seconds of the onset of myocardial ischemia, abnormal inward motion and thickening of the affected myocardial segment occurs. Wall motion abnormalities precede changes in the ECG or PAC. Clinical studies suggest that many episodes of ischemia detected by TEE are missed by standard intraoperative ECG monitoring.[52,53] However, not all wall motion abnormalities are because of ischemia. Ventricular pacing, conduction abnormalities, translational motion of the heart, stunned myocardium, and changes in loading conditions can all mimic myocardial ischemia on TEE.

Transesophageal echocardiography is the only intraoperative monitor that provides information on the structure and function of the mitral, aortic, tricuspid, and pulmonic valves. The severity of stenotic or regurgitant valvular disease can be determined using Doppler studies. One of the most important indications for TEE in the operating room is in the assessment of patients requiring valvular surgery. The use of TEE before cardiopulmonary bypass provides new information or prompts changes in valve surgery in 9 to 13% of cases.[47] In patients undergoing mitral valve repair, postcardiopulmonary bypass TEE revealed persistent valvular dysfunction in 6 to 11% of patients, leading to second pump runs in 3 to 10% of cases.[47]

Transesophageal echocardiography may be used to determine the etiology of acute hypotension in the perioperative period. Left ventricular failure or dysfunction can be

differentiated from other common causes of severe hypotension, such as hypovolemia or decreased systemic vascular resistance. Unusual causes of acute hypotension, including pericardial tamponade, pulmonary embolism, and aortic dissection, can be rapidly diagnosed with TEE. The early detection of the cause of hemodynamic instability allows for the appropriate therapy to be instituted (volume expansion, inotropes, vasopressors).

Transesophageal echocardiography is moderately invasive and is associated with major and minor complications. Major complications (esophageal trauma, dysrhythmias, hemodynamic instability) occur in 0.2 to 0.5% of examinations.[47] Minor complications (lip injuries, dental injuries, hoarseness, dysphagia) occur in 0.1 to 13% of cases and may be related to endotracheal intubation rather than TEE.[47] Complication rates may be reduced when examinations are performed by experienced practitioners. Most complication rates have been reported from studies in awake patients; some complications may be less frequent in anesthetized surgical patients.

MONITORING NEUROLOGIC FUNCTION

The best assessment of neurologic function is a thorough neurologic examination that evaluates the integration of brain and spinal cord function. However, anesthesia, sedation, and muscle relaxants, as well as existing neuropathology or trauma, may significantly impair the sensitivity or even the ability to perform a standard neurologic examination in the operating room. Therefore, monitoring neurologic function has become an important component of anesthesia care. Intraoperative neurologic monitoring often guides anesthesia and surgical decision making. Many intraoperative factors have the potential to influence spontaneous or evoked neural activity. General anesthesia can influence synaptic transmission and neural activity directly or by altering physiologic factors such as blood flow or blood pressure.

Intracranial Pressure Monitoring

Intracranial pressure (ICP) monitoring was initially used in trauma, where the relationship between uncontrolled ICP elevation and fatality has been firmly established.[54] ICP can be monitored by insertion of a subarachnoid bolt, a ventricular catheter, or an epidural transducer, or by insertion of a fiberoptic sensor in the cranial cavity. Each of these techniques requires a burr hole for intracranial access.

The cerebrospinal fluid (CSF) pressure wave is pulsatile and oscillates with the cardiac and respiratory cycle. Normal ICP is less than 15 mm Hg. Continuous recordings of the ICP in neurotrauma victims demonstrate three distinct pathologic waveforms. *A waves* (plateau waves) are found in patients with elevated baseline ICP and consist of a further elevation of ICP for periods from 5 to 20 minutes; A waves result from abrupt increases in regional cerebral blood volume where cerebral blood flow is decreased because of brain swelling, venous obstruction, or obstruction of CSF flow. *B* and *C waves* are of lesser magnitude and are related to respiratory pattern and blood pressure. Unlike A waves, they are not thought to be useful in guiding therapy or predicting outcome.

Intracranial pressure monitoring assumes that *cerebral perfusion pressure* (CPP = MAP - ICP) is uniformly distributed and that intracranial hypertension results in ischemia, displacement, compression, or herniation of the brain. ICP monitoring does not measure neural function or neural recovery.

Electroencephalogram

The electroencephalogram (EEG) represents the spontaneous electrical activity of the superficial cerebral cortex as recorded from either the scalp or surface electrodes. The EEG signal originates from postsynaptic excitatory and inhibitory potentials produced by the pyramidal cells located in the outer cerebral cortex. In the operating room, the EEG signal can often be recorded to assess cortical activity. Signal processing requires the amplification of small voltages (10 to 100 mV), which are 1,000 times smaller than ECG signals. Conventional EEG analysis uses scalp electrodes positioned at standardized points referenced to cranial dimensions. The voltage difference between a pair of EEG electrodes is amplified and compared with measurements using a reference

electrode. This method, differential amplification, reduces artifacts. The resulting signal is then passed through electronic filters, which reduce or remove unwanted frequencies, and is then displayed as voltage over time. The EEG is usually characterized by activity in four frequency bands: *beta* (>112 Hz), *alpha* (8–12 Hz), *theta* (4–8 Hz), and *delta* (<4 Hz).

In unanesthetized patients, the EEG trace demonstrates background rhythms regulated by "pacemaker neurons" of the lower brain structures and the local electrical activity resulting from cortical neurons underlying the active electrode. During anesthesia, the background alpha rhythm predominates. With deeper anesthesia or during ischemia, EEG activity generally decreases in both amplitude and frequency. A total of 50% of the brain's oxygen consumption has been attributed to the energy requirement for the generation of EEG activity.

Electroencephalographic monitoring has been advocated for the intraoperative detection of cerebral ischemia during carotid endarterectomy, during deliberate hypotension, for the intraoperative or perioperative assessment of pharmacologic interventions, for identification of epileptic foci, or for the assessment of coma or brain death.[55]

Deep anesthesia, cerebral ischemia, or other pathologic states abolish or reduce normal neural EEG activity (alpha and beta rhythms), and slower frequencies (delta and theta) predominate. Sleep or surgical anesthesia typically increases amplitude (synchronization), whereas arousal characteristically decreases amplitude (desynchronization). High concentrations of isoflurane or desflurane can cause periods of electrical silence interspersed with brief episodes of activity. This pattern is termed *burst suppression.* Similar effects are seen by many intravenous sedative drugs such as barbiturates. Increasing depth of anesthesia often results in EEG slowing with increases in amplitude, leading to burst suppression. At the highest levels of anesthesia, the EEG can become *isoelectric*, mimicking the effect of hypothermia or brain hypoxia. EEG interpretation requires experienced observers and the ability to integrate the changes with anesthetic, physiologic, and surgical events.

Processing Electroencephalographic Data

Several signal-processing techniques have been used to improve the ability of clinicians to interpret changes in the EEG and evaluate trends. The EEG signal is usually digitized, processed, and then graphically displayed for interpretation. Real-time analysis using Fourier transformation to identify amplitudes and frequencies of interest or a periodic analysis are often performed to convert voltage/time data to power spectral information, where power versus frequency information is graphically displayed over epochs (e.g., the *compressed spectral array*).

The *spectral edge frequency* is often calculated and displayed to summarize the changes in the power spectrum. The spectral edge is the frequency that is just above 95% of the power contained in the raw EEG. Monitoring the spectral edge

has been considered useful in detection of cerebral ischemia and anesthetic depth.[56] Other descriptors such as the peak power frequency or the median power frequency have been used to describe EEG data under anesthesia.[57]

The *bispectral index* (BIS) is a variable derived from the EEG that is a measure of the hypnotic effect of anesthetic agents. The BIS is the first processed EEG descriptor that purports to predict depth of consciousness. Previous EEG parameters, such as the spectral edge frequency, do not change in a linear manner with increasing depth of anesthesia. Furthermore, different anesthetic agents have differing effects on the processed EEG.

The calculation of the BIS integrates four different processed EEG descriptors into a single variable. These four parameters were selected on the basis of EEG data collected from thousands of anesthetics. The EEG data were correlated with the clinical state of the patient (level of consciousness, response to surgical incision). Each parameter has a particular stage of anesthesia where it performs most accurately. The BetaRatio parameter reflects light sedation, the SynchFastSlow detects surgical levels of anesthesia, and the burst suppression ratio (BSR) and QUAZI predominate during deep levels of anesthesia.[58] The parameters are then ranked and

combined to yield a single number, the BIS. The range of valves for the BIS is from 0 to 100, with decreasing numbers indicating deeper levels of sedation or anesthesia. BIS valves of less than 60 appear to predict absence of consciousness.

Clinical studies have demonstrated that the BIS can reliably predict the level of sedation, loss of consciousness, and the probability of recall using a variety of anesthetic agents.[59,60,61,62] The BIS does not appear to be as reliable in predicting movement in response to a noxious stimulation. Motor responses to painful stimuli may be mediated by subcortical structures, which are not measured by the BIS monitor. The use of the BIS can facilitate faster emergence and improved recovery from general anesthesia by allowing more precise titration of anesthetic effect.[63]

Other monitoring systems have been developed for clinical use that process EEG data in order to quantify depth of anesthesia. The *Patient State Index* (PSI) monitor records the EEG from anterior and posterior scalp sites. The EEG is analyzed using a multivariate algorithm that quantifies the most probable level of sedation or anesthesia. PSI values range from 0 to 100, with lower numbers indicating deeper states of hypnosis. These PSI values correlate well with level of consciousness and anesthesia, and use of PSI monitoring may allow for faster emergence and recovery from anesthesia.[64] The *Narcotrend* monitor classifies the EEG into 14 distinct stages from stage A (awake) to stage F1 (isoelectric EEG). Decreasing Narcotrend stages during anesthesia have been associated with decreasing BIS values.[65] Clinical studies suggest that the Narcotrend monitor is able to distinguish all states of anesthesia accurately.[66]

Evoked Potential Monitoring

Stimulation of neural structures to evoke responses is useful for monitoring the functional integrity of brainstem, visual, auditory, or peripheral neural pathways. Evoked potentials (EPs) represent small electrical signals generated in neural pathways after periodic stimulation. In the cortex and subcortex, EPs are smaller than the background EEG, and it is necessary to remove the random background electrical activity to record EP data. Computer signal averaging and filtering permits display of the EP voltages over time. EPs are usually quantitated by the time from stimulation (*latency*) and the *amplitude* of the peaks generated by the neural structures of interest. Three sensory pathways are available for intraoperative monitoring.[67]

Brainstem auditory evoked responses (BAERs) are monitored by stimulation of the cochlea using pulsed sound waves in the ear. Three to five waves are usually recorded using electrodes placed near the ear and cortex. BAERs are useful in assessing brainstem function in comatose patients and during surgical procedures of the cerebellopontine angle, floor of the fourth ventricle, or procedures in proximity to the fifth, seventh, or eighth cranial nerves.[68] Unlike other EPs, the BAERs are relatively resistant to the effects of anesthesia. A commercially available auditory evoked potential monitor has been developed that allows clinicians to accurately determine the depth of anesthesia in the perioperative setting.[69]

Visual evoked potentials (VEPs) are produced by flashing light to stimulate the retina and recording the EPs over the occipital cortex. VEPs assess the integrity of the visual pathway and have been used during resection of pituitary tumors, craniopharyngiomas, or surgery in the vicinity of the optic tracts. Unlike BAERs, VEPs are technically difficult to obtain during anesthesia, and questions have arisen about their usefulness in surgery.

Somatosensory evoked potentials (SSEPs) are produced by stimulating peripheral nerves and recording responses from electrodes monitoring the transmission of the EPs through the sensory pathway. The nerves usually stimulated are the median, ulnar, peroneal, or posterior tibial. Surface electrodes are placed to record the signal from peripheral nerves, plexuses, nerve roots, the dorsal columns, the brainstem lemniscal pathways to the thalamus, and the sensory cortex.

Median nerve SSEPs have been used to monitor cerebral function in patients undergoing neurosurgical procedures or those with cerebral ischemia. In these patients, examination of the timing and amplitude of the response measured over the contralateral scalp at 20 milliseconds (N20) represents the cortical response to stimulation. Similarly, examination of the negative waves occurring 11 to 14 milliseconds interrogates spinal roots, spinal cord, and brainstem.

Monitoring the responses of upper or lower extremity nerves may assist in evaluating spinal cord function during instrumentation of the spine or during thoracoabdominal surgery, where spinal cord ischemia is a possible risk factor. Deterioration of spinal cord function decreases the amplitude and increases the latency of the SSEP waveform. Monitoring of SSEPs is thought to be a sensitive indicator of the spinal cord's functional integrity. Despite the fact that SSEP monitoring does not evaluate the function of the motor pathway, it appears to be useful during spinal surgery, notably for correction of scoliosis.[70] Intraoperative SSEPs should be regarded as an extension of the sensory neurologic examination during anesthesia care, but may not totally replace the "wake-up" test. During anesthesia, monitoring both the area of risk and the contralateral pathways helps identify changes resulting from surgery as opposed to those as a result of other global variables, such as the effect of anesthesia.

Motor evoked potentials (MEPs) provide a means of assessing descending motor pathways during neurosurgical, orthopaedic, or vascular procedures. MEPs can be obtained by transcranial electrical stimulation, transcranial magnetic stimulation, or direct spinal cord stimulation.[71] Attenuation of transcranially elicited MEPs by commonly used anesthetic techniques has limited their usefulness during surgery. Further investigation with MEPs is needed to define fully their use during surgery.[72]

Facial nerve stimulation is commonly performed during procedures in the posterior fossa. Intentional stimulation or surgical irritation of the facial nerve can be evaluated visually or by evaluating the electromyogram. Although facial nerve function is rather insensitive to anesthetic influences, muscle relaxants need to be limited to provide adequate monitoring conditions.

TEMPERATURE MONITORING

The ability to monitor body temperature is a standard of anesthesia care. The continual observation of temperature changes in anesthetized patients allows for the detection of accidental heat loss or malignant hyperthermia. Humans maintain their core temperature by balancing heat production from metabolism and the many environmental factors that supply heat or cool the body. Regional temperature information from skin, muscle, the body cavities, spinal cord, and brain are integrated in the central nervous system. Conceptually, thermoregulation involves the integration of "set points," which, when exceeded, trigger temperature-dissipating, temperature-conserving, or heat-producing mechanisms. Both general and regional anesthesia inhibit afferent and efferent control of thermoregulation.[73,74] In addition, the operating room environment and surgical exposure often contribute to excessive heat losses. Heat loss is common during surgery because the surgical environment transfers heat from the patient and anesthesia reduces heat production and diminishes the capability of patients to monitor and maintain thermoregulation.

Heat is produced as a consequence of cellular metabolism. In adults, thermoregulation involves the control of basal metabolic rate, muscular activity, sympathetic arousal, vascular tone, and hormone activation balanced against exogenous factors that determine the need for the body to create heat or to adjust the transfer of heat to the environment.

Heat losses may result from radiation, conduction, convection, and evaporation. Radiation refers to the infrared rays emanating from all objects above absolute temperature. Conduction refers to the transfer of heat from contact with objects. Convection refers to the transfer of heat from air passing by objects. Evaporation represents the heat loss resulting when water vaporizes. For every gram of water evaporated, 0.58 kcal of heat is lost.

Perioperative hypothermia predisposes patients to increases in metabolic rate (shivering) and cardiac work, decreases in drug metabolism and cutaneous blood flow, and impairments of coagulation. Clinical studies have demonstrated that patients in whom intraoperative hypothermia develops are at a higher risk for development of postoperative myocardial ischemia and wound infection compared with patients who are normothermic in the perioperative period.[75,76] Anesthesiologists frequently monitor temperature and attempt to maintain central core temperature at near-normal values in all patients undergoing anesthesia.

Central core temperatures can be estimated using probes that can be placed into the bladder, distal esophagus, ear canal, trachea, nasopharynx, or rectum.[77] Pulmonary artery blood temperature is also a good estimate of central core temperature.

Temperature is usually measured using electrical probes containing calibrated thermistors or thermocouples that serve as temperature transducers. Thermistors respond to temperature changes by changing their electrical resistance. Thermocouples are constructed by passing current through a circuit where the electrodes are made of two dissimilar metals. The current measured is directly proportional to the temperature difference between the two metal junctions. Thermocouple temperature probes maintain one junction at a known temperature and place the second junction on the temperature probe tip. Skin temperature can also be monitored using liquid crystal thermometry. Although convenient, temperature strips do not correlate with core temperature measurements.[78]

Thermoregulatory responses are based on a physiologically weighted average reflecting changes in the mean body temperature. Mean body temperature is estimated by the following equation:

Mean temperature = 0.85 T core + 0.15 T skin

Skin temperature monitoring has been advocated to identify peripheral vasoconstriction but is not adequate to determine alterations in mean body temperature that may occur during surgery. Core temperature sites have been established as reliable indicators of changes in mean temperature. During routine noncardiac surgery, temperature differences between these sites are small. When anesthetized patients are being cooled, changes in rectal temperature often lag behind those of other probe locations, and the adequacy of rewarming is best judged by measuring temperature at several locations.

FUTURE TRENDS IN MONITORING

Diagnostic and therapeutic advances in medicine have had a great impact on the strategies and techniques available for intraoperative monitoring. Today's anesthesia practice has narrowed the distinction between laboratory medicine and patient monitoring. Technologic advances in instrument design, computerization, and engineering have made it possible to have ready access to serum chemistries, hematologic profiles, assessment of coagulation, and arterial blood gas measurements. Modern monitoring systems have the potential to transfer processed and raw data from the operating room to information management systems, which offer the potential for creating meaningful paperless anesthesia records and enhanced archiving of the conduct of anesthesia care as depicted by real-time monitoring trends.

The U.S. Department of Health and Human Services proposed implementation of patient record systems in 1996.[79] Proprietary systems for automated anesthesia records are now in the marketplace. These offer file sharing so that information that is traditionally viewed as patient monitoring can also be used for billing, ordering supplies, and quality improvement. Although computerization of the hospital environment has direct and indirect costs, the benefits to physicians, patients, insurers, and hospital administrators indicate that, like in other business environments, information management is coming to operating room monitoring and anesthesiology.[80,81] The clinical and administrative data that can be obtained from anesthesia work stations integrated with hospital information systems should enhance the quality of care and improve the intraoperative monitoring of anesthetized patients.

Chapter 25

Epidural and Spinal Anesthesia

Christopher M. Bernards

KEY POINTS

1	The epidural fat and the epidural venous plexus do not form a continuous "sheet" surrounding the spinal cord as is often depicted. Rather, the epidural fat lies in discrete pockets in the posterior and lateral epidural space and the epidural veins travel primarily in the anterior and lateral epidural space and are normally absent in the posterior epidural space.
2	Clinicians must develop a three-dimensional mental picture of the spinal anatomy so that when they contact boney structures during attempted epidural or spinal needle placement they can redirect the needle in a reasoned and systematic manner and not subject the patient to random needle "pokes" in an effort to place the block.
3	Serious systemic toxicity during attempted epidural block is almost always the result of inadvertent local anesthetic injection directly into the vasculature. Consequently, an appropriate test dose designed to identify intravascular injection is critical.
4	Physical characteristics (e.g., height, weight, cerebrospinal fluid [CSF] volume) and age do have an effect on spinal and epidural block characteristics. However, the magnitude of the effects are relatively small and of such low predictive power that these characteristics are not useful predictors of local anesthetic dose in any individual patient.
5	The risk of hemodynamic complications of epidural and spinal anesthesia increases with increasing block height.
6	Lidocaine appears to be worse than other local anesthetics in terms of the risk of neurological toxicity (i.e., cauda equina syndrome and transient radicular irritation).
7	Recent human studies suggest that the new preservative free formulation of chloroprocaine is safe for spinal anesthesia. This drug may offer a viable alternative to lidocaine for short duration spinal anesthesia.

8 Administration of drugs that impair coagulation can put patients at increased risk of spinal hematoma. Our understanding of the relative risk of different classes of drugs affecting the clotting system is constantly evolving. Clinicians are directed to the consensus statement from the American Society for Regional Anesthesia and Pain Medicine for the most recent recommendations (www.asra.com/items_of_interest/consensus_statements/)

There are no absolute indications for spinal or epidural anesthesia. However, there are clinical situations in which patient preference, patient physiology, or the surgical procedure makes central neuraxial block the technique of choice. There is also growing evidence that these techniques may improve outcome in selected situations. Spinal and epidural anesthesia have been shown to blunt the "stress response" to surgery,[1] to decrease intraoperative blood loss,[2,3] to lower the incidence of postoperative thromboembolic events,[2,3,4,5] and to decrease morbidity and mortality in high-risk surgical patients.[6,7] In addition, both spinal and epidural techniques can be used to extend analgesia into the postoperative period, where their use has been shown

to provide better analgesia than can be achieved with parenteral opioids.[8] In addition, central neuraxial analgesia has become an indispensable technique to provide analgesia to nonsurgical patients. Thus, these techniques are an indispensable part of modern anesthetic practice, and every anesthesiologist should be adept at performing them.

ANATOMY

Proficiency in spinal and epidural anesthesia requires a thorough understanding of the anatomy of the spine and spinal cord. The anesthesiologist must be familiar with the surface anatomy of the spine but must also develop a mental picture of the three-dimensional anatomy of deeper structures. In addition, one must appreciate the relationship between the cutaneous dermatomes, the spinal nerves, the vertebrae, and the spinal segment from which each spinal nerve arises.

Vertebrae

The *spine* consists of 33 *vertebrae* (7 cervical, 12 thoracic, 5 lumbar, 5 fused sacral, and 4 fused coccygeal) (Fig. 25-1). With the exception of C1, the cervical, thoracic, and lumbar vertebrae consist of a *body* anteriorly, two *pedicles* that project posteriorly from the body, and two *laminae* that connect the pedicles (Fig. 25-2). These structures form the *vertebral canal*, which contains the spinal cord, spinal nerves, and epidural space. The laminae give rise to the *transverse processes* that project laterally and the *spinous process* that projects posteriorly. These bony projections serve as sites for muscle and ligament attachments. The pedicles contain a superior and inferior *vertebral notch* through which the spinal nerves exit the vertebral canal. The superior and inferior *articular processes* arise at the junction of the lamina and pedicles and form joints with the adjoining vertebrae. The first cervical vertebra differs from this typical structure in that it does not have a body or a spinous process.

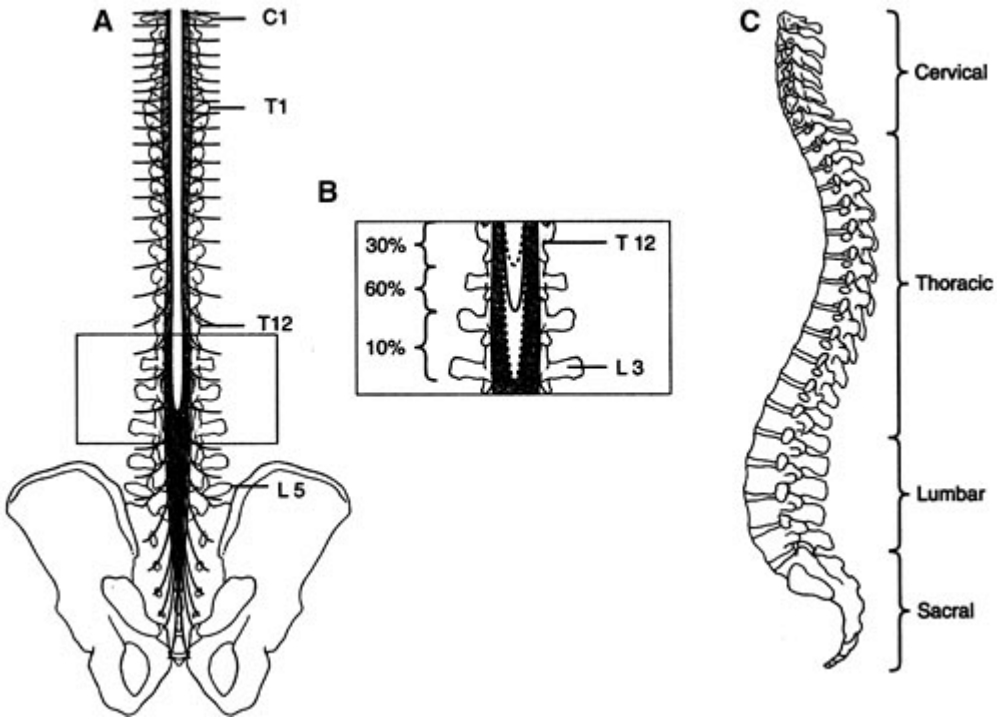

FIGURE 25-1. Posterior **(A)** and lateral **(C)** views of the human spinal column. Note the inset **(B)**, which depicts the variability in vertebral level at which the spinal cord terminates.

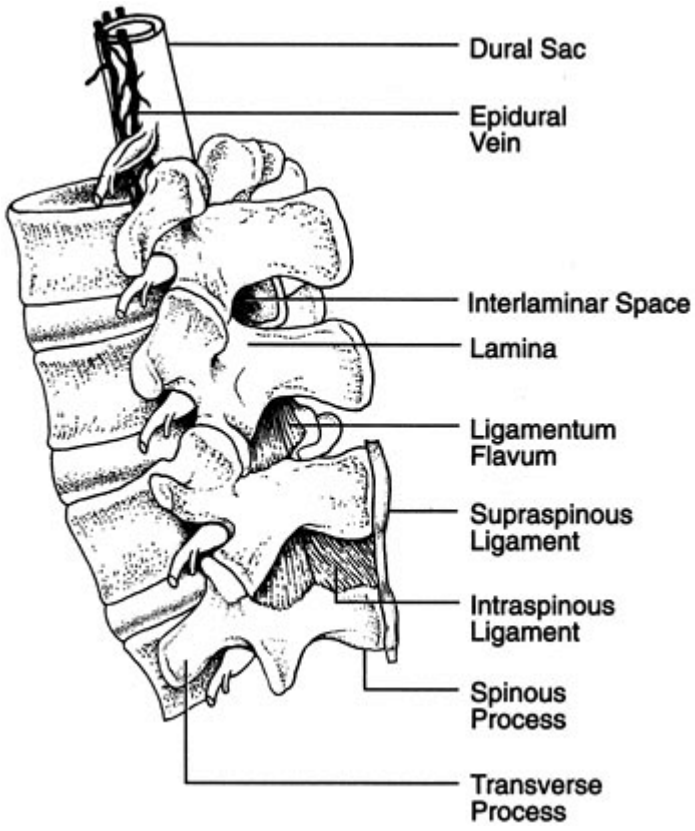

FIGURE 25-2. Detail of the lumbar spinal column and epidural space. Note that the epidural veins are largely restricted to the anterior and lateral epidural space.

The five sacral vertebrae are fused together to form the wedge-shaped *sacrum*, which connects the spine with the iliac wings of the pelvis (see Fig. 25-1). The 5th sacral vertebra is not fused posteriorly, giving rise to a variably shaped opening known as the *sacral hiatus*. Occasionally other sacral vertebrae do not fuse posteriorly, giving rise to a much larger sacral hiatus. The *sacral cornu* are bony prominences on either side of the hiatus and aid in identifying it. The sacral hiatus provides an opening into the sacral canal, which is the caudal termination of the epidural space. The four rudimentary coccygeal vertebrae are fused together to form the *coccyx*, a narrow triangular bone that abuts the sacral hiatus and can be helpful in identifying it. The tip of the coccyx can often be palpated in the proximal gluteal cleft and by running one's finger cephalad along its smooth surface, the sacral cornu can be identified as the first bony prominence encountered.

Identifying individual vertebrae is important for correctly locating the desired interspace for epidural and spinal blockade. The spine of C7 is the first prominent spinous process encountered while running the hand down the back of the neck. The spine of T1 is the most prominent spinous process and immediately follows C7. The 12th thoracic vertebra can be identified by palpating the 12th rib and tracing it back to its attachment to T12. A line drawn between the iliac crests crosses the body of L5 or the 4-5 interspace.

Ligaments

The vertebral bodies are stabilized by five ligaments that increase in size between the cervical and lumbar vertebrae (see Fig. 25-2). From the sacrum to T7, the *supraspinous ligament* runs between the tips of the spinous processes. Above T7 this ligament continues as the *ligamentum nuchae* and attaches to the occipital protuberance at the base of the skull. The *interspinous ligament* attaches between the spinous processes and blends posteriorly with the supraspinous ligament and anteriorly with the ligamentum flavum. The *ligamentum flavum* is a tough, wedge-shaped ligament composed of elastin. It consists of right and left portions that span adjacent vertebral laminae and fuse in the midline to varying degrees.[7,8] The ligamentum flavum is thickest in the midline, measuring 3 to 5 mm at the L2–3 interspace of adults. This ligament is also farthest from the spinal meninges in the midline, measuring 4 to 6 mm at the L2–3 interspace.[9] As a result, midline insertion of an epidural needle is least likely to result in unintended meningeal puncture. The anterior and posterior *longitudinal ligaments* run along the anterior and posterior surfaces of the vertebral bodies.

Epidural Space

The epidural space is the space that lies between the spinal meninges and the sides of the vertebral canal (Fig. 25-3). It is bounded cranially by the foramen magnum, caudally by the sacrococcygeal ligament covering the sacral hiatus, anteriorly by the posterior longitudinal ligament, laterally by the vertebral pedicles, and posteriorly by both the ligamentum flavum and vertebral lamina. The epidural space is not a closed space but communicates with the paravertebral space by way of the intervertebral foramina.[10] The epidural space is shallowest anteriorly where the dura may in some places fuse with the posterior longitudinal ligament. The space is deepest posteriorly, although the depth varies because the space is intermittently obliterated by contact between the dura mater and the ligamentum flavum or vertebral lamina. Contact between the dura mater and the pedicles also interrupts the epidural space laterally. Thus, the epidural space is composed of a series of discontinuous compartments that become continuous when the potential space separating the compartments is opened up by injection of air or liquid. A rich network of valveless veins (Batson's plexus) courses through the anterior and lateral portions of the epidural space with few if any veins present in the posterior epidural space (see Fig. 25-2).[11] The epidural veins anastomose freely with extradural veins, including the pelvic veins, the azygous system, and the intracranial veins. The epidural space also contains lymphatics and segmental arteries running between the aorta and the spinal cord.

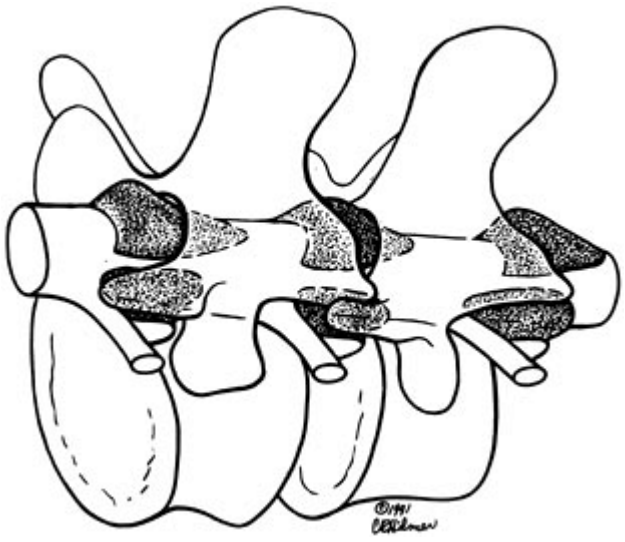

FIGURE 25-3. The compartments of the epidural space (*stippled areas*) are discontinuous. Areas where no compartments are indicated represent a potential space where the dura mater normally abuts the sides of the vertebral canal. (Reprinted with permission from Hogan Q: Lumbar epidural anatomy: A new look by cryomicrotome section. Anesthesiology 75:767, 1991.)

Epidural Fat

The most ubiquitous material in the epidural space is fat, which is principally located in the posterior and lateral epidural space (see Fig. 25-3).[10] Interestingly, the epidural fat appears to have clinically important effects on the pharmacology of epidurally and intrathecally administered drugs. For example, using a pig model, Bernards et al showed that there is a linear relationship between an opioid's lipid solubility and its terminal elimination half-time in the epidural space, its mean residence time in the epidural space, and its concentration in epidural fat.[12] In addition, net transfer of opioid from the epidural space to the intrathecal space was greatest for the least lipid soluble opioid (morphine) and least for highly lipid soluble opioids (fentanyl, sufentanil). In effect, increasing lipid solubility resulted in opioid "sequestration" in epidural fat, thereby, reducing the bioavailability of drug in the underlying subarachnoid space and spinal tissue.

Epidural fat also appears to play a role in the pharmacokinetics of epidurally administered local anesthetics. Specifically, sequestration in epidural fat likely explains why a highly lipid soluble local anesthetic like etidocaine is only approximately equipotent with lidocaine in the epidural space despite the fact that etidocaine is roughly seven times more potent than lidocaine in vitro. Because of its much greater lipid solubility, etidocaine is more likely than lidocaine to be sequestered in epidural fat, thereby reducing the amount of drug available to produce block in the spinal nerve roots and spinal cord. Consistent with this hypothesis, Lebeaux and Tucker showed that after administering 80 mg etidocaine and 50 mg lidocaine into the epidural space of sheep, the amount of etidocaine still present in epidural fat 12 hours later was more than 100 times greater than the amount of lidocaine.[13] Thus, sequestration in epidural fat appears to play an important role in the pharmacokinetics of local anesthetics just as it does for epidural opioids.

Meninges

The spinal meninges consist of three protective membranes (dura mater, arachnoid mater, and pia mater), which are continuous with the cranial meninges (Fig. 25-4).

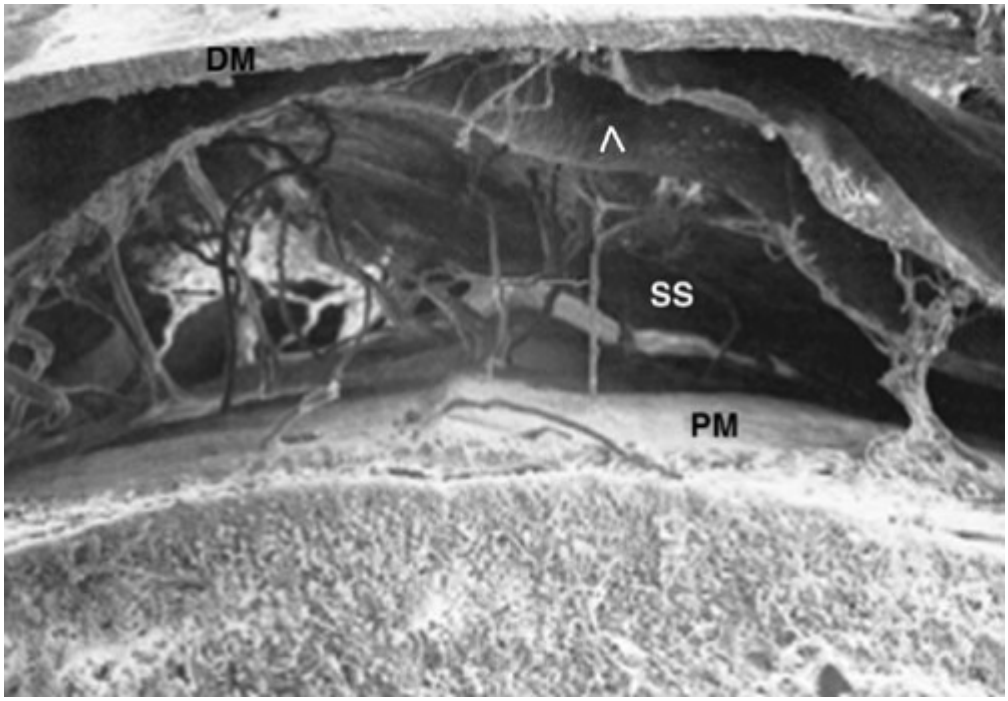

FIGURE 25-4. The spinal meninges of the dog, demonstrating the pia mater (*PM*) in apposition to the spinal cord, the subarachnoid space (*SS*), the arachnoid mater (*AM*), trabeculae (*arrow*), and the dura mater (*DM*). The separation between the arachnoid mater and the dura mater demonstrates the subdural space. The subdural space is only a potential space in vivo but is created here as an artifact of preparation. (Reprinted with permission from Peters A, Palay SL, Webster H (eds): The Fine Structure of the Nervous System: The Neurons and Supporting Cells. Philadelphia, WB Saunders, 1976.)

Dura Mater

The dura mater is the outermost and thickest meningeal tissue. The spinal dura mater begins at the foramen magnum where it fuses with the periosteum of the skull, forming the cephalad border of the epidural space. Caudally, the dura mater ends at approximately S2 where it fuses with the filum terminale. The dura mater extends laterally along the spinal nerve roots and becomes continuous with the connective tissue of the epineurium at approximately the level of the intervertebral foramina. The dura mater is composed of randomly arranged

collagen fibers and elastin fibers arranged longitudinally and circumferentially.[14] The dura mater is largely acellular except for a layer of cells that forms the border between the dura and arachnoid mater.

There is controversy regarding the existence and clinical significance of a midline connective tissue band, the *plica medianis dorsalis*, running from the dura mater to the ligamentum flavum. Anatomic studies using epiduroscopy[15] and epidurography[16] have demonstrated the presence of the *plica medianis dorsalis* and have led to speculation that this tissue band may on occasion be responsible for difficulty in inserting epidural catheters and for unilateral epidural block. However, using cryomicrotome sections to investigate the epidural space, Hogan failed to find evidence of a substantial connection between the dura mater and the ligamentum flavum.[10] He speculated that the injection of either air or contrast required for the earlier studies may have compressed epidural contents (e.g., fat) and produced an artifact mimicking a connective tissue band. In addition, Hogan has shown in a clinical study that there is no significant impediment to spread of injectate across the midline.[17] Thus, the *plica medianis dorsalis* does not appear to be clinically relevant with respect to clinical epidural anesthesia.

The inner surface of the dura mater abuts the arachnoid mater. There is a potential space between these two membranes called the *subdural space* (see Fig. 25-4). Occasionally a drug intended for either the epidural space or the subarachnoid space is injected into the subdural space.[18] Subdural injection has been estimated to occur in 0.82% of intended epidural injections.[19] The radiology literature suggests that the incidence of subdural injection during intended subarachnoid injection may be as high as 10%.[20]

Arachnoid Mater

The arachnoid mater is a delicate, avascular membrane composed of overlapping layers of flattened cells with connective tissue fibers running between the cellular layers. The arachnoid cells are interconnected by frequent tight junctions and occluding junctions. These specialized cellular connections likely account for the fact that the arachnoid mater is the principal physiologic barrier for drugs moving between the epidural space and the spinal cord.[21]

In the region where the spinal nerve roots traverse the dura and arachnoid membranes, the arachnoid mater herniates through the dura mater into the epidural space to form arachnoid granulations. As with the cranial arachnoid granulations, the spinal arachnoid granulations serve as a site for material in the subarachnoid space to exit the central nervous system (CNS). Although some have postulated that the arachnoid granulations are a preferred route for drugs to move from the epidural space to the spinal cord, the available experimental data suggest that this is not the case.[22]

The *subarachnoid space* lies between the arachnoid mater and the pia mater and contains the CSF. The spinal CSF is in continuity with the cranial CSF and provides an avenue for drugs in the spinal CSF to reach the brain. In addition, the spinal nerve roots and rootlets run in the subarachnoid space.

Pia Mater

The spinal pia mater is adherent to the spinal cord and is composed of a thin layer of connective tissue cells interspersed with collagen. Trabeculae connect the pia mater with the arachnoid mater and the cells of these two meninges blend together along the trabeculae. Unlike the arachnoid mater, the pia mater is fenestrated in places so that the spinal cord is in direct communication with the subarachnoid space. The pia mater extends to the tip of the spinal cord where it becomes the *filum terminale*, which anchors the spinal cord to the sacrum. The pia mater also gives rise to the dentate ligaments, which are thin connective tissue bands extending from the side of the spinal cord through the arachnoid mater to dura mater. These ligaments serve to suspend the spinal cord within the meninges.

Spinal Cord

In the first-trimester fetus, the spinal cord extends from the foramen magnum to the end of the spinal column. Thereafter, the vertebral column lengthens more than the spinal cord so that at birth the spinal cord ends at about the level of the third lumbar vertebra. In the adult, the caudad tip of the spinal cord typically lies at the level of the first lumbar vertebra. However, in 30% of individuals the spinal cord may end at T12, while in 10% it may extend to L3 (see Fig. 25-1).[23] A sacral spinal cord has been reported in an adult.[23] Flexion of the vertebral column causes the tip of the spinal cord to move slightly cephalad.

The spinal cord gives rise to 31 pairs of *spinal nerves*, each composed of an *anterior motor root* and a *posterior sensory root*. The nerve roots are in turn composed of multiple rootlets.

The portion of the spinal cord that gives rise to all of the rootlets of a single spinal nerve is called a cord segment. The skin area innervated by a given spinal nerve and its corresponding cord segment is called a *dermatome* (Fig. 25-5). The intermediolateral gray matter of the T1 through L2 spinal cord segments contains the cell bodies of the *preganglionic sympathetic neurons*. These sympathetic neurons run with the corresponding spinal nerve to a point just beyond the

intervertebral foramen where they exit to join the sympathetic chain ganglia.

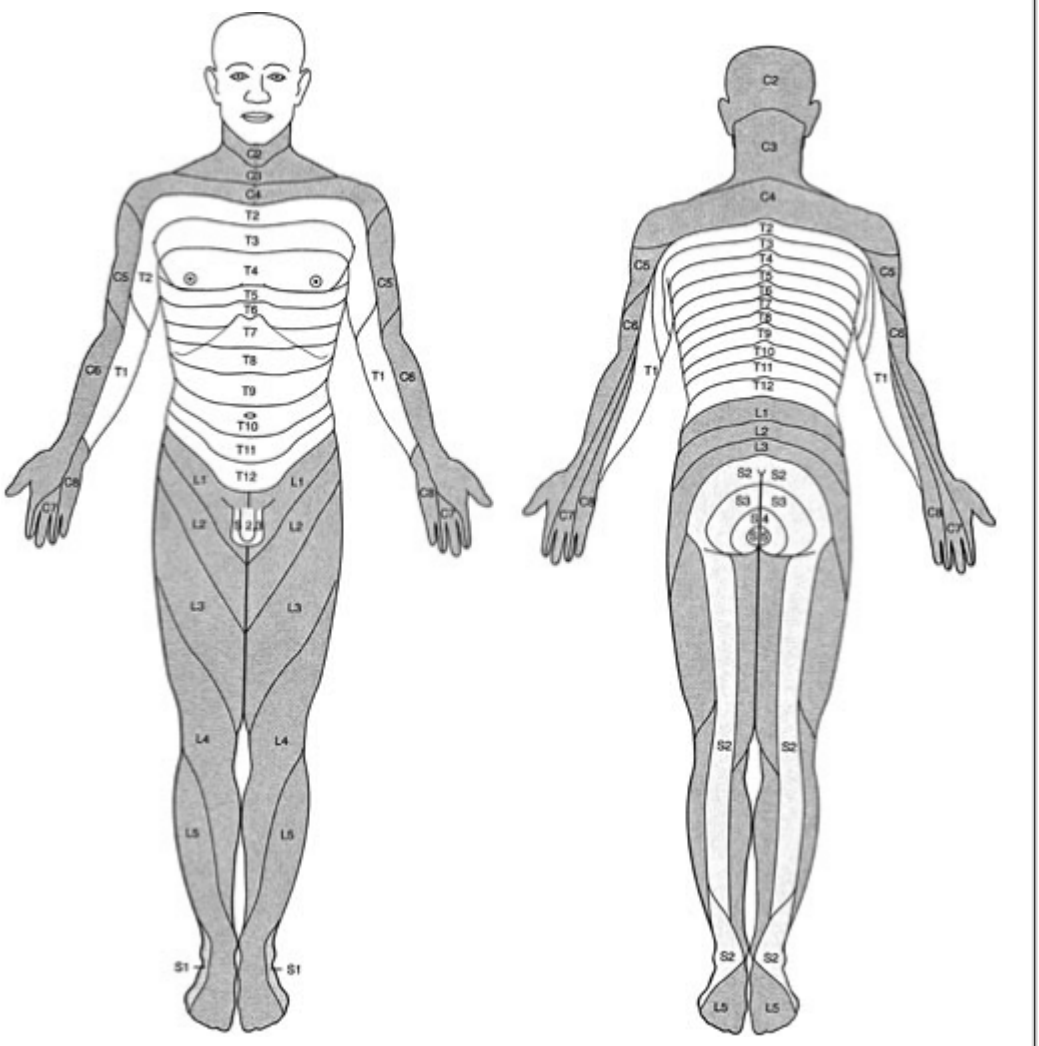

FIGURE 25-5. Human sensory dermatomes.

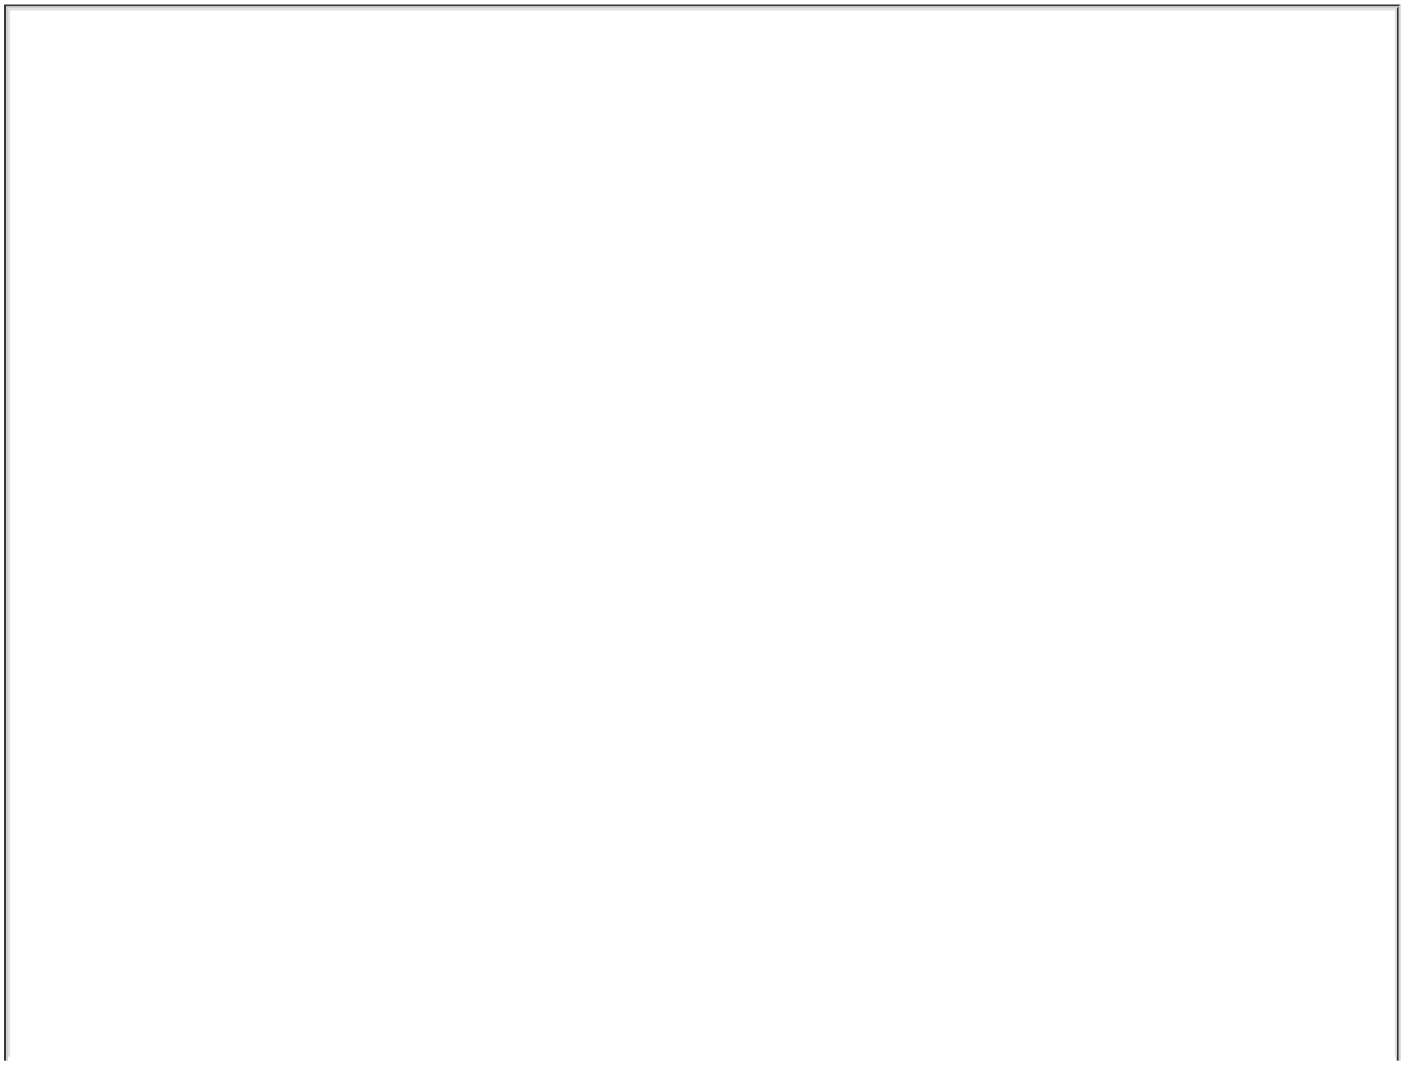
The spinal nerves and their corresponding cord segments are named for the intervertebral foramen through which they run. In the cervical region, the spinal nerves are named for the vertebra forming the caudad half of the intervertebral foramen; for example, C4 emerges through an intervertebral foramen formed by C3 and C4. In the thoracic and lumbar region, the nerve roots are named for the vertebrae forming the cephalad half of the intervertebral foramen; for example, L4 emerges through an intervertebral foramen formed by L4 and L5. Because the spinal cord ends between L1 and L2, the thoracic, lumbar, and sacral nerve roots run increasingly longer distances in the subarachnoid space to get from their spinal cord segment of origin to the intervertebral foramen through which they exit. Those nerves that extend beyond the end of the spinal cord to their exit site are collectively known as the cauda equina (see Fig. 25-1).



TECHNIQUE

Spinal and epidural anesthesia should be performed only after appropriate monitors are applied and in a setting where equipment for airway management and resuscitation are immediately available. Before positioning the patient, all equipment for spinal block should be ready for use, for example, local anesthetics mixed and drawn up, needles uncapped, prep solution available, and so on. Preparing all equipment ahead of time will minimize the time required to perform the block and thereby enhance patient comfort.

Needles

Spinal and epidural needles are named for the design of their tips (Fig. 25-6). The Whitacre and Sprotte spinal needles have a "pencil-point" tip with the needle hole on the side of the shaft. The Greene and Quincke needles have beveled tips with cutting edges. The pencil-point needles require more force to insert than the bevel-tip needles but provide a better tactile "feel" of the various tissues encountered as the needle is inserted. In addition, the bevel has been shown to cause the needle to be deflected from the intended path as it passes through tissues while the pencil-point needles are not deflected.[24] Epidural needles have a larger diameter than spinal needles to facilitate the injection of fluid or air when using the "loss-of-resistance" technique to identify the epidural space. In addition, the larger diameter allows for easier insertion of catheters into the epidural space. The Tuohy epidural needle has a curved tip to help control the direction that the catheter moves in the epidural space. The Hustead needle tip is also curved, although somewhat less than the Tuohy needle. The Crawford needle tip is straight, making it less suitable for catheter insertion. The outside diameter of both epidural and spinal needles is used to determine their gauge. Larger gauge (i.e., smaller diameter) spinal needles are less likely to cause postdural puncture headaches (PDPH), but are more readily deflected than smaller gauge needles. Epidural needles are typically sized 16 to 19 gauge and spinal needles 22 to 29 gauge. Spinal needles smaller than 22 gauge are often easier to insert if an introducer needle is used. The introducer is inserted into the interspinous ligament in the intended direction of the spinal needle and the spinal needle is then

inserted through the shaft of the introducer. The introducer prevents the spinal needle from being deflected or bent as it passes through the interspinous ligament.[24] Needles of the same outside diameter may have different inside diameters. This is important because inside diameter determines how large a catheter can be inserted through the needle and determines how rapidly CSF will appear at the needle hub during spinal needle insertion. All spinal and epidural needles come with a tight-fitting stylet. The stylet prevents the needle from being plugged with skin or fat and importantly prevents dragging skin into the epidural or subarachnoid spaces, where the skin may grow and form dermoid tumors.

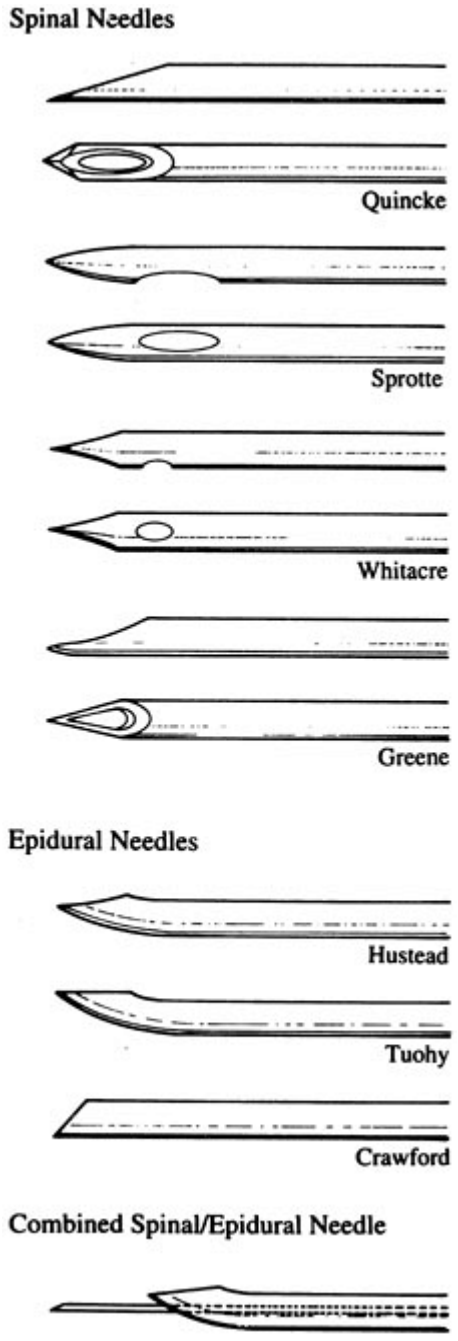


FIGURE 25-6. Some of the commercially available needles for spinal and epidural anesthesia. Needles are distinguished by the design of their tips.

Sedation

If the patient desires, light sedation is appropriate before placement of spinal or epidural block. Generally, the patient should not be heavily sedated because successful spinal and epidural anesthesia requires patient participation to maintain good position, evaluate block height, and indicate to the anesthesiologist about paresthesias if the needle contacts neural elements. In addition, patient cooperation is required to properly evaluate an epidural test dose; and sedation with as little as 1.5 mg midazolam plus 75 µg fentanyl has been shown to reduce the reliability of patient reports of subjective symptoms of intravenous local anesthetic injection.[25] Once the block is placed and adequate block height assured, the patient can be sedated as deemed appropriate.

Spinal Anesthesia

Position

Careful attention to patient positioning is critical to successful spinal puncture. Poor positioning can turn an otherwise easy spinal anesthetic into a challenge for both the anesthesiologist and the patient. Spinal needles are most often inserted with the patient in the lateral decubitus position and this technique is described in detail later. However, both the prone jackknife and sitting positions offer advantages under specific circumstances. The sitting position is sometimes used in obese patients because it is often easier to identify the midline with the patient sitting. In addition, the sitting position allows one to restrict spinal block to the sacral dermatomes (saddle block) when using hyperbaric local anesthetic solutions. Spinal block is generally performed in the prone jackknife position only when this is the position to be used for surgery. The use of hypobaric local anesthetic solutions with the patient in the prone jackknife position produces sacral block for perirectal surgery.

In the lateral decubitus position, the patient lies with the operative side down when using hyperbaric local anesthetic solutions and with the operative side up when using hypobaric solutions, thus assuring that the earliest and most dense block occurs on the operative side. The back should be at the edge of the table so that the patient is within easy reach. The patient's shoulders and hips are both positioned perpendicular to the bed to help prevent rotation of the spine. The knees are drawn to the chest, the neck is flexed, and the patient is instructed to actively curve the back outward. This will spread the spinous processes apart and maximize the size of the interlaminar foramen. It is useful to have an assistant who can help the patient maintain this position. Using the iliac crests as a landmark, the L2–3, L3–4, and L4–5 interspaces are identified and the desired interspace chosen for needle insertion. Interspaces above L2-3 are avoided to decrease the risk of hitting the spinal cord with the needle. Some find it helpful to mark the spinous processes flanking the desired interspace with a skin marker. This obviates the need to reidentify the intended interspace after the patient is prepped and draped.

The patient is prepped with an appropriate antiseptic solution and draped. All antiseptic solutions are neurotoxic, and care must be taken not to contaminate spinal needles or local anesthetics with the prep solution. How one drapes is a matter of personal preference, but the author finds that prepping and draping out a large area (e.g., T12-S1) with towels is preferable to using a commercial one-piece drape with a limited center hole. Draping a large area permits easier identification of a rotated or inadequately flexed back and allows one to readily move to another interspace if this becomes necessary.

Midline Approach

For the midline approach to the subarachnoid space, the skin overlying the desired interspace is infiltrated with a small amount of local anesthetic to prevent pain when inserting the spinal needle. One should avoid raising too large a skin wheal because this can obscure palpation of the interspace, especially in obese patients. Additional local anesthetic (1 to 2 mL) is then deposited along the intended path of the spinal

needle to a depth of 1 to 2 inches. This deeper infiltration provides additional anesthesia for spinal needle insertion and helps identify the correct path for the spinal needle.

The spinal needle or introducer needle is inserted in the middle of the interspace with a slight cephalad angulation of 10 to 15 degrees (Fig. 25-7). The needle is then advanced, in order, through the subcutaneous tissue, supraspinous ligament, interspinous ligament, ligamentum flavum, epidural space, dura mater, and finally arachnoid mater. The ligaments produce a characteristic "feel" as the needle is advanced through them, and the anesthesiologist should develop the ability to distinguish a needle that is advancing through the high-resistance ligaments from one that is advancing through lower-resistance paraspinous muscle. This will allow early detection and correction of needles that are not advancing in the midline. Penetration of the dura mater produces a subtle "pop" that is most easily detected with the pencil-point needles. Detection of dural penetration will prevent inserting the needle all the way through the subarachnoid space and contacting the vertebral body. In addition, learning to detect dural

penetration will allow one to insert the spinal needle quickly without having to stop every few millimeters and remove the stylet to look for CSF at the needle hub.

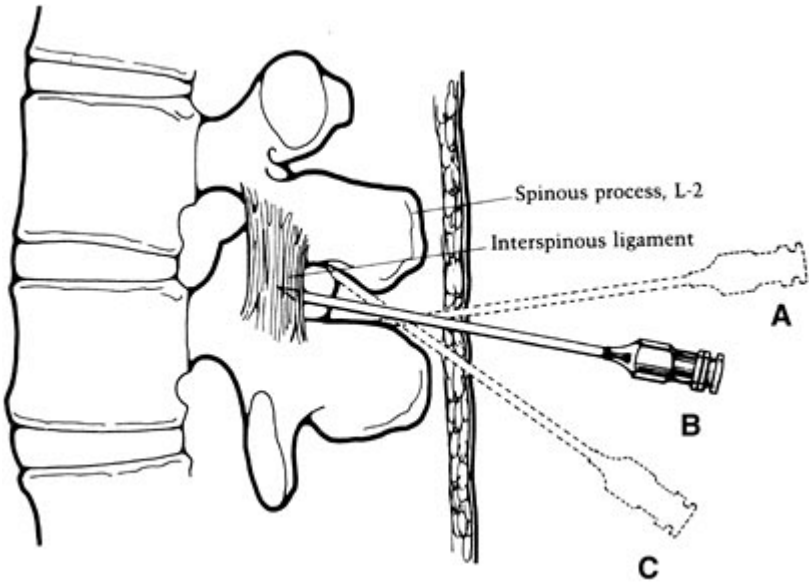

FIGURE 25-7. Midline approach to the subarachnoid space. The spinal needle is inserted with a slight cephalad angulation and should advance in the midline without contacting bone **(B)**. If bone is contacted, it may be either the caudad **(A)** or the cephalad spinous process **(C)**. The needle should be redirected slightly cephalad and reinserted. If bone is encountered at a shallower depth, then the needle is likely walking up the cephalad spinous process. If bone is encountered at a deeper depth, then the needle is likely walking down the inferior spinous process. If bone is repeatedly contacted at the same depth, then the needle is likely off the midline and walking along the lamina. (Reprinted with permission from Mulroy MF: Regional Anesthesia: An Illustrated Procedural Guide. Boston, Little Brown, 1989.)

Once the needle tip is believed to be in the subarachnoid space, the stylet is removed to see if CSF appears at the needle hub. With small diameter needles (26 to 29 gauge) this generally requires 5 to 10 seconds, but may require $\geqslant$1 minute in some patients. Gentle aspiration may speed the appearance of CSF. If CSF does not appear, the needle orifice may be obstructed by a nerve root and rotating the needle 90 degrees may result in CSF flow. Alternatively, the needle orifice may not be completely in the subarachnoid space and advancing an additional 1 to 2 mm may result in brisk CSF flow. This is particularly true of pencil-point needles, which have their orifice on the side of the needle shaft proximal to the needle tip. Finally, failure to obtain CSF suggests that the needle orifice is not in the subarachnoid space and the needle should be reinserted.

2 If bone is encountered during needle insertion, the anesthesiologist must develop a reasoned, systematic approach to redirecting the needle. Simply withdrawing the needle and repeatedly reinserting it in different directions is not appropriate. When contacting bone, the depth should be immediately noted and the needle redirected slightly cephalad. If bone is again encountered at a greater depth, then the needle is most likely walking down the inferior spinous process and it should be redirected more cephalad until the subarachnoid space is reached. If bone is encountered again at a shallower depth, then the needle is most likely walking up the superior spinous process and it should be redirected more caudad. If bone is repeatedly encountered at the same depth, then the needle is likely off the midline and walking along the vertebral lamina (see Fig. 25-7).

When redirecting a needle it is important to withdraw the tip into the subcutaneous tissue. If the tip remains embedded in one of the vertebral ligaments, then attempts at redirecting the needle

will simply bend the shaft and not reliably change needle direction. When using an introducer needle, it must also be withdrawn into the subcutaneous tissue before being redirected. Changes in needle direction should be made in small increments because even small changes in needle angle at the skin may result in fairly large changes in position of the needle tip when it reaches the spinal meninges at a depth of 4 to 6 cm. Care should be exercised when gripping the needle to ensure that it does not bow. Insertion of a curved needle will cause it to veer off course.

If the patient experiences a paresthesia, it is important to determine whether the needle tip has encountered a nerve root in the epidural space or in the subarachnoid space. When the paresthesia occurs, immediately stop advancing the needle, remove the stylet, and look for CSF at the needle hub. The presence of CSF confirms that the needle encountered a cauda equina nerve root in the subarachnoid space and the needle tip is in good position. Given how tightly packed the cauda equina nerve roots are, it is surprising that all spinal punctures do not produce paresthesias. If CSF is not visible at the hub, then the paresthesia probably resulted from contact with a spinal nerve root traversing the epidural space. This is especially true if the paresthesia occurs in the dermatome corresponding to the nerve root that exits the vertebral canal at the same level that the spinal needle is inserted. In this case the needle has most likely deviated from the midline and should be redirected toward the side opposite the paresthesia. Occasionally, pain experienced when the needle contacts bone may be misinterpreted by the patient as a paresthesia and the anesthesiologist should be alert to this possibility.

Once the needle is correctly inserted into the subarachnoid space, it is fixed in position and the syringe containing local anesthetic is attached. CSF is gently aspirated to confirm that the needle is still in the subarachnoid space and the local anesthetic slowly injected ($\leqslant$0.5 ml/s-1). After completing the injection, a small volume of CSF is again aspirated to confirm that the needle tip remained in the subarachnoid space while the local anesthetic was deposited. This CSF is then reinjected and the needle, syringe, and any introducer removed together as a unit. If the surgical procedure is to be performed in the supine position, the patient is helped onto his back. To prevent excessive cephalad spread of hyperbaric local anesthetic, care should be taken to ensure that the patient's hips are not raised off the bed as they turn.

Once the block is placed, strict attention must be paid to the patient's hemodynamic status with blood pressure and/or heart rate supported as necessary. Block height should also be assessed early by pin prick or temperature sensation. Temperature sensation is tested by wiping the skin with alcohol and may be preferable to pin prick because it is not painful. If, after a few minutes, the block is not rising high enough or is rising

too high, the table may be tilted as appropriate to influence further spread of hypobaric or hyperbaric local anesthetics.

Paramedian Approach

The paramedian approach to the epidural and subarachnoid spaces is useful in situations where the patient's anatomy does not favor the midline approach, e.g., inability to flex the spine or heavily calcified interspinous ligaments. This approach can be used with the patient in any position and is probably the best approach for the patient in the prone jackknife position.

The spinous process forming the lower border of the desired interspace is identified. The needle is inserted ~1 cm lateral to this point and is directed toward the middle of the interspace by angling it ~45 degrees cephalad with just enough medial angulation (~15 degrees) to compensate for the lateral insertion point. The first significant resistance encountered should be the ligamentum flavum. Bone encountered prior to the ligamentum flavum is usually the vertebral lamina of the cephalad vertebra and the needle should be redirected accordingly. An alternative method is to insert the needle perpendicular to the skin in all planes until the lamina is contacted. The needle is then walked off the superior edge of the lamina and into the subarachnoid space. The lamina provides a valuable landmark that facilitates correct needle placement; however, repeated needle contact with the periosteum can be painful.

Lumbosacral Approach

The lumbosacral (or Taylor) approach to the subarachnoid and epidural spaces is simply a paramedian approach directed at the L5-S1 interspace, which is the largest interlaminar space. This approach may be useful when anatomic constraints make other approaches unfeasible. The patient may be positioned laterally, prone or sitting, and the needle inserted at a point 1 cm medial and 1 cm inferior to the posterior superior iliac spine. The needle is angled cephalad 45 to 55 degrees and just medial enough to reach the midline at the level of the L5 spinous process. As with the paramedian approach, the interspinous ligament is bypassed and the first significant resistance felt should be the ligamentum flavum.

Continuous Spinal Anesthesia

Inserting a catheter into the subarachnoid space increases the utility of spinal anesthesia by permitting repeated drug administration as often as necessary to extend the level or duration of spinal block. A common and reasonable recommendation for subsequent dosing or "topping up" of continuous spinal blocks is to administer half the original dose of local anesthetic when the block has reached two thirds of its expected duration.

The technique is similar to that described for "single shot" spinal anesthesia except that a needle large enough to accommodate the desired catheter must be used. After inserting the needle and obtaining free-flowing CSF, the catheter is simply threaded into the subarachnoid space a distance of 2 to 3 cm. It is often easier to insert the catheter if it is directed cephalad or caudad instead of lateral. If the catheter does not easily pass beyond the needle tip, rotating the needle 180 degrees may be helpful or another interspace may be used. The catheter should never be withdrawn back into the needle shaft because of the risk of shearing the catheter off into the subarachnoid space.

A variety of catheters and needles are available for continuous spinal anesthesia. Commonly, 18-gauge epidural needles and 20-gauge catheters are used. However, needles and catheters this size carry a higher risk of PDPH, especially in young patients. Because of this risk, smaller needle and catheter combinations have been developed with catheters ranging in size from 24 to 32 gauge. Although smaller catheters decrease the risk of PDPH, they have also been associated with multiple reports of neurologic injury, specifically, cauda equina syndrome (see Complications). For this reason, the United States Food and Drug Administration has advised against using any catheter smaller than 24 gauge for continuous spinal anesthesia.

Epidural Anesthesia

For the novice, correct placement of an epidural needle can be technically more challenging than spinal needle placement because there is less room for error. However, with experience, epidural needle placement is often easier than spinal needle placement because the larger gauge needles used for epidural anesthesia are less likely to be deflected from their intended path and they produce much better tactile feel of the interspinous and flaval ligaments. In addition, the loss of resistance technique provides a much clearer end point when entering the epidural space than does the subtle pop of a spinal needle piercing the dura mater.

Patient preparation, positioning, monitors, and needle approaches for epidural anesthesia are the same as for spinal anesthesia. Unlike spinal anesthesia, epidural anesthesia may be performed at any intervertebral space. However, at vertebral levels above the termination of the spinal cord, the epidural needle may accidentally puncture the spinal meninges and damage the underlying spinal cord. To prevent accidental meningeal puncture, the anesthesiologist must learn to identify the interspinous ligaments and the ligamentum flavum by their feel. In addition, epidural needles must be advanced slowly and, most importantly, under control.

After proper positioning, sterile skin preparation, and draping, the desired interspace is identified and a local anesthetic skin wheal is raised at the point of needle insertion. Because epidural needles are relatively blunt, it is sometimes helpful to pierce the skin with a $\geqslant$18-gauge hypodermic needle before inserting the epidural needle. For epidural anesthesia using the midline

approach, the epidural needle is inserted through the subcutaneous tissue and into the interspinous ligament. The interspinous ligament has a characteristic "gritty" feel, much like inserting a needle into a bag of sand. This is especially true of younger patients. If the interspinous ligament is not clearly identified, then one should be suspicious that the needle is not in the midline. After engaging the interspinous ligament, the needle is advanced slowly through it until an increase in resistance is felt. This increased resistance represents the ligamentum flavum.

The epidural needle must now traverse the ligamentum flavum and stop within the epidural space before puncturing the spinal meninges. Numerous techniques for identifying the epidural space have been used successfully; however, the loss of resistance to fluid has the advantage of simplicity, reliability, and, most importantly, a higher success rate when compared to the use of air for loss of resistance.[26] In addition, use of fluid instead of air for loss of resistance decreases the risk of postdural puncture headache in the event of accidental meningeal puncture.[27]

A glass syringe or a specially designed low resistance plastic syringe is filled with 2 to 3 mL of saline and a small (0.1 to 0.3 mL) air bubble. The syringe is attached to the epidural needle and the plunger pressed until the air bubble is visibly compressed. If the needle tip is properly embedded within the ligamentum flavum, it should be possible to compress the air bubble without injecting fluid. In this way the air bubble serves as a gauge of the appropriate amount of pressure to exert on the syringe plunger. If the air bubble cannot be compressed without injecting fluid, then the needle tip is most likely not in the ligamentum flavum. In this case, the needle tip may still be in the

interspinous ligament, or it may be off the midline in the paraspinous muscles. To differentiate between these possibilities, one can carefully advance the needle and syringe a few millimeters in an effort to engage the ligamentum flavum. If it is still not possible to compress the air bubble, withdraw the needle into the subcutaneous tissue, and reinsert it.

Once the ligamentum flavum is identified, the needle is slowly advanced with the nondominant hand while the dominant hand maintains constant pressure on the syringe plunger (Fig. 25-8). As the needle tip enters the epidural space, there will be a sudden and dramatic loss of resistance as the saline is rapidly injected. Saline injection into the epidural space can be moderately painful and patients should be forewarned. If the needle is advancing obliquely through the ligamentum flavum, it is possible to enter into the paraspinous muscles instead of the epidural space. In this case the loss of resistance will be less dramatic. To help verify that the needle has entered the epidural space, 0.5 mL of air can be drawn into the syringe and injected. In the epidural space there will be virtually no resistance to air injection, while in the paraspinous muscles air injection will encounter demonstrable resistance.

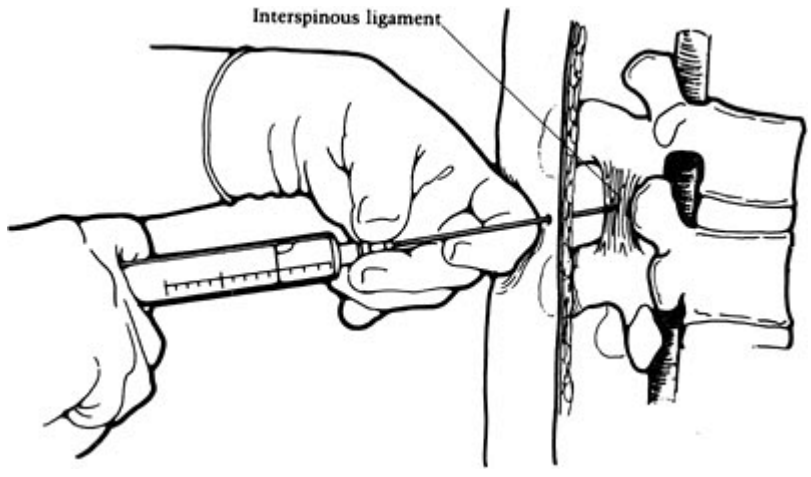

FIGURE 25-8. Proper hand position when using the loss-of-resistance technique to locate the epidural space. After embedding the needle tip in the ligamentum flavum, a syringe with 2 to

3 mL saline and an air bubble is attached. The left hand rests securely on the back and the fingers of the left hand grasp the needle firmly. The left hand advances the needle slowly and under control by rotating at the wrist. The fingers of the right hand maintain constant pressure on the syringe plunger but do not aid in advancing the needle. If the needle tip is properly engaged in the ligamentum flavum, it should be possible to compress the air bubble without injecting the saline. As the needle tip enters the epidural space, there will be a sudden loss of resistance and the saline will be suddenly injected. (Reprinted with permission from Mulroy MF: Regional Anesthesia: An Illustrated Procedural Guide. Boston, Little Brown, 1989.)

After entering the epidural space, stop advancing the needle. Because the dura mater abuts the ligamentum flavum in many places, the dura may now be tented over the needle tip and advancing the needle any farther than necessary heightens the risk of accidental meningeal puncture, i.e., "wet tap." When the syringe is disconnected from the needle, it is common to have a small amount of fluid flow from the needle hub. This is usually the saline flowing back out of the epidural space but could be CSF if the needle accidentally entered the subarachnoid space. CSF can often be distinguished by the fact that CSF will usually flow out in a volume greatly exceeding that used for the loss of resistance, CSF will be warm compared to saline, and CSF will test positive for glucose.

If a "single shot" technique is to be used, then a local anesthetic test dose should be administered to help rule out undetected subarachnoid or intravenous (iv) needle placement. After a negative test dose, the desired volume of local anesthetic should be administered in small increments (e.g., 5 mL) at a rate of 0.5 to 1 mL/s-1. Slow, incremental injection decreases the risk of pain during injection and allows detection of adverse reactions to accidental iv or subarachnoid placement before the entire dose is administered.

Continuous Epidural Anesthesia

Use of a catheter for epidural anesthesia affords much greater flexibility than the "single shot" technique because the catheter can be used to prolong a block that is too short, to extend a block that is too low, or to provide postoperative analgesia. On the downside, catheters may migrate into an epidural vein, into the subarachnoid space, or out an intervertebral foramen. Catheter use is also more likely to result in unilateral epidural block, a clinical fact shown to result from catheter tips that end up in the anterior epidural space or migrate out an intervertebral foramina.[17,28] An ever-changing selection of epidural catheters is commercially available. They differ in diameter, stiffness, location of injection holes, presence or absence of a stylet, construction material, and the like. Whichever catheter is chosen, it is important to verify that it passes easily through the epidural needle before the needle is placed in the epidural space. Epidural catheters are usually inserted through either Tuohy or Hustead needles because their curved tips help direct the catheter away from the dura mater. The needle bevel should be directed either cephalad or caudad, although the direction of the bevel does not guarantee that the catheter will travel in that direction. The catheter will typically encounter resistance as it reaches the curve at the tip of the needle, but steady pressure will usually result in passage into the epidural space. If the catheter will not pass beyond the needle tip, it is possible that the needle opening is not completely in the epidural space or that some structure in the epidural space is preventing catheter insertion (e.g., epidural fat). In this instance, the needle can be carefully advanced 1 to 2 mm more or rotated 180 degrees and the catheter reinserted. Although either of these maneuvers may result in successful catheter placement, they also increase the risk of accidental meningeal puncture. Alternatively, the procedure can be repeated at another interspace or with a different needle approach, for example, paramedian. Occasionally a catheter will advance only a short distance past the needle tip. This raises the possibility that the needle tip is not in the epidural space and needs to be repositioned. In this case, the catheter should not be withdrawn back into the epidural needle because of the risk that the catheter tip will be sheared off by the bevel's sharp edge. Rather, the needle and catheter should be pulled out in

tandem and the procedure repeated.

The catheter should be advanced only 3 to 5 cm into the epidural space. Placing a longer length of catheter in the epidural space increases the risk that it will enter an epidural vein, puncture the spinal meninges, exit an intervertebral foramen, wrap around a nerve root, or wind up in some other disadvantageous location. Once the catheter is appropriately positioned in the epidural space, the needle is slowly withdrawn with one hand as the catheter is stabilized with the other. After the needle is removed, the length of catheter in the epidural space is confirmed by subtracting the distance between the skin and the epidural space from the length of catheter below the skin. Documenting this distance is important when trying to determine if catheters used in the postoperative period have been dislodged.

An epidural test dose must be administered through the catheter to test for iv or subarachnoid placement before incrementally delivering the entire epidural drug dose. In addition, because of the risk of undetected iv or subarachnoid migration of the catheter over time, additional test doses must be administered before each top-up dose is given through the catheter. As with continuous spinal anesthesia, a reasonable guideline for top-up doses is to administer half the initial local anesthetic

dose at an interval equal to two thirds the expected duration of the block.

Epidural Test Dose

3 The epidural test dose is designed to identify epidural needles or catheters that have entered an epidural vein or the subarachnoid space. Failure to perform the test may result in intravascular injection of toxic doses of local anesthetic or total spinal block. Aspirating the catheter or needle to check for blood or CSF is helpful if positive, but the incidence of false-negative aspirations is too high to rely on this technique alone.[29]

The most common test dose is 3 mL of local anesthetic containing 5 mg/mL-1 epinephrine (1:200,000). The dose of local anesthetic should be sufficient that subarachnoid injection will result in clear evidence of spinal anesthesia. Intravenous injection of this dose of epinephrine typically produces an average 30 beats per minute—one heart rate increase between 20 and 40 seconds after injection.[30,31] Heart rate increases may not be as evident in some patients taking β-blocking drugs; reflex bradycardia usually occurs in these patients.[30,32] In β-blocked patients, a systolic blood pressure increase of $\geqslant$20 mm Hg may be a more reliable indicator of intravascular injection.[30,32]

Importantly, the sensitivity of the standard 15 μg epinephrine test dose has been shown to be markedly diminished by preexisting high thoracic epidural anesthesia and/or concurrent general anesthesia.[33] Larger epinephrine doses may be effective at detecting intravenous injection in these settings, but that has not been shown experimentally.

Isoproterenol has also been used to detect intravascular injection.[34] In addition, air injection combined with a precordial doppler to detect the characteristic murmur has been used successfully to test for iv placement of epidural catheters.[29] These techniques have been developed for use in laboring women where the sensitivity of epinephrine as a test dose is disturbingly low because maternal heart rate increases during contractions are often as large as those produced by epinephrine.[35] The clinical indications for these alternative tests of intravascular injection await additional larger studies.

Combined Spinal–Epidural Anesthesia

Combined spinal–epidural anesthesia (CSEA) is a useful technique by which a spinal block and an epidural catheter are placed simultaneously. This technique is popular because it combines the rapid onset, dense block of spinal anesthesia with the flexibility afforded by an epidural catheter. There are special epidural needles with a separate lumen to accommodate a spinal needle available for CSEA (see Fig. 25-6). However, the technique is easily performed by first placing a standard epidural needle in the epidural space and then inserting an appropriately sized spinal

needle through the shaft of the epidural needle and into the subarachnoid space. The desired local anesthetic is injected into the subarachnoid space, the spinal needle removed, and a catheter placed in the epidural space via the epidural needle. The catheter can then be used to extend the height or duration of intraoperative block or can be used to provide postoperative epidural analgesia.

An interesting pharmacologic aspect of CSEA is the observation that after the peak spinal block height is established, both saline and local anesthetic injected into the epidural space are effective at pushing the block level higher.[36,37,38] This observation has been interpreted to indicate that the mechanism by which the epidural "top-up" increases block height is by a volume effect (i.e., compression of the spinal meninges forcing CSF cephalad) as well as a local anesthetic effect.

A potential risk of this technique is that the meningeal hole made by the spinal needle may allow dangerously high concentrations of subsequently administered epidural drugs to reach the subarachnoid space. Anecdotal case reports and in vitro animal studies suggest that this may be a legitimate concern.[35,39,40,41] Although CSEA shows great promise, additional prospective studies are necessary to identify the relative risks and limitations of the technique.

PHARMACOLOGY

Successful spinal or epidural anesthesia requires a block that is high enough to block sensation at the surgical site and lasts for the duration of the planned procedure. However, because variability between patients is considerable (Figs. 25-9 and 25-10), reliably predicting the height and duration of central neuraxial block that will result from a particular local anesthetic dose is difficult. Thus, recommendations regarding local anesthetic choice and dose must be viewed as approximate guidelines. The clinician must understand the factors governing spinal and epidural block height and duration to individualize local anesthetic choice and dose for each patient and procedure.

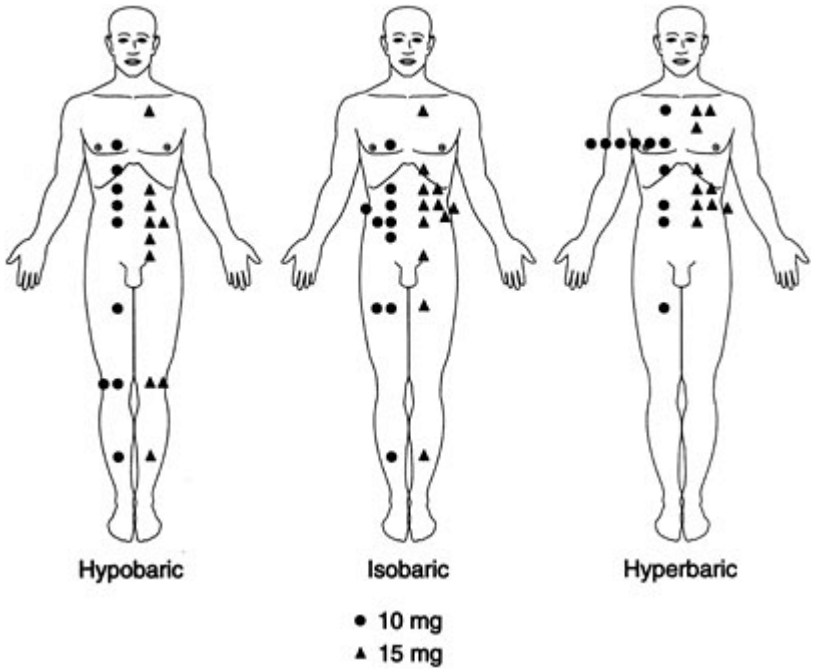

FIGURE 25-9. Peak spinal block height following 10- and 15-mg doses of hypobaric, isobaric, and hyperbaric tetracaine solutions injected at L3-4 with patients in the lateral horizontal position. Note that dose has no influence on block height and that there is considerable interindividual variability in peak block height, especially with the hypobaric solution. (Adapted with permission from Brown DT, Wildsmith JA, Covino BG, Scott DB: Effect of baricity on spinal anaesthesia with amethocaine. Br J Anaesth 52:589, 1980.)

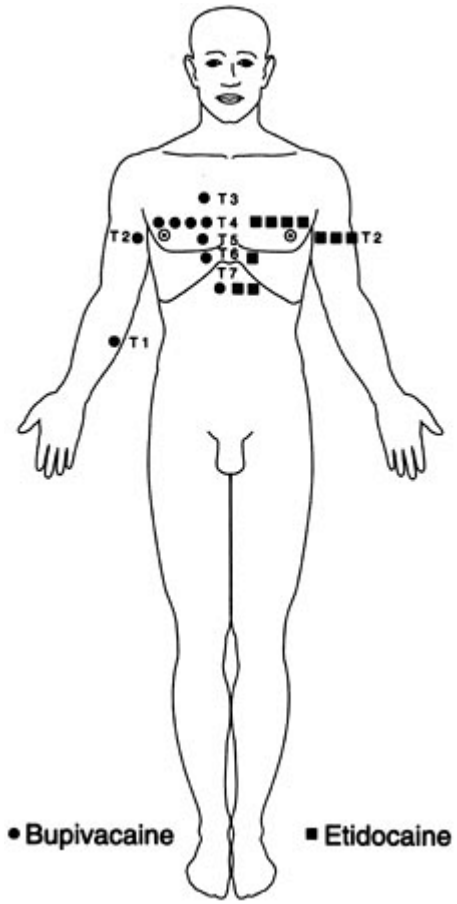

FIGURE 25-10. Peak epidural block height following 20 mL of 0.75% bupivacaine and 1.5% etidocaine injected via a catheter at the L1-2 interspace. Note that despite a well-controlled technique, the interindividual variability in block height is considerable and demonstrates the difficulty in accurately predicting block height in an individual patient. (Adapted with permission from Sinclair CJ, Scott DB: Comparison of bupivacaine and etidocaine in extradural blockade. Br J Anaesth 56:147, 1984.)

Spinal Anesthesia

Block Height

Table 25-1 lists some common surgical procedures that are readily performed under spinal anesthesia and the block height that is usually sufficient to ensure patient comfort. Also listed are techniques that are appropriate to achieve the desired block height. The rationale for these recommendations is explained in the following section.

TABLE 25-1 Representative Surgical Procedures Appropriate for Spinal Anesthesia

·SURGICAL PROCEDURE	·SUGGESTED BLOCK HEIGHT	·TECHNIQUE	·COMMENTS
Perianal Perirectal	L1-2	Hyperbaric solution/sitting position Hypobaric solution/jackknife position Isobaric solution/horizontal position	Patients must remain in relative head-up or head-down position when using hypobaric and hyperbaric solutions to maintain restricted spread during the procedure
Lower extremity Hip Transurethral resection of the prostate Vaginal/cervical	T10	Isobaric solution	Hypobaric and hyperbaric solutions are also suitable but may produce higher blocks than necessary
Herniorraphy Pelvic procedures Appendectomy	T6-8	Hyperbaric solution/horizontal position	Isobaric solutions injected at L2-3 interspace may also be suitable
Abdominal Cesasean section	T4-6	Hyperbaric solution/horizontal position	Upper abdominal procedures usually require concomitant

			general anesthesia to prevent vagal reflexes and pain from traction on diaphragm, esophagus, and the like

Baricity and Patient Position. The height of spinal block is thought to be determined by the cephalad spread of local anesthetic within the CSF. Table 25-2 lists some of the many

P.701

variables that have been proposed to influence the spread of local anesthetics within the subarachnoid space. Many of these variables have been shown to be of negligible clinical importance. Of those factors that do exert significant influence on local anesthetic spread, the baricity of the local anesthetic solution relative to patient position is probably the most important. Baricity is defined as the ratio of the density (mass/volume) of the local anesthetic solution divided by the

P.702

density of CSF, which averages 1.0003 ± 0.0003 g/mL-1 at 37°C. Solutions that have the same density as CSF have a baricity of 1.0000 and are termed isobaric. Solutions that are more dense than CSF are termed hyperbaric, whereas solutions that are less dense than CSF are termed hypobaric.

Table 25-3 lists the baricity of local anesthetic solutions commonly used for spinal anesthesia. For practical purposes, solutions with a baricity <0.9990 can be expected to reliably behave hypobarically in all patients. Hypobaric solutions are typically prepared by mixing the local anesthetic solution in distilled water. Solutions with a baricity of ⩾1.0015 can be expected to reliably behave hyperbarically. Hyperbaric solutions are typically prepared by mixing the local anesthetic in 5% to 8% dextrose. The baricity of the resultant solution depends on the amount of dextrose added; however, dextrose concentrations between 1.25 and 8% result in equivalent block heights.[42,43] Lower dextrose concentrations have been shown to have a concentration-dependent effect on block height, with 0.33% producing a block to T9.5 on average, 0.83% producing a block to T7.2, and 8% producing a block to T3.6.[44]

TABLE 25-3 Baricity of Solutions Commonly Used for Spinal Anesthesia

	▪BARICITY[a]
▪HYPERBARIC	
Tetracaine: 0.5% in 5% dextrose	1.0133
Bupivacaine: 0.75% in 8.25% dextrose	1.0227
Lidocaine: 5% in 7.5% dextrose	1.0265
Procaine: 10% in water	1.0104
▪ISOBARIC[b]	
Tetracaine: 0.5% in normal saline	0.9997
Bupivacaine: 0.75% in saline	0.9988

Bupivacaine: 0.5% in saline	0.9983
Lidocaine: 2% in saline	0.9986
▪HYPOBARIC	
Tetracaine: 0.2% in water	0.9922
Bupivacaine: 0.3% in water	0.9946
Lidocaine: 0.5% in water	0.9985
[a]Measured at 37°C, except for hypobaric 0.5% lidocaine measured at 25°C. At 37°C, this solution's baricity is less.	
[b]These solutions are slightly hypobaric but are used clinically as if they were isobaric.	
Data from Horlocker TT, Wedel DJ: Density, specific gravity, and baricity of spinal anesthetic solutions at body temperature. Anesth Analg 76:1015, 1993; Lambert D, Covino B: Hyperbaric, hypobaric and isobaric spinal anesthesia. Resident Staff Physician 33:79, 1987; Greene NM: Distribution of local anesthetic solutions within the subarachnoid space. Anesth Analg 64:715, 1985; and Bodily N, Carpenter R, Owens B: Lidocaine 0.5% spinal anaesthesia: A hypobaric solution for short-stay perirectal surgery. Can J Anaesth 39:770, 1992.	

Baricity is important in determining local anesthetic spread and thus block height because gravity causes hyperbaric solutions to flow downward in CSF to the most dependent regions of the spinal column, whereas hypobaric solutions tend to rise in CSF. In contrast, gravity has no effect on the distribution of truly isobaric solutions. Thus, the anesthesiologist can exert considerable influence on block height by choice of anesthetic solution and proper patient positioning. Spinal block can be restricted to the sacral and low lumbar dermatomes ("saddle block") by administering a hyperbaric local anesthetic solution with the patient in the sitting position[45] or by administering a hypobaric solution with the patient in the prone jackknife position. Similarly, high thoracic to midcervical levels of anesthesia can be reached by administering hyperbaric solutions with the patient in the horizontal and Trendelenburg positions[46,47] or by administering hypobaric solutions with the patient in a semisitting position. However, this use of hypobaric solutions is not recommended because the high block achieved and the diminished venous return associated with the upright posture can lead to significant cardiovascular compromise.

The sitting, Trendelenberg, and jackknife positions have marked influences on the distribution of hypobaric and hyperbaric solutions because these positions accentuate the effect of gravity. However, most spinal anesthetics are administered as hyperbaric solutions injected while patients are in the horizontal lateral position after which they are turned to the horizontal supine position. In this situation the influence of gravity is more subtle because the dependent areas of the spinal column do not deviate as much from the horizontal. While the patient is turned laterally, gravity has a small but measurable effect on local anesthetic distribution in that hyperbaric solutions will produce a denser, longer lasting block on the dependent side, while hypobaric solutions will have

the opposite effect.[48] This makes hypobaric solutions ideal for unilateral procedures performed in the lateral position (e.g., hip surgery). Hyperbaric solutions can be used to advantage for unilateral procedures performed in the supine position if the operative side is dependent during drug injection and the patient is left in the lateral position for at least 6 minutes.[48] Despite differences in block density and duration, peak block height will be comparable between the dependent and nondependent sides.

When the patient is turned supine following hyperbaric drug injection in the lateral position, the normal spinal curvature will influence subsequent movement of the injected solution. Hyperbaric solutions injected at the height of the lumbar lordosis will tend to flow cephalad to pool in the thoracic kyphosis and caudad to pool in the sacrum (Fig. 25-11). Pooling of hyperbaric local anesthetic solutions in the thoracic kyphosis has been evoked to explain the clinical observation that hyperbaric solutions tend to produce blocks with an average height in the midthoracic region (see Fig. 25-9). In addition, hyperbaric solutions have also been observed to produce blocks with a bimodal distribution, that is, one group of patients with

blocks centered in the low thoracic region and a second group of patients with blocks centered in the high thoracic region.[49,50] The presumed explanation for this observation is that the lumbar lordosis produces "splitting" of the local anesthetic solution with some portion flowing caudad toward the sacrum and the remainder flowing cephalad into the thoracic kyphosis. The cephalad extent of the block then depends on what fraction of the injected drug flows cephalad. Consistent with this hypothesis is the fact that eliminating the lumbar lordosis by maintaining the hips flexed has been shown to significantly reduce[50] or eliminate[49] the bimodal distribution of blocks without affecting maximal block height.

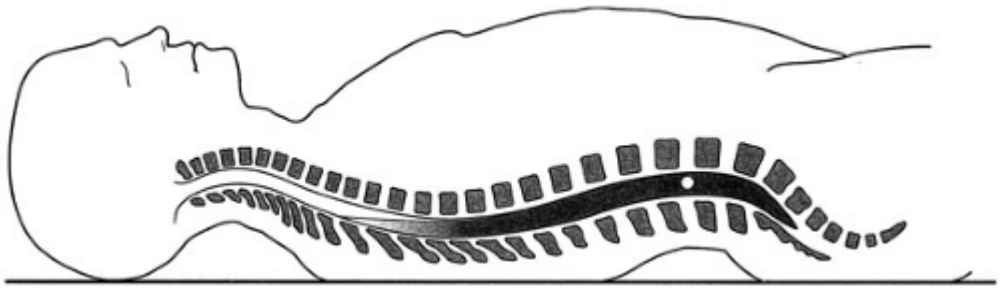

FIGURE 25-11. In the horizontal supine position, hyperbaric local anesthetic solutions injected at the height of the lumbar lordosis (*circle*) flow down the lumbar lordosis to pool in the sacrum and in the thoracic kyphosis. Pooling in the thoracic kyphosis is thought to explain the fact that hyperbaric solutions produce blocks with an average height of T4-6.

Obviously, gravity influences the distribution of hyperbaric and hypobaric solutions only until they are sufficiently diluted in CSF so that they become isobaric. At this point, the local anesthetic solution no longer moves in response to changes in patient position and the block is said to be "fixed." Interestingly, the time required for a local anesthetic solution to become fixed may be considerable. Povey et al showed that hyperbaric bupivacaine injected in the sitting position produces a saddle block that is restricted to the lumbar segments for as long as the subjects remained sitting.[45,46] However, even 60 minutes after bupivacaine injection the block spread to midthoracic levels after turning the patients supine. Similarly, Bodily et al[51] found that hypobaric lidocaine administered in the jackknife position rose as many as 6 dermatomes when patients were

allowed to sit upright in the recovery room as long as 60 minutes after lidocaine injection. Whether it is also possible to affect spread so long after injecting hyperbaric or hypobaric solutions in the horizontal position is unclear. Nonetheless, these findings demonstrate that in some situations it may be possible to exert influence on block height by adjusting patient position for at least 60 minutes after local anesthetic injection.

In contrast to the situation with hyperbaric solutions, patient position has no effect on the distribution of isobaric solutions because these solutions are not influenced by gravity. Consequently, isobaric solutions tend not to spread as far from the site of injection and produce blocks with an average height in the low thoracic region (see Fig. 25-9).[43,52] The obvious caveat is that the local anesthetic solution must be truly isobaric in the patient in whom it is used. Because of the variability in CSF density among patients, it is difficult to produce reliably isobaric local anesthetic solutions. Nonetheless, as indicated in Table 25-3, several local anesthetic solutions are used as if they were isobaric. It is noteworthy that while isobaric solutions produce an average block height that is lower than comparable hyperbaric solutions,[43,52,53,54] the "isobaric" solutions produce blocks with a much greater variability in height.[55,56,57] Logan et al have termed plain bupivacaine "an unpredictable spinal anesthetic agent."[55] The greater variability in spread may stem in part from the fact that these solutions are actually slightly hypobaric and their spread has been shown to be affected by patient position.[58,59] Temperature-related changes in baricity may also play a role in the variability in distribution of these nearly isobaric solutions. For example, Steinstra and van Poorten[60] have shown that the distribution of plain bupivacaine is significantly altered by changes in temperature of the injected solution. In addition, McClure et al[61] have shown that increasing the volume and decreasing the concentration of isobaric tetracaine also increases the variability in block height. These and other unknown factors may play a role in the unpredictability of these nearly isobaric solutions. Although unpredictability is cause for concern, it should be pointed out that the lower average block height achieved offers potential advantages for surgical procedures below the umbilicus because of the decreased incidence of cardiovascular side effects associated with lower blocks. The isobaric solution that has been shown to most reliably produce a low thoracic block is 10 mg of tetracaine crystals diluted in 1- or 2-mL room temperature saline and injected in the horizontal position.[61]

Dose, Volume, and Concentration. Studies aimed at determining the effect of these three interdependent variables on block height are difficult to conduct and interpret because it is not possible to change one variable without simultaneously changing another. Nonetheless, it is possible to draw some conclusions regarding the effect of these variables on block height. Several studies with isobaric tetracaine and bupivacaine solutions have found that neither injected volume nor drug concentration affects block height when dose is held constant.[61,62,63,64,65] Drug dose does appear to play a small role in determining block height with isobaric bupivacaine. Two studies have found that 10 mg of isobaric bupivacaine results in significantly lower blocks than does 15 or 20 mg, but there is no difference in block height between the two higher doses.[66,67] In contrast, two studies that examined the effect of different doses of isobaric tetracaine found that doses between 5 and 15 mg had no effect on block height, producing blocks with an average height of T9-T10.[52,68]

Drug dose and volume appear to be relatively unimportant in predicting the spread of hyperbaric local anesthetic solutions injected in the horizontal position. Increasing the dose and volume of hyperbaric tetracaine, while holding concentration constant, does not affect block height when doses between 7.5 and 15 mg are used.[52,68,69] Similarly, increasing the dose and volume of hyperbaric 0.5% bupivacaine does not increase block height when doses between 10 and 20 mg are used.[70,71] However, doses of hyperbaric 0.5% bupivacaine <10 mg have been shown to result in blocks that are ~2.5 dermatomes lower than those achieved with doses >10 mg.[70] The fact that bupivacaine dose affects block height only at the extreme low end of the usual dose range is consistent with the experience with isobaric bupivacaine reported earlier. The fact that drug dose is relatively unimportant in determining block height with hyperbaric solutions likely results from an overwhelming effect of baricity and patient position in determining spread of these solutions.

Injection Site. The site of injection can have an important effect on block height in some situations. In particular, sensory block height resulting from isobaric 0.5% bupivacaine is reduced

by 2 dermatomes per interspace when comparing different groups of patients who received injections at the L2-3, L3-4, or L4-5 interspaces.[72,73] In an even more convincing study, this group of investigators performed repeated blocks in the same patient and found that by moving from the L3-4 to the L4-5 interspace means block height could be reduced from T6 to T10 when using isobaric 0.5% bupivacaine.[74] In contrast, Sundnes et al[70] found no relationship between injection site and block height when using a hyperbaric bupivacaine solution, presumably because of the overwhelming effect of gravity and patient position on distribution of hyperbaric local anesthetics. Whether isobaric and hyperbaric solutions of other local anesthetics will behave similarly is not clear.

Patient Characteristics. In young adults, it was determined that the most important variable governing block height with hyperbaric local anesthetic solutions may be lumbosacral CSF volume.[75] However, it is unclear if these findings can be extrapolated to other local anesthetics or patient ages.

Higuchi and colleagues performed a detailed examination of the effect of lumbar CSF volume, CSF density, lumbar CSF motion, patient age, patient weight, patient height, and patient body mass index (BMI) on spinal block with isobaric bupivacaine.[76] Multiple linear regression demonstrated that neither patient age nor height correlated with any clinical characteristic of spinal block. However, CSF volume and weight were correlated with peak block height. CSF volume was the only variable to correlate with time to voiding. BMI was the only significant predictor of time to onset of complete sensory block.

Although these variables were statistically significant predictors of several important aspects of spinal block, the

coefficients of determination (R^2) were generally small (average: 0.23; range: 0.08 to 0.46), indicating that these variables account for a relatively small amount of the variability in each of the block outcomes examined. Clearly, other factors contribute significantly to the clinical characteristics of spinal block with isobaric bupivacaine.

4 While these studies are mechanistically important, their clinical application is necessarily limited by the difficulty in determining an individual patient's CSF volume, CSF density, and velocity of CSF movement.

Importantly, several investigators have found that patient age, weight, BMI, and height are either not predictive of clinical characteristics of spinal block[77,78,80,81,82] or are of such low predictive power as to be unreliable predictors in any individual patient.[57,72,79,83,84]

Onset

Most patients can sense the onset of spinal block within a very few minutes after drug injection regardless of the local anesthetic used. However, there is a significant difference among drugs in the time to reach peak block height. Lidocaine and mepivacaine tend to reach peak block height between 10 and 15 minutes, whereas tetracaine and bupivacaine may require >20 minutes before peak block height is reached.

Duration

Spinal blocks do not end abruptly after a fixed period of time. Rather, they recede gradually from the most cephalad dermatome to the most caudad. As a result, surgical anesthesia lasts significantly longer at sacral levels than at thoracic levels. Therefore, when discussing the duration of spinal block it is necessary to distinguish between duration at the surgical site and the time required for the block to completely resolve. The former is important for providing adequate surgical anesthesia, and the latter is important for assuring a timely recovery. A thorough understanding of the factors that govern block duration is necessary if the clinician is to choose techniques that result in an appropriate duration of spinal blockade.

Local Anesthetic. The principal determinant of spinal block duration is the local anesthetic drug

employed. Procaine is the shortest acting local anesthetic for subarachnoid use, lidocaine and mepivacaine are agents of intermediate duration, while bupivacaine and tetracaine are the longest acting drugs available for use in the United States. Table 25-4 lists the range of times required for sensory block to regress 2 dermatomes and to completely resolve with the local anesthetics most commonly used for spinal anesthesia. Although drug choice is the principal determinant of block duration, other variables are responsible for the wide range of block duration found in Table 25-4.

TABLE 25-4 Dose and Duration of Local Anesthetics Used for Spinal Anesthesia

		·DURATION OF SENSORY BLOCK (MIN)[b]		
·DRUG	·DOSE (MG)[a]	·2-DERMATOME REGRESSION	·COMPLETE RESOLUTION	·PROLONGATION BY ADRENERGIC AGONISTS (%)[c]
Procaine	50–200	30–50	90–120	30–50
Chloroprocaine	30–100	30–50	70–150	NR
Lidocaine	25–100	40–100	140–240	20–50
Bupivacaine	5–20	90–140	240–380	20–50
Tetracaine	5–20	90–140	240–380	50–100

[a]The lowest doses are used primarily for very restricted blocks, e.g., saddle block, lest they become too dilute to be effective.

[b]Duration is influenced by dose and block height. The duration of surgical anesthesia will obviously depend upon the surgical site.

[c]The effect of adrenergic agonists depends on the dose and choice of agonist. Prolongation is greatest at lumbar and sacral dermatomes and least at thoracic dermatomes.

NR: Not Recommended; see text for explanation.

Drug Dose. Increasing local anesthetic dose clearly increases the duration of spinal block.[66,67,69,85,86] For example, Brown et al[52] demonstrated that duration of sensory block at L1 following 15 mg tetracaine was ~20% greater than following 10 mg. Sheskey et al[67] demonstrated an ~40% increase in block duration at L2 when comparing 10 mg bupivacaine with 15 mg. Similarly, Axelsson et al.[85] found that duration of sensory block at L2 was nearly doubled when comparing 10 mg bupivacaine with 20 mg.

Block Height. If drug dose is held constant, higher blocks tend to regress faster than lower

blocks.[86] Consequently, isobaric local anesthetic solutions will generally produce longer blocks than hyperbaric solutions using the same dose. The conventional wisdom is that greater cephalad spread results in relatively lower drug concentration in the CSF and spinal nerve roots. As a result, it takes less time for local anesthetic concentration to decrease below the minimally effective concentration.

Adrenergic Agonists. Adrenergic agonists, such as epinephrine, phenylephrine, and more recently clonidine, are added to local anesthetics in an effort to prolong the duration of spinal anesthesia. Their effectiveness depends on the local anesthetic with which they are combined. In addition, they are more effective at prolonging block in the lumbar and sacral dermatomes than in thoracic dermatomes.

Epinephrine is typically administered in doses of 0.2 to 0.3 mg and phenylephrine in doses of 2 to 5 mg. There is evidence to suggest a relationship between the dose of vasoconstrictor added and the duration of spinal anesthesia; however, the relationship is not strong.[87,88,89,90] At the maximal doses used clinically, phenylephrine (5 mg) prolongs spinal block to a greater degree than epinephrine (0.5 mg).[91,92] At lower doses, epinephrine (0.2 to 0.3 mg) and phenylephrine (2 to 3 mg) appear to be equally effective in prolonging spinal block.[90,93] Thus, both choice of adrenergic agonist and dose administered appear to play a role in determining block duration.Clonidine has most commonly been added to intrathecal local anesthetics in a dose of 75 to 150 milligram to prolong spinal block.[94,95] At these doses, it is at least as effective as moderate doses of phenylephrine and epinephrine at prolonging sensory block but has been associated with greater decreases in blood pressure in some[94] but not all studies.[95] Interestingly, clonidine also prolongs spinal block when administered orally.[96,97,98]

Tetracaine is the local anesthetic that is most dramatically prolonged by addition of adrenergic agonists. The duration of tetracaine spinal block may be increased 70% to 100% at

lumbar and sacral dermatomes by addition of phenylephrine. Epinephrine may prolong tetracaine spinal anesthesia by 40% to 60%. Clonidine prolongs tetracaine spinal block by 50% to 70%, with the larger effect occurring at lumbar dermatomes.

Bupivacaine spinal block is also prolonged by adrenergic agonists, although the effect is somewhat less than that seen with tetracaine (see Table 25-4). Epinephrine in doses of 0.2 mg prolongs bupivacaine spinal block by 20% to 30%, but only in lumbar dermatomes. Larger doses of epinephrine (0.3 to 0.5 mg) prolong sensory block in thoracic dermatomes as well by 30% to 50%. Clonidine prolongs bupivacaine spinal block by 30% to 50% as well.

The effect of adrenergic agonists on the duration of lidocaine spinal block is controversial. Some clinical studies have demonstrated that adrenergic agonists clearly prolong lidocaine spinal block,[88,99,100,101] whereas others have concluded that adrenergic agonists do not produce clinically useful prolongation.[102,103] This discrepancy may be explained, in part, by the fact that spinal block duration is so variable that studies using small numbers of patients may lack sufficient statistical power to detect real differences in mean block duration between groups. This problem was obviated in an interesting study by Chiu et al[104] who used a crossover study design to demonstrate that 0.2 mg of epinephrine significantly prolonged lidocaine sensory block in lumbar and sacral dermatomes. Thus, the available data suggest that adding epinephrine to lidocaine will result in a somewhat longer block, at least in lumbar and sacral dermatomes, than would be achieved if epinephrine were not added.

The mechanism by which adrenergic agonists prolong spinal block is not clear. Originally, epinephrine and phenylephrine were added to local anesthetics with the intent of reducing local spinal cord blood flow and thereby slowing the rate of drug elimination from the spinal cord and CSF. There are animal studies that support this mechanism[105,106] and others that do not.[107,108] Animal studies with clonidine indicate that it does reduce regional spinal cord blood flow.[109] There are no human studies that have investigated the effect of intrathecal adrenergic agonists on spinal cord blood flow. However, there are human studies that demonstrate that epinephrine decreases the rate of local anesthetic clearance from the CSF[110,111] and also slows the rate at which subarachnoid local anesthetic appears in the plasma.[99] These findings are consistent with a

vasoconstrictor-mediated decrease in drug clearance from the spinal cord; however, they are not proof that this is the only or even the principal mechanism by which adrenergic agonists prolong spinal anesthesia.

Adrenergic agonists are potent analgesic agents in their own right when administered into the subarachnoid space.[112] Analgesia results from inhibition of nociceptive afferents, an effect that is mediated by stimulation of α-adrenergic receptors in the spinal cord dorsal horn. In addition, large intrathecal doses of α-adrenergic agonists have been shown to produce flaccidity in animal models by hyperpolarizing motor neurons.[113] Thus, prolongation of motor and sensory block by adrenergic agonists may be due, in part, to direct inhibitory effects of these drugs on sensory and motor neurons.

Epidural Anesthesia

Any procedure that can be performed under spinal anesthesia can also be performed under epidural block and requires the same block height (see Table 25-1). As with spinal anesthesia, there is a great deal of variability among patients in spread (see Fig. 25-10) and duration of epidural block (Table 25-5). Therefore, to choose the most appropriate local anesthetic and dose for a particular clinical situation, the anesthesiologist must be familiar with the variables that affect spread and duration of epidural anesthesia.

TABLE 25-5 Local Anesthetics used for Surgical Epidural Block

	·DURATION OF SENSORY BLOCK		
·DRUG[a]	·TWO-DERMATOME REGRESSION (MIN)	·COMPLETE RESOLUTION (MIN)	·PROLONGATION BY EPINEPHRINE (%)
Chloroprocaine 3%	45–60	100–160	40–60
Lidocaine 2%	60–100	160–200	40–80
Mepivacaine 2%	60–100	160–200	40–80
Ropivacaine 0.5–1.0%	90–180	240–420	No
Etidocaine 1–1.5%	120–240	300–460	No
Bupivacaine 0.5–0.75%	120–240	300–460	No

[a]These concentrations are recommended for surgical anesthesia; more dilute concentrations are appropriate for epidural analgesia.

Block Spread

Injection Site. Unlike spinal anesthesia, epidural anesthesia produces a segmental block that spreads both caudally and cranially from the site of injection (Fig. 25-12). Thus, injection site is arguably the most important determinant of the spread of epidural block.*Caudal* epidural blocks are largely restricted to sacral and low lumbar dermatomes. Low thoracic levels can be reached with caudal injections if large volumes are used (e.g., 30 mL). However, the block at thoracic dermatomes tends to be patchy and short lived following caudal injection.[114] *Lumbar* local anesthetic injections with volumes of 10 mL often extend caudad to include all sacral dermatomes, although the onset of block in the L5 and S1 roots is often delayed and may be patchy.[115] Twenty-milliliter volumes produce better quality sacral anesthesia following lumbar injection. The slow onset at L5 and S1 is thought to result from their larger diameter and consequent slower drug penetration. Lumbar injections can be extended to midthoracic levels (T4-6) when 20-mL volumes of local anesthetic are used. *Thoracic* injections produce a symmetric segmental band of anesthesia, the width of which depends on the dose of local anesthetic administered. When using a mid to upper thoracic injection site, it is prudent to reduce the local anesthetic doses by ~30% to 50% relative to lumbar doses to prevent excessive cephalad spread. It is generally not feasible to produce surgical anesthesia in low lumbar and sacral dermatomes with midthoracic or higher injection sites. Thoracic epidural block is ideally suited for anesthesia of the chest and abdomen.

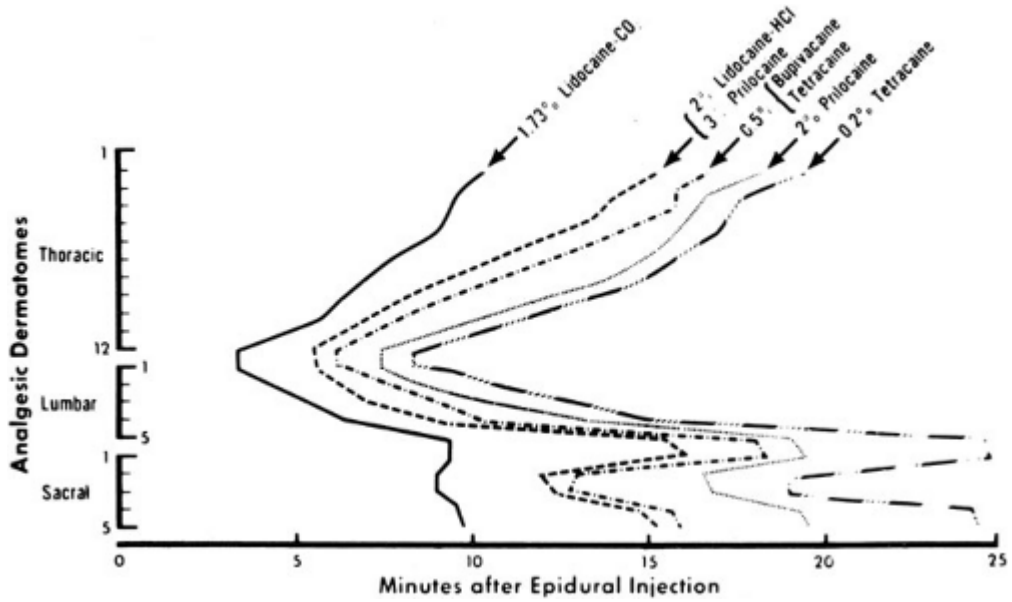

FIGURE 25-12. Spread of epidural sensory block over time following injection of various local anesthetic solutions at the L2-3 interspace. All solutions contained epinephrine 1:200,000. Sensory block spreads both cephalad and caudad from the site of injection with time. Note the delay in onset of block at the L5 and S1 dermatomes with all solutions tested. (Reprinted with permission from Bromage PR: Epidural Analgesia. Philadelphia, WB Saunders, 1978.)

Dose, Volume, and Concentration. Within the range typically used for surgical anesthesia, drug concentration is relatively unimportant in determining block spread. However, drug dose and volume are important variables determining both spread and quality of epidural block. If drug concentration is held constant, increasing the volume of local anesthetic (and thereby the dose) will result in significantly greater average spread and greater block density. However, the relationship is nonlinear. For example, doubling the volume and dose of 1.5% lidocaine or 0.75% bupivacaine from 10 mL to 20 mL has been shown to increase spread by only three to four spinal segments.[115,116] Volume appears to be important in determining block spread independent of drug

dose, but again the relationship is nonlinear. Erdemir et al showed that tripling the injected volume of lidocaine from 10 mL to 30 mL while holding the dose constant (300 mg) increased the cephalad extent of block by only 4.3 dermatomes.[117] This tendency toward greater spread is thought to be explained by the observation that increasing the volume of solution injected into the epidural space increases cephalad distribution.[118]

Position. When using a single-shot technique, maintaining patients in the lateral position during and after epidural injection of surgical doses of local anesthetics does not seem to have a clinically important effect on spread of the block from side to side.[119] Similarly, studies examining the effect of patient position on cephalad spread of epidural block have generally found that the effect of posture on spread is not clinically important.[120] Interestingly, Ponhold et al[121] demonstrated that maintaining a 30 degree head-up position significantly increased the frequency of adequate block at the L5 and S1 nerve roots even though there was no effect on the cephalad extent of anesthesia.

Patient Characteristics

Age. Most,[115,116,122,123,124,125] but not all,[126] studies that have examined the effect of age on epidural block have demonstrated greater spread in older patients. However, the effect of age is probably clinically significant only when comparing adults whose ages differ by three or more decades. Even so, the difference in block height is not likely to be more than 3 or 4 dermatomes. Greater spread in older patients is thought to be related to a less-compliant epidural space and diminished ability for epidural solutions to leak out of intervertebral foramina.[118,127] Both of these age-related changes would be expected to result in more extensive spread of solutions within the epidural space.

Height and Weight. The correlation between patient height[115,116,125,126] or weight[125,126] and spread of epidural block is weak and of little clinical significance except perhaps in patients who are extremely tall, extremely short, or morbidly obese.

Pregnancy. Studies examining the effect of pregnancy on spread of epidural block are conflicting. Some studies have demonstrated greater spread at term[128] and during early pregnancy,[129] suggesting that greater spread during pregnancy is not simply the result of anatomic changes associated with pregnancy. However, other studies have not found a significant difference in spread of epidural block between pregnant and nonpregnant women.[130,131]

Atherosclerosis. Atherosclerosis has been suggested as an important determinant of the spread of epidural block.[128] However, subsequent studies have failed to find any relationship between block spread and atherosclerosis.[116,122,132]

Given the myriad factors that have some effect on spread of epidural anesthesia, how should anesthesiologists choose an appropriate local anesthetic dose for a single-shot epidural block? A useful recommendation is to assume that a 20-mL volume of all local anesthetics intended for surgical anesthesia will produce a midthoracic block on average after lumbar injection. If there are multiple reasons to expect that the block may spread excessively in an individual patient (e.g., advanced age, obesity, very short stature, high injection site) or if the procedure does not require a high block, then reduce the dose accordingly. If there are multiple reasons to expect that the spread may be reduced from the average, then increase the volume accordingly. Obviously, choice of the appropriate local anesthetic dose is obviated if an epidural catheter is used. In this situation, begin

with a lower dose than one anticipates will be needed and administer additional local anesthetic as necessary to extend the block to the desired level.

Onset

The onset of epidural block with all local anesthetics can usually be detected within 5 minutes in the dermatomes immediately surrounding the injection site. The time to peak effect differs somewhat among local anesthetics. Shorter acting drugs generally reach their maximum spread in

15 to 20 minutes, whereas longer acting drugs require 20 to 25 minutes. Increasing the dose of local anesthetic speeds the onset of both motor and sensory block.

Duration

Local Anesthetic. As with spinal anesthesia, choice of local anesthetic is the most important determinant of the duration of epidural block. Chloroprocaine is the shortest duration drug used for epidural anesthesia, lidocaine and mepivacaine provide blocks of intermediate duration, and bupivacaine, ropivacaine, and etidocaine produce the longest lasting epidural block. Table 25-5 lists local anesthetics commonly used for epidural block and approximate duration of surgical anesthesia. Of note, tetracaine and procaine are not generally used for epidural block because of the poor quality block that these drugs produce.

Importantly, when used epidurally some local anesthetics exhibit considerable separation in both the intensity and duration of sensory and motor block. Etidocaine produces the most intense motor block and is unusual among local anesthetics in that motor block may considerably outlast sensory block.[133] The phenomenon of the postoperative patient who is in pain yet still unable to move his or her legs has led some anesthesiologists to abandon etidocaine for epidural use. This is unfortunate because etidocaine's superior muscle relaxation is sometimes beneficial intraoperatively. Bupivacaine has the opposite sensorimotor profile in that low concentrations of bupivacaine produce sensory block that is relatively more intense than motor block. This separation of sensory and motor block underlies the common practice of using dilute bupivacaine solutions for epidural analgesia.

Dose. Increasing the dose of local anesthetic administered results in increased duration[115,134,135,136] and density[115,135,136] of epidural block.

Age. Studies that have evaluated the effect of age on epidural block duration are inconclusive. Veering et al.[124] found that duration of epidural block with plain bupivacaine was not significantly affected by age. Nydahl et al.[123] found that epidural block using bupivacaine with epinephrine was actually shorter in older patients. In contrast, Park et al.[122] found that epidural block using lidocaine with epinephrine was slightly but significantly longer in older patients. Additional studies are necessary to clarify the effect of age on duration of epidural block.

Adrenergic Agonists. Epinephrine, in a concentration of 5 mcg/mL (1:200,000), is the most common adrenergic agonist added to epidural local anesthetics. It has been shown to prolong the duration of lidocaine and mepivacaine epidural block by as much as 80%.[137] The mechanism by which epinephrine prolongs epidural block is not clear. Vasoconstrictors have been assumed to prolong block by producing local vasoconstriction and thus decreased local anesthetic clearance from the epidural space. The fact that epinephrine reduces peak plasma concentrations of some local anesthetics following epidural injection is considered to be supportive evidence of this mechanism. However, iv infusion of epinephrine also decreases peak plasma concentration of epidurally administered local anesthetics, presumably by increasing their volume of distribution.[138] Thus, it is unclear what role local vasoconstriction plays in epinephrine's ability to prolong epidural block. As discussed earlier for spinal anesthesia, prolongation of motor and sensory block may be due, in part, to direct inhibitory effects of epinephrine on sensory and motor neurons.

Epinephrine does not significantly prolong the duration of anesthesia when added to concentrated solutions of bupivacaine,[139,140] etidocaine,[135,140] or ropivacaine[141] that are generally used for surgical anesthesia. However, epinephrine does appear to prolong analgesia and improve the quality of block when added to more dilute solutions of these local anesthetics, such as those used for labor analgesia.[142,143,144]

Summary

The extent and duration of both spinal and epidural block are influenced by a number of variables, some of which are under the control of the anesthesiologist. Understanding the impact of these variables will allow the anesthesiologist to rationally select the most appropriate drug and dose for any clinical situation. However, even the most experienced anesthesiologist will still have blocks

that are not adequate for the planned procedure. The frequency of failed blocks can be kept to a minimum if the clinician aims to produce blocks that are a little higher and a little longer than seems necessary. It is often easier to deal with a block that is too high or too long than to cover up for a block that is too low or too brief.

PHYSIOLOGY

Neurophysiology

The physiology of local anesthetic neural blockade is discussed in detail in Chapter 17. This section briefly presents aspects of the physiology of neural blockade that are unique to spinal and epidural anesthesia.

Site of Action

The site of action of spinal and epidural anesthesia is not precisely known. Following epidural administration, local anesthetic is found in the spinal nerves within the epidural space, in spinal nerve rootlets within the CSF, and in the spinal cord. Similarly, following intrathecal administration in animals, local anesthetic is found in all sites between the spinal nerve rootlets and the interior of the spinal cord.[145,146] Thus, neural blockade can potentially occur at any or all points along the neural pathways extending from the site of drug administration to the interior of the spinal cord.

In an interesting study in humans, Boswell et al demonstrated that patients are able to feel paresthesias during direct electrical stimulation of the spinal cord under spinal anesthesia.[147] Cortical evoked potentials from direct spinal cord stimulation were also maintained under spinal anesthesia, although amplitudes were decreased. In contrast, paresthesias and cortical evoked potentials from tibial nerve stimulation were abolished by spinal anesthesia. These investigators concluded that neural pathways within the spinal cord were largely intact during spinal anesthesia and that the spinal nerve rootlets were the principal site of neural blockade.

The site of epidural block is less well localized. Monkey studies suggest that epidural block occurs largely at sites within the spinal meninges, including the cauda equina nerve roots, dorsal root entry zone, and the long tracts of spinal cord white matter.[148] However, these findings are not entirely consistent with the segmental onset of epidural anesthesia (see Fig. 25-12) or with the limited segmental blocks that can be produced with

small doses of lumbar epidural local anesthetics in humans. These clinical observations are most readily explained by block of the segmental spinal nerves as they traverse the epidural or paravertebral spaces. In reality, epidural block likely occurs at both extradural and subdural sites with extradural radicular block predominating early and subdural spinal block predominating later. This supposition is consistent with human studies by Urban who rigorously examined the anatomic pattern of analgesia that occurred during onset and regression of epidural block.[149] He concluded that local anesthetics initially acted on radicular structures followed later by actions within the spinal cord.

Interestingly, human studies demonstrate that somatosensory evoked potentials are maintained during epidural anesthesia, although amplitudes are decreased and latencies increased. This contrasts with spinal block in which evoked potentials are completely eliminated and supports the clinical impression that epidural block is generally less dense than that achieved with spinal anesthesia.

Differential Nerve Block

Differential block refers to a clinically important phenomenon in which nerve fibers subserving different functions display varying sensitivity to local anesthetic blockade. In vivo sympathetic nerve fibers appear to be blocked by the lowest concentration of local anesthetic followed in order by fibers responsible for pain, touch, and motor function. This observation has led to the widely

held belief that differences in sensitivity to local anesthetic blockade is explained solely by differences in fiber diameter, with smaller diameter neurons exhibiting greater sensitivity than larger diameter neurons. While the mechanism for differential block in spinal and epidural anesthesia is not known, it is clear that fiber diameter is not the only, or perhaps not even the most important, factor contributing to differential block.[150,151] Differential block is also discussed in Chapter 17.

Differential block occurs with both peripheral nerve blocks and central neuraxial blocks. In the peripheral nervous system, differential block is a temporal phenomenon with sympathetic block occurring first followed in time by sensory and motor block. In contrast, with spinal and epidural anesthesia differential block is manifest as a spatial separation in the modalities blocked. This is seen most clearly with spinal anesthesia where sympathetic block may extend as many as 2 to 6 dermatomes higher than pin-prick sensation,[152] which in turn extends 2 to 3 dermatomes higher than motor block. This spatial separation is believed to result from a gradual decrease in local anesthetic concentration within the CSF as a function of distance from the site of injection. With epidural anesthesia, similar zones of differential sensory and sympathetic block are found.[153]

Perhaps the most troublesome consequence of differential block is the occasional patient who has intact touch and proprioception at the surgical site despite adequate blockade of pain sensation. Even the most stoic patients are likely to find this unpleasant and may lie in fear that the procedure will soon become painful. In no instance should the anesthesiologist downplay the distress this may cause patients. Reassurance and judicious sedation as necessary are usually sufficient to overcome this problem.

Another important neurophysiologic aspect of central neuroaxial block is that it produces sedation,[154] potentiates the effect of sedative hypnotic drugs,[155,156,157] and markedly decreases minimum alveolar concentration (MAC).[158] The mechanism(s) underlying these effects is not known but "deafferentation," that is, the loss of ascending sensory input to the brain, is commonly invoked as causative.

Cardiovascular Physiology

Cardiovascular side effects, principally hypotension and bradycardia, are arguably the most important and most common physiologic changes during spinal and epidural anesthesia. Understanding the homeostatic mechanisms responsible for control of blood pressure and heart rate is essential for understanding and treating the cardiovascular changes associated with spinal and epidural anesthesia.

Spinal Anesthesia

5 Blockade of sympathetic efferents is the principal mechanism by which spinal anesthesia produces cardiovascular derangements. As would be expected, the incidence of significant hypotension or bradycardia is generally related to the extent of sympathetic blockade, which in turn parallels block height.[159,160] However, the severity of cardiovascular changes has been shown not to correlate with peak block height in one study[161] and to correlate poorly in another (Fig. 25-13).[159] Additional risk factors associated with hypotension include age >40 to 50 years, concurrent general anesthesia, obesity, hypovolemia, and addition of phenylephrine to the local anesthetic.[159,162]

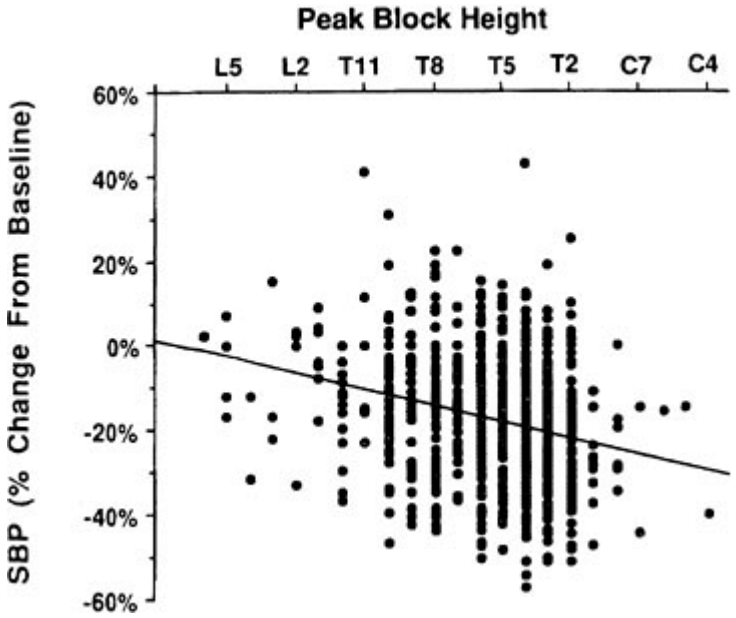

FIGURE 25-13. The relationship between peak block height and change in systolic blood pressure (SBP) during spinal anesthesia. Although there is a statistically significant correlation between block height and decrease in systolic blood pressure, the interindividual variability is so great that the relationship has little predictive value. This is reflected in the R^2 of 0.07 for the linear regression line. (From Carpenter RL, Caplan RA, Brown DL *et al*: Incidence and risk factors for side effects of spinal anesthesia. Anesthesiology 76:906, 1992.)

Hypotension during spinal anesthesia is the result of both arterial and venodilation. Venodilation increases volume in capacitance vessels, thereby decreasing venous return and right-sided filling pressures.[161,163,164,165] This fall in preload is thought to be the principal cause of decreased cardiac output during high spinal anesthesia. Arterial dilation during spinal anesthesia results in significant decreases in total peripheral resistance (Fig. 25-14).[164,166] Thus, the hypotension that accompanies 30% to 40% of spinal anesthetics may be the result of reductions in afterload, reductions in cardiac output, or both (see Fig. 25-14).

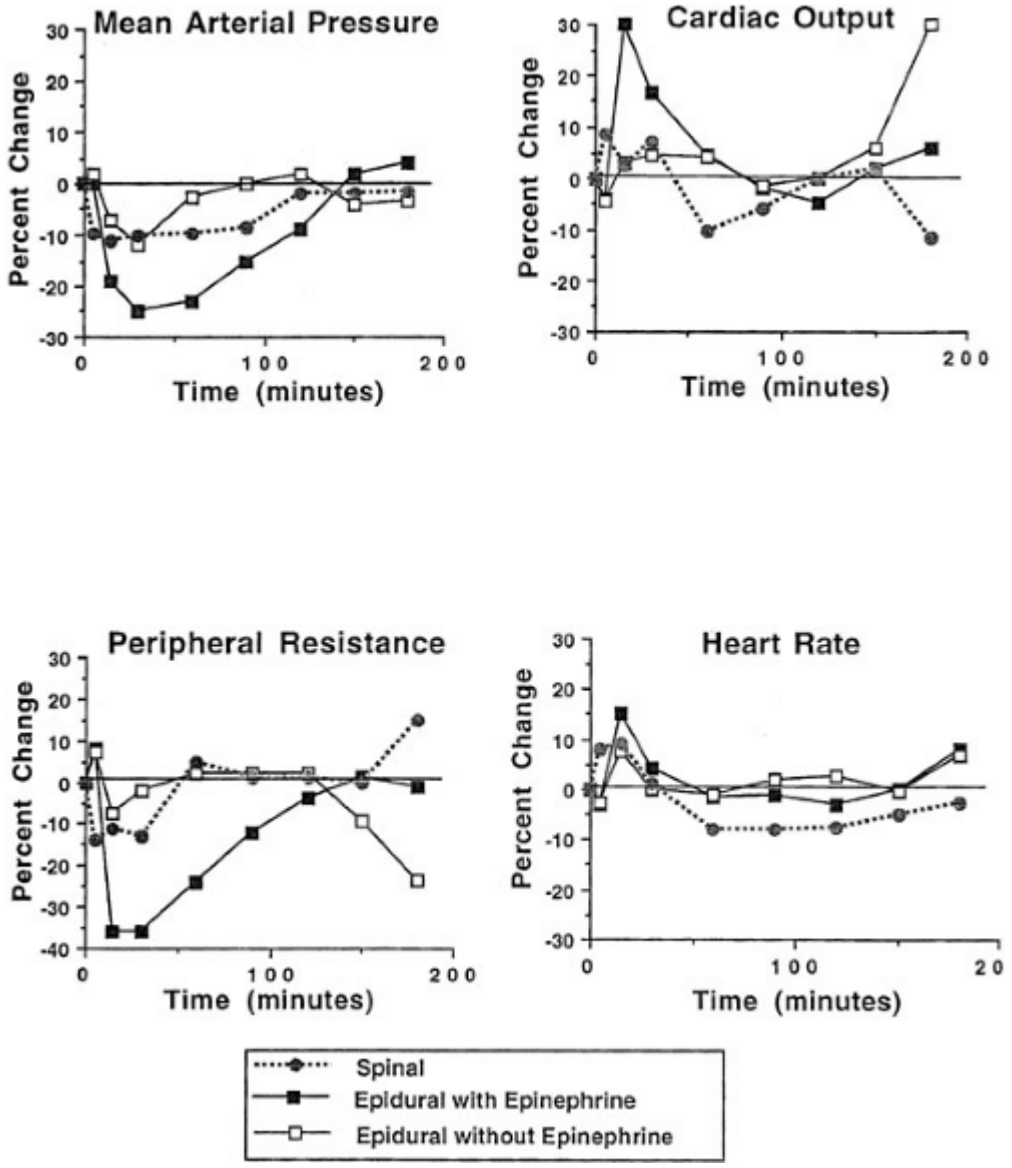

FIGURE 25-14. The cardiovascular effects of spinal and epidural anesthesia in volunteers with T5 blocks. The effects of spinal anesthesia and epidural anesthesia without epinephrine were generally comparable and are both qualitatively and quantitatively different from the effects of epidural anesthesia with epinephrine. (Modified from Bonica JJ, Kennedu WF Jr, Ward RJ, Tolas AG: A comparison of the effects of high subarachnoid and epidural anesthesia. Acta Anaesthesiol Scand [Suppl] 23:429, 1966.)

Heart rate does not change significantly during spinal anesthesia in most patients (see Fig. 25-14). However, clinically significant bradycardia occasionally occurs with a reported incidence of 10% to 15%. As with hypotension, the risk of bradycardia increases with increasing block height.[159] Additional

risk factors associated with bradycardia include age younger than 50 years, ASA 1 physical status, and concurrent use of βblockers.[159,162] The mechanism responsible for bradycardia is not clear. Blockade of the sympathetic cardioaccelerator fibers originating from T1-4 spinal segments is often suggested as the cause. The fact that bradycardia is more common with high blocks supports this mechanism. However, significant bradycardia sometimes occurs with blocks that are seemingly too low to block cardioaccelerator fibers. Diminished venous return has also been proposed as a cause of bradycardia during spinal anesthesia. Intracardiac stretch receptors have been shown to reflexively decrease heart rate when filling pressures fall.[167] Consistent with this mechanism, Jacobsen et al demonstrated a significant reduction in left ventricular volumes and

heart rate during hypotensive episodes in two patients during epidural anesthesia.[168] They concluded that central volume depletion elicited a vagally mediated reflex slowing of heart rate. Similarly, Baron et al demonstrated that vagal activity is enhanced by decreased venous return during epidural anesthesia.[169] However, this mechanism does not operate at all times in all patients. Anzai and Nishikawa demonstrated significant heart rate increases in 40 patients who had their filling pressures suddenly decreased by body tilt during spinal anesthesia.[165] In reality, both blockade of cardioaccelerator fibers and decreased filling pressures as well as other unrecognized factors likely contribute to bradycardia during spinal anesthesia.

Although bradycardia is usually of moderate severity and well tolerated, there have been reports of sudden, unexplained, severe bradycardia and asystole during both spinal and epidural anesthesia.[170,171] In addition, multiple case reports document that spinal anesthesia can also produce second- and third-degree heart block[172,173,174] and that preexisting first-degree block may be a risk factor for progression to higher grade blocks during spinal anesthesia.[172] These reports document the need for continued vigilance with prompt and, if needed, aggressive treatment of the cardiovascular changes that accompany central neuraxial blockade.

Epidural Anesthesia

The hemodynamic changes produced by epidural anesthesia are largely dependent on whether or not epinephrine is added to the local anesthetic solution (see Fig. 25-14).[175] High epidural block with nonepinephrine-containing solutions results in decreased stroke volume, cardiac output, total peripheral resistance, and arterial pressure. The magnitude of these changes is generally less than that seen with comparable levels of spinal block.[175] As with spinal anesthesia, these hemodynamic changes are believed to result from venous and arterial dilation induced by sympathetic blockade. In contrast, when epinephrine-containing solutions are used for epidural anesthesia, stroke volume and cardiac output increase significantly (see Fig. 25-14).[175] However, peripheral resistance falls

dramatically, resulting in a decrease in arterial pressure greater than that seen with nonepinephrine-containing solutions. β-2–adrenergic-mediated vasodilatation produced by low doses of absorbed epinephrine accounts for the greater decrease in peripheral vascular resistance and blood pressure. Decreased peripheral resistance may also contribute to the marked increase in cardiac output. However, epinephrine-induced venoconstriction with a resultant increase in venous return may also play an important role in increasing cardiac output.[176]

Treating Hemodynamic Changes

Treatment of hypotension secondary to spinal and epidural block must be aimed at the root causes: decreased cardiac output and/or decreased peripheral resistance. Bolus crystalloid administration has often been advocated as a means of restoring venous return and thus cardiac output during central neuraxial blockade. However, the effectiveness of this therapy in normovolemic patients is controversial. Prehydrating patients with 500 to 1,500 mL of crystalloid does not reliably prevent hypotension, but it has been shown to decrease the incidence of hypotension during spinal anesthesia in some,[177,178] but not all, studies.[160] Similarly, prehydration with crystalloid has been shown not to be effective in preventing hypotension during spinal anesthesia for cesarean section.[179] Thus, although judicious crystalloid preloading of patients before central neuraxial blocks may benefit some patients, this practice cannot be relied on to prevent clinically significant hypotension in all or even most patients. The reason for this is that increasing preload can only increase stroke volume, which has limited ability to restore blood pressure if heart rate or systemic vascular resistance remains low. In this regard colloids offer an interesting alternative to crystalloids for preloading before central neuraxial blocks. Marhofer and colleagues have shown that 500 mL 6% hetastarch actually increases systemic vascular resistance index (SVRI) in elderly patients having spinal anesthesia, while 1,500 mL crystalloid significantly decreases SVRI.[180]

Vasopressors are a more reliable approach to treating hypotension secondary to central neuraxial blockade. Drugs with both α- and β-adrenergic activity have been shown to be superior to pure α-

agonists for correcting the cardiovascular derangements produced by spinal and epidural anesthesia.[181,182] Ephedrine is the drug most commonly used to treat hypotension. Ephedrine boluses of 5 to 10 mg increase blood pressure by restoring cardiac output and peripheral vascular resistance. Dopamine, in low to moderate doses, has also been shown to correct the hemodynamic changes induced by central neuraxial block.[183,184] Dopamine may be preferable to ephedrine for long-term infusion because tachyphylaxis can develop to repeated ephedrine boluses. Pure α-adrenergic agonists, most commonly phenylephrine, are also used to correct hypotension during spinal anesthesia. However, α-agonists increase blood pressure largely by increasing systemic vascular resistance, sometimes at the expense of further decreasing cardiac output.[182] In addition, phenylephrine boluses have been shown to produce transient left ventricular dysfunction during epidural anesthesia with nonepinephrine-containing local anesthetics.[185] A potential, but as yet unstudied, role for α-agonists may be to treat hypotension that occurs during epidural anesthesia with epinephrine-containing local anesthetics. Because the principal derangement in this situation is a marked decrease in systemic vascular resistance, α-agonists may be an appropriate choice for treating hypotension in this setting.

Deciding when to treat hemodynamic derangements during spinal and epidural anesthesia is perhaps more difficult than deciding how to treat them. There are currently no studies that clearly define the lower limit of acceptable blood pressure or heart rate for any group of patients. In the absence of such data, several authors have recommended treating blood pressure if it decreases more than 25% to 30% below baseline or in normotensive patients, if systolic pressure falls below 90 mm Hg. Recommendations regarding bradycardia suggest initiating treatment if heart rate falls below 50 to 60 beats/minutes-1. These recommendations are reasonable, although not universally applicable. Ultimately, anesthesiologists must decide what is an acceptable blood pressure and heart rate for an individual patient based on that patient's underlying medical condition.

Respiratory Physiology

Spinal and epidural blocks to midthoracic levels have little effect on pulmonary function in patients without preexisting lung disease. Drugs used perioperatively for sedation during spinal or epidural block likely have a larger impact on pulmonary function than the block per se. In particular, lung volumes, resting minute ventilation, dead space, arterial blood gas tensions, and shunt fraction show little or no change during spinal or epidural anesthesia. Interestingly, the ventilatory response to hypercapnia is actually increased by spinal and epidural block.[186,187]

High blocks associated with abdominal and intercostal muscle paralysis can impair ventilatory functions requiring active exhalation. For example, expiratory reserve volume, peak expiratory flow, and maximum minute ventilation may be significantly reduced by high spinal and epidural blocks. The negative impact of high blocks on active exhalation suggests caution when using spinal or epidural anesthesia in patients with obstructive pulmonary disease who may rely on their accessory muscles of respiration to maintain adequate ventilation.

Patients with high spinal or epidural blocks may complain of dyspnea despite normal or elevated minute ventilation. This likely results from the patient's inability to feel the chest wall move while breathing. This is understandably frightening to the patient, but reassurance is usually effective in alleviating their fear. The anesthesiologist must be alert to the possibility that the complaint of dyspnea stems from incipient respiratory failure secondary to respiratory muscle paralysis. A normal speaking voice, as opposed to a faint gasping voice, suggests ventilation is normal.

Gastrointestinal Physiology

The gastrointestinal effects of spinal and epidural anesthesia are largely the result of sympathetic blockade. The abdominal organs derive their sympathetic innervation from T6-L2. Blockade of these fibers results in unopposed parasympathetic activity by way of the vagus nerve. Consequently, secretions increase, sphincters relax, and the bowel becomes constricted. Some surgeons believe this improves surgical exposure. Nausea is a common complication of spinal and epidural anesthesia. The etiology is unknown but an increased incidence of nausea during spinal anesthesia is associated with blocks higher than T5, hypotension, opioid premedication, and a

history of motion sickness.[159,162]

Endocrine-Metabolic Physiology

Surgery produces numerous endocrine and metabolic changes, including increased protein catabolism and oxygen consumption as well as increases in circulating concentrations of catecholamines, growth hormone, renin, angiotensin, thyroid-stimulating hormone, β-endorphin, glucose, and free fatty acids, among others.[1] These endocrine–metabolic changes have collectively been termed the "surgical stress response."

The mechanisms responsible for the stress response are complex and incompletely understood. However, afferent sensory information from the surgical site plays an important role in initiating and maintaining these changes.[1] Not surprisingly, spinal and epidural anesthesia have been shown to inhibit many of the endocrine–metabolic changes associated with the stress response. The inhibitory effect is greatest with lower abdominal and lower extremity procedures and least with upper abdominal and thoracic procedures.[1] The salutary effect of spinal and epidural anesthesia is believed to result from blockade of the afferent sensory information that helps initiate the stress response.

Although some aspects of the surgical stress response may be beneficial, it is generally viewed as maladaptive and possibly a contributor to postoperative morbidity and mortality.[1] Despite the ability of central neuraxial block to decrease the stress response, there is as yet no clear evidence that this results in decreased morbidity or mortality.

COMPLICATIONS

Backache

Although postoperative backache occurs following general anesthesia, it is more common following epidural and spinal anesthesia.[188] Compared with spinal anesthesia, back pain following epidural anesthesia is more common (11% versus 30%) and of longer duration.[189] Importantly, back pain has been cited in one study as the most common reason for patients to refuse future epidural block.[189] The etiology of backache is not clear, although needle trauma, local anesthetic irritation, and ligamentous strain secondary to muscle relaxation have been offered as explanations.

Postdural Puncture Headache

Postdural puncture headache is a common complication of spinal anesthesia with a reported incidence as high as 25% in some studies. The risk of PDPH is less with epidural anesthesia, but it occurs in up to 50% of young patients following accidental meningeal puncture with large diameter epidural needles. The headache is characteristically mild or absent when the patient is supine, but head elevation rapidly leads to a severe fronto-occipital headache, which again improves on returning to the supine position. Occasionally cranial nerve symptoms (e.g., diplopia, tinnitis) and nausea and vomiting are also present. The headache is believed to result from the loss of CSF through the meningeal needle hole resulting in decreased buoyant support for the brain. In the upright position the brain sags in the cranial vault putting traction on pain-sensitive structures. Traction on cranial nerves is believed to cause the cranial nerve palsies occasionally seen.

The incidence of PDPH decreases with increasing age (Fig. 25-15) and with the use of small diameter spinal needles with noncutting tips.[190,191] Inserting cutting needles with the bevel aligned parallel to the long axis of the meninges has also been shown to decrease the incidence of PDPH.[191,192] Some authors have suggested that parallel insertion spreads dural fibers, whereas perpendicular insertion cuts the fibers resulting in a larger meningeal hole. However, the collagen fibers of the dura mater are arranged randomly; therefore, as many fibers will be cut with parallel insertion as with perpendicular insertion. A more likely explanation arises from the fact that the dura mater is under longitudinal tension. Thus, a slit-like hole oriented perpendicular to this longitudinal tension will tend to be pulled open while a hole oriented parallel to this tension will be

pulled closed. Some studies have suggested that women are at greater risk of developing PDPH. However, if age differences are accounted for, there does not appear to be a gender difference in the incidence of PDPH.[191] Folklore aside, remaining supine following meningeal puncture does not decrease the incidence of PDPH. Finally, use of fluid, instead of air, for loss of resistance during attempted epidural anesthesia does not alter the risk of accidental meningeal puncture, but does markedly decrease the risk of subsequently developing PDPH.[27] PDPH usually resolves spontaneously in a few days to a week for most patients. However, there are reports of PDPH persisting for months following meningeal puncture. Initial treatment is appropriately conservative if this meets the patient's needs. Bed rest and analgesics as necessary are the mainstay of conservative treatment. Caffeine has also been shown to produce short-term symptomatic relief.[193]

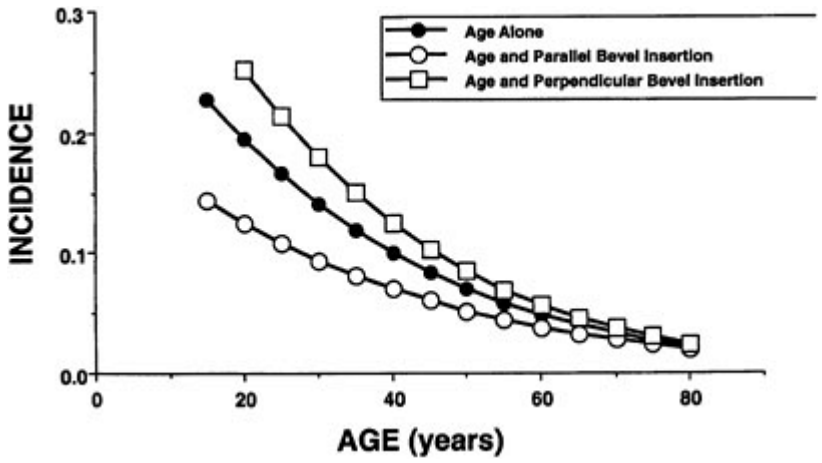

FIGURE 25-15. The incidence of postdural puncture headache decreases as patient age increases. When using beveled needles, the incidence is higher than average at any given age if the needle is inserted perpendicular to the spinal meninges and lower if inserted parallel to the spinal meninges. (Modified from Lybecker H, Møller JT, May O, Nielsen HK: Incidence and prediction of post-dural puncture headache: A prospective study of 1021 spinal anesthesias. Anesth Analg 70:389, 1990.)

Epidural Blood Patch. Patients who are unable or unwilling to await spontaneous resolution should be offered epidural blood patch. Epidural blood patch is believed to form a clot over the meningeal hole, thereby preventing further CSF leak while the meningeal rent heals. Ten to 20 mL of autologous blood is aseptically injected into epidural space at or near the interspace at which the meningeal puncture occurred. This is effective in relieving symptoms within 1 to 24 hours in 85% to 95% of patients; ~90% of patients who fail an initial blood patch will respond to a second patch. The most common side effects of blood patch are backache and radicular pain, although transient bradycardia and cranial nerve palsies have also been reported.

The timing of epidural blood patch has been controversial. Early studies suggested that prophylactic blood patch in patients at high risk for PDPH was ineffective. This led several authors to suggest that blood patch should not be performed before patients develop symptoms of PDPH. Subsequent studies, which used larger volumes of blood in the epidural space (15 to 20 mL), have shown that prophylactic blood patch is effective in preventing PDPH in patients in whom the meninges were accidentally punctured during attempted epidural anesthesia.[194,195] Prophylactic blood patch is not appropriate for most patients but is worth considering in high-risk outpatients for whom a return trip to the hospital for epidural blood patch would be difficult.

Epidurally administered fibrin glue has been shown to be an effective alternative to blood

administration for treatment of PDPH.[196] Whether it is superior to blood requires further study but it may be an attractive alternative for some patients. In the future it may be necessary to drop the term "blood patch" in favor of "meningeal patch."

Hearing Loss

Lamberg et al demonstrated that a transient (1 to 3 days) mild decrease in hearing acuity (greater than 10 dB) is common after spinal anesthesia with an incidence of roughly 40% and a 3:1 female:male predominance.[197] Similarly, Gültekin et al[198] demonstrated a 45% incidence of hearing impairment in subjects undergoing prilocaine spinal anesthesia but a much lower incidence (18%) in patients having bupivacaine spinal anesthesia. The mechanism of hearing loss in these studies is unclear, but the marked female predominance, the absence of PDPH, and the difference in incidence between prilocaine and bupivacaine suggest that CSF leak is not the cause.

Systemic Toxicity

Systemic toxicity of local anesthetics is discussed in detail in Chapter 17. Systemic toxicity does not occur with spinal anesthesia because the drug doses used are too low to cause toxic reactions even if injected intravenously. Both CNS and cardiovascular toxicity may occur during epidural anesthesia. CNS toxicity may result from local anesthetic absorption from the epidural space but more commonly occurs following accidental intravascular injection of local anesthetic. In contrast, cardiovascular toxicity from epidural local anesthetics can only occur unintended intravascular injection because the plasma concentrations of local anesthetics required to produce serious cardiovascular toxicity are very high. An adequate IV test dose and incremental injection of local anesthetics are the most important methods to prevent both CNS and cardiovascular toxicity during epidural anesthesia.

Total Spinal

Total spinal anesthesia occurs when local anesthetic spreads high enough to block the entire spinal cord and occasionally the brainstem during either spinal or epidural anesthesia. Profound hypotension and bradycardia are common secondary to complete sympathetic blockade. Respiratory arrest may occur as a result of respiratory muscle paralysis or dysfunction of brainstem respiratory control centers. Management includes vasopressors, atropine, and fluids as necessary to support the cardiovascular system, plus oxygen and controlled ventilation. If the cardiovascular and respiratory consequences are managed appropriately, total spinal block will resolve without sequelae.

Neurologic Injury

Serious neurologic injury is a rare but widely feared complication of epidural and spinal anesthesia. Multiple large series of spinal and epidural anesthesia report that neurologic injury occurs in ~0.03% to 0.1% of all central neuraxial blocks, although in most of these series the block was not clearly proven to be causative.[199] Persistent paresthesias and limited motor weakness are the most common injuries, although paraplegia and diffuse injury to cauda equina roots (*cauda equina syndrome*) do occur rarely. Injury may result from direct needle trauma to the spinal cord or spinal nerves, from spinal cord ischemia, from accidental injection of neurotoxic drugs or chemicals, from introduction of bacteria into the subarachnoid or epidural space, or very rarely from epidural hematoma.[199]

6 Importantly, local anesthetics intended for epidural and intrathecal use can themselves be neurotoxic in concentrations used clinically.[200] In particular, hyperbaric 5% lidocaine has been implicated as a cause of multiple cases of cauda equina syndrome following subarachnoid injection through small-bore ("microspinal") catheters during continuous spinal anesthesia.[201] Hyperbaric solutions injected through these high-resistance catheters have been shown to produce very little turbulence and thus poor mixing of the local anesthetic within CSF.[202] Nerve injury is believed to result from pooling of toxic concentrations of undiluted lidocaine around dependent cauda equina nerve roots. Consequently, the U.S. Food and Drug Administration has banned the

use of these small-gauge catheters for continuous spinal anesthesia. Although the combination of microspinal catheters and high concentrations of lidocaine have clearly been implicated in causing cauda equina syndrome, this complication has also occurred when using larger (20 gauge) catheters,[201] 2% lidocaine,[203] and 0.5% tetracaine.[201] A common thread in all of these reports has been the apparent maldistribution of the local anesthetic within the CSF. Maldistribution should be suspected whenever spinal block is unexpectedly restricted and maneuvers, such as altering patient position or drug baricity, should be employed to improve drug distribution before additional drug is injected through a continuous spinal catheter. If these maneuvers fail to improve drug distribution, an alternative anesthetic technique should be employed.

The mechanism by which local anesthetics produce cauda equina syndrome is not yet clear; however, in vitro evidence suggests that local anesthetics produce excitotoxic damage by depolarizing neurons and increasing intracellular calcium concentrations.[204] It is also unclear as yet whether adjuncts added to local anesthetics, for example, epinephrine, contribute to cauda equina syndrome. However, based on animal studies, it has been argued that epinephrine should not be added to intrathecal lidocaine.[205] Rather, if a prolonged duration of spinal anesthesia is necessary, then a longer acting drug like bupivacaine should be used.

Transient Neurologic Symptoms (TNS). In addition to cauda equina syndrome, the occurrence of *transient neurologic symptoms* (TNS) or *transient radicular irritation* (TRI) has also emerged as a concern following central neuraxial blockade. TRI is defined as pain, dysesthesia, or both in the legs or buttocks after spinal anesthesia and was first proposed as a recognizable entity by Schneider.[206] All local anesthetics have been shown to cause TRI although the risk appears to be greater with lidocaine than other local anesthetics.[207,208,209,210,211,212,213]

In a large epidemiologic study of nearly 2,000 patients, Freedman et al characterized the clinical picture of TRI.[214] They found that patients receiving lidocaine were significantly more likely to develop TRI than were patients receiving spinal tetracaine or bupivacaine although TRI did occur with these latter two drugs as well. Additional risk factors for TRI included surgery in the lithotomy position when lidocaine, but not when bupivacaine or tetracaine, was used, and outpatient status; obesity was a borderline risk factor. Variables shown not to increase the risk of TRI included lidocaine dose, type of spinal needle, addition of epinephrine to lidocaine, paresthesia, hypotension, and blood tinged CSF among others. In a separate study, Sakura has shown that the addition of phenylephrine is a risk factor for TRI when using 0.5% tetracaine for spinal anesthesia.[215]

Pain from TRI was not trivial, with the majority of patients rating it as moderate (VAS = 4 to 7/10). The pain usually

resolved spontaneously within 72 hours but a very few patients required 6 months.[214]

The mechanism responsible for TRI is unknown; however, it would be inappropriate to conclude that TRI is simply a milder manifestation of cauda equina syndrome. Differences in clinical presentation, risk factors, and so on suggest that these are not simply two points along a continuum of the same process.

Chloroprocaine

Chloroprocaine was introduced into clinical practice in 1951 and was used for spinal anesthesia beginning in that year. In the early 1980s, however, clinicians reported multiple cases of neurological injury following intrathecal injection of chloroprocaine. Importantly, the chloroprocaine solution available at the time contained either methylparaben as an antimicrobial or bisulfite as an antioxidant. Subsequent animal studies demonstrated that bisulfite and metabisulfite at low pH were capable of causing neurological injury, but that plain chloroprocaine was not. Nonetheless, concern about the potential for chloroprocaine-mediated neurotoxicity led to its nearly complete abandonment as a spinal anesthetic. This occurred despite the fact that the U.S. Food and Drug Administration had concluded that chloroprocaine was not more neurotoxic than lidocaine, bupivacaine, or mepivacaine. This abandonment of chloroprocaine for spinal use was facilitated by the clinical impression that lidocaine was a safer alternative for short duration

spinal anesthetics.

7 However, we now recognize that lidocaine is not without risk of neurological toxicity. This observation, coupled with the fact that a preservative-free chloroprocaine formulation is now available, has led to a reevaluation of chloroprocaine as a short-acting spinal anesthetic. In 2004, Kouri and Kopacz compared the block characteristics of 40 mg plain 2% lidocaine with 40 mg plain 2% preservative-free chloroprocaine in humans using a double-blind, randomized crossover study design.[216] They found that both drugs produced identical average block heights (T8), but that chloroprocaine resulted in more rapid resolution of sensory block (103 ± 13 minutes versus 126 ± 16 minutes.) and faster attainment of discharge criteria (104 ± 12 minutes versus 134 ± 14 minutes). In addition, seven of eight volunteers experienced TNS following intrathecal lidocaine while none experienced TNS following 2% chloroprocaine. In other studies from the same research group, chloroprocaine spinal block height and duration were shown to be positively correlated with chloroprocaine dose[217] and addition of dextrose was shown not to alter spinal block characteristics except that it increased postvoid bladder volume.[218] This group also performed studies to determine the effect of epinephrine and fentanyl as block-prolonging adjuvants to spinal chloroprocaine. Vath and Kopacz found that the addition of 20 µg fentanyl to 40 mg chloroprocaine increased average peak block height (T5 versus T9), prolonged the time for sensory block regression to L1 (78 ± 7 minutes versus 53 ± 19), and modestly increased the time to complete regression (104 ± 7 minutes versus 95 ± 9 minutes).[219] Interestingly, Smith et al. found that epinephrine (0.2 mg) increased chloroprocaine block duration but that it's use was associated with a high incidence of myalgia, arthralgia, malaise, and anorexia that lasted up to 48 hours.[217] The authors had no explanation for the epinephrine-associated side effects, but recommended against its use with intrathecal chloroprocaine.

Thus, these studies, coupled with concerns about the potential for lidocaine-mediated neurotoxicity, raise the possibility that chloroprocaine will reenter the mainstream as a spinal anesthetic, especially for ambulatory anesthesia. Additional, larger studies demonstrating chloroprocaine's safety will help to clarify this drug's role in spinal anesthesia.

Importantly, as of this writing, chloroprocaine is not specifically indicated for spinal anesthesia, therefore, its use is "off-label." But then so to is the use of multiple drugs that are routinely administered intrathecally, including plain bupivacaine, fentanyl, and sufentanil.

Spinal Hematoma

Spinal hematoma is a rare but potentially devastating complication of spinal and epidural anesthesia, with an incidence estimated to be less than 1 in 150,000. Patients most commonly present with numbness or lower extremity weakness, a fact that can make early detection difficult in patients receiving perioperative spinal local anesthetics for pain control. Early detection is critical because a delay of more than 8 hours in decompressing the spine reduces the odds of good recovery.[220]

8 Coagulation defects are the principal risk factor for epidural hematoma. This raises the legitimate question as to how to treat patients who are or who will be anticoagulated. This issue has been addressed in a Consensus Statement from the American Society for Regional Anesthesia and Pain Medicine[221] and the recommendations presented here are taken from this consensus statement. In brief, patients taking nonsteroidal anti-inflammatory drugs with antiplatelet effects (e.g., cyclooxygenase-1 inhibitors) or receiving subcutaneous unfractionated heparin for DVT prophylaxis are not viewed as being at increased risk of spinal hematoma.

In contrast, other classes of antiplatelet drugs, like thienopryidine derivatives (e.g., ticlopidine, clopidogrel) and GP IIb/IIIa antagonists (e.g., abciximab, eptifibitide, tirofiban) have a more potent effect on platelet aggregation and neuraxial block should generally not be performed in patients taking these or similar medications. Further, the consensus statement recommends that ticlopidine be discontinued for 2 weeks and clopidogrel for 1 week before performing central neuraxial blocks. The GP IIb/IIIa antagonists have a shorter duration of action, thus it is recommended that abciximab should be discontinued 24 to 48 hours before central neuraxial block

and eptifibitide, and tirofiban 4 to 8 hours beforehand.

Patients receiving fractionated low-molecular weight heparin (e.g., enoxaprin, dalteparin, tinzaparin) are considered to be at increased risk of spinal hematoma. Patients receiving these drugs preoperatively at thromboprophylactic doses should have the drug held for 10 to 12 hours before central neuraxial block. At higher doses, such as those used to treat established DVT, central neuraxial block should be delayed for 24 hours after the last dose. For patients in whom low-molecular-weight heparin is begun after surgery, single-shot central neuraxial blocks are not contraindicated provided that the first low-molecular-weight heparin dose is not administered until 24 hours postoperatively if using a twice daily dosing regimen and 6 to 8 hours if using a once-daily dosing regimen. If an indwelling central neuraxial catheter is in place, it should not be removed until 10 to 12 hours after the last low-molecular- weight heparin dose and the subsequent doses should not begin until at least 2 hours after catheter removal.

Patients who are "fully anticoagulated" (i.e., have elevated PT or PTT) or who are receiving thrombolytic or fibrinolytic therapy are considered to be at increased risk of spinal hematoma. These patients should not receive central neuraxial block except in very unusual circumstances where other options are not viable.

Importantly for those patients who may have an epidural or intrathecal catheter placed, its removal is nearly as great a risk for spinal hematoma as its insertion and the timing of removal and anticoagulation should be coordinated. Also, drugs/regimens not considered to put patients at increased risk of neuraxial bleeding when used alone (e.g., minidose

unfractionated heparin and NSAIDS) may in fact increase risk when combined. This discussion is necessarily abbreviated and the reader who confronts these issues clinically should review the complete consensus statement.

CONTRAINDICATIONS

The only absolute contraindication to spinal or epidural anesthesia is patient refusal. However, several preexisting conditions increase the relative risk of these techniques and the anesthesiologist must carefully weigh the expected benefits before proceeding. Some conditions that increase the apparent risk of central neuraxial block include the following:

1. Hypovolemia or shock increase the risk of hypotension.
2. Increased intracranial pressure increases the risk of brain herniation when CSF is lost through the needle, or if a further increase in intracranial pressure follows injection of large volumes of solution into the epidural or subarachnoid spaces.
3. Coagulopathy or thrombocytopenia increase the risk of epidural hematoma.
4. Sepsis increases the risk of meningitis.
5. Infection at the puncture site increases the risk of meningitis.

Preexisting neurologic disease, particularly diseases that wax and wane (e.g., multiple sclerosis), have been considered a contraindication to central-neuraxial block by some authors. However, there is no evidence to suggest that spinal or epidural anesthesia alters the course of any preexisting neurologic disease. Recommendations to avoid regional anesthesia in these patients stem largely from a medicolegal concern that the anesthetic may be incorrectly blamed for any subsequent worsening of the patient's preexisting condition. Although this is a legitimate concern, it is not a reason to avoid central-neuraxial block if this is an otherwise appropriate choice.

SPINAL OR EPIDURAL ANESTHESIA?

Spinal and epidural anesthesia each have advantages and disadvantages that may make one or the other technique better suited to a particular patient or procedure. Controlled studies

comparing both techniques for surgical anesthesia have consistently found that spinal anesthesia takes less time to perform, produces more rapid onset of better quality sensorimotor block, and is associated with less pain during surgery. Despite these important advantages of spinal anesthesia, epidural anesthesia offers advantages, too. Chief among them are the lower risk of PDPH, less hypotension if epinephrine is not added to the local anesthetic, the ability to prolong or extend the block via an indwelling catheter, and the option of using an epidural catheter to provide postoperative analgesia.

Chapter 26

Peripheral Nerve Blockade

Michael F. Mulroy

KEY POINTS

1	Peripheral nerve blocks provide longer and more localized pain relief than neuraxial techniques while also avoiding the side effects of systemic medication.
2	Larger volumes of local anesthetic may increase the success potential of peripheral blocks, but the total milligram dosage must be limited to avoid systemic toxicity because of slow absorption. Higher concentrations of local anesthetics on peripheral nerves will increase the degree of motor blockade, but larger volumes of more dilute solutions can be used with less risk of toxicity.
3	Nerve blocks associated with bony or vascular landmarks are more reliable and easy to perform than those that depend on surface landmarks alone.
4	Several peripheral nerve blocks are acceptable alternatives to neuraxial techniques in the anticoagulated patient.
5	Peripheral nerve stimulators are useful tools to facilitate nerve blockade, but they do not eliminate the risk of nerve injury. In the adult patient, responsiveness must be maintained to allow reporting of nerve contact or pain on injection.

GENERAL PRINCIPLES

Regional anesthesia of the extremities and of the trunk is a useful alternative to general anesthesia in many situations. Peripheral nerve blocks have attracted renewed interest because of their salutary role in reducing postoperative pain[1] and shortening outpatient recovery.[2]

Local Anesthetic Drug Selection and Doses

1 The pharmacology of local anesthetics is reviewed at length in Chapter 17. Although high concentrations of drug are needed to produce rapid onset of anesthesia in the epidural space, lower concentrations (e.g., 1% to 1.5% lidocaine, 0.25% to 0.5% bupivacaine) are more appropriate on peripheral nerves because of concerns about local and systemic toxicity. Local toxicity of these anesthetics appears to be concentration dependent.[3]

2 Lower concentrations are also indicated when larger volumes are required to anesthetize poorly localized peripheral nerves or to block a series of nerves. The use of a high-

concentration solution may be useful to increase motor blockade but increases the total milligram dose of local anesthetic.

The absorption of drug and the duration of anesthesia vary with the dose, drug, location injected, and presence of vasoconstrictors. The highest blood levels of local anesthetic occur after intercostal blockade, followed by epidural, caudal, and brachial plexus blockade. Similarly, the duration depends on the blood supply of the area of injection. Equivalent doses of local anesthetic may produce only 3 to 4 hours of anesthesia when placed in the epidural space, but 12 to 14 hours in the arm and 24 to 36 hours when placed on the sciatic nerve. In general, the addition of epinephrine 1:200,000 to 1:400,000 is advantageous in prolonging the duration of blockade and in reducing systemic blood levels of local anesthetic. Its use is not appropriate in the vicinity of "terminal" blood vessels, such as in the digits or penis, or when using an intravenous (IV) regional technique. The recommended doses and drugs in this chapter assume the addition of epinephrine to the solution. In general, the recommendations will be for an effective volume for a sensory block: the final choice of drug, volume, and concentration will be the determinants of the duration of block and the degree of motor blockade.

Nerve Localization

3 The blockade techniques associated with reliable proximity of nerves to bones or arteries are the easiest technically to perform (e.g., intercostal, axillary). Less reliable landmarks, such as the psoas compartment or obturator foramen, require either large volumes of local anesthetic solution or the establishment of a distinct localization of the desired nerve to provide adequate anesthesia. Paresthesias are the traditional sign of successful localization, but the use of electrical stimulation has gained popularity with the development of improved equipment.[4] A low-current electrical impulse applied to a peripheral nerve produces stimulation of motor fibers and identifies the proximity of the nerve without actual needle contact or patient discomfort. Because the nerve stimulator does not technically contact the nerve, its use may reduce the chance for nerve injury, although it still may occur and paresthesias have been elicited with this technique before motor responses. A familiarity with anatomy and technique is still necessary to bring the needle into proximity to the nerve. The ideal stimulator should have a variable-amperage output. This allows a high current to be delivered in the exploration phase and then a progressively lower current to document proximity of the nerve. The accuracy of the localization can be improved by the use of insulated needles. Current flow can also be improved by using the positive (red) pole of the stimulator as the ground (or reference) electrode and the negative (black) lead as the connection to the needle itself. Whereas 1 to 2 mA can be used to produce the first motor twitch, actual injection of anesthetic should be delayed until stimulation is produced by as little as 0.3 to 0.5 mA. At that point, 2 to 3 mL of local anesthetic should be sufficient to abolish motor twitch, indicating that it is appropriate to inject the remainder of the proposed dose.

Seeking a sensory paresthesia with the needle remains an acceptable alternative, though there is potential for intraneural injection if paresthesias are obtained. This is usually signaled by a complaint from the patient of a "cramping" or "aching" pain during the initial injection. If this occurs, the needle should be immediately withdrawn by a few millimeters and a small test injection repeated. Even without intraneural injection, residual neuropathy of peripheral nerves appears more likely if paresthesias are obtained. A third problem with this technique is the inevitable associated discomfort; patient education and sedation must be handled appropriately.

Another alternative is the use of ultrasound guidance to localize nerves, especially if located near an artery (axillary or femoral). These techniques show promise, but require more complex equipment and experience. The choice of localization technique depends on many factors, especially the experience and training of the operator.

Equipment

Although reusable syringes and needles can be manufactured to a higher standard, their cost and concern about infection generally lead to a preference for disposable equipment. There is a large

number of high-quality disposable kits available on the market, and many of the major manufacturers customize their packages at the request of large institutions willing to commit to purchasing a sufficient volume. The use of disposable trays places the burden of sterilization on the manufacturer, although the liability for checking the sterility of contents always remains with the user.

Needles used for regional techniques are often modified from standard injection needles. For peripheral blockade, the "short bevel" or "B bevel" is often used to reduce the potential for injury to nerves. Other modifications, such as the "pencil-point" insulated needle, have been introduced in attempts to reduce nerve injury.

Special syringes are also useful for performing peripheral nerve blockades. Plastic and glass are equally useful. With respect to size, a 10-mL syringe is usually a good compromise. Large volumes are often required for peripheral nerve blockade, so that 3- and 5-mL syringes are rarely adequate. Larger than 10-mL volume often presents such bulk and weight that fine control is hampered. If a larger syringe is used, it is usually advisable to attach it to the needle by a short length of extension tubing. The use of finger rings (the "control syringe") is helpful in controlling injection, facilitating aspiration, and allowing the operator to refill the syringe with one hand (Fig. 26-1). Luer-Lok adapters for the syringe-hub connection are also advantageous. Although friction fittings produce tight seals, the amount of force required for attaching or removing the syringe may displace a needle that has been meticulously maneuvered into the appropriate close contact with a nerve.

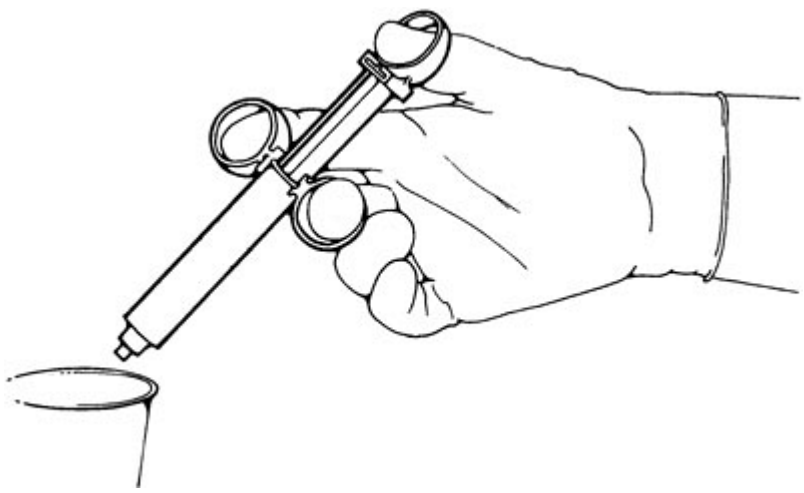

FIGURE 26-1. The three-ring ("control") syringe. Use of this adaptation to the plunger of a standard 10-mL syringe allows greater control of injection, easier aspiration, and the opportunity to refill the syringe with one hand. Plastic adapters are available for disposable syringes as demonstrated. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Continuous Catheters

A recent addition to the armamentarium of the regional anesthesiologist is continuous-infusion catheters adapted for peripheral nerve blockade. Kits are available that include a standard polyamide catheter, such as previously used for epidural analgesia, combined with a Tuohy needle for insertion that has been modified to include nerve stimulation capability. These kits allow the localization of a peripheral nerve with an electrical current and the threading of a catheter to lie contiguous to that nerve to provide prolonged postoperative analgesia. Further enhancements include the development of stimulating catheters, which include an electrode in the catheter tip that allows more precise localization of the catheter as it is advanced alongside the nerve.

Catheter infusions provide prolonged postoperative analgesia following major joint replacement, as well as significant analgesia of an extremity following short-stay orthopedic surgery.[1] Standard precautions are required to preserve the sterility of the catheter and the insertion site, but complications have been rare with these techniques and new devices. There are a number of continuous-infusion devices now available, both in inpatient and outpatient configuration, which allow delivery of dilute local anesthetic concentrations for as long as 72 hours after surgery. These devices range from simple pressure infusion plastic apparatuses that deliver a fixed flow rate to many that can be preprogrammed to variable flow rates and include a patient-controlled supplemental bolus

feature. The selection of the ideal catheter and infusion device combination for a specific patient and situation requires individual review of the available options.

The selection of antiseptic solutions is usually a local preference. Chlorhexadine, alcohol, and organic iodine preparations are current standards for skin asepsis. For major deep nerve blockade, a wide area of skin preparation is more desirable, and the borders of the clean area can be extended by draping on four sides with sterile towels. Regional anesthesia does not require the same degree of sterile preparation and gowning as indicated for surgery, but strict attention to asepsis is desirable to reduce the chance of infection.

Common Complications

Systemic toxicity of local anesthetics is not the most common but is the most serious concern.[5] This syndrome and the problems of allergy and other unique toxicities are addressed in Chapter 17. Central nervous system excitation and myocardial depression are the two most common hazards associated with high blood levels of local anesthetics. No peripheral nerve blockade using significant quantities of local anesthetic should be performed without oxygen and appropriate resuscitation equipment immediately available. This includes blockades using small quantities of anesthetic near cerebral vessels, such as stellate ganglion or cervical plexus blockade. With peripheral nerve blockade, careful use of a test dose and small incremental injections are appropriate if intravascular injection is a risk. Toxicity can also occur owing to slow absorption of high doses. Patients should be observed carefully for 20 to 30 minutes following injection because peak levels occur at this time.

While complications of peripheral blockade appear less frequent than after neuraxial blockade, peripheral nerve damage does appear to be a frequent cause for filing of a malpractice claim.[6] Peripheral neuropathy usually results from intraneural local anesthetic injection or needle trauma, although there are other causes.[7] Careful attention should be paid to positioning the patient with numb extremities. Postoperative follow-up is important in confirming that neurologic function has returned to normal. If a deficit is detected, early neurologic assessment is critical in determining whether a preexisting neuropathy was involved. Fortunately, most of these syndromes resolve uneventfully, but full recovery of some peripheral injuries requires several months as a result of slow regeneration of injured peripheral nerves. Sympathetic concern and involvement of the anesthesiologist in arranging physical therapy during recovery help reduce patient dissatisfaction.

4 Other minor complications such as pain at the site of injection and local hematoma formation are not uncommon but are usually of short duration and respond to reassurance by the anesthesiologist. Hematoma around a peripheral nerve is not of the same significance as that in the epidural or subarachnoid space. Again, expressed concern and help with local therapy and analgesics alleviate patient dissatisfaction.

PATIENT PREPARATION

Patient Selection

In general, all patients scheduled for extremity, thoracic, abdominal, or perineal surgery should be considered candidates for peripheral regional anesthetic techniques. These can be used as the only anesthetic, as a supplement to provide analgesia and muscle relaxation along with general

anesthesia, or as the initial step for provision of prolonged postoperative analgesia such as with intercostal blockade or continuous peripheral nerve catheters. Adamant refusal of regional anesthesia by a patient is a contraindication to the procedure. However, patient refusal is frequently a "relative" refusal. If the patient's real objections are to "being awake" or "being aware," this can be managed by the use of sedatives and amnestic drugs. Other contraindications include local infection and severe systemic coagulopathy. The presence of preexisting neurologic disease is often discussed. Some data are available in the case of spinal anesthesia, but the use of peripheral nerve blockade in this situation is unclear. Although some physicians avoid any procedure that may confuse the picture of postoperative neuropathy, others believe that if there is a clear difference in the potential injury and the preexisting disease, regional techniques are appropriate. There are no clear answers in this regard, and full patient education and cooperation are most appropriate. Finally, the level of patient anxiety is an important consideration. Extreme apprehension regarding surgery necessitates heavy sedation, and the advantages of regional anesthesia in providing rapid recovery, alertness, and protection of airway reflexes may be negated. The use of regional anesthesia in these situations is a matter of judgment and experience.

Premedication and Sedation

The best preparation for a regional technique is careful patient education. Supplemental medication is also useful. In addition to the general comments about premedication discussed in earlier chapters, regional anesthesia techniques have special requirements. First, sedation must be adjusted to the required level of patient cooperation. With either the elicitation of a paresthesia or electrical stimulation technique, medication must be light enough to allow the patient to identify and report nerve contact. Although a mild dose of opioid (50 to 100 μg of fentanyl or equivalent) will help ease the discomfort of nerve localization, patient responsiveness must be maintained. This does not preclude the use of an amnestic agent. Small doses of propofol or midazolam may provide excellent amnesia at levels of consciousness that still allow cooperation.

Monitoring

5 Although current discussions of "monitoring" typically include mechanical and electrical devices, repetitive assessment of the patient's mental status when receiving local anesthetics is of paramount importance. The anesthesiologist must maintain frequent verbal contact with these patients and ideally have an uninvolved assistant available to assess the level of consciousness at all times. There are no electrical or mechanical devices that detect rising blood levels of local anesthetic; close observation for peak levels owing to iv (within 2 minutes) and subcutaneous (~20 minutes) absorption is essential. An electrical or mechanical pulse counter is appropriate to detect the pulse rise seen with epinephrine when it is included in a test dose. Pulse monitoring is also useful as an indicator of systemic toxicity with bupivacaine. A baseline blood pressure should be obtained whenever any sympathetic blockade is performed and at frequent intervals thereafter. Beyond these specific comments, the standards for monitoring and record keeping on any patient undergoing regional anesthesia are the same as for patients undergoing any general anesthetic.

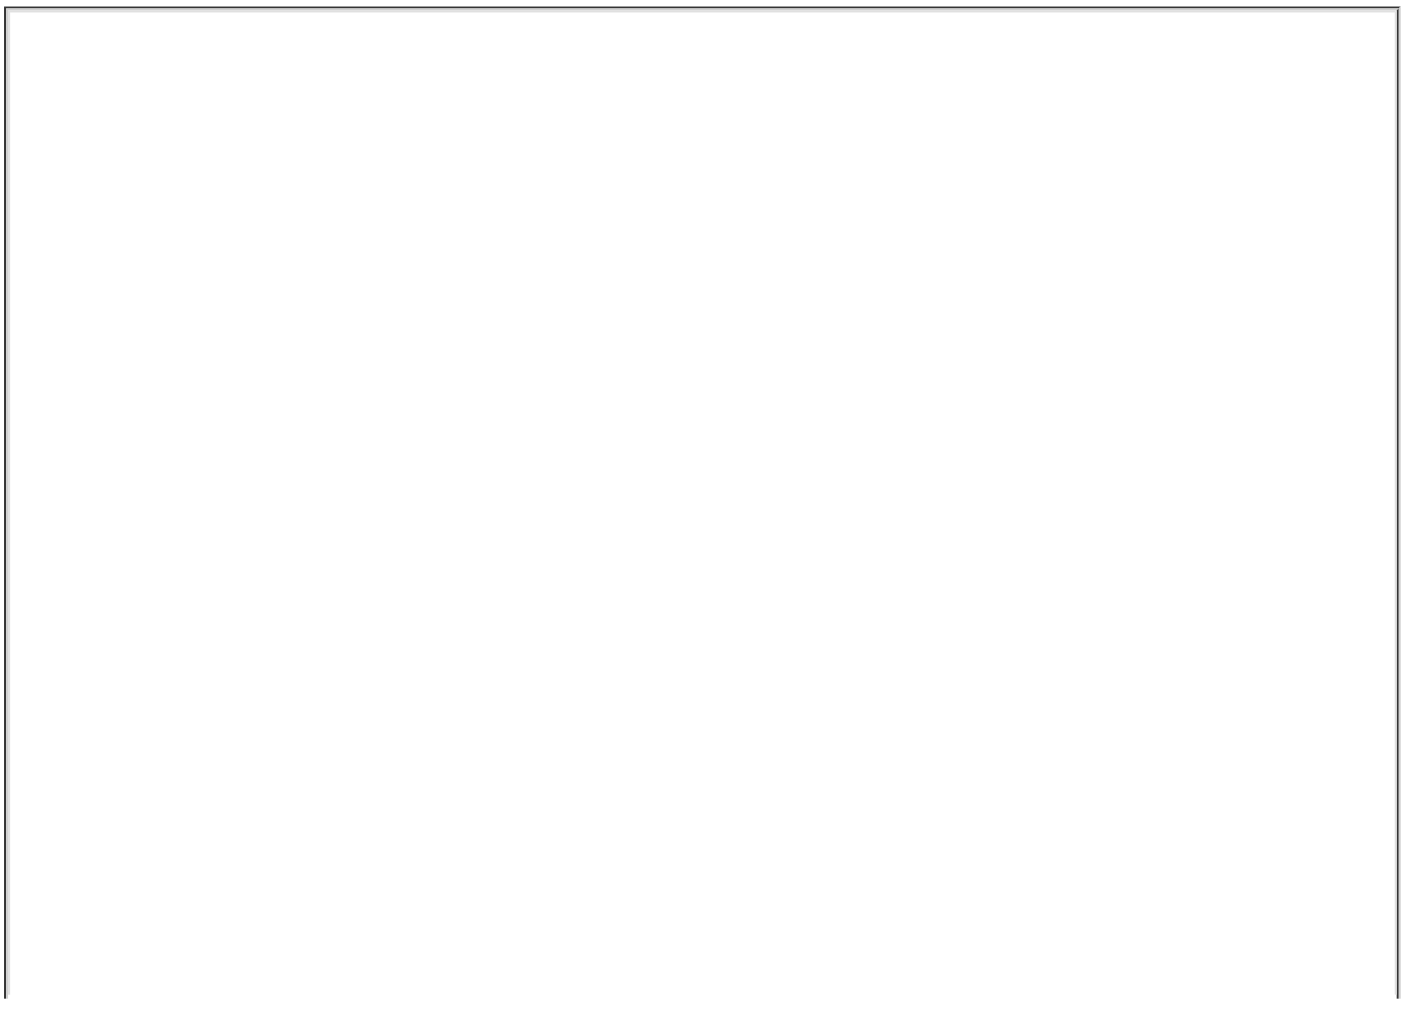
Discharge Criteria

Concern is occasionally expressed about discharging patients from postanesthesia care units when an extremity is still anesthetized. If regional anesthesia is administered to provide

prolonged analgesia, numbness may be expected to persist for 10 (with intercostal anesthesia) to 24 (with sciatic blockade) hours after bupivacaine or ropivacaine administration. Patients with numb extremities have been successfully discharged from the postanesthesia care unit to the floors as long as their mental alertness is adequate. Outpatients may be discharged home with numb arms or legs (or even with continuous peripheral nerve infusions) as long as the patient is reliable and adequate instruction about ambulation and care of the insensitive extremity is

provided.

SPECIFIC TECHNIQUES



The remainder of this chapter is devoted to the details of the performance of specific types of blockade, arranged by sections of the body. No attempt has been made to describe every regional technique practiced, but to focus on those of clinical usefulness to the anesthesiologist.

Head and Neck

Regional anesthesia of the head and neck has limited surgical application. Concern about control and maintenance of the airway makes many anesthesiologists uncomfortable with regional techniques when intraoperative airway intervention is awkward. Trigeminal nerve blockade and occipital nerve blockade are used for diagnostic or neurolytic blockade for chronic pain syndromes. Cervical plexus blockade is useful for some surgical procedures on the neck, and topical–regional airway anesthesia is effective in reducing the subjective discomfort and hemodynamic responses to tracheal intubation.

Trigeminal Nerve Blockade

Sensory and motor nerve function of the face is provided by the branches of the fifth cranial (trigeminal) nerve. The roots of this nerve arise from the base of the pons and send sensory branches to the large gasserian (or semilunar) ganglion, which lies on the superior margin of the petrous bone just inside the skull above the foramen ovale. A smaller motor fiber nucleus lies behind it and sends motor branches to one terminal nerve, the mandibular. The three major branches of the trigeminal each have a separate exit from the skull (Fig. 26-2). The uppermost ophthalmic branch passes through the sphenoidal fissure into the orbit. The main terminal fibers of this nerve, the frontal nerve, bifurcate into the supratrochlear and supraorbital nerves. These two branches traverse the orbit along the superior border and exit on the front of the face in the easily palpated supraorbital notch for the former and along the medial border of the orbit for the latter.

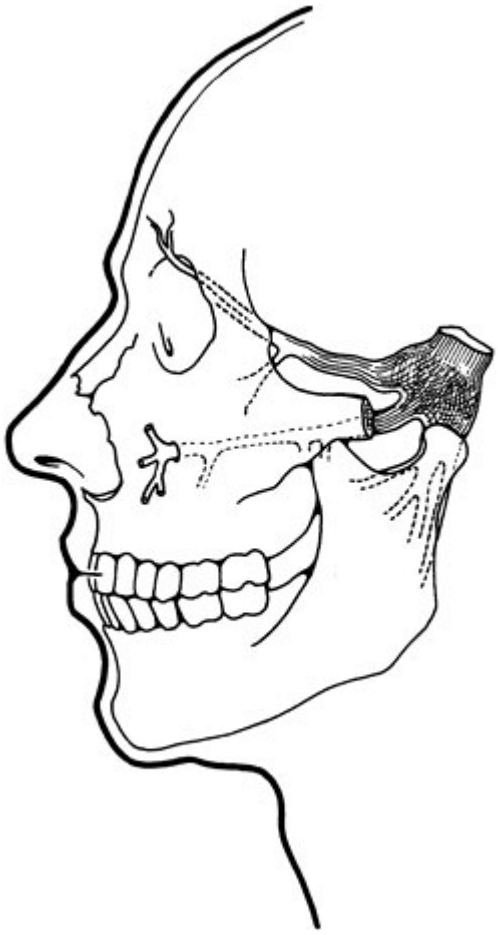


FIGURE 26-2. Lateral view of major branches of the trigeminal nerve. Each major branch exits the skull by a separate foramen. The ophthalmic branch travels in the orbit. The maxillary and mandibular branches emerge from the skull medial to the lateral pterygoid plate, which serves as the landmark for their identification. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

The two major branches of the trigeminal nerve are the middle (maxillary) and lower (mandibular). The maxillary nerve contains only sensory fibers and exits the skull through the foramen rotundum. It passes beneath the skull anteriorly through the sphenomaxillary fossa. At this point, it lies medial to the lateral pterygoid plate on each side. At the anterior end of this channel, it again moves superiorly to reenter the skull in the infraorbital canal in the floor of the orbit. In the sphenomaxillary fossa, it branches to form the sphenopalatine nerves and to give off the posterior dental branches. The anterior dental nerves arise from the main trunk as it passes through the infraorbital canal. The terminal infraorbital nerve emerges from the foramen of the same name just below the eye and lateral to the nose and gives off the terminal palpebral, nasal, and labial nerves. The mandibular nerve is the third and largest branch of the trigeminal, and the only one to receive motor fibers. It exits the skull posterior to the maxillary nerve through the foramen ovale. At this point, it is just posterior to the lateral pterygoid plate of the sphenoid bone. The motor nerves separate into an anterior branch immediately below the foramen ovale. The main branch continues as the inferior alveolar nerve medial to the ramus of the mandible. This nerve curves anteriorly to follow the mandible and exits as a terminal branch through the mental foramen. The mental nerve provides sensation to the lower lip and jaw.

Gasserian Ganglion Blockade

Ideally, the simplest blockade of the trigeminal nerve is performed in the central ganglion. It is

used for treatment of disabling trigeminal neuralgia. This blockade is technically the most difficult and has the most undesirable potential for the complications; it is usually performed by neurosurgeons under fluoroscopic guidance and will not be described in detail here.

Superficial Trigeminal Nerve Branch Blockade

Fortunately, most anesthetic applications of trigeminal blockade can be more easily performed by injection of the individual terminal superficial branches. This is relatively simple because the three superficial branches and their associated foramina all lie in the same sagittal plane on each side of the face (Fig. 26-3). Each of these foramina is readily palpable, and these nerves can be easily blocked with superficial injections of small quantities of local anesthetic. Although the bony landmarks are usually sufficient themselves, paresthesias are desirable before alcohol injection. Each of these blocks can be performed with

the patient in the supine position. The procedure for blockade follows:

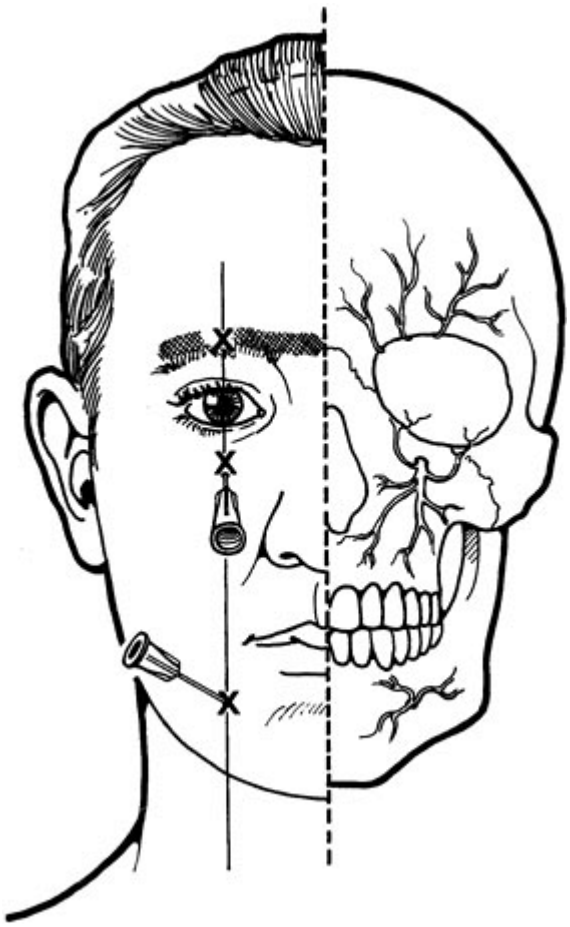

FIGURE 26-3. Terminal branches of the trigeminal nerve. Each of the three terminal branches (the supraorbital, infraorbital, and mental) exits its respective bony canal in the same sagittal plane, approximately 2.5 cm from the midline. The infraorbital canal is angled slightly cephalad, while the mental canal can be entered if the needle is directed medially and slightly caudad. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

1. The supraorbital notch is easily palpated along the medial superior rim of the orbit, usually 2.5 cm from the midline. Two to 3 mL of local anesthetic injected immediately in the vicinity of the notch produces anesthesia of the ipsilateral forehead. Anesthesia of the supratrochlear nerve by superficial infiltration of the medial aspect of the orbital rim is

needed if the band of anesthesia is to cross the midline.

2. The infraorbital foramen lies below the inferior orbital rim in the same plane at approximately the same distance from the midline as the supraorbital notch (usually 2.5 cm). If the foramen cannot be palpated directly, it can be sought by gently probing with a small-gauge needle. This needle should be introduced through a skin wheal approximately 0.5 cm below the expected opening, because the canal angles cephalad from this point toward the orbital floor. Again, injection of a small quantity of local anesthetic immediately in the vicinity of the foramen produces anesthesia of the middle third of the ipsilateral face.
3. The mental nerve also emerges approximately 2.5 cm from the midline, usually midway between the upper and lower borders of the mandible. The mental canal angles medially and inferiorly so that, in this case, needle insertion should start approximately 0.5 cm above and 0.5 cm lateral to the anticipated location of the orifice if it cannot be palpated directly. In older patients, resorption of the superior margin of the mandibular bone will make the foramen appear to lie more superiorly along the ramus. Again, 2 mL of local anesthesia injected into the canal produces anesthesia of the mandibular area.

Maxillary Nerve Blockade

If anesthesia in superior dental nerves is also required or if superficial infraorbital nerve blockade does not produce adequate anesthesia, proximal block of the maxillary nerve is required. This can be performed by a lateral approach to the sphenopalatine fossa. The procedure for blockade follows:

1. The patient lies supine with a small towel under the occiput and the head turned slightly away from the side to be blocked. The zygomatic arch is marked along its course, and the patient is asked to open and close the mouth slowly so that the curved upper border of the mandible can be identified. The lowest point of the mandibular notch is palpated, and an "X" is marked at this spot, which is usually at the midpoint of the zygoma. A skin wheal is raised at the "X" after the appropriate skin preparations.
2. With the patient's jaw in the open position, a 7.5-cm needle is introduced through the "X" and directed 45 degrees cephalad and slightly anterior. This direction should be toward the imagined posterior border of the globe of the eye.
3. The needle should contact the pterygoid plate. It is then withdrawn and redirected slightly anterior until it succeeds in passing beyond the pterygoid plate. At this point, the nerve should lie approximately 1 cm deeper. A paresthesia in the nose or the upper teeth confirms the nerve localization.
4. Anesthesia can be achieved by injecting 5 mL into the fossa, either on obtaining the paresthesia or blindly by advancing 1 cm beyond the plate. The major complication of concern is spread of the anesthetic to adjacent structures, especially to the nerves in the orbit.

Mandibular Nerve Blockade

This nerve can also be blocked for inferior dental pain. It is the only branch where anesthesia carries the risk of loss of motor (mastication) function. The procedure for blockade follows:

1. Head position and landmarks are the same as those described for the maxillary nerve blockade.
2. A 5-cm needle is introduced through the skin wheal and directed medially but slightly posterior and without the cephalad angulation required for maxillary nerve anesthesia. This

leaves the needle approximately perpendicular to the skin in all planes.

3. When the pterygoid plate is contacted, the needle is redirected posteriorly until it passes beyond the plate. It should contact the nerve 0.5 to 1 cm deep to this point.

4. Paresthesia of the jaw or cheek confirms identification of the nerve. Five to 10 mL of solution injected incrementally at this point should produce anesthesia of the terminal branches. If paresthesias are essential, exploration should be carried gently cephalad and caudad from the initial point where the needle passes posterior to the plate. As with maxillary blockade, paresthesias can be painful to the patient, and the use of an assistant to secure the head is occasionally necessary. Facial nerve anesthesia can occasionally be seen when large volumes are injected to block the mandibular nerve. This is of little consequence unless neurolytic agents are used. A more serious complication is the possibility of intravascular injection in this highly vascularized area. Injection should be performed incrementally with small quantities and

there should be constant observation for signs of central toxicity.

Cervical Plexus Blockade

Sensory and motor fibers of the neck and posterior scalp arise from the nerve roots of the second, third, and fourth cervical nerves. This cervical plexus is unique in that the sensory fibers separate from the motor fibers early in their course and can be blocked separately. Classic plexus anesthesia along the tubercles of the vertebral body produces both motor and sensory blockade. The transverse processes of the cervical vertebrae form peculiar elongated troughs for the emergence of their nerve roots. These troughs lie immediately lateral to a medial opening for the cephalad passage of the vertebral artery. The trough at the terminal end of the transverse process divides into an anterior and a posterior tubercle, which can often be easily palpated. These tubercles also serve as the attachments for the anterior and middle scalene muscles, which thus form a compartment for the cervical plexus as well as for the brachial plexus immediately below. The compartment at this level is less developed than the one formed around the brachial plexus. The motor branches (including the phrenic nerve) curl anteriorly around the lateral border of the anterior scalene and proceed caudad and medially toward the muscles of the neck. They give anterior branches to the sternocleidomastoid muscle as they pass behind it. The sensory fibers, as mentioned, also emerge behind the anterior scalene muscle but separate from the motor branches and continue laterally to emerge superficially under the posterior border of the sternocleidomastoid muscle. They provide sensory anesthesia to the anterior and posterior skin of the neck and shoulder.

Anesthesia of either the superficial cervical nerves or the cervical plexus itself can be used for operations on the lateral or anterior neck such as thyroidectomy and carotid endarterectomy. In carotid surgery, local infiltration of the carotid bifurcation may be necessary to block reflex hemodynamic changes associated with glossopharyngeal stimulation.

1. The patient is placed supine with a small towel under the head, with the head turned slightly to the side opposite the one to be blocked.

2. The mastoid process is identified and marked. The transverse processes can often be palpated. If not, the most prominent tubercle, that of C6, is marked, and a line is drawn between it and the mastoid process (Fig. 26-4).

3. The cervical processes should be felt approximately 0.5 cm posterior to the line drawn between the mastoid and the sixth cervical tubercle. The second vertebral process should lie approximately 1.5 cm below the mastoid itself. (There is no process for the first vertebra.)

4. The third and fourth processes lie approximately 1.5 cm below their respective superior neighbors.

5. Skin wheals are raised at the three "X" marks that have been placed over the transverse processes.
6. A 3.75-cm needle is introduced perpendicular to the skin and directed posterior and slightly caudad at each "X" until it rests on the transverse process. It is important to maintain a caudad direction to avoid entry directly into the intervertebral foramina. The needle is walked caudad. It should slip off the bone if it is truly on the process rather than continuing to contact bone if it is on the vertebral body. It is important to contact the transverse process as far laterally as possible to avoid any contact of the needle with the vertebral artery (Fig. 26-5).
7. A syringe is connected to the needle, and 5 mL of local anesthetic solution is deposited along the transverse process. Anesthesia in the distribution of the nerve should follow within 5 minutes.

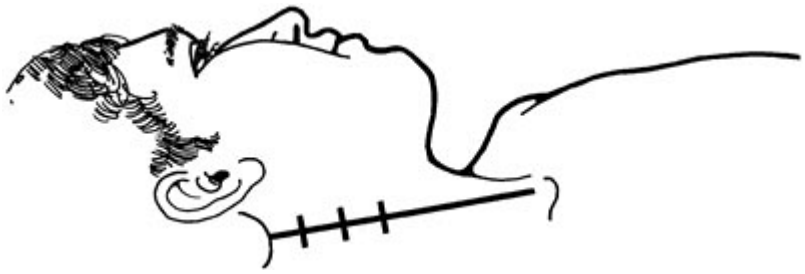

FIGURE 26-4. Superficial landmarks for cervical plexus blockade. A line is drawn from the mastoid process to the prominent tubercle of C6. The transverse processes of C2, C3, and C4 lie 0.5 cm posterior to this line and at 1.5-cm intervals below the mastoid. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

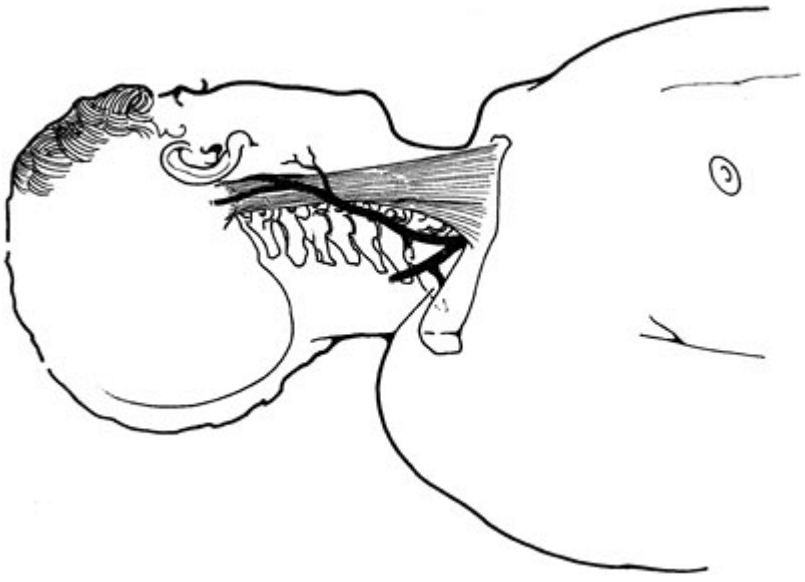

FIGURE 26-5. Anatomy of deep cervical plexus blockade. The transverse processes lie under the lateral border of the sternocleidomastoid muscle, each with a distal trough or sulcus that defines the path of nerve exit. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

The major potential complication of this procedure is intravascular injection into the vertebral artery. If the needle is advanced too far medially into the vertebral foramen, epidural or even subarachnoid anesthesia may be produced. This is more likely in the cervical region because of longer sleeves of dura that accompany these nerve branches.

Phrenic nerve blockade occurs with deep cervical plexus anesthesia. This blockade is not indicated in any patient who depends on the diaphragm for tidal ventilation, nor is bilateral blockade desirable in most patients. Recurrent laryngeal nerve or vagal blockade can also occur because of diffusion of the local anesthetic. This is a troublesome but not serious complication. It may interfere with the ability to evaluate vocal cord function following thyroid surgery.

Superficial Cervical Plexus Blockade. This is performed in the same position as deep cervical plexus blockade and results in anesthesia only of the sensory fibers of the plexus. The procedure for blockade follows:

1. An "X" is made along the posterior border of the sternocleidomastoid muscle at the level of C4. This usually corresponds with the junction of the external jugular vein as it crosses the posterior border of the muscle (Fig. 26-6).

2. A skin wheal is raised at this mark, and superficial local anesthetic infiltration is performed along the posterior border of the sternocleidomastoid muscle 4 cm above and below the level of the "X." Ten to 12 mL of local anesthetic solution usually provides sensory anesthesia of the anterior neck and shoulder.

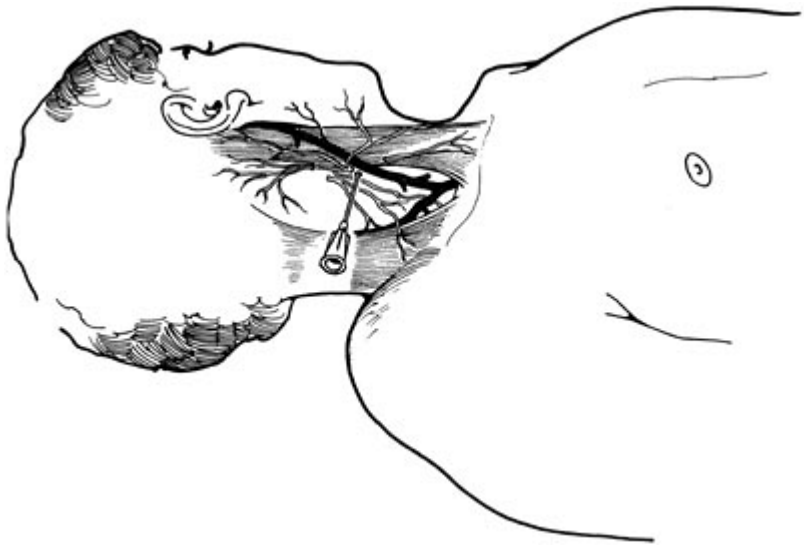

FIGURE 26-6. Superficial cervical plexus blockade. The sensory fibers of the plexus all emerge from behind the lateral border of the sternocleidomastoid muscle. A needle inserted at its midpoint, usually where the external jugular vein crosses the muscle, can be directed superiorly and inferiorly to block all these terminal branches. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins,

2002.)

Occipital Nerve Blockade

The ophthalmic branch of the trigeminal nerve provides sensory innervation of the forehead and anterior scalp, but the remainder of the scalp is innervated by fibers of the greater and lesser occipital nerves, terminal branches of the cervical plexus. These nerves can be blocked by superficial injection at the point on the posterior skull where they emerge from below the muscles of the neck (Fig. 26-7). Anesthesia is rarely used for surgical procedures; it is more often applied as a diagnostic step in evaluating head and neck pain complaints. The procedure for blockade follows:

FIGURE 26-7. Occipital nerve blockade. The greater and lesser branches of the occipital nerve emerge from under the muscles at the level of the nuchal ridge on the posterior scalp. They can be easily blocked by a subcutaneous ridge of anesthetic solution. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

1. The block is performed in the sitting position, with the patient leaning the head forward to expose the prominent nuchal ridge of bone at the posterior base of the skull.
2. The external occipital protuberance is identified in the midline, and a mark is placed lateral to this prominence along the nuchal line at the lateral border of the insertion of the erector muscles of the neck, usually 2.5 cm from the midline. The branches of the greater occipital nerve usually pass laterally from behind the muscle to cross the nuchal line at this point.
3. After skin preparation, a small needle is introduced through the mark to the depth of the skull itself. A ridge of 1 to 4 mL of local anesthetic (1% lidocaine or equivalent) is then deposited across the path of the emerging nerves just above the level of the bone. Paresthesias are occasionally encountered but are not essential for obtaining simple skin anesthesia.
4. If more anterior anesthesia of the scalp is required, the lesser occipital nerve branches are also blocked by advancing the needle subcutaneously from this point in an anterior direction

toward the mastoid process. A band of anesthetic solution is deposited along the line between the skin entry and the mastoid. A larger volume (6 to 8 mL) is required.

Complications of this technique are rare. Care must be taken not to advance the needle anteriorly under the skull, as the foramen magnum might be entered unintentionally with a long needle. Local hematoma may be produced with the superficial injection, but this is only a temporary problem.

Airway Anesthesia

Manipulation of the airway either during laryngoscopy or during tracheal intubation is often associated with laryngospasm, coughing, and undesirable cardiovascular reflexes (see also Chapter 22). The anesthesiologist can abolish or blunt these reflexes by anesthetizing one or all of the sensory pathways involved. The nasal mucosa is innervated by fibers of the sphenopalatine ganglion, a branch of the middle division of the fifth cranial nerve. These branches lie on the lateral wall of the nasal passages on each side, under the mucosa just posterior to the middle turbinate (Fig. 26-8). The branches of these fibers continue caudad to provide sensory innervation to the superior portion of the pharynx, uvula, and tonsils. Anesthesia of the maxillary branch of the trigeminal nerve is possible but not a practical solution for airway anesthesia. Transmucosal topical application of local anesthetic is more appropriate. Below the sphenopalatine fiber distribution, sensory innervation of the oral pharynx and supraglottic regions is provided by branches of the glossopharyngeal nerve. These nerves lie laterally on each side of the pharynx submucosally in the region of the posterior tonsillar pillar. Direct submucosal injection can be performed but carries the risk of unintentional intravascular injection into several blood vessels in this area. Topical anesthesia of the terminal branches in the mouth and throat is again an easier approach, but deep injection of the glossopharyngeal nerve may be required to block the gag reflex completely. The larynx itself is innervated by the superior laryngeal branch of the vagus nerve in the area above the vocal cords. This branch leaves the main vagal trunk in the carotid sheath and passes anteriorly. Its internal branch penetrates the thyrohyoid membrane and divides to provide the sensory fibers to the cords, epiglottis, and arytenoids.

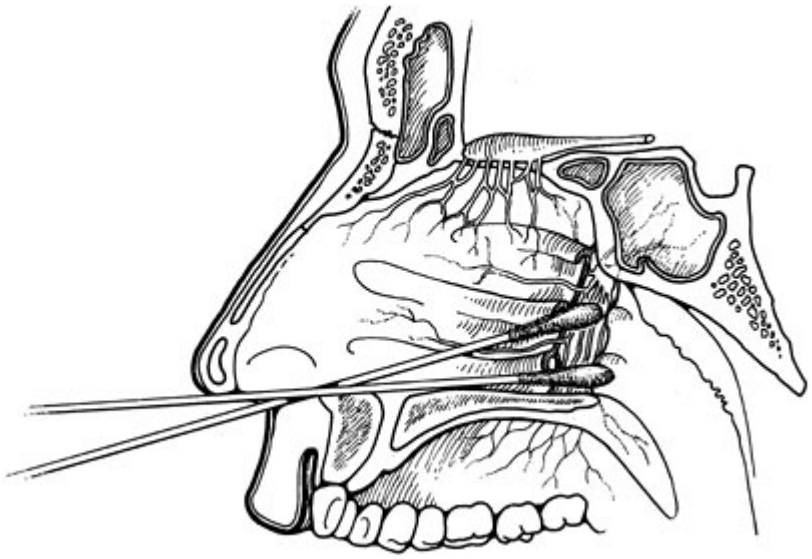

FIGURE 26-8. Nasal airway anesthesia. Cotton pledgets soaked with anesthetic are inserted along the inferior and middle turbinates to produce anesthesia of the underlying sphenopalatine ganglion by transmembrane diffusion of the solution. Wide pledgets also are needed to provide maximal topical anesthesia and vasoconstriction of the nasal mucosa. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

The recurrent laryngeal nerve provides innervation to the areas below the vocal cords, including motor innervation for all but one of the intrinsic laryngeal muscles. The trachea itself is innervated by the recurrent laryngeal nerve. Topical anesthesia is again the simplest approach to this nerve.

Airway anesthesia can be performed by anesthetizing one or all of these sensory distributions. Full anesthesia facilitates procedures such as nasal intubation or fiberoptic laryngoscopy. Airway anesthesia below the vocal cords is best avoided if there is concern about potential pulmonary aspiration of gastric contents. Topical postpharyngeal anesthesia may also ablate protective laryngeal reflexes.

Many patients find it more comfortable to be semiupright or sitting when topical anesthesia is sprayed into the posterior pharynx. These positions allow them greater ease in swallowing excess solutions and may reduce gagging. In whatever position chosen, there should be a firm support behind the head to reduce involuntary withdrawal motions by the patient, which might dislocate needles being used for injections.

1. For nasal mucosal anesthesia, cotton pledgets soaked with anesthetic solution are introduced through the nares and passed along the turbinates all the way to the posterior end of the nasal passage (see Fig. 26-8). A second set of pledgets is introduced with a cephalad angulation to follow the middle turbinate back to the mucosa overlying the sphenoid bone. This pledget is the more critical because anesthesia in this mucosal area is most likely to anesthetize the branches of the sphenopalatine ganglia as they pass along the lateral wall of the airway. Bilateral anesthesia is preferable, even if a nasal tube is to be inserted only on one side; bilateral blockade of the sphenopalatine fibers also produces posterior pharyngeal anesthesia caudad to this level. The pledgets should be allowed to remain in contact with the nasal mucosa for at least 2 to 3 minutes to allow adequate diffusion of local anesthetic. Cocaine in a 4% solution has been the traditional topical anesthetic for this application because of its unique vasoconstrictive properties. Alternate solutions have been recommended, primarily a mixture of 3% to 4% lidocaine and 0.25% to 0.5% phenylephrine.
2. Topical anesthesia to the posterior pharynx can be performed while the nasal applicators are in place. This can be done with a commercial spray or with an atomizer filled with a 4% solution of lidocaine. (A higher concentration of local anesthetic is required to penetrate mucosal membranes.) For effective anesthesia in the posterior pharyngeal wall, topical application is performed in two stages. First, the tongue itself is sprayed with a local anesthetic, and the patient is encouraged to gargle and swallow the residual liquid in the mouth. The numb tongue is then grasped with a gauze pad with one hand while the spray device is inserted into the mouth with the other. The patient is then encouraged to take rapid deep breaths (“pant like a puppy”) while the spray is applied on inspiration. The inspiratory flow of gases should be enough to draw the lidocaine solution into the posterior pharynx and even to the vocal cords themselves. If superior laryngeal nerve blockade has been performed before this, it is likely that the aerosol will be carried into the trachea itself. Again, a few minutes are needed for adequate onset of topical anesthesia in the pharynx. Topical anesthesia is less effective if there are copious secretions. Premedication with an anticholinergic is frequently beneficial.
3. Superior laryngeal nerve blockade can also be performed while the nasal pledgets are in place (Fig. 26-9). This nerve is blocked bilaterally by identifying the superior ala of the thyroid cartilage, which usually lies just inferior to the posterior portion of the hyoid bone on each side. A 5-mL syringe with a 1% lidocaine solution with a 23-gauge, 1.75-cm needle is used. The index finger of one hand retracts the skin of the neck caudad down over the thyroid cartilage; the needle is inserted until it rests on the superior margin of the cartilage. The tension on the skin is then released and the needle is withdrawn slightly and allowed to

walk superiorly off the cartilage. The needle is then reinserted and passed through the thyrohyoid membrane, which is perceived as a discernible resistance. After careful aspiration, 2.5 mL of solution is injected into the space below the membrane. This procedure is repeated on the opposite side. This blockade can be

performed as part of total airway anesthesia or it can be used independently to provide increased acceptance of indwelling endotracheal tubes in the intensive care unit.

4. The glossopharyngeal nerve can be blocked by a direct injection into the base of the anterior tonsillar pillar if persistent gagging is a problem. The tongue is retracted medially with a gloved finger or a tongue blade to expose the base of the anterior pillar. A long 25-gauge (spinal) needle is inserted 0.5 cm subcutaneously into the base of the pillar 0.5 cm lateral to the base of the tongue. After careful aspiration, 2 mL of 1.5% lidocaine is injected, and the procedure is repeated on the opposite side. This produces anesthesia of the lingual branch (base of the tongue) and may even anesthetize the pharyngeal and tonsillar branches by diffusion. This allows laryngoscopy with less gagging and hemodynamic response.
5. Tracheal anesthesia can be performed by a direct transcricoid ("transtracheal") injection. This is accomplished by raising a small skin wheal over the cricothyroid membrane. A 20-gauge iv catheter is then inserted gently through this skin wheal and through the membrane. Entry into the trachea can be confirmed by the ability to aspirate air through the catheter. The steel stylet is then removed, and the plastic catheter is left in the trachea. A syringe with 4 mL of 4% lidocaine is attached to the catheter, and the local anesthetic is sprayed into the trachea during inspiration. The flow of air usually carries the local anesthetic distally; the resultant cough continues to spread the anesthetic more proximally up to the underside of the vocal cords and the larynx.
6. After each of these steps has been completed, the pledgets can be removed from the nasal passages and nasal intubation performed. If tracheal or laryngeal anesthesia has been omitted because of concern about aspiration, there should be some pharmacologic intervention to reduce the cardiovascular response to the passage of the tube into the trachea. This can be facilitated by pretreatment with iv β-adrenergic-blocking drugs, by administration of sedation, or by administration of propofol immediately after the airway is secured.

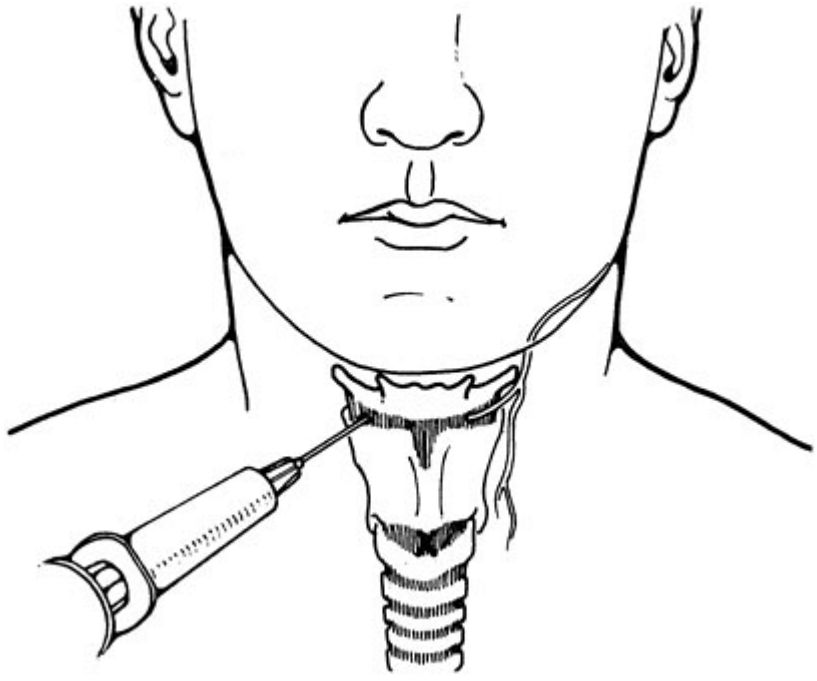

FIGURE 26-9. Superior laryngeal nerve blockade. The needle is advanced superiorly off the lateral wing of the thyroid cartilage to drop through the thyrohyoid membrane. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Complications of these techniques are rare. Systemic toxicity from the local anesthetics is a distinct possibility because of the large quantities of drug required to produce sufficient mucosal anesthesia. If all four stages of airway anesthesia are undertaken, the total milligram doses applied usually exceed the maximal recommended dose for peripheral injection. Fortunately, the mucosal absorption is less than the peripheral absorption, but close attention to the patient's mental status and preparation for treatment of toxicity are necessary. Aspiration of gastric contents is also a possibility when the protective reflexes of the airway are interrupted.

Upper Extremity

The innervation of the upper extremity is conveniently derived from five closely approximated nerve roots, extending from C5 to T1 (the brachial plexus). These roots undergo a series of mergers and divisions that produce the terminal nerves of the arm and hand. The plexus branches are close enough to each other to allow reliable anesthesia to be achieved at several points associated with consistent bony or vascular landmarks.

In their proximal course, the nerve roots lie in a well demarcated fascial envelope formed by the anterior fascia of the middle scalene muscle and the posterior fascia of the anterior scalene. These muscles attach to the posterior and anterior tubercles of the transverse processes of the cervical vertebrae from which the nerves emerge. The tubercle can be used as a faithful landmark to guide localization of the nerve, and the fascial planes serve to keep anesthetic solution injected between them close to the nerve bundle. The fascia extends outward for a variable distance from the lateral border of the muscles to enclose the nerves in a "sheath," which can extend below the clavicle. This enclosed bundle passes over the first rib just behind the midpoint of the clavicle (and just posterior to the insertion of the anterior scalene on the rib), where it is joined by the subclavian artery. At the midpoint of the rib, the plexus has consolidated into only three trunks; these rapidly subdivide into the terminal branches. The musculocutaneous nerve is the first major branch to leave the companionship of its partners as it passes into the body of the coracobrachialis muscle high in the axilla. As the individual nerves form, separate compartments in the sheath are formed by developing septa, and blockade of all the nerves with a single injection is not reliable below the clavicle.

Although many approaches to the brachial plexus have been described, there are basically four anatomic locations where anesthetics are placed: (1) the interscalene groove near the transverse processes, (2) the subclavian sheath at the first rib, (3) near the coracoid process in the infraclavicular fossa, and (4) surrounding the axillary artery in the axilla. Because of the specific configuration of the nerves at each of these levels, the anesthesia produced is different with each approach and applicable to different situations.[8] Interscalene injection at the level of the sixth cervical transverse process produces extension of the blockade to the lower fibers of the cervical plexus and is ideally suited for shoulder operations and upper arm procedures. It frequently spares the lowest branches of the plexus, the C8 and T1 fibers, which innervate the caudad (ulnar) border of the forearm. Blockade at the level of the first rib is most reliable in producing anesthesia of all four terminal nerves of the forearm and hand. Injection in the infraclavicular fossa produces excellent anesthesia of the entire arm and hand, although multiple injections may be required. The axillary technique is simpler but carries the risk of missing the musculocutaneous and medial antebrachial cutaneous nerves that depart the sheath high in the axilla, and thus might produce inadequate anesthesia of the forearm. The choice of the appropriate approach depends not only on the patient's anatomy but also on the site of surgery.

The terminal branches can also be anesthetized by local anesthetic injection along their peripheral

courses as they cross the joint spaces, or by the injection of a dilute local anesthetic solution intravenously below a pneumatic tourniquet on the upper arm ("intravenous regional," or Bier block).

Brachial Plexus Blockade: Interscalene Approach

Localization of the nerves uses a combination of the muscular and bony landmarks surrounding the nerves.[9] The use of long-acting local anesthetics will provide analgesia for 12 to 14 hours. For longer analgesia, insertion of a continuous catheter is effective for procedures such as shoulder rotator cuff repairs,[10] although securing the catheters in the mobile neck tissues is a challenge.

1. The patient is positioned supine with the head turned to the side opposite that to be blocked. A small towel is placed under the occiput. The arm on the side to be blocked is held at the side, and the patient is asked to hold the shoulder down by pretending to reach for the hip.
2. The lateral border of the sternocleidomastoid muscle is identified and marked, and the patient is then asked to raise the head slightly into a "sniffing" position. This tenses the scalene muscles behind the sternocleidomastoid muscle, and the groove between the anterior and middle scalene is palpated by rolling the fingers posteriorly off the lateral border of the sternocleidomastoid muscle. This groove is marked along its entire extent, as

   high up as possible. The patient then relaxes the muscles of the neck, and the level of the cricoid cartilage is marked. The index finger then gently palpates in the groove at the level of the cricoid (Fig. 26-10). The prominent transverse process of C6 can often be felt directly.
3. After aseptic skin preparation, a skin wheal is raised in the groove at the level of the cricoid. A 22-gauge, 3.75-cm needle is introduced through the wheal perpendicular to the skin in all planes so that it is directed medially, caudad, and slightly posteriorly (Fig. 26-11).
4. The needle is advanced until the tubercle is contacted or nerve localization is elicited (Fig. 26-12). If bone is contacted before nerve, the needle is withdrawn and redirected in small steps in an anteroposterior plane until the nerves are identified.
5. Once the nerve is located (usually a motor response in the deltoid or biceps, or a paresthesia to the thumb or upper arm), the needle is fixed in this position with one hand while 25 to 30 mL of local anesthetic solution is injected. Careful aspiration is performed first, and the initial injection is performed in small increments to detect intraneural or intraarterial placement of the needle. A larger volume (30 to 40 mL) is required if greater spread is desired, such as to the cervical plexus or inferiorly to the C8 to T1 fibers.
6. If a catheter is to be inserted, the needle entry point may be moved a centimeter cephalad and the corresponding angle of insertion is a little steeper and more tangential to the course of the plexus. The opening of the tip of the introducing needle should be directed laterally. After the catheter is introduced a few centimeters beyond the tip, the proximal end may be secured more firmly by tunneling 3 to 4 cm below the skin by passing it back through an intravenous catheter that has been introduced subcutaneously near the entry site. Securing catheters in the freely mobile neck is a challenge.
7. If arm surgery requiring a tourniquet is planned, a subcutaneous ring of anesthetic across the axilla is usually required to block the superficial intercostobrachial fibers crossing from the chest wall into the axilla.

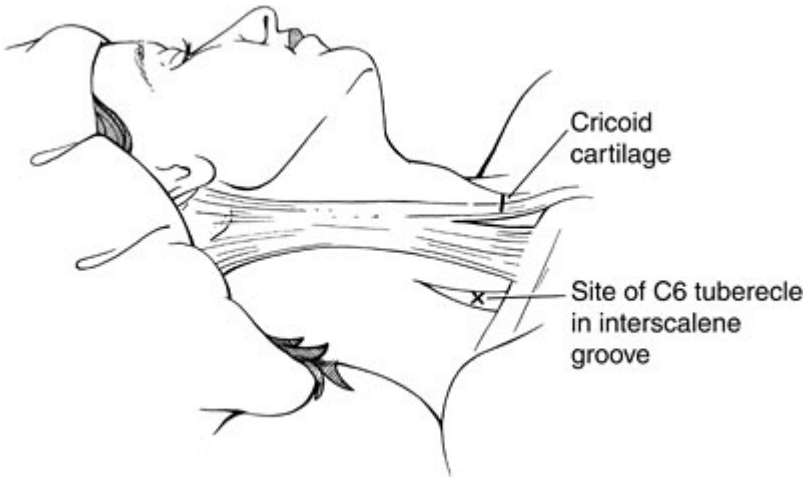

FIGURE 26-10. Superficial landmarks for interscalene brachial plexus blockade. The sternocleidomastoid muscle is identified, and the anterior scalene muscle is found by moving the fingertips over the lateral border of the larger muscle while it is slightly tensed. The groove between the anterior and middle scalene muscles can usually be felt easily, along with the tubercle of the sixth cervical vertebra, which lies at the level of the cricoid cartilage. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

FIGURE 26-11. Hand position for interscalene blockade. The needle is directed medially and caudad into the interscalene groove while one hand exerts constant control of the depth by resting on the clavicle. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

FIGURE 26-12. Needle direction for interscalene blockade. The needle is always kept in a 45-degree caudad direction; medial insertion allows the point to pass into the intervertebral foramen and produces epidural, spinal, or intra-arterial injection of anesthetic. Note the relation of the vertebral artery and the nerve roots to the transverse processes. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Complications from this approach are related to the structures located in the vicinity of the tubercle. The cupola of the lung is close and can be contacted if the needle is directed too far caudad. Pneumothorax should be considered if cough or chest pain is produced while exploring for the nerve. If the needle is allowed to pass directly medially, it may enter the intervertebral foramina, and injection of local anesthetic may produce spinal or epidural anesthesia. The vertebral artery passes posteriorly at the level of the sixth vertebra to lie in its canal in the transverse process; direct injection into this vessel can rapidly produce central nervous system toxicity and convulsions.

Careful aspiration and incremental injections are helpful in avoiding both of these potential problems.

Even with appropriate injection, the local anesthetic solution spreads to contiguous nerves. This produces cervical plexus blockade with high volumes, including the motor fibers to the diaphragm, which may be a problem in patients with respiratory insufficiency. A Horner's syndrome is common because of spread to the sympathetic chain on the anterior vertebral body.

Neuropathy of the C6 root is a potential problem because the needle may unintentionally pin the nerve root against the tubercle and predispose to intraneural injection. The needle should be withdrawn slightly if the first injection produces the characteristic "crampy" pain sensation.

Inadequate anesthesia is most likely to occur in the ulnar distribution. As mentioned previously, this may be reduced by the use of higher volumes.

Brachial Plexus Blockade: Supraclavicular Approach

The description of the approach to the brachial plexus at this level is originally attributed to Kulenkampff. Current techniques avoid medial direction of the needle, as originally described, which may contact the pleura.

1. The patient lies in the same position as for interscalene blockade, with the ipsilateral arm held at the side and pulled downward to exaggerate the landmarks of the clavicle and the neck muscles.
2. The outline of the clavicle is drawn on the skin, as well as the interscalene groove (as described previously). The midpoint of the clavicle is marked. An "X" is placed posterior to this midpoint in the interscalene groove, usually 1 cm behind the clavicle. On the thin patient, the pulsation of the subclavian artery can be appreciated in the groove or just anterior to it.
3. After aseptic preparation, a skin wheal is raised at the mark, and a 3.75-cm, 22-gauge needle attached to a 10-mL syringe is introduced in the sagittal plane and advanced caudad until the first rib is contacted (Fig. 26-13). It is important that the direction of the needle remain perpendicular to the rib, which usually requires that the syringe remain parallel to the axis of the head and neck. If the rib is not contacted, careful exploration should be carried out first laterally to the mark and, last of all, medially. The greatest danger of contacting the pleura occurs when probing medially.
4. If a nerve response is not obtained on needle insertion, exploration is continued until the rib is identified. A 5-cm needle may be needed to reach the rib in the heavier patient. Once the rib is contacted, the needle is walked in an anteroposterior plane until a nerve response is found. Again, the needle is kept in the sagittal plane on the dorsal surface of the rib during exploration. If the needle advances beyond the anterior or posterior border of the rib as it curves medially at these two points, it is simply redirected in the opposite direction until the rib is found again. Medial direction is avoided. While exploring along the direction of the rib, the needle should be withdrawn almost to the skin before redirection for each pass. If it is lifted only a few millimeters from the rib, it may simply push the nerve bundle ahead of it without making contact.
5. If no nerve response is obtained, the artery can be used as a landmark. Once it is entered with the needle, a series of injections posterior to it can be used to produce a "wall" of 40 mL of anesthetic solution in this area.
6. An alternate approach is to introduce the needle just above the clavicle from the anterior surface of the body, and advance it directly posterior, following a line that would be traversed by a plumb bob toward the floor (assuming the patient is supine). If no nerve response is encountered, the syringe and needle are withdrawn and rotated caudally in small increments and advanced again. Theoretically, the needle will encounter the nerves before contacting the rib or the pleura. The safety of this approach may be improved by starting with an even greater cephalad angulation, 40 degrees off the vertical.[11]
7. If a nerve response is produced during the course of exploration, the anesthetic solution is injected while the needle is fixed in position. Twenty-five to 40 mL of local anesthetic will produce adequate analgesia. Multiple nerve responses are not required.
8. If a tourniquet is to be used, a ring of subcutaneous anesthesia should be infiltrated along the axilla to block the sensory fibers from the chest wall that cross here to innervate the inner aspect of the upper arm.

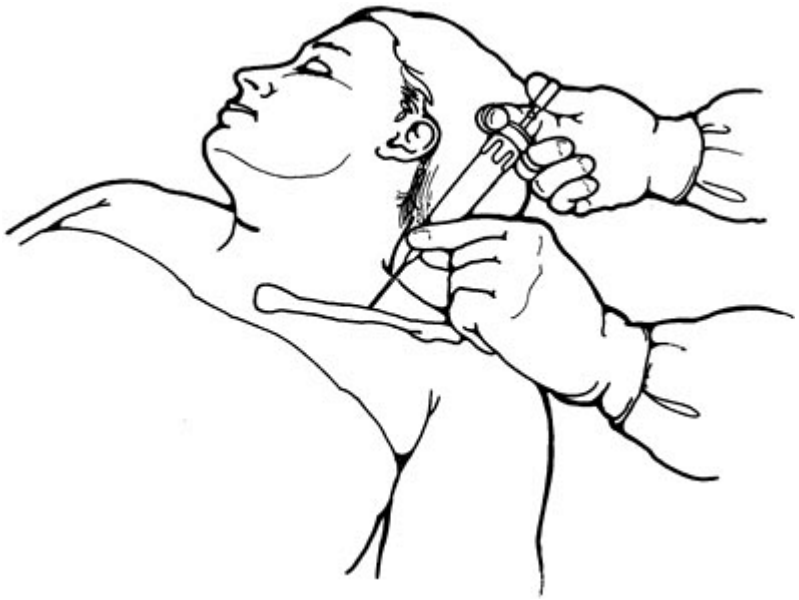

FIGURE 26-13. Hand position for supraclavicular blockade. The needle is directed caudad behind the midpoint of the clavicle in the interscalene groove. Again, control of depth is maintained by the hand resting on the clavicle. The syringe is kept in the sagittal plane parallel to the patient's head to prevent medial angulation, which would increase the chance of pneumothorax. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Pneumothorax is the most serious complication of this technique. Although it is rare in experienced hands, it does occur more frequently with this approach to the brachial plexus than with any other approach. This may limit the use of this technique, particularly in outpatients, in whom the insertion of a chest tube would then require hospitalization. Other complications of peripheral blockade of the brachial plexus do not occur with any greater frequency with this blockade than with other methods of blockade.

Brachial Plexus: Infraclavicular Block

Approaching the brachial plexus in the infraclavicular area at the point where the plexus passes below the coracoid process appears to have a lower risk of pneumothorax (Fig. 26-14). Here the plexus consists of three cords, with the musculocutaneous nerve already departed from the bundle. Nerve localization is more challenging than with other techniques because of the depth from the skin, but the approach in the infraclavicular area offers the potential of excellent analgesia of the entire arm with only two separate injections, and also allows for the introduction for continuous catheters to provide prolonged postoperative pain relief. The original description of this

procedure was a complex one that was limited in its accuracy; more recent anatomic and radiographic studies have provided a simpler approach,[12] as follows:

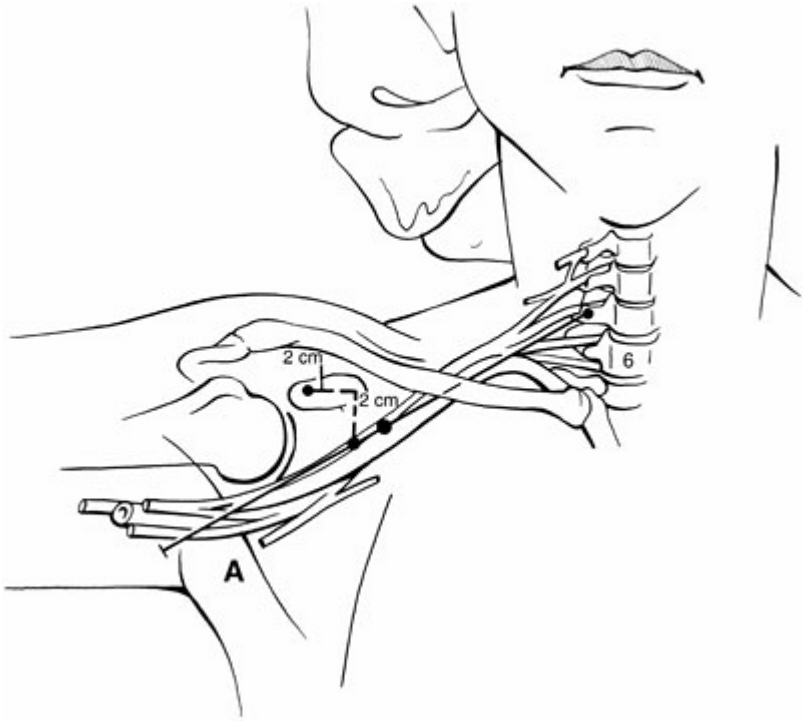

FIGURE 26-14. Infraclavicular approach. The nerves and trunks of the brachial plexus lie basically along a straight line that can be projected from the lateral tubercle of the C6 vertebral body to the axillary artery in the axilla. At the midpoint of this line, the plexus consists of three trunks, with the musculocutaneous nerve potentially having already departed from the neurovascular bundle. This midpoint lies below the clavicle and lateral to the rib cage. The nerves can be identified by drawing a line ending 2 cm medially from the cricoid process and 2 cm inferiorly. A needle inserted directly posterior at this point should contact the nerves at a depth of between 5 and 10 cm. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

1. Patient is placed in the supine position with the arm at the side. The coracoid process is palpated below the clavicle and marked with a circle. A line is drawn 2 cm medially and then extended 2 cm inferiorly from this point, and an "X" is placed on the skin.
2. After skin preparation and skin wheal, a 10-cm needle is inserted directly perpendicularly through the "X" and advanced through the pectoralis muscle, searching for a nerve response. The first response obtained is usually the musculocutaneous nerve. This nerve can be blocked by an injection of 5 mL of local anesthetic. For complete anesthesia of the hand, a separate response in the hand itself needs to be obtained. When movement or sensation in the hand is elicited, a further 25 mL of local anesthetic can be injected, presumably within the neurovascular sheath at this point. The sheath usually lies just caudad to the musculocutaneous nerve. The artery may be also identified easily at this point, and careful aspiration is required to prevent intravascular injection.
3. If a response is not elicited before contact is made with bone (usually the scapula posteriorly), then the needle is withdrawn to near the skin and reintroduced with a slightly different angulation, usually in a caudad direction. Several passes may be required because the nerves lie at an average depth of 5 cm from the skin. At this point, small changes in needle angulation may produce wide variations in the location of the tip of the needle.
4. If a catheter is to be threaded, it should be only in response to nerve localization in the hand itself. The tip of the Tuohy needle should be directed laterally to allow the catheter to

run in the direction of the nerves. It should be advanced only a short distance beyond the tip of the needle because of the risk of puncturing the artery at this level. The catheter can be secured to the skin and remain indwelling for several days.[13]

Complications of this technique include hematoma formation and nerve injury. The risk of pneumothorax is minimized by avoiding any medial deviation of the needle point.

Brachial Plexus: Axillary Technique

The axillary technique carries the least chance of pneumothorax and thus may be a preferred technique for the outpatient. The nerves are anesthetized around the axillary artery, where they have regrouped into their terminal branches. Because of the observation that the single sheath may be broken up into separate compartments by fascial septa surrounding individual nerves in the axilla, local anesthetic should be injected at multiple sites in the axilla in contrast to the single injections possible with proximal approaches. Another obstacle to the single-injection technique at this level is the early departure of the musculocutaneous branch from the sheath high in the axilla.

1. The patient lies supine with the arm extended 90 degrees from the side and flexed at the elbow. Extension beyond 90 degrees potentially compresses the axillary artery because of the pressure from the head of the humerus and may make identification of the landmarks more difficult. A pillow under the forearm also reduces rotation of the shoulder joint, which can obscure the pulse.
2. The axillary artery is marked as high in its course in the axilla as is practical. It is usually felt in the intramuscular groove between the coracobrachialis and the triceps muscles. It also passes between the insertions of the pectoralis major and the latissimus dorsi muscles on the humerus.
3. After aseptic preparation, a skin wheal is raised over the proximal portion of the artery. The index and middle fingers of the nondominant hand straddle the artery just below this point, both localizing the pulsation and compressing the neurovascular bundle below the intended site of injection (Fig. 26-15).

4. Common Approaches

   A) *Direct Nerve Localization.* The traditional method is to identify each of the nerves with either a paresthesia or nerve stimulator technique. Ideally, the nerves serving the area of proposed surgery are sought first. The median and the musculocutaneous nerves lie on the superior aspect of the artery (as viewed by the operator), whereas the ulnar and radial nerves lie below and behind the vessel (Fig. 26-16). A three-ring syringe is especially useful in this technique to allow aspiration during the nerve search, to help identify the potential for switching to a transarterial approach if the artery is entered. When a nerve response is obtained, 5 to 10 mL are injected, taking precautions to avoid intraneural injection. Firm pressure is maintained on the distal sheath to encourage the solution to move centrally from the point of injection, hopefully to include the point of origin of the musculocutaneous nerve. With the multiple-injection technique, other nerve responses should be elicited within 5 minutes of the original injection. Beyond this time, spread of the solution may produce hypesthesia of the other nerves, which prevents their identification. The second nerve response should be sought on the side of the artery opposite the original one. While some have had success in patients in simply injecting a large volume on a single-nerve response, most practitioners have found the need to identify at least two or three separate nerves to ensure success.

   Alternatively, all four major peripheral nerves may be stimulated and anesthetized lower in the arm, at the junction of the upper and middle third of the humerus

(midhumeral approach[14]). At this point, the median nerve is stimulated subcutaneously near the artery, the ulnar nerve is deeper and medial to the artery, the musculocutaneous nerve is under the biceps and 2 to 4 cm away from the artery, and the radial nerve is behind the humerus.

B) *Perivascular infiltration.* Using the same approach with a shorter, smaller gauge needle, 5 to 10 mL of local anesthetic is injected closely on each side of the artery, using multiple passes with a moving needle *not* seeking nerve responses, producing a "wall" of solution that intercepts the paths of each of the branches. After initial infiltration, sensation or motor function is tested in the peripheral nerve distribution within 5 minutes. If anesthesia is not present, reinjection of the area is again performed with multiple passes. This approach is simpler and can be performed rapidly, but requires clear identification of the pulse.

C) *Transarterial.* Another simple alternative is to deliberately enter the artery with the needle. The needle is advanced through the vessel until aspiration confirms that it has passed just posterior; at this point, half the anesthetic solution is injected incrementally with careful attention to avoid intravascular placement. The needle is then withdrawn back through the vessel until aspiration confirms that it is just anterior to the artery. The other half of the solution is injected. This technique is simple and effective and should be kept in mind as an alternative if the vessel is unintentionally entered during either of the aforementioned techniques.

5. If forearm anesthesia is required, supplementary anesthesia of the musculocutaneous nerve may be obtained by injecting an additional 5 to 10 mL of anesthetic solution into the body of the coracobrachialis muscle. This muscle can be easily grasped between the thumb and forefinger, and the entry into its fascial compartment is readily identified. Alternatively a direct nerve response can be elicited with a stimulator. This step may be required even if 40 mL of solution is used in the perivascular injection because the musculocutaneous nerve may be spared as often as 25% of the time even with this or larger volumes. A supplemental subcutaneous injection of 5 mL inferior to the artery is also required to anesthetize the medial antebrachial cutaneous nerve.
6. If a continuous technique is desired, a catheter can be threaded centrally after nerve localization, or simply after identifying the "sheath" by perceiving the characteristic fascial pop on entry that is more easily appreciated with the larger blunter needles used for catheter insertion. Securing the catheter in the axilla is challenging, and may require immobilization of the arm.

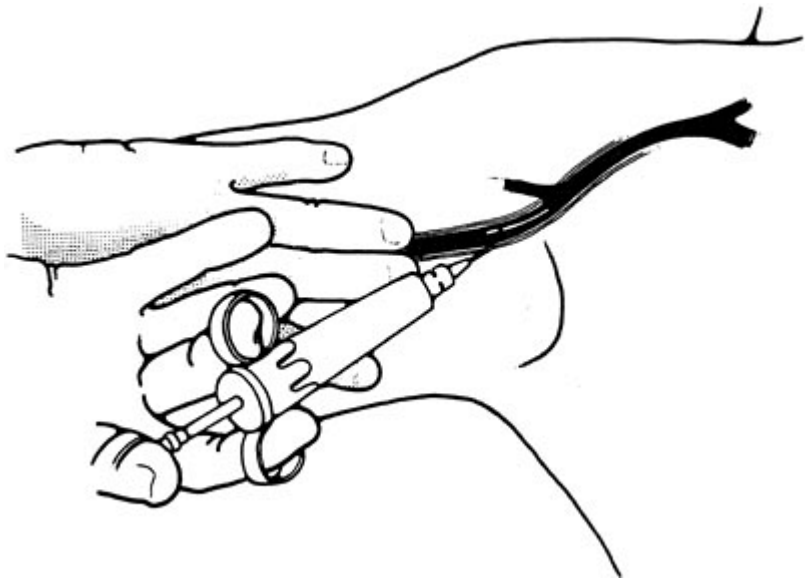

FIGURE 26-15. Hand position for axillary blockade. Two fingers of equal length straddle the artery while the needle is introduced along its long axis with a central angulation. The palpating fingers serve not only to identify the vessel but also to compress the perivascular sheath and encourage the spread of anesthetic solution centrally. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

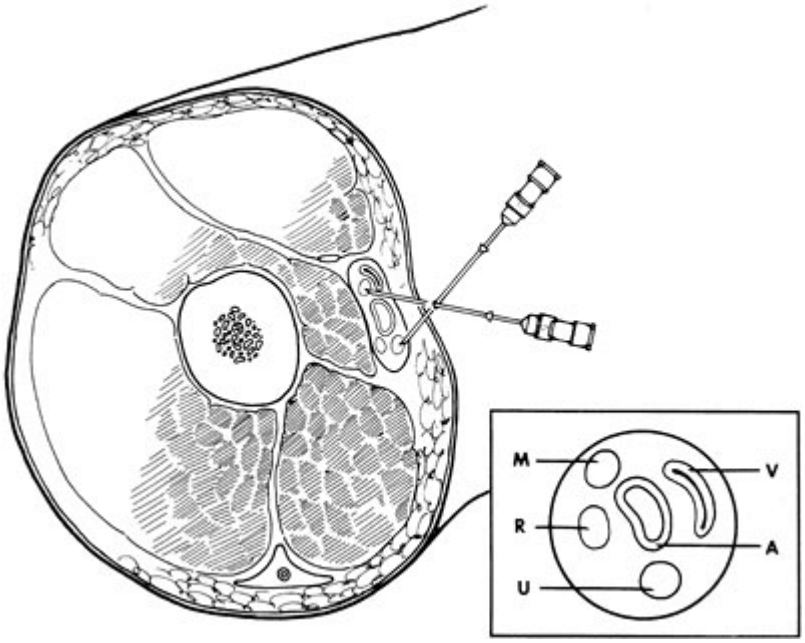

FIGURE 26-16. Needle position for axillary injection. The median (*M*) and musculocutaneous nerves lie on the superior side of the artery (*A*), although the latter may have already departed the axillary sheath at the level of injection. The ulnar nerve (*U*) lies inferior, and the radial nerve (*R*) is inferior and posterior. *V*, vein.

The complications of the axillary approaches to the brachial plexus are minimal compared with those of the more proximal approaches. The problem of neuropathy is the foremost consideration, and the relative risk with various techniques remains controversial. Hematoma can occur if the vessel is punctured, but this is rarely a problem. The use of small-gauge needles may reduce this possibility. The advantages of any one technique in reducing complications remains unclear, and the success rate of the various techniques is variable and appears to depend on personal familiarity.

Intravenous Regional Anesthesia (Bier Block)

The simplest technique of arm anesthesia is the injection of local anesthetic into the venous system below an occluding tourniquet.

1. A small-gauge (20 or 22) iv plastic catheter is inserted in the arm to be blocked on the dorsum of the hand. It is taped firmly in place, and a heparin port or small syringe is attached and saline is injected to maintain patency. A pneumatic tourniquet is applied over the upper arm.
2. The arm is elevated to promote venous drainage. An elastic bandage may be applied to produce further exsanguination. After exsanguination, the tourniquet is inflated to 300 mm

Hg or 2.5 times the patient's systolic blood pressure and is tested for adequate occlusion of the radial pulse.

3. The arm is returned to the horizontal position, a 50-mL syringe with 0.5% lidocaine is attached to the previously inserted cannula, and the contents are injected. The forearm discolors, and the patient perceives a transient "pins and needles" sensation as anesthesia ensues over the following 5 minutes. Epinephrine should not be added to the local anesthetic solution.
4. For short procedures, the cannula can be removed at this point. If surgery may extend beyond 1 hour, the cannula can be left in place and reinjected after 90 minutes.
5. Beyond 45 minutes of surgery, many patients experience discomfort at the level of the tourniquet. Special "double-cuff" tourniquets are available for this blockade to alleviate this problem. The proximal cuff is inflated first, allowing anesthesia to be induced in the area under the distal cuff. If discomfort ensues, the distal cuff is inflated over the anesthetized area of skin, and the uncomfortable proximal cuff is released. This step is critical because the major risk of this procedure is premature release of solution into the circulation. If a double cuff is used, both cuffs should be tested before starting and the proper sequence for inflation and deflation meticulously followed. The potential for leakage of anesthetic into the circulation is greater with these narrower cuffs used in the double setup. Because the shifting process also increases the potential for unintentional release of anesthetic, the use of a single, wider cuff may be better for short procedures.
6. If surgery is completed in less than 20 minutes, the tourniquet is left inflated for at least that total period of time. If 40 minutes has elapsed, the tourniquet can be deflated as a single maneuver. Between 20 and 40 minutes, the cuff can be deflated, reinflated immediately, and finally deflated after 1 minute to delay the sudden absorption of anesthetic into the systemic circulation, although this may not lower the eventual peak levels achieved.
7. The duration of anesthesia is minimal beyond the time of tourniquet release. Although bupivacaine may produce a slight prolongation of analgesia, the advantage is short. Furthermore, the cardiotoxicity of systemic levels of bupivacaine makes this drug a less desirable choice for a Bier block.

The simplicity of this technique is offset by the significant risk of systemic local anesthetic toxicity if the tourniquet fails or is released prematurely. Careful testing of the tourniquet and slow injection of solution into a peripheral (not antecubital) vein will reduce the chance of leakage under the tourniquet. Systemic blood levels are time dependent, and careful attention should be paid to the sequence of tourniquet release and to patient monitoring during this period. A separate iv site for injection of resuscitation drugs is needed as well as ready availability of all appropriate resuscitative equipment. With careful attention to these details, this technique is one of the most effective and reliable available to the anesthesiologist.

Distal Upper Extremity Blockade

The nerves to the hand can be blocked at the point where they cross the two major joints, the elbow and the wrist (Fig. 26-17). At these two levels, the overlying muscles are thinned and the bony landmarks are more prominent, allowing easier identification of the nerves. Peripheral blockade is usually not as dense as central blockade but may be useful in anesthetizing one branch that was missed with a central blockade or in providing localized anesthesia on the hand. Because the sensory branches to the forearm from the musculocutaneous nerve and the internal cutaneous nerve have already branched so extensively that adequate anesthesia of the forearm is not easily obtained, blockade at the elbow really produces no greater anesthesia than blockade at the wrist.

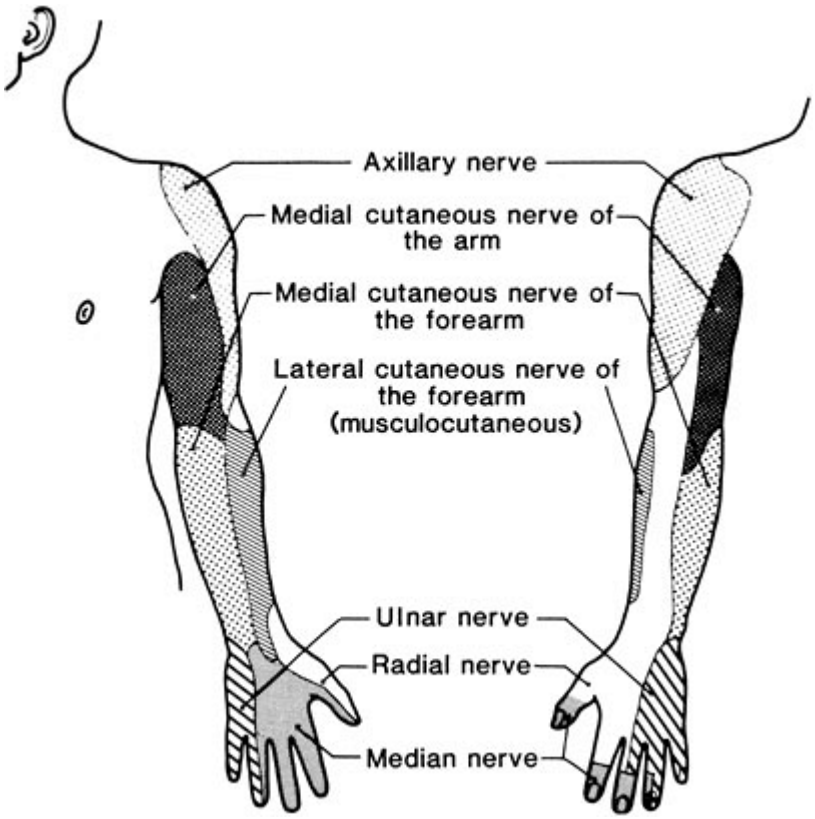

FIGURE 26-17. Sensory dermatomes of the arm. Sensation is provided by the terminal nerves, as identified. This pattern is different from the classic dermatomal distribution of the nerve roots. Different patterns of anesthesia develop if the blockade is performed at the root level (interscalene blockade) versus the terminal nerve level (axillary blockade). (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Blockade at the Elbow. Two nerves to the hand cross this joint on the inner aspect. The ulnar travels posteriorly in its well-known superficial groove.

1. The ulnar nerve is blocked by injection of 1 to 4 mL of local anesthetic proximal to the groove formed by the medial condyle of the humerus and the olecranon with the joint flexed at approximately 30 degrees. Further flexion may cause the nerve to roll medially and anterior to the condyle. Paresthesias can usually be readily obtained, but direct injection on an elicitation of a paresthesia or directly into the groove under pressure is not advised because of the risk of damage to the nerve. If the injection is made deep to the fascia, anesthesia should commence within 5 minutes.
2. The median nerve crosses the joint in the company of the brachial artery. A line is drawn between the two condyles on the inner aspect of the joint, and a skin wheal is raised at the point where this line crosses the pulsation of the brachial artery, usually 1 cm to the ulnar side of the biceps tendon. A needle is introduced perpendicularly at this point, and nerve responses are sought immediately adjacent to the artery. Five milliliter of solution is sufficient to produce anesthesia, and, again, intraneural injection is carefully avoided.
3. The radial nerve is identified along the same intracondylar line, approximately 2 cm lateral to the biceps tendon. Another skin wheal is raised here, and, again, a needle is inserted to search for nerve responses in a fan-shaped pattern. If nerve responses are not obtained, a "wall" of anesthetic solution can be deposited here but with less chance of reliable anesthesia.

Blockade at the Wrist. The nerves lie more superficially at this joint and are closely associated with easily identified landmarks (Fig. 26-18).

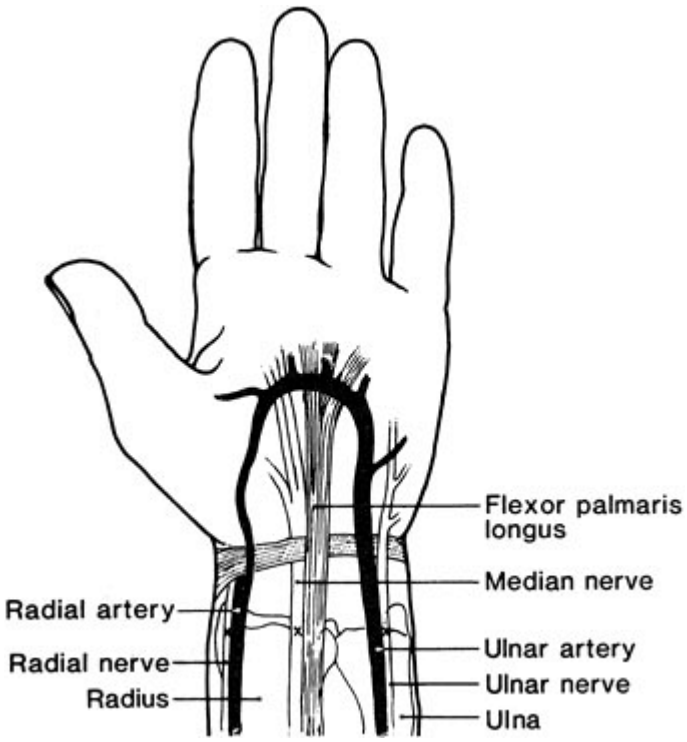

FIGURE 26-18. Terminal nerves at the wrist. The median nerve lies just to the radial side of the flexor palmaris longus. The ulnar and radial nerves lie just "outside" their respective arteries. The radial nerve has already begun branching at this level and must be blocked by a wide subcutaneous ridge of anesthetic. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

1. The ulnar nerve lies between the ulnar artery and the flexor carpi ulnaris. A skin wheal is raised at the level of the styloid process on the palmar side of the forearm between these two landmarks. A small-gauge needle is inserted, and 3 mL of solution is injected into the area, with or without paresthesias.
2. At the same level on the forearm, the median nerve lies between the tendons of the palmaris longus and the flexor carpi radialis. If only the palmaris longus can be felt, the nerve is just to the radial side of this tendon. A skin wheal is raised, and a needle is inserted until it pierces the deep fascia. Three milliliter of solution produces anesthesia.
3. The radial nerve requires a broader injection because it has already started to ramify as it crosses the wrist. The anatomic "snuffbox" formed by the tendons of the extensor pollicus longus and extensor pollicis brevis tendons is located, and 3 mL of solution is injected here. A subcutaneous wheal is then raised from this point, extending over the dorsum of the wrist 3 to 4 cm onto the back of the hand.

Suprascapular Block

The suprascapular nerve is another terminal branch of the brachial plexus that can be anesthetized by a separate injection. Anesthesia of this nerve provides postoperative pain relief following shoulder arthroscopy or reconstructive surgery. The nerve arises from the superior trunk of the brachial plexus in the neck, courses through the suprascapular notch, and then passes

behind the lateral border of the spine of the scapula to the infraspinatus fossa. It has two terminal branches, a sensory articular branch to the shoulder joint and a motor branch to the supraspinatus muscle. The technique for nerve blockade is as follows:

1. The patient is placed in the upright sitting position, leaning forward so that the scapulae are accentuated. The spine of the scapula is identified and marked along its entire length. The inferior tip of the scapula is then identified, and the original line of the spine is bisected at a point immediately superior to this inferior tip.
2. A skin wheal is raised approximately 1 cm superior and 1 cm lateral from this midpoint of the scapular spine, and a 3.75-cm needle is advanced through the skin until contact is made with the superior surface of the scapula. The needle is then withdrawn and redirected cephalad and medially toward the midline until the edge of the suprascapular notch is encountered. At this point, the patient may perceive a paresthesia into the shoulder joint, or the nerve stimulator may produce an internal rotation of the arm itself.
3. Once the nerve is localized, 10 mL of local anesthetic is injected. Even in the absence of nerve localization, this volume of solution injected into the notch should produce adequate anesthesia of the shoulder joint.

Trunk

Anesthesia of the abdomen and chest is most simply obtained with spinal and epidural injections of local anesthetics, as discussed in Chapter 25. In some situations, a narrower band of intercostal or paravertebral anesthesia is preferable, or epidural injection may be hazardous because of the presence of an infection or coagulopathy. In many clinical situations, it may also be desirable to separate the anesthesia of the somatic and sympathetic fibers that occurs in combination when axial blockades are performed. The sympathetic nerves separate from their somatic counterparts early in their course, which makes independent somatic and sympathetic blockade a practical consideration. Sympathetic blockade is most commonly performed at the major ganglia, particularly the stellate, celiac, and lumbar plexus. These blockades often require multiple injections and are technically more difficult than axial anesthesia, but they do offer advantages in certain clinical situations.

The somatic nerves of the chest emerge from their respective intervertebral foramina and pass through the narrow, triangular-shaped paravertebral space. In this triangle, they give off the sympathetic branch and also a small dorsal branch, which provides sensation to the midline of the back. The main trunks then pass into the intercostal groove along the ventral caudad surface of each rib. An artery and vein travel along with each of these nerves in the groove under the protection of the overhanging external edge of the rib. The fasciae of the internal and external intercostal muscles provide interior and external borders of this intercostal groove. As the nerves travel beyond the midaxillary line, they give off a lateral sensory branch while the main trunk continues on to the anterior abdominal wall to provide sensory and motor innervation for the trunk and abdomen down to the level of the pubis. The intercostal groove becomes much less well defined anterior to the midaxillary line, and the nerve begins to move away from its protected position. The lowermost intercostal nerve (the twelfth) is much less closely applied to its accompanying rib and is not as easy to identify and anesthetize using a classic intercostal blockade technique. The upper lumbar roots form the ilioinguinal nerves, which pass laterally within the muscles of the abdominal wall at the level of the iliac crest and eventually move anteriorly to provide innervation of the groin region as the ilioinguinal nerves.

The anatomic basis for separate sympathetic anesthesia is the early separation of sympathetic fibers. The white rami communicantes join the sympathetic ganglia, which lie anteriorly on each side of the vertebral bodies. These preganglionic fibers

of the sympathetic system usually arise only from the first thoracic through the second lumbar segments. The spinal ganglia formed by these fibers constitute the sympathetic trunks, which

extend upward into the neck and caudad along the lumbar spine. They give terminal sympathetic branches to all the areas of the body. The sympathetic innervation of the head and the lower extremities is derived from fibers that originate from the spinal cord, join sympathetic trunks, and then pass cephalad or caudad along the chain of ganglia before reaching their target organs. Segmental sympathetic innervation of the body from the cervical to the sacral roots is provided by postganglionic nerves departing from the chains (the gray rami communicantes), which rejoin the somatic nerves early in their course. In the head (where motor and sensory innervation is by cranial nerves), the sympathetic fibers reach their end organs by traveling with the arterial vascular supply. The sympathetic ganglia in the neck lie along the lateral border of the relatively flat vertebral bodies. In the chest, the vertebral bodies become more rounded, and the chain of ganglia lies more posteriorly on the lateral side of the vertebral body near the head of each rib. In the abdomen and pelvis, the sympathetic chains begin to move anteriorly and lie on the ventral surface of the vertebral bodies and thus are more widely separated from their respective somatic nerves.

Intercostal Nerve Blockade

Anesthesia of the intercostal nerves provides both motor and sensory anesthesia of the abdominal wall from the xiphoid to the pubis. The sixth to eleventh ribs are usually easily identified, and their accompanying nerves are reliably blocked by injections along the easily palpated sharp posterior angulation of the ribs, which occurs between 5 and 7 cm from the midline in the back. Ribs above the fifth are difficult to palpate because of the overlying scapula and paraspinous muscles and are therefore most easily blocked using the paravertebral technique. Establishing five or six levels of intercostal nerve blockade is a useful anesthetic procedure for providing analgesia and motor relaxation for upper abdominal procedures such as cholecystectomy and gastric surgery. Unilateral blockade of these nerves is a useful treatment for the pain of rib fracture and also serves to reduce postoperative analgesia requirements in patients with subcostal incisions. Several segments must be blocked in each of these applications because of the overlap of the intercostal nerves. This technique is also useful in reducing the pain associated with the insertion of chest tubes or percutaneous biliary drainage procedures.

1. For the performance of intercostal blockade, the patient may be in the lateral, sitting, or prone position. For operative anesthesia, the prone position is most practical. A pillow is placed under the abdomen to provide slight flexion of the thoracic spine. The arms are draped over the edge of the stretcher or operating table so that the scapula falls away laterally from the midline. The anesthesiologist stands at the patient's side. Most anesthesiologists prefer to stand on the side that allows their dominant hand to hold the syringe at the caudad end of the patient.
2. The spinous processes in the midline from T6 through T12 are marked (Fig. 26-19). The ribs are then identified along the line of their most extreme posterior angulation. For the twelfth rib, this is usually 7 cm from the midline. At the level of the sixth rib, this posterior angulation is best appreciated somewhat more medially, usually 5 cm from the midline. These two ribs are marked first at their inferior borders, and a line is drawn between these two points. The rest of the ribs between them are identified, and a mark is placed on the inferior border of each rib along the angled parasagittal plane identified by the first line between the sixth and twelfth ribs.
3. After aseptic preparation, sedation and analgesia are provided for the patient, and a skin wheal is raised at each mark.
4. The ribs are blocked starting with the lowermost and moving upward.
5. Starting with the lowest rib on the side closest to the anesthesiologist, the index finger of the cephalad hand is placed on the skin above the identifying mark; this finger should lie immediately over the midpoint of the rib. The skin is then retracted in a cephalad direction, so that the previous mark now lies over the rib itself, somewhat toward the inferior side. The anesthesiologist's other hand inserts a 22-gauge, 3.75-cm needle directly onto the rib. This

needle is attached to a 10-mL syringe filled with local anesthetic. The syringe and needle are held in such a way that they maintain a constant 10-degree cephalad angulation.

6. Once the needle is safely "parked" on the dorsal surface of the rib, the cephalad hand releases the tension on the skin and takes control of the needle and syringe (Fig. 26-20). This is done by placing the ulnar border of the hand firmly against the skin and grasping the hub of the needle firmly between the thumb and index finger. The middle finger of this hand rests along the shaft of the needle to provide guidance. Once the syringe is firmly gripped by the cephalad hand, the fingers of the

caudad hand are placed in an "injection" position, either in the rings of a three-ring syringe or on the plunger of a straight syringe.

7. The needle and syringe are then raised slightly off the bone and walked in a caudad direction until they pass below the inferior border of the rib. The entire needle and syringe unit is kept at a 10-degree cephalad angle to the rib at all times. As it passes the inferior border, the needle is advanced 4 to 6 mm under the rib, with the needle actually pointing slightly cephalad into the intercostal groove.
8. Once in the groove, aspiration is performed, and 3 to 5 mL of local anesthetic solution is injected.
9. As soon as the injection is complete, the needle is withdrawn from the groove and moved cephalad and "parked" again on the safe dorsal surface of the rib. The fingers of the caudad hand are then removed from the injection position and assume control of the syringe again. The cephalad hand now relinquishes control and is moved up to the next rib to repeat this cyclic process.
10. The ribs on the opposite side are blocked in a similar manner. This can be done with the anesthesiologist standing on the same side and reaching across the back, or by moving to the opposite side of the patient.
11. Intercostal nerve blockades can be supplemented by a number of somatic paravertebral nerve blockades or sympathetic blockade of the celiac plexus. Care should be taken to adjust the total dose of drug in such combinations of techniques so that the maximal recommended amounts are not exceeded.

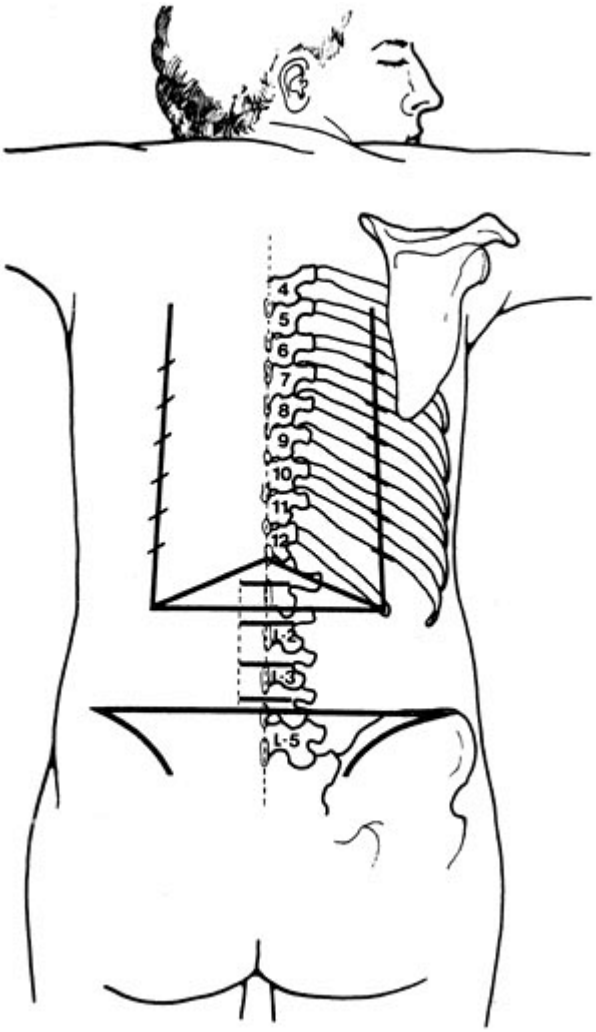

FIGURE 26-19. Landmarks for intercostal blockade. The inferior borders of the ribs are identified at their most prominent points on the back. The marks then usually lie along a line that angles slightly medially from the twelfth to the sixth rib. The triangle drawn between the twelfth ribs and their spinous processes is used for the celiac plexus blockade. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

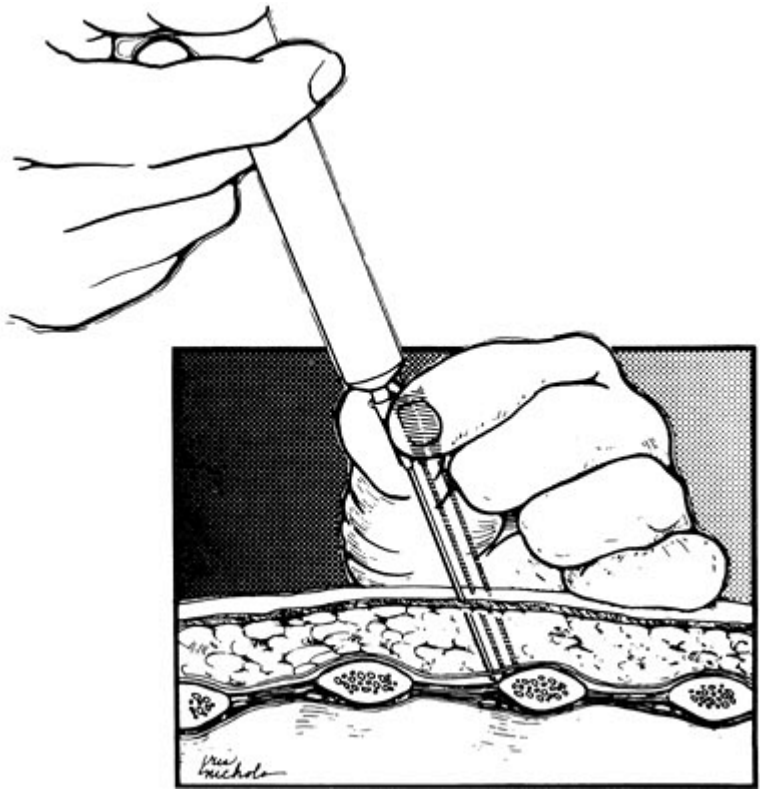

FIGURE 26-20. Hand and needle positions for intercostal blockade. The depth of the needle is controlled by the hand resting on the back. The other hand injects solution when the needle is under the rib, but that is the only function performed while the needle is near the pleura. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Despite frequent concern about the incidence of pneumothorax with intercostal blockade, this complication is rare in experienced hands. This depends primarily on maintaining strict safety features of the described technique. Emphasis should be placed on absolute control of the syringe and needle at all times, particularly during the injection.

A common complication is related to the sedation required to perform this blockade in the prone position. Overdose can lead to airway obstruction and respiratory depression in the prone position. Attention must be paid to the patient's mental status because this blockade produces the highest blood levels of local anesthetics when compared with any other regional anesthetic technique. When the blockade is performed for postoperative pain relief, the dose should be reduced to 0.25% bupivacaine or ropivacaine to minimize the chance for toxicity.

It is possible to produce partial spinal or epidural anesthesia if the injection is made close to the midline and the anesthetic tracks along a dural sleeve to the epidural or subarachnoid space. Respiratory insufficiency can also be seen if the intercostal muscles are blocked in a patient who depends on them for ventilation. Patients with chronic obstructive disease with ineffective diaphragm motion are not good candidates for this technique.

Paravertebral Blockade

The upper five ribs are more difficult to palpate laterally, and blockade of their associated intercostal nerves is best performed with a paravertebral injection. This approach is technically more difficult and has slightly greater potential for complications because of the proximity of the lung and of the intervertebral foramina. Anatomically, the injection is made into the triangle formed by the intervertebral body, the pleura, and the plane of the transverse processes (Fig. 26-21). The intervertebral foramina at each level lie between the transverse processes and

approximately 2 cm anterior to the plane formed by the transverse processes in their associated fasciae. At this point, the sympathetic ganglia lie close to the somatic nerves, and coincidental sympathetic blockade is usually attained. This is also related to the injection of larger volumes of local anesthetic, which is required because location of the nerve is less reliable with this technique. Nevertheless, it is a useful technique for segmental anesthesia, particularly of the upper thoracic segments. It is also useful if a more proximal blockade is needed, such as to relieve the pain of herpes zoster or of a proximal rib fracture. Lumbar paravertebral blockade has been used successfully for outpatient hernia operations, providing significant postoperative analgesia.

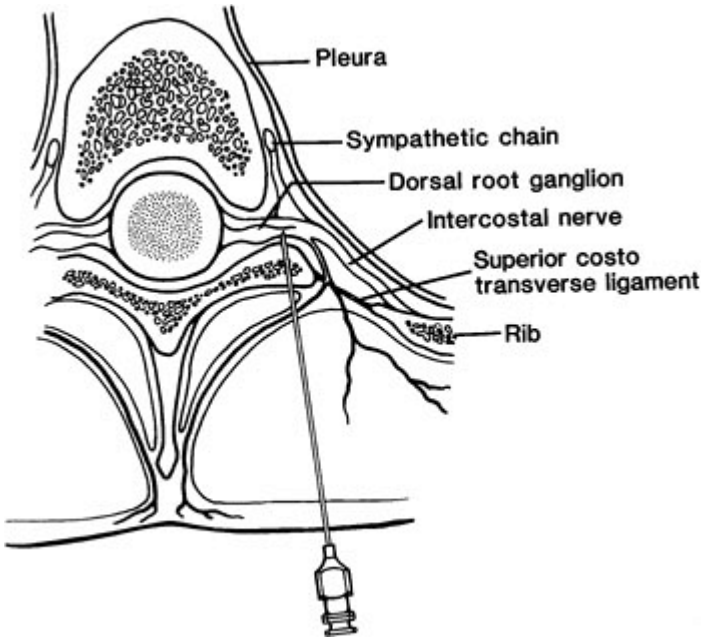

FIGURE 26-21. Paravertebral blockade. As it exits the intervertebral foramen, the thoracic somatic nerve enters a small triangular space formed by the vertebral body, the plane of the transverse process, and the pleura. Medial direction of the needle is obviously important in reducing the chance of a pneumothorax.

The paravertebral approach varies somewhat, depending on the spinal level. In the upper thoracic spine, the transverse process is located lateral to the spinous process of the vertebral body above it. In the lower thoracic spine, the spinous processes are less steeply angled, so that the eleventh and twelfth spinous processes lie between the associated transverse processes. In the lumbar region, the spinous processes are straight, and the transverse processes lie opposite their own respective spinous process. Thus, paravertebral blockade in the upper thoracic region is performed at each level by identifying the spinous process of the vertebra above the level to be blocked; in the lumbar region, the spinous process of the level to be blocked is used to locate the transverse process.

1. This blockade is also performed in the sitting or prone position, with a pillow under the patient's abdomen to produce flexion of the thoracic and lumbar spine. The spinous processes in the region to be blocked are marked. These can be identified by counting upward from the fourth lumbar process (which usually lies just at or above the line joining the two iliac crests) or by counting down from the seventh cervical process (which is the most prominent in the cervical region).
2. Transverse lines are drawn across the cephalad border of the spinous processes and extended laterally to overlie the transverse process (~1 to 4 cm). In the lumbar region, the

lines overlie the transverse process of the associated vertebra. In the thoracic region, they indicate the transverse process of the vertebral body immediately below the associated spinous process. Finally, a vertical line is drawn parallel to the spine 3 to 4 cm lateral to it, joining the transverse lines from the spinous processes. For a diagnostic blockade, a single nerve may need to be anesthetized. For pain control, several levels must be identified. The injection of at least three segments (as in intercostal blockade) is required to produce reliable segmental blockade because of sensory overlap.

3. After aseptic skin preparation, skin wheals are raised at the intersections of the vertical and transverse lines.
4. A 22-gauge needle is introduced through the skin wheal in the sagittal plane and directed slightly cephalad to contact the transverse process. A 7.5-cm needle is usually required in the average patient, and the transverse process lies between 3 and 5 cm from the skin. Gentle cephalad or caudad exploration may be required to identify the bone. The depth of the transverse process is carefully noted on the needle shaft.
5. The needle is now withdrawn from the transverse process and walked inferiorly to pass below its caudad edge. This usually requires more perpendicular direction relative to the skin. The needle is advanced 2 cm below the transverse process and angled slightly medial to attempt to contact the vertebral body. Nerve responses are not sought unless a neurolytic injection is planned. When the needle has entered the paravertebral space, 5 to 10 mL of local anesthetic solution is injected after careful aspiration.

The complication of pneumothorax is more likely in the thoracic region with a paravertebral technique than with intercostal blockade. The needle should be directed medially as it passes below the transverse process and never more than 2 cm beyond the transverse process (see Fig. 26-21). If cough or chest pain occurs, a chest radiograph should be performed to rule out pneumothorax. Subarachnoid injection is also more likely in the thoracic area because of the extension of the dural sleeves to the level of the intervertebral foramina. Careful aspiration is important but may not prevent the unintentional injection of local anesthetic into a subdural pocket. Total spinal anesthesia can result with a 5- to 10-mL injection. Systemic toxicity is also a possibility because of the need for relatively large volumes of local anesthetic. Attention must be paid to the total milligram dose injected. The volume required for each level obviously limits the concentrations that can be used and the total number of levels that can be blocked. If lumbar paravertebral injections are combined with intercostals, the concentration and total volume for both blockades may have to be reduced.

Intrapleural Anesthesia

Upper abdominal analgesia can also be obtained by inserting an epidural catheter into the intrapleural space for injection or infusion of local anesthetic. The anesthetic appears to diffuse through the parietal pleura onto the intercostal nerves and produces anesthesia similar to that provided by injection of multiple intercostal nerve blocks. It may also act on the sympathetic nerves by diffusion to the ganglia lying along the anterior vertebral borders.

1. As with intercostal block, the technique can be performed with the patient in the prone, lateral, or sitting position.
2. The seventh or eighth intercostal space is identified 8 to 10 cm from the midline and marked at the upper border of the lower rib.
3. A skin wheal is made at this site, and a blunt-tipped epidural needle (e.g., Touhy) is inserted with the bevel directed cephalad and advanced over the inferior rib in a slightly medial and cephalad angle through the intercostal muscles. Once in the intercostal layers, the stylet is removed, and an air-filled 5-mL glass syringe is attached.
4. The needle is advanced farther until the parietal pleura is punctured, signaled by a negative

pressure that moves the plunger of the syringe forward. The syringe is removed, and a standard epidural catheter is threaded 5 to 6 cm beyond the tip. Aspiration is performed to exclude perforation of the lung or a blood vessel.

5. Twenty milliliter of 0.5% bupivacaine or ropivacaine with epinephrine is injected into the pleural space, and the catheter is carefully taped to the skin. Reinjection is required every 3 to 6 hours, or a constant infusion of 0.25% bupivacaine (0.125 $mL/kg^{-1}/h^{-1}$) or 0.2% ropivacaine can be initiated.

There have been several enthusiastic reports of success with this technique, but limitations have been described. Pain relief is usually reliable, and respiratory depression is not a problem. However, the duration is short enough that large quantities of local anesthetic are required to maintain analgesia, and systemic toxicity has been reported in 1.3% of patients.[15] The incidence of pneumothorax (averaging 2%) is not inconsequential, especially with first attempts. Puncture of the lung also occurs, apparently with a higher incidence if a loss-of-resistance technique is used rather than the passive identification process described earlier. A major limitation is the unilateral analgesia, which limits this technique to procedures such as cholecystectomy and nephrectomy, rib fracture, and treatment of herpetic pain. Loss of local anesthetic solution to thoracostomy drainage makes this technique unreliable for thoracotomy pain.

Ilioinguinal Blockade

The L1 nerve root (occasionally joined by a branch of the T12 root) provides sensory innervation to the lowermost portion of the abdominal wall and the groin by means of its superior iliohypogastric branch and its inferior ilioinguinal branch. These nerves travel in a path similar to that of the intercostal nerves, but without the convenient bony landmark of a rib to identify them. Nevertheless, they can be anesthetized relatively easily in the groin because of their relationship to the anterosuperior

iliac spine. Anesthesia of these two nerves is useful in providing lower abdominal wall anesthesia to supplement intercostal blockade. It is more commonly used to produce field anesthesia for inguinal hernia repair surgery. Anesthesia of these nerves alone is not sufficient for hernia repair; subcutaneous infiltration is also necessary.

1. The patient lies in a supine position, and the anterosuperior iliac spine is identified. An "X" is placed on the skin 2.5 cm medial to the spine and slightly cephalad.
2. After aseptic preparation, a skin wheal is raised at the "X."
3. A 2.5-cm, 22-gauge needle is introduced through the "X" and

directed perpendicular to the skin until it reaches the fascia of the external oblique muscle. A "wall" of local anesthetic solution is then laid down between this point and the iliac spine and also opposite the mark on an imaginary line extending toward the umbilicus. Injections are made at and below the level of the external oblique, with some solution injected at the level of the internal oblique. A total of 10 to 15 mL of anesthetic is usually required.

4. If field anesthesia for inguinal hernia repair is required, further subcutaneous infiltration of anesthetic is performed along the skin crease of the groin and along the imaginary line extending to the umbilicus. This produces a triangular-shaped area of skin anesthesia. For hernia operations, further anesthesia of the spermatic cord is required. This is usually performed by local injections in the area of the cord and the internal ring. Although epinephrine is useful in the subcutaneous and ilioinguinal blockade, it should be avoided in solutions used to anesthetize the base of the penis or the spermatic cord (see Penile Blockade section). Further anesthesia of the groin area and below can be obtained by blockade of the femoral and lateral femoral cutaneous nerves, but this may result in

unwanted weakness of the leg musculature, which may prevent ambulation.

Complications of this procedure are extremely rare. Hematoma formation and unwanted motor blockade of the femoral nerve are possible, but rare. More commonly, anesthesia produced by this technique is inadequate for hernia repair because the patient is still able to perceive the discomfort of peritoneal traction. Administration of local anesthesia by the surgeon or systemic opioids may be required.

Penile Blockade

If surgery is confined to the penis (e.g., circumcision, urethral procedures), the organ should be blocked with simple local infiltration. Two skin wheals are raised at the dorsal base of the penis, one on each side just below and medial to the pubic spine. A 25-gauge, 3.75-cm needle is introduced on each side, and 5 mL of anesthetic is deposited superficially and deep along the lower border of the pubic ramus to anesthetize the dorsal nerve. An additional 5 mL is infiltrated in the subcutaneous tissue around the underside of the shaft to produce a complete ring of anesthetic. A larger needle or a second injection site may be needed to complete the ring. Twenty to 25 mL of 0.75% lidocaine or 0.25% bupivacaine usually suffices. Epinephrine is strictly avoided.

Sympathetic Blockade

Stellate Ganglion

Separate blockade of the sympathetic fibers of the upper extremity and head can be achieved by a single injection of a local anesthetic on the stellate ganglion. The ganglion is the large fusion of the first thoracic sympathetic ganglion with the lower cervical ganglion on each side, and it lies on the generally flat lateral border of the vertebral body of C7. All the fibers to the middle and superior cervical ganglia pass through this lowermost collection and thus can be anesthetized with a single injection. Although technically simple, the location of this ganglion near the carotid artery, the vertebral artery, and the pleura makes this a challenging blockade. It is useful in providing pain relief for sympathetic dystrophies of the upper arm. Stellate ganglion blockade may relieve the pain of acute herpes zoster infection of the head or neck region. It has also been advocated as a means of reducing post-thoracotomy pain by blocking the sympathetic sensory fibers to the pleural cavity. The procedure for blockade follows:

1. The patient is placed in a supine position with a small towel or pillow under the neck, and the arms are held at the side.
2. The medial border of the sternocleidomastoid muscle on the involved side is marked, as is the level of the cricoid cartilage. Gentle palpation approximately 2 cm lateral to the cartilage often reveals the anterior tubercle of the transverse process of the sixth cervical vertebra (*Chassaignac's tubercle*). A circle is marked over this tubercle, and an "X" is placed 1.5 to 2 cm caudad to this mark at the same distance from the midline. This "X" should overlie the tubercle of the seventh cervical vertebra and should fall at the medial border of the sternocleidomastoid muscle body and approximately two fingerbreadths above the clavicle itself.
3. A skin wheal is made at the "X" after aseptic skin preparation.
4. With the index and middle finger of one hand, the sternocleidomastoid muscle and the carotid sheath are retracted laterally (Fig. 26-22). A 22- or 25-gauge, 3.75-cm needle is introduced through the "X" and passed directly posterior until it rests on bone. A paresthesia of the brachial plexus implies that the needle is too far laterally and has passed beyond the transverse process. It may have to be readjusted slightly more medially and perhaps more cephalad or caudad.
5. Once bone is contacted, the needle is withdrawn a few millimeters, and careful aspiration is

performed to rule out contact with the vertebral artery. A 2-mL test dose is injected to evaluate further an unrecognized intravascular position. The patient's mental status must be closely observed.

6. If no change occurs, a total of 10 mL of local anesthetic can be injected incrementally with frequent aspiration. One percent lidocaine or 0.25% bupivacaine or their equivalents are more than adequate to produce anesthesia of the sympathetic nerves.
7. Onset of sympathectomy is usually, but not reliably, indicated by the appearance of a *Horner's syndrome* on the ipsilateral side. Ptosis, miosis, and anhydrosis usually develop within 10 minutes, as well as vasodilatation in the arm. Nasal congestion is another common sign usually associated with Horner's syndrome.

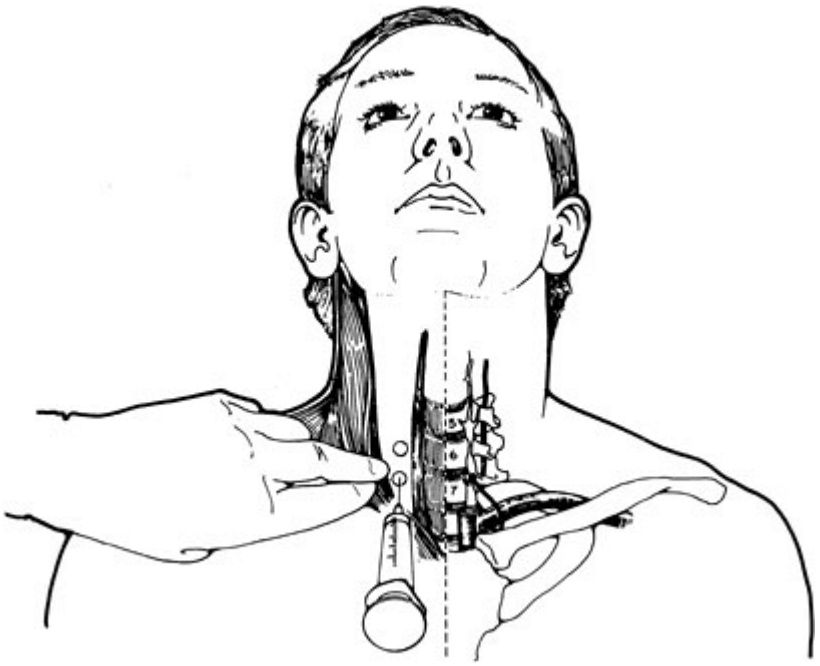

FIGURE 26-22. Stellate ganglion blockade. The sternocleidomastoid muscle and the carotid sheath are retracted laterally with one hand while the needle is introduced directly onto the lateral border of the seventh vertebral body, just medial to the transverse process. The vertebral artery passes posteriorly at this level to enter its canal in the transverse process, but here it lies near the level of intended injection. After contacting bone, the needle is withdrawn slightly and careful aspiration is performed before incremental injection. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

There are several potential complications of stellate ganglion blockade. The pleura can be punctured, with resulting pneumothorax. Intravascular injection is the most serious complication because of the proximity of the vertebral artery to the site of injection. Careful aspiration and incremental injections are essential. Only a few milligrams of local anesthetic is required to produce cerebral symptoms when injected directly into the vertebral circulation. Cardiovascular changes are possible with the loss of the cardiac accelerator fibers from the cervical sympathetic ganglia. This is particularly a problem if bilateral blockade is performed, a procedure rarely indicated. Hoarseness from recurrent laryngeal nerve paralysis is a minor but troublesome side effect. Somatic anesthesia of the brachial plexus nerves can be produced by injection behind the level of the tubercle, and phrenic nerve paralysis has also been reported. Subarachnoid injection is also a possibility if the needle is misplaced. The close association of so many vital structures has discouraged the use of neurolytic agents in the region of the stellate ganglion.

Celiac Plexus

The thoracic sympathetic ganglia send branches anteriorly that merge as greater and lesser splanchnic nerves to pass below the diaphragm and around the aorta to coalesce in a diffuse periaortic supplementary sympathetic ganglion known as the celiac plexus. This extensive network is usually located at the level of the first lumbar vertebra in the retroperitoneal space, along the aorta at the level of the origin of the celiac artery. Fibers from this ganglion send postganglionic innervation to all the intraabdominal organs and appear to carry pain sensation from many of the intraperitoneal organs such as the pancreas and liver. Injection into this retroperitoneal space allows anesthetic solution to diffuse around the ganglia and the splanchnic nerves to provide blockade of these fibers. This blockade produces supplementary intraabdominal anesthesia when used in conjunction with intercostal blockade or general anesthesia. It is more commonly applied as a neurolytic sympathetic blockade for the relief of pain from malignancy of the pancreas, liver, or other upper abdominal organs.

1. As with intercostal blockade, the patient is placed in the prone position with the thoracic spine flexed by the use of a pillow under the abdomen.
2. The spinous processes of the twelfth thoracic and the first lumbar vertebral bodies are identified and marked along their entire extent. The twelfth rib is likewise identified and marked 7 cm from the midline. A line is drawn between the twelfth ribs on each side, usually crossing the midline at the level of the spinous process of the L1 vertebra. Lines are also drawn from the spinous process of the twelfth thoracic vertebra to the points on these ribs on both sides. The net result is a shallow triangle, with the spinous process of the twelfth vertebra at its apex (see Fig. 26-19).
3. Skin wheals are raised bilaterally at the marks along the ribs after aseptic skin preparation. Deeper infiltration of local anesthetic with a 22-gauge needle is often helpful in improving patient tolerance of this procedure.
4. On each side, a 12.5-cm, 22- or 20-gauge needle is introduced through the skin wheals and advanced anteriorly and medially and cephalad along the two lines of the triangle that was previously drawn (Fig. 26-23). The needle should be passed at approximately a 45-degree angle anteriorly so that it will contact the lateral border of the vertebral body of L1 at a depth of approximately 5 cm from the skin. (The twelfth spinous process partially overlies the L1 vertebral body.)
5. When contact with a vertebral body is made, the needle is withdrawn several centimeters, and the angle of insertion is steepened so that it advances more anteriorly with subsequent passage, in the hope that it will walk off the anterior border of the vertebral body. The periosteum may be encountered several times during this attempt and should always be palpated gently because of the associated discomfort. Intravenous sedation may be required for tolerance of this blockade, although it must be kept to a minimum if evaluation of a diagnostic pain blockade is desired.
6. Once the anterior border of the vertebral body is reached, the needle is advanced 2 to 3 cm beyond this, and careful aspiration is performed. On the left side, advancement should be halted whenever aortic pulsation is appreciated. If the artery is unintentionally

punctured, the needle should be withdrawn slightly and cleared immediately of blood. On the right side, the needle can often be advanced 1 to 2 cm farther than the needle on the left side.

7. If radiographic confirmation is desired, it is obtained at this point, before injection of the anesthetic. The bony landmarks themselves are usually sufficient to identify the retroperitoneal space anterior to the first lumbar vertebral body. If neurolytic agents are to be used or if the anatomy is difficult, fluroscopic confirmation is desirable.
8. Careful aspiration is performed, and a test dose is injected on each side to rule out

subarachnoid or intravascular injection.

9. A large volume of local anesthetic solution is required. Twenty to 25 mL of 0.75% lidocaine or 0.25% bupivacaine is usually adequate.
10. The most reliable sign of successful anesthesia is the disappearance of pain in patients or the appearance of hypotension in normal patients. Patients with pain must remain supine for several hours and should have appropriate iv fluid supplementation to avoid orthostatic hypotension. Gradual ambulation is mandatory.

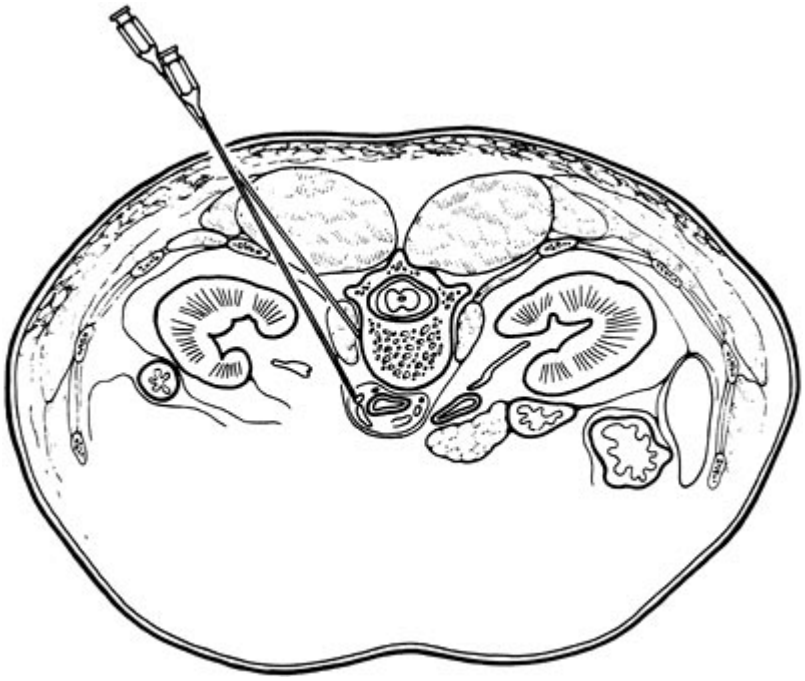

FIGURE 26-23. Celiac plexus blockade. The surface landmarks are described in Figure 26-19. The needles are advanced medially and superiorly to contact the lateral aspect of the vertebral body. They are then advanced more anteriorly to pass beyond the vertebra to the prevertebral space, where the greater and lesser splanchnic nerves and their subsequent celiac plexus lie. No attempt is made to advance the needles to the anterior aspect of the vessels. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Hypotension is the most common complication of celiac plexus blockade. It can be reduced by the administration of 1L of balanced salt solution before performing the blockade. The most serious complication is the development of paralysis from unrecognized subarachnoid injection of a neurolytic drug. Radiographic confirmation of needle location is advisable before injection of any neurolytic drug. Even with correct placement of neurolytic drugs, back pain is common and patients may require iv opioids. This pain can be reduced by diluting the alcohol solution with an equal volume of local anesthetic such that a total volume of 50 mL is injected, consisting of 25 mL of alcohol and 25 mL of anesthetic. Even with this approach, diaphragmatic irritation (manifested as shoulder pain) is not uncommon. The duration of pain relief in the patient with chronic pain is unpredictable but is often 2 to 6 months. The blockade can be repeated as often as necessary, although a trial diagnostic blockade with a local anesthetic agent is indicated before each use of neurolytic drugs. One minor side effect of celiac plexus blockade is the increased peristalsis of the gut produced by the shift in the balance of the parasympathetic and sympathetic innervations. This may produce diarrhea within the first 12 hours after the blockade and may be a source of relief to patients on chronic opioid therapy for cancer pain.

Lumbar

As with the sympathetic innervation of the head and arm, the sympathetic nerves to the lower extremities all exit the cord above L2 and all pass through a common "gateway" ganglion in the sympathetic chain at the L2 level. Thus, as in the neck, sympathetic blockade of the lower extremity can be achieved by a single injection of one ganglion. The approach to this ganglion is similar to paravertebral anesthesia, as discussed previously, except that in the lumbar region, the sympathetic chain lies much more anterior from the somatic nerves, and thus a clean separation of sympathetic blockade from somatic blockade can be attained more easily.

As in the upper extremity, lumbar sympathectomy can be used in the treatment of sympathetic dystrophies. It is also occasionally used in patients with severe vascular disease in the lower extremities to give some indication of whether the patient would profit from permanent chemical or surgical sympathectomy.

1. The patient position is similar to that for celiac plexus blockade. The patient lies prone with a pillow under the lumbar spine.
2. The spinous processes of L2 and L3 are identified and marked over their entire course. A horizontal line is drawn through the midpoint of the L2 spinous process and extended 5 cm to either side of the midline. An "X" is placed at this point, which should overlie the space between the transverse process of the second and third vertebrae or the caudad edge of the second transverse process.
3. A skin wheal is raised after aseptic skin preparation at each "X."
4. A 10-cm needle is introduced on each side through the "X," angled 30 to 45 degrees cephalad, and advanced until it contacts the transverse process (Fig. 26-24).
5. The depth of the needle insertion is marked, and the needle is then withdrawn slightly, angled caudad, and walked inferiorly off the transverse process (usually in a direction perpendicular to the skin). A slight medial angulation is used in the hope of contacting the vertebral

   body below the transverse process. The needle is advanced 5 cm below the depth of the transverse process. If it encounters a vertebral body, it is angled slightly more anteriorly to walk off that body at the desired depth.
6. Once the needle is in position, careful aspiration is performed, and a test dose is injected on both sides. Ten milliliter of local anesthetic solution injected on each side should produce sympathetic blockade. Again, 1% lidocaine, 0.25% bupivacaine, or an equivalent concentration is more than sufficient to produce sympathetic nerve blockade. If a neurolytic drug such as phenol is used, confirmation of needle position by radiography should be obtained. A slightly more caudad site of injection may be more effective for neurolytic blockade; injection of smaller quantities at several levels may be more appropriate for neurolytic drugs.
7. Care is taken not to inject anesthetic solution as the needle is withdrawn, because this may produce a somatic nerve blockade as the needle passes the course of the L2 nerve root.
8. Vasodilatation and increase in skin temperature should be noted within the leg in 5 to 10 minutes. This can be quantitated objectively if a skin temperature probe is placed on the foot before the start of the blockade.

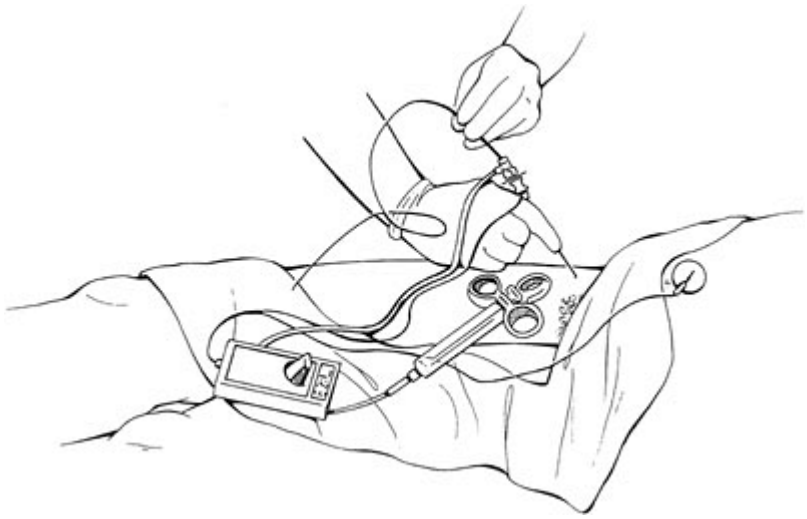

FIGURE 26-24. Lumbar sympathetic blockade. The needle is first placed on the transverse process of L2 and then advanced below it to pass 5 cm deeper. The needle can be angled slightly medially to contact the body of the vertebra; the sympathetic chain lies along the anterior margin of these bodies. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Complications with this technique are unusual, but, again, intravascular or subarachnoid injection can be a potential problem. The most troublesome and frequent complication is simultaneous blockade of the L2 somatic nerve root. This produces a band of anesthesia across the lateral and anterior thigh, which may confuse the evaluation of a diagnostic sympathetic blockade.

Hypogastric Plexus

At the terminal end of the prevertebral sympathetic chain is the superior hypogastric plexus, which extends from the lower one-third of the fifth lumbar vertebral body to the upper third of the first sacral vertebral body. Fibers passing through this ganglion provide visceral sensation to the pelvic organs. Malignancies in the pelvis often produce chronic pain syndromes that involve transmission of nociception through this ganglion plexus, and significant relief can be obtained by the performance of neurolytic blocks in this area.[16]

1. The patient is placed in the prone position with a pillow under the pelvis to reduce the lumbar lordosis.
2. The L4-5 intervertebral space is identified and marked, and a line drawn at the midline of this space. An "X" is then placed on the skin 5 to 7 cm lateral to this interspace on both sides.
3. Aseptic skin preparation is performed, and a skin wheal raised at the "X" marks at each side.
4. Fifteen-centimeter, 22-gauge needles are then introduced through the skin wheals and directed medially. Both needles are advanced at approximately a 45-degree angle with a 30-degree caudad deflection to approach the anterolateral body of the L5-S1 space. If the L5 vertebral body is encountered, the needle is redirected more anteriorly. The use of fluoroscopy and contrast dye documents the correct placement of the needles just anterior to the L5-S1 intervertebral space.
5. After careful aspiration to exclude intravascular placement, anesthesia can be obtained with 8 mL of 0.25% bupivacaine for a diagnostic block. For neurolytic procedures, an equal volume of 10% phenol can be used on each side.

The major risk of this block is intravascular placement of the drug. The side effects and complications of neurolytic agents apply here if they are used.

Lower Extremity

The nerves to the lower extremity are most easily blocked by the spinal, caudal, or epidural techniques described in Chapter 25. There are occasions when anesthesia by these routes is contraindicated because of systemic sepsis or coagulopathy, or when selective anesthesia of one leg or foot is needed. Peripheral nerve blockade is possible because the motor and sensory fibers to the lower extremities are somewhat similar to those of the upper extremities in that they form a series of intertwined branching roots and divisions that are enclosed in a fascial sheath before they emerge as the terminal nerves to the extremity. They can also be successfully blocked by a single injection in one plane, although the anatomic landmarks identifying this fascial sheath are not as clearly defined as those in the upper extremity. Because of this, the majority of lower extremity blockades are performed more distally, where the nerves have already separated into terminal branches. Thus, in addition to the fascial compartment approach (psoas blockade), there are peripheral approaches described at the hip, knee, and ankle.

The nerves to the legs emerge from the roots of L2 through the third sacral spinal segments (Fig. 26-25). The upper nerve roots from L2 to L4 form the lumbar plexus, which then ramifies eventually to form the lateral femoral cutaneous, femoral, and obturator nerves. These primarily provide sensorimotor innervation of the upper leg, although a branch of the femoral nerve commonly extends along the medial side of the knee as far down as the big toe. A branch of this lumbar plexus, the lumbosacral trunk of L4 and L5, joins the sacral fibers to form the major trunks of the large nerve of the posterior thigh and lower leg, the sciatic. The sciatic nerve is made up of two main trunks, the tibial and the common peroneal, which divide just above the knee. As in the brachial plexus, the upper nerve roots emerge from their foramina into a compartment lined by the fasciae of muscles anterior and posterior to it. In this case, the

quadratus lumborum is posterior, while the posterior fascia of the psoas muscle provides the anterior border of the compartment before the nerves move into the body of the muscle. The sacral roots have a similar envelope except that the posterior border is the bone of the ilium.

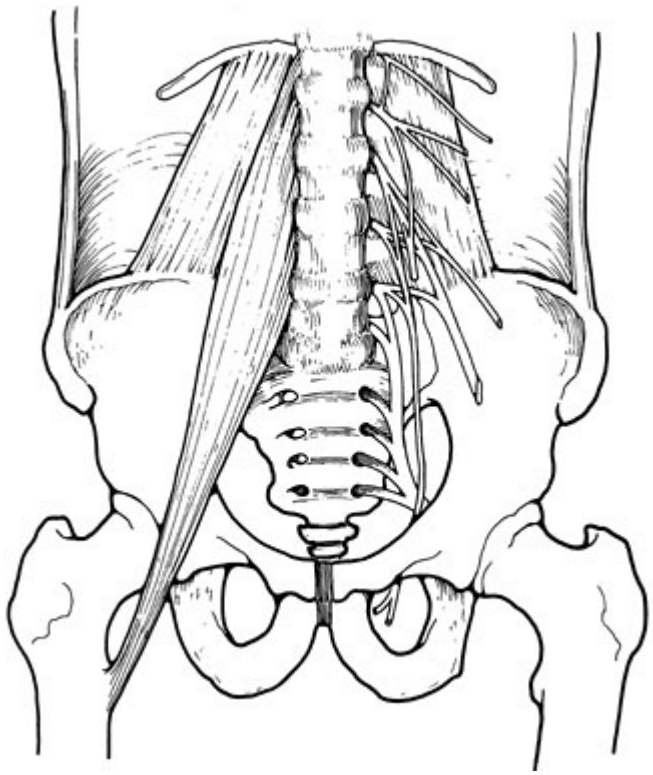

FIGURE 26-25. Psoas compartment anatomy. The roots of the lumbar plexus emerge from their foramina into a fascial plane between the quadratus lumborum muscle posteriorly and the psoas muscle anteriorly. The origin of the lumbosacral plexus is broader than the corresponding brachial plexus in the neck, and the lower sacral roots cannot be easily reached by a single injection. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

The lumbar plexus branches form their three terminal nerves early. Each of these passes anteriorly and laterally to circle around the pelvis and emerge anteriorly in the groin. The femoral nerve becomes associated with the femoral artery in the area of the groin and passes under the inguinal ligament just lateral to the artery. The lateral femoral cutaneous nerve migrates laterally early and passes under the inguinal ligament near the anterosuperior iliac spine. The third branch of the lumbar plexus, the obturator, remains somewhat medial and posterior in the pelvis and emerges under the superior ramus of the pubis through the obturator foramen to supply motor and sensory fibers to the medial thigh and medial border of the knee.

The branches of the sacral plexus also travel laterally within the pelvis before exiting posteriorly through the sciatic notch as the sciatic nerve. This largest nerve of the body is actually the conjunction of two trunks. The lateral trunk forms from the roots of L4 through S2 and eventually emerges as the common peroneal nerve. Other branches of L4 through S3 form the medial trunk, eventually becoming the tibial nerve. These combined nerves exit through the sciatic notch and pass anteriorly to the piriformis muscle between the ischial tuberosity and the greater trochanter of the femur. They curve caudad and descend the posterior thigh immediately behind the femur. After their bifurcation high in the popliteal fossa, the peroneal nerve provides the motor and sensory fibers to the anterior calf and dorsum of the foot. The tibial nerve remains posterior and provides sensation to the calf and sole of the foot. There are three major branches that cross the knee: the femoral, tibial, and peroneal. By the time these nerves reach the ankle, there are five branches that cross this joint to provide innervation for the skin and muscles of the foot.

Psoas Compartment Blockade

The fascial compartment of the lumbar plexus is more difficult to identify than that of the brachial plexus in the upper extremity and lies much deeper beneath the skin than its equivalent in the neck (see Fig. 26-25). Nevertheless, psoas compartment blockade is useful if single-injection anesthesia of the leg is desired.[17]

1. The patient is placed in the lateral position. The spinous processes of the lumbar vertebrae and the posterior superior iliac spine are identified, and a line drawn parallel to the spine from the top of this iliac spine (Fig. 26-26). Another line is drawn perpendicular to this one intersecting the L4 spine. This line is then trisected, and an "X" is placed on the skin at the junction of the lateral third and medial two-thirds of the line.
2. After aseptic preparation, a skin wheal is raised at the "X." A 10-cm needle is advanced perpendicular to the skin in all planes and passed through the muscles of the back. The transverse process of the vertebral body is sought, which may lie at a depth of between 5 and 8 cm. Once the bone is contacted, the needle is redirected caudally and advanced 2 cm further. Regardless of the depth of the bone from the skin, the nerve roots should lie 2 cm further. Although in some patients the well-demarcated fascial planes can identify the entry into the perineural sheath, anesthesia is more reliable if nerve responses are obtained. If they are not obtained at a 2.5-cm depth beyond the bone, probing with the needle in a fan-like manner should be performed in a cephalad-caudad plane (which is perpendicular to the known paths of the emerging nerves).
3. When a nerve response is obtained, the needle is fixed in position and careful aspiration and

administration of a test dose are used to rule out intravascular or subarachnoid placement. Thirty-five to 45 mL of local anesthetic solution is usually required to fill the sheath. Fifteen to 20 minutes may be required for spread of the anesthetic to all the roots of the lumbosacral plexus. It may take longer to produce anesthesia of the caudad branches (the lower sacral fibers that form the tibial nerve), or they may not be anesthetized at all.

4. A catheter may be inserted here, with the direction of the bevel ideally lateral and away from the neuraxial canal. Infusions provide postoperative analgesia for knee and hip replacement surgeries.

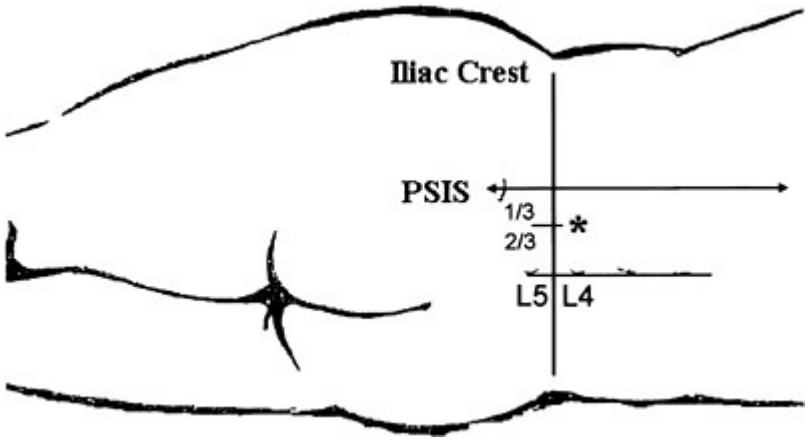

FIGURE 26-26. Psoas block. The nerves of the lumbar plexus can be approached posteriorly by insertion of a needle at a point lying lateral to the L4 spinous process, two thirds of the way between a line drawn along the spinous processes themselves, and a parallel line intersecting the posterior superior iliac spine. (Reprinted with permission from Capdevilla X, Macaire P, Dadure C, *et al*: Anesth Analg 94:1606, 2003.)

Complications of this technique include hematoma in the muscle sheath and retroperitoneal space or the kidney. Neuropathy of the nerves is possible. Unintended spread to the epidural or even subarachnoid space has also been reported. Inadequate anesthesia of some of the branches may occur more frequently than these rare complications.

Anesthesia at the Level of the Hip

Many anesthesiologists feel more confident when administering regional anesthesia in the hip region when nerve responses are sought for each of the major nerves. This technique is cumbersome and usually requires the patient to assume at least two separate positions for the injections. The anesthesia requires a larger volume of anesthetic drug. Each of the four nerves may be blocked selectively on an individual basis. Anesthesia of the lateral femoral cutaneous nerve is occasionally used to provide sensory anesthesia for obtaining a skin graft from the lateral thigh. It can also be blocked as a diagnostic tool to identify cases of meralgia paresthetica. A sciatic nerve blockade alone provides adequate anesthesia for the sole of the foot and lower leg. Procedures on the knee require anesthesia of the femoral and the obturator nerves, although postoperative analgesia of the knee can usually be provided by femoral nerve block alone. Femoral nerve block provides significant postoperative analgesia for the first 18 hours after total knee arthroplasty, and the use of a continuous technique can facilitate rehabilitation.[18]

Sciatic Nerve Blockade, Classic Posterior Approach

1. The patient lies with the side to be blocked uppermost and rolls slightly anterior, flexing the knee so that the

ankle of the involved side rests on top of the knee of the opposite side (Fig. 26-27). This position rotates the femur so that the trochanter is more easily palpated and the muscles overlying the sciatic nerve become stretched.

2. The superior aspect of the greater trochanter of the hip is marked with a circle. A similar circle is placed on the posterosuperior iliac spine, and a line is drawn between these two points.

3. A perpendicular line is drawn from the midpoint of this original line and extended 5 cm in the caudad direction. An "X" is marked at this point. A third line drawn between the greater trochanter and the sacral hiatus should intersect this "X." In the taller patient, the original perpendicular may need to be extended caudad to intersect with the third line, and the nerve may lie closer to the intersection of the second and third lines than to the original "X."

4. A skin wheal is raised at the "X" after aseptic skin preparation.

5. A 10-cm needle is introduced perpendicular to the skin in all planes, and nerve responses of the lower leg and foot are sought. If they are not obtained at the full depth of the needle, the needle is withdrawn to the skin and reintroduced in a fanwise fashion in a path perpendicular to the imagined course of the nerve in the hip. This path can usually be visualized by following the muscular groove on the back of the thigh up and into the imagined position of the sciatic notch. The bony edges of the sciatic notch itself may be encountered. These should be noted, and the search continued. The nerve should lie at approximately this depth as it emerges from inside the pelvis. If localization cannot be obtained in the first 10 minutes, the landmarks should be reassessed.

6. When a nerve response in the foot is obtained, the needle is held immobile, and 25 mL of local anesthetic is injected. A low concentration of local anesthetic may be needed if several nerves are to be blocked, which requires a large total volume of anesthetic in several locations.

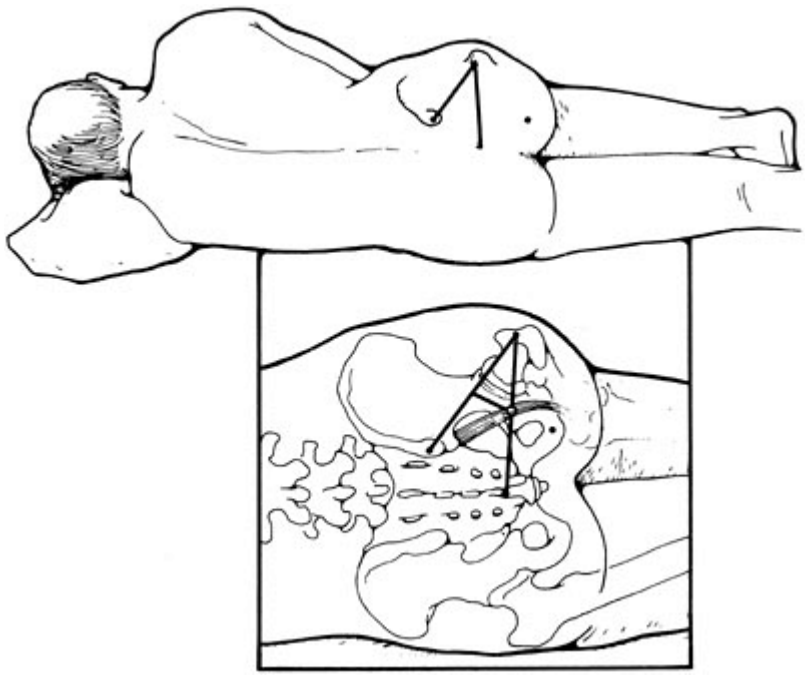

FIGURE 26-27. Sciatic nerve blockade, classic posterior approach. With the patient in the lateral position and the hip and knee flexed, the muscles overlying the sciatic nerve are

stretched to allow easier identification. The nerve lies beneath a point 5 cm caudad along the perpendicular line that bisects the line joining the posterosuperior iliac spine and the greater trochanter of the femur. This is also usually the intersection of that perpendicular line with another line joining the greater trochanter and the sacral hiatus. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Sciatic Nerve Blockade, Supine Approach (Lithotomy). If a patient is uncomfortable in the lateral position or cannot be turned to the side because of a fracture or pain, the nerve can be blocked with the patient in the supine position. An assistant is required to elevate the leg into a lithotomy-type position so that the posterior aspect can be reached.

1. With the patient supine, the hip is flexed by an assistant so that the upper leg is at a 90-degree angle to the torso.
2. The greater trochanter is identified as well as the ischial tuberosity, and a line is drawn between these two. An "X" is marked on the midpoint of this line.
3. A skin wheal is raised at the "X" after aseptic skin preparation. A 10-cm needle is introduced, and nerve responses are sought in a direction along the length of this line (which is perpendicular to the course of the nerve).
4. When a nerve response in the foot is obtained, 25 mL of local anesthetic is injected.

Lateral Femoral Cutaneous Nerve Blockade. The other three nerves of the leg can be blocked at the level of the hip with the patient in the supine position.

1. In the supine position, the anterosuperior iliac spine is identified and marked. An "X" is placed on the skin 2.5 cm below and 2.5 cm medial to the spine.
2. A skin wheal is raised at the "X" after aseptic preparation.
3. A 3.75-cm, 22-gauge needle is introduced through the wheal and directed laterally until a "pop" is felt as it pierces the fascia lata. Three to 5 mL of local anesthetic solution is injected as the needle is withdrawn slowly. The needle is then reinserted slightly medially, and the procedure is repeated until a "wall" of anesthesia has been spread over a 5-cm area above and below the fascia lata extending medially from the level of the anterosuperior spine. A total of 15 to 20 mL of local anesthetic may be required. No nerve responses are sought.

Femoral Nerve Blockade. This blockade can be performed blindly, or nerve responses can be sought for a "three-in-one" blockade (see Lumbar Plexus ["Three-in-One"] Blockade section). The procedure for "blind" blockade follows:

1. In the supine position, a line is drawn from the anterosuperior iliac spine to the pubic tubercle. The femoral artery is identified as it passes below this line, and an "X" is marked on the skin lateral to the artery 2.5 cm below the line.
2. After aseptic preparation, a skin wheal is raised at the mark.
3. A 5-cm, 22-gauge needle is introduced through the "X" and passed perpendicular to the skin until it lies next to the artery and slightly deep to it (Fig. 26-28).
4. Five milliliter of local anesthetic is injected slowly as the needle is withdrawn. The needle is

then reinserted slightly more laterally, and the process is repeated twice to create a "wall" of anesthesia lateral to and slightly deep to the femoral artery.

5. Anesthesia of the thigh should ensue within 5 to 10 minutes.

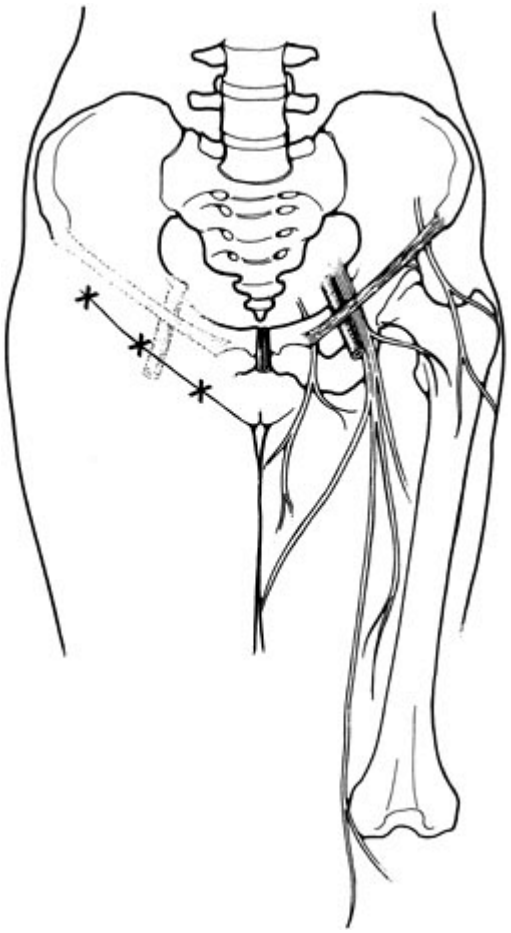

FIGURE 26-28. Blockade of the anterior lumbosacral branches in the groin. The lateral femoral cutaneous nerve emerges approximately 2.5 cm medial to the anterosuperior iliac spine and is best blocked 2.5 cm caudad to this point. The femoral nerve emerges alongside and slightly posterior to the femoral artery and is again easily approached approximately 2.5 cm below the inguinal ligament. On that same line, the obturator nerve emerges from the obturator canal but is deeper and less reliably located. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Obturator Nerve Blockade. This nerve is more difficult to locate because of its depth.

1. In the supine position, the pubic tubercle is identified and an "X" is placed 1.5 cm below and 1.5 cm lateral to this structure. This should lie medial to the femoral artery, and a line drawn between the three "Xs" used for these three nerve blockades should be parallel to the line between the superior spine and the pubic tubercle.

2. After aseptic skin preparation, a skin wheal is raised at the "X," and a 7.5-cm, 22-gauge needle is introduced through the "X" perpendicular to the skin.
3. The needle is advanced until it contacts bone, which should be the inferior ramus of the pubis. The needle is withdrawn slightly and redirected laterally and slightly caudad to enter

the obturator foramen. It is advanced another 2 to 3 cm, and 5 mL of anesthetic is injected as the needle is withdrawn through the presumed depth of the obturator foramen.

4. The needle is then reinserted slightly more laterally, and the process is repeated again until 20 mL of anesthetic solution has been injected to form another "wall" along the presumed path of the obturator nerve (see Fig. 26-28).
5. Alternatively, motor response to a nerve stimulator (adduction of the thigh) can confirm nerve localization.

Lumbar Plexus ("Three-in-One") Blockade. The concept of a single-injection blockade for the lumbar plexus, utilizing the fascial plane that the femoral nerve travels in as it crosses the pelvis, is popular. The premise of this block is that injection of a large quantity of local anesthetic solution in this plane will spread upward into the pelvis and anesthetize the obturator and lateral femoral cutaneous nerves at the point where they still travel in conjunction with the femoral nerve. Unfortunately, the obturator is frequently missed with this technique.[19] Because it is essential to have the needle exactly in the plane of the nerve, eliciting nerve responses is critical for this approach.

1. Preparation for femoral nerve blockade is made as described previously.
2. The needle is inserted in a cephalad manner rather than in a perpendicular angle recommended previously (Fig. 26-29). It is advanced alongside the artery angled at about 45 degrees so that it passes under the inguinal ligament. A nerve response is sought, recognizing that the nerve lies slightly posterior to and occasionally partially under the femoral artery. When the nerve response is obtained, the needle is fixed and the fingers of an assistant are used to compress the femoral artery and the neural sheath below the inguinal ligament while the operator injects 40 mL of anesthetic solution. The injection is performed incrementally after careful aspiration.
3. A continuous perineural catheter can be inserted with this approach, keeping the bevel of the introducing needle directed cephalad to allow the catheter to advance centrally in the fascial plane. Advancement of more than 5 cm of catheter may result in coiling or other misdirection.[20]
4. An alternative to direct localization is identification of the fascial plane by the penetration of the two fascial sheaths by the "pop" sensation of the needle passing through them (the "fascia iliaca block).[21] A needle is introduced 1 cm caudad to the junction of the lateral and middle third of a line marking the inguinal ligament. The needle will first pierce the fascia lata, then the fascia iliaca, and will lie in the nerve compartment. Local anesthetic can be injected directly, or the needle angled 30 degrees cephalad and a catheter threaded. This technique requires little patient cooperation, and is ideal in children, or for repeating a partially successful block (when further stimulation of the femoral nerve may not be successful).

FIGURE 26-29. Continuous femoral catheter. The inguinal approach to the femoral nerve can also be used for the insertion of a continuous catheter. The needle is inserted just lateral to the artery and a motor response is sought in the quadriceps muscle, producing patellar elevation. On identification of the nerve, a continuous catheter is threaded cephalad from this point. A 45-degree angulation of the needle facilitates easy passage of the catheter and encourages spread of the local anesthetic proximally. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Complications of these techniques are rare. Hematomas can occur in any of the areas of injection and are annoying but rarely serious. The problem of systemic toxicity is significant because of the large volumes of anesthetic solution required. As mentioned previously, careful attention must be paid to the total milligram dose involved when multiple injections are used. Neuropathy is a possibility. Intraneural injection must be avoided by watching for signs of any discomfort at the time of

actual injection. If the technique is used for analgesia following outpatient surgery, quadriceps weakness may limit ambulation, and crutches may be needed to enable patient discharge home.

Popliteal Fossa Blockade

The nerves of the lower leg can also be anesthetized by injections at the level of the knee. The success of this technique depends on locating the sciatic nerve near its bifurcation into the tibial and peroneal branches high in the popliteal fossa (Fig. 26-30). Supplemental anesthesia of the femoral nerve is needed to block its terminal saphenous branch, which serves the medial anterior calf and the dorsum of the foot. Insertion of a continuous perineural catheter can provide prolonged analgesia for foot procedures.[22]

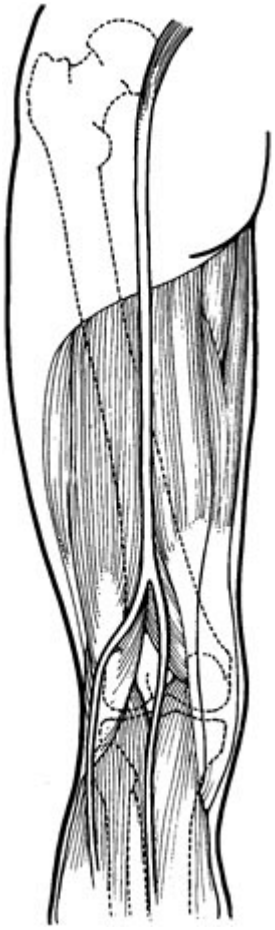

FIGURE 26-30. Popliteal fossa blockade. The two major trunks of the sciatic bifurcate in the popliteal fossa 7 to 10 cm above the knee. A triangle is drawn using the heads of the biceps femoris and the semitendinosus muscles and the skin crease of the knee; a long needle is inserted 1 cm lateral to a point 5 cm cephalad on the line from the skin crease that bisects this triangle. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Classical Approach.

1. The patient is placed in a prone position. The triangular borders of the popliteal fossa are outlined by drawing the borders of the biceps femoris and the semitendinosus muscles. The base of the triangle is the skin crease behind the knee. The patient can help identify the muscles by slightly flexing the lower leg.
2. After the triangle is drawn, a perpendicular line is drawn from the midpoint of the base to the apex of the triangle. Six centimeters from the base, an "X" is drawn 1 cm lateral to this bisecting line.
3. After aseptic skin preparation, a skin wheal is raised at the "X."
4. A 7.5- or 10-cm needle is introduced through the "X" and directed 45 degrees cephalad along the middle of the triangle (Fig. 26-31). A fanwise search is conducted perpendicular to this line until the nerve is contacted. If the femur is contacted by the needle, the depth is noted. The nerve should lie midway between the skin and the femur.
5. Once a nerve response is obtained, the needle is fixed in position and 30 to 40 mL of local anesthetic solution is injected.

6. A perineural catheter can be inserted here, and advanced 5 cm beyond the needle.
7. The femoral branches can be injected in the same position by raising a subcutaneous wheal of 5 to 10 mL of local anesthetic along the medial tibial head just below the knee.

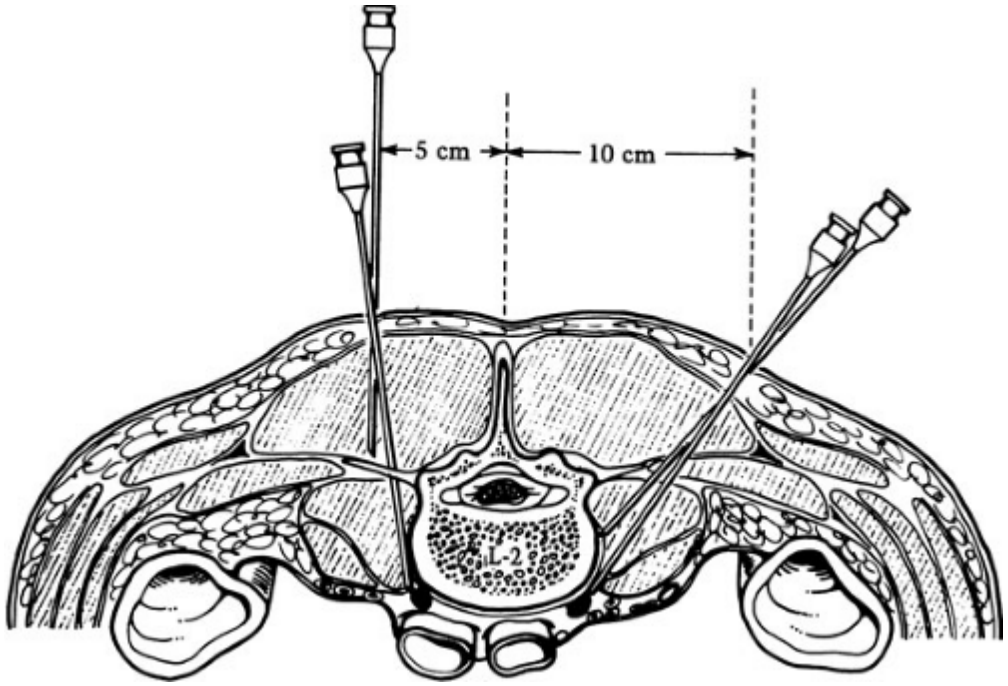

FIGURE 26-31. Popliteal fossa blockade, needle direction. The needle is inserted at the point described in Figure 26-32 and angled 45 degrees cephalad. The nerves usually are contacted halfway between the skin and the femur. This approach is suitable for single injection or catheter insertion. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Lateral Approach. An alternative approach to the block of the popliteal fossa is from the lateral side while the patient is lying supine.

1. On the lateral side of the knee, the groove between the biceps femoris tendon and the vastus lateralis muscle is identified and marked. An "X" is placed 7 cm cephalad to the lateral femoral epicondyle.
2. A 22-gauge, 10-cm needle is inserted at this mark at a horizontal plane. The shaft of the femur is usually contacted within about 5 cm. The needle is then redirected 30 degrees posteriorly to search for the sciatic nerve or its divisions at approximately the same depth of the femur. A response to nerve stimulation in the foot (toe movement is particularly helpful) identifies the nerve, usually the common peroneal nerve that lies laterally. A second nerve response of the tibial nerve may be sought. Ten to 15 mL of anesthesia injected around each nerve provides adequate anesthesia.

Ankle Blockade

All the nerves of the foot can be blocked at the level of the ankle. Although this approach is ideal in producing the least amount of immobility of the lower extremity, it is technically more difficult because at least five nerves must be anesthetized (Fig. 26-32). Several of these nerves can be blocked by simple infiltration of a "wall" of anesthesia, but increased reliability can be produced by seeking paresthesias of the major branches. If paresthesias are not sought, this blockade may

less time-consuming than other techniques, even though five separate injections are required. The procedure for blockade follows:

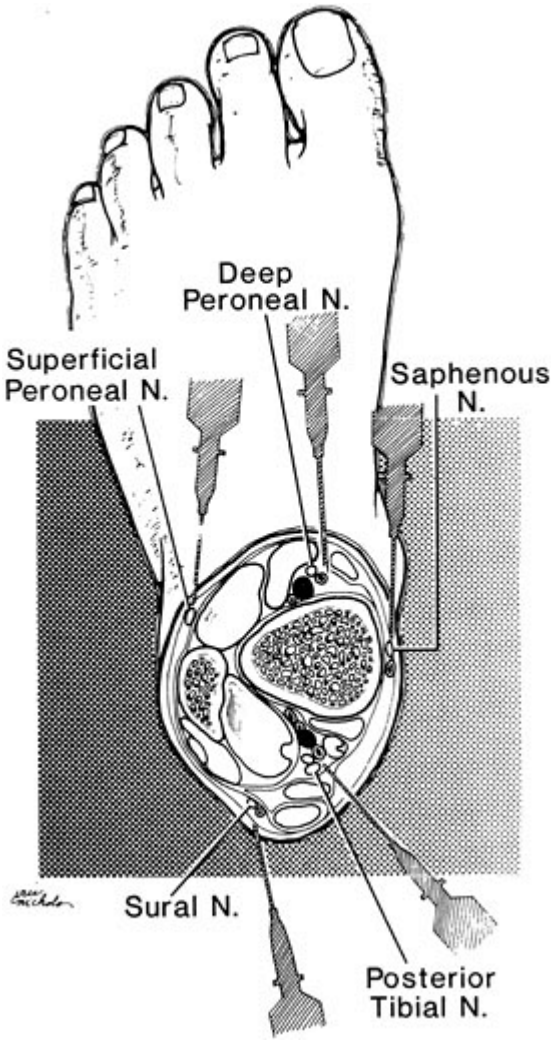

FIGURE 26-32. Ankle blockade. Injections are made at five separate nerve locations. The superficial peroneal nerve, sural nerve, and saphenous nerve are usually blocked simply by subcutaneous infiltration because they may have already generated many superficial branches as they cross the ankle joint. Paresthesias can be sought in the posterior tibial or the deep peroneal nerve, but the bony landmarks usually suffice to provide adequate localization for the deeper injections. (Reproduced with permission from Mulroy M: Handbook of Regional Anesthesia. Philadelphia, Lippincott Williams & Wilkins, 2002.)

1. Posterior tibial nerve. The posterior tibial nerve is the major nerve to the sole of the foot. It can be approached with the patient either in the prone position or with the hip and knee flexed so that the foot rests on the bed. The medial malleolus is identified, along with the pulsation of the posterior tibial artery behind it. A needle is introduced through the skin just behind the posterior tibial artery and directed 45 degrees anteriorly, seeking a paresthesia in the sole of the foot. Five milliliter of a local anesthetic produce anesthesia if a paresthesia is identified. If not, a fan-shaped injection of 10 mL can be performed in the triangle formed by the artery, the Achilles tendon, and the tibia itself.
2. Sural nerve. With the foot in the same position, the other posterior nerve of the ankle can be blocked by injection on the lateral side. The subcutaneous injection of a ridge of

anesthesia behind the lateral malleolus, filling the groove between it and the calcaneus, produces anesthesia of the sural nerve. This will require another 5 mL of local anesthetic.

3. Saphenous nerve. The last three branches of the ankle lie anteriorly. The patient is either turned supine, or the leg can now be extended so that the anesthesiologist's attention is turned to the anterior surface. The saphenous nerve is anesthetized by infiltrating 5 mL of local anesthetic around the saphenous vein at the level where this vein passes anterior to the medial malleolus. A wall of anesthesia between the skin and the bone itself suffices to block the nerve.
4. Deep peroneal nerve. This is the major nerve to the dorsum of the foot and lies in the deep plane of the anterior tibial artery. Pulsation of the artery is sought at the level of the skin crease on the anterior midline surface of the ankle. If it can be felt, 5 mL of local anesthetic is injected just lateral to this. If the artery is not palpable, the tendon of the extensor hallucis longus can be identified by asking the patient to extend the big toe. Injection can be made into the deep planes below the fascia using either one of these landmarks.
5. Superficial peroneal branches. Finally, a subcutaneous ridge of anesthetic solution is laid along the skin crease between the anterior tibial artery and the lateral malleolus. This subcutaneous ridge overlies the previous subfascial injection for the deep peroneal nerve. Another 5 to 10 mL of local anesthetic may be required to cover this area.

Anesthesia of the foot should ensue within 15 minutes after performance of these five injections. Complications of this blockade are rare, although neuropathy can be produced. Care should be taken not to pin any of the deep nerves against the bone at the time of injection, and intraneural injection should be avoided as usual.

James E. Cottrell

KEY POINTS

1	The intracranial compartment has a fixed volume. Increases in the volume of the brain, the blood, or the cerebral spinal fluid can lead to an increase in intracranial pressure; this may compromise blood flow or cause the brain to herniate.
2	Hypoxia and ischemia lead to neuronal death. With severe insults the neurons die of necrosis, which leads to inflammation and extensive damage to other neurons in the area; after less severe insults, neurons may be damaged so they cannot function properly and die of a regulated cell death process called apoptosis, which does not injure adjacent neurons.
3	Both intravenous and volatile anesthetic agents reduce brain metabolism. It is the balance of this effect with blood flow, because of flow metabolism coupling, that determines the extent of the increase or decrease in cerebral blood flow with a particular anesthetic agent.
4	Cerebral preconditioning and augmentation of endogenous processes of repair, including both neurogenesis and diaschisis, are promising approaches to cerebral protection.
5	Until and unless the deleterious effects of mild hypothermia can be reduced, or the brain can be cooled without reducing systemic temperature below 35°C, clinical evidence does not support induction of intra-operative mild hypothermia for neurosurgical procedures.
6	Current evidence cautions against the use of prophylactic etomidate prior to temporary vessel occlusion, magnesium loading in ischemic stroke patients, intra-operative nitrous oxide and ketamine, intra-operative moderate hypothermia in subarachnoid hemorrhage (SAH) patients, postoperative nimodipine and tirilazad, and postoperative hypothermia in head trauma

	patients.
7	Electrophysiologic and cerebral oxygenation/metabolism monitors are used perioperatively to assess cerebral function and pharmacologic interventions and to detect cerebral ischemia.
8	Image-guided neurosurgical procedures are used for diagnosis, three-dimensional localization, and resection of intracranial lesions.
9	The administration of anesthesia to neurosurgical patients requires an understanding of the basic principles of neurophysiology and the effects of anesthetic agents on intracranial dynamics.
10	Neuroanesthetic management of patients with supratentorial disease maximizes therapeutic modalities that reduce intracranial pressure.
11	Because of the relatively confined space within the posterior fossa, the challenge of infratentorial surgery is to prevent further neurologic damage from surgical position and exploration.
12	The anesthetic goals for intracranial aneurysm surgery are to avoid aneurysm rupture, maintain cerebral perfusion pressure and transmural aneurysm pressure, and provide a "slack" brain.
13	With more extensive arteriovenous malformations, hypothermia and high-dose barbiturates have been recommended for brain protection. Induced hypotension may also be required to reduce lesion size and blood flow.
14	Severe intracranial hypertension can precipitate reflex arterial hypertension and bradycardia (Cushing's triad). A reduction in systemic blood pressure in these patients can further aggravate cerebral ischemia by reducing cerebral perfusion pressure.

NEUROPHYSIOLOGY AND NEUROANESTHESIA

To understand how anesthetics act on the nervous system and how these actions may affect the practice of neuroanesthesia, one first needs to understand the basic principles of neurobiology. The following description of cellular neurophysiology provides background information only; greater detail may be sought elsewhere.[1]

Membrane Potentials

Neurons have an electrical potential across their cell membrane owing to different intra- and extracellular ion concentrations. These concentration differences lead to an opposing voltage called the *equilibrium potential.* Sodium (Na) and potassium (K) are the main ions responsible for membrane potentials in neurons. The equilibrium potential for K (E_K) is approximately -90 mV and for Na (E_{Na}) +45 mV. An ion's contribution to the membrane potential of a neuron is determined by

its conductance, which is proportional to the membrane's permeability for that ion. Because the conductance to potassium (g_K) is much higher than the sodium conductance (g_{Na}) in an unexcited neuron, the resting membrane potential (approximately -60 mV) is nearer to the potassium equilibrium potential (-90 mV) than the sodium equilibrium potential (+45 mV).

The conductance of ions across the cell membrane is through channels, which are proteins that span the membrane; gates open and close these channels. During rest, most of the sodium channels have their gates closed, whereas more potassium channels have gates in the open position. That is why there is a greater conductance to K in resting neurons.

Neurons transmit signals over long distances by propagating action potentials, which are rapid depolarizations of the membrane, along their axons. The action potential is caused by a rapid increase in the sodium conductance (because of the opening of the sodium activation gate) and a slower increase in the potassium conductance. These conductance changes are triggered by a depolarization of the cell membrane, and therefore the channels that open in response to the depolarization are described as voltage-sensitive channels. When the neuron depolarizes past a threshold voltage level, an action potential is generated. The peak voltage of the action potential is approximately +20 mV; this level is attained because, at the peak, the sodium conductance is much greater than the potassium conductance. The voltage during the action potential returns rapidly to resting levels (repolarizes) because the sodium conductance shuts itself off by closing a second gate (inactivation gate) in the channel, and the potassium conductance increases as a result of the opening of potassium channels.

Synaptic Transmission

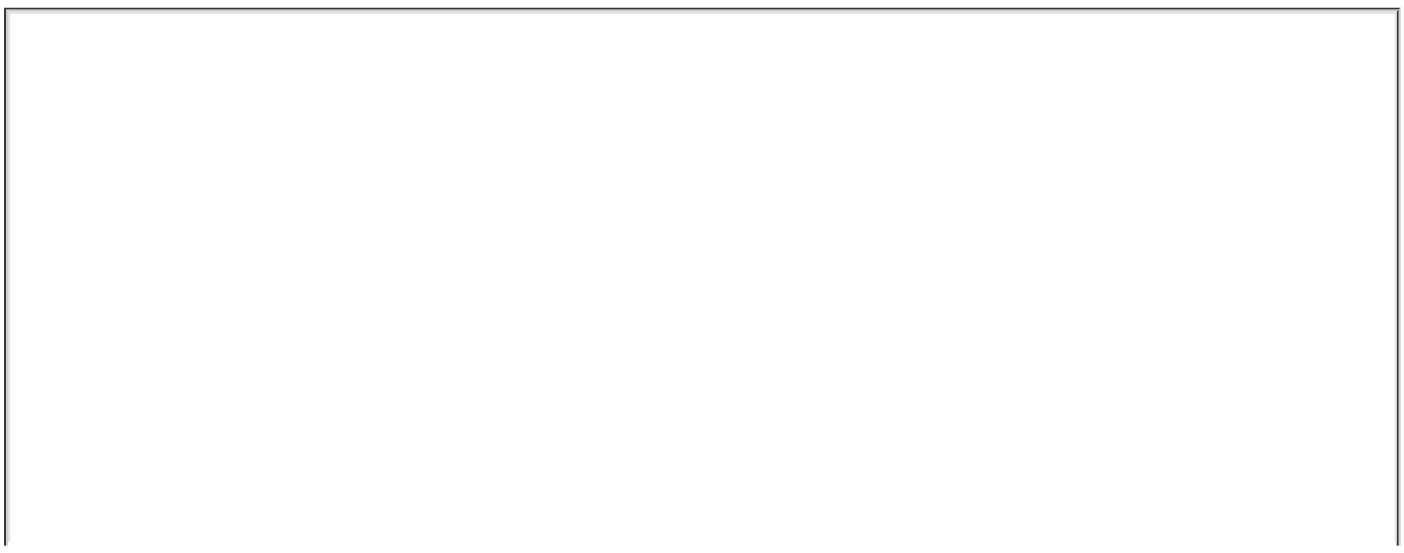
Neurons communicate using chemical synapses. The chemical, called a transmitter, is released from the presynaptic neuron, diffuses across the synaptic cleft, and combines with a receptor molecule on the postsynaptic neuron. The release of the neurotransmitter is initiated by an action potential traveling down the axon of the presynaptic neuron, causing the depolarization of the presynaptic terminal. This depolarization leads to the opening of voltage-dependent calcium channels and the entry of calcium from the extracellular fluid into the terminal. Vesicles containing the neurotransmitter then fuse with the terminal membrane, releasing the neurotransmitter into the synaptic cleft. The combination of the neurotransmitter with its receptor located on the postsynaptic cell alters ion channels associated with the receptor. These channels are described as ligand-gated channels. The opening of these ion channels leads to a change in the membrane potential of the postsynaptic neuron. If the transmitter is excitatory, this postsynaptic neuron is depolarized and therefore is more likely to generate an action potential. If the transmitter is inhibitory, the neuron is hyperpolarized and is less likely to generate an action potential.

In addition to opening ion channels, neurotransmitters work through intracellular second messengers. One example of a second messenger is cyclic cAMP, which activates protein kinases to phosphorylate proteins and changes their activity. Ion channels may be phosphorylated, which may change their conductance. A group of proteins that bind guanosine triphosphate, called G proteins, are activated when a transmitter binds to a specific receptor molecule. In some cases these G proteins activate ion channels directly, but in other cases they can either stimulate (G_s) or inhibit (G_i) adenylate cyclase, the enzyme that converts adenosine triphosphate (ATP) into cyclic AMP. G proteins can also activate the phosphatidylinositol second-messenger system; in this case, a transmitter binds to a receptor, which causes another G protein (G_p) to activate phospholipase C. This membrane-bound enzyme breaks down a membrane phospholipid into diacylglycerol and inositol trisphosphate, both of which are second messengers. Diacylglycerol activates protein kinase C, which will then phosphorylate other proteins, whereas inositol trisphosphate increases cytosolic calcium by releasing it from intracellular stores (endoplasmic reticulum).

There are many neurotransmitters in the brain. In this chapter two common neurotransmitters and their receptors are examined.

γ-Aminobutyric acid (GABA) is a major inhibitory amino acid transmitter that is active throughout

the brain and reduces the excitability of neurons by hyperpolarizing them. There are two major GABA receptors. Activation of the $GABA_A$ receptor opens chloride channels; this activity is enhanced by benzodiazepines and barbiturates. The $GABA_B$ receptor acts via a second messenger to open potassium channels, but does not affect chloride channels.[2] The response to $GABA_B$ receptor activation has a slower onset and a more prolonged activation than the response to the $GABA_A$ receptor. Both receptors may be present on the same neuron, providing a mechanism for rapid and prolonged inhibition.



Glutamate is the major excitatory transmitter in the brain. Its activation depolarizes neurons, making it more likely that they will fire action potentials. There are three main inotropic

glutamate receptors, which have been named for their preferential pharmacologic agonists. Most of the AMPA and kainate receptors allow sodium and potassium but not calcium through their channels.[3] These channels are responsible for the normal excitatory responses seen with glutamate. The third glutamate receptor, the *N*-methyl-D-aspartate receptor (NMDA), is activated when neurons are depolarized; the channels associated with this receptor are not opened by glutamate at normal resting membrane potentials. These channels allow passage of calcium as well as sodium and potassium. NMDA receptor activation is important in changing a neuron's excitability over a period of hours and days (long-term potentiation); this has been correlated with learning in animals.[3] Glutamate receptors have also been associated with neuronal injury after ischemia and anoxia. In addition to inotropic effects, glutamate activates metabotropic receptors, which act via a second messenger. Inositol trisphosphate, a second messenger, releases calcium from intracellular stores; this can affect the excitability of the neuron.

The information here is a simple description of how synapses operate to convey information from one neuron to another. This process is finely controlled; there are neurotransmitters that act on presynaptic terminals to regulate the amount of transmitter the terminal releases. There are compounds called *neuromodulators* that, when applied to a neuron alone, have no observable effect on the excitability of that neuron but alter the effect of other excitatory or inhibitory inputs to that neuron.

Brain Metabolism

The main substance used for energy production in the brain is glucose.[4] When oxygen levels are sufficient, glucose is metabolized to pyruvate in the glycolytic pathway (Fig. 27-1). This biochemical process generates ATP from adenosine diphosphate and inorganic phosphate and produces the reduced form of nicotinamide adeninedinucleotide (NADH) from nicotinamide adenine dinucleotide (NAD). Pyruvate from this reaction then enters the citric acid cycle, which, with regard to energy production, primarily generates NADH from NAD. The mitochondria use oxygen to couple the conversion of NADH back to NAD with the production of ATP from ADP and inorganic phosphate. This process, called *oxidative phosphorylation*, forms three ATP molecules for each NADH converted. The process of aerobic metabolism yields 38 ATP molecules for each glucose molecule metabolized.

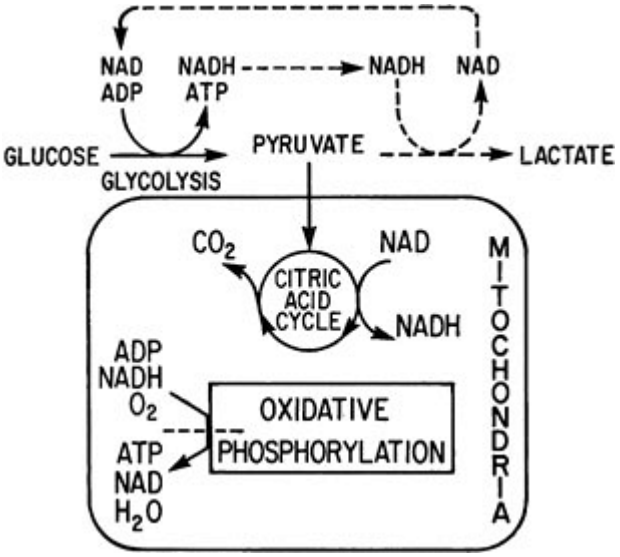


FIGURE 27-1. Energy metabolism in the brain. *Dotted lines* indicate reactions that occur during ischemia. The *dotted line* across the oxidative phosphorylation reaction indicates that this reaction is blocked during ischemia.

This pathway requires oxygen; if oxygen is not present, the mitochondria can neither make ATP nor regenerate NAD from NADH. The metabolism of glucose requires NAD as a cofactor and is blocked in its absence. Thus, in the absence of oxygen, glycolysis proceeds by a modified pathway termed *anaerobic glycolysis*; this modification involves the conversion of pyruvate to lactate, regenerating NAD. There is a net hydrogen ion production, which lowers the intracellular pH. A major problem with anaerobic glycolysis, in addition to lowering pH, is that only two molecules of ATP are formed for each molecule of glucose metabolized. This level of ATP production is insufficient to meet the brain's energy needs.

When the oxygen supply to a neuron is reduced, mechanisms that reduce and/or slow the fall in ATP levels include: (1) the utilization of phosphocreatine stores (a high-energy phosphate that can donate its energy to maintain ATP levels), (2) the production of ATP at low levels by anaerobic glycolysis, and (3) a rapid cessation of spontaneous electrophysiologic activity.

Pumping ions across the cell membrane is the largest energy requirement in the brain (Table 27-1). The sodium, potassium, and calcium concentrations of a neuron are maintained against large electrochemical differences with respect to the outside of the cell. When a neuron is not excited (firing action potentials), there is a slow leak of potassium out of the cells and of sodium into the cells. Neuronal activity markedly increases the flow of potassium, sodium, and calcium; this increases the rate of ion pumping required to maintain the neuron's ion concentration. Because ion pumping uses ATP as an energy source, the ATP requirement of active neurons is greater than that for resting neurons. If energy production does not meet the demand of energy use in the brain, the neurons first become unexcitable and then are irreversibly damaged.[5,6]

TABLE 27-1 Cellular Processes That Require Energy

Intracellular signaling
Metabolism of DNA, RNA, proteins, lipids, carbohydrates, and other molecules
Transporting of molecules within cells and across the cell membrane
Pumping ions across membranes to maintain ion gradients
Synaptic transmission

Neuronal plasticity (structural and biochemical changes)

Neurons require energy to maintain their structure and internal function. The cell's membranes, internal organelles, and cytoplasm are made of carbohydrates, lipids, and proteins, which require energy for their synthesis. Ion channels, enzymes, and structural components are important protein molecules that are continuously formed, modified, and broken down in the cell. If ATP is not available, protein synthesis cannot continue and the neuron will die. Carbohydrates and lipids are also continuously synthesized and degraded in normally functioning neurons; their metabolism also requires energy. Most cellular synthesis takes place in the cell body; thus, energy is required for the transport of components down the axon to the nerve terminal. The importance of this transport is illustrated by the death of the distal end of an axon when it is severed from its cell body. Thus, energy is required to maintain the integrity of neurons even in the absence of electrophysiologic activity.

The overall metabolic rate for the brain of a young adult man (mean age, 21 years) is 3.5 mL O_2/min/100 g brain tissue or 5.5 mg glucose/min/100 g.[4] This rate is virtually the same in elderly men (mean age, 71 years). Children (mean age, 6 years) have a markedly higher metabolic rate of 5.2 mL O_2/min/100 g brain tissue. Although the reasons for this high metabolic rate are unknown, it may reflect extra energy requirements for the growth and development of the nervous system.[4]

Cerebral Blood Flow

The brain receives approximately 15% of cardiac output, yet makes up only 2% of total body weight.[4] The disproportionately large blood flow is a result of the high metabolic rate of the brain. Global blood flow and metabolic rate remain fairly stable. Regional blood flow and metabolic rate of the brain can change dramatically; when metabolic rate goes up in a region of the brain, the blood flow to that region also increases. The mechanism of this coupling of blood flow and metabolism is not known; however, an increase in either potassium or hydrogen ion concentrations in the extracellular fluid surrounding arterioles may lead to dilatation and increased flow. Other agents that may mediate the coupling are calcium, adenosine, nitric oxide, and the eicosanoids (e.g., prostaglandins).[5] None of these mechanisms need be exclusive, and more than one or all of them may contribute to this exquisite coupling of flow and metabolism.

Increasing carbon dioxide level causes vasodilatation and increased blood flow (Fig. 27-2). Increasing the carbon dioxide tension from 40 to 80 mmHg doubles the flow; reducing the carbon dioxide from 40 to 20 mmHg halves the flow.[7,8] These changes are transient, and blood flow returns to normal in 6 to 8 hours, even if the altered carbon dioxide levels are maintained. These effects may be related to the hydrogen ion concentration. High carbon dioxide levels increase the extracellular hydrogen ion concentration and blood flow, whereas low carbon dioxide levels decrease the extracellular hydrogen ion concentration and reduce blood flow. The bicarbonate concentration in the extracellular fluid of the brain adjusts, bringing the pH back to normal, even

though the carbon dioxide levels remain altered.[9] This has important clinical implications in patients hyperventilated for prolonged periods. If normocarbia is rapidly reestablished, brain interstitial fluid pH will decrease and cerebral blood flow (CBF) will increase dramatically, perhaps increasing intracranial pressure (ICP).

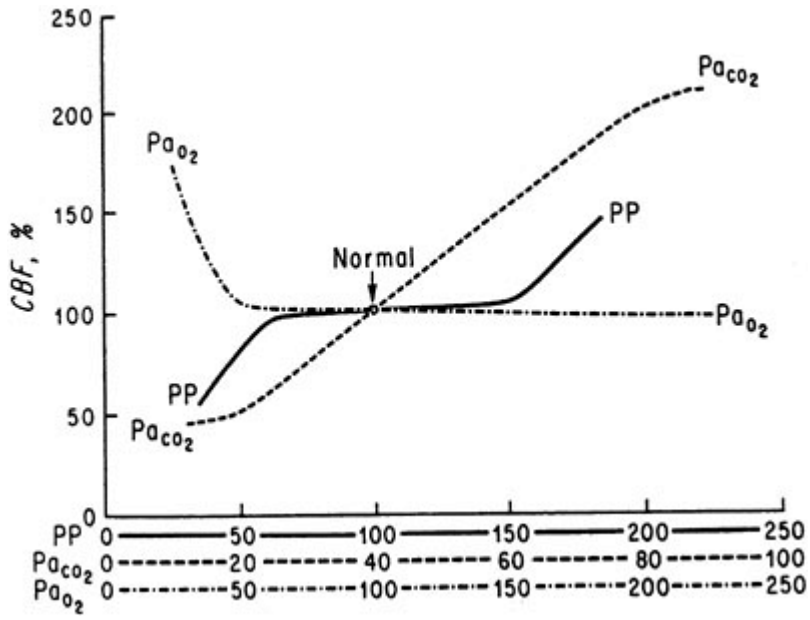

FIGURE 27-2. The effect of perfusion pressure (PP), arterial carbon dioxide pressure ($PaCO_2$), and arterial oxygen pressure (PaO_2) on cerebral blood flow. Each parameter on the abscissa is varied independently while the other parameters are held at their normal levels. (Reprinted with permission from Michenfelder JD: Anesthesia and the Brain, pp 6, 94–113. New York, Churchill Livingstone, 1988.)

If a patient is hypoventilated, carbon dioxide increases, pH decreases, and blood flow increases throughout the brain. The arterioles could become maximally dilated throughout the brain, impeding the ability to direct flow to areas of high metabolic demand. Thus, this luxury flow caused by high carbon dioxide levels throughout the brain could "steal" blood flow from areas that require extra oxygen and produce metabolites. This is particularly important during focal ischemia with the blockage of an intracerebral artery. The vessels supplying collateral flow to the area of the blocked artery would already be maximally dilated because of the metabolic demands of the ischemic tissue, and high Pa_{CO2} would cause blood flow to be shunted away to areas of less demand. The blood flow to the brain can be manipulated to advantage during focal ischemia. Reducing carbon dioxide with hyperventilation or reducing metabolism with agents such as thiopental would reduce blood flow to most areas of the brain, and the vessels in the ischemic area would be maximally dilated because of low pH. These manipulations, which are sometimes called *inverse steal*, could have the effect of maximizing blood flow to compromised areas.[10] The clinical relevance of flow redistribution because of hypocarbia has been questioned.[11]

The CBF autoregulates with respect to pressure changes. In normotensive individuals, mean arterial pressure (MAP) can vary from 50 to 150 mmHg and CBF will be maintained constant because of an adjustment of the cerebral vascular resistance (see Fig. 27-2). This phenomenon is a myogenic response of the arterioles because of their ability to constrict in response to an increased distending pressure. This response takes a few minutes to develop; therefore, after a rapid increase in MAP, there is a short period (about 1 to 3 minutes) of increased blood flow.[12] If mean blood pressure falls below 50 mmHg, CBF is reduced; at a pressure of 40 mmHg, mild symptoms of cerebral ischemia occur.[12] Patients who are hypertensive demonstrate a shift of autoregulation to a higher blood pressure. Their lower limit of autoregulation could be well above 50 mmHg; their upper limit of autoregulation is also increased. This shift, a result of hypertrophy

of the vessel wall, takes 1 or 2 months to become established.[13]Autoregulation can be abolished by trauma, hypoxia, and certain anesthetic and adjuvant anesthetic drugs. When blood pressure exceeds the autoregulated range, it can cause a disruption of the blood-brain barrier and cerebral edema.

The cerebral vasculature is also regulated by neurogenic factors that seem to have their greatest influence on the larger cerebral vessels. They control flow to large areas of the brain and play less of a role in the regulation of local CBF.[12] The innervation includes cholinergic, adrenergic, and serotonergic systems. Sympathetic activation leads to increased MAP and shifts the autoregulatory curve to the right, increasing the pressure at which the breakthrough of autoregulation occurs.[13]

Cerebrospinal Fluid

The neurons in the brain are exquisitely sensitive to changes in their environment. Small alterations in extracellular ion levels can profoundly alter neuronal activity. Substances that circulate in the blood, such as catecholamines, if not sequestered from direct contact with the brain, might also disrupt brain function. Thus the composition of the fluid surrounding the

brain is tightly regulated and distinct from extracellular fluid in the rest of the body (Table 27-2).[14] There are two barriers, the blood-brain barrier and the blood-cerebrospinal fluid barrier, that maintain the difference between blood and cerebrospinal fluid (CSF) composition.

TABLE 27-2 Composition of cerebrospinal fluid and serum in man

	·CSF	·SERUM
Sodium (mEq/l)	141	140
Potassium (mEq/l)	2.9	4.6
Calcium (mEq/l)	2.5	5.0
Magnesium (mEq/l)	2.4	1.7
Chloride (mEq/l)	124	101
Bicarbonate (mEq/l)	21	23
Glucose (mg/100 mL)	61	92
Protein (mg/100 mL)	28	7,000
pH	7.31	7.41
Osmolality (mOsm/kg H_2O)	289	289

(eds): Anesthesia and Neurosurgery, p 95. St Louis, CV Mosby, 1994.

Brain capillary endothelial cells (the blood-brain barrier) have tight junctions that prevent extracellular passage of substances between the endothelial cells. They also have a low level of pinocytotic activity, which reduces the transport of large molecules across the cells. Processes of astrocyte glial cells are interposed between the neurons of the brain and the capillaries. The functional importance of the astrocytes to the blood-brain barrier is currently unknown; however, they are located wherever the blood-brain barrier is present and appear to be necessary for the development and perhaps the maintenance of the barrier. The blood-brain barrier impedes the flow of ions such as potassium, calcium, magnesium, and sodium; polar molecules such as glucose, amino acids, and mannitol; and macromolecules such as proteins.[14] Lipid-soluble compounds, water, and gases such as carbon dioxide, oxygen, and volatile anesthetics pass rapidly through the blood-brain barrier. Many substances that do not cross the blood-brain barrier are required for brain function; these substances are transported across the capillary endothelial cell by carrier-mediated processes. These processes consist of either active transport, which requires the expenditure of energy, or passive transport, which does not. Passive transport, also referred to as *facilitated diffusion*, can move molecules into the brain only if their concentration in the blood is higher than their concentration in the brain. Glucose is an example of a molecule that enters the brain by passive transport. All of these transport processes have a limited capacity. The blood-brain barrier can become disrupted by acute hypertension, osmotic shock, disease, tumor, trauma, irradiation, and ischemia.

Cerebrospinal fluid is primarily formed in the choroid plexus of the cerebral ventricles. The capillaries of the choroid plexus have fenestrations and intercellular gaps that allow free movement of molecules across the endothelial cells; however, they are surrounded by choroid plexus epithelial cells, which have tight junctions and form the basis of the blood-CSF barrier. It is these cells that secrete the CSF. The CSF volume in the brain is between 100 and 150 mL; it is formed and reabsorbed at a rate of 0.3 to 0.4 mL/min. This allows a complete replacement of the CSF volume three or four times a day. The blood-CSF barrier is similar to the blood-brain barrier in that it allows the free movement of water, gases, and lipid-soluble compounds but requires carrier-mediated active or passive transport processes for glucose, amino acids, and ions. Proteins are largely excluded from the CSF. The CSF is primarily formed by the transport of sodium, chloride, and bicarbonate with the osmotic movement of water. Two clinically used substances that reduce CSF formation are furosemide, which inhibits the combined transport of sodium and chloride, and acetazolamide, which reduces bicarbonate transport by inhibiting carbonic anhydrase.[15] The CSF flows from the lateral ventricles to the third and fourth ventricles and then to the cisterna magna. It then flows around the brain and spinal cord in the cerebral and spinal subarachnoid space. The fluid in the subarachnoid space provides cushioning for the brain, reducing the effect of head trauma. The CSF is absorbed into the venous system of the brain by the villi in the arachnoid membrane. These arachnoid villi allow one-way flow of CSF from the subarachnoid space into the venous sinuses when CSF pressure is greater than the pressure in these sinuses. Owing to the high rate of CSF formation and its absorption into the venous system,

proteins and other matter released into the brain extracellular fluid are removed. If the foramina connecting the ventricles or the arachnoid villi are blocked, pressure builds and hydrocephalus develops.

Intracranial Pressure

1 The brain is enclosed in the cranium, which has a fixed volume; therefore, if any of the components located in the cranial vault increase in volume, the ICP will increase (Table 27-3). An increase in volume of one of these components can increase ICP and result in two major deleterious effects on the organism. The first is to reduce blood flow to the brain. The cerebral perfusion pressure (CPP) is determined by the MAP minus the ICP. If ICP increases to a greater extent than MAP, CPP is reduced. If ICP rises sufficiently, the brain can become ischemic. The second important effect of increased ICP is its ability to induce brain herniation. This herniation could be across the meninges, down the spinal canal, or through an opening in the skull. Herniation can rapidly lead to neurologic deterioration and death.

TABLE 27-3 The Three Major Components That Occupy Space in the Skull

The brain, which includes neurons and glia
The cerebrospinal fluid and extracellular fluid
The blood perfusing the brain

The ICP in humans is normally less than 10 mmHg. Under normal circumstances, a small increase in intracranial volume will not greatly increase ICP because of the elastance of the components located in the cranium (Fig. 27-3). After a certain point, however, the capacity of the system to adjust to increased volume is exceeded and even a small increase in volume will increase ICP.[16] Increases in ICP can be caused by the following: (1) increased CSF volume because of blockage of the circulation or absorption of the CSF, as described earlier; (2) increased blood volume from vasodilatation or hematoma; and (3) increased brain tissue volume caused by a tumor or edema.

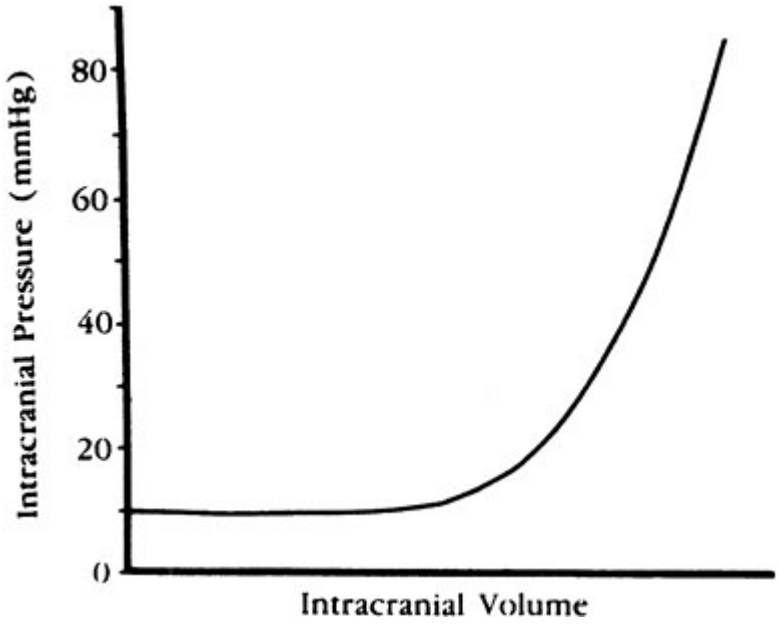

FIGURE 27-3. The effect of increasing volume on intracranial pressure. At first, as volume is increased, pressure does not increase, owing to the elastance of intracranial structures. This elastance is exceeded and then a small increase in volume can cause a large increase in intracranial pressure. (Modified from Miller JD, Garibi J, Pickard JD: The effects of induced changes of cerebrospinal fluid volume during continuous monitoring of ventricular pressure. Arch Neurol 28:265, 1973.)

Brain edema is typically classified as cytotoxic or vasogenic. The former is because of neuronal damage, which leads to increased sodium and water in the brain cells, and therefore an increase in intracellular volume. Vasogenic edema is caused by a breakdown of the blood-brain barrier and the movement

of protein from the blood into the brain's extracellular space. Water moves osmotically with the protein, increasing the extracellular fluid volume in the brain.

Pathophysiology

The brain is the organ most sensitive to ischemia; therefore, when the blood supply to the brain is limited, ischemic damage to neurons can occur.[17] To understand the rationale for treatments used to protect the brain against anoxic and ischemic damage, one needs an appreciation of the pathophysiologic mechanisms that may lead to this damage. The central event precipitating damage is reduced energy production because of blockage of oxidative phosphorylation. This causes ATP production per molecule of glucose to be reduced by 95%. At this rate of production, ATP levels fall, leading to the loss of energy-dependent homeostatic mechanisms. (Complete ischemia would block all ATP production.) The activity of ATP-dependent ion pumps is reduced and the intracellular levels of sodium and calcium increase, while intracellular potassium levels decrease (Fig. 27-4). These ion changes cause the neurons to depolarize and release excitatory amino acids such as glutamate. High levels of glutamate further depolarize the neurons and allow more calcium to enter through the NMDA receptor channel. The high intracellular calcium level is thought to trigger a number of events that could lead to the anoxic or ischemic damage. These include increasing the activity of proteases and phospholipases.[17] The latter would increase the levels of free fatty acids and free radicals. Free radicals are known to damage proteins and lipids, whereas free fatty acids interfere with membrane function. In addition, there is a buildup of lactate and hydrogen ions. All of these processes, coupled with the reduced ability to synthesize proteins and lipids because of the reduced ATP levels, may lead to irreversible damage with

ischemia. In addition, phospholipase activation leads to the production of excess arachidonic acid, which, on reoxygenation, can form eicosanoids, including thromboxane, prostaglandins, and leukotrienes. Thromboxane can cause intense vasoconstriction and reduced blood flow in the postischemic period, while leukotrienes can increase edema. Thus, procedures that may protect against ischemia should interfere with these damaging mechanisms (Table 27-4). Specific agents that might accomplish these objectives are detailed in the section on brain protection later in the chapter.

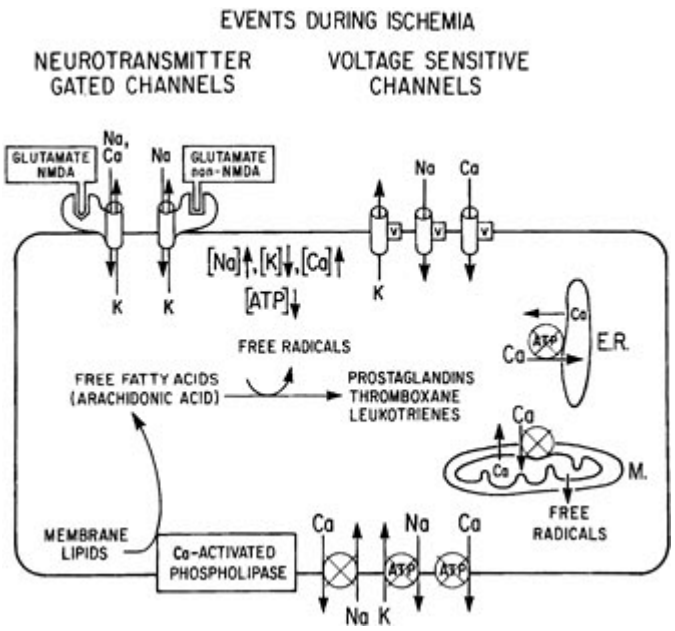

FIGURE 27-4. The effect of hypoxia or ischemia on ion and metabolite levels in neurons. For clarity, ion channels are shown on the top membrane and ion pumps on the bottom membrane; their actual location can be on any membrane surface. *Circles* indicate energy-driven pumps, and a *crossed-through circle* indicates that this pump is blocked or has reduced activity during ischemia. *V* indicates a voltage-dependent channel.

TABLE 27-4 Procedures That May Protect Against Ischemic Damage

Maintaining blood flow
Maintaining ATP levels by reducing the metabolic rate
Blocking sodium or calcium influx
Scavenging free radicals
Blocking the release of or receptors for excitatory amino acids
Inhibiting proteins that activate or contribute to damage (e.g., proteases, phospholipases, and some kinases)
Activating proteins that induce repair or rescue from apoptosis and necrosis (e.g., some kinases)

Ischemia can be either global or focal in nature; an example of the former would be cardiac arrest, of the latter, a localized stroke. The mechanisms leading to neuronal damage are probably similar for both, but there are important distinctions between the two. In focal ischemia there are

three regions. The first receives no blood flow and responds the same as globally ischemic tissue; the second, called the *penumbra*, receives collateral flow and is partially ischemic; the third is normally perfused. If the insult is maintained for a prolonged period, the neurons in the penumbra will die. More neurons in the penumbra will survive if collateral blood flow is increased. Mechanisms such as inverse steal (described in the Cerebral Blood Flow section) will enhance collateral blood flow, and hence neuron survival, in focal but not global ischemia.

Epileptic activity is sudden, excessive, and synchronous discharges of large numbers of neurons. Aside from those patients with established epilepsy, this massive increase in activity is seen

in patients with ionic and electrolyte imbalances, disorders of brain metabolism, infection, brain tumor, brain trauma, or elevated body temperature.[18] The electroencephalogram (EEG) shows spikes, which are rapid changes in voltage corresponding to excess activity in many neurons. During the epileptiform activity, sodium and calcium ions enter the cells and potassium leaves. Thus the cells use more energy (ATP) for ion pumping. High extracellular potassium may be responsible for the large and progressive depolarization of the neurons that is commonly found. The mechanisms that lead to permanent neuronal damage with epilepsy may be similar to those that damage cells during ischemia. Intracellular calcium levels rise, which may precipitate the damage. It is clear that during epileptiform activity the energy demand, and hence the cerebral metabolic rate (CMR) and blood flow, increases greatly. Thus, in conditions in which blood flow to the brain may be compromised, it is imperative to avoid excess brain activity. Anticonvulsant medications increase neuronal inhibition or reduce excitatory processes in the brain. Epileptic activity may be accompanied by systemic lactic acidosis, reduced arterial oxygenation, and increased carbon dioxide; therefore, it is important to maintain ventilation, oxygenation, and blood pressure. Prolonged or recurring epileptic activity can lead to profound brain damage.

Brain trauma can directly lead to permanent physical neuronal damage. Primary damage can also be caused by brain herniation or severing of blood vessels in the brain, resulting in direct ischemia. Reversal of the primary damage is not possible; however, much of the brain injury in trauma patients is secondary and occurs following the initial insult.[19] Calcium influx resulting from the trauma has been implicated as a trigger for the damage. It is important to prevent the secondary ischemia that frequently follows brain trauma and is possibly a result of the release of vasoconstrictive substances during reperfusion. In addition, hemorrhage may increase intracranial blood volume and ICP, reducing CPP. The intracranial blood can be damaging by directly promoting free-radical formation using the iron in hemoglobin. Secondary damage may be reduced with proper monitoring and treatment. Treatment includes reducing ICP, maintaining blood flow, reducing vasospasm, removing blood from the subarachnoid space, and perhaps using pharmacologic agents that interfere with the cascade of events that lead to neuron damage.

Brain tumors are expanding, space-occupying lesions that may significantly increase ICP and lead to reduced CPP or brain herniation. Frequently, the blood vessels supplying the tumor have a leaky blood-brain barrier, which may contribute to vasogenic brain edema and elevated ICP.

2 Thus, for several pathophysiologic events in the brain, ATP depletion; ionic imbalance (particularly high intracellular calcium levels); free-radical formation; and kinase, protease, and phospholipase activation have been implicated as triggers of neuronal damage. A common mechanism of neuronal cell death for various pathophysiologic events may exist. There are two major processes that lead to neuronal death. The first, necrosis, is characterized by a disintegration of the cell and an activation of microglia and the immune response.[20,21] The immune response and inflammation activates and recruits neutrophils and macrophages that produce free radicals and damage adjacent neurons. This expands the lesion in volume and time allowing for continued and expanded neuronal damage.[21] The second process, apoptosis or programmed cell death, involves an active process, which does not damage adjacent neurons.[20] Apoptosis uses a metabolic process that is normally used to kill off unneeded neurons. This process is responsible for the death of many neurons during development and can be reactivated when neurons are damaged subsequent to ischemia.[22] A severe insult, such as would be encountered in the core of an ischemic area, leads predominantly to necrosis, while less-compromised areas undergo a greater degree of apoptosis. The mitochondria, which produce ATP for the cell when oxygen is

available, are thought to be central to the initiation of apoptosis (Fig. 27-5). The release of a mitochondrial protein, cytochrome c, can initiate this process by leading to the activation of caspases that then cause the programmed cell death. The pathway of apoptosis is tightly regulated; some molecules, such as *bcl-2*, inhibit this process while other similar molecules, such as *bad* and *bax*, stimulate apoptosis.[23] Neurons can undergo apoptosis in the absence of ischemia. Neurons have receptors for trophic factors such as nerve growth factor, neurotrophins, and brain-derived growth factor. These factors activate receptors that phosphorylate tyrosine residues on certain proteins, thereby inhibiting apoptosis. If these growth factors are not present, the receptors are not activated and the proteins are not phosphorylated; then the neurons will undergo apoptosis. Indeed the loss of growth factors subsequent to neuronal degeneration after ischemia can exacerbate the delayed neuronal loss.

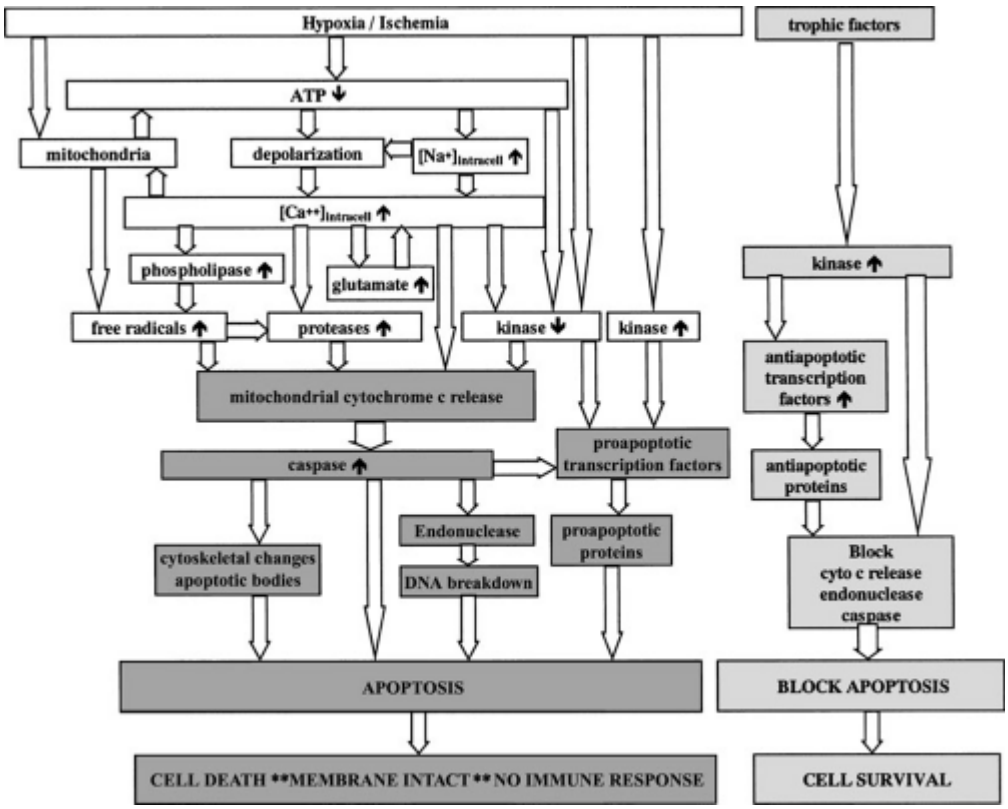

FIGURE 27-5. The effect of hypoxia or ischemia on cellular changes leading to apoptosis. The mitochondria are central to the activation of apoptosis, when hypoxic or ischemic triggers activate mitochondrial release of cytochrome c this leads to the activation of a caspase, which activates other caspases, endonucleases, and other proapoptotic proteins. This causes a cell suicide in which there is little damage to surrounding cells. Trophic factors can activate kinases that activate proteins that arrest apoptosis and can lead to cell survival. This is a complex pathway with control points that can either block or initiate cell death.

NEUROANESTHESIA

Effects of Anesthetics and Other Adjunctive Drugs on Brain Physiology

Volatile Anesthetics

3 Halothane, enflurane, sevoflurane, desflurane, and isoflurane have direct vasodilatory effects that increase CBF (Table 27-5). Halothane with nitrous oxide (1.5 minimal alveolar concentrations [MAC]) has been shown to increase blood flow almost 65%, whereas enflurane and

isoflurane have a lesser effect at equal anesthetic potency.[24] Enflurane increased blood flow approximately 35%; isoflurane caused an even smaller increase. The increase in CBF returns to baseline levels approximately 3 hours after the initial exposure to 1.3 MAC of anesthetic. Sevoflurane and desflurane appear similar to isoflurane with respect to CBF;[25,26] however, desflurane increases CBF to a greater and sevoflurane to a lesser extent than isoflurane.[27,28] Desflurane has been reported to impair autoregulation.[29] The importance of increased CBF is its influence on ICP. Increasing blood flow would tend to increase the amount of blood in the brain, which could lead to increases in ICP under conditions of abnormal intracranial elastance. In animal studies, sevoflurane demonstrated a smaller increase of ICP than isoflurane, while desflurane showed a larger increase; these differences disappeared with hyperventilation.[30] In any case if high ICP is a potential problem it is better to use an intravenous agent such as propofol since it does not have any direct vasodilatory effect.[31] The volatile anesthetics reduce the CMR; isoflurane reduces the metabolic rate to a greater extent than halothane. Sevoflurane reduces CMR to a similar extent as isoflurane.[32] It is thought that isoflurane's metabolic effect, which reduces CBF, competes with its direct vasodilatory action to limit the net increase in CBF with this agent. Enflurane has been shown to induce seizure-type discharges; this effect is potentiated by hypocapnia. Seizures induced with 1.5 MAC enflurane, hypocapnia, and an auditory stimulus increased CMR and blood flow by 50%.[33] The main advantage of desflurane over isoflurane is a faster onset and recovery from anesthesia. Studies have indicated that it can cause greater ICP increases than isoflurane in patients with altered intracranial elastance.[34] Therefore, it is not recommended for patients with space-occupying lesions. Desflurane has also been shown to cause sympathetic hyperactivity in healthy volunteers.[35] Sevoflurane has the potential for toxicity, since it can be converted to toxic agents; however, the concentration of these agents is normally below the toxic threshold. Sevoflurane has been shown to be a useful alternative to halothane for pediatric induction, however there are

reports of epileptiform discharges in patients given sevoflurane at induction doses (1.5 to 2 MAC).[36] Sevoflurane demonstrated cerebral protection during incomplete ischemia in rats when compared to fentanyl with nitrous oxide.[37] These considerations make sevoflurane and isoflurane the volatile anesthetics of choice for neuroanesthesia. However, both of these agents are vasodilators and have the potential to increase ICP under certain circumstances.[24]

TABLE 27-5 Effects of Anesthetics on CBF/$CMRO_2$

	·CBF	·$CMRO_2$	·DIRECT CEREBRAL VASODILATION
Halothane	↑ ↑ ↑	↓	Yes
Enflurane	↑ ↑	↓	Yes
Isoflurane	↑	↓ ↓	Yes
Desflurane	↑	↓ ↓	Yes
Sevoflurane	↑	↓ ↓	Yes
N_2O alone	↑	↑	—

N_2O with volatile anesthetics	↑ ↑	↑	—
N_2O with intravenous anesthetics	0	0	—
Thiopental	↓ ↓ ↓	↓ ↓ ↓	No
Etomidate	↓ ↓	↓ ↓	No
Propofol	↓ ↓	↓ ↓	No
Midazolam	↓	↓	No
Ketamine	↑ ↑	↑	No
Fentanyl	↓ /0	↓ /0	No

Nitrous oxide can increase CBF and ICP.[24,38] Barbiturates and hypocapnia in combination may prevent these increases. There are indications that, even when given independently, barbiturates, benzodiazepines, and morphine are effective in blunting nitrous oxide's effect on CBF and ICP. In contrast, a volatile anesthetic may add to the increases in CBF obtained with nitrous oxide. Although the data on nitrous oxide's effect on brain metabolism are far from unequivocal, the evidence seems to indicate that there can be a substantial increase in CMR if nitrous oxide is administered alone.[38] Although nitrous oxide is commonly used in neuroanesthesia, its use should be carefully considered given its potential effects on CBF, CMR, and ICP.[39]

Intravenous Anesthetics

Barbiturates decrease the CMR and CBF.[24] A major problem with barbiturates is that they can substantially reduce MAP, which, if not controlled, can reduce CPP. At high doses (10 to 55 mg/kg), thiopental can produce an isoelectric EEG and decrease the CMR by 50%.[40] This direct metabolic effect of thiopental leads to constriction of the cerebral vasculature and thereby reduces CBF. Barbiturates are also effective in reducing elevated ICP and controlling epileptiform activity. Methohexital is an exception with regard to epileptiform activity; it can activate some seizure foci in patients with temporal lobe epilepsy.[41]

Etomidate, like the barbiturates, reduces CMR and CBF.[24] In addition to the indirect effect of reduced cerebral metabolism on blood flow, etomidate is also a direct vasoconstrictor even

before metabolism is suppressed.[24] Its advantage over the barbiturates is that it does not produce clinically significant cardiovascular depression. Prolonged use of etomidate may suppress the adrenocortical response to stress.[42]

Propofol is a rapidly acting intravenous anesthetic that, like etomidate and the barbiturates, reduces the CMR and CBF.[24] It reduces the CMR to a similar extent as sevoflurane,[43] but since it does not increase cerebral blood flow it is able to reduce ICP. However, because it also reduces MAP, its effect on CPP must be carefully monitored.[44] Recent studies have shown a lower jugular bulb oxygen saturation during hyperventilation for patients undergoing propofol anesthesia when

compared to patients anesthetized with sevoflurane; thus care must be taken when hyperventilating patients anethetized with propofol.[45] Propofol demonstrated longer lasting ventilatory depression when compared with barbiturates.[46]

Benzodiazepines have been shown to reduce CMR and CBF;[24] however, this effect is not as pronounced as that with the barbiturates. As with the barbiturates, the blood flow reduction by benzodiazepines is thought to be secondary to a reduction in CMR. Benzodiazepines may reduce ICP owing to their effect on CBF. Flumazenil is a benzodiazepine antagonist that has been shown to reverse the CMR-, CBF-, and ICP-lowering effects of the benzodiazepine midazolam.[47] Thus, flumazenil should be used cautiously, if at all, in patients with high ICP or abnormal intracranial elastance.

The opioid anesthetics, morphine and fentanyl, cause either a minor reduction or no effect on CBF and CMR when compared with conditions in the unstimulated brain.[24] There is controversy concerning the effects of sufentanil: some studies demonstrate a reduction in CBF and metabolism,[48,49] whereas others report an increase in blood flow and ICP.[50] The duration of the increased blood flow and ICP effects of sufentanil in these earlier cited studies was short and could be overcome by hypocapnia. In animal studies, alfentanil decreased CBF and metabolism after 35 minutes and had no significant effect on ICP.[51] In patients with brain tumors, alfentanil increased CSF pressure.[52] Its effect on CSF pressure was less than that found with sufentanil but greater than that found with fentanyl. Alfentanil had the greatest effect on MAP and CPP.[50] Remifentanil, a rapidly metabolized opioid, had similar effects to fentanyl on CBF; both agents maintained CO_2 reactivity.[53] Remifentanil's main advantage is that it allows a more rapid neurologic assessment of the patient. Aside from the difference in recovery time, there appear to be only minor differences between the different opioid anesthetics.[54] Opioid anesthetics do not substantially suppress metabolism as does propofol; however, there was no difference in cognitive function following coronary artery bypass surgery comparing these two classes of anesthetics.[55]

Dexmedetomidine is an α-2 selective agonist that has analgesic and sedative effects. It is useful since the patient is sedated but cooperative.[56] Dexmedetomidine has been shown to reduce arousal and decrease cerebral blood flow.[57]

Ketamine, a dissociative anesthetic, activates certain areas in the brain and can increase CBF and CMR.[58,59] It is therefore not commonly used in neuroanesthesia.

Barbiturates, propofol, and benzodiazepines are intravenous agents recommended for neuroanesthesia; opioids, particularly fentanyl and remifentanil, have also proved useful.

BRAIN PROTECTION

Morbidity and mortality rates for elective neurosurgery are so low that detecting a decrease in mortality is virtually out of the question and daunting sample sizes would be required to detect less than a 30% improvement in major morbidity. Accordingly, inferences about cerebral protection are limited to those that we can draw from the laboratory, from clinical trials of therapies that are instituted subsequent to ischemic injury—primarily in stroke and head-trauma patients—and from the small number of clinical trials that test for prophylactic neuroprotection in neuro- and cardiac surgery.

Cerebral Preconditioning

Using the retina as a model for the CNS, Barbe and co-authors found that subjecting rats to heat shock (15 minutes at 41°C) protected neurons from high-intensity light damage if the rats were allowed to recover for 18 hours subsequent to heat exposure.[60] This phenomenon was soon replicated in a model of cerebral ischemia[61] and induction of endogenous proteins of repair, and the genes that code for them are now well documented.[62] Among the most intriguing recent genomic discoveries is Stenzel-Poore and colleagues' finding that ischemic preconditioning in a homeothermic mammal elicits "an evolutionarily conserved endogenous response to decreased blood flow and oxygen limitation such as seen during hibernation."[63]

Perhaps preconditioning will bring us closer to a vision articulated by James Cottrell more than a decade ago: "Much research has been directed toward enabling homeothermic mammals to gain the benefits of hypothermia without paying the costs, as do hibernators. If that research succeeds, we may eventually be able to provide brain protection during protracted periods of 'ischemic' CBF and even induce circulatory arrest in neurosurgical patients without going on bypass."[62]

Clinically acceptable means of accomplishing cerebral preconditioning are being sought. Experimental results suggest the possibility of preop hyperbaric oxygen, normobaric 100% oxygen exposure, electroconvulsive shock, and the potassium channel opener diazoxide among other candidates.[62] The first human trial of a cerebral preconditioning agent[64] employs a substance that is endogenously produced in the brain after hypoxic or ischemic insults—erythropoietin (EPO).

Although EPO is well characterized in its systemic role as a cytokine growth hormone that increases the production of erythrocytes by preventing their apoptotic self-destruction during differentiation, EPO's role in the brain has only recently been elucidated. EPO is produced in the adult mammalian brain primarily by astrocytes in the ischemic penumbra. EPO receptors (EPOr) are upregulated by neurons in the ischemic penumbra, and the EPO ->> EPOr interaction in these and other cerebral and cerebrovascular cell types has been reported to stimulate proteins of repair, diminish neuronal excitotoxicity, reduce inflammation, inhibit neuronal apoptosis, and stimulate both neurogenesis and angiogenesis subsequent to experimental ischemic, hypoxic, and toxic injury.[62]

Limiting their study to ischemic stroke patients whose treatment could begin within 8 hours of the onset of symptoms, Ehrenreich and co-authors found that intravenous injection of recombinant EPO once daily for 3 days led to 60- to 100-fold increases of EPO in the CNS, reduced serum concentrations of the glial marker of cerebral injury S100β, reduced infarct size, and improved recovery.[64] If these results hold up in a multicenter, randomized, controlled trial, there is reason to hope that EPO would be even more effective as a prophylactic protectant—because we might be able to harness EPO's preconditioning effects by initiating administration 24 to 48 hours prior to surgery, deliver EPO during surgery (often intraventricularly, which is particularly effective), and maintain administration in the neuro ICU.

Unfortunately, EPO has the attribute of increasing hematocrit—a potentially deleterious effect in the context of ischemic injury. Fortunately, nonhematopoietic analogues of EPO, such as asialoEPO, have been developed and are showing equivalent potency as neuroprotectants in the laboratory.

Neurogenesis and Diaschisis

4 The old adage that neurogenesis is only for the young has been shown to be wrong.[65] Activated neural stem cells contribute to stroke-induced neurogenesis and neuroblast migration toward the infarct boundary in adult rats[66] and therapy of stroke in rats with a nitric oxide donor and human bone marrow stromal cells enhances angiogenesis and neurogenesis subsequent to 2 hours of middle cerebral artery occlusion. This kind of evidence lends encouragement to the hypothesis that adult neurogenesis is functional and that "neural precursors resident in the brain initiate a compensatory response to stroke that results in the production of new neurons. Moreover, administration of growth factors can enhance this compensatory response… [and] we may eventually be able to manipulate these precursors to improve recovery of function in individuals afflicted by this devastating injury."[67]

At the other end of the ladder of repair, "Stroke produces an area of focal damage and distant areas of reduced blood flow and metabolism, termed *diaschisis*… diaschisis may be part of a process of structural reorganization after injury."[68] In other words, perhaps the brain is such a tightly integrated circuit that dysfunctional subcircuits add noise to the system and need to be removed to facilitate rewiring. Accordingly, we should be cautious, if not outright skeptical, of proposed therapies that nonselectively impede programmed cell death or *apoptosis*—that is, the prevailing assumption seems to be that all neuron death is bad, but this may be wrong.

Mild Hypothermia and Postoperative Fever

5 Laboratory results have demonstrated since 1956 that the beneficial attributes of mild hypothermia are likely to outweigh its real but manageable untoward effects when neurosurgical procedures are high risk and/or protracted. Berntman et al found that one degree of hypothermia (to 36°C) maintains ATP at normoxic levels during an hypoxic insult that depletes ATP by half at normothermia (37°C), and three degrees of hypothermia (to 34°C) more than doubled preservation of phosphocreatine.[69] These results suggest the possibility that the initial decline of CMR during hypothermia is greater than has been previously assumed.[70,71]

Unfortunately, the most current and definitive clinical trial of mild hypothermia has conclusively shown a failure to improve outcome after surgery for repair of a ruptured cerebral aneurysm. The Intraoperative Hypothermia for Intracranial Aneurysm Surgery Trial (IHAST) was completed in 2003. With 499 patients randomized to undergo aneurysm clipping at 33°C compared to 501 controls at 36.5°C, the study had ample power to detect a 10% increase in the frequency of good outcomes. Mild hypothermia was not beneficial.

Preliminary results for Intention-to-Treat analysis indicate that 66% of patients in the hypothermic group had a good outcome at 90 days versus 63% of patients in the normothermic group. Because people do not easily cool down as scheduled, only 373 of the 499 patients assigned to the hypothermic group actually reached a core temperature below 33.5°C, while 467 of the 501 normothermic patients maintained core temperature above 36°C.[72] In a planned secondary analysis of these patients who were within 0.5°C of their target temperature during aneurysm clipping, 62% of the hypothermic patients had a good outcome versus 63% of the normothermic patients. It is of interest to note that the warmer patients in the entire hypothermic group (>33.5°C, N = 126) had more good outcomes (77%) than the cooler patients (<33.5°C, N = 373) in the hypothermic group (62%) ($p<0.003$, two-way Fisher exact).[73] The only statistically significant intergroup difference in adverse outcomes was a higher incidence of bacteremia in the hypothermic group.

Why has so much laboratory evidence for a therapeutic benefit of mild hypothermia not been born out in aneurysm patients? It should be remembered that almost all of that evidence is from, or is analogous to, models of ischemic stroke, as distinct from hemorrhagic stroke, and the few hemorrhagic stroke models that do exist have applied hypothermia before, during, or within a few hours of the intracranial bleed—as distinct from several days postrupture. If there is any benefit of intraoperative mild hypothermia for hemorrhagic stroke patients, it may not be detectable because it is dwarfed by damage that precedes surgery (the initial bleed) and damage that occurs in the postsurgical ICU (vasospasm, etc.). The initial bleed may also activate functional diaschisis and postinjury repair mechanisms to which intra-operative mild hypothermia is not therapeutically additive.

The multi-institutional study of postoperative mild hypothermia in head-injury patients came to an even more discouraging conclusion—the study was terminated by its

Safety Monitoring Board after enrollment of 392 patients.[74] A decrease in the number of hypothermic patients with ICP >30 mmHg (59% vs. 41%) did not produce a difference in mortality (28% vs. 27% in the normothermic group) and normothermic patients experienced fewer bouts of critical bradycardia and hypotension, and fewer medical complications.

These findings accord well with results from a clinical study of the effect of prolonged mild hypothermia on electrolyte balance. Polderman and co-authors found that serum magnesium, phosphate, and potassium fell to critical levels "despite the fact that moderate and, in some cases, substantial doses of electrolyte supplementation were given."[75] More generally, some of the most competent laboratory studies indicate that hypothermia administered subsequent to an ischemic event only delays neuronal death, and other in vivo work suggests that if there is a window of opportunity for inducing protective post-ischemic hypothermia, it is very narrow.[62]

Indeed, the narrowness of that window may account for reports of neuroprotective effects from mild hypothermia after cardiac arrest. In both major studies,[76,77] most patients were mildly

hypothermic on admission, and it is reasonable to speculate that their brains began to cool as soon as they lost CBF. Patients assigned to the hypothermic groups were cooled further for 12 to 24 hours, while those assigned to the normothermic groups were passively warmed to normothermia or above over a 6- to 8-hour period, such that the hypothermic groups began to cool immediately and were kept cool for a substantial period of time while patients in the normothermic groups began to cool immediately but did not remain hypothermic for a substantial period of time. Put differently, both groups of patients became hypothermic within the window of opportunity, but the opportunity for a protective effect may have been lost too soon thereafter in the normothermic patients.

Evidence that this consideration might be critically important comes from the definitive head-injury study: "Among the patients who had normothermia on admission, the outcomes were similar in the two treatment groups….[But] among the patients who had hypothermia on admission and were treated with hypothermia, 61 percent had poor outcomes, as compared with 78 percent of those with hypothermia on admission who were in the normothermia group (P = 0.09)…[and] among patients 45 years of age or younger who had hypothermia on admission, 52 percent of those assigned to the hypothermia group had poor outcomes, as compared with 76 percent in the normothermia group (P = 0.02)."[74]

Until and unless the deleterious effects of mild hypothermia can be reduced, or the brain can be cooled without reducing systemic temperature below 35°C, clinical evidence does not support induction of perioperative hypothermia for neurosurgical procedures that do not entail circulatory bypass.

Nevertheless, fever in the neurosurgical or cardiac intensive care unit associates strongly with poor outcome.[62] In vitro results indicate that just as hypothermia preserves ATP, reduces CA^{2+} influx, and improves electrophysiologic recovery from hypoxia, so does hyperthermia deplete ATP, increase CA^{2+} influx, and impair recovery.[78,79] A potentially promising development in ICU temperature control is the concept of low normothermia—keeping nonventilated patients servo-controlled at 36°C in order to provide substantial assurance against bouts of fever.[80]

Anesthetic and Adjuvant Drugs

Clinically verified pharmacological brain protection is even more elusive than the benefits of mild hypothermia. Delayed neuronal necrosis, apoptosis, diaschisis, and neurogenesis can cause protection, which appears to be evident within 1 to 100 hours of experimental infarct, to vanish after 3 to 6 months. Accordingly, decades of laboratory research on the short-term cerebroprotective effects of general anesthetics, both inhalational and intravenous, is called into question by studies that have found no long-term differences.[81,82] Until and unless long-term laboratory studies suggest a difference in the neuroprotective efficacy of general anesthetics that are widely used for neurosurgery, clinical decisions about which anesthetic is most appropriate should be based on considerations other than potential to provide superior cerebral protection per se. Nevertheless, as with hypothermia, the search continues for the optimal anesthetic in subgroups of patients.

Barbiturates

As with mild hypothermia, reduction of CMR is a catch-all term that may or may not indicate cerebral protection. Although an intellectual backlash has challenged the operating hypothesis that lowering CMR has a substantial protective effect,[83] all known means of lowering CMR entail simultaneous negative effects, with the continuum of drugs, techniques, and toxins that reduce CMR ranging, on balance, from protective to damaging. Nakashima and co-authors found that for similar reductions of CMR obtained with hypothermia, pentobarbital, or isoflurane, hypothermia resulted in substantially longer times to depolarization of cerebral cortex subsequent to cardiac arrest.[84] Concomitantly, Verhaegen and co-authors found that hypothermia reduces CMR during ischemia proportionately more than does pentobarbital or isoflurane.[85]

Accordingly, we find mild hypothermia near the protective end of the continuum, followed at some distance by anesthetics (reversible neurotoxins), then moving to the damaging end, we find

nonreversible neurotoxins followed at some distance by blunt trauma—all of which lower cerebral metabolism. The point here is that the benefit of reducing CMR remains constant while the cost of doing so varies from minor to lethal. From this perspective it seems rash to challenge the efficacy of reducing CMR in and of itself.

Some of the proximate mechanisms by which barbiturates lower CMR include reduction of calcium influx, sodium channel blockade, inhibition of free-radical formation, potentiation of GABAergic activity, and inhibition of glucose transfer across the blood-brain barrier. All of these mechanisms are consistent with Goodman and co-authors' report that pentobarbital coma markedly reduces lactate, glutamate, and aspartate in the extracellular space of head-injured patients with severely increased ICP.[86] An in vitro investigation suggests that thiopental also delays the loss of transmembrane electrical gradients caused by application of NMDA and AMPA. This stands in marked contrast to the effect of propofol, which can aggravate glutamate excitotoxicity and increase neuronal damage.[87]

Sodium Channel Blockade—Lidocaine

Sodium influx is the first step in the ischemic cascade. Truncating initial steps of the cascade, as distinct from blocking glutamate receptors and scavenging free radicals, reduces damage done by downstream events and lowers the probability of interfering with endogenous mechanisms of repair. In addition to blocking sodium influx, lidocaine may also reduce postnecrotic injury. Recent in vivo data suggest that lidocaine truncates "ischemic damage in the penumbra by blocking the apoptotic cell death pathways that involve cytochrome C release and caspase-3 activation."[88] These appear to be some of the mechanisms by which experimental, prophylactic, low-dose lidocaine has demonstrated neuroprotective properties both in vitro[89,90] and in vivo.[91,92]

Looking for neuroprotection in cardiac valve patients, Mitchell and co-authors found that lidocaine infusion begun

at induction of anesthesia and continued for 48 hours with a target plasma concentration between 6 and 12 μmol/L increased scores in 6 of 11 neuropsychological tests and in patients' memory inventory.[93] Similar results were obtained by Wang and co-authors in coronary artery bypass patients,[94] but a third trial of lidocaine in cardiac patients failed to find a protective effect and found an adverse effect in diabetic patients.[95] Nevertheless, initial data presentation indicates a substantial positive effect in nondiabetic lidocaine patients compared to nondiabetic controls. An additional consideration is that these patients were maintained at 30 to 32°C during surgery—which cardiac colleagues tend to think of as not hypothermic—but which may provide a level of neuroprotection to which lidocaine is not additive.

Calcium Channel Blockade—Magnesium

Magnesium blocks both ligand and voltage dependant calcium entry, has shown considerable neuroprotection in animal experiments, and appears to neurologically protect preterm infants if administered to their mothers immediately before birth. The fact that magnesium is also powerfully protective in vitro[96] suggests that it may critically reduce calcium influx in addition to improving CBF subsequent to cerebrovascular dilation. Recent laboratory work indicates that magnesium deficiency exacerbates traumatic brain injury while magnesium loading shortly subsequent to trauma reduces injury. If the same holds for stroke patients, efficacy is most likely to be realized by the FAST-MAG (Field Administration of Stroke Treatment—Magnesium) trial. A preliminary report on the first 20 FAST-MAG patients indicates that paramedics can administer a 4 g loading dose of magnesium sulfate en route to the hospital without substantial complications.[97] In distinction, the long-awaited RCT of not-fast MgSO4 (within 12 hours of stroke) has shown rather conclusively (2,386 patients) that magnesium loading is not neuroprotective and may increase mortality in stroke patients.[98]

For reasons detailed earlier regarding intra-operative hypothermia in stroke patients, cardiac patients are probably a better model for testing the general neuroprotective efficacy of MgSO4. Unfortunately, however, a meta-analysis indicates that the only benefit of prophylactic magnesium

in cardiac surgery patients is a reduction in postsurgical atrial fibrillation.

Additional Clinical Trials—Remacemide and High-dose Mannitol

Remacemide reduces glutamate release, and so excitotoxicity, by blocking NMDA channels. Evidence for a prophylactic beneficial effect of this NMDA blocker was gleaned by combining scores from nine neuropsychological tests in coronary artery bypass patients. Those data allow the inference ($p<0.03$) that in exchange for a higher risk of dizziness during 9 days of drug administration, patients in the treatment group retained more of their ability to learn.[99]

"Comatose patients with severe diffuse brain swelling and recent clinical signs of impending brain death"[100] have a justifiably lower threshold for being subjected to experimental treatments. Cruz and colleagues reported dramatic success with administration of high-dose mannitol versus conventional-dose mannitol in such patients randomized in the emergency room to receive either 1.4 g/kg or 0.7 g/kg mannitol. "Ultra-early improvement of bilateral abnormal pupillary widening was significantly more frequent in the high-dose mannitol group than in the conventional-dose group" as was the number of patients with Good or Moderate (GOS) 6-month clinical outcomes (10 in the high-dose group versus 2 in the conventional-dose group, $p<0.02$). These stark results beg to be tested in a multinational randomized controlled trial.[101]

What to Avoid

As with postoperative mild hypothermia in head-injury patients (see earlier), evidence against some anesthetic and adjuvant drugs is stronger than the evidence in their favor.

Calcium Channel Blockers—Postoperative

Several clinical trials and two meta-analyses suggest that calcium channel blockers nimodipine, nicardipine, and AT877 reduce the frequency of vasospasm subsequent to subarachnoid hemorrhage and/or improve outcome.[102] The most favorable finding of the recent meta-analyses suggests that nimodipine improves outcome, on average, by preventing one poor outcome in 1 out of every 13 patients treated.[100] Whether the reduction in blood pressure that accompanies these Ca^{2+} blockers improves outcome relative to hypertensive, hypervolemic, hemodilution remains controversial. Neither meta-analysis was able to detect a statistically significant reduction in mortality. Two subsequently published clinical trials, one that administered nimodipine within 24 hours of acute stroke[103] and one that administered nimodipine within 6 hours of stroke,[104] failed to detect a beneficial effect.

The most disturbing reports yet published about nimodipine, disturbing for medical research in general, are two systematic reviews that reveal a lack of evidence to justify Phase 3 clinical trials. Contrary to conventional assumption, published laboratory experiments found as many negative as positive results, and animal experiments and clinical studies ran simultaneously. Making matters worse, several methodologically sound clinical studies of calcium antagonists in ischemic stroke patients remained unpublished. In each of those unpublished studies, results were significantly worse for patients in the treatment groups.[105]

Etomidate

EEG burst suppression with etomidate prior to temporary vessel occlusion gained prominence eleven years ago on the basis of a clinical trial for which there was no control group, no alternative drug tested, and no historical standard for comparison. Despite the absence of supportive clinical evidence, and the presence of troubling laboratory results,[106] etomidate remains the standard regimen for cerebral protection at several institutions. We now have clinical evidence that the standard propylene glycol formulation of etomidate induces more cerebral tissue hypoxia, tissue acidosis, and neurological deficits than an EEG-equivalent dose of desflurane.[107]

Nitrous Oxide and Ketamine

In 1938 C.D. Courville published "The pathogenesis of necrosis of the cerebral gray matter

following nitrous oxide anesthesia"—an article that presents photographs of vacuolated cortical neurons from patients who died subsequent to administration of nitrous oxide (N_2O).[108] Sixty years later, Jevtovic-Todorovic and co-authors published compelling evidence that N_2O causes vacuolation of both the endoplasmic reticulum and mitochondria of neurons in the posterior cingulate and retrosplenial cortices of rats.[109] Are we on our way to where we might have been if Courville's work had received more sustained attention?[110]

Nitrous oxide's mechanism of action is NMDA receptor antagonism, and like other NMDA

antagonists, N_2O has been shown to reduce damage from excessive glutamate release. Unfortunately, however, because NMDA also excites inhibitory neurons, NMDA blockade causes inhibition of GABA release, and thus general disinhibition. This is probably a component of the mechanism by which N_2O, like other NMDA antagonists (e.g., ketamine, phencyclidine, dextrorphan, MK-801), can cause neuronal damage.[111]

The question of N_2O's effect on the neuroprotective efficacy of primary anesthetics has been addressed by several investigations. Following Arnfred and Secher's demonstration that thiopental more than doubles survival time in mice subjected to hypoxia while N_2O reduces survival,[112,113] it was found that co-administration of N_2O virtually eliminates the protective effect of thiopental in the same model.[114] Two years later, Baughman and co-authors found that N_2O cut the protective effect of isoflurane in half.[115] More recently, Jevtovic-Tedrovic and co-authors found that N_2O converts a nontoxic dose of ketamine into a substantially toxic dose in rats,[116] and adding N_2O to isoflurane or isoflurane with midazolam substantially exacerbates those agents' pro-apoptotic effect during the brain growth spurt in developing rats.[117]

Evidence that the earlier-mentioned clinical and laboratory findings resulted in part from a direct neurotoxic effect of N_2O is bolstered by our findings in the hippocampal slice model, where nitrous oxide markedly reduced electrophysiological recovery from severe hypoxia without affecting fundamental biochemical parameters like ATP concentration, Ca influx, K efflux, and Na influx.[118] Direct neurotoxicity aside, N_2O has been repeatedly shown to increase CMR, CBF, and ICP when used alone, but these effects are variable when N_2O is used as an adjunct anesthetic, with or without hypocapnia, and with or without EEG burst suppression. Recent evidence indicates that N_2O disturbs CBF/$CMRO_2$ coupling in humans receiving sevoflurane.[43] In patients with folic acid deficiency, a single exposure to N_2O can cause spinal cord degeneration.[119] Less direct, but also less rare, exposure to N_2O causes a substantial increase in plasma homocysteine, which can increase coagulation, decrease flow-mediated vasodilation, and increase postoperative myocardial ischemia—all of which complicate recovery in the neuro ICU. Prolonged hyperhomocysteinemia is also an independent risk factor for cerebrovascular disease.

Perhaps the most pressing question regarding the use of N_2O in neurosurgical patients has been framed by Enlund, Edmark, and Revenas: "It is no consolation for the patient who suffers from an irreversible neurological sequela after nitrous oxide exposure that he happens to be the first one at your clinic for the last five years. For those like us who administer drugs, or for the regulatory authorities, such an incident might nevertheless be acceptable provided that a great number of patients receive indispensable benefits, which outweigh a severe side effect. Are there such pros [benefits] from nitrous oxide?"[120]

Steroids—Tirilazad

Clinical application of the 21-amino steroid tirilazad looked promising.[121] Unfortunately, more substantive results from a North American trial in subarachnoid hemorrhage patients failed to reach statistical significance,[122] and a follow-up study of high-dose tirilazad in women depended on an idiosyncratic grouping of data to reach statistical significance.[123] A detailed commentary on that analysis concluded that "any eventually proven therapeutic efficacy is likely to be modest,"[124] and a systematic review of tirilazad use in 1,757 stroke patients concluded that "Tirilazad mesylate increases death and disability by about one fifth when given to patients with acute ischemic stroke."[125] A recent reanalysis of initially promising results has revealed a failure to adjust for imbalances in baseline characteristics.

Caution and Hope

6 Current evidence cautions against the use of prophylactic etomidate prior to temporary vessel occlusion, magnesium loading in ischemic stroke patients, intra-operative nitrous oxide and ketamine, intra-operative moderate hypothermia in subarachnoid hemorrhage (SAH) patients, postoperative nimodipine and tirilazad, and postoperative hypothermia in head-trauma patients. On the positive side, cerebral preconditioning and augmentation of endogenous processes of repair may deliver standard-of-care brain protection to neurosurgical patients within a decade.

MONITORING

Electroencephalogram

7 The EEG can be used to monitor cerebral function during general anesthesia. The primary use of intraoperative EEG monitoring is the detection of cerebral ischemia during carotid endarterectomy, cerebral aneurysm, and arteriovenous malformation management and cardiopulmonary bypass procedures. EEG monitoring is also used for intraoperative or perioperative assessment of pharmacologic interventions, such as barbiturate-induced burst suppression, during deliberate hypotension, and for the assessment of coma or brain death. Another important intra-operative application of EEG is in the diagnosis and management of intractable epilepsy.

The EEG waves recorded on the surface of the scalp are spontaneous electrical potentials generated by the pyramidal cells of the granular cortex. The EEG signal consists of graded summations of inhibitory and excitatory postsynaptic potentials that create dipole fields in the dendrites of the pyramidal cells. When a number of dipoles develop at once, the summation creates electrical potentials large enough to produce detectable voltage on the scalp.

The EEG waveforms are interpreted by pattern recognition and quantification. Specific complexes are described in terms of morphology, spatial and temporal distribution, and reactivity of the waveforms. Quantification involves measuring frequency and amplitude. Frequency is measured in hertz (Hz) and is defined as the number of times per second the wave crosses the zero voltage line. Amplitude, which is measured in microvolts (μV), is the electrical height of the wave. The frequency bands are divided into delta (0–3 Hz), theta (4–7 Hz), alpha (8–13 Hz), and beta (>13 Hz) rhythms (Table 27-6).

TABLE 27-6 EEG Frequency Ranges

Delta rhythm (0–3 Hz)	Deep sleep, deep anesthesia, or pathologic states (e.g., brain tumors, hypoxia, metabolic encephalopathy)
Theta rhythm (4–7 Hz)	Sleep and anesthesia in adults, hyperventilation in awake children and young adults
Alpha rhythm (8–13 Hz)	Resting, awake adult with eyes closed; predominantly seen in occipital leads
Beta rhythm (>13 Hz)	Mental activity, light anesthesia

The traditional EEG is a plot of voltage against time. Sixteen channels are usually recorded, allowing analysis of activity of different regions of the brain. EEG waveform changes associated

with anesthetic drugs, PaO_2, $PaCO_2$, and temperature are described in Table 27-7.

TABLE 27-7 EEG Changes Associated with Anesthetic Drugs, PaO_2, $PaCO_2$, and Temperature

▪INCREASED FREQUENCY
Barbiturates (low dose) Benzodiazepines (low dose) Etomidate (low dose) Propofol (low dose) Ketamine N_2O (30–70%) Inhalation agents (<1 MAC) Hypoxia (initially) Hypercarbia (mild) Seizures
▪DECREASED FREQUENCY/INCREASED AMPLITUDE
Barbiturates (moderate dose) Etomidate (moderate dose) Propofol (moderate dose) Opioids Inhalation agents (>1 MAC) Hypoxia (mild) Hypocarbia (moderate to extreme) Hypothermia
▪DECREASED FREQUENCY/DECREASED AMPLITUDE
Barbiturates (high dose) Hypoxia (mild) Hypercarbia (severe) Hypothermia (<35°C)
▪ELECTRICAL SILENCE
Barbiturates (coma dose) Etomidate (high dose) Propofol (high dose) Desflurane (2 MAC) Isoflurane (2 MAC) Sevoflurane (2 MAC) Hypoxia (severe) Hypothermia (<15–20°C) Brain death

The EEG response to anesthetic agents can vary from cortical excitation through depression to isoelectricity. Usually,

anesthetic induction produces a decrease in alpha and an increase in beta activity. As the depth of anesthesia increases, EEG frequency decreases until theta and delta activity predominate. By further increasing the dose of anesthesia, the EEG changes to a burst suppression pattern, which coincides with near-maximal depression of cerebral metabolic activity. Complete electrical silence or isoelectricity follows an additional increase in anesthesia. Anesthesia-induced burst suppression is used to provide cerebral protection by metabolic suppression. EEG monitoring verifies burst suppression and electrical silence and is valuable when determining the dose of drug required to induce and maintain barbiturate coma.

Efforts to use the EEG as a monitor of depth of anesthesia have been problematic because of the variety of agents used to maintain anesthesia and because some anesthetic agents do not follow the general pattern described above.[33] Several different cerebral-monitoring techniques based on EEG-derived algorithms, electromyograms, auditory evoked responses, or combinations of these have been introduced to more precisely determine "depth of anesthesia" during surgery.[126,127,128] These various techniques are currently under investigation with promising results.[129,130] A recently published multicenter, randomized controlled trial revealed that Bispectral index (BIS) monitoring reduced the risk of awareness in at-risk adult surgical patients (cardiac surgery, cesarean section, and trauma surgery) undergoing relaxant general anesthesia.[130]

Intraoperative EEG monitoring allows early detection of cerebral hypoxia and ischemia. Inadequate PaO_2 or insufficient CBF is reflected within seconds in the EEG.[131] Hypoxia may initially produce EEG activation, which is followed by slowing and eventually electrical silence.

Other physiologic parameters that affect EEG waveforms are $PaCO_2$, temperature, and sensory stimulation. Hypocarbia causes EEG slowing. Mild hypercarbia causes increased frequency, and severe hypercarbia produces a decrease in frequency and amplitude. When body temperature falls below 35°C, hypothermia causes a progressive slowing of activity. Complete electrical silence occurs at 15 to 20°C. Sensory stimulation is associated with EEG activation.

When monitoring an EEG during anesthesia, the changes resulting from hypoxia or ischemia must be distinguished from the drug and physiologic effects that also may influence the EEG. Because of this, the EEG must always be interpreted within the clinical context in which it is observed.

A specific intra-operative application of the EEG, called *electrocorticography* (ECoG), is the localization of epileptic foci during surgery for intractable epilepsy. For these procedures, recording electrodes are applied on or in the brain. The craniotomy can be performed under local anesthesia with conscious sedation (typically using propofol and fentanyl) or under a light general anesthetic using nitrous oxide, narcotic and low dose isoflurane (maximum 0.25% end-tidal concentration). The anesthetic administered must avoid pharmacologic cortical depression, which would prevent provocative seizure activity. Provocative techniques and agents, such as hyperventilation, low-dose barbiturates (methohexital 10 to 50 mg, thiopental 25 to 50 mg), propofol 10 to 20 mg, or etomidate 2 to 4 mg, have been used to activate the foci. Under general anesthesia, alfentanil 20 to 50 μg/kg and fentanyl 10 μg/kg also have been used to successfully produce ECoG activation.

Computerized EEG Processing

The development of the computer-processed EEG has facilitated intraoperative EEG monitoring. The most widely used and best validated technique is *power-spectrum analysis*, which uses a computer to perform a Fourier transformation. A given epoch of EEG (usually 2 to 8 seconds) is converted from a plot of voltage against time to a plot of power (amplitude squared) against frequency. With this technique, data are displayed in one of three formats: the compressed spectral array, the density spectral array, and the band spectral array or power bands. For example, to generate the compressed spectral array format, the Fourier transformation converts the irregular EEG waves to equivalent sine waves of known frequency and power (Fig. 27-6).[131] This display shows time and power as one axis (vertical) and frequencies on the horizontal axis.

The Fourier spectral data from successive segments are stacked one on top of the other, creating a pseudo three-dimensional display; that is, the plot is shifted vertically with time and compressed. A major advantage of power-spectrum analysis is that it retains almost all the information in the original EEG. Power-spectrum analysis has documented value as a monitor of cerebral ischemia and possible value in the determination of anesthetic depth.[126] The main disadvantages of this analysis technique are lack of detection of spike activity, inclusion of artifact within frequency bands, and limited review of raw EEG data to determine reliability of the ongoing input.

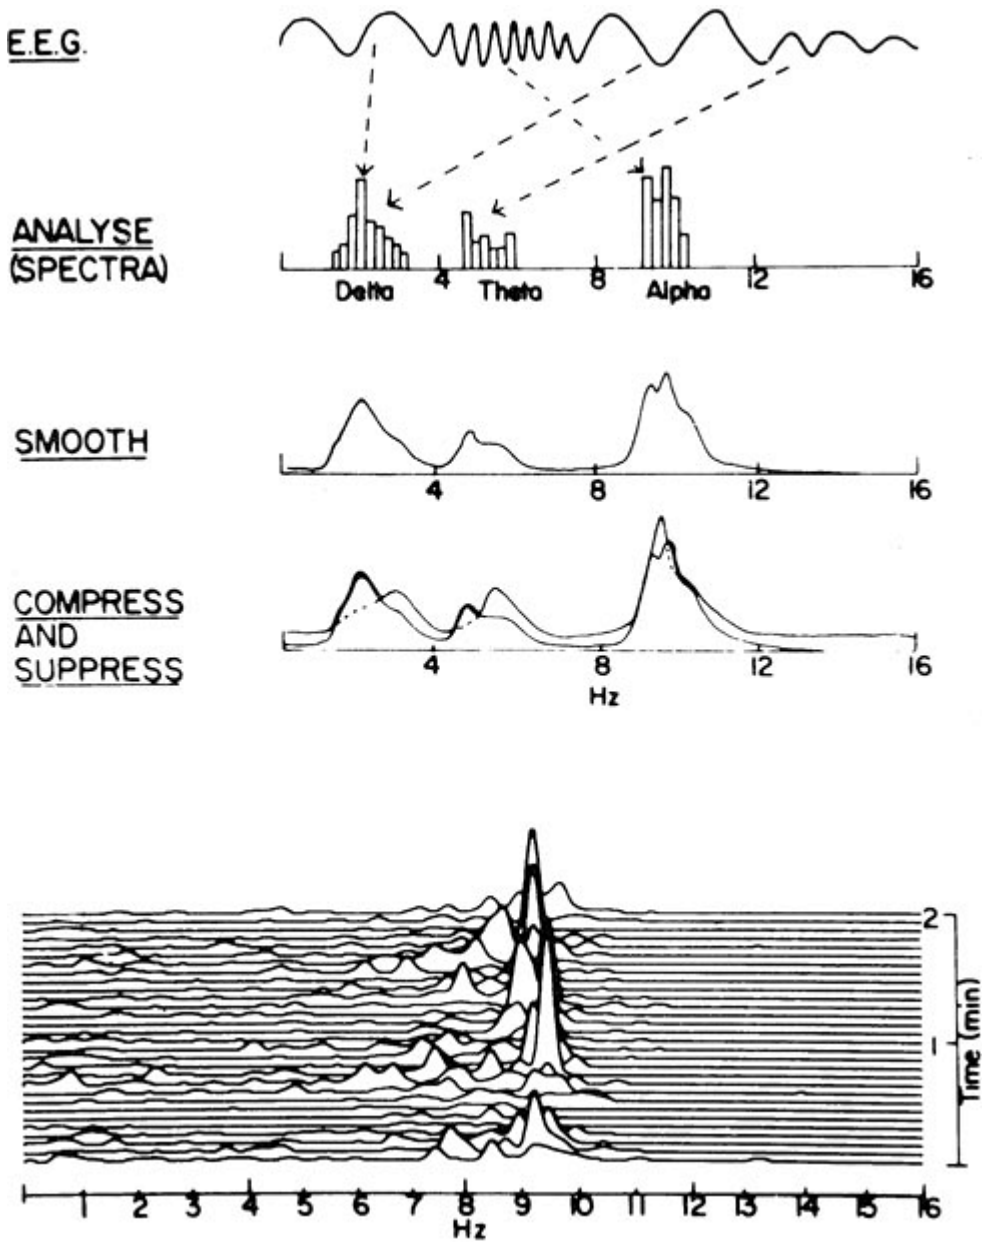

FIGURE 27-6. Schematic diagram of technique used to generate compressed spectral array. Below the diagram is an example of compressed spectra of the alpha rhythm from a normal subject. (Reprinted with permission from Stockard JJ, Bickford RG: The neurophysiology of anesthesia. In Gordon E (ed): A Basis and Practice of Neuroanesthesia, 2nd ed, pp 3–49. Amsterdam, Elsevier, 1981.)

Several technical matters must be considered to effectively implement intraoperative EEG monitoring. Awake controls should be obtained before induction of general anesthesia. Monitoring should be continuous throughout anesthesia and

continue until the patient is awake. Bilateral data must be obtained, especially during cerebrovascular procedures. For example, during a carotid endarterectomy, bilateral changes may indicate anesthetic or systemic effects, whereas ipsilateral changes on the operating side are most likely consistent with surgical trauma or ischemia. Marked changes in anesthetic depth, systemic blood pressure, $PaCO_2$, and brain temperature must be avoided in order to distinguish between anesthetic and physiologic effects on the EEG and those resulting from hypoxia or ischemia.

Evoked Potentials

Evoked potentials are used intraoperatively to monitor the integrity of specific sensory and motor pathways. Sensory evoked potentials (SEPs) evaluate the functional integrity of ascending sensory pathways, whereas motor evoked potentials (MEPs) test the functional integrity of descending motor pathways.

There are major differences between evoked potentials and the EEG. The EEG is a recording of spontaneous, random electrical activity that has a nonspecific function and generates a relatively large signal, for example, 50 μV or more. Evoked potentials are comparatively small-amplitude responses (0.1 to 20 μV) to a specific stimulus that are pathway-specific.

Sensory Evoked Potentials

The application of a sensory stimulus—a click, a flash, a shock—results in an afferent nerve impulse that can be detected by appropriately placed surface electrodes as transient potential differences. The amplitude of these evoked potentials is very small and obscured by normal background bioelectric activity from the EEG, electrocardiogram (ECG), muscle activity, and other extraneous electrical activity. Signal averaging is required to extract the evoked responses from this background noise. The background noise is random and is eliminated by the averaging process.

Three SEP modalities are employed clinically: *somatosensory* (SSEP), *auditory* (BAEP), and *visual* (VEP). The waves of the evoked potential are thought to represent potentials from specific neural generators. The individual peaks in the waveform are described in terms of polarity (negative, positive), post-stimulus latency (msec), and peak-to-peak amplitude (μV or nV). They are also described by the distance separating the neural generators and recording electrodes (near-field, far-field).

Anesthetic Considerations for Sensory Evoked Potential Recording. Compromise or injury of a neurologic pathway is manifested as an increase in the latency and/or a decrease in the amplitude of evoked potential waveforms. For SSEPs, a 50% reduction in amplitude from baseline in response to a specific surgical maneuver is considered to be a significant change warranting action to avert potential damage. For BAEPs, an increase in latency of more than 1 millisecond is considered clinically significant. Accordingly, anesthetic, physiologic, and environmental factors capable of producing this pattern of alteration must be controlled when recording evoked potentials. All anesthetics that have been studied influence evoked potentials to some extent. Table 27-8 summarizes the

known effects of intravenous and inhaled agents. The sensitivity of evoked potentials to drug effects varies with the sensory modality being monitored. Evoked potentials of cortical origin (i.e., the cortical component of the somatosensory evoked potentials [SSEP] and visual evoked potentials [VEP]) are more vulnerable to anesthetic influences than brainstem potentials (e.g., brainstem auditory evoked potentials [BAEP] and the subcortical components of SSEP). In general, to obtain satisfactory intraoperative SEP recordings, it is important to maintain constant anesthetic drug levels. Specifically, bolus administration of intravenous agents and step changes in inspired inhalation agent concentration must be avoided, especially at times when neurologic injury might occur. When recording cortical evoked potentials (SSEPs or VEPs), one should employ intravenous techniques. High concentrations of volatile agents essentially eliminate cortical evoked potentials. However, end-tidal concentrations of 0.5 MAC of a volatile agent are compatible with satisfactory recordings in patients who are neurologically normal. The newer

inhaled agents, desflurane and sevoflurane, may permit the use of higher inhaled concentrations during electrophysiological monitoring.

TABLE 27-8 Effects of Intravenous and Inhaled Agents on Sensory Evoked Potentials

BAEPs = brainstem auditory evoked potentials; cSSEPs = cortical somatosensory evoked potentials; VEPs = visual evoked potentials; ↑ = increased; ↓ = decreased; 0 = no change; — = no data; Lat = latency; Amp = amplitude; • = response abolished.

[a]1.5 MAC will occasionally abolish the response.

[b]At 1.7 to 2.5 MAC, 100% ↑ in amplitude (fusion to a single cortical high-amplitude wave with abolition of all later wave components).

In general, volatile agents cause a dose-dependent increase in latency and a decrease in amplitude of the cortical SSEP or VEP.[132] As exemplified in a study by Peterson et al (Fig. 27-7),

reductions in SSEP amplitude greater than 50% were observed with 1 MAC halothane, 0.5 MAC enflurane, and 0.5 MAC isoflurane, all administered with 60% nitrous oxide in oxygen.[133] The authors concluded that halothane disrupted the SSEP the least, and enflurane disrupted it the most. At doses of 1.5 MAC sevoflurane and desflurane, increases in cortical latency and decreases in amplitude occur. Desflurane up to 1 MAC without nitrous oxide is compatible with cortical median nerve SSEP monitoring during scoliosis surgery. At 1.5 MAC without nitrous oxide, the amplitude of cortical SSEPs is preserved at 60% of baseline with desflurane. Visual evoked potentials tend to be more sensitive than cortical SSEPs to the effects of anesthetics. Nitrous oxide alone has been shown to produce significant decreases in amplitude with minimal latency changes in the cortical SSEP, but it decreases amplitude and increases latency in the VEP. When nitrous oxide is administered in combination with a volatile anesthetic, it produces a profound depressant effect on SSEPs and VEPs.

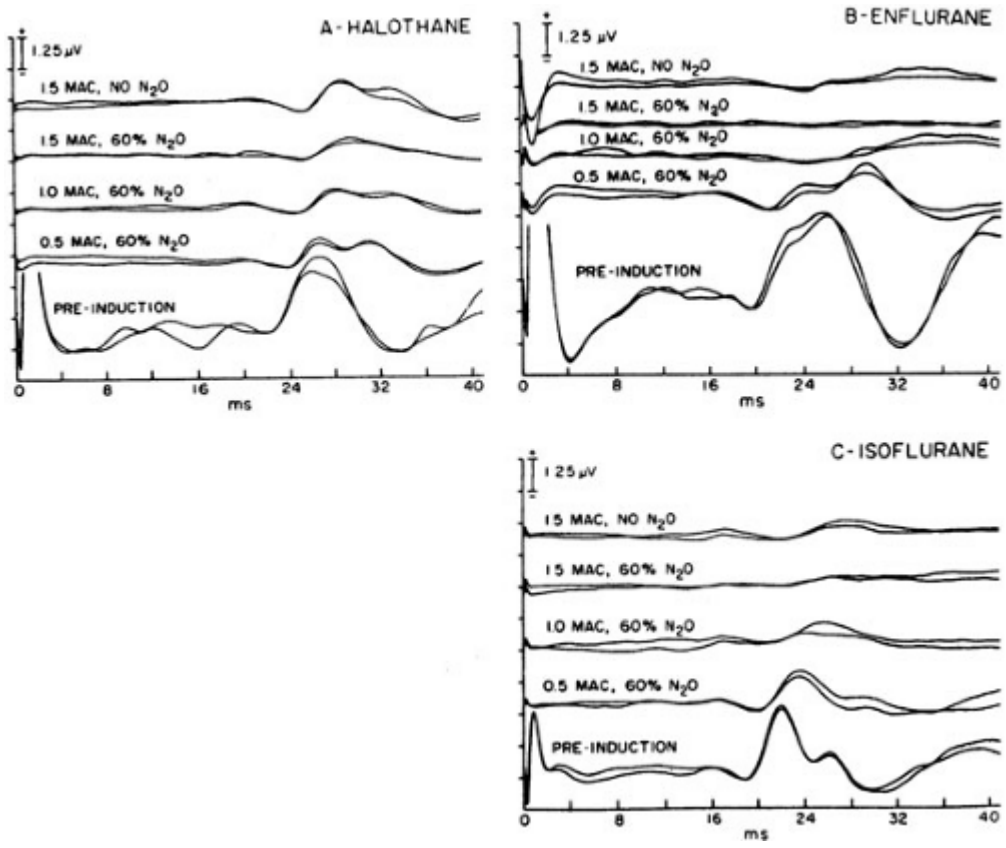

FIGURE 27-7. The responses of cortical somatosensory evoked potentials to various MACs of halothane, enflurane, and isoflurane. A marked alteration of evoked potentials occurs at 1 MAC and higher levels of inhaled agents, and a modest improvement of the response occurs when N_2O is withdrawn. (Reprinted with permission from Peterson DO, Drummond JC, Todd MM: Effects of halothane, enflurane, isoflurane, and nitrous oxide in multilevel somatosensory evoked potentials. Anesthesiology 65:35, 1986.)

Brainstem responses are considerably more resistant to anesthetic influences than are cortical responses. For example, clinically used concentrations of the inhaled agents tend to increase the latencies of early or subcortical peaks of the BAEP with minimal amplitude effects. Most anesthetic regimens are compatible with recording of brainstem responses. However, as with the other evoked potential modalities, large step changes (greater than 0.5 MAC) in inspired inhalation agent concentration should be avoided during critical periods.

Studies on the effects of intravenous agents demonstrate that induction doses of thiopental, etomidate, and fentanyl preserve SSEP recordings. Increasing doses of thiopental result in dose-

dependent increases in latency and decreases in amplitude in cortical SSEPs and progressive increases in latency in BAEPs. Very high doses of thiopental, exceeding that which produce an isoelectric EEG, alter SSEPs and BAEPs predictably, but waveforms are preserved. VEPs are more sensitive than the other sensory modalities to the effects of barbiturates with only the early potentials persisting at low doses and increasing in latency at higher doses. Either bolus administration or intravenous infusion of etomidate causes increases in latency and increases in amplitude of cortical SSEPs and slight decreases in amplitude of cervical potentials. Etomidate produces minimal changes in the early or subcortical peaks of the BAEP, but causes a dose-dependent attenuation and prolongation of the middle latency cortical peaks. Etomidate alone does not change VEP amplitudes (P100 or N70), but increases latency (P60, N70, and P100). During fentanyl–nitrous oxide anesthesia, etomidate causes decreases in amplitude and increases in latency of VEPs. The benzodiazepines produce minimal SSEP and VEP changes and no changes in BAEPs. Propofol increases the latency and decreases the amplitude of cortical SSEPs. Propofol (2 mg/kg iv followed by an infusion) increases the BAEP latency of I, III, and V waves without changing the amplitudes. Propofol completely suppresses middle latency auditory potentials.

The opioids produce minimal changes in SEP waveforms. For example, fentanyl causes minimal latency prolongation and amplitude depression of the SSEP waveforms. Compared with the combination of fentanyl and nitrous oxide, the remifentanil/isoflurane technique preserved cortical amplitude better and with less variability in latency and amplitude. High-dose opioid administration also has been shown to be compatible with reproducible recordings of SSEPs. Opioids also produce minimal to no effect on BAEP recordings. Furthermore, low-dose continuous infusions of opioids tend to depress SEPs less than intermittent bolus injections.

Because opioids preserve SEP recordings even in relatively high doses, they are recommended for use as infusions during intra-operative monitoring. As with all intravenous agents used, bolus administration should be avoided during critical times when neurologic injury might occur.

Clonidine and dexmedetomidine are α-2 receptor agonists that are used to decrease anesthetic requirements. Clonidine administered alone or added to 1 MAC isoflurane does not change cortical SSEP latency or amplitude. Dexmedetomidine affects SSEP amplitude minimally and has been shown to blunt isoflurane's effect on SSEP amplitude. Both agents can be used as an anesthetic adjuvant without compromising SSEP monitoring.

Physiologic factors such as temperature, systemic blood pressure, PaO_2, and $PaCO_2$ can alter SEPs and must be controlled during intra-operative recordings.[132] Both hypothermia and hyperthermia alter all SEPs. In addition, fluids used to irrigate the brain or spinal cord can cause marked changes in recordings despite normal core temperature measurement. Therefore, body temperature–irrigating fluids should be used. Systemic hypotension below levels of cerebral autoregulation produces progressive decreases in amplitude of cortical SSEPs until the waveform is lost. During scoliosis surgery, SSEP changes have been observed that resolved with increases in systemic blood pressure, suggesting that spinal cord manipulation during "safe" levels of hypotension may cause significant ischemia. Changes in PaO_2 and $PaCO_2$ also alter SEPs, probably reflecting changes in blood flow or oxygen delivery to neural structures.

Motor Evoked Potentials

A motor evoked potential (MEP) can be produced by direct (epidural) or indirect (transosseous) stimulation of the brain or spinal cord. Following transcranial stimulation, the signal descends through both the dorsolateral and ventral spinal cord. It is primarily localized in the pyramidal tracts, and can be recorded from spinal cord (epidural space), peripheral nerve, and muscle using conventional electromyographic and evoked potential averaging techniques. Stimulation of the motor cortex elicits contralateral peripheral nerve signals, electromyographic signals, or limb movements.

Transosseous activation of motor neurons is accomplished by either electrical or magnetic stimulation. Transcranial electrical stimulation of the motor cortex is a reliable method of eliciting intraoperative MEPs. It is achieved by delivering brief high-voltage pulses through scalp

electrodes. Transcranial magnetic stimulation is produced by placing a magnetic coil over the motor cortex. This technique is painless and noninvasive and does not require direct contact with the scalp. Because high-resistance tissues such as bone and skin are transparent to magnetic fields, smaller voltages can be used to stimulate neural elements below the surface.

With either electrical or magnetic stimulation, there is concern that repetitive cortical stimulation can induce epileptic activity, neural damage, and cognitive or memory dysfunction. Guidelines for transcranial MEP stimulation recommend intermittent rather than continuous stimulation over several hours and cautious use in patients with a history of seizures, possible skull fractures, or implanted metallic devices. Disruptions of the calvarium—that is, a skull fracture—could focus the current toward certain regions of the brain and potentially cause neural damage. Other situations of concern are patients with cardiac pacemakers and central venous or pulmonary artery catheterization. Transcranial MEP stimulation should probably be avoided in these patients.

There are several indications for intraoperative monitoring of MEPs. They are especially useful in preserving motor function during procedures in which surgically induced damage may be specific to the motor system. For example, surgical removal of intramedullary tumors can result in selective damage to corticospinal tracts, and MEPs are used to guide surgical resection. During scoliosis surgery, a direct monitor of motor pathway function obviates the need for the intraoperative wake-up test and provides continuous information about motor function throughout the surgical procedure. During cerebrovascular procedures and resection of cerebral tumors involving the motor cortex or subcortical motor pathways, the ability to guide the surgical resection by monitoring motor function prevents postoperative motor deficits. Paralysis is an unpredictable complication that can occur after aortic aneurysm surgery. Myogenic MEP monitoring can detect ventral horn ischemia during aortic reconstruction, thus allowing the surgeon to initiate strategies to improve spinal cord perfusion. In all of these procedures, MEPs should be monitored in conjunction with SSEPs to fully evaluate the functional integrity of both motor and sensory pathways.

Motor evoked potentials are extremely sensitive to depression by anesthetics.[134] The volatile agents are powerful depressants of myogenic MEPs. Nitrous oxide appears to be less suppressive than other inhaled agents. Moderate doses of up to 50% N_20 have been used successfully to supplement other agents during myogenic MEP monitoring. Benzodiazepines, barbiturates, and propofol also produce marked depression of myogenic MEP. However, successful recordings have been obtained during propofol anesthesia by controlling serum propofol concentrations and increasing stimuli rates. Fentanyl, etomidate, and ketamine have little or no effect on myogenic MEP and are compatible with intra-operative recording. Muscle relaxants affect the recorded electromyographic response by depressing myoneural transmission. By adjusting a continuous infusion of muscle relaxant to maintain one or two twitches in a train of four, reliable MEP responses have been recorded.

Although it appears that MEPs are more sensitive to the effects of anesthetic agents, reliable responses have been recorded with a nitrous oxide–narcotic technique and with agents such as ketamine or etomidate. Multistimulus techniques can improve monitoring during anesthesia with more depressive agents such as propofol. As with SEPs, hypothermia, hypoxia, and hypotension will alter MEPs under anesthesia.

Cranial Nerve Monitoring

Potential injury to the cranial nerves can occur during posterior fossa and lower brainstem procedures. The integrity of these cranial nerves can be preserved by monitoring the electromyographic (EMG) potential of cranial nerves with motor components (V, VII, IX, X, XI, XII). Both spontaneous and triggered muscle activity can be recorded. Recordings can be obtained by placing two wire electrodes within the muscle or using surface electrodes. Simultaneous spontaneous EMG and compound muscle action potential (CMAP) recordings can be obtained by using intramuscular wire and surface electrodes. Intramuscular wire electrodes increase the sensitivity for detecting spontaneous EMG activity, while surface electrodes allow for more reliable monitoring of CMAP amplitude and morphology. With accidental surgical trespass, spontaneous

neural activity changes into phasic "bursts" or "train" activity, which suggests injury potential. Evoking the nerves with electrical stimulation facilitates identification and hence preservation of the cranial nerve. Although it is possible to record EMG potentials during partial neuromuscular blockade, it is recommended that muscle relaxants not be administered during cranial nerve monitoring.

Intracranial Pressure Monitoring

Since Lundberg's[135] report in 1960, continuous ICP monitoring has been used to guide the perioperative management of patients with head injury, large brain tumor, ruptured intracranial aneurysm, cerebrovascular occlusive disease, and hydrocephalus. With continuous ICP monitoring, it is possible to optimize CPP (MAP-ICP) in critically ill neurosurgical patients. It also allows early detection and prompt treatment of brain hemorrhage, swelling, and herniation. An important intra-operative indication for ICP monitoring is to detect intracranial hypertension in the multiple trauma patients during a nonneurosurgical procedure.

Techniques used to monitor ICP include ventricular catheters, subdural-subarachnoid bolts or catheters, various epidural transducers, and intraparenchymal fiberoptic devices (Fig. 27-8). The intraventricular catheter is the standard method of monitoring ICP. This technique requires a small scalp incision and a burr hole through the skull. A soft, nonreactive plastic catheter is introduced into the lateral ventricle and connected by sterile tubing filled with saline solution to an external transducer. The intraventricular catheter measures CSF pressures reliably. It allows therapeutic CSF drainage and can also be used for compliance testing. There are, however, several potential problems with this technique. This device depends on the transmission of ICP through fluid-filled tubing that can occlude, thus damping or obliterating the recording. In a patient with severe brain swelling or a large mass lesion and small ventricles, it may be technically difficult to locate the lateral ventricle. Besides not being able to pass the catheter into the CSF, there is a possibility of brain tissue damage,

hematoma, and infection. Studies report a low infection rate for the first 4 days after catheter placement. Catheter removal is, therefore, recommended on or before the fifth day, with replacement at a different site if continued ICP monitoring is necessary.

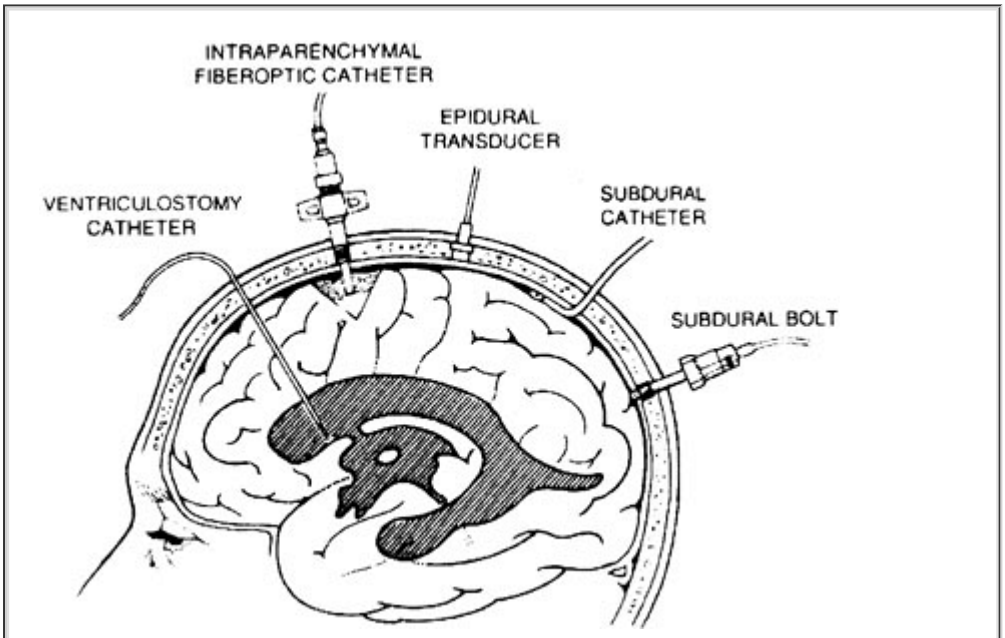

FIGURE 27-8. Techniques used to measure intracranial pressure.

The subdural-subarachnoid bolt usually consists of some type of hollow screw fixed to the calvarium, with the tip passing through the incised dura. The advantages of the bolt are that it

does not require brain tissue penetration or knowledge of ventricular position and can be placed in any skull location that avoids major venous sinuses. There are several disadvantages to use of this technique. The bolt cannot be used to lower ICP by CSF drainage or to test compliance reliably. As with the intraventricular catheter, the bolt is connected to a transducer with tubing filled with sterile saline. Not only can the tubing block, but also brain substance can obstruct the tip of the bolt; in either situation, the recording may be damped or lost. Drilling side holes just proximal to the tip of the bolt compensates for this problem to some extent. Subdural devices are easily inserted, but can malfunction if they are not coplanar to the brain surface or if they become loose. The major complication of this procedure is infection, commonly meningitis, osteomyelitis, or a localized infection. Epidural bleeding and focal seizures, if the bolt is inserted too deeply, can also occur.

Two primary types of epidural transducers have been developed. One uses a device that has a pressure-sensitive membrane mounted close to or contacting the dura; the other type, known as the Ladd epidural transducer, is based on the principle of the Numoto pressure switch. Although the risk of infection to the brain is lower because of the extradural placement, there are several disadvantages associated with using these devices. Placement in this potential space is more difficult, and there is a risk of bleeding. Technical problems in positioning and calibrating the transducer in situ can also occur. Another shortcoming of the epidural transducer is that intracranial compliance testing and therapeutic CSF drainage cannot be performed.

Intraparenchymal ICP monitoring techniques allow direct measurement of brain tissue pressure, which may be important in edema formation and regional capillary blood flow. Intraparenchymal devices use a fiberoptic catheter that is inserted within cortical gray matter. In comparison to ventriculostomies, these monitors are easier to insert, have a smaller diameter, and are less disruptive of brain tissue. Because there is no fluid column, the risk of infection is lower.

Cerebral monitoring devices are being developed with miniaturized sensors, transducers, and probes using fiberoptic solid state technology. These devices can be inserted into the subdural, intraparenchymal, or intraventricular compartments. Because these are solid-state monitors, the problems of infection, leaks, catheter occlusion, and drift that attend fluid- or air-filled systems are minimized or avoided. Animal and human studies show that pressure recordings obtained with these devices are accurate and reliable. The main disadvantage of these devices is that they cannot be recalibrated in situ. Another limitation is that they cannot be used for CSF drainage or compliance testing unless inserted in conjunction with a ventriculostomy.

New generations of fiberoptic ICP monitors allow simultaneous measurement of ICP, local CBF using laser Doppler flowmetry, brain tissue oxygen pressure (PO_2), carbon dioxide pressure (PCO_2), pH, and other metabolic markers. By simultaneously monitoring ICP, local CBF, and brain tissue oxygenation, early signs of ischemia can be identified and the effectiveness of therapeutic maneuvers more fully determined. The various ICP monitors are seldom used intra-operatively. They are most valuable in managing critically ill neurosurgical patients in the intensive care unit.

All of the clinically available monitors have recognized advantages and disadvantages. Despite the problems associated with these devices, ICP monitoring provides useful information for evaluating the patient's condition, progress, and need for therapy. Research efforts continue to improve monitoring techniques in terms of reliability, accuracy, and safety.

Transcranial Doppler Ultrasound

Transcranial Doppler (TCD) ultrasound is used for clinical imaging of intracranial vasculature. TCD uses a 2-MHz probe, which is range-gated. The probe is placed over low-density bone regions of the skull, and the beam is focused on the desired vessel. The ultrasonic beam reflects off the blood flowing in the vessel, producing a Doppler shift that is proportional to blood flow velocity. This technique can provide continuous assessment of the systolic, diastolic, and mean flow velocities in the target vessel. Any downstream resistance is proportional to the difference between systolic and diastolic velocities. One commonly used resistance index is the “pulsatility index” defined as:

$$PI = \frac{\text{Systolic Velocity} - \text{Diastolic Velocity}}{\text{Mean Velocity}}$$

TCD does not measure CBF. It determines velocity and direction of the moving column of blood in a major artery. The TCD is used to monitor flow velocity in large vessels in the Circle of Willis and its major branches. The transtemporal approach above the zygomatic arch allows insonating the anterior, middle, and posterior cerebral arteries. The suboccipital route, through the foramen magnum, allows insonating the basilar and vertebral arteries.

TCD has several applications both in critical care and intra-operatively. It can be used to determine the "reserve" of cerebral blood vessels by measuring CO_2 reactivity and autoregulation and to estimate CPP by using the PI. TCD also is used to identify patients with vasospasm, hyperemia, emboli, stenosis, abnormal collateral blood flow, and inadequate CBF. For intra-operative application, the probe is affixed to the temporal bone with a strap. During craniotomy, a skin adhesive is applied to mount the probe.

Limitations of this technique include between-subject variation of TCD velocities, within-subject variation if vessel diameter changes in response to vasoactive agents or conditions, and error from changing the angle of insonation. However, the advantages of TCD are that it is noninvasive and nonradioactive

and provides continuous information about the cerebral circulation.

Cerebral Oxygenation / Metabolism Monitors

Brain Tissue Oxygenation

A multiparameter sensor is available for measuring brain tissue PO_2, PCO_2, pH, and temperature using a combined electrode–fiberoptic system. The sensor was originally designed for continuous intra-arterial blood gas monitoring. It is supplied as a sterile, disposable device comprising two modified optical fibers for the measurements of PCO_2 and pH, a miniaturized Clark electrode for PO_2 measurement, and a thermocouple for determining temperature. Coupled with a dialysis catheter, the device permits measurement of other metabolic markers, including lactate, glucose, and excitotoxic amino acids. This sensor is invasive, requiring insertion into the cortex tissue of interest under direct visualization. The measurements obtained are limited to the parenchyma where the electrode is inserted.

Jugular Bulb Venous Oximetry

Continuous or intermittent estimation of the global balance between cerebral oxygen demand and supply can be achieved by jugular bulb venous oximetry. This is done by measuring the oxygen saturation of jugular venous blood ($SjVO_2$) through percutaneous retrograde cannulation of the internal jugular vein with an intravascular catheter with embedded optical fibers. Normal $SjVO_2$ is 60 to 70%. In the absence of anemia and any change in oxygen saturation, increases in $SjVO_2$ to above 75% are indicative of absolute or relative hyperemia; that is, supply is in excess of metabolic requirement. This can occur as a result of reduced metabolic need (e.g., a comatose or brain-dead patient) or from excessive flow (e.g., severe hypercapnia). A value less than 50% reflects increased oxygen extraction and indicates a potential risk of ischemic injury. This may be because of increased metabolic demand (e.g., fever or seizure) not matched by an equivalent increase in flow, or it may be because of an absolute reduction in flow. Changes in the oxygenation of systemic blood also influence the saturation of blood in the jugular bulb.

This monitor is used intraoperatively and postoperatively to diagnose cerebral ischemia from inadequate perfusion pressure or excessive hyperventilation. Its major limitation is that it does not detect focal ischemia.

Transcranial Oximetry

Near-infrared spectroscopy (NIRS) is a noninvasive optical method for monitoring cerebral

regional oxygenation. It is based on the principle that light in the near-infrared range (700 to 900 nm) readily penetrates skin and bone, but reflects off certain chromophores in the brain, such as oxy- and deoxyhemoglobin and cytochrome AA[3]. Therefore, by monitoring the absorption of light at several wavelengths in the near-infrared range, brain tissue concentrations of oxy- and deoxyhemoglobin, total hemoglobin, and hemoglobin oxygen saturation can be measured. The tissue field beneath the sensor contains capillaries, arteries, and veins, reflecting a mixed vascular saturation, which NIRS monitors. Cerebral oximetry can be used to monitor ischemia in several clinical neurosurgical conditions, including carotid endarterectomy, head injury, and subarachnoid hemorrhage. Its major limitations include intersubject variability, variable optical path length, potential contamination from extracranial blood, and lack of a definable threshold. At present, it is considered a trend monitor, with each patient acting as his or her own control. In situations of potential regional ischemia, for example, carotid endarterectomy and temporary clip application during intracranial aneurysm surgery, bilateral monitoring should be used.

NEURORADIOLOGY

Common neuroradiology procedures are computed tomography (CT), magnetic resonance imaging (MRI), angiography, and a variety of invasive interventional procedures. These require total immobility on the part of the patient. Therefore, uncooperative patients, specifically children, fearful adults, and retarded or obtunded patients, would require general anesthesia. All the standard equipment and monitors required for the administration of a general anesthetic and possible cardiopulmonary resuscitation must be present.

Computed Tomography Scan

The CT scan produces a series of cross-sectional images by computerized processing of x-ray absorption measurements (photon attenuation data as measured by sodium iodide crystals rotating about the patient's head). Performance of a brain scan requires that the patient lie on a table with his or her head inside a rotating gantry that makes a 180° arc, producing one axial slice or cut. Depending on the generation of the scanner, the rotation may take from a few seconds to 4.5 minutes per cut. Eight cuts are usually required for a complete examination of the head. When contrast enhancement is indicated, the dye may be infused intravenously and the scan repeated. The patient must remain supine and immobile throughout the entire scan.

CT scanning is an excellent modality for detecting skull fractures and acute subarachnoid hemorrhage. It is relatively insensitive for viewing structures within the posterior fossa because image degradation results from artifact produced by the interface of bone and brain parenchyma. For trauma patients, spiral acquisition CT is becoming more popular. Larger anatomic regions can be imaged as the patient is moved at a continuous, constant speed through the scanning field with the x-ray tube rotating continuously.

Most CT examinations are performed without an anesthesiologist present. Oral or intravenous sedation is used for many pediatric examinations and is usually administered by radiology personnel. Iodinated contrast medium, which is particularly valuable in studies of vascular malformations, vascularized tumors, and blood-brain defects, may also be administered orally or intravenously. When general anesthesia is requested, the patient's "nothing-by-mouth" status must be determined. Other issues that need to be resolved before the administration of general anesthesia are remote access to the patient and the establishment of monitoring and equipment that meets the same standard of care that exists in the operating room.

The CT scanner uses ionizing radiation. The radiation exposure during CT is similar to that of a conventional skull radiograph (1.0 to 2.5 rad). Exposure values for personnel attending the patient are minimal (e.g., 1 to 2 mrad/hr for the anesthesiologist positioned next to the scan). However, radiation monitoring badges and lead aprons should be worn by personnel who participate in CT scanning on a regular basis.

Magnetic Resonance Imaging

Magnetic resonance imaging is a noninvasive diagnostic technique that is superior to CT in many

CNS disorders. This technique employs a strong magnetic field and pulsed radiofrequency energy to generate images. When a biologic specimen is placed within a static magnetic field, certain atomic nuclei

(nuclei with an odd number of protons, such as ^{1}H nuclei) act like magnets and are aligned. The atoms are then subjected to a radiofrequency pulse that deflects their orientation. When the radiofrequency pulse is discontinued, the nuclei rotate back into alignment with the static magnetic field. The energy released as the nuclei "relax" is used to create the MR image. The magnet of the MRI system is in the form of a tube that can accommodate the human body. The patient must remain still during investigation, which may last 1 hour, to prevent imaging artifacts.

The MRI is an extremely valuable diagnostic tool that provides excellent contrast between gray and white brain matter. The images can be displayed in axial, coronal, or sagittal planes. Because there is no dental or bony artifact, the MRI is superior to the CT scan in examining the posterior fossa. Other areas optimally imaged by MRI include the pineal gland region, sella and parasellar structures, the limbic system, cranial nerves, internal auditory canal, the cerebellopontine angle, and leptomeninges. Magnetic resonance angiography (MRA) provides images of arterial and dural sinus blood flow. Magnetic resonance spectroscopy provides noninvasive biochemical measurements of specific brain metabolites and can be helpful in the early detection of stroke.

The intense magnetic field creates unique challenges for the anesthesiologist. The high-static magnetic field (0.12 to 2.00 tesla [T]) and the radiofrequency energy transmitted during image acquisition may damage or cause malfunction of electrical, electronic, or mechanical life support and monitoring equipment. Conversely, the radiofrequency energy generated by these devices can interfere with MR signal detection, producing artifacts that degrade the image. Another problem unique to MRI is that ferromagnetic substances placed within the magnetic field are propelled toward the scanner. A list of MRI-compatible equipment and monitors has been published.[136]

Laryngoscopes are not magnetic, but the batteries are. Therefore, to use a laryngoscope within the scanning room, plastic- or paper-coated batteries must be used. A prebent RAE tube is recommended owing to limited vertical space within the scanner. Very long breathing tubes are required, and either pipeline gases or a remotely placed anesthesia machine can be used. Aluminum cylinders can be used safely within the scanning room. MRI-compatible anesthesia machines and ventilators are available. The anesthesia machine can be bolted to the wall or modified by removal of ferromagnetic components. The ventilators are pneumatically driven and volume-cycled and have fluidic controls. The ventilator is completely powered by high-pressure oxygen delivered by a wall source or from large cylinders placed outside the imaging room, and electronic parts have been replaced with plastic, aluminum, or nonmetallic alloys.

The implementation of monitoring during MRI is difficult because of remote access to the patient and the interactions between various monitoring devices and the MR scanner, as previously described. For example, standard ECG monitors produce problems with image degradation from wire leads acting as antennas and with artifact produced by radiofrequency pulses and static magnetic fields. Burns under ECG electrodes have been reported. MR-compatible ECG monitors, cables, fasteners, and electrodes have been developed. However, this ECG provides only heart rate and rhythm and cannot be used to monitor ischemia. Additional suggestions for improving ECG monitoring include placing electrodes close together near the three-dimensional center of the imager and twisting the leads. Both noninvasive and invasive pressure monitoring have been successfully used during MRI. Blood pressure is easily measured with an ordinary cuff and long pressure tubing without metal connections. The blood pressure dial must be kept away from the magnetic field. Automated blood pressure devices without metal connectors have also been used. Using nonmetallic components, pressure transducers connected to intravascular catheters for central venous, pulmonary artery, and arterial pressure monitoring can function near the magnet. Transducers are affixed along the side of the magnet at its midpoint to minimize artifact. Shielded electric extension cables couple the transducers to the monitors located outside the scanning room. There have been reports of image degradation with the pulse oximeter. Placing the oximeter a distance from the magnet and the probe on the patient's toe, which is usually outside the magnet, and using a fiberoptic cable may improve image quality. Monitoring of heart rate and

respiration can be achieved using nonmetallic precordial or esophageal stethoscopes; however, the drum-like noise of the scanner may obscure auscultated heart and breath sounds. A standard vascular Doppler has also been used to monitor heart rate. Capnography is possible with long tubing and high-powered suction. Changes in respiratory rate are easily observed, but the end-tidal CO_2 reading may be less than the actual value. Although temperature monitoring is particularly important in the cold MRI suite, especially in pediatric patients, it has been difficult to implement. The wires conducting the signal from the thermistor may function as an antenna for radiofrequency signals and produce imaging artifact and burns. Nonferromagnetic disposable temperature strips may be used. All efforts to minimize patient heat loss should be implemented: using bags of warmed intravenous fluids, heating pads, and airway humidification and covering the patient.

Guidelines for using the MRI have been issued and are updated by the Institute for Magnetic Resonance Safety, Education and Research.[137] It is recommended that women in the first trimester of pregnancy not be scanned because of possible developmental consequences. Patients with demand pacemakers should not be scanned because the varying magnetic field can induce electric currents in the pacemaker wires, which may be mistaken for the natural electrical activity of the heart, inhibiting pacemaker output. Metallic objects such as vascular clips or shrapnel can move and become displaced when exposed to the magnetic field. Patients who have a large metallic implant or prosthesis can be scanned until the heat at the site of the implant or prosthesis becomes uncomfortable. There is a possibility that induced currents can affect myocardial contractility or produce arrhythmias. Full resuscitation facilities should be available.

Positron Emission Tomography

Biochemical or physiologic processes involved in cerebral metabolism can be imaged with positron emission tomography (PET). After receiving intravenous radionuclide, such as fluorodeoxyglucose (FDG), the patient is scanned in a specialized detector system. This system detects the positron energy emitted from the radionuclide. Computerized reconstruction procedures produce tomographic images. The information from PET can be overlaid on CT or MR images to improve anatomic localization of detected activity. When the MRI is normal in a patient with seizures, PET might provide localizing information prior to focal resection treatment. The injection of FDG renders the patient radioactive for 24 hours. The usual protocol involves two initial scans lasting 15 to 20 minutes followed by another scan in 2 to 3 hours. PET scanners do not require nonferromagnetic monitors and equipment.

Cerebral Angiography

Angiography is used to delineate the vasculature of the brain. Catheters are usually introduced through the common femoral artery, which has replaced direct carotid artery puncture.

Digital subtraction angiography reduces the required volume of intra-arterial contrast and the overall duration of the procedure.

There are several risks and problems associated with angiography, including an incidence of neurologic problems related to angiography itself. In addition, arterial spasm, hematoma, and local infection can occur at the site of needle puncture. Subintimal dissection or occlusion of the vessel may result from injection into the vessel wall. Iodine-containing contrast media produce vasodilation and a burning sensation in the distribution of the injected vessel. Septicemia, cerebral embolism, anaphylactic reactions to the iodinated contrast material, and, rarely, seizures or death are all potential complications of cerebral angiography.

The introduction of low-ionic and nonionic contrast material has reduced both the discomfort and toxicity associated with angiography. Because of this, patients usually do not require general anesthesia and are able to tolerate the procedure with minimal or no sedation. When general anesthesia is requested for children or uncooperative adults, the angiogram quality may be enhanced by hyperventilation. Hypocarbia is thought to improve study quality by slowing the cerebral circulation and improving delineation of tumor blood vessels, perhaps through an inverse

steal phenomenon.

Interventional Neuroradiology

Interventional neuroradiology (INR) has developed from traditional neuroradiology and neurosurgery to procedures that treat CNS disease by endovascular access.[138] Procedures such as therapeutic embolization and superselective angiography of vascular malformations, coiling of cerebral aneurysms, balloon angioplasty of occlusive cerebrovascular disease or cerebral vasospasm, therapeutic carotid occlusion for giant aneurysms and brain tumors, and others may be performed. Because these procedures are inherently dangerous, anesthesiologists can help prevent and manage morbidity and mortality.

Most interventional neuroradiology procedures can be accomplished with conscious sedation. The agents chosen for conscious sedation must alleviate pain and discomfort and provide anxiolysis, patient immobility, and a rapid return to consciousness for neurologic testing. A variety of sedation regimens, most often using a combination of midazolam, opioid, and propofol, have been successfully administered. The goal of drug titration is to render the patient well-sedated with a patent airway.

General anesthesia is always administered for small children and uncooperative adult patients. In addition, many neuroradiologists now prefer general anesthesia to reduce motion artifacts and to improve the quality of images during high-risk procedures, even though it prevents awake neurologic testing. The specific choice of anesthesia and airway control via endotracheal tube or laryngeal mask airway may be guided by the condition and physical status of the patient. Cannulation of the femoral artery is the most stimulating portion of the procedure, and the total anesthetic requirement is usually minimal. Total intravenous techniques or combinations of inhalation and intravenous agents with muscle relaxant are chosen with the goal of maintaining adequate systemic and intracranial hemodynamics and immobility throughout the procedure and producing a rapid return to consciousness during emergence.[139]

Before initiating anesthesia, the patient is made comfortable with padding under head, neck, and body, and all pressure points are protected. Two large-bore intravenous catheters are inserted, and standard monitoring is applied. Arterial pressure is monitored for intracranial and spinal cord procedures and whenever blood pressure manipulation is required. Awake neurologic assessment and other CNS monitors (e.g., EEG, evoked potentials, or transcranial Doppler) may be used. During and after these procedures, careful management of coagulation is required to prevent thromboembolic complications. It is important to communicate with the radiologist concerning the degree, timing, and continuation of anticoagulation. A clot with devastating embolic potential can easily develop on a catheter during the procedure, if heparinization is not adequately maintained. At the end of the procedure, protamine may or may not be necessary for heparin reversal. Special techniques such as deliberate hypotension or hypertension and hypercapnia may be requested during certain procedures.

Complications during instrumentation of the cerebral vasculature can be sudden and dramatic. Simultaneous with airway maintenance, it is important to determine whether the problem is hemorrhagic or occlusive. Hemorrhagic disasters require immediate heparin reversal with protamine and low normal blood pressure. Occlusive disasters require deliberate hypertension, titrated to neurologic examination, with or without direct thrombolysis. Other resuscitative measures that might be initiated include rapid fluid infusion, 15° head-up position, hyperventilation, diuretics, anticonvulsants, hypothermia (33 to 34°C), and thiopental infusion titrated to EEG burst suppression.

ANESTHETIC MANAGEMENT OF NEUROSURGICAL PATIENTS

9 The administration of anesthesia to neurosurgical patients requires an understanding of the basic principles of neurophysiology and the effects of anesthetic agents on intracranial dynamics, as reviewed in the previous sections of this chapter.

Preoperative Evaluation

During the preoperative evaluation, the patient's overall medical condition must be considered and integrated into the formulation of an anesthetic management plan. Neurosurgical procedures tend to be lengthy, requiring unusual positioning of the patient and the institution of special techniques such as hyperventilation, cerebral dehydration, and deliberate hypotension. Not all patients can tolerate the position desired by the surgeon; this must be addressed and, if possible, evaluated preoperatively. Furthermore, in patients with cardiac disease, routine institution of osmotherapy or hyperventilation may compromise organ function. Such patients must be medically optimized and, when indicated, cardiac monitoring should be instituted. Except for neurosurgical emergencies (e.g., head trauma or impending herniation), most neurosurgical procedures can be delayed to treat medically unstable conditions.

The preoperative evaluation must include a complete neurologic examination with special attention to the patient's level of consciousness, presence or absence of increased ICP, and extent of focal neurologic deficits. The signs and symptoms frequently associated with intracranial hypertension are headache, nausea, papilledema, unilateral pupillary dilation, and oculomotor or abducens palsy. With advanced stages of intracranial hypertension, the patient exhibits a depressed level of consciousness and irregular respiration. The clinical signs do not reliably indicate the level of ICP. Only a direct CSF pressure measurement can be used to quantitate the pressure; however, indirect evidence of elevated ICP can be determined by evaluating the MRI or CT scan for a mass lesion accompanied by a midline shift of 0.5 cm or greater and/or encroachment of expanding brain on CSF cisterns.

The location of the lesion in the supratentorial or infratentorial compartment will determine the clinical presentation and

anesthetic management. Supratentorial disease is usually associated with problems in the management of intracranial hypertension, whereas infratentorial lesions cause problems related to mass effects on vital brainstem structures and elevated ICP as a result of obstructive hydrocephalus.

Fluid and electrolyte abnormalities are common in patients with reduced levels of consciousness. Patients are usually dehydrated and develop electrolyte abnormalities because of decreased fluid intake, iatrogenic water restriction, neuroendocrine abnormalities, and diuresis from diuretics, steroid-related hyperglycemia, and x-ray contrast agents. Fluid and electrolyte abnormalities must be corrected before induction of anesthesia to prevent cardiovascular instability.

COMMON INTRACRANIAL PATHOLOGY

Supratentorial Intracranial Tumors

Supratentorial tumors (meningiomas, gliomas, and metastatic lesions) change intracranial dynamics predictably. Initially, when the lesion is small and slowly expanding, volume-spatial compensation occurs by compression of the CSF compartment and nearby cerebral veins, which prevents increases in ICP. As the lesion grows, compensatory mechanisms become exhausted, and any further increase in tumor mass will cause progressively greater increases in ICP. Primary or metastatic tumors or chronic subdural hematomas can present as chronic mass lesions. Because of the ability of the intracranial compartment to compensate up to a point, patients may exhibit minimal neurologic dysfunction despite the presence of a large mass, elevated ICP, and shifts in the position of brain structures.

Significant changes in ICP can occur with supratentorial tumors if they develop a central area of hemorrhagic necrotic tissue or a wide border of brain edema. As the tumor enlarges, it can outstrip its blood supply, developing a central hemorrhagic area that may expand rapidly, increasing ICP. Brain edema surrounding the tumor increases the effective bulk of the tumor and represents an additional portion of the brain that is not autoregulating. In such situations of compromised intracranial compliance, small increases in arterial pressure may produce large

increases in CBF, which can markedly increase intracranial volume and ICP with its attendant complications—cerebral ischemia and herniation. In addition to hypertension, other causes of increased cerebral blood volume, such as hypercarbia, hypoxia, vasodilating agents, and jugular venous obstruction, can adversely affect cerebral hemodynamics and must be avoided perioperatively.

Anesthetic Techniques and Drugs

10 The goal of neuroanesthetic care for patients with supratentorial tumors is to maximize therapeutic modalities that reduce intracranial volume. ICP must be controlled before the cranium is opened, and optimal operating conditions obtained by producing a slack brain that facilitates surgical dissection. Various maneuvers and pharmacologic agents have been used to reduce brain bulk (Table 27-9). For example, administration of diuretics or steroids, hyperventilation, and systemic blood pressure control may be implemented preoperatively to reduce cerebral edema and brain bulk, thereby reducing ICP. The application of these methods selectively or together, when necessary, is often accompanied by marked clinical improvement.

TABLE 27-9 Clinical Control of Intracranial Hypertension

Diuretics: Osmotic: Mannitol (0.25–1 g/kg iv), hypertonic saline (under investigation). Furosemide: 0.5–1 mg/kg iv alone or 0.15–0.3 mg/kg iv in combination with mannitol.
Corticosteroids: Dexamethasone (effective for localized cerebral edema surrounding tumors; requires 12–36 hours).
Adequate ventilation: $PaO_2 \geqslant 100$ mmHg, $PaCO_2$ 33–35 mmHg; hyperventilation on demand.
Optimize hemodynamics (MAP, CVP, PCWP, HR): Target normotension and maintain cerebral perfusion pressure (CPP = MAP-ICP) to avoid cerebral ischemia.
Fluid therapy: Target normovolemia before anesthetic induction to prevent hypotension. Use glucose-free isoosmolar crystalloid solutions to prevent increases in brain water content (from hypoosmolality) and ischemic damage (from hyperglycemia).
Position to improve cerebral venous return (neutral, head-up position).
Drug-induced cerebral vasoconstriction (e.g., thiopental, propofol).
Temperature control: Avoid hyperthermia perioperatively. Consider using mild intraoperative hypothermia.
Cerebral spinal fluid drainage—to acutely reduce brain tension.

Clinical Control of Intracranial Hypertension. Rapid brain dehydration and ICP reduction can be produced by administering the osmotic diuretic, mannitol, or the loop diuretic, furosemide. Mannitol is given as an intravenous infusion in a dose of 0.25 to 1.0 g/kg. Its action begins within 10 to 15 minutes and is effective for approximately 2 hours. Larger doses produce a longer duration of action but do not necessarily reduce ICP more effectively. Furthermore, larger doses and repeated administration can result in metabolic derangement. Mannitol is effective when the blood-brain barrier is intact. By increasing the osmolality of blood relative to the brain, mannitol pulls water across an intact blood-brain barrier from brain to blood to restore the osmolar balance. When the blood-brain barrier is disrupted, mannitol may enter the brain and increase osmolality. Mannitol could pull water into the brain as the plasma concentration of the agent declines and cause a rebound increase in ICP. This rebound increase in ICP may be prevented by maintaining a mild fluid deficit. Mannitol has been shown to cause vasodilation of vascular smooth muscle, which is dependent on dose and rate of administration. Mannitol-induced vasodilation affects intracranial and extracranial vessels and can transiently increase cerebral blood volume and ICP while simultaneously decreasing systemic blood pressure. Because mannitol may initially increase ICP, it should be given slowly ($\geqslant$10-minute infusion) and in conjunction with maneuvers that decrease intracranial volume (e.g., steroids or hyperventilation). Prolonged use of mannitol

may produce dehydration, electrolyte disturbances, hyperosmolality, and impaired renal function.

Hypertonic saline, another osmotic diuretic, is currently under investigation.[140] Hypertonic saline solutions have been shown to reduce ICP in animal models and in human studies and may be more effective than other diuretics in certain clinical conditions, for example, patients with refractory intracranial hypertension or in those who require brain debulking and maintenance of intravascular volume.[140,141] Hypertonic saline also can be used as an alternative or adjunct to intraoperative use of mannitol. There are several potential adverse effects of hypertonic saline therapy (Table 27-10). Significant complications such as central pontine myelinolysis and intracranial hemorrhage have not been reported in human studies. Different types of hypertonic saline solutions with different methods

of infusion (bolus and continuous) have been reported in the literature. Published data are encouraging, but more studies are required to determine dose-response curves and the safety and efficacy of these solutions.

TABLE 27-10 Hypertonic Saline: Potential Adverse Effects of Intravenous Administration

·CENTRAL NERVOUS SYSTEM	·SYSTEMIC
Decreased level of consciousness	Hyperosmolality Hypernatremia
Seizures	Congestive heart failure
Central pontine myelinolysis[a]	Hypokalemia
Subdural and intraparenchymal hemorrhage[a]	Hyperchloremic acidosis Coagulopathy
Rebound cerebral edema	Phlebitis Renal failure

[a]Not reported in human studies.

Hypertonic agents, either mannitol or hypertonic saline, should be administered cautiously in patients with preexisting cardiovascular disease. In these patients, the transient increase in intravascular volume may precipitate left ventricular failure. Furosemide may be a better agent to reduce ICP in patients with impaired cardiac reserve.

The loop diuretic furosemide reduces ICP by inducing a systemic diuresis, decreasing CSF production, and resolving cerebral edema by improving cellular water transport. Furosemide lowers ICP without increasing cerebral blood volume or blood osmolality; however, it is not as effective as mannitol in reducing ICP. Furosemide can be given alone as a large initial dose (0.5 to 1 mg/kg) or as a lower dose with mannitol (0.15 to 0.30 mg/kg). A combination of mannitol and furosemide diuresis has been shown to be more effective than mannitol alone in reducing ICP and brain bulk but causes more severe dehydration and electrolyte imbalances. With combined therapy, it is necessary to monitor electrolytes intraoperatively and replace potassium as indicated.

Corticosteroids reduce edema around some brain tumors; however, steroids require many hours or

days before a reduction in ICP becomes apparent. The administration of steroids preoperatively frequently causes neurologic improvement that can precede the ICP reduction. One explanation for this is that the neurologic improvement is accompanied by partial restoration of the previously abnormal blood-brain barrier. Postulated mechanisms of action for steroidal reduction in brain edema are brain dehydration, blood-brain barrier repair, prevention of lysosomal activity, enhanced cerebral electrolyte transport, improved brain metabolism, promotion of water and electrolyte excretion, and inhibition of phospholipase A_2 activity. The potential complications of continuous perioperative steroid administration are hyperglycemia, glucosuria, gastrointestinal bleeding, electrolyte disturbances, and increased incidence of infection. Therefore, the potential risks and benefits of continuous steroid administration need to be evaluated in these patients.

Hyperventilation reduces brain volume by decreasing CBF through cerebral vasoconstriction. For every 1 mm Hg change in $PaCO_2$, CBF changes by 1–2 mL/100 g/min. The duration of effectiveness of hyperventilation for lowering ICP may be as short as 4 to 6 hours, depending on the pH of the CSF. Hyperventilation is only effective when the CO_2 reactivity of the cerebrovasculature is intact. Impaired responsiveness to changes in CO_2 tension occurs in areas of vasoparalysis, which are associated with extensive intracranial disease such as ischemia, trauma, tumor, and infection.

The typical target $PaCO_2$ is 30 to 35 mmHg. A $PaCO_2$ less than 25 to 30 mmHg in some pathologic conditions may be associated with ischemia caused by extreme cerebral vasoconstriction.[142,143] By monitoring global cerebral oxygenation with, for example, $SjVO_2$, the therapeutic effectiveness of hyperventilation can be determined and more safely applied.

The autoregulation of CBF has been discussed, as has the relationship between blood pressure and ICP when autoregulation is disturbed. The therapeutic goals are to maintain CPP and to control intracranial dynamics so that cerebral ischemia, edema, hemorrhage, and herniation are avoided. Severe hypotension results in cerebral ischemia and should be treated with volume replacement, inotropes, or vasopressors as dictated by clinical need. Severe hypertension, conversely, can worsen cerebral edema and cause intracranial hemorrhage and herniation. The β-adrenergic blockers propranolol and esmolol and the combined α- and β-adrenergic blocker labetalol are effective in reducing systemic blood pressure in patients with raised ICP with minimal or no effect on CBF or ICP.

Restricted fluid intake was a traditional approach to intracranial decompression therapy but is now rarely used to lower ICP. Severe fluid restriction over several days is only modestly effective in reducing brain water and can cause hypovolemia, resulting in hypotension, inadequate renal perfusion, electrolyte and acid-base disturbances, hypoxemia, and reductions in CBF. In patients who are dehydrated preoperatively, intravascular volume must be restored to normal before induction of anesthesia to prevent hypotension in response to anesthetic agents and positive-pressure ventilation. Fluid resuscitation and maintenance fluids in the routine neurosurgical patient are provided with glucose-free isoosmolar crystalloid solutions to prevent increases in brain water content from hypoosmolality. For routine craniotomy, the patient receives hourly maintenance fluids and replacement of urine output. Blood loss is replaced at approximately a 3:1 ratio (crystalloid:blood) down to a hematocrit of approximately 25 to 30%, depending on the patient's physiologic status.

Solutions containing glucose are avoided in all neurosurgical patients with normal glucose metabolism, since these solutions exacerbate ischemic damage and cerebral edema. Hyperglycemia augments ischemic damage by promoting neuronal lactate production, which worsens cellular injury. Intravenous fluids containing glucose and water ($D_5W_{0.45\%}$ NaCl or D_5W) are particularly problematic because the glucose is metabolized and the free water remains in the intracranial fluid compartment, resulting in brain edema. Brain water can interfere with surgical exposure and, after closure of the skull, can compromise cerebral perfusion. In normal patients, both preoperative dexamethasone treatment and general anesthesia–induced gluconeogenesis may elevate resting glucose levels. Therefore, blood glucose levels should be monitored during craniotomy and maintained at near low-normal range. This should be accomplished mainly by withholding glucose.

For most neurosurgical patients, a neutral head position, elevated 15 to 30°, is recommended to

decrease ICP by improving venous drainage. Flexing or turning of the head may obstruct cerebral venous outflow, causing a dramatic ICP elevation that has been shown to resolve with resumption of a neutral head position. Lowering the head impairs cerebral venous drainage, which can quickly result in an increase in brain bulk and ICP.

The application of positive end-expiratory pressure (PEEP) to mechanically ventilated patients can potentially increase ICP. This effect occurs when PEEP increases mean intrathoracic pressure, impairing cerebral venous outflow and cardiac output. When PEEP is required to maintain oxygenation, it should be applied cautiously and with appropriate monitoring to

minimize decreases in cardiac output and increases in ICP. PEEP levels of 10 cm H_2O or less have been used without significant increases in ICP or decreases in CPP. When higher levels of PEEP are required to optimize the PaO_2-PEEP–CPP relationship, both central venous pressure and ICP monitoring are indicated.

The administration of pharmacologic agents that increase cerebral vascular resistance can acutely reduce ICP. Thiopental and propofol are potent cerebral vasoconstrictors that can be used for this purpose. The effects of these agents on CBF, cerebral metabolic rate for oxygen ($CMRO_2$), ICP, and CPP are reviewed in this chapter. These agents are usually administered during induction of anesthesia but may also be administered in anticipation of noxious stimuli or to treat persistently elevated ICP in the intensive care unit.

Although rarely used to reduce ICP, hypothermia does this by decreasing brain metabolism, CBF, cerebral blood volume, and CSF production.[144] Drugs that centrally suppress shivering, muscle relaxants, and mechanical ventilation are required when hypothermic techniques are employed. Intraoperatively, a modest degree of hypothermia, approximately 34°C, has been recommended as a way to confer neuronal protection during focal ischemia. Hypothermic techniques are also employed to cool febrile neurosurgical patients. Hyperthermia is particularly dangerous in neurosurgical patients because it increases brain metabolism, CBF, and the propensity for cerebral edema.

To acutely reduce brain tension, CSF drainage either by direct surgical puncture of the lateral ventricle or by lumbar spinal catheter can be employed. Lumbar CSF drainage should be used cautiously and only when the dura is open and the patient is at least mildly hyperventilated to prevent acute brain herniation. Brain tension can be effectively reduced by draining 10 to 20 mL of CSF.

Premedication

Lethargic patients do not receive premedication. Patients who are alert and anxious may receive an anxiolytic (e.g., midazolam 5 mg po) before coming to the operating room. If there is any doubt about the patient's level of consciousness, the patient may be given sedation or analgesics in the operating room after an intravenous route is established. For the preinduction insertion of invasive monitoring devices in an awake, conversant patient, premedicants (e.g., small doses of opioids) should be considered to alleviate the discomfort from needle punctures.

Monitoring

In addition to the routine monitors, measurement of intra-arterial blood pressure, arterial blood gases, central venous pressure, and urine output is recommended for all major neurosurgical procedures. An arterial cannula is inserted before induction of anesthesia to continuously monitor blood pressure and to estimate CPP. When the arterial pressure transducer is at midhead level (usually the level of the external auditory meatus), MAP approximates the MAP at the level of the circle of Willis. Cerebral perfusion pressure is calculated as the difference between MAP and central venous pressure in patients without intracranial hypertension or the ICP in those with intracranial hypertension. When the cranium is open, ICP equals atmospheric pressure and CPP equals MAP. With direct arterial pressure monitoring, the hemodynamic consequences of the pharmacologic agents administered during anesthesia are recognized instantly. In addition, the arterial catheter provides ready access for intraoperative measurement of arterial blood gases,

hematocrit, serum electrolytes, glucose, and osmolality. Arterial blood gas measurement is necessary to verify the adequacy of hyperventilation. In the elderly and those with ventilation/perfusion mismatch, end-tidal CO_2 may correlate poorly with the $PaCO_2$. Therefore, the difference between $PaCO_2$ and end-tidal CO_2 must be determined for a given patient in a given position. Radial, femoral, or brachial arteries are suitable for short-term cannulation; however, after ulnar artery collateral blood flow is tested, cannulation of the radial artery is preferred.

Because most neurosurgical patients are dehydrated preoperatively and then subjected to intraoperative diuresis, the measurement of cardiac preload and urine output is important. A right atrial catheter reflects cardiac preload and is used to determine the preoperative fluid deficit and rate of intra-operative fluid infusion. When possible, the central venous pressure catheter should be inserted through an antecubital vein instead of the jugular or subclavian veins. This avoids increased ICP from both the head-down position and decreased cerebral venous outflow. The position of the antecubital central venous pressure can be verified by chest radiograph, transducer pressure waveform, or p-wave configuration on the ECG.

Urine output is also measured as an indicator of perioperative fluid balance. During craniotomy, a diuresis occurs initially following the administration of osmotic or loop diuretics. Reduced urine output may reflect either hypovolemia or release of antidiuretic hormone.

Preoperative ICP monitoring is rarely used in patients for elective supratentorial tumor operations. ICP monitoring is an invasive procedure that can cause bleeding or infection. When performed with local anesthesia before induction, the procedure can be uncomfortable to the patient.

Muscle Relaxants

An increase in ICP has been reported after administration of succinylcholine in animals and humans. Intravenous administration of succinylcholine is reported to produce activation of the EEG and increases in CBF and ICP in dogs with normal brains.[145] These cerebral effects have been attributed to succinylcholine-induced increases in muscle afferent activity that produce cerebral stimulation. In many, but not all, patients with compromised intracranial compliance, succinylcholine has been shown to increase ICP. This increase can be blocked with a full, paralyzing dose of vecuronium or a pretreatment (defasciculating) dose of metocurine.[144] The nondepolarizing agent apparently eliminates the massive afferent input to the brain after succinylcholine.

To achieve muscle relaxation for intubation of the trachea, succinylcholine is not recommended for elective neurosurgical cases; however, succinylcholine remains the best agent for achieving total paralysis for the rapid-sequence intubation of the trachea. Therefore, in an emergency room or ICU setting, when there is a risk of aspiration or a need for immediate reassessment of neurologic status, succinylcholine should be used. Simultaneously, an effort should be made to control anesthetic depth to protect against the ICP-elevating effects of such noxious stimuli as laryngoscopy, intubation, or tracheal suctioning. In the hemiplegic (or paraplegic) patient, succinylcholine is avoided because of the risk of hyperkalemia. Succinylcholine-induced hyperkalemia has also been reported after closed head injury and ruptured cerebral aneurysms in patients who were not hemiplegic or paraplegic.

Nondepolarizing muscle relaxants are used during induction and maintenance of anesthesia in neurosurgical patients. Agents that release histamine are avoided, however. Histamine alone may lower blood pressure and increase ICP, thus lowering CPP. When the blood-brain barrier is disrupted, histamine can produce cerebrovasodilation and increases in CBF. Depending on the dose and rate of administration, most of the benzylisoquinolinium compounds (*d*-tubocurarine, metocurine, atracurium, mivacurium) have the potential to release histamine and thus increase ICP. Doxacurium and cisatracurium produce minimal to no histamine release over a wide dose

range. Atracurium in intubating doses is reported to have no significant effect on ICP, blood pressure, or CPP in neurosurgical patients. The release of laudanosine by atracurium does not appear to have clinical significance in humans. Laudanosine has been reported to produce seizure

activity in animals.

The steroidal compounds (pancuronium, pipecuronium, vecuronium, and rocuronium) may be better relaxants for neurosurgical patients because they do not directly affect ICP. Pancuronium does not produce an increase in CBF, $CMRO_2$, or ICP in dogs.[144] However, pancuronium's vagolytic effects can cause increases in heart rate and blood pressure, which may elevate ICP in patients with disturbed autoregulation. Pipecuronium, another long-acting agent, is reported to have no significant effect on ICP or CPP in patients with intracranial tumors and no hemodynamic side effects. Vecuronium has no effect on ICP, heart rate, or blood pressure in neurosurgical patients. To achieve relatively rapid airway control (within 90 seconds), a priming dose of vecuronium (0.01 mg/kg) can be administered followed by a higher dose (0.10 mg/kg), or high doses of vecuronium (to 0.4 mg/kg) can be safely administered without hemodynamic consequence. Rocuronium also has no effect on ICP in neurosurgical patients, but may have some mild vagolytic activity in higher doses (0.9 mg/kg).

Induction, Maintenance, and Emergence

When the patient is brought into the operating room, a gross neurologic examination should be repeated and documented because changes in the patient's neurologic status can occur overnight. In patients with elevated ICP by clinical exam, CT scan, and/or ICP measurement, osmotherapy may be indicated before induction of anesthesia. After appropriate monitoring devices are applied, the cooperative patient is asked to hyperventilate while preoxygenation is provided. Before laryngoscopy and intubation of the trachea, the patient is smoothly and deeply anesthetized with agents that reduce ICP. In the presence of elevated ICP, thiopental is commonly used to induce anesthesia; however, alternative agents such as propofol or midazolam can be used depending on the patient's medical condition. The following induction sequence is suggested: The intravenous administration of thiopental (3 to 5 mg/kg) or propofol (1.25 to 2.5 mg/kg) is followed by an opioid (fentanyl, 3 to 5 μg/kg) and muscle relaxant. If no airway difficulties are anticipated, a nondepolarizing muscle relaxant is administered while controlled hyperventilation with 100% oxygen is instituted. In patients who have been vomiting because of elevated ICP, cricoid pressure is applied during mask ventilation. To deepen the anesthetic, fentanyl is administered in 50-μg increments to a total dose of 10 μg/kg, depending on the blood pressure response. Lidocaine (1.5 mg/kg) is also administered intravenously 90 seconds before intubation to suppress laryngeal reflexes. When the peripheral muscle twitch response disappears, an additional 2 to 3 mg/kg bolus of thiopental is administered, and endotracheal intubation is performed as rapidly and smoothly as possible. An esmolol infusion or bolus may also be used to reduce the heart rate and blood pressure response to laryngoscopy and intubation. After induction of anesthesia, ventilation of the lung is controlled mechanically. Arterial blood gases are measured after intubation to establish the arterial end-tidal CO_2 gradient.

Routine institution of hyperventilation is no longer recommended in neurosurgical patients because of the risk of cerebral ischemia in some pathologic conditions. In other words, surgical conditions should define the $PaCO_2$ level for each patient. For example, in patients with significant intracranial hypertension or when using volatile agents, $PaCO_2$ is usually adjusted between 30 to 35 mmHg to reduce brain bulk.[146] After direct visualization of the brain and/or discussion with the neurosurgeon, the $PaCO_2$ level should be adjusted as necessary.

Since anesthetics affect the intracranial environment, there continues to be controversy over the best choice of anesthetic technique for neurosurgical patients, that is, intravenous- or volatile-based techniques. In practice, the anesthetics most frequently administered to neurosurgical patients are either propofol-opioid or isoflurane-opioid.[31] The opioids selected are usually fentanyl or remifentanil. There have been no large clinical outcome studies conducted comparing anesthetic techniques. Our choice of anesthetics has been based primarily on information derived from experimental and clinical studies of cerebral hemodynamics (CBF, $CMRO_2$), ICP and recovery characteristics of different agents.

A popular maintenance technique for neurosurgical patients is the continuous infusion of propofol with remifentanil or fentanyl. In brain tumor patients, this technique has been shown to reduce

ICP more effectively than either isoflurane or sevoflurane,[31] and in nonneurosurgical patients, propofol with remifentanil produced a quicker emergence than either desflurane or sevoflurane.[147] This technique would seem ideal for neurosurgical patients; however, questions have been raised regarding the risk of cerebral hypoperfusion with propofol anesthesia.[148,149] Studies suggest that propofol anesthesia produces a reduction of CBF larger than a reduction of CMR, resulting in a decrease of the CBF/CMR ratio.[149,150] In susceptible patients, the risk of cerebral hypoperfusion may be even greater when patients are hyperventilated under propofol anesthesia.[149,150]

Nitrous oxide, 50 to 70% in oxygen, is administered by some to decrease the total dose of intravenous agent or the required concentration of volatile agent. The cerebrovascular effects of nitrous oxide are not benign,[38,144] and studies report that at equipotent doses, isoflurane has less adverse effects on ICP and CBF than nitrous oxide. In patients with elevated ICP or low compliance, some clinicians avoid the administration of either nitrous oxide or high concentrations of isoflurane (i.e., greater than 1.0%). Alternatively, an opioid–thiopental or propofol anesthetic technique may be employed with midazolam or low-dose isoflurane added for amnesia. When severe intracranial hypertension exists and the brain is tight despite adequate hyperventilation and the administration of steroids and diuretics, a totally intravenous technique using a thiopental infusion (2 to 3 mg/kg/hr) and fentanyl boluses or infusion (1 to 4 μg/kg/hr) is recommended.

In the usual craniotomy for excision of a supratentorial tumor, the conduct of the anesthetic is aimed at awakening and extubating the patient at the end of the procedure to permit early assessment of surgical results and postoperative neurologic follow-up. The risks and benefits of an early versus delayed recovery in neurosurgical patients have been reviewed.[151] The authors recommend extubation of the neurosurgical patient only when there is complete systemic and brain homeostasis. There are several conditions listed in Table 27-11 that can delay awakening in neurosurgical patients and should be considered prior to developing an extubation plan.

TABLE 27-11 Causes of Delayed Awakening

Preoperative decreased level of consciousness
Large intracranial tumor
Residual anesthetics
Metabolic or electrolyte disturbances
Residual hypothermia
Surgical complications Seizures
Cerebral edema
Hematoma
Pneumocephalus
Vessel occlusion/ischemia

Intracranial hematoma and major cerebral edema are the most feared complications after intracranial surgery. In a retrospective study of 11,214 craniotomy patients, a relationship was demonstrated between perioperative hypertension and the development of postoperative hematomas.[152] Therefore, emergence from anesthesia should be as smooth as possible, avoiding straining or bucking on the endotracheal tube. Bucking can cause arterial hypertension and elevated ICP, which can lead to postoperative hemorrhage and cerebral edema. To avoid bucking, muscle relaxants are not reversed until the head dressing is applied. Intravenous lidocaine (1.5 mg/kg) can be administered 90 seconds before suctioning and extubation to minimize cough, straining, and hypertension. Antihypertensive agents such as labetalol and esmolol also are also administered during emergence to control systemic hypertension.

The patient is extubated only when fully reversed from paralysis, and when he or she is awake and

following commands. If the patient is not responsive, the endotracheal tube remains in place until the patient is awake and following commands. A brief neurologic examination is performed before and after extubation of the trachea. The patient is positioned with the head elevated 15 to 30° and transferred to the recovery room with oxygen by mask and oxygen saturation monitoring. Close monitoring and care, including frequent neurologic examinations, are continued in the recovery room.

Awake Craniotomy

Awake craniotomy with functional mapping is recommended for removal of tumors involving the eloquent cortex. Functional mapping is performed by stimulating the brain with a small electrical charge. A neuropsychologist then performs neurocognitive testing and/or monitors motor responses during mapping and later tumor resection. This technique allows maximal tumor resection with minimal postoperative neurological deficits from retraction, edema and/or resection of eloquent tissue. Other advantages include avoidance of general anesthesia and need for more intensive monitoring intra-operatively and postoperatively, a low complication rate, and reduction in resource utilization (e.g., shorter intensive care time and total hospital stay).[153,154]

Preoperative selection, evaluation, and preparation of the patients for awake craniotomy is slightly different than for general anesthesia. The patient must be cooperative and able to participate in neurocognitive testing. In addition, the patient must have an uncomplicated airway and be a candidate for general anesthesia. Most centers provide the patient with detailed information about the procedure and what to expect in verbal, written, and visual form.

In the operating room, there are several challenges for the anesthesiologist. As with any craniotomy, optimal operating conditions providing adequate surgical exposure and brain relaxation are required. For the awake craniotomy, the patient must be positioned very comfortably with bolsters and additional padding. Adequate analgesia and sedation are needed for head frame application, skin incision, craniotomy, and opening of the dura. During cortical mapping and tumor resection, the patient must be fully alert and cooperative, and able to participate in complex neurocognitive testing.

Several different anesthetic protocols have been reported for awake craniotomy.[154] These include neurolept anesthesia, propofol with or without opioid infusions, and asleep, awake, asleep techniques using laryngeal mask airways. Dexmedetomidine, a highly specific α-2 adrenoreceptor agonist, has been recommended for use during awake craniotomy.[155] It has the advantage of providing sedation and analgesia without respiratory depression.

All awake procedures with sedation run the risk of respiratory depression and poor patient cooperation. Complications such as seizures, increased ICP, hypertension, nausea, and vomiting, which are more likely to occur during craniotomy, also require prompt treatment.[153,156] Most anesthetic protocols include prophylaxis with antihypertensives, anticonvulsants and antiemetics to prevent these complications from occurring.

Infratentorial Intracranial Tumors

The perioperative management of infratentorial tumors poses significant surgical and anesthetic challenges because of the relatively confined space within the posterior fossa. The posterior fossa contains the medulla, pons, cerebellum, major motor and sensory pathways, primary respiratory and cardiovascular centers, and lower cranial nerve nuclei. Because of the posterior fossa's small size, a localized tumor can significantly compromise these vital brainstem structures and cranial nerves. Consequently, when evaluating patients with infratentorial tumors, the anesthesiologist should be aware that these patients have the potential to develop profound neurologic damage. Patients may exhibit depressed levels of consciousness secondary to increased ICP from obstructive hydrocephalus and/or exhibit signs of brainstem compression with depressed respiration and cranial nerve palsies. Preoperative endotracheal intubation and respiratory support may be required.

Special Anesthetic Considerations

Patient Position. A major challenge of infratentorial surgery is preventing further neurologic damage from the position of the patient and exploration. There is considerable controversy among neurosurgeons as to the best position for infratentorial surgery.[157]

Exploration of the posterior fossa has been traditionally performed in the sitting position because it provides excellent surgical exposure and facilitates venous and CSF drainage. From the standpoint of the anesthesiologist, the sitting position provides better ventilation and easier access to the chest, airway, endotracheal tube, and extremities. Furthermore, facial and conjunctival edema is reduced. However, the sitting position is associated with significant risks. In older or debilitated patients, the sitting position can produce cardiovascular instability, resulting in hypotension with cerebral and cardiovascular compromise. A significant risk of venous air embolism occurs in patients operated on in the sitting position, and an attendant risk of paradoxical air embolism may also occur in patients with a patent foramen ovale or other right-to-left shunt.

Other problems associated with the sitting position are peripheral nerve injury, pneumocephalus, jugular venous obstruction, and quadriplegia. Peripheral nerve injuries to the ulnar, sciatic, or lateral peroneal nerves can result if care is not taken in positioning and padding the respective pressure points. Pneumocephalus occurs frequently in patients who have surgery performed in the sitting position.[157] Pneumocephalus may develop into tension pneumocephalus postoperatively, producing serious neurologic dysfunction. Nitrous oxide has been implicated in the pathogenesis of tension pneumocephalus.[157] Because of this, when used, nitrous oxide should be discontinued before dural and cranial closure and avoided if surgery recurs within 14 days. Jugular venous obstruction causing swelling of the face and tongue may result from hyperflexion of the neck. To avoid this, head flexion should be limited by placing two

fingers between the mandible and sternum. Paraplegia, triplegia, and quadriplegia have been reported following surgery in the sitting position. This complication has been attributed to mechanical compression of the cervical spinal cord or vertebrobasilar blood vessels and stretching of spinal cord blood vessels, causing ischemia during head flexion. If hypotension occurs, the brainstem and cervical spinal cord are rendered even more vulnerable to an ischemic insult. During positioning for posterior fossa exploration, cases of position-related brainstem and cervical spinal cord ischemia have been reported. Therefore, flexion of the head on the cervical spine may be hazardous in some patients with large posterior fossa tumors and in elderly or arthritic patients. A preoperative examination of the mobility of the cervical spine, including a review of radiologic studies to determine the width of the cervical canal, should be performed to establish whether the patient can tolerate the position required for surgery. In addition, the application of SEP monitoring during positioning for surgery may be used to detect position-related ischemia.

Other positions used for posterior fossa exploration are the lateral, prone, and "park bench" or three-fourths prone positions. These alternative positions have been advocated because of the lower incidence of air emboli and greater cardiovascular stability associated with them. Potential disadvantages of these positions are malignant cerebellar edema and venous hemorrhage. To date, there is no evidence that operative position affects postoperative outcome. In a study that reviewed 579 posterior fossa craniectomies, patients in the sitting position had less blood loss and postoperative cranial nerve dysfunction than patients operated on in the horizontal position (supine, prone, lateral, and park bench), and there was no difference in the incidence of hypotension and postoperative cardiopulmonary complications between groups.[158] The incidence of venous air embolism in this series of patients was significantly greater in sitting versus horizontal patients (45 vs. 12%), but it was not associated with a significantly increased morbidity or mortality.[158] The authors concluded that there are significant advantages and disadvantages to both sitting and horizontal positions and that these positions can be used safely.

Because of various advantages and disadvantages to both sitting and horizontal positions, no one best position exists for all patients requiring exploration of the posterior fossa. The selection of the most appropriate position for an individual patient should be based on the location of the

tumor, surgical exposure, the patient's medical condition, and consideration of the risks and benefits.

Monitoring. During posterior fossa exploration, surgical retraction or manipulation of the brainstem or cranial nerves can cause significant cardiac dysrhythmia or alterations in blood pressure. Adequate warning of brainstem compromise is obtained by monitoring the ECG for alterations in cardiac rate and rhythm. In addition, direct arterial pressure monitoring provides continuous information on sudden changes in systemic blood pressure and an estimate of CPP. (To estimate CPP in the sitting position, the arterial transducer should be zeroed to the highest point on the skull.) The hemodynamic consequences of dysrhythmias or air embolism are also instantly recognized with direct arterial pressure monitoring.

Electrophysiologic monitoring of SEPs is used to detect ischemia and compromise of the brainstem or cranial nerves. For example, BAEPs are monitored during surgery for acoustic neuroma to help preserve function of cranial nerve VIII or during posterior fossa procedures to monitor brainstem ischemia. Depending on the tumor's location, SSEPs may also be used to detect brainstem compromise. Position-related ischemia has been observed during monitoring with either BAEPs or SSEPs. Electromyography is used during resection of acoustic neuromas and microvascular decompression to test seventh nerve function when the face is not accessible to palpation or visual assessment.

Venous Air Embolism. Venous air embolism may occur whenever the operative field is elevated 5 cm or more above the right atrial level. Whereas the incidence of air embolism is on average 40 to 45% in patients operated on in the sitting position, entrainment of air also occurs during operations performed in the lateral, supine, or prone positions. The primary pathophysiologic event in venous air embolism is intense vasoconstriction of the pulmonary circulation, which results in ventilation/perfusion mismatch, interstitial pulmonary edema, and reduced cardiac output as pulmonary vascular resistance increases.

Air may also pass directly through the pulmonary circulation or through right-to-left intracardiac shunts (e.g., probe-patent foramen ovale) to the coronary and cerebral circulation when right atrial pressure exceeds left atrial pressure. A patent foramen ovale exists in 20 to 30% of the population on autopsy study. In the sitting position, a reported 50% of patients develop right atrial pressure greater than left atrial pressure and thus have the potential for paradoxical air embolism. The calculated risk of paradoxical air embolism is 5 to 10%. Preoperative screening with precordial two-dimensional contrast echocardiography during a Valsalva maneuver and cough has been suggested as a method to identify patients with patent foramen ovale. An alternative technique is to perform contrast TEE with a ventilation maneuver after induction of anesthesia, but before surgery.[159] If a patent foramen ovale is detected with either screening method, a position other than sitting is recommended for surgery because of the risk of paradoxical air embolism.

Monitors used for detecting venous air embolism are listed in Table 27-12. The two-dimensional transesophageal echocardiogram detects air bubbles with an echocardiographic probe placed behind the heart. The transesophageal echocardiogram is slightly more sensitive than the precordial Doppler, but is invasive and cumbersome. The transesophageal echocardiogram has the advantage of monitoring air in the right and left cardiac chambers and the aorta, and thus can be used to detect both venous and arterial air embolism.

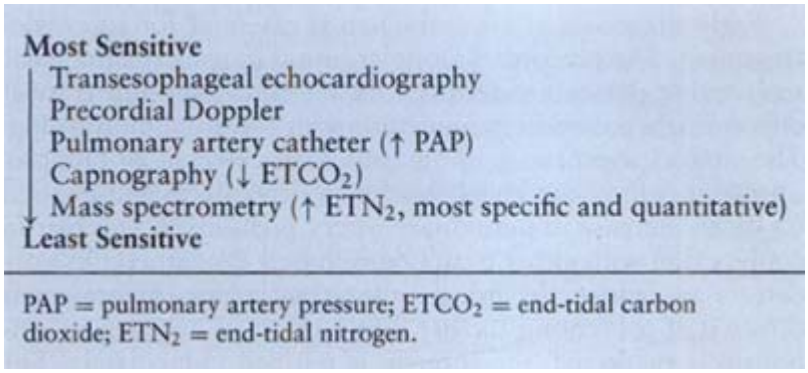

TABLE 27-12 Monitors for Detection of Venous Air Embolism

The precordial Doppler ultrasound transducer is the most sensitive noninvasive monitor of venous air embolism. It detects amounts of air as small as 0.25 mL. The transducer is positioned along the right parasternal border between the third and sixth intercostal spaces to maximize audible signals from the right atrium. Proper placement is confirmed by rapid injection of 5–10 mL of saline into a right atrial catheter. The resultant turbulent flow changes the Doppler sounds to a high-pitched noise similar to the sounds produced by intravascular air.

Pulmonary artery (PA) catheterization has been advocated for patients who undergo surgery in the sitting position. Passage of air into the pulmonary circulation leads to mechanical obstruction and reflex vasoconstriction from local hypoxemia. The PA catheter detects the resultant hypertension. (The change in pulmonary artery pressure correlates with the hemodynamic significance of the embolus because pulmonary artery pressure increases proportionally with the volume of air entering the pulmonary arteries.) Pulmonary artery pressure measurement is slightly more sensitive than capnography for detecting venous air embolism, but it is invasive. The PA catheter lumen is poorly designed for air aspiration. In addition, the fixed distance between the PA catheter tip and the right atrial port makes it difficult to position for both pulmonary capillary wedge pressure measurement and air aspiration. The catheter can be used to identify patients at risk for paradoxical air embolism, that is, patients who develop right atrial pressure greater than pulmonary capillary wedge pressure. When this occurs, measures to elevate pulmonary capillary wedge pressure, such as volume loading or repositioning, are undertaken.

In the operating room, exhaled gases can be measured by infrared analysis, mass spectrometers, and analyzers based on Raman scattering. The infrared absorption technique is the most popular method of measuring the concentration of CO_2 in the airway. The capnograph is very useful for diagnosing venous air embolism. Small volumes of intravascular air produce a ventilation/perfusion mismatch, which is reflected in a reduced end-tidal CO_2. The capnograph complements the capabilities of the precordial Doppler by differentiating hemodynamically insignificant emboli that are heard with the Doppler from significant emboli. Doppler sounds without reduction in end-tidal CO_2 usually indicate insignificant amounts of air.

End-tidal N_2 monitoring is specific for detecting air but is slightly less sensitive than end-tidal CO_2 in detecting subclinical air embolism. As intravascular air in the pulmonary circulation crosses the capillary–alveolar membrane, it is exhaled, increasing the end-tidal N_2 concentration. The advantage of knowing the value of the end-expired N_2 is the ability to calculate the volume of air entrained. When a patient is ventilated with an air–oxygen mixture, the increase in end-tidal N_2 with venous air embolism may not be evident. In addition, other causes of increases in end-tidal N_2 must be eliminated, such as a leak in the breathing circuit or an incomplete seal around the

endotracheal tube cuff.

A central venous pressure catheter is inserted whenever there is a risk for venous air embolism. When the catheter is correctly positioned, entrained air can be aspirated from the right atrium. It is suggested that the optimal position for the tip of a single orifice catheter is 3.0 cm above the superior vena cava and the right atrial junction. The position of the right atrial catheter may be confirmed by a chest film, by using a saline-filled catheter as a unipolar lead and following the configuration of the P waves on the ECG, or by transducing a venous waveform. Multiorifice right atrial catheters are more effective than single-orifice catheters in aspirating air from the circulation.

Early diagnosis of air embolism is essential for successful treatment. The precordial Doppler unit is considered the basic monitoring device for detection of air embolism and is most effective when used in conjunction with end-tidal monitoring. The clinical significance of air embolism detected by Doppler ultrasonography can be assessed by a decrease in end-expired C_2 or an increase in pulmonary artery pressure. A Doppler in conjunction with either a capnograph or a PA catheter usually detects air before physiologic alteration begins. Treatment is directed at preventing further influx of air. Whenever air embolism is suspected, the surgeon is notified immediately. The surgical field is flooded with saline and packed, and bone edges are waxed. Nitrous oxide, if present, is discontinued to prevent further expansion of embolized air. Neck veins are compressed as a means of increasing jugular venous pressure, which prevents further air entry and helps to localize the source of air. Aspiration of air from the right atrial catheter is attempted. With significant air embolism, patient position should be changed to lower the head to heart level when possible. If necessary, vasopressors and volume infusion are administered to treat hypotension. Positive end-expiratory pressure or Valsalva maneuver are avoided because they increase right atrial pressure and the likelihood of paradoxical embolus from venous air embolism.

Anesthetic Management. When selecting an anesthetic technique for patients in the sitting position, conditions of particular concern are cardiovascular stability and risk of air embolism. In changing an anesthetized patient from the supine to sitting position, a mild transient postural hypotension occurs in about one third of cases and marked hypotension in about 2 to 5% of cases.[144,157] General anesthesia with positive-pressure ventilation is associated with a reduction in blood pressure mainly caused by a decrease in cardiac output. As patients are placed into the sitting position, venous return is impeded, causing further reductions in cardiac output and blood pressure. Therefore, efforts are directed at promoting venous return and maintaining cardiac output during the anesthetic management of these patients. An anesthetic technique that causes the least impairment of cardiovascular performance should be administered when patients are placed in the sitting position. Measures to avoid hypotension are also instituted. These include adequate preoperative hydration, wrapping the legs with elastic bandages, and flexing the patient's hips and knees at heart level. The patient's position is slowly changed, titrating position against systemic blood pressure. Administration of fluids (balanced salt solutions) and small amounts of vasopressors may be necessary.

The choice of anesthetic technique must take into account the hemodynamic consequences of the selected surgical position and the requirements of facial or evoked potential monitoring. In sitting position cases, the use of nitrous oxide remains controversial because of the potential to expand embolized air or contribute to tension pneumocephalus.[144,157] Because of these concerns, an anesthetic technique without nitrous oxide is usually administered, for example, air–oxygen, potent inhalation agent with opioids and muscle relaxant. When electrophysiologic monitoring is instituted, a propofol-based intravenous technique with opioid and muscle relaxant is recommended, and for facial nerve monitoring, this technique without supplementary administration of muscle relaxant provides successful monitoring conditions.

Postoperative Concerns. The potential for significant cardiorespiratory and neurologic deterioration exists in the immediate postoperative period following posterior fossa exploration. Therefore, direct arterial pressure and ECG monitoring should be continued for the first 24 to 48 hours postoperatively, and neurologic examinations should be performed frequently.

Central apnea requiring postoperative ventilatory support may result from damage to respiratory

centers caused by extensive posterior fossa exploration. If respiratory centers have been manipulated but not destroyed, respiratory impairment is temporary. Postoperative impairment of swallowing and pharyngeal sensation may occur secondary to stretch or manipulation of cranial nerves IX, X, and XII. These patients are at increased risk for aspiration pneumonia or hypoxia and therefore should remain intubated until airway protective reflexes return.

Systemic hypertension frequently occurs after posterior fossa surgery and requires immediate treatment to prevent brain edema and hematoma formation. Postoperative hypertension usually resolves within the first 24 hours. Atrial

and ventricular ectopic beats may also occur within the first 24 hours.

Because of the proximity of respiratory and cardiovascular centers, any edema, hematoma, or infarction of the brainstem and cerebellum can produce serious compromise. When a patient fails to awaken satisfactorily from anesthesia, bleeding or acute swelling of the structures in the posterior fossa must be suspected. In addition, patients who are awake and talking may become unresponsive secondary to obstructive hydrocephalus or brainstem compression. Decreased level of consciousness is an early reliable sign of brainstem compression. More serious signs are systemic hypertension, bradycardia, and irregular or absent respirations. Reintubation and prompt surgical intervention to relieve pressure on the brainstem are necessary.

The preoperative level of consciousness and intra-operative conditions will determine whether the patient is extubated at the end of the procedure. A patient with a depressed level of consciousness preoperatively should not be expected to improve immediately after surgery. In general, patients who require preoperative mechanical ventilation usually require postoperative mechanical ventilation. Furthermore, if the surgical procedure is extensive, producing an engorged, swollen brain, postoperative mechanical ventilation is usually necessary.

Pituitary Tumors

The pituitary gland is located at the base of the skull in the sella turcica, a bony cavity within the sphenoid bone, and it is divided into anterior (adenohypophysis) and posterior (neurohypophysis) lobes. A fold of dura (the diaphragma sella) on the superior surface of the sella is pierced by the infundibular stalk, which connects the posterior lobe of the pituitary gland to the hypothalamus. The hypothalamus regulates hormone release from the anterior pituitary through regulatory peptides (hypothalamic releasing and inhibiting factors) that reach the anterior pituitary by a complex portal vascular system. Control of hypothalamic secretion is complex and occurs from neuronal and chemical influences, including feedback from target organ hormones. The larger glandular anterior pituitary secretes at least seven hormones. The smaller posterior pituitary stores and secretes two hormones, antidiuretic hormone and oxytocin, which are synthesized in specialized hypothalamic neurons and transported as granules in axons down the pituitary stalk to the posterior pituitary gland. The anterior and posterior pituitary hormones are listed in Table 27-13.

TABLE 27-13 Pituitary Gland Hormones

·ANTERIOR PITUITARY	·POSTERIOR PITUITARY
Growth hormone	Antidiuretic hormone
Prolactin	Oxytocin
Gonadotropins:	

Follicle-stimulating hormone
Luteinizing hormone
Adrenocorticotropin (ACTH)
β-Lipotropin
Thyrotropin (TSH)

Pituitary tumors can be divided into two general categories, nonfunctioning and hypersecreting. Nonfunctioning pituitary tumors are usually diagnosed when they become large and produce symptoms related to mass effects by impinging on adjacent structures. Headache, impaired vision, cranial nerve palsies, increased ICP, and hypopituitarism may result. The most common nonfunctioning tumors are chromophobe adenomas, craniopharyngiomas, and meningiomas. As these tumors enlarge, they can cause selective or global impairment of pituitary function by compressing the normal gland. A sudden enlargement of the pituitary caused by spontaneous hemorrhage or infarction into the tumor produces a symptom complex known as pituitary apoplexy, a life-threatening condition characterized by acute neurologic deficits and a rapid decline in pituitary function. Therapy includes rapid administration of corticosteroids and emergency surgical decompression.

Functioning pituitary adenomas produce an excess of one or more of the anterior pituitary hormones, and therefore are usually diagnosed when the tumors are small. The most frequently occurring are prolactinomas followed by growth hormone- and adrenocorticotropin-secreting adenomas. Adenomas secreting thyrotropin or follicle-stimulating hormone and luteinizing hormone are rare. Adenomas secreting both growth hormone and prolactin are common, however. Prolactinomas may produce the amenorrhea-galactorrhea syndrome in females and decreased libido and impotence in males. Excessive production of growth hormone before puberty results in gigantism; after puberty, in acromegaly. Cushing's disease develops from an adrenocorticotropin-secreting adenoma that causes bilateral adrenal hyperplasia.

Special Anesthetic Considerations

Preoperative Evaluation. The preoperative evaluation of patients with pituitary tumors requires an assessment of endocrine function and associated medical disorders. Endocrine tests are performed in the basal state and are supplemented by appropriate provocative tests (Table 27-14). These tests diagnose hyperfunctioning or hypofunctioning tumors, the extent of endocrine disturbance, and the adequacy of treatment.

TABLE 27-14 Preoperative Endocrine Studies for Pituitary Tumors

·ANTERIOR PITUITARY FUNCTION TESTS
Basal levels of pituitary hormones: GH, prolactin, ACTH, TSH, FSH, LH Serum levels: cortisol (AM and PM), thyroxine, testosterone, estradiol Urinary levels: 17-ketosteroids, 17-hydroxycorticosteroids, free cortisol, estrogens

Provocative and suppression tests as indicated: GH reserve—glucagon stimulation
GH suppression—glucose suppression (acromegaly)
Prolactin reserve—chlorpromazine or thyrotropin-releasing hormone provocative testing
Low- and high-dose dexamethasone suppression (Cushing's syndrome)
Metyrapone test (Cushing's syndrome)

·POSTERIOR PITUITARY FUNCTION TESTS

ADH reserve: Serum and urine osmolality before and after 8–12 hours' water deprivation.

In Cushing's disease, the increased corticotropin and cortisol can produce multiple systemic effects such as diabetes mellitus with insulin-resistant hyperglycemia, hyperaldosteronism with hypokalemia and metabolic alkalosis, hypertension, mild congestive heart failure, and obesity. These patients require preoperative evaluation and management of hypertension, diabetes, and electrolyte imbalances, as well as a cardiovascular evaluation for ischemic heart disease and congestive heart failure.

Patients with acromegaly exhibit a general overgrowth of skeletal, connective, and soft tissues. Hands and feet become markedly enlarged and facial features become coarse. All major organs increase in size, including the heart, lungs, liver, and kidneys. These patients also require an evaluation for systemic hypertension, diabetes, ischemic heart disease, cardiomegaly, and congestive heart failure, with appropriate medical management instituted before surgery. Significant anatomic airway changes can occur in acromegalics, making airway management difficult. Facial bone hypertrophy, particularly of the mandible and nose, thick tongue and lips, and hypertrophy of nasal turbinates, soft palate, tonsils, epiglottis, and larynx create difficulties with mask fit and visualization of the larynx. Glottic stenosis caused by soft tissue overgrowth may cause preoperative hoarseness and dyspnea. These patients usually require a smaller endotracheal tube than anticipated based on the size of the patient's facial features, and may be predisposed to postextubation edema. Stretching or compression of the recurrent laryngeal nerves from laryngeal soft tissue or thyroid gland enlargement may result in vocal cord paralysis. Because of these anatomic changes, a thorough preoperative airway examination is required. Patients complaining of hoarseness, dyspnea, or inspiratory stridor should undergo indirect laryngoscopy and x-ray examination of the neck to analyze airway conformation and lumen diameter. Based on this evaluation, preparations for difficult airway management and intubation should be anticipated. For patients with difficult airways and glottic abnormalities, an awake fiberoptic intubation is recommended. This obviates the need for a tracheostomy in all but the most severe cases. Patients without upper airway or vocal cord involvement can be managed in the routine manner.

Pressure effects on the normal pituitary gland from parasellar tumors or other lesions can cause panhypopituitarism. Patients who have panhypopituitarism require replacement therapy with appropriate hormones. These patients should be euthyroid before surgery. Glucocorticoid replacement is required when thyroxine replacement is begun to avoid stressing the insufficient adrenocortical axis. Because glucocorticoids are also necessary to facilitate renal excretion of a water load, diabetes insipidus is usually not observed in the patient with pituitary insufficiency until cortisol replacement therapy is instituted. Preoperatively, the patient with panhypopituitarism will be receiving oral steroid and thyroxine therapy and, when indicated, intranasal instillation of synthetic vasopressin.

During the preanesthetic evaluation, the size and location of the tumor and its effect on intracranial dynamics should be determined. Pituitary microadenomas do not produce mass effects. Pituitary tumors with suprasellar extension, craniopharyngiomas, and other suprasellar tumors may exert a mass effect. In these patients, the CT scan or MRI and the neurologic examination are evaluated for signs of increased ICP. All patients scheduled for pituitary surgery are given supplemental short-acting glucocorticoid therapy perioperatively. Because the surgery involves manipulation or removal of the anterior pituitary, transient or permanent deficiency of adrenocorticotropin and cortisol secretion may result. To assess function of the optic nerves and chiasm, a visual examination, including examination of the visual fields, is performed. When transsphenoidal surgery is planned, an otolaryngologic examination of the nasal passages and nasopharynx is also performed, and a nasal culture is obtained to guide antibiotic therapy in the event of postoperative infection.

Surgical Considerations. Since the introduction of the operating microscope, transsphenoidal excision has been recommended for all pituitary tumors that do not have marked suprasellar extension. Advantages of the transsphenoidal approach include the following: lower morbidity and mortality rates with decreased incidence and severity of diabetes insipidus; elimination of frontal lobe retraction and external scars; magnified visualization and removal of small tumors, which spares normal tissue; decreased frequency of blood transfusions; and shorter hospitalization. Relative disadvantages include the possibility of CSF leakage and meningitis (which is rare with the use of antibiotics), inability to visualize neural structures adjacent to a large tumor, inaccessibility of tumors extending into middle and anterior fossae, and the possibility of bleeding from cavernous sinuses or carotid arteries (which can lead to intracranial hemorrhage, brainstem compression, and significant blood loss). The transcranial approach to the sella permits direct visualization of suprasellar structures: the vascular sinus ring, optic chiasm, hypothalamus, and pituitary stalk. This approach is recommended for pituitary tumors of uncertain diagnosis and those that have significant suprasellar extension with optic nerve or hypothalamic involvement. With this approach, there is potential for damage to the olfactory nerves, frontal lobe vasculature, and optic nerves and chiasm. In addition, the incidence of permanent diabetes insipidus and anterior pituitary insufficiency is increased.

Anesthetic Considerations. The anesthetic management of patients undergoing pituitary surgery is not fundamentally different from that of patients undergoing other craniotomies. Basic neuroanesthetic principles apply whether the transsphenoidal or transcranial approach is used. With the transcranial approach, however, intra-operative measures to control ICP are instituted because of pressure effects, the necessity for brain retraction, and the potential for greater blood loss.

During transsphenoidal procedures, central venous pressure is not routinely monitored. When the patient is positioned with a significant head-up tilt, however, air embolism may occur during this procedure. Therefore, precordial Doppler monitoring and right atrial catheterization are recommended for detection and treatment of air embolism when a significant surgical site–cardiac gradient (15° or more) exists.

Evoked potential monitoring of VEPs may be used during pituitary surgery to monitor direct compression or compromise of blood supply to optic nerves and chiasm. Technical difficulties that cause intra-operative recording problems include changes in pupil size, deviation of eyes, goggle size and bulkiness, and stimulus delivery (light flashes). Because VEPs are entirely cortical in origin, they are also more vulnerable to the effects of general anesthetics.

For transsphenoidal procedures, a sublabial incision and dissection through the nasal septum is performed; therefore, oral endotracheal intubation is required. The nasal septum can be prepared with 4% cocaine pledgets placed in the nares, followed by injection of 2% lidocaine with epinephrine 1:200,000 into the submucosa. This combination develops a dissection plane, decreases bleeding, and buffers the hypertensive response to nasal dissection. Initially, the cocaine and epinephrine may cause hypertension, tachycardia, and dysrhythmias, and drugs to treat these responses should be available. After oral endotracheal intubation with a RAE tube, the oropharynx is packed with saline-soaked gauze to minimize blood pooling in the glottis,

esophagus, and stomach. Intra-operative C-arm fluoroscopy of the skull (lateral views) is used during this procedure, rendering the patient's head and arms relatively inaccessible once the patient is draped.

Potential intraoperative complications during transsphenoidal procedures relate to the anatomic landmarks surrounding the sella turcica. The cavernous sinuses occupy the lateral walls of the sella and contain venous structures, the internal carotid artery, and cranial nerves III, IV, V, and VI. The optic chiasm, with its associated optic nerves and tracts, lies directly above the diaphragma sella in front of the pituitary stalk. Surgical manipulation in the region surrounding the sella can result in the following: hemorrhage from the venous sinuses or internal carotid artery, arterial spasm or thrombotic occlusion

secondary to arterial manipulation, venous air embolism if head-up tilt is excessive, cranial nerve weakness secondary to trauma or stretching, and visual complications secondary to damage of the optic nerve or chiasm.[160]

The chosen anesthetic technique should permit gross visual acuity examination before patient extubation. If vision is the same or improved, extubation can proceed. If acuity is worse, further diagnostic studies and emergent decompressive surgery may be required. After transsphenoidal surgery, the patient will awaken with nasal packing, necessitating mouth breathing postoperatively. Therefore, these patients must be fully awake and following commands before extubation of the trachea.

Postoperative Concerns. In the immediate postoperative period after either transsphenoidal or transcranial procedures, the primary concerns are corticosteroid coverage and fluid balance. Dexamethasone followed by prednisone is given for 5 days after surgery or until postoperative testing shows an intact pituitary–adrenal axis. Fluid balance is assessed by strict attention to hourly fluid intake and output and urine specific gravity. Development of diabetes insipidus is uncommon during surgery but may occur early in the postoperative course. Diabetes insipidus is commonly seen during the first 12 hours postoperatively and usually lasts for 2 to 4 days. Diagnosis is based on the following: polyuria (2 to 15 L/day), hypernatremia, high serum osmolality ($\geqslant$300 mOsm/kg), decreased urine osmolality (200 mOsm/kg), and decreased urine specific gravity (1.005 or less). Therapy includes replacement of urine losses with intravenous fluids. When urine volumes are excessive, exogenous vasopressin is given, for example, aqueous vasopressin (5 to 10 IU, iv or im, q 6 hr) or the synthetic analog of ADH, desmopressin acetate (0.5 to 2 μg, iv, q 8 hr; 1 to 4 mg, sc q 6 to 12 hr; or nasal inhalation 10 to 20 μg).

Other complications of pituitary tumor surgery include CSF rhinorrhea, hypothalamic injury or stroke, cerebral ischemia, and meningitis. After transsphenoidal surgery, patients must be carefully monitored in the recovery room for airway obstruction caused by bleeding and secretions in the pharynx. Frequent neurologic examinations are performed to note any changes in mental status. Patients who have had an uncomplicated hospital course after transsphenoidal surgery are often discharged within 5 to 6 days.

Cerebrovascular Malformations

Intracranial Aneurysms

SAH from rupture of an intracranial aneurysm is a devastating disease, affecting an estimated 27,000 Americans annually.[161,162] Despite considerable advances in the management of these patients, outcome remains poor with overall mortality rates of 25% and significant morbidity among approximately 50% of survivors. In the most recent studies, the overall incidence of SAH is 8 to 10 per 100,000 people. The peak incidence for rupture is in the fifth and sixth decades of life and is greater for women than men. Several potential risk factors for aneurysm rupture have been identified (Table 27-15).

TABLE 27-15 Potential Risk Factors for Aneurysm Rupture

Cigarette smoking
Hypertension
Alcohol consumption
Cocaine and amphetamine abuse
Oral contraceptive use
Plasma cholesterol >6.3 mmol/l
Genetic conditions, e.g., ADPKD
Familial (first-degree relatives)

The management of patients with unruptured intracranial aneurysms (UIAs) remains controversial.[162,163,164,165] The International Study of Unruptured Intracranial Aneurysms (ISUIA) was recently published.[165] Four thousand, sixty patients were assessed—1,692 did not undergo aneurysmal repair, 1,917 underwent open surgery, and 451 underwent endovascular procedures. The study revealed that rupture rates were often equaled or exceeded by the risks associated with surgical or endovascular repair of comparable lesions. Patients' age was a strong predictor of surgical outcome; the size and location of an aneurysm predicted both surgical and endovascular outcomes.

A patient with aneurysmal SAH is classified according to the Hunt and Hess Classification (Table 27-16) or the World Federation of Neurosurgeons (WFNS) SAH scale (Table 27-17). These classifications are used by neurosurgeons to estimate surgical risk and outcome. Higher grades, or patients who are clinically more impaired, are associated with the presence of cerebral vasospasm, intracranial hypertension, and increased surgical mortality. In general, the poorer the grade on hospital admission, the worse the prognosis.

TABLE 27-16 Hunt and Hess Classification of Patients with Subarachnoid Hemorrhage

▪GRADE	▪CRITERIA
0	Unruptured aneurysm
I	Asymptomatic, or minimal, headache and slight nuchal rigidity
II	Moderate to severe headache, nuchal rigidity, no neurologic deficit other than cranial nerve palsy
III	Drowsiness, confusion, or mild focal deficit
IV	Stupor, moderate to severe hemiparesis, early decerebration, vegetative disturbance
V	Deep coma, decerebrate rigidity, moribund

(Adapted from Hunt WE, Hess RM: Surgical risk as related to time of intervention in the repair of intracranial aneurysms. J Neurosurg 28:14, 1968.)

TABLE 27-17 World Federation of Neurosurgeons (WFNS) SAH Scale

▪WFNS GRADE	▪GCS SCALE[a]	▪MOTOR DEFICIT
I	15	Absent
II	13–14	Absent
III	13–14	Present
IV	7–12	Present or absent
V	3–6	Present or absent

SAH = subarachnoid hemorrhage; GCS = Glasgow Coma Scale.

[a] Refer to Table 27-20 for definition of scale.

(Adapted from Drake CG, Hunt WE, Sank K *et al:* Report of World Federation of Neurological Surgeons Committee on a universal subarachnoid hemorrhage grading scale. J Neurosurg 68:985, 1988.)

The presence of blood in the subarachnoid space causes an abrupt, marked rise in ICP, which often results in systemic hypertension and dysrhythmias. The abrupt increase in ICP accounts for the acute onset of a sudden, severe headache. The classic presentation of aneurysmal SAH is that of severe headache associated with stiff neck, photophobia, nausea, vomiting, and often transient loss of consciousness. With this presentation, the diagnosis of SAH is obvious. In about 50% of patients, a small bleed or "warning leak" precedes a major aneurysmal rupture. Warning symptoms and signs tend to be mild and nonspecific (headache, dizziness, orbital pain, slight motor or sensory disturbance) and are generally ignored or misdiagnosed by both patient and physician.

The diagnosis of SAH is made by the combination of clinical findings and a noncontrast CT scan of the head. When performed within a day of aneurysm rupture, CT reveals high-density (white) blood clot in basal subarachnoid cisterns in about 95% of patients. This has traditionally been followed by selected cerebral angiography to document the presence and anatomic features of the aneurysm. More recently, spiral CT angiography (CTA) has been used for detection and evaluation

of intracranial aneurysms. Compared to conventional angiography, the minimally invasive CTA has high specificity, sensitivity and diagnostic accuracy in detecting intracranial aneurysms.

Aneurysms are classified according to location and size. They arise at a branch of bifurcation, usually at a point where a major vessel makes a turn changing the axial flow of blood.

Complications. There are several potential complications of SAH and surgical treatment of aneurysms (Table 27-18). The most important of these are intracranial hypertension, rebleeding, vasospasm, and hydrocephalus.

TABLE 27-18 Potential Complications of Subarachnoid Hemorrhage

Rebleeding
Vasospasm
Intracranial hypertension
Hydrocephalus
Hyponatremia/volume contraction
Seizures

Rebleeding occurs most commonly during the first 24 hours following initial SAH. The chance of rebleeding is about 4% within the first day; after 48 hours, it is 1.5% per day, with a cumulative rebleeding rate of 19% by the end of 2 weeks.[166] Recurrent aneurysmal hemorrhage is a devastating complication associated with increased morbidity and mortality.

Because of the incidence of rebleeding with conservative management of SAH, early aneurysm clipping (days 0 to 3) is currently recommended for patients who are alert on admission. The debate over "early versus late" surgery was largely resolved following the report of The International Cooperative Study on the Timing of Aneurysm Surgery (ICSTAS).[167,168] In this trial, overall management results demonstrated a similar mortality (20%) and good outcome (60%) for patients with surgery planned for early (0 to 3 days) and late (11 to 14 days) intervals. The least favorable outcome and highest mortality occurred in patients with planned surgery for days 7 to 10 after SAH. Patients who were alert on admission did best with early surgery. When only the North American patients were analyzed, early surgery (days 0 to 3) provided the best results in lower grade patients.[168] There was no difference in the incidence of intra-operative rupture between early and late surgery, and although there was a relationship between "tightness" of the brain during surgery and the interval from SAH to operation, aneurysm dissection was no more difficult in early than in late surgery.[168] The timing of surgery does not influence the risk for cerebral vasospasm.

Cerebral vasospasm is a major cause of morbidity and mortality in SAH patients.[167] Angiographic evidence of vasospasm can be detected in up to 70% of patients. However, clinical vasospasm with ischemic deficits is observed in approximately 30% of patients, most often between days 4 and 12, with a peak at 6 to 7 days following SAH.[167] The clinical syndrome of vasospasm is often

heralded by worsening headache and increasing blood pressure. It is characterized by progressive symptoms of confusion and lethargy, followed by focal motor and speech impairments corresponding to the arterial territory involved. The syndrome may resolve gradually or progress to coma and death within a period of hours to days. The diagnosis of vasospasm is confirmed by angiography. The transcranial Doppler (TCD) is a safe, repeatable, noninvasive method to identify and quantify vasospasm and can be used to evaluate the effectiveness of various therapies.

The mechanism responsible for vasospasm is unknown; however, structural and pathologic changes have been demonstrated in the vessel wall. There is also evidence that vasospasm after SAH correlates with the amount of blood in the subarachnoid space, and removal of extravasated blood decreases the occurrence and severity of ischemic deficits. The component in blood implicated in causing cerebral arterial vasospasm is oxyhemoglobin.

Many drugs have been investigated for prevention or treatment of vasospasm but most are ineffective. The calcium channel blocker nimodipine has become standard prophylactic therapy. However, the efficacy of prophylactic nimodipine after SAH has been seriously challenged.[102] A meta-analysis showed a reduction in vasospasm in nimodipine groups, but a corresponding reduction in mortality was slight and not statistically significant compared to control groups.

"Triple-H" therapy—hypervolemia, hypertension, and hemodilution—has become the mainstay of treatment for ischemic neurologic deficits caused by cerebral vasospasm.[170,171] To improve cerebral blood flow to areas of impaired autoregulation, cerebral perfusion pressure is increased by intravascular volume expansion and induced hypertension. Intravascular volume expansion is accomplished with infusion of crystalloid, colloid, or blood to a pulmonary capillary wedge pressure of 12 to 18 mmHg or a central venous pressure of 10–12 mmHg. If this regimen does not reverse the deficit, a vasopressor (e.g., dopamine) is introduced to raise systemic blood pressure until the neurologic deficits subside or reverse. This therapy can worsen cerebral edema, increase ICP, and cause hemorrhagic infarction. Systemic complications include pulmonary edema and cardiac failure in patients at risk. Hemodilution, the last component of triple-H therapy, decreases blood viscosity and improves cerebral blood flow. The optimal hematocrit thought to maximize the oxygen delivery to tissues has been estimated at 33%, but may be higher in ischemic brain. A randomized controlled trial of triple-H therapy has not been undertaken,[170] and there is uncertainty about its efficacy in reducing the occurrence of delayed ischemic deficits and death after SAH.[171]

Another method for treating symptomatic vasospasm is cerebral angioplasty. Transluminal angioplasty can be used to dilate constricted major cerebral vessels in patients who are refractory to conventional treatment.[144] Superselective intra-arterial infusion of papaverine dilates distal vessels not accessible to angioplasty. However, intra-arterial papaverine may be neurotoxic. There is a move away from its use in favor of intra-arterial verapamil.[172] Transluminal angioplasty procedures are usually performed under general anesthesia to minimize movement and permit accurate placement of the intra-arterial balloon used to dilate the cerebral vessels. The risks of angioplasty include aneurysm rupture, intimal dissection, vessel rupture, ischemia, and infarction.

Intracranial hypertension is present to some degree in most patients following an SAH. In the uncomplicated case, intracranial hypertension does not require specific treatment. Intracranial pressure gradually returns to normal by the end of the first week. If an intracerebral hemorrhage, intraventricular hemorrhage, vasospasm, or hydrocephalus develops, intracranial hypertension may be severe and require treatment. Patients may require emergency ventriculostomy, steroids, diuretics, or intubation and hyperventilation. Intracranial pressure should be lowered gradually, especially in patients with unclipped aneurysms. Abrupt lowering of ICP by lumbar puncture, ventricular drainage, or rapid infusion of mannitol can induce rebleeding.

Acute (obstructive) *hydrocephalus* after SAH complicates approximately 20% of cases.[173] Although controversial, ventriculostomy has been recommended for treating acute hydrocephalus in patients with diminished level of consciousness after SAH.[173] Ventriculostomy has been associated with increased bleeding and infection.

Endovascular Treatment of Cerebral Aneurysms

Endovascular embolization is a therapeutic alternative to surgical clipping of some cerebral aneurysm. Initially, only patients with high risk or inaccessible aneurysms and/or co-morbid medical conditions were candidates for INR procedures. These procedures are now recommended for treatment of unruptured intracranial aneurysms, depending on aneurysm location, size and age of patient.[165]

A randomized trial comparing clipping and coiling of ruptured aneurysms was recently published [The International Subarachnoid Aneurysm Trial (ISAT)].[174] The study enrolled 2,143 patients treated at 43 centers, mostly in Europe. The study was stopped early by the data safety and monitoring committee. At stopping, 801 patients were treated by endovascular therapy and 793 patients were treated surgically and followed for 1 year. Death or dependency occurred in 23.7% of endovascular cases and 30.6% of surgical cases; a relative risk reduction of 22.6% with endovascular therapy ($p = 0.0019$) was reported.[174] This study has been criticized for not including a representative population, studying only ruptured aneurysms, and poor surgical results and follow-up.[175]

The endovascular technique most commonly performed for occlusion of cerebral aneurysms is insertion of Guglielmi detachable coils (GDC). The field is rapidly evolving and new techniques (microballoons, neurovascular stents) and investigational devices (liquid embolic agents, bioactive coils) are being developed and investigated. An anesthesiologist is present for most of these procedures to monitor the patient, to provide appropriate anesthesia for the procedure, and to manage complications that arise. The reader is referred to an earlier section in this chapter for discussion of anesthetic management during INR procedures.

Special Anesthetic Considerations

Preoperative Evaluation. When the neurologic examination is performed, the patient's clinical grade is noted (see Table 27-17). The patient's CT scan or MR image is evaluated to assess the presence and severity of intracranial hypertension. The severity, acuteness, and stage of the SAH as well as the presence of intracranial hypertension and the timing of surgery will determine the anesthetic management. Because the circle of Willis is proximal to the hypothalamus, an SAH in this area can cause a variety of disturbances related to hypothalamic dysfunction (e.g., ECG changes, temperature instability, various changes in endocrine [pituitary] function, various electrolyte disturbances). Sympathetic overactivity and overstimulation of both adrenal cortex and medulla can contribute to hypertension and diabetes, requiring treatment with insulin.

Electrolyte abnormalities frequently occur secondary to the *syndrome of inappropriate antidiuretic hormone* (SIADH) secretion or diabetes insipidus. Hyponatremia is the most common electrolyte disturbance detected and is often associated with a high urinary sodium and osmolality, which is expected with SIADH. Unlike a patient with SIADH, however, the patient with SAH usually has a contracted intravascular volume despite hyponatremia. This cerebral salt-wasting syndrome may be caused by release of atrial natriuretic factor from damaged brain. The recommended therapy is to maintain normovolemia with isotonic saline solutions. Other factors contributing to intravascular volume contraction in these patients are supine diuresis secondary to increased thoracic blood volume, negative nitrogen balance, decreased erythropoiesis, increased catecholamine levels, and iatrogenic blood loss. Fluid balance and electrolyte abnormalities should be corrected prior to surgery.

Most aneurysm surgery requires significant intravascular volume shifts (diuresis followed by volume loading) and extensive systemic blood pressure manipulations (deliberate hypotension or hypertension). Therefore, patients with a history of hypertension, ischemic heart disease, and/or congestive heart failure must be in optimal condition to tolerate the hemodynamic changes required for this surgery. Depending on the degree of cardiovascular disease, inadvertent or deliberate hypotension may be poorly tolerated. When patients have significant hypertension, the blood pressure should be lowered gradually to normotensive levels to avoid cerebral ischemia. Agents such as propranolol, labetalol, or esmolol are used in neurosurgical patients because these

agents do not affect cerebral blood volume or ICP. When the systemic blood pressure is lowered, a critical level below which neurologic deficits occur may be observed. Systemic blood pressure below this level should be avoided intra-operatively.

Electrocardiographic abnormalities are commonly associated with ruptured cerebral aneurysms. The ECG changes include ST-segment depression or elevation, T-wave inversion or flattening, U waves, prolonged Q-T intervals, and dysrhythmia. The ECG changes are not necessarily associated with increased operative morbidity and mortality or consistent increases in serum myoglobin or creatine kinase. They usually resolve within 10 days following SAH and require no special treatment. When indicated, cardiac troponin-I levels should be drawn to determine the clinical significance of these abnormalities. When cardiac dysrhythmia and occasional frank subendocardial ischemia result in cardiac failure, appropriate treatment must be instituted.

12 **Anesthetic Management.** The anesthetic goals for intracranial aneurysm surgery are to avoid aneurysm rupture, maintain cerebral perfusion pressure and transmural aneurysm pressure, and provide a "slack" brain. Patients in WFNS scale I or II who appear anxious should receive premedication. Cerebral perfusion pressure is maintained by using drugs in doses that avoid sudden or profound decreases in systemic blood pressure or increases in ICP. Similarly, transmural pressure, which is defined as the difference between mean arterial pressure and ICP, must be maintained. (The pressure within an aneurysm is equal to the systemic blood pressure.) The relationship between transmural pressure and wall stress or tension of the aneurysm is linear. An increase in mean arterial pressure or fall in ICP will increase transmural pressure, wall stress, and risk of aneurysm rupture. Methods to control brain volume and ICP, such as hyperventilation, diuretics, spinal drainage, and head position, facilitate surgical exposure and minimize the retraction pressure that can cause tissue injury.

Standard monitoring plus an arterial pressure catheter is routinely used. A CVP or PA catheter is recommended in WFNS scale III or higher to provide a more accurate measure of the patient's volume status and cardiac function intraoperatively

and postoperatively in the prevention or management of cerebral vasospasm. Electrophysiologic monitoring with the EEG or SSEPs may be used to monitor the adequacy of cerebral perfusion during induced hypotension or temporary/permanent aneurysm clip application. When barbiturates are administered for brain protection, the EEG is used to guide the dose required to achieve a burst suppression pattern.

To minimize the risk of hypertension and aneurysmal rupture during induction of anesthesia, intravenous lidocaine and the β-adrenergic antagonist esmolol or labetalol are recommended. Following induction, ventilation is mechanically controlled to maintain normocarbia if ICP is normal. If intracranial hypertension is present, the $PaCO_2$ can be lowered to 30–35 mmHg. A deep plane of anesthesia must be established prior to insertion of head pins, scalp incision, turning the bone flap, and opening the dura in order to avoid a hypertensive response. When intracranial hypertension is present, anesthesia should be deepened with additional doses of thiopental and fentanyl until the skull is opened. Several techniques can be instituted during aneurysm surgery to provide a "slack" brain and facilitate dissection. These are hyperventilation of the lungs, osmotic diuresis, barbiturate administration, and CSF drainage during the procedure. A lumbar subarachnoid catheter or spinal needle is inserted after induction to allow CSF drainage during the procedure. Excessive loss of CSF must be avoided during insertion of the lumbar drain because it can decrease ICP, thus increasing aneurysmal transmural pressure and the potential for rupture. Removal of CSF after opening the dura is done cautiously with guidance by the surgeons.

The drugs most frequently used to maintain anesthesia during aneurysm surgery are fentanyl or remifentanil and propofol infusions in conjunction with 0.5 MAC of a potent inhalation agent in oxygen and nondepolarizing muscle relaxant. The total dose of fentanyl should not exceed 10 to 12 μg/kg, unless postoperative ventilation is planned. In conditions of poor intracranial compliance, a continuous infusion of thiopental (1 to 3 mg/kg/hr following a bolus dose of 5 mg/kg) may be substituted for propofol as the primary anesthetic. Potential disadvantages to using thiopental are blood pressure instability and prolonged recovery from anesthesia. With this

technique, a pulmonary artery catheter should be inserted to monitor and optimize cardiovascular performance and intravascular volume. Following an uneventful aneurysm clip application, the thiopental infusion is discontinued to prevent a delay in recovery.

Prior to aneurysm clipping, isotonic crystalloid solutions without glucose are administered to replace overnight fluid losses and provide hourly maintenance fluid requirements. When the aneurysm is secured, intra-operative fluid deficits are replaced and additional volume is administered. At the time of aneurysm dissection, blood is available for transfusion in case the aneurysm ruptures. A bolus of thiopental (3 to 5 mg/kg) may be given before temporary occlusion of a major intracranial vessel and before aneurysm clipping. If temporary occlusion lasts longer than 10 minutes, recirculation should be established, and additional thiopental administered before reapplying the temporary clip. Following aneurysm clipping, the central venous pressure and pulmonary capillary wedge pressure are raised to 10 to 12 mmHg or 12 to 18 mmHg, respectively, with crystalloid, colloid, or blood. A postoperative hematocrit of 30 to 35% is desirable. As discussed previously, intravascular volume expansion with hemodilution is recommended to reduce the risk of postoperative cerebral vasospasm.

When considering the use of *deliberate hypotension* during aneurysm dissection, the risk–benefit ratio must be assessed for each patient. The potential benefit of deliberate hypotension must be weighed against the risk of causing cerebral ischemia or ischemia to other organs. Patients with a history of cardiovascular disease, occlusive cerebrovascular disease, intracerebral hematoma, fever, anemia, and renal disease are not good candidates for deliberate hypotension. Such patients should only be subjected to moderate reductions in systemic blood pressure (20 to 30 mmHg), if at all. When deliberate hypotension is required, the best choice among the agents listed in Table 27-19 is probably the drug or drug combination with which you have the most experience. Commonly used agents to induce hypotension have been sodium nitroprusside, isoflurane, and esmolol.

TABLE 27-19 Dosage, Mechanism of Action, Advantages, and Disadvantages of Commonly used Agents for Inducing Hypotension

·DRUG	·DOSAGE	·MECHANISM OF ACTION	·ADVANTAGES	·DISADVANTAGES
Sodium nitroprusside	0.5–10 μg/kg/min	Nitric oxide-mediated direct vasodilatation	Rapid onset/offset titration control	Cyanide toxicity ↑ ICP Rebound hypertension Coagulation abnormalities ↑ Pulmonary shunting
Nitroglycerin	1–10 μg/kg/min	Nitric oxide-mediated direct vasodilatation	Rapid onset/offset titration control	↑ ICP Rebound hypertension Coagulation abnormalities ↑ Pulmonary shunting
Trimethaphan	1–5 mg/min	Ganglionic	Rapid	Histamine release

		blockade	onset/offset	Cerebral compromise below MAP 55 mm Hg ↓ Pseudocholinesterase
Esmolol	0.2–0.5 mg/kg/min loading dose 50–200 μg/kg/min	β-adrenergic blockade	Rapid onset/offset	Limited efficacy Cardiac depression Bronchospasm
Labetalol	20 mg test dose 0.5–2 mg/min (total 300 mg)	α- and β-adrenergic blockade	Reduced probability of adverse effects	Limited efficacy Bronchospasm
Prostaglandin E_1	0.1–0.65 μg/kg/min	Direct vasodilatation	Rapid onset ↓ Reflex tachycardia Stable CBF	Slow offset Bradycardia Hyperthermia
Nicardipine	Begin 5 mg/h infusion, max 15 mg/h	Coronary and peripheral vasodilatation	Rapid onset ↓ Reflex tachycardia	Slow offset Resists antihypotensive therapy ↑ Pulmonary shunting
Inhalation anesthetics	Titrate by inspired concentration	Vasodilatation and myocardial depression	Provides surgical anesthesia	↑ ICP ↑ Cerebral edema ↓ Vital organ blood flow

Overall, deliberate hypotension has declined in use and has been replaced by temporary clipping. The temporary occlusion of a feeding artery produces an acute reduction in focal blood flow and a slack aneurysm, thus eliminating the need for deliberate hypotension and its systemic effects. Depending on the location of the aneurysm, either somatosensory evoked potentials or brainstem auditory evoked potentials can be used to monitor the safety of temporary occlusion.

The major intraoperative complication of aneurysm surgery is hemorrhage. When an aneurysm ruptures intra-operatively, there is potential for major ischemic damage from hypotension and the surgical efforts to control bleeding. Hemorrhagic death is also possible. When the leak is small and the dissection is complete, it may be possible for the surgeon to gain control with suction and then apply the permanent clip to the neck of the aneurysm. Alternatively, temporary clips can be applied proximal and distal to the aneurysm to gain control. Thiopental may be given to provide some protection prior to the placement of the temporary clip. During temporary occlusion,

normotension should be maintained to maximize collateral perfusion. If temporary occlusion is not planned or not possible and blood loss is not significant, the mean arterial pressure may be transiently decreased to 50 mmHg or lower to facilitate surgical control. When bleeding is excessive, aggressive fluid resuscitation and blood transfusion must commence immediately. Administration of cerebroprotective agents may not be possible because of associated hemodynamic effects. Under these conditions, deliberate hypotension is not advised as the intravascular volume must be restored first.

Intraoperative Cerebral Protection. Thiopental has been the drug of choice for intra-operative cerebral protection during aneurysm surgery. In animal models, barbiturates have shown protection during incomplete focal ischemia but not during global ischemia.[144] Barbiturates are the only agents shown to be useful in humans.[144]

Many practitioners institute mild intraoperative hypothermia (32 to 34°C) during aneurysm surgery to enhance the brain's ability to tolerate ischemia. Unfortunately, its value remains unproven. An NIH supported multicenter trial of the use of mild intraoperative hypothermia (IHAST, The International Hypothermia in Aneurysm Trial) was completed in 2003.[72] The investigators found no alteration in outcome, when patients received intraoperative cooling prior to aneurysm clipping.[176]

Emergence. The primary goals at the conclusion of surgery are to avoid coughing, straining, hypercarbia, and hypertension. For patients in Grades I and II who have no intra-operative complications, the endotracheal tube should be removed in the operating room and a neurologic examination performed. Patients who have intraoperative complications or have depressed consciousness preoperatively (Grades III toV) should remain intubated and receive mechanical ventilation until their neurologic status improves.

Postoperative Concerns. Variation in systemic blood pressure is common postoperatively and contributes significantly to morbidity and mortality in patients following aneurysm repair. Causes of hypertension include preexisting hypertension, pain, and CO_2 retention from residual anesthesia. The treatment of postoperative hypertension is critical to prevent the formation of cerebral edema or hematoma. Antihypertensive

drugs should be administered after respiratory depression and pain are eliminated as causes. The hypertensive response usually subsides within 12 hours. When indicated, preoperative antihypertensive drugs are reinstituted and maintained.

After clipping of the aneurysm, cerebral vasospasm continues to pose a threat to neurologic integrity. Postoperative hypotension must be avoided, and the patient's intravascular volume must be accurately assessed with either a central venous pressure or pulmonary artery catheter. As previously discussed, a higher than normal intravascular fluid volume should be maintained.

Arteriovenous Malformations

An arteriovenous malformation (AVM) of the brain consists of a tangle of congenitally malformed blood vessels that forms an abnormal communication between the arterial and venous systems. The arterial afferents flow directly into venous efferents without the usual resistance of an intervening capillary bed; thus, oxygenated blood is shunted directly into the venous system, leaving surrounding brain tissue transiently or permanently ischemic. These lesions predominate in males over females (2:1), with the onset of complaints between the ages of 10 and 40. The chief clinical features are parenchymal hemorrhage or SAH, focal epilepsy, and progressive focal neurologic sensory-motor deficits occurring in a child or young adult. A vein of Galen AVM in infants may present with hydrocephalus and/or high-output cardiac failure. The natural history of AVMs is not completely understood.[177] The risk of hemorrhage is approximately 1 to 4% per year. The rate of rebleeding is 6% in the first year after a hemorrhage and about 2% per year thereafter.[176] Mortality from initial hemorrhage is high, with reports between 10 and 30%. Recurrence of hemorrhage with a fatal outcome is a constant danger. There are several options for the management of AVMs, including surgical excision, embolization, stereotactic radiosurgery (proton beams, gamma rays, or linear accelerator), a combination of the above, and leaving AVMs

alone. Arteriovenous malformations of suitable size and location can be managed successfully with surgical excision. Surgical mortality ranges from 0.6 to 14% and correlates with size, location, and pattern of involvement of the AVM.[177] Early postoperative morbidity ranges from 17 to 23%; however, outcome studies report improvement in morbidity over time.[177] To avoid intraoperative or postoperative massive brain swelling or hemorrhage of large AVMs, operations may be staged or follow preoperative embolization.

Special Anesthetic Considerations

In addition to providing anesthesia for craniotomy and resection of the AVM, anesthesia may be required for radiologic embolization of the AVM. Closed embolization of cerebral AVMs is uncomfortable and invasive. This procedure may be performed under local anesthesia with sedation or under general anesthesia. It has been performed successfully with various combinations of sedative drugs (fentanyl, midazolam, or propofol) that allow neurologic examinations during the procedure and permit immediate diagnoses of complications.[138,177] Children, uncooperative patients, and those with intracranial hypertension or airway problems usually require general anesthesia. General anesthesia does not allow direct neurologic

assessment. Potential complications of embolization procedures are embolic or ischemic stroke and hemorrhage from the AVM, either acute or delayed.[178] New onset or preexisting seizures may occur during the embolization procedure, requiring treatment with benzodiazepines or barbiturates.

13 The anesthetic management of patients with AVMs is similar to the management of patients for aneurysm surgery. Depending on the presentation, the anesthetic approach is modified. For example, a large bleed may present with symptoms relating to mass effects and require maneuvers to reduce ICP. High flow through a large intact AVM may cause a "steal" with resulting cerebral ischemia and require different techniques to improve CPP. With more extensive lesions, hypothermia and high-dose barbiturates have been recommended for brain protection. Induced hypotension may also be required to reduce lesion size and blood flow.

Hyperemic complications, defined as perioperative edema or hemorrhage, may occur after removal of the AVM. Although the mechanism is unclear, one theory proposes that breakthrough cerebral edema and hemorrhage result when blood flow from the surgically obliterated AVM is diverted to the surrounding brain. The smaller vessels in the brain surrounding the AVM are not accustomed to the higher pressure-flow state, and autoregulation is exceeded, resulting in severe brain swelling, edema, and hemorrhage. The clinical syndrome of cerebral hyperperfusion with normal CPP has been called *normal perfusion pressure breakthrough*.[177] Other studies report information that is not consistent with this theory.[177,179] Immediate treatment should include the simultaneous application of high-dose barbiturates, osmotic diuretics, hyperventilation, and maintenance of a low-normal MAP. When marked brain swelling occurs intraoperatively, the patient should remain intubated, hyperventilated, and sedated postoperatively. Hypertension during emergence and postoperatively must be controlled, preferably with β-blockers, to prevent bleeding into the bed of the AVM.

HEAD INJURY

Head injury is a leading cause of permanent disability and death, occurring most frequently in adolescents, young adults, and people older than 75 years of age. In all age groups, males are affected two times more often than females and are more likely to sustain severe head injury. The leading causes of traumatic brain injuries (TBI) are motor vehicle crashes, violence, and falls. More than 50% of patients with severe head injury have multiple injuries resulting in significant blood loss, systemic hypotension, and hypoxia.[180]

Classification of severe head injury is based on the Glasgow Coma Scale (Table 27-20), which defines neurologic impairment in terms of eye opening, speech, and motor function. The total score that can be obtained is 15, and severe head injury is determined by a score of 8 or less persisting for 6 hours or more. The Glasgow Coma and Glasgow Outcome Scales permit

comparison between series of traumatically head-injured patients based on initial clinical presentation and eventual outcome. The prognosis after head injury depends on the type of lesion sustained, the age of the patient, and the severity of the injury as defined by the Glasgow Coma Scale. In general, mortality is closely related to the initial score on the coma scale. For any given lesion and score, however, the elderly have a poorer outcome than do younger patients.

(Adapted from Teasdale G, Jennett B: Assessment of coma and impaired consciousness: A practical scale. Lancet 2:81, 1974; and Jennett B: Assessment of the severity of head injury. J Neurol Neurosurg Psychiatry 39:647, 1976.)	

Following head trauma, the primary injury results from the biomechanical effect of forces applied to the skull and brain at the time of the insult and is manifested within milliseconds. Currently, there is no treatment for the primary injury. Secondary injury occurs minutes to hours after the impact and represents complicating processes initiated by the primary injury, such as ischemia, brain swelling and edema, intracranial hemorrhage, intracranial hypertension, and herniation. Factors that aggravate the initial injury include hypoxia, hypercarbia, hypotension, anemia, and hyperglycemia. These contributing factors to secondary injury are preventable. Seizures, infection, and sepsis that may occur hours to days after injury will further aggravate brain damage and must also be prevented or treated promptly.

Secondary insults complicate the course of more than 50% of head-injured patients.[180,181] An outcome study using data from the Traumatic Coma Data Bank revealed that hypotension occurring after head injury is profoundly detrimental, with more than 70% of patients experiencing significant morbidity and mortality (Table 27-21).[181] Furthermore, the combination of hypoxia and hypotension is significantly more detrimental than that of hypotension alone (>90% of patients with severe outcome or death). These findings confirm the importance of avoiding hypovolemic shock in head-injured patients. The management goal in head-injured patients is to initiate timely and appropriate therapy to prevent secondary brain injury. When the initial injury is not fatal, subsequent neurologic damage and systemic complications should be preventable in most patients.

TABLE 27-21 Impact of Hypoxia and Hypotension[a] on Outcome after Severe Head Injury (GCS ⩽ 8)

		·OUTCOME PERCENTAGE

[a]At time of hospital arrival.

Data adapted from the Traumatic Coma Data Bank[181]

Primary injury or biomechanical trauma to brain parenchyma includes concussion, contusion, laceration, and hematoma. Not all severely head-injured patients require surgery. Generalized brain injury with edema or contusion is a common finding in patients, whether or not a surgically correctable mass lesion is present. Diffuse cerebral swelling occurs because of sudden intracerebral congestion and hyperemia. Twenty-four hours or more after the initial insult, cerebral edema develops in the extracellular spaces of the white matter. Nonoperative treatment of diffuse cerebral swelling includes hyperventilation, diuresis with mannitol and furosemide, and barbiturates in conjunction with ICP monitoring.

Depressed skull fractures and acute epidural, subdural, and intracerebral hematomas usually require craniotomy. Chronic subdural hematomas are often evacuated through burr holes. Depressed skull fractures under lacerations should be elevated and debrided within 24 hours to minimize the risk of infection. Bony fragments and penetrating objects should not be manipulated in the emergency room, because they may be tamponading a lacerated vessel or dural sinus. Traumatic epidural hematoma is an infrequent complication of head injury, usually the result of a motor vehicle accident. The initial injury tears middle meningeal vessels or dural sinuses and causes unconsciousness. When a spasm and clot occur in the vessel(s), the bleeding stops and the patient recovers, experiencing a lucid interval. Over the next several hours, the vessel bleeds and the patient rapidly deteriorates (especially with arterial bleeding). In rapidly deteriorating conditions, treatment should not be delayed pending radiologic evaluation. Emergency evacuation is necessary. Venous epidural hematomas develop more slowly, and there may be time for diagnostic testing. The clinical presentation of acute subdural hematomas ranges from minimal deficits to unconsciousness and signs of a mass lesion (hemiparesis, unilateral decerebration, and pupillary enlargement). A lucid interval may occur. The most common cause of subdural hematoma is trauma, but it may occur spontaneously and is associated with coagulopathies, aneurysms, and neoplasms. It is considered acute if the patient becomes symptomatic within 72 hours, subacute between 3 and 15 days, and chronic after 2 weeks. Subacute and chronic subdural hematoma are usually observed in patients over age 50 years. There may be no history of head trauma. The clinical presentation in these patients may vary from focal signs of brain dysfunction to a depressed level of consciousness or development of an organic brain syndrome. Intracranial hypertension is usually associated with acute subdural hematoma. Intensive medical therapy to correct elevated ICP and control brain edema and swelling may be required before, during, and after hematoma evacuation. With intracerebral hematomas, the clinical picture may vary from minimal neurologic deficits to deep coma. Large, solitary intracerebral hematomas should be evacuated. Lesions causing delayed neurologic deterioration from fresh hemorrhage are also evacuated but carry a poor prognosis. Depending on the degree of cerebral injury, patients with intracerebral hematomas may require intensive medical therapy to control intracranial hypertension and cerebral edema. Coup and contrecoup injuries usually cause cerebral contusion and intracerebral hemorrhage. In general, contused brain tissue is not removed; occasionally,

however, contused tissue over the frontal or temporal poles may be removed to control edema formation and prevent herniation.

Emergency Therapy

Emergency therapy should begin at the site of the accident, in the ambulance, and most certainly, in the emergency room. The first step is to secure an open airway and ensure adequate ventilation to prevent secondary injury from hypoxia and hypercarbia. Before securing the airway in a head-injured patient, a quick assessment of the patient's neurologic status and concomitant injuries should be made.

The incidence of cervical spine injuries in surviving head-injury victims is 1 to 3% in adults and 0.5% in children.[182,183] Victims of head-first falls or high-speed motor vehicle accidents have a 10% or greater chance of cervical spine fractures. X-ray evaluation with a cross-table lateral view can miss 20% of cervical spine fractures.[183] To increase the reliability of radiographic evaluation, anteroposterior and odontoid views, in addition to a lateral view, have been recommended. Reportedly, this combination misses only 7% of fractures.[182] When a cervical spine fracture has not been excluded by x-ray evaluation, cervical alignment with in-line stabilization is recommended during emergent intubation.[184,185] (In-line stabilization requires an assistant to stabilize the patient's head by positioning his or her hands along the side of the head with fingertips on the mastoid holding the occiput down on a backboard.)

When facial fractures and soft tissue edema prevent direct visualization of the larynx, a fiberoptic intubation or intubation with an illuminated stylet or intubating laryngeal mask airway may be attempted. In the presence of severe facial and/or laryngeal injuries, a cricothyrotomy may be required. Nasal intubations are avoided in the presence of a suspected basal skull fracture, severe facial fractures, and bleeding diathesis.

For patients without facial injuries, the simplest and most expeditious approach to intubation is preoxygenation followed by rapid-sequence induction with cricoid pressure and maintenance of in-line stabilization. All head-injured patients are assumed to have a full stomach. Awake, oral intubation without anesthetic agents may be possible in the severely injured patient, but this is difficult in the awake or uncooperative, combative patient. Depending on the patient's cardiovascular status, virtually any of the intravenous induction agents, except ketamine, can be used. The choice of muscle relaxants is

controversial. Succinylcholine can increase ICP. In the setting of acute airway compromise, full stomach, and need to perform subsequent neurologic examinations, the benefits of rapid onset and elimination of succinylcholine may outweigh the risk of transiently increasing ICP.

Following control of the airway in the head-injured patient, attention should focus on resuscitation of the cardiovascular system. Transient hypotension after head injury is not uncommon, but sustained hypotension usually results from hemorrhage secondary to other systemic injuries. These injuries must be sought and aggressively treated.

When multiple trauma complicates head injury, there is no ideal crystalloid resuscitation fluid. A major concern during resuscitation is the development of cerebral edema. Animal investigations reveal that total serum osmolality is a key factor in brain edema formation.[186,187] When serum osmolality is reduced, cerebral edema develops in normal and abnormal brain. This occurs because the blood-brain barrier is relatively impermeable to sodium. Solutions containing sodium in concentrations lower than that in serum cause water movement into the brain, increasing brain water. Thus, hypoosmolar solutions (0.45% NaCl and lactated Ringer's solution) are more likely than isoosmolar fluids (0.9% saline) to increase brain water content. Large-volume fluid resuscitation with isoosmolar crystalloids reduces colloid oncotic pressure and increases peripheral tissue edema. However, in animal investigations, the brain behaves differently than other tissues, and profound lowering of colloid oncotic pressure with maintenance of serum osmolality does not result in edema in normal brain[186] and in some head-injury models.[187,188] These results can be explained by the unique structure of the blood-brain barrier and the fact that colloid oncotic pressure gradients generate weak forces in comparison with osmolar gradients.[186] Some doubt has

been cast on the applicability of these laboratory findings to clinical practice. The cryogenic-injury model used in these experiments may not be equivalent to head injury in patients. In head-injured patients, brain capillary permeability may be rendered similar to that of peripheral tissues when the blood-brain barrier is damaged. In addition, the time course of these experiments did not allow observation of edema developing 24 to 48 hours after initial resuscitation, which occurs in head-injured patients. An investigation using the percussive head-injury model in rats has shown that reduction in colloid oncotic pressure can aggravate cerebral edema under certain conditions.[189] Therefore, it seems reasonable to avoid a profound reduction in colloid oncotic pressure in clinical practice. Isoosmolar colloid solutions, such as 5% albumin or 6% hetastarch, can be administered to maintain oncotic pressure and intravascular volume. Fresh whole blood, when available, is the ideal colloid resuscitation fluid for hypovolemic patients with ongoing blood loss.

Hypertonic saline solutions (3%, 7.5%) can be very useful for volume resuscitation in head-injured patients because they lower ICP, increase blood pressure, and may improve regional CBF.[190] Hypertonic saline produces an osmotic diuretic effect on the brain that is similar to that of other hyperosmolar solutions (e.g., mannitol). Hypertonic saline therapy may be more effective than other diuretics in certain clinical conditions, for example, in patients with refractory intracranial hypertension[141] or in those who require brain debulking and maintenance of intravascular volume.[140] With long-term use, there is concern over the physiologic implications of elevated serum sodium, such as a depressed level of consciousness and/or seizures. More studies are required to determine dose-response curves and the safety and efficacy of these solutions.

During fluid resuscitation of the head-injured patient, the goals are to maintain serum osmolality, avoid profound reduction in colloid oncotic pressure, and restore circulating blood volume. Immediate therapy is directed at preventing hypotension and maintaining CPP above 60 mmHg.[191] When indicated, an ICP monitor is inserted to guide fluid resuscitation and prevent severe elevations in ICP. Isoosmolar crystalloid solutions, colloid solutions, or both are administered acutely to restore circulating blood volume. Glucose-containing solutions should not be administered because of a significant association between plasma glucose levels and worse neurologic outcome in head-injured patients. Substantial blood loss requires transfusion with crossmatched or fresh whole blood. A minimum hematocrit between 30 and 33% is recommended to maximize oxygen transport.

Hypertension, tachycardia, and increased cardiac output often develop in patients with isolated head trauma, especially young adults.[144] ECG abnormalities and fatal arrhythmias have been reported. The hyperdynamic circulatory responses and ECG changes may result from a surge in epinephrine that accompanies head injury.[144] Either labetalol or esmolol can be used to control hypertension and tachycardia in this situation.

14 In some patients, severe intracranial hypertension precipitates reflex arterial hypertension and bradycardia (Cushing's triad). A reduction in systemic blood pressure in these patients can further aggravate cerebral ischemia by reducing CPP. Systemic blood pressure must be lowered cautiously when intracranial hypertension is severe. In such cases, a reduction of ICP may interrupt this reflex response.

After stabilization of head-injured patients, including control of airway and systemic blood pressure, therapeutic interventions to control intracranial hypertension are instituted. The head is elevated 15° and maintained in a neutral position without rotation or flexion. Mannitol, 0.25 to 1 g/kg, is given to lower ICP acutely, or a combination of furosemide and mannitol may be administered. Hyperventilation and barbiturate therapy may be considered when other measures have failed.[191,192] Appropriate monitoring must be instituted and hypotension avoided.

Mechanical hyperventilation to a $PaCO_2$ 25 to 30 mmHg was routinely employed in head-injured patients based on an assumption that hyperventilation, by reducing CBF, will reduce ICP, thereby preserving CPP and CBF. Clinical investigations suggest that head-injured patients are ischemic within the first 24 hours of injury.[143,194] In these patients hyperventilation may further decrease CBF and aggravate cerebral ischemia.

Recently published guidelines for the management of severe traumatic brain injury no longer recommend hyperventilation to a $PaCO_2$ of 25 to 30 mmHg as a first-tier therapy.[192,193] In fact, the 2000 guidelines recommend avoiding the use of prophylactic hyperventilation ($PaCO_2 \leqslant 35$ mmHg) therapy during the first 24 hours after severe TBI.[193] When hyperventilation is initiated for control of intracranial hypertension, the $PaCO_2$ should be maintained in the range of 30 to 35 mmHg in order to accomplish ICP control while minimizing the associated risk of ischemia. Hyperventilation to $PaCO_2$ values less than 30 mmHg should be considered only when second-tier therapy of refractory intracranial hypertension is required. Continuous measurement of jugular bulb oxygen saturation or CBF monitoring is recommended during hyperventilation to guide therapy.[192] In emergency situations, we should continue to hyperventilate patients in whom the clinical control of intracranial hypertension is the primary concern. However, when the clinical situation no longer requires it or there is evidence of cerebral ischemia, normocapnic ventilation should be instituted.

Anesthetic Management

The patient is evaluated by CT scan and taken directly to the operating room. There is usually minimal time available for resuscitation and preanesthetic assessment. Information that should be obtained preoperatively is described in Table 27-22.

The anesthetic management is a continuation of the initial resuscitation, including airway management, fluid and electrolyte balance, and ICP control. The routine monitors for major neurosurgical procedures are applied.

TABLE 27-22 Pre-anesthetic Assessment of the Head-Injured Patient

Airway (cervical spine)
Breathing: ventilation and oxygenation
Circulatory status
Associated injuries
Neurologic status (Glasgow Coma Scale)
Preexisting chronic illness
Circumstances of the injury: Time of injury
Duration of unconsciousness
Associated alcohol or drug use

Major goals of anesthetic management are to optimize cerebral perfusion and oxygenation, to avoid secondary damage, and to provide adequate surgical conditions. Cerebral perfusion pressure (CPP = MAP - ICP) should be maintained between 60 and 110 mmHg. If ICP increases to a greater extent than MAP, CPP is reduced, and the brain becomes ischemic. Uncontrolled increases in ICP can result in herniation and death. The choice of anesthetic agents depends on the condition of the patient. In the hemodynamically stable patient with severe intracranial hypertension, narcotics in conjunction with a thiopental infusion (2 to 3 mg/kg/h) and nondepolarizing muscle relaxant can be administered with oxygen and air. In patients with less severe intracranial hypertension, anesthesia can be maintained with various combinations of barbiturates, benzodiazepines, narcotics, and sub-MAC concentration of a potent inhalation agent. Anesthetic management is directed at avoidance of secondary brain injury. Intraoperative hypotension secondary to blood loss or precipitated by anesthetic drugs must be avoided by appropriate volume expansion. Maintenance of ventilation ($PaCO_2$ of 35 mmHg) and oxygenation ($PaO_2 \geqslant 60$ mmHg) is extremely important.

Intraoperative brain swelling or herniation from the operative site may complicate hematoma decompression. Such causes as improper patient positioning, contralateral intracerebral hematoma, venous drainage obstruction from packing, and acute hydrocephalus from intraventricular hemorrhage must be eliminated. In this setting, the adequacy of hyperventilation must also be verified. A large alveolar-arterial CO_2 gradient may exist, so that end-tidal CO_2 may not reflect arterial CO_2. The respiratory system and equipment should be reviewed to ensure normal peak inspiratory and expiratory pressures. Hemopneumothorax, high intra-abdominal pressures, a kinked endotracheal or expiratory tube, or a stuck expiratory valve can produce marked peak inspiratory or expiratory pressures as well as hypoxemia and hypercarbia. Fluid and electrolyte balance must be reevaluated in patients with cerebral swelling. Mannitol loses its effect after 1 to 3 hours, and it may be necessary to repeat the mannitol bolus to increase osmolarity. Volume overload and hyponatremia may also cause cerebral swelling and must be corrected. If cerebral swelling persists, the anesthetic should be converted to opioid and thiopental infusions with oxygen and air. Thiopental may be given in a series of boluses over 5 to 10 minutes to a total dose of 5 to 25 mg/kg, followed by an infusion of 4 to 10 mg/kg/h. To avoid barbiturate-induced myocardial depression and hypotension, it may be necessary to increase preload and add a vasopressor such as dopamine. Malignant brain swelling may require removal of brain tissue and a temporary scalp closure with a loose dural patch to minimize ICP after closure.

Emergence from anesthesia usually involves transporting an intubated, ventilated, and anesthetized patient to the intensive care unit. Even in an uncomplicated craniotomy for evacuation of hematoma, a period of postoperative ventilation is recommended because brain swelling is maximal 12 to 72 hours after injury. Hypertension and coughing or bucking on the endotracheal tube should be avoided because it can lead to significant intracranial bleeding. Labetalol or esmolol can be used to treat hypertension, and supplemental barbiturates are given to sedate the patient.

Systemic Sequelae

The systemic effects of head injury are diverse and can complicate management.[195] These include cardiopulmonary problems (airway obstruction, hypoxemia, shock, adult respiratory distress syndrome, neurogenic pulmonary edema, ECG changes), hematologic problems (disseminated intravascular coagulation), endocrinologic problems (pituitary dysfunction— i.e., diabetes insipidus, SIADH), metabolic problems (nonketotic hyperosmolar hyperglycemic coma), and gastrointestinal problems (stress ulcers, hemorrhage). Conditions not discussed elsewhere in this chapter are reviewed.

Aspiration, pneumonia, fluid overload, and trauma-related adult respiratory distress syndrome are common causes of pulmonary dysfunction in head-injured patients. A fulminant pulmonary edema may also occur. Neurogenic pulmonary edema is characterized by marked pulmonary vascular congestion, intra-alveolar hemorrhage, and a protein-rich edema fluid. Specific features of this syndrome are its rapid onset, its relationship to hypothalamic lesions, and the ability to prevent or attenuate it by α-blockers and CNS depressants. Neurogenic pulmonary edema is thought to result from massive sympathetic discharge from injured brain secondary to intracranial hypertension. Traditional therapy for pulmonary edema of cardiac origin is ineffective, and the outcome is frequently fatal. Therapy consists of immediate pharmacologic or surgical relief of intracranial hypertension, supportive respiratory care, and careful fluid management.

In head-injured patients, several clotting abnormalities may be present. Disseminated intravascular coagulation has been reported after mild and severe brain trauma and anoxic brain damage, and it presumably develops after release of brain tissue thromboplastin into the systemic circulation. Treatment of the underlying disease process usually results in spontaneous recovery of the coagulation defects. Occasionally, administration of cryoprecipitate, fresh frozen plasma, platelet concentrates, and blood may be required.

Anterior pituitary insufficiency after head injury is a rare occurrence. However, patients exhibiting post-traumatic diabetes insipidus may develop a delayed impairment of anterior pituitary hormones, requiring replacement therapy. Posterior pituitary dysfunction occurs more frequently

after head trauma. Diabetes insipidus may occur after craniofacial trauma and basal skull fracture. Its clinical presentation includes polyuria, polydipsia, hypernatremia, high-serum osmolality, and dilute urine. Frequently, post-traumatic diabetes insipidus is transient, and treatment is based on water replacement. If the patient cannot maintain fluid balance, exogenous vasopressin may be administered. The SIADH secretion is associated with hyponatremia, serum and extracellular fluid hypoosmolality, renal excretion of sodium, urine osmolality greater than serum osmolality, and normal renal and adrenal function. The patient develops symptoms and signs of water intoxication (anorexia, nausea, vomiting, irritability, personality changes, and neurologic abnormalities). SIADH secretion usually begins 3 to 15 days after

trauma, lasting no more than 10 to 15 days with appropriate therapy. Treatment includes water restriction with or without hypertonic saline.

Many factors in neurosurgical patients predispose to nonketotic hyperosmolar hyperglycemic coma, such as steroids, prolonged mannitol therapy, hyperosmolar tube feedings, phenytoin, and limited water replacement.[195] Diagnostic criteria for nonketotic hyperosmolar hyperglycemic coma are hyperglycemia, glucosuria, absence of ketosis, plasma osmolality >330 mOsm/kg, dehydration, and CNS dysfunction. Hypovolemia and hypertonicity are the immediate threats to life. Serum sodium may be high, normal, or low, depending on the state of hydration. Serum potassium is low. Serial laboratory tests are essential. Once sodium deficits are replaced and blood pressure and urine output are stable, water deficits are replaced with 0.45% saline. Hyperglycemia usually responds to relatively small doses of insulin. Intermittent furosemide therapy may be given for cerebral edema prophylaxis in the elderly, the adult-onset diabetic, or the patient with compromised renal function.

SUMMARY

Guidelines for the management of severe traumatic brain injury were published by The Brain Trauma Foundation in 1996.[192] Revisions to the guidelines were published in 2000 in a document that discusses various management protocols and treatments in light of supporting evidence.[193] Management updates are being published on the Web as new information is made available and the guidelines are revised.[191] Publication of these recommendations, guidelines, and/or standards by The Brain Trauma Foundation reflects on ongoing effort to improve outcome in this high-risk population through evidence-based management and standardized care.

Chapter 28

Respiratory Function in Anesthesia

M. Christine Stock

KEY POINTS

1	In a person with normal lungs, both breathing and coughing can be performed exclusively by the diaphragm.
2	In the adult, the tip of an orotracheal tube moves an average of 3.8 cm with flexion and extension of the neck, but can travel as much as 6.4 cm. In infants and children, displacement of even 1 cm can move the tube above the vocal cords or below the carina.
3	The following anatomy should be considered when contemplating the use of a double-lumen tube. The adult right main-stem bronchus is ~2.5 cm long before it branches into lobar bronchi. In 10% of adults, the right upper lobe bronchus departs from the right main-stem bronchus less than 2.5 cm above the carina. In 2 to 3% of adults, the right upper lobe bronchus opens into the trachea, above the carina.
4	When lung compliance is small, larger changes in pleural pressure are needed to create the same Vt. Patients with low lung compliance breathe with smaller Vt and more rapidly, making spontaneous respiratory rate the most sensitive clinical index of lung compliance.
5	Carotid and aortic bodies are stimulated by PaO_2 values less than 60 to 65 mm Hg. Thus, patients who depend on hypoxic ventilatory drive do not have PaO_2 values >65 mm Hg. The peripheral receptors' response will not reliably increase ventilatory rate or minute ventilation to herald the onset of hypoxemia during general anesthesia or recovery.
6	There are three etiologies of hyperventilation: arterial hypoxemia, metabolic acidemia, and central etiologies (e.g., intracranial hypertension, hepatic cirrhosis, anxiety, pharmacologic agents).
7	Increases in dead space ventilation primarily affect CO_2 elimination (with minimal influence on arterial oxygenation), and physiologic shunt increase primarily affects arterial oxygenation (with minimal influence on CO_2

	elimination).
8	During spontaneous ventilation, the ratio of alveolar ventilation to dead space ventilation is 2:1. The alveolar-to-dead space ventilation ratio during positive-pressure ventilation is 1:1. Thus, minute ventilation during mechanical ventilatory support must be greater than that during spontaneous ventilation to achieve the same $PaCO_2$.
9	$PaCO_2 \geqslant PETCO_2$ unless the patient inspires or receives exogenous CO_2. The difference between $PaCO_2$ and $PETCO_2$ is due to dead space ventilation. The most common reason for an acute increase in dead space ventilation is decreased cardiac output.
10	The best evaluation of the efficiency with which the lungs oxygenate the arterial blood is the calculation of shunt fraction. It is the only index of oxygenation that takes into account the contribution of mixed venous blood to arterial oxygenation.
11	When functional residual capacity (FRC) is reduced, lung compliance falls and results in tachypnea, and venous admixture increases, creating arterial hypoxemia.
12	There is no compelling evidence that defines rules or parameters for ordering preoperative pulmonary function tests. Rather, they should be obtained to ascertain the presence of the reversible pulmonary dysfunction (bronchospasm) or to define the severity of advanced pulmonary disease.
13	Smoking patients should be advised to *stop* smoking at least 2 months prior to an elective operation to decrease the risk of postoperative pulmonary complications (PPCs).
14	The operative site is one of the most important determinants of the risk of PPC. The highest risk for PPC is associated with nonlaparoscopic upper abdominal operations, followed by lower abdominal and intrathoracic operations.
15	The single most important aspect of postoperative pulmonary care and prevention of PPC is getting the patient out of bed, preferably walking.

Anesthesiologists directly manipulate pulmonary function. Thus, a sound and thorough working knowledge of applied pulmonary physiology is essential to the safe conduct of anesthesia. This chapter discusses pulmonary anatomy, the control of ventilation, oxygen and carbon dioxide transport, ventilation–perfusion relationships, lung volumes and pulmonary function testing, abnormal physiology and anesthesia, the effect of smoking on pulmonary function, and assessing risk for PPCs.

FUNCTIONAL ANATOMY OF THE LUNGS

This section emphasizes functional lung anatomy, with structure described as it applies to the mechanical and physiologic function of the lungs.

Thorax

The thoracic cage is shaped like a truncated cone, with small superior and large inferior openings and diaphragms attached at the base. The sternal angle is located in the horizontal plane that passes through the vertebral column at the T4 or T5 level. This plane separates the superior from the inferior mediastinum. The predominant ventilatory changes in thoracic diameter occur in the anteroposterior direction in the upper thoracic region and in the lateral or transverse direction in the lower portion of the thorax.

Muscles of Ventilation

1 The ventilatory muscles are endurance muscles. Poor nutrition, chronic obstructive pulmonary disease (COPD) with gas trapping, and increased airway resistance predispose to the development of ventilatory failure due to ventilatory muscle fatigue. The ventilatory muscles include the diaphragm, intercostal muscles, abdominal muscles, cervical strap muscles, sternocleidomastoid muscles, and the large back and intervertebral muscles of the shoulder girdle. The primary ventilatory muscle is the diaphragm, with minor contributions from the intercostal muscles. Normally, at rest, inspiration requires work and expiration is passive. As ventilatory effort increases, abdominal muscles assist with rib depression and increase intra-abdominal pressure to facilitate forced exhalation causing the "stitch" athletes experience when they actively exhale. With a further increase in effort, the cervical strap muscles help elevate the sternum and upper portions of the chest. Finally, the large back and paravertebral muscles of the shoulder girdle become important during maximum ventilatory effort. In a person with normal lungs, both breathing and coughing can be performed exclusively by the diaphragm.

Ventilatory muscles must create sufficient force to lift the ribs to create subatmospheric pressure in the intrapleural space. Breathing is an endurance phenomenon, thus involving fatigue-resistant fibers, characterized by a slow-twitch response to electrical stimulation. They comprise approximately 50% of the diaphragmatic fibers and, because of their high oxidative capacity, function mostly as endurance units.[1] Fast-twitch muscle fibers, which are susceptible to fatigue, have rapid responses to electrical stimulation, impart strength, and allow the muscle to produce greater force over a short period of time. Thus, the diaphragm is composed of fast-twitch fibers that are useful during brief periods of maximal ventilatory effort (coughing, sneezing) and slow-twitch fibers provide endurance (breathing without rest).[2] The muscles of the abdominal wall, the most powerful muscles of expiration, are important for expulsive efforts such as coughing.[3]

To perform work, a muscle must be firmly anchored at both its origin and insertion. The diaphragm is unique because its insertion is mobile—an untethered central tendon that originates from fibers directly attached to the vertebral bodies and the costal portions of the lower ribs and sternum. Diaphragmatic contraction results in descent of the diaphragmatic dome and expansion of the thoracic base. These changes result in decreased intrathoracic and intrapleural pressure, with a corresponding increase in intra-abdominal pressure.

The cervical strap muscles are active even during breathing at rest. They are the most important inspiratory accessory muscles, and become the primary inspiratory muscles when diaphragmatic function is impaired, as in patients with cervical spinal cord transection.

Lung Structures

With an intact respiratory system, the expandable lung tissue completely fills the pleural cavity. The visceral and parietal pleurae are constantly in contact with each other, creating a potential intrapleural space in which pressure decreases when the diaphragm descends and the rib cage expands. At passive end inspiration, the resultant subatmospheric intrapleural pressure is a reflection of the opposing and equal forces between the tendency of the lung to collapse and the chest wall musculature to remain expanded. These equal and opposing forces at end inspiration result in the functional residual capacity (FRC), the volume of gas in the lungs at passive end

expiration. The intrapleural space normally has a slightly subambient pressure (-2 to -3 mm Hg) at FRC. With inspiration, the intrapleural pressure becomes more negative as the chest wall expands. Major divisions of the right and left lung are listed in Table 28-1. Working knowledge of the bronchopulmonary segments is important for localizing lung pathology, interpreting lung radiographs, identifying lung regions during bronchoscopy, and operating on the lung. Each bronchopulmonary segment is separated from its adjacent segments by well-defined connective tissue planes. Therefore, pulmonary pathology initially tends to remain segmental.

TABLE 28-1 Major Divisions of the Lung

▪LUNG SIDE/LOBE	▪BRONCHOPULMONARY SEGMENT
▪RIGHT	
Upper	Apical
	Anterior

Lingula	Superior

	Inferior
Lower	Superior
	Posterior basal
	Anteromedial basal
	Lateral basal

The lung parenchyma can be subdivided into three airway categories based on functional lung anatomy (Table 28-2). The conductive airways provide basic gas transport but no gas exchange. The next group, which has smaller diameters, is transitional airways. Transitional airways are conduits for gas movement, and additionally perform limited gas diffusion and

exchange. Finally, the smallest respiratory airways' primary function is gas exchange.

TABLE 28-2 Functional Airway Divisions

TYPE	FUNCTION	STRUCTURE
Conductive	Bulk gas movement	Trachea to terminal bronchioles
Transitional	Bulk gas movement	Respiratory bronchioles
	Limited gas exchange	Alveolar ducts
Respiratory	Gas exchange	Alveoli
		Alveolar sacs

Conventionally, large airways with diameters of >2 mm create 90% of total airway resistance. The number of alveoli increases progressively with age, starting at approximately 24 million at birth and reaching the final adult count of 300 million by the age of 8 to 9 years. The alveoli are associated with about 250 million precapillaries and 280 billion capillary segments, resulting in a surface area of ~70 m^2 for gas exchange.

Conductive Airways

In the adult, the trachea is a fibromuscular tube ~10 to 12 cm long with an outside diameter of ~20 mm. Structural support is provided by 20 U-shaped hyaline cartilages, with the open part of the U facing posteriorly. The cricoid membrane tethers the trachea to the cricoid cartilage at the level of the sixth cervical vertebral body. The trachea enters the superior mediastinum and bifurcates at the sternal angle (the lower border of the fourth thoracic vertebral body). Normally,

half of the trachea is intrathoracic and half is extrathoracic. Both ends of the trachea are attached to mobile structures. Thus, the adult carina can move superiorly as much as 5 cm from its normal resting position. Airway "motion" becomes important in the intubated patient. In the adult, the tip of an orotracheal tube moves an average of 3.8 cm with flexion and extension of the neck but can travel as far as 6.4 cm.[4] In infants and children, tracheal tube movement with respect to the trachea is even more critical: displacement of even 1 cm can move the tube above the cords or below the carina.

The next airway generation is composed of the right and left main-stem bronchi. The diameter of the right bronchus is generally greater than that of the left. In the adult, the right bronchus leaves the trachea at ~25° from the vertical tracheal axis, whereas the angle of the left bronchus is ~45°. Thus, inadvertent endobronchial intubation or aspiration of foreign material is more likely to occur in the right lung than the left. Furthermore, the right upper lobe bronchus dives almost directly posterior at ~90° from the right main bronchus. Foreign bodies and fluid aspirated by a supine subject usually fall into the right upper lobe. In children younger than 3 years of age, the angles created by the right and left main-stem bronchi are approximately equal, with takeoff angles of about 55°.

3 The adult right main bronchus is ~2.5 cm long before it initially branches into lobar bronchi. However, in 10% of adults, the right upper lobe bronchus departs from the right main-stem bronchus less than 2.5 cm from the carina. Furthermore, in ~2 to 3% of adults, the right upper lobe bronchus opens into the trachea, above the carina. Patients with these anomalies require special consideration when placing double-lumen tracheal tubes, especially if one contemplates inserting a right-sided endobronchial tube. After the right upper and middle lobe bronchi divide from the right main bronchus, the main channel becomes the right lower lobe bronchus.

The left main bronchus is ~5 cm long before its initial branching point to the left upper lobe and the lingual. Then, it continues on as the left lower lobe bronchus.

The bronchioles, typically 1 mm in diameter, are devoid of cartilaginous support and have the highest proportion of smooth muscle in the wall. Of the three to four bronchiolar generations, the final generation is the terminal bronchiole, which is the last airway component that does not participate in gas exchange.

Transitional Airways

The respiratory bronchiole, which follows the terminal bronchiole, is the first site in the tracheobronchial tree where gas exchange occurs. In adults, two or three generations of respiratory bronchioles lead to alveolar ducts, of which there are four to five generations, each with multiple openings into alveolar sacs. The final divisions of alveolar ducts terminate in alveolar sacs that open into alveolar clusters.

Respiratory Airways and the Alveolar–Capillary Membrane

The pulmonary capillary beds are the densest capillary networks in the body. This extensive vascular branching system starts with pulmonary arterioles in the region of the respiratory bronchioles. Each alveolus is closely associated with ~1,000 short capillary segments.

The alveolar–capillary interface is complicated but well designed to facilitate gas exchange. Viewed with electron microscopy, the alveolar wall consists of a thin capillary epithelial cell, a basement membrane, a pulmonary capillary endothelial cell, and a surfactant lining layer. The flattened, squamous type I alveolar cells cover ~80% of the alveolar surface. Type I cells contain flattened nuclei and extremely thin cytoplasmic extensions that provide the surface for gas exchange. Type I cells are

highly differentiated and metabolically limited, which makes them highly susceptible to injury. When type I cells are damaged severely (during acute lung injury or adult respiratory distress syndrome), type II cells replicate and modify to form new type I cells.[5]

Type II alveolar cells are interspersed among type I cells, primarily at alveolar–septal junctions. These polygonal cells have vast metabolic and enzymatic activity, and manufacture surfactant. The enzymatic activity required to produce surfactant is only 50% of the total enzymatic activity present in type II alveolar cells.[6] The remaining enzymatic activity modulates local electrolyte balance, as well as endothelial and lymphatic cell functions. Both type I and type II alveolar cells have tight intracellular junctions, thus providing a relatively impermeable barrier to fluids.

Type III alveolar cells, alveolar macrophages, are an important element of lung defense. Their migratory and phagocytic activities result in the ingestion of foreign materials within alveolar spaces.[7] Although functional pulmonary macrophages reduce the incidence of lung infection,[8] they are also an integral part of the lung inflammatory response. Therefore, whether their presence is good (to reduce the change of infection) or bad (because they contribute to the inflammatory response) is highly controversial.[9]

Finally, numerous finger-like projections of the capillary endothelial cells greatly increase their surface area. They also provide intimate contact between the capillary endothelial cell and the entire circulating blood volume. Thus, the alveolar-capillary membrane has two primary functions: transport of respiratory gases (oxygen and carbon dioxide), and the production of a wide variety of local and humoral substances.

Pulmonary Vascular Systems

Two major circulatory systems supply blood to the lungs: the pulmonary and bronchial vascular networks. The pulmonary vascular system delivers mixed-venous blood from the right ventricle to the pulmonary capillary bed via the pulmonary arteries. After gas exchange occurs in the pulmonary capillary bed, oxygen-rich and carbon dioxide-poor blood is returned to the left atrium via the pulmonary veins. The pulmonary veins run independently along the intralobar connective tissue planes. The pulmonary capillary system adequately provides for the metabolic and oxygen needs of the alveolar parenchyma. However, the bronchial arterial system must provide oxygen to the conductive airways and pulmonary vessels. Anatomic connections between the bronchial and pulmonary venous circulations create an absolute shunt of ~2 to 5% of the total cardiac output, and represents "normal" shunt.

LUNG MECHANICS

Lung movement is entirely passive and responds to forces external to the lungs. During spontaneous ventilation, the external forces are produced by ventilatory muscles. The lungs' response is governed by the impedance of the chest wall and by the airways. This impedance, or hindrance, falls mainly into two categories: (1) elastic recoil of the lung and gas–liquid interface, and (2) resistance to gas flow.

Elastic Work

The lungs' natural tendency is to collapse; thus, expiration at rest is normally passive because gas flows out of the lungs when they elastically recoil. The thoracic cage exerts an outward-directed force, and the lungs exert an inward-directed force. Together these forces result in a subatmospheric intrapleural pressure. Because the outward force of the thoracic cage exceeds the inward force of the lung, the overall tendency of the lung is to remain inflated when it resides within the thoracic cage. At FRC, the outward and inward forces on the lung are equal. Thus, at passive end-exhalation, the respiratory muscles are relaxed and the lung returns to its resting volume within the relaxed thorax: FRC. Gravitational forces create a more subatmospheric pressure in nondependent areas of the lung than in dependent areas. In the upright adult, the difference in intrapleural pressure from the top to the bottom of the lung is ~7 cm H_2O.

Surface tension at an air–fluid interface produces forces that tend to further reduce the area of interface. The gas pressure within a bubble is always higher than the surrounding gas pressure because of the bubble's surface tension. Thus, the bubble remains inflated. The alveoli resemble bubbles in this respect, although alveolar gas communicates with the atmosphere via the airways, unlike a bubble. The Laplace equation describes this phenomenon: $P = 2T/R$, where P is the

pressure within the bubble (dyn · cm^{-2}), T is the surface tension of the liquid (dyn · cm^{-1}), and R is the radius of the bubble (cm).

During inspiration, the surface tension of the liquid in the lung increases to 40 mN/m, a value close to that of plasma. During expiration, this surface tension falls to 19 mN/m, a value lower than that of most other fluids. The alveoli experience hysteresis, that is, different pressure–volume relationships during inspiration and expiration. In contrast to a bubble, the pressure within an alveolus decreases as the radius of curvature decreases. Thus, gas tends to flow from larger to smaller alveoli, thereby maintaining stability and preventing lung collapse.

The alveolar transmural pressure gradient, or transpulmonary pressure, is the difference between intrapleural and alveolar pressure and is directly proportional to lung volume. Intrapleural pressure can be safely measured with a percutaneously inserted catheter;[10] however, clinicians rarely perform this technique. Esophageal pressure can be used as a reflection of intrapleural pressure, but the esophageal balloon must reside in the midesophagus to avoid inaccurate measurement.[11] Commercially available esophageal pressure monitors increase the ease and accuracy of measuring esophageal pressure as a reflection of intrapleural pressure.[12] These monitors are useful for estimating the elastic work performed by the patient during spontaneous ventilation, mechanical ventilation, or a combination of spontaneous and mechanical ventilation. By estimating intrapleural pressure on a real-time basis, it is possible to quantitate the patient's work of breathing as one intervenes. For example, low levels of inspiratory pressure support can compensate for the work of breathing imposed by the endotracheal tube.[13]

Physiologic work of breathing includes elastic work (inspiratory work required to overcome the elastic recoil of the pulmonary system) and resistive work (work to overcome resistance to gas flow in the airway). For a patient in whom breathing apparatus is employed, the concept of total work of breathing encompasses physiologic work plus equipment-imposed ventilatory work: the work performed by the patient to overcome the resistance imposed by the breathing apparatus. Examples of imposed work include the resistance imposed by tracheal tubes and demand valves.

If the lungs are slowly inflated and deflated, the pressure–volume curve during inflation differs from that obtained during deflation. The two curves form a hysteresis loop that becomes progressively broader as the tidal volume is increased (Fig. 28-1). A greater pressure than anticipated is required during inflation, and recoil pressure is less than expected during deflation. Thus, the lung accepts deformation poorly and, once deformed, assumes its original shape slowly. This elastic hysteresis is important for the maintenance of normal lung compliance

but is not clinically significant. Thus, in the following discussion, it is ignored.

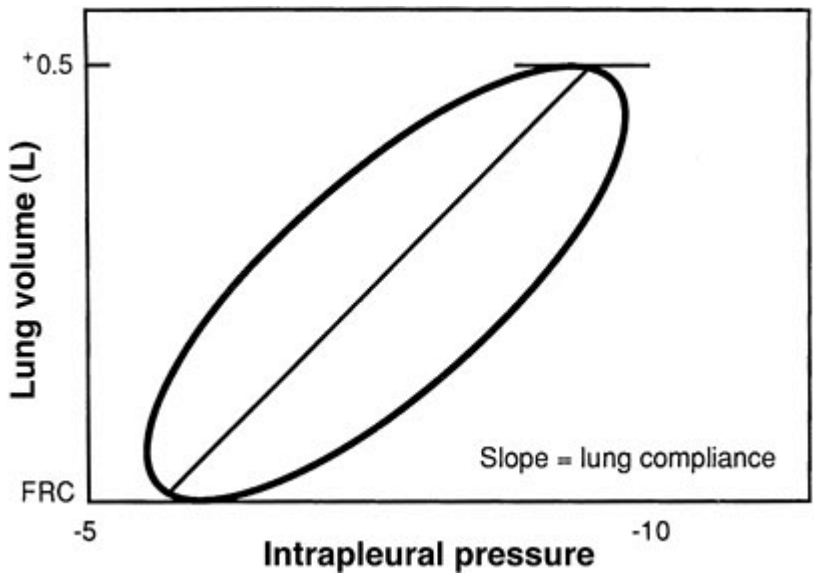

FIGURE 28-1. Dynamic pressure–volume loop of resting tidal volume. Quiet, normal

breathing is characterized by hysteresis of the pressure–volume loop. The lung is more resistant to deformation than expected and returns to its original configuration less easily than expected. The slope of the line connecting the zenith and nadir lung volumes is lung compliance, ~500 mL/3 cm H_2O = 167 mL/cm H_2O.

4 The sum of the pressure–volume relationships of the thorax and lung results in a sigmoidal curve (Fig. 28-2). The vertical line drawn at end expiration coincides with FRC. Normally, humans breathe on the steepest part of the sigmoidal curve, where compliance is highest. The compliance of the curve is represented by the slope of the curve ($\Delta V/\Delta P$). In restrictive diseases, the curve shifts to the right, the slope is depressed, or both. These changes result in smaller FRCs and lower lung compliance. When lung compliance is small, larger changes in intrapleural pressure are needed to create the same tidal volume; that is, the thorax has to suck harder to get the same volume of gas into the lungs. The body, being a smart organism, prefers to move less gas with each breath rather than sucking harder to achieve the same tidal volume. Thus, patients with low lung compliance typically breathe with smaller tidal volumes at more rapid rates, making spontaneous ventilatory rate one of the most sensitive indices of lung compliance.

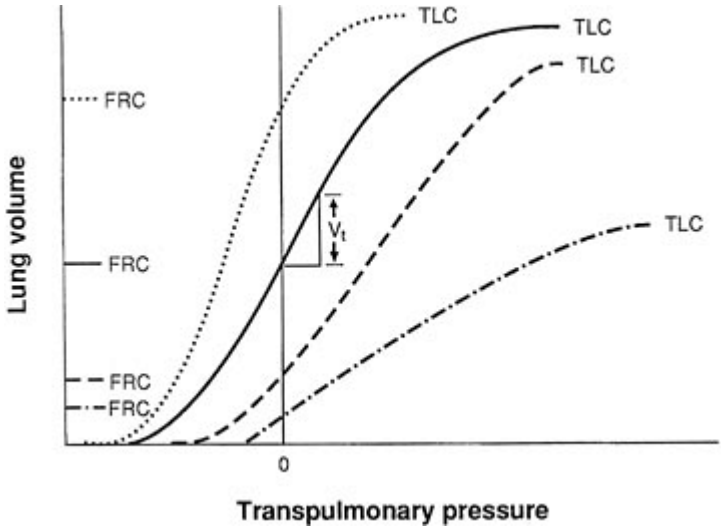

FIGURE 28-2. Pulmonary pressure–volume relationships at different values of total lung capacity (TLC), ignoring hysteresis. The *solid line* depicts the normal pulmonary pressure–volume relationships. Humans normally breathe on the linear, steep part of this sigmoidal curve, where the slope, which is equal to compliance, is greatest. The *vertical line* at zero defines functional residual capacity (FRC), regardless of the position of the curve on the graph. Mild restrictive lung disease, indicated by the *dashed line*, shifts the curve to the right with little change in slope. However, with restrictive disease, the patient breathes on a lower FRC, at a point on the curve where the slope is less. Severe restrictive pulmonary disease profoundly depresses the FRC and diminishes the slope of the entire curve (*dashed-dotted line*). Obstructive disease (*dotted line*) elevates both FRC and compliance.

Continuous positive airway pressure (CPAP) will shift the vertical line to the right, thus allowing the patient to breathe on a steeper and more favorable portion of the volume–pressure curve, resulting in a slower ventilatory rate with a larger tidal volume.

At the other end of the spectrum, patients with diseases that increase lung compliance experience larger than normal FRC (gas trapping), and their pressure–volume curves shift to the left and steepen. These patients expend less elastic work to inspire, but elastic recoil is reduced

significantly. Chronic obstructive lung disease and acute asthma are the most common examples of diseases with high lung compliance. If lung compliance and FRC are sufficiently high that elastic recoil is minimal, the patient must use ventilatory muscles to actively expire. The difficulty these patients experience in emptying the lungs is compounded by the increased airway resistance.

Both compliance and inspiratory elastic work can be measured for a single breath by measuring airway (Paw), intrapleural (Ppl) pressures, and tidal volume. If esophageal pressure is measured carefully, the esophageal pressure values can be substituted for Ppl values. Lung compliance, C_L, the slope of the volume–pressure curve, is given by the equation

$$C_L = \frac{\Delta V}{\Delta P_L} + \frac{Vt}{P_{L_i} - P_{L_e}} = \frac{Vt}{(Paw_i - Ppl_i) - (Paw_e - Ppl_e)} \quad (28\text{-}1)$$

where P_L is transpulmonary pressure, PL_i and PL_e are transpulmonary pressure at end-inspiratory and end-expiratory, Vt is tidal volume, Paw_e and Paw_i are expiratory and inspiratory airway pressures, and Ppl_e and Ppl_i are expiratory and inspiratory intrapleural pressures.

Elastic work (W_{el}) is performed during inspiration only because expiration is passive during normal breathing. The area within the triangle in Figure 28-2 describes the work required to inspire. The equation that yields elastic work (and the area of the triangle) is

$$\begin{aligned} W_{el} &= \tfrac{1}{2}(Vt)(P_{L_i} - P_{L_e}) \\ &= \tfrac{1}{2}(Vt)[(Paw_i - Ppl_i) - (Paw_e - Pple)] \end{aligned} \quad (28\text{-}2)$$

$= \frac{1}{2}(Vt)[(Paw_i - Ppl_i) - (Paw_e - Pple)]$

Resistance to Gas Flow

Both laminar and turbulent flows exist within the respiratory tract, usually in mixed patterns. The physics of each, however, is significantly different and worth consideration.

Laminar Flow

Below critical flows, gas proceeds through a straight tube as a series of concentric cylinders that slide over one another. Fully developed flow has a parabolic profile with a velocity of zero at the cylinder wall and a maximum velocity at the center of the advancing "cone." Peripheral cylinders tend to be stationary, and the central cylinder moves fastest. This type of streamlined flow is usually inaudible. The advancing conical front means that some fresh gas reaches the end of the tube before the tube has been completely filled with fresh gas. A clinical implication of laminar flow in the airways is that significant alveolar ventilation can occur even when the tidal volume (Vt) is less than

anatomic dead space. This phenomenon, noted by Rohrer in 1915,[14] is important in high-frequency ventilation.

Laminar gas flows in a straight, unbranched tube encounter meets resistance that can be calculated by the following equation:

$$R = \frac{8 \times \text{length} \times \text{viscosity}}{\pi \times (\text{radius})^4} = \frac{P_B - P_A}{\text{flow}} \quad (28\text{-}3)$$

where P_B and P_A are barometric and alveolar pressures. The inverse relationship between resistance and the fourth power of the radius explains the critical importance of narrowed air passages. Viscosity is the only physical gas property that is relevant under conditions of laminar flow. Helium has a low density, but its viscosity is close to that of air. Therefore, helium will not improve gas flow if the flow is laminar. Usually, flow is turbulent when there is critical airway narrowing or abnormally high airway resistance, making low-density helium useful therapy (see next section).

Turbulent Flow

High flow rates, particularly through branched or irregularly shaped tubes, disrupt the orderly flow of laminar gas. Turbulent flow is usually audible and is almost invariably present when high resistance to gas flow is problematic. Turbulent flow usually presents with a square front so fresh gas will not reach the end of the tube until the amount of gas entering the tube is almost equal to the volume of the tube. Thus, turbulent flow effectively purges the contents of a tube. Four conditions that will change laminar flow to turbulent flow are high gas flows, sharp angles within the tube, branching in the tube, and a change in the tube's diameter.

Resistance during laminar flow is inversely proportional to gas flow rate. Conversely, during turbulent flow, resistance increases in proportion to the flow rate. A detailed description of these phenomena is beyond the scope of this chapter, but the reader is referred to descriptions by Nunn.[15]

Increased Airway Resistance

Bronchiolar smooth muscle hyperreactivity (true bronchospasm), mucosal edema, mucous plugging, epithelial desquamation, tumors, and foreign bodies all increase airway resistance. The normal response to increased inspiratory resistance is increased inspiratory muscle effort, with little change in FRC.[16] Accessory muscles act according to the degree of resistance. The conscious subject can detect small increases in inspiratory resistance.[17]

Emphysematous patients retain remarkable ability to preserve an adequate alveolar ventilation, even with gross airway obstruction. In patients with preoperative FEV_1 values <1 L, $PaCO_2$ is normal in most patients. Furthermore, asthmatic patients compensate well for increased airway resistance and also keep the mean $PaCO_2$ in the lower end of normal range.[18] Thus, an increased $PaCO_2$ in the setting of increased airway resistance deserves serious attention and may signal that the patient's compensatory mechanisms are nearly exhausted.

Mild expiratory resistance does not result in activation of the expiratory muscles in conscious or anesthetized subjects. The initial work to overcome expiratory resistance is performed by augmenting inspiratory force until a sufficiently high lung volume is achieved so elastic recoil overcomes expiratory resistance.[19] The immediate effects of excessive expiratory resistance are to use accessory muscles to force gas from the lungs. This response is useful during acute increases in expiratory resistance. However, patients who chronically use accessory muscles to expire are at risk for ventilatory muscle fatigue if they experience an acute worsening of ventilatory work, most commonly precipitated by pneumonia or heart failure.

Physiologic Changes in Respiratory Function Associated with Aging

Physiologic aging of the lung is associated with dilation of the alveoli, enlargement of the airspaces, decrease in exchange surface area, and loss of supporting tissue. Changes in the aging lung and chest wall result in decreased lung recoil, and increased residual volume and FRC. Compliance of the chest wall diminishes, thereby increasing the work of breathing compared with younger subjects. Respiratory muscle strength decreases with aging and is strongly correlated with nutritional status and cardiac index. Expiratory flow rates decrease with a flow–volume curve suggestive of small airway resistance. Despite these changes, the respiratory system is able to maintain adequate gas exchange at rest and during exertion throughout life, with only modest decrements in PaO_2 and no change in $PaCO_2$. The respiratory centers lose sensitivity to hypoxemia and hypercapnia; thus, the elderly exhibit a blunted ventilatory response when challenged by heart failure, airway obstruction, or pneumonia.

CONTROL OF VENTILATION

Mechanisms that control ventilation are extremely complex, requiring integration with many parts of the central and peripheral nervous systems (Fig. 28-3). LeGallois, who localized the respiratory centers in the brainstem in 1812, demonstrated that breathing does not depend on an intact cerebrum. Rather, breathing depends on a small region of the medulla near the origin of the vagus nerves.[21] Countless studies in the past two centuries have greatly increased our knowledge and

understanding of the anatomic components of ventilatory control. However, experimental work performed in animals is difficult to apply to humans because of interspecies variation.

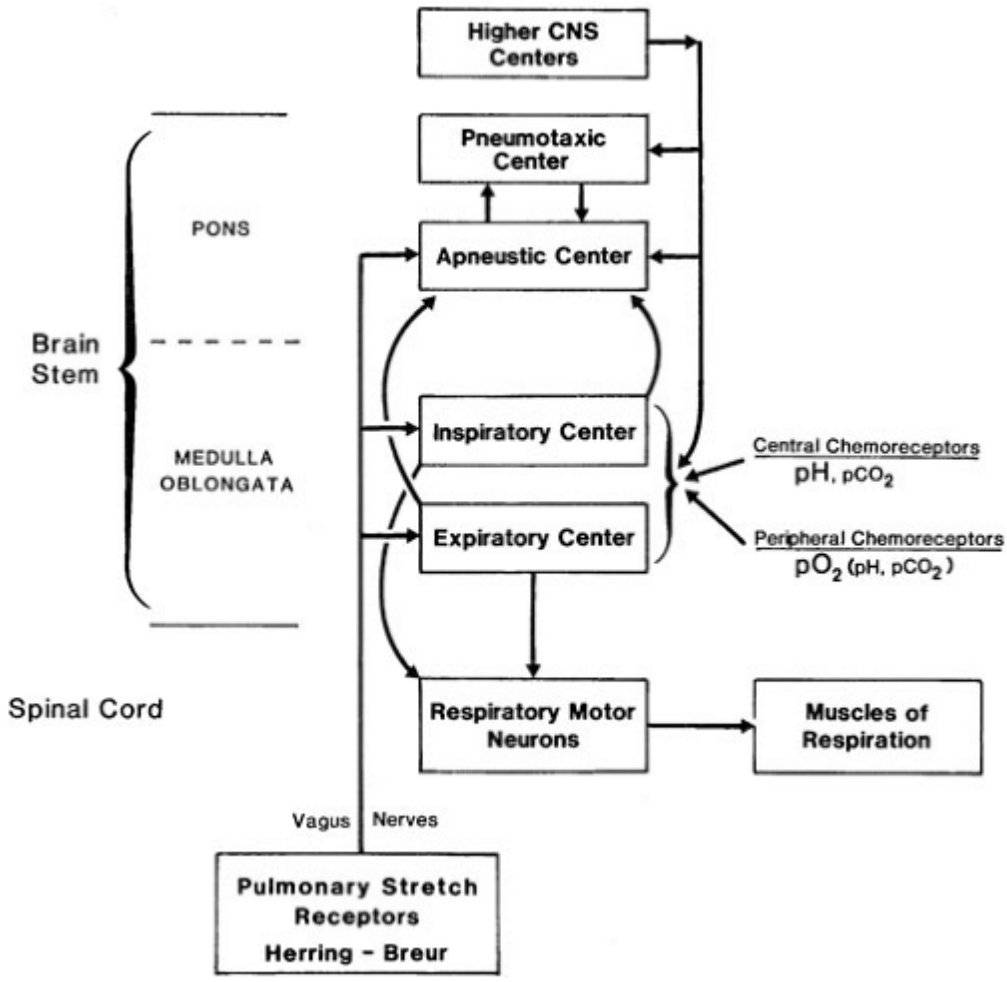

FIGURE 28-3. Classic central nervous system (CNS) respiratory centers. Diagram illustrates major respiratory centers, neurofeedback circuits, primary neurohumoral sensory inputs, and mechanical outputs.

Generation of Ventilatory Pattern

Refer to Table 28-3 for definitions of terms used in this section. A *respiratory center* is a specific area in the brain that integrates any neural traffic resulting in spontaneous ventilation. Within the pontine and medullary reticular formations, there are several discrete respiratory centers that function as the control system (see Fig. 28-3).

TABLE 28-3 Definition of Respiratory Pattern Terminology

▪WORD	▪DEFINITION
Eupnea	"Good breathing": continuous inspiratory and expiratory movement without interruption
Apnea	"No breathing": cessation of ventilatory effort at passive end-

	expiration (lung volume = FRC)
Apneusis	Cessation of ventilatory effort with lungs filled at TLC
Apneustic ventilation	Apneusis with periodic expiratory spasms
Biot	Ventilatory gasps interposed between periods of ventilation apnea; *also* "agonal ventilation"
FRC, fucntional residual capacity; TLC, total lung capacity.	

Initial descriptions of brainstem respiratory functions are based on classic ablation and electrical stimulation studies. Another method for localizing respiratory centers entails recording action potentials from different areas of the brainstem with microelectrodes. This method is based on the assumption that local brain activity that occurs in phase with respiratory activity is evidence that the area under study has "respiratory neurons."[22] These techniques are imperfect for precisely localizing discrete respiratory centers.

Medullary Centers

The medulla oblongata contains the most basic ventilatory control centers in the brain. Specific medullary areas are active primarily during inspiration or during expiration, with many neural inspiratory or expiratory interconnections. The inspiratory centers that reside in the dorsal respiratory group (DRG) are located in the dorsal medullary reticular formation. The DRG is the source of elementary ventilatory rhythmicity[23,24] and serves as the "pacemaker" for the respiratory system.[25] Whereas resting lung volume occurs at end expiration, the electrical activity of the ventilatory centers is at rest at end inspiration. The rhythmic activity of the DRG persists even when all incoming

peripheral and interconnecting nerves are sectioned or blocked completely. Isolating the DRG in this manner results in ataxic, gasping ventilation with frequent maximum inspiratory efforts: apneustic breathing.

The ventral respiratory group (VRG), which is located in the ventral medullary reticular formation, serves as the expiratory coordinating center. The inspiratory and expiratory neurons function by a system of reciprocal innervation, or negative feedback.[22] When the DRG creates an impulse to inspire, inspiration occurs and the DRG impulse is quenched by a reciprocating VRG impulse. This VRG transmission prohibits further use of the inspiratory muscles, thus allowing passive expiration to occur.

Pontine Centers

The pontine centers process information that originates in the medulla. The apneustic center is located in the middle or lower pons. With activation, this center sends impulses to inspiratory DRG neurons and is designed to sustain inspiration. Electrical stimulation results in inspiratory spasm.[26] The middle and lower pons contain specific areas for phase-spanning neurons.[27] These neurons assist with the transition between inspiration and expiration, and do not exert direct control over ventilatory muscles.

The pneumotaxic respiratory center is in the rostral pons. A simple transection through the

brainstem that isolates this portion of the pons from the upper brainstem reduces ventilatory rate and increases tidal volume. If both vagus nerves are additionally transected, apneusis results.[28] Thus, the primary function of the pneumotaxic center is to limit the depth of inspiration. When maximally activated, the pneumotaxic center secondarily increases ventilatory frequency. The pneumotaxic center performs no pacemaking function and has no intrinsic rhythmicity.

Higher Respiratory Centers

Many higher brain structures clearly affect ventilatory control processes. In the midbrain, stimulation of the reticular activating system increases the rate and amplitude of ventilation.[29] The cerebral cortex also affects breathing pattern, although

precise neural pathways are not known. Occasionally, the ventilatory control process becomes subservient to other regulatory centers. For example, the respiratory system plays an important role in the control of body temperature because it supplies a large surface area for heat exchange. This is especially important in animals in which panting is a primary means of dissipating heat. Then, ventilatory pattern is influenced by neural input from descending pathways from the anterior and posterior hypothalamus to the pneumotaxic center of the upper pons.

Vasomotor control and certain respiratory responses are closely linked. Stimulation of the carotid sinus not only decreases vasomotor tone, but also inhibits ventilation. Alternatively, stimulation of the carotid body chemoreceptors (see Chemical Control of Ventilation section) results in an increase in both ventilatory activity and vasomotor tone.

Reflex Control of Ventilation

Reflexes that directly influence ventilatory pattern usually do so to prevent airway obstruction. *Deglutition*, or swallowing, involves the glossopharyngeal and vagus nerves. Stimulation of the anterior and posterior pharyngeal pillars of the posterior pharynx induces swallowing. During swallowing, inspiration ceases momentarily, is usually followed by a single large breath, and briefly increases ventilation.

Vomiting significantly modifies normal ventilatory activity.[30] Swallowing, salivation, gastrointestinal reflexes, rhythmic spasmodic ventilatory movements, and significant diaphragmatic and abdominal muscular activity must be coordinated over a very brief interval. Because of the obvious risk of aspirating gastric contents, it is advantageous to inhibit inspiration during vomiting. Input into the respiratory centers occurs from both cranial and spinal cord nerves.

Coughing results from stimulation of the tracheal subepithelium, especially along the posterior tracheal wall and carina.[31] Coughing also requires coordination of both airway and ventilatory muscle activity. An effective cough requires deep inspiration and then forced exhalation against a momentarily closed glottis to increase intrathoracic pressure, thus allowing an expulsive expiratory maneuver.

Proprioception in the pulmonary system, the qualitative knowledge of the gas volume within the lungs, probably arises from smooth muscle spindle receptors. These proprioceptors, which are located within the smooth muscle of all airways, are sensitive to pressure changes. Airway stretch reflexes can be demonstrated during distention of isolated airways so airway pressure, rather than volume distention, appears to be the primary stimulation.[32] Clinical conditions in which pulmonary airway stretch receptors are stimulated include pulmonary edema and atelectasis.

Golgi tendon organs (tendon spindles), which occur in series arrangements within ventilatory muscles, facilitate proprioception. The intercostal muscles are rich in tendon spindles, whereas the diaphragm has a limited number. Thus, the pulmonary stretch reflex primarily involves the intercostal muscles but not the diaphragm. When the lungs are full and the chest wall is stretched, these receptors send signals to the brainstem that inhibit further inspiration.

In 1868, Hering and Breuer reported that lightly anesthetized, spontaneously breathing animals

would cease or decrease ventilatory effort during sustained lung distention.[33] This response was blocked by bilateral vagotomy. The *Hering–Breuer reflex* is prominent in lower-order mammals and is sufficiently active in lower mammals that even 5 cm H_2O CPAP will induce apnea. In humans, however, the reflex is only weakly present, as evidenced by the fact that humans will continue to breathe spontaneously with CPAP in excess of 40 cm H_2O.

Chemical Control of Ventilation

Peripheral Chemoreceptors

In a simplistic view of chemical ventilatory control, the peripheral chemoreceptors primarily respond to lack of oxygen, and the central nervous system (CNS) receptors primarily respond to changes in PCO_2, pH, and acid-base disturbances.

5 The peripheral chemoreceptors are composed of the carotid and aortic bodies. The carotid bodies, located at the bifurcation of the common carotid artery, have predominantly ventilatory effects. The aortic bodies, which are scattered about the aortic arch and its branches, have predominantly circulatory effects. The neural output from the carotid body reaches the central respiratory centers via the afferent glossopharyngeal nerves. Output from the aortic bodies travels to the medullary centers via the vagus nerve. Both carotid and aortic bodies are stimulated by decreased PaO_2, but not by decreased SaO_2 or CaO_2. When PaO_2 falls to less than 100 mm Hg, neural activity from these receptors begins to increase. However, it is not until the PaO_2 reaches 60 to 65 mm Hg that neural activity increases sufficiently to substantially augment minute ventilation. Thus, patients who depend on hypoxic ventilatory drive have PaO_2 values in the mid-60s. Once these patients' PaO_2 values exceed 60 to 65 mm Hg, ventilatory drive diminishes and PaO_2 falls until ventilation is again stimulated by arterial hypoxemia. When we withdraw mechanical ventilation from the patient who depends on hypoxic ventilatory drive, the PaO_2 must fall to less than 65 mm Hg so the patient will regain hypoxic ventilatory drive.

The carotid bodies are also sensitive to decreased pH_a, but this response is minor. Similarly, changes in $PaCO_2$ do not stimulate these receptors sufficiently to alter minute ventilation. Increases in blood temperature, hypoperfusion of the carotid bodies themselves, and some chemicals will stimulate these receptors. Sympathetic ganglion stimulation by nicotine or acetylcholine will stimulate the carotid and aortic bodies; this effect is blocked by hexamethonium. Blockade of the cytochrome electron transport system by cyanide will prevent oxidative metabolism and thus stimulate these receptors.

Ventilatory effects resulting from stimulation of these receptors cause increased ventilatory rate and tidal volume. Hemodynamic changes resulting from stimulation of these receptors include bradycardia, hypertension, increases in bronchiolar tone, and increases in adrenal secretion. The carotid body chemical receptors have been termed *ultimum moriens* ("last to die"). Although the peripheral receptors' response to hypoxemia was formerly believed to be resistant to the influences of anesthesia, potent inhaled anesthetics appear to depress hypoxic ventilatory response by depressing carotid body response to hypoxemia.[34] The peripheral receptors' response is not sufficiently robust to reliably increase ventilatory rate or minute ventilation to herald the onset of arterial hypoxemia during general anesthesia or recovery from anesthesia. Furthermore, flumazenil, in a 1-mg intravenous dose, only partially reversed the diazepam-induced depression of hypoxic ventilatory drive.[35] Mora's data further suggest that humans may develop tolerance to respiratory depressant effects of diazepam.

Central Chemoreceptors

Approximately 80% of the ventilatory response to inhaled carbon dioxide originates in the central medullary centers. Acid-base regulation involving carbon dioxide, H^+, and bicarbonate is related primarily to chemosensitive receptors located in the medulla close to or in contact with the cerebrospinal fluid (CSF). The chemosensitive areas of the brainstem are in the infralateral aspects of the medulla near the origin of cranial

nerves IX and X. The area just beneath the surface of the ventral medulla is exquisitely sensitive to the extracellular fluid H^+ concentration.[36] Although the central response is the major factor in the regulation of breathing by carbon dioxide, carbon dioxide has little direct stimulating effect on these chemosensitive areas. These receptors are primarily sensitive to changes in H^+ concentration. Carbon dioxide has a potent but indirect effect by reacting with water to form carbonic acid, which dissociates into hydrogen and bicarbonate ions.[37]

Increased $PaCO_2$ is a more potent ventilatory stimulus than increased arterial H^+ concentration from a metabolic source. Carbon dioxide, but not H^+, passes readily through the blood-brain and blood-CSF barriers. Local buffering systems immediately neutralize H^+ in arterial blood and body fluids. In contrast, the CSF has minimal buffering capacity. Thus, once carbon dioxide crosses into the CSF, H^+ are created and trapped in the CSF, resulting in a CSF H^+ concentration considerably greater than that found in the blood. Because carbon dioxide crosses the blood-brain barrier readily, the PCO_2 values in the CSF, cerebral tissue, and jugular venous blood rise quickly and to the same degree as the $PaCO_2$, although the central values are ~10 mm Hg higher than those measured in arterial blood.

The ventilatory response to changes in $PaCO_2$ (increased Vt, increased respiratory rate) is rapid and peaks within 1 to 2 minutes after the change in $PaCO_2$. With the same level of carbon dioxide stimulation, the resultant increase in ventilation declines over a period of several hours, probably as a result of bicarbonate ions that are actively transported from the blood into the CSF through the arachnoid villi.[38] Central medullary chemoreceptors also respond to temperature change. Cold CSF (with normal pH) or local anesthetic applied to the medullary surface will depress ventilation.

Ventilatory Response to Altitude

Ventilatory response and adaptation to high altitude are good examples of the integration of peripheral and central chemoreceptor control of ventilation. The following mechanism of acclimatization was proposed by Severinghaus and coworkers in 1963 and has since been confirmed.[39]

Following ascent from sea level to 4,000 m, acute exposure to high altitude and low PIO_2 results in arterial hypoxemia. This decrease in PaO_2 activates the peripheral hypoxemic ventilatory drive by stimulating the carotid and aortic bodies, and causes increased minute ventilation. As minute ventilation increases, $PaCO_2$ and CSF PCO_2 decrease, causing concomitant increases in pH_a and CSF pH. The alkaline shift of the CSF decreases ventilatory drive via medullary chemoreceptors, partially offsetting hypoxemic drive. A temporary equilibrium is attained within minutes, with $PaCO_2$ only 2 to 5 mm Hg less than normal and PaO_2 approximately 45 mm Hg. This initially profound hypoxemia probably causes the acute respiratory distress and other associated symptoms (headache, diarrhea) associated with rapid ascent. However, the CNS is able to restore CSF pH to normal (7.326) by pumping bicarbonate ions out of the CSF over 2 to 3 days. In 2 to 3 days, CSF bicarbonate concentration decreases approximately 5 mEq/L and restores CSF pH to within 0.01 pH unit of values at sea level. Then, centrally mediated ventilatory drive returns to normal, and hypoxic drive and stimulation of peripheral receptors can proceed unopposed. Thus, after 3 days' exposure to 4,000 m altitude, ventilatory adaptation would result in a new equilibrium, with $PaCO_2$ approximately 30 mm Hg and PaO_2 approximately 55 mm Hg. Following descent to sea level, the low CSF bicarbonate concentration persists for several days, and the climber "overbreathes" until CSF bicarbonate and pH values return to normal.

Breath-Holding

Most adults with normal lungs and gas exchange can hold their breath for ~1 minute when breathing room air without previously hyperventilating. After 1 minute of breath-holding under these circumstances, PaO_2 decreases to ~65 to 70 mm Hg and $PaCO_2$ increases by ~12 mm Hg. In the absence of supplemental oxygen and hyperventilation, the "breakpoint" at which normal people are compelled to breathe is remarkably constant at a $PaCO_2$ of 50 mm Hg.[40,41] However, if the individual breathes 100% oxygen prior to breath-holding, he or she should be able to hold his or her breath for 2 to 3 minutes, or until $PaCO_2$ rises to 60 mm Hg. Hyperventilation sufficient to

reduce $PaCO_2$ to 20 mm Hg can lengthen the period of breath-holding to 3 to 4 minutes.[42] Hyperventilation with 100% oxygen prior to breath-holding should extend the apneic period to 6 to 10 minutes. The $PaCO_2$ rate of rise in awake, preoxygenated adults with normal lungs who hold their breath without previous hyperventilation is 7 mm Hg/min in the first 10 seconds, 2 mm Hg/min in the next 10 seconds, and 6 mm Hg/min thereafter.[41]

The duration of voluntary breath-holding is directly proportional to lung volume at onset, and is probably related both to oxygen stores in the alveoli and to the rate at which $PaCO_2$ rises. With smaller lung volumes, the same amount of carbon dioxide is emptied into a smaller volume during the apneic period, thus increasing the carbon dioxide concentration more rapidly than occurs with larger lung volumes. Of note, apneic patients during general anesthesia actually "breath-hold" at FRC rather than at vital capacity, which would tend to accelerate the rate of rise of carbon dioxide. Despite this difference in lung volume, the rate of rise of $PaCO_2$ in apneic anesthetized patients is 12 mm Hg during the first minute and 3.5 mm Hg/min thereafter, significantly lower than in the awake state.[42,43] During anesthesia, metabolic rate and carbon dioxide production are significantly less than during ambulatory wakefulness, which probably accounts for the different rates of rise in carbon dioxide levels.

Hyperventilation with room air prior to prolonged breath-holding during exercise is inadvisable. During underwater swimming after poolside hyperventilation, the urge to breathe is first stimulated by a rising $PaCO_2$. Swimmers who hyperventilate with room air prior to swimming long distances underwater frequently lose consciousness from arterial hypoxemia before the $PaCO_2$ is sufficiently increased to stimulate the "need" to breathe.

Hyperventilation rarely is followed by an apneic period in awake humans, despite a markedly depressed $PaCO_2$. However, minute ventilation may decrease significantly. Aggressive intermittent positive-pressure breathing treatments for patients with COPD can depress minute ventilation sufficiently to create arterial hypoxemia if they breathe room air after cessation of therapy.[44] In contrast, even mild hyperventilation during general anesthesia will produce prolonged apneic periods.[45]

Quantitative Aspects of Chemical Control of Breathing

The ventilatory responses to oxygen and carbon dioxide can be assessed quantitatively. Unfortunately, the quantitative indices of hypoxemic sensitivity are not clinically useful because the normal range is wide and confounded by many environmental factors. The reader is referred to a classical discussion of the quantitative indices of hypoxemic sensitivity.[46]

Ventilatory responses to $PaCO_2$ changes are measured in several ways, provided that carbon dioxide production remains constant. When subjects voluntarily increase minute ventilation to a prescribed level, the $PaCO_2$ decreases hyperbolically. The plot of minute ventilation (independent variable) and $PaCO_2$ (dependent variable) is the metabolic hyperbola (Fig. 28-4).

The metabolic hyperbola is cumbersome to evaluate and difficult to use clinically.

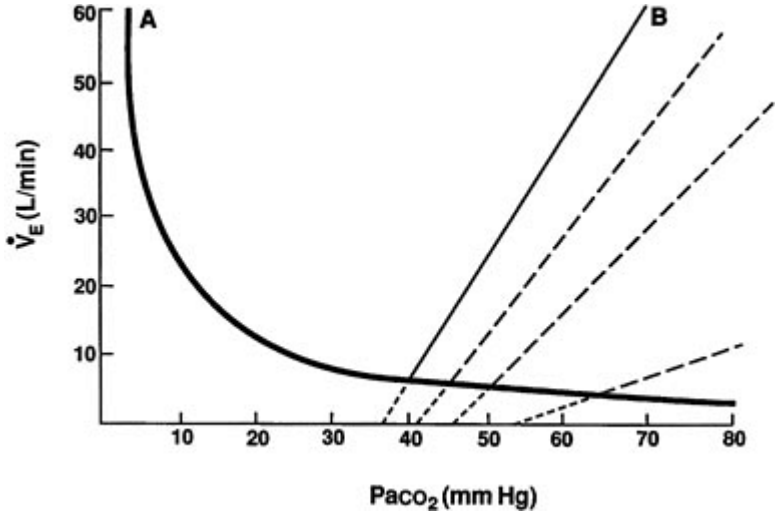

FIGURE 28-4. Carbon dioxide–ventilatory response curve. The metabolic hyperbola, curve A, is generated by varying $\dot{V}_E$ and measuring changes in carbon dioxide concentration. The hyperbolic configuration makes it cumbersome for clinical use. The carbon dioxide–ventilatory response curve, B is linear between approximately 20 and 80 mm Hg. It is generated by varying $PaCO_2$ (usually by controlling inspired carbon dioxide concentration) and measuring the resultant $\dot{V}_E$. This is the most commonly used test of ventilatory response. The slope defines "sensitivity"; the setpoint, or resting $PaCO_2$, occurs at the intersection of the metabolic hyperbola and the carbon dioxide–ventilatory response curve; and the apneic threshold can be obtained by extrapolating the carbon dioxide–ventilatory response curve to the *x*-intercept. In the absence of surgical stimulation, increasing doses of potent inhaled anesthesia or opioids will shift the curve to the right and eventually depress the slope (*dashed lines*). Painful stimulation will reverse these changes to varying and unpredictable degrees.

The curve more commonly used is the $PaCO_2$ ventilatory response curve (see Fig. 28-4). It describes the effect of changing $PaCO_2$ on the resultant minute ventilation. Usually, subjects inspire carbon dioxide to raise $PaCO_2$, and the effect on minute ventilation is measured. Creating these curves and observing how they change in various circumstances allows quantitative study of factors that affect the chemical carbon dioxide control of ventilation. The carbon dioxide response curve approaches linearity in the range most often encountered in life: at $PaCO_2$ values between 20 and 80 mm Hg. Once the $PaCO_2$ exceeds 80 mm Hg, the curve becomes parabolic, with its peak ventilatory response at a $PaCO_2$ between 100 and 120 mm Hg. Increasing the $PaCO_2$ to higher than 100 mm Hg allows carbon dioxide to act as a ventilatory and CNS depressant, the origin of the term "carbon dioxide narcosis," with 1 minimum alveolar concentration (MAC) being approximately 200 mm Hg.

The slope of the carbon dioxide response curve is considered to represent carbon dioxide sensitivity. Normal carbon dioxide sensitivity ranges from 0.5 to 0.7 L/min/mm Hg CO_2. When $PaCO_2$ reaches 100 mm Hg, carbon dioxide sensitivity is at its peak and normally reaches as high as 2.0 L/min/mm Hg CO_2. The *setpoint*, the point of intersection of the carbon dioxide response curve and the metabolic hyperbola, defines normal resting $PaCO_2$. Extrapolation of the carbon dioxide response curve to the *x*-intercept (where minute ventilation is 0) defines the apneic threshold. In awake, normal adults, the apneic threshold normally occurs at a $PaCO_2$ of ~32 mm Hg, although adults usually continue to breathe when they achieve the apneic threshold because the sensation of apnea is disturbing to awake adults. The slope of the curve is a measure of the

response of the entire ventilatory mechanism to carbon dioxide stimulation.

Once PaO_2 exceeds 100 mm Hg, it no longer influences the carbon dioxide response curve. When the PaO_2 is between 65 and 100 mm Hg, its effect on the carbon dioxide response curve is small. However, when PaO_2 falls to less than 65 mm Hg, the carbon dioxide response curve shifts to the left and its slope increases, probably as a result of increased ventilatory drive stimulated by the peripheral chemoreceptors. Thus, during measurements of carbon dioxide ventilatory response, the subject should breathe supplemental oxygen.

The carbon dioxide response curve can be generated rapidly by increasing the fraction of inspired carbon dioxide ($FICO_2$) by requiring the subject to rebreathe exhaled gas. The results obtained with this technique are less pure because the $FICO_2$ is not controlled.

6 Three clinical states result in a left shift and/or a steepened slope of the carbon dioxide response curve. These same three situations are the only causes of true hyperventilation, that is, an increase in minute ventilation such that the decreased $PaCO_2$ creates respiratory alkalemia (either primary or compensatory). The three causes of hyperventilation (enhanced carbon dioxide response) are arterial hypoxemia, metabolic acidemia, and central etiologies. Examples of central etiologies that cause hyperventilation include drug administration, intracranial hypertension, hepatic cirrhosis, and nonspecific arousal states such as anxiety and fear. Aminophylline, salicylates, and norepinephrine stimulate ventilation independent of peripheral chemoreceptors. Opioid antagonists, given in the absence of opioids to presumably normal people, do not stimulate ventilation. However, when given after opiate administration, they do reverse the effects of opioids on the carbon dioxide response curve.

Ventilatory depressants displace the carbon dioxide response curve to the right or decrease its slope or both. Changes in physiology that depress ventilation include metabolic alkalemia, denervation of peripheral chemoreceptors, normal sleep, and drugs. During normal sleep, the carbon dioxide response curve is displaced to the right, with the degree of displacement depending on the depth of sleep. Usually, $PaCO_2$ increases up to 10 mm Hg during deep sleep. Hypoxemic responses are not impaired by sleep, which is convenient for continued survival at high altitude.

Opioids displace the carbon dioxide response curve to the right with little change in slope at sedative doses. With higher, "anesthetic" doses, the curve shifts farther to the right and its slope is depressed, simulating the effect of potent inhalation agents on the carbon dioxide response curve (see Fig. 28-4). In the absence of other ventilatory depressant drugs, opioids induce pathognomonic changes in ventilatory patterns: a decreased ventilatory rate with an increased tidal volume. Not until opioids nearly induce apnea is tidal volume decreased. Large narcotic doses usually result in apnea before consciousness is lost. Like sex, breathing requires both ability and desire.

Barbiturates in sedative or light hypnotic doses have little effect on the carbon dioxide response curve. In doses adequate to allow skin incision, barbiturates shift the carbon dioxide response curve to the right. The ventilatory pattern resulting from barbiturate administration is characterized by decreased tidal volume and increased ventilatory rate. Potent inhaled anesthetics displace the carbon dioxide response curve to the right and decrease the slope, the degree depending on the anesthetic dose and the level of surgical stimulation. As the inhaled anesthetic dose increases, the carbon dioxide response curve eventually becomes horizontal (slope = 0), resulting in essentially no ventilatory response to $PaCO_2$ changes.

Potent inhaled anesthetics and opioids displace the setpoint to the right, implying that the resting, steady-state $PaCO_2$ is higher and minute ventilation lower. Furthermore, when the carbon dioxide response curve shifts to the right, the apneic threshold also increases (see Fig. 28-4). Surgical

stimulation reverses the ventilatory response changes induced by inhaled anesthetics and opioids, but the degree of reversal is not predictable.

OXYGEN AND CARBON DIOXIDE TRANSPORT

This chapter discusses only external respiration, in which oxygen moves from the ambient environment into the pulmonary capillaries, and carbon dioxide leaves the pulmonary capillaries to enter the atmosphere. The movement of gas across the alveolar–capillary membrane depends on the integrity of the pulmonary and cardiac systems. Unless it is otherwise stated, the reader should assume the ventilation and perfusion of alveolar–capillary units are normal. Abnormal distribution of ventilation or perfusion of the lungs is discussed later (see Ventilation–Perfusion Relationships section).

Bulk Flow of Gas (Convection)

Convection, in which all gas molecules move in the same direction, is the primary mechanism responsible for gas flow in large and most small airways, down to the bronchi and bronchiolar airways of the fourteenth or fifteenth generation. Because the cross-sectional area of the airways progressively increases as gas moves toward the lung periphery, the average velocity of gas particles decreases as they travel toward the alveoli. As a result, the greatest part of airway resistance occurs in the larger airways, where gas molecules travel more quickly. During normal quiet ventilation, gas flow within convective airways is mainly laminar, thus reducing resistance to gas flow (see Resistance to Gas Flow section).

Gas Diffusion

Diffusion within a gas-filled space is random molecular motion that results in complete mixing of all gases. In the lung, diffusion gradually becomes the predominant mode of gas transport, beginning with the terminal bronchioles (sixteenth airway generation). Once gas reaches the small alveolar ducts, alveolar sacs, and alveoli, both diffusion and regional $\dot{V}/\dot{Q}$ relationships influence gas transport. Historically, clinicians assumed defects in gas diffusion were responsible for arterial hypoxemia. However, the most frequent cause of arterial hypoxemia is physiologic shunt (see Ventilation–Perfusion Relationships section).[47]

The other usage of "diffusion" refers to the passive movement of molecules across a membrane that is governed primarily by concentration gradient. In this sense, carbon dioxide is 20 times more diffusible across human membranes than is oxygen; therefore, carbon dioxide crosses membranes easily. As a result, hypercarbia is never the result of defective diffusion; rather, it is the result of inadequate alveolar ventilation with respect to carbon dioxide production.

True diffusion defects that create arterial hypoxemia are rare. The most common reason for a measured decrease in diffusing capacity (see Pulmonary Function Testing section) is mismatched ventilation and perfusion, which functionally results in a decreased surface area available for diffusion.

Distribution of Ventilation and Perfusion

The efficiency with which oxygen and carbon dioxide exchange at the alveolar–capillary level highly depends on the matching of capillary perfusion and alveolar ventilation. At this level, the marriage between the lung and the circulatory system must be well matched and intimate.

Distribution of Blood Flow

Blood flow within the lung is mainly gravity dependent. Because the alveolar–capillary beds are not composed of rigid vessels, the pressure of the surrounding tissues can influence the resistance to flow through the individual capillaries. Thus, blood flow depends on the relationship between pulmonary artery pressure (Ppa), alveolar pressure (PA), and pulmonary venous pressure (PpV) (Fig. 28-5). West created a lung model that divides the lung into three zones.[47,48] Zone 1 conditions occur in the most gravity-independent part of the lung above the level where pulmonary artery pressure is equal to alveolar pressure. Because alveolar pressure is approximately equal to atmospheric pressure, pulmonary artery pressure in zone 1 is

subatmospheric but necessarily greater than pulmonary venous pressure (PA > Ppa > PpV). Alveolar pressure that is transmitted to the pulmonary capillaries promotes their collapse, with a consequent theoretical blood flow of zero to this lung region. Thus, zone 1 receives ventilation in the absence of perfusion and creates alveolar dead space ventilation. Normally, zone 1 areas exist only to a limited extent. However, in conditions of decreased pulmonary artery pressure, such as hypovolemic shock, zone 1 enlarges.

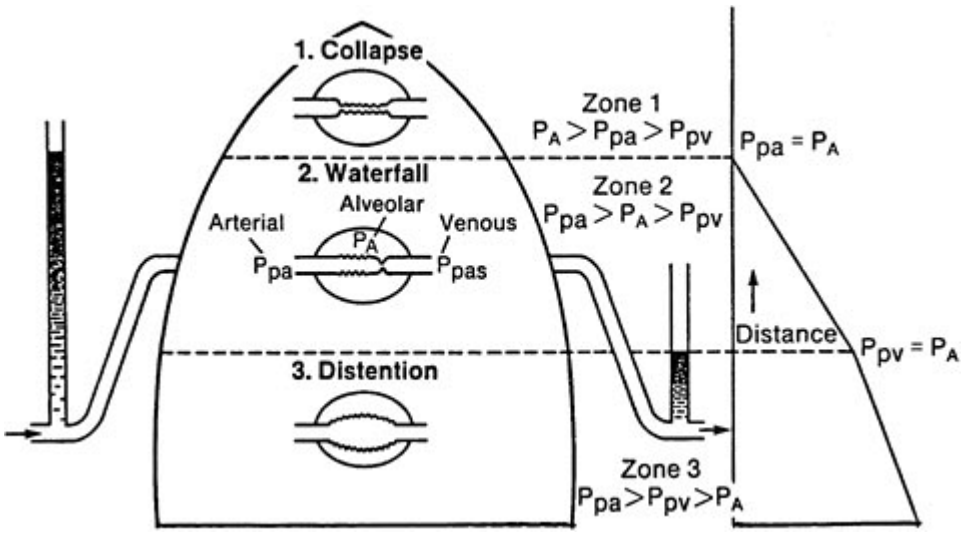

FIGURE 28-5. Distribution of blood flow in the isolated lung. In zone 1, alveolar pressure (P_A) exceeds pulmonary artery pressure (P_{pa}), and no flow occurs because the vessels are collapsed. In zone 2, arterial pressure exceeds alveolar pressure, but alveolar pressure exceeds pulmonary venous pressure (P_{pv}). Flow in zone 2 is determined by the arterial–alveolar pressure difference ($P_{pa} - P_A$), which steadily increases down the zone. In zone 3, pulmonary venous pressure exceeds alveolar pressure, and flow is determined by the arterial–venous pressure difference ($P_{pa} - P_{pv}$), which is constant down this pulmonary zone. However, the pressure across the vessel walls increases down the zone so their caliber increases, as does flow. (From West JB, Dollery CT, Naimark A: Distribution of blood flow in isolated lung: Relation to vascular and alveolar pressures. J Appl Physiol 19:713, 1964.)

Zone 3 occurs in the most gravity-dependent areas of the lung where Ppa > PpV > PA and blood flow is primarily governed by the pulmonary arterial to venous pressure difference. Because gravity also increases pulmonary venous pressure, the pulmonary capillaries become distended. Thus, perfusion in

zone 3 is lush, resulting in capillary perfusion in excess of ventilation, or physiologic shunt.

Finally, zone 2 occurs from the lower limit of zone 1 to the upper limit of zone 3, where Ppa > PA > PpV. The pressure difference between pulmonary artery and alveolar pressure determines blood flow in zone 2. Pulmonary venous pressure has little influence. Well-matched ventilation and perfusion occur in zone 2, which contains the majority of alveoli.

Distribution of Ventilation

Alveolar pressure is the same throughout the lung; therefore, the more negative intrapleural pressure at the apex (or the least gravity-dependent area) results in larger, more distended apical alveoli than in other areas of the lung. The transpulmonary pressure (Paw – Ppl), or distending pressure of the lung, is greater at the top and lower at the bottom, where intrapleural pressure is less negative. Despite the smaller alveolar size, more ventilation is delivered to dependent pulmonary areas. The decrease in intrapleural pressure at the base of the lungs during inspiration is greater than at the apex because of diaphragmatic proximity. Thus, more gas is sucked into

dependent areas of the lung.

Ventilation–Perfusion Relationships

As discussed previously, the majority of blood flow is distributed to the gravity-dependent part of the lung. During a spontaneous breath, the largest portion of the tidal volume also reaches the gravity-dependent part of the lung. Thus, the nondependent area of the lung receives a lower proportion of both ventilation and perfusion, and dependent lung receives greater proportions of ventilation and perfusion. Nevertheless, ventilation and perfusion are not matched perfectly, and various

$$\frac{\dot{V}_A}{\dot{Q}}$$

ratios result throughout the lung. The ideal

$$\frac{\dot{V}_A}{\dot{Q}}$$

ratio of 1 is believed to occur at approximately the level of the third rib. Above this level, ventilation occurs slightly in excess of perfusion, whereas below the third rib the

$$\frac{\dot{V}_A}{\dot{Q}}$$

ratio becomes less than 1 (Fig. 28-6).

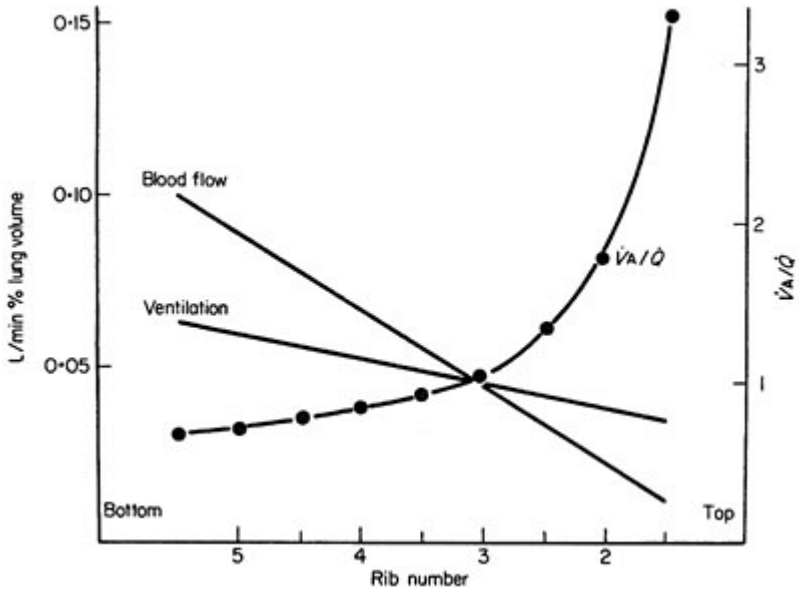

FIGURE 28-6. Distribution of ventilation, blood flow, and ventilation–perfusion ratio in the normal, upright lung. Straight lines have been drawn through the ventilation and blood flow data. Because blood flow falls more rapidly than ventilation with distance up the lung, ventilation–perfusion ratio rises, slowly at first, then rapidly. (From West JB: Ventilation/Blood Flow and Gas Exchange, 4th ed. Oxford, England, Blackwell Scientific, 1985.)

In a simplified model, gas exchange units can be divided into normal (

$$\frac{\dot{V}_A}{\dot{Q}}$$

= 1:1), dead space (

$$\frac{\dot{V}_A}{\dot{Q}}$$

= 1:0), shunt ($\frac{\dot{V}A}{\dot{Q}}$ = 0:1), or a silent unit ($\frac{\dot{V}A}{\dot{Q}}$ = 0:0) (Fig. 28-7). Although this model is helpful in understanding $\frac{\dot{V}A}{\dot{Q}}$ relationships and their influences on gas exchange, $\frac{\dot{V}A}{\dot{Q}}$ really occurs as a continuum. In the lungs of a healthy, upright, spontaneously breathing individual, the majority of alveolar-capillary units are normal gas exchange units. The $\frac{\dot{V}A}{\dot{Q}}$ ratio varies between absolute shunt (in which $\frac{\dot{V}A}{\dot{Q}}$ = 0) to absolute dead space (in which $\frac{\dot{V}A}{\dot{Q}}$ = ∞). Rather than absolute shunt, most units with low $\frac{\dot{V}A}{\dot{Q}}$ mismatch receive a small amount of ventilation relative to blood flow. Similarly, most dead space units are not absolute, but rather are characterized by low blood flow relative to ventilation.

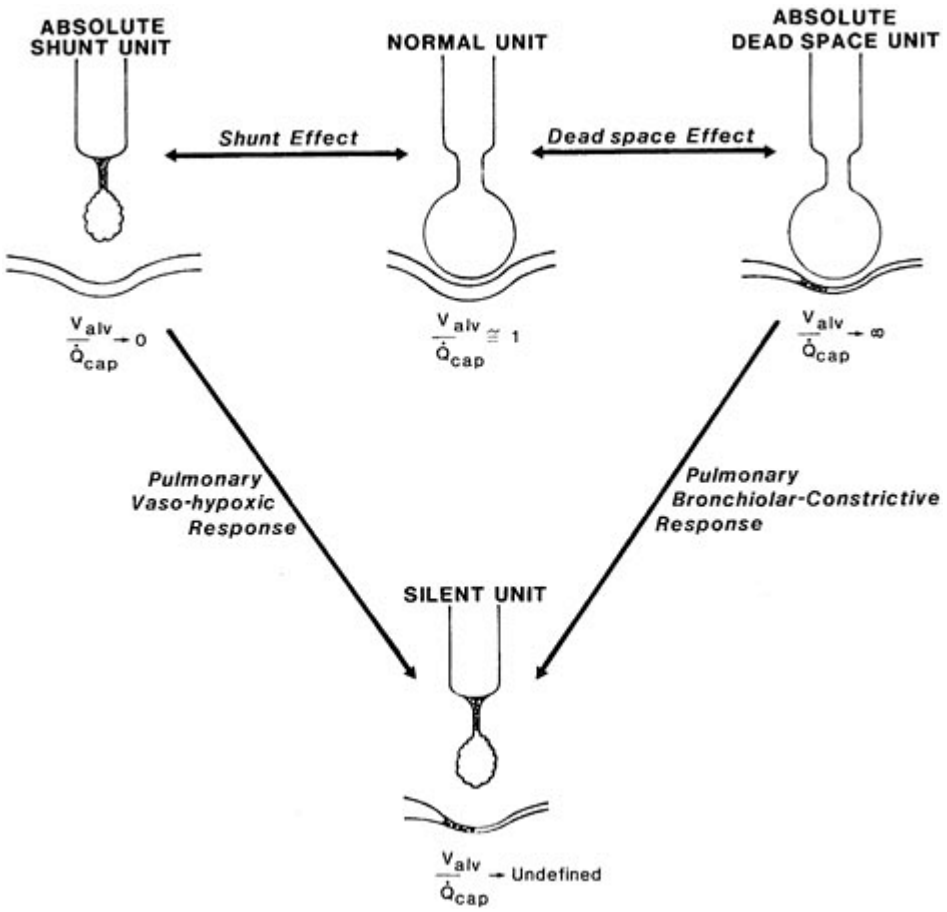

FIGURE 28-7. Continuum of ventilation–perfusion relationships. Gas exchange is maximally effective in normal lung units and only partially effective in shunt and dead space effect units. It is totally absent in silent units, absolute shunt, and dead space units.

Hypoxic pulmonary vasoconstriction, stimulated by alveolar hypoxia, severely decreases blood flow. Thus, poorly ventilated alveoli also receive minuscule blood flow. Furthermore, decreased regional pulmonary blood flow results in bronchiolar constriction and diminishes the degree of dead space ventilation.[49,50] When either phenomena occurs, the shunt or dead space units effectively become silent units in which little ventilation or perfusion occurs.

7 Many pulmonary diseases result in both physiologic shunt and dead space abnormalities. However, most disease processes can be characterized as producing either primarily shunt or dead space in their early stages. Increases in dead space ventilation primarily affect carbon dioxide elimination and have little influence on arterial oxygenation until dead space ventilation exceeds 80 to 90% of minute ventilation ($\dot{V}E$). Similarly, physiologic shunt primarily affects arterial oxygenation with little effect on carbon dioxide elimination until the physiologic shunt fraction exceeds 75 to 80% of the cardiac output. Defective to absent gas exchange can be the net effect of either abnormality in the extreme.

Physiologic Dead Space

Each inspired breath is composed of gas that contributes to alveolar ventilation (V_A) and gas that becomes dead space ventilation (VD). Thus, tidal volume (Vt) = VA + VD. In the normal, spontaneously breathing person, the ratio of alveolar-to-dead space ventilation for each breath is 2:1. Conveniently, the rule of "1, 2, 3" applies to normal, spontaneously breathing persons. For each breath, 1 mL/lb (lean body weight) becomes VD, 2 mL · lb^{-1} becomes VA, and 3 mL · lb^{-1} constitutes the Vt.

Physiologic dead space consists of anatomic and alveolar dead space. Anatomic dead space ventilation, approximately 2 mL/kg ideal body weight, accounts for the majority of physiologic dead space. It arises from ventilation of structures that do not exchange respiratory gases: the oronasopharynx to the terminal and respiratory bronchioles. Clinical conditions that modify anatomic dead space include tracheal intubation, tracheostomy, and large lengths of ventilator tubing between the tracheal tube and the ventilator Y-piece.

Alveolar dead space ventilation arises from ventilation of alveoli where there is little or no perfusion. Because disease changes anatomic dead space little, physiologic dead space is primarily influenced by changes in alveolar dead space. Rapid changes in physiologic dead space ventilation most often arise from changes in pulmonary blood flow, resulting in decreased perfusion to ventilated alveoli. The most common etiology of acutely increased physiologic dead space is an abrupt decrease in cardiac output. Another pathologic condition that interferes with pulmonary blood flow, and thereby creates dead space, is pulmonary embolism, whether due to thrombus or to fat, air, or amniotic fluid. Although there may be obstruction to blood flow with some types of pulmonary emboli, the greatest decrease in pulmonary blood flow is due to vasoconstriction

induced by locally released vasoactive substances such as leukotrienes.

Chronic pulmonary diseases create dead space ventilation by irreversibly changing the relationship between alveolar ventilation and blood flow; this alteration is especially prominent in patients with COPD. Furthermore, acute diseases such as adult respiratory distress syndrome can cause an increase in dead space ventilation owing to intense pulmonary vasoconstriction. Finally, therapeutic or supportive manipulations such as positive-pressure ventilation or positive airway pressure therapy can increase alveolar dead space because depressed venous return to the right heart will decrease cardiac output. Intravenous fluid administration will usually overcome this problem.

Assessment of Physiologic Dead Space

Because the lung receives nearly 100% of the cardiac output, assessment of physiologic dead space ventilation in the acute setting yields valuable information about pulmonary blood flow and, ultimately, about cardiac output. If pulmonary blood flow decreases, the most likely cause is a decreased cardiac output. Thus, it is clinically useful to be able to readily assess the degree of physiologic dead space ventilation.

There are two easy and several difficult ways to assess dead space ventilation. A comparison of minute ventilation and $PaCO_2$ allows a gross qualitative assessment of physiologic dead space ventilation. The $PaCO_2$ is determined only by alveolar ventilation and $\dot{V}CO_2$. If $\dot{V}CO_2$ remains constant, $PaCO_2$ also will remain constant as long as minute ventilation supplies the same degree of alveolar ventilation. If the spontaneously breathing individual must increase minute ventilation to maintain the same $PaCO_2$, he or she has experienced an increase in dead space ventilation because less of the minute ventilation is contributing to alveolar ventilation. Alternatively, a mechanically ventilated patient with a fixed minute ventilation and no increase in $\dot{V}CO_2$ also experiences an increased dead space ventilation if the $PaCO_2$ rises. Hence, when $PaCO_2$ in a mechanically ventilated patient increases, it is necessary to determine if the cause is increased dead space ventilation or an increased $\dot{V}CO_2$.

8 The mechanically ventilated patient with normal lungs has a dead space to alveolar ventilation ratio (VD/VA) of 1:1 rather than 1:2, as during spontaneous ventilation. If mechanical Vt is 1,000 mL, 500 mL contributes to VA, and 500 mL contributes to VD. At rest, the required $\dot{V}$

A with normal

$\dot{V}$

CO_2 is approximately 60 mL/kg/min. A 70-kg man would then require a

$\dot{V}$

A of 4,200 mL/min. During spontaneous breathing, the required

$\dot{V}$

E would be 6,300 mL/min, but during mechanical ventilation

$\dot{V}$

E would have to be 8,400 mL/min. Using this calculation, if a 70-kg resting patient requires

$\dot{V}$

E much in excess of 8,400 mL/min, either

$\dot{V}$

D or

$\dot{V}$

CO_2 is increased. A rule of thumb for mechanically ventilated patients is that doubling baseline minute ventilation decreases $PaCO_2$ from 40 to 30 mm Hg, and quadrupling minute ventilation decreases $PaCO_2$ from 40 to 20 mm Hg.

9 The $PaCO_2$ will be greater than or equal to end-tidal $PaCO_2$ ($PETCO_2$) unless the patient inspires or receives exogenous carbon dioxide (e.g., from peritoneal insufflation). The difference between $PETCO_2$ and $PaCO_2$ is due to dead space ventilation. Measurement of this difference—which is simple, readily obtainable, and fairly inexpensive—yields reliable information relative to the degree of dead space ventilation. Clinical situations that change pulmonary blood flow sufficiently to increase dead space ventilation can be detected by comparing $PETCO_2$ with temperature-corrected $PaCO_2$. Yamanaka and Sue[51] found that the $PETCO_2$ in ventilated patients varied linearly with the dead space to tidal volume ratio (VD/Vt) and that $PETCO_2$ correlated poorly with $PaCO_2$. Thus, in the critically ill, mechanically ventilated patient, and in anesthetized patients, monitoring $PETCO_2$ gives far more information about ventilatory efficiency or dead space ventilation than it does about the absolute value of $PaCO_2$.

Anesthesiologists commonly measure $PETCO_2$ to detect venous air embolism during anesthesia. A lowered cardiac output

alone, in the absence of venous air embolism, may sufficiently decrease pulmonary perfusion so dead space ventilation increases and $PETCO_2$ falls. Thus, a depressed $PETCO_2$ is a sensitive but nonspecific monitor. Air in the pulmonary arteries mechanically interferes with blood flow and also causes pulmonary arterial constriction, further decreasing pulmonary blood flow. A decreased $PETCO_2$ suggests that a physiologically significant air embolism has occurred. The same physiologic considerations apply to detecting pulmonary thromboembolism.

Some clinicians use the divergence of $PETCO_2$ from $PaCO_2$ as a reflection of pulmonary blood flow for other applications. During intentional pharmacologic or surgical manipulation of pulmonary blood flow, the difference between $PaCO_2$ and $PETCO_2$ serves as a useful physiologic monitor of the effectiveness of these interventions. Furthermore, regarding $PETCO_2$ as a reflection of pulmonary perfusion is a useful tool for studying and monitoring the effectiveness of resuscitation efforts and may provide a marker for survival after resuscitation.[52]

The most quantitative technique used to measure physiologic dead space uses a modification of the Bohr equation:

$$\frac{V_D}{Vt} = \frac{PaCO_2 - P\bar{E}CO_2}{PaCO_2} \qquad (28\text{-}4)$$

where P

$\overline{E}$

CO_2 is the PCO_2 from the mixture of all expired gases over the period of time during which measurements are made. This calculation estimates the fraction of each breath that does not contribute to gas exchange. In spontaneously breathing patients, normal VD/Vt is between 0.2 and 0.4, or ~0.33. In patients receiving positive-pressure ventilation, VD/Vt becomes ~0.5. The major

limitation of performing this calculation is the difficulty in collecting exhaled gas for P

$\overline{E}$

CO_2 measurement. Exhaled gases, collected in cumbersome 8–l bags, can easily be contaminated with inspired air or supplemental oxygen. The measurement will also be inaccurate if the patient does not maintain a steady ventilatory pattern. Therefore, extreme care must be taken to ensure all measurements are performed accurately. In practice, this measurement is rarely performed.

Physiologic Shunt

Whereas physiologic dead space ventilation applies to areas of the lung that are ventilated but poorly perfused, physiologic shunt occurs in lung that is perfused but poorly ventilated. The physiologic shunt (

$\dot{Q}$

SP) is that portion of the total cardiac output (

$\dot{Q}$

T) that returns to the left heart and systemic circulation without receiving oxygen in the lung. When pulmonary blood is not exposed to alveoli or when those alveoli are devoid of ventilation, the result is *absolute shunt*, in which

$\dot{V}$

A/

$\dot{Q}$

= 0. *Shunt effect*, or *venous admixture*, is the more common clinical phenomenon and occurs in areas where alveolar ventilation is deficient compared with the degree of perfusion: 0 <

$\dot{V}$

A/

$\dot{Q}$

< 1.

Because blood passing through areas of absolute shunt receives no oxygen, arterial hypoxemia resulting from absolute shunt is minimally reversed with supplemental oxygen. Alternatively, supplemental oxygen supplied to patients with arterial hypoxemia due to venous admixture will increase the PaO_2. Although ventilation to these alveoli is deficient, they do carry a small amount of oxygen to the capillary bed.

A small percentage of venous blood normally bypasses the right ventricle and empties directly into the left atrium. This anatomic, absolute shunt arises from the venous return from the pleural, bronchiolar, and thebesian veins. This venous drainage accounts for 2 to 5% of total cardiac output and explains the small shunt that normally occurs. Anatomic shunts of greatest magnitude are usually associated with congenital heart disease that causes right-to-left shunt. Intrapulmonary anatomic shunts can also cause anatomic shunt. For example, the arterial hypoxemia associated with advanced hepatic failure (hepatopulmonary syndrome) is due, in part, to arteriovenous malformations.[53,54] Diseases that may cause absolute shunt include acute lobar atelectasis, extensive acute lung injury, advanced pulmonary edema, and consolidated pneumonia. Disease entities that tend to produce venous admixture include mild pulmonary edema, postoperative atelectasis, and COPD.

Assessment of Arterial Oxygenation and Physiologic Shunt

The simplest assessment of oxygenation is qualitative comparison of the patient's FIO_2 and PaO_2. The highest possible PaO_2 for any given FIO_2 (and $PaCO_2$) can be calculated from the alveolar gas equation:

$$P_{AO_2} = F_{IO_2}(P_b - P_{H_2O}) - \frac{P_{ACO_2}}{R} \qquad (28\text{-}5)$$

where PAO_2 and $PACO_2$ are alveolar PO_2 and PCO_2, PH_2O is water vapor pressure at 100% saturation and 37°C, P_b is barometric pressure, and R is respiratory quotient. Assuming one makes the calculation for a well-perfused alveolus, the alveolar and arterial PCO_2 are equal. Therefore, $PaCO_2$ can be substituted for $PACO_2$. Respiratory quotient (R) is the ratio of O_2 consumed (

$\dot{V}$

O_2) to CO_2 produced ($\dot{V}CO_2$):

$$\frac{\dot{V}co_2}{\dot{V}o_2} = \frac{200\,mL/min}{250\,mL/min} = 0.8 \qquad (28\text{-}6)$$

Oxygen tension–based indices do not reflect mixed venous contribution to arterial oxygenation and can be misleading.[55] Even if venous admixture is small, mixed venous blood with very low oxygen content will magnify the effect of a small shunt. Oxygen tension–based indices, for example, PaO_2/FIO_2, alveolar to arterial PO_2 difference ($DA\text{-}aO_2$), and ratio PaO_2/PAO_2, do not take into account the influence of $C\bar{v}O_2$ on arterial oxygenation. Therefore, in critically ill patients who are hypoxemic, the insertion of a pulmonary artery catheter to assess shunt and to measure cardiac output may be essential to understanding the influence of cardiac function on arterial oxygenation.

$DA\text{-}aO_2$ is a useful quantitative assessment of arterial oxygenation mainly when arterial hemoglobin is well saturated when normal $DA\text{-}aO_2$ is <5 mm Hg. When PaO_2 is less than 150 mm Hg (and certainly when it is less than 100 mm Hg), the relationship between oxygen content and oxygen tension is nonlinear, thus making $DA\text{-}aO_2$ more difficult to interpret.

10 The assessment of arterial oxygenation requires, at least, knowledge of FIO_2 and either PaO_2 or SaO_2. Oxygen tension–based indices of oxygenation are useful, but they do not take into account the contribution of mixed venous blood to arterial oxygenation. Mixed venous blood can become extremely desaturated in the critically ill patient owing to inadequate cardiac output, anemia, arterial hypoxemia, or increased $\dot{V}O_2$. The best knowledge of the efficiency with which the lungs oxygenate the arterial blood can be obtained only by calculating shunt fraction or ventilation–perfusion ratio (VQI).

Physiologic Shunt Calculation

The clinical reference standard for the calculation of physiologic shunt fraction is derived from a two-compartment pulmonary blood flow model where one compartment performs ideal gas exchange and contains perfectly married alveolar–capillary units. The other compartment is the shunt

compartment and contains pulmonary capillaries that enjoy no exposure to ventilated alveoli. Using the Fick relationship, the following equation can be derived:

$$\frac{\dot{Q}_{SP}}{\dot{Q}_T} = \frac{Cc'O_2 - Cao_2}{Cc'O_2 - C\bar{v}o_2} \qquad (28\text{-}7)$$

where $\dot{Q}SP/\dot{Q}T$ is the shunt fraction ($\dot{Q}SP$ is blood flow through the physiologic shunt compartment, $\dot{Q}T$ is total cardiac output), and $Cc'O_2$ and $\dot{C}\bar{v}O_2$ are end-capillary and mixed-venous oxygen contents, respectively. Normal intrapulmonary shunt is approximately 5%. Because this equation is based on an artificial two-compartment model, the absolute value is physically meaningless. A calculated $\dot{Q}SP/\dot{Q}$

T of 25% means that if the lung existed in two compartments, 25% of the cardiac output would travel through the shunt compartment. Because the lung does not exist in two compartments, this equation only grossly estimates pulmonary oxygen exchange defects. Nevertheless, it remains our best tool for clinically evaluating the efficiency with which the lungs oxygenate arterial blood. Observing shunt fraction change with therapeutic intervention or with the progress of disease is more valuable than knowing the absolute value per se.

Because hemoglobin concentration is uniform throughout the vascular system, the oxygen contents in the shunt equation are determined primarily by oxyhemoglobin saturation. Thus, the shunt equation can be approximated by substituting saturation values for each term; the new value, called *ventilation–perfusion ratio* (VQI),[55] is determined as follows:

$$\text{VQI} = \frac{\text{Sc}'\text{O}_2 - \text{Sao}_2}{\text{Sc}'\text{O}_2 - \text{S}\bar{\text{v}}\text{O}_2} \cong \frac{1 - \text{Sao}_2}{1 - \text{S}\bar{\text{v}}\text{O}_2} \qquad (28\text{-}8)$$

If the patient is neither breathing a hypoxic gas mixture nor has a methemoglobin or carboxyhemoglobin value in excess of 5 to 6%, $Sc'O_2$ must equal 1 because the model requires a perfect alveolar–capillary interface. This substitution results in the final expression in the previous equation. The absolute values of VQI are meaningless, although "normal" should be 0 to 4%. Like

$$\dot{Q}$$

SP/

$$\dot{Q}$$

T, the importance of these values lies in their trend as disease and treatment progress.

SaO_2 and

$$\dot{S}_V$$

O_2 can be estimated continuously with pulse oximetry and by using a pulmonary artery catheter with oximetry capability. By interfacing the outputs of these two devices with a computer, VQI can be calculated continuously. The greatest advantage of calculating

$$\dot{Q}$$

SP/

$$\dot{Q}$$

T or VQI to assess arterial oxygenation is that these values include the contribution of mixed venous blood.

PULMONARY FUNCTION TESTING

Anesthesiologists frequently care for patients with significant pulmonary dysfunction. It is important for the anesthesiologist to be able to interpret tests of pulmonary function intelligently and to know which tests will help define dysfunction if the patient's history and physical are suggestive of disease. This section discusses lung volumes, tests of pulmonary mechanics, and diffusing capacity.

Lung Volumes and Capacities

Known, reproducible pulmonary gas volumes and capacities provide a reliable basis for comparison between normal and abnormal measurements.[56] Because normal measurements vary with size, height is most frequently used to define "normal." Lung capacities are composed of two or more lung volumes. Lung volumes and capacities are schematically illustrated in Figure 28-8.

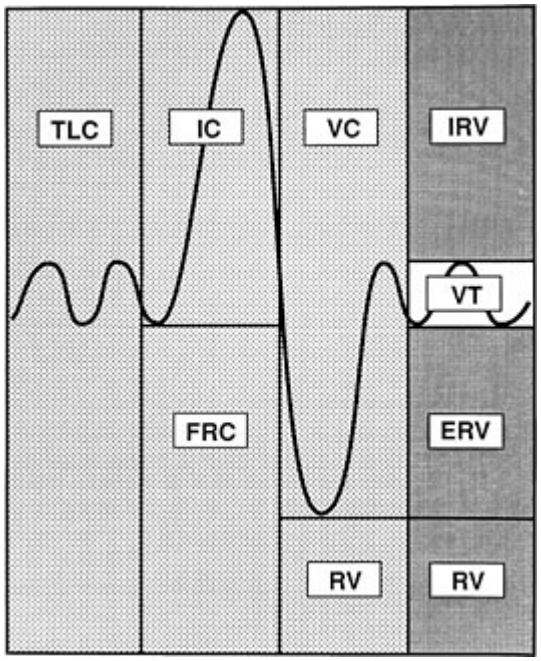

FIGURE 28-8. Lung volumes and capacities. The darkest bar on the far right depicts the four basic lung volumes that sum to create TLC. Other lung capacities are composed of two or more lung volumes. The overlying spirographic tracing orients the reader to the relationship between the lung volumes and capacities and the spirogram. ERV, expiratory reserve volume; FRC, functional residual capacity; IC, inspiratory capacity; IRV, inspiratory reserve volume; RV, residual volume; TLC, total lung capacity; VC, vital capacity; VT, tidal volume.

Tidal volume is the volume of gas that moves in and out of the lungs during quiet breathing and is ~6 to 8 mL/kg. Tidal volume falls with decreased lung compliance or when the patient has reduced ventilatory muscle strength.

Vital capacity is usually ~60 mL/kg but may vary as much as 20% from normal in healthy individuals. Vital capacity correlates well with the capability for deep breathing and effective coughing. It usually is decreased by restrictive pulmonary disease such as pulmonary edema or atelectasis. Vital capacity may also be reduced by the mechanically induced restriction that occurs with problems such as pleural effusion, pneumothorax, pregnancy, large ascites, or ventilatory muscle weakness.

The *inspiratory capacity* is the largest volume of gas that can be inspired from the resting expiratory level and is frequently decreased in the presence of significant extrathoracic airway obstruction. This measurement is one of the few simple tests that can detect extrathoracic airway obstruction. Most routine pulmonary function tests measure only exhaled flows and volumes, which may be relatively unaffected by extrathoracic obstruction until it is severe. Changes in the absolute volume of inspiratory capacity usually parallel changes in vital capacity. *Expiratory reserve volume* is not of great diagnostic value.

11 *Functional residual capacity* (FRC) is the volume of gas remaining in the lungs at passive end expiration. *Residual volume* is that gas remaining within the lungs at the end of forced maximal expiration. The FRC serves two primary physiologic functions. It determines the point on the pulmonary volume-pressure curve for resting ventilation (see Fig. 28-2). The tangent defined by the midportion pulmonary volume–pressure curve at FRC defines lung compliance. Thus, FRC determines the elastic pressure–volume relationships within the lung. Furthermore, FRC is the resting expiratory volume of the lung. As such, it greatly influences ventilation–perfusion relationships within the lung. When FRC is reduced, venous admixture (low $[\dot{V}]_A/[\dot{Q}]$ increases and results in arterial hypoxemia (see Oxygen and Carbon Dioxide

Transport and Lung Mechanics sections).

Further, the FRC may be used to quantify the degree of pulmonary restriction. Disease processes that reduce FRC and lung compliance include acute lung injury, pulmonary edema, pulmonary fibrotic processes, and atelectasis. Mechanical factors also reduce FRC, for example, pregnancy, obesity, pleural effusion, and posture. The FRC decreases 10% when a healthy subject lies down. Ventilatory muscle weakness or paralysis will also decrease FRC. In contrast, patients with COPD have excessively compliant lungs that recoil less forcibly. Their lungs retain an abnormally large volume at the end of passive expiration, a phenomenon called *gas trapping*.

Frc Measurement

The FRC and residual volume must be measured indirectly because residual volume cannot be removed from the lung. The multiple-breath nitrogen washout test is performed by having the subject breathe 100% oxygen for several minutes so alveolar nitrogen is gradually "washed out." With each breath, the volume of gas and the concentration of nitrogen in the exhaled gas are measured. A rapid nitrogen analyzer coupled to a spirometer or pneumotachometer provides a breath-by-breath analysis of nitrogen washout. Electronic signals proportional to nitrogen concentrations and exhaled volumes (or flow, if a pneumotachometer is used) are integrated to derive the exhaled volume of nitrogen for each breath. Then, the values for all breaths are summed to provide a total volume of nitrogen washed out of the lungs. The test proceeds until the alveolar nitrogen concentration is reduced to less than 7%, usually requiring 7 to 10 minutes. FRC is calculated using the equation:

$$\text{FRC} = \text{N}_2 \text{ volume} \times \frac{[\text{N}_2]_\text{f}}{[\text{N}_2]_\text{i}} \qquad (28\text{-}9)$$

where $[N_2]_i$ and $[N_2]_f$ are the fractional concentrations of alveolar nitrogen at the beginning and end of the test, respectively.

Pulmonary Function Tests

Forced Vital Capacity

The forced vital capacity (FVC) is the volume of gas that can be expired as forcefully and rapidly as possible after maximal inspiration. Normally, FVC is equal to vital capacity. Because forced expiration significantly increases intrapleural pressures but changes airway pressure little, bronchiolar collapse, obstructive lesions, and gas trapping are exaggerated. Thus, FVC may be reduced in chronic obstructive diseases even when the vital capacity appears near normal. FVC is nearly always decreased by restrictive diseases. FVC values <15 mL/kg are associated with an increased incidence of PPCs, probably because these patients cough ineffectively.[57] FVC reduced to this level represents a profound defect, most commonly seen in quadriplegics or severe neuromuscular disease. Finally, FVC is largely dependent on patient effort and cooperation.

Forced Expiratory Volume

FEV_T is the forced expiratory volume of gas over a given time interval during the FVC maneuver. The interval, described by the subscript T, is the time elapsed in seconds from the onset of expiration. Because FEV_T records a volume of gas expired over time, it is actually a measure of flow. By measuring expiratory flow at specific intervals, the severity of airway obstruction can be ascertained. Decreased FEV_T values are common in both obstructive and restrictive disease patterns. The most important application of FEV_T is its comparison with the patient's FVC. Normal subjects can expire at least three-fourths of FVC within the first second of the forced expiratory maneuver. The FEV_1, the most frequently employed value, is normally greater than or equal to 75% of the FVC, or $FEV_1/FVC \geqslant 0.75$.

Normally, an individual can expire 50 to 60% of FVC in 0.5 second, 75 to 85% in 1 second, 94% in 2 seconds, and 97% in 3 seconds. Cooperative patients with obstructive disease will exhibit a

reduced FEV_1/FVC in most cases. However, patients with restrictive disease usually have normal FEV_1/FVC ratios. The validity of the evaluation of the FEV_1/FVC is highly dependent on patient cooperation and effort. It is possible to deliberately produce an artificially low FEV_1/FVC.

Forced Expiratory Flow

$FEF_{25-75\%}$ is the average forced expiratory flow during the middle half of the FEV maneuver. This test is also called maximum midexpiratory flow rate. The length of time required for a subject to expire the middle half of the FVC is divided into 50% of the FVC. The spirogram in Figure 28-9 marks the place from 25 to 75% of FVC, constituting the middle 50% of FVC. The straight line connecting the 25% and 75% volumes has a slope approximately equal to average flow. A normal value for a healthy 70-kg man is approximately 4.7 L/sec (or 280 mL/min). Normally, both the absolute value and the percentage of predicted value for the individual being studied are recorded. A normal value is 100 ± 25% of predicted. Decreased flow rates indicate medium-size airway obstruction. This value is typically normal in restrictive diseases. This test is fairly sensitive in the early stages of obstructive airway disease. Decreased $FEV_{25-75\%}$ frequently will be observed before other obstructive manifestations occur. Although somewhat effort dependent, the test is much more reliable and reproducible than FEV_1/FVC.

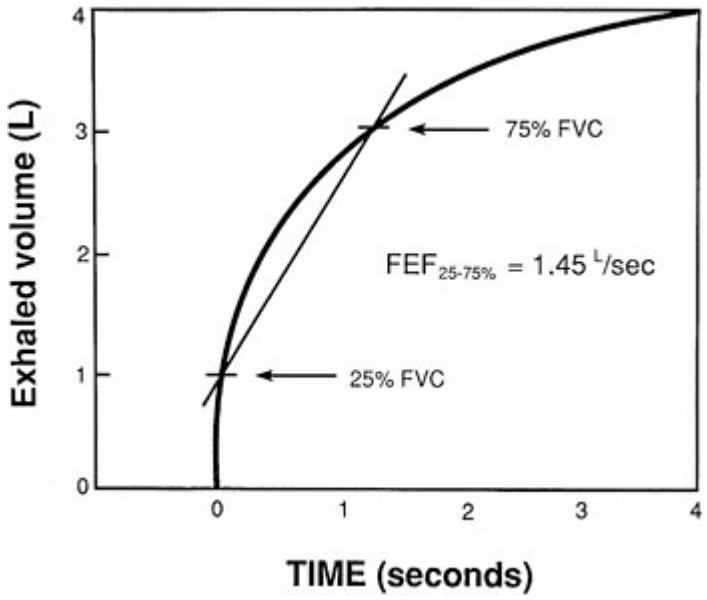

FIGURE 28-9. $FEF_{25-75\%}$. The spirogram depicts a 4 L FVC on which the points representing 25% and 75% FVC are marked. The slope of the line connecting these points is the $FEF_{25-75\%}$.

Maximum Voluntary Ventilation

Maximum voluntary ventilation (MVV) is the largest volume of gas that can be breathed in 1 minute by voluntary effort. The MVV is measured by having the subject breathe as deeply and as rapidly as possible for 10, 12, or 15 seconds. The results are extrapolated to 1 minute. The subject is instructed to set his or her own ventilatory rate and move more than tidal volume but less than vital capacity in each breath.

MVV measures the endurance of the ventilatory muscles and indirectly reflects lung–thorax compliance and airway resistance. MVV is the best ventilatory endurance test that can be performed in the laboratory. Values that vary by as much as 30% from predicted values may be normal so only large reductions in MVV are significant. Healthy, young adults average ~170 L/min. Values are lower in women and decrease with age in both sexes. Because this maneuver exaggerates air trapping and exerts the ventilatory muscles, MVV is decreased greatly in patients

with moderate to severe obstructive disease. MVV is usually normal in patients with restrictive disease.

Flow–Volume Loops

The flow–volume loop graphically demonstrates the flow generated during a forced expiratory maneuver followed by a forced inspiratory maneuver, plotted against the volume of gas expired (Fig. 28-10). The subject forcefully exhales completely, then immediately and forcefully inhales to vital capacity. The expired and inspired volumes are plotted on the abscissa and flow is plotted on the ordinate. Although various numbers can be generated from the flow–volume loop, the configuration of the loop itself is probably the most informative part of the test.

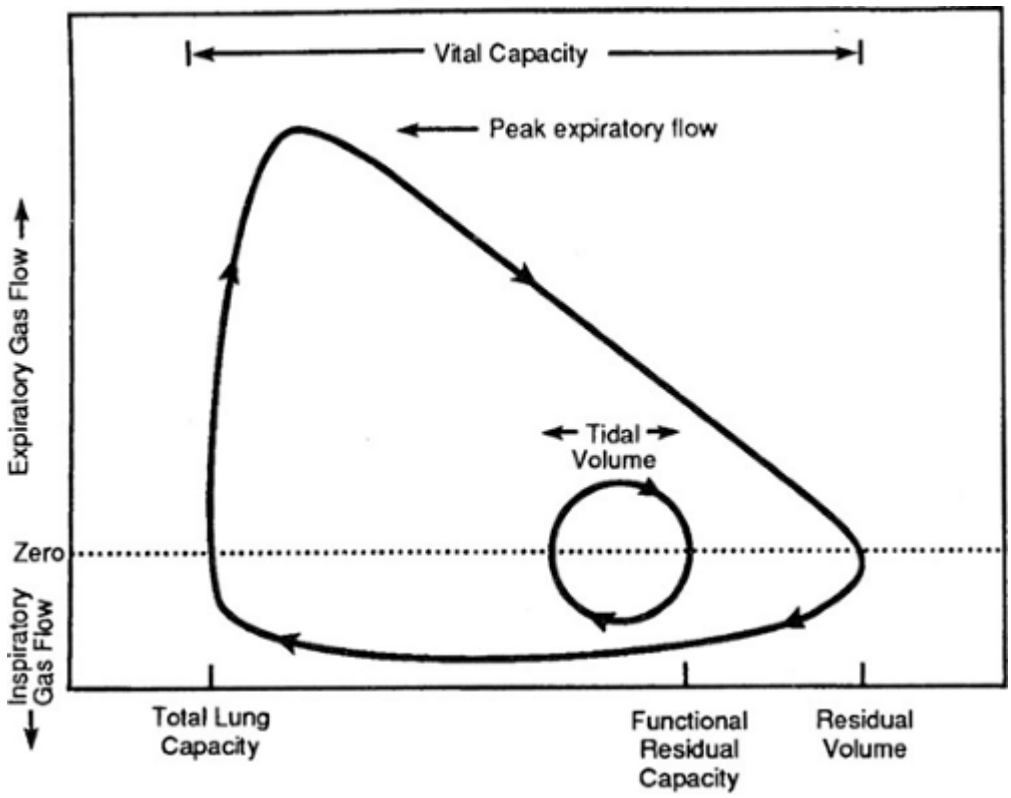

FIGURE 28-10. Flow–volume loop. The figure depicts a normally configured adult flow–volume loop. The slope of the loop after the subject reaches peak expiratory flow is nearly linear.

Flow–volume loops were formerly useful in the diagnosis of large airway and extrathoracic airway obstruction prior to the availability of precise imaging techniques. Imaging techniques such as MRI give more precise and useful information in the diagnosis of upper airway and extrathoracic obstruction and superceded the use of flow–volume loops for diagnosis of these conditions. Therefore, it is rare that flow–volume loops are useful for preoperative pulmonary evaluation in the modern era of imaging.

Carbon Monoxide Diffusing Capacity

Because PO_2 in the pulmonary capillary blood varies with time as it moves through the pulmonary capillary bed, oxygen cannot be used to assess diffusing capacity. A gas mixture containing carbon monoxide is the traditional diagnostic gas used to measure diffusing capacity. Its partial pressure in the blood is nearly zero, and its affinity for hemoglobin is 200 times that of oxygen.[58] Carbon monoxide diffusing capacity (DLCO) collectively measures all the factors that affect the diffusion of gas across the alveolar–capillary membrane. The DLCO is recorded in mL CO/min/mm Hg at

STPD.

In persons with normal hemoglobin concentrations and normal [V with dot above]$_A$/[Q with dot above] matching, the main factor limiting diffusion is the alveolar–capillary membrane. Small amounts of carbon dioxide and inspired gas can produce measurable changes in the concentration of inspired gas compared with expired gas. There are several methods for determining DLCO, but all methods measure diffusing capacity according to the equation

$$\text{DLCO} = \frac{\text{mL CO transferred/min}}{\text{mean } P_{A}CO_2 - \text{mean capillary } PCO_2} \quad (28\text{-}10)$$

The average value for resting subjects when the single-breath method is used is 25 mL CO/min/mm Hg. DLCO values can increase to two or three times normal during exercise.

The DLO_2 may be estimated from the DLCO by multiplying DLCO by 1.23, although the DLCO is usually the reported value. DLCO can be divided by the lung volume at which the measurement was made to obtain an expression of diffusing capacity per unit lung volume.

Some of the other factors that can influence DLCO are as follows:

1. Hemoglobin concentration: decreased hemoglobin concentration decreases the DLCO
2. Alveolar PCO_2: an increased $PACO_2$ raises DLCO
3. Body position: the supine position increases DLCO
4. Pulmonary capillary blood volume

Diffusing capacity is decreased in alveolar fibrosis associated with sarcoidosis, asbestosis, berylliosis, oxygen toxicity, and pulmonary edema. These states are frequently categorized as diffusion defects, but low DLCO is probably more closely related to loss of lung volume or capillary bed perfusion. DLCO is decreased in obstructive disease because of the decreased alveolar surface area, loss of capillary bed, the increased distance from the terminal bronchiole to the alveolar–capillary membrane, and [V with dot above]$_A$/[Q with dot above] mismatching. Space-occupying lesions and lung resection also decrease diffusing capacity. In short, the decrease in measured DLCO is actually caused by abnormal [V with dot above]$_A$/[Q with dot above] matching in most cases. Few disease states truly inhibit oxygen diffusion across the alveolar–capillary membrane.

Pulmonary Function Tests Summary

Although we have a host of pulmonary function tests from which to choose, spirometry is the most useful, cost-effective, and commonly used test.[59] Screening spirometry yields VC, FVC, and FEV_1. From these values, two basic types of pulmonary dysfunction can be identified and quantitated: obstructive defects and restrictive defects. The primary criterion for airflow obstruction is decreased FEV_1/FCV ratio. Other measurements, such as $FEF_{25\text{-}75\%}$, can be used to support the diagnosis of an obstructive defect or to assist in making decisions (e.g., whether to institute bronchodilation). A restrictive defect is a proportional decrease in all lung volumes; thus, VC, FVC, and FEV_1 all are reduced, but FEV_1/FVC remains normal. When there is a question about whether a decreased VC is due to restriction, TLC should be measured. Reduced TLC defines a restrictive defect but is not necessary unless VC on screening spirometry is reduced. The American Thoracic Society published an experts' consensus concerning interpretation of lung function tests.[60] Table 28-4 summarizes the distinction between pulmonary function results obtained from those with restrictive and obstructive defects. Refer to the "Pulmonary Function Postoperatively" section for a discussion on the use of pulmonary testing.

TABLE 28-4 Pulmonary Function Tests in Restrictive and Obstructive Lung Disease

·VALUE	·RESTRICTIVE DISEASE	·OBSTRUCTIVE DISEASE
Definition	Proportional decreases in all lung volumes	Small airway obstruction to expiratory flow
FVC	↓↓↓	Normal or slightly ↑
FEV_1	↓↓↓	Normal or slightly ↓
FEV_1/FVC	Normal	↓↓↓
$FEF_{25-75\%}$	Normal	↓↓↓
FRC	↓↓↓	Normal or ↑ if gas trapping
TLC	↓↓↓	Normal or ↑ if gas trapping

FEV, forced expiratory volume; FRC, functional residual capacity; FVC, forced vital capacity; TLC, total lung capacity; ↓↓↓, ↑↑↑ = large decrease or increase, respectively; ↓, ↑ = small/moderate decrease or increase, respectively.

Preoperative Pulmonary Assessment

Markedly impaired pulmonary function is likely in patients who have the following:

1. Any chronic disease that involves the lung
2. Smoking history, persistent cough, and/or wheezing
3. Chest wall and spinal deformities
4. Morbid obesity
5. Requirement for single-lung anesthesia or lung resection
6. Severe neuromuscular disease

Preoperative pulmonary evaluation must include history and physical examination, and may include chest radiograph, arterial blood gas analysis, and screening spirometry, depending on the patient's history. A history of sputum production, wheezing or dyspnea, exercise intolerance, or limited daily activities may yield more practical information than does formal testing. Arterial blood analysis, which should be sampled while the patient breathes room air, adds information regarding gas exchange and acid-base balance. Arterial blood gas sampling is primarily useful if the patient's history suggests that he or she may be chronically hypoxemic or may "retain" CO_2 (ie, a patient with a chronic, compensated arterial academia).

Preoperative assessment of pulmonary function may alert the anesthesiologist to the special needs of a patient with respiratory disease and may allow improvement of pulmonary function before an elective operation. The goals one might hope to achieve through preoperative pulmonary function

would be to predict the likelihood of pulmonary complications, obtain quantitative baseline information concerning pulmonary function, and identify patients who may benefit from therapy to improve pulmonary function preoperatively. For patients who will have lung resections, pulmonary function testing does provide some predictive benefit.[61] For all other patients, however, overwhelming evidence suggests that preoperative pulmonary function testing does not predict or assign risk for PPCs.[62,63]

12 In 2002, the American Society of Anesthesiologists' Taskforce on Preanesthetic Evaluation published a practice advisory[64] wherein they recommended that "there is insufficient evidence to identify explicit decision parameters or rules for ordering preoperative tests on the basis of specific clinical characteristics." Review of the literature[65] also reveals that specific measurements of lung function do not predict PPCs.

Rather, the clinician obtains more information from the patient's history. In a series of 272 adults undergoing nonthoracic surgery, McAlister et al.[66] found that the following historical factors independently increased the risk of PPC: age >65 years, smoking >40 pack-years, COPD, asthma, productive cough, and exercise intolerance of less than one flight of stairs.

The need to obtain baseline pulmonary function data should be reserved for those patients with severely impaired preoperative pulmonary function, such as quadriplegics or myasthenics, so assessment for weaning from mechanical ventilation and/or tracheal extubation might be based on the patient's baseline pulmonary function. Ideally, tests should be chosen to quantify specific pulmonary problems.

Arterial blood gases (ABG) are not indicated unless the patient's history suggests arterial hypoxemia or severe enough COPD that one suspects CO_2 retention. Then, the ABG should be used in essentially the same manner as one might use preoperative PFTs: to look for reversible disease, or to define the severity of the disease at its baseline. Defining baseline PaO_2 and $PaCO_2$ is particularly important if one anticipates postoperatively ventilating a patient who has severe COPD. Table 28-5 summarizes the respiratory physiology formulas discussed in this chapter.

TABLE 28-5 Respiratory Formulas

	▪NORMAL VALUES (70 KG)
Alveolar oxygen tension	110 mm Hg
$PAO_2 = (PB - 47)\ FIO_2 - (PACO_2/R)$	($FIO_2 = 0.21$)
Alveolar-arterial oxygen gradient	<10 mm Hg
$A\text{-}aO_2 = PAO_2 - PaO_2$	($FIO_2 = 0.21$)
Arterial-to-alveolar oxygen ratio, a/A ratio	>0.75
Arterial oxygen content	20 mL/100 mL blood
$CaO_2 = (SaO_2)\ (Hb \times 1.34) + PaO_2\ (0.0031)$	

Mixed venous oxygen content	15 mL/100 mL blood
$C\bar{v}O_2 = (S\bar{v}O_2)(Hb \times 1.34) + P\bar{v}o_2 (0.0031)$	
Arterial-venous oxygen content difference	4–6 mL/100 mL blood
$Ca\text{-}\bar{v}O_2 = CaO_2 - C\bar{v}O_2$	
Intrapulmonary shunt	<5%
$\dot{Q}sp/\dot{Q}T = (CC''O_2 - CaO_2)/(CC''O_2 - C\bar{v}O_2)$	
where $CC''O_2 = (Hb \times 1.34) + (PAO_2 \times 0.0031)$	
Physiologic dead space	0.33
$VD/VT = (PaCO_2 - P\overline{E}CO_2)/PaCO_2$	
Oxygen consumption	250 mL/min
$\dot{V}O_2 = CO\ (CaO_2 - C\bar{v}O_2)$	
Oxygen transport	1,000 mL/min
$O_2T = CO\ (CaO_2)$	
Respiratory quotient	0.8
$\dot{V}CO_2$	
$\dot{V}O_2$	

CaO_2, arterial oxygen content; $C\bar{v}O_2$, mixed venous oxygen content; $Cc''O_2$, end-pulmonary capillary oxygen content; CO, cardiac output; FIO_2, fraction inspired oxygen; Hb, hemoglobin concentration; O_2T, oxygen transport; PB, barometric pressure; $\dot{Q}sp/\dot{Q}T$, intrapulmonary shunt; $PACO_2$, alveolar carbon dioxide tension; $PaCO_2$, arterial carbon dioxide tension; PAO_2, alveolar oxygen tension; PaO_2, arterial oxygen tension; $P\overline{E}CO_2$, mixed expired carbon dioxide tension; $P\bar{v}O_2$, mixed venous oxygen tension; SaO_2, arterial oxygen saturation; $S\bar{v}O_2$, mixed venous oxygen saturation; VD, dead space gas volume; VT, tidal volume; $\dot{V}O_2$, oxygen consumption (mL/min); $\dot{V}CO_2$, carbon dioxide

production (mL/min); R, respiratory quotient.

ANESTHESIA AND OBSTRUCTIVE PULMONARY DISEASE

Patients with marked obstructive pulmonary disease are at increased risk for both intraoperative and PPCs. For example, patients with reduced FEV_1/FVC or reduced midexpiratory flow not only suffer airway obstruction, but also usually exhibit increased airway reactivity. Because of the hazard of provoking reflex bronchoconstriction during laryngoscopy and tracheal intubation, patients with COPD or asthma should receive aggressive bronchodilator therapy preoperatively. High alveolar concentrations of potent inhalational anesthetics will blunt airway reflexes and reflex bronchoconstriction but require a fairly robust cardiovascular system. Adjunctive intravenous administration of opioids and lidocaine prior to airway instrumentation will decrease airway reactivity. Furthermore, a single dose of corticosteroids may help prevent postoperative increases in airway resistance.

Spontaneous ventilation during general anesthesia in patients with severe obstructive disease is more likely to result in hypercarbia than in patients with normal pulmonary function.[67] Preoperative FEV_1 reduction correlates with the $PaCO_2$ increase during anesthesia. Slower rates of mechanical ventilation (8–10 breaths · min^{-1}) should be used to allow time for exhalation. Low ventilatory rates necessitate larger tidal volume if one desires a normal $PaCO_2$, but larger V_t and resultant higher peak airway pressure may predispose the patient to pulmonary barotrauma. Tidal volume and inspiratory flows should be adjusted to keep peak airway pressure less than 40 cm H_2O,[68,69] if possible. Higher inspiratory flows produce a shorter inspiratory time and, usually, a high peak airway pressure. Thus, a balance that avoids high peak airway pressure and excessively large V_t that allows the longest possible expiratory time should be sought.

Ideally, depending on the procedure and the duration of anesthesia, one would extubate the patient's trachea at the end

of the operation. The irritating tracheal tube increases both airway resistance and reflex bronchoconstriction, limits the ability of the patient to clear secretions effectively, and increases the risk of iatrogenic infection. For some patients with obstructive disease (eg, the young asthmatic), many advocate tracheal extubation during deep anesthesia at the conclusion of the operation.

ANESTHESIA AND RESTRICTIVE PULMONARY DISEASE

Restrictive disease is characterized by proportional decreases in all lung volumes. The decreased FRC produces low lung compliance and also results in arterial hypoxemia because of low [V with dot above]$_A$/[Q with dot above] mismatching. These patients typically breathe rapidly and shallowly.

Positive-pressure ventilation of patients with restrictive disease is fraught with high peak airway

pressures because more pressure is required to expand stiff lungs. Lower mechanical tidal volumes at more rapid rates reduce the risk of barotrauma but augment ventilation-induced cardiovascular depression and increase the chances of developing atelectasis. Larger tidal volumes should be avoided, because of the increased risk of both barotrauma[70] and volutrauma.[71] Various lung protective strategies have been developed to ventilate patients with profound restrictive lung disease (see Chapter 56).

Because the FRC is small, a lower oxygen store is available during apneic periods. Even preoxygenation with an FIO_2 of 1.0 can result in arterial hypoxemia seconds after the cessation of breathing or disconnection from a ventilator circuit. Patients with severe restrictive diseases tolerate apnea poorly. Because arterial hypoxemia develops so rapidly, transportation of these patients within the hospital should be performed with a pulse oximeter.

Even healthy individuals develop mild restrictive defects during anesthesia. FRC decreases 10 to 15% when healthy, spontaneously breathing individuals lie supine. Controlled ventilation further reduces FRC only slightly. General anesthesia consistently decreases FRC by a further 5 to 10%,[72] which usually results in decreased lung compliance.[73] The FRC reaches its nadir within the first 10 minutes of anesthesia[72,74,75] and is independent of whether ventilation is spontaneous or controlled. The diminished FRC persists in the postoperative period but may be restored postoperatively by the use of positive end-expiratory pressure or CPAP.[72,76,77] However, once positive airway pressure is removed, FRC plummets to previously diminished levels, which reach a postoperative nadir 12 hours after operation.[78]

EFFECTS OF CIGARETTE SMOKING ON PULMONARY FUNCTION

Smoking affects pulmonary function in many ways. The irritant smoke decreases ciliary motility and increases sputum production. Thus, these patients have a high volume of sputum and decreased ability to clear it effectively. As smoking habits persist, airway reactivity and the development of obstructive disease become problematic. Studies of the pathogenesis of COPD suggest that smoking results in an excess of pulmonary proteolytic enzymes, which directly cause damage to the lung parenchyma.[79] Exposure to smoke increases synthesis and release of elastolytic enzymes from alveolar macrophages—cells instrumental in the genesis of COPD due to smoking. Further damage to the lung tissue is probably caused by reactive metabolites of oxygen, such as hydroxyl radicals and hydrogen peroxide, which are usually used by the macrophages to kill microorganisms. The immunoregulatory function of the macrophages is also changed by cigarette smoking, with changes occurring in the presentation of antigens and interaction with T lymphocytes.[80] Other direct effects on lung tissue caused by smoking include increased epithelial permeability[81] and changed pulmonary surfactant.[82] The airway irritation or small airway reactivity evoked by inhaling cigarette smoke is the result of activation of sensory endings located in the central airways, which is primarily caused by nicotine.[83]

Early in the disease, mild $[\dot{V}]_A/[\dot{Q}]$ mismatch, bronchitic disease, and airway hyperreactivity are primary problems. Later, these problems are accompanied by the hallmarks of COPD: gas trapping, flattened diaphragmatic configuration (which decreases the efficiency with which the diaphragm functions), and barrel chest deformity. Lung compliance increases significantly so limited elastic recoil prevents complete passive emptying. As a result, many patients exhale forcibly to reduce gas trapping.

With gas trapping, ventilation and perfusion become increasingly mismatched. Large areas of dead space ventilation and venous admixture occur. Carbon dioxide elimination is inefficient because of dead space ventilation. The typical minute ventilation for patients with advanced obstructive lung disease can be one and one-half to two times normal. In addition, venous admixture produces arterial hypoxemia that is exquisitely sensitive to low concentrations of supplemental oxygen. Gas exchange is further impaired by the increased carboxyhemoglobin concentration that results from inspiring smoke. Normal carboxyhemoglobin concentration in nonsmokers is approximately 1%; in smokers, however, it can be as high as 8 to 10%. Cessation of smoking, even for 12 to 24 hours preoperatively, can decrease CO concentration to near normal.

Smoking is one of the main and most prevalent risk factors associated with postoperative

morbidity.[84] COPD patients who smoke have a twofold to sixfold[85] risk of developing postoperative pneumonia compared with nonsmokers. Further, smokers' relative risk of PPC is doubled, even if they do not have evidence of clinical pulmonary disease or abnormal pulmonary function.[86] The incidence of PPC in smokers can be reduced by abstinence from smoking, although there is no consensus on the minimal or optimal duration of preoperative smoking abstinence.[87,88,89] Warner et al.[84] studied 200 patients undergoing coronary artery bypass grafting and found that patients who continued to smoke or stopped less than 8 weeks before the operation had a complication rate nearly four times that of patients who had quit smoking more than 8 weeks preoperatively. These data further demonstrated that those who quit smoking less than 8 weeks preoperatively had a higher rate of complication than those who continued to smoke. Normalization of mucociliary function requires 2 to 3 weeks of abstinence from smoking, during which time sputum increases. Several months of smoking abstinence is required to return sputum clearance to normal.[90] In a study of brupopion-assisted smoking cessation, Hurt and coworkers demonstrated decreased risk of postoperative complications even after 4 weeks of abstinence from smoking.[91]

13 Smokers who decrease, but do not stop, cigarette consumption without the aid of nicotine replacement therapy, continue to acquire equal amounts of nicotine from fewer cigarettes by changing their technique of smoking to maximize nicotine intake.[92] Levels of serum nicotine and cotinine and urinary mutagenesis levels remain unchanged. Thus, *reduction* in the number of cigarettes smoked will likely have little effect on the risk of developing PPCs.[85] Smoking patients should be advised to *stop* smoking 2 months prior to elective operations to maximize the effect of smoking cessation,[84] or for at least 4 weeks

to benefit from improved mucociliary function and some reduction in PPC rate. If patients cannot stop smoking for 4 to 8 weeks preop, it is controversial whether they should be advised to stop smoking 24 hours preoperatively. A 24-hour smoking abstinence would allow carboxyhemoglobin levels to fall to normal but may increase the risk of PPC.

PULMONARY FUNCTION POSTOPERATIVELY

Risk of Postoperative Pulmonary Complications

Postoperative Pulmonary Function

The changes in pulmonary function that occur postoperatively are primarily restrictive, with proportional decreases in all lung volumes and no change in airway resistance. The decrease in FRC, however, is the yardstick by which the severity of the restrictive defect is gauged. This defect is generated by abdominal contents that impinge on and prevent normal movement of the diaphragm, and by an abnormal respiratory pattern devoid of sighs and characterized by shallow, rapid respirations. The normal resting respiratory rate for adults is 12 breaths per minute, whereas the postoperative patient in the ward usually breathes approximately 20 breaths per minute. Furthermore, most (but not all) factors that tend to make the restrictive defect worse are also those associated with a higher risk of PPCs.

14 The operative site is one of the single most important determinants of the degree of pulmonary restriction and the risk of PPCs. Nonlaparoscopic upper abdominal operations cause the most profound restrictive defect, precipitating a 40 to 50% decrease in FRC compared with preoperative levels, when conventional postoperative analgesia is employed. Lower abdominal and thoracic operations cause the next most severe change in pulmonary function, with decreases in FRC to 30% of preoperative levels. Most other operative sites—intracranial, peripheral vascular, otolaryngologic—have approximately the same effect on FRC, with reductions to 15 to 20% of preoperative levels.

Postoperative Pulmonary Complications

Two problems confound interpretation of the literature examining PPCs. First, there is no clear definition of what constitutes a PPC. For example, some clinical studies include only pneumonia,

whereas others add atelectasis and/or ventilatory failure. Thus, to interpret data concerning rates of PPCs, it is important to discern what complications are specifically being addressed. Second, the criteria by which the diagnosis of postoperative pneumonia or atelectasis is made vary from study to study. For this discussion, PPCs include atelectasis and pneumonia only. Reasonable, well-accepted diagnostic criteria for these diagnoses include change in the color and quantity of sputum, oral temperature exceeding 38.5°C, and a new infiltrate on chest radiograph.

The operative site is an important risk factor for the development of PPCs. Nonlaparoscopic upper abdominal operations increase risk for PPC at least twofold,[88] with rates of occurrence varying from 20 to 70%.[93] Lower abdominal and intrathoracic operations are associated with slightly less risk, but still higher risk than extremity, intracranial, and head/neck operations.

Patients with COPD are at risk for PPC. These patients' risks can be minimized by ensuring they do not have an active pulmonary infection and any increased resistance associated with reactive airways disease is minimized by the use of therapeutic bronchodilation. Interestingly, those with asthma are not at increased risk for atelectasis or pneumonia. However, exacerbation of asthma in the postoperative period can be problematic. Careful attention must be given to ensuring the continuation of bronchodilating regimens and steroid administration through the perioperative period.

There are several strategies by which it is possible to reduce risk of PPC: the use of lung-expanding therapies postoperatively, choice of analgesia,[94] and cessation of smoking. After upper abdominal operations, which are associated with the highest incidence of PPCs, FRC recovers over 3 to 7 days. With the use of intermittent CPAP by mask, FRC will recover within 72 hours.[95] Patients correctly use incentive spirometers only 10% of the time unless therapy is supervised.[96] Stir-up regimens are as effective as incentive spirometry at preventing PPCs,[95] and they are less expensive than supervised incentive spirometry; thus, they are preferred over incentive spirometry therapy.

15 After median sternotomy for cardiac operations, FRC does not return to normal for several weeks, regardless of postoperative pulmonary therapy.[97] The persistently low FRC in this population is probably due to mechanical factors such as a widened mediastinum, intrapleural fluid, and altered chest wall compliance. The single most important aspect of postoperative pulmonary care is getting the patient out of bed, preferably walking.

The choice of anesthetic technique for intraoperative anesthesia does not change the risk for PPC independent of the operative site or duration of the operation. Operations exceeding 3 hours are associated with a higher rate of PPC. Choice of postoperative analgesia strongly influences the risk of PPC.[88] The use of postoperative epidural analgesia, particularly for abdominal and thoracic operations, markedly decreases the risk of PPC and appears to decrease length of stay in the hospital.

Although obesity is associated with marked restrictive defects, some studies demonstrate that obesity does not independently increase the risk of PPC, whereas others do demonstrate increased independent risk for PPCs in the obese population.[98] Similarly, there are data both to support[98] and refute advanced age as an independent risk factor for PPCs.

Several authors have attempted to assess the influence of overall health on PPC risk. The use of indices that weight and score various aspects of physiology and health shows that patients who are in a poor state of health preoperatively tend to be at higher risk of PPC.[89]

Patients with obstructive airway disease and decreased expiratory flows may benefit from preoperative bronchodilator therapy and formal pulmonary toilet.[99] High-risk patients with COPD who receive bronchodilation, chest physical therapy, deep breathing, forced oral fluids (>3 L/day), and preoperative instruction in postoperative respiratory techniques, as well as those who stop smoking for more than 2 months preoperatively, experience a PPC rate approximately equal to that observed in normal patients.[100] Interestingly, although a regimen of this nature significantly reduces the incidence of PPCs,[101] airway obstruction and arterial hypoxemia are not measurably reversed during the 48 to 72 hours of preoperative therapy.[102] It is possible that the reduced complication rate results from the additional attention that these patients receive rather than from

the specific regimen employed.

Chapter 29

Anesthesia for Thoracic Surgery

Edmond Cohen

Steven M. Neustein

James B. Eisenkraft

KEY POINTS

1	It is important to determine prior to the onset of anesthesia and surgery whether the patient will be able to tolerate the planned lung resection.
2	Preoperative assessment of vital capacity (VC) is critical because at least three times the tidal volume (VT) is necessary for an effective cough.
3	Smoking increases airway irritability, decreases mucociliary transport, and increases secretions. It also decreases forced vital capacity (FVC) and forced expiratory flow $(FEF)_{25-75\%}$, thereby increasing the incidence of postoperative pulmonary complications.
4	A lobectomy or pneumonectomy is a relative indication for lung separation using a double-lumen tube (DLT).
5	The most important advance in checking the proper position of a DLT is the introduction of the pediatric flexible fiberoptic bronchoscope.
6	During one-lung ventilation (OLV), the dependent lung should be ventilated using a VT that results in a plateau airway pressure <25 cm H_2O at a rate adjusted to maintain $PaCO_2$ at 35 ± 3 mm Hg.
7	The choice of anesthetic technique for OLV must take into consideration the effects on oxygenation and therefore on hypoxic pulmonary vasoconstriction (HPV).
8	The need for OLV is much greater with video-assisted thoracoscopic surgery (VATS) than with open thoracotomy because it is not possible to retract the lung during VATS as it is during an open thoracotomy.
9	The potential advantages offered by high-frequency positive-pressure

	ventilation (HFPPV) during thoracic anesthesia are that lower VT and inspiratory pressures result in a quiet lung field for the surgeon, with minimal movements of airway, lung tissue, and mediastinum.
10	Myasthenia gravis, a disorder of the neuromuscular junction, is a chronic disorder characterized by weakness and fatigability of voluntary muscles with improvement following rest.
11	The key disadvantage of inadequate pain relief is postoperative atelectasis, limited inspiratory thoracic cage expansion, and great discomfort on the part of the patient.

The number of noncardiac thoracic surgical operations has dramatically increased in more recent years and is expected to increase further in the future.[1] This is because lung cancer is currently the most common cause of cancer mortality in the United States and throughout the world. The American Cancer Society estimates that lung cancer will be responsible for approximately 160,440 deaths in the United States during 2004 (28% of all cancer deaths), in comparison with 127,210 deaths from the combined mortality due to colorectal, breast, and prostate cancer[2,3] (Fig. 29-1). Approximately 173,770 new cases of lung cancer will be diagnosed in 2004, accounting for 13% of all new cancer cases. In 2004, an estimated 91,000 males in the United States will die from lung cancer. Worldwide, almost 600,000 deaths were due to lung cancer in 1995, and it is projected that this number will continue to increase. Although lung cancer has long been the leading cause of cancer death in men, it surpassed breast cancer as the leading cause of cancer death in women only relatively recently. Although overall cancer incidence rates are declining, lung cancer incidence rates among women continues to increase. However, it is now far ahead of breast cancer, more than 50% of women in the United States will die from lung cancer than from breast cancer in 2004 (68,510 versus 40,110). Since the mid-1970s, it represents an increase of 400% among women.

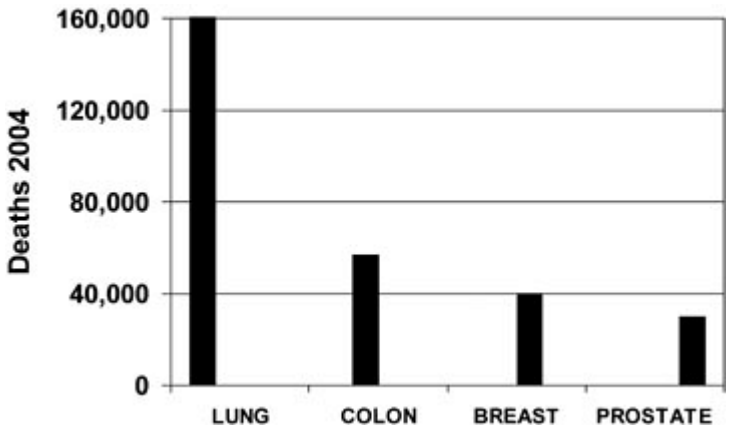

FIGURE 29-1. Lung cancer is the leading cause of cancer-related mortality. (Based on data from Jemal A, Tiwari RC, Murray T *et al*: Cancer statistics. CA Cancer J Clin 54:8, 2004.)

The increase in noncardiac thoracic surgery has been associated with, and sometimes has been made possible by, advances in anesthesia care. Indeed, thoracic anesthesia is developing into a subspecialty in its own right, with several texts dedicated exclusively to this subject.[4,5] The physiologic, pharmacologic, and clinical considerations for the patient undergoing pulmonary surgery are reviewed, followed by sections on anesthesia for diagnostic and therapeutic procedures, high-frequency ventilation, and special situations, including bronchopleural fistula and tracheal reconstruction. A discussion of myasthenia gravis is included because of the relationship between the thymus gland and myasthenia, and because thymectomy is one of the most commonly performed surgical procedures in these patients. The chapter concludes with a review of the postoperative management of the patient who has undergone noncardiac thoracic surgery.

PREOPERATIVE EVALUATION

1 In addition to the routine assessment for any type of major surgery, the preoperative evaluation of the patient for thoracic surgery should focus on the extent and severity of pulmonary disease and cardiovascular involvement. Prior to the onset of anesthesia and surgery, it is important to determine whether the patient will be able to tolerate the planned lung resection. To find out postoperatively that the patient cannot tolerate the resection would be catastrophic.

History

Dyspnea. Dyspnea occurs when the requirement for ventilation is greater than the patient's ability to respond appropriately. Dyspnea is quantitated as to the degree of physical activity required to produce it, the level of activity possible (e.g., ability to walk on level ground or climb stairs), and management of daily activities. Severe exertional dyspnea usually implies a significantly diminished ventilatory reserve and a forced expiratory volume in 1 second (FEV_1) of less than 1,500 mL, with possible need for postoperative ventilatory support.

Cough. Recurrent productive cough for 3 months of the year for 2 consecutive years is necessary to make the diagnosis of chronic bronchitis. Cough indirectly increases airway irritability. If the cough is productive, the volume, consistency, and color of the sputum should be assessed. Sputum should be cultured to rule out infection and to establish whether there is a need for preoperative antibiotic therapy. Blood-stained sputum or episodes of gross hemoptysis should alert the anesthesiologist to the possibility of a tumor invading the respiratory tract (e.g., the main-stem bronchus), which might interfere with endobronchial intubation.

Cigarette Smoking. Cigarette smoking increases the risk of chronic lung disease and malignancy, as well as the incidence of postoperative pulmonary complications. The number of pack-years (packs smoked per day multiplied by the number of years) is directly related to measurable changes in respiratory gas flow and closing capacity, making these patients prone to postoperative atelectasis and arterial hypoxemia.

Exercise Tolerance. Patients who can walk up three or more flights of stairs are at reduced risk, and those unable to climb two flights are generally at increased risk.[6] The best evaluation is actually the history of the patient's quality of life.[7] An otherwise healthy patient, with good exercise tolerance, generally does not require additional screening tests.

Risk Factors for Acute Lung Injury. In some cases, thoracic surgery may lead to acute lung injury postoperatively. Perioperative risk factors that have been identified include preoperative alcohol abuse and patients undergoing pneumonectomy. Intraoperative risk factors include high ventilatory pressures and excessive amounts of fluid administration.[8]

Physical Examination

The physical examination of the patient should address the following aspects.

Respiratory Pattern

The presence of cyanosis and clubbing, the breathing pattern, and the type of breath sounds should be noted.

Cyanosis. The presence of peripheral cyanosis (in the fingers, toes, or ears) should be distinguished from causes of poor circulation (acrocyanosis). The presence of central cyanosis (in the buccal mucosa) is usually secondary to arterial hypoxemia. If cyanosis is present, the arterial hemoglobin saturation with oxygen is 80% or less (PaO_2 < 50 to 52 mm Hg), which indicates a limited margin of respiratory reserve.

Clubbing. Clubbing is often seen in patients with chronic lung disease, malignancies, or congenital heart disease associated with right-to-left shunt.

Respiratory Rate and Pattern. A patient's inability to complete a normal sentence without pausing for breath is an

indication of severe dyspnea. Inspiratory paradox, the abdomen moving in while the chest moves out, suggests diaphragmatic fatigue and respiratory dysfunction. The patient should be assessed for paroxysmal retraction (Hoover's sign), limited diaphragmatic movement because of hyperinflation, and asymmetry of chest movement secondary to phrenic nerve involvement, hemothorax, pleural effusion, and pneumothorax. The pattern and rate of breathing have important roles in distinguishing between obstructive and restrictive lung disease. For constant minute ventilation, the work done against airflow resistance decreases when breathing is slow and deep. Work done against elastic resistance decreases when breathing is rapid and shallow (e.g., as in pulmonary infarct or pulmonary fibrosis).

Breath Sounds. Wet sounds (crackles) are usually caused by excessive fluid in the airways and indicate sputum retention or edema. Dry sounds (wheezes) are produced by high-velocity gas flow through bronchi and are a sign of airway obstruction. Distant sounds are an indication of emphysema and possibly bullae. The trachea should be in the midline. Displacement of the trachea may be secondary to a number of causes, including mediastinal mass, and should alert the anesthesiologist to a potentially difficult intubation of the trachea or airway obstruction on induction of anesthesia.

Evaluation of the Cardiovascular System

One of the most important factors in the evaluation of a patient scheduled for thoracic surgery is the presence of an increase in pulmonary vascular resistance secondary to a fixed reduction in the cross-sectional area of the pulmonary vascular bed. The pulmonary circulation is a low-pressure, high-compliance system capable of handling an increase in blood flow by recruitment of normally underperfused vessels. This acts as a compensatory mechanism that normally prevents an increase in pulmonary arterial pressure. In chronic obstructive pulmonary disease (COPD), there is distention of the pulmonary capillary bed with decreased ability to tolerate an increase in blood flow (decreased compliance). Such patients demonstrate an increase in pulmonary vascular resistance when cardiac output increases because of a decreased ability to compensate for an increase in pulmonary blood flow. This results in pulmonary hypertension, signs of which include a narrowly split second heart sound, increased intensity of the pulmonary component of the second heart sound, and right ventricular and atrial hypertrophy.

An increase in pulmonary vascular resistance is of significance in the management of the patient during anesthesia because several factors, such as acidosis, sepsis, hypoxia, and application of positive end-expiratory pressure (PEEP), all further increase the pulmonary vascular resistance and increase the likelihood of right ventricular failure.

In patients with ischemic or valvular heart disease, the function of the left side of the heart should also be carefully evaluated (see Chapter 31).

Electrocardiogram

A patient with COPD may present with electrocardiographic features of right atrial and ventricular

hypertrophy and strain. These include a low-voltage QRS complex due to lung hyperinflation and poor R-wave progression across the precordial leads. An enlarged P wave ("P pulmonale") in standard lead II is diagnostic of right atrial hypertrophy. The electrocardiographic changes of right ventricular hypertrophy are an R/S ratio of greater than 1.0 in lead V_1 (i.e., R-wave voltage exceeds S-wave voltage).

Chest Radiography

Hyperinflation and increased vascular markings are usually present with COPD. Prominent lung markings often occur in bronchitis, whereas they are decreased in emphysema, particularly at the bases, where actual bullae may be present in severe cases. Hyperinflation, with an increased anteroposterior chest diameter, may be present, together with an enlarged retrosternal air space of greater than 2 cm in diameter seen in a lateral chest radiograph.

The location of the lung lesion should be assessed by posteroanterior and lateral projections on chest radiography. In addition to tracheal or carinal shift, a mediastinal mass may indicate difficulty with ventilation, a difficult and bloody dissection, difficulty in placing a double-lumen tube (DLT) (because of deviation of the main-stem bronchus), or a collapsed lobe owing to bronchial obstruction with possible sepsis. Review of a computed tomography (CT) study is also useful, and often provides more information about tumor size and location than the chest radiograph.

Arterial Blood Gas Analysis

A common finding in arterial blood gas analysis of patients with COPD is hypoventilation and CO_2 retention. The "blue bloaters" (chronic bronchitics) are cyanotic, hypercarbic, hypoxemic, and usually overweight. They are in a state of chronic respiratory failure and have a decreased ventilatory response to CO_2. In these patients, the high $PaCO_2$ increases cerebrospinal fluid bicarbonate concentration, the medullary chemoreceptors become reset to a higher level of CO_2, and sensitivity to CO_2 is decreased. Such patients hypoventilate when given high oxygen concentrations to breathe because of a decreased hypoxic drive.

The "pink puffers" (patients with emphysema) are typically thin, dyspneic, and pink, with essentially normal arterial blood gas values. They present with an increase in minute ventilation to maintain their normal $PaCO_2$, which explains the increase in work of breathing and dyspnea. The preoperative PaO_2 correlates with the intraoperative PaO_2 during one-lung ventilation (OLV), but the intraoperative PaO_2 during two-lung ventilation correlates more closely.[9]

Pulmonary Function Testing and Evaluation for Lung Resectability

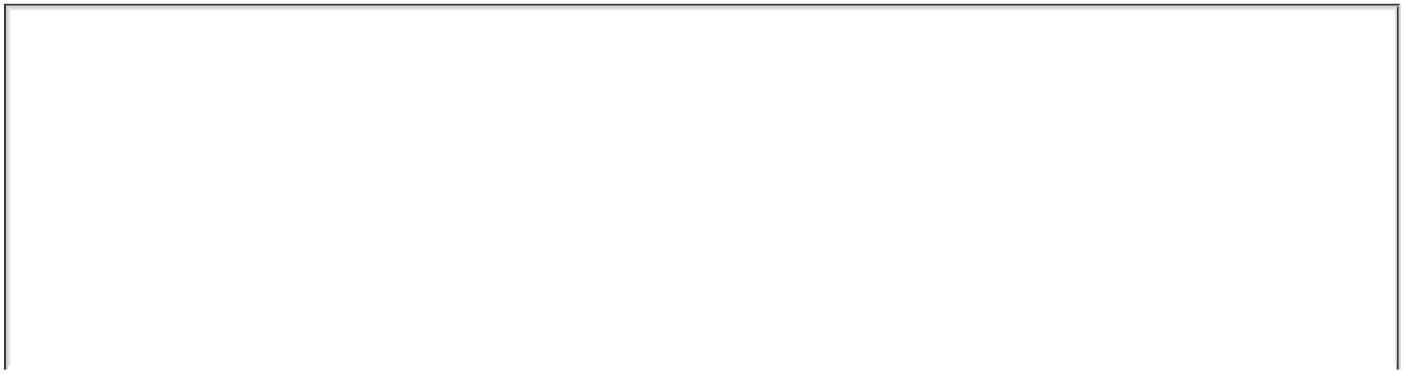
There are three goals in performing pulmonary function tests in a patient scheduled for lung resection. The first is to identify the patient at risk of increased postoperative morbidity and mortality. In thoracic surgery for lung cancer, the specific question is: How much lung tissue may be safely removed without making the patient a pulmonary cripple?" This should be weighed against the 1-year mean survival rate of the patient with surgically untreated lung carcinoma. The second goal is to identify the patient who will need short-term or long-term postoperative ventilatory support. The third goal is to evaluate the beneficial effect and reversibility of airway obstruction with the use of bronchodilators.

Effects of Anesthesia and Surgery on Lung Volumes

Anesthesia and postoperative medications can cause changes in lung volumes and ventilatory pattern. Total lung capacity (TLC) decreases after abdominal surgery but not after surgery on an extremity. Vital capacity is decreased by 25 to 50% within 1 to 2 days after surgery and generally returns to normal after 1 to 2 weeks. Residual volume (RV) increases by 13%, whereas expiratory reserve volume decreases by 25% after lower abdominal surgery and 60% after upper abdominal

and thoracic surgery. Tidal volume (VT) decreases by 20% within 24 hours after surgery and gradually returns to normal after 2 weeks. Pulmonary compliance decreases by 33% with similar reductions in functional residual capacity (FRC) secondary to small airway closure. Most of the patients who undergo lung resection are smokers with a certain degree of COPD and are prone to postoperative complications in direct relation to the amount of lung to be resected (lobectomy or pneumonectomy) and to the severity of the preoperative lung disease.

Spirometry



Forced vital capacity (FVC), forced expired volume in one second (FEV_1), and peak expiratory flow can be measured at the patient's bedside using a spirometer. The measurement can be recorded as a volume–time trace or as a flow–volume loop. A vital capacity of at least three times the VT is necessary for an effective cough. A vital capacity of <50% of predicted or <2 L is an indication of increased risk.[10] An abnormal preoperative vital capacity can be identified in 30 to 40% of postoperative deaths. A patient with an abnormal vital capacity has a 33% likelihood of complications and a 10% risk of postoperative mortality.

FEV_1 is a more direct indication of airway obstruction. In the past, an FEV_1 of less than 800 mL in a 70-kg male had been considered an absolute contraindication to lung resection. However, with the advent of thoracoscopic surgery and improved postoperative pain management, patients with smaller lung volumes are now successfully undergoing surgery. It is preferable to indicate the percentage of predicted, rather than just using the absolute value. The percentage of predicted takes into account the age and size of the patient, and the same number may have a different implication in another patient. Mortality in patients with an FEV_1 >2 L is 10%, and in patients whose FEV_1 is <1 L is between 20% and 45%.[11]

The ratio FEV_1/FVC is useful in differentiating between restrictive and obstructive pulmonary disease. It is normal in restrictive disease because both FEV_1 and FVC decrease, whereas in obstructive disease the ratio is usually low because the FEV_1 is markedly decreased. Maximum voluntary ventilation (MVV) is a nonspecific test, and is an indicator of both restriction and obstruction. Although MVV has not been systematically evaluated as a predictor of morbidity, it is generally accepted that an MVV <50% of predicted value is an indication of high risk. A ratio of RV to TLC (RV/TLC) of >50% is generally indicative of a high-risk patient for pulmonary resection. Mittman[12] found that an RV/TLC ratio of >40% was associated with a 30% mortality rate, compared with a 7% mortality when RV/TLC was <40% (normal range 20 to 25%). By multiplying the preoperative FEV_1 by the percentage of lung tissue expected to remain following resection, a predicted postop (PPO) FEV_1 can be calculated. Patients with a PPO FEV_1 value >40% are at reduced risk, and those with PPO FEV_1 <30% are at increased risk.[13] Those patients who fall into the latter category are more likely to need postoperative ventilation.

Flow–Volume Loops

The flow–volume loop displays essentially the same information as a spirometer but is more convenient for measurement of specific flow rates (Fig. 29-2). The shape and peak airflow rates during expiration at high lung volumes are effort dependent, but indicate the patency of the larger airways. Effort-independent expiration occurs at low lung volumes and usually reflects small airways resistance, best measured by forced expiratory flow (FEF) during the middle half of the FVC ($FEF_{25-75\%}$).

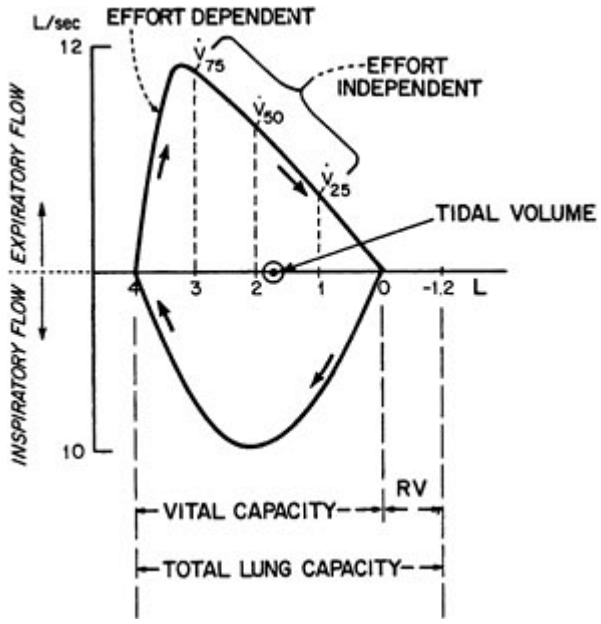


FIGURE 29-2. Flow–volume loop in a normal subject. $\dot{V}_{75}$, $\dot{V}_{50}$, and $\dot{V}_{25}$ represent flow at 75%, 50%, and 25% of vital capacity, respectively. RV, residual volume. (Reproduced with permission from Goudsouzian N, Karamanian A: Physiology for the Anesthesiologist, 2nd ed. Norwalk, CT, Appleton-Century-Crofts, 1984.)

In general, patients with obstructive airways disease (Fig. 29-3), such as asthma, bronchitis, and emphysema, have grossly decreased FEV_1/FVC ratios because of increased airways resistance and a decrease in FEV_1. Peak expiratory flow rate and MVV are usually decreased, whereas total lung capacity increases secondary to increases in RV. In these patients, the effort-independent portion of the flow–volume curve is markedly depressed inward, with reduction of the flow rate at 25 to 75% of FVC.

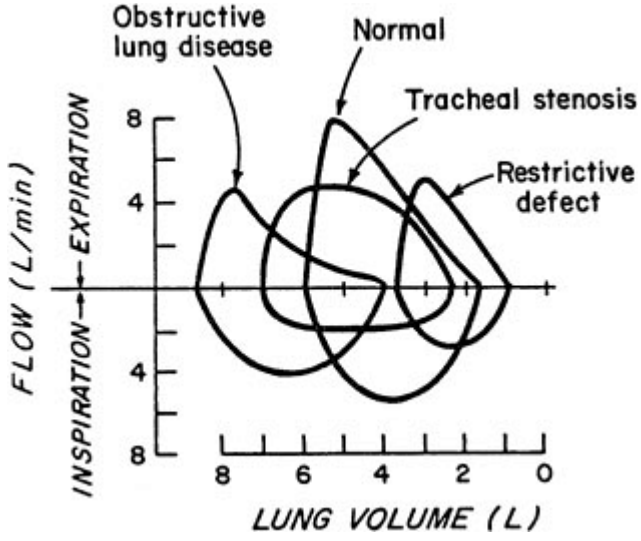

FIGURE 29-3. Flow–volume loops relative to lung volumes (1) in a normal subject, (2) in a patient with chronic obstructive pulmonary disease (COPD), (3) in a patient with fixed

obstruction (tracheal stenosis), and (4) in a patient with pulmonary fibrosis (restrictive defect). Note the concave expiratory form in the patient with COPD and the flat inspiratory curve in the patient with a fixed obstruction. (Reprinted with permission from Goudsouzian N, Karamanian A: Physiology for the Anesthesiologist, 2nd ed. Norwalk, CT, Appleton-Century-Crofts, 1984.)

In patients with restrictive disease (see Fig. 29-3), such as pulmonary fibrosis and scoliosis, there is a decrease in FVC with a relatively normal FEV_1. Because the airways resistance is normal, FEV_1/FVC is also normal. TLC is markedly decreased, whereas MVV and $FEF_{25-75\%}$ are usually normal. The flow–volume curves of these patients are normal in shape, but the lung volumes and peak flow rates are decreased.

Significance of Bronchodilator Therapy. Pulmonary function tests are usually performed before and after bronchodilator therapy to assess the reversibility of the airways obstruction. This is useful in the assessment of the degree of airways obstruction and the patient's effort ability. After treatment with bronchodilators, increases in peak expiratory flow compared with a baseline indicate reversibility of airways obstruction (often seen in asthmatic patients). A 15% improvement in pulmonary function tests may be considered a positive response to bronchodilator therapy and indicates that this therapy should be initiated before surgery. The overall prognosis of COPD is better related to the level of spirometric function after bronchodilator therapy than to a baseline function.

Split-Lung Function Tests

Regional lung function studies serve to predict the function of the lung tissue that would remain after lung resection. A whole (two)-lung test may fail to estimate whether the amount of postresection lung tissue will allow the patient to function at a reasonable level of activity without disabling dyspnea or cor pulmonale.

Regional Perfusion Test. This involves the intravenous injection of insoluble radioactive xenon (^{133}Xe). The peak radioactivity of each lung is proportional to the degree of perfusion of each lung.

Regional Ventilation Test. Using an inhaled, insoluble radioactive gas, the peak radioactivity over each lung is proportional to the degree of ventilation. Combining radiospirometry with whole-lung testing (FEV_1, FVC, maximal breathing capacity) has resulted in a fair degree of correlation between predicted volumes and pulmonary function tests measured after pneumonectomy.

Regional Bronchial Balloon-Occlusion Test. This test simulates the postresection condition preoperatively by using balloon occlusion of the bronchus to the segment of the lung to be resected. Spirometry and arterial blood gas analysis are then performed with the remaining functional lung.

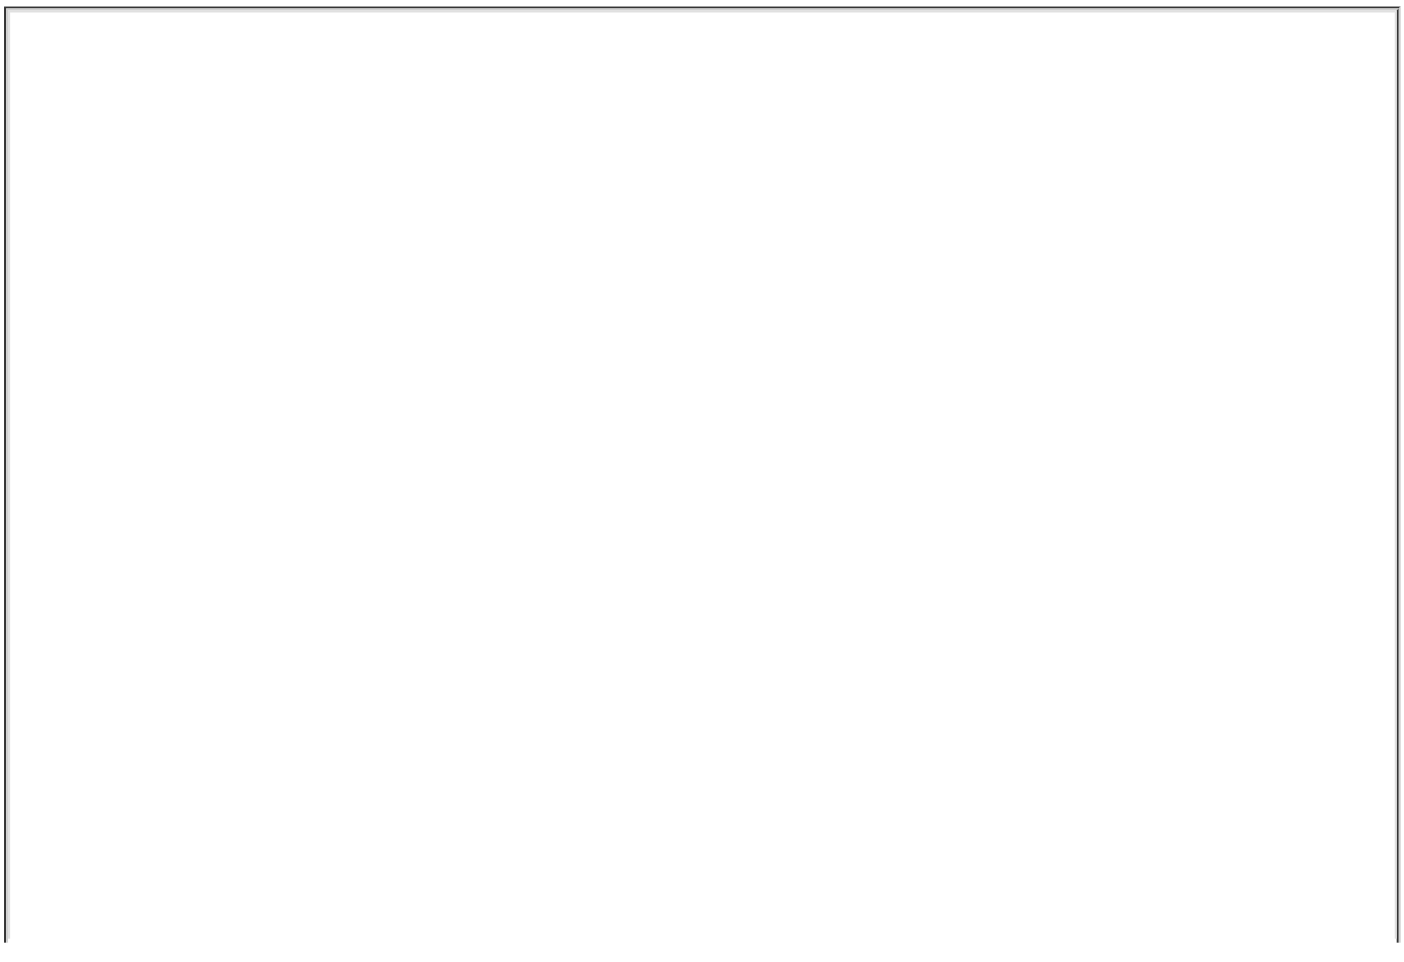
Computed Tomography and Positron Emission Tomography Scans. Patients normally undergo CT scanning. The CT scan provides anatomic sections through the chest. It can delineate the size of the tumor. It can also reveal if there is airway or cardiovascular compression,

Positron emission tomography (PET) scans use a glucose analog that is labeled with a radionuclide positron emitter. This scan can detect tumor based on the metabolic activity. Because malignant tumors are growing at such a fast rate compared with healthy tissue, the tumor cells will use up more of the sugar that has the radionuclide attached to it. There is greater uptake by malignant mediastinal lymph nodes than benign nodes. PET may be more accurate than CT for mediastinal staging.[14] Currently, PET scans can be used to further evaluate lesions that are seen on a CT scan. The PET scan can also be used to follow the results of lung cancer treatments.[15]

The CT and PET scans can be done at the same time to produce a PET-CT scan. A mass that is

seen on the CT scan is more likely to be malignant if it also demonstrates enhanced glucose uptake on the PET scan.

Pulmonary Artery Balloon-Occlusion Test



The postoperative stress on the right ventricle and remaining pulmonary vascular bed can be simulated by occluding the pulmonary artery of the lung to be resected using a specially designed balloon-tipped pulmonary artery (PA) catheter that has a pressure-sensing port just proximal to the balloon. This test may be performed with or without exercise. If, on balloon occlusion of the pulmonary artery of the lung to be resected, the mean pulmonary artery pressure increases to >40 mm Hg, PaO_2 is <60 mm Hg, or $PaCO_2$ is >45 mm Hg, it is unlikely that the patient will be able to tolerate pneumonectomy without experiencing postoperative respiratory failure or cor pulmonale. Due to the usefulness of the noninvasive split-lung function tests, the bronchial and pulmonary artery balloon occlusion tests are rarely performed for clinical evaluation.

Diffusing Capacity for Carbon Monoxide

The ability of the lung to perform gas exchange is reflected by the diffusing capacity for carbon monoxide (DLCO). It is impaired in such disorders as interstitial lung disease, which affects the alveolar-capillary site. A predicted postoperative DLCO <40% is associated with increased risk. Predicted postoperative diffusing capacity percent is the strongest single predictor of risk of complications and mortality after lung resection. There is little interrelationship of predicted postoperative diffusing capacity percent and predicted postoperative FEV_1, indicating that these values should be assessed independently when estimating operative risk.[16]

Maximal Oxygen Consumption. The maximal oxygen consumption (VO_2 max) is a predictor of postoperative complications. Patients with a VO_2 max >15 to 20 mL/kg per minute are at reduced risk.[17] A VO_2 max <10 mL/kg per minute indicates very high risk for lung resection.[18] A simpler test that can be performed is exercise oximetry—a decrease of 4% during exercise is associated with increased risk.[19] A 6-minute walk test less than 2,000 feet has been correlated both with a VO_2 max < 15 mL/kg per minute, and with a decrease in oximetry reading during exercise.

The preoperative evaluation of the patient for lung resection is summarized in Fig. 29-4.

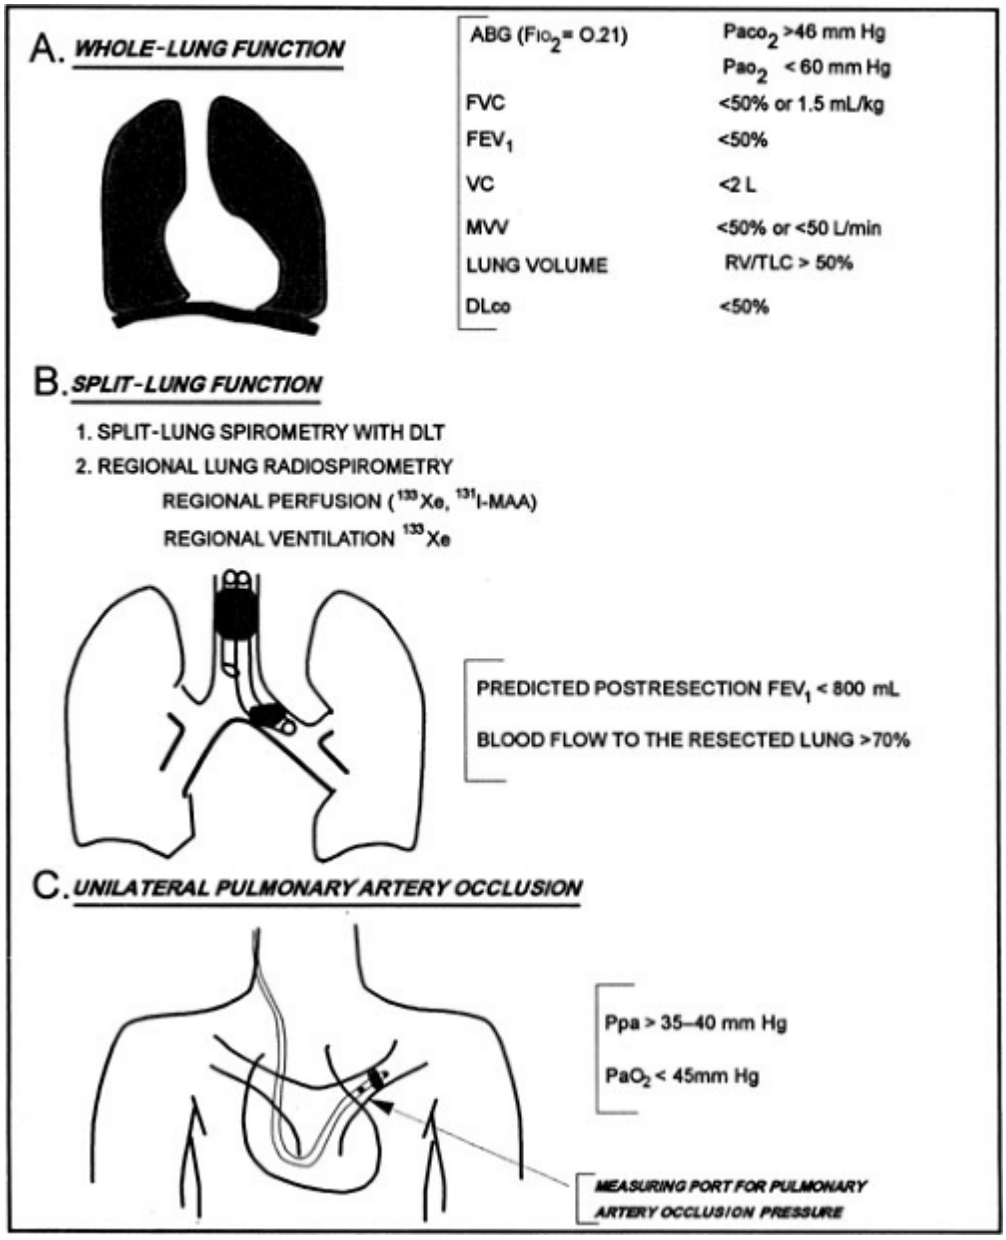


FIGURE 29-4. The order of tests to determine the cardiopulmonary status of the patient and the extent of lung resection that would be tolerated. **A.** The whole-lung function test is a basic screening test. **B.** The split-lung function tests are regional tests to determine the involvement of the diseased lung to be removed. **C.** Tests that mimic the postoperative cardiopulmonary function are the decisive tests to determine if the patient will be able to tolerate the planned resection. (Adapted with permission from Neustein SM, Cohen E: Preoperative evaluation of thoracic surgical patients. In Cohen E [ed]: The Practice of Thoracic Anesthesia, p 187. Philadelphia, JB Lippincott, 1995.)

PREOPERATIVE PREPARATION

The wide spectrum of physiologic changes that occurs during thoracic surgery puts patients at great risk of developing postoperative complications. Morbidity and mortality increase when these changes are superimposed on an acutely or chronically compromised patient. Several conditions, including infection, dehydration, electrolyte imbalance, wheezing, obesity, cigarette smoking, cor pulmonale, and malnutrition, show particular correlations with postoperative complications. Proper, vigorous preoperative preparation can improve the patient's ability to face the surgery with a decreased risk of morbidity and mortality. It is important that conditions predisposing to

postoperative complications be rigorously treated before surgery.

Smoking

3 Approximately 33% of adult patients presenting for surgery are smokers, and there is extensive evidence that they are at increased risk for development of postoperative respiratory complications.[20] Smoking increases airway irritability, decreases mucociliary transport, decreases FVC and $FEF_{25-75\%}$, and increases secretions, thereby increasing the incidence of postoperative pulmonary complications. In contrast, cessation of smoking for a period of longer than 4 to 6 weeks before surgery is associated with a decreased incidence of postoperative complications.[21] Furthermore, cessation of smoking for 48 hours before surgery has been shown to decrease the percentage of carboxyhemoglobin, to shift the oxyhemoglobin dissociation curve to the right, and to increase oxygen availability. It should be emphasized, however, that most of the beneficial effects of cessation of smoking, such as improvement in ciliary function, improvement in closing volume, increase in

$FEF_{25-75\%}$, and reduction in sputum production, usually occur 2 to 3 months after smoking has ceased.

Infection

Acute or chronic infection should be vigorously treated before surgery. Broad-spectrum antibiotics are commonly used. Treatment of the acutely ill patient depends on the results of the Gram's stain of the sputum and blood cultures. In one prospective study, the incidence of mortality was lower in the group treated with prophylactic antibiotics compared with the untreated group (9% versus 17%), and a lower incidence of postoperative pulmonary infection was also found.[22] Although not all surgeons routinely administer antibiotics prophylactically to their patients, any infection present before surgery should be vigorously treated.

Hydration and Removal of Bronchial Secretions

Correction of hypovolemia and electrolyte imbalance should be accomplished before surgery because adequate hydration decreases the viscosity of bronchial secretions and facilitates their removal from the bronchial tree. Humidification of inspired gas is extremely useful. The use of mucolytic drugs, such as acetylcysteine (Mucomyst), or oral expectorants (potassium iodide) can be beneficial to patients with viscous secretions. Commonly used methods for removing secretions from the bronchial tree include postural drainage, vigorous coughing, chest percussion, deep breathing, and the use of an incentive spirometer. These modalities often require patient cooperation and frequent verbal encouragement to maximize the benefit.

Wheezing and Bronchodilation

The presence of acute wheezing represents a medical emergency, and elective surgery should be postponed until effective treatment has been instituted. Chronic wheezing is often seen in patients with COPD and is attributable to the presence of gas flow obstruction secondary to smooth muscle contraction, accumulation of secretions, and mucosal edema. Smooth muscle contraction may occur in small airways only (detectable by changes in $FEF_{25-75\%}$) or may be widespread, with a large reduction of FEV_1 and FVC. The efficacy of bronchodilators in reversing the bronchospastic component is extremely important. A trial of bronchodilators and measurement of their effects on pulmonary function should be performed in any patient who shows evidence of air flow obstruction. Several classes of bronchodilators are available.

Sympathomimetic Drugs. Sympathomimetic drugs increase the formation of 3′5′-cyclic adenosine monophosphate (cAMP). The balance between cAMP, which produces bronchodilation, and cyclic guanosine monophosphate, which produces bronchoconstriction, determines the state of contraction of the bronchial smooth muscle. Increasing cAMP production therefore causes relaxation of the bronchial tree. Sympathomimetic drugs, such as epinephrine, isoproterenol,

isoetharine, and ephedrine, all have mixed β_1 and β_2 sympathetic agonist effects. The β_1 (cardiac effects) of these drugs are often undesirable in patients with COPD. Selective β_2 sympathomimetic drugs, such as albuterol, terbutaline, and metaproterenol, given as inhaled aerosols, are the preferred drugs for the treatment of bronchospasm, particularly in patients with cardiac disease.

Phosphodiesterase Inhibitors. Phosphodiesterase inhibitors inhibit the breakdown of cAMP by cytoplasmic phosphodiesterase. The methylxanthines, such as aminophylline, increase the level of cAMP, resulting in bronchodilation. In addition, aminophylline improves diaphragmatic contractility and increases the patient's resistance to fatigue. Therapeutic blood levels of aminophylline are 5 to 20 µg/mL and can be achieved by infusing a loading dose of 5 to 7 mg/kg over 20 minutes, followed by a continuous intravenous infusion of 0.5 to 0.7 mg/kg/hr. Aminophylline may cause ventricular arrhythmias, and this side effect should be borne in mind when treating patients who have myocardial ischemia. Because newer medications have fewer side effects, aminophylline is now rarely used.

Steroids. Although not true bronchodilators, steroids are traditionally considered to decrease mucosal edema and may prevent the release of bronchoconstricting substances. They are of questionable benefit in acute bronchospasm. Steroids may be administered orally, parenterally, or in aerosol form, such as beclomethasone by inhaler.

Cromolyn Sodium. Cromolyn sodium stabilizes mast cells and inhibits degranulation and histamine release. It is useful in the prevention of bronchospastic attacks but is of little value in the treatment of the acute situation.

Parasympatholytic Drugs. Parasympatholytics include atropine and ipratropium. In the past, atropine has been avoided in patients with COPD and bronchitis because of concern regarding increases in the viscosity of mucus produced by this agent. However, atropine blocks the formation of cyclic guanosine monophosphate and therefore has a bronchodilator effect. Marini et al.[23] found that inhaled atropine alone improved FEV_1 in 85% of patients with COPD. When atropine was given in combination with terbutaline, the FEV_1 improved in 93% of patients, whereas terbutaline alone improved FEV_1 in only 56% of patients. Antimuscarinic drugs such as atropine therefore potentiate the bronchodilator effect of the sympathomimetic agents.

In conclusion, the preoperative preparation of the patient for thoracic surgery should focus on those conditions that are treatable before surgery so the patient is in optimal condition at the time of surgery.

INTRAOPERATIVE MONITORING

All patients undergoing anesthesia for thoracic surgical procedures require use of standard American Society of Anesthesiologists or ASA monitors. These include an electrocardiogram (lead II and, if possible, V_5), chest or esophageal stethoscopes for heart and breath sound auscultation, and a temperature probe. A chest stethoscope may be placed over the dependent hemithorax to assess dependent lung ventilation. Pulse oximetry, which is a standard of care, is especially valuable during thoracic surgery because hypoxemia may occur during OLV.

Arrhythmias occur commonly both during and after thoracic surgery, making the usual need for continuous electrocardiographic monitoring even more important. Intraoperative supraventricular tachyarrhythmias may be caused by cardiac manipulation. Arrhythmias that occur during OLV may be a sign of inadequate oxygenation or ventilation. Postoperative arrhythmias may be related to sympathetic nervous system stimulation from pain or to a decreased pulmonary vascular bed following lung resection. Patients who present for lung resection often have COPD owing to cigarette smoking, have right-sided heart strain, and are prone to multifocal atrial tachyarrhythmias.

The axis of electrocardiogram lead II parallels that of the P wave, making this lead useful for arrhythmia detection. The simultaneous monitoring of lead V_5 also allows for monitoring of anterolateral wall myocardial ischemia. The use of multiple leads increases the sensitivity for ischemia detection.[24] The following invasive monitors are also indicated and have led to marked

improvements in patient care.

Direct Arterial Catheterization

Peripheral arterial catheterization has become an essential tool for the anesthesiologist in the management of patients undergoing major thoracic surgical procedures. It allows for continuous beat-to-beat measurement of blood pressure and frequent sampling for the determination of arterial blood gases. Continuous blood pressure readings are critical during thoracic surgery because surgical manipulations or intravascular volume shifts can cause sudden major changes in the blood pressure. Immediate recognition of these changes allows time for proper identification of the etiology and the institution of appropriate treatment.

Serial arterial blood gas determinations are performed as needed in the management of patients undergoing one-lung anesthesia or during cases in which a part of the lung may be "packed away" for a period. Arterial hypoxemia may occur because of shunting through the collapsed lung and inadequate hypoxic pulmonary vasoconstriction (HPV). Significant changes in acid-base status and hyperventilation or hypoventilation can also be identified.

A radial artery catheter can be placed in either extremity during thoracic surgery. For a mediastinoscopic examination, one approach is to place the catheter in the right arm and to use it to monitor for possible compression of the innominate artery by the mediastinoscope.[25] This can help avoid central nervous system complications that might result from inadequate cerebral blood flow via the right carotid artery (see Mediastinoscopy section). The other approach would be to place the arterial catheter in the left radial artery, allowing for continuous blood pressure measurements, uninterrupted by innominate artery compression. If this is done, a pulse oximeter probe should be placed on the right upper extremity to monitor for innominate artery compression. During thoracotomy, the radial artery catheter is often placed in the dependent arm to aid in stabilizing the catheter. However, an "axillary roll" must be placed under the patient's dependent hemithorax to protect the axilla and avoid compression of the axillary artery and brachial plexus in the dependent ("down") arm. Placement of the arterial catheter in the dependent arm can be used to monitor for possible axillary artery compression, which may occur if the patient is not properly positioned. In rare cases, the arterial catheter can be placed in the brachial, femoral, or dorsalis pedis artery if the ulnar collateral circulation is believed to be inadequate.

Central Venous Pressure Monitoring

The continuous venous pressure (CVP) reflects the patient's blood volume, venous tone, and right ventricular performance; however, it is also affected by central venous obstructions and alterations of intrathoracic pressure (e.g., PEEP). Serial measurements are more useful than an individual number, and the response of the CVP to a volume infusion is a useful test of right ventricular function. The CVP reflects right-sided heart function, not left ventricular performance. Catheters for measuring CVP may be placed for thoracotomies, and in particular, patients undergoing pneumonectomy. Uses of CVP catheters or large-bore introducers include (1) insertion of a transvenous pacemaker where necessary, (2) infusion of vasoactive drugs, and (3) insertion of a PA catheter, which may subsequently be required during surgery or in the postoperative period.

The CVP catheter can be placed centrally from either the external or the internal jugular vein, from the subclavian veins, or from one of the arm veins. The success rate is highest using the right internal jugular vein, and a pacemaker or PA catheter can be inserted most easily from this vein. The major disadvantage of using the external jugular vein during thoracotomy is that the catheter often kinks when the patient is turned to the lateral decubitus position. The subclavian technique leads to a high incidence of pneumothorax, which can be disastrous if it occurs in the dependent lung during OLV.

Pulmonary Artery Catheterization

The PA catheter is most reliably inserted through the right internal jugular vein using a modified Seldinger technique. Insertion of the PA catheter through either the external jugular vein or the subclavian vein often leads to obstruction of the catheter when the patient is placed in the lateral decubitus position. Pulmonary artery rupture is the most serious complication associated with the use of the PA catheter. Risk factors for this complication include hypothermia, pulmonary hypertension, anticoagulation, and being elderly or female. Pulmonary artery perforation most commonly manifests as hemoptysis. Misinterpretation of data from a PA catheter is a real risk in a patient with cardiac and pulmonary disease undergoing thoracic surgery with OLV. These errors can be produced by altered ventilatory modes, the location of the PA catheter tip, ventricular compliance changes, or ventricular interdependence.[26] A major limitation of the PA catheter is the assumption that the pulmonary capillary wedge pressure (PCWP) provides a good approximation of left ventricular end-diastolic volume. The use PCWP directly to assess preload assumes a linear relationship between ventricular end-diastolic volume and ventricular end-diastolic pressure. However, alterations in ventricular compliance affect this pressure–volume relationship during surgery. Decreases in ventricular compliance can occur with myocardial ischemia, shock, right ventricular overload, or pericardial effusion. Numerous investigators have demonstrated a poor correlation between PCWP and left ventricular end-diastolic volume in acutely ill patients.[27] This correlation is further worsened by the application of PEEP. Therefore, whenever PCWP is used to estimate left ventricular preload, the number must be interpreted in light of the clinical situation. The interdependence of the right and left ventricles must also be remembered when interpreting PCWP. Ventricular interdependence can cause misdiagnosis when the interventricular septum encroaches on the left ventricular cavity, leading to increased values of PCWP. A PCWP associated with a decreased cardiac output can be interpreted as left ventricular failure, when, in fact, left ventricular end-diastolic volume may not be increased but decreased because of compression of the left ventricle by a distended right ventricle. This situation can occur with acute respiratory failure and high levels of PEEP. Techniques such as echocardiography, which directly measure ventricular dimensions, are necessary to resolve this complex situation.

Because most of the pulmonary blood flow is to the right lower lobe, the tip of a flow-directed PA catheter is usually located in the right lower lobe. During a left thoracotomy with OLV, the catheter tip would then be in the dependent lung and should provide accurate hemodynamic measurements. However, during a right thoracotomy with OLV, the catheter tip should be in the nondependent lung. Cohen et al.[28] reported that during right thoracotomies with the tip of the PA catheter in a West zone 1 or zone 2 region of the right lung, hemodynamic measurements may be inaccurate. These authors found that values for cardiac output measurements were lower during right thoracotomies than left thoracotomies, and the derived parameters of stroke volume index and oxygen delivery were also inappropriately low. Therefore, hemodynamic data derived from a PA catheter whose tip is located in the nondependent collapsed lung must be carefully evaluated.

A PA catheter capable of monitoring $S\bar{v}O_2$ is also available. Four mechanisms can account for a decreased $S\bar{v}O_2$: (1) decreased SaO_2, (2) decreased cardiac output, (3) increased oxygen consumption, and (4) decreased hemoglobin concentration. $S\bar{v}O_2$ represents a measure of global tissue oxygen extraction and consumption and is, in general, directly related to cardiac output *via* the Fick formula. The monitoring of $S\bar{v}O_2$ has been evaluated in patients undergoing one-lung anesthesia.[29] Changes in $S\bar{v}O_2$ were mainly dependent on changes in SaO_2.

Transesophageal Echocardiography

Transesophageal echocardiography (TEE) is a useful intraoperative monitor for ventricular function, valvular function, and wall motion changes that might reflect ischemia. Its use in thoracic surgical patients has been limited, but it is widely used in patients undergoing lung

transplant. In one study, central lung tumors were seen with TEE in nine of nine patients, peripheral lung tumors in one of three patients, and an anterior mediastinal mass in one of one patients.[30] In this study, TEE revealed pulmonary artery compression in five patients and pulmonary artery infiltration in two patients. In another study investigating echocardiographic recognition of mediastinal tumors, TEE revealed that the tumors were often adjacent to the heart and identified those patients in whom there was compression of the innominate vein or pulmonary artery, or infiltration of the heart.[31]

Intraoperative TEE has also revealed tumor invasion of the heart, indicating that a resection by thoracotomy without cardiopulmonary bypass was not feasible.[32] In one case report, TEE monitoring during an attempted resection of a tumor invading the left atrium showed embolization of the tumor.[33] Fragments of the tumor were seen to pass through the aortic valve. This patient subsequently died of disseminated metastases. In an exploratory thoracotomy for hemothorax, intraoperative TEE revealed the presence of a subacute aortic dissection, which was believed to be the etiology of the hemothorax.[34]

Monitoring of Oxygenation and Ventilation

Oxygenation

During the administration of all thoracic surgical anesthetics, the concentration of inspired oxygen in the breathing system must be measured using an oxygen analyzer with a low oxygen

concentration limit alarm. Such analyzers vary in sophistication from fuel cells, polarographic and paramagnetic analyzers, to mass and Raman spectrometers that can monitor all the gases used during anesthesia. Adequacy of blood oxygenation must also be ensured, and adequate illumination and exposure of the patient are necessary to assess the color of shed blood or the presence of cyanosis of the lips, nail beds, or mucous membranes. Most patients undergoing thoracic surgical or diagnostic procedures have an arterial catheter in place for continuous monitoring of blood pressure and sampling of arterial blood for blood gas determinations. In such cases, baseline arterial blood gas values should be obtained when breathing room air (FIO_2 = 0.21) before starting the procedure and repeated regularly and/or whenever indicated during surgery. Arterial blood is usually analyzed for oxygen tension (PaO_2), and a value for saturation is calculated from the oxyhemoglobin dissociation curve, correcting for temperature, pH, and $PaCO_2$.

The oxygen *content* of arterial blood can be measured by analyzing arterial blood in a laboratory cooximeter or calculated (see Chapter 28). Pulse oximetry is a standard of care for noninvasive assessment of blood oxygenation. The pulse oximeter reading (S_pO_2) is fairly accurate in predicting hemoglobin saturation with oxygen over the range of 70 to 100%. The importance of pulse oximetry has also been demonstrated during OLV, when rapid assessment of oxygenation is extremely important, and when arterial blood gas analysis may involve some delay.[35] Pulse oximetry does not, however, eliminate the need for arterial blood gas analysis during thoracic surgery. A low SpO_2 reading provides the clinician with an indication for sampling and laboratory analysis of arterial blood, but an erroneously high SpO_2 reading may also occur.[36]

Ventilation

All patients must be continually monitored to ensure adequacy of ventilation. Monitoring includes qualitative signs such as chest excursion (visual observation of the lungs when the chest is open) and auscultation of breath sounds. In addition, during OLV, a stethoscope can be placed on the chest wall under the ventilated dependent lung. During controlled ventilation, circuit low-pressure and high-pressure alarms with an audible signal must be used. The respiratory rate, VT, minute volume, and inflation pressures should be observed.

Adequacy of ventilation should be confirmed by monitoring arterial blood gases and $PaCO_2$, in particular. This may be estimated continuously and noninvasively by using a capnograph. The end-tidal CO_2 concentration represents alveolar CO_2 ($PACO_2$), which approximates $PaCO_2$. There is normally a small arterial-to-alveolar CO_2 difference (4 to 6 mm Hg), depending on alveolar dead

space. The capnogram waveform is also helpful in diagnosing airway obstruction, incomplete relaxation, and even malposition of the DLT. In the latter application, a capnograph is coupled with each port of the DLT (one or two capnographs may be used), and the correct position of the DLT is identified by simultaneous and synchronous CO_2 readings on each of the two analyzers. The waveforms from each lung are examined for shape, height, and rhythm, depending on the correct position of the tube and on the ventilation/perfusion ($\dot{V}/\dot{Q}$) ratio for each lung.[37] During two-lung ventilation, a decrease in end-tidal CO_2 in the gas from one lumen of the DLT suggests that the tube may be malpositioned. During OLV, systemic hypoxemia is usually a greater problem than hypercarbia.[38] This is because CO_2 is approximately 20 times more diffusible than oxygen and $PaCO_2$ is more dependent on ventilation, compared with PaO_2, which is more dependent on perfusion.

More recently, devices have been introduced clinically that use one small noninvasive digital sensor clipped to the earlobe to provide continuous monitoring of $PaCO_2$, S_PO_2, and pulse rate. Optoelectronic components, micro-pH electrode, temperature sensors, and a mixed-signal microcontroller reside on a digital sensor print. The measurement principles used are the Severinghaus-type PCO_2 electrode and a two-wavelength reflectance pulse oximeter.

Physiology of one-Lung Ventilation

Physiology of the Lateral Decubitus Position. Ventilation and blood flow in the upright position are discussed in Chapter 28. These variables will now be considered as they pertain to the lateral decubitus position under six circumstances that are encountered during thoracic surgery.

Lateral Position, Awake, Breathing Spontaneously, Chest Closed. In the lateral decubitus position, the distribution of blood flow and ventilation is similar to that in the upright position, but turned by 90 degrees (Fig. 29-5). Blood flow and ventilation to the dependent lung are significantly greater than to the nondependent lung. Good V/Q matching at the level of the dependent lung results in adequate oxygenation in the awake patient who is breathing spontaneously. There are two important concepts in this situation. First, because perfusion is gravity dependent, the vertical hydrostatic pressure gradient is smaller in the lateral than in the upright position; therefore, zone 1 is usually less extended. Second, in regard to ventilation, the dependent hemidiaphragm is pushed higher into the chest by the abdominal contents compared with the nondependent lung hemidiaphragm. During spontaneous ventilation, the conserved ability of the dependent diaphragm to contract results in an adequate distribution of VT to the dependent lung. Because most of the perfusion is to the dependent lung, the V/Q matching in this position is maintained similar to that in the upright position.

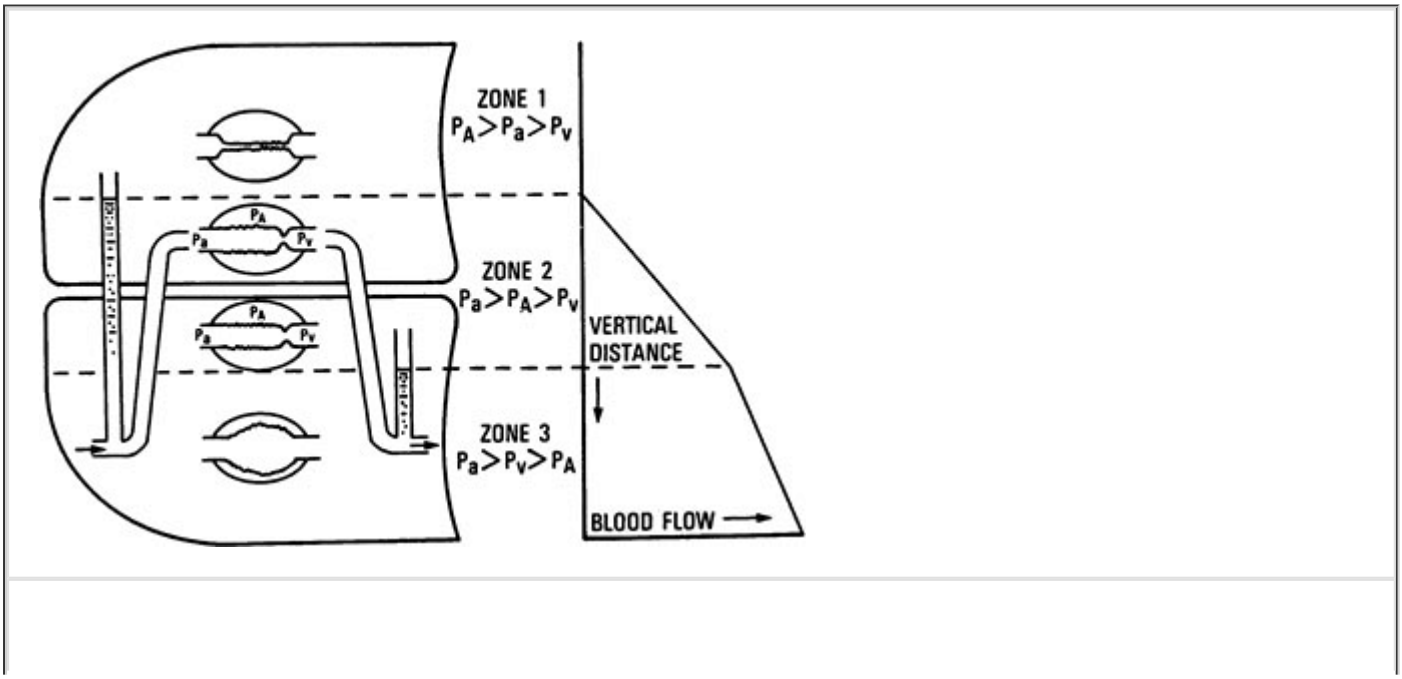

FIGURE 29-5. Schematic representation of the effects of gravity on the distribution of pulmonary blood flow in the lateral decubitus position. Vertical gradients in the lateral decubitus position are similar to those in the upright position and cause the creation of West zones 1, 2, and 3. Consequently, pulmonary blood flow increases with lung dependency, and is largest in the dependent lung and least in the nondependent lung. P_a, pulmonary artery pressure; P_A, alveolar pressure; P_v, pulmonary venous pressure. (From Benumof JL: Physiology of the open-chest and one lung ventilation. In: Thoracic Anesthesia, p 288. New York, Churchill Livingstone, 1983.)

Lateral Position, Awake, Breathing Spontaneously, Chest Open. Controlled positive-pressure ventilation is the most common way to provide adequate ventilation and ensure gas exchange in an open chest situation. Frequently, thoracoscopy is performed using intercostal blocks with the patient breathing spontaneously to allow proper lung examination. The thoracoscope provides an adequate seal of the open chest to prevent a

"free" open-chest situation. Two complications can arise from the patient breathing spontaneously with an open chest. The first is mediastinal shift, usually occurring during inspiration (Fig. 29-6). The negative pressure in the intact hemithorax, compared with the less negative pressure of the open hemithorax, can cause the mediastinum to move vertically downward and push into the dependent hemithorax. The mediastinal shift can create circulatory and reflex changes that may result in a clinical picture similar to that of shock and respiratory distress. Sometimes, depending on the severity of the distress, the patient needs to be tracheally intubated immediately, with initiation of positive-pressure ventilation, and the anesthesiologist must be prepared to intubate in this position without disturbing the surgical field. The second phenomenon is paradoxical breathing (Fig. 29-7). During inspiration, the relatively negative pressure in the intact hemithorax compared with atmospheric pressure in the open hemithorax can cause movement of air from the nondependent lung into the dependent lung. The opposite occurs during expiration. This gas movement reversal from one lung to the other represents wasted ventilation and can compromise the adequacy of gas exchange. Paradoxical breathing is increased by a large thoracotomy or by an increase in airways resistance in the dependent lung. Positive-pressure ventilation or adequate sealing of the open chest eliminates paradoxical breathing.

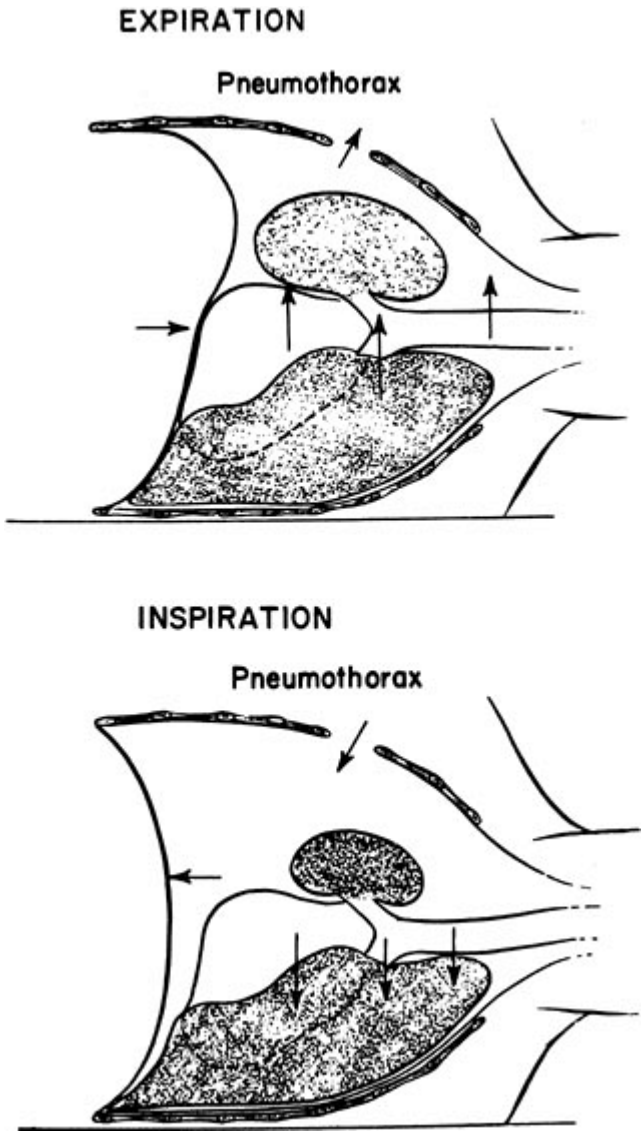

FIGURE 29-6. Schematic representation of mediastinal shift in the spontaneously breathing, open-chested patient in the lateral decubitus position. During inspiration, negative pressure in the intact hemithorax causes the mediastinum to move downward. During expiration, relative positive pressure in the intact hemithorax causes the mediastinum to move upward. (From Tarhan S, Moffitt EA: Principles of thoracic anesthesia. Surg Clin North Am 53:813, 1973.)

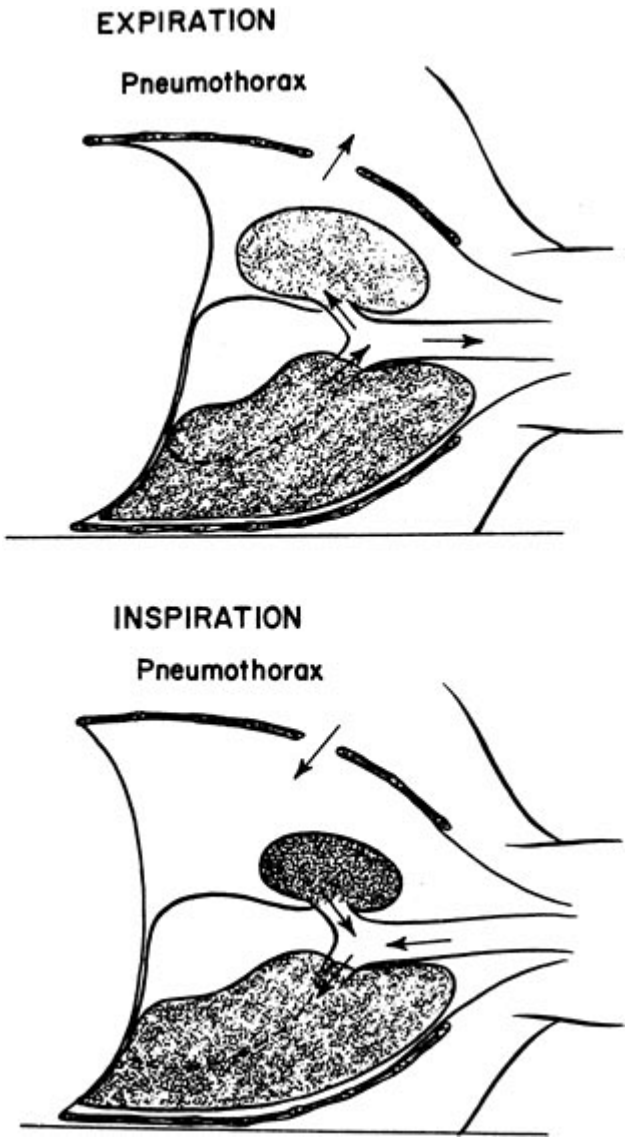

FIGURE 29-7. Schematic representation of paradoxical respiration in the spontaneously breathing, open-chested patient in the lateral decubitus position. During inspiration, movement of gas from the exposed lung into the intact lung and movement of air from the environment into the open hemithorax cause collapse of the exposed lung. During expiration, the reverse occurs, and the exposed lung expands. (From Tarhan S, Moffitt EA: Principles of thoracic anesthesia. Surg Clin North Am 53:813, 1973.)

Lateral Position, Anesthetized, Breathing Spontaneously, Chest Closed. The induction of general anesthesia does not cause significant change in the distribution of blood flow, but it has an important impact on the distribution of ventilation. Most of the VT enters the nondependent lung, and this results in a significant

$$\frac{\dot{V}}{\dot{Q}}$$

mismatch. Induction of general anesthesia causes a reduction in the volumes of both lungs secondary to a reduction in FRC. Any reduction in volume in the dependent lung is of a greater magnitude than that in the nondependent lung for several reasons. First, the cephalad displacement of the dependent diaphragm by the abdominal contents is more pronounced and is increased by paralysis. Second, the mediastinal structures pressing on the dependent lung or poor positioning of the dependent side on the operating table prevents the lung from expanding properly. The aforementioned factors will move lungs to a lower volume on the S-shaped volume-pressure curve (Fig. 29-8). The nondependent lung moves to a steeper position on the compliance

curve and receives most of the VT, whereas the dependent lung is on the flat (noncompliant) part of the curve.

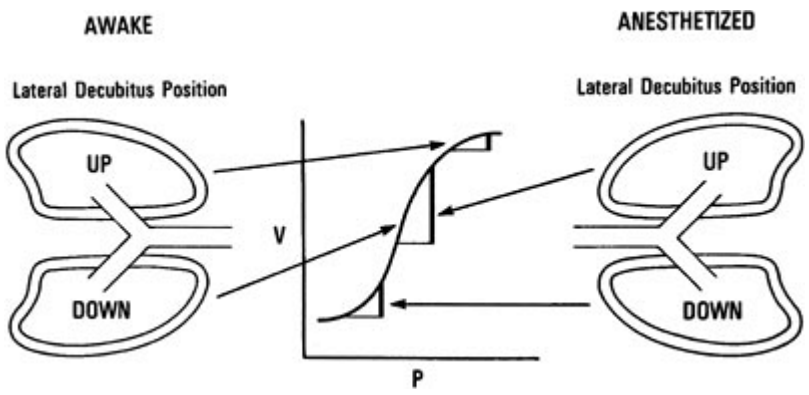

FIGURE 29-8. The left-hand side of the schematic shows the distribution of ventilation in the awake patient (closed chest) in the lateral decubitus position, and the right-hand side shows the distribution of ventilation in the anesthetized patient (closed chest) in the lateral ducubitus position. The induction of anesthesia has caused a loss in lung volume in both lungs, with the nondependent (up) lung moving from a flat, noncompliant portion to a steep, compliant portion of the pressure–volume curve, and the dependent (down) lung moving from a steep, compliant part to a flat, noncompliant part of the pressure–volume curve. Thus, the anesthetized patient in the lateral decubitus position has most tidal ventilation in the nondependent lung (where there is the least perfusion) and less tidal ventilation in the dependent lung (where there is the most perfusion). V, volume; P, pressure. (From Benumof JL: Anesthesia for Thoracic Surgery, p 112. Philadelphia, WB Saunders, 1987.)

Lateral Position, Anesthetized, Breathing Spontaneously, Chest Open. Opening the chest has little impact on the distribution of perfusion. However, the upper lung is now no longer restricted by the chest wall and is free to expand, resulting in

a further increase in

$$\frac{\dot{V}}{\dot{Q}}$$

mismatch as the nondependent lung is preferentially ventilated, owing to a now increased compliance.

Lateral Position, Anesthetized, Paralyzed, Chest Open. During paralysis and positive-pressure ventilation, diaphragmatic displacement is maximal over the nondependent lung, where there is the least amount of resistance to diaphragmatic movement caused by the abdominal contents (Fig. 29-9). This further compromises the ventilation to the dependent lung and increases the V/Q mismatch.

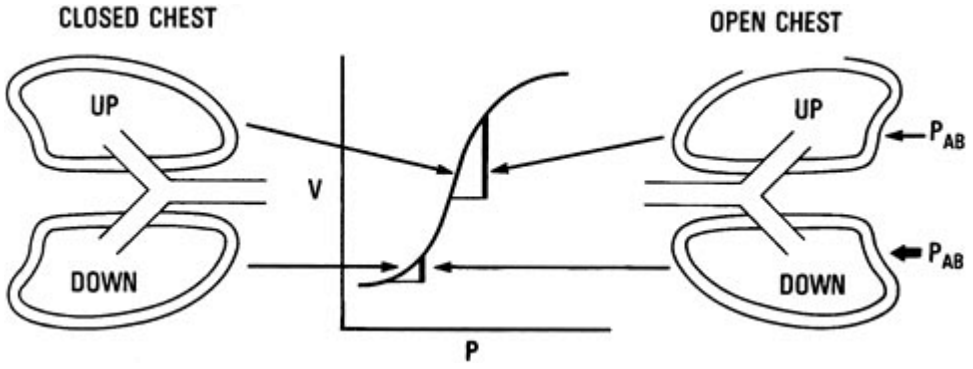

FIGURE 29-9. This schematic of a patient in the lateral decubitus position compares the closed-chested anesthetized condition with the open-chested anesthetized and paralyzed condition. Opening the chest increases nondependent lung compliance and reinforces or maintains the larger part of the tidal ventilation going to the nondependent lung. Paralysis also reinforces or maintains the larger part of tidal ventilation going to the nondependent lung because the pressure of the abdominal contents (P_{AB}) pressing against the upper diaphragm is minimal, and it is therefore easier for positive-pressure ventilation to displace this less resisting dome of the diaphragm. V, volume; P, pressure. (From Benumof JL: Anesthesia for Thoracic Surgery, p 112. Philadelphia, WB Saunders, 1987.)

one-Lung Ventilation, Anesthetized, Paralyzed, Chest Open. During two-lung ventilation in the lateral position, the mean blood flow to the nondependent lung is assumed to be 40% of cardiac output, whereas 60% of cardiac output goes to the dependent lung (Fig. 29-10). Normally, venous admixture (shunt) in the lateral position is 10% of cardiac output and is equally divided as 5% in each lung. Therefore, the average percentage of cardiac output participating in gas exchange is 35% in the nondependent lung and 55% in the dependent lung.

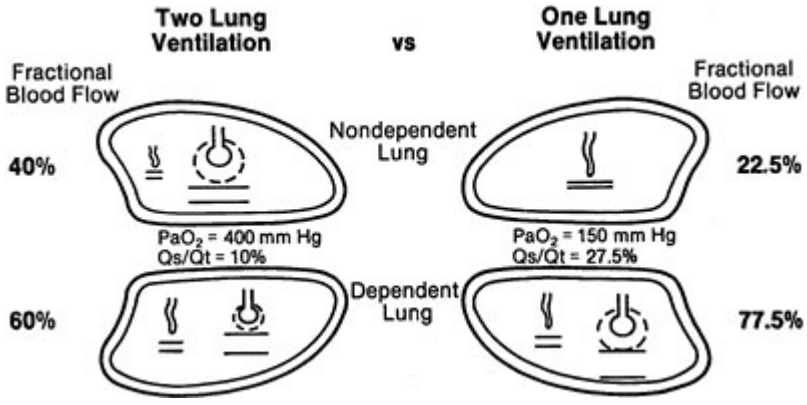

FIGURE 29-10. Schematic representation of two-lung ventilation versus one-lung ventilation (OLV). Typical values for fractional blood flow to the nondependent and dependent lungs, as well as PaO_2 and

$\dot{Q}$

s/

t for the two conditions, are shown. The $\frac{\dot{R}}{\dot{Q}}$ s/t during two-lung ventilation is assumed to be distributed equally between the two lungs (5% to each lung). The essential difference between two-lung ventilation and OLV is that, during OLV, the nonventilated lung has some blood flow and therefore an obligatory shunt, which is not present during two-lung ventilation. The 35% of total flow perfusing the nondependent lung, which was not shunt flow, was assumed to be able to reduce its blood flow by 50% by hypoxic pulmonary vasoconstriction. The increase in $\frac{\dot{Q}}{\dot{R}}$ s/t from two-lung to OLV is assumed to be due solely to the increase in blood flow through the nonventilated, nondependent lung during OLV. (From Benumof JL: Anesthesia for Thoracic Surgery, p 112. Philadelphia, WB Saunders, 1987.)

OLV creates an obligatory right-to-left transpulmonary shunt through the nonventilated, nondependent lung because the V/Q ratio of that lung is zero. In theory, an additional 35% should be added to the total shunt during OLV. However, assuming active HPV, blood flow to the nondependent hypoxic lung will be decreased by 50% and therefore is (35/2) = 17.5%. To this, 5% must be added, which is the obligatory shunt through the nondependent lung. The shunt through the nondependent lung is therefore 22.5% (see Fig. 29-10). Together with the 5% shunt in the dependent lung, total shunt during OLV is 22.5% + 5% = 27.5%. This results in a PaO_2 of approximately 150 mm Hg (FIO_2 = 1.0).[39]

Because 72.5% of the perfusion is directed to the dependent lung during OLV, the matching of ventilation in this lung

is important for adequate gas exchange. The dependent lung is no longer on the steep (compliant) portion of the volume-pressure curve because of reduced lung volume and FRC. There are several reasons for this reduction in FRC, including general anesthesia, paralysis, pressure from abdominal contents, compression by the weight of mediastinal structures, and suboptimal positioning on the operating table. Other considerations that impair optimal ventilation to the dependent lung include absorption atelectasis, accumulation of secretions, and the formation of a fluid transudate in the dependent lung. All these create a low V/Q ratio and a large $P(A\text{-}a)O_2$ gradient.

ONE-LUNG VENTILATION

Absolute Indications for one-Lung Ventilation

Separation of the lungs to prevent spillage of pus or blood from an infected or bleeding source is an absolute indication for OLV (Table 29-1). Life-threatening complications, such as massive atelectasis, sepsis, and pneumonia, can result from bilateral contamination. Bronchopleural and bronchocutaneous fistulae both represent low-resistance pathways for the VT delivered by positive-pressure ventilation, and both prevent adequate alveolar ventilation. Giant cysts or unilateral bullae may rupture under positive-pressure ventilation. This can be avoided by selective lung ventilation. During bronchopulmonary lavage, an effective separation of the lungs is mandatory to avoid accidental spillage of fluid from the lavaged lung to the nondependent ventilated lung. Video-assisted thoracoscopic surgery (VATS) requires lung separation and is becoming the most common indication for OLV. Finally, minimally invasive cardiac procedures

require the lung to be collapsed.

TABLE 29-1 Indications For One-Lung Ventilation

▪ABSOLUTE

1. Isolation of each lung to prevent contamination of a healthy lung
   a. Infection (abscess, infected cyst)
   b. Massive hemorrhage
2. Control of distribution of ventilation to only one lung
   a. Bronchopleural fistula
   b. Bronchopleural cutaneous fistula
   c. Unilateral cyst or bullae
   d. Major bronchial disruption or trauma
3. Unilateral lung lavage
4. Video-assisted thoracoscopic surgery

▪RELATIVE

1. Surgical exposure—high priority
   a. Thoracic aortic aneurysm
   b. Pneumonectomy
   c. Upper lobectomy
2. Surgical exposure—low priority
   a. Esophageal surgery
   b. Middle and lower lobectomy
   c. Thoracoscopy under general anesthesia

Modified from Benumof JL: Physiology of the open-chest and one lung ventilation. In Kaplan JA (ed): Thoracic Anesthesia, p 299. New York, Churchill Livingstone, 1983.

Relative Indications for one-Lung Ventilation

4 In clinical practice, a DLT is commonly used for a lobectomy or pneumonectomy; these represent relative indications for lung separation. Upper lobectomy, pneumonectomy, and thoracic aortic aneurysm repair are relatively high-priority indications. These procedures are technically difficult, and optimal surgical exposure and a quiet operative field are highly desirable. Lower or middle lobectomy and esophageal resection are of lower priority. Nevertheless, many surgeons are accustomed to operating with the lung collapsed, which minimizes lung trauma from retractors and manipulation, improves visualization of lung anatomy, and facilitates identification and separation of anatomic structures and lung fissures. Thoracoscopy, if not performed with an intercostal block in the spontaneously breathing patient, is greatly facilitated by collapse of the lung under examination.

Methods of Lung Separation

Bronchial Blockers

Bronchial Blocker. Lung separation can be achieved with a reusable bronchial blocker. Magill described an endobronchial blocker that is placed using a bronchoscope and directed to the

nonventilated lung. Inflation of the cuff at the distal end of the blocker serves to block ventilation to that lung. The lumen of the blocker permits suctioning of the airway distal to the catheter tip. Depending on the clinical circumstance, oxygen can be insufflated through the catheter lumen. A conventional endotracheal tube is then placed in the trachea. This technique can be useful in achieving selective ventilation in children younger than 12 years of age. However, because the blocker balloon requires a high distending pressure, it easily slips out of the bronchus into the trachea, obstructing ventilation and losing the seal between the two lungs. This displacement can be secondary to changes in position or to surgical manipulation. The loss of lung separation can be a life-threatening situation if it was performed to prevent spillage of pus, blood, or fluid from bronchopulmonary lavage. For this reason, bronchial blockers are rarely used in current practice.

Arterial Embolectomy (Fogarty) Catheter. Selective airway occlusion can be achieved by the use of a Fogarty catheter designed for embolectomy procedures (Fig. 29-11). Placement of the embolectomy catheter is best performed under direct vision with the aid of a fiberoptic bronchoscope. A conventional endotracheal tube is then placed alongside the catheter after withdrawing the bronchoscope. Alternatively, the bronchial blocker may be inserted through the lumen of a standard tracheal tube if the rubber diaphragm in a swivel connector is first perforated for passage of the blocker. The swivel connector is then placed between the tracheal tube and the Y-piece of the breathing circuit. A fiberscope can be inserted through the lumen of the tracheal tube to facilitate positioning of the blocker under direct vision.

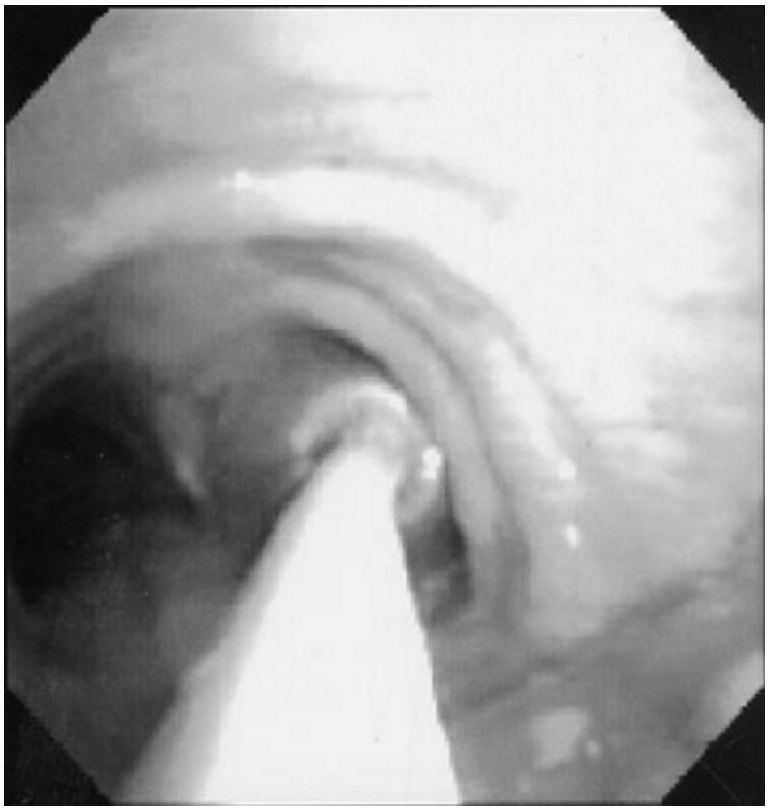

FIGURE 29-11. Use of a Fogarty catheter to block the right main-stem bronchus.

Univent Tube. The Univent (Fuji Systems Corp., Tokyo, Japan) is a single-lumen endotracheal tube with a movable endobronchial blocker (Fig. 29-12). In the Univent tube, the bronchial blocker is housed in a small channel bored in the wall of the tube. After intubation of the trachea, the movable blocker is manipulated into the desired main-stem bronchus with the aid of a fiberoptic bronchoscope.[40] Disadvantages of the Univent tube are that correct positioning of the blocker may be difficult to achieve or maintain. The Univent tube may be ideal for cases in which a tube change (e.g., from single to double lumen) may be difficult (e.g., mediastinoscopy followed by thoracotomy), or in cases of bilateral lung transplantation. The Univent tube has the advantage

blockers: it is a single-lumen tube, and there is no need to change the tube at the end of the procedure if postoperative ventilatory support is required. This is particularly important in cases of difficult intubation, prolonged surgery with airway edema, such as thoracic aortic aneurysm surgery or extensive neurosurgical procedures on the spine with massive fluid replacement, and altered anatomy of the airway. It is also possible to suction through the blocker lumen or to apply continuous positive airway pressure (CPAP) to improve oxygenation in cases of hypoxemia.

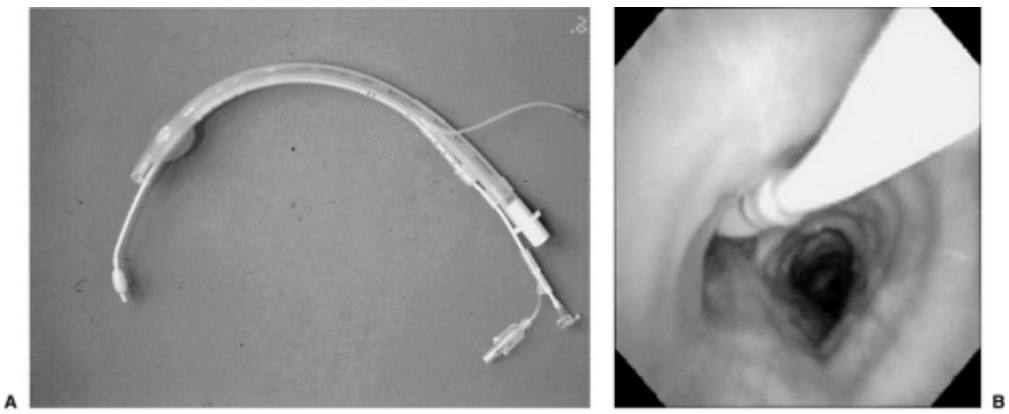

FIGURE 29-12. A. The Univent tube also allows lung separation using a single-lumen endotracheal tube. **B.** The Univent bronchial blocker positioned in left main-stem bronchus.

The disadvantages of the Univent tubes are that the external diameter is relatively large, the blocker can dislocate during surgical manipulation, and satisfactory bronchial seal and lung separation are sometimes difficult to achieve. The bronchial blocker is somewhat stiff and sometimes will not easily be directed into the main bronchus. This is particularly true for the left side. The bulky external diameter can also make it difficult to pass the tube between the vocal cords.

The first-generation Univent tube's bronchial blocker was difficult to direct into the selected main bronchus. The blocker would spin (torque) on its long axis, which made it difficult to control. The second generation, the Torque Control Blocker (TCB) Univent, was more recently introduced. It consists of a silicon endotracheal tube that has a high friction coefficient. The TCB provides better control, which facilitates direction of the blocker into the target main-stem bronchus.

Double-Lumen Endobronchial Tubes

Double-lumen endobronchial tubes are currently the most widely used means of achieving lung separation and OLV. There are several different types of DLT, but all are essentially similar in design in that two catheters are bonded together. One lumen is long enough to reach a main-stem bronchus, and the second lumen ends with an opening in the distal trachea. Lung separation is achieved by inflation of two cuffs: a proximal tracheal cuff, and a distal bronchial cuff located in the main-stem bronchus (see Positioning Double-Lumen Tubes section). The endobronchial cuff of a right-sided tube is slotted or otherwise designed to allow ventilation of the right upper lobe because the right main-stem bronchus is too short to accommodate both the right lumen tip and a right bronchial cuff.

Robertshaw Tube. The Carlens tube (which had a carinal hook) was the first clinically available DLT and was used by pulmonologists for split function spirometry testing (Fig. 29-13A). Subsequently, the Robertshaw design DLT (which lacked a carinal hook) was developed to

facilitate thoracic surgery (Fig. 29-13B). This DLT is available in left-sided and right-sided forms. The absence of a carinal hook facilitates insertion. This tube design has the advantages of having D-shaped, large-diameter lumens that allow easy passage of a suction catheter, offer low resistance to gas flow, and have a fixed curvature to facilitate proper positioning and reduce the possibility of kinking. The original red rubber Robertshaw tubes were available in three sizes: small, medium, and large. Red rubber tubes are rarely used now and have been replaced by clear, polyvinyl chloride (PVC) disposable Robertshaw-design DLTs. These are available in both right-sided and left-sided versions and in 35F,

37F, 39F, and 41F. A 28F is available for use in pediatric cases. The advantages of the disposable tubes include relative ease of insertion and proper positioning, easy recognition of the blue color of the endobronchial cuff when fiberoptic bronchoscopy is used, confirmation of position on a chest radiograph using the radiopaque lines in the wall of the tube, and continuous observation of tidal gas exchange and respiratory moisture through the clear plastic. The right-sided endobronchial tube is designed to minimize occlusion of the opening of the right upper lobe bronchus. The right endobronchial cuff is doughnut-shaped and allows the right upper lobe ventilation slot to ride over the opening of the right upper lobe bronchus. The tube is also suitable for use in long-term ventilation in the intensive care unit because it has a high-volume, low-pressure cuff. These disposable PVC tubes are generally considered the tubes of choice for achieving lung separation and OLV.[41]

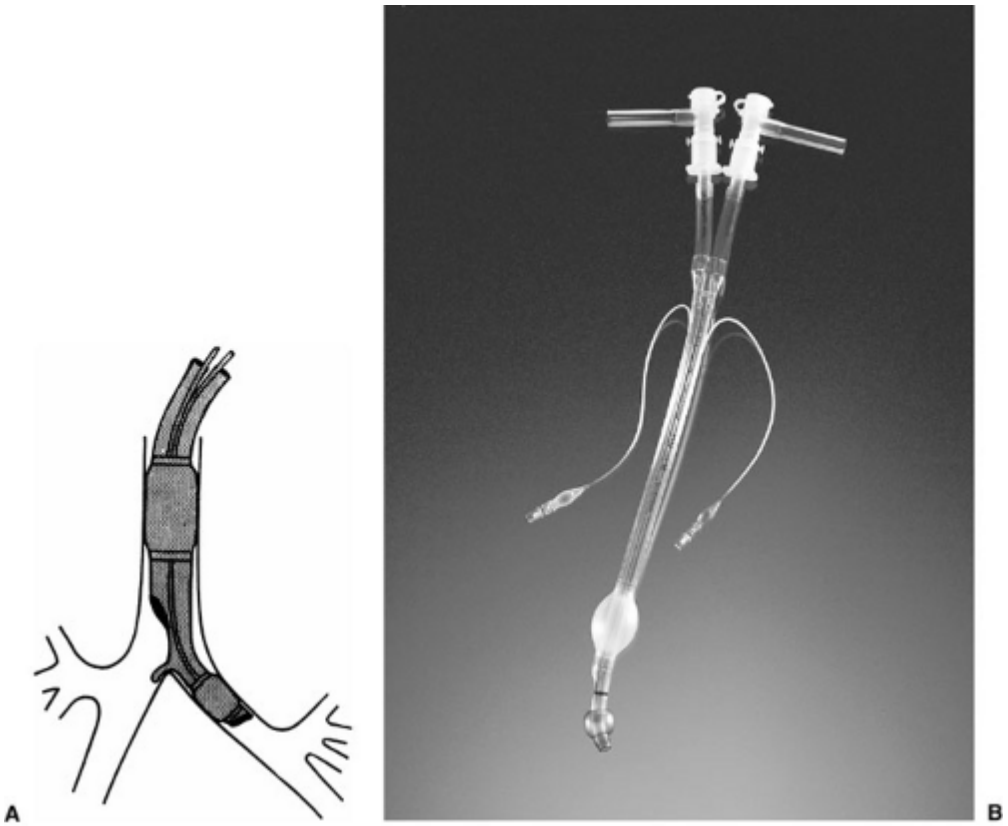

FIGURE 29-13. A. Left main-stem endobronchial intubation using a Carlens tube. Note carinal "hook" used for correct positioning. **B.** A left-sided Robertshaw type double-lumen tube constructed from PVC. (A: From Hillard EK, Thompson PW: Instruments used in thoracic anaesthesia. In Mushin WW [ed]: Thoracic Anaesthesia, p 315. Oxford, Blackwell Scientific, 1963. B: Courtesy of Nellcor Puritan Bennett, Inc., Pleasanton, California.)

Positioning Double-Lumen Tubes. This section concentrates on the insertion of Robertshaw-design DLTs (both disposable and nondisposable) because they are the most widely used. Before insertion, the DLT should be prepared and checked. The tracheal cuff (high-volume, low-pressure)

can accommodate up to 20 mL of air, and the bronchial cuff should be checked using a 3-mL syringe. The tube should be coated liberally with water-soluble lubricant, and the stylet should be withdrawn, lubricated, and gently placed back into the bronchial lumen without disturbing the tube's preformed curvature. The Macintosh 3 blade is preferred for intubation of the trachea because it provides the largest area through which to pass the tube. The insertion of the tube is performed with the distal concave curvature facing anteriorly. After the tip of the tube is past the vocal cords, the stylet is removed and the tube is rotated through 90 degrees. A left-sided tube is rotated 90 degrees to the left, and a right-sided tube is rotated to the right. Advancement of the tube ceases when moderate resistance to further passage is encountered, indicating that the tube tip has been firmly seated in the main-stem bronchus. It is important to remove the stylet before rotating and advancing the tube to avoid tracheal or bronchial laceration. Rotation and advancement of the tube should be performed gently and under continuous direct laryngoscopy to prevent hypopharyngeal structures from interfering with proper positioning. Once the tube is believed to be in the proper position, a sequence of steps should be performed to check its location.

First, the tracheal cuff should be inflated, and equal ventilation of both lungs established. If breath sounds are not equal, the tube is probably too far down, and the tracheal lumen opening is in a main-stem bronchus or is lying at the carina. Withdrawal of the tube by 2 to 3 cm usually restores equal breath sounds. The second step is to clamp the right side (in the case of the left-sided tube) and remove the right cap from the connector. Then, the bronchial cuff is slowly inflated to prevent an air leak from the bronchial lumen around the bronchial cuff into the tracheal lumen. This ensures excessive pressure is not applied to the bronchus and helps avoid laceration. Inflation of the bronchial cuff rarely requires more than 2 mL of air. The third step is to remove the clamp and check that both lungs are

ventilated with both cuffs inflated. This ensures the bronchial cuff is not obstructing the contralateral hemithorax, either totally or partially. The final step is to clamp each side selectively and watch for absence of movement and breath sounds on the ipsilateral (clamped) side; the ventilated side should have clear breath sounds, chest movement that feels compliant, respiratory gas moisture with each tidal ventilation, and no gas leak. If peak airway pressure during two-lung ventilation is 20 cm H_2O, it should not exceed 40 cm H_2O for the same VT during OLV.

Other methods that have been used for ensuring the correct placement of a DLT include fluoroscopy, chest radiography, selective capnography, and use of an underwater seal. Determination of the presence of gas leaks when positive pressure is applied to one lumen of a DLT is easily done in the operating room. If the bronchial cuff is not inflated and positive pressure is applied to the bronchial lumen of the DLT, gas leaks past the bronchial cuff and returns through the tracheal lumen. If the tracheal lumen is connected to an underwater seal system, gas will be seen to bubble up through the water. The bronchial cuff can then be gradually inflated until no gas bubbles are seen and the desired cuff seal pressure can be attained. This test is of extreme importance when absolute lung separation is needed, such as during bronchopulmonary lavage.

5 The most important advance in checking for proper position of a DLT is the introduction of the pediatric flexible fiberoptic bronchoscope (Fig. 29-14). Smith et al.[42] showed that when the disposable DLT was believed to be in correct position by auscultation and physical examination, subsequent fiberoptic bronchoscopy showed that 48% of tubes were, in fact, malpositioned. Such malpositions, however, are usually of no clinical significance.[43] When using a left-sided DLT, the bronchoscope is usually first introduced through the tracheal lumen. The carina is visualized, but no bronchial cuff herniation should be seen. The upper surface of the blue endobronchial cuff should be just below the tracheal carina. The bronchial cuff of the disposable DLT is easily visualized because of its blue color. The bronchoscope should then be passed through the bronchial lumen, and the left upper lobe bronchial orifice should be identified. When a right-sided DLT is used, the carina should be visualized through the tracheal lumen but, more important, the orifice of the right upper lobe bronchus should be identified when the bronchoscope is passed through the right upper lobe ventilating slot of the DLT. Pediatric fiberoptic bronchoscopes are available in several sizes: 5.6, 4.9, and 3.6 mm in external diameter. The 4.9-

mm diameter bronchoscope can be passed through DLTs of 37F and larger. The 3.6-mm diameter bronchoscope is easily passed through all sizes of DLT. In general, it is recommended that the largest size that can pass through the lumen of a DLT be used because it provides better visualization and facilitates identification of the bronchial anatomy.

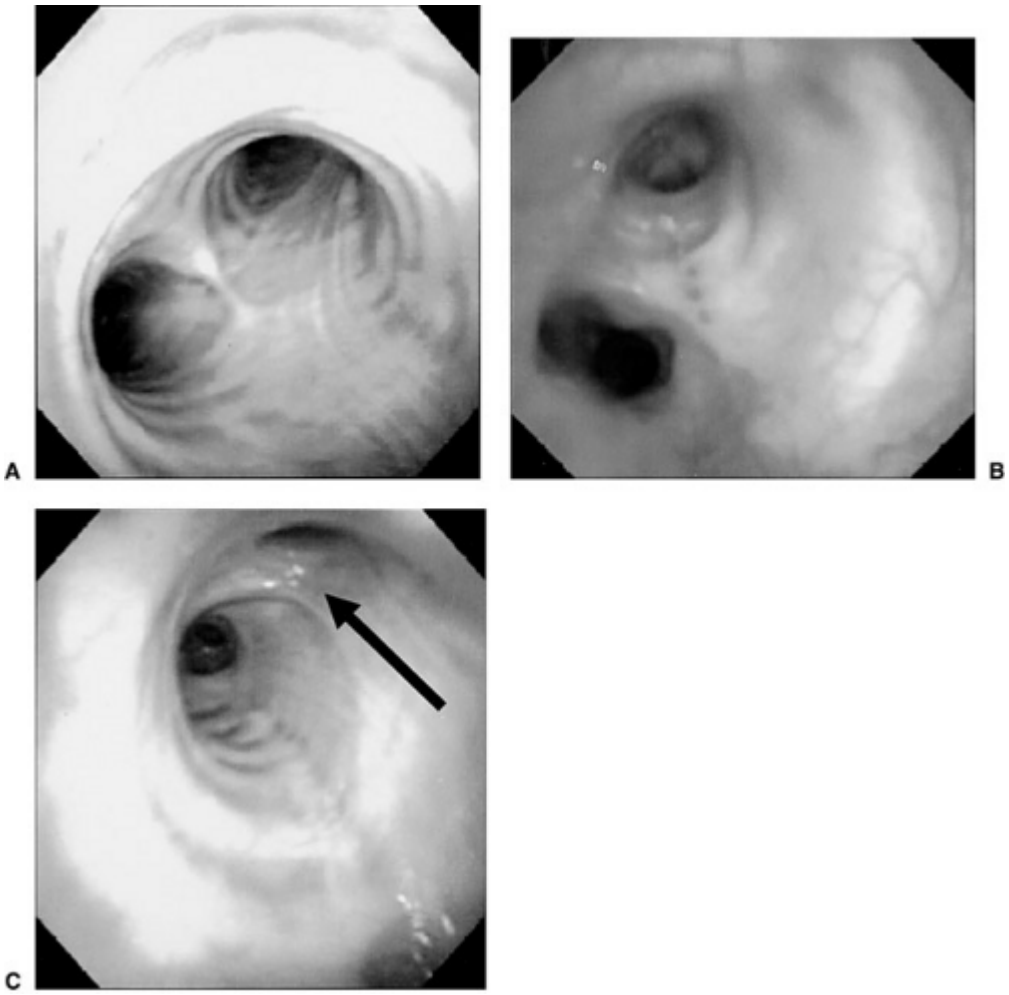

FIGURE 29-14. Fiberoptic bronchoscopic view of the main carina **(A)**, the "left bronchial carina" **(B)**, and the right bronchus **(C)** Note right upper lobe orifice *(arrow)*.

Problems of Malposition of the Double-Lumen Tube. The use of a DLT is associated with a number of potential problems, the most important of which is malposition. There are several

possibilities for tube malposition. The DLT may be accidentally directed to the side opposite the desired main-stem bronchus. In this case, the lung opposite the side of the connector clamp will collapse. Inadequate separation, increased airway pressures, and instability of the DLT usually occur. In addition, because of the morphology of the DLT curvatures, tracheal or bronchial lacerations may result. If a left-sided DLT is inserted into the right main-stem bronchus, it obstructs ventilation to the right upper lobe. It is therefore essential to recognize and correct such a malposition as soon as possible.

Second, the DLT may be passed too far down into either the right or the left main-stem bronchus (Fig. 29-15). In this case, breath sounds are very diminished or not audible over the contralateral side. This situation is corrected when the tube is withdrawn and until the opening of the tracheal lumen is above the carina.

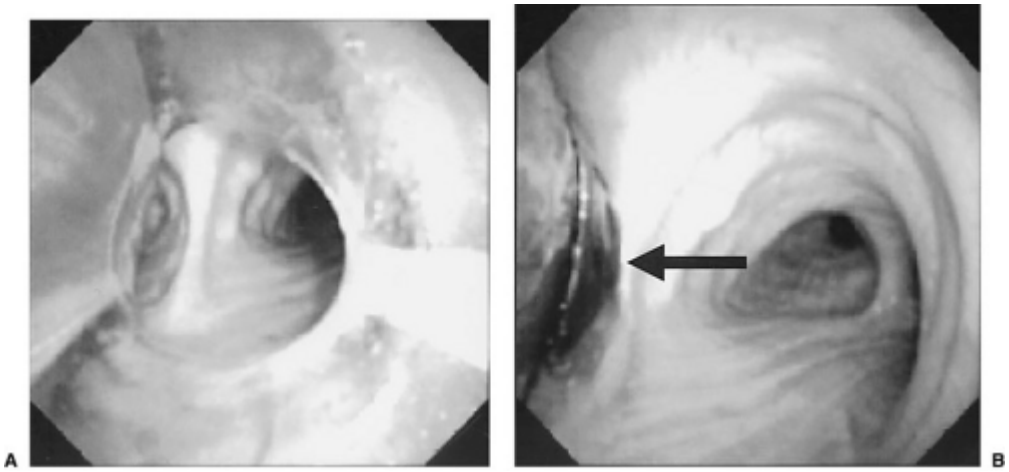

FIGURE 29-15. Malposition of the left bronchial limb of the double-lumen tube (DLT). **A.** The limb is too far into the left bronchus because the cuff if not evident. **B.** DLT withdrawn and balloon is now in view, indicating appropriate position of the DLT.

Third, the DLT may not be inserted far enough, leaving the bronchial lumen opening above the carina. In this position, good breath sounds are heard bilaterally when ventilating through the bronchial lumen, but no breath sounds are audible when ventilating through the tracheal lumen because the inflated bronchial cuff obstructs gas flow arising from the tracheal lumen. The cuff should be deflated and the DLT rotated and advanced into the desired main-stem bronchus.

Fourth, a right-sided DLT may occlude the right upper lobe orifice. The mean distance from the carina to the right upper lobe orifice is 2.3 ± 0.7 cm in men and 2.1 ± 0.7 cm in women.[44] With right-sided DLTs, the ventilatory slot in the side of the bronchial catheter must overlie the right upper lobe orifice to permit ventilation of this lobe. The margin of safety, however, is extremely small, and varies from 1 to 8 mm.[44] It is, therefore, difficult to ensure proper ventilation to the right upper lobe and avoid dislocation of the DLT during surgical manipulation. When right endobronchial intubation is required, a disposable right-sided DLT is perhaps the best choice because of the slanted doughnut shape of the bronchial cuff, which allows the ventilation slot to ride off the right upper lobe ventilation orifice and increases the margin of safety.

Fifth, the left upper lobe orifice may be obstructed by a left-sided DLT. Traditionally, it was believed the take-off of the left upper lobe bronchus was at a safe distance from the carina and that it would not be obstructed by a left-sided DLT. However, the mean distance between the left upper lobe orifice and the carina is 5.4 ± 0.7 cm in men and 5.0 ± 0.7 cm in women.[44] The average distance between the openings of the right and left lumens on the left-sided disposable tubes is 6.9 cm.[44] Therefore, an obstruction of the left upper lobe bronchus is possible while the tracheal lumen is still above the carina. There is also a 20% variation in the location of the blue endobronchial cuff on the disposable tubes because this cuff is attached to the tube at the end of the manufacturing process.

Finally, bronchial cuff herniation may occur and obstruct the bronchial lumen if excessive volumes are used to inflate the cuff. The bronchial cuff has also been known to herniate over the tracheal carina, and in the case of a left-sided DLT, to obstruct ventilation to the right main-stem bronchus.

Another rare complication with DLTs is tracheal rupture. Overinflation of the bronchial cuff, inappropriate positioning, and trauma owing to intraoperative dislocation that resulted in bronchial rupture have been described in association with the Robertshaw tube and the disposable DLT.[45] Therefore, the pressure in the bronchial cuff should be assessed and decreased if the cuff is found to be overinflated. If absolute separation of the lungs is not needed, the bronchial cuff should be

deflated and then reinflated slowly to avoid excessive pressure on the bronchial walls. The bronchial cuff should also be deflated during any repositioning of the patient unless lung separation is absolutely required during this time.

Lung Separation in the Patient with a Tracheostomy

Occasionally, a patient with a permanent tracheotomy is scheduled for surgery on the lung that requires isolation. Examples of such patients include those who have undergone resection of a tumor in the floor of the mouth or on the base of the tongue, followed by extensive reconstructive surgery with creation of a permanent tracheal stoma. Routine follow-up may

reveal a lung lesion that requires a diagnostic procedure. Conventional double-lumen endobronchial tubes are designed to be inserted through the mouth, not through a tracheal stoma. The standard DLTs are usually too stiff to negotiate the curve required for insertion through a tracheal stoma and are difficult to position.[46]

A separately inserted bronchial blocker, either within or alongside a single-lumen tube that has been placed through the tracheostomy, may permit adequate lung separation.[47] Compared with an orotracheal or nasotracheal single-lumen tube, passing a Fogarty catheter (to function as a bronchial blocker) through a tracheostomy into a main-stem bronchus may be easier because of the shorter distances involved.

Saito et al.[48] described a spiral, wire-reinforced, double-lumen endobronchial tube made of silicone (Koken Medical, Tokyo, Japan) that is designed for placement through a tracheostomy. The middle section of the tube consists of two thin-walled silicone catheters with an internal diameter of 5 mm, glued together and reinforced with a stainless steel spiral wire and covered with a silicone coating with two pilot balloons. The distal section, which contains the bronchial lumen and the bronchial cuff, is made of wire-reinforced silicone to avoid excessive flexibility. The dimensions are based on the Mallinckrodt DLT. The bronchial cuff is located 1.2 cm from the tip, and the distance between the tip orifice and the tracheal orifice is 4.9 cm. In a clinical trial in patients with permanent tracheal stomas, the tubes functioned well in achieving lung separation, with no sign of kinking or movement, and permitted easy passage of a suction catheter.

Lung Separation in the Patient with a Difficult Airway

An airway may be recognized initially as difficult when conventional laryngoscopy reveals a grade III or IV view. When separation of the lungs is required and the patient has a clearly recognized difficult airway, then awake intubation using a flexible fiberoptic bronchoscope can be planned to place a double-lumen, Univent, or single-lumen tube. The single-lumen tube may then be exchanged for a double-lumen or Univent tube using a tube exchanger plus laryngoscopy, or a Fogarty embolectomy catheter may be passed through the lumen of the single-lumen tube to act as an independent bronchial blocker. Furthermore, depending on the expected extent and the duration of the surgical procedure and the degree of fluid shift, an airway not initially classified as difficult may become difficult secondary to facial edema, secretions, and laryngeal trauma from the initial intubation.[49,50]

A logical approach to lung separation is shown in Fig. 29-16. When lung separation is mandated and the patient has a recognized difficult airway, awake intubation using flexible fiberoptic bronchoscopy can be attempted using a DLT, Univent, or single-lumen tube. The same approach may be used for the patient with an unrecognized difficult airway and a failure to intubate with conventional laryngoscopy. When using a DLT over a fiberoptic bronchoscope, the anesthesiologist should keep in mind that it is a bulky tube with a large external diameter, and because of the length of the DLT, only a limited part of the fiberoptic bronchoscope is available for manipulation. In addition, the mismatch between the flexibility of the fiberoptic bronchoscope and the rigidity of the DLT makes it harder to advance over the fiberoptic bronchoscope. The Univent tube has the same bulky external diameter and is also often difficult to pass between the vocal cords, particularly in a patient who is awake.

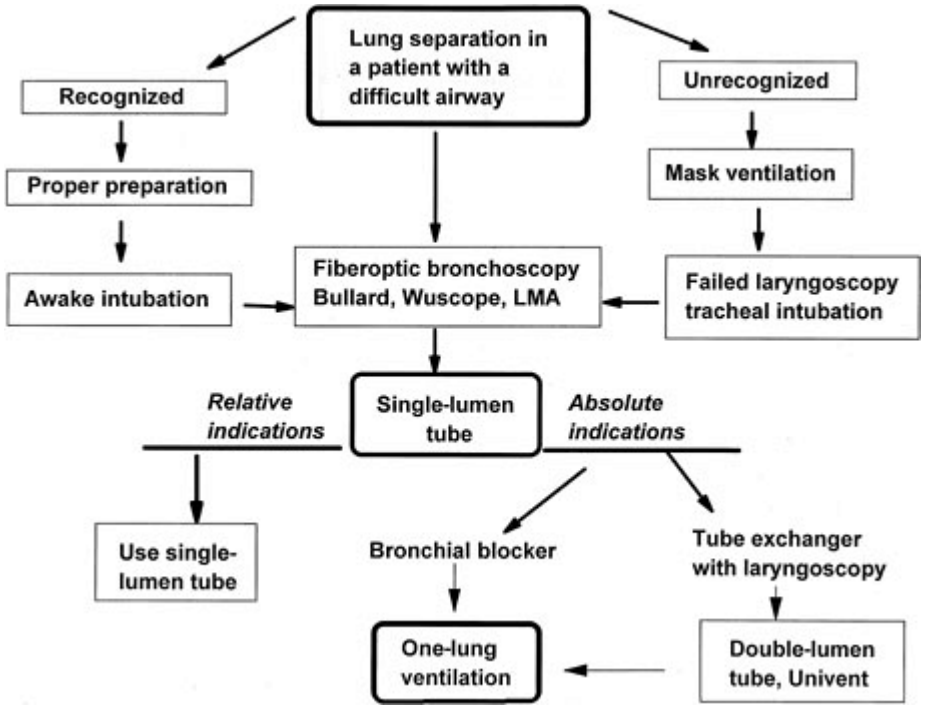

FIGURE 29-16. Lung separation in a patient with a difficult airway. (Adapted from Cohed E, Benumot JL. Lung separation in the patient with a difficult airway. Curr Opin Anesthesiol 12:1, 29–35, 1999.)

Single-Lumen Tube Can Be Successfully Placed. If a failure to provide lung separation could result in a life-threatening situation, there are two possibilities to provide OLV when a single-lumen tube is already in place. First, depending on the indication for lung isolation, a tube exchanger can be used to switch to a DLT or a Univent tube. The second possibility is to direct a bronchial blocker through the single-lumen tube into the selected main-stem bronchus. These two methods, however, offer limited protection or an inadequate seal in cases such a lung lavage, pulmonary abscess, or hemoptysis, where a DLT would be the tube of choice.

Use of a Tube Exchanger. Several tube exchangers are commercially available (Cook Critical Care, Bloomington, IN; Sheridan Catheter Corporation, Argyle, NY). On these tube exchangers, the depth is marked in centimeters, and they are available in a wide range of external diameters and easily adapted for either oxygen insufflation or jet ventilation. The size of the tube exchanger and the size of the tube to be inserted should be tested before use in a patient. The 11F tube changer will pass through a 35 to 41F DLT, whereas the 14F tube exchanger does not pass through a 35F. To prevent lung laceration, the tube exchanger should never be inserted against resistance. Finally, when passing any tube over an airway guide, a laryngoscope

should be used to facilitate passage of the tube over the airway guide past supraglottic tissues.

Use of Modern Bronchial Blockers. The use of a bronchial blocker is discussed earlier in this chapter. An independently passed bronchial blocker may be used with a single-lumen tube to obtain lung isolation, thereby avoiding the use of a double-lumen or Univent tube in a patient with a difficult airway. The most commonly used independent bronchial blocker was a number 7.0 Fogarty embolectomy catheter, which has an occlusion balloon that can range in volume from 5.0 to 8.0 mL (see Fig. 29-11). The balloon should be inflated to a volume sufficient to occlude the lumen of the main-stem bronchus and to hold the catheter in place. The fiberoptic bronchoscope is passed through a bronchoscopy elbow, down a single-lumen tube to visualize the carina, and past the Fogarty balloon-tipped catheter into the appropriate main-stem bronchus. The

Fogarty catheter is supplied with a wire stylet in place, which can be curved at the distal end to

facilitate passage through the bronchoscopy elbow and down the single-lumen tube. The catheter balloon is then inflated under direct vision using the bronchoscope, with enough volume to occlude the main bronchus. The balloon of the Fogarty catheter is a high-pressure, low-volume design and can exert significant pressure on the mucosa of the bronchial wall.

Drawbacks to the use of the Fogarty catheter as a bronchial blocker include difficulty in directing the blocker into the desired bronchus, even with help of a fiberscope, and the inability to effectively suction the airway distal to the blocker. Also, during the surgical manipulation, the blocker may slip into the trachea, resulting in life-threatening acute airway obstruction.

The Arndt Endobronchial Blocker. In an attempt to overcome the potential problems described previously, a snare-guided bronchial blocker has been introduced (Cook Critical Care, Bloomington, IN) (Fig. 29-17). A fiberscope is passed through the loop of the bronchial blocker and then guided into the desired bronchus. The blocker is then slid distally over the fiberscope and into the selected bronchus. Bronchoscopic visualization confirms blocker placement and bronchial occlusion. The string (snare) is then removed through the blocker and the 1.8-mm diameter lumen may then be used as a suction port or for insufflation of oxygen. Disadvantages of the Arndt blocker are its high cost and the inability to reinsert the snare (string) once it has been pulled out, making it impossible to redirect the blocker should this become necessary. Finally, the external diameter is somewhat larger, which requires it to be passed through a single-lumen tube of at least 7.5 to 8.0 mm in internal diameter. In a more recent study, the effectiveness of these devices to provide lung isolation during elective thoracic procedures was evaluated. A left-sided double-lumen tube (Mallinckrodt Medical, Tyco.) was compared with the Fogarty catheter and the wired-snare Arndt blocker. The study found that the Arndt blocker took longer to position and, because of the limited size of the suction lumen, lung deflation took longer even with application of suction. It is important that time needed to position and to collapse the lung should be evaluated. Although the additional 5 minutes to deflate the lung may be statistically significant, it is of little clinical significance. Once the lung was collapsed, the management was similar in all three groups.[51]

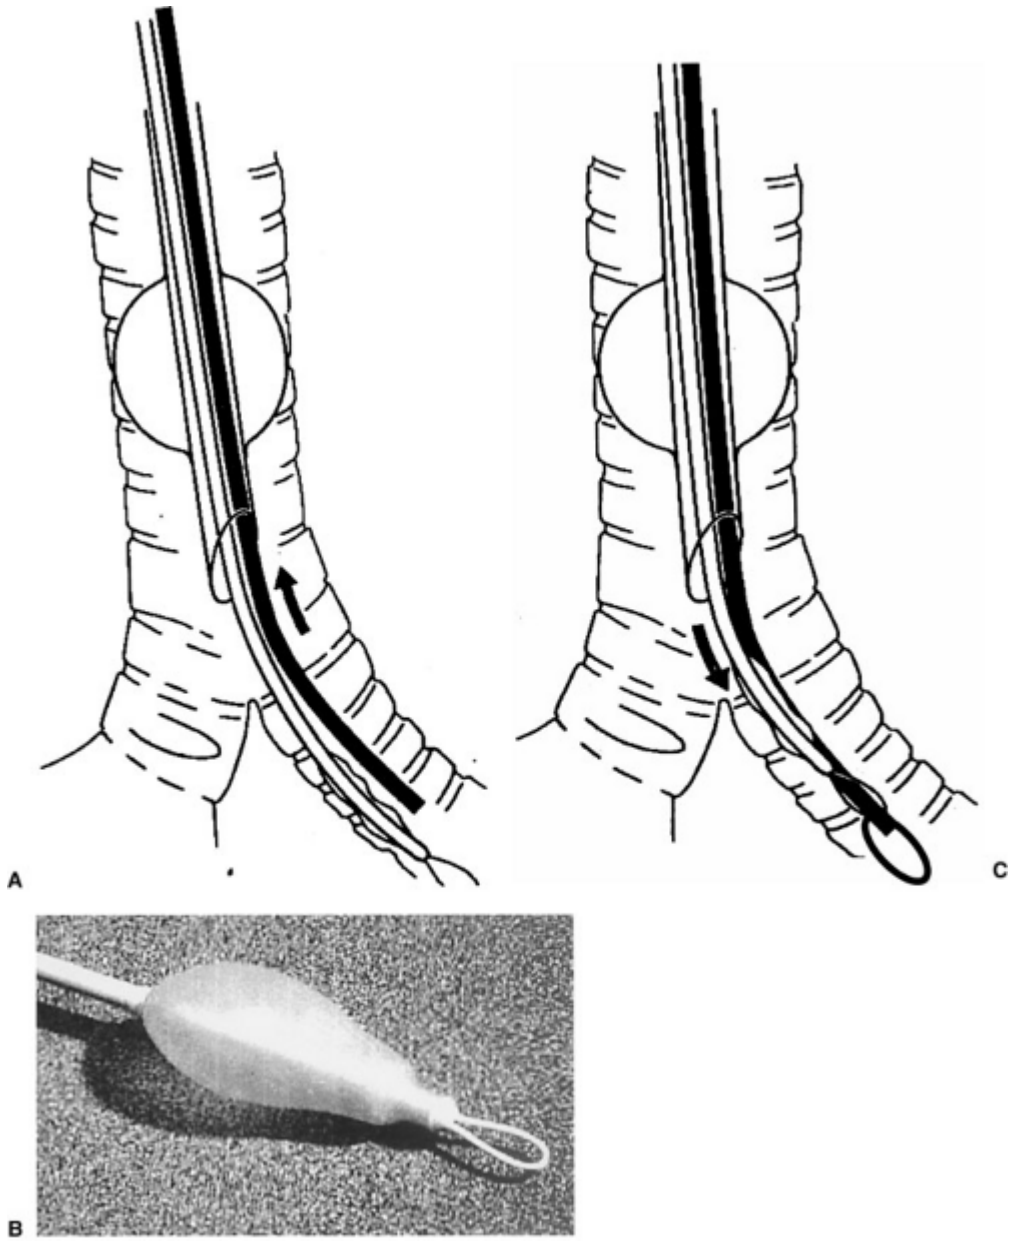

FIGURE 29-17. The Arndt endobronchial blocker is a wire-guided blocker that allows a direct placement with the use of a fiberoptic bronchoscope. The fiberoptic bronchoscope is inserted through the wire loop at the tip of the blocker, which is then slid over the bronchoscope into the selected bronchus. **A.** The fiberoptic bronchoscope is passed through the wire loop and guided into the left main bronchus. **B.** The wire loop at the tip of the blocker with the high-volume, low-pressure cuff. **C.** The bronchoscope is retracted leaving the blocker in place.

The Cohen Flexitip endobronchial blocker is designed for use as an independent bronchial blocker inserted through a single-lumen endotracheal tube with the aid of a small diameter (4.0-mm) fiberoptic bronchoscope (Fig. 29-18). The blocker has a rotating wheel that deflects the soft tip by more than 90 degrees and easily directs it into the desired bronchus. The blocker cuff is a high-volume, low-pressure balloon inflated via 0.4-mm lumen inside the wall of the blocker. It has a pear shape that provides adequate seal of the bronchus. Generally, it takes between 6 and 8 mL of air to seal the bronchus with the cuff. The cuff is a distinctive blue color that is easily recognizable by fiberoptic bronchoscopy. It is best to inflate the cuff under "direct vision" via the fiberoptic bronchoscope. The blocker size is 9F. It has a central main lumen (1.6 mm) that allows limited suctioning of secretions and insufflation of oxygen to the collapsed lung in case of hypoxemia.

Conclusion of the Surgical Procedure

Depending on the extent and the duration of the surgical procedure and the degree of fluid shift, an airway, initially not classified as difficult, may become difficult secondary to facial edema, secretions, and laryngeal trauma from the original intubation. In these cases, when planning to provide lung separation, the postoperative period should be considered and the appropriate tube placed. Many procedures that are not considered to represent absolute indications for lung

separation are lengthy and complex. Complex lung resection, with or without chest wall resection, thoracoabdominal esophagogastrectomy, thoracic aortic aneurysm resection with or without total circulatory arrest, or an extensive vertebral tumor resection, may result in facial edema, secretion, and hemoptysis, requiring postoperative ventilatory support. Other indications for postoperative ventilatory support are marginal respiratory reserve, unexpected blood loss or fluid shift, hypothermia, and inadequate reversal of residual neuromuscular blockade.

If a Univent tube was used to provide OLV, the blocker may be fully retracted and the Univent tube can be used as a single-lumen tube. If an independent bronchial blocker was used, then the blocker is removed, leaving the single-lumen tube in place. The problem arises when a DLT was inserted for lung separation. In a patient with a difficult airway and subsequent facial edema, the DLT may be left in place after surgery.

If the decision to leave the DLT in place is made, it is important to keep in mind that the intensive care unit staff is usually less experienced in managing such a tube, which may easily become dislocated. In addition, it is more difficult to suction through the lumens, and a longer, narrower suction catheter is needed to reach the tip of the endobronchial lumen. Another possibility is to withdraw the DLT to place the 19- to 20-cm mark at the teeth so the endobronchial lumen is above the carina and both lungs can be ventilated via the bronchial lumen. Tracheal extubation from the DLT should be considered after diuresis and steroid therapy to allow reduction of the facial and airway edema.

If it is necessary to change the DLT to a single-lumen tube, a tube exchanger must be used to maintain access to the airway, as previously discussed. Tube exchange may be performed under direct vision using a Bullard or Wu laryngoscope. With these laryngoscopes, the tube exchanger or a stylet can be placed under direct vision through the vocal cords alongside the existing tube to permit passage of a single-lumen tube (Fig. 29-19).

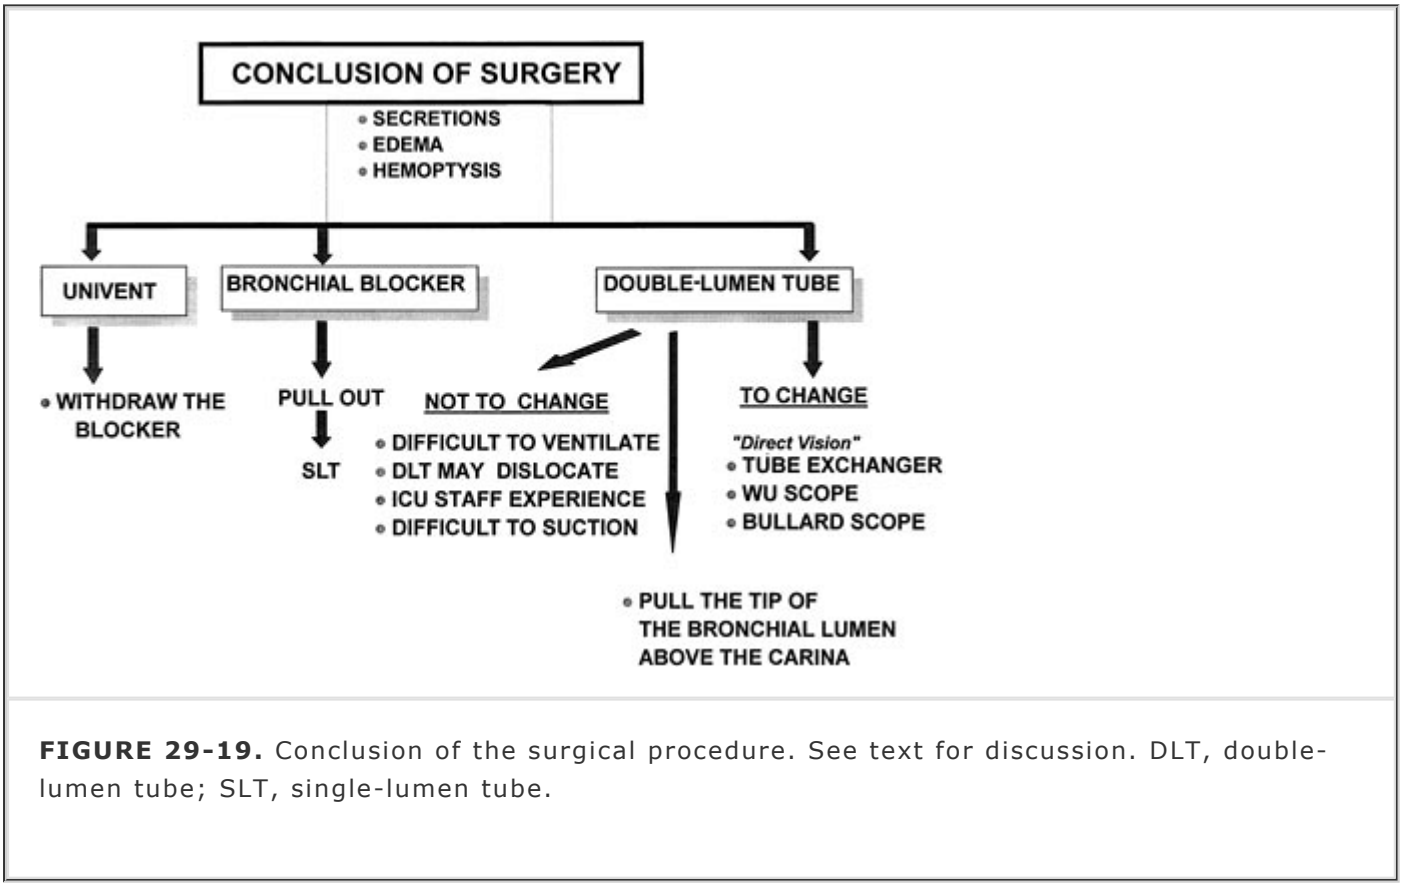

FIGURE 29-19. Conclusion of the surgical procedure. See text for discussion. DLT, double-lumen tube; SLT, single-lumen tube.

In summary, the clinician should be able to master different methods of lung separation and make himself or herself familiar with the devices available to provide OLV. In addition, one should always plan in advance for the postoperative period when choosing the method of lung separation. Finally, in these cases, a close dialog with the surgical team is of vital importance.

MANAGEMENT OF ONE-LUNG VENTILATION

This section discusses the management of OLV in a paralyzed patient in the lateral decubitus position with an open chest. Inspired oxygen fraction (FIO_2), VT and respiratory rate, dependent lung, PEEP, and nondependent lung CPAP are reviewed, and an approach to the management of OLV is presented.

Inspired Oxygen Fraction

An FIO_2 of 1.0 is usually used during OLV. This high oxygen concentration serves to protect against hypoxemia during the procedure. In many studies, an FIO_2 of 1.0 has been used and resulted in a shunt of 25 to 30% and mean PaO_2 values between 150 and 210 mm Hg during OLV.[52] In addition to a higher margin of safety, high FIO_2 values cause vasodilatation of the vessels in the dependent lung, which increases the capability of this lung to accept blood flow redistribution due to

nondependent lung HPV. A high FIO_2 may, however, cause absorption atelectasis and potentially further increase the degree of shunt because of the collapsed alveoli. The risk can be reduced by using a lower FIO_2, by the application of positive-pressure ventilation, or by the use of a high VT and PEEP. Theoretically, a high FIO_2 can also cause lung injury owing to oxygen toxicity, although this complication is unlikely to occur in the time frame of a surgical operation. Lower FIO_2 values (0.25 to 0.50) have also been used, with resulting mean PaO_2 values between 62 and 87 mm Hg.[53,54]

The use of an FIO_2 less than 1.0 during OLV offers the benefits of reducing the risk of absorption atelectasis and may permit use of lower concentrations of potent inhaled anesthetics, which in higher concentrations might be more depressant

to the myocardium, particularly in high-risk patients. An FIO_2 <1.0 may also be indicated in patients with bleomycin toxicity. The combination of N_2O/O_2 with pulse oximetry monitoring may represent an optimal solution in such cases. However, the risk-benefit ratio for each patient should always be carefully considered.

Tidal Volume and Respiratory Rate

6 It was recommended that during OLV, the dependent lung be ventilated with a VT of 10 to 12 mL/kg. Tidal volumes ranging between 8 and 15 mL/kg produced no significant effect on transpulmonary shunt or PaO_2.[55] A VT <8 mL/kg can result in a decrease in FRC and enhanced formation of atelectasis in the dependent lung. A VT >15 mL/kg can increase the pulmonary vascular resistance of the dependent lung (similar to the application of PEEP) and divert blood flow into the nondependent lung. The value of 10 to 12 mL/kg is a middle range between 8 and 15 mL/kg and appears to have the smallest effect on PaO_2 and shunt fraction. In a more recent study, Tugrul et al.[56] compared pressure-controlled ventilation with volume-controlled ventilation. They suggested that pressure control may be preferred for management of OLV because the lower peak airway pressure was associated with perfusion of the dependent lung and less transpulmonary shunt. More recently, there is a trend for clinicians to decrease the VT as necessary to avoid increases in airway pressure, thereby making acute lung injury less likely to occur.

The respiratory rate should be adjusted to maintain a $PaCO_2$ of 35 ± 3 mm Hg. Elimination of CO_2 is usually not a problem during OLV if the DLT is positioned correctly. The shunt during OLV has little influence on $PaCO_2$ values because the arteriovenous PCO_2 difference is normally only 6 mm Hg. Furthermore, CO_2 is 20 times more diffusible than O_2 and will be eliminated faster. It is also important not to hyperventilate the patient's lungs because hypocapnia increases vascular resistance in the dependent lung, inhibits nondependent lung HPV, increases shunt, and decreases PaO_2. Hypocarbia is believed to inhibit HPV secondary to a vasodilator effect. Because hypocarbia can only be achieved by hyperventilating the dependent lung, it raises the mean intra-alveolar

pressure and therefore increases the vascular resistance in that lung. Finally, OLV decreases the deadspace-to-tidal volume (VD/VT) ratio and enhances CO_2 elimination.[57]

Positive End-Expiratory Pressure to the Dependent Lung

The beneficial effect of selective PEEP 10 cm H_2O ($PEEP_{10}$) to the dependent lung is caused by an increased lung volume at end expiration (FRC), which improves the V/Q relationship in the dependent lung. The increase in FRC prevents airway and alveolar closure at end expiration. Therefore, it is not surprising that attempts have been made to improve oxygenation OLV by the application of PEEP to the dependent lung. However, the results were somewhat disappointing. Most of the studies showed either no change in PaO_2, a decrease, or a slight increase in PaO_2,[52,57] probably owing to the PEEP inducing an increase in lung volume that caused compression of the small interalveolar vessels and increased pulmonary vascular resistance. If this increase in resistance is limited to the dependent lung, blood flow can be diverted only to the nondependent (nonventilated) lung, increasing shunt fraction and further decreasing PaO_2.

The studies of PEEP cited previously used an FIO_2 of 1.0 with a mean PaO_2 OLV of between 150 and 200 mm Hg, at which further improvement in PaO_2 is clinically unnecessary. The possibility that the application of PEEP can improve PaO_2 in a diseased dependent lung (low lung volume and low V/Q ratio) with a low PaO_2 (<80 mm Hg) during OLV has been addressed by Cohen et al.[58] They found that application of $PEEP_{10}$ during OLV in patients with a low PaO_2 may increase FRC to normal values, resulting in a lower pulmonary vascular resistance and in an improved V/Q ratio and PaO_2. Presumably, patients with a higher PaO_2 had a dependent lung with an adequate FRC, and the application of PEEP had the negative effect of redistributing blood flow away from the dependent ventilated lung (Fig. 29-20).

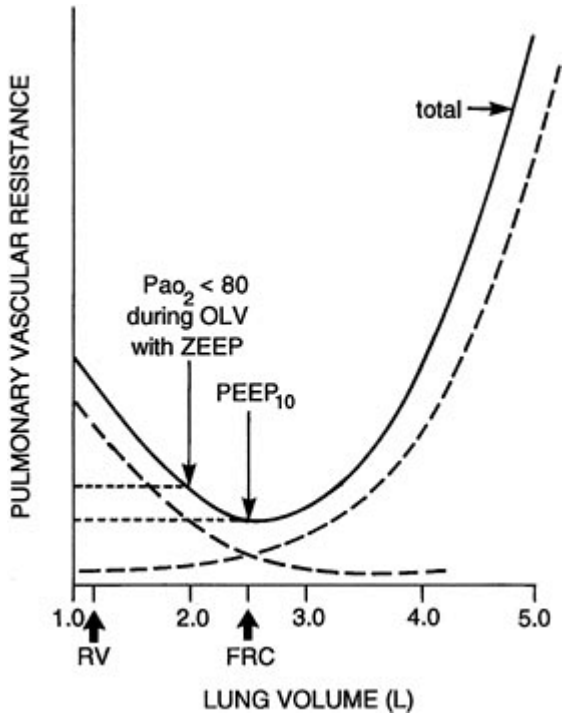

FIGURE 29-20. Effect of 10 cm H_2O PEEP on FRC. It is postulated that, in patients having PaO_2 <80 mm Hg with ZEEP, FRC is low. $PEEP_{10}$ increases FRC and thereby increases PaO_2. $PEEP_{10}$, positive end-expiratory pressure [10 cm H_2O]; OLV, one-lung ventilation; FRC, functional residual capacity; RV, residual volume; ZEEP, zero end-expiratory pressure.

Continuous Positive Airway Pressure to the Nondependent Lung

The single most effective maneuver to increase PaO_2 during OLV is the application of CPAP to the nondependent lung. This has been clearly demonstrated in several studies.[52,54,59] A lower level of CPAP (5 to 10 cm H_2O) maintains the patency of the nondependent lung alveoli, allowing some oxygen uptake to occur in the distended alveoli. CPAP should be applied after delivering an inspiratory VT to the nondependent lung to keep it slightly expanded. CPAP, applied by insufflation of oxygen

under positive pressure, keeps this lung "quiet" and prevents it from collapsing completely. Insufflation of oxygen without maintaining a positive pressure failed to improve PaO_2,[52] although some improvement in PaO_2 occurred after 45 minutes of OLV (from 140 ± 107 to 206 ± 76 mm Hg) with oxygen insufflation only.[60] Intermittent reinflation of the collapsed (nondependent) lung with oxygen also resulted in a significant improvement in PaO_2.[61] The beneficial effects of CPAP 10 cm H_2O ($CPAP_{10}$) are not attributable solely to the effect of positive pressure in diverting blood flow away from the collapsed lung because (in dogs) the hyperinflation of nitrogen into the nondependent lung under 10 cm H_2O failed to improve PaO_2.

The application of high-level CPAP (15 cm H_2O) is not beneficial. At this pressure, the lung becomes overdistended, which interferes with surgical exposure. Also, this level of CPAP might have hemodynamic consequences, whereas $CPAP_{10}$ has been shown to have no significant hemodynamic effects.[54]

CPAP can be applied to the nondependent lung using a number of simple systems, all of which have essentially the same features: an oxygen source, tubing to connect the oxygen source to the nonventilated lung, a pressure relief valve, and a pressure gauge.[5] The catheter to the nondependent lung is usually insufflated with 5 L/min of oxygen using a modified Ayres T-piece (pediatric) circuit, and the valve on the expiratory limb is adjusted to the desired pressure as read on the attached gauge. Instead of a pressure gauge or manometer inserted into the circuit, a weighted pop-off valve, such as a ball or spring-loaded PEEP valve, can be used.

High-frequency ventilation with oxygen to the nondependent lung and conventional ventilation to the dependent lung has also been used to improve PaO_2 during OLV (see High-Frequency Ventilation section).

Clinical Approach to Management of one-Lung Ventilation

Once the patient is in the lateral position, the position of the DLT should be rechecked. Two-lung ventilation should be maintained for as long as possible, and when OLV needs to be instituted, it is generally recommended that an FIO_2 of 1.0 be used. The lung should be ventilated using a VT that results in a plateau airway pressure <25 cm H_2O at a rate adjusted to maintain $PaCO_2$ at 35 ± 3 mm Hg. This is usually monitored with the use of a capnometer or other multigas analyzer.

After initiation of OLV, depending on the lung pathology and the intensity of hypoxic pulmonary vasoconstriction, PaO_2 can continue to decrease for up to 45 minutes.[57] Frequent monitoring of arterial blood gases and use of a pulse oximeter continue throughout the operative period. It is also essential to work closely with the surgeon. If there are any questions concerning the position of the DLT, and if fiberoptic bronchoscopy is not available, the surgeon can palpate the tube and help manipulate it into the correct position with direct digital guidance.

If hypoxemia occurs during OLV, the position of the DLT should be rechecked using a fiberoptic bronchoscope. If the dependent lung is not severely diseased, a satisfactory PaO_2 on two-lung ventilation should not decrease to dangerously hypoxic levels on OLV. If a left thoracotomy is being performed using a right-sided DLT, ventilation to the right upper lobe should be ensured. After the tube position has been confirmed as correct, $CPAP_{10}$ should be applied to the nondependent lung after a VT that expands the lung. In most cases, the PaO_2 increases to a safe level. During thoracoscopy, application of CPAP is usually not possible because it impedes the surgeon. This is especially so during VATS procedures. In this case, PEEP to the ventilated lung may be tried.

In the very rare case in which the PaO_2 remains low despite these maneuvers, intermittent two-

lung ventilation can be reinstituted with the surgeon's cooperation. Also, depending on the stage of surgical dissection, if a pneumonectomy is being performed, ligation of the pulmonary artery eliminates the shunt.

During OLV, the peak airway pressure, the actual VT delivered (measured by a spirometer), the shape of the capnogram, and, if available, the pressure–volume loop, should be checked continuously. A sudden increase in peak airway pressure may be secondary to tube dislocation because of surgical manipulation, resulting in impaired ventilation. In addition, the ability to auscultate by a stethoscope over the dependent lung is extremely important.

If any questions arise about the stability of the patient, or if the patient becomes hypotensive, dusky, or tachycardic, two-lung ventilation should be resumed until the problem has been resolved. Because of pericardial manipulation (during left thoracotomy in particular) and pulling on the great vessels, cardiac arrhythmias and hypotension are not uncommon. Cardiotonic drugs should be prepared and kept available for use during any thoracic surgical procedure. Most thoracic surgical procedures represent only relative indications for OLV, and the benefits of OLV should always be weighed against the risks to the patient.

CHOICE OF ANESTHESIA FOR THORACIC SURGERY

The choice of anesthesia technique for a thoracic surgical procedure must take into account the patient's cardiovascular and respiratory status and the particular effects of anesthetic drugs on these and other organ systems. Thoracic surgical patients are more likely than others to have increased airway reactivity and a propensity to develop bronchoconstriction. This is because many of these patients are cigarette smokers and have chronic bronchitis or COPD. In addition, surgical manipulation of the airways and bronchial tree by instruments, a DLT, or the surgeon makes bronchoconstriction more likely to occur. The potent inhaled anesthetic agents have all been shown to

decrease airway reactivity and bronchoconstriction provoked by hypocapnia or inhaled or irritant aerosols. Their mechanism of action is probably a direct one on the airway musculature itself, and potent inhaled anesthetic agents are therefore the drugs of choice in patients with reactive airways. For an inhalation induction, halothane or sevoflurane might be preferable because they are the least pungent of the three drugs, although once the patient is asleep isoflurane may be the preferred drug because it raises the cardiac arrhythmia threshold and provides greater cardiovascular stability than halothane. Fentanyl does not appear to influence bronchomotor tone, but morphine may increase tone by a central vagotonic effect and by releasing histamine.

In most patients, anesthesia is safely induced with thiopental or propofol. In patients with reactive airways, ketamine may be the drug of choice for induction because it has a bronchodilator effect and has been successfully used in the treatment of asthma. Thiopental has been associated with bronchospasm in asthmatic patients, although the reactivity in such cases may be related to inadequate levels of anesthesia before instrumentation of the airway. Shimizu et al.[62] compared the effects of isoflurane and sevoflurane on PaO_2 during OLV in 20 patients undergoing thoracotomy and found no significant difference between the groups in PaO_2, concluding that both agents can be used safely. In an in vitro study, Loer et al.[63] showed that desflurane inhibits HPV, with an ED_{50} of 1.6 minimum alveolar concentration (MAC). Thus, overall, the potent inhaled anesthetics are the drugs of choice during thoracic surgery.

Propofol infused in doses of 6 to 12 mg/kg/hr does not abolish HPV during OLV in humans.[64] Propofol infusion in combination with remifentanil is probably the technique of choice for producing a stable OLV with no effect on HPV. Propofol is widely used during OLV and has been investigated in terms of its effect on oxygenation. Kellow et al.[65] compared the effects of propofol and isoflurane anesthesia on right ventricular function and shunt fraction during thoracic surgery, and found that isoflurane, but not propofol, was associated with an increase in shunt fraction due to HPV inhibition. However, propofol was associated with a reduction in cardiac index and right ventricular ejection fraction.

The neuromuscular blocking drugs of choice for thoracic procedures are those that lack a

histamine-releasing or vagotonic effect and that have some sympathomimetic effect. In this respect, pancuronium, vecuronium, rocuronium, and cisatracurium probably represent the drugs of choice. Succinylcholine is useful to provide rapid profound relaxation for intubation of the trachea and is not associated with an increase in airways reactivity.

Intravenous lidocaine (1.0 to 1.5 mg/kg) can be used before manipulations of the airway to prevent reflex bronchospasm. It has also been given by infusion to depress airway reactivity in patients who have poor cardiovascular function and cannot tolerate normal doses of the potent inhaled agents. Intravenous lidocaine has also been used to treat bronchospasm occurring during anesthesia. Lidocaine nebulized and administered via the airways has a similar salutary effect on bronchial tone.

Atropine may be used to block the antimuscarinic effects of acetylcholine and thereby protect against cholinergically induced bronchoconstriction. It may be administered intravenously or in nebulized form (see Bronchoscopy section).

HYPOXIC PULMONARY VASOCONSTRICTION

General anesthesia may impair pulmonary gas exchange, and arterial hypoxemia may occur as a result. In patients undergoing halothane–oxygen anesthesia with spontaneous two-lung ventilation, Nunn[66] found a calculated shunt of 14% of pulmonary blood flow as compared with a calculated shunt of 1% in normal, conscious, supine patients measured using the same techniques. He suggested that the large shunt observed was probably due to perfusion of totally unventilated parts of the lung. Marshall et al.[67] confirmed this and concluded that postoperative hypoxemia may also be a result of the residual effects of the anesthetic on venous admixture. With this background, many investigators have studied the regulation of the pulmonary circulation through a homeostatic mechanism called HPV, which normally diverts blood away from hypoxic regions of the lung and thereby optimizes the gas exchange function of the lung.

Hypoxic pulmonary vasoconstriction was first described by Von Euler and Liljestrand in 1946.[68] They were studying changes in the pulmonary circulation of the cat in response to changes in inspired gas mixtures and found that 10.5% inspired O_2 (in N_2) mixtures caused an increase in pulmonary artery pressure. Breathing 100% O_2 caused a decrease in pulmonary artery pressure. They concluded that the increased pressure during hypoxia was caused by a direct effect on the pulmonary vessels. Whereas they delivered hypoxic gas mixtures to both lungs, others have studied the effects of the size of the hypoxic segment and the size of the hypoxic stimulus on perfusion pressure and on flow diversion. Pulmonary perfusion pressure (in dogs) increased with the size of the hypoxic segment from zero (smallest hypoxic segment) to approximately 2.2 times baseline for the hypoxic whole lung. Flow diversion, as a percentage of flow to the test segment under normoxic conditions, decreased with increasing size of the hypoxic test segment from a maximum of 75% for very small segments to zero when the whole lung was made hypoxic. Flow diversion increased linearly as PaO_2 was decreased over the range of 128 to 28 mm Hg. In both flow diversion and changes in perfusion pressure, the response to HPV was predictable, continuous, and maximal at a predicted PaO_2 of 30 mm Hg (4% oxygen). Thus, HPV causes an increase in both perfusion (pulmonary artery) pressure and flow diversion.[69]

7 The choice of anesthetic technique for OLV must take into consideration the effects on oxygenation and therefore on HPV. Normally, collapse of the nonventilated, nondependent lung results in activation of reflex HPV in this lung. This causes local increases in pulmonary vascular resistance and diversion of blood flow to other, better oxygenated parts of the pulmonary vascular bed (i.e., the dependent oxygenated and ventilated lung). The stimulus to HPV appears to be a function of both PaO_2 and P$\bar{v}O_2$ in isolated rat lungs ventilated with hypoxic mixtures, but in the atelectatic lung the stimulus is the P$\bar{v}O_2$.[70] A decrease in cardiac output may potentiate HPV by lowering S$\bar{v}O_2$. The response is believed to be accounted for by each smooth muscle cell in the pulmonary arterial wall responding to the oxygen tension in its vicinity. Because HPV causes flow diversion,

PaO_2 should be higher than if there were no HPV. The relationship between PaO_2 and the size of the hypoxic segment (Fig. 29-21) shows that, when not much of the lung is hypoxic, HPV has little effect on PaO_2 because shunt is small in this situation. When most of the lung is hypoxic, there is no significant normoxic region to which the hypoxic region can divert flow, and then it does not matter, in terms of PaO_2, whether the hypoxic region has active HPV. When the amount of lung made hypoxic is 30 to 70%, such as occurs during OLV, there may be a large difference between the PaO_2 to be expected with normal HPV compared with that expected in its absence. HPV can raise PaO_2 from potentially dangerous levels to higher and safer ones. Conversely, inhibition of HPV may cause or contribute to hypoxemia during anesthesia.

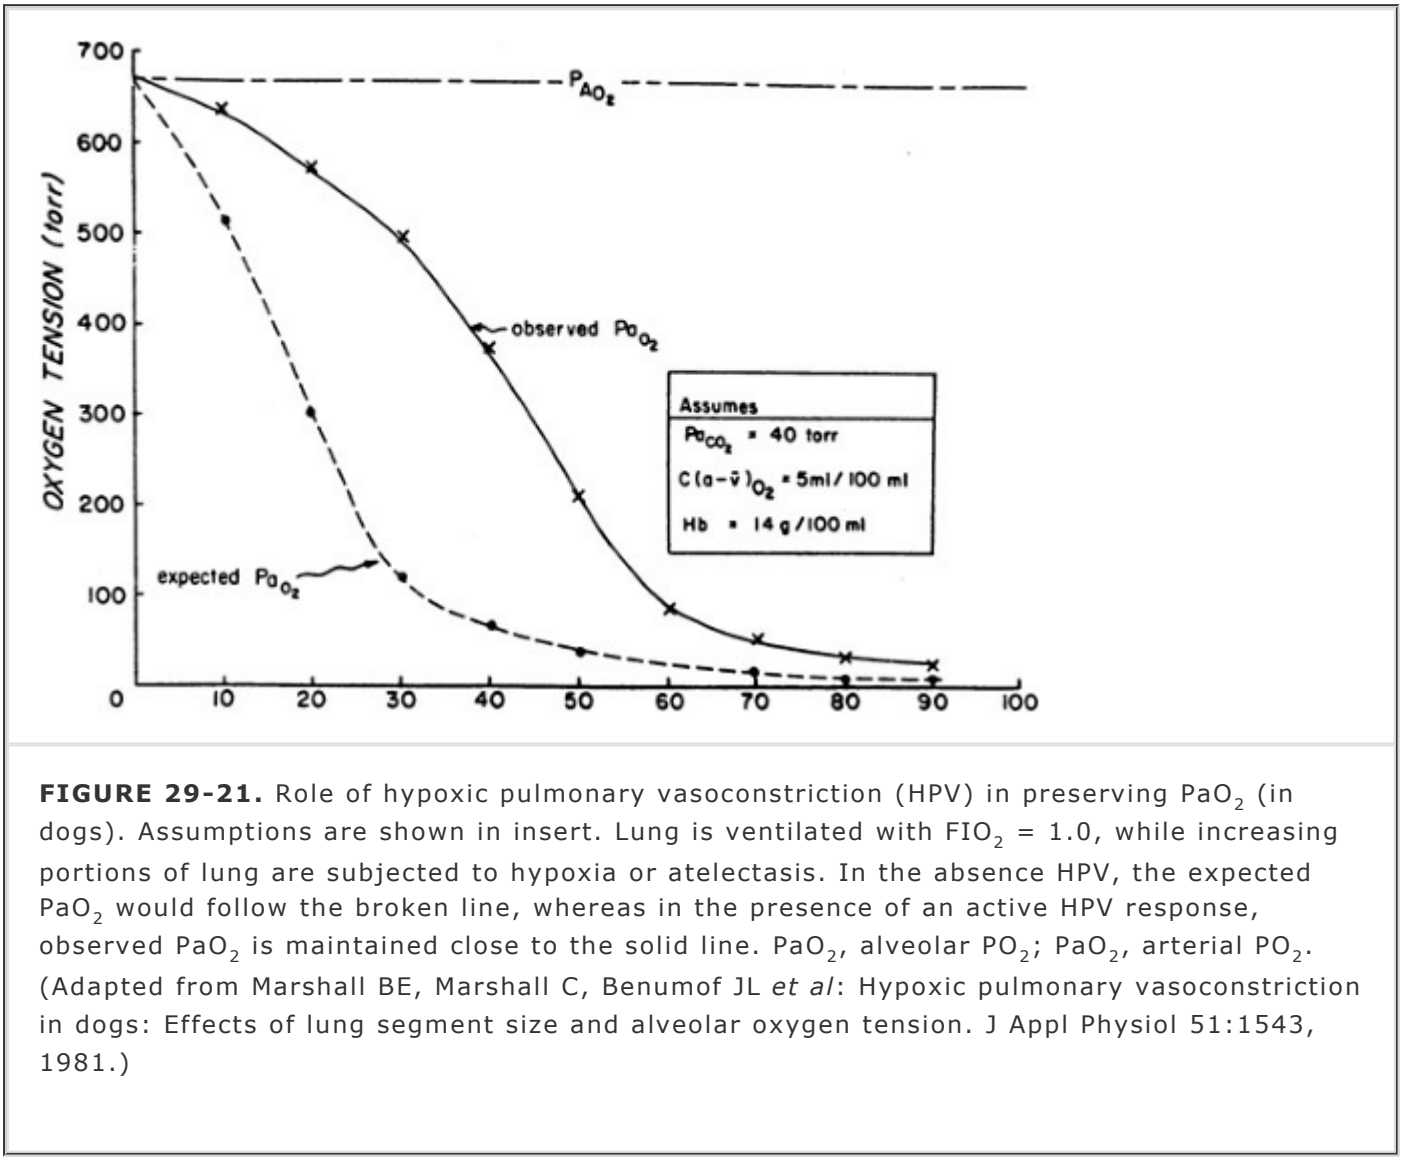

FIGURE 29-21. Role of hypoxic pulmonary vasoconstriction (HPV) in preserving PaO_2 (in dogs). Assumptions are shown in insert. Lung is ventilated with FIO_2 = 1.0, while increasing portions of lung are subjected to hypoxia or atelectasis. In the absence HPV, the expected PaO_2 would follow the broken line, whereas in the presence of an active HPV response, observed PaO_2 is maintained close to the solid line. PaO_2, alveolar PO_2; PaO_2, arterial PO_2. (Adapted from Marshall BE, Marshall C, Benumof JL *et al*: Hypoxic pulmonary vasoconstriction in dogs: Effects of lung segment size and alveolar oxygen tension. J Appl Physiol 51:1543, 1981.)

Effects of Anesthetics on Hypoxic Pulmonary Vasoconstriction

The inhalation anesthetics and many of the intravenous drugs used in anesthesia have been studied for their effects on HPV. The results have not always been consistent. Benumof[71] classified the preparations used to study these effects as in vitro, in vivo nonintact, in vivo intact, and human studies. Based on the results of these three types of preparation, it is generally believed that inhaled agents inhibit HPV, whereas intravenous drugs do not have this effect.[72]

Human studies are perhaps the most significant because of their applicability to the clinical situation. Bjertnaes[73] used perfusion scans (scintigraphy) to assess the effect of anesthetics on human HPV. In his patients, lung separation was achieved using a DLT. One lung could then be ventilated with 100% O_2 and the other with 100% nitrogen. HPV was assessed in the presence and absence of ether, halothane, and intravenous drugs (thiopental and fentanyl). Based on his scintigraphic findings, Bjertnaes concluded that the inhaled agents, in clinically useful

concentrations, inhibited HPV in humans.

Jolin Carlsson et al.[74] used separate lung ventilation and a triple-gas washout technique to study HPV in eight patients. They demonstrated the presence of HPV in response to 8% O_2 in 92% nitrogen in the test lung but found no further change with the addition of 1.0% or 1.5% end-tidal isoflurane, and blood gas readings remained essentially unaltered. Attempts to use higher concentrations caused unacceptable hypotension. These authors concluded that isoflurane might be indicated for anesthesia in the presence of lung disease or during OLV because arterial oxygenation might be better preserved than would be the case with an anesthetic that more effectively inhibited HPV. Thus, although it is possible that higher concentrations of isoflurane might have caused a clear change in the differential blood flow distribution, at clinically used concentrations the effect of HPV in their subjects was all but unmeasurable.

Weinreich et al.[75] used a ketamine infusion and found a lower incidence of hypoxemia (defined as PaO_2 <70 mm Hg) than other studies reporting the use of halothane for OLV. Rees and Gaines[76] compared a ketamine–oxygen technique with an enflurane (1 to 3% inspired)–oxygen technique for OLV and found no differences between the groups in PaO_2 or shunt. These findings suggested that ketamine afforded no advantage over enflurane during OLV.

Rogers and Benumof[77] compared the effects of inhaled (isoflurane and halothane) with intravenous (methohexital and ketamine) anesthesia during OLV and concluded that the inhaled anesthetics at approximately 1 MAC do not significantly affect HPV in humans, as evidenced by a lack of significant differences in PaO_2 between use of the two techniques. The conclusions of this study have been questioned because the period of clinical exposure to the potent inhaled agents was very short. Thus, clinically relevant tissue concentrations of anesthetic may not have been achieved.

In a subsequent study, Benumof et al.[78] investigated the changes in PaO_2 and shunt that occurred after conversion from 1 MAC halothane or isoflurane anesthesia to intravenous anesthesia (fentanyl, diazepam, and sodium thiopental) during OLV for thoracic surgery in 12 patients. In this study, they found that during one-lung atelectasis, 1 MAC halothane anesthesia slightly but significantly increased shunt and decreased PaO_2 (compared with intravenous anesthesia), whereas 1 MAC isoflurane anesthesia very slightly but nonsignificantly increased shunt and decreased PaO_2 (compared with intravenous anesthesia). Fundamental differences between the two studies[77,78] were in the duration of the periods of OLV with the potent inhaled agent and in the MAC multiples of the drugs used. In the earlier study,[78] end-tidal concentrations of halothane and isoflurane were kept constant for approximately 20 minutes at 1.45 and 1.15 MAC, respectively. In the later study,[78] patients were maintained on one-lung anesthesia with the potent inhaled agent (1 MAC) for 40 minutes before final measurements under these conditions were taken. The authors also concluded that halothane and isoflurane had only a small inhibitory effect on the one-lung HPV response.[78] A randomized crossover study during OLV with an FIO_2 of 1.0 found that 1 MAC isoflurane anesthesia was associated with greater PaO_2 values than was 1 MAC enflurane.[79] Shimizu et al.[62] compared the effects of isoflurane and sevoflurane on PaO_2 during OLV in 20 patients undergoing thoracotomy and found no significant difference between the groups in PaO_2, concluding that both agents can be used safely. In an in vitro study, Loer et al.[63] showed that desflurane inhibits HPV, with an ED_{50} of 1.6 MAC.

Beck et al.[80] studied 40 patients requiring OLV randomized to receive propofol (4–6 mg/kg per hour) or sevoflurane

(1 MAC) for anesthesia maintenance. During OLV shunt fraction increased in both groups, but there was no significant difference between groups. It was concluded that inhibition of HPV by sevoflurane may only account for small increases in shunt fractions and that much of the overall shunt fraction during OLV has other causes.

Overall, the potent inhaled anesthetics are the drugs of choice during thoracic surgery. The technique chosen should, however, always be dictated by the needs of the particular patient, so in the presence of cardiovascular instability or poor oxygenation when depression of HPV is a possibility, a balanced technique may be chosen. Propofol in doses of 6 to 12 mg/kg per hour does

not appear to abolish HPV during OLV in humans.[64]

Other Determinants of Hypoxic Pulmonary Vasoconstriction

Aside from potent inhaled agents, other drugs and maneuvers used during anesthesia may also have an inhibitory effect on regional or whole-lung HPV. Factors associated with an increase in pulmonary artery pressure antagonize the effect of increased resistance caused by HPV and result in increased flow to the hypoxic region. Such indirect inhibitors of HPV include mitral stenosis, volume overload, thromboembolism, hypothermia, vasoconstrictor drugs, and a large hypoxic lung segment. Direct inhibitors of HPV include infection; vasodilator drugs, such as nitroglycerin and nitroprusside; hypocarbia; and metabolic alkalemia. All these potential inhibitors should be considered when evaluating a patient for hypoxemia during thoracic surgery.

Potentiators of Hypoxic Pulmonary Vasoconstriction

Whereas in the past most research effort has been directed to studying inhibition of HPV, more recent research has investigated substances that may potentiate it. Almitrine, a respiratory stimulant drug, has been found to improve PaO_2 in patients with COPD and to have this effect in the absence of ventilatory stimulation. Indirect evidence suggested that it may potentiate HPV in intact dogs, although a subsequent and more extensive study in dogs concluded that almitrine caused nonspecific pulmonary vasoconstriction that was greater in the 100% oxygen-ventilated lung than in the hypoxic lung regions, thus causing a reduction of the HPV response.[81]

It has been suggested that prostaglandins may play a role in HPV inhibition, and therefore, prostaglandin inhibitors have been investigated as potentiators of HPV. Ibuprofen, a cyclooxygenase inhibitor, has been found to potentiate HPV in hypoxic isolated rat lung preparations and to reverse the inhibition of HPV caused by halothane. In an animal model, lidocaine has also been found to have salutary effects in terms of reversing depression of HPV. The value, if any, of such potentiators in humans undergoing one-lung anesthesia has not yet been reported.

Nitric Oxide and one-Lung Ventilation

Nitric oxide is an endothelial-derived relaxing factor that appears to be an important mediator for smooth muscle relaxation.[82] HPV is inhibited by inhaled nitric oxide. Inhibition of nitric oxide synthase improved, but did not completely restore, HPV in dogs suffering from sepsis.[83] Frostell et al.[84] showed that inhalation of nitric oxide selectively induced vasodilation and reversed HPV in healthy humans without causing systemic vasodilatation. It was theorized that intravenous administration of almitrine (to increase HPV) causing vasoconstriction throughout the lung, together with inhalation of nitric oxide to inhibit HPV locally and cause increased flow in the ventilated regions, would improve V/Q matching and PaO_2 in patients with V/Q mismatching or during OLV.[85]

Moutafis et al.[86] studied the effects of inhaled nitric oxide in combination with almitrine infusion during OLV in 40 patients undergoing thoracoscopic procedures. They found that inhaled nitric oxide alone did not affect PaO_2 during OLV, but the additional infusion of almitrine 16 mg/kg/min caused a marked increase in PaO_2. These authors suggested that this nonventilatory technique should be of value during special thoracic procedures, such as thoracoscopy, where there is a need to manipulate the pulmonary circulation to improve PaO_2 but measures such as PEEP and CPAP cannot be used. Moutafis et al.[87] also reported the use of almitrine infusion/nitric oxide inhalation to improve PaO_2 during OLV for bronchopulmonary lavage.

Although the use of almitrine appears to be attractive, this drug is not without side effects.[88] Also, the manufacturer has not made it available outside France. Possible alternatives to almitrine might be phenylephrine[89] and prostaglandin $F_{2\alpha}$.[90]

ANESTHESIA FOR DIAGNOSTIC PROCEDURES

Bronchoscopy

Early bronchoscopes were of the rigid type, but in 1966, the Machida and Olympus Companies introduced the first practical bronchofiberscopes. Since then, they have been improved dramatically and have simplified many otherwise complicated bronchoscopies. The indications for bronchoscopy are shown in Table 29-2 and the instruments of choice in Table 29-3. Operator preferences and experience may play a major role in the choice of instrument.

Before bronchoscopy is performed, the patient must be evaluated for chronic lung disease, respiratory obstruction, bronchospasm, coughing, hemoptysis, and infectivity of secretions. Medications should be reviewed, and the need for a more major procedure should always be anticipated. Thus, bronchoscopy may lead to thoracotomy or sternotomy. The planned technique for bronchoscopy should be discussed with the surgeon before the operation, and all equipment and connectors should be checked for compatibility. Monitoring during bronchoscopy should include an electrocardiogram, a blood pressure cuff, a precordial stethoscope, and a pulse oximeter. If thoracotomy is planned, an arterial cannula should also be placed, as well as other monitors (e.g., PA or CVP catheters) that may be indicated by the patient's condition. Many anesthetic techniques are useful for bronchoscopy.

Local Anesthesia

The patient should first be pretreated with a drying agent. The local anesthetics most commonly used are lidocaine and tetracaine. In all cases, the total dose of anesthetic must be considered and the potential for toxicity recognized. A nebulizer can be used to spray the oropharynx and base of the tongue, or the patient may gargle with viscous (2%) lidocaine. The tongue is then held forward, and pledgets soaked in local anesthetic are held in each piriform fossa using Krause forceps to achieve block of the internal branch of the superior laryngeal nerve. Tracheal anesthesia is achieved by a transtracheal injection of local anesthetic, or by spraying the vocal cords and trachea under direct vision using a laryngoscope or through the suction channel of the bronchofiberscope. Alternatively, a superior laryngeal nerve block can be performed by an external approach, and a glossopharyngeal block can be used to depress the gag reflex. These blocks cause depression of airway reflexes, so that patients must be kept on nothing by mouth for several hours after the examination. If fiberoptic bronchoscopy is to be performed transnasally, the nasal mucosa should be pretreated topically with 4% cocaine, or viscous lidocaine may be administered through the nares. Local anesthesia for bronchoscopy has the advantages of a patient who is awake, cooperative, and breathing spontaneously. Sedatives may be added to make the patient more comfortable. Disadvantages of local anesthesia include poor tolerance of any bleeding by the patient and the occasional lack of patient cooperation.

General Anesthesia

General anesthesia for bronchoscopy is often combined with topical laryngeal anesthesia so less

general anesthesia is needed. A balanced technique uses N_2O/O_2, incremental doses of an intravenous drug such as thiopental, an opioid, and a neuromuscular blocking drug. A potent inhaled anesthetic technique is also satisfactory. The use of N_2O and potent inhaled agents may create an operating room atmosphere contamination problem for the waste anesthesia gases, but limited scavenging may be possible by placing a suction catheter in the patient's oropharynx. Unless there is some contraindication, ventilation of the lungs is usually controlled. In any patient undergoing a thoracic diagnostic procedure for a suspected malignancy, the possibility of the myasthenic syndrome with sensitivity to nondepolarizing muscle relaxants must always be considered. The doses of neuromuscular blocking drugs should be titrated to effect using a neuromuscular monitoring system.

Rigid Bronchoscopy

A modern rigid ventilating bronchoscope is essentially a hollow tube with a blunted, beveled tip. Various sizes and designs are available; however, in all of them, a side arm is provided for connection to an anesthesia source. A number of techniques have been described for maintaining ventilation and oxygenation during rigid bronchoscopic examination.

Apneic Oxygenation. After preoxygenation and induction of general anesthesia, skeletal muscle paralysis and cessation of intermittent positive-pressure breathing, the $PaCO_2$ increases. During the first minute the increase is ~6 mm Hg. Subsequently, the average rate of increase is 3 mm Hg/min. Oxygen is insufflated at 10 to 15 L/min through a small catheter placed above the carina. If the patient has been adequately denitrogenated, this technique can provide adequate oxygenation for more than 30 minutes.[91] The apneic period should not be allowed to extend beyond 5 minutes, however, because the technique is limited by buildup of CO_2, respiratory acidosis, and cardiac dysrhythmias.

Apnea and Intermittent Ventilation. Oxygen and anesthesia gases are delivered to the bronchoscope via the anesthesia circuit. Ventilation is possible only when the eyepiece is in place, which limits the period for instrumentation by the surgeon. Intermittent ventilation of the lungs is achieved by squeezing the reservoir bag. In this way, assuming a good bronchoscope fit in the airway, compliance is constantly monitored, the risk of barotrauma is reduced, and VT may be estimated. The disadvantage of this technique is that there may be a leak around the bronchoscope, which could lead to hypoventilation and hypercarbia. Packing of the oropharynx can reduce the leak, and improve ventilation in the case of such a gas leak.

Sanders Injection System. Sanders applied the Venturi principle to provide ventilation of the lungs by attaching a jet ventilator to the bronchoscope.[92] Oxygen from a high-pressure source (50 psig) is delivered, using a controllable pressure-reducing valve and toggle switch, to a 2.5 to 3.5-cm 18- or 16-gauge needle inside and parallel to the long axis of the bronchoscope. When the toggle switch is depressed, the jet of oxygen entering the bronchoscope entrains room air, and the air–oxygen mixture resulting at the distal tip of the bronchoscope emerges at a pressure to provide adequate ventilation and oxygenation. The intraluminal tracheal pressure depends on the driving pressure from the reducing valve; the size of the needle jet; and the length, internal diameter, and design

of the bronchoscope. Increasing the size of the needle jet increases the total gas flow for any given driving pressure. For each combination of gas driving pressure, jet orifice, and bronchoscope diameter, only one inflation pressure can be attained, regardless of the volume or compliance of the lung. As long as the proximal end of the bronchoscope is open, the system is strictly pressure limited, and the pressure does not increase because of obstruction at the distal end. Pressure varies inversely with the cross-sectional area of the bronchoscope so insertion of a suction catheter or biopsy forceps into the lumen causes the intratracheal pressure to increase. Provided there is not a tight fit between the bronchoscope and the airway, the risk of barotrauma is low. If the fit is tight, driving pressure should be decreased.

The advantages of the Sanders system are that because continuous ventilation is possible (because the presence of an eyepiece is not necessary for ventilation of the lungs), the duration

of the bronchoscopy procedure is minimized, but the efficiency also permits extended bronchoscopy. A disadvantage is that entrainment of air by the oxygen jet results in a variable FIO_2 at the distal end of the bronchoscope, ventilation of the lungs may be inadequate if compliance is poor, and adequacy of ventilation may be difficult to assess. A comparison between the intermittent ventilation and Sanders techniques found that PaO_2 was satisfactory with either method but was higher in the intermittent ventilation group.[93] $PaCO_2$ was lower and arterial pH higher in the Sanders group, indicating superiority of this method, particularly for long procedures.

The basic Sanders technique has been modified to increase FIO_2 and to deliver N_2O and potent inhaled anesthetics. The 16-gauge oxygen jet has been replaced with a longer jet (Carden side arm) that allows ventilation with 100% oxygen and the development of much higher pressures at the tracheal end of the bronchoscope, while using a driving pressure of 50 psig. The Sanders injector system may also be used with a ventilating bronchoscope, the side arm of which is connected to a supply of anesthesia gases so the injection jet entrains the anesthesia gases.[94]

Mechanical Ventilator. Ventilation of the lungs may be achieved by connecting a mechanical ventilator to an anesthesia circuit that is connected to the bronchoscope side arm.

High-Frequency Positive-Pressure Ventilation. HFPPV has been used in conjunction with rigid bronchoscopy and has been compared with the Sanders injector in patients with tracheobronchial stenosis. With HFPPV of up to 150 breaths/min, blood gases were identical with both techniques. At a frequency of 500 breaths/min, oxygenation deteriorated and CO_2 was not removed effectively. HFPPV has the advantage that the tracheobronchial wall remains perfectly immobilized during ventilation.[95]

Other Techniques. Cuirass ventilation, external chest compression, and a ventilating catheter or endotracheal tube placed alongside the bronchoscope have also been used to provide ventilation during bronchoscopy.

Fiberoptic Bronchoscopy

The recent generations of fiberscopes, with their improved optics and smaller diameters, have revolutionized bronchoscopy. Examination of the fifth order of bronchial branching is now possible, and the diagnostic potential of this instrument is thereby enhanced. The flexibility has also been applied in preoperative assessment of the airway, management of difficult tracheal intubations, endotracheal tube positioning and change, bronchial toilet, correct positioning of DLTs, bronchial blockade, and evaluation of the larynx and trachea.

Nasal fiberoptic bronchoscopy under topical anesthesia is well tolerated by most awake patients. A suction catheter in the mouth is useful to remove oral secretions. Oral insertion is also possible in both awake and asleep patients and should be performed via a specially designed airway, which guides the fiberscope over the back of the tongue and prevents potential damage to it by the patient's teeth.

Physiologic Changes Associated with Fiberoptic Bronchoscopy. In all patients, insertion of the fiberoptic bronchoscope is associated with hypoxemia. The average decline in PaO_2 is 20 mm Hg and lasts for 1 to 4 hours after the procedure. By 24 hours, the blood gas tensions are usually back to normal. It is therefore recommended that if the initial PaO_2 is 70 mm Hg (FIO_2 = 0.21), bronchoscopy should be performed only with the administration of supplemental oxygen. This can be provided using mouth-held nasal prongs, a special face mask with a diaphragm through which the fiberscope can be passed, or an endotracheal tube with a T-piece diaphragm adapter.

During and after fiberoptic bronchoscopy, patients experience increased airway obstruction. Thus, in 35 patients, insertion of the bronchoscope was associated with an increase in FRC (17 to 30%) and decreases in PaO_2, vital capacity, FEV_1, and forced inspiratory flow.[96] All returned to baseline by 24 hours. These changes are believed to be secondary to direct mechanical activation of irritative reflexes in the airway and, possibly, to mucosal edema. They may be avoided if atropine, either intramuscular or aerosolized into the airway, is administered before the procedure. Isoproterenol has a similar salutary effect on lung function but is associated with an increased

incidence of cardiac arrhythmias. Overall, atropine is recommended as premedication for fiberoptic bronchoscopy. Concern that atropine may have an overall undesirable effect by increasing viscosity of secretions in patients with COPD is unsubstantiated.

The standard adult fiberoptic bronchoscope has an external diameter of 5.7 mm and a 2-mm diameter suction channel. If suction at 1 atm is applied to the fiberscope, air is removed at a rate of 14 L/min. If the fiberscope is in the airway, this causes decreases in FIO_2, PAO_2, and FRC, leading to decreased PaO_2. Suctioning should therefore be kept brief. The adult fiberscope can be passed through endotracheal tubes of 7 mm or greater internal diameter. Clearly, passage through an endotracheal tube decreases the cross-sectional area available for ventilating the patient, so if fiberoscopy is planned, an endotracheal tube of the largest possible diameter should be used.

Insertion of the bronchoscope also causes a significant PEEP effect that may result in barotrauma in ventilated patients. If PEEP is already being used, it should be discontinued before passage of the fiberscope. A postendoscopy chest radiograph is advisable to exclude the presence of mediastinal emphysema or pneumothorax. In patients whose tracheas are intubated with endotracheal tubes of less than 8 mm internal diameter, use of pediatric fiberscopes, which have smaller diameters, would be more appropriate.

The suction channel of the adult fiberoptic bronchoscope has been used to oxygenate and ventilate the lungs of patients. By attaching a jet ventilation system (similar to that used to drive the Sanders injector for rigid bronchoscopy) to the suction connection at the head of a fiberoptic bronchoscope, successful ventilation of the lungs of patients undergoing gynecologic procedures was achieved.[97] A driving pressure of 50 psig of oxygen was used with a ventilatory rate of 18 to 20 breaths/min. This technique permitted adequate ventilation of patients with normally compliant lungs and chest walls. Ventilation of the lungs should be performed only with the tip of the instrument in the trachea because a more peripheral location may produce barotrauma.

Neodymium-yttrium-aluminum garnet (Nd-YAG) lasers are used for the resection of obstructing and endobronchial lesions. This procedure is performed under general anesthesia. The lasers may be introduced into the bronchial tree through a

fiberoptic bundle passed via the suction port of the fiberoptic bronchoscope. During laser resection, FIO_2 should be kept to a minimum and titrated against oxygen saturation (as continuously monitored by pulse oximeter) to make endotracheal fire less likely (see Chapter 8). Laser therapy of bronchial tumors is also possible using a rigid bronchoscope. HFPPV through a rigid bronchoscope provides satisfactory operating conditions for laser resection of tracheal tumors and has the advantage of producing airway immobility.

Complications of Bronchoscopy

Complications of rigid bronchoscopy include mechanical trauma to the teeth, hemorrhage, bronchospasm, loss of a sponge, bronchial or tracheal perforation, subglottic edema, and barotrauma. The incidence of complications is much lower with fiberoptic bronchoscopy. Nevertheless, complications may arise owing to overdose with topical anesthetic, insertion trauma, local trauma, hemorrhage, upper airway obstruction related to passage of the instrument through an area of tracheal stenosis, hypoxemia, and bronchospasm. In most cases, it is best to intubate the trachea with an endotracheal tube after bronchoscopy under general anesthesia. This permits avoidance or treatment of some of these problems, particularly the increased airway irritability. Intubation also facilitates effective suctioning of the trachea and bronchi, and allows the patient to recover more gradually from general anesthesia.

DIAGNOSTIC PROCEDURES FOR MEDIASTINAL MASS

Patients with an anterior mediastinal mass present a special problem for the anesthesiologist. Although such masses may cause obvious superior vena cava obstruction, they may also cause obstruction of major airways and cardiac compression, which are less obvious and may become apparent only on induction of anesthesia. Many cases of anesthetic related airway compression from anterior mediastinal mass have been reported. In one case, total occlusion of the trachea

starting 2 to 3 cm above the carina and extending to both main-stem bronchi was observed, and a bronchoscope was passed through the obstruction.[98] In the second case of this report, extrinsic compression of the left main-stem bronchus occurred on inspiration during recovery from anesthesia. In the third case, flow–volume studies were performed with the patient in the upright and supine positions, with marked reductions in FEV_1 and peak expiratory flow in the latter position. These findings suggested potential obstruction with onset of anesthesia; radiation therapy to the mediastinum was commenced, after which the flow–volume studies showed improved function. The planned surgical procedure was then performed under local anesthesia. In a more recent series of 105 patients with mediastinal masses, the incidence of intraoperative cardiorespiratory complications was 38%, and the incidence of postoperative respiratory complications was 11%.[99] No cases of airway collapse were reported during anesthesia. In this series, patients were at increased risk of complications if there were preoperative cardiorespiratory signs and symptoms, obstructive and restrictive dysfunction on PFTs, and greater than 50% tracheal compression on CT scan.[99] In another series of patients with mediastinal mass, four patients had abnormal spirometry, but underwent general anesthesia without sequealae.[100] In severe cases of airway compression, femoral vessels may be cannulated prior to induction to institute cardiopulmonary bypass.[101]

The mass may be sensitive to radiation therapy, which could shrink the tumor and make an induction of general anesthesia less hazardous. However, a serious potential disadvantage of preoperative radiation therapy is that it may affect tissue histologic appearance, thereby preventing an accurate diagnosis. Furthermore, if the patient is a child, it may be difficult to obtain tissue samples under local anesthesia. In a series of 44 patients ages 18 years of age or younger with anterior mediastinal masses who underwent general anesthesia before radiation or chemotherapy, no fatalities occurred. However, seven patients did have airway compromise.[102] This report concluded that general anesthesia may be safely induced before radiation therapy and that the benefits of obtaining an accurate tissue diagnosis outweighed the risks. Others have disagreed with these conclusions, stating that anesthesia is not safe when the reported rate of life-threatening complications is 16 to 20%. In another report in a series of children, it was found to be safe to induce general anesthesia if the CT scan revealed that the tracheal cross-sectional area and peak expiratory flow rates were at least 50% of predicted.[103]

Airway obstruction caused by an anterior mediastinal mass has been attributed to changes in lung and chest wall mechanics associated with changes in position or to onset of paralysis in muscles that previously maintained airway patency. Preoperative evaluation of a patient with an anterior mediastinal mass to avoid life-threatening total airway obstruction is shown in Fig. 29-22.[98] It is important to determine in the history if the patient has dyspnea in the supine position and to examine the CT scan to determine the extent of the tumor and its effect on surrounding structures. If such obstruction occurs, it may be relieved by passage of a rigid bronchoscope or anode tube past the obstruction, by direct laryngoscopy,[104] or by changing the position of the patient.

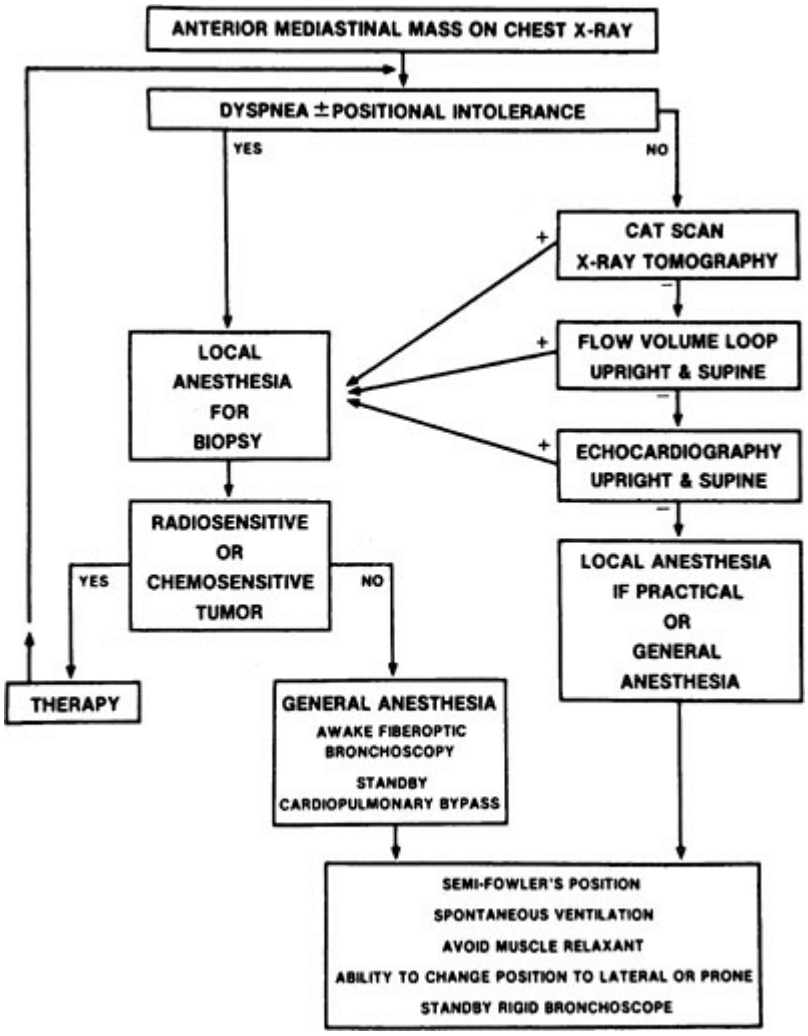

FIGURE 29-22. Flow chart describing the preoperative evaluation of the patient with an anterior mediastinal mass. +, indicates positive finding; -, indicates negative workup. (Reprinted from Neuman GC, Weingarten AE, Abramowitz RM *et al:* Anesthetic management of the patient with an anterior mediastinal mass. Anesthesiology 60:144, 1984.)

In a situation in which the biopsy procedure cannot be performed under local anesthesia and there is concern that muscle paralysis may result in airway compression, fiberoptic intubation of the awake patient followed by general anesthesia with spontaneous ventilation has been described for thoracotomy. Thus, during spontaneous inspiration, the normal transpulmonary pressure gradient distends the airways and helps maintain their patency, even in the presence of extrinsic compression.

Mediastinoscopy

Mediastinoscopy was introduced as a means of assessing spread of bronchial carcinoma. The lymphatics of the lung drain first to the subcarinal and paratracheal areas, and then to the sides of the trachea, the supraclavicular areas, and the thoracic duct. Examination of these nodes has provided a tissue diagnosis and greater selectivity of patients for thoracotomy. It is most useful in right-lung tumors because left-lung cancers tend to spread to subaortic nodes that are more accessible by an anterior mediastinoscopy in the second or third interspace (Chamberlain procedure). The transcervical approach to the thymus is an adaptation of mediastinoscopy.

The anesthetic considerations for mediastinoscopy follow naturally from an understanding of the anatomy of this procedure and its potential complications. For cervical mediastinoscopy, the patient is placed in a reverse Trendelenburg (i.e., head-up) position, and the mediastinoscope is

inserted into the superior mediastinum through a transverse incision just above the suprasternal notch. The instrument is advanced along the anterior aspect of the trachea and passes behind the innominate vessels and the aortic arch (Fig. 29-23). The left recurrent nerve is vulnerable as it loops around the aortic arch, and any of these structures may be traumatized. Because of scarring, previous mediastinoscopy may be considered a contraindication to a repeat examination. Relative contraindications include superior vena cava obstruction, tracheal deviation, and aneurysm of the thoracic aorta.

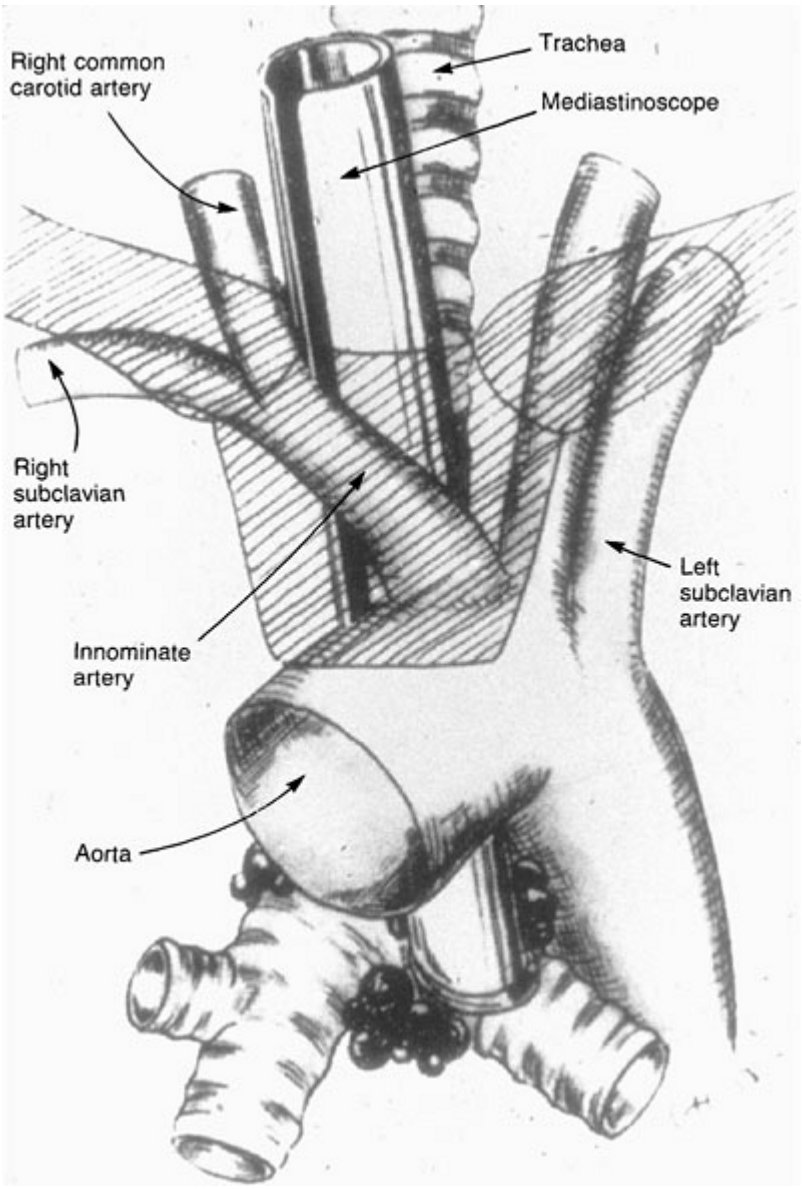

FIGURE 29-23. Anatomic relationships during mediastinoscopy. Note the position of the mediastinoscope behind the right innominate artery and aortic arch and anterior to the trachea. (From Carlens E: Mediastinoscopy: A method for inspection and tissue biopsy in the superior mediastinum. Dis Chest 36:343, 1959.)

Preoperative evaluation should include a search for airway obstruction or distortion. Review of a CT scan is very helpful in this regard. Evidence of impaired cerebral circulation, history of stroke, or signs of the Eaton-Lambert syndrome resulting from oat cell carcinoma should be sought. Blood must be available for the procedure because hemorrhage is a real risk and may be life threatening.

Most surgeons and anesthesiologists prefer general anesthesia using an endotracheal tube and continuous ventilation because this offers a more controlled situation and greater flexibility in

terms of surgical manipulation. The anesthetic technique should include a muscle relaxant to prevent the patient from coughing because this may produce venous engorgement in the chest or trauma by the mediastinoscope to surrounding structures.

The incidence of morbidity with mediastinoscopy has been reported as 1.5 to 3.0%, and that of mortality, 0.09%. The most common complication is hemorrhage (0.73%) because of the proximity of major vessels and the vascularity of certain tumors. Tamponade may be the only recourse, and thoracotomy or median sternotomy may be required to achieve hemostasis. Needle aspiration of any structure is essential before any biopsy is taken. If severe bleeding occurs, induced arterial hypotension may be helpful in reducing the size of the tear in a vessel. If bleeding is venous, fluids given via an upper limb vein may enter the mediastinum, in which case a large-bore catheter should be placed in a lower limb vein. A venous laceration may also result in air embolism, particularly if the patient is breathing spontaneously. Some recommend the use of a precordial Doppler probe if the risk of air embolism is likely.

Pneumothorax is the second most common complication (0.66%). It is usually right sided, often recognized at the time of the occurrence, and is treated according to size. A symptomatic pneumothorax should be treated by chest tube decompression.

Recurrent laryngeal nerve injury occurred in 0.34% of cases and was permanent in 50% of these cases. The nerve may be damaged by the mediastinoscope or be involved in tumor. Such injury is not a problem unless both nerves are damaged, in which case upper airway obstruction may result. Autonomic reflexes may be initiated by manipulation of the trachea or the aorta, the latter having pressor receptors located in the arch. Vagally mediated reflexes may be blocked by atropine.

"Factitious" cardiac arrest has been reported when the right radial pulse was monitored using a plethysmograph, and the tracing suddenly disappeared in the presence of a normal electrocardiogram. A normal pulse returned after the mediastinoscope was removed, and the cause of the apparent arrest was pressure on the innominate artery by the instrument. Decreases in right arm as compared with left arm blood pressure have been reported in cases undergoing mediastinoscopy. Duration was 15 to 360 seconds. This is of particular significance if there is a history of impaired cerebral circulation or transient ischemic attacks, or if a carotid bruit is present, because transient left hemiparesis may occur after mediastinoscopy. It is therefore recommended that blood pressure be monitored

in the left arm and that the right radial pulse be monitored continuously during mediastinoscopy. A decrease in the right radial pulse amplitude is an indication for repositioning the mediastinoscope, especially in a patient with a history of cerebrovascular disease.

Other reported complications include acute tracheal collapse, tension pneumomediastinum, mediastinitis, hemothorax, and chylothorax. A chest radiograph taken in the immediate postoperative period is a useful precaution in all patients after mediastinoscopy.

Thoracoscopy

Thoracoscopy (medical thoracoscopy) involves the insertion of an endoscope into the thoracic cavity and pleural space. It is used for the diagnosis of pleural disease, effusions, and infectious disease (especially in immunosuppressed patients and those with acquired immunodeficiency syndrome) and for staging procedures, chemical pleurodesis, and lung biopsy. It is usually performed by the pulmonary physician in the clinic, under local anesthesia. It is also used in therapeutic procedures such as CO_2 laser treatment of spontaneous pneumothorax or bullous emphysema[105] and Nd-YAG laser vaporization of malignant pleural tumors. A small incision is made in the lateral chest wall, and with the insertion of the instrument, fluid and biopsy specimens are easily obtained.

This procedure may be performed using local, regional, or general anesthesia, the choice depending on the expected duration of the procedure and the physical status of the patient. The most common methods are local anesthetic infiltration or intercostal nerve blocks two spaces

above and below the usual sixth intercostal space. Intercostal blocks also anesthetize the parietal pleura. Pneumothorax is a potential complication of an intercostal block, but it would not have clinical sequelae during a thoracoscopy because it is created as part of the surgical procedure. The collapse of the lung provides the surgeon with a working space, and a chest tube is placed at the conclusion of the surgery. The addition of a stellate ganglion block helps suppress the cough reflex that is sometimes provoked during manipulation of the hilum of the lung.

When air enters the pleural cavity under inspection, a partial pneumothorax occurs, permitting good surgical visualization. Changes in PaO_2, $PaCO_2$, and cardiac rhythm are usually minimal when the procedure is performed using local or regional anesthesia. (The physiology of this situation was discussed in the Lateral Position, Awake, Breathing Spontaneously, Chest Open section.)

With local anesthesia, the spontaneous pneumothorax is usually well tolerated because the skin and chest wall form a seal around the thoracoscope and limit the degree of lung collapse. Occasionally, however, the procedure is poorly tolerated, and general anesthesia must be induced. The insertion of a DLT with the patient in the lateral position may be difficult, in which case the patient may be temporarily placed in the supine position for the intubation.

If general anesthesia is required, either a single-lumen tube or a DLT may be used. Because positive-pressure ventilation interferes with endoscopic visualization, a DLT is preferable. In addition, if pleurodesis is being performed, general anesthesia through a DLT allows for complete reexpansion of the lung and avoids the pain associated with instillation of talc for recurrent pneumothorax.

Video-Assisted Thoracoscopic Surgery

Video-assisted thoracoscopic surgery (VATS) (see Chapter 38) entails making small incisions in the chest wall, which allows the introduction of a video camera and surgical instruments into the thoracic cavity.[106] Generally, it is performed by a thoracic surgeon in the operating room under general anesthesia. Although the first thoracoscopy was performed by Jacobeus in 1910, using what was at that time a cystoscope, in more recent years the surgical techniques, instruments, and video technology have been improved to permit a wide variety of procedures to be performed using VATS. These now include diagnostic procedures for evaluation of pleural disease and effusions, staging of lung cancer, and the identification of parenchymal disease, including nodules, mediastinal tumors, and pericardial disease. They also include therapeutic procedures such as operations for pleural disease, including pleurodesis, decortication and drainage of empyema, resection of lung tissue or bullae, pericardial window or stripping, and esophageal surgery. Even lung lobectomies can now be performed by VATS.

Anesthesia Considerations

8 As with a traditional thoracotomy, the patient needs to be in the lateral decubitus position, and lung collapse is needed for adequate surgical exposure. This generally mandates the use of a lung separation technique. VATS is most commonly performed under general anesthesia with OLV. The need for OLV is much greater with VATS than with open thoracotomy because it is not possible to retract the lung during VATS as it is during an open thoracotomy. The operated lung should be deflated as soon as possible after tracheal intubation and positioning because it may take over 30 minutes for complete lung collapse to occur. Also, the surgeon enters the thoracic cavity much sooner during VATS than with open thoracotomy. Suction applied to the airway can help facilitate a more rapid deflation of the lung. In some cases, carbon dioxide is insufflated into the pleural cavity to facilitate visualization. Insufflation pressures should be maintained as low as possible and the CO_2 inflow rate kept less than 2 L/min. Higher pressures can cause mediastinal shift, hemodynamic compromise, increases in airway pressure, and increases in end-tidal CO_2. Hemodynamic compromise presents a picture similar to that due to tension pneumothorax. Significant hemodynamic changes can be produced when pressures of as little as 5 mm Hg are used to insufflate CO_2 into the chest cavity.[107]

CPAP is commonly used for the treatment of hypoxemia during OLV for thoracotomy and is usually very effective. However, during VATS, CPAP interferes with the surgical exposure and is therefore

best avoided. It would be preferable to use PEEP to the nonoperated (dependent lung). In addition, a lower PaO_2 may have to be tolerated during VATS compared with a thoracotomy.

Postoperative Concerns

There is less pain after VATS than open thoracotomy, and an epidural catheter is usually placed before surgery only if there is a likelihood that a thoracotomy may need to be performed. After a positive biopsy during VATS, an open thoracotomy may be required to perform a lobectomy or pneumonectomy. The patient's respiratory function is better preserved after VATS, and their recovery is faster. However, postoperative arrhythmias, which commonly occur after thoracotomy, have also been reported after VATS.[108] Other complications that may occur include bleeding, pulmonary edema, and pneumonia.

ANESTHESIA FOR SPECIAL SITUATIONS

Management of patients with bronchopleural fistula (BPF), empyema, cysts, and bullae, as well as those requiring

tracheal reconstruction, is considered here. Many of these cases are appropriately managed using high-frequency ventilatory techniques; therefore, these techniques are described first.

High-Frequency Ventilation

With conventional positive-pressure ventilation, VT and rates usually exceed or approach those in the normal, spontaneously breathing patient. Gas transport to the alveoli occurs by convection in the larger airways, and then by convection and molecular diffusion in the more distal airways and alveoli. High-frequency ventilation differs from conventional positive-pressure ventilation in that smaller VT and more rapid rates are used. Gas transport may depend more on molecular diffusion, high-velocity flow, and coaxial gas flow in the airways, with gas in the center moving distally and that in the periphery moving proximally.

There are three different types of high-frequency ventilation. HFPPV uses small VT at rates of 60 to 120 breaths/min (1 to 2 Hz). The ventilator used (e.g., Bronchovent) has a negligible internal compliance so the VT generated, which usually approximates the dead space volume, equals the volume set on the ventilator and represents all fresh gas. The high instantaneous gas flows generated facilitate gas exchange and movement in the conducting airways.

HFPPV may be delivered by an open or a closed system. An example of the former is the percutaneous placement of a transtracheal catheter or placement of a catheter through the nose or mouth with its distal end above the carina. Inflow is intraluminal and outflow is extraluminal. This technique has been used during bronchoscopy, tracheal resection, and reconstructive surgery. When open systems are used, the gas outflow pathway is not established mechanically and depends on natural airway patency. It is therefore subject to compromise. Also, aspiration is a potential complication with open systems.

The closed system is superior because it integrates both airway patency and outflow protection. A closed system is represented by a catheter placed in a short segment of an endotracheal tube for delivery of the HFPPV, whereas the remainder of the tube lumen represents the exit pathway for gas. A quadruple-lumen endotracheal tube (Hi-Lo Jet Tracheal Tube, Mallinckrodt, Inc., Argyle, NY) has been designed specifically for delivery of HFPPV. One lumen is for the HFPPV delivery, one for gas outflow, one for cuff inflation, and one for measuring airway pressures at the distal end of the tube. The use of a closed system also permits application of PEEP, a situation not possible with an open arrangement.

High-frequency jet ventilation (HFJV) uses a pulse of a small jet of fresh gas introduced from a high-pressure source (50 psig) into the airway through a small catheter or additional lumen in an endotracheal tube. Rates used are usually 100 to 400 breaths/minute. The fresh gas jet entrains gas from an injection cannula side-port reservoir. This system is somewhat analogous to the Sanders injector system described in the Bronchoscopy section, and FIO_2 is similarly variable. The

jet and entrained gas flows cause forward motion of the mass of gas in the airways. HFJV can be used with an open system or with a closed arrangement, as described earlier. In the latter, PEEP may be added to enhance oxygenation. Also, with use of high fresh gas flows from an anesthesia circuit, inhaled anesthetics may be delivered as an entrained gas mixture.

High-frequency oscillation ventilation uses a mechanism that oscillates gas at rates of 400 to 2,400 breaths/minute. It has not been described in association with thoracic surgical procedures. In this system, VT is small (50 to 80 mL), and gas exchange occurs through enhanced molecular diffusion and coaxial airway flow.

9 The potential advantages offered by HFPPV during thoracic anesthesia are that lower VT and inspiratory pressures result in a quiet lung field for the surgeon, with minimal movements of airway, lung tissue, and mediastinum. Thus, HFPPV has been used to ventilate both the nondependent and the dependent lung during thoracic surgical procedures, with adequate arterial blood gas measurements obtained throughout. At high frequencies (>6 Hz), however, CO_2 retention may become a problem.

High-frequency jet ventilation has been used to ventilate the nondependent lung to improve PaO_2 during one-lung anesthesia, whereas the dependent lung was ventilated with conventional intermittent positive-pressure ventilation. PaO_2 increased compared with that obtained during simple collapse of the nondependent lung. A study comparing HFJV with CPAP to the nondependent lung during conventional intermittent positive-pressure ventilation to the dependent lung found that both improved PaO_2 significantly during closed and open stages of the surgery. When the chest was open, HFJV maintained satisfactory cardiac output, whereas CPAP usually decreased cardiac output; however, there were no significant differences in $PaCO_2$ between HFJV and CPAP. Because similar increases in PaO_2 may be obtained using selective CPAP to the nondependent lung and much simpler equipment than that necessary to deliver high-frequency ventilation, the use of CPAP would seem preferable to high-frequency ventilation to increase PaO_2 during most one-lung anesthesia situations.

The lower pressures and VTs associated with high-frequency ventilation result in a small leak through BPFs, and HFJV is now generally considered the conservative treatment of choice in this condition. Another advantage of high-frequency ventilation is that the rapid rate small VT can be delivered through small tubes or catheters so if an airway has to be divided, the passage of a small tube across the surgical field permits ventilation of the distal airway and lung tissue. This use has been applied during sleeve resection of the lung, tracheal reconstruction, and surgery for tracheal stenosis. In all three situations, the surgeon is able to work easily around the small catheter used to provide the high-frequency ventilation.

Bronchopleural Fistula and Empyema

A bronchopleural fistula (BPF) is an abnormal communication between the bronchial tree and the pleural cavity. Occasionally, there is an additional communication to the surface of the chest, a cutaneous BPF. BPF occurs most commonly after pulmonary resection for carcinoma. Other causes include traumatic rupture of a bronchus or bulla (sometimes caused by barotrauma or PEEP), penetrating chest wound, or spontaneous drainage into the bronchial tree of an empyema cavity or lung cyst. The incidence of BPF is higher after pneumonectomy than following other types of lung resection. The problems associated with BPF and empyema are that positive-pressure ventilation may result in contamination of healthy lung, loss of air, decreased alveolar ventilation leading to CO_2 retention, and the development of a tension pneumothorax.

If an empyema is present, it should be drained under local anesthesia before any surgery to close the BPF. Drainage is performed with the patient sitting up and leaning toward the affected side. Empyemas are often loculated, and complete drainage is not always possible. A drain to an underwater seal system is left in the cavity before administration of anesthesia for surgery of the BPF, and after drainage of an empyema, a chest radiograph should be obtained to determine the efficacy of the procedure.

The priorities in the anesthetic management of BPF are the isolation of the affected side in terms

the patient is awake using a DLT with the patient breathing spontaneously. Supplemental oxygen should be administered, and the patient should be constantly reassured. Neuroleptanalgesia is satisfactory in providing a suitably cooperative patient, and the airway is then pretreated with topical anesthesia. The endobronchial tube selected should be such that the bronchial lumen is on the side opposite the BPF. Selection of the largest possible tube provides a close fit in the trachea, which helps stabilize the tube. Once the tube is adequately positioned in the trachea, there may be a considerable outpouring of pus from the tracheal lumen if an empyema is present; therefore, this lumen should be immediately suctioned using a large-bore suction catheter. The healthy and possibly the affected lung may then be ventilated; adequacy of oxygenation and ventilation is assessed by pulse oximetry and arterial blood gas analysis.

An alternative technique is to insert the DLT under general anesthesia, with the patient breathing spontaneously to avoid a tension pneumothorax. With either technique, the chest drainage tube must be left unclamped to avoid any bouts of coughing and to prevent the buildup of a tension pneumothorax in the event that a predisposing valvular mechanism exists. In patients who do not have an empyema, use of a single-lumen tube has been described and may be satisfactory if the BPF and air leak are small. A rapid-sequence induction with ketamine or thiopental followed by a relaxant has also been described, but is associated with considerable risk of contamination and tension pneumothorax.

BPF may also be treated conservatively using various ventilatory techniques. Thus, the bronchus of the normal lung may be intubated and ventilated, allowing the BPF to rest and heal. This approach may result in an intolerable shunt, however, and PEEP may be necessary to maintain PaO_2. Differential lung ventilation using a DLT has also been described, the healthy lung being ventilated with normal VT, while the affected lung is exposed to a smaller VT or to CPAP with oxygen at pressures just below the critical opening pressure of the fistula. The critical opening pressure of the BPF can be assessed by determining the lowest level of CPAP that must be applied to the bronchus on the affected side to produce continuous bubbling through the underwater seal chest drain.

For a large BPF, HFJV may be the nonsurgical treatment of choice. The use of small VTS results in minimal gas loss through the fistula, which may heal more quickly. In addition, hemodynamic effects are usually minimal and spontaneous efforts at ventilation are usually abolished, thereby decreasing the work of breathing and eliminating the need for relaxants or excessive sedation.

Lung Cysts and Bullae

Air-filled cysts of the lung are usually bronchogenic, postinfective, infantile, or emphysematous. They may be associated with COPD or be an isolated finding. A bulla is a thin-walled space filled with air that results from the destruction of alveolar tissue. The walls are, therefore, composed of visceral pleura, connective tissue septa, or compressed lung tissue. In general, bullae represent an area of end-stage emphysematous destruction of the lung.

Patients may be considered for surgical bullectomy when dyspnea is incapacitating, when the bullae are expanding, when there are repeated pneumothoraces owing to rupture of bullae, or if the bullae compress a large area of normal lung. Most of these patients have severe COPD and CO_2 retention, and little functional respiratory reserve. The first consideration in management is maintenance of a high FIO_2. If the bulla or cyst communicates with the bronchial tree, positive-pressure ventilation may cause it to expand or even to rupture if it is compliant, producing a situation analogous to tension pneumothorax. If the bulla is very compliant, most of the applied VT may be wasted in this additional dead space. Nitrous oxide should be avoided because it causes expansion of any air spaces in the body, including bullae. Once the chest is open, even more of the VT may enter the compliant bulla, which is no longer limited by chest wall integrity, and an increase in ventilation is needed until the bulla is controlled.

The anesthetic management of these patients is challenging, particularly if the disease is bilateral. Ideally, a DLT is inserted with the patient awake or under general anesthesia but breathing

spontaneously. The avoidance of positive-pressure ventilation (when possible) helps decrease the likelihood of the potential problems described previously, although oxygenation may be precarious with spontaneous ventilation. Once the endotracheal tube is in place, each lung may be controlled separately, and adequate ventilation can be applied to the healthy lung if bilateral disease is not present. Gentle positive-pressure ventilation with rapid, small VT and pressures not to exceed 10 cm H_2O may be used during the induction and maintenance of anesthesia, especially if the bullae have been shown to have no or only poor bronchial communication by preoperative ventilation scanning. While the surgery is being performed, as each bulla is resected, the operated lung can be separately ventilated to check for air leaks and the presence of additional bullae.

If positive-pressure ventilation is to be applied before the chest is opened, the possibility of a tension pneumothorax must be kept in mind, and treatment should be readily available. The diagnosis of pneumothorax may be made by a unilateral decrease in breath sounds (this may be difficult to distinguish in a patient with bullous disease), increase in ventilatory pressure, progressive tracheal deviation, wheezing, or cardiovascular changes. Treatment of a pneumothorax involves the rapid placement of a chest tube. An added risk of chest tube placement is the creation of a cutaneous BPF, which causes problems for ventilation. Alternatively, general anesthesia is induced only after the surgeon has prepared the operative field and draped the patient. In the event of sudden deterioration in the patient's condition during induction, the surgeon may perform an immediate median sternotomy. In any event, the time from induction of anesthesia to sternotomy must be kept to a minimum. Thoracoscopic laser ablation of bullae has also been described.[108]

To avoid these problems in a patient with known bullae, HFJV has been used in a patient with a large bulla undergoing coronary artery bypass graft and in another patient undergoing bilateral bullectomy. If bilateral bullectomy is to be performed, a median sternotomy is usually used. Benumof[109] described the use of sequential OLV using a DLT in the management of a patient needing bilateral bullectomy. The side with the largest bulla and least lung function, as assessed before surgery by ventilation and perfusion scans, should be operated on first. In this way, the lung with the better function should support gas exchange first. If hypoxemia develops during this one-lung situation, application of CPAP to the nonventilated lung during the deflation phase of a tidal breath should increase PaO_2.

Unlike most cases of pulmonary resection, patients after bullectomy are left with a greater amount of functional lung tissue than was previously available to them, and the mechanics of respiration are improved. At the end of the procedure, the DLT is replaced by a single-lumen tube, and the patients generally require several days to be weaned from the ventilator. During this time, the positive airway pressure used should be minimized to avoid causing a pneumothorax owing to rupture of suture or staple lines or of residual bullae.

Lung Volume Reduction Surgery

Emphysematous changes are common in the general population, occasionally resulting in pneumothoraces. A significant

number of these patients require surgical intervention. Many surgical procedures have been performed to alleviate the dyspnea in severely emphysematous patients, some with beneficial effect and others without any proven beneficial outcome. More recently, laser and videoscopic technology have been used to ablate small bullae.[105,110,111] Lung volume reduction surgery (LVRS) should not be confused with excision of giant bullae. In these (bullae) cases, the presumed mechanism of improvement in lung function, exercise tolerance, and oxygenation is secondary to reexpansion of more normal, underlying compressed lung.[111]

In 1959, Brantigan et al.[112] reported on the surgical management of diffuse emphysema:

> In patients with distended lungs caused by severe COPD, the normal outward circumferential pull on the bronchioles had been lost, causing their collapse during expiration. Reducing overall lung volume, by means of multiple wedge

> excisions or plications, would restore the elastic pull on the small airways and reduce expiratory airway obstruction.… Thus, in these patients with severe dyspnea, a distended chest, and a flattened diaphragm, surgical excision of a functionless but nonbullous area by multiple wedge resections, can relieve the dyspnea. Thus, lung volume reduction results in the use of "bilateral multiple wedge excisions of bullous and nonbullous areas of the lung in patients with diffuse emphysema to improve pulmonary mechanics."

The Brantigan procedure did not receive wide acceptance. In the absence of an automated stapler, surgery was performed with a hand-sutured line of resection, which resulted in a high incidence of persistent air leak and an 18 to 20% mortality rate. The procedure was resurrected by Cooper et al.[113] after their experience with lung transplantation in patients with severe emphysema. The critical issue was to determine the optimal size of donor lungs for emphysematous recipients. The TLC of the recipient is much larger than that of the donor lung. If the lung does not fill the recipient chest, complications such as prolonged air leak and pleural effusion will persist. Their conclusion was that the ability of the chronically distended chest to configure to a smaller volume gave credence to the notion that downsizing the lungs in an emphysematous patient might improve respiratory mechanics by alleviating the overdistention. This is the basis of a resurgence of interest in the Brantigan proposal as to the surgical options for diffuse bullous emphysema (e.g., lung volume reduction).

Outcome of Lung Volume Reduction Surgery

LVRS rapidly gained popularity.[114,115,116,117] Evidence of a short-term beneficial effect was observed. By decreasing the FRC and returning the diaphragm to a more normally curved and lengthened configuration, improvement in the mechanical function of the diaphragm and intercostal muscles was noted.[118] These benefits may be evidenced by an increased contribution of the abdominal compartment to tidal volume and diminished paradoxical motion of the chest wall and abdomen during inspiration in postoperative patients.[119] In addition, recovery of ventricular function (cardiopulmonary interdependence) was seen.[120] A decreased central respiratory drive and ventilatory response to CO_2 was also noted.[121] Inspiratory lung resistance correlated significantly (and inversely) with the improvement in FEV_1 after surgery.[122] This suggests that patients with a greater loss of elastic recoil, but with intact airway structure, may derive the most benefit from the procedure.

Finally, the RV/TLC ratio was the only preoperative predictor of the increase in forced vital capacity following LVRS, and an increase in FEV_1 was largely attributable to the increase in FVC.[123,124,125,126,127,128,129,130]

The National Emphysema Treatment Trial

Due to the large number of potential procedures that could be performed in the Medicare patient population, in the absence of sufficient evidence of beneficial outcome, the National Institutes of Health (NIH) and the Health Care Financing Administration (HCFA) concluded in 1995 that "although initial results were promising, LVRS was often being performed with sufficient evaluation and a randomized study should be undertaken to evaluate the procedure critically." (Note: The HCFA has been renamed The Centers for Medicare & Medicaid Services.) The National Emphysema Treatment Trial (NETT) was established as a randomized multicenter prospective clinical trial of medical versus surgical treatment of patients with severe bilateral emphysema. In addition, comparison of the surgical approaches, sternal split versus bilateral video-assisted thoracoscopy, would be evaluated.[117,131] Twenty-five hundred (n = 2,500) patients were to be enrolled in the trial, with survival as the primary outcome. The other parameters to be evaluated included the maximum exercise capacity, pulmonary function, and oxygen requirement for distance walking 6 minutes; quality of life; and costs. The study was designed to determine which patients would benefit from the procedure and what is the best surgical approach (median sternotomy or bilateral video-assisted thoracoscopy); to establish the cost-effectiveness; and

finally, to assess the utility as an alternative, or more likely as a bridge, to lung transplantation.

In 2001, the NETT Research Group published a preliminary report (*n* = 1,033 patients) entitled "Patients at High Risk of Death After Lung Volume–Reduction Surgery."[131] This report recommended not performing surgery on the highest-risk patients with emphysema. The investigators concluded that the operation harmed some patients and did not benefit those who survived. In an accompanying editorial, Dr. Jeffrey Drazen, the Editor-in-Chief of the *New England Journal of Medicine*, agreed: "At this time, it does not make sense to use lung-volume–reduction surgery in patients whose emphysema is so severe that they meet these exclusion criteria."[132]

However, a subsequent report from the NETT that described the results of all 1,228 randomized patients divided the subjects into four groups, depending on the extent of the emphysema and their exercise capacity.[133] The first group with upper lobe emphysema and a low exercise capacity had a significant reduction in mortality with surgery. The other two groups, those with upper lobe emphysema and high exercise capacity and those with non–upper lobe emphysema and low exercise capacity, had similar mortality with surgery or medical therapy. Only the fourth group with non–upper lobe emphysema and high exercise capacity had a higher mortality with surgery (Fig. 29-24). The place of LVRS in the management of emphysema remains controversial and should be applied selectively.

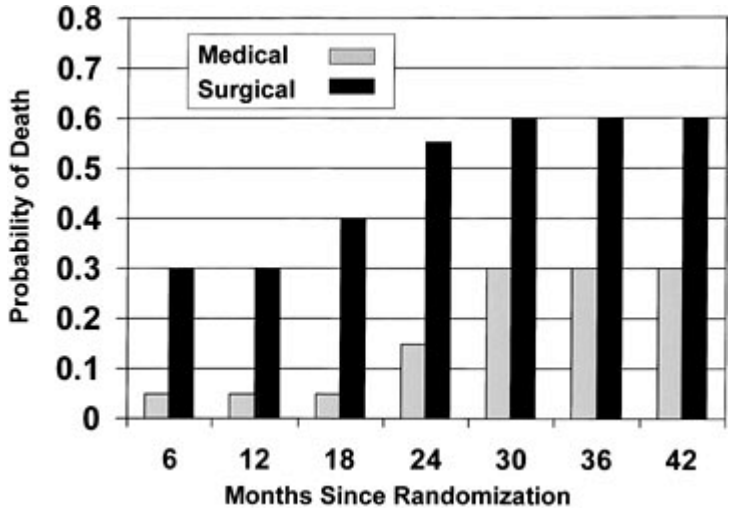

FIGURE 29-24. Mortality rates in the medical versus surgical treatment for the NETT trial. (Based on data from Fishman A, Martinez F, Naunheim K *et al*: A randomized trial comparing lung-volume-reduction surgery with medical therapy for severe emphysema. N Engl J Med 348:2059, 2003.)

Patient Selection

The patient selection criteria are summarized in Table 29-4. Indications for a good outcome include age younger than 75 years, FEV_1 > 0.5 L (FEV_1 of 15 to 20% of predicted is less useful as a predictor of postoperative respiratory support), PaO_2 > 55 mm Hg, and $PaCO_2$ 40 to 45 mm Hg (>50 mm Hg is of concern).

TABLE 29-4 Lung volume reduction surgery

·PATIENT SELECTION

Progressive emphysema Severe, symptomatic dyspnea Radiographic evidence of diffuse emphysema Identifiable distention and hyperinflated lung tissue FEV_1 <40%, RV >150%, TLC >120% predicted No previous chest surgery Smoking cessation Acceptable cardiac function
·CONTRAINDICATIONS
Age >75 years Uniformly destroyed lungs FEV_1 <15% of predicted $Paco_2$ >55 mm Hg O_2 >6 L/min Pulmonary hypertension Severe kyphoscoliosis Predominance of chronic bronchitis, asthma Active infection Inability to complete preoperative rehabilitation program
FEV_1, forced expiratory volume in 1 second; RV, residual volume; TLC, total lung capacity.

Lung Volume Measurement. Body plethysmography (BP) versus inert gas (IG) technique provides some information on the degree of trapped gas in the emphysematous lung (trapped gas index = IG/BP).

Ventilation–Perfusion Scan. The ideal candidate presents with 30 to 40% reduction in perfusion to the upper lobes. In the case of α_1-antitrypsin deficiency, decreased perfusion is also evident in the lower lobes. The least favorable candidates by

scanning are those with a patchy, mottled pattern, uniformly affecting the lung.[134]

Anesthetic Management

Bronchodilator therapy is continued until the morning of surgery. Morphine and atropine premedication is administered to facilitate insertion of bronchoscopes and tracheal intubation. In addition to steroids, bronchodilators are commonly used intraoperatively. A thoracic epidural catheter is best placed before induction of anesthesia in the sitting position at T3–T4 level.[135,136] During induction of anesthesia, increases in intrathoracic pressure after neuromuscular blockade should be avoided. These patients are intravascularly depleted and have large wasted muscle mass. They commonly present with polycythemia, which may give a false impression of adequate hydration. Therefore, hydration, stable hemodynamic induction with an agent such as etomidate, and gentle ventilation may attenuate the increase in intrathoracic pressure and the degree of hypotension. Patients who have undergone surgery for emphysematous conditions are best managed with spontaneous ventilation as soon as possible after the procedure. Therefore, short-acting neuromuscular blocking agents (rocuronuim, cisatracurium, vecuronium) are indicated. Pain relief must be optimal as soon as possible because it enables early tracheal extubation and early mobilization, which is crucial to the recovery of these patients. OLV is an absolute requirement,

whether the procedure is performed by sternal split or bilateral thoracoscopy.[137] This author (EC) prefers using a double-lumen tracheal tube over endobronchial blockers for complete and reliable isolation and rapid lung deflation. However, whichever tube is used in these patients with a marginal respiratory reserve, perfect isolation and confirmation with fiberoptic bronchoscopy are mandatory.

In the post anesthesia care unit (PACU), it is important to recognize the early signs of tension pneumothorax and dynamic hyperinflation as possible complications. Adequate analgesia, chest physiotherapy, incentive spirometry, and early ambulation are all important for a successful outcome.

Anesthesia for Resection of the Trachea

Tracheal resection and reconstruction are technically difficult for the surgeon and challenging for the anesthesiologist. Indications for this type of procedure include congenital lesions (agenesis, stenosis), neoplasia (primary or secondary), injuries (direct or indirect), infections, and postintubation injuries (caused by an endotracheal tube or tracheotomy). For the surgical team, the major problems are maintenance of ventilation to the lungs while the airway is being operated on and postoperative integrity of the anastomoses. In this respect, the presence of lung disease sufficiently severe to require postoperative ventilatory support is a relative contraindication to tracheal resection or reconstruction.

Monitoring of these patients should include placement of an arterial cannula in the left radial artery to permit continuous measurement of blood pressure during periods of innominate artery compression. Steroids should be administered to help reduce any tracheal edema, and a high FIO_2 should be used throughout the procedure to ensure an adequate oxygen reserve at all times in the FRC so temporary interruptions of ventilation are less likely to produce hypoxemia.

Numerous methods have been reported to provide oxygenation and ventilation of the lungs during these procedures. A small-bore anode tube may be placed through and distal to an upper tracheal lesion so resection may occur around the tube. This technique is useful only in mild stenoses. Alternatively, an endotracheal tube may be passed through the glottis to above the stenosis, and a sterile endotracheal or bronchial tube may later be inserted into the trachea opened distal to the site of stenosis, with the sterile anesthesia tubing being led across the surgical field. After resection of the lesion, the sterile and distally placed endotracheal tube is withdrawn, and the upper tube (originally passed through the glottis) is advanced across the anastomosis. With low tracheal or bronchial lesions, resection and reconstruction may be performed around an endobronchial or DLT. During these procedures, the patient is kept in a head-down position to minimize aspiration of blood and debris into the alveoli, and ventilation must be carefully monitored throughout.

Clearly, the presence of a large-bore tube in the airway may make these resections technically difficult, and the use of high-frequency ventilation techniques may improve surgical access.

Thus, a small-diameter catheter or catheters may be placed across or through the stenotic lesion or transected airway(s) and ventilation to the distal airways and lungs maintained using HFPPV or HFJV. Potential disadvantages of these high-frequency ventilation techniques are that, by necessity, the system is "open" (see High-Frequency Ventilation section), and egress of gas during exhalation may be compromised if the stenosis is tight. Also, the catheter may become occluded by blood and become displaced, and distal aspiration of debris or blood may occur. With complex resections, two anesthesia teams with two machines and anesthesia circuits or sets of ventilating equipment may be necessary to ensure adequate ventilation of the two distal airway segments, although during carinal resections, HFPPV to the left lung alone usually provides adequate oxygenation and ventilation.

After tracheal resection or reconstructive surgery, patients should be kept with their neck and head flexed to reduce tension on the anastomotic suture lines. In some cases, this is maintained by using sutures between the chin and the anterior chest wall. Extubation of the trachea is

performed as early as possible to minimize tracheal trauma due to the endotracheal tube and cuff.

Bronchopulmonary Lavage

This procedure involves irrigation of the lung and bronchial tree, and is used as a treatment for alveolar proteinosis, radioactive dust inhalation, cystic fibrosis, bronchiectasis, and asthmatic bronchitis. Lung lavage is performed under general anesthesia using a DLT so one lung may be ventilated while the other is being treated with lavage fluid.[138]

The preoperative assessment of these patients should include ventilation–perfusion scans so lavage can be performed first on the more severely affected lung (i.e., the one with the least ventilation). If involvement is equal, the left lung is generally lavaged first because gas exchange should be better through the larger, right lung. Patients are premedicated and supplied with supplemental oxygen en route to the operating room.

Anesthesia is induced with an intravenous drug and maintained with an inhaled agent in oxygen to maintain the highest possible FIO_2. Muscle relaxation facilitates placement of the DLT, and the cuff seal should be checked to maintain perfect separation at a pressure of 50 cm H_2O to prevent leakage of lavage fluid around the cuff. A fiberoptic bronchoscope is useful to check the position of the bronchial cuff of the DLT. Monitoring should include an arterial catheter, and a stethoscope should be placed over the ventilated lung to check for rales, the presence of which may indicate leakage of lavage fluid into this lung.

The patient is maintained on an FIO_2 of 1.0 throughout the procedure. Before lavage, this serves to denitrogenate the lungs so only oxygen and carbon dioxide remain. Instillation of fluid then allows these gases to be absorbed, resulting in greater access by the fluid to the alveolar spaces than if the more insoluble nitrogen bubbles remained.

Once the trachea is intubated, the patient is turned so the side to be lavaged is lowermost, and the DLT position and seal are checked once again. With the patient in a head-up position, warmed heparinized isotonic saline is infused by gravity from a reservoir 30 cm above the midaxillary line into the catheter to the dependent lung, while the nondependent lung is ventilated. When fluid ceases to flow in (usually after 700 to 1,000 mL in an adult), the patient is placed in a head-down position and fluid is allowed to drain out. The lavage is continued until the effluent is clear (as opposed to the milky fluid that drains initially when lavage is being performed for alveolar proteinosis), at which point the lung is suctioned and ventilation is reestablished with large VT (and pressures) because compliance is decreased owing to loss of surfactant. With each lavage, inflow and outflow volumes are monitored so the patient is not "drowned" in fluid, and there is no excessive absorption or leakage to the ventilated side. At least 90% of the saline volume should be recovered with each lavage. Two-lung ventilation is reestablished and, as compliance improves, an air–oxygen mixture (addition of nitrogen) may be introduced to help maintain alveolar patency. After a further period of ventilation, in most patients, the trachea can be extubated in the operating room. In the posttreatment period, patients are encouraged to cough and engage in breathing exercises to fully reexpand the treated lung. From 3 days to 1 week after lavage of the first lung, the patient may return to the operating room for lavage of the other lung.

Problems sometimes encountered with this procedure include spillage of lavage fluid from the treated to the ventilated lung. This must be managed by stopping the lavage and ensuring functional separation of the lungs before continuing. DLT positioning is critical. Spillage may cause profound decreases in oxygenation, which may necessitate terminating the procedure and maintaining two-lung ventilation with oxygen and PEEP.

During periods when lavage fluid is being instilled into the dependent lung, oxygenation usually improves because the increased intra-alveolar pressure caused by the fluid produces diversion of the pulmonary blood flow to the nondependent, ventilated lung. Conversely, when the fluid is drained out of the dependent lung, hypoxemia may occur.[138] In some cases in which severe hypoxemia was anticipated during right lung lavage, the risk has been reduced by passing a balloon-tipped catheter into the right main pulmonary artery (checked by radiography) and inflating the balloon during periods of right lung drainage. In this way, blood flow to the

dependent, right, nonventilated lung is minimized during periods of drainage. This technique is not without risk (e.g., pulmonary artery rupture) and is reserved for those patients considered to be at greatest risk for hypoxemia during lavage. Almitrine by infusion and nitric oxide by inhalation have also been reported to improve oxygenation during bronchopulmonary lavage.[88]

If the patient has recently had a diagnostic open lung biopsy, a BPF may be present. If this is a possibility, a chest tube should be inserted on the side of the BPF, and this side should be lavaged first. The chest drain is removed several days later.

Limitations in the sizes of available DLTs preclude their use for lavage in patients weighing less than 40 kg. In such cases, cardiopulmonary bypass may be required to provide oxygenation during lavage.

Myasthenia Gravis

10 The thoracic anesthesiologist will most likely have to manage patients with myasthenia gravis (MG) for thymectomy, which is now considered the treatment of choice in most cases of MG. MG is a disorder of the neuromuscular junction, the function of which is altered routinely in the modern practice of anesthesia. The worldwide prevalence of the disease is 1 per 20,000 to 30,000 of the population; it is more common in women than men in a 6:4 ratio. People of any age may be affected, but peaks of incidence occur in the third decade for women and the fifth decade for men. MG is a chronic disorder characterized by weakness and fatigability of voluntary muscles with improvement following rest.[139] Onset is usually slow and insidious, any skeletal muscle or group of muscles may be affected, and the condition is associated with relapses and remissions. The most common onset is ocular; if the disease remains localized to the eyes for 2 years, the likelihood of progression to generalized MG is low. In some cases, the disease is generalized and may involve the bulbar musculature, causing problems with breathing and swallowing. Peripheral muscle involvement may cause

weakness, clumsiness, and difficulty in holding up the head or in walking. The most commonly used clinical classification of MG is shown in Table 29-5.

TABLE 29-5 Clinical classification of Myasthenia Gravis

I	Ocular myasthenia—Involvement of ocular muscles only. Mild with ptosis and diplopia. Electrophysiologic testing of other musculature is negative for MG.
IA	Ocular myasthenia with peripheral muscles showing no clinical symptoms but showing a positive electromyogram for MG.
II	Generalized myasthenia
IIA	Mild—Slow onset, usually ocular, spreading to skeletal and bulbur muscles. No respiratory involvement. Good response to drug therapy. Low mortality rate.
IIB	Moderate—As IIA but progressing to more severe involvement of skeletal and bulbar muscles. Dysarthria, dysphagia, difficulty chewing. No respiratory involvement. Patient's activities limited. Fair response to drug therapy.
III	Acute fulminating myasthenia—Rapid onset of severe bulbar and skeletal weakness with involvement of muscles of respiration. Progression usually within

	6 months. Poor response to therapy. Patient's actvities limited. Low mortality rate.
IV	Late severe myasthenia—Severe MG developing at least 2 years after onset of group I or group II symptoms. Progression of disease may be gradual or rapid. Poor response to therapy and poor prognosis.
MG, myasthenia gravis.	
Adapted from Osserman KE, Genkins G: Studies in myasthenia gravis—A review of a 20-year experience in over 1200 patients. Mt Sinai J Med 38:497, 1971.	

In MG, there is a decrease in the number of postsynaptic acetylcholine receptors at the end plates of affected muscles. This causes a decrease in the margin of safety of neuromuscular transmission. MG is an autoimmune disorder, and most of the affected patients have circulating antibodies to the acetylcholine receptors. These antibodies may cause complement-mediated lysis of the postsynaptic membrane or direct blockade of the receptors, or may modulate the receptor turnover such that the degradation rate exceeds the resynthesis rate. Studies of the end plate area show loss of synaptic folds and a widening of the synaptic cleft.

The diagnosis of MG is suspected from the history and confirmed by pharmacologic, electrophysiologic, or immunologic testing. Patients cannot sustain or repeat muscular contraction. The electrical counterpart of this is a decrement in the muscle action potentials evoked by repetitive stimulation of a motor nerve. Mechanical and electrical (electromyography) decrements improve with 2 to 10 mg of intravenous edrophonium (Tensilon test). MG patients characteristically are sensitive to *d*-tubocurarine. When the routine electromyographic results are equivocal, a regional curare test may be performed using a tourniquet to isolate the limb and limit the action of the drug. In the regional curare test, electromyograms are performed before and after the administration of 0.2 mg of curare. In equivocal cases, a positive result of a test for antiacetylcholine receptor antibodies is considered diagnostic.

Medical Therapy

Anticholinesterases are used to prolong the action of acetylcholine at the postsynaptic membrane and may also exert their own agonist effect at the acetylcholine receptors. They are the most commonly used therapy in MG (Table 29-6). Myasthenic patients learn to regulate their medication and titrate dose against optimum effect. Overdosage causes the muscarinic effects of acetylcholine and may cause a cholinergic crisis. Underdosage causes weakness or a myasthenic crisis. In a patient with weakness, distinction between the two types of crisis may be made by performing a Tensilon test or by examining pupillary size, which will be large (mydriatic) in a myasthenic crisis but small (miotic) in a cholinergic crisis. Muscarinic side effects are treatable with atropine.

TABLE 29-6 Anticholinesterase drugs used to treat myasthenia gravis

·DRUG	·DOSE (mg) ·ORAL	·IV	·IM	·EFFICACY

Pyridostigmine (Mestinon)	60	2.0	2.0–4.0	1
Neostigmine (Prostigmine)	15	0.5	0.7–1.0	1

iv, intravenous; im, intramuscular.

The immunologic basis of MG has led to the use of immunosuppressive drugs such as steroids, azathioprine, cyclophosphamide, and, most recently, cyclosporine. Steroids often produce initial deterioration before an improvement. The usual regimen is prednisone 1 mg/kg on alternate days. The other drugs mentioned represent third and fourth lines of treatment.

Plasma exchange or plasmapheresis may produce dramatic but transient improvements in muscle strength with decreases in antiacetylcholine receptor antibody titers. Usually reserved for severe MG, plasma exchange has been shown to improve respiratory function in both operated and nonoperated patients with MG. Plasmapheresis causes a decrease in plasma cholinesterase levels that may prolong the effect of drugs such as succinylcholine that are normally broken down by this enzyme system.

Abnormalities are found in 75% of thymus glands removed from patients with MG (85% show hyperplasia, 15% thymoma). After thymectomy, approximately 75% of patients either go into remission or show some improvement. Thymectomy is now considered the treatment of choice in most patients with MG, except for those in Osserman class I (see Table 29-5).

Management of General Anesthesia

When possible, patients with MG should be admitted for elective surgery while in remission.[140] On admission, the patient's physical and emotional states should be optimized. Other diseases occasionally associated with MG should be excluded (Table 29-7). The patient's current drug therapy should be reviewed and possible drug interactions considered. Because patients are less active while in the hospital, their anticholinesterase dosage may need to be decreased. If the patient has a history of respiratory disease or bulbar involvement, preoperative evaluation should include respiratory function studies. Breathing exercises and instruction in the use of incentive spirometers may be indicated. Patients should be told of the possible need for postoperative intubation of the trachea and ventilation of the lungs. Ideally, patients with MG should be scheduled to be the first case of the day in the operating room. Patients receiving steroid therapy should receive perioperative coverage.

TABLE 29-7 Disorders Associated with Myasthenia Gravis

Thymoma	Multiple sclerosis
Thyroid disease	Ulcerative colitis
Hyperthyroidism	Leukemia
Hypothyroidism	Lymphoma
Thyroiditis	Convulsive disorders

Idiopathic thrombocytopenic purpura Rheumatoid arthritis Systemic lupus erythematosus Anemias Pernicious Hemolytic	Extrathymic neoplasia Sjögren's syndrome Scleroderma

Because the trachea is to be intubated and the lungs ventilated for the planned procedure in the patient with MG, anticholinesterase therapy should be withheld on the morning of

surgery so the patient is weak on arrival at the operating room. This avoids interactions with other drugs used in the operating room. Anticholinesterase therapy may be continued if the patient is physically or psychologically dependent on it. Premedication is satisfactorily achieved with a benzodiazepine or barbiturate. Opioids are usually avoided because of the risk of producing respiratory depression.

Monitoring should be dictated by the patient's state and planned surgical procedure, but should include an assessment of neuromuscular transmission (by means of a mechanomyogram/twitch monitor, an integrated electromyographic monitor, or an accelograph monitor) if agents affecting neuromuscular transmission are to be used.

Induction of anesthesia is readily achieved with a short-acting barbiturate or propofol. In elective cases, intubation of the trachea, maintenance, and relaxation are readily achieved using potent inhaled anesthetics. Anesthesia may be deepened using a potent inhaled agent and the trachea intubated under its effect. Myasthenic patients are more sensitive than normal patients to the neuromuscular depressant effects of the potent inhaled agents. In patients with MG, isoflurane at 1.9 MAC end-tidal concentration induced a neuromuscular block of 30 to 50%, whereas halothane at 1.8 MAC induced a block of 10 to 20%. Both agents produced fade in the train-of-four ratio of 41% and 28%, respectively.[141] Because these inhaled agents are easily administered and withdrawn, they are the most commonly used anesthetic drugs for patients with MG. At the end of the procedure, the drug is discontinued and recovery of neuromuscular function begins.

Nondepolarizing Relaxants. In some cases, patients with MG cannot tolerate the cardiovascular depressant effects of the potent inhaled anesthetics, in which case neuromuscular blocking drugs may be used, titrating dose against monitored effect. Patients with MG are sensitive to the nondepolarizing relaxants. A usual defasciculating dose in a normal patient may represent an ED_{90} in a patient with MG.[140] All nondepolarizing relaxants have been successfully and uneventfully used with careful monitoring in patients with MG. They should be titrated in 1/10 to 1/20 of the usual dose. Atracurium is probably the preferred agent because of its short elimination half-life (20 minutes), small volume of distribution, lack of cumulative effect, and high clearance. The Hofmann elimination pathway results in atracurium having very reproducible pharmacodynamics and kinetics, and most patients do not require reversal if monitored carefully. The ED_{90} of atracurium in patients with MG is approximately one-fifth of that in normal patients.[142] Relaxation is readily maintained thereafter using an atracurium infusion, and recovery time is not prolonged with this drug. Cisatracurium is also an appropriate choice.[143] Sensitivity to nondepolarizing relaxants is increased during the coadministration of a potent inhaled anesthetic.[144]

Although other short-duration or intermediate-duration nondepolarizing agents may be used, they do have cumulative effects, which may represent a potential disadvantage. Long-acting relaxants

are probably best avoided in patients with MG. Myasthenic patients show increased sensitivity to mivacurium. Because mivacurium is metabolized by cholinesterase, anticholinesterase drugs prolong the recovery from this relaxant.[145] If necessary, the other nondepolarizers may be reversed by increments of anticholinesterase drugs, while neuromuscular transmission is carefully monitored to obtain maximum antagonism yet avoid a cholinergic crisis. All anticholinesterases have been safely used. Edrophonium may be the drug of choice because its onset of action is rapid and higher doses have a prolonged duration of action. Because of the risk of cholinergic crisis with anticholinesterase agents, the rapid, predictable, spontaneous recovery from atracurium (or cisatracurium) may represent an additional advantage in that reversal may not be necessary.[140]

The sensitivity of patients with MG to nondepolarizing relaxants is very variable, depending on the individual patient, the severity of MG, and the treatment. Mann et al.[146] showed that MG patients who have a T4/T1 ratio <0.9 in the preanesthetic period show increased sensitivity to atracurium. They suggest that neuromuscular monitoring using TOF stimulation should begin in the preinduction period following administration of adequate analgesia (fentanyl 2 μg/kg). Itoh et al.[147] found that patients with ocular MG were less sensitive to vecuronium than were those with generalized MG. They also found that in patients with clinical MG, sensitivity to vecuronium was unrelated to presence or absence of antibodies to the acetylcholine receptor. Seronegative patients were as sensitive to vecuronium as seropositive patients.[148] There are conflicting reports as to the sensitivity of patients with MG in remission. All such patients should be considered sensitive to nondepolarizers until proven otherwise.

Succinylcholine. Myasthenic patients are resistant to the neuromuscular blocking effects of succinylcholine. The ED_{95} is 2.6 times normal in these patients.[149] Clinically, however, the use of succinylcholine has been without incident, with the usual clinical doses producing adequate relaxation for endotracheal intubation and a normal recovery time, despite the occasionally reported early onset of phase II block. Doses of 0.2 to 1.0 mg/kg have been used in a number of patients with MG, and most did not show fasciculation before becoming paralyzed. Fade in response to train-of-four stimulation was observed in some patients during recovery, but recovery was not delayed. Prior administration of an anticholinesterase may complicate the response to succinylcholine by delaying its metabolism.

When a rapid-sequence intubation of the trachea is required, rapid onset of muscle relaxation may be achieved with succinylcholine or with moderate doses of a nondepolarizer in the latter case, with an associated prolongation of effect. A succinylcholine (1.5 mg/kg)–vecuronium (0.01 mg/kg) sequence has been safely used in three patients with MG for thymectomy. The authors suggested that this technique may be particularly advantageous when rapid-sequence induction of anesthesia is indicated.[150]

Nonrelaxant Techniques. Because of concerns over the use of muscle relaxants in MG patients, there are many reports of successful use of nonrelaxant techniques. Della Rocca et al.[151] studied 68 consecutive MG patients undergoing transsternal thymectomy randomized to receive propofol/O_2/N_2O/fentanyl or sevoflurane/N_2O/O_2/fentanyl. All were tracheally extubated in the operating room, and none required intubation for postoperative respiratory depression. Madi-Jebara et al.[152] described the use of sevoflurane as the sole anesthetic combined with intrathecal sufentanil-morphine for analgesia in an adult patient who underwent transsternal thymectomy. Abe et al.[153] described propofol anesthesia combined with thoracic epidural

anesthesia for thymectomy in 11 patients with MG. Chevalley et al.[154] reported use of propofol combined with epidural bupivacaine and sufentanil in 12 MG patients undergoing similar procedures. They commented that the shift away from use of muscle relaxants provided optimal operating condition and improved patient comfort. Lorimar and Hall[155] used a total intravenous anesthetic (TIVA) technique with propofol and remifentanil for transsternal thymectomy in an MG patient. Baraka et al.[156] described a 19-year-old myasthenic patient with a thymoma who received remifentanil and sevoflurane anesthesia for a 2-hour thymectomy. Although the trachea was extubated 10 minutes after discontinuation of remifentanil, the patient was unresponsive to verbal stimuli and remained somnolent for 12 hours. Because the patient had been receiving pyridostigmine for the months prior to surgery, they suggest that the delayed arousal may have

been due to possible inhibition by pyridostigmine of the nonspecific esterases that normally hydrolyze remifentanil. Ingersoll-Weng et al.[157] reported use of a dexmedetomidine infusion/isoflurane technique for transsternal thymectomy in a 52-year-old female. The patient was stable at the start of surgery but became asystolic on sternal retraction and received open cardiac massage. Resuscitation was successful, the dexmedetomidine infusion was discontinued, and surgery was completed uneventfully. Several factors may have contributed to the asystolic arrest, including a centrally mediated increase in parasympathetic activity resulting from dexmedetomidine in a patient who was also being treated with pyridostigmine, which also increases vagal tone. Thus, pyridostigmine may have interacted with dexmedetomidine in an additive or synergistic manner.

Other Drug Interactions. Medications with neuromuscular blocking properties should be used with caution in patients with MG, particularly if relaxants are being used concurrently. Such drugs include antiarrhythmics (quinidine, procainamide, calcium channel blockers), diuretics (by causing hypokalemia), nitrogen mustards, quinine, and aminoglycoside antibiotics. Dantrolene has been used safely in a patient with MG.

Recovery From Anesthesia. Recovery from anesthesia must be carefully monitored in these patients. Extubation of the trachea should be performed when the patients are responsive and able to generate negative inspiratory pressures of greater than -20 cm H_2O. After extubation of the trachea, patients are carefully observed in the recovery area or the intensive care unit. As soon as possible, patients should resume their usual pyridostigmine regimen. Cases of mild respiratory depression may be treatable with parenteral anticholinesterase; more severe cases may require reintubation of the trachea and mechanical ventilation of the lungs. In the immediate postoperative period, postthymectomy patients often show a marked improvement in their condition and a decreased need for anticholinesterase therapy.

Postoperative Respiratory Failure

Myasthenic patients are at increased risk for development of postoperative respiratory failure. There have been several attempts to predict before surgery which patients with MG will require prolonged postoperative ventilation of the lungs.[158] For patients who underwent transsternal thymectomy, positive predictors were a duration of MG >6 years; history of chronic respiratory disease, other than that directly caused by MG; pyridostigmine dosage >750 mg/day; and a preoperative vital capacity <2.9 L. This predictive system was not found useful when applied in patients with MG undergoing transsternal thymectomy at other centers, and of no value in patients with MG undergoing other types of surgical procedure.[158] In a study of 52 MG patients following thymectomy, Mori et al.[159] concluded that those patients who received >250 mg of pyridostigmine were at greater risk for respiratory failure requiring reintubation. Each patient should therefore be treated on his or her own merits.

A study of patients undergoing transsternal thymectomy suggested that the need for postoperative mechanical ventilation correlated best with preoperative maximum static expiratory pressure. It was concluded that expiratory weakness, by reducing cough efficacy and ability to clear secretions, was the main predictive determinant. Adequate clearance of secretions is essential in these patients and may occasionally necessitate bronchoscopy.

In general, the postoperative morbidity in terms of respiratory failure is lower after transcervical rather than transsternal thymectomy.[158] Techniques described that may be useful in reducing postoperative ventilatory failure include preoperative plasma exchange and high-dose perioperative steroid therapy. If the anticipated duration of the surgical procedure is 1 to 2 hours, preoperative oral anticholinesterase therapy may be of value because the peak effect of the drug coincides with the conclusion of the surgical procedure and attempts at tracheal extubation.

Postoperative Care

In the immediate postoperative period, pain relief for patients with MG is usually provided by opioid analgesics, such as meperidine, but in reduced doses. The analgesic effect of morphine and other opioid analgesics has been reported to be increased by anticholinesterases, which has led to

the recommendation that the dose of opioid analgesics be reduced by one-third in patients receiving anticholinesterase therapy. Combined regional and general anesthesia techniques have also been used to provide good surgical conditions and improved postoperative analgesia in patients with MG undergoing thymectomy. Combined epidural–general anesthesia has been reported to provide excellent intraoperative and postoperative conditions for both surgeon and patient.[160,161]

Myasthenic Syndrome (Eaton-Lambert Syndrome)

The myasthenic syndrome is a very rare disorder of neuromuscular transmission that is sometimes associated with small cell carcinoma of the lung. Complaints of weakness may be mistaken for MG, but in Eaton-Lambert syndrome, symptoms do not respond to administration of anticholinesterases or steroids, and activity improves strength. The defect in this condition is believed to be prejunctional, associated with diminished release of acetylcholine from nerve terminals, and improved by agents such as 4-aminopyridine, guanidine, and germine that increase repetitive firing. Affected patients are particularly sensitive to the effects of all muscle relaxants, which should be used with great caution or avoided entirely.[162] The possibility of Eaton-Lambert syndrome should be considered in all patients with known malignant disease and those patients undergoing diagnostic procedures for suspected carcinoma of the lung. Anesthesia considerations in these patients are essentially the same as in those with MG.[163]

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Postoperative Pain Control

11 After extubation of the trachea, respiratory therapy and pain management become critical components of postoperative care. Adequate postoperative pain control is necessary to

ensure a good respiratory effort.[144,164] Administration of intravenous opioids has been the standard form of pain management for years. These drugs may improve pulmonary function slightly or allow respiratory therapy maneuvers; however, meperidine (50 mg) has been shown to be relatively ineffective at allowing patients to increase their ability to cough. Advantages of intravenous opioids are the ease of administration, relatively low toxicity, and the lack of a need for close medical supervision. The key disadvantage is the inadequate pain relief leading to postoperative atelectasis and great discomfort on the part of the patient. The administration of sufficient opioid to treat pain adequately is likely to cause sedation and respiratory depression.

Patient-controlled analgesia (PCA) has been reported to decrease the amount of postoperative pain, drug use, sedation, and pulmonary complications.[165] PCA also eliminates the delays associated with personnel-administered medications and in general is very well accepted by patients. Subcutaneous PCA with hydromorphone has been reported to be as effective as intravenous PCA. Complications related to the use of PCA are presented elsewhere in this volume (see Chapter 55).

Many clinicians have suggested the use of intercostal nerve blocks before, during, or after thoracic surgery to decrease pain and improve postoperative respiratory function. Studies have documented a decrease in requirements for postoperative opioids, improved respiratory function, and some decrease in time of hospital stay. The intercostal blocks can be performed externally before or after surgery using a standard technique. However, the easiest method during thoracic surgery is to have the surgeon perform the blocks under direct vision from inside the thorax while the chest is open. Bupivacaine 0.5%, in doses of 2 to 3 mL, can be placed in the five intercostal spaces around the incision and in intercostal spaces where chest tubes will be placed. This provides 6 to 24 hours of moderate pain relief, but patients still complain of diaphragmatic and shoulder discomfort caused by the chest tubes. Larger volumes of local anesthetic (e.g., 5 to 10 mL) should not be used in the intercostal space because of the high absorption rate and attendant systemic toxicity that can be produced, as well as the possibility of pushing the drug centrally and producing a paravertebral sympathetic or epidural block with central sympatholysis and severe hypotension. The intraoperative placement of catheters in intercostal grooves allows for a

continuous postoperative intercostal nerve block. The technique reduces pain and improves pulmonary function. Although bupivacaine has been used in most reports, use of lidocaine has also been described.

A prolonged intercostal nerve block may be obtained by cryoanalgesia, a technique of freezing the nerve under direct vision at the time of thoracotomy. A cryoprobe is applied directly to the nerve to disrupt the axon but not the support structures. In this way, conduction is interrupted until the nerve regenerates over the next 1 to 6 months, by which time full structure and function are usually restored. Hypoesthesia in the scar and adjacent skin is a common late finding. During the postoperative period, the patients are numb in the segments thus treated. Ideally, any drains or chest tubes should be located within the area made analgesic with the cryoprobe to minimize immediate postoperative discomfort. Cryoanalgesia provides excellent analgesia when supplemented with other pain treatments. Because cryoanalgesia is of prolonged duration, it is not used routinely after thoracotomy but rather in cases in which prolonged analgesia would be necessary, such as after surgery for chest trauma.

Another approach to postoperative pain control after thoracic surgery is the use of epidural or subarachnoid opioids. Epidural morphine produces profound analgesia lasting from 16 to 24 hours after thoracotomy and does not cause a sympathetic block or sensory or motor loss. These are significant advantages over other methods of administering opioids or local anesthetics. The opioids have been successfully used by both the thoracic and lumbar epidural routes. Morphine, in a dose of 5 to 7 mg diluted in 15 to 20 mL of fluid, has been used in the lumbar epidural technique. This technique has led to a 30% increase in postoperative expiratory flow rates without significant side effects, even in patients with chronic lung disease.

Epidural morphine has been shown to decrease pain and improve respiratory function in postthoracotomy patients.[164] The successful use of lumbar epidural sufentanil or fentanyl diluted to 20 mL has also been reported.[165] There have been reports of severe respiratory depression with epidural fentanyl and several reports with sufentanil. The addition of epinephrine, 5 mg/mL, to sufentanil administered in the thoracic epidural space decreases the plasma concentration of sufentanil and increases the duration of block. Lumbar epidural hydromorphone (1.25 to 1.5 mg) has been reported to provide excellent analgesia, with fewer side effects than epidural morphine. Severe respiratory depression was reported in one patient who received hydromorphone via a thoracic epidural catheter. A prophylactic low-dose infusion of naloxone, or nalbuphine, an agonist–antagonist drug, can reduce the incidence of respiratory depression.

Subarachnoid (intrathecal) morphine, in a dose of 10 to 12 μg/kg, has been successfully used after thoracic surgery.[166] With this technique, the drug acts directly on the spinal cord, and analgesia can be produced with a smaller dose than by the epidural or intravenous routes. When morphine is given intrathecally before the induction of anesthesia, a decrease in the dose of anesthetic drugs required may occur. All patients who have received subarachnoid or epidural opioids must be closely observed for potential side effects, including delayed respiratory depression, urine retention, pruritus, nausea, and vomiting. These effects appear to be dose related and may be reversed with naloxone.

Noxious stimuli, including surgical incision, may lead to changes in the central nervous system that exacerbate postoperative pain. The administration of analgesic agents before surgery is termed preemptive analgesia and may prevent these neuroplastic changes, thereby decreasing postoperative pain. The administration of lumbar epidural fentanyl before thoracotomy incision reduced postoperative pain scores and use of PCA morphine by a small but significant amount, compared with administration of lumbar epidural fentanyl after skin incision.[167]

Intrapleural analgesia is another technique for postoperative pain treatment. Although the mechanism has not been fully elucidated, the injection of local anesthetic between the pleural layers is believed to block multiple intercostal nerves or the pain fibers traveling with the thoracic sympathetic chain. The surgeon can place the catheter under direct vision while the chest is open. Catheter malposition has been documented after percutaneous placement, especially if the patient is not breathing spontaneously. The chest tubes should not be suctioned for approximately 15 minutes after injection of local anesthetic to avoid loss of the anesthetic into the drainage. The

efficacy of interpleural blockade for postthoracotomy pain relief has been reported to be both poor and good.[164]

Complications Following Thoracic Surgery

Atelectasis

Patients who require thoracotomy often have preexisting pulmonary disease that, when combined with the operative procedure, is likely to result in significant pulmonary dysfunction and possibly pneumonia. Atelectasis, the most significant cause

of postoperative morbidity, has been reported to occur in up to 100% of patients undergoing thoracotomy for pulmonary resection. It occurs more commonly in the basal lobes than in the middle or upper lung regions. It may be secondary to reduction of normal respiratory effort due to splinting from pain, obesity, intrathoracic blood and fluid accumulation, and decreased compliance, all of which lead to rapid, shallow, constant VT. Such a respiratory pattern produces small airway closure and obstruction with inspissated secretions, resulting ultimately in alveolar air resorption and terminal airway collapse. A poor cough and limited clearance of secretions add to the problem. Other sources of atelectasis include mucous plugging, which can obstruct a lobe or even an entire lung, and incomplete reexpansion of the remaining lung tissue after one-lung anesthesia. The diagnosis of atelectasis can be made by clinical findings, chest radiography, or arterial blood gas analysis. This problem is best resolved by increasing resting lung volume or FRC. The latter can be increased by an increase in transpulmonary pressure (difference between airway pressure and interpleural pressure) or in lung compliance.

The tracheas of many patients can be extubated shortly after thoracic surgical procedures using standard extubation criteria. These patients should be observed in the operating room for at least 5 minutes following extubation, and many will require a high FIO_2 by facemask. Some patients with COPD undergoing extensive thoracic surgical procedures require postoperative ventilation to avoid atelectasis and other pulmonary complications. Mechanical ventilation increases airway pressure and, to a lesser extent, interpleural pressure; therefore, transpulmonary pressure increases.

In addition to the use of incentive spirometry and bronchodilators, coughing and clearance of secretions, and mobilizing the patient, adequate analgesia is essential to the prevention and treatment of atelectasis. Atelectasis caused by collapse of lung tissue distal to a mucous plug can be treated by positioning the patient in the lateral decubitus position with the fully expanded lung in the dependent position. This improves V/Q matching and facilitates clearance of mucus from the nondependent obstructed lung. However, the patient should not be placed with the operative side in the dependent position after a pneumonectomy because of the risk of cardiac herniation.

The other major complications after thoracic surgery can be grouped into cardiovascular, pulmonary, and related problems.

Cardiovascular Complications

Cardiovascular complications are often the most difficult to manage in patients with associated respiratory insufficiency. The low cardiac output syndrome and postoperative cardiac arrhythmias are the most common and life threatening of these problems. In the postoperative period, advanced hemodynamic monitoring is used to make the differential diagnosis of left or right ventricular failure and the low output syndrome. A key monitor is the PA catheter, which facilitates assessment of hemodynamics. Other diagnostic modalities, such as echocardiography, may be required to rule out the presence of pericardial effusions or tamponade after opening the pericardium during certain types of thoracic surgical procedure. The low cardiac output syndrome must be differentiated from hypovolemia resulting from intrathoracic hemorrhage, tamponade, pulmonary emboli, or the effects of mechanical ventilation with PEEP. Postoperative fluid administration can lead to pulmonary edema resulting from the resection of lung tissue and the concomitant reduction of the pulmonary vascular bed. A postoperative pulmonary embolism can

originate from the remaining pulmonary artery stump or tumor tissue. Therapeutic interventions for postoperative myocardial dysfunction include inotropic drugs, vasodilators, and combinations of these drugs, as needed, to improve ventricular function. The goal is to shift the Starling function curve up and to the left by reducing preload of either the left or right side of the heart and increasing cardiac output. Vasodilators are very effective at decreasing right ventricular afterload and improving right ventricular function because this side of the heart is especially afterload dependent. Combinations of inotropes and vasodilators, such as isoproterenol and nitroglycerin, or combined drugs, such as amrinone, can be especially useful in the treatment of right-sided heart failure.

Postoperative cardiac arrhythmias are common after thoracic surgery. Patients following pulmonary resection have postoperative supraventricular tachycardias with a frequency and severity proportional to both their age and the magnitude of the surgical procedure. Many factors contribute to these arrhythmias, including underlying cardiac disease, degree of surgical trauma, intraoperative cardiac manipulation, stimulation of the sympathetic nervous system by pain, a reduced pulmonary vascular bed, effects of anesthetics and cardioactive drugs, and metabolic abnormalities.

In a series of 300 thoracotomies for lung resection, atrial fibrillation occurred in 20% of patients with malignant disease but in only 3% with benign disease.[168] A similar incidence of arrhythmias is observed after pneumonectomies. Multifocal atrial tachycardia often occurs in patients with COPD and concomitant right-sided cardiac dysfunction. The right side of the heart may be further strained by the reduction in the size of the pulmonary vasculature from the lung resection, especially after right pneumonectomy. The prophylactic use of digitalis in thoracic surgical patients is controversial, particularly in patients with signs of congestive heart failure. Arguments against its use include the potential toxic effects of the drug and the difficulty in assessing adequacy of digitalization in the absence of heart failure. A prospective, placebo-controlled, randomized study demonstrated no advantage to prophylactic digitalization of patients undergoing thoracic surgery.[169] Part of the argument for its use is the drug's efficacy in reducing the incidence of potentially fatal complications in older patients. In some studies, it has been reported to reduce the incidence of perioperative arrhythmias. If digitalis therapy is to be instituted, normokalemia should be ensured to reduce the likelihood of digitalis toxicity.

Supraventricular tachycardias can also be treated with either beta-blocking or calcium channel-blocking drugs after ruling out underlying reversible physiologic abnormalities, such as hypoxia. Verapamil has been the standard treatment for these problems until the introduction of the ultrashort-acting beta-blocker, esmolol. Esmolol has been shown to be equally effective in controlling the ventricular rate in patients with postoperative atrial fibrillation or flutter and in increasing the conversion rate to regular sinus rhythm from 8 to 34%. Owing to its short duration of action (beta elimination half-life of 9 minutes) and β_1-cardioselectivity, it is the drug of choice in the postoperative period to control these arrhythmias. Esmolol, in an intravenous loading dose of 500 µg/kg given over 1 minute followed by an infusion of 50 to 200 µg/kg/min, has been shown to be effective in the control of supraventricular tachycardias.

Bleeding and Respiratory Complications

Hemorrhage and pneumothorax are always major concerns after intrathoracic surgery. Because of these problems, interpleural thoracostomy tubes with an underwater seal system are routinely used after thoracic surgery. Slippage of a suture on any major vessel or airway in the chest can lead to the slow or rapid development of hypovolemic shock or a tension pneumothorax. Drainage of more than 200 mL/hr of blood is an indication for surgical reexploration for hemorrhage. Management of the pleural drainage system is fraught with confusion. The chest bottles must be kept below the level of the chest, and the tubes should not be clamped during patient transport. These tubes can be lifesaving, but errors in technique can lead

to serious complications. The creation of a pneumothorax in the nonoperative chest by central venous catheter placement is very hazardous because this lung is essential both intraoperatively during one-lung anesthesia and postoperatively after contralateral lung resection. Dehiscence of

the bronchial stump may lead to the formation of a BPF, which carries a mortality rate of 20%. Surgical treatment may be needed, in which case ventilation of the patient's lungs may be difficult because of loss of VT through the fistula. A double-lumen endobronchial tube positioned in the contralateral main-stem bronchus or the use of HFJV may be required for safe management. HFJV allows ventilation with lowered peak airway pressures. However, there have been reports in which ventilation by HFJV was difficult. If a double-lumen endobronchial tube is placed, the lung with the fistula can be ventilated independently with either CPAP or HFJV.

Neurologic Complications

Central and peripheral neurologic injuries can occur during intrathoracic procedures. Such injuries often result in serious and disabling loss of function and are very distressing to the patient. Peripheral nerves can be injured, either in the chest or in other parts of the body, by pressure or stretching. It has been recognized for years that most of these postoperative neuropathies are caused by malpositioning of the patient on the operating table, with subsequent stretching or compression of the nerves. The nerve injury may be apparent immediately after surgery or may not become obvious until several days later. These patients often complain of a variety of unpleasant sensations, including paresthesias, cold, pain, or anesthesia in the area supplied by the affected nerves. The brachial plexus is especially vulnerable to trauma during thoracic surgery, owing to its long superficial course in the axilla between two points of fixation, the vertebrae above and the axillary fascia below. Stretching is the chief cause of damage to the brachial plexus, with compression playing only a secondary role. Branches of the brachial plexus may also be injured lower in the arm by compression against objects such as an ether screen or other parts of the operating table. Intrathoracic nerves can be directly injured during a surgical procedure by being transected, crushed, stretched, or cauterized. The intercostal nerves are the ones most frequently injured during intrathoracic surgical procedures. The recurrent laryngeal nerve can become involved in lymph node tissue and injured at the time of a node biopsy, especially when the biopsy is performed through a mediastinoscope. This nerve can also be injured during tracheostomy or radical pulmonary dissections. The phrenic nerve is frequently injured during pericardiectomy, radical pulmonary hilar dissections, division of the diaphragm during esophageal surgery, or dissection of mediastinal tumors.

Prevention is the treatment of choice for these intraoperative nerve injuries. Analgesics may be necessary to control postoperative pain in the distribution of the nerve injury and to aid in maintaining joint mobility during the healing phase. Subsequent surgical procedures may be necessary to move a swollen ulnar nerve at the elbow or to stent a partially paralyzed vocal cord.

Chapter 30

Cardiovascular Anatomy and Physiology

Lake Carol L.

KEY POINTS

1	The two coronary arteries originate from the sinuses of Valsalva in the cusps of the aortic valve. The left coronary artery branches into the anterior descending and circumflex branches, whereas the right coronary artery branches to the sinus and atrioventricular (AV) nodes.
2	Cardiac innervation includes sympathetic fibers from the stellate ganglion and caudal cervical sympathetic trunks, as well as parasympathetic fibers from the recurrent laryngeal and thoracic vagus. Vagal innervation affects the atrial musculature, sinoatrial (SA) and AV nodes, and ventricular myocardium, whereas sympathetic fibers are in all portions of the atria, ventricles, and conduction system.
3	The venous pressure waveform (seen in the right atrium [RA], left atrium [LA], and pulmonary wedge pressure tracings) includes the a wave of atrial contraction, the ***V*** wave representing the gradual increase in atrial blood volume as blood returns from the periphery, and the ***Y*** wave resulting from opening of the AV valve combined with ventricular relaxation.
4	Extracellular ions cross the cell membranes of myocardial cells through specialized membrane proteins called the ion channels, which are named for the ion most rapidly transferred and characterized by conductance, selectivity, gating, and density. Density is the number of channels per square micrometer. Gating is the property of the channel that allows it to be activated or inactivated in response to voltage changes or binding of an agonist.
5	Coronary perfusion is 4% of the cardiac output or about 250 mL/minute. Coronary circulation consists of large, low-resistance epicardial vessels and higher resistance intramyocardial arteries and arterioles. Coronary perfusion mainly occurs during diastole.
6	Myocardial oxygen consumption is 8 to 10 mL/100 g per minute; therefore, coronary venous blood is only 30% saturated, and its pO_2 is 18 to 20 mm Hg. Coronary perfusion is autoregulated to maintain a constant flow over a range of perfusion pressure between 50 and 120 mm Hg at any myocardial oxygen

	demand. Above and below these limits, coronary flow varies with perfusion pressure.
7	Cardiac output, the volume of blood pumped by the heart each minute, is the product of heart rate and stroke volume. It is determined by preload, afterload, heart rate, contractility, and ventricular compliance.
8	Cardiac output is distributed to the systemic circulation as follows: brain 12%, heart 4%, liver 24%, kidneys 20%, muscle 23%, skin 6%, and intestines 8%. The veins accommodate 64% of the blood, and 15% is in the heart and pulmonary circulation at any time.
9	Arterial pressure is the lateral pressure exerted by contained blood on the walls of the vessels. Mean arterial pressure is the product of cardiac output and systemic vascular resistance. As blood moves peripherally in circulation, pulse pressure and systolic pressure increase, while mean pressure remains constant.
10	Peripheral vascular tone is controlled by central and autonomic nervous function, cardiac output, peripheral vascular resistance, hormonal mechanisms (catecholamines, renin-angiotensin system, atrial natriuretic peptide, antidiuretic hormone), and nitric oxide.

Perioperative management of patients during either cardiac or noncardiac surgery requires an extensive knowledge of cardiovascular anatomy and physiology. In addition, knowledge of genomics and proteomics will be essential as these fields revolutionize their approaches to diagnosis, risk assessment, and therapies for cardiovascular disease.[1] Whereas genomics is the sequencing, modification, and functioning of the DNA and messenger RNA (mRNA) of the genome, proteomics is the sequence, modification, and function of the proteins of a biological system (see Chapter 7).

ANATOMY

Heart

Transesophageal echocardiography[2] (Fig. 30-1) visualizes the functional anatomy of the four cardiac chambers, four valves, and great vessels.

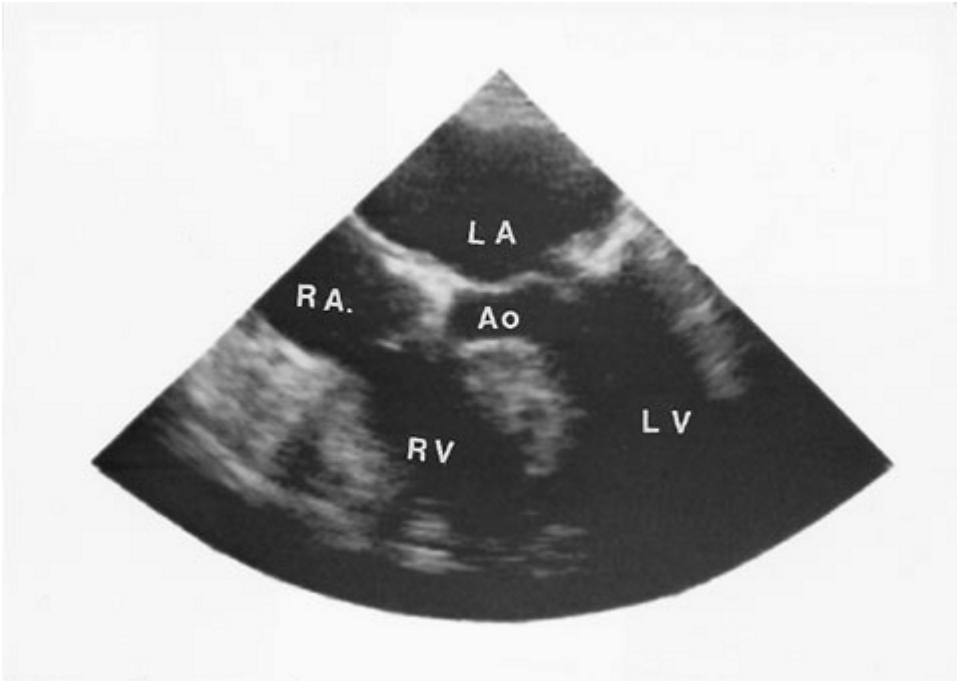

FIGURE 30-1. The functional anatomy of all four cardiac chambers, atrioventricular valves, aortic outflow track, and interatrial and interventricular septa are easily visualized using either transthoracic or transesophageal echocardiography. LA, left atrium; RA, right atrium; Ao, aorta; RV, right ventricle; LV, left ventricle.

Right Atrium

Systemic veins drain into the right atrium (RA) via the superior vena cava (SVC), inferior vena cava (IVC), and coronary sinus. The ostium of the IVC is guarded by the eustachian valve, whereas the ostium of the coronary sinus is guarded by the Thebesian valve. The right and left atria are separated by the interatrial septum with its central fossa ovalis, the remnant of the fetal foramen ovale.

Blood leaving the RA passes through the anterior, posterior, and medial leaflets of the tricuspid valve. The anterior leaflet, the largest, is attached to the crista supraventricularis (the structure dividing the inflow [sinus] and outflow [infundibular] portions of the right ventricle [RV]) and controlled by the anterior papillary muscle (APM). The APM originates from a prominent intraventricular muscle, the moderator band, and the anterolateral ventricular wall. Connecting the papillary muscles to the valve leaflets are strong, fibrous structures known as the chordae tendineae.

Right Ventricle

The RV is a pocket wrapped around one-third of the left ventricle (LV), and its muscle fibers are continuous with those of the LV. The inflow portion contains prominent muscle bands (moderator, septal, and parietal) and muscle bundles known as trabeculae carneae. The crista supraventricularis also joins the interventricular septum and LV to the right ventricular free wall.

Pulmonary Artery and Peripheral Pulmonary Circulation

The pulmonic valve separates the right ventricular infundibulum (right ventricular outflow tract) from the main pulmonary artery (PA). It is a trileaflet valve (right, left, and anterior cusps) normally about 4 cm^2 in area. As it originates from the superior portion of the RV, the PA passes under the aorta before it bifurcates into the right and left pulmonary arteries. The remnant of the fetal ductus arteriosus, the ligamentum arteriosum, connects the upper aspect of the bifurcation

to the inferior aortic surface.

Most pulmonary arteries run adjacent to the airways. Pulmonary arteries branch into arterioles and thence into capillaries, which spread over the alveolar surfaces between two alveolar endothelial layers. Larger pulmonary arteries (>1 mm internal diameter) are elastic, but the smooth muscle layer is reduced distal to the respiratory bronchioles. The pulmonary arteries and veins of the lower lobes are normally larger and more prominent than those of the upper lobes. The pulmonary circulation is innervated by the sympathetic system, and α_2 and probably α_1 receptors are present.[3]

The size of the peripheral pulmonary vessels indicates pulmonary blood volume and flow. With left-to-right cardiac shunts, the main PA and hilar vessels are prominent. With pulmonary hypertension, however, dilation of the main PA and abrupt tapering of the peripheral pulmonary vessels are noted.

Left Atrium

The left atrium (LA) is slightly larger than the right, and receives one or two pulmonary veins on its left and two or three on its right side. It has three major functions: (1) reservoir for pulmonary venous blood, (2) conduit to empty its contents into the LV, and (3) active contractile chamber.[4] Leaving the LA, blood traverses the mitral valve consisting of two major anteromedial and posterolateral leaflets, papillary muscles, and chordae tendineae. The normal adult mitral valve is about 6 to 8 cm^2 in area. The blood supply to the mitral chordae and papillary muscles is often quite tenuous.[5]

Left Ventricle

Normally, the LV is thicker (8 to 15 mm) and more densely trabeculated than the right. Its internal dimension is also greater, about 4.5 cm compared with 3.5 cm for the RV.[6] The interventricular septum has a membranous superior portion near the aortic valve and a muscular inferior portion. Both ventricles consist of an inner layer, the endocardium covered with endothelium, the myocardium or muscle layer, and the outer layer, the epicardium.

Aorta and its Branches

1 The aortic valve is adjacent to the mitral valve, separated only by the fibrous tissue framework that comprises the annuli of both valves. Three cusps, the right and left (coronary) and posterior (noncoronary) cusps, form the valve. A normal aortic valve is about 3 to 4 cm^2 in area. The aorta at the level of the valve dilates to form the Sinuses of Valsalva in which the coronary ostia are located.

The ascending aorta just beyond the aortic valve has no branches. Major branches of the aorta, the innominate, left carotid, and left subclavian arteries, arise from the aortic arch. The innominate artery subdivides into the right subclavian and right carotid arteries.

Coronary Circulation

Two coronary arteries, right and left, originate from the sinuses of Valsalva in the aortic valve to supply blood to the myocardium. The left coronary artery usually has a short common or left main coronary artery before bifurcation into anterior descending and circumflex branches. The anterior descending artery courses downward over the anterior left ventricular wall and supplies the interventricular groove through its diagonal and septal perforator branches. Occlusive disease in the anterior descending distribution produces ischemic electrocardiographic changes in leads V_3 to V_5. The circumflex branch follows the AV groove, giving off the obtuse marginal branch and supplying all the posterior LV and part of the right ventricular wall.[7] Electrocardiogram (ECG) changes resulting from circumflex coronary artery disease are seen in leads I and aV_L (Fig. 30-2 and Table 30-1).

TABLE 30-1 Coronary Artery Distribution

·LEFT CORONARY ARTERY
Anterior descending branch Right bundle branch Left bundle branch Anterior and posterior papillary muscles (mitral) Anterolateral left ventricle
·CIRCUMFLEX BRANCH
Lateral left ventricle
·RIGHT CORONARY ARTERY
SA and AV nodes Right atrium and ventricle Posterior interventricular septum Posterior fascicle of left bundle branch Interatrial septum
AV, atrioventricular; SA, sinoatrial.

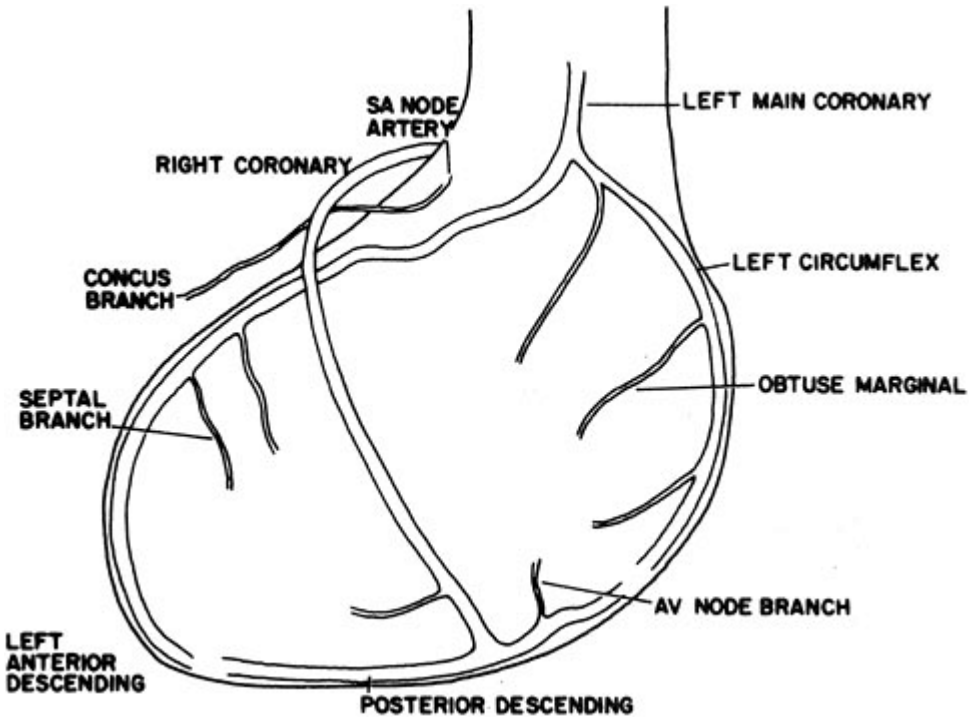

FIGURE 30-2. In this lateral view, the normal left coronary artery divides into the anterior descending and circumflex coronary arteries. The right coronary artery usually gives off the

arteries to the sinoatrial (SA) and atrioventricular (AV) nodes before terminating on the inferior surface of the heart as the posterior descending artery.

The sinus node and AV nodal arteries originate from the right coronary artery. The right atrial myocardium is also supplied by the sinus node artery. The right coronary artery terminates on the diaphragmatic surface of the heart as the posterior descending artery[8] (see Fig. 30-2). The blood supply to the AV node and common bundle of His is the AV branch of the right coronary artery (in 90% of hearts) and the septal perforating branches of the left anterior descending coronary artery (in 10% of hearts).[9] Branches to the interatrial septum and posterior interventricular septum also arise from the AV nodal artery. The right bundle branch and the left anterior fascicle are supplied by branches of the left anterior descending artery but can be supplied by the AV nodal artery. Both the left anterior and posterior descending coronary arteries supply the posterior fascicle.[9] Significant right coronary artery occlusion causes ischemic changes in ECG leads II, III, and aV_F, as well as conduction abnormalities.

Coronary Dominance. Descriptions of the coronary circulation often refer to the dominance of one or the other coronary artery. Dominance is determined by which artery crosses the

crux or junction between atria and ventricles to supply the posterior descending coronary branch. In about 50% of humans, the right coronary artery is dominant; in 20%, the left; and in 30%, a balanced pattern exists. Areas of the myocardium affected by stenosis or occlusion of individual coronary arteries are listed in Table 30-1. Collateral vessels may develop between the major coronary arteries in response to myocardial ischemia.

Peripheral Venous Circulation

Major veins follow a course similar to that of the arteries. From the head, the internal and external jugular veins join the subclavian veins of either side. The course of the external jugular vein is often tortuous and variable, and it has two sets of valves, one at the entrance to the subclavian vein and the other about 4 cm superior to the clavicle. From the arms, the basilic (medial aspect) and cephalic veins join as the brachial vein. This vein becomes the axillary vein in the axilla and thence the subclavian. Normally, subclavian veins from both sides unite to form the SVC.

Cardiac veins, the great and middle cardiac veins and the posterior left ventricular vein, drain into the coronary sinus. Near the orifice of the great cardiac vein, the oblique vein of Marshall (vein of the LA) enters the coronary sinus. Anterior cardiac veins and the small cardiac vein may enter the RA independently of the coronary sinus. Thebesian veins, which traverse the myocardium, drain into various cardiac chambers. Thebesian venous flow, coupled with bronchial and pleural venous flows, contributes the normal 1 to 3% arteriovenous shunt.

Cardiac Conduction System

The system for electrical activation of the heart, the conduction system, consists of the SA node, the AV node, the bundle of His, right and left bundle branches, and the Purkinje system. Nodal cells of both spider and spindle pacemaker cell types are found in the center of the SA node, whereas atrial cells are found near the periphery.[10] The SA node is in the right atrial wall at the junction of the RA with the SVC. The SA and AV nodes are connected via the internodal conduction system, which consists of three tracts: the anterior (Bachmann's bundle), middle, and posterior internodal systems.[11] Conduction also spreads rapidly through the atrial musculature to the LA via Bachmann's bundle. In human hearts, the AV node is located in the floor of the RA, near the ostium of the coronary sinus.[7] The AV node consists of four areas, the A-N transitional zone containing cells smaller than normal atrial cells, the compact node, the posterior nodal extension, and a lower nodal cell bundle.[12] The fibers forming the common bundle of His pass along the superior edge of the membranous interventricular septum to the apex of the muscular portion of

the septum. Here the bundle divides into right and left bundle branches, which extend subendocardially along the surfaces of both ventricles. The right bundle branch emerges in the right ventricular endocardium near the moderator band at the base of the anterior papillary muscle. It usually extends for some distance without dividing, but one branch passes through the moderator band and the other passes over the right ventricular endocardial surface. Subdivision of the left bundle into anterior and posterior fascicles occurs shortly after its origin. There is also a small collection of short medial fascicles that originate from the left bundle just after the anterior fascicle and activate the septal myocardium. The posterior fascicle terminates in the posterior papillary muscle.

Peripherally, the fascicles of both right and left bundle branches subdivide to form the Purkinje network. The left bundle branch fascicles make their initial functional contact with the endocardium of the interventricular septum below the aortic valve. Right bundle branch fascicles contact ventricular subendocardium near the base of the anterior papillary muscle.

Cardiac and Vascular Nerves

Sympathetic System

2 Nerves to the heart and blood vessels originate from sympathetic neurons of the thoracolumbar region and parasympathetic nerves originate from the cervical region. Sympathetic fibers come from the stellate ganglion and the caudal cervical sympathetic trunks. From these trunks arise the right dorsal medial and dorsal lateral cardiac nerves, which frequently unite to form one large nerve that follows the course of the left main coronary artery. It further separates into branches along the anterior descending and circumflex coronary arteries.

Parasympathetic System

Parasympathetic preganglionic neurons arise in the medulla oblongata in the dorsal vagal nucleus and the nucleus ambiguous. These fibers enter the thorax as branches from the recurrent laryngeal and thoracic vagus nerve. The dorsal and ventral cardiopulmonary plexuses between the aortic arch and the tracheal bifurcation receive both sympathetic and parasympathetic branches. From the plexuses emerge three large cardiac nerves, the right and left coronary cardiac nerves and the left lateral cardiac nerve. Parasympathetic nerves are particularly abundant near the coronary sinus and SVC. Ganglia occur within the heart, usually close to the structures innervated by the short postganglionic neurons. Postganglionic transmission occurs from stimulation of nicotinic cholinergic receptors at the postganglionic junction by acetylcholine. Release of acetylcholine at the neuroeffector junction activates muscarinic receptors in the heart.

Cerebral Vasomotor Center

Afferent nerves from the heart ascend via the tenth cranial nerve (vagus) and spinal cord to the nucleus tractus solitarius and the dorsal vagal nucleus and nucleus ambiguous to form the parasympathetic motor efferent system of the medullary vasomotor center. Sympathetic activation of heart and vasculature originates in the rostral ventrolateral (RVL) medulla, ventromedial rostral medulla, and parvocellular region of the paraventricular nucleus. The RVL neurons receive multiple inputs from other medullary nuclei and modulate sympathetic output.[13] Although the vasomotor center independently regulates arterial pressure, blood flow distribution, and cardiac contractility, higher centers such as the cerebral cortex, hypothalamus, and pons also influence cardiovascular responses (Fig. 30-3).

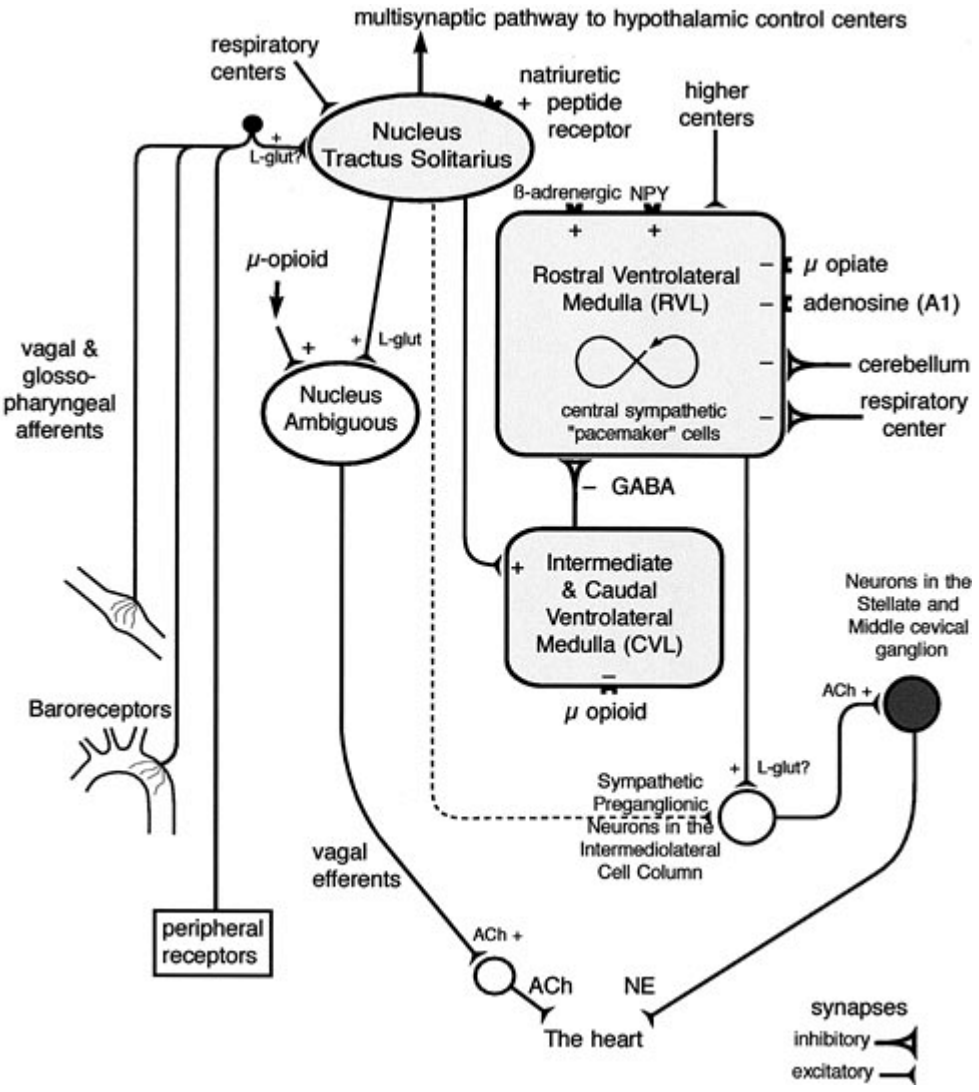

FIGURE 30-3. The central nervous system exerts considerable control over the heart and circulation via the rostral ventrolateral medulla (RVL), nucleus tractus solitarius, and intermediate and caudal ventrolaterial medulla. The RVL contains neurons that provide regular output to sympathetic preganglionic neurons like a pacemaker. The baroreceptor pathway, effects of GABAergic input, and opioid effects on RVL are also depicted. (Reprinted with permission from Lynch C, Lake CL: Cardiovascular anatomy and physiology. In Youngberg J, Lake C, Roizen M *et al* (eds): Cardiac, Vascular and Thoracic Anesthesia, p 136. Philadelphia, Churchill Livingstone, 2000.)

Cardiac Receptors. Vagal receptors located in various cardiac chambers are sensitive to changes in heart rate or chamber pressure. Vagal innervation affects the atrial musculature, the SA and AV nodes, and the ventricular myocardium.[14] The greatest concentrations of parasympathetic nerves are in the SA node, with lesser numbers in the AV node, RA, LA, and ventricles. Parasympathetic α_1 but not α_2 receptors have been identified. Stimulation of cardiac parasympathetic nerves causes negative chronotropic and dromotropic effects.[15]

Sympathetic fibers extend to all portions of the atria, ventricles, and conduction system. α_1, α_2, β_1, and β_2 subtypes of adrenergic receptors are present. Human RA contains about 74% β_1 and 26% β_2 receptors.[16] The proportions of β receptors differ in the ventricle, with 86% β_1 and 14% β_2.

Neural Supply of the Peripheral Vasculature

Innervation of the peripheral circulation, with the exception of the cerebral and coronary vasculature, originates from the thoracolumbar sympathetic fibers. Vasodilation results from reduced sympathetic tone or activation of vasodilatory receptors. Stimulation of α-adrenergic fibers causes constriction in the arterial vascular beds of the skin, skeletal muscle, splanchnic organs, kidneys, and systemic veins. Stimulation of β_2 receptors dilates systemic veins and arteries of the muscle, splanchnic, and renal circulations.

Pericardium

The normal pericardium consists of thick fibrous and serous visceral layers. It has certain anatomic functions, among which are the isolation of the heart from other mediastinal structures, maintenance of the heart in optimal functional shape and position, minimization of cardiac dilatation, and prevention of adhesions.[17] The pericardium also contains vagal nerve branches.

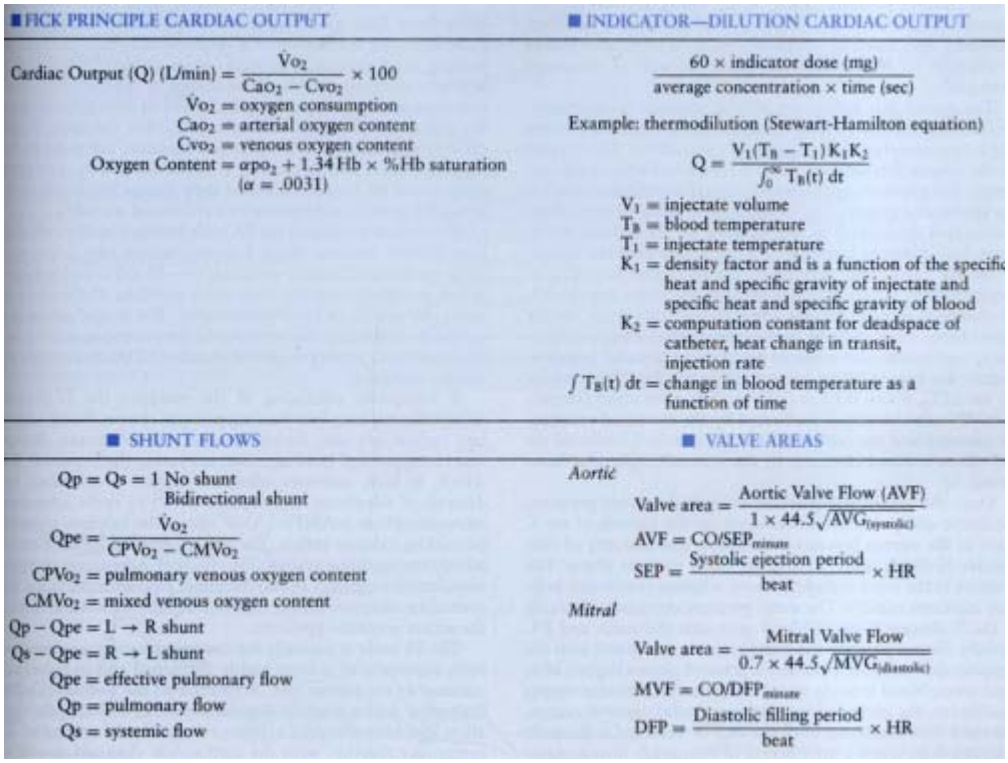
CARDIOVASCULAR DIAGNOSTIC PROCEDURES

Abnormalities of both the anatomy and physiology of the cardiovascular system are diagnosed by invasive catheterization when noninvasive procedures such as echocardiography (cross reference section on echocardiography) or magnetic resonance angiography insufficiently define the defects.

Cardiac Magnetic Resonance Imaging

Cardiac magnetic resonance imaging (CMRI) is rapidly becoming the most comprehensive technique for evaluation and quantification of global and regional wall motion, wall thickening (contractility), ejection fraction, myocardial mass, ejection fraction, and blood flow (magnitude, direction, and shunt).[18] It is complementary to echocardiography for diagnosis of congenital cardiac defects.[19] The combination of CMRI and pharmacologic stress with dobutamine or adenosine stress assesses contractile reserve. Thus, its use may replace resting/stress echocardiography, thallium scintigraphy, and positron emission tomography for evaluation of myocardial viability (stunning, hibernating, or scarring).[20] However, it cannot substitute for coronary angiography in the evaluation of small branch arteries.

Catheterization



In all age groups, cardiac catheterization is usually performed via the femoral vessels. Occasionally, the brachial vessels are used in adults if the femoral vessels cannot be entered or catheters cannot be manipulated through the abdominal aorta.[21] The passage of catheters through either the venous or the arterial system is guided by fluoroscopy. Pressure measurements are made in each cardiac chamber or great vessel, their pressure waveforms recorded, and vascular or ventricular angiography performed. Normal pressure values and oxygen saturations are presented in Table 30-2. Oxygen saturation is greater in the IVC than in the SVC, owing to the contribution of blood from the renal veins. Normal pressure waveforms are

seen in Figure 30-4. Measurements commonly made or calculated during cardiac catheterization are detailed in Tables 30-3 and 30-4. These include cardiac output, measurement of valve areas,[22] and calculation of shunt flows.

TABLE 30-2 Normal Catheterization Data

▪SITE	▪PRESSURE(mm Hg)	▪OXYGEN SATURATION (%)
Inferior vena cava	0–8	80 ± 5
Superior vena cava	0–8	70 ± 5

Right atrium	0–8	75 ± 5
Right ventricle	15–30/0–8	75 ± 5
Pulmonary artery	15–30/4–12	75 ± 5
Pulmonary wedge	5–12 (mean)	75 ± 5
Left atrium	12 (mean)	95 ± 1
Left ventricle	100–140/4–12	95 ± 1
Aorta	100–140/60–90	95 ± 1

■ FICK PRINCIPLE CARDIAC OUTPUT

$$\text{Cardiac Output (Q) (L/min)} = \frac{\dot{V}o_2}{Cao_2 - Cvo_2} \times 100$$

$\dot{V}o_2$ = oxygen consumption
Cao_2 = arterial oxygen content
Cvo_2 = venous oxygen content
Oxygen Content = $\alpha po_2 + 1.34\,Hb \times \%Hb$ saturation
($\alpha = .0031$)

■ INDICATOR—DILUTION CARDIAC OUTPUT

$$\frac{60 \times \text{indicator dose (mg)}}{\text{average concentration} \times \text{time (sec)}}$$

Example: thermodilution (Stewart-Hamilton equation)

$$Q = \frac{V_1(T_B - T_1)K_1K_2}{\int_0^\infty T_B(t)\,dt}$$

V_1 = injectate volume
T_B = blood temperature
T_1 = injectate temperature
K_1 = density factor and is a function of the specific heat and specific gravity of injectate and specific heat and specific gravity of blood
K_2 = computation constant for deadspace of catheter, heat change in transit, injection rate
$\int T_B(t)\,dt$ = change in blood temperature as a function of time

■ SHUNT FLOWS

Qp = Qs = 1 No shunt
Bidirectional shunt

$$Qpe = \frac{\dot{V}o_2}{CPVo_2 - CMVo_2}$$

$CPVo_2$ = pulmonary venous oxygen content
$CMVo_2$ = mixed venous oxygen content
Qp – Qpe = L → R shunt
Qs – Qpe = R → L shunt
Qpe = effective pulmonary flow
Qp = pulmonary flow
Qs = systemic flow

■ VALVE AREAS

Aortic

$$\text{Valve area} = \frac{\text{Aortic Valve Flow (AVF)}}{1 \times 44.5\sqrt{AVG_{(systolic)}}}$$

$$AVF = CO/SEP_{minute}$$

$$SEP = \frac{\text{Systolic ejection period}}{\text{beat}} \times HR$$

Mitral

$$\text{Valve area} = \frac{\text{Mitral Valve Flow}}{0.7 \times 44.5\sqrt{MVG_{(diastolic)}}}$$

$$MVF = CO/DFP_{minute}$$

$$DFP = \frac{\text{Diastolic filling period}}{\text{beat}} \times HR$$

TABLE 30-3 Measurements During Cardiac Catherization

TABLE 30-4 Hemodynamic Variables: Calculations and Normal Values

·VARIABLE	·CALCULATION	·NORMAL VALUES

Cardiac index (CI)	CO/BSA	2.5–4.0 L/min/m^2
Stroke volume (SV)	CO/HR	60–90 mL/beat
Stroke index (SI)	SV/BSA	40–60 mL/beat/m^2
Mean arterial pressure (MAP)	Diastolic pressure + one-third pulse pressure	80–120 mm Hg
Systemic vascular resistance (SVR)	MAP-CVP/CO × 79.9	1200–1500 dyn/cm/s^5
Pulmonary vascular resistance (PVR)	PAP-PWP/CO × 79.9	100–300 dyn/cm/s^5
Right ventricular stroke work index (RVSWI)	0.0136 (PAP-CVP) SI	5–9 g/m/beat/m^2
Left ventricular stroke work index (LVSWI)	0.0136 (MAP-PWP) SI	45–60 g/m/beat/m^2

BSA, body surface area; CO, cardiac output; CVP, mean central venous pressure; MAP, mean arterial blood pressure; PAP, mean pulmonary artery pressure; PWP, pulmonary wedge pressure.

FIGURE 30-4. The events of the cardiac cycle from filling of the atria to ventricular emptying are demonstrated using waveforms from the aorta, pulmonary artery, right and left ventricles, and central veins. The relationship between the electrocardiogram and the phases of the cardiac cycle shows that ventricular systole occurs immediately following the QRS complex. The changes in ventricular pressure–volume waveform coincide with ventricular ejection and filling. ECG, electrocardiogram; LV, left ventricle.

Angiography

Cineangiography with iodinated dyes is performed to quantitate ventricular contractility, to evaluate shunting between cardiac chambers, to demonstrate valvular regurgitation, or to delineate vascular outlines (e.g., pulmonary venous return, aortic dissection, pulmonary embolism). Angiography assesses the amount of valvular regurgitation by grading the amount of contrast agent reentering the chamber preceding the valve. For instance, in the case of aortic regurgitation, 1+ regurgitation is a small amount of contrast material entering the LV during diastole but clearing with each systole. The LV is faintly opacified during diastole and fails to clear with systole with 2+ regurgitation. In 3+ aortic regurgitation, the LV is progressively opacified during diastole and eventually completely opacified, whereas in 4+ aortic regurgitation, the LV is completely opacified on the first diastole and remains opacified for several beats. A similar grading system is used during echocardiography.

Coronary Arteriography

Selective coronary angiography using either the retrograde brachial technique of Sones or the percutaneous femoral approach of Amplatz or Judkins selectively evaluates each coronary artery for the presence and extent of coronary occlusive disease, aneurysm formation, or congenital anomalies (see Fig. 30-2). Coronary arteriography occasionally causes ventricular ectopy, the Bezold-Jarisch reflex, ventricular asystole, or fibrillation. More common are T-wave changes, bradycardia, and mild hypotension. Even in normal coronary arteries, injection of the right coronary artery produces T-wave inversion in lead II and injection of the left artery produces T-wave peaking in lead II.[23] These changes revert to normal when the catheter is removed from the coronary ostia or the blood pressure is increased by having the patient cough.

Determination of Shunts

A shunt exists when arterial and venous blood mix at either an intracardiac or an extracardiac location, usually as a result of a congenital cardiac malformation. The site of a shunt can be determined by measurement of oxygen saturations in various cardiac chambers. A 10% step-up in oxygen saturation at the atrial level indicates left-to-right shunting into the RA. A 5% step-up at the ventricular or aorticopulmonary level indicates shunting at that site.

PHYSIOLOGY

Cardiac Cycle

3 The cardiac cycle begins with the filling of the right and left atria while the tricuspid and mitral valves are closed (see Fig. 30-4).[24,25] The V wave on the venous pressure waveform represents the gradual increase in atrial blood volume as blood returns from the periphery. Once the aortic valve has closed but ventricular pressure still exceeds atrial pressure, the ventricle undergoes isovolumetric relaxation. About 0.02 to 0.04 seconds after closure of the aortic valve, atrial and ventricular pressures equalize, and a small gradient develops across the AV valves as ventricular pressure decreases further. The AV valve cusps bulge into the ventricle and separate slightly. After crossover of the atrial and ventricular pressure waves, the AV valves open completely. The V wave of the atrial pressure waveform crests when the atria are filled, and the

tricuspid and mitral valves open to initiate ventricular filling. The Y wave results from opening of the AV valves combined with ventricular relaxation. Effective atrial systole at resting heart rates contributes about 5 to 20% of the stroke volume. Acute atrial fibrillation increases atrial pressures, reduces atrial compliance, increases atrial oxygen consumption, and eliminates the contribution of the atria to ventricular filling.[26]

During initial ventricular filling, ventricular volume increases rapidly, the rapid filling phase, during which time the ventricular pressure continues to decrease because ventricular expansion exceeds filling. Peak ventricular filling in early diastole occurs at 500 to 700 mL/sec as ventricular relaxation actually produces a negative intracavitary pressure (diastolic suction). The elastic recoil of the heart and great vessels during diastole contributes to the accelerated filling phase of the ventricle, particularly during tachycardia.

A period of reduced ventricular filling follows the rapid filling phase. The third heart sound, S_3, occurs at the point of transition from rapid ventricular filling to reduced filling. The nadir of the ventricular pressure curve at the end of the rapid filling phase probably marks the end of ventricular relaxation and the beginning of elastic distention of the ventricle. The upswing in the ventricular pressure abolishes forward movement of blood and can force the AV valves into a semiclosed position unless venous return is great. The previous ventricular contraction provides much of the energy for the subsequent diastolic expansion through the energy expenditure of the gross movement and deformation of the heart during systole.[27] Atrial systole, the A wave on the venous pressure waveform, which coincides with the P wave on the ECG, concludes ventricular filling.

Right atrial pressure, a guide to right atrial and right ventricular function, is indirectly assessed by observation of the level of jugular venous pressure, the end-expiratory peak pulsation of the internal jugular vein above the sternal angle with the subject in a 30° reverse Trendelenburg position. Normally, the level is <4 cm. A sustained increase in the level of >1 cm during abdominal compression (hepatojugular reflux) indicates abnormal right ventricular function. Only when biventricular function is normal can the central venous pressure be used as a guide to left ventricular function.

There are three phases of activity in the LA: (1) the reservoir phase of inflow during ventricular diastole, (2) a conduit phase of passive emptying during ventricular end

diastole, and (3) contraction and active emptying during ventricular end diastole.[28] Each left atrial function is affected by atrial relaxation, stiffness, and contractility.[28]

In hearts with poorly functioning ventricles, atrial contraction is important and a fourth heart sound, S_4, which occurs 0.04 seconds after the P wave, results from vibrations of left ventricular muscle and mitral valve. The S_4 is most likely to occur with vigorous atrial contraction. The adequacy of ventricular filling is determined by the distensibility (compliance) of the ventricles, the filling time, and the effective filling pressure. The effective filling pressure is the transmural ventricular pressure. Tachycardia also decreases the time available for ventricular filling, decreasing filling time from 400 to 500 milliseconds at a heart rate of 60 beats per minute to 10 milliseconds or less at 160 beats per minute. Mitral stenosis, ischemic heart

disease, and hypertrophic cardiomyopathy slow ventricular filling and alter ventricular distensibility. The intraventricular pressure just prior to the beginning of ventricular contraction is end-diastolic pressure (Table 30-2). However, normal end-diastolic pressures do not imply normal ventricular function. Increased end-diastolic pressures occur with hypervolemia or changes in ventricular compliance as well as decreased contractility.

The period just before the sudden increase in ventricular pressure is presystole, which includes atrial systole and the time just before isovolumetric ventricular contraction. The Z point on the venous pressure waveform is the period when atrial and ventricular pressures are essentially equal immediately preceding ventricular systole. The isovolumetric phase of ventricular contraction is marked by the C wave on the venous waveform. Isovolumetric contraction is the

period between closure of the AV valves and opening of the semilunar (aortic, pulmonic) valves. Intraventricular pressure increases, but there is no change in intraventricular volume. After this point, the AV valves close, atrial diastole begins, the ventricles begin to contract, and ventricular pressure soon exceeds atrial pressure. Ventricular systole occurs immediately after the QRS complex on the ECG, about 0.12 to 0.20 seconds after atrial contraction. AV valve closure is facilitated by the increased ventricular pressure and the cessation of atrial systole. Closure of the AV valves is noted clinically by the normally split first heart sound, S_1.

Once the ventricular pressure exceeds the aortic pressure, the aortic and pulmonic valves open (at the summit of the C wave of the venous pressure waveform). The majority of ventricular ejections occur during the rapid ejection phase. The pressure in the aorta is slightly lower, whereas ventricular pressure increases rapidly. The atrial pressure decreases, resulting in the X descent because blood goes into the aorta and PA. Initially the output into the aorta exceeds the runoff into the peripheral circulation. Peak aortic pressure occurs slightly after peak aortic blood flow. As aortic runoff and ventricular output equilibrate, the period of reduced ventricular ejection occurs. Forward flow continues until the end of ventricular diastole, protodiastole, when a brief period of retrograde flow initiates aortic and pulmonic valve closure. On pressure waveforms, semilunar valve closure is marked by a notch or incisura. The second heart sound, S_2, results from rapid deceleration of blood causing vibration of the outflow tracks and great vessels and closure of the semilunar valves.

Cardiac Electrophysiology

Cellular Electrophysiology

4 Cardiac pacemaker cells have an intracellular ionic composition that differs from that found in the extracellular fluid. The most important ions are calcium, sodium, and potassium. An active transport system in the cell membrane, the sodium–potassium pump, maintains normal concentration gradients for sodium and potassium by pumping sodium ions out of the cell and potassium ions into the cell. Extracellular ions cross the cell membrane through specialized membrane proteins, the ion channels, which are characterized by their conductance, selectivity, gating, and density. Because a more detailed discussion of the cardiac channels is beyond the scope of this chapter, the reader is referred to reviews on specific channels.[29,30,31] Conductance is the rate (ions/msec) at which ions pass through the channel. In a given channel, each ion has a particular conductance. Channels are named for the ion most rapidly transferred because some ions, but not others, are transported. Some channels rectify or pass current in one direction across the membrane more easily than the other. Density is described as the number of channels per square micrometer. However, density may be variable over the cellular sarcolemma.

Channels have three states: resting, open (activated), and inactivated. Gating is the property of the channel that allows it to be activated or inactivated in response to voltage changes or binding of an agonist. If gating kinetics are rapid, the channel activates or opens quickly. If the change in channel conformation is slow, channel activation is delayed as with delayed rectifier potassium channels. Examples of cardiac channels, which directly or indirectly control cardiac function, are given in Table 30-5. After an ion channel is activated, it may stay open until closed by another stimulus such as repolarization or inactivated (closed) in response to a continued stimulus.

TABLE 30-5 Cardiac Ion Channels

▪CHANNEL SUBUNITS	▪ION CURRENT	▪FUNCTION
Sodium (Nav 1.5)	I_{Na}	Conduction atrium, ventricle, Purkinje

HCN (hyperpolarization-activated, cyclic nucleotide binding)	If (pacemaking)	Diastolic depolarization
Kir 2.1	IK_1	Terminal repolarization, resting potential
Kir 3.1/3.4	IK_{ACH}	Mediation of acetylcholine effects
$Ca_v3.1/3.3$	$I_{Ca.t}$	Role uncertain
$Ca_v1.2$ I_{CaL}	α subunit	
Ether-a-go-go related (ERG)	I_{Kr}(α subunit)	Phase 3 repolarization
Kv4.2/4.3	I_{to}(α subunit)	Early phase 1 repolarization
minK	I_{ks}(β subunit)	Necessary to form I_{ka} with KvLQT1
MIRP1 (minK-related channel subunit)	Modulates I_{kr}, I_f, I_{to}	Function unclear
KvLQT1	I_{ka}(α subunit)	Phase 3 repolarization
KChIP2	I_{to} (β subunit)	Necessary to form I_{to}
Kv1.5/3.1	I_{kur}	Phase 1–2 repolarization
Data from Schram G, Pourrier M, Melnyk P, Nattel S: Differential distribution of cardiac ion expression as a basis for regional specialization in electrical function. Circ Res 90:939, 2002.		

The central portion of the SA node contains spider cells that have a faster intrinsic phase 4 depolarization rate, a less negative maximum diastolic potential (~-50 mV), and a longer action potential duration than other portions of the node or atrial, AV nodal, or His-Purkinje cells. The longer action potential duration and shorter interval between spontaneous action potentials preserves SA dominance and limits invasion by ectopic impulses.

β Receptors, consisting of the receptor, the G protein (guanosine triphosphate binding protein) system,[26] and adenylate cyclase are also located in the cell membrane. Receptors recognize and bind agonists, activating the G protein Gs, which, in turn, activates adenylate cyclase to stimulate hydrolysis of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). cAMP

opens the calcium channel, permitting calcium influx. The entire complex forms a transmembrane signaling system (Fig. 30-5). β-Adrenergic receptor stimulation augments subsarcolemmal calcium release via the ryanodine receptors during diastolic depolarization and during the action potential upstroke.

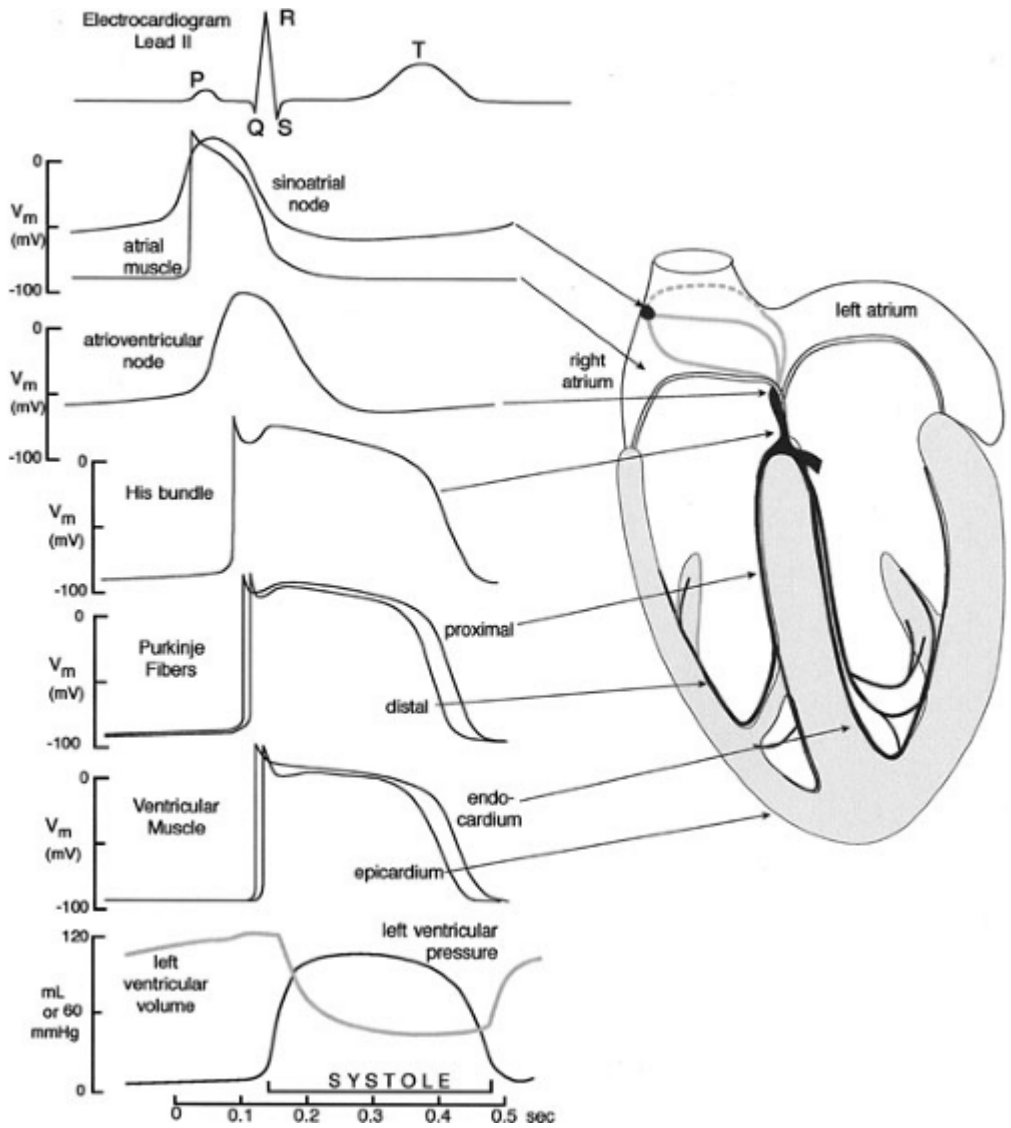

FIGURE 30-5. The action potential of an automatic cell such as the sinoatrial node differs from that of the ventricular muscle cell in that the cell slowly depolarizes spontaneously during phase 4. The inward current I_f is responsible for diastolic depolarization. The action potential in a Purkinje cell has the most rapid rate of depolarization, 400 to 800 V/sec. When the cell is stimulated, an action potential occurs due to a rapid influx of sodium ions (inward current) into the cell (phase 0). Phase 1 includes a notch caused by the "early outward current," I_{to}, which is a transient K efflux, probably activated by an intracellular calcium increase. Phase 2 is the plateau of the action potential resulting principally from calcium entry (inward currents I_{CaL} and I_{CaT}) through the slow channel of the cell membrane. During phase 3, repolarization of the cell occurs (outward current I_{K1}), while during phase 4, the sodium entering during phase 0 is actively pumped out of the cell. In a ventricular muscle cell, unlike the automatic cells, there is no spontaneous phase 4 depolarization. (Reprinted with permission from Lynch C, Lake CL: Cardiovascular anatomy and physiology. In Youngberg J, Lake C, Roizen M *et al* (eds): Cardiac, Vascular, and Thoracic Anesthesia, p 87. Philadelphia, Churchill Livingstone, 2000.)

The SA node is normally the dominant pacemaker because, in it, automaticity is most highly

developed and impulses are initiated at the fastest rate. Activation of the sodium-calcium exchanger during diastolic depolarization, as well as cyclic variation in subsarcolemmal calcium release via the ryanodine receptor, act together with the cardiac ion channels to ensure the sinus node is the dominant pacemaker. Cardiac pacemaker regulation is critically dependent on the calcium release via ryanodine receptors.[32] In SA nodal cells, when the internal membrane potential reaches -50 mV, the depolarization rate increases to 1 to 2 V/sec, causing a slowly depolarizing action potential. Automaticity decreases in order from SA node, AV node, His bundle, proximal Purkinje fibers, and distal Purkinje fibers. The rate of phase 4 depolarization is faster in the SA node than in the AV node and faster in the AV node than in the terminal Purkinje fibers, causing less highly developed pacemakers to be depolarized by the propagated wave from above before they spontaneously depolarize. Interactions between sympathetic and parasympathetic innervations also affect the intrinsic depolarization rate.

The compound action potential in cells results from the integrated activity of different ionic transmembrane currents at different times in the cardiac cycle (see Fig. 30-5). Ionic transfer is facilitated by the energy released from the hydrolysis of ATP. The cardiac potassium current has four subunits: ether-a-go-go, mink-related channel subunit 1, long QT interval-related subunit, and beta subunit of I_{Ks} (minK). Pacemaker cells in the unexcited state are maintained at a resting potential of -80 mV by the selective inward rectifier current I_{K1}. These channels with inward rectification pass inward current more easily than outward and thus limit outward current flow. Thus, the resting membrane potential is around the equilibrium potential for potassium. As the slow spontaneous depolarization of phase 4 proceeds, there is an increase in the permeability of the membrane, which permits positively charged sodium ions

to move across the cell membrane into the cell, resulting in depolarization at a threshold potential of ~-65 to 70 mV. This sodium influx (fast sodium current, I_{Na}) reverses the transmembrane potential from -80 mV to +20 to 30 mV and initiates the rapid depolarization (phase 0) of the action potential in a cardiac pacemaker cell (see Fig. 30-5). Phase 0 lasts only 1 to 2 milliseconds. The sodium channels open and sodium ions enter the cell, causing the cell membrane potential to move toward the sodium equilibrium potential of +50 mV. During phase 0, there is also a decrease in permeability to potassium. At about -30 mV, inward calcium transfer (I_{CaL}) begins through the L-type (long-lasting, high-threshold) channels that require greater than -40 mV to activate for opening. The spread of depolarization throughout the atrial and ventricular muscle results in the P wave and the QRS complex of the ECG, respectively. After excitation, the cell membrane undergoes an initial period of rapid repolarization (phase 1), followed by a variable period when the membrane potential is close to 0, the plateau of the action potential. Early repolarization results from inactivation of the sodium current and activation of the potassium current I_{TO}. The principal subunits of I_{TO} are Kv1.4, Kv4.2, and Kv4.3. The plateau is caused by low potassium conductance with inward rectification of I_{K1} causing a small outward current. The outward current is balanced by inward current through the L-type calcium channel $I_{Ca\text{-}L,}$ inward flux of chloride ions through the ATP-dependent cystic fibrosis transmembrane regulator channel, and slowly inactivating sodium channels.

Four K^+ currents participate in repolarization, including I_{TO_1}, the transient outward current during the initial phase of repolarization; I_{TO2}, the slow inactivating current; and delayed rectifier K currents I_{Kr} and I_{Ks} during final repolarization.[33] Rapid repolarization during phase 3 results from inactivation of L-type calcium current and increasing outward current through the delayed rectifier potassium channels. The duration of the action potential is rate dependent, owing to enhanced calcium entry. During phase 4, the resting membrane potential is generated by active exchange of intracellular sodium for potassium through the sodium-potassium adenosine triphosphatase or sodium pump. The resting potassium conductance that maintains the resting potential is G_{K1}, the inward (anomalous) rectifier. In the latter part of phase 4, the resting membrane potential is stable in ventricular muscle cells until the cell is excited again. In automatic cells such as the SA and AV nodes, slow, spontaneous depolarization occurs during phase 4 as a result of the hyperpolarization-activated inward current I_f and I_{K2}. The hyperpolarization-activated cation

channel is more abundant in the SA node than in Purkinje cells or ventricular myocardium.

During depolarization, the cell membrane is absolutely refractory to other stimuli because almost all the sodium channels inactivate. The end of the absolute refractory period is signaled by the earliest transient depolarization that can be elicited because sufficient numbers of sodium channels that can be activated are present. The absolute refractory period ends at the beginning of the T wave of the ECG. Once repolarization reaches the threshold potential, the cell is relatively refractory, although an unusually strong stimulus can produce depolarization. This period is marked by the T wave of the ECG. The earliest propagated action potential defines the end of the effective or functional refractory period.

Action Potential Alterations

Changes in the action potential itself or factors that affect the action potential alter the rate of firing of an automatic cell. The rate of an automatic cell depends on the slope of phase 4 depolarization, the resting membrane potential [RMP], and the threshold potential.[34] The RMP is the maximum diastolic potential achieved at the end of repolarization. The variable expression of the previously described ion channels in different parts of the heart produces the characteristic electrophysiology of the pacemakers, conduction tissue, atria, and ventricles. Factors affecting the action potential are listed in Table 30-6.[34,35,36,37] In addition to effects on the action potential, alterations in potassium current affect membrane electrical stability. Low extracellular K^+ reduces conductance through the inward rectifier channel (G_{K1}). Thus, there is greater cellular excitability and tendency for ectopy. With increased extracellular K, more potassium current escapes from the cell and the membrane is relatively stable.

TABLE 30-6 Action Potential Alterations[30,31,32]

▪EFFECTS ON PHASE 4
Hypothermia ↓ slope Hypothermia ↑ rate Hypoxia ↑ slope Ischemia ↑ slope Hyperkalemia ↓ rate Hypokalemia ↑ rate Hyponatremia ↓ slope Hypercarbia ↑ slope Increased pH ↑ slope
▪EFFECTS ON ACTION POTENTIAL DURATION
Hypercalcemia ↓ Hypocalcemia ↑
▪EFFECTS ON DIASTOLIC DEPOLARIZATION
Hypoxia ↓ max diastolic potential Hyperkalemia ↓ max diastolic potential Hypercarbia ↓ max diastolic potential (Purkinje only) Hypercarbia ↓ diastolic depolarization

Increased pH ↓ diastolic depolarization

Clinical Electrophysiology

The first wave of the normal ECG is the P wave, which is produced by atrial depolarization resulting from an action potential in the SA node. It is usually upright, except in lead aV_R, and 0.11 seconds in duration. Sinus node rate exhibits a circadian rhythm, decreasing nocturnally. Sinus node recovery time is also prolonged at night.[38]

An electrical impulse travels from the SA node to the AV node in 0.04 seconds via atrial tissue, specialized atrial conducting tissue, or the anterior, middle, and posterior tracts of the RA. Transmission is further delayed in the AV node because its conduction velocity is about 0.2 m/sec. The effective refractory period of the AV node demonstrates circadian rhythm and is increasingly prolonged at night. The P-R interval (normally 0.2 milliseconds or less), which occupies the time between atrial and ventricular depolarization, is nearly isoelectric, because atrial repolarization is not recordable. Significant interactions between the parasympathetic and sympathetic nervous systems control the conduction through the AV node with predominantly sympathetic activity.[39]

Ventricular depolarization begins ~0.12 to 0.20 seconds in adults and 0.15 to 0.18 seconds in children after depolarization of the SA node to produce the QRS complex.[40] The entire QRS complex should be <0.10 seconds. The first negative wave of the QRS complex is the Q wave, which should be ⩽0.04 seconds in duration and less than one-fourth of the subsequent R wave in amplitude. The first positive wave in the QRS is the R wave, and the second negative wave is the S wave. The

right and left branches of the bundle of His connecting with the Purkinje fibers conduct the depolarizing impulse rapidly over the endocardial surface of the heart. Normally, in sinus rhythm the earliest area of ventricular activation is the trabecular area on the anterior right ventricular surface about 18 to 25 milliseconds after the surface QRS complex. Activation then spreads toward the apex and base of the heart, with the latest activation at the cardiac base. Electrical activation also spreads from endocardium to epicardium.

On the ECG, the time from the end of ventricular depolarization to the beginning of repolarization, the ST segment, is isoelectric. More than 1 mm of elevation in the standard leads or 2 mm of elevation in the precordial leads is abnormal in this segment. No more than 0.5 mm of depression should be seen in any lead. The J point, the junction between the QRS complex and the ST segment, is depressed or elevated with the ST segment. Ventricular repolarization results in the T wave. T waves are normally upright in leads I, II, and V_3 to V_6, inverted in lead aV_R, and variable in leads II, aV_L, aV_F, V_1, and V_2. The T wave should not exceed 5 mm in height in the standard leads or 10 mm in the precordial leads. The QT interval, varying inversely with heart rate, should be slightly less than one-half of the RR interval.[41] The U wave, a small upright deflection after the T wave, is usually nondetectable.

Neural Regulation

Neural regulation of the heart is complex. The dominance of either the sympathetic or the parasympathetic system varies with age and physical condition, but the inhibitory parasympathetic system usually predominates.[42,43] Parasympathetic stimulation, particularly of the right vagus nerve, decreases heart rate by slowing the SA node. Lower pacemakers such as the AV node or His bundle may take over, causing "nodal rhythm." Vagal stimulation tends to suppress ventricular automaticity, which may facilitate termination of ventricular dysrhythmias. Intense vagal stimulation depresses both atrial and ventricular contractility by stimulation of cardiac muscarinic receptors that alter the myocyte cAMP level, by inhibition of norepinephrine release from nearby sympathetic nerve terminals by acetylcholine, and by inhibition of adrenergic receptor activation. One of the G proteins, Gi, which inhibits adenylcyclase, lowering the levels of cAMP, is coupled with the muscarinic receptor to control potassium channels and decrease heart rate.

Stimulation of the stellate ganglion or other sympathetic cardiac fibers increases heart rate, contractility, and ejection fraction. The right stellate ganglion has a greater effect on heart rate, whereas the left has more effect on contractility. Abnormalities of sympathetic cardiac nerve tone occur in long QT interval syndromes.[44]

The role of the cardiac *α* receptors is unclear, but their action is modulated by G protein signal transduction (Fig. 30-6). β_1 Receptors of the heart have positive chronotropic, inotropic, and lusitropic effects on the heart by stimulation of adenylcyclase. Action potentials may be restored by β_1 stimulation owing to increased numbers of calcium channels that can be activated in sufficient density to permit regenerative ionic flux along a fiber. Activation of cardiac β_2 receptors also increases rate and contractility, particularly in end-stage heart failure. The effects of norepinephrine on contractility are mediated by increased calcium entry through more active calcium

channels and increased sarcoplasmic reticular uptake of calcium. Increased sarcoplasmic uptake of calcium has a lusitropic effect, while making the increased calcium (in the sarcoplasmic reticulum [SR]) available for subsequent contractions (see Fig. 30-10).

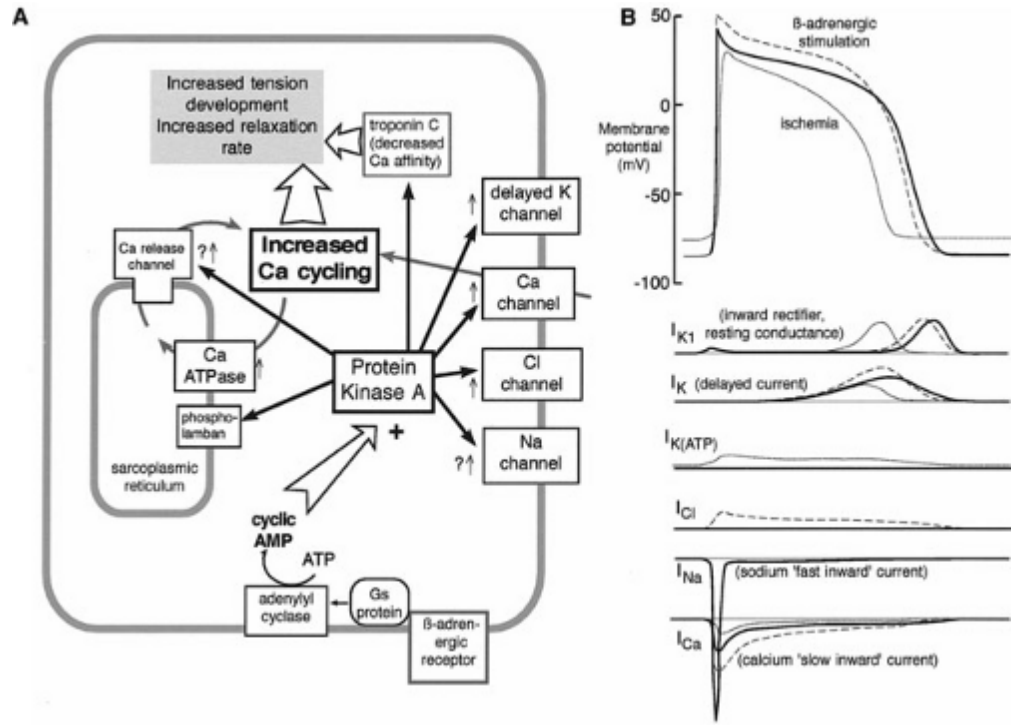

FIGURE 30-6. Effects of adrenergic stimulation on the heart. *β*-Adrenergically stimulated

protein phosphorylation occurs owing to activation of protein kinase A and increased cyclic adenosine monophosphate production. Increased cycling of Ca^{2+} and phosphorylation of multiple ion channels (Ca, Cl, Na, and delayed K) occurs. AMP, adenosine monophosphate; ATP, adenosine triphosphate; ATPase, adenosine triphosphatase. (Reprinted with permission from Lynch C, Lake CL: Cardiovascular anatomy and physiology. In Youngberg J, Lake C, Roizen M *et al* (eds): Cardiac, Vascular, and Thoracic Anesthesia, p 100. Philadelphia, Churchill Livingstone, 2000.)

Atrial Receptors

Parasympathetic receptors type A, type B, and receptors innervated by group C fibers reflexly alter intravascular volume or heart rate. The primary locations of type A and B receptors are the cavoatrial junction, pulmonary venous–atrial junction, atrial appendage, and atrial body.[45] Type A receptors may actually respond to heart rate rather than atrial pressure.[45] Type B receptors are stretch receptors whose discharge is closely related to atrial volume and varies with the rate of atrial pressure increase.

Ventricular Receptors

Stimulation of ventricular receptors causes either cardiovascular excitation or depression. Types of ventricular receptors include the pressure-sensitive coronary baroreceptors, mechanoreceptors (innervated by nonmyelinated vagal afferent fibers), and sympathetic mechanosensitive or chemosensitive receptors.[45]

The Bainbridge reflex, described later in this chapter, is mediated by the parasympathetic receptors. Myocardial ischemia increases discharge of both vagal and sympathetic receptors. The sympathetic afferent fibers may transmit the pain sensation associated with coronary occlusion. Postcardiotomy hypertension results from a cardiogenic reflex transmitted through the sympathetic afferent fibers of the stellate ganglion.[45] Finally, opiate receptors of the K type, found in vagus, cardiac, and sympathetic ganglia, may mediate dysrhythmias, particularly during ischemia and reperfusion.[46,47]

Both cardiac contraction and conduction are modulated through the β-adrenergic receptors and guanine nucleotide binding proteins or G proteins. G protein molecules consist of seven transmembrane α-helical segments, which create a central cleft to which various ligands can bind. When binding occurs, the receptor undergoes a conformational change. An example of the G protein signaling system in the heart is the binding of catecholamines to the β-adrenergic receptor, which in turn, activates the stimulatory G protein and adenyl cyclase, increasing intracellular cAMP, cardiac contractility, and heart rate (see Fig. 30-6). However, a detailed discussion of the G proteins is beyond the scope of this chapter and may be found in other sources.[48]

Coronary Circulatory Physiology

5 About 4% of the cardiac output, or 250 mL/min, perfuses the coronary arteries of a 70-kg person. Physiologically, the coronary circulation consists of large, low-resistance epicardial vessels and higher-resistance intramyocardial arteries and arterioles. Myocardial flow, pressure, and oxygen consumption are integrally related. Coronary blood flow is locally regulated by metabolic, mechanical, anatomic, and possibly myogenic factors.[49] Numerous methods to measure human myocardial blood flow have been described.[50] Coronary flow is determined by the duration of diastole and the difference between diastolic aortic pressure and left ventricular end-diastolic pressure. During systole, about 15 to 25% of the coronary flow distends and is stored in the extramural coronary arteries. Only a small amount actually perfuses the myocardium. During diastole, this stored blood perfuses the myocardium[51] (Fig. 30-7). The majority of left coronary artery flow occurs in diastole because intramyocardial pressure is lowest at that time.[52] Right

coronary artery flow occurs in both systole and diastole because intramyocardial pressure is lower in the thinner RV. Intramyocardial pressure affects coronary flow to a small extent because of the varying stiffness of ventricular muscle over the cardiac cycle.[52] Coronary flow also decreases from epicardium to endocardium as a consequence of extravascular pressure.

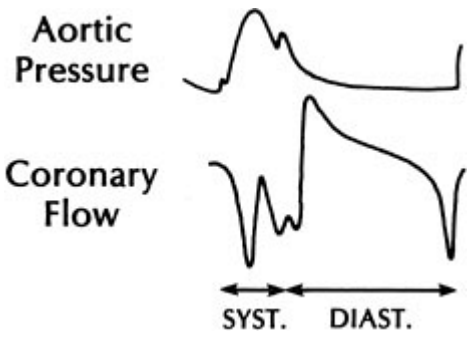

FIGURE 30-7. This diagrammatic relationship between aortic pressure and coronary flow demonstrates that little coronary flow occurs during systole, while the majority occurs during diastole. This relationship is particularly true to the left coronary artery that supplies the left ventricle. The right ventricle, being thinner and developing less pressure, produces less impediment to systolic coronary flow.

The zero flow pressure, normally about 12 to 50 mm Hg, is a minimum coronary pressure required to initiate flow. The source of this pressure is the collapsed intramyocardial coronary microvessels when tissue pressures exceed intraluminal pressures and intracavitary back pressure. At least half of coronary vascular resistance results from vessels larger than 100 μm in diameter, whereas 10% results from coronary veins.[53] Coronary flow ceases completely at 20 mm Hg, the critical closure or critical flow pressure.[54]

6 Myocardial oxygen consumption is high; therefore, coronary venous blood is only 30% saturated and its PO_2 of 18 to 20 mm Hg is the lowest anywhere in the body. Because oxygen extraction cannot be increased further, coronary flow must increase if the heart requires additional oxygen.

Coronary Autoregulation

Coronary perfusion is autoregulated to maintain a constant flow over a range of perfusion pressures (usually between 50 and 120 mm Hg) at any given myocardial oxygen demand.[55] Above and below these limits, coronary flow varies with perfusion pressure. The term *autoregulation* refers strictly to pressure-dependent changes in coronary resistance unrelated to changes in myocardial metabolism.[55] The principal site of coronary autoregulation is the coronary arteriole, a <150-μm–diameter vessel, although small coronary arteries (>150 μm) can be recruited to increase flow during hypoperfusion.[56] Nevertheless, the coronary arterioles are not fully dilated even during hypoperfusion states.[57]

However, changes in myocardial oxygen demand alter autoregulation. The involved metabolite, therefore, is oxygen (specifically, myocardial oxygen tension, PO_2) acting through mediators such as adenosine.[51] Adenosine-induced vasodilation is inversely related to arterial diameter, with the greatest dilation occurring in smaller vessels.[56] Hyperoxia decreases, and a low PO_2 of 49 mm Hg increases coronary blood flow and myocardial oxygen consumption independently of changes in oxygen content or delivery.[58] The threshold oxygen tension for autoregulation is 32 mm Hg.[59]

Coronary autoregulation is also closely coupled with coronary venous PO_2, particularly at PO_2 <25 mm Hg.[51,59] Decreased heart rate attenuates autoregulation, whereas pharmacologic coronary constriction augments it.[59]

The autoregulatory mechanism extends into different myocardial layers.[51] Autoregulation is greater in the subepicardium than in the subendocardium, possibly because of the transmural gradient to which the subendocardial vessels are exposed.[59] Autoregulation in the right coronary artery may be less than in the left coronary artery. Pressure and flow-dependent changes in myocardial oxygen consumption in the RV explain this difference.[59]

Immediately after occlusion of a coronary artery, reperfusion flow increases beyond preocclusion levels, a process termed *reactive hyperemia.* In a related process, *reactive dilation*, large coronary arteries dilate after relief of occlusion; however, unlike in reactive hyperemia, the onset is delayed to 60 seconds and sustained for 150 seconds after relief of occlusion.[60]

The most important regulators of coronary vascular tone are metabolic and involve multiple pathways. Modulation of basal tone and normal autoregulation is mediated by glybenclamide-sensitive K_{ATP} channels, which are enhanced by adenosine receptor activation.[61,62] Other mediators and pathways such as oxygen, potassium, pH, carbon dioxide, endothelium-derived relaxing factor, prostaglandins, prostacyclin, histamine, and ATP may also be involved in regulating coronary tone.[49] Prostaglandin E_1 dilates the coronary arteries, probably acting through adenosine as a mediator. Prostaglandin E_2, however, is a coronary vasoconstrictor.[63] Acetylcholine increases coronary flow. Acting through the H_1 receptor, histamine contracts epicardial coronary arteries, provoking spasm, but the H_2 receptor mediates vasodilation.[64] Histamine also promotes production of prostaglandin in the heart.[64] Although norepinephrine (or sympathetic cardiac nerve stimulation) causes coronary constriction through its *a* effects, the associated increase in myocardial contractility increases coronary flow. Similarly, vagal stimulation may directly produce coronary vasodilation, but the associated decrease in heart rate and contractility causes secondary coronary vasoconstriction.

Coronary Flow Reserve

Coronary flow increases during maximal dilation of the coronary arteries. The difference between resting and maximal coronary flow is the coronary flow reserve. Coronary flow is heterogeneous throughout the myocardium, although there is correlation between regional flows in neighboring myocardial areas.[65] Although coronary vasodilation occurs in response to ischemia or other endogenous stimuli, maximal flow, which is normally unavailable to the heart, may be achieved with pharmacologic agents. Exhaustion of autoregulatory vasodilator reserve does not necessarily mean that exhaustion of pharmacologic vasodilator reserve has occurred. Coronary flow reserve can be decreased by decreased maximal flow and increased regulated coronary flow.[66] Maximal coronary flow is decreased by tachycardia, increased blood viscosity, increased myocardial contractility, and myocardial hypertrophy.[51]

As epicardial coronary artery stenosis occurs, so does arteriolar vasodilation to maintain flow at normal levels. Once the vasodilator reserve is exhausted (usually at stenoses of >90%), however, an increase in the stenosis of the coronary artery will decrease flow. Administration of a vasodilator to a vascular bed served by a normal and a stenotic coronary artery connected by collaterals will dilate the normal arterioles but produce little change in the arterioles served by the stenotic artery because they are maximally dilated. The increased flow to the normal arterioles is termed "coronary steal."

Endocardial/Epicardial Flow Ratio

The distribution of coronary flow is as important as total flow. The ratio of flow in the endocardium to that in the epicardium, the endo/epi ratio, is used to assess flow distribution. Subepicardial flow is usually adequate; thus, if the endo/epi ratio remains constant, adequate subendocardial blood flow is inferred.[65] However, with maximal coronary vasodilation, the endo/epi ratio varies with the coronary perfusion pressure.[51] The ratio is minimally affected by

changes in afterload but reduced by increased left ventricular preload. The latter results either from a disproportionate increase in subendocardial diastolic tissue pressure or an increase in coronary sinus pressure.[51] However, increased right ventricular preload decreases right ventricular blood flow without altering its intramyocardial distribution.[67]

Transient subendocardial ischemia accompanies the onset of severe exercise. Although anemia increases coronary blood flow by autoregulation, severe anemia decreases the endo/epi ratio, indicating subendocardial ischemia.[51] Hypoxia, in contrast, increases both coronary blood flow and the endo/epi ratio.

Neural Influences

Coronary arteries are also responsive to neural stimuli.[68] Parasympathetic and sympathetic nerves extend to the precapillary coronary vessels. Parasympathetic stimulation directly activates coronary muscarinic receptors, inducing dilation.

Sympathetic stimulation causes coronary dilatation as a result of the metabolic factors produced by increased MVO_2 and direct β receptor stimulation. α_2 Adrenoceptors or muscarinic receptors are present in the sympathetic nerve endings of coronary arteries. Activation of α-adrenergic receptors by norepinephrine and acetylcholine (via the vagus nerve) reduces sympathetic neurotransmitter output, which would reduce the dilation of these vessels causing coronary vasoconstriction. α_2 Agonists also mediate release of endothelial-derived relaxing factor in coronary arteries. β_1-Adrenergic receptors predominate over α_1 receptors in canine circumflex coronary artery.[69] Termination of the sympathetic cardiac effects results from extensive neuronal uptake of norepinephrine.[70] Only small amounts of the norepinephrine released by the heart enter the systemic circulation.[70]

Coronary artery spasm may result from unopposed α_1-adrenoceptor stimulation in the presence of β-adrenergic blockade or when a pure α agonist is given. Acute coronary occlusion attenuates the baroreflex responses of heart rate and systemic vascular resistance.[57]

Cardiac Output

7 Cardiac output is the volume of blood pumped by the heart each minute. It is the product of the heart rate and the volume of each beat (stroke volume) but is determined by preload, afterload, heart rate, contractility, and ventricular compliance. Cardiac output measurements are usually corrected for the size of the patient by dividing the output by the body surface area to give the cardiac index. A normal cardiac index is 2.5 to 3.5 L/min/m^2 and may be determined by the Fick principle or indicator-dilution methods (Fig. 30-8 and see Table 30-4). Cardiac output increases with increased heart rate, preload, or contractility and decreased afterload.

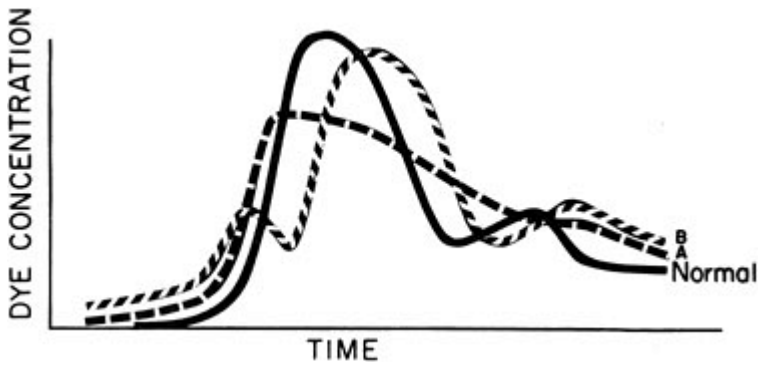

FIGURE 30-8. A normal dye dilution cardiac output curve has an uninterrupted build-up

slope, a steep disappearance slope with a short disappearance time, and a prominent recirculation peak. In right-to-left shunts *(A)*, there is a deformity on the build-up slope by the abnormal early appearance of the dye in the arterial circulation. Left-to-right **(B)** shunting causes a decreased peak dye concentration, absence of the recirculation peak, and prolongation of the disappearance time. Determinants

Preload. Preload is defined as the end-diastolic stress on the ventricle (end-diastolic fiber length or end-diastolic volume). The determinants of preload are blood volume, venous tone, ventricular compliance, ventricular afterload, and myocardial contractility. The distribution of the blood volume between intrathoracic and extrathoracic compartments also affects preload. Extrathoracic blood volume increases with

standing, whereas the negative intrathoracic pressure during inspiration increases intrathoracic blood volume.

Stroke volume is determined by the volume of blood in the heart at the beginning of systole (end-diastolic volume [EDV]) and the amount of blood remaining in the ventricle at closure of the aortic valve at the end of systole (end-systolic volume [ESV]). The degree of stretch of the left ventricular fibers, influenced by the amount of blood in the ventricle, determines the amount of work the ventricle can do.[71] An increase in preload increases EDV and wall tension.

EDV is not synonymous with end-diastolic pressure, nor are the two linearly related. The ejection fraction, normally 0.6 to 0.7, is the ratio of the stroke volume to the EDV:

Ejection fraction = EDV - ESV/EDV

Severe impairment of ventricular function is present when the ejection fraction is <0.4.

Afterload. Afterload is the wall stress or tension faced by the myocardium during ventricular ejection. It is the force opposing ventricular fiber shortening during ejection. Left ventricular afterload depends on the shape, size, radius, and wall thickness of the ventricle, the principal factors being the radius (related to preload and chamber volume) and aortic impedance (controlled by arterial compliance and systemic vascular resistance). Other factors involved in afterload include arterial wall stiffness (aortic), blood viscosity, and the mass of blood in the aorta. Usually, the ejection phase stress is implied in discussions of afterload, although there are wall stresses during the isovolumetric contraction phase.

Clinically, systemic vascular resistance is frequently used as an estimate of afterload (Table 30-4). However, systemic vascular resistance reflects only peripheral arteriolar tone rather than left ventricular systolic wall tension. A true measure of left ventricular afterload, such as left ventricular end-systolic wall stress, which incorporates left ventricular chamber pressure, ventricular dimensions, wall thickness, and peripheral loading conditions, should be used to accurately assess afterload.[72] However, these measurements require direct intraventricular pressure determination and echocardiographic evaluation of wall thickness and ventricular dimensions. Compared with left ventricular end-systolic wall stress, systemic vascular resistance underestimates afterload when afterload is increased or decreased or contractility is improved.[72]

When afterload is reduced, the ventricle shortens more quickly and completely.[73] An increase in afterload decreases the extent and velocity of shortening and increases active tension and the time to peak tension in cardiac muscle. Wall tension, ventricular radius, and EDV are also increased to maintain stroke volume. In the poorly contractile heart, acute increases in afterload severely reduce stroke volume. Hypertrophy occurs in ventricles facing a chronic increase in afterload so wall stress and shortening characteristics return toward normal.

Heart Rate. Heart rate is primarily determined by the automaticity of the sinus node. However, its intrinsic rate depends on neural and humoral influences. An increase in heart rate increases cardiac output, even if the stroke volume remains constant, by increasing the extent and velocity of shortening and *d*P/*d*t.[74] The increase of *d*P/*d*t with heart rate is even more pronounced if end-diastolic dimensions are maintained by volume infusion.[74] At heart rates between 120 and 160 beats/min, cardiac output increases but not as much as at more optimal heart rates (Fig. 30-9). An increase in heart rate shortens the filling time between beats, reducing EDV. Because most cardiac filling occurs during the first half-second of the rapid filling phase, cardiac output decreases at heart rates >160 beats/min because of inadequate filling time.

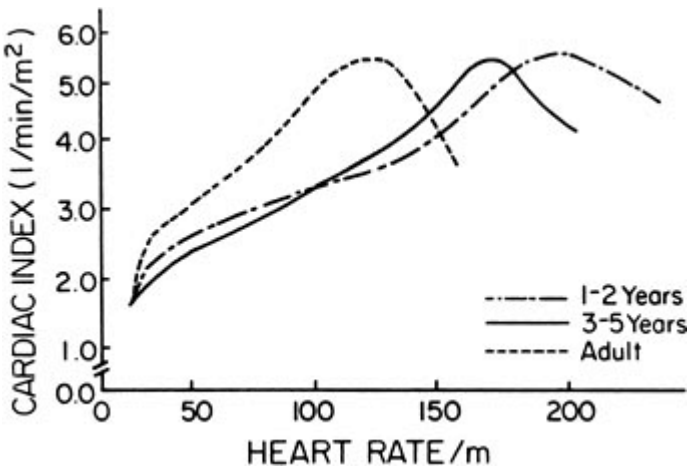

FIGURE 30-9. The effect of heart rate on cardiac output varies with age. In children, an increase in heart rate increases cardiac output because the immature heart is relatively noncompliant and does not increase its stroke volume in response to increased demands. In the adult, however, an increase in heart rate over 120 beats per minute does not increase cardiac index. (Reprinted with permission from Wetsel RC: Critical Care State of the Art. p 9. Fullerton, Society of Critical Care Medicine, 1981.)

Cardiac output is also increased during the heartbeat after a ventricular extrasystole. This extrasystolic potentiation results from increased ejection fraction, decreased left ventricular EDV, and enhanced diastolic filling. The mechanism is probably increased availability of calcium to the contractile mechanism.[75]

Contractility. Contractility is the inotropic state independent of changes in preload, afterload, or heart rate.

Cardiac Systole. Myocardial contraction begins when the action potential, acting through the T-tubule system of the SR, results in calcium release into the sarcoplasm. A cAMP-dependent protein kinase in the heart stimulates calcium transport by the vesicles of the SR (Fig. 30-10). Intracellular cAMP protein kinase is activated and transfers the terminal phosphate of ATP to troponin I, phospholamban, or other intracellular proteins. Troponin has three components: troponin I, the inhibitory factor inhibiting the magnesium-stimulated adenosine triphosphatase of actomyosin; troponin C, which is the calcium-sensitive factor; and troponin T, the tropomyosin-binding subunit.

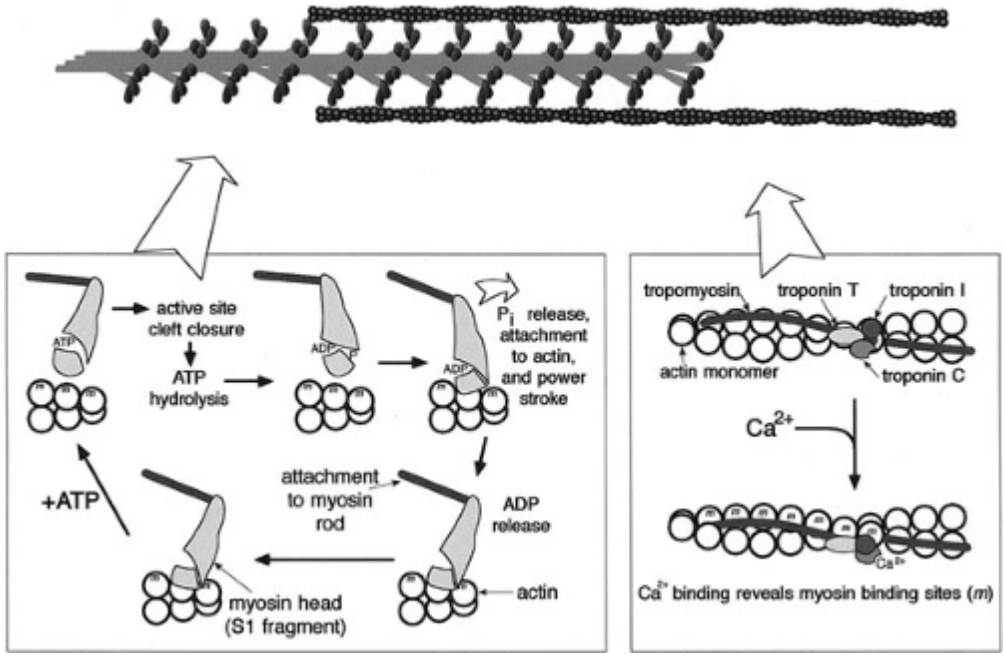

FIGURE 30-10. Left. A schematic diagram of the actin filament with its individual monomers and active myosin binding sites (*m*). The myosin head (S1 fragment) is dissociated from actin by binding with adenosine triphopshate (ATP). Subsequent ATP hydrolysis and release of inorganic phosphate (P_i) "cocks" the head group into a tension-generating conformation. Attachment of the myosin head to actin allows the head to apply tension to the myosin rod and to the actin filament. **Right**. Calcium binding to troponin C causes troponin I, the inhibitory subunit, to decrease its affinity for actin. Via tropomyosin, seven *m* sites on actin monomers are revealed. ADP, adenosine diphosphate. (Adapted from Rayment I, Holden HM, Whitaker M *et al*: Structure of the actin–myosin complex and implications for muscle contraction. Science 261:58, 1993, with permission of C. Lynch III.)

The actin and myosin filaments forming the myofibrils of the cardiac myocyte are functionally divided into sarcomeres. The sarcomere is further divided into three major subdomains, the electron-lucent I band composed primarily of actin; the

Z line, where actin filaments from adjacent sarcomeres meet and SR is juxtaposed to the T-tubule system (junctional SR); and the electron-dense A band composed of myosin thick filaments (further subdivided by the M band into two symmetric bundles). Junctional SR is characterized by a larger lumen containing calsequestrin, a protein that provides extra "releasable" calcium and has low calcium-binding affinity. Calcium entering the myocyte through the L-type calcium channels primarily activates release of SR calcium, a process called calcium-induced calcium release. A portion of the entering calcium binds to calcium release channels to activate their opening, permitting rapid efflux of stored calcium from the SR lumen into the myoplasm to bind to troponin C.

Phospholamban, a membrane-bound protein that modulates the activity of calcium-stimulated magnesium adenosine triphosphatase, permits increased calcium uptake and calcium release by the SR in its phosphorylated state.[76] Adenosine triphosphatase from the calcium pump, which couples hydrolysis of one molecule of ATP with the active transport of two calcium ions, is the channel through which the activator calcium is released to initiate systole. The increased free calcium is bound to troponin C, releasing the inhibition of actin-myosin interaction by the troponin–tropomyosin complex. Contraction of actin and myosin occurs (see Fig. 30-10). The strength of contraction depends on the length of the sarcomere and the amount of activator calcium because cardiac contractility is controlled by the degree of activation of the myocytes. Likewise, relaxation depends on the rate of calcium delivery to troponin, the quantity of available

calcium, and the rate of calcium removal from troponin.[77]

Diastole. Myocardial relaxation occurs as a result of reuptake of or binding of calcium ion by the SR, a lusitropic or relaxing effect of cAMP.[78] Relaxation is a load-dependent process. In the relaxing heart, load is the premature lengthening of cardiac muscle. Myocardial relaxation depends on internal restoring forces such as cardiac fibers, hemodynamic loading such as the impedance of the arterial system, and external restoring forces resulting from deformation of the wall of the intact heart.[79]

Alterations in Contractility. Cardiac output is increased by increasing load, either volume or pressure (heterometric autoregulation); by the Anrep effect (homeometric autoregulation); the treppe phenomenon; or by a change in the inotropic state independent of the previous mechanisms.

The Anrep effect improves ventricular performance several beats after the initial stretching of the myocardial fibers, owing to abruptly increased aortic or left ventricular pressure. It results from increased contractility with more rapid activation of the contractile process, increased developed force, and increased velocity of shortening. Homeometric autoregulation is operative for only a few minutes as the initially increased ventricular EDV and circumference decrease with recovery of stroke work.[79]

Rate-dependent variations in contractility, collectively known as force-frequency relationships (FFRs), include the treppe phenomenon, positive staircase effect, or Bowditch's phenomenon. An increase in heart rate increases the developed tension, whereas a decreased stimulation frequency reduces tension development. FFRs result from a variation in myofibril calcium sensitivity and an alteration in activator calcium. The ratio of systolic pressure to echocardiographic measurement of ESV plotted against various heart rates during exercise permits clinical evaluation of myocardial contractility.[80]

A long pause between beats also increases the force of contraction; this is known as the Woodworth phenomenon or reverse (negative) staircase effect.[81] Increasing contractility increases the ejection fraction if ESV decreases while EDV remains the same. Contractility is decreased by hypoxia, cardiomyopathy, myocardial ischemia, or infarction.

Compliance. Compliance is the nonlinear change in ventricular EDV/change in end-diastolic pressure. The rapidity of diastolic filling is a major determinant of cardiac output, which is reduced by decreased compliance. Although ventricular contractility may be normal, reduced relaxation from coronary artery disease, hypertrophic cardiomyopathy, cardiac tamponade, and hypertensive heart disease impairs diastolic filling, which, in turn, limits cardiac output.

Myocardial Mechanics

The mechanical function of the heart is evaluated by *ejection phase indices* (Starling stroke volume versus end-diastolic pressure curves, stroke work versus end-diastolic pressure,

force-velocity curves, ejection fraction, velocity of circumferential fiber shortening), *preload recruitable stroke work, isovolumic phase indices* (rate of left ventricular pressure development at 40 mm Hg pressure, [dP/dtP_{40}]; maximum dP/dt; maximal velocity of contractile element shortening, V_{max}; point of maximum $dP/dt/P$ or Vpm), and *end-systolic indices* (pressure–volume or pressure–length relationship at end systole). Many of these measurements are complicated and affected by preload or afterload as noted in Table 30-7. A measurement of the coupling between ventricular performance and the peripheral arterial circulation is obtained by measurement of ventricular time-varying elastance.[82]

TABLE 30-7 Measures of Myocardial Contractility

·INDICES	·USEFULNESS

·EJECTION PHASE INDICES	
Stroke volume versus EDP	Useful for acute contractility if ventricular function curve obtained
	Afterload sensitive
Stroke work versus EDP	Not useful for basal contractility
Ejection fraction (EF)	Useful for basal contractility when EDV is known
	Afterload dependent
Maximum acceleration of aortic blood flow	Afterload dependent
Mean velocity of circumferential fiber shortening (V_{cf})	Afterload dependent
	More sensitive for basal contractility than EF
Mean normalized systolic ejection rate	Afterload dependent
	Less useful than mean V_{cf}
Maximum chamber elastance	Useful for acute contractility changes
	Nonlinear behavior complicates interpretation
·ISOVOLUMIC PHASE INDICES	
$dP/dt/P_{40}$ mm Hg pressure	Useful in acute contractility changes
	Not useful for basal contractility
Maximum dP/dt	Dependent on timing of aortic valve opening
V_{pm}	Useful in acute contractility changes
	Most reliable measure for acute contractility

	changes
	Dependent on preload/afterload if increased
V_{max}	Not as useful as $dP/dt/P_{40}$
	Decreases with increased preload or afterload
	Useful for basal contractility
P, intraventricular pressure; V_{pm}, velocity of shortening of contractile elements.	
Prepared by C. Lynch with data from Strobeck JE, Sonnenblick EH: Pathophysiology of heart failure: Deficiency in cardiac contraction. In Cohn JN (ed): Drug Treatment in Heart Failure, p 13. Secaucus, NJ, Advanced Therapeutics Communications International, 1988.	

Starling (Ventricular Function) Curve

If the cardiac muscle is stretched, it develops greater contractile tension because of changes in myofibril calcium sensitivity and alterations in the amount of activator calcium. This observation is the basis of Starling's law: "The law of the heart is therefore the same as that of skeletal muscle, namely, that the mechanical energy set free on passage from the resting to the contracted state depends…on the length of the muscle fibers."[83] Atrial and ventricular muscle obeys Starling's law. Increased preload or initial fiber length increases resting tension, velocity of tension development, and peak tension. An increase in venous return stretches the muscle fibers to increase contractility and improve cardiac output. However, this process occurs only at subnormal filling pressures. In the upright position, ventricular filling pressures decrease to ~4 mm Hg, and the normal heart operates on the ascending limb of the ventricular function curve. Peak ventricular output occurs at filling pressures of ~10 mm Hg in normal humans.[84] Whether the heart can fall onto a descending limb of the length–stroke volume curve like skeletal muscle is unclear.[84] On the descending limb, the heart decompensates and further increases in EDV decrease stroke volume, but disengagement of actin and myosin does not occur. In all probability, the heart moves to a different curve.

Ventricular function curves are influenced by afterload, although they incorporate the effects of preload alterations (Fig. 30-11). Starling curves are used clinically when weaning patients from cardiopulmonary bypass, to assess the effects of anesthetic agents on the heart, and to guide fluid and pharmacologic therapy in the perioperative period. The increased stretch and end-diastolic length produced by atrial (atrial kick) or early contracting ventricular fibers (idioventricular kick) increase ventricular stroke volume. Both of these effects are manifestations of Starling's law.

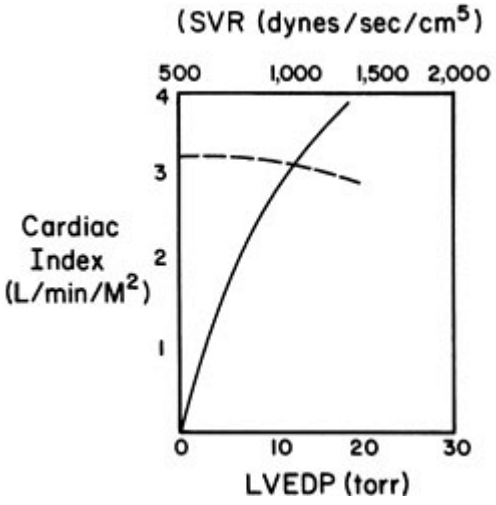

FIGURE 30-11. The ventricular function (Starling) curve of the normal left ventricle (*solid line*) is affected much more by changes in preload (left ventricular end-diastolic pressure) than it is by an increase in afterload (*dotted line*). The failing heart moves to a curve downward and to the right of the normal heart. Venodilator therapy decreases preload without increasing cardiac index (the heart moves to the left on the curve), while reduction of afterload increases cardiac index without a change in preload. Combined preload and afterload reduction decrease filling pressure and increase cardiac index. SVR, systemic vascular resistance; LVEDP, left ventricular end diastolic pressure.

Pressure–Volume Loops

Another index of contractility that is less affected by preload, afterload, or other conditions is the pressure–volume loop, an end-systolic index (Fig. 30-12). At end systole, ejection ceases, and the aortic valve closes with the ventricle at minimum dimension and volume.

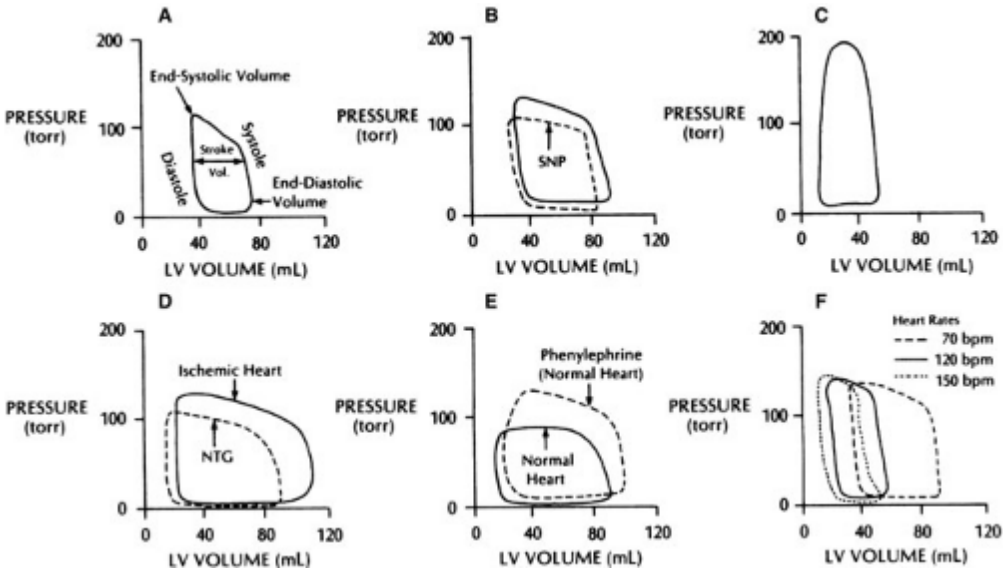

FIGURE 30-12. Ventricular pressure–volume loops. **A.** The relationship of ventricular pressure and volume over the entire cardiac cycle. The loop begins on the bottom left with opening of the mitral valve and filling of the ventricle to end-diastolic volume. When multiple pressure–volume loops are created, the slope of the individual end-systolic pressure–volume relations indicates myocardial contractility. An extension of the bottom portion of the loop

(without ventricular systole) would give a diastolic pressure–volume relation for the ventricle. Isovolumetric contraction begins at the lower right portion of the curve with closure of the mitral valve. The aortic valve opens at the upper right portion of the loop and ventricular ejection begins. At the upper left of the loop, the aortic valve closes (end-systolic volume) and isovolumetric relaxation returns the loop to the starting point. Stroke volume is the difference between the volume at the end of diastole and the end of systole. The area of the loop is stroke work. **B.** The effects of afterload reduction with sodium nitroprusside (SNP) on the pressure–volume loop. **C.** The changes in the pressure–volume loop in a patient with aortic stenosis with a high peak systolic pressure and steep diastolic slope representing reduced ventricular compliance. **D.** An ischemic heart has its pressure–volume shifted upward and to the right. **E.** The effects of increasing the afterload of a normal heart with phenylephrine. **F.** In a normal heart, an increase in heart rate markedly reduces left ventricular volume. LV, left ventricle; NTG, nitroglycerin. See also Figure 30-13.

In such loops, the height and width of the loop are determined by the ventricular systolic pressure and stroke volume. The area subtended by the systolic portion of the curve provides a measure of stroke work during ejection, whereas the area of the diastolic limb is a measure of diastolic work performed during ventricular filling and distention. The volume

between the systolic and diastolic portions of the loop is the stroke volume. Cardiac work, the product of pressure and volume, is the area of the pressure–volume loop, which is linearly related to myocardial oxygen consumption under various hemodynamic conditions.[85] In a given ventricle, all the end-systolic points are positioned on the same line, which represents the elastance of that ventricle (the change in end-systolic pressure/change in ESV, although elastance is actually the linear relationship between length and force). Contractility is directly proportional to elastance, with the slope of this relationship becoming steeper with increased contractility and flatter with decreased contractility. The slope of the end-systolic pressure–volume relation is linear and correlates well with the ejection fraction.[86]

Pressure–volume loops also reveal information about ventricular compliance. Compliance actually changes during each contraction. The normal relationship between diastolic pressure and volume is curvilinear. There is a relatively gentle slope at low end-diastolic pressures (e.g., little change in pressure for large changes in volume). At end-diastolic pressures at the upper limits of normal ($\geqslant$12 mm Hg), the curve becomes steeper, and pressure is almost exponentially related to EDV. Ventricular compliance decreases under such conditions. The ventricular end-systolic pressure–volume relationship may be dependent on the type of loading intervention but can be used to assess left ventricular performance under various conditions[87] (see Figs. 30-12 and 30-13). However, one limitation of pressure–volume loops is that pressure may

inaccurately reflect end-systolic afterload. The ratio of pressure to volume at end systole can also be used as an index of contractile function. However, this assumes that at higher pressures there are larger volumes at a given inotropic state.

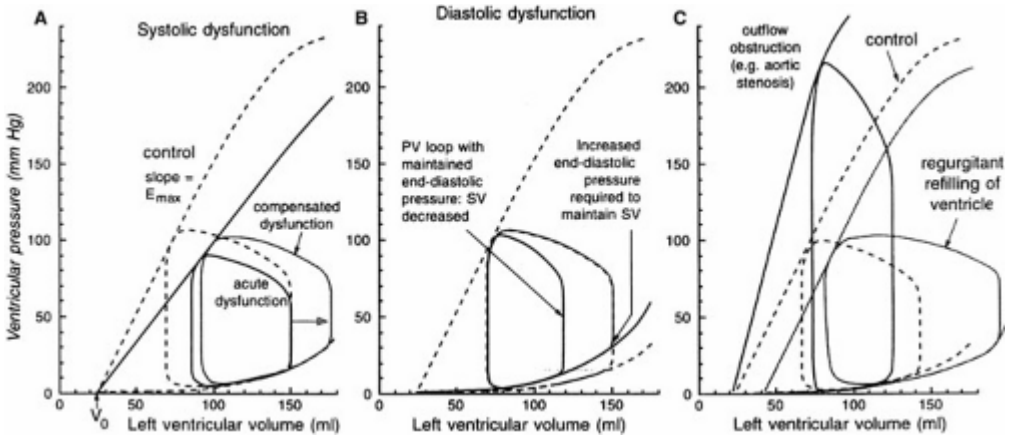

FIGURE 30-13. A: The ventricular pressure–volume relationship in systolic dysfunction demonstrates depressed E_{max} and decreased stroke volume (SV). With compensation, the SV is restored by an increased end-diastolic volume. **B:** With diastolic dysfunction, SV is decreased unless end-diastolic pressure increases to maintain it. **C:** As in Figure 30-12C, ventricular outflow obstruction usually enhances systolic function because of ventricular hypertrophy, but associated diastolic dysfunction decreases SV while increasing total ventricular work. With regurgitant ventricular filling, a compensatory increase in stroke volume occurs. (Reprinted with permission from Lynch C, Lake CL: Cardiovascular anatomy and physiology. In Youngberg J, Lake C, Roizen M *et al* (eds): Cardiac, Vascular, and Thoracic Anesthesia, p 119. Philadelphia, Churchill Livingstone, 2000.)

Although pressure–volume loops are most often used to consider ventricular function, they can also be used to analyze atrial function (stroke volume [EDV-ESV] and emptying fraction [stroke volume/EDV], particularly of the LA)[4] (Fig. 30-14). However, these measures are dependent on LA loading conditions. The LA pressure–volume loop consists of two horizontal loops in a figure-of-eight pattern, including an active or A loop and the passive V loop. The A loop begins at atrial end diastole (the pressure immediately before atrial contraction), with the active component proceeding in a counterclockwise direction during atrial systole until blood is ejected through the mitral valve into the LV (active LA stroke work). The passive V loop proceeds in a clockwise direction over time. The total reservoir volume of the LA can be determined from the maximum and minimum volumes of the A and V loops.

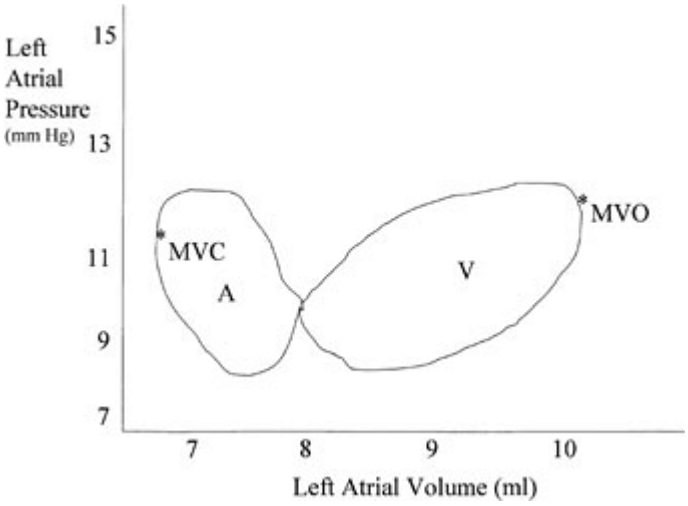

FIGURE 30-14. An atrial pressure–volume loop has the appearance of a figure eight. *A* represents active atrial contraction and proceeds in a counterclockwise direction. *V* represents left atrial reservoir function and proceeds in a clockwise direction over time. Mitral valve opening (MVO) and closure (MVC) are depicted. (Adapted from Pagel PS, Kehl F, Gare M *et al*: Mechanical functions of the left atrium. Anesthesiology 98:975, 2003.)

Pressure–Length Loops

Measurement of a pressure–length loop is a reproducible and sensitive method to evaluate total or regional systolic and diastolic myocardial function. However, it requires direct measurement of changes in myocardial length and intraventricular pressure. Ventricular segment length is plotted on the *x*-axis and ventricular pressure on the *y*-axis (Fig. 30-15). Normal loops are rectangular and include four segments: isovolumic contraction (*right*), ejection (*top*), isovolumic relaxation (*left*), and filling (*bottom*). The area of the loop represents ventricular stroke work.[88] Pressure–length loops are altered by changes in preload, afterload, inotropic state, and ischemia. Ischemia increases postsystolic shortening and systolic lengthening, as depicted in Figure 30-15 (*inset*).[89]

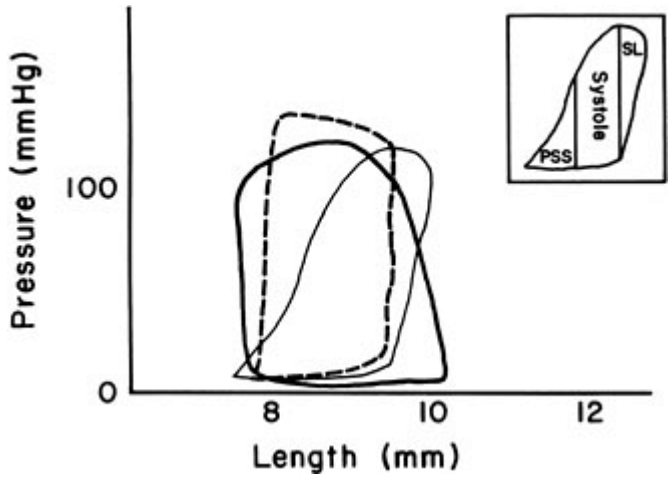

FIGURE 30-15. The normal pressure–length loop (*thick black line*) is a rectangle whose area indicates total ventricular work. Ischemia (*thin solid line*) causes the loop to lean toward the right because of increased systolic lengthening and postsystolic shortening (*inset*). Increased afterload (*dotted line*) causes the loop to become taller at a similar preload. Post systolic shortening (PSS); systolic lengthening (SL). (Reprinted with permission from Lake CL (ed): Clinical Monitoring for Anesthesia and Critical Care, p 181. Philadelphia, WB Saunders, 1994.)

Force–Velocity Curve

Myocardial contractility can also increase when the myocardial fibers increase their developed force or velocity of shortening without a change in fiber length. Force–velocity curves evaluate contractility (velocity of shortening) at constant fiber length in a passively stretched muscle (preloaded), which is stimulated to contract against either no load or an afterload. Force–velocity curves are much more sensitive indicators of contractility than Starling curves and are based on the Hill model of isolated muscle.

As afterload is increased, the initial rate of shortening follows a hyperbolic relationship (Fig. 30-16). The force or tension developed during contraction is measured by dP/dt_{max}, the maximum rate of rise of intraventricular pressure during the isometric phase of ventricular contraction. The point

of the curve where no shortening occurs, although the muscle develops maximal force, is termed P_0. Extrapolation of

the curve back to zero load where the maximal velocity of shortening occurs is termed V_{max}. Both preload and afterload affect dP/dt_{max}. As preload increases, the maximum isometric tension that the muscle develops increases, but the maximal velocity of shortening is unchanged. An increase in myocardial contractility increases both the developed tension and the maximum velocity of shortening, shifting the force–velocity curve upward and to the right.

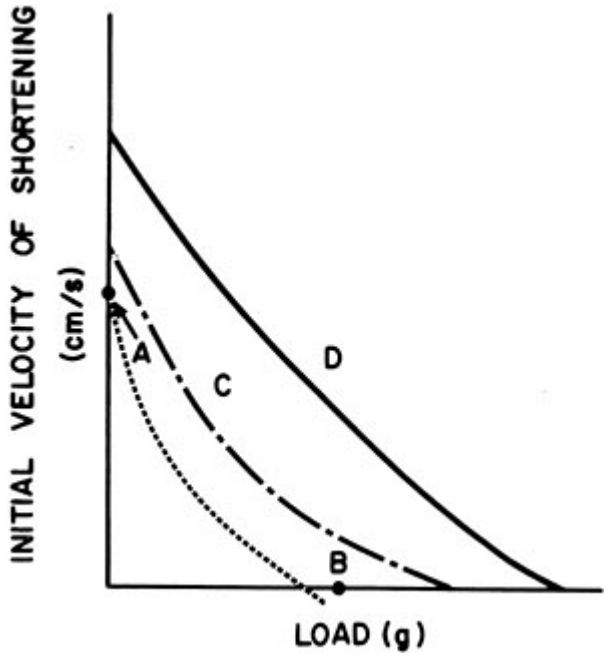

FIGURE 30-16. A force velocity curve of cardiac muscle shows the point of maximal shortening with no load or V_{max} (point A). Point B is P_0 where no shortening occurs, although tension development is maximal. Curve C is a force–velocity curve with increased preload. Curve D demonstrates increased myocardial contractility. On any curve, load (afterload) increases from left to right. (Reprinted with permission from Lake CL: Cardiovascular Anesthesia, p 10. New York, Springer-Verlag, 1985.)

Preload Recruitable Stroke Work

Stroke work is linearly related to left ventricular EDV. A plot of EDV against stroke work demonstrates that stroke work increases with increased preload and decreases with unloading. Thus, the preload recruitable stroke work is determined by plotting stroke work from successive pressure–volume loops during alterations in preload.

Cardiac Work

Because of the difficulties in obtaining the data for pressure–volume loops or force–velocity curves under clinical conditions, cardiac work is often measured as a substitute. Cardiac work describes pump function in terms of the load carried and the distance moved. Calculation of cardiac work standardized to body surface area (left and right ventricular stroke work indexes) is shown in Table 30-4. Using cardiac work instead of cardiac output or stroke volume to describe pump function has several advantages: (1) calculation includes heart rate, preload, and afterload—the major variables affecting cardiac function; (2) stroke work index defines the area of the pressure–volume loop; and (3) stroke work index measures both systolic and diastolic performance.[90]

Ventricular End-Systolic Elastance

Direct measurements of end-systolic elastance are complicated and impractical clinically. However, Hayashi and coworkers developed a method to estimate this parameter using only ventricular and aortic pressures. The derived equation $k = (E_{es}/E_a)^{0.51}$, where k is the slope of the two straight lines (one for the isovolumic phase and the second for the ejection phase). E_{es} is ventricular elastance, and E_a is arterial elastance. However, the complexity of the measurements, the substitition of end-ejection pressure for end-systolic pressure, and the determination of the method in animals may not permit application in patients.

Right Ventricular Function

The functional significance of the RV in normal circulatory homeostasis is minimal. Although the right ventricular spiral muscles contract during systole, direct left ventricular assistance to right ventricular contraction has been demonstrated.[91] Compared with the LV, intraventricular pressure develops more gradually in the RV and declines more slowly during diastole. Right ventricular pumping capability depends on (1) pressure against which it ejects, (2) filling volume, and (3) right ventricular contractility.[92] The RV obeys Starling's law except that its curve is upward and to the left of the left ventricular curve. At higher end-diastolic pressures, the RV response is flatter than that of the LV. Increases in filling volume increase right ventricular stroke volume up to the limit imposed by the restraint of the pericardium (normally, ~20% acute increase in cardiac volume).[93] The contractility of the RV depends on sympathetic tone, myocardial structural integrity, and chemical content of the coronary perfusate.[92] Normal right ventricular systolic pressures are only 30 to 40 mm Hg because the recruitable vasculature of the pulmonary circulation allows between 5 and 20 L of blood to flow within it. Peak ejection occurs later than in the LV, and the ejection fraction is only 0.4. This difference in function results because the right ventricular free wall is flattened by the pull of the interventricular septum toward the LV during systole, giving a bellows-like action for expulsion of blood.[93] Because of this mechanism, right ventricular function is less likely to be impaired during right coronary arterial occlusion.[93]

During systole, right ventricular stroke volume is more sensitive to afterload than left ventricular stroke volume. Factors that oppose blood flow from the RV (afterload) include the resistance of the pulmonary vascular bed, pulmonary arterial impedance, the mass of the pulmonary blood, blood viscosity, and pulse wave reflection altering PA pressure. In diastole, the RV is twice as distensible (more compliant) as the LV.[92]

Under conditions of pressure overload, such as increased pulmonary vascular resistance or left ventricular failure, the RV hypertrophies to generate systemic pressures. Although acute right ventricular failure is compatible with life, the symptoms caused by increased venous pressure suggest that right ventricular function is important for maintenance of normal venous pressures.[93]

Ventricular Interdependence

Because the ventricles are anatomically associated, alterations of volume and pressure in one ventricle affect these parameters in the other.[94] During normal respiration with negative intrathoracic pressure, increased venous return increases right ventricular EDV during inspiration, pulmonary vascular capacitance increases, left ventricular diastolic volume decreases, and left ventricular stroke volume increases, but left ventricular transmural pressure is unchanged. Important factors in ventricular interdependence are septal position and deformability, pulmonary venous capacitance, right ventricular distensibility, the transseptal pressure gradient, and the presence of the pericardium.

In vitro experimental animal models confirm that when left ventricular pressure increases, diastolic compliance and systolic ventricular function decrease in the RV and vice versa. The mechanisms are the Frank-Starling effect caused by decreased ventricular diastolic volume and decreased systolic ventricular function.[95] The etiology of the depressed systolic function is unclear.[95] Computer models confirm that hypertrophy from right ventricular pressure overload,

which increases septal thickness and decreases septal compliance, decreases transfer of pressure and volume between the ventricles, limiting ventricular interdependence.

Myocardial Metabolism

Knowledge of myocardial metabolism is essential to the preservation of the heart during conditions of stress, cardiac arrest, or elective asystole during cardiac surgery. Metabolism includes both substrate utilization and oxygen consumption.

Sources of Energy

The energy supply of the heart is derived primarily from lactate and fatty acids delivered by the coronary blood. Free or nonesterified fatty acids (palmitic and oleic acids) are the preferred fuel. Myocardial uptake of fatty acids is almost linear, with the plasma concentration above the threshold of 345 μmol/L.[96] Fatty acid uptake by the heart from either fatty acid–albumin complexes or lipoprotein triglyceride occurs by passive diffusion or carrier-mediated transport. During fasting, free fatty acids are always used as fuel. The heart has a limited ability to synthesize fatty acids from acetyl coenzyme A, except for the formation of structural lipids. The oxidation of fatty acids and ketone bodies inhibits uptake of glucose, pyruvate oxidation, and glycolysis while facilitating glycogen synthesis.[96] Oxidation of nonesterified fatty acids accounts for 90% of myocardial oxygen consumption.

Fuel selection by the heart probably depends on regulatory enzymes controlled by factors other than substrate availability and product removal. Myocardial lactate utilization is regulated by the arterial lactate concentrations and pyruvate oxidation in the Krebs tricarboxylic acid cycle. Glucose, pyruvate, acetate, and triglycerides can also be used by the heart as energy sources. Utilization of glucose by the myocardium depends on the arterial glucose and insulin concentrations. Glucose is normally used postprandially. However, glucose use by the myocardium as the primary energy source occurs only with high glucose levels, insulin secretion, or hypoxia. Glucose is the only substrate used by the heart anaerobically. As long as the entry of acetyl coenzyme A into the Krebs cycle is not inhibited, the heart will use as much pyruvate as it is given. Substrates such as fructose, glycogen, or proteins are used for energy only during special circumstances, such as starvation, diabetic ketoacidosis, or anoxia.

Myocardial Oxygen Consumption

The heart has one of the highest metabolic rates of any organ. At rest it uses 8 to 10 mL of oxygen per 100 g of myocardium per minute. The subendocardium requires about 20% more oxygen than the epicardium. Myocardial oxygen consumption ($M\dot{V}O_2$) is determined by heart rate, wall tension, and myocardial contractility. The relative importance of each factor is difficult to evaluate because they are interrelated through wall tension.[97] Less important factors include the oxygen costs of shortening of muscle fibers, electrical activation, and catecholamines, as well as the basal oxygen requirements and the level of arterial oxygenation. Tension development constitutes about 50% of $M\dot{V}O_2$ (Table 30-8).

TABLE 30-8 Factors Involved in Myocardial Oxygen Supply and Demand

·MYOCARDIAL OXYGEN CONSUMPTION (DEMAND)
Heart rate Contractile state

Myocardial wall tension Arterial oxygen content Basal oxygen requirements Oxygen cost of muscle fiber shortening Oxygen cost of electrical activation
▪MYOCARDIAL OXYGEN SUPPLY
Aortic diastolic pressure Left ventricular end-diastolic pressure Coronary artery diameter Arterial oxygen content

Myocardial wall tension is related to the tension–time index, left ventricular end-diastolic pressure, and ventricular size. Wall tension can be divided into its components: the rate of force development, the magnitude of force development, the interval during which force is generated and maintained for each contraction, and the frequency with which force is developed per unit time.[97] Wall tension is measured according to Laplace's law:

$T = Pr/2h$

where radius (r) is cardiac radius, T is cardiac tension, P is interventricular pressure, and h is ventricular muscle thickness. Increases in ventricular chamber pressure or volume increase both the magnitude of force development and the force maintained during ejection.

Myocardial Supply–Demand Ratio

A balance must always exist between oxygen consumption (demand) and myocardial oxygen supply if ischemia is to be avoided. Factors important to this relationship are shown in Table 30-8. Myocardial oxygen supply depends on the diameter of the coronary arteries, left ventricular end-diastolic pressure, aortic diastolic pressure, and arterial oxygen content. In the normal heart, the coronary perfusion pressure is the difference between the aortic diastolic pressure and the left ventricular

end-diastolic pressure. Myocardial blood flow is determined by the blood pressure at the coronary ostia, arteriolar tone, intramyocardial pressure or extravascular resistance, coronary occlusive disease, heart rate, coronary collateral development, and blood viscosity.

Myocardial blood flow is reduced by a low aortic diastolic pressure and increased pulmonary wedge pressure (both of which increase subendocardial tissue pressure), and tachycardia, which shortens diastole, reducing the duration of blood flow. Increasing preload or intracavitary pressure increases wall tension and oxygen demand, while decreasing subendocardial perfusion.

Myocardial oxygen supply is also affected by the level of arterial oxygenation. Oxygen content resulting from PaO_2; hemoglobin; 2,3-diphosphoglycerate; and pH, PCO_2, or temperature effects on the oxyhemoglobin dissociation curve can be an important factor in patients with obstructive lung disease or severe anemia. Normal oxygen extraction by the heart is 60 to 70% and changes little with increased cardiac work because coronary vascular resistance decreases. However, if the coronary vascular resistance response is limited, oxygen extraction can be increased to more than 90%.[97] An increase in oxygen extraction and coronary vasodilation constitutes the metabolic reserve of the heart in the case of increased demand.

Heart rate and diastolic ventricular volume are the two factors most likely to produce ischemia if either or both are increased. Increased myocardial contractility or afterload, by increasing arterial

pressure and myocardial oxygen supply, offsets their tendency to increase myocardial oxygen consumption.

Distribution of Cardiac Output

8 The cardiac output is distributed to the systemic circulation as follows: brain 12%, heart 4%, liver 24%, kidneys 20%, muscle 23%, skin 6%, and intestines 8%. About 15% of the blood volume remains in the heart and pulmonary circulation, with the remainder in the systemic circulation. Of the blood in the systemic circulation, about 64% is in the veins. The total tissue blood flow in a given vascular bed is a function of the effective perfusion pressure and vascular resistance. Effective perfusion pressure is the difference between arterial and venous pressure across the vascular bed. Autoregulation maintains a constant blood flow in the face of changes in perfusion pressure in the cerebral, renal, coronary, hepatic arterial, intestinal, and muscle circulations. Reflexes that alter circulatory distribution are in Table 30-9.[98,99,100,101,102,103,104,105,106] The carotid sinus, a dilated portion of the common carotid artery just before its bifurcation, contains two types of receptors that sense pressure in the carotid sinus, providing the most important aspect of reflex circulatory control. The cardiovascular reflexes may interact to regulate blood pressure. An example is when there is decreased activity and firing of fibers in the afferent limb of the von Bezold-Jarisch reflex, causing release of vasomotor inhibition, increased medulary outflow, and increased blood pressure, but the baroreceptor reflex attenuates the increased blood pressure response so no effective change in blood pressure occurs.[104]

TABLE 30-9 Cardiovascular Reflexes[98,99,100,101,102,103,104,105,106]

▪ CAROTID SINUS (PRESSORECEPTOR, BARORECEPTOR)	
Anatomy:	Carotid-afferent nerve of Hering (glossopharyngeal)
	Aortic-vagus
	Cardiovascular centers in medulla
Stimulus:	Increased blood pressure
Response:	Inhibition of sympathetic and increase in parasympathetic activity, causing decreased cardiac contractility, heart rate, and vasoconstrictor tone
Other:	Gain determined by pulse pressure
	Reduces arterial pressure fluctuation to one-third of expected threshold 60 torr, limits 175–300 torr
▪VALSALVA MANEUVER	
Anatomy:	Same as pressoreceptor reflex

Stimulus:	Forced expiration against closed glottis
Response:	Increased venous pressure in head, upper extremities, with decreased right heart venous return causing decreased blood pressure and cardiac output, and reflex increase in heart rate; the tachycardia coupled with coupling of the E and A waves on the mitral transvelocity curve indicates normal left ventricular filling pressures[132]
Other:	Glottic opening increases venous return to right heart, resulting in forceful right and then left ventricular contraction, followed by transient bradycardia
▪MÜLLER MANEUVER	
Anatomy:	Decreased pleural pressure increasing left ventricular volume through afterload reduction
Stimulus:	Inspiratory effort against a closed airway
Response:	Right ventricular end-diastolic volume and left ventricular end-diastolic pressure increase, while left ventricular end-diastolic volume is unchanged or decreased, and ejection fraction is unchanged
Other:	Net effect on left ventricular function depends on ventricular interdependence, heart rate, and contractility (position of the heart on diastolic pressure–volume curve)
	Müller maneuver may cause ventricular akinesis due to increased wall stress, increasing myocardial oxygen demand, or increased left ventricular transmural pressure, decreasing motion in nonfunctional ventricular myocardium
▪ von BEZOLD–JARISCH[103,104]	
Anatomy:	Ventricular chemoreceptors and mechanoreceptors with afferent pathway in unmyelinated vagal C fibers
Stimulus:	Noxious stimuli to either ventricle associated with myocardial ischemia, profound hypovolemia, coronary reperfusion, aortic stenosis, neuraxial anesthesia associated with sympathetic blockade and "empty" ventricle, or even vasovagal syncope
Response:	Hypotension, bradycardia, parasympathetically induced coronary vasodilation, and inhibition of sympathetic outflow from vasomotor centers

Other:	Reperfusion of previously ischemic tissue elicits reflex
▪CARDIOGENIC HYPERTENSIVE CHEMOREFLEX[105]	
Anatomy:	Chemoreceptors located between the aorta and pulmonary artery and supplied by the left coronary artery
	Afferent reflex pathway is intrathoracic vagal branches and the efferent path is via phrenic, vagal, and sympathetic routes
Stimulus:	Serotonin
Response:	Arterial pressure increases markedly in 4–6 sec owing to increased inotropy and peripheral vasoconstriction
Other:	Reflex may be responsible for hypertension during angina, myocardial infarction, and after coronary bypass grafting and is abolished by vagotomy, atropine, or local anesthesia of the intertruncal space
▪CUSHING'S REFLEX	
Anatomy:	Increased cerebrospinal fluid (CSF) pressure compresses cerebral arteries
Stimulus:	Cerebral ischemia secondary to increased CSF pressure
Response:	An increase in arterial pressure sufficient to reperfuse the brain
	Intense sympathetic activity causes severe peripheral vasoconstricion as a result of this reflex
▪BAINBRIDGE ATRIAL REFLEX[106]	
Anatomy:	Primarily mediated through vagal myelinated afferent fibers; activation of sympathetic afferent fibers may also occur[39]
	Increased right atrial pressure directly stretches the SA node and enhances its automaticity, increasing the heart rate
Stimulus:	Increased vagal tone and distention of the right atrium or central veins
Response:	Depends upon the preexisting heart rate

	With preexisting tachycardia, there is no effect
	Volume loading at a slow heart rate causes progressive tachycardia
	Global atrial distention in response to high pressures causes bradycardia, hypotension, and decreased systemic vascular resistance
Other:	Experimental distention of the cavoatrial junctions or other small portions of the atria increases heart rate, but clinical conditions such as heart failure usually do not produce such locally increased atrial pressure[106]
▪CHEMORECEPTOR	
Anatomy:	Carotid and aortic bodies chemoreceptors whose nerve fibers pass through the nerve of Hering and the vagus nerve to the medullary vasomotor centers
Stimulus:	Decreasing oxygen tension or increased hydrogen ion concentrations
Response:	Increased pulmonary ventilation and blood pressure with decreased heart rate (carotid body chemoreceptors)
	Stimulation of the aortic bodies causes tachycardia
Other:	Normally, the peripheral chemoreceptors are minimally active
▪OCULOCARDIAC	
Anatomy:	Afferent fibers run with the short or long ciliary nerves to the ciliary ganglion, and then with the ophthalmic division of the trigeminal nerve to the gasserian ganglion
Stimulus:	Traction on the extraocular muscles (more especially the medial rather than the lateral rectus) or pressure on the globe
Response:	Bradycardia and hypotension as a consequence of this reflex
Other:	Demonstrated in 30–90% of patients undergoing ophthalmic surgery and attenuated by IV atropine
▪CELIAC (VAGOVAGAL)	

Anatomy:	Vagal stimulation via mesenteric traction, rectal distention, traction on gallbladder, respiratory tract receptors
Response:	Bradycardia, apnea, hypotension with narrowed pulse pressure
Other:	Traction on the mesentery or gallbladder, stimulation of vagal nerve fibers in the respiratory tract, or rectal distention stimulates afferent vagal nerve endings to cause bradycardia, apnea, and hypotension (vagovagal reflex)
	Manipulation around the celiac plexus decreases systolic pressure, narrows pulse pressure, and slightly decreases heart rate
SA, sinoatrial.	

Peripheral Circulatory Physiology

The peripheral circulation consists of resistance and capacitance vessels. The majority of the resistance is in the arterial circulation, which consists of the Windkessel vessels, the precapillary resistance vessels, and the capillary exchange vessels. The Windkessel vessels are distensible elastic arteries such as the aorta and large muscular arteries that damp the pulsatile output of the ventricle. The arterioles, the precapillary resistance vessels, are muscular vessels that provide more than 60% of the peripheral resistance. At the most distal portion of the terminal, arterioles are precapillary sphincters that regulate the flow of blood into specific capillary beds. The capillary exchange vessels contribute about one-fourth of the total peripheral resistance, although most capillaries consist of a single endothelial cell layer without any surrounding smooth muscle. The systemic veins are the capacitance system.

Arterial Pulses and Blood Pressure

Arterial Pulse

The arterial pulse is a wave of vascular distention resulting from the impact of the stroke volume of each beat being ejected into a closed system. The wave of distention begins at the base of the aorta and passes over the entire arterial system with each heartbeat. The pulse is not caused by the passage of the blood itself. The pulse waveform is the result of the combined effects of the forward-propagating pressure wave and its reflectance back toward the heart from various parts of the vasculature. Wave reflection may occur in high-resistance arterioles, branching points, or sites of changes in arterial distensibility, but the major source is the arteriole. The velocity of the pulse wave depends on the elasticity of the vessel. The pulse wave velocity is most rapid in the least distensible arteries. In the aortic arch, the pulse wave travels 3 to 5 m/sec, and the aortic pulse waveform precedes the brachial waveform by about 0.05 seconds. In large distensible arteries such as the subclavian, the pulse wave travels 7 to 10 m/sec, whereas in the small nondistensible peripheral arteries it travels about 15 to 30 m/sec. Such differences become important when timing the counterpulsation of an intraaortic balloon.

The arterial pressure waveform changes as it moves peripherally (Fig. 30-17). In central aortic waveforms, the closure of the aortic valve is indicated by a notch or incisura on the descending limb. In contrast, peripheral pulse waveforms have greater amplitude, more pronounced diastolic wave, and lower mean pressure, and the foot of the wave is delayed.[107] The dicrotic notch,

corresponding to the incisura, is more prominent. Systolic pressure is higher, whereas mean and diastolic pressures are slightly lower in the periphery. Such changes are best explained by a tubular model of the vascular system. In such a system, the contour of the pressure wave depends on the velocity of the pressure wave, the duration of the pulse, and the length of the tube.[107]

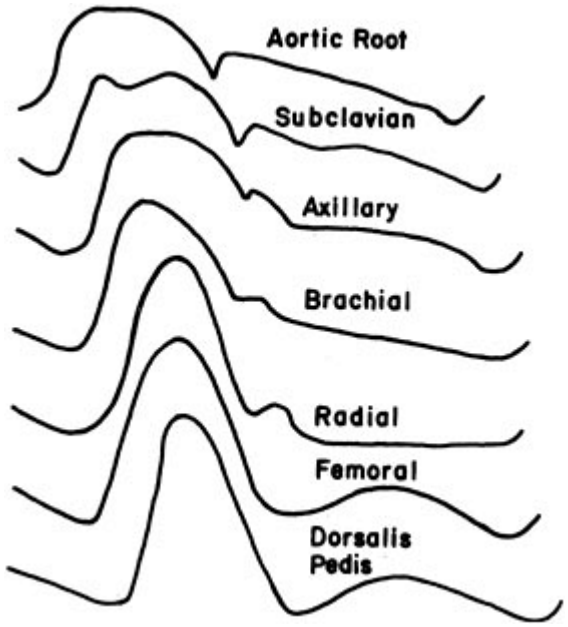

FIGURE 30-17. The change in the pulse waveform as it moves from the aortic root to the dorsalis pedis artery is dramatic. These changes result from both forward wave propagation and wave reflection at branch points in the circulation. The waveform has a greater amplitude, higher systolic pressure, lower diastolic pressure, and reduced mean pressure in the peripheral circulation. (Reprinted with permission from Shah N, Bedford RF: Invasive and noninvasive blood pressure monitoring. In Lake CL, Hines R, Blitt CD (eds): Clinical Monitoring: Practical Applications for Anesthesia and Critical Care, p 182. Philadelphia, WB Saunders, 2001.)

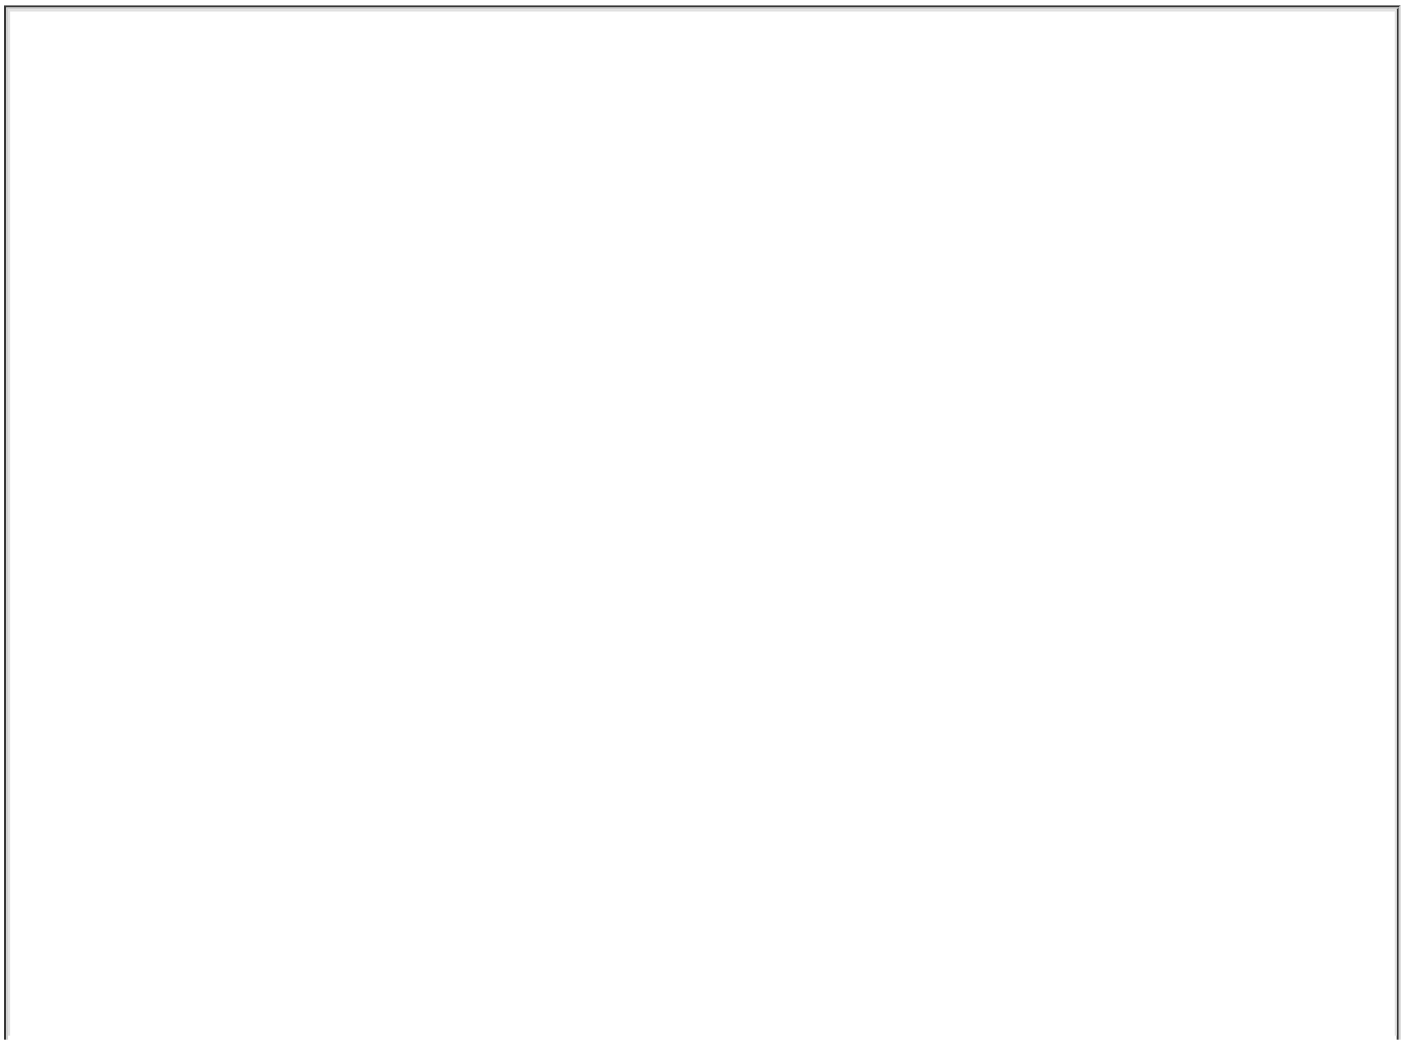
Pulse contour also changes with hemodynamic conditions. In children, wave reflection facilitates cardiac performance by a relative decrease in arterial pressure during systole and a relative increase during diastole. As aging occurs, wave reflection occurs earlier in the cardiac cycle, increasing systolic pressure and decreasing diastolic pressure. In shock, the pulse wave velocity is reduced by hypotension, increased heart rate reduces the duration of cardiac systole, and peripheral vasoconstriction increases the peripheral reflection coefficient. Pulse waveforms vary in atrial fibrillation; beats with short systolic durations demonstrating diastolic waves and those with long durations having accentuated systolic peaks. Patients with hypertrophic cardiomyopathy have double systolic pulse waveforms because the initial systolic wave of ventricular ejection occurs during the first half of systole and the reflected wave returns during the same systole.[107]

Blood Pressure

9 Arterial pressure is the lateral pressure exerted by the contained blood on the walls of the vessels. Mean arterial pressure is the



product of the cardiac output and the systemic vascular resistance. If a normal arterial waveform is present, mean pressure is about one-third the difference between the systolic and diastolic pressures. However, mean pressure remains constant, whereas pulse pressure and systolic pressure increase as blood moves peripherally in the circulation.

Arterial pressure varies with the respiratory cycle. It normally decreases 6 mm Hg or less during inspiration because pulmonary venous capacitance increases during inspiration to a greater extent than the increase in right-sided heart venous return and output, thus causing a decrease in left ventricular stroke output and pressure. These changes are exaggerated in pericardial tamponade, causing pulsus paradoxus. Clinically, auscultation of the blood pressure is performed until the first heart sound is heard intermittently. Further deflation of the cuff to the pressure where all beats are heard yields the difference known as the paradoxical pulse.

Factors Controlling Peripheral Vascular Tone

10 Factors controlling blood pressure include central and autonomic nervous function, cardiac output, peripheral vascular resistance, and hormonal mechanisms, including antidiuretic hormone, catecholamines, the renin-angiotensin system, and atrial natriuretic peptide.[108] Three medullary centers—the nucleus tractus solitarius, the caudal ventrolateral medulla, and the rostal ventrolateral medulla—are important in blood pressure control. Arteriolar tone is regulated by intrinsic and extrinsic mechanisms. The intrinsic mechanism is the inherent myotonic activity of vascular smooth muscle cells and vascular endothelial cells. Extrinsic factors include neural (sympathetic) and humoral factors. Sympathetic neural activity provides rapid alteration of tone in response to a need for greater blood flow. During normal conditions, sympathetic tone maintains blood vessels in a partially constricted state, vasomotor tone. Figure 30-18 details the intracellular mechanisms for peripheral vasodilation and vasoconstriction. Nitric oxide (NO) and prostacyclin production and endothelin release from endothelial cells produce vasodilation and vasoconstriction, respectively, in large arteries. The natriuretic peptides and NO are two major pathways for synthesis of cyclic guanosine monophosphate (cGMP). The effectors of cGMP are the cGMP-regulated phosphodiesterases and cGMP-dependent protein kinase (cGK or PKG) in vascular smooth muscle cells and platelets. Relaxation of vascular smooth muscle occurs through the Rho pathway of vascular smooth muscle by phosphorylation of Rho A to inhibit Rho kinase and, in turn,

activate myosin light-chain phosphate to dephorylate myosin light chain.[109]

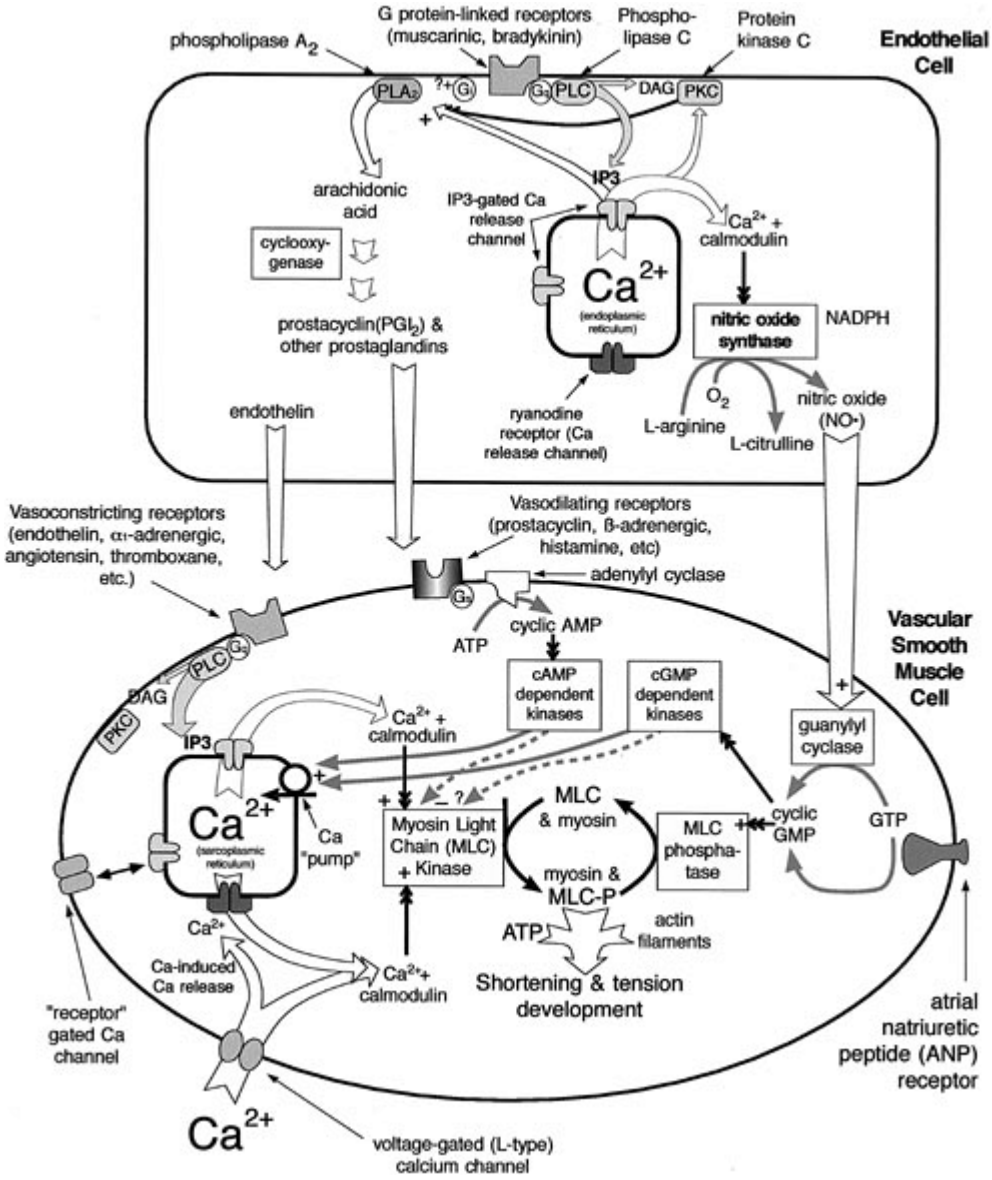


FIGURE 30-18. Vascular smooth muscle and endothelial function. Both endothelial cells and vascular smooth muscle cells have intracellular stores of calcium that can be released by the production of inositol triphosphate (IP_3). In both types of cells, agonist binding to specific receptors results in activation of phospholipase C (PLC) via guanine protein Gq (*a*). In the vascular smooth muscle cell, PLC activation results in IP_3 formation and release of intracellular calcium. Calcium binds to calmodulin, activating myosin light chain kinase (MLC), which then phosphorylates, causing myosin to interact with actin, producing shortening or tension generation. In contrast, in the endothelial cell, calcium binds to calmodulin to activate nitric oxide synthase, producing nitric oxide (NO). NO can diffuse to the vascular smooth muscle and modulate its behavior via activation of guanylate cyclase. Phospholipase A can be activated by G protein–linked pathways or by phosphokinase C and calcium, resulting in production of arachidonic acid. Arachidonic acid generates prostacyclin via the cyclooxygenase system, allowing relaxation of vascular smooth muscle. ATP, adenosine triphosphate; AMP, adenosine monophosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; GMP, guanosine monophosphate; GTP, guanosine triphosphate. Philadelphia, Churchill Livingstone, 2000.)

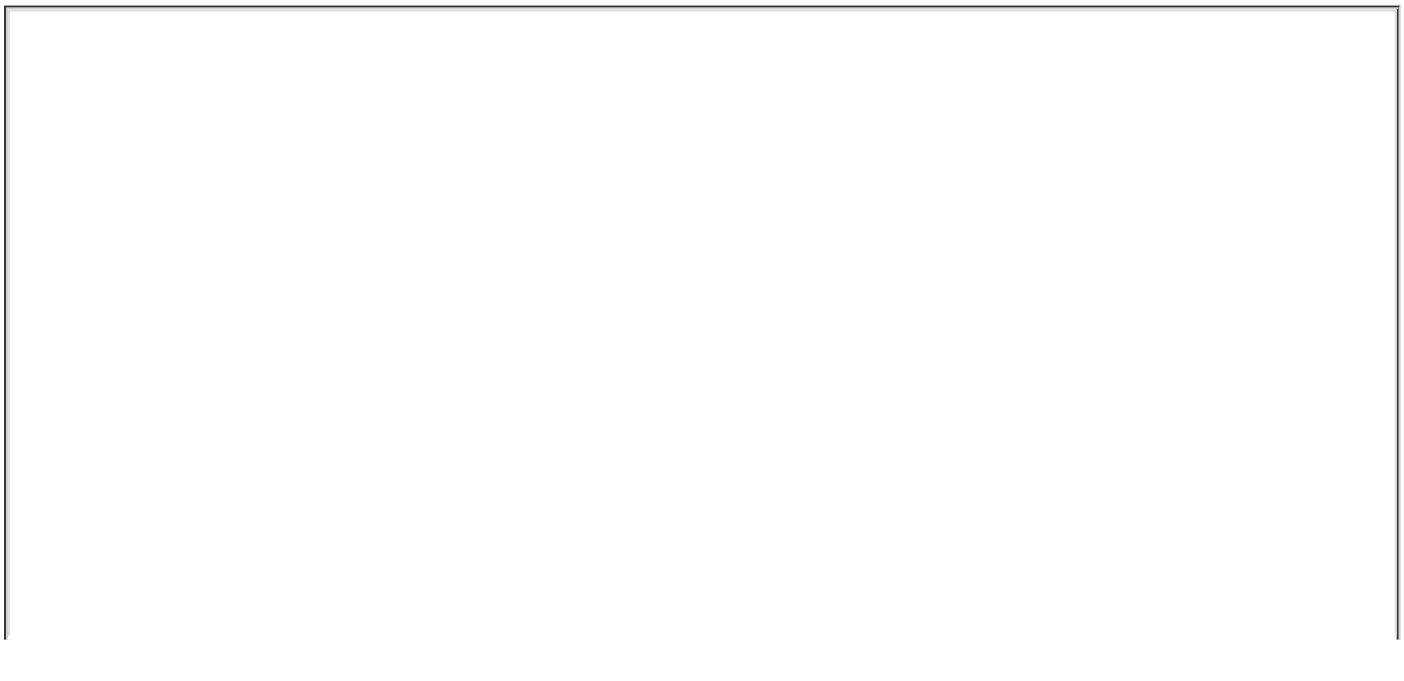

Endothelin

There are four active endothelin isoforms (1–4) of which endothelin-1 (ET-1) exerts a major effect on blood pressure through its actions on vascular smooth muscle.[110] It is formed by cleavage of preproendothelin-1 to big ET-1 and by ET-converting enzymes to ET-1. ET-1 acts by binding to two specific receptor subtypes: endothelin-A and endothelin-B in vascular smooth muscle and in atrial and ventricular smooth muscle layers. Endothelin-A is the major subtype producing vasoconstriction. Although endothelin-B also produces vasoconstriction through actions on vascular smooth muscle cells, it produces vasodilation via the release of NO and prostacyclin in endothelial cells. In addition to vasoconstriction, ET-1 stimulates production of vascular endothelial growth factor and potentiates the effects of platelet-derived growth factor and transforming growth factor-β. ET-1 is particularly abundant in pulmonary vasculature, where its production is stimulated by hypoxia.[111]

Nitric Oxide (No)

NO, the endothelium-derived relaxing factor (EDRF), is a short-lived substance that activates soluble guanylate cyclase to increase intracellular cyclic guanosine 3′,5′-monophosphate, causing relaxation of vascular smooth muscle. It is formed from L-arginine by the enzyme nitric oxide synthase (NOS) in various mammalian tissues, particularly vascular endothelium. All three NOS isoforms—endothelial (e or NOSIII), inducible (i or NOSII), neuronal (n)—are expressed in cardiac myocytes. The calcium-sensitive enzymes nNOS and eNOS, as well as NO are activated when intracellular calcium increases as a result of extracellular calcium entry or intracellular calcium release. Basal release of NO occurs in all except cerebral and coronary vessels. Atherosclerosis impairs endothelium-dependent relaxation. Decreased production of NO may also contribute to both systemic and pulmonary hypertension. Hypoxia impairs endothelium-dependent vasodilation owing to inhibition of NO production and decreased half-life.[112] It also inhibits platelet adhesion and aggregation.

NO also has significant cardiac effects through both vascular-dependent and vascular-independent pathways.[113] The vascular-dependent effects include regulation of coronary tone, thrombogenicity, and angiogenesis, whereas the independent effects are fine regulation of excitation-contraction coupling, mitochondrial respiration, and modulation of autonomic signaling. The multiple effects of NO in myocardial cells are shown in Figure 30-19. In addition to the vascular effects, NO has a positive inotropic effect at low concentrations and a negative inotropic effect at higher concentrations.[113] Although the chronotropic effects are dependent on the experimental model, it appears that NO promotes negative chronotropic effects through nNOS-mediated effects in the cardiac ganglia and eNOS effects in the myocytes.[113] Activation of eNOS causes increased resistance to ventricular arrhythmias in dogs, and mice deficient in eNOS have lower thresholds to arrhythmogenic drugs.[114,115]

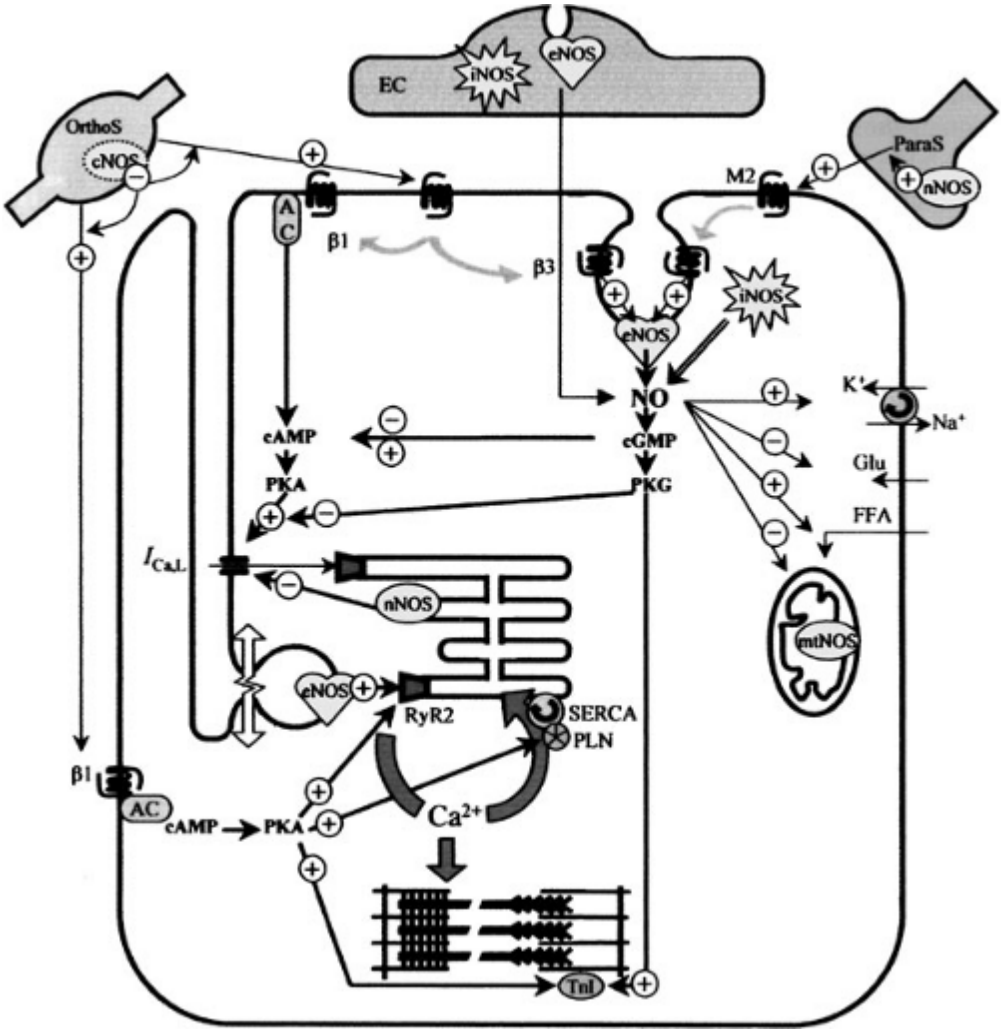

FIGURE 30-19. Effects of endogenous nitric oxide (NO) on myocardial cells. The intracellular effectors of endogenous NO are expressed in sympathetic (orthoS), parasympathetic (paraS), or the myocardial cells themselves. On the left side is the classic stimulatory effect on excitation-contraction coupling acting through β-adrenergic signaling. β-Adrenoceptor activation activates adenylcyclase and subseqently protein kinase A (PKA)-dependent phosphorylation of voltage-operated calcium channels (L-type calcium current I_{CaL}), ryanodine receptors (RyR2), and phospholamban (PLN) to de-repress the sarcoplasmic and endoplasmic reticulum Ca^{++}-ATPase (SERCA) to produce positive inotropic effects and phosphorylation of troponin I (TnI) to produce positive lusitropic effects. The right side of the figure shows modulating effects of NO on the β-adrenergic pathway, including phosphodiesterase regulation of cAMP levels through phosphodiesterase II (PDEII)-induced decreases and phosphokinase G (PKG)-mediated downregulation of L-type calcium current (all cyclic guanosine monophosphate [cGMP]-mediated effects). (Reprinted with permission from Massion PB, Feron O, Dessy C *et al*: Nitric oxide and cardiac function. Circ Res 93:388, 2003.)

Natriuretic Peptides

Atrial natriuretic peptide (ANP) is a peptide stored in the perinuclear granules of human atrial myocytes and to a lesser extent

in the ventricle.[116] Brain or B-type natriuretic peptide (BNP) is also produced primarily in atrium, whereas natriuretic peptide C is localized in the central nervous system. Natriuretic peptide receptors A, B, and C are receptor guanylyl cyclases, consisting of intracellular and extracellular

domains. ANP is released in response to increased vascular volume (atrial distention), epinephrine, vasopressin, morphine, and increased atrial pressure. Normal circulating plasma levels are 25 to 100 μg/mL.[117]

The primary effects of ANP are direct peripheral vasodilation, suppression of antidiuretic hormone (ADH) release when the ADH is elevated by hemorrhage or dehydration, inhibition of aldosterone release, and direct renal effects such as increased glomerular filtration, natriuresis, and diuresis. Factors such as renal perfusion pressure and renal sympathetic nerve activity in conjunction with physiologic plasma concentrations of ANF produce natriuresis.[118] Kaliuresis does not occur. Atrial natriuretic factor affects not only blood pressure (by decreasing cardiac output and vascular resistance), but also water and electrolyte balance and blood volume. It has no direct inotropic or chronotropic properties.

Renin–Angiotensin System

Renin is a proteolytic enzyme produced in the granular juxtaglomerular cells of the kidney. Its release is governed by the macula densa, an intrarenal stretch-type receptor, circulating potassium, angiotensin II, epinephine, and concentrations of ADH, and by the renal sympathetic nerves. Renin secretion is also inversely related to renal perfusion.[119] The half-life of renin is 4 to 15 minutes, during which it initiates the formation of angiotensin I from angiotensinogen, which is synthesized in the liver. Angiotensin I is biologically inactive until it is cleaved by angiotensin-converting enzyme in lung and other tissues to angiotensin II. Angiotensin II and angiotensin III, formed by hydrolysis of angiotensin II, stimulate the secretion of aldosterone and inhibit renin release through a negative-feedback loop. The half-life of angiotensin II is about 30 seconds.

Sympathetic Nervous System

Norepinephrine is the important agonist at the α_1 receptor, mediating smooth muscle vasoconstriction in arteries and veins independently of neural supply. Epinephrine is more potent as a β_2 receptor agonist than is norepinephrine. β_2 Receptors, located in both presynaptic and postsynaptic regions, dilate arteries by stimulation of adenylcyclase.

Specific Peripheral Circulations

Pulmonary Circulation

The pulmonary circulation is a low-pressure, high-flow system that has five principal functions: (1) metabolic transport of humoral substances and drugs;[120] (2) transport of blood through the lungs; (3) reservoir for the LV; (4) filtration of venous drainage; and (5) transport of gas, fluid, and solutes across the walls of exchanging vessels. Normally, all circulating blood passes through the pulmonary circulation at least once each minute, but only 500 mL is present at a given time. Pulmonary pressures and resistances are only 80 to 90% of those in the

systemic circulation. However, the pulmonary vessels are very reactive to hypoxia, sympathetic activation, and endogenous constrictors.

Metabolic Transport

The pulmonary vascular endothelium is important for removal, biosynthesis, and release of various vasoactive hormones, including biogenic amines, prostaglandins, leukotrienes, and peptides. Norepinephrine is removed by the lung by a carrier-mediated, temperature-sensitive and drug-sensitive transport process. Epinephrine, histamine, vasopressin, and dopamine, however, are unaltered by transpulmonary passage.[120] Almost complete removal of 5-hydroxytryptamine, ATP, and monophosphate occurs in the lungs. Acetylcholine and bradykinin are inactivated by the lungs. Prostaglandins of the E and F series are also removed either by a carrier-mediated, energy-requiring process or by rapid degradation by 15-hydroxyprostaglandin dehydrogenase. Prostacyclin is not inactivated in the lung. Many drugs such as propranolol, lidocaine, bupivacaine, captopril,

and fentanyl are removed extensively during transpulmonary passage.

Intravascular Transport

The passage of blood and its distribution to various segments of the lung depend on pulmonary blood flow, pulmonary vascular resistance or impedance, left atrial pressure, transmural distending pressure, and distensibility of the pulmonary vessel walls. Blood flow to the lung apex is less than that to the base because of regional differences in pulmonary venous, alveolar, and arterial pressures. However, the pulmonary circulation accommodates a large increase in flow with little change in pressure by a substantial decrease in resistance. Pulmonary resistance is about one-fifth systemic and pulmonary impedance is about one-half systemic; pulse wave reflections are stronger in the pulmonary beds—although the reflecting sites are similar, the vascular bed is smaller. Abundant vascular smooth muscle is present in pulmonary vessels, distributed evenly between arteries and veins. Muscular arterioles are absent in the lung.

Capillary endothelium, endothelial basement membrane, interstitial space, epithelial basement membrane, and alveolar epithelium form the alveolocapillary membrane, which separates the blood and gas phases in the lung. The pulmonary veins perform primarily a reservoir function, preventing pulmonary edema in the event of reduced left ventricular compliance.[121]

Measurements of Pulmonary Tone

Measurements of pulmonary tone are essential to therapeutic investigations. However, the available measurement methods are either difficult or have significant limitations. Normal values for pulmonary vascular resistance are given in Table 30-4.

PA pressures are clinically measured using flow-directed catheters. Wedging of the tip of these catheters in a small branch of the PA measures the pulmonary wedge pressure or occluded pressure (PAoP) (Table 30-2). As the pressure of the column of blood from the tip of the catheter (beyond the point of balloon occlusion) equilibrates with left atrial pressure, PAoP is achieved. Normally, left atrial pressure is similar to left ventricular end-diastolic pressure in the absence of mitral valvular stenosis. Other reasons for a PAoP that is greater than left ventricular end-diastolic pressure include increased airway pressures or the presence of an intra-atrial mass. Normally, the PAoP is 1 to 4 mm Hg lower than pulmonary end-diastolic pressure. However, with tachycardia or increased pulmonary resistance, the pulmonary wedge pressure may be the same or slightly higher than pulmonary end-diastolic pressure.

PA pressure is not linearly related to either flow or left atrial pressure. An increase in pulmonary flow or left atrial pressure is unaccompanied by a proportional increase in pulmonary arterial pressure. Therefore, calculated pulmonary vascular resistance decreases when either pulmonary flow or left atrial pressure increases. The nonlinearity results from distention or recruitment of vessels when flow or pressure increases. However, in zone 3 of the lung (where left atrial pressure is greater than airway pressure), PA pressure is the most important factor determining pulmonary blood flow.[122] Therefore, regardless of the effect on the pulmonary vascular tone, agents or manipulations that change pulmonary flow or left atrial pressure will change calculated pulmonary vascular resistance. Only if a particular intervention does not change pulmonary flow or left atrial pressure, or if the changes in pulmonary resistance can be explained only by active changes in pulmonary tone (e.g., a decrease in PA pressure accompanied by an increase in pulmonary blood flow), is pulmonary vascular resistance unchanged. Even in these circumstances, however, reflex effects caused by the drug or maneuver cannot be eliminated.[123]

Another major factor affecting indirect measurements is airway pressure because the degree of lung inflation and the ventilatory pressure directly influence pulmonary pressure–flow relationships. Either increases or decreases in lung volume beyond normal functional residual capacity increase pulmonary resistance because of compression of small intra-alveolar vessels.

Effects of Drugs and Maneuvers on Pulmonary Tone

Baseline pulmonary tone, stimulation of pulmonary chemoreceptors, autonomic influences,

bronchospasm, and other physiologic or nonphysiologic conditions actively or passively affect the pulmonary vasculature or modify its response to drugs. These factors are summarized in Table 30-10.

TABLE 30-10 Alterations In Pulmonary Vascular Resistance

·FACTORS	·CHANGES
·ACTIVE CHANGES	
Sympathetic stimulation	Increased or unchanged
Parasympathetic stimulation	Unchanged
Catecholamines	Increased
Angiotensin	Increased
Acetylcholine	Decreased
Histamine	Increased/decreased
Bradykinin	Decreased
Serotonin	Increased
Prostaglandin E_1	Decreased
Prostaglandin F	Increased
Hypoxia	Increased
Hypercarbia	Increased or unchanged
Acidemia	Increased
·PASSIVE CHANGES	
Pulmonary hypertension	Decreased
Left atrial hypertension	Decreased

Increased pulmonary interstitial pressure	Increased
Increased blood viscosity	Increased
Increased pulmonary blood volume	Decreased

Data from Murray JP: The Normal Lung, p 128. Philadelphia, WB Saunders, 1976; Perloff WH: Physiology of the heart and circulation. In Swedlow DB, Raphaely RC (eds): Cardiovascular Problems in Pediatric Critical Care, p 1. New York, Churchill Livingstone, 1986; Stalcup A *et al*: Inhibition of angiotensin-converting enzyme activity in cultured endothelial cells by hypoxia. J Clin Invest 63:966, 1979; Hyman AL *et al*: Autonomic regulation of the pulmonary circulation. J Cardiovasc Pharmacol 7(suppl 3)S80, 1985.

Alveoli in a poorly ventilated area of lung that contains hypoxic gas cause the precapillary arterial vessels supplying that area to constrict to divert blood away from the area. This process is termed hypoxic pulmonary vasoconstriction. Pulmonary hypertension does not occur because the hypoxia is localized. If hypoxia is generalized, pulmonary hypertension ensues.[124] Metabolic acidosis slightly enhances hypoxic pulmonary vasoconstriction, whereas respiratory acidosis has no effect.[125] Metabolic and respiratory alkalosis decrease it.[125] Drugs such as nitroprusside, nitroglycerin, and inhalation anesthetics decrease hypoxic pulmonary vasoconstriction, resulting in worsening of venous admixture and arterial PO_2.[126] However, increased PA pressure from whatever mechanism inhibits hypoxic pulmonary vasoconstriction.

Renal Circulation

Renal blood flow is well in excess of the amount needed for renal perfusion. It is autoregulated so glomerular filtration remains relatively constant despite changes in arterial pressure between 70 and 180 mm Hg. The autoregulatory mechanisms operate sluggishly so oscillations in pressure of even several seconds' duration are not compensated by constant flow.[127] Mechanisms proposed to explain renal autoregulation include (1) tubuloglomerular feedback (vasoactive hormonal release from the juxtaglomerular apparatus in response to the quantity or quality of filtrate reaching the macula densa), and (2) myogenic response of renal vascular smooth muscle (changes in afferent/efferent arteriole tone). The myogenic response causes renal resistance vessels to constrict when perfusion pressure increases. The tubuloglomerular feedback mechanism provides fine-tuning via sensing of the distal tubule sodium chloride by the macula densa. Preglomerular or postglomerular resistance is then altered by vasoactive substances

such as adenosine, NO, ATP, or renin. In particular, the renal medulla may have impaired autoregulatory capacity because it receives only a small fraction of total renal blood flow and its oxygen tension is low. Glomerular capillary pressure, about two-thirds of systemic pressure, is increased by dilation of the afferent arteriole or constriction of the efferent arteriole. Other factors affecting glomerular filtration include the total surface area available for filtration and the permeability of the glomerular membrane.

The main purpose of the excessive renal flow is to provide energy for active renal tubular reabsorption of sodium. Renal oxygen consumption is high, and the arteriovenous oxygen content difference is low. Of the blood delivered to the glomeruli, about 20% is filtered to form an ultrafiltrate of plasma. The main driving force is the glomerular hydrostatic pressure, which is essentially the systemic arterial pressure modified by the renal vasculature. The ultrafiltrate collects in Bowman's space before passing into the renal tubular system.

Physiology of the Venous System

Systemic veins have a conduit and a reservoir function. Because the smallest postcapillary venules lack muscular layers, and venules and small veins have only small amounts of muscle, the postcapillary resistance is usually small. However, postcapillary resistance is important because the ratio of precapillary to postcapillary resistance determines the capillary filtration pressure. The major capacitance vessels include medium and large veins, as well as the venae cavae. About 60% of the systemic blood volume is in small veins and venules whose diameters range from 20 μm to 2 mm.[128]

The term *vascular capacitance* is used for the vascular pressure–volume relationship at a given level of venous tone. Venous tone is normally at 70% of maximum in the erect human. Venodilation to accommodate as much as 70 to 75% of the systemic blood volume buffers sudden increases in arterial blood pressure by allowing sequestration of blood in systemic veins. The compliance of the venous system is regulated by venomotor tone, which is controlled by cerebral autonomic impulses. Sympathetically mediated venoconstriction adds about 1 L of blood to the circulation, but passive constriction from a reduction in venous pressure contributes about two-thirds of the total volume mobilized. Individual organs contribute about 30 to 50% of their blood volume by sympathetically mediated venoconstriction.

Venous return (VR), the rate of flow of blood from the periphery to the heart, is a major determinant of cardiac preload. In a steady state, cardiac output is equal to VR. It is determined by the pressure gradient from the peripheral vascular beds (P_{MS} or mean systemic pressure) to the right side of the heart (P_{RA}) and the resistance to venous return (R_V).[129] This gradient is described by P_{MS} - P_{RA} resulting in the formula

$$VR = (P_{MS} - P_{RA})/R_V$$

The upstream driving pressure from the peripheral tissue to the RA is the mean circulatory filling pressure or mean systemic pressure. The term *mean systemic pressure* should not be confused with *mean arterial pressure.* The mean circulatory filling pressure, which is an equalization of pressures between the venous and arterial beds when flow is 0, is usually about 10 mm Hg, similar to the mean systemic filling pressure. It is increased by catecholamines or increased sympathetic activity.[128] An increase in right atrial pressure decreases the pressure gradient and venous return. The resistance to venous return is primarily determined by large veins, such as the venae cavae and peripheral large and medium-size veins that are responsive to autonomic influences or vasoactive mediators. Factors that increase VR include redistribution of blood from vascular beds with low volume and high flows to those with high volume and low flow, polycythemia or conditions increasing blood viscosity, and venous constriction.[129] Cutaneous venous tone is determined by thermoregulatory mechanisms rather than systemic pressure regulatory mechanisms.

Loss of venous tone, as in autonomic neuropathy or during anesthesia, limits the normal compensatory increases in venous tone to changes in posture, positive airway pressure, or decreased blood volume. If these factors are excessive, ventricular preload is adversely affected. Venoconstriction induced by hypovolemia, anxiety, or exercise augments intrathoracic blood volume and preload.

Physiology of the Pericardium

The pericardium has limited but important physiologic functions in the maintenance of biventricular systolic and diastolic function.[130] As dilatation of the LV occurs, intrapericardial pressure limits right ventricular filling and reduces forward flow to the lungs, possibly preventing pulmonary edema. Shifts of the left ventricular diastolic pressure–volume relationship are equal to changes in pericardial pressure and volume. During cardiac tamponade, increased intrapericardial fluid causes hypotension, decreased cardiac output, myocardial ischemia, and tachycardia. However, a vagally mediated depressive reflex is also operative, contributing further to the decreased cardiac output resulting from the presence of pericardial fluid.[131] Increased intrapericardial pressure results in an underfilled ventricle, which operates on the ascending limb

of Starling's curve.

Chapter 31

Anesthesia for Cardiac Surgery

Nikolaos Skubas
Adam D. Lichtman
Aarti Sharma
Stephen J. Thomas

KEY POINTS

1	Decreasing O_2 demand is as important as modifying O_2 supply.
2	Intraoperative ischemia is usually silent and is not always accompanied by hemodynamic changes.
3	A slow, small in size, and well-perfused heart are the goals.
4	The pulmonary artery catheter does not always reliably detect ischemia.
5	Echocardiography is more sensitive than electrocardiogram (ECG) in detecting ischemia: a myocardial segment is healthy if it moves inward and thickens.
6	Echocardiographic ejection fraction does not always represent contractility.
7	Impaired relaxation mandates volume augmentation and relatively slow, sinus rhythm, while a dilated ventricle requires unloading and inotropes.
8	There is no "ideal" anesthetic.
9	In aortic stenosis, a preload-dependent, hypertrophic ventricle requires adequate diastolic time and perfusion pressure.
10	In chronic aortic insufficiency, a dilated ventricle requires increased preload and decreased afterload.
	In mitral stenosis, the left ventricle (LV) is "lazy" and "under used," and

11	requires a slow heart rate to fill.
12	In mitral regurgitation, a preload-dependent and dilated LV benefits from afterload reduction and fast heart rate.
13	Maintenance of perfusion pressure should not take precedence over ventilation (never forget your ABCs).
14	Fast-track anesthetic techniques depend on higher concentration of inspired volatile agents, use of vasoactive medications (beta-blockers) and smaller doses of benzodiazepines and opioids.
15	The combination of systolic systemic and diastolic pulmonary pressures characterize the performance of the LV, and the combination of systolic pulmonary and central venous pressures the performance of the right ventricle (RV).

Anesthetizing patients for open heart surgery is exciting, intellectually challenging, and emotionally rewarding. Competent and skillful clinical management requires a thorough understanding of normal and altered cardiac physiology; an intimate knowledge of the pharmacology of anesthetic, vasoactive, and cardioactive drugs; and a familiarity with the physiologic derangements associated with cardiopulmonary bypass and the surgical procedures themselves. This chapter presents a brief overview of the subject to familiarize the reader with the critical physiologic and technical considerations when caring for cardiac surgical patients. The initial discussions concerning coronary artery and valvular heart disease lay the physiologic and some of the pharmacologic groundwork on which anesthetic planning and therapeutic decisions are based. First, we describe the balance of myocardial oxygen supply and demand, with particular reference to the patient with coronary artery disease. Next, we focus on those variables that regulate myocardial performance, specifically myocardial contractility, heart rate, and loading conditions (both preload and afterload). Then, we discuss the mechanics of cardiopulmonary bypass. Following this, we describe anesthetic considerations relevant to all adults undergoing cardiac surgery either with or without cardiopulmonary bypass (CPB), including preoperative evaluation, choice of monitoring techniques, selection of anesthetic drugs, and the actual conduct of the anesthetic before, during, and after bypass. The chapter concludes with some special topics, as well as a brief introduction to the child with congenital heart disease. Some of the issues discussed are controversial because the field is continuously evolving. We have tried, whenever possible, to suggest what is the consensus about these topics, but, inevitably, our own preferences will be apparent. For the sake of brevity, numerous tables are included that summarize data and provide readily accessible guidelines for the various phases of the operative procedure. Many monographs are available for those who desire more detailed analysis of any aspect of cardiac anesthesia.[1,2]

CORONARY ARTERY DISEASE

Prevention or treatment of ischemia during coronary artery bypass graft (CABG) surgery reduces the incidence of perioperative myocardial infarction. Hemodynamic management is tailored to avoid factors known to increase myocardial oxygen demand (M

O_2), particularly during the vulnerable pre-CPB period. Optimizing oxygen delivery to the myocardium is equally important for the successful management of these patients because it is well recognized that most ischemic events occur with minimal or no change in M

$\dot{V}O_2$.[3,4] The determinants of myocardial oxygen supply and demand are shown in Figure 31-1 and are also discussed in Chapter 30.

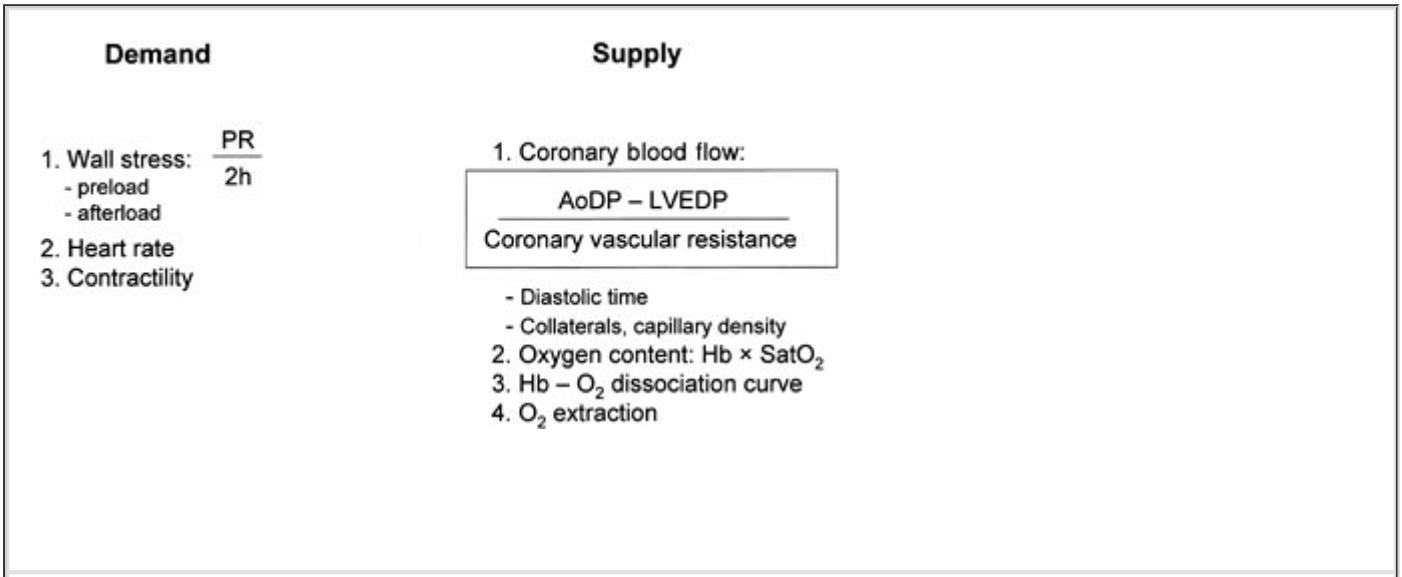

FIGURE 31-1. Myocardial oxygen balance. P, intracavitary pressure; R, ventricular radius; h, wall thickness; AoDP, diastolic arterial pressure; LVEDP, left ventricular end-diastolic pressure; Hb, hemoglobin; $SatO_2$, arterial oxygen saturation.

Myocardial Oxygen Demand

The principal determinants of M

$\dot{V}O_2$ are wall tension and contractility.[5] Laplace's law states that wall tension is directly proportional to intracavitary pressure and ventricular radius, and inversely proportional to wall thickness. Therefore, myocardial oxygen demand can be reduced by interventions that (1) prevent or promptly treat ventricular distention, and (2) decrease myocardial oxygen consumption.

Myocardial Oxygen Supply

1 Increases in myocardial oxygen requirements can be met only by raising coronary blood flow. Blood oxygen content is important, as is oxygen extraction by the myocardium, but these are infrequent reasons for intraoperative ischemia because oxygenation and blood volume are usually well maintained during anesthesia. Blood in the coronary sinus is 50% saturated (P O_2 ~27 mm Hg), and although extraction can be increased somewhat under conditions of stress, it is inadequate to meet the continuously increasing demand. Therefore, the principal mechanism for matching oxygen supply to alterations in M

$\dot{V}O_2$ is exquisite regulation and control of coronary blood flow.

Coronary Blood Flow

The critical factors that modify coronary blood flow are the perfusion pressure and vascular tone of the coronary circulation, the time available for perfusion (determined namely by heart rate), the severity of intraluminal obstructions, and the presence of (any) collateral circulation. The area most vulnerable to ischemia is the subendocardium of the left ventricle (LV), where the metabolic requirements are increased because of greater systolic shortening.[6]

Perfusion of the left ventricular subendocardium takes place almost entirely during diastole, whereas the right ventricular subendocardium is perfused mostly during systole, provided there is no pulmonary hypertension. This temporal disparity is explained by the different intraventricular pressures developing during systole.

The left ventricular coronary perfusion pressure is often defined as the difference between aortic diastolic pressure (AoDP) and left ventricular end-diastolic pressure (LVEDP). This is an oversimplification because there is no single AoDP. Rather, it is likely that there is a range of pressures that drive blood to the subendocardium. In the presence of intraluminal obstruction or increased vascular tone, this pressure gradient is reduced (Fig. 31-2). It is convenient and useful to consider ventricular filling pressure (the pulmonary artery occlusion pressure as the closest surrogate) as the end pressure. Therefore, a low ventricular filling pressure is ideal both in terms of improving perfusion (higher pressure gradient) and of reducing M

$\dot{V}$

O_2 (decreased ventricular volume and wall tension). The consequences of systemic pressure are more difficult to predict because the cost of increasing perfusion pressure (~afterload) is an increase in M

$\dot{V}$

O_2. However, it has been shown experimentally that at any given heart rate, ischemia is induced more likely by hypotension than hypertension.

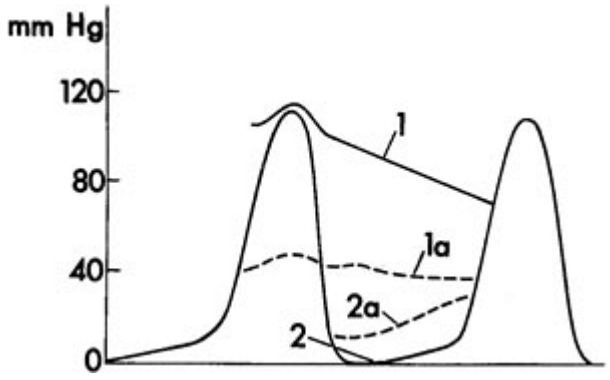

FIGURE 31-2. The pressure relationships between the aorta (*1*) and the left ventricle (*2*) determine coronary perfusion pressure. In coronary artery disease, myocardial perfusion may be compromised by decreased pressure distal to a significant stenosis (*1a*) (not quantifiable clinically) and/or by an increase in left ventricular end-diastolic pressure (*2a*). (Reprinted with permission from Gorlin R: Coronary Artery Disease, p 75. Philadelphia, WB Saunders, 1976.)

Alterations in the tone of the small intramyocardial arterioles regulate diastolic vascular resistance, allowing the matching of oxygen supply with metabolic demand over a wide range of perfusion pressures. The difference between autoregulated,

baseline flow and blood flow available under conditions of maximal vasodilation is termed coronary vascular reserve, and is normally three to five times higher than basal flow. As epicardial stenosis becomes more pronounced, progressive vasodilation of these resistance vessels allows preservation of basal flow, but at the cost of reduced reserve. Whenever demand increases above available reserve, signs, symptoms, and metabolic evidence of ischemia develop.

Prinzmetal et al.[7] first described angina and myocardial infarction in patients with angiographically normal coronary vessels. Subsequently, Maseri et al. and others have

repeatedly emphasized the frequency with which reductions in oxygen supply cause ischemia so small adjustments in coronary vascular tone at the site of existing obstructions can cause substantial reductions in luminal cross-sectional area.[8] Alterations in vessel diameter at the stenotic area are possible because at least two-thirds of plaques or atheromas are not concentric. It is now apparent that anesthesia is not protective against "supply" ischemia, which occurs frequently during surgery (Fig. 31-3).[4] The etiology of this is unclear, but it may be caused by circulating catecholamines, local effects of blood components such as platelets at areas of unstable atherosclerotic plaques, or other as yet undetermined factors. It is not uncommon for an anesthetized patient to show signs of ischemia without any change in heart rate, blood pressure, or ventricular filling pressures. In fact, most ischemic episodes are not accompanied by hemodynamic changes.[4] Drugs such as nitroglycerin or calcium entry blockers may be used to prevent and/or treat such episodes of coronary spasm,[9] although prophylactic use of these agents is usually ineffective.

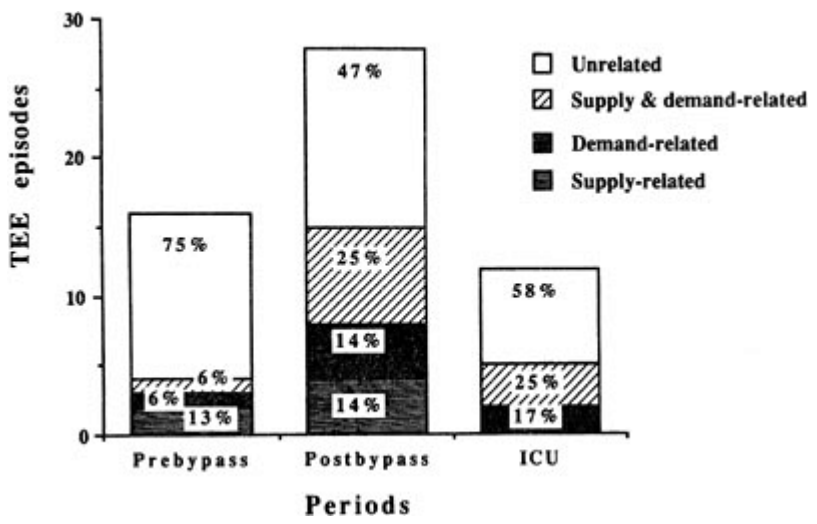

FIGURE 31-3. Association of transesophageal echocardiographic (TEE) wall motion changes with hemodynamic indices of supply and demand from continuous monitoring of 50 patients undergoing coronary artery bypass surgery. (Reproduced with permission from Leung JM, O'Kelly BV, Mangano DT *et al:* Relationship of regional wall motion abnormalities to hemodynamic indices of myocardial oxygen supply and demand in patients undergoing CABG surgery. Anesthesiology 73:802, 1990.)

Hypotension, vasospasm, and acute thrombosis decrease coronary perfusion pressure, reduce coronary blood flow, and limit oxygen delivery to the myocardium. Unstable angina pectoris and/or acute coronary thrombosis are the results of plaque rupture with ensuing platelet activation and thrombus formation. The presence of the potentially hyperreactive normal vessel wall adjacent to the thrombus may result in vasospasm and total occlusion of the vessel lumen in the presence of a previously nonocclusive eccentric plaque or thrombus. This type of acute thrombosis is believed to be the cause of acute myocardial infarction and sudden death (generally ischemia-induced cardiac dysrhythmias).

Hemodynamic Goals

Although the precise relationship between intraoperative ischemia and postoperative myocardial infarction remains controversial, there is consensus that one of the primary goals of any successful anesthetic is prevention of myocardial ischemia.[10] Failing that, prompt identification and treatment of new ischemic episodes is essential. As is evident from the previous discussion and from the summary in Table 31-1, anesthetic decisions are designed to reduce and control those factors that increase myocardial oxygen demand (heart rate, contractility, and wall tension). At the same time, every attempt is made to optimize coronary blood flow, notably,

maintaining coronary perfusion pressure and increasing diastolic time. The buzz words for patients with coronary artery disease are "slow, small, and well perfused." Combinations of anesthetics, sedatives, muscle relaxants, and vasoactive drugs are selected to provide this hemodynamic milieu. Techniques to effectively prevent or treat alterations in coronary vascular tone—antiplatelet drugs, specific bradycardic agents, and so on—are still evolving and await further clinical trial before definitive recommendations can be made.[10]

TABLE 31-1 Coronary Artery Disease—Hemodynamic Goals

P	Keep the heart small: ↓wall tension (diameter) and LVEDP; ↑perfusion pressure gradient
A	Maintain: hypertension better than hypotension
C	Depression (if LV function is within normal)
R	Slow
Rhythm	Sinus
M $\dot{V}O_2$	Monitor for and treat "supply"-related disturbances; control of myocardial O_2 demand is not enough
CPB	Elevated filling pressures are usually not needed after CABG

A, afterload; C, contractility; CABG, coronary artery bypass graft; CPB, cardiopulmonary bypass; LVEDP, left ventricular end-diastolic pressure; M $\dot{V}O_2$, myocardial oxygen consumption; P, preload; R, rate; ↑, increase; ↓, decrease.

Monitoring for ischemia

Electrocardiogram

The ideal monitoring technique is not yet available. Analysis of the ST segment in multiple leads (most commonly leads II and V_4 or V_5) is currently the standard. Patients likely to develop right ventricular ischemia[19] or those with disease of the right coronary artery might benefit from monitoring of leads V_{4R} or V_{5R}. Computerized ST segment trending and interactive monitors that alarm when the ST segment deviates from the programmed algorithm aid in the detection of intraoperative events overlooked by even the most astute observer.

Heart Rate and Blood Pressure

Multiple attempts have been made to determine ischemic thresholds using commonly measured hemodynamic variables. Among the earliest of these was the rate–pressure product (RPP = heart rate × peak systolic arterial pressure). The RPP was considered an easily determined index of M $\dot{V}O_2$. Although RPP may correlate with oxygen demand, especially during exercise, it is not a

sensitive or specific indicator of intraoperative ischemia; identical RPPs can be produced from multiple combinations of heart rate and blood pressure. Favorable conditions for oxygen balance are more likely those of lower heart rate and higher blood pressure than tachycardia and hypotension.

Neither the pressure–rate *ratio* (P/RR), nor the mean arterial pressure (MAP)/heart rate ratio are any more predictive or reliable than the RPP.

Pulmonary Artery Catheter

4 Sudden elevations in pulmonary artery or capillary wedge pressure indicating systolic and/or diastolic left ventricular dysfunction, large a waves reflecting decreased ventricular compliance, and v waves signaling the development of ischemia-induced papillary muscle dysfunction and/or mitral regurgitation are purported signs of ischemia that may be detected with a pulmonary artery catheter (PAC). Several studies contradict this long-held dogma and demonstrate that the PAC is of little value as a monitor of myocardial ischemia. Leung et al.[11] found that only 10% of all regional wall motion abnormalities were associated with an acute rise in pulmonary capillary wedge pressure in 40 patients undergoing elective CABG surgery. Haggmark et al.[12] found that neither an increase in the pulmonary capillary wedge pressure nor the occurrence of an abnormal pulmonary capillary wedge pressure waveform was a sensitive indicator for myocardial ischemia in 53 patients with coronary artery disease undergoing vascular surgery. A prospective study of 1,094 patients by Tuman et al.[13] showed that even high-risk cardiac surgical patients may be safely managed without routine use of a PAC, and if the need for it developed intraoperatively, delayed placement of a PAC did not influence outcome. Fontes et al. assessed the limitations of PAC in the management of critically ill patients in the ICU. Compared with transesophageal echocardiography, PAC predicted normal left ventricular function well, but performed poorly in judging preload and ventricular dysfunction.[14] A more recent study showed no benefit from PACs in high-risk surgical patients.[15] Nevertheless, the PAC is still frequently used in cardiac surgical patients to measure cardiac output and as a guide, albeit not ideal, to volume status.

Intraoperative Transesophageal Echocardiography

Since its introduction in the 1980s, transesophageal echocardiography (TEE) has become an invaluable diagnostic and monitoring tool during cardiac surgery. TEE permits assessment of ventricular volume, global and regional function, estimation and quantitation of valvular pathology, measurement of valve gradients and calculation of filling pressures, visualization of the thoracic aorta, and detection of intracardiac air.

Basics. Multiple image planes are necessary to reconstruct the three-dimensional (3D) structure of the heart. The American Society of Echocardiography (ASE)/Society of Cardiovascular Anesthesiologists task force for intraoperative echocardiography has published guidelines for performing a comprehensive intraoperative echocardiographic examination.[16] These recommendations describe a series of 20 standard tomographic views of the heart and great vessels that should be included in a comphrehensive intraoperative echocardiographic examination. With experience, a thorough examination can be performed in less than 10 minutes.

Evaluation of Ventricular Function. Although various techniques are available to quantify ventricular function, qualitative assessment currently predominates in the clinical arena. The transgastric midpapillary short-axis view of the LV (Fig. 31-4) is the standard initial view for evaluation of size and function. The presence of the papillary muscles ensures the same view is consistently obtained on repeated examinations. Using two-dimensional (2D) echocardiography, global left ventricular function is usually evaluated by calculating the ejection fraction.

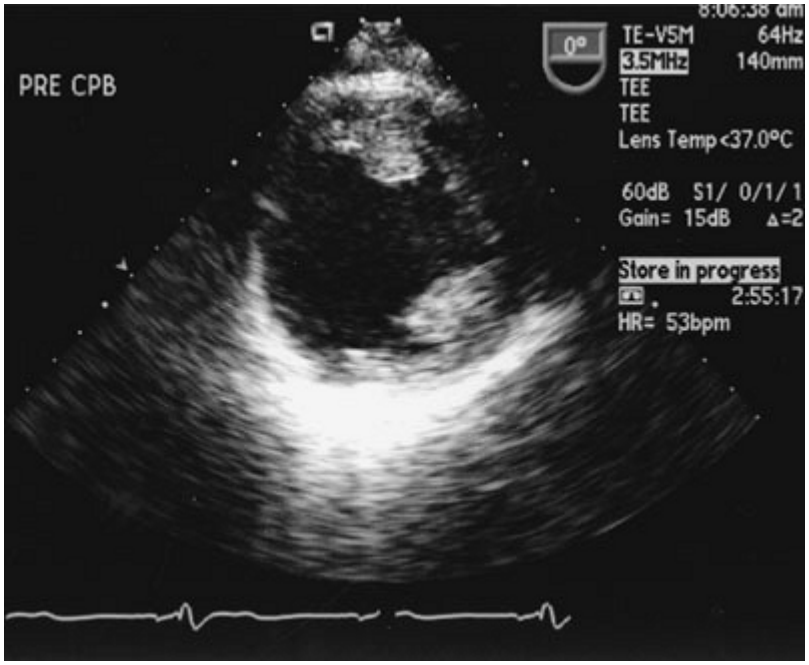

FIGURE 31-4. Transgastric short-axis view of the left ventricle at the midpapillary level. The body of the anterolateral papillary muscle is seen at 5 o'clock, and that of the posteromedial at 12 o'clock. In this case, the imaging depth is set at 14 cm, rather than the typical 12 cm so that the entire left ventricle is visualized.

ischemia. The ventricular distribution of the coronary arteries and their branches are depicted in Figure 31-5. All major branches of the coronary arteries supply segments of the ventricle viewed in the transgastric midpapillary short-axis level, enhancing the utility of this view as a monitor for ischemia. The grading of the wall motion is shown in Figure 31-6 and Table 31-2.

TABLE 31-2 Grades of Segmental Systolic Motion

·CLASS OF MOTION	·SYSTOLIC WALL THICKENING	·RADIAL(INWARD) SHORTENING
1. Normal	Marked	>30%
2. Hypokinetic	Minimal to moderate	10 to 30%
3. Akinetic	None	None or <10%
4. Dyskinetic	Thinning	Outward motion

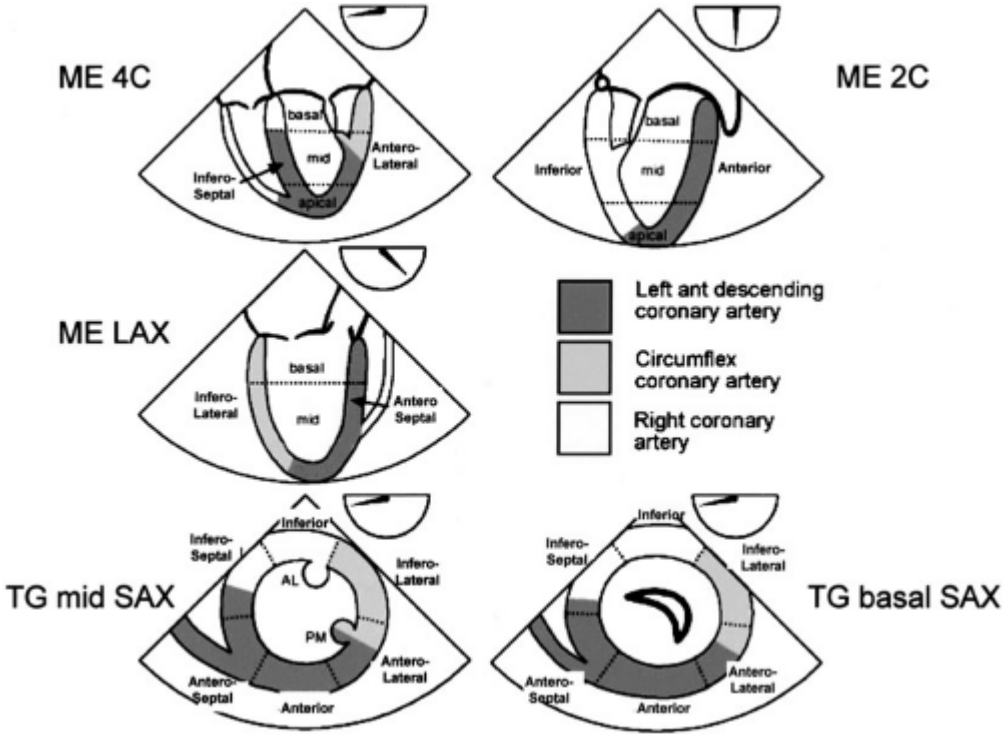

FIGURE 31-5. The distribution of the three major coronary arteries in relation to two-dimensional TEE images. The left ventricle (LV) is divided vertically into three levels: basal, mid, and apical. The basal and mid levels are each divided circumferentially into six segments, the apical level into four (for a total of 16 segments). For the LV midesophageal (ME) views, the transducer is positioned posterior to the LA at the level of the mitral valve, and the imaging depth is adjusted to include the entire LV. By rotating the multiplane transducer to different angles, the following views are obtained: ME 4C (four chamber) at 10° to 20° (until the aortic valve is not in view), ME 2C at 80° to 100° (until the right atrium and ventricle disappear), and ME long axis (LAX) view at 120° to 160° (until the LV outflow tract and the proximal aorta come into view). The transgastric (TG) views of the LV are obtained by advancing the probe into the stomach: At an angle of 0° the short axis (SAX) view appears, and the probe is withdrawn or advanced as needed to reach the basal or midpapillary (mid) level. (Modified with permission from Sidebotham D, Legget AMM: Practical Perioperative Transesophageal Echocardiography. Edinburgh, Scotland, Butterworth Heinemann, 2003.)

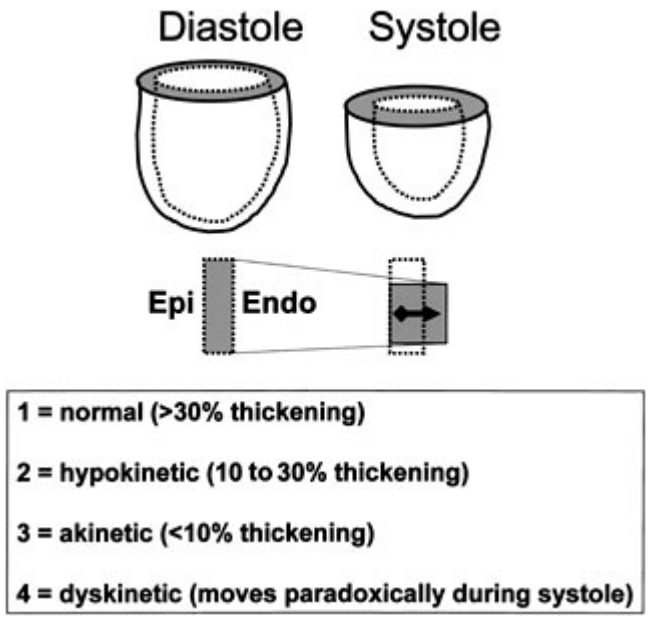

FIGURE 31-6. Definitions for changes in regional wall motion. During systole, the base of the left ventricle descends toward the apex and the myocardium thickens while the endocardium moves toward the center of the left ventricular cavity. The systolic segmental wall motion is evaluated for both inward excursion and thickening. The grading scale has been used extensively in the intraoperative echocardiograpic literature. All 16 segments are examined by obtaining five cross-sectional views of the LV.

The TEE diagnosis of segmental wall motion abnormalities (SWMAs) is based on visual assessment of wall motion *and* wall thickness. The use of cine loops (side-by-side comparison of the ventricle over time) of the transgastric midpapillary short-axis view of LV improves the ability to recognize new wall motion abnormalities. In one study, however, the short-axis

midpapillary view detected only 17% of all SWMAs, emphasizing the importance of evaluating the ventricle in multiple planes with careful standardization of location and edge definition.[17] Training will increase the operator's ability to attain the required images and to recognize new SWMA in real time.

5 Although ventricular wall motion is clearly very sensitive to coronary blood flow, the definition of ischemia is difficult. There is little agreement on a "gold standard" for the diagnosis of ischemia. Most studies have compared SWMA with changes in ST segments recorded on ECG. The concordance between SWMA and ECG evidence of ischemia is variable, ranging from 30% to 100%.[18,19] This discrepancy may exist for a number of reasons, for example, because SWMAs are more sensitive to compromised coronary blood flow than is ECG. Thus, SWMAs on TEE can appear when the compromise in coronary flow is still insufficient to produce ECG changes. If the compromise in coronary flow is enough to produce ECG evidence of ischemia, TEE SWMAs will precede these ECG changes.

Not all SWMAs are indicative of ischemia. Nonischemic myocardium adjacent to ischemic or infarcted myocardium may be interpreted as SWMAs, a phenomenon known as "tethering." SWMAs also occur with pacing, bundle branch blocks, and myocarditis, as well as tachycardia and hypovolemia. Differentiating stunned myocardium (postischemic ventricular dysfunction despite adequate blood flow that shows gradual improvement) from ischemia is important because treatment differs. Stunned myocardium requires supportive measures such as inotropic infusions until function returns, whereas inadequate revascularization with ongoing ischemia requires an assessment of graft patency and consideration of further revascularization. In the future, echocardiographic contrast agents that delineate coronary perfusion territories may refine this

the deformation (strain), deformation rate (strain rate), and timing of systolic and diastolic events, if applicable in the operating room, will offer more objective insight into regional myocardial function.[20]

Quantification of Ventricular Function. A range of 2D echocardiographic methods are employed to define ventricular systolic function (Table 31-3). The LV is often enlarged/dilated with chronic systolic dysfunction and in regurgitant valvular lesions with chronic volume overload. A disproportional increase in wall thickness (concentric hypertrophy) suggests the chronic pressure overload of aortic stenosis or systemic hypertension. Marked septal hypertrophy and abnormal anterior systolic motion of the anterior mitral leaflet are signs indicative of hypertrophic cardiomyopathy. The discovery of thrombus or outpouching of the free wall of the LV implies the presence of ischemic heart disease.

TABLE 31-3 Evaluation of Left Ventricular Systolic Function

	·TEE VIEW	·COMMENT
A. Initial estimation		
Size of ventricle—2D		
Dilated if —ESd >4.5 cm —EDd >7 cm	TG SAX	Seek coexisting valvular or ventricular structural abnormalities
B. Global function		
"Eyeball"—2D		
Visual evaluation of LV global function	TG SAX (usually)	Quick, easy, and widely used. Accuracy affected by echocardiographer's experience
Fractional area change—2D FAC = [(EDA - ESA) / EDA] × 100)		
% change of LV area	TG mid SAX	Quick, widely used, and accurate, provided there are no regional abnormalities
Ejection fraction (Quinones method)—M-Mode EF = (EDd^2 - ESd^2) / EDd^2		
% change of LV internal diameters between ESd and EDd	TG mid SAX	Easy and accurate calculation, provided that there are no regional motion abnormalities in base or apex

Ejection fraction—2D EF = [(EDV - ESV) / EDV] × 100		
Volume calculation using — Area-length method: volume = $8A^2/3\pi L$ (A, area; L, length) — Method of discs (modified Simpson's)	ME 2C and 4C	Planimetry (tracing) of endocardial border, calculation performed by software. Very accurate but tedious and time-consuming
Stroke volume (2D and Doppler) SV = CSA × VTI		
Cross-sectional area (CSA = $D^2 \times 0.785$) from diameter (D), and VTI at LV outflow tract	DTG	Easy to perform but prone to errors if D or VTI wrongly measured/traced
Tei index—Doppler = [(ICT + IRT) / ET]		
Global myocardial performance index based on ICT, IRT, and ET	Combination of any ME and DTG	Quick, inversely related to heart function, not "real" time measurement
dP/dt—Doppler		
Maximum rate of LV pressure change over time (calculated from change of MR velocity from 1 to 3 m/sec during ICT)	Any ME	Afterload independent, requires mitral regurgitation signal
C. Regional function		
Regional wall motion abnormalities—2D		
Visual evaluation of wall thickening	ME and TG	Widely used and reliable but dependent on echocardiographer's experience. Drop-out of echo signal in regions parallel to ultrasound propagation introduces inaccuracy. Cannot differentiate actively contracting from passively drawn (scar) segments. The epicardium is not always visible for evaluation of thickening

Tissue velocities—tissue Doppler		
Longitudinal myocardial shortening velocity reflects subendocardial contraction and is a more sensitive marker of impaired contractile function than reduced wall motion	ME at periphery of MA	Requires newer echocardiographic machines (cannot distinguish between actively contracting or passively following tissue). Velocities decrease toward apex
Strain—tissue Doppler		
Deformation of a myocardial segment	Any view	Allows objective comparison between different segments, difficult to implement in real time in OR environment, requires newer echocardiographic machines

2D, two-dimensional; DTG, deep transgastric; EDd, end-diastolic diameter; ESd, end-systolic diameter; ET, ejection time; ICT, isovolumic contraction time; IRT, isovolumic relaxation time; LV, left ventricle; MA, mitral valve annulus; ME, midesophageal; MR, mitral regurgitation; SAX, short axis; TEE, transesophageal echocardiography; TG, transgastric; VTI, velocity time integral.

Most experienced anesthesiologists rely on a visual estimate of the LV global function using the transgastric short-axis view at the midpapillary level. Although subjective, it is the preferred method in the often demanding cardiac operating room environment.

6 The fractional area of change (FAC) infers the systolic decrease in ventricular volume measured along the short axis, and is a reliable and quick index of systolic function.[21] Nevertheless, FAC still demonstrates intraobserver variability of 10% and an interobserver variability of 6 to 23%.[22] Because the FAC method assesses global left ventricular function based on a single short-axis view, it is inherently inaccurate in the setting of ventricular assymetry. In addition, FAC does not take into account the apical contraction nor does it represent systole along the long axis of the ventricle. Such variability, coupled with the time required to manually trace the endocardial border, limits the clinical utility of the FAC method.

A single measurement of the LV short-axis diameter from the TG SAX view at midpapillary level is sufficient for calculation of EF (Quinones method), provided the wall motion is either normal or diffusely abnormal (i.e., there are no distinct SWMAs). When the formula was tested against angiography, the authors found excellent correlation.[23]

More sophisticated and complex approaches to determine left ventricular systolic function calculate ventricular volumes. The end-diastolic volume and end-systolic volume are then used to calculate the EF. The methods recommended by the ASE[16] are the method of discs and the area-length method (Fig. 31-7). Alternatively, the stroke volume can be measured by a combination of 2D and pulsed-Doppler measurements.

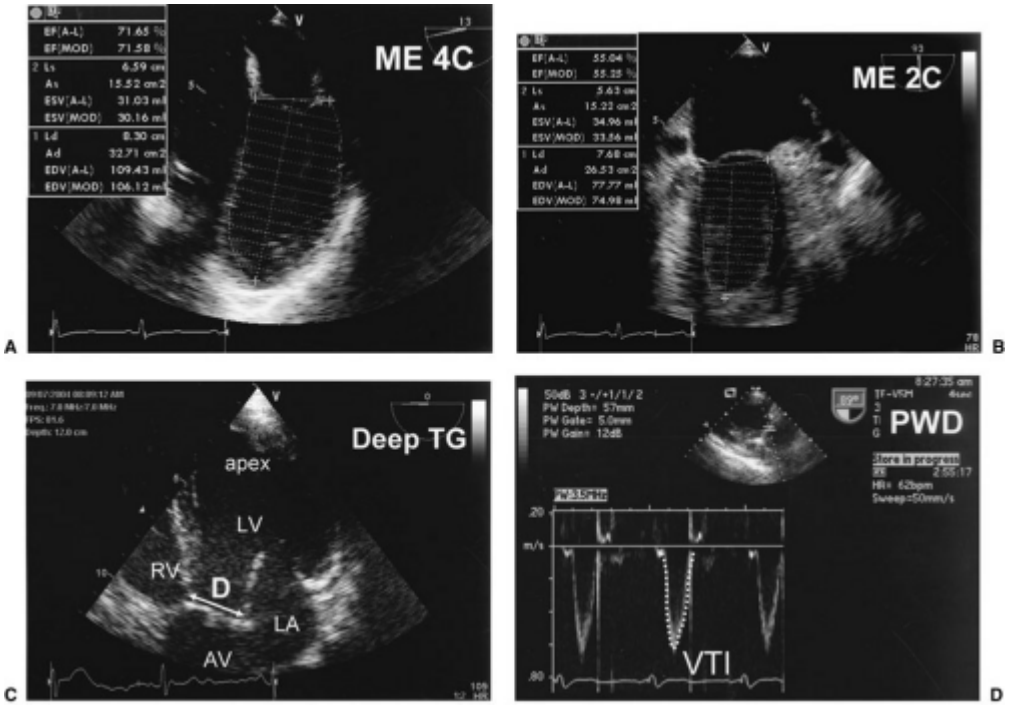

FIGURE 31-7. Evaluation of ventricular systolic function. **A, B.** Calculation of *ventricular* volume. The ME 4C and ME 2C of the left ventricle (LV) are obtained, and the endocardial border is traced in end-systole and end-diastole, from one side of the mitral annulus to the opposite. The *method of discs* (MOD) or modified Simpson's method assumes that the LV cavity contains twenty discs, centered along the long axis of the ventricle. The discs have the same thickness, but different diameter. The volume of each disc is calculated from its cross-sectional area and thickness. The *area-length* (A-L) method calculates the ventricular volume from the same traced area (A) and the length (L) of the LV long axis. Using either method, the stroke volume (SV) is calculated as the difference between end-diastolic volume (EDV) and end-systolic volume (ESV), and ejection fraction (EF) is calculated as SV/EDV. **C, D.** Calculation of *stroke* volume. The diameter (D) of the LV outflow tract is measured just proximal to the aortic valve using the deep transgastric (deep TG) view of the LV **(C)**. The cross-sectional area is then calculated as $\pi(D/2)^2$ or $D^2 \times 0.785$. The velocity of the blood passing through this area is displayed with pulsed wave Doppler (PWD) **(D)**, its envelope is traced and the velocity time integral (VTI) obtained. SV is calculated as $D^2 \times 0.785 \times VTI$. Other cylindrical sites (ascending aorta, main pulmonary artery) can be also used. It is important to measure D accurately as any error is subsequently squared. The SV calculation assumes the blood flow at this location is laminar and parallel to the ultrasound beam (any deviation in the angle between the ultrasound beam and the blood flow will underestimate the VTI). RV, right ventricle; LV, left ventricle; AV, aortic valve; LA, left atrium.

The Tei index incorporates systolic (isovolumic contraction and ejection) and diastolic (isovolumic relaxation) time intervals, measured by Doppler, to derive a number representing global LV function, both systolic and diastolic. The index is independent of heart rate or blood pressure and can be easily obtained with two simple measurements from the conventional Doppler echocardiogram. The index correlates well with both peak positive and negative dP/dt and reflects the overall cardiac function better because patients more commonly have features of both systolic and diastolic dysfunction.[24]

The rate of rise of LV intraventricular pressure (dP/dt) during systole can be used as a less load dependent index of systolic function.[25] Normal values are >1,200 mm Hg/second and severely depressed systolic function is present if <800 mm Hg/second.

Tissue Doppler imaging is a new techique to quantify tissue contraction and relaxation. For

example, the average peak systolic velocity from six sites of the base of the LV at the mitral annulus correlates well with LV ejection fraction, and a cutoff value of mean systolic mitral annular velocity of ⩾7.5 cm/second has a sensitivity of 79% and a specificity of 88% in predicting preserved global systolic function.[26]

Currently, there is no echocardiographic measurement of global ventricular function that is both quick and accurate. Therefore, qualitative assessment remains the most frequently used modality. An experienced observer can reasonably estimate ejection fraction if there is good endocardial definition and the ventricular areas of interest are well visualized. One should bear in mind that the echocardiographically derived ejection fraction is not always proportional to cardiac output: hypovolemia reduces cardiac output in the presence of unchanged ejection fraction (normal inotropic state), whereas stroke volume may be normal in the presence of depressed ejection fraction (dilated ventricle with poor systolic function). This emphasizes that EF is dependent not only on contractility, but also on preload and afterload.

Right Ventricle. The right ventricle (RV) is a complex anatomic structure draped over the anteromedial portion of the LV. There are no accepted 3D representations of the RV. In the transgastric short-axis midpapillary view, the RV appears crescent shaped, with the septum forming the medial wall. In the midesophageal four-chamber view, the tricuspid vavle plane is anchored slightly lower than the mitral annulus, and the right ventricular apex reaches to about two-thirds the length of the the interventricular septum. The right ventricular border is irregular due to trabeculation. Contraction of the RV is also complex. It involves a shortening of the long axis and an

inward movement of the free wall, which is primarily responsible for the ejection of blood. Collectively, these properties make it difficult to accurately evaluate RV function.[27]

The diagnosis of right ventricular infarct requires a change in right ventricular function from normal to akinesis or dyskinesis.[28] If the right ventricular apex extends as deep as the left ventricular apex, the RV is moderately dilated, and if it extends beyond the LV apex, the dilation is severe. Abnormalities of shape and motion of the interventricular septum (normally curved toward the RV) signify volume (diastolic flattening) and pressure (systolic bulging toward the LV) overload. A leftward bulging of the interatrial septum, the presence of tricuspid regurgitation, or pulmonary hypertension are surrogate findings in pressure or volume overload of the RV. Quantitative measurements of the RV with linear parameters have not been found to accurately reflect right ventricular function. Automated border detection has been applied to normovolemic RVs to generate pressure–area loops to evaluate right ventricular contractility.[29] It is not clear if this method is accurate with hypervolemic ventricles.[30] The myocardial systolic velocity (measured at the lateral border of the tricuspid annulus with tissue Doppler) significantly correlates with the right ventricular ejection fraction (assessed by ventriculography), and a value of <11.5 cm/second predicts right ventricular dysfunction (EF <45%) with good sensitivity and specificity.[31]

If the RV appears dilated, this should trigger an evaluation for a culprit lesion such as an atrial septal defect, tricuspid, or pulmonic regurgitation. Long-standing right ventricular

pressure overload can result in right ventricular dilation; however, hypertrophy is more common. Right ventricular hypertrophy is diagnosed with a diastolic right ventricular free wall thickness greater than 0.5 cm.

Diastolic Function and Filling Pressures. Although not well recognized, diastolic heart failure is common as an isolated disease in the elderly, increases the burden of heart failure among patients with systolic dysfunction, and is associated with increased morbidity and mortality.[32] The gold standards for evaluation of diastolic heart function (i.e., the rate of relaxation and pressure–volume loops are not feasible for daily perioperative practice). Doppler echocardiography has emerged as the principal tool for assessment of LV diastolic function.

Pulsed-wave Doppler examination of transmitral flow demonstrates an early (E) and a late (A) diastolic velocity, corresponding to early, rapid diastolic filling and atrial contraction, respectively.

Faster relaxation results in an increased pressure gradient and greater filling in early diastole. The E/A ratio is usually about 2, decreasing with normal aging to 0.75 to 1.5 around the sixth decade of life. In disease states, relaxation is impaired reducing early LV filling. Simultaneously, there is a compensatory increase in filling with atrial contraction (E/A < 1) (Fig. 31-8). These patients depend on a relatively slow sinus rhythm and adequate preload to maintain a normal cardiac output. When the chamber compliance is decreased (stiff myocardium, increased pericardial restraint, increased volume), the associated increased left artial (LA) pressure results in proportionally greater filling in early diastole, resulting in a normal E/A pattern (pseudonormal pattern). The Valsalva maneuver is simple to perform in a mechanically ventilated patient and helps in unmasking the underlying abnormal LV relaxation. In cases of pseudonormal pattern, the decreased cardiac filling during Valsalva maneuver lowers the LA pressure resulting in an E/A ratio <1.[33] With disease progression, there is severe decrease in LV compliance, which leads to a further increase in LA pressure and results in a very high E/A ratio (restrictive pattern). These patients become more sensitive to alterations in filling volume, with relatively small increases in volume reflected by marked increases in filling pressures.

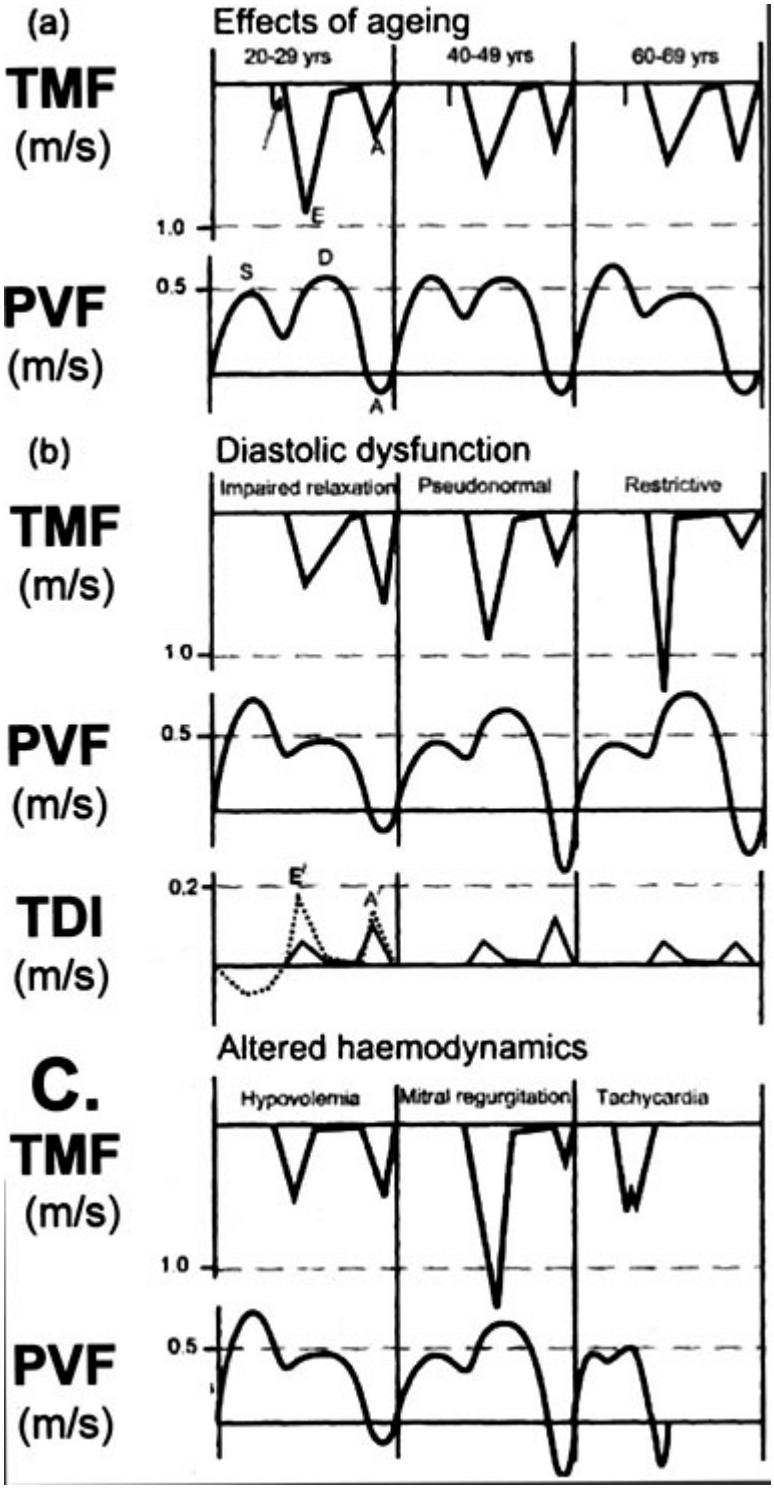

FIGURE 31-8. Echocardiographic evaluation of diastolic function. **a.** With increasing age the myocardium becomes progressively thicker and less compliant, and left venticular (LV) filling depends more on atrial contribution. This is reflected in transmitral flow (TMF): early diastolic filling velocity (E) decreases, and the ratio between early and late (A, atrial) velocities decreases. These changes are also reflected in the pulmonary venous flow (PVF) velocities: the ratio between systolic and diastolic (S/D) velocities increases with aging. **b.** With impaired relaxation, early LV filling is reduced, and the E/A ratio is <1. As LV compliance progressively worsens, left atrial pressure increases. There is proportionally greater filling in early diastole and less with atrial contraction (E/A > 1 in pseudonormal, and E/A > 2 in restrictive diastolic dysfunction). PVF: the S/D ratio remains <1. Although the classic Doppler velocities (TMF and PVF) do not always distinguish between healthy and disease states (compare velocities in the age group 20 to 29 years with the pseudonormal pattern of diastolic dysfunction), tissue Doppler imaging (TDI) velocities remain persistently

reduced once diastolic dysfunction occurs. **c.** The Doppler velocities are affected not only by the intrinsic diastolic function of the LV, but also by various other factors. Hypovolemia reduces the initial gradient between the LA and LV (E reduced, S/D > 1), a full LA (e.g., in moderate or severe mitral regurgitation) will create a pattern similar to one found in restrictive diastolic dysfunction (E/A > 2, S/D < 1), whereas tachycardia reduces the diastolic time interval and causes fusion of E and A velocities. (Reproduced with permission from Sidebotham D, Legget AMM: Practical Perioperative Transesophageal Echocardiography. Edinburgh, Scotland, Butterworth Heinemann, 2003.)

7 Pulmonary venous flow Doppler echocardiography provides additional information for the evaluation of diastolic function. The flow from the pulmonary veins to the LA occurs both during ventricular systole (LA relaxation, as well as downward motion of the mitral annulus and base of the heart produce a systolic [S] velocity) and diastole ([D] velocity). There is also a retrograde (rA) velocity back into the pulmonary veins during atrial contraction. When LA pressure is normal, LA filling occurs primarily in systole (S/D > 1), whereas with increasing LA pressure, LA filling occurs during diastole (S/D < 1). Comparison of the atrial contraction events (A and rA waves) provide additional information: rA > 35 cm/second, rA duration > 30 milliseconds or rA duration > A duration predict an LA pressure >15 mm Hg, usually found in moderate and severe diastolic dysfunction.[34]

Aorta. Neurologic dysfunction in cardiac surgical patients continues to be a devastating complication.[35] Stroke, defined as a fixed neurologic deficit lasting longer than 24 hours, occurs with an incidence of 2 to 5% in patients undergoing CABG with CPB, whereas more subtle neurologic dysfunction is detected in 30 to 60% of these patients.[35,36] Risk factors that have been identified include a history of neurologic disease, older age, and presence of aortic atherosclerosis.[37] Detecting aortic atherosclerotic disease allows surgical modifications that may decrease a patient's morbidity and mortality. Prior to echocardiography, detection of aortic atherosclerotic disease relied on surgical palpation or radiographic evidence of its presence. Although successful for detection of severe aortic calcification, these techniques do not reliably predict aortic atheromas.[38] TEE can accurately detect the presence of both aortic

calcification and atherosclerosis.[39] Because TEE is easy to perform, reproducible, quantifiable, and carries minimum risk, it has become the diagnostic method of choice for detecting aortic atheromas. The severity of aortic atherosclerotic disease is graded according to the scale depicted in Figure 31-9.

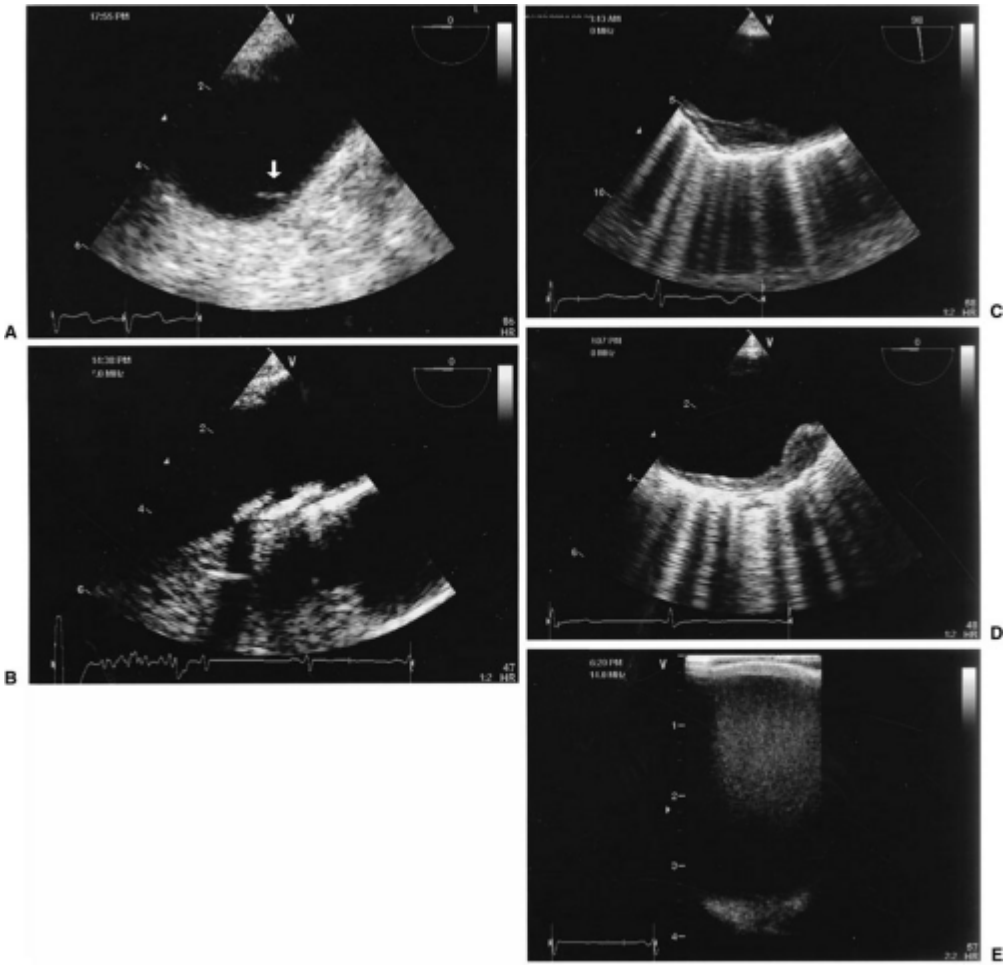

FIGURE 31-9. Assessment and grading of aortic atherosclerosis: I, normal thickening; II, intimal hyperplasia; III, plaque/atheroma <5 mm; IV, plaque/atheroma >5 mm; V, mobile atheroma of any size. **A.** Grade V mobile atheroma in the distal arch (*white arrow*). **B.** Grade III atherosclerotic plaque heavily calcified. **C.** Grade IV atheroma in the descending aorta (short-axis view). **D.** Grade IV atheroma in the descending aorta (long-axis view). **E.** Grade I (epiaortic scan) of ascending aorta.

TEE completely and accurately images the descending thoracic aorta. However, owing to the interposition of the trachea and/or the right mainstem bronchus between the esophagus and the ascending aorta, the distal ascending aorta and proximal aortic arch are almost invisible. Complete and accurate examination of this segment of the aorta requires direct examination with an epiaortic probe. The presence of a grade III, IV, or V descending thoracic aorta is associated with an increased incidence of postoperative morbidity (stroke) and mortality.[37,40] In a series of 189 patients who underwent a CABG with CPB and intraoperative TEE examination of the descending aorta, no strokes were noted in individuals with grades I and II aortas, whereas stroke rates of 5.5% (2/36), 10.5% (2/19), and 45% (5/11) were documented for descending aortas grades 3, 4, and 5[37] (Fig. 31-10). In a subsequent study, an epiaortic examination of the ascending aorta was performed in all patients with a grade 4 or 5 descending thoracic aorta. If a grade V ascending thoracic aorta was documented, there was a 71% (5/7) incidence of stroke. It has been shown that if a complete TEE examination of the thoracic aorta is negative for atheromatosis, it is highly unlikely that there is significant atherosclerotic disease in the ascending aorta and proximal aortic arch. If the TEE examination reveals significant atheromatosis (>3 mm) in the descending aorta, there is a 34% chance of significant disease in the ascending aorta, and epiaortic scanning is applicable.[41] Thus, TEE is a very sensitive, but only mildly specific, method of determining the extent of atherosclerosis in the thoracic aorta.

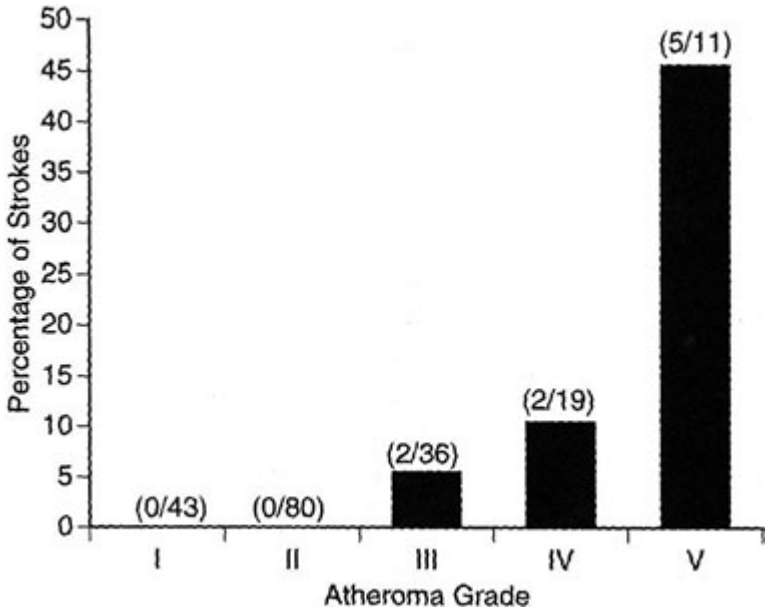

FIGURE 31-10. Risk of perioperative stroke versus descending thoracic aortic grade. Numbers in parentheses represent the number of patients who suffered a stroke out of the total number of patients with that descending aortic grade. (Reproduced with permission from Hartman GS, Yao FS, Bruefach M *et al:* Severity of aortic artheromatous disease diagnosed by transesophageal echocardiography predicts stroke and other outcomes associated with coronary artery surgery: A prospective study. Anesth Analg 83:701, 1996.)

Despite the shortcomings of TEE in imaging the thoracic aorta for atherosclerosis, it remains a primary tool for rapid and accurate evaluation of patients with suspected thoracic aortic pathology, especially aortic dissections. TEE has consistently demonstrated a 95 to 100% sensitivity and specificity

in diagnosing an acute aortic dissection[42] (Fig. 31-11). It is important to recognize that artifacts may appear as an aortic dissection. These artifacts can be classified as linear artifacts or mirror-image artifacts. Linear artifacts may mimic intimal flaps. They frequently occur in the ascending aorta when the aortic diameter is greater than the left atrial diameter. Mirror-image artifacts are more common in the transverse and descending aorta and appear as a double-barrel aorta. These are produced by the aortic-lung tissue interface. Numerous methods can be used to decrease the risk of interpreting an artifact as a dissection. Performing a complete 2D assessment of the aorta in multiple image planes will eliminate the majority of artifacts. Applying color flow Doppler to the aorta may also distinguish a dissection from an artifact. Dissections will disrupt the blood flow pattern to produce a mosaic color flow image, a pattern not seen with artifacts. Finally, M-mode echocardiography can be used to demonstrate independent movement of the true aortic flap, a property not consistent with an artifact. Epiaortic evaluation of the ascending aorta should be performed if an acute dissection is suspected secondary to surgical cannulation of the aorta.

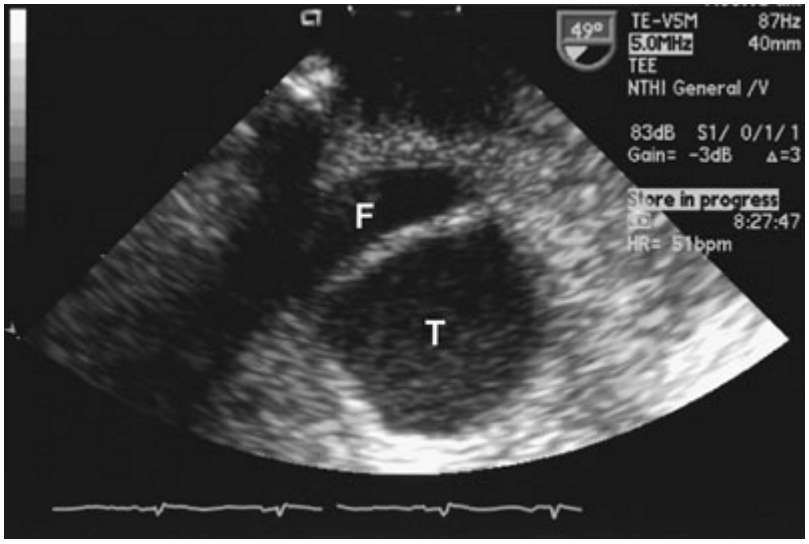

FIGURE 31-11. Aortic dissection. Two-dimensional short-axis view of the descending aorta demonstrates the presence of an intimal flap separating the true lumen (T) from the false lumen (F).

Selection of Anesthetic

There is no one "ideal" anesthetic for patients with coronary artery disease. The choice of anesthetic should depend primarily on the extent of preexisting myocardial dysfunction and the pharmacologic properties of the drugs themselves. The fit patient who has angina only on heavy exertion and good ventricular function profits from having M

$\dot{V}$

O_2 decreased with a volatile-based technique. Conversely, the patient with severe congestive heart failure and a scarred myocardium might be better served by a less depressant technique. These examples illustrate the point that myocardial depression is harmful only in the patient whose heart cannot be further depressed without fear of precipitating overt heart failure. Most patients with mild or even moderate dysfunction may benefit from some degree of myocardial depression, decreasing oxygen demand, and alleviating or at least decreasing episodes of ischemia.

Early extubation is popular for both on as well as off-pump cardiac procedures. There are multiple approaches to achieve early extubation in the cardiac surgical patient. The choice of anesthetic should be based on known hemodynamic, pharmacologic, and pharmacokinetic effects of each drug as they apply to the particular patient, the experience of the anesthesiologist, and the relative cost-benefit of each agent. Volatile anesthetics with low-dose narcotics and total intravenous anesthesia with short-acting drugs (e.g., midazolam, alfentanil, remifentanil, propofol) have been used to effect early extubation. Another interesting approach is the combination of the opiates, sufentanil and morphine, instilled intrathecally before induction.

Opioids

The primary advantages of opioids are lack of myocardial depression, maintenance of a stable hemodynamic state, and reduction of heart rate (except for meperidine). Problems include (1) hypertension and tachycardia during surgical stimulation (sternotomy and aortic manipulation), especially in patients with good ventricular function; (2) predictable hypotension when combined with benzodiazepines; (3) lack of titratability when used in high doses; and (4) a low incidence of intraoperative recall. An opioid-based technique may be of value in the patient with severe myocardial dysfunction, whereas in a patient with normal ventricle, it may be inadequate and need to be combined with other anesthetics or vasoactive drugs. The planned time of extubation is now

one of the major factors determining the selection and dosage of opioid.

Inhalation Anesthetics

The desirable features of volatile anesthetics include dose dependency, easy reversibility, titratable myocardial depression, amnesia, and suppression of sympathetic responses to surgical stress and cardiopulmonary bypass. Disadvantages include myocardial depression, systemic hypotension (whether induced by decreased contractility or vasodilation), and lack of postoperative analgesia. Combinations of opioids and volatile anesthetics retain their advantages with minimal untoward effects. It is likely that any volatile anesthetic agent could be used in a balanced technique.

Isoflurane is a coronary vasodilator, as are the other volatile anesthetics (although to a lesser degree). This dose-related effect is clinically insignificant in doses less than 1 minimum alveolar concentration (MAC). Clinical studies using isoflurane to clinical rather than pharmacologic endpoints have not shown increased episodes of ischemia or a worsened outcome.

Desflurane and sevoflurane have the fastest recovery of all volatile anesthetics. Desflurane has a rapid uptake and distribution, allowing it to be useful in cases where hemodynamic swings are dramatic. It has a cardiac profile similar to that of isoflurane. Of concern is the fact that a sudden increase in inspired concentration can lead to a marked increase in heart rate, mean arterial pressure, and plasma epinephrine levels, making it riskier for use in patients with coronary artery disease. In patients undergoing noncardiac surgery, desflurane does increase pulmonary artery pressure, wedge pressure, and pulmonary vascular resistance compared with isoflurane.[43] Studying sympathetic nervous system activity, Helman et al. found an increase in sympathetic activity and myocardial ischemia in patients anesthetized with desflurane as the sole anesthetic agent for coronary artery bypass surgery compared with patients anesthetized with sufentanil.[44] In contrast, the hemodynamic profile of sevoflurane also resembles that of isoflurane.[45] Compared with isoflurane, in a technique combining fentanyl with the inhalational anesthetic, sevoflurane had an acceptable cardiovascular profile prior to cardiopulmonary bypass and had similar outcome data to isoflurane.[46]

Intravenous Sedative Hypnotics

An alternative adjuvant anesthetic to a low-dose opioid technique is a titratable intravenous infusion of a short-acting sedative, such as midazolam, propofol, or dexmedatomidine. These can be continued postoperatively in the intensive care unit (ICU), and afford a predictable and fairly rapid awakening after discontinuation.

Treatment of ischemia

The use of anesthetics or vasoactive drugs that enable the heart to return to the slower-rate, smaller-size, and well-perfused state is frequently essential during anesthesia. The principal vasoactive drugs are nitrates, β-blockers, peripheral vasoconstrictors, and calcium-entry blockers. Clinical scenarios for their use are given in Table 31-4. These drugs are discussed extensively in Chapter 12 and are reviewed only briefly here. Volatile anesthetics can also be used to control blood pressure and reduce contractility.

TABLE 31-4 Treatment of Intraoperative Ischemia

·DEMAND: INCREASED	·CLINICAL MANIFESTATION	·SUPPLY: DECREASED
Rx usual suspects, β-	↑ HR ↓	Atropine, pacing

blocker		
↑ Anesthetic depth	↑ BP ↓	↓ Anesthetic depth, vasoconstrictor
NTG	↑ PCWP ↓	NTG, inotrope
	No changes	NTG, calcium channel blockers, ?heparin
↑, increase; ↓, decrease; BP, blood pressure; HR, heart rate; NTG, nitroglycerin; PCWP, pulmonary capillary wedge pressure.		

Nitrates

Nitroglycerin is the drug of choice for the acute treatment of coronary vasospasm. It is a systemic venodilator (reduces venous return and decreases wall tension and M

$\dot{V}$

O_2) and a coronary arterial dilator (effective in both stenosed coronaries and in collateral beds). The evidence for the prophylactic use of nitroglycerin is unconvincing for prevention of either intraoperative ischemic episodes or postoperative cardiac complications. At higher doses, it dilates arterial beds and may cause systemic hypotension. The recommended trynitroglycerol (nitroclycerin) (TNG) dose is 0.5 to 3 mcg/kg per minute and is reduced in the presence of hepatic and/or renal disease. TNG may cause methemoglobinemia, especially in patients with methemoglobin reductase deficiency. TNG is administered via special intravenous tubing that does not adsorb the drug.

Sodium Nitroprusside

Sodium nitroprusside (SNP), which is comparable to other nitrovasodilators, decreases peripheral vascular resistance by metabolic or spontaneous reduction to nitric oxide. Similar to TNG, SNP improves ventricular compliance in the ischemic myocardium. The recommended SNP dose is 0.5 to 3 mcg/kg per minute, and is reduced in the presence of hepatic and/or renal disease. Adverse effects include cyanide and thiocyanate toxicity, rebound hypertension, intracranial hypertension, blood coagulation abnormalities, increased pulmonary shunting, and hypothyroidism. Cyanide is produced when SNP is metabolized; 1 mg of SNP contains 0.44 mg of cyanide. Toxic blood levels (>100 mg/dL) occur when >1 mg/kg SNP is administered within 2 hours or when >0.5 mg/kg/hr is administered within 24 hours. The presenting signs of cyanide toxicity include the triad of elevated mixed venous O_2 (Pv_{O2}), requirements for increasing SNP dose (tachyphylaxis), and metabolic acidosis.[47] In addition, the patient may appear flushed. Greater risk of cyanide toxicity exists in patients who are nutritionally deficient in cobalamine (vitamin B_{12} compounds) or in dietary substances containing sulfur. Measurement of blood cyanide and pH will enable detection of abnormalities in high-risk patients for whom larger than recommended amounts of SNP have been used (8 to 10 mcg/kg per minute). Treatment should consist of discontinuing infusion, administering 100% O_2, and administering amyl nitrate (inhaler) or intravenous sodium nitrite and intravenous thiosulfate, except in those patients with abnormal renal function, for whom hydroxocobalamin is recommended. A cyanide antidote kit is commercially available (Eli Lilly Co.). Circulating levels of thiocyanate increase when renal function is compromised, and central nervous system abnormalities result when thiocyanate levels reach 5 to 10 mg/dL. Lowering the SNP dose requirement can be achieved with captopril, trimethaphan,

diltiazem, nicardipine, metoprolol, and esmolol, thereby reducing the consequent buildup of cyanide. SNP can also cause inhibition of platelet aggregation; however, more recent evidence indicates that this complication is reversible and transitory.[48] Once dissolved, SNP deteriorates in the presence of light. The container, therefore, should be wrapped in aluminum foil. An unstable SNP ion in aqueous solution reacts with various substances within 3 to 4 hours, forming colored salts. Other drugs should not be infused in the same solution as SNP.

Vasoconstrictors

Vasoconstrictors are useful adjuncts in the prevention and treatment of ischemia because they increase systemic blood pressure. Administration of an α-adrenergic agent such as phenylephrine improves coronary perfusion pressure, albeit at the expense of increasing afterload and $M\dot{V}O_2$. In addition, concomitant venoconstriction increases venous return and left ventricular preload. Nitroglycerin is sometimes added to counteract any increase in preload. In most situations, the increase in coronary perfusion pressure more than offsets any increase in wall tension. Peripheral vasoconstriction is indicated during episodes of systemic hypotension, especially those caused by reduced surgical stimulation or drug-induced vasodilation (e.g., when nitroglycerin results in unacceptably low arterial pressure).

Beta Blockers

β-Adrenergic blockade improves myocardial oxygen balance by preventing or treating tachycardia and by decreasing contractility. Myocardial depression can result in increased ventricular end-systolic volume and wall tension. Clinically, this is not usually a problem. Indications for β-blockers include treatment of sinus tachycardia not resulting from the usual causes (e.g., light anesthesia, hypovolemia), slowing the ventricular response to supraventricular dysrhythmias, decreasing heart rate and contractility in hyperdynamic states, and control of ventricular dysrhythmias. The use of atenolol has been shown to improve long-term survival in patients with heart disease undergoing noncardiac surgery.[49,50] Intravenous preparations include propranolol, metoprolol, labetalol, and esmolol. Propranolol is a nonselective β-blocker with an elimination half-life of 4 to 6 hours. Metoprolol is similar to propranolol but has the purported advantage of β_1 selectivity. Labetalol combines β-blocking properties with those of α-blockade and is useful in treating hyperdynamic and hypertensive situations. Esmolol is a short-acting β_1-blocker that is cardioselective, with a half-life of only 9.5 minutes. It is particularly useful in treating transient increases in heart rate owing to episodic sympathetic stimulation.

Calcium Channel Blockers

Calcium channel blockers are useful in slowing the ventricular response in atrial fibrillation and flutter, as coronary vasodilators, and in the treatment of postoperative hypertension. In vitro, all calcium entry blockers depress contractility, reduce coronary and systemic vascular tone, decrease sinoatrial node firing rate, and impede atrioventricular conduction. Unlike the β-blockers, which are similar both in structure and pharmacodynamic effect, the calcium entry blockers vary remarkably in their predominant pharmacologic action. The negative inotropic effect is greatest with verapamil and less with nifedipine, diltiazem, and isradipine (in decreasing order). Verapamil is useful in the treatment of supraventricular tachycardia and slowing the ventricular response in atrial fibrillation and/or flutter; however, its myocardial depressant effects may limit its usefulness in some patients. In patients with reduced myocardial function, intravenous diltiazem is effective in the treatment of atrial fibrillation and flutter by slowing atrioventricular conduction with minimal myocardial depression. It is also useful in decreasing sinus rate. Nifedipine and diltiazem are coronary vasodilators used as antianginal agents and in the prevention of coronary vasospasm.

Nifedipine, isradipine, amlodipine, and nicardipine are prominent peripheral vasodilators. Owing to their systemic vasodilatory effects, intravenous isradipine and nicardipine have been shown to be effective in the treatment of postoperative hypertension in cardiac surgical patients, with minimal

side effects.[51,52] Magnesium has use in the treatment of myocardial ischemia. It has coronary artery vasodilating properties, reduces the size of myocardial infarction in the setting of acute ischemia, and decreases mortality associated with infarction.[53] In addition, it is an antiarrhythmic and minimizes myocardial reperfusion injury.

VALVULAR HEART DISEASE

Alterations in loading conditions are the initial physiologic burdens imposed by valvular heart lesions, both stenotic and regurgitant. For example, the LV is pressure overloaded in aortic stenosis and volume overloaded in aortic insufficiency and mitral regurgitation. In mitral stenosis, however, the LV is both volume-underloaded and pressure-underloaded, whereas the RV faces progressively increasing left atrial and pulmonary artery pressure. Compensatory mechanisms consist of chamber enlargement, myocardial hypertrophy, and variations in vascular tone and level of sympathetic activity. These mechanisms in turn induce secondary alterations, including altered ventricular compliance, development of myocardial ischemia, chronic cardiac dysrhythmias, and progressive myocardial dysfunction.[54] Myocardial contractility is often transiently depressed but may progress to irreversible impairment even in the absence of clinical symptoms. Conversely, the patient with aortic stenosis may complain of dyspnea, not because of impaired systolic function, but because of reduced ventricular compliance, increased left ventricular end-diastolic pressure, and increased pulmonary pressure.

The patient presenting for valve repair or replacement often has pulmonary hypertension, severe ventricular dysfunction, and chronic rhythm disorders. Anesthetic management is predicated on understanding the altered loading conditions, preserving the compensatory mechanisms, maintaining circulatory homeostasis, and anticipating problems that may arise during and after valve surgery. In this section, we briefly describe the pathophysiology, the desirable hemodynamic profile, and other pertinent anesthetic considerations for each valvular lesion.

TEE has become the standard of care in the perioperative management of patients undergoing valve surgery.[55] TEE can further refine the preoperative diagnosis, identify valvular pathology and the mechanism of disease, and quantify the degree of stenosis and/or regurgitation. Studies have shown a change in the perioperative plan regarding valve surgery in as many as 19% of cases as a result of the prebypass echocardiographic exam.[54,55] Prompt evaluation of the surgical results by TEE also affects the operative course: depending on the surgical intervention, 5 to 18% of the time TEE reveals findings that result in an immediate return to CPB.[56] However, the detailed assessment of valvular function pre-CPB and post-CPB is complex. 2D echocardiography and color flow Doppler can provide a gross evaluation of valve function, but complete assessment requires Doppler evaluation of blood flow velocities. Comprehensive reviews of these topics can be found in standard textbooks of echocardiography. Ultimately, the decision to intervene is clinical and must take into account the patient's individual situation. Both valve replacement and repair result

in a level of valve pathology that may or may not be in the best interest of the patient.

Aortic Stenosis

In a normal adult, the aortic valve (AV) is composed of three semilunar cusps attached to the wall of the aorta. The normal AV diameter is 1.9 to 2.3 cm with an aortic valve area (AVA) of 2 to 4 cm^2. The outpouchings of the aortic wall immediately above the valve cusps are called the sinuses of Valsalva. These are symmetric with a diameter 0.2 to 0.3 cm greater than the AV annular diameter. The cusps and the corresponding sinuses are named according to their relation to the coronary ostia: left, right, and noncoronary. On the ventricular side of the aortic valve is the cylindrical outflow tract. Its borders are the inferior surface of the anterior leaflet of the mitral valve, the interventricular septum, and the left ventricular free wall. The normal diameter of the left ventricular outflow tract (LVOT) is 2.2 cm ± 0.2 cm.

Etiologies of aortic stenosis include (1) bicuspid AV, a congenital lesion, where the mechanical shear stress leads to injury and stenosis of the valve orifice; (2) degeneration of normal, tricuspid AV from autoimmune phenomena (rheumatic fever), leading to calcification and fusion along the

commissures; (3) cardiovascular risk factors (hypercholesterolemia, male gender, smoking), which initiate a "response to injury" similar to that seen in atherosclerosis, where the cusps become calcified, thickened, and deformed, with a decreased ability to separate; and (4) conditions associated with chronically elevated stroke volume and altered calcium metabolism (Paget's disease, hyperparathyroidism, renal failure associated with arteriovenous fistula). Rheumatic disease causes mixed aortic stenosis and AV regurgitation, and coexists with mitral valve disease.[57]

Pathophysiology

The progressive narrowing of the AV orifice results in chronic obstruction to left ventricular ejection. Intraventricular systolic pressure increases to preserve forward flow. "Concentric" ventricular hypertrophy, in which the wall gradually thickens but the chamber size remains unchanged, is the compensatory response normalizing the concomitant increase in wall tension. Contractility is preserved and ejection fraction is maintained at a normal range until late in the disease process (Fig. 31-12). Signs and symptoms of aortic stenosis occur when the AV orifice is reduced to 0.8 cm^2.[58]

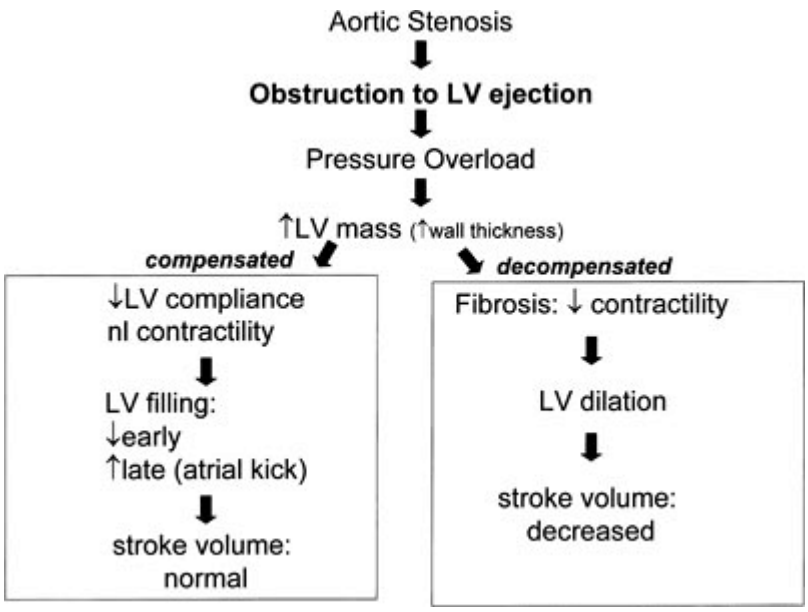

FIGURE 31-12. The physiologic consequences of aortic stenosis. LV, left ventricle.

The cost of this concentric hypertrophy is decreased diastolic compliance and a precarious balance between myocardial oxygen supply and M$\dot{V}O_2$. Hypertrophy-induced impairment of diastolic relaxation ("stiff" ventricle) impedes early left ventricular filling and atrial contraction is often critical for maintaining adequate ventricular filling and stroke volume. The "atrial kick" may account for up to 30 to 40% of left ventricular end-diastolic volume. The ventricular filling pressure, as reflected by pulmonary capillary wedge pressure, may vary widely with only small changes in ventricular volume.

The enlarged muscle mass has increased basal myocardial oxygen requirements, while demand per beat rises because of the elevated intraventricular systolic pressure. Simultaneously, with a capillary density often inadequate for the hypertrophic muscle, supply may be further compromised, when perfusion pressure is reduced (as when the aortic diastolic pressure is decreased and/or the ventricular filling pressure is increased), and total vasodilator reserve may be impaired. This situation is compounded in the presence of coronary obstruction. Often, patients with aortic stenosis will present in heart failure.

Anesthetic Considerations

9 The ideal hemodynamic environment for the patient with aortic stenosis is summarized in Table 31-5. Maintenance of adequate ventricular volume and sinus rhythm is crucial. Hypotension must be prevented and treated promptly if it develops. Anticipation of likely hemodynamic changes is essential (e.g., expected decreases in blood pressure following spinal anesthesia). Coronary perfusion pressure must be maintained to prevent the catastrophic cycle of hypotension-induced ischemia, subsequent ventricular dysfunction, and worsening hypotension. Bradycardia is a common clinical etiology for hypotension in the patient with aortic stenosis. Slowing the heart rate and increasing diastolic time will not increase stroke volume in the thick, concentrically hypertrophied LV. Therefore, bradycardia will induce a fall in total cardiac output and systemic arterial pressure. This is especially pertinent in the elderly patient, in whom sinus node disease and reduced sympathetic responses may predispose to significant bradycardia. Tachycardia must be avoided because it reduces the duration of diastolic coronary perfusion.

TABLE 31-5 Aortic Stenosis—Hemodynamic Goals

P	Full
A	Maintain coronary perfusion gradient
C	Usually not a problem, may require inotropic support if persistent hypotension
R	Avoid bradycardia (↓CO) and tachycardia (ischemia)
Rhythm	Sinus: may need cardioversion or β-blockers
M $\dot{V}O_2$	Avoid tachycardia and hypotension (ischemia is an ever-present risk)
CPB	Contractility augmentation may be required transiently secondary to myocardial stunning; blood pressure may need to be controlled later

A, afterload; C, contractility; CPB, cardiopulmonary bypass; M $\dot{V}O_2$, myocardial oxygen consumption; P, preload; R, rate.

Ischemia may be difficult to detect because the characteristic electrocardiographic changes are often obscured by signs of LV hypertrophy and strain. Elevated LV filling pressures, although not necessarily reflecting increased volume, often require

treatment to optimize coronary perfusion pressure.[59] Nitroglycerin is useful in this regard, but it must be remembered that minimal reductions in ventricular volume are required; therefore, very low doses of nitroglycerin should be used and titrated to effect. As an alternative, an arterial dilator, such as nicardipine or sodium nitroprusside[60] will lower afterload without affecting ventricular volume.

Transesophageal Echocardiography in Aortic Stenosis

The short-axis view of the aortic valve during systole can provide both a diagnosis and the mechanism of aortic stenosis. All three cusps of the aortic valve should be identified during systolic excursion. In degenerative calcification, the systolic orifice becomes smaller as the leaflet cusps become calcified, thickened, and deformed, resulting in a decreased ability to separate. In contrast, rheumatic valve calcification is along the commissures resulting in fusion and a progressive decrease in the valve orifice area. Although the rheumatic process usually involves the mitral valve, it can simultaneously or in isolation affect the aortic valve. A bicuspid aortic valve occurs in 2% of the population and predisposes the individual to aortic stenosis, as well as aortic regurgitation and endocarditis. Frequently, bicuspid valves have a raphe in the large cusp, which may be mistaken as a commissure during diastole. Trileaflet valves, if heavily calcified and fibrotic, may be indistinguishable from biscuspid valves.

The systolic AVA can be accurately estimated by planimetery. In the midesophageal aortic valve long-axis view, a systolic leaflet separation >1.3 cm reliably excludes severe aortic stenosis. Associated 2D findings with aortic stenosis may include concentric hypertrophy of the LV, left ventricular diastolic dysfunction, and a poststenotic aortic root dilatation that can become severe enough to require surgical correction.

Doppler interrogation across the stenotic aortic valve permits determination of the pressure gradient and AVA. Color flow Doppler across a stenotic aortic valve will show a mosaic of aliased turbulent flow. In about 90% of the patients, the deep transgastric long-axis view allows excellent alignment of the ultrasound beam with aortic blood flow angle (<30). If this view cannot be obtained, rotation to an angle between 60° to 120° from the transgastric midpapillary short-axis view may align the ultrasound beam with the aortic blood flow. Using the modified Bernoulli equation ($4V^2$ = pressure gradient), the peak and mean aortic valve gradients can be determined from the peak and mean blood flow velocities across the stenotic valve. It is important to note that the cardiac catheterization data frequently report the left ventricular peak to aortic peak pressure gradient. These pressures occur at different times in the cardiac cycle, and the gradient is consistently less than the peak instantaneous gradient measured by Doppler. However, the mean gradients measured by echocardiography and catheterization should be the same. The pressure gradient depends on the flow through the orifice. The severity of the stenosis may be underestimated if the cardiac output is reduced; conversely, it is overestimated if flow is increased from aortic regurgitation or inotropic support. If one of these scenarios is suspected, the AVA should be calculated using the continuity equation (Fig. 31-13).[61] The continuity equation assumes the flow across any two orifices should be the same. In this case, LVOT flow equals aortic valve flow. Doppler-derived flow measurements are the product of the velocity time integral

(VTI) and the area of the orifice. The VTI of the LVOT is measured with pulsed Doppler, whereas the LVOT diameter is measured with 2D echocardiography. Continuous-wave Doppler can measure the peak velocity through the stenotic lesion. The AVA is then calculated from the continuity equation:

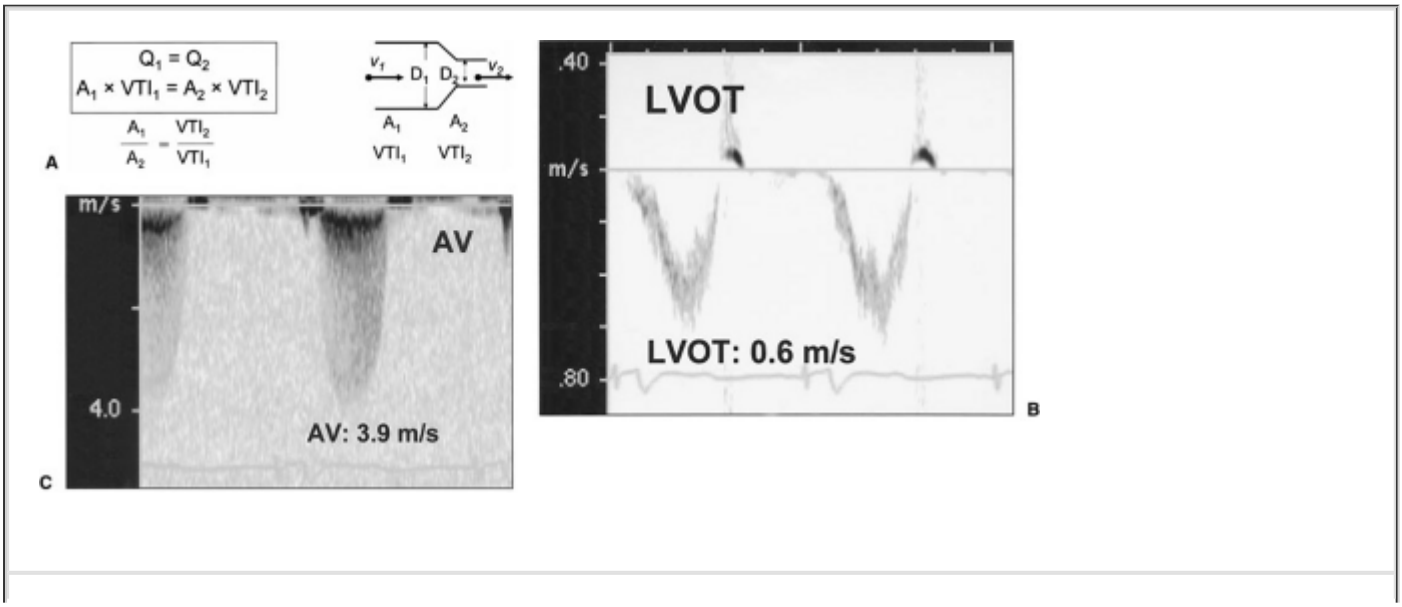

FIGURE 31-13. Transesophageal echocardiography (TEE) in aortic stenosis. **A.** The continuity equation calculates the orifice of a stenotic aortic valve, using the concept of conservation of flow. The volume across any orifice is the product of the orifice area (A) and the integral of its velocity (VTI). Therefore, flow Q_1 across an orifice with diameter D_1 and surface A_1 has a velocity v_1 and VTI_1 and is equal to flow Q_2 across an orifice with diameter D_2, surface A_2, and velocity v_2 and VTI_2. By rearranging the continuity equation, $A_2 = (A_1 \times VTI_1), VTI_2$. **B, C.** If A_1 is the orifice of the left ventricular outflow tract (LVOT) and A_2 is the orifice of the aortic valve (AV), then area of AV = $(LVOT \times VTI_{LVOT}), VTI_{AV}$. Because the flow duration across the LVOT and the AV is the same, VTI can be replaced by AVA = LVOT × (V_{LVOT}, V_{AV}). The AVA is inversely related to the VTI (or v) ratio of the LVOT and the AV. In the above TEE pictures, the LVOT velocity is 0.6 m/s **(B)**, the AV velocity is 3.9 m/s **(C)**, and the LVOT diameter was measured 2.12 cm. The continuity equation calculated an AVA of 0.54 cm^2. In general, if the ratio $Vmax_{AV}/Vmax_{LVOT}$ is >4, then the AVA is probably <1 cm^2 (assuming an LVOT diameter of ~2 cm).

$VTI_{AV} \times Area_{AV} = VTI_{LVOT} \times Area_{LVOT}$

$Area_{AV} = VTI_{LVOT} \times Area_{LVOT}/VTI_{AV}$

The severity of aortic stenosis can be estimated by employing these echocardiographic modalities and the grading criteria outlined in Table 31-6.

TABLE 31-6 Echocardiographic Findings in Aortic Stenosis

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (or idiopathic hypertrophic subaortic stenosis or asymmetric septal hypertrophy) is a genetically determined disease characterized by histologically abnormal myocytes and myocardial hypertrophy developing a priori, in the absence of a pressure or volume overload. The hypertrophic LV is not dilated.[62]

Pathophysiology

The physiologic consequences of hypertrophic cardiomyopathy (similar to those detailed for aortic stenosis) are depicted in Figure 31-14. Some degree of subvalvular obstruction is present in 20 to 30% of patients. During systole, the left ventricular outflow tract is narrowed by apposition of the hypertrophic interventricular septum to the anterior leaflet of the mitral valve. Blood is ejected rapidly through this area, creating a Venturi effect, and the anterior mitral valve leaflet is pulled even closer to the septum (systolic anterior motion [SAM]). The timing and duration of septal–leaflet contact determine the severity and clinical significance of the obstruction: early, prolonged contact can generate pressure gradients of 100 mm Hg. If the apposition occurs later, it is of little importance, even if a pressure gradient still exists, because most of the stroke volume has already been ejected. This type of obstruction is dynamic, and is accentuated by any intervention that reduces ventricular size. Therefore, increases in contractility and heart rate or decreases in either preload or afterload are harmful because they facilitate septal–leaflet contact. Another hypothesis proposed for systolic anterior motion of the mitral valve is an abnormally displaced mitral apparatus. The systolic anterior motion of the anterior mitral valve leaflet results in a posteriorly directed mitral regurgitation jet.

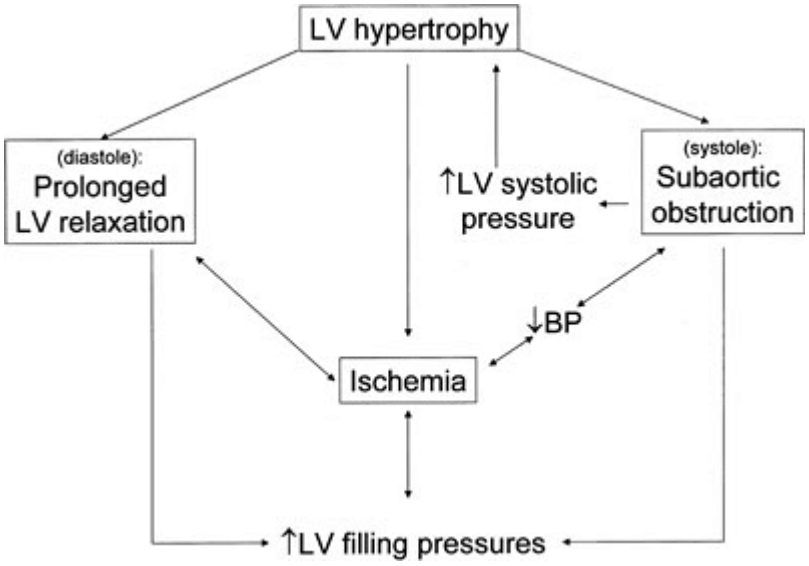

FIGURE 31-14. The physiologic interrelationships of primary left ventricular hypertrophy in hypertrophic cardiomyopathy. LV, left ventricle; BP, blood pressure.

The ventricles are hypertrophic, even in the absence of a pressure gradient. In addition, there is evidence of alterations in the small intramyocardial vessels. As expected, myocardial oxygen balance is tenuous, and the development of ischemia is an ever-present possibility.

Anesthetic Considerations

Treatment options for HCM include alcohol ablation of the interventricular septum, dual-chamber cardiac pacing, and septal myectomy. Anesthetic management for patients undergoing septal myectomy focuses on maintenance of ventricular filling and reduction in the factors predisposing to outflow tract obstruction or ischemia (Table 31-7). Myocardial depression is desirable, and volatile anesthetics are useful, although their

tendency to cause junctional rhythm is of some concern. Because of the dependence of preload on atrial contraction, these patients will benefit from atrial pacing if junctional rhythm occurs. Methods to achieve this include transesophageal pacing or use of a pulmonary artery catheter with pacing capability. This permits the administration of volatile anesthetics without fear of compromising sinoatrial conduction. In addition, control of atrial rate and rhythm is beneficial during the prebypass period.

TABLE 31-7 Hypertrophic Cardiomyopathy— Hemodynamic Goals

P	Full, one of first treatments for hypotension
A	Increased: treat aggressively if hypotension
C	Prefer depression
R	Normal range

Rhythm	Sinus rhythm crucial. Atrial pacing modalities (PA cath, transesophageal) may be helpful
M $\dot{V}O_2$	Not a problem
CPB	Start with volume and vasoconstrictors: avoid inotropes. Check carefully for residual gradient and SAM

A, afterload; C, contractility; CPB, cardiopulmonary bypass; M $\dot{V}O_2$, myocardial oxygen consumption; P, preload; PA, pulmonary artery; R, rate; SAM, systolic anterior motion of the mitral valve.

Although infrequent, hypertrophic cardiomyopathy occasionally coexists with valvular aortic stenosis and may explain unanticipated difficulties in separating from bypass following seemingly uncomplicated aortic valve replacement. If this is suspected, measurement of the gradient between the LV and the outflow tract will resolve this dilemma. In addition, dynamic left ventricular outflow obstruction is occasionally observed following mitral valve repair. In this case, anterior septal motion of the mitral valve can be observed echocardiographically. Pharmacologic management of hypotension is with volume replacement and vasoconstrictors rather than inotropes and vasodilators.

Aortic Insufficiency

Aortic valve insufficiency is the result of annular dilatation or abnormal leaflet motion.[63] Annular dilatation can occur with aneurysms or dissections of the ascending aorta. Because the aortic cusp area is 40% greater than the cross-sectional area of a normal aortic root, small increases in the diameter of the aortic annulus can be accommodated before the valve becomes incompetent. Abnormal leaflet motion and coaptation can be noted with calcific degeneration, rheumatic disease, bicuspid aortic valves, and endocarditis.

Pathophysiology

The fundamental physiologic derangement is chronic volume overload (Fig. 31-15). Chamber size increases gradually, sometimes to massive proportions, increasing wall stress and inducing mural hypertrophy. The chamber enlargement is of a greater magnitude than the increase in ventricular wall thickness and is termed *eccentric hypertrophy.* Despite the enormous increases in end-diastolic volume, end-diastolic pressures are usually within the normal range, evidence of a significant increase in chamber compliance. As a result, and in contrast to aortic stenosis, considerable alterations in left ventricular volume can occur with only minimal changes in left ventricular filling pressure. Although the ventricle may pump three to four times the normal cardiac output, M $\dot{V}O_2$ does not increase extraordinarily because the oxygen cost for muscle shortening is low. The diastolic runoff and the moderate vasodilation reduce the ventricular afterload. This will allow patients to be relatively symptom-free even when contractility is reduced so it is difficult to evaluate the myocardial contractile state from clinical signs and symptoms. This is important in terms of planning the anesthetic, but perhaps even more so with respect to the timing of aortic valve replacement. Ideally, the valve should be replaced just prior to the onset of irreversible myocardial damage. Therefore, continued follow-up of these patients emphasizes repeated noninvasive measurements of contractility, usually after some form of afterload stress, either pharmacologic-induced or exerciseinduced.

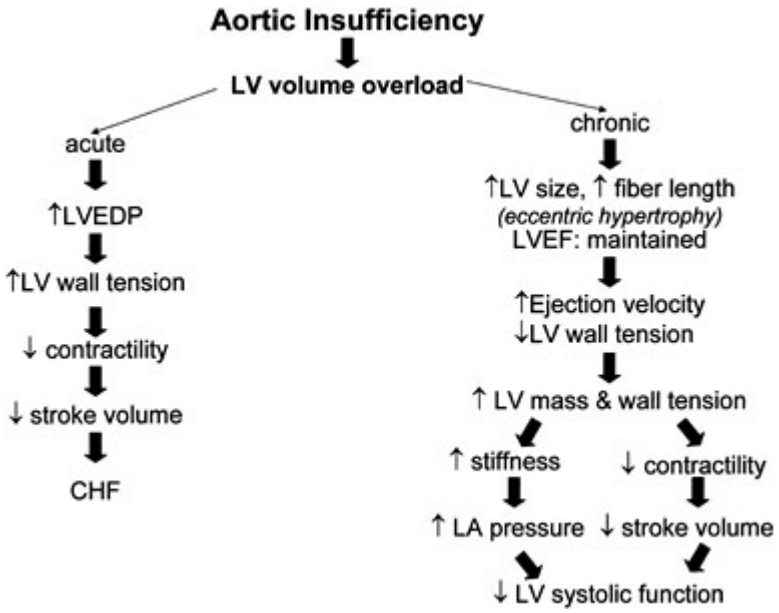

FIGURE 31-15. The physiologic consequences of aortic insufficiency. CHF, congestive heart failure; LA, left atrium; LV, left ventricle; LVEDP, left ventricular end-diastolic pressure; LVEF, left ventricular ejection fraction.

In acute aortic insufficiency the previously normal-size and normally compliant LV is presented with a large regurgitant volume. As a result left ventricular end-diastolic pressure rises rapidly (along the steep portion of the diastolic pressure–volume relation). Severe congestive heart failure is the cardinal clinical sign (Table 31-8). Myocardial contractility becomes impaired as left ventricular end-diastolic pressure increases. Compensatory mechanisms include tachycardia and peripheral vasoconstriction, but occasionally hypotension and low cardiac output ensue. In acutely ill patients, emergency aortic valve replacement is required, whereas in less severe circumstances mild systemic vasodilation and inotropic support can return hemodynamics toward normal.

TABLE 31-8 Acute versus chronic aortic insufficiency

	·CHRONIC	·ACUTE
Left ventricular size	↑	—
Left ventricular compliance	↑	—
Left ventricular end-diastolic pressure	—	↑
Effective cardiac output	Normal	↓
Systemic vascular resistance	—	↑
Pulmonary edema	No	Yes

Pulse pressure	↑	↑
Heart rate	—	↑

↑, increase; ↓, decrease; —, no change.

Anesthetic Considerations

10 Full, mildly vasodilated, and modestly tachycardic describe the optimal cardiovascular state for patients with aortic insufficiency (Table 31-9). Vasodilation promotes forward flow, although additional intravascular volume may be necessary to maintain preload. The ideal heart rate is somewhat controversial. It is likely that changes in heart rate alone will not alter forward or regurgitant flow; each will be proportionately reduced. Tachycardia reduces the diastolic run-off from the aorta to the LV and results in a reduction of the ventricular volume and wall tension, and increase in the diastolic blood pressure and coronary perfusion gradient, offsetting any increase in oxygen demand secondary to an increased heart rate.

Bradycardia should be avoided as it results in ventricular distention and elevations in left atrial pressure and pulmonary congestion.

TABLE 31-9 Aortic Insufficiency—Hemodynamic Goals

P	Normal to slightly ↑
A	Reduction beneficial with anesthetics or vasodilators; increases augment regurgitant flow
C	Usually adequate
R	Modest tachycardia reduces ventricular volume, raises aortic diastolic pressure
Rhythm	Usually sinus; not a problem
M $\dot{V}_{O_2}$	Not usually a problem
CPB	Observe for ventricular distention (↓ HR, ↑ VFP) when going onto CPB

P, preload; A, afterload; C, contractility; R, rate; M $\dot{V}o_2$, myocardial oxygen balance; CPB, postcardiopulmonary bypass; HR, heart rate; VFP, ventricular filling pressure.

Ventricular distention may occur with the onset of CPB if the heart rate slows or if there is unexpected ventricular fibrillation. Monitoring of the heart size, rate, rhythm, and ventricular filling pressure are especially important in these patients. If distention occurs, the insertion of a left ventricular vent or the immediate application of an aortic cross-clamp should relieve the problem. The presence of moderate to severe aortic insufficiency (AI) affects the surgeon's approach to CPB. An incompetent aortic valve may prevent the delivery of cardioplegia to the coronary system to produce diastolic arrest of the heart. After application of the aortic cross-clamp, the cardioplegia is normally injected into the aortic root, delivering this solution to the coronary system, producing a diastolic arrest of the heart. If moderate to severe AI is present, the cardioplegia will fill and distend the LV, increasing the ischemic insult incurred during CPB. As a result, in the presence of AI the surgeon may elect to arrest the heart by injecting cardioplegia directly into the coronary ostia or the coronary sinus.

Transesophageal Echocardiography in Aortic Insufficiency

Echocardiographic examination will demonstrate the structural findings associated with aortic regurgitation mentioned previously and the effects of volume overload on the LV. Doppler will identify the aortic regurgitant jet, localize its site, and help grade its severity (Table 31-10 and Fig. 31-16).

TABLE 31-10 Echocardiographic Findings in Aortic Insufficiency

·2D	
• Valve anatomy and structural deformities	Perforations, vegetations in endocarditis
• Leaflet motion, coaptation	Usually abnormal, flail leaflet, wide coaptation defect
• LV size	Normal (acute AI), significantly enlarged (severe AI)
·DOPPLER	
• Color flow	

• Regurgitant flow	
• Ratio AI jet width/LVOT diameter	<25% in mild (1+), ⩾ 65% in severe (4+)
• Continuous wave	Diastolic jet deceleration (PHT): >500 msec in mild, <200 msec in severe
• Pulsed wave	Thoracic aorta flow: brief, early reversal (mild AI), prominent holodiastolic (severe AI)
2D, two-dimensional; AI, aortic insufficiency; LV, left ventricle; LVOT, left ventricular diameter; PHT, pressure half time.	

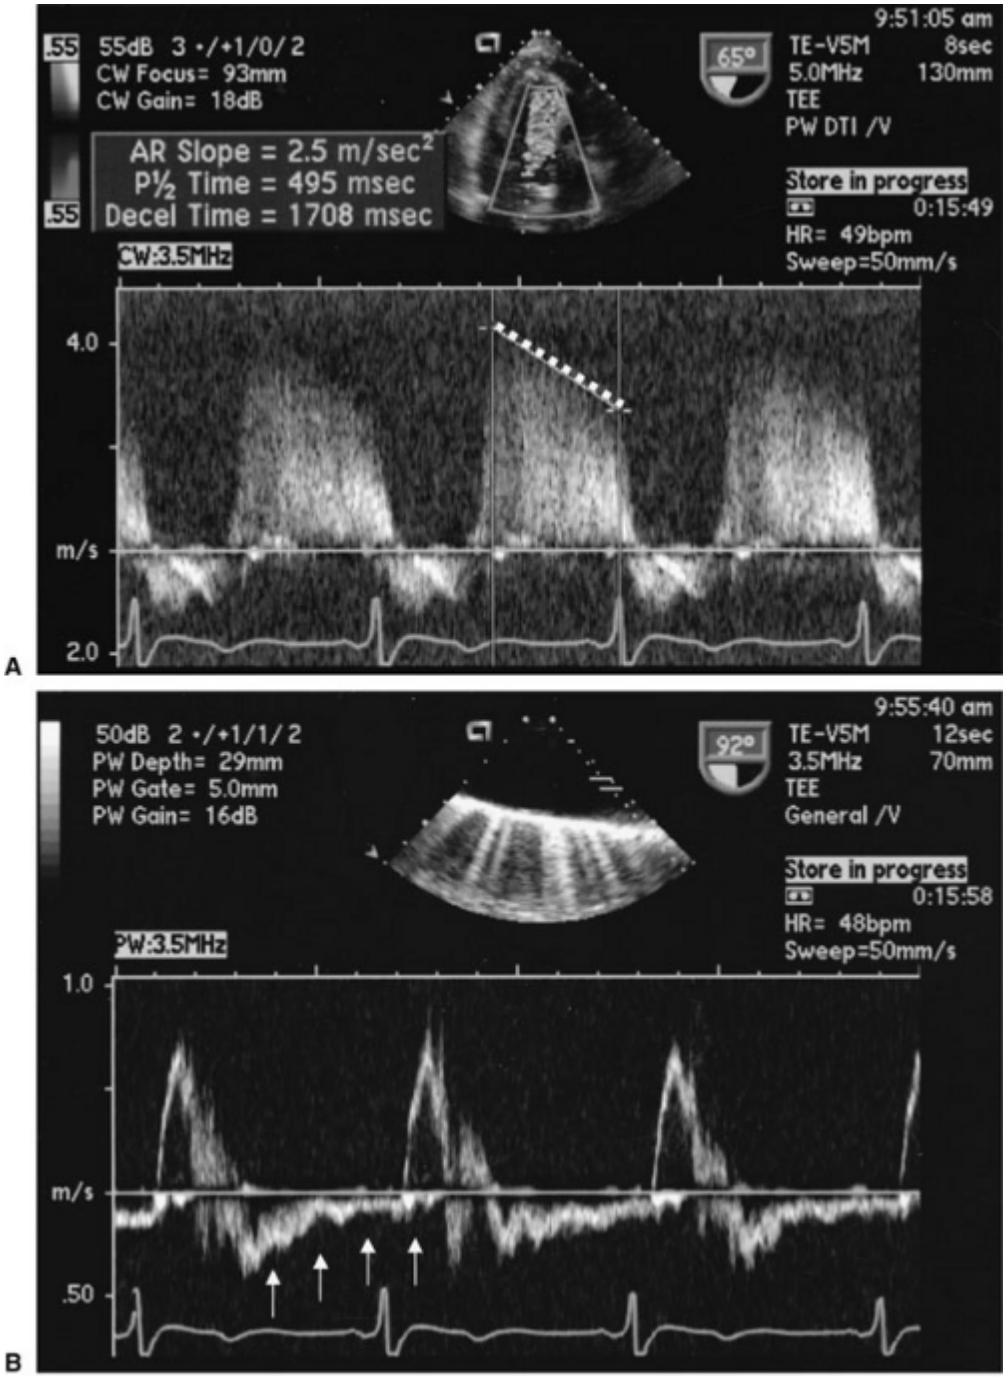

FIGURE 31-16. Transesophageal echocardiography (TEE) in aortic insufficiency. **A.** Continuous wave Doppler across the jet of aortic insufficiency (AI) typically demonstrates a pandiastolic flow signal (the systolic portion is forward flow across the aortic valve). The peak velocity in early diastole corresponds to the peak aortic to left ventricular diastolic pressure gradient as defined by the modified Bernoulli equation ($P = 4v^2$). The slope or decay of this pressure gradient reflects the severity of AI. When AI is severe, the equilibration of pressure between the aorta and the left ventricle is rapid and the PHT (the time it takes for the pressure gradient to decrease by 50%) shorter. With less severe AI, the equilibration of pressures between the aorta and the left ventricle is slower, resulting in a relatively flat slope and a prolonged PHT. **B.** Aortic diastolic flow reversal. Flow reversal is best recorded with pulsed wave Doppler in the lower descending aorta. As AI increases in severity, the duration and the velocity of the flow reversal (*arrows*) increase.

Accurate evaluation of aortic insufficiency is essential in determining the feasibility of performing an AV repair. Successful AV repairs are often performed during repair of aortic dissections and

have been reported with aneurysms and bicuspid aortic valves.

Mitral Stenosis

Stenosis of the mitral valve (MV) is usually of rheumatic origin, and clinical symptoms develop within 3 to 5 years following initial infection. Debilitating symptoms such as fatigue and dyspnea on exertion do not begin for another decade or two.

Pathophysiology

The spectrum of physiologic disruption in patients with mitral stenosis is presented in Figure 31-17. Distal to the obstructed MV and unlike any other valvular lesion, the LV is not subjected to either pressure or volume overload. It is small, relatively underloaded, with preserved systolic function. However, one-third of patients may demonstrate contractile abnormalities on angiography, presumably as a result of rheumatic carditis or involvement of the subvalvular apparatus. Proximally, the narrowed MV orifice results in increased left atrial pressure (LAP) and volume.

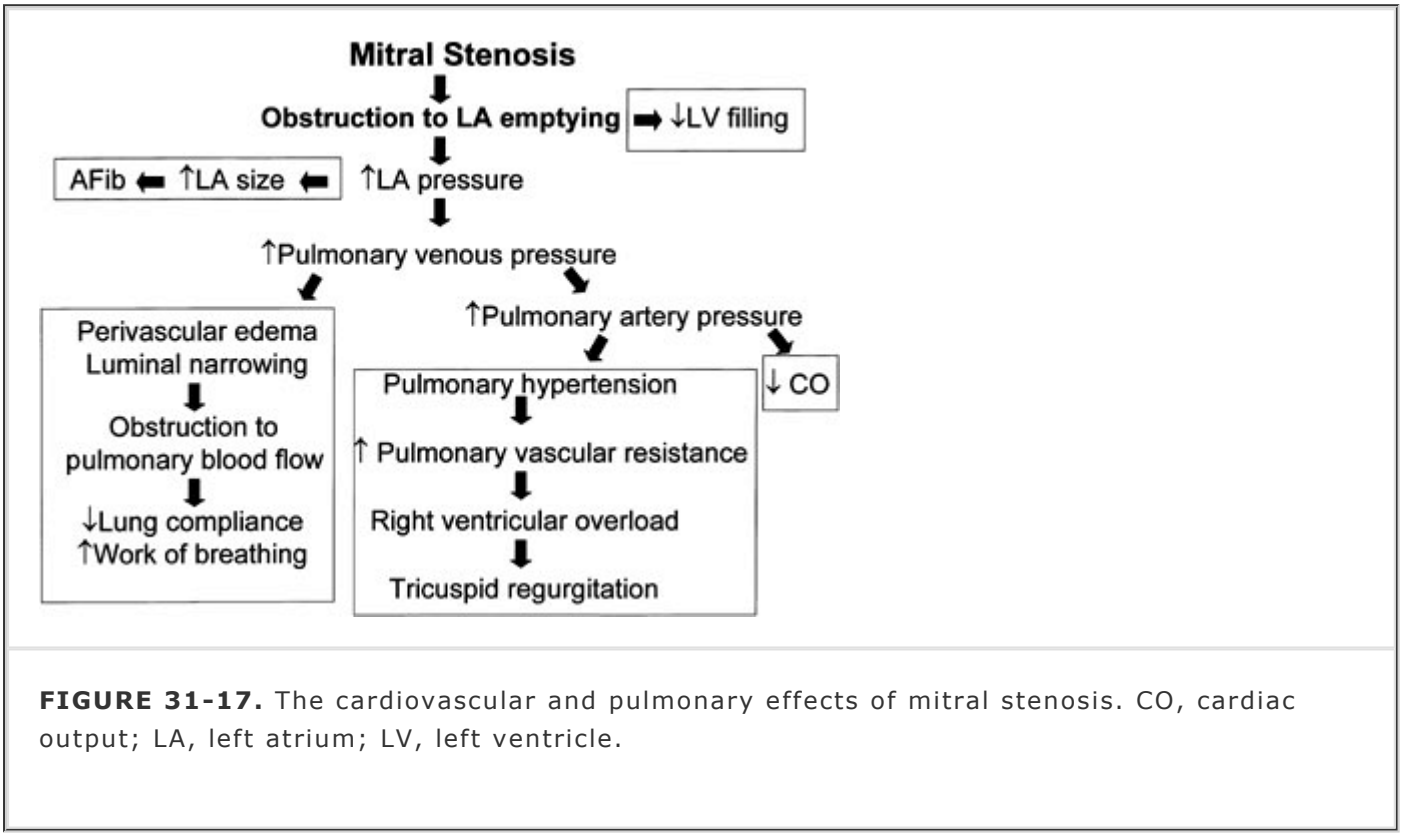

FIGURE 31-17. The cardiovascular and pulmonary effects of mitral stenosis. CO, cardiac output; LA, left atrium; LV, left ventricle.

The relationship between LAP and the size of the MV orifice area (MVA) is expressed in the formula derived by Gorlin and Gorlin:

$$\text{Valve area} = \text{flow}/\text{K} \cdot \sqrt{(\text{pressure gradient})}$$

where flow (i.e., flow during time that MV is open) is cardiac output/diastolic filling time; pressure gradient is LAP minus left ventricular diastolic pressure (LVDP); and K is the hydraulic pressure constant. This calculation assumes no regurgitant flow. If we consider a constant MVA, rearrange terms, and eliminate the constant, we have a more useful expression of the clinical variables determining atrial and ventricular pressures:

$\text{LAP - LVDP} = [(\text{cardiac output})/(\text{diastolic time})]^2$

Therefore, whenever cardiac output increases or the diastolic filling period decreases, the gradient across the MV is altered by the square of the original changes. This explains why tachycardia or increases in forward flow, seen classically with pregnancy, thyrotoxicosis, or infection, can precipitate pulmonary edema. As LAP increases, left ventricular filling pressure may actually decrease. Thus, the development of atrial fibrillation causes hemodynamic embarrassment, not so

much because of the loss of atrial kick but because of the rapid rate that ensues.

In mitral stenosis, the paradoxical situation exists of a patient in pulmonary edema with a relatively empty LV. Therefore, the treatment is not inotropic or vasodilator therapy, but rather attempts to reduce the heart rate or diagnose and treat the cause responsible for the increased flow. The pulmonary capillary wedge pressure can be used as an index of left ventricular filling, even during episodes of tachycardia or increased flow, keeping in mind that it is higher than the true left ventricular end-diastolic pressure, at least by the amount of the pressure gradient.

Upstream from the LA, the persistently elevated LAP is reflected through the pulmonary circulation, leading to right ventricular pressure overload with compensatory right ventricular hypertrophy and elevated strain. The progression and severity of pulmonary hypertension are variable and reflect further narrowing of the valve orifice and irreversible reactive changes in the pulmonary vasculature. Right ventricular dysfunction may develop in response to this increase in afterload. Tricuspid annular dilatation and insufficiency may result from this hemodynamic nightmare.

Chronically elevated LAP causes perivascular edema in the lung, increased vascular pressure in the dependent portions of the lung, redistribution of blood to the upper lung fields, and an increased work of breathing.

Anesthetic Considerations

Preemption is the cornerstone of prebypass anesthetic management (Table 31-11). Avoiding tachycardia precludes episodes of left atrial and pulmonary hypertension with potential right ventricular dysfunction, as well as inadequate left ventricular filling with concomitant systemic hypotension. Preoperative maintenance of digitalis and beta-blocking drugs, selection of anesthetics with no propensity to increase heart

rate, and attainment of anesthetic levels deep enough to suppress autonomic responses are methods to achieve these goals. Episodes of pulmonary hypertension and potential right-sided heart failure stemming from pulmonary vasoconstriction must also be prevented. It is wise to avoid hypoxia, hypercarbia, and acidosis because they increase pulmonary vascular resistance.

TABLE 31-11 Mitral Stenosis—Hemodynamic Goals

P	Maintain, avoid hypovolemia
A	Prevent pulmonary vasoconstriction (hypoxia, hypercarbia) Inotropes may be required for systemic hypotension
C	Usually okay. RV dysfunction may be a problem with long-standing pulmonary hypertension
R	Low end of normal. Avoid tachycardia
Rhythm	Keep ventricular response controlled in atrial fibrillation
M $\dot{V}O_2$	Not a problem

CPB	LV seeing higher preloads—filling pressures may be elevated. Heart not immediately "better"

A, afterload; C, contractility; CPB, cardiopulmonary bypass; LV, left ventricle; M $\dot{V}O_2$, myocardial oxygen consumption; P, preload; R, rate; RV, right ventricle.

Treatment of hypotension in patients with mitral stenosis can present a challenging dilemma. Although these patients normally take diuretics, hypovolemia is not usually the cause; hence, the response to volume administration is often disappointing. Use of a vasoconstrictor to offset mild peripheral vasodilation is acceptable, bearing in mind the effect of pulmonary vasoconstriction on right ventricular function. It is often prudent to select a drug with some inotropic effect such as ephedrine or epinephrine instead of relying on a pure vasoconstrictor, such as phenylephrine. In separating from CPB, much is made of right ventricular failure (discussed subsequently); more commonly, however, it is the LV that is dysfunctional. This may be because of intraoperative injury or sudden increase in flow to and distention of the chronically underloaded LV. After bypass, prominent V waves may be present in the left atrial pressure curve. This almost always reflects increased left atrial filling from the right side rather than mitral regurgitation because cardiac output is increased after bypass when compared with preinduction values.

Transesophageal Echocardiography in Mitral Stenosis

The normal MV consists of a semilunar-shaped anterior leaflet, comprising two-thirds of the total MV surface area and neighboring the noncoronary aortic cusp and a crescent-shaped posterior leaflet. The leaflets are composed of thin, flexible, fibrous tissue, thicker in the base and tips and thinner in their centrum, and are connected to each other at the anterolateral and posteromedial commissures (the closure "lines" of the two mitral leaflets). The mitral annulus is D-shaped, and the posterior leaflet is continous with the atrial and the ventricular myocardium, making this leaflet more pone to being displaced when either chamber enlarges. During diastole, the leaflets open and "drop" inside the LV, forming a funnel-shaped orifice, 4 to 6 cm^2 in diameter. In systole, the LV systolic pressure and the contraction of the two papillary muscles cause the two leaflets to coapt along their free edges. Strong, fibrous cords (chordae tendinae) connected to the anterolateral and posteromedial papillary muscles, create a tensor mechanism and prevent the prolapse of the closed leaflets into the LA during systole.

The grading of the severity of mitral stenosis is outlined in Table 31-12. The echocardiographic signs of mitral stenosis are seen in Figure 31-18.

TABLE 31-12 Echocardiographic Findings in Mitral Stenosis

▪MODALITY	▪MILD MS(MVA > 1.5 cm^2)	▪SEVERE MS(MVA < 1 cm^2)
▪2D		

•Valve anatomy and structural deformities •Leaflet motion, coaptation	Thickened, calcified, diastolic doming
•Left atrium	In severe MS (MVA <1 cm^2): dilated with spontaneous echo contrast and/or thrombus in left atrial appendage
•Right ventricle	In severe MS: signs of failure (dilatation, tricuspid regurgitation, pulmonary hypertension)
·DOPPLER	
•Continuous wave	
•Diastolic deceleration (PHT) •Mean transmitral pressure gradient	Fast: <150 msec (mild MS), slow: >220 msec (severe MS) Low: <6 mm Hg (mild MS), high: >12 mm Hg (severe MS)
2D, two-dimensional; MS, mitral stenosis; MVA, mitral valve area; PHT, pressure half time.	

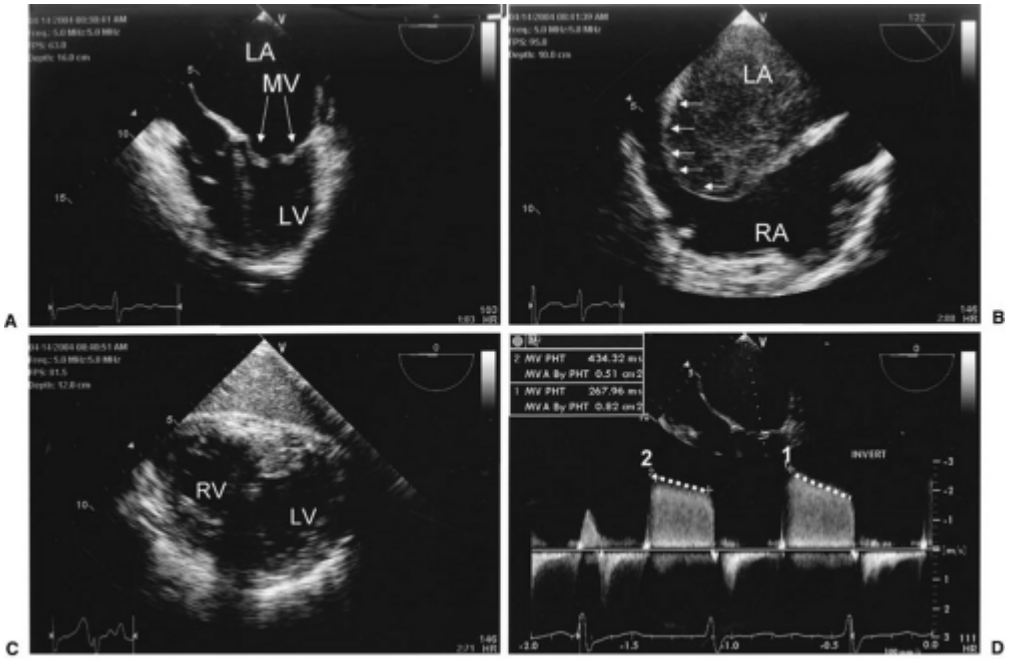

FIGURE 31-18. Echocardiographic signs of mitral stenosis. **A–C.** Two-dimensional echocardiography. **A.** Midesophageal four-chamber view. The mitral valve (MV) leaflets (*arrows*) appear thickened and barely separate in diastole. Left atrium (LA) size is increased. **B.** Midesophageal bicaval view. LA pressure is much higher than the right atrium (RA)

pressure: interatrial septum (*arrows*) bulges towards the RA. There is sluggish blood flow that presents as vague, diffuse echo contrast ("smoke"). **C.** Transgastric short-axis view. The left ventricle (LV) is underfilled, small in size and the right ventricle (RV) demonstrates hypertrophy (pressure overload). **D.** Continuous wave Doppler echocardiography across the MV. The mitral valve area (MVA) is calculated using the pressure half-time method (PHT). Notice the dependence of the method on the duration of the diastolic period: beat 2 (which is shorter than beat 1 in this patient with atrial fibrillation and variable R-R interval) has a longer PHT and a smaller calculated MVA than beat 1.

Mitral Regurgitation

Mitral regurgitation (MR) results from several mechanisms permitting blood to flow from the LV to the LA during systole. Mechanical etiologies of MR include annular dilatation (chronic ischemic heart disease), leaflet prolapse, restricted leaflet motion (rheumatic heart disease), and leaflet perforation (endocarditis). Acute MR occurs with papillary muscle dysfunction or chordal rupture following myocardial infarction and may require emergency surgical repair[64] (Table 31-13).

TABLE 31-13 Etiologies of Mitral Regurgitation

	·ETIOLOGY	·CHARACTERISTICS	·LOCATION
Primary (structural)	MV prolapse	Myxomatous degeneration	Leaflet
	Redundant tissue	Ruptured chordae	Leaflet
	Rheumatic	Thickened, calcified, restricted leaflets	Leaflet
		Commissural fusion	Leaflet
	Congenital	Cleft MV, double orifice MV	Leaflet
	Miscellaneous	Fenfluramine	Leaflet
	Endocarditis	Perforated leaflets, vegetations	Leaflet
	Papillary muscle rupture	Post myocardial infarction	Tensor apparatus
Functional	Annular dilatation	Dilated cardiomyopathy	Annulus
	LV wall regional	Ischemic heart disease	Tensor

	ischemia		apparatus
LV, left ventricle; MV, mitral valve.			

Pathophysiology

Chronic volume overload similar to that described with AI is the cardinal feature of MR[65] (Fig. 31-19). The LA acts as a low-pressure vent during left ventricular ejection: there is no isovolumetric contraction period because blood is immediately ejected retrograde with the onset of ventricular systole. Total left ventricular stroke volume consists of the forward flow via the aorta and the retrograde flow into the LA. Atrial and ventricular chamber enlargement, ventricular wall hypertrophy, and increased blood volume are the compensatory responses. Ventricular compliance increases; thus, the large end-diastolic volume does not cause striking increases in left ventricular end-diastolic pressure. Despite progressive myocardial damage (decreased contractility), patients may have minimal symptoms because of reduced afterload. The increase in oxygen cost (required for additional muscle shortening) is small because there is little pressure development. Ejection fraction, a parameter heavily afterload dependent, can be misleading in patients with MR: normal or minimally reduced ejection fractions can be present even with severe impairment of contractile function. The regurgitant blood volume is related to the size of the regurgitant orifice, the time available for retrograde flow, and the pressure gradient across the valve. Regurgitant orifice size, in turn, depends on ventricular size. Therefore, both increases in heart rate and preload reduction decrease the amount of regurgitant flow by diminishing ventricular volume. Arteriolar

dilators are effective by reducing the ventriculoatrial pressure gradient.

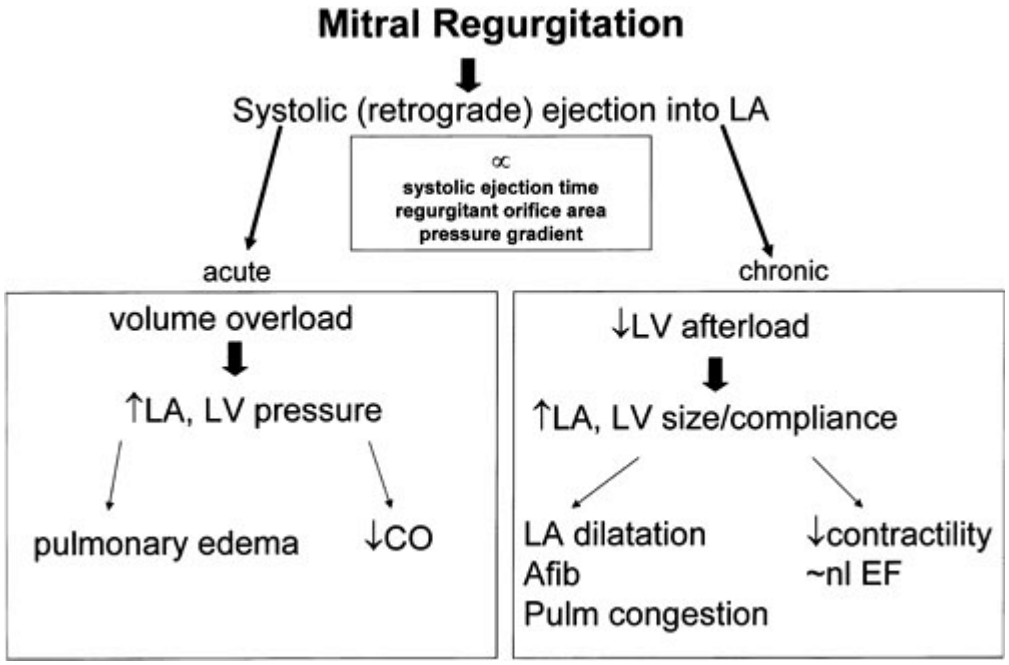

FIGURE 31-19. The physiologic consequences of mitral regurgitation.

Repairing or replacing the valve increases left ventricular afterload and that often unmasks the dysfunction of the myocardium. However, the decrease in left ventricular systolic function is mostly due to decreased preload after the correction of MR and does not necessarily indicate true impairement of left ventricular systolic performance. Administration of inotropes and/or vasodilators, as well as judicious increase in preload, may be necessary to successfully separate from bypass.

When MR is of acute onset, the hemodynamic picture is different. Volume overload of the LA and ventricle occurs in the absence of compensatory ventricular enlargement. Ventricular filling pressures increase dramatically, as do pulmonary pressures. Cardiac output decreases, and pulmonary edema develops. If this occurs in the setting of acute myocardial infarction, cardiac performance may be inadequate despite pharmacologic support. Intra-aortic balloon assistance and emergency surgery may be lifesaving.

Anesthetic Considerations

12 Selection of anesthetics that promote vasodilation and tachycardia is ideal in the patient with MR (Table 31-14). Active pharmacologic intervention is usually unnecessary because most patients are not teetering on the brink of myocardial failure. However, in some patients, especially those with acute MR, aggressive pharmacologic management may be required. In the absence of acute deterioration, difficulties in management are usually limited to the postbypass period. Paradoxically, after the administration of vasodilators and inotropes, a patient occasionally deteriorates even further. This is seen after valve repair, not replacement. In these patients, the pathophysiologic and clinical picture is that of hypertrophic cardiomyopathy, and systolic anterior motion of the anterior mitral leaflet is demonstrable by echocardiography. The risk of systolic anterior motion after repair is increased when the anteroposterior length of the anterior leaflet is longer than the transverse diameter, when there is excessive leaflet tissue, a nondilated LV cavity or/and a narrow angle between the mtitral and aortic annuli. If this scenario is suspected, a trial of volume expansion and vasoconstrictors is indicated.

TABLE 31-14 Mitral Regurgitation—Hemodynamic Goals

P	Usually slightly increased; however, preload reduction may reduce regurgitant flow
A	Decrease with anesthetics, vasodilators
C	May be depressed, titrate myocardial depressants carefully
R	Slightly increased
Rhythm	If atrial fibrillation present, control ventricular response
M $\dot{V}O_2$	Compromised if MR coexists with ischemic heart disease
CPB	Newly competent valve increases afterload, often necessitating inotropic support

A, afterload; C, contractility; CPB, cardiopulmonary bypass; MR, mitral regurgitation; M $\dot{V}O_2$, myocardial oxygen consumption; P, preload; R, rate.

Transesophageal Echocardiography in Mitral Regurgitation

The presence and severity of MR are major determinants of outcome in cardiac surgical patients. The etiology of the regurgitation and the accurate localization of the site of MR are two important factors in deciding if the mitral valve should be repaired or replaced. In the suitable patient population, a repair has become the treatment of choice. It avoids the morbidity associated with valvular prostheses and long-term anticoagulation, late valve-related events are lower, and there

is better long-term survival. Pathology localized to the posterior leaflet or to a focal portion of the anterior leaflet is most amenable to repair. Conversely, mitral repair is more difficult when there is heavy calcification of the annulus or extensive disease of the anterior leaflet of the MV. This has resulted in the desire for increasingly sophisticated TEE evaluation of mitral regurgitation.

Because of close proximity of the ultrasound probe to the MV, higher resolution, and multiplane capabilities, TEE is particularly well suited to identify the underlying mechanism of MR. Successful valve repair depends on accurate description of the location and identification of the mechanism of regurgitation. Therefore, precise and reliable functional information about the valve is necessary. A systematic TEE examination of the MV using standard, universally accepted, cross-sectional views is necessary.

The approach to evaluation of MR severity should integrate multiple parameters rather than depend on a single measurement (Table 31-15). It is also important to distinguish between the amount of MR and its hemodynamic consequences: a modest regurgitant volume that develops acutely into a small, noncompliant LA may cause severe pulmonary congestion and systemic hypotension. Conversely, some patients with chronic, severe MR remain asymptomatic due to compensatory mechanisms and a dilated, compliant LA. Maximum regurgitant flow rate, regurgitant orifice area, and proximal jet width provide the best results compared with contrast angiography, and they are superior to Doppler color flow jet area and pulmonary venous flow ratio, and should be systematically used whenever image quality is sufficient[66] (Fig. 31-20).

TABLE 31-15 Echocardiographic Findings in Mitral Regurgitation

▪MODALITY	▪MILD MR	▪SEVERE MR
▪2D		
•Valve and leaflet anatomy	Flail leaflet and ruptured papillary muscle (severe MR)	
•Left atrium	Enlarged (in severe but not acute MR)	
•Left ventricle	Enlarged in chronic, significant MR	
	Regional wall motion abnormalities, dysfunctional papillary muscle	
▪DOPPLER		
Color flow		
•Jet area (% LA area)	<4 cm^2 (<20%): mild MR, >10 cm^2 (>40%): severe MR	
•Vena contracta	<0.3 cm (mild MR), ⩾0.7 cm (severe MR)	
•EROA by PISA	<0.2 cm^2(mild MR), >0.4 cm^2(severe MR)	
Pulsed wave		
•Mitral inflow	Prominent atrial (A) wave	Dominant early (E) wave >1.2 m/sec
•Pulmonary venous flow	Systolic dominance (mild MR)	Systolic flow reversal (severe MR)
Continuous wave		
•Jet density	Incomplete, faint jet (mild MR)	Dense jet (severe MR)

2D, two-dimensional; EROA, effective regurgitant orifice area; LA, left atrium; MR, mitral regurgitation; PISA, proximal isovelocity surface area.

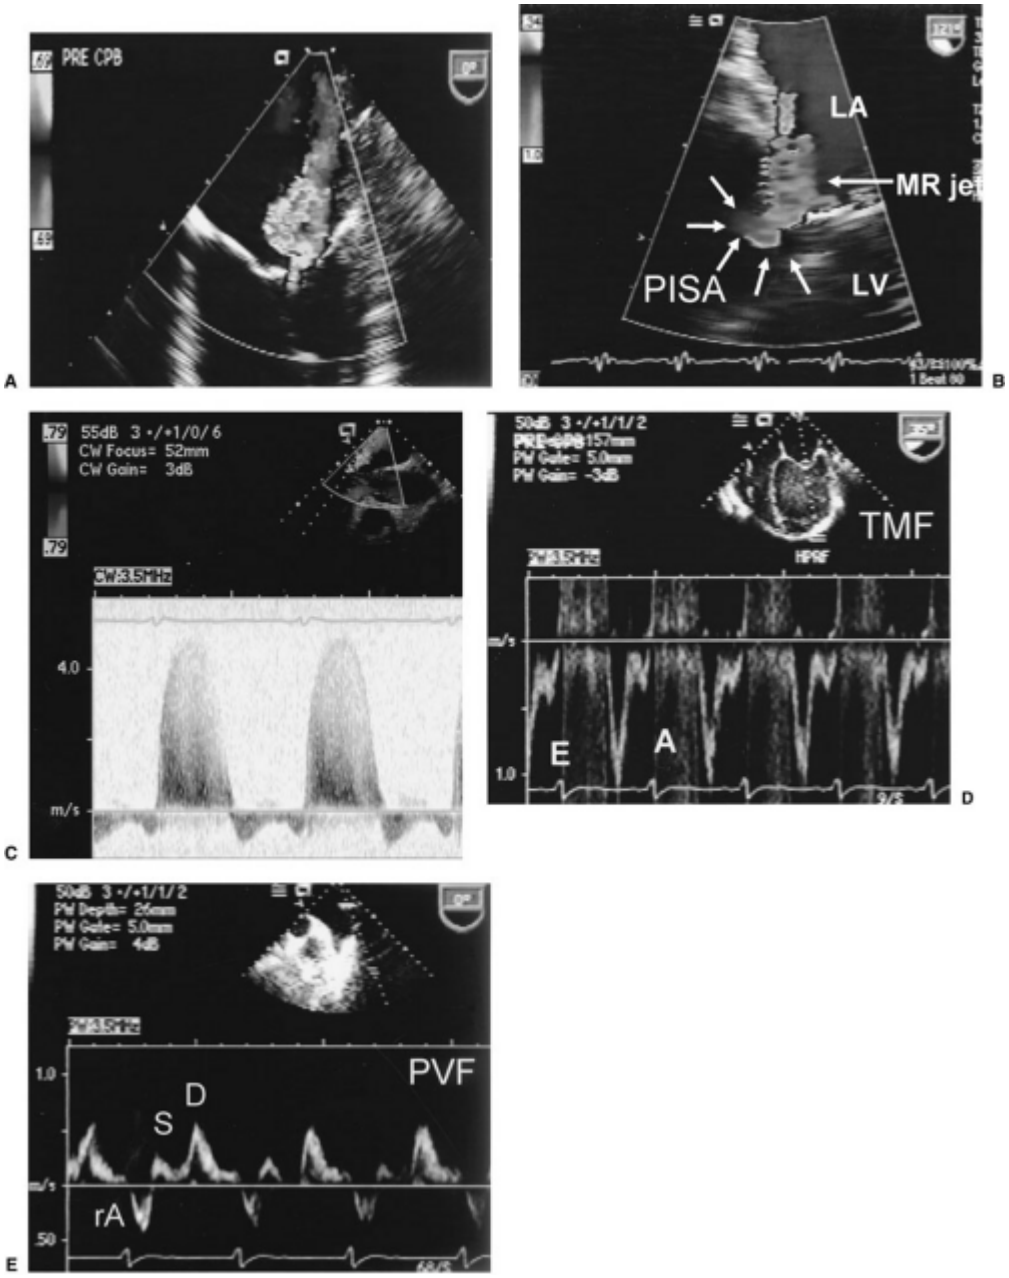

FIGURE 31-20. Echocardiographic evaluation of mitral regurgitation severity. **A.** Jet area: the visual examination of the mitral regurgitation (MR) jet by color Doppler flow is the most widely used method, but also the least accurate. More accurate measurements include width of the vena contracta and effective regurgitant orifice area (EROA) calculated from PISA. The vena contracta is the width of the neck (or narrowest portion) of the MR jet. It is often dynamic and may change during systole. **B.** Proximal isovelocity surface area (PISA): the PISA method is based on the principle of flow = velocity × area. As flow approaches an orifice, it forms concentric shells of decreasing surface area and increasing velocity. Doppler color flow mapping can depict such shells. The flow through any such hemispheric shell (*arrows*) equals its surface area π the velocity that defines the shell ($2\pi^2$ × [velocity]). The EROA is equal to PISA flow ÷ MR jet peak velocity. **C.** The maximal velocity and intensity of the MR jet are depicted with continuous wave Doppler. An early peaking, dense, triangular in shape MR jet characterizes severe MR. **D, E:** The hemodynamic effects of MR on the left ventricle (LV) filling are shown using pulsed wave Doppler recordings of the transmitral flow (TMF) and pulmonary venous flow (PVF). The increased gradient between the left atrium (LA) and the LV in early diastole gives rise to accelerated blood flow, whereas the atrial contraction fails to generate adequate velocity as it contracts against a full LV (E:A > 1). Therefore, retrograde flow into the pulmonary vein during atrial contraction (rA) is accentuated. During systole, the more severe the MR, the more the LA fills retrograde from

the LV, reducing pulmonary systolic (S) venous flow. During diastole, as the LA empties into the LV, blood enters from the pulmonary veins (S < D). Sampling through all pulmonary veins is recommended because the MR jet may selectively affect one or more pulmonary vein (s), depending on the orientation of the regurgitant jet. Elevation of LA pressure of any etiology (e.g., atrial fibrillation) also results in blunting of the systolic forward pulmonary vein flow.

CARDIOPULMONARY BYPASS

On May 6, 1953, Dr. John Gibbon, Jr., used CPB with an oxygenator to successfully close an atrial septal defect in an 18-year-old girl. This first successful use of CPB brought about the dawn of modern cardiac surgery. Since that day in 1953, technology has evolved but the fundamental components of the CPB machine remain unchanged.

Circuits

CPB systems require large-bore cannulae that drain systemic venous blood into a reservoir (Fig. 31-21). This is accomplished by placing a large two-stage cannula in the right atrium that drains blood from both the atrium and the inferior vena cava. This single cannula allows most venous blood to be drained into the CPB machine reservoir; however, some systemic venous return is able to enter the heart. In open cardiac chamber procedures such as valve surgery or when a bloodless field is required, separate cannulae are placed into the superior and

inferior vena cava directly. Caval snares can effectively prevent systemic venous blood from entering the heart.

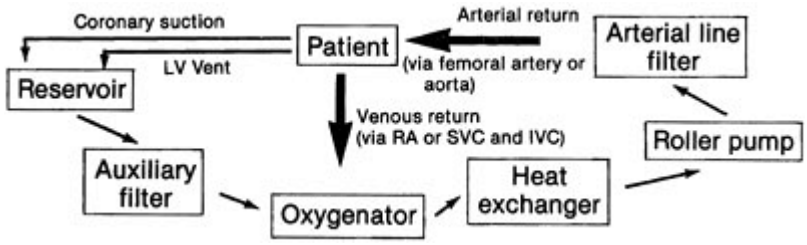

FIGURE 31-21. The basic circuit for cardiopulmonary bypass. IVC, inferior vena cava; LV, left ventricle; RA, right atrium; SVC, superior vena cava. (Reprinted with permission from Thomson IR: Technical aspects of cardiopulmonary bypass. In Thomas SJ (ed): Manual of Cardiac Anesthesia, 2nd ed, p 480. New York, Churchill Livingstone, 1993.)

During CPB, the rate of venous drainage depends on several factors. These include proper placement of the cannulas, intravascular volume, and the hydrostatic pressure gradient (height of the right atrium above the venous reservoir). CPB machines are low to the floor to create a greater potential difference in driving pressure between the right atrium and the venous reservoir.

In the event of poor venous drainage, this differential may be augmented by raising the height of the operating table. From this reservoir, the blood enters a heat exchanger/oxygenator where the blood is warmed/cooled and oxygenated, and carbon dioxide is removed. The now oxygenated blood is returned to the arterial circulation via another large cannulae, and the cycle continues for the duration of CPB. Arterial cannulas may be placed in the ascending aorta, femoral, or axillary arteries. Surgeon preference, patient anatomy, and surgical procedure will dictate the location of the arterial cannula.

In addition to systemic venous blood, additional sources of blood may be returned back to the CPB machine. Coronary suction scavenges waste blood from the surgical field. Vents are used to decompress the LV and aspirate air from the heart during de-airing procedures. Ventricular venting is particularly important in patients with aortic insufficiency, large coronary sinus or bronchial blood flow, or when heart positioning restricts drainage. Venting prevents the development of myocardial ischemia secondary to ventricular distention. Common vent sites include the left superior pulmonary vein across the MV into the LV, the LV apex, or cardioplegia cannula in the aortic root. In the event of acute ventricular distention, the surgeon may make a stab wound in the LV apex to decompress a rapidly dilating heart.

In addition to the basic components, modern CPB systems have extra optional components. These include bubble and debris filters on the arterial side of the circuit, inline blood gas monitoring, separate circuits to deliver cardioplegia, and volatile agent vaporizers. In addition, monitors may be placed in key locations in the circuit to detect problems such as low blood levels in the oxygenator (to prevent pumping of air to the arterial side of the circuit) and systemic line pressure (to detect possible arterial cannula obstruction/aortic dissection).

Oxygenators

Oxygenators serve two main purposes: (1) to oxygenate deoxygenated venous blood and (2) to remove carbon dioxide. Older bubble oxygenators are very efficient and work on the principle of direct gas–blood contact. Oxygen is relatively insoluble compared with carbon dioxide and requires either a high partial pressure or a large surface area to ensure diffusion. This surface interaction is the source of its efficiency. By altering the size of the bubbles, the total surface area of the interface may be altered (i.e., smaller bubbles, larger interface). This large surface area aids in the transfer of gases. Factors that effect diffusion of gases include the differential partial pressures of each gas at the liquid-bubble interface and gas solubility.

Bubble oxygenators are divided into two sections. The first is a mixing chamber where fresh gas flows through a perforated plate or screen that forms the gas bubbles. The second is a reservoir/heat exchanger. After gas exchange occurs in the mixing chamber, the oxygenated blood is directed into the reservoir, allowed to settle, and then passed through a defoaming matrix. This causes the gas bubbles to destabilize and break down prior to the blood return to the patient.

Bubble oxygenators are not without problems. With long CPB times, there is time-dependent destruction of formed blood elements due to the very nature of the bubble–blood interface. This interface is responsible for hemolysis, platelet destruction, protein denaturation, microemboli, and activation of the complement cascade via the alternate pathway. With bypass times less than 90 minutes, this is seldom observed.

Membrane oxygenators eliminate the blood–gas interface. Membrane oxygenators use microporous membranes that allow a transient blood–gas interface. After a brief time, protein deposition over the membrane prevents a continued blood–gas interface, but allows continued gas diffusion. These micropores act as channels in the membrane, allowing the diffusion of both oxygen and carbon dioxide. Membrane oxygenators use bundles of hollow microporous polypropylene fibers contained in a plastic housing.[67] In this housing, blood flows around the fibers, while fresh gas is passed through the microporous fibers. This allows fresh gas to diffuse through the micropores into the passing blood. With this arrangement, oxygen tension is controlled by FIO_2 and carbon dioxide elimination by total gas flow.

Pumps

In extracorporeal circulation, a pump is required to circulate blood through the circuit tubing and back to the patient. Roller and centrifugal pumps are the most commonly seen types in clinical practice. Roller pumps are the earliest type of pump and were the first used in extracorporeal circulation. In the roller pump, a length of tubing (polyvinyl chloride, silicone rubber, latex rubber) is placed in the periphery of a 210° rigid curved housing. In the center of this housing are two metal arms set 180° apart with rollers at each end. This permits constant flow over a range of arterial inflow resistance. When the arm rotates, the tubing is alternately compressed and released against the housing so one side of the arm is compressing while the other is releasing the tubing. Alternately compressing and releasing the tubing generates forward flow without the possibility of retrograde flow. It is important to note that the tubing must not be totally compressed because unacceptable destruction of blood elements will result. The advantages of roller pumps are their simplicity and ease of use. Disadvantages include destruction of blood elements, spallation (development of plastic microemboli due to tubing compression), and complications from inflow and outflow occlusion of the pump. If pump inflow is occluded, negative pressure will develop in the roller head, causing cavitation or the development of microscopic bubbles. If pump outflow becomes occluded, excessive pressure may develop proximal to the occlusion, causing the tubing connections to separate or causing the tubing to burst. Roller pumps are seldom used as the primary pump in CPB. They are most frequently used for delivering cardioplegia and vent/cardiotomy suction. In the event of power failure in the

operating room, a hand crank may be used to operate the pump to develop adequate pump flow and systemic blood pressure.

Increasingly, centrifugal pumps are replacing roller head pumps. These pumps use a magnetically controlled impeller housed within a rigid plastic cone. This impeller is either composed of vanes or stacked smooth plastic cones that rotate to provide flow. By magnetically coupling the impeller to an electric motor located in the CPB machine, the speed of the electric motor (rpm) equals rotational speed of the drive head. By rotating rapidly, a pressure drop across the impeller occurs, causing blood to be sucked into the housing and then be ejected. One major difference between roller head and centrifugal pumps is that flow from centrifugal pumps will vary with changes in pump preload and afterload. It is for this reason that a flow meter must be placed on the downstream side of the bypass circuit. Advantages of centrifugal pumps include less blood trauma, lower line pressures, less cavitation, lower risk of massive air emboli, and elimination of tubing wear and spallation.

Despite the reliability of both roller and centrifugal pumps to provide systemic pressure on CPB, neither is able to deliver physiologically significant pulsatile blood flow. Pulsatile flow is the native pattern of blood flow in the human body, and the lack of this type of flow has been cited as a cause of renal dysfunction, production of ischemic metabolic byproducts, and higher need for inotropic and mechanical support. Studies show that the use of pulsatile flow on bypass confers increased survival in high-risk patients and decreases the inflammatory response seen with bypass.[68,69] Despite years of speculation, controversy still exists as to whether pulsatile flow is in fact better than standard flow. Until these controversies are resolved, nonpulsatile flow will remain the most common type seen in cardiac surgery.

Heat Exchanger

Systemic hypothermia is used in cardiac surgery as a method of myocardial and neurologic protection. Hypothermia's beneficial effects include reduction in metabolic rate and oxygen consumption, preservation of high-energy phosphate substrates, and reduction in excitatory neurotransmitter release. For each degree centigrade reduction in temperature, there is a reduction of 8% in metabolic rate. At 28°C, there is approximately a 50% reduction in metabolic rate. Both passive and active cooling can achieve moderate systemic hypothermia. Using passive cooling, patients' core temperatures are allowed to equalize with ambient temperature. This may be either a slow or a rapid process, depending on variables such as body surface area exposed and

ambient temperature. More commonly, patients undergoing cardiac surgery are actively cooled and then rewarmed at the conclusion of the surgical repair. This is accomplished by using a heat exchanger. A heat exchanger is a device where either heated or cooled nonsterile water is circulated around a conducting material with good thermal properties, such as aluminum or stainless steel, in contact with the patient's blood. This method allows uniform warming and cooling without hot or cold spots and delivers consistent thermal regulation over a spectrum of temperatures. Separate heat exchangers are used in CPB circuits for the delivery of cardioplegia. Often, to increase the efficiency of heat exchangers, a countercurrent system is employed.

Prime

The most common prime used in adult cardiac surgery is a balanced salt solution. This solution attempts to mimic the composition of blood plasma. Using crystalloid solutions such as lactated Ringer's allows the pump prime to achieve similar osmolarity and electrolyte composition as blood plasma. In addition to using lactated Ringer's, many institutions add albumin to decrease postoperative edema, mannitol to promote diuresis, additional electrolytes (calcium to prevent hypocalcemia due to citrate in transfused blood), corticosteroids (antiinflammatory), and extra heparin (ensure a safety level of anticoagulation). Many institutions use a standard volume prime for all adult patients, whereas others use a minimum volume based on body weight or body surface area. Priming volumes may also vary due to circuit configurations and individual specifications, but the average prime volume is 1,500 to 2,500 mL. Of note, there is active research into the area of oxygen-carrying compounds that may be added to pump prime. These substances include perflurocarbons and hemoglobin-based compounds that may extend the ability of patients to tolerate anemia on CPB that would otherwise require blood transfusion.

In infants, children, small adults, and patients with preoperative anemia, blood may be added to the pump prime prior to going on CPB. This is done to prevent excessive dilutional anemia and resulting drop in oxygen-carrying capacity. The exact hematocrit that can be tolerated on CPB has been debated, but hematocrits of as low as 17% have been reported to be well tolerated by patients undergoing cardiac operations. However, the trend currently seems to favor higher levels to avoid renal and neurologic consequences.[70,71,72] If hypothermia is used on CPB, then some degree of anemia is desirable.[73] Decreases in hematocrit help offset changes in blood viscosity due to hypothermia and may improve systemic flow.

Anticoagulation

To prevent patient death and thrombosis of the CPB circuit, systemic anticoagulation is required prior to insertion of cannulas and initiation of CPB. Contact between patient blood and components of the CPB circuit initiate activation of the coagulation cascade. To avoid this effect, heparin is used as the anticoagulant of choice. Heparin is a polyionic mucopolysaccharide extracted from either bovine lung or porcine intestinal mucosa. Anticoagulant activity varies between commercial preparations and between the bovine and porcine versions. Heparin is provided in units with 1 U, according to the U.S. Pharmacopoeia, maintaining fluidity of 1 mL of citrated sheep plasma for 1 hour after recalcification. Following intravenous injection, the peak onset of heparin is less than 5 minutes, with a half-life of approximately 90 minutes in normothermic patients. In hypothermic patients, there is a progressive increase in the half-life proportional to the degree of hypothermia. Heparin's anticoagulant effect is derived from its ability to potentiate the activity of antithrombin III (AT III), a plasma glycoprotein that contains a lysine residue. Heparin binding at this site alters the structural configuration of AT III, increasing its thrombin inhibitory potency greater than 1,000-fold. By inhibiting thrombin, AT III prevents the formation of fibrin clot via both the intrinsic and extrinsic pathways, in addition to inhibiting factors IX, Xa, XIa, XIIa, kalikrein, and plasmin. In addition, heparin also binds to factor II, which, independent of AT III, inhibits thrombin. In patients receiving heparin preoperatively and those with congenital deficiencies of AT III, higher than expected, doses of heparin may be required to adequately achieve anticoagulation. In the event of inadequate anticoagulation due to relative or absolute deficiency of AT III, exogenous AT III can be administered by transfusing fresh frozen plasma or by administering a commercial preparation of human AT III concentrate (Thrombate III).

The dosing and measurement of heparin has changed over many years. In the past, heparin was dosed empirically using

doses between 200 and 400 U/kg; redosing was time based. One common question that occurs frequently is why is the partial thromboplastin (PTT) not used clinically in cardiac surgery to measure heparin level. Modern PTT assays are so sensitive that heparin levels far lower than those required for safe initiation of CPB cause the sample blood to become almost unclottable within the time frame of the test. Currently, the two methods for determining adequate heparinization are the measuring activated clotting time (ACT) or blood heparin concentration. The ACT consists of adding blood to tubes containing either diatomaceous earth (celite) or kaolin, warming and rotating the tube, and recording the time until clot formation. Generally, ACTs greater than 480 seconds are considered acceptable for the initiation of CPB. The exception to this is when the serine protease inhibitor aprotinin is used. If celite-containing tubes are used, ACTs of 700 seconds are required due to the effect of aprotinin on the test. Aprotinin delays activation of the intrinsic pathway via factor XIIa, in addition to inhibiting kallikrein. This will prolong the celite ACT artifactually. Many early case reports of thrombosis with "adequate" ACTs were written prior to this understanding of how aprotinin interacts with the celite ACT test. Adding kaolin activates the intrinsic pathway and binds to aprotinin, reducing its anticoagulant effect in vitro and producing a more accurate ACT.

An alternative method to the ACT test uses heparin/protamine titration. In this method, a known dose of protamine is added to a heparinized sample of blood and followed until the optimum dose of protamine that produces a clot in the shortest amount of time is determined. By knowing the neutralization ratio of heparin and protamine (usually 1 mg to 100 U of heparin), the heparin concentration in the sample can be determined. The advantages cited with this method include the fact that conditions such as hypothermia, hemodilution, and even surgical incision alter ACTs. However, because heparin levels do not always correlate with anticoagulant effect, many centers prefer to use qualitative tests of heparin function such as the ACT. Using the ACT method is also easier and less expensive.

Allergies to heparin are rare; more commonly, patients may present with a history of heparin-induced thrombocytopenia (HIT). HIT contains two subtypes; the first is generally mild in which there is a transient decrease in platelet count. The second type is a more severe autoimmune-mediated decrease in the platelet count due to the formation of antigenic heparin compounds that activate platelets in the face of endothelial injury. This endothelial injury predisposes to the formation of platelet clots and microvascular thrombosis. In patients with HIT that require systemic anticoagulation, alternatives to heparin are required. These include defibrinogenating agents (ancrod obtained from pit viper venom), hirudin, bivalirudin, and factor inhibitors. Hirudin, which is isolated from the salivary gland of the medicinal leech (Hirudo medicinalis) and bivalirudin (Hirulog), are direct inhibitors of thrombin. This action is independent of AT III. The use of these agents is uncommon, and the reader is advised to consult one of the several reviews on this subject.[74]

Blood Conservation in Cardiac Surgery

Due to declining donation and restrictions on those that may donate, blood and its component products are a finite resource that are increasingly difficult to replace. In addition, the costs associated with the processing of blood are high and affect the economics of health care. In concert with the decrease in the supply of blood products, patients are increasingly demanding "bloodless" surgeries to lessen the risks of blood transfusion (infection, incompatibility reactions, transfusion error). Due to the nature of cardiac surgery, there is often a high risk of transfusion. Bleeding that may be significant can be encountered during reoperation from the use of anticoagulants and platelet function inhibitors preoperatively, and ill-defined surgical bleeding. The inherent risk of platelet dysfunction and derangements in coagulation due to extracorporeal circulation cannot be minimized. In the past, blood conservation included the use of intraoperative autologous blood donation, as well as the scavenging of shed blood and reinfusion. New techniques have emerged to reduce the need for homologous blood. These include the use of

antifibrinolytics (ε-aminocaproic acid, tranexemic acid, aprotinin, desmopressin [DDAVP]), ultrafiltration, blood fractionization, and the use of improved topical hemostaic agents.

Intraoperative autologous hemodilution is a well-described method of removing whole blood from a patient prior to systemic heparinization and coagulopathy from CPB. Using blood collection bags containing anticoagulant whole blood is removed, and crystalloid or colloid fluids are administered, making up for the circulating volume removed. Following CPB, the blood is transfused returning red blood cells, active platelets, and coagulation factors. Contraindications for the use of intraoperative autologous blood donation include preoperative anemia, unstable angina/high-grade left main coronary artery disease, and aortic stenosis.

Intraoperative blood salvage is another method of blood conservation that is used in cardiac surgery. This method is as simple as blood suctioned from the surgical field being anticoagulated, filtered, and reinfused, or as complicated as cell washing machines. The first method is simple and easy to perform with a minimum of equipment needed. Unfortunately, shed blood may worsen the coagulopathy associated with CPB because factors that cause coagulopathy are not removed in the filtering process. Cell washing is the more frequently seen method of cell salvage seen in the operating room. Cell washing is composed of four steps: harvesting of the patient's blood, processing of the shed blood and removal of the serum, storage of the red blood cells, and reinfusion of the high hematocrit red blood cells. Final hematocrits of reinfused red cells may reach 70%. Contraindications to the use of intraoperative cell salvage include infection, malignancy, and use of topical hemostatic agents.

Antifibrinolytic agents such as aprotinin and ε-aminocaproic acid have become the standard in most cardiac centers. These protease inhibitors and lysine analogs bind to plasminogen and plasmin, blocking the ability of fibrinolytic enzymes to bind at lysine residues of fibrinogen. The administration of these antifibrinolytics decreases bleeding after bypass and reduces the risk of blood transfusion.[75] Aprotinin is a naturally occurring fibrinolytic that possesses properties that the synthetic lysine analogs do not. These include aprotinin's ability to inhibit kallikrein, preservation of platelet glycoprotein receptors (Gib, GIIb/IIIa), inhibition of the proinflammatory cytokine release seen on CPB, and the inhibition of plasmin and protein C. These actions have a remarkable effect on intraoperative bleeding, post-CPB coagulopathy, and transfusion requirements.[76] The use of aprotinin is not without risks. There is a small but significant risk of anaphylaxis on reexposure due to its animal-derived protein structure. It is significantly more costly to use compared with the lysine analogs and despite studies refuting the fact, there is concern that aprotinin many cause graft thrombosis and renal failure, especially following hypothermia and circulatory arrest. [77]

One of the unwanted effects of extracorporeal circulation is the hemodilution associated with the pump prime. One method that has been used with success to avoid excess hemodilution and reduce the need for blood transfusion is retrograde autologous priming (RAP). In RAP, the crystalloid prime contained within the arterial and venous lines is drained into

a recirculation bag prior to the initiation of CPB and replaced by blood-drained retrograde via the arterial cannula. This reduces hemodilution and the drop in systemic vascular resistance associated with the initiation of CPB. When using this technique, care must be taken to avoid acute hypovolemic hypotension due to the patient exsanguination. Other reported benefits of RAP include reduced extravascular lung water and weight gain.[78,79]

Another technique used in conjunction with CPB to reduce postoperative bleeding and the need for transfusion is ultrafiltration. During ultrafiltration/hemoconcentration, plasma water is separated from low molecular weight solutes, intravascular cell components, and plasma proteins using a semipermeable membrane. Using a hydrostatic pressure difference created by external suction plasma, water is removed by the gradient created across the ultrafiltration membrane. Most ultrafiltration devices are composed of a rigid plastic housing containing bundles of semipermeable hollow fibers, which is placed inline with the CPB circuit. The exact timing of the ultrafiltration process depends on the technique employed. Conventional ultrafiltration is initiated during rewarming and is based on the volume within the CPB circuit and exogenous fluid given. Modified

ultrafiltration used commonly in pediatric cardiac surgery consists of ultrafiltration after separation from CPB when blood is pumped retrograde from the aortic cannula through the hemofilter/hemoconcentrator and returned to the right atrium. Advantages of hemoconcentration include a reduction in free water, preservation of hemostasis, and decrease in levels of circulating inflammatory mediators. By employing hemoconcentration, levels of formed blood elements including erythrocytes, platelets, and coagulation factors are augmented. This translates into a net increase in hemoglobin and hematocrit, and a decrease in postoperative bleeding and need for transfusion.[80]

Similar to hemoconcentration is blood fractionation. In this process, blood elements are removed and made into a concentrate that is removed from the patient prebypass. These concentrates are then retuned to the patient following CPB, thereby avoiding dilutional coagulopathy and activation of these blood elements while on CPB.

Much work is also being done in the field of blood substitutes. These hemoglobin-based compounds are made from blood in which the hemoglobin is chemically extracted for its oxygen-carrying capacity. The goal being a shelf-stable product devoid of the infectious complications of transfusion. Although not possessing all the qualities of banked blood, these compounds show great promise and are being actively studied.[81]

Myocardial Protection

The most common method of myocardial protection used today is that of intermittent hyperkalemic cold cardioplegia and moderate systemic hypothermia. The fundamental concept of cold cardioplegia is that a cold solution (10 to 15°C) of either blood or crystalloid with a supranormal concentration of potassium is injected into the coronary arteries or veins to induce diastolic electrical arrest. Cardioplegia may be delivered by using a separate roller head circuit from the CPB machine, a pneumatic infusion device, or a handheld gravity system. Cardioplegia is injected anterograde, retrograde, or as a combination of the two. Anterograde cardioplegia solution is injected via the aortic root into the native coronaries. The cardioplegia follows the normal anatomic flow of blood. In coronary artery bypass surgery, individual grafts may be used to deliver cardioplegia once distal anastamoses have been completed. In patients with significant aortic insufficiency, the anterograde technique is not effective due to the incompetent AV allowing cardioplegia to flow into the LV bypassing the coronary ostia. In this case, following aortic cross-clamp, an aortotomy is made and handheld cannulae are placed in the individual coronary ostia under direct vision and cardioplegia is delivered. In addition, in patients with severe coronary disease due to diffuse multiple or high-grade ostial lesions, anterograde cardioplegia may provide inadequate myocardial protection. In this case, retrograde cardioplegia may be employed. Retrograde cardioplegia is injected via a ballon-tipped catheter placed in the coronary sinus, bypassing the obstructed coronaries and achieving greater myocardial protection. Often, both anterograde and retrograde are used in combination to maximize the effects of cardioplegia.

Depending on the time required for surgical repair, multiple injections of cardioplegia may be necessary. This washes out metabolic by-products, adds new high-energy and oxygen-carrying substrates, and continues hypothermic diastolic arrest.

In addition to anterograde and retrograde cardioplegia, many other techniques have been used for myocardial protection. These include single-injection hyperkalemia with aortic cross-clamp, intermittent cross-clamp with periods of reperfusion, and hypothermic ventricular fibrillation. Many different solutions of cardioplegia exist. Some use osmotically active agents—albumin, energy substrates such as glucose-containing and phosphate-containing compounds citrate to chelate calcium, and nitroglycerin or nitroprusside—to facilitate uniform perfusion of the solution.

For the anesthesiologist monitoring a patient on CPB, the sentinel events of cardioplegic electrical arrest and resumption of electrical activity must be keenly followed. Events that must be watched for, are left ventricular distention and lack of rapid electrical arrest. These events may be evidence of poor myocardial protection and the possibility of difficulty in separation from CPB. Transesopegeal echocardiography is particularly helpful in diagnosing ventricular distention and its

relief by venting or manual decompression.

PREOPERATIVE EVALUATION

The preoperative visit appropriately concentrates on the cardiovascular system but should also focus on the assessment of pulmonary, renal, hepatic, neurologic, endocrine, and hematologic functions. Equally invaluable is discussing with the patient the anticipated events on the day of surgery, including transport to the operating room, preoperative routines (O_2 mask, vascular cannulation, anesthetic induction), and by finally, the awakening process in the recovery room or ICU. The importance of communicating to the anesthesiologist any symptoms such as chest pain, shortness of breath, or the need for nitroglycerin during transport or the preinduction period should be emphasized to the patient. The depth and detail of the explanation should be custom tailored to each patient.

Data from history, physical examination, and laboratory investigations are used to define the cardiovascular anatomy and functional state. Pertinent findings suggestive of left and/or right ventricular dysfunction are described in Table 31-16. Increases in the severity or frequency of anginal attacks or the presence of ischemia-induced ventricular dysfunction suggest that large areas of myocardium are at risk. A history of arrhythmias should be obtained, including the type, severity, associated symptoms, prior intervention, and successful treatment. Integration of this information leads to appropriate selection of monitoring devices and anesthetic techniques.

TABLE 31-16 Preoperative Findings Suggestive of Ventricular Dysfunction

History

- CAD: previous MI, chest pain/pressure
- CHF (intermittent or chronic): fatigue, DOE, orthopnea, PND, ankle swelling

Physical examination

- Vital signs: hypotension, tachycardia (severe CHF)
- Engorged neck veins, apical impulse displaced laterally, S_3, S_4, rales, pitting edema, pulsatile liver, ascites

Electrocardiogram

- Ischemia/infarct, rhythm, conduction abnormalities

Chest radiograph

- Cardiomegaly, pulmonary vascular congestion/pulmonary edema, pleural effusion, Kerley B lines

Cardiovascular testing

- Catheterization data: LVEDP > 18 mm Hg, EF < 0.4, CI < 2.0 L/min/m^2

CAD, coronary artery disease; CHF, congestive heart failure; CI, cardiac index; DOE, dyspnea on exertion; EF, ejection fraction; LVEDP, left ventricular end-diastolic pressure; MI, myocardial infarction; PND, paroxysmal nocturnal dyspnea.

Conditions commonly associated with heart disease, such as hypertension, diabetes mellitus, and

cigarette smoking, must also be evaluated. The latter is extremely important and may be useful in differentiating whether episodes of intraoperative pulmonary hypertension are caused primarily by pulmonary

or cardiac factors. Higher systemic arterial pressures may be desirable throughout surgery in patients with a history or other evidence of carotid artery disease. Evidence for renal dysfunction must be sought because the most common cause of postoperative renal failure is preexisting renal insufficiency. If renal reserve is reduced, intraoperative measures such as diuretics or dopamine may be used, although no data showing an improved outcome are available.

Current Drug Therapy

Almost without exception, cardiovascular drugs, including cardiac antiarrhythmics (e.g., amiodarone), β-blockers or calcium channel blockers, and nitrates are continued until the time of surgery. Interactions between these drugs and anesthetics are more often beneficial than harmful in maintaining hemodynamic control during periods of surgical stress.

Concern about intraoperative hypotension and increased requirement for vasopressor support in patients receiving β-blockers or calcium channel blockers or angiotensin-converting enzyme inhibitors is unwarranted. Digoxin is prescribed less frequently to suppress cardiac dysrhythmias, control the ventricular response to atrial fibrillation, and improve contractility in patients with congestive heart failure. Continuation until the time of surgery seems advisable for those patients in whom it is being used for rate or rhythm control. Signs or symptoms of digoxin excess, including ventricular ectopy, atrial tachydysrhythmias, and variable degrees of atrioventricular block should be sought. The latter is typically manifested by slowing and regularization of the ventricular response to atrial fibrillation. This represents digoxin-induced atrioventricular blockade with a regular junctional escape rhythm. Noncardiac symptoms include gastrointestinal distress or visual disturbances. Toxicity is more common in patients concomitantly receiving drugs that increase digoxin levels (e.g., nifedipine, verapamil, amiodarone) or reduce potassium levels (e.g., diuretics). Most cardiac antidysrhythmics should also be continued to the time of surgery. Their pharmacology is well known (see Chapters 12 and 21), and they usually present little problem with anesthetic management.

Physical Examination

As mentioned previously, the physical examination seeks to elicit signs of cardiac decompensation such as an S_3 gallop, rales, jugular venous distention, or pulsatile liver. Routes for vascular access should be assessed, and the status of peripheral arteries should be evaluated. As always, the airway should be carefully evaluated with respect to ease of mask ventilation and intubation of the trachea. Other pertinent points are described in Table 31-17.

TABLE 31-17 Preoperative Physical Examination

Vital Signs

- Current values and range

Height, weight

- For calculations of drug dosages, pump flow, cardiac index

Airway

- Evaluate, identify difficulties for ventilation, intubation

Neck

- Landmarks for jugular vein cannulation
- Vein engorgement (CHF)
- Bruits (carotid artery disease)

Heart

- Murmurs: characteristic of valve lesions, S_3 (elevated LVEDP), S_4 (decreased compliance), click (MVP prolapse)
- Lateral PMI displacement (cardiomegaly)
- Precordial heave, lift (hypertrophy, wall motion abnormality)

Lungs

- Rales (CHF)
- Rhonchi, wheezes (COPD, asthma)

Vasculature

- Peripheral pulses
- Sites for venous and arterial access

Abdomen

- Pulsatile liver (CHF, tricuspid regurgitation)

Extremities

- Peripheral edema (CHF)

Nervous System

- Motor or sensory deficits

CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; LVEDP, left ventricular end-diastolic pressure; MVP, mitral valve prolapse; PMI, point of maximum impulse.

Premedication

Even the most thorough preoperative psychological preparation is often inadequate to assuage the anxieties and apprehensions of a patient facing cardiac surgery. Premedication will assist in providing a calm, anxiety-free but arousable and hemodynamically stable patient who is prepared for surgery. Selection of drug and dosage is predicated on the patient's age, cardiovascular state, level of anxiety, and location. If the patient is coming from home, often there is inadequate time for adequate premedication. Heavy premedication is ideal for the

fit person scheduled for CABG. Inadequate sedation may predispose to hypertension, tachycardia, or coronary vasospasm, all potential causes of myocardial ischemia. However, the frail, 50-kg cachetic patient with severe valvular dysfunction fares better with light premedication to avoid

possible respiratory depression or loss of endogenous catecholamine support. Additional sedation can always be given in the operating room under direct observation by the anesthesiologist.

Premedication for cardiac surgery often combines the sedative and analgesic properties of an opioid (morphine, 0.1 to 0.2 mg/kg) with the sedative and amnestic properties of scopolamine (0.006 mg/kg) or a benzodiazepine (diazepam 0.05 to 0.1 mg/kg, midazolam 0.03 to 0.05 mg/kg, or lorazepam 0.04 mg/kg). The possibility of oversedation, hypercarbia, or hypoxia following premedication is always of concern.

Premedication may have a previously unappreciated but profound effect on intraoperative hemodynamics. Thomson et al.[82] administered a standard high-dose fentanyl anesthetic to patients premedicated with either morphine and scopolamine or lorazepam. In general, the patients receiving lorazepam were hemodynamically less responsive in that they had less hypertension, more hypotension, and a greater requirement for vasoactive drugs. Clonidine has also been used as a premedication with similar intraoperative effects. The difficulty with premedication currently is that the patients arrive in the hospital on the same day of surgery.

Monitoring

We emphasize only those aspects of monitoring particularly relevant to cardiac surgery because the subject is discussed extensively in Chapter 24.

Pulse Oximeter

The need for multiple vascular cannulations and applications of numerous monitoring devices often prolongs the preinduction period. The pulse oximeter should be positioned prior to catheter insertion to detect clinically unsuspected episodes of hypoxemia, especially if additional intravenous sedation has been administered. Attention must be focused on the whole patient, even during the hunt for successful vascular access.

Electrocardiogram

Regional ischemia may be localized by appropriate lead monitoring: lead II (and/or leads III, AVF: right coronary artery distribution) for the inferior, leads V_4, V_5 (left anterior descending [LAD] artery) for the anterior, and leads I and AVL (circumflex artery) for the lateral wall of the LV. If the standard leads prove inadequate for detection and analysis of cardiac dysrhythmia, esophageal or epicardial leads may be used. Occasionally, intraoperative myocardial injury causes substantial reductions in QRS voltage. Monitoring an ECG via a surgically placed ventricular pacing wire provides adequate voltage to facilitate dysrhythmia analysis or to trigger an intra-aortic balloon pump, if necessary. A strip-chart recorder documents and facilitates detailed analysis of both ST segment alterations and complex dysrhythmias.

Temperature

Central temperature can be measured with esophageal, tympanic, urinary bladder catheter probes or with a thermistor from a pulmonary artery catheter. Obviously, this last method is not reliable during the period of aortic cross-clamping when there is no flow through the heart. Rectal and toe probes record peripheral temperatures, which lag behind central measurements during both cooling and rewarming periods.

Arterial Blood Pressure

Systemic arterial pressure is always monitored invasively. The radial or femoral artery is usually cannulated, although the brachial and axillary arteries may also be used. The exact site is often a matter of personal or institutional preference. Criteria include convenience, selection of the fullest or most bounding pulse, and avoidance of the dominant hand. In addition, during dissection of the internal mammary artery, the ipsilateral radial or brachial artery pulse may be transiently occluded; therefore, an artery opposite a planned internal mammary artery is selected. Occasionally, the site of surgery dictates appropriate placement; for example, the right radial

artery should be used for procedures involving the descending thoracic aorta because the left subclavian artery may be included in the proximal aortic clamp. Following cardiopulmonary bypass, radial artery pressure is often misleading and may be as much as 30 mm Hg lower than central aortic pressure.[83] The mechanism is believed to be peripheral vasodilation during rewarming. Whenever such a discrepancy is suspected, aortic pressure can be estimated by palpation by the surgeon, or if direct measurement is needed, a needle may be placed directly into the aorta. The gradient between aortic and radial pressure usually disappears within 45 minutes of separation from bypass.

Central Venous Pressure/Pulmonary Artery Catheter

Access to the central circulation is mandatory for infusion of cardioactive drugs. In addition, right atrial or central venous pressure accurately reflects right ventricular filling pressure and is of critical importance whenever right ventricular dysfunction is suspected. In patients with normal LV function, transduced right atrial pressure is often assumed to be a reliable guide of left-sided filling. This relationship is less predictable in the presence of severe left ventricular dyssynergy, pulmonary hypertension, or reduced left ventricular compliance. In these instances, insertion of a pulmonary artery catheter for measurement of pulmonary capillary wedge pressure provides a somewhat better index of left ventricular filling, although TEE data are far more valid. In addition, determination of cardiac output and calculation of derived hemodynamic indices offer additional information to guide hemodynamic and anesthetic management.

Indications for pulmonary artery catheterization vary greatly among institutions. In some these catheters are used routinely, whereas in others they are limited to patients with specific disease states such as severe left ventricular dysfunction or pronounced pulmonary hypertension. Additional indications include combined procedures (valvular plus coronary) or those that require prolonged intraoperative time (cardiac reoperations or use of one or both internal mammary arteries). Insertion of a pacing pulmonary artery catheter can be helpful whenever exact control of rate and rhythm is desirable, for example, in patients with hypertrophic cardiomyopathy or those with significant bradycardia secondary to β blockade.

When pulmonary artery catheters are used, disagreement still exists as to whether they should be placed before or after the induction of anesthesia. In some patients, early insertion of the catheter and determination of baseline hemodynamic values can beneficially influence anesthetic selection and guide the induction sequence. However, the anxious and uncomfortable hypertensive patient is better served by a smooth anesthestic induction followed by catheter placement.

It must be remembered that the catheter often migrates toward the periphery of the lung with cardiac manipulation before and during CPB. Therefore, it seems prudent to pull the catheter back a few centimeters prior to the initiation of bypass to prevent permanent wedging or possible pulmonary artery

rupture. Despite the controversy concerning the routine use of these catheters, there is no disagreement that the capability to measure both cardiac output and ventricular filling pressures must be available in any institution performing cardiac surgery. Whether this is done with a pulmonary artery catheter, direct cannulation of the LA and dye dilution techniques, or TEE is immaterial. The critically ill patient requires these measurements to determine the effectiveness of vasoactive drugs, adjust dosage, and evaluate the need for further pharmacologic or mechanical intervention.

Echocardiography

2D TEE is the newest, most complex, and most expensive diagnostic device. Detection of ischemia by online evaluation of new regional wall motion abnormalities and its utility in assessing valvular lesions (before and after repair) and the ascending aorta have been mentioned. Other applications specific to cardiac surgical patients are also useful. It is well known that, following CPB, ventricular filling pressure, irrespective of site of measurement (left ventricular end-diastolic pressure, LA, pulmonary capillary wedge pressure), is a poor and often misleading indicator of

ventricular volume status.[84,85] Direct estimation of left ventricular volume with 2D TEE more appropriately directs fluid infusion and selection of vasoactive drugs in patients who are difficult to wean from bypass. In addition, residual valve lesions, intracardiac air, or new areas of ischemia are readily identified. Global dysfunction suggesting residual cross-clamp effect, inadequate cardioplegia, or reperfusion injury can be detected.

Central Nervous System Function and Complications

Monitoring of the brain during extracorporeal bypass is difficult, with a lack of standardized equipment or criteria. Neurologic complications after cardiac surgery can be devastating to patients and their families, significantly affecting their quality of life, while exponentially increasing the economic cost of recovery after cardiac surgery. Thus, many investigators have more recently focused on methods to determine the etiology and improve the detection, prevention, and treatment of postoperative neurologic complications in patients undergoing cardiac surgery.

The incidence of stroke after CABG surgery is approximately 3% (1 to 5%). There is a much higher incidence (60 to 70%) of subtle cognitive deficits that can be elicited by detailed neuropsychometric testing. It is known that the neuropsychiatric deficits do improve over the initial 2 to 6 months after cardiac surgery; however, a significant percentage of patients (13 to 39%) have residual impairment. The etiology of perioperative neurologic complications is believed to be predominantly secondary to emboli (air, atheroma, other particulate matter) than to hypoperfusion in susceptible patients (e.g., preexisting cerebrovascular disease). Most overt strokes after cardiac surgery are focal and likely due to macroemboli, whereas the cognitive changes are subtle and probably result from microemboli. Risk factors for neurologic complications include advanced age (>70 years), preexisting cerebrovascular disease (e.g., carotid artery stenosis >80%), history of prior stroke, peripheral vascular disease, ascending aortic atheroma, and diabetes. Operative factors include the duration of CPB, intracardiac procedure (e.g., valve replacement), excessive warming during and following CPB, and perhaps perfusion pressure on CPB.[86,87,88,89] Intraoperative hyperglycemia, which could theoretically result in worsened neurologic damage, has not been associated with poorer neurologic outcome.[90]

Historically, intracardiac (e.g., valvular) procedures are associated with a greater risk of neurologic complications (presumably secondary to greater risk of air emboli) than closed cardiac (i.e., CABG) procedures. As discussed earlier, TEE has given both anesthesiologists and surgeons an appreciation for the adequacy of the de-airing process after intracardiac procedures. From studies using transcranial Doppler to detect cerebral emboli, it is now known that the time points of maximal risk for embolization are at aortic cannulation, onset of CPB, weaning from CPB, and decannulation.[91]

The role of TEE in evaluating the ascending and descending aorta is described previously. There are several management options undergoing investigation for patients with severely diseased aortas, especially those with mobile atheromas who are at increased risk of stroke. These include hypothermic fibrillatory arrest with left ventricular vent and no cross-clamp, single cross-clamp (i.e., distal and proximal grafts performed during same cross-clamp), relocation of proximal grafts to area of nondiseased aorta, no proximal grafts (internal mammary arteries only) either on CPB or using off-pump coronary artery bypass, hypothermic ischemic arrest with resection, and graft replacement of diseased aorta.

Cerebral protection is rather limited. Hypothermia is excellent in that it decreases cerebral metabolic rate and prolongs ischemic tolerance; however, profound hypothermia is not practical for routine cardiac surgery. Unfortunately, during routine CPB the patient is normothermic when the highest risk of embolization exists, (unclamping, during rewarming, and with initial ventricular ejection). Sodium thiopental has been shown to be cerebroprotective in intracardiac procedures,[92] but not in CABG surgery.[93] This difference may be a result of the "reversible" neurologic impairment secondary to gas emboli, which is more likely during intracardiac procedures than CABG surgery.

Selection of Anesthetic Drugs

The task confronting the anesthesiologist is to render the patient undergoing cardiac surgery analgesic, amnesic, and unconscious, while suppressing the endocrine and autonomic responses to intraoperative stress. Equally important is preservation of compensatory cardiovascular mechanisms and prevention of perioperative episodes of myocardial ischemia. Although these goals are not unique to the cardiac surgical patient, they are sometimes a bit more difficult to accomplish because of the severity of ischemic and/or valvular disease. Notwithstanding institutional and personal bias with respect to choice of anesthetic, there are no data that document superiority of any anesthetic for either coronary or valvular surgery. The large outcome studies of Tuman et al. and Slogoff and Keats indicate that the choice of anesthetic has no effect on outcome in CABG patients.[93a,93b] As was previously emphasized, the most critical factor governing anesthetic selection is the degree of ventricular dysfunction. Anticipated difficulties during the tracheal intubation sequence, the expected length of surgery, and the anticipated time until extubation of the trachea also influence choice of anesthetic. It is desirable to be able to alter anesthetic depth to accommodate the varying intensity of surgical stress. During intubation of the trachea, incision, sternotomy, pericardiotomy, and manipulation of the aorta, there is intense stimulation and sympathetic response. The period of prepping and draping following intubation of the trachea requires minimal levels of anesthetic, as does the period of hypothermic bypass.

There is no one best technique. Familiarity with all anesthetics and their physiologic and pharmacologic effects in the patient with severe cardiac disease allows great flexibility in anesthetic selection. In addition, it provides numerous

options applicable to the cardiac patient undergoing noncardiac surgery.

Potent Inhalation Anesthetics

These drugs are useful both as primary anesthetic drugs and as adjuvants to treat or prevent "breakthrough" hypertension associated with high-dose opioid techniques. The balance of myocardial oxygen supply and M

$\dot{V}$

O_2 is usually altered favorably by reduction in contractility and afterload. Deleterious declines in perfusion must be prevented or treated, and the possibilities of increases in wall tension must be considered. These agents have been used successfully in all types of valve surgery without untoward effects, although they are sometimes associated with more hemodynamic variability than is seen with opioids. Use of these drugs involves no more hemodynamic intervention than upfront loading with opioids, and the ability to rapidly increase and decrease concentrations permits easy adjustment to variable levels of surgical stimulation. Volatile anesthetics can be administered during bypass through a vaporizer mounted on the pump; they are also appropriate in the postbypass period, assuming cardiac function is adequate. Volatile anesthetics seem to be more important now, in combination with short-acting opiates or hypnotics, because the volume of off-bypass procedures is increasing and the urge to fast-track continues.

Opioids

The opioids lack negative inotropic effects in the doses used clinically and have thus found widespread use as the primary agents for cardiac surgery. This era began in 1969, when high doses of morphine were used to anesthetize patients for aortic valve replacement.[94] However, hypotension, histamine release, increased fluid requirements and, often, inadequate anesthesia resulted in a decline in the use of morphine in favor of the more potent fentanyl derivatives. Aside from bradycardia, fentanyl and its analogs are relatively devoid of cardiovascular effects and have proved to be effective anesthetics. As a primary anesthetic agent, fentanyl (50 to 100 μg/kg) or sufentanil (10 to 20 μg/kg) and oxygen provide hemodynamic stability, although they do not consistently prevent a hypertensive response to periods of increased surgical stimulation. In patients with good ventricular function, although high doses of opioids produce unconsciousness

and characteristic electrocardiographic slowing, patient recall of intraoperative events remains a potential problem. Adjuvant agents are frequently used to supplement the opioids—benzodiazepines to provide amnesia and volatile anesthetics or vasodilators to control hypertension. Superiority of any one opioid has not been demonstrated for either coronary or valvular surgery. The use of high-dose opioids prolongs the time until emergence and extubation when compared with techniques primarily based on volatile anesthetics and is no longer in fashion. Alfentanil, with an elimination half-life shorter than that of fentanyl or sufentanil, is suitable for infusion techniques and may provide optimal conditions for early extubation of the trachea. Remifentanil, an ultrashort-acting opioid, is 30 times more potent than alfentanil and undergoes hydrolysis by nonspecific esterases in minutes. Its predictable and rapid elimination is unaffected by hepatic or renal disease, making it an optimal drug for infusion techniques.

Combinations of the fentanyl-type drugs and benzodiazepines, whether given concomitantly or as premedication, result in hypotension secondary to a fall in systemic vascular resistance.[95] Any opioid in high doses can produce excessive bradycardia. Vecuronium or cisatracurium may magnify this problem, whereas pancuronium is often useful in preventing it. Abdominal and chest wall rigidity commonly occur with rapid injection of high doses of opioids and can be severe enough to render ventilation impossible. A low dose (priming) of nondepolarizing muscle relaxant should be given prior to opioid administration.

Nitrous Oxide

In many centers, nitrous oxide is not used during cardiac surgery. Increases in pulmonary vascular resistance associated with nitrous oxide have been demonstrated, with the greatest response in patients with preexisting pulmonary hypertension. Nitrous oxide is also a mild myocardial depressant and elicits a compensatory sympathetically mediated increase in systemic vascular resistance. These minimal changes may not be well tolerated in patients with minimal cardiovascular reserve.

It is well known that nitrous oxide increases the size of any air-filled cavity. The possibility of expansion of air introduced into the circulation either before or during bypass should preclude its use immediately before, during, or after bypass.

Induction Drugs

The benzodiazepines, barbiturates, propofol, and etomidate can be used as supplements to either inhalation or opioid anesthetics and, more important, are excellent as sole induction drugs in patients with cardiac disease. Obviously, dosage requirements must be altered to fit the clinical situation.

Neuromuscular Blocking Drugs

Muscle relaxants are part of an anesthetic plan for cardiac surgery. Although they are not essential to surgical exposure of the heart, muscle paralysis facilitates intubation of the trachea, prevents shivering, and attenuates skeletal muscle contraction during defibrillation. In addition, muscle relaxants are necessary to prevent or treat opioid-induced truncal rigidity. The chief criteria for selection are the hemodynamic and pharmacokinetic properties associated with each relaxant, the patient's myocardial function, the presence of coexisting disease, current pharmacologic regimen, and anesthetic technique.

Intraoperative Management

In this section, we describe the anesthetic management of a patient undergoing a cardiac surgical procedure from the time of arrival in the operating room until care is transferred to ICU personnel. Because the physiologic and pharmacologic rationales for anesthetic selection are previously discussed, this is rather a sequential description of what occurs and what is required during surgery. Anticipation of needs specific to each stage of the procedure and ready availability of necessary equipment and drugs prevents untoward hemodynamic aberrations and last-minute

scrambling.

Preparation

The operating room must be readied prior to arrival of the patient. The anesthesia machine is checked, and all supplies necessary for airway management (or any additional equipment if a difficult tracheal intubation is anticipated) should be available. Drugs—anesthetic, emergency, and infusions—should be prepared and ready for use. Heparin must be drawn up prior to induction of anesthesia in the unlikely event of the need to "crash" onto bypass. All monitoring equipment should be switched on, be working, and be calibrated. Typed and cross-matched blood should be available in the operating suite. Table 31-18 provides a checklist to aid in proper preoperative preparation of the operating room.

TABLE 31-18 Anesthetic Preparation for Cardiac Surgery

Anesthesia machine

- Routine check

Airway

- Nasal cannula for O_2
- Ventilation/intubation equipment
- Suction
- Difficult airway anticipated?: special equipment
- Inspired gas humidifier

Circulatory access

- Catheters for peripheral and central IV and arterial access
- IV fluids and infusion tubing and pumps
- Fluid warmer

Monitors

- Standard ASA: ECG leads, blood pressure cuff, pulse oximeter, neuromuscular blockade monitor
- Temperature: various probes (nasal, tympanic, bladder, rectal)
- Transducers (arterial, pulmonary, and central venous pressure): calibrated and zeroed
- Cardiac output computer: proper constant inserted
- Anticoagulation (ACT)
- Recorder

Medications

- General anesthetic: hypnotic/induction, amnestic/benzodiazepine-volatile, opioid, muscle relaxant
- Heparin (predrawn)
- Cardioactive
  —In syringes: nitroglycerin, $CaCl_2$, phenylephrine/ephedrine, epinephrine
  —Infusions: nitroglycerin, inotrope

- Antibiotics

Miscellaneous

- Pacemaker with battery
- Compatible blood in operating room

ASA, American Society of Anesthesiologists; ACT, activated clotting time; ECG, electrocardiogram.

Preinduction Period

A conversation prior to entering the operating room serves to evaluate the patient's general status and level of anxiety, and to assess the effectiveness of premedication (if ordered). The patient is reminded to report if chest pain, shortness of breath, or other symptoms occur. Supplemental oxygen via nasal cannula should be administered once the patient has been transferred to the operating table; electrocardiographic leads, noninvasive blood pressure, and peripheral oxygen saturation cuff are placed; and a set of initial vital signs is recorded. Angina should be promptly treated with oxygen, sublingual or intravenous nitroglycerin, additional sedation, or if related to anxiety-induced hypertension or tachycardia, with prompt induction of general anesthesia.

One or two large-bore intravenous cannulas are inserted after site infiltration with local anesthetic (additional routes for infusion are desirable in patients undergoing repeat cardiac surgery). In some centers, anesthesia is then induced, and following intubation of the trachea, arterial and central venous cannulas are inserted. In other centers, however, these cannulae are inserted prior to the anesthetic. Preinduction or postinduction insertion of central venous or pulmonary artery catheters has been discussed previously. Once they are inserted, however, initial values for all pressures and cardiac output should be recorded, and baseline determinations of arterial blood gases, hematocrit, and activated coagulation time should be obtained.

Throughout the preinduction period, while the intravenous and pressure monitoring catheters are inserted, the anesthesiologist must never divert his or her attention from the patient. Placing a functioning pulse oximeter with the volume loud enough to be easily heard should precede line placement. Continuous monitoring of the vital signs, careful observation of the patient, and periodic verbal contact facilitate detection of hemodynamic or electrocardiographic abnormalities, increased anxiety, or excessive response to intravenous sedation.

Induction and Intubation

13 The exact choice and sequence of drugs are a subtle—sometimes not so subtle—combination of art and science. The choice of specific agents (e.g., sedative, opioid, volatile drug, muscle relaxant), dose, and speed of administration depend primarily on the patient's cardiovascular reserve and desired cardiovascular profile. A smooth transition from consciousness to blissful sleep is desired without untoward airway difficulties (e.g., coughing, laryngospasm, truncal rigidity) or hemodynamic responses (e.g., hypotension from relative overdose, loss of sympathetic tone, or myocardial depression; or hypertension caused by airway insertion; or jaw thrust). A "slow cardiac induction" sometimes causes, rather than alleviates, these potential problems. However, an awake tracheal intubation, after proper sedation, may be appropriate in a bull-necked, obese patient if ventilation and intubation appear to be difficult. The necessity for individual approach to each patient cannot be overemphasized.

Deep planes of anesthesia, brief duration of laryngoscopy, and innumerable pharmacologic

regimens have been proposed for eliminating the hypertension and tachycardia associated with intubation of the trachea. None is uniformly successful, and all drug interventions carry some degree of risk, small though they may be. In addition, in some patients, especially those with a slow heart rate prior to induction of anesthesia, the reflex response to intubation of the trachea is primarily vagal, and severe bradycardia and rarely sinus arrest can occur. Furthermore, more recent evidence suggests that intubation of the trachea is a strong stimulus for coronary vasoconstriction irrespective of the anesthetic because left ventricular blood flow is dramatically altered in the absence of hemodynamic changes. Therefore, the response to tracheal intubation may be variable, although usually short lived. Nevertheless, identification of persistently abnormal hemodynamics or ischemia should be sought and treated.

After verification of successful intubation of the trachea, the endotracheal tube is secured, and the eyes and all pressure points are protected. The importance of frequent checks of all monitors during these busy minutes cannot be overemphasized.

Preincision Period

The period of time from tracheal intubation until skin incision is one of minimal stimulation as the surgical team attends to insertion of a bladder catheter, temperature probe, positioning, prepping, and draping. As a result, hypotension often develops, regardless of the anesthetic used. It may be necessary to reduce the anesthetic depth or alternatively support the systemic pressure with a vasoconstrictor. The potential risks of vasoconstriction in patients with poor left or right ventricular performance must be kept in mind. Deeper planes of anesthesia are obviously necessary immediately prior to incision and sternotomy.

Incision to Bypass

As previously emphasized, the prebypass period is characterized by periods of intense surgical stimulation that may cause hypertension and tachycardia, or induce ischemia. Anticipating these events and deepening the anesthetic may be effective, but a vasodilator or other adjuvant is often required. Hypotension can occur during the less stressful moments before bypass, but it is more commonly associated with cardiac manipulation in preparation for, and during, atrial cannulation. This may interfere with venous return or produce episodic ectopic beats or sustained supraventricular dysrhythmias. Atrial fibrillation is not uncommon. Depending on the blood pressure and heart rate response, appropriate treatment may range from nothing to vasoconstrictors, cardioversion, or rapid cannulation and institution of bypass. Maintaining adequate intravascular volume may attenuate the extent of blood pressure decrease. This is a critical period, and continual observation of the surgical field is essential.

Prebypass, ST segment analysis and frequent TEE observation (if used) is important in identifying and localizing new ischemia. If it occurs, it should be treated appropriately and the surgeon notified. During all cardiac procedures (perhaps more so than with any other type of surgery), hemodynamic change must be immediately correlated with events in the surgical field. The hemodynamic consequences of sometimes necessary manipulations (retracting, lifting, and, in general, "mugging" the heart) are unpredictable. This occurs more often during reoperations, when dissection may be difficult, tedious, and time consuming, and when retraction of the heart is necessary. Also, following CPB when grafts and suture lines are inspected and, if necessary, repaired. Bleeding, sometimes unexpectedly profuse, may compound the problem. In rare cases in which a cardiac chamber is entered and bleeding is uncontrollable, heparin is administered, the femoral vessels are cannulated, and cardiopulmonary bypass is begun using coronary suction from the field as the major means of venous return. Communication between the anesthesiologist and the surgeon is necessary to keep both apprised of the situation and to ensure the heart gets a periodic "rest."

Cardiopulmonary Bypass

After heparin administration, the cannulas are inserted, and adequate levels of anticoagulation are

checked to ensure the patient is ready for the institution of CPB (Table 31-19). Attention is focused on adequacy of venous drainage, unobstructed arterial return, sufficient gas exchange, and provision of necessary anesthetics and muscle relaxants. The anesthetic requirements are decreased if systemic hypothermia is used.

TABLE 31-19 Checklist Before Initiating Cardiopulmonary Bypass

Laboratory values

- Heparinization: adequate (ACT or other method)
- Hematocrit

Anesthetic

- Maintenance: amnestics, opioids, muscle relaxants are supplemented

Monitors

- Arterial pressure: initial hypotension and then return
- CVP: indicates adequate venous drainage
- PCWP:
  —Elevated?: LV distention (inadequate drainage, AI)
  —Pull back PAC 1 to 2 cm

Patient/field

- Cannulas in place:
  —No kinks or clamps or air locks
  —Arterial cannula is free of bubbles
- Face:
  —Suffusion?: inadequate SVC drainage
  —Unilateral blanching?: innominate artery cannulation
- Heart:
  —Signs of distention (AI, ischemia)

Support

- Usually not required

ACT, activated clotting time; AI, aortic insufficiency; CVP, central venous pressure; LV, left ventricle; PAC, pulmonary artery catheter; PCWP, pulmonary capillary wedge pressure; SVC, superior vena cava.

There is complete agreement that once full CPB is established, it is no longer necessary to ventilate the lungs. However, there is no such consensus about what exactly to do with the lungs during the period of bypass. Some anesthesiologists completely disconnect the patient from the anesthesia machine; others maintain the lungs slightly inflated with low levels of positive end-expiratory pressure using 100% oxygen or various mixtures of room air. No specific method is associated with superior postoperative pulmonary function.

During the initial minutes of bypass, systemic pressure initially drops to 30 to 40 mm Hg as pulsatile flow ceases and the hemodilution effect of the dilute prime becomes apparent. Once

adequate mixing is obtained, blood pressure increases to levels determined primarily by flow rate, and secondary by total vascular resistance (Table 31-20). There is no consensus as to what constitutes the ideal blood pressure or flow rate for adequate vital organ perfusion, especially of the brain, during bypass. Commonly, flow rates are maintained at approximately 50 to 60 mL/kg/min, with systemic blood pressures in the 50 to 60 mm Hg range. Some surgeons believe that a higher perfusion pressure affords better myocardial protection for the cold fibrillating heart, rather than cardioplegia. Others opt for a mean pressure equal to patient's age!

TABLE 31-20 Checklist During Cardiopulmonary Bypass

Laboratory Values

- Heparinization: adequate (ACT or other method)
- ABGs (uncorrected): is there acidosis?
- Hematocrit, Na^+, K^+, ionized Ca^{++}, glucose

Anesthetic

- Discontinue ventilation

Monitors

- Arterial hypotension:
  —Inadequate venous return Venous cannula: malposition, clamp, kink, air lock Bleeding, hypovolemia, IVC obstruction, table too low
  —Pump: poor occlusion, low flow
  —Arterial cannula: misdirected, kinked, partiallyclamped, aortic dissection
  —Decreased vascular tone: anesthetics, hemodilution, idiopathic
  —Transducer/monitor malfunction: radial artery cannulamalpositioned, dampened waveform
- Arterial hypertension:
  —Pump: high flow
  —Arterial cannula: misdirected
  —Vasoconstriction: light anesthetic plane, response tohypothermia
  —Transducer/monitor malfunction: radial artery cannulamalpositioned/kinked
- Venous pressure:
  —Transducer higher than atrial level?
  —True obstruction to chamber drainage? (CVP: right, PCWP/LA: left heart)
- EEG
- Adequate body perfusion:
  —Flow and pressure?
  —Acidosis
  —Mixed venous blood oxygen saturation
- Temperature
- Urine output

Patient/field

- Conduct of the operation
- Heart: distention, fibrillation
- Cyanosis, venous engorgement, skin temperature
- Movement
- Signs of light anesthesia/hypercapnia: breathing/diaphragmatic movement

Support

- Assist adequacy of pump flow:
  —Anesthetics/vasodilators for hypertension
  —Constrictors for hypotension

ACT, activated clotting time; CVP, central venous pressure; EEG, electroencephalogram; IVC, inferior vena cava; LA, left atrium; PCWP, pulmonary capillary wedge pressure.

Monitoring and Management During Bypass

The common etiologies of blood pressure changes during CPB are listed in Table 31-20. Of primary importance is continuous observation of the surgical field and cannulas to ensure nothing mechanical is awry. Attention can then be directed to other causes of hypotension or hypertension and their appropriate treatment. Additional areas that require periodic monitoring and occasional intervention during bypass are also described in Table 31-20. Maintenance of adequate depths of anesthesia is obviously important during bypass, although clinical signs are few. Use of bispectral monitoring may aid in determing the approximate anesthetic depth. Anesthetic requirements are decreased during the period of hypothermia but return toward normal when the patient is rewarmed.

Arterial pH and mixed venous oxygen saturation, often measured online, are used to assess the adequacy of perfusion. Urine output is also monitored, but so many variables (e.g., arterial and venous pressure, flow rate, temperature, diuretic history) influence this that it is difficult to draw meaningful conclusions from this measurement. In addition, postoperative renal failure develops from either aggravation of preexisting renal dysfunction or persistent low cardiac output following bypass. Although many institutions administer diuretics routinely, they are just as assiduously avoided elsewhere.

Rewarming

When surgical repair is nearly complete, gradual rewarming of the patient begins. A gradient of approximately 10°C is

maintained between the patient and the perfusate to prevent formation of gas bubbles. Patient awareness becomes a possibility as the potentiation of anesthetic effects due to hypothermia dissipates. If adequate doses of anesthetics have not been given, administration during rewarming should be considered to prevent recall of intraoperative events. Use of volatile anesthetics is helpful if a smooth postbypass course is anticipated and early weaning from mechanical ventilation and extubation are planned. On completion of the surgical repair, various maneuvers are performed to remove any residual air in the ventricles. The anesthesiologist is called on to vigorously inflate the lungs to remove air from the pulmonary veins and aid in filling the cardiac chambers. TEE is particularly useful in assessing the effectiveness of the de-airing process. The heart is defibrillated (if needed) and allowed to beat to replace some of the oxygen debt. The field is tidied up, and preparations are made to separate from CPB.

Discontinuation of Cardiopulmonary Bypass

14 Prior to discontinuing CPB, the patient should be normothermic, the surgical field must be dry, the appropriate laboratory values must be checked, the pulmonary compliance must be

evaluated, and ventilation of the lungs begun (Table 31-21). If necessary, heart rate and rhythm are regulated either pharmacologically or electrically (appropriate pacing, defibrillation, cardioversion). The venous cannula(s) are then occluded incrementally and sufficient pump volume is transfused into the patient, while the bypass flow is slowly decreased (Fig. 31-22). During this time, the cardiac function is constantly evaluated from hemodynamic data and direct inspection of the heart, and the need for vasoactive or cardioactive drugs is assessed. The potential disparity, previously alluded to, between radial artery and aortic pressures must be kept in mind. Contractility, rhythm, and ventricular filling can all be estimated by careful observation of the beating heart. For example, a low blood pressure and a vigorously contracting, relatively empty ventricle suggest that volume and perhaps a vasoconstrictor are all that is needed to wean the patient from bypass, whereas adequate blood pressure in the presence of a sluggish and overdistended heart may be treated with a vasodilator and/or a small dose of an inotrope. See Figure 31-23 for a general approach to termination of cardiopulmonary bypass.

TABLE 31-21 Checklist Before Separation From Cardiopulmonary Bypass

Laboratory values

- Hematocrit, ABGs
- K^+: ?elevated (cardioplegia)
- Ionized Ca^{2+}

Anesthetic/machine

- Lung compliance: evaluate (hand ventilation)
- Lungs are ventilated (manual or mechanical)
- Vaporizers: off
- Alarms: on

Monitors

- Normothermia (37°C nasopharyngeal, 35.5°C bladder, 35°C rectal)
- ECG: rate, rhythm, ST
- Transducers recalibrated and zeroed
- Arterial and filling pressures
- Recorder (if available)

Patient/field

- *Look at the heart!*
- De-aired: check lead II, TEE
- Eyeball contractility, size, rhythm
- LV vent clamped/removed, caval snares released
- Bleeding: no major sites (grafts, suture lines, LV vent site)
- Vascular resistance: CPB flow ∝ MAP ÷ resistance

Support

- As needed

ABG, arterial blood gas; CPB, cardiopulmonary bypass; ECG, electrocardiogram; LV, left

ventricle; MAP, mean arterial pressure; TEE, transesophageal echocardiography.

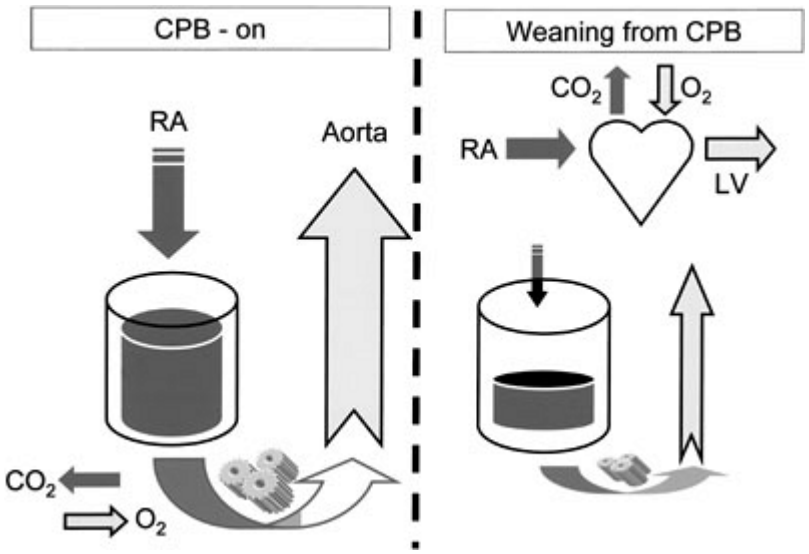

FIGURE 31-22. Weaning from cardiopulmonary bypass (CPB). While on CPB, the venous return to the heart is diverted from the right atrium (RA) to the CPB reservoir. The drainage is passive (by gravity). From the venous reservoir, the blood is "ventilated," CO_2 is removed and O_2 is added, and then returned to the patient, usually into the aorta but occasionally via the femoral or axillary arteries. During weaning from CPB, the venous return to the CPB is reduced by gradually occluding the venous cannula, directing more of its contents to the right heart and lungs. LV, left ventricle.

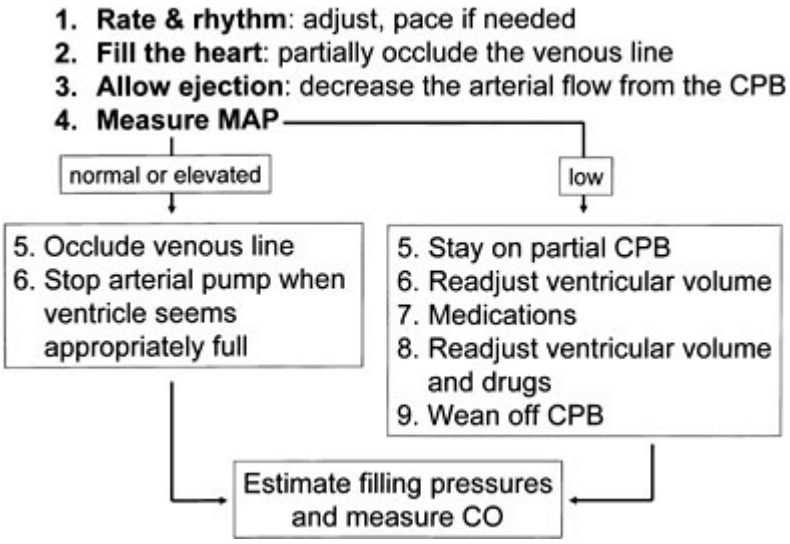

FIGURE 31-23. General approach to termination of cardiopulmonary bypass (CPB). CO, cardiac output; MAP, mean arterial pressure.

Inadequate cardiac performance must prompt a search for possible etiologies (Table 31-22); structural defects require more than mere regulation of inotropes or vasodilators. If the clinical picture is suggestive of coronary air emboli with diffuse ST segment elevation and a hypocontractile heart, continuous support on CPB with a high perfusion pressure and an empty ventricle is indicated.

TABLE 31-22 Etiology of Right or Left Ventricular Dysfunction After Cardiopulmonary Bypass

Ischemia

- Inadequate myocardial protection
- Intraoperative infarction
- Reperfusion injury
- Coronary spasm
- Coronary embolism (air, thrombus, calcium)
- Technical difficulties (kinked or clotted grafts)

Uncorrected structural defects

- Nongraftable vessels, diffuse coronary artery disease
- Residual or new valve pathology
- Hypertrophic cardiomyopathy
- Shunts
- Preexisting cardiac dysfunction

CPB-related factors

- Excessive cardioplegia
- Unrecognized cardiac distention

CPB, cardiopulmonary bypass.

Our approach to patients with inadequate cardiac output is summarized in Table 31-23. The heart rate is adjusted as much as possible. Following that, ventricular filling is optimized by transfusing blood from the pump. It is important not to overdistend the heart by transfusing to an arbitrary level of filling pressure because this may result in further myocardial dysfunction. Looking at the heart to monitor the response to small incremental volume infusions is important. The ratio of systemic to pulmonary artery pressure is also helpful: both pressures should increase in the same direction (as in Fig. 31-24A). Change in opposite directions (e.g., pulmonary pressure increases and systemic pressure decreases) (see Fig. 31-24C) is suggestive of left ventricular failure.

TABLE 31-23 Steps for Improving Systemic Flow

1	Heart rate (A-, V-, A/V-pacing) and rhythm
2	Preload: optimize (beware of altered compliance postbypass)
3–4	Afterload reduction if blood pressure is high and/or contractility augmentation (inotrope if low CO)
5	Preload: recheck and adjust

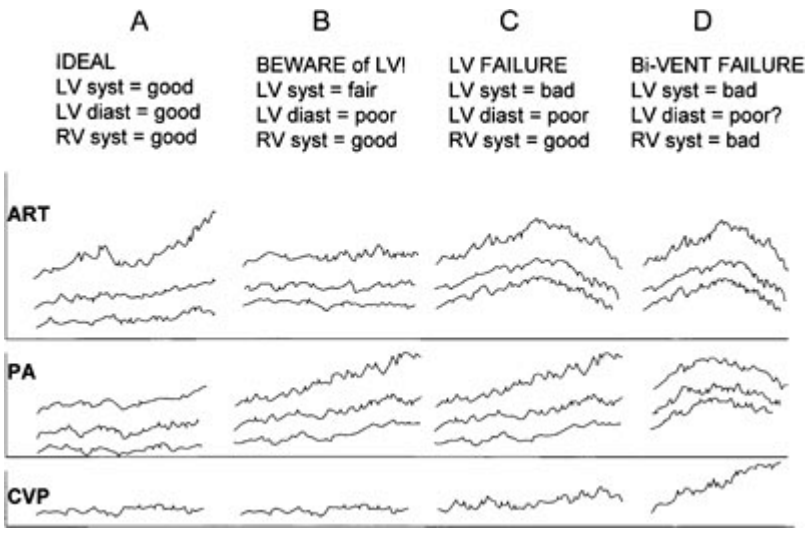

FIGURE 31-24. Algorithm for the diagnosis and treatment of hemodynamic abnormalities at termination of cardiopulmonary bypass. CO, cardiac output; CVP, central venous pressure; IABP, intra-aortic balloon pump; LVAD, left ventricular assist device; NO, nitric oxide; PGI_2, prostacyclin; RV, right ventricle; SVR, systemic vascular resistance.

If pharmacologic support is required, an integration of cardiac physiology (see Chapter 31) and pharmacology (see Chapter 12) will lead to the rational selection of an appropriate drug or drugs. Numerous algorithms are available to guide decision making; one is described in (Fig. 31-25). This algorithm uses systemic arterial and pulmonary artery pressures, and cardiac output. If TEE is available, myocardial contractility and valvular function can be more readily assessed. A search for new wall motion changes, paravalvular leaks, or new mitral insufficiency is appropriate. After integrating available data, a diagnosis is made and appropriate treatment is begun. Continual reassessment of the situation is necessary to document the efficacy of treatment or to suggest new diagnoses and therapeutic approaches. If cardiac output is low and systemic pressure is adequate (see Fig. 31-24A, B), an arteriolar dilator may improve forward flow by decreasing afterload. If systemic pressure is too low (see Fig. 31-24C, D), thus prohibiting the use of vasodilators, an inotrope should be selected instead. Each inotropic drug has a distinct profile with respect to its effects on rate, contractility, systemic and pulmonary vascular resistance, and cardiac dysrhythmogenic potential. By first defining the hemodynamic problem and then deciding what needs treatment and in what order, the most suitable drug for the situation should be selected, rather than always selecting the standard

"institutional inotrope." If these initial therapies are insufficient to promote adequate forward flow, various combinations of drugs may be tested. If systemic perfusion is still inadequate, mechanical circulatory support is required.

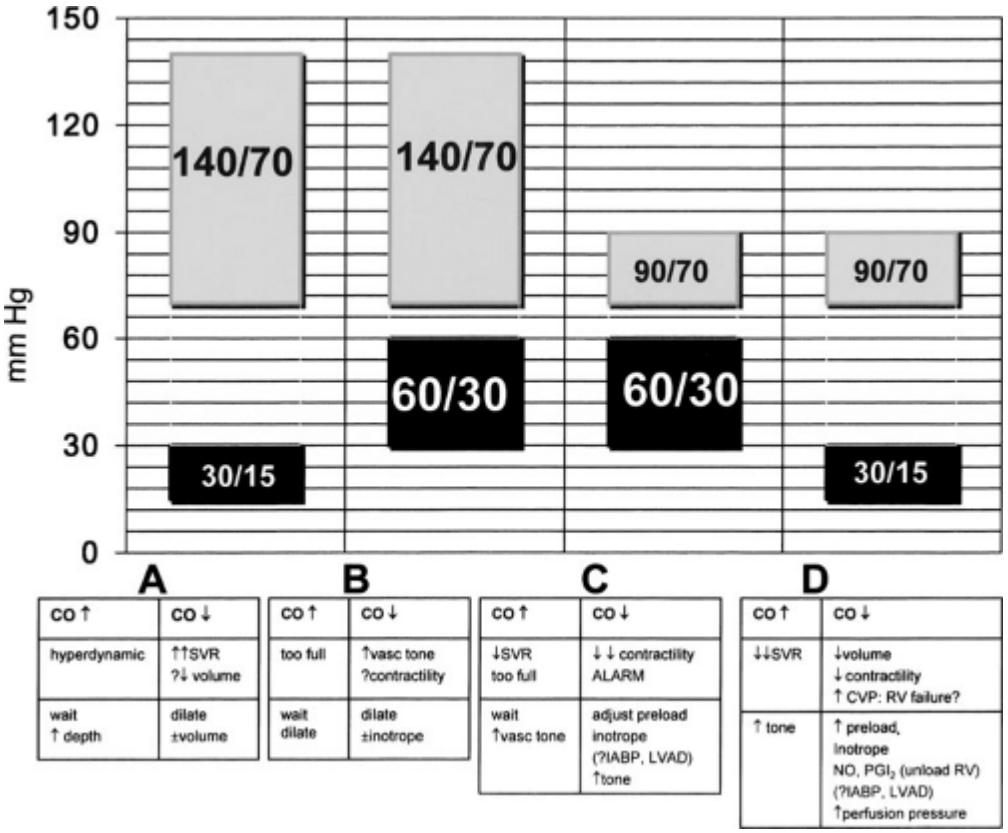

FIGURE 31-25. Hemodynamic abnormalities at termination of cardiopulmonary bypass. ART, arterial pressure; bi-vent, biventricular; CVP, central venous pressure; diast, diastolic function; LV, left ventricle; PA, pulmonary artery pressure; RV, right ventricle; syst, systolic function.

A therapeutic approach to right ventricular failure (see Fig. 31-24D)

is outlined in Table 31-24. When pulmonary arterial pressure is normal or decreased, the etiology is usually severe right ventricular ischemia secondary to intraoperative events or air. The initial response is to return to full bypass, improve perfusion, and await recovery and improvement of contractility. If this does not occur, inotropic and vasodilator therapy is established. In patients who have right ventricular failure secondary to high pulmonary vascular resistance, the mainstay of therapy is reduction of pulmonary vascular resistance with vasodilators, such as prostaglandin E_1 (PGE_1) or nitric oxide, and inotropic support. The phosphodiesterase III inhibitors, amrinone and milrinone, are particularly useful because they significantly decrease pulmonary vascular resistance and increase contractility. Overdistention of the ventricle must be assiduously avoided. Combination therapy with differential infusions refers to infusion of inotropes with vasoconstrictive properties into the left side of the circulation to maintain systemic perfusion, while avoiding an increase of the pulmonary circulation resistance. Persistent right ventricular failure precluding separation from CPB may require the insertion of a right ventricular assist device.

TABLE 31-24 Right Ventricular Failure

	·PAP	
	·INCREASED	·NORMAL OR DECREASED

Intra-aortic Balloon Pump

The simplest and most readily available mechanical support device is the intra-aortic balloon pump. It consists of a 25-cm long sausage-shaped balloon composed of nonthrombogenic polyurethane mounted on a 90-cm vascular catheter. It is usually inserted into the femoral artery, either percutaneously or after surgical exposure, and advanced so the distal tip is below the left subclavian artery (to prevent emboli to the head vessels) and the proximal above the renal arteries. Occasionally, when peripheral vascular disease prohibits passage of the balloon via the femoral artery, it is inserted via the ascending aorta. The intra-aortic balloon pump is the only method that decreases myocardial oxygen demand and increases oxygen supply to the myocardium.

The intra-aortic balloon pump does not pump blood. Rather, it uses the principle of synchronized counterpulsation to assist a beating, ejecting heart: blood volume is moved in a direction "counter" to normal flow. The balloon is inflated during diastole and deflated during systole. The balloon inflation elevates aortic diastolic blood pressure (diastolic augmentation), thus increasing the coronary perfusion gradient proximally, and enhances forward flow distally. During the subsequent systole, the LV will eject facing a lower systemic diastolic pressure (afterload reduction, reduced M

$\dot{V}$

O_2) (Fig. 31-26). Proper timing of balloon deflation is necessary to reduce end-diastolic pressure as much as possible to maximally off-load the ventricle. The indications and contraindications for intra-aortic balloon pump placement are listed in Table 31-25. Myocardial function often improves with the use of the intra-aortic balloon pump, and systemic perfusion and vital organ function are preserved.[96] It is crucial to control heart rate and suppress atrial and ventricular dysrhythmias to ensure proper balloon timing. As cardiac function returns, the assist ratio is gradually weaned from every beat to every other beat and so on and, assuming no further cardiac deterioration, it is removed.

TABLE 31-25 Intra-Aortic Balloon Pump Indications and Contraindications

Indications
Complications of myocardial ischemia

- Hemodynamic: cardiogenic shock
- Mechanical: mitral regurgitation, ventricular septal defect
- Intractable dysrhythmias
- Extension of infarct: postinfarction angina

Acute cardiac instability

- Angina: unstable, preinfarction
- Cath lab mishap: failed PTCA
- Bridge to transplantation
- Cardiac contusion
- ?Septic shock

Open heart surgery

- Separation from cardiopulmonary bypass
- Ventricular failure: right or left
- Increasing inotropic requirement
- Progressive hemodynamic deterioration
- Refractory ischemia

Contraindications

- Severe aortic insufficiency
- Inability to insert
- Irreversible cardiac disease (patient is not a transplant candidate)
- Irreversible brain damage

PTCA, percutaneous transluminal coronary angioplasty.

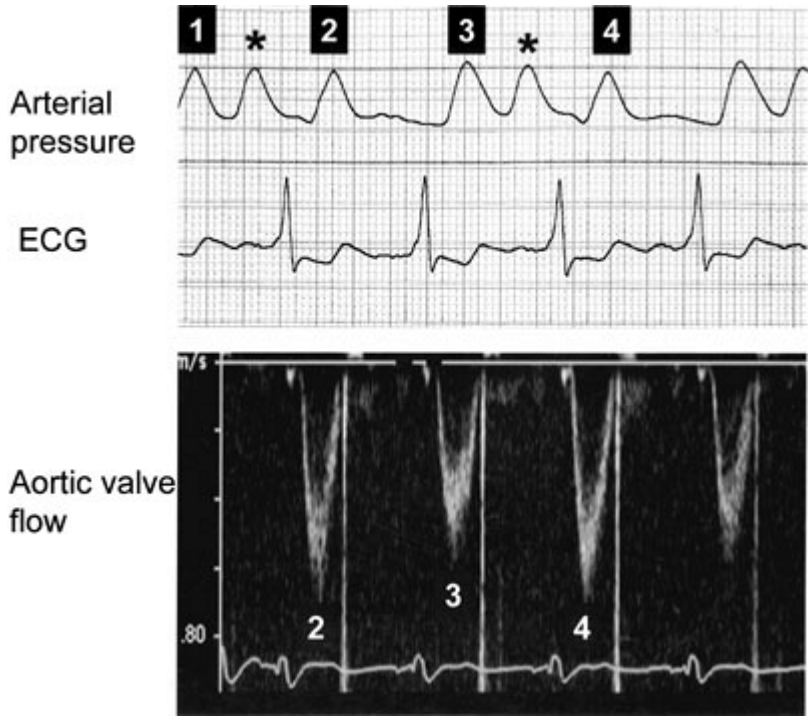

FIGURE 31-26. The physiologic effects of intra-aortic balloon pump (IABP) counterpulsation. The IABP is inflated during diastole (*asterisk*), every other beat (rate 1:2). The arterial systolic pressure is decreased after IABP augmentation (compare beats 2 and 4 to beats 1 and 3). The diastolic arterial pressure is augmented during IABP inflation (*asterisk*). The flow through the aortic valve (~stroke volume) as demonstrated when pulsed wave Doppler echocardiogram (ECG) shows the increased forward flow after augmentation (beats 2 and 4).

Complications associated with the intra-aortic balloon pump are primarily related to ischemia distal to the site of balloon insertion. Direct trauma to the vessel, arterial obstruction, and thrombosis are most common, although aortic perforation and balloon rupture occur rarely. Platelet destruction and thrombocytopenia may also occur.

Ventricular Assist Device

Infrequently (1%), the heart is unable to meet systemic metabolic demands despite maximal pharmacologic therapy and insertion of the intra-aortic balloon pump. Under these circumstances, devices that actually pump blood and bypass either the LV or RV are required. These devices are effective when the injury that produced myocardial dysfunction took place intraoperatively and, more important, if it is reversible. Markedly impaired cardiac function after bypass is not necessarily synonymous with cell death but, rather, may represent temporary "stunning" of the myocardium. Survival ranges from 20 to 30%, often with minimal or no decline in cardiac function.

A second group of patients who have shown benefit from assist devices are those with chronic heart failure. These devices allow for hemodynamic support as a temporizing measure prior to heart transplantation. In the failing heart, it is important to make decisions promptly, and move swiftly to an assist device after the various therapeutic options are exhausted. Very often, mechanical support for one ventricle unmasks previously unrecognized failure in the other, necessitating additional pharmacologic or mechanical intervention.

Postcardiopulmonary Bypass

The procedure is not over when the patient is safely "off pump." Continued vigilance is mandatory during decannulation, protamine administration, "drying up," and chest closure. Anesthetics are administered when clinically indicated. Atrial or junctional dysrhythmias may be caused by removal of the atrial cannulas, but often disappear once they are out. Heparin is reversed with protamine following removal of the atrial cannulas; the arterial return cannula remains in place for continued transfusion of pump contents. When this is completed and bleeding is controlled, the arterial cannula is removed, and after bleeding is considered to be under control, the chest is closed. During decannulation, the possibility exists for unexpected bleeding from the atrial or aortic suture lines, and this sometimes requires rapid transfusion. Continued vigilance for new ischemia (manifested by ST segment changes, ectopy, atrial arrhythmia, regional wall motion abnormalities by TEE) is important because it may indicate a correctable problem with the grafts. Valve patients should have the adequacy of the repair or replacement (i.e., perivalvular leak, residual stenosis) assessed by TEE.

Reversal of Anticoagulation

Protamine, a polycationic protein derived from salmon sperm, is used to neutralize heparin. The initial and total doses administered vary widely. Some use a fixed ratio of protamine to heparin, others use 2 to 4 mg/kg, and still others look to automated protamine titrations to suggest the initial dose. Regardless of the method selected, further requirements are assessed by repeated measures of the activated coagulation time or other clotting assay(s), as well as by the appearance of the surgical field.

Protamine administration is associated with a broad spectrum of hemodynamic effects.[97,98] Idiosyncratic responses include type I anaphylactic reactions and both immediate and delayed anaphylactoid responses. True anaphylaxis, mercifully rare, is characterized by increased airway pressure, decreased systemic vascular resistance with systemic hypotension, and skin flushing.[99] Increased incidence of reactions has been reported in patients sensitized to protamine from previous cardiac catheterization, hemodialysis, cardiac surgery, or exposure to neutral protamine Hagedorn insulin. Perhaps the most devastating complication associated with protamine is sudden and profound pulmonary hypertension accompanied by an elevated central venous pressure, a flaccid distended RV, and systemic hypotension. This complication, which may occur in approximately 1% of patients, is mediated by release of thromboxane and C5a anaphylatoxin.[100,101] The reaction is extremely short lived, and although reinstitution of bypass is required on rare occasions, it is usually not necessary. Whether protamine is administered via the right atrium, LA, or aorta or peripherally probably makes no difference. However, slow administration into a peripheral venous site is advisable. Monitoring of the effectiveness of anticoagulation and its reversal is the subject of a more recent review.[102]

Postbypass Bleeding

Persistent oozing following heparin reversal is not uncommon. The usual causes include inadequate surgical hemostasis or reduced platelet count or function, and neither is identified by a prolonged activated coagulation time. Insufficient doses of protamine, dilution of coagulation factors, and, very rarely, "heparin rebound" belong in the differential diagnosis.

After adequate hemostasis is obtained, the chest is closed. This is occasionally associated with transient decreases in blood pressure, which usually respond to volume infusion. If hypotension persists, the chest should be reopened to rule out cardiac tamponade, a kinked graft, or other serious problems.

As the surgeon completes skin closure, the anesthesiologist prepares for an orderly, unhurried transfer of the patient from the operating room to the recovery room or ICU. Medicated infusions must be regulated, as clinically indicated, with portable infusion pumps. Additional syringes with emergency cardiac medications and necessary equipment for airway management should be carried, and blood pressure(s) and ECG are constantly monitored.

MINIMALLY INVASIVE CARDIAC SURGERY

15 Despite advantages in cardiac surgery and perfusion technology, the deleterious effects of CPB are well documented. These include stroke and neurocognitive defects, renal failure, pulmonary insufficiency, coagulopathy, and activation of a systemic inflammatory response. The desire to avoid these complications, as well as complications associated with sternotomy, were factors leading to development of techniques not requiring CPB. In addition to the medical concerns, patients and insurance providers are demanding shorter hospital stays, faster recuperation, and less painful and invasive surgery. As the population ages, older patients with multiple comorbid medical conditions have become increasingly common. Avoidance of aortic manipulation and cross-clamping, especially in the elderly, is associated with lower stroke rates.[103]

New procedures include minimally invasive direct coronary artery bypass (MIDCAB) followed by the off-pump coronary artery bypass (OPCAB), robotic surgery, and, in the not too distant future, percutaneous valve repair/replacement performed in the cath lab. Initially, MIDCAB was described as an

alternative to angioplasty for single-vessel LAD coronary artery disease because internal mammary artery grafts have higher patency rates than angioplasty. To access the LAD and provide adequate exposure for graft anastamosis, MIDCABs were initially performed via a left thoracotomy using one-lung ventilation.

MIDACB success allowed the development of other forms of minimally invasive surgery. These

include the use of parasternal and inframammary incisions, minithoracotomies, and partial sternotomy. Despite effectively decreasing complications seen from sternotomy (large scar, infection, brachial plexus palsy, and 4- to 8-week recovery period), these alternate incisions provide limited exposure and increasing surgical difficulty. As a result, use of these incisions is more limited and may be supplanted in time by robotic exposure. Another type of minimally invasive cardiac surgery uses port access technology.[104] A small sternotomy is made and catheters are placed percutaneously in the femoral artery and internal jugular vein to facilitate CPB. These catheters include an endovascular aortic balloon that acts as cross-clamp, a pulmonary artery catheter to act as vent, and a coronary sinus catheter placed for retrograde cardioplegia administration. In most cases, the anesthesiologist is required to place these. This technique is used in only a few centers and is not commonly seen. Readers are directed to more recent review articles on this subject.[104]

Following success with minimally invasive surgery, the time was right for the development of off-bypass cardiac surgery, where exposure is via a sternotomy but CPB is not used. The first experiences with off-pump surgery were "simple" left internal mammary artery (LIMA) to LAD grafts supplemented with angioplasty. Off pump then developed into multivessel complete coronary revascularizations. During this period, the lack of specialized cardiac stabilization devices required the use of pharmacologic manipulation of heart rate and myocardial contractility. Heart rates between 40 and 50 beats per minute were considered ideal. This facilitated surgery by allowing the surgeon to operate on a relatively slow and stable target, while not causing undue hypotension. Agents such as short-acting β-blockers, calcium channel blockers, adenosine, and anticholinesterases were used to achieve optimal surgical conditions. With the development of improved retractors and stabilization devices, the need for bradycardia has for the most part disappeared. Other advances include the use of intracoronary shunts, blowers to improve visualization, and sutureless anastomotic devices.

Changes in surgical technique also forced changes in anesthetic technique. High-dose narcotics were abandoned in favor of shorter-acting agents that facilitate early extubation. In addition, the lull period seen on CPB was replaced by the need to constantly monitor hemodynamics and intervene rapidly in the face of changing hemodynamics. Monitoring for OPCAB is well described. Use of an arterial line is mandatory because changes in hemodynamics occur rapidly and may be catastrophic during cardiac manipulation. Central access is also necessary for the infusion of drugs and volume. The use of a pulmonary artery catheter is not mandatory but does provide information about cardiac output and other indices. One major problem associated with OPCAB is that exposure of the diseased coronaries and subsequent graft placement often requires positioning of the heart that is associated with hypotension and ischemia. Unfortunately, standard monitors used in cardiac surgery may not be useful in detecting this ischemia. In OPCAB, positioning and retraction of the heart often results in a low amplitude ECG with axis deviation. These changes may cause ST-T-wave changes to be obscured or falsely minimized. Due to the heart being obscured by lap pads in the pericardial well or being lifted out of the chest, TEE may be unreliable in detecting regional wall motion changes signifying ischemia. Changes in pulmonary artery pressure may signify acute MR due to positioning. However, displacement of the heart may cause falsely elevated central venous and pulmonary pressures despite hypovolemia. Direct observation of the heart and communication with the surgeon are critical in avoiding hemodynamic swings.

The coronary artery to be anastamosed must be isolated proximally and distally. This is performed using either an occluder clip or a snare. Following occlusion, there is usually a period of myocardial ischemia distal to the occlusion. The location of the coronary lesion will determine severity of ischemia. Preexisting high-grade lesions will predispose to collateral formation, which may ameliorate potential ischemia. Right coronary lesions may predispose to bradycardia, atrial arrhythmias, and heart block. The availability of cardiac pacing and rapid cardioversion are essential. Left-sided lesions may cause malignant ventricular arrhythmias and hemodynamic collapse. Sudden hemodymaic collapse may be rescued using inotropes, vasoconstrictors, and volume but may necessitate placement of an intra-aortic balloon pump or conversion to full CPB. The sequence of graft placement must be understood in light of each patient's unique situation. As

a rule, the most critical lesion is bypassed last and the least critical performed first. This allows for the greatest amount of blood to be redirected to the myocardium prior to the largest ischemic insult.

Several techniques may be used to avoid rapid hemodynamic changes: optimizing preload prior to positioning, judicious use of inotropes and α-agonists, and changing table position to include the Trendelenburg position. The Trendelenburg position redistribution of intravascular volume facilitates to the heart. Noromthermia contributes to early extubation and the prevention of coagulopathy. Aggressive pain control improves patient satisfaction and contributes to early extubation. Techniques for pain control in OPCAB and minimally invasive surgery include systemic opioids and nonsteroidal agents such as ketorolac (in patients without renal insufficiency), local infiltration of the surgical incision, and regional anesthesia. Regional techniques including thoracic epidurals, and neuraxial narcotic are used with great success, although anticoagulation is a concern in patients with neuraxial regional anesthetics.[105]

Anticoagulant protocols are controversial. Both heparin and protamine doses vary between centers. Some do not routinely reverse heparin or give half doses of protamine due to the suspicion that OPCAB may cause hypercoagulability.[106]

Despite great interest in OPCAB as a way to decrease the complications associated with CPB, many remain skeptical of the benefits. Several studies have shown the superiority of OPCAB in regard to improved neurologic outcome, whereas others have not.[107] Many have argued that the advantages of CABG on CPB include a still bloodless field allowing for a better anastamosis and long-term graft patency.[108] Other studies have refuted this to prove equal long-term graft patency rates and decreased length of hospital stays.[109,110] These proponents of OPCAB tend to be very familiar with the technique and perform off-pump surgery frequently. This frequency seems to make them technically facile in the peculiarities unique to off-pump surgery. As such, this may account for varying results from center to center. Currently, there is no consensus as to the superiority of standard CABG versus OPCAB. Approximately 20% of centers that perform CABG do so off bypass with the majority of centers performing it infrequently or not at all.

Relatively new to the area of minimally invasive cardiac surgery is that of endoscopic and robotic cardiac surgery. In these techniques, trocars are placed in the chest in anatomic locations to allow the use of long-handled surgical instruments or manipulators. Supporters of its routine use cite decreased pain, faster healing, and greater patient satisfaction. For the most part, the anesthetic considerations for endoscopic and robotic surgery are similar to standard minimally invasive off-pump surgery.[111] These include one-lung ventilation, positioning issues, and normothermia. One major difference is that, just as in port access surgery, TEE is crucial in the placement of percutaneous cannulas.

Due to the high cost of the equipment and training required, few centers perform robotic surgery. However, just as endoscopic and video-assisted surgery has become ubiquitous in general surgery, it may have a larger role in cardiac surgery in the future.

POSTOPERATIVE CONSIDERATIONS

Bring Backs

Postoperative reexploration is needed in 4 to 10% of cases. The indications are persistent bleeding, excessive blood loss, cardiac tamponade, and, infrequently, unexplained poor cardiac performance (rule out tamponade). Surgery is usually required within the first 24 hours but also later in cases of delayed tamponade. The possibility of cardiac tamponade must always be included in the differential diagnosis of the postoperative "dwindles" because the classic symptoms and signs are often absent.

Tamponade

Cardiac tamponade exists when venous return is impaired because of elevated intrapericardial pressure. Normally, the pressure surrounding the heart is within 1 to 3 mm Hg of atmospheric,

and the intracavitary pressures can be monitored using atmospheric pressure as the zero reference point. In tamponade, the intracardiac pressures are deceptively elevated and do not reflect the actual volume state. Because the surrounding (intrapericardial) pressure is increased, the distending pressure (transmural pressure = intracavitary pressure – extracavitary pressure) is actually decreased. Cardiac chamber collapse is a critical feature of cardiac tamponade, and the chambers with the lowest intracardiac pressure (atria and RV in diastole) are most likely to be compressed. The stroke volume is limited, and cardiac output depends on heart rate. Compensatory mechanisms include peripheral vasoconstriction to preserve venous return and systemic blood pressure, as well as tachycardia. Myocardial ischemia may occur because of the tachycardia and reduced coronary perfusion pressure.

Clinically, patients present with dyspnea, orthopnea, tachycardia, paradoxical pulse, and hypotension, but the intubated, sedated, mechanically ventilated patient in the postanesthesia care unit following cardiac surgery may have varied clinical and hemodynamic presentations. Owing to its often atypical presentation in the cardiac surgical patient, the diagnosis of tamponade should be considered whenever hemodynamic deterioration or signs of low output failure occur in these patients. In postoperative cardiac patients, the pericardium is no longer intact, and loculated areas of clot may compress only one chamber, causing isolated increases in filling pressure (i.e., mimicking right and/or left ventricular dysfunction). Urine output is usually diminished. Serial chest films typically show progressive mediastinal widening. The diagnosis of tamponade may be confirmed by transthoracic echocardiography (TTE) or TEE. Despite the usually present diastolic collapse of the right atrium, RV and/or LV diastolic collapse are the most sensitive and specific signs of cardiac tamponade.[112] In addition, there is excessive respiratory variation of the Doppler flow velocities across the tricuspid and mitral valves. Because of the existing extracardiac compression, respiration increases the ventricular interdependence and affects the diastolic filling of the two ventricles differently. During mechanical inspiration, the increased intrathoracic pressure will impede the RV and augment the LV filling, respectively. The pulsed-wave Doppler echocardiographic examination of the diastolic tricuspid flow will show marked decrease in the velocity of the early (E) wave as the already compromised filling gradient between the extrathoracic veins and the intrathoracic RV is further reduced. During the same time, the early diastolic mitral flow will increase as the increased intrathoracic pressure is transmitted to the intrathoracic pulmonary veins, increasing the filling gradient of the LV. The opposite effects take place during mechanical exhalation, when the effects of positive ventilation dissipate. The TTE approach may have important limitations: a retrosternal collection may be very difficult to be visualized in a postoperative patient, and subcostal views are rarely feasible early in the postoperative period because of the presence of chest tubes, pacemaker wires, and/or local tenderness in the subxyphoid area. Therefore, TEE is a better diagnostic tool in the immediate postoperative period.

The cure for cardiac tamponade is surgical; anesthetics can only further depress cardiac function. Therefore, drugs are selected that will preserve the compensatory mechanisms sustaining forward flow. Drugs with vasodilator (either venous or arteriolar) or myocardial depressant properties should be avoided in patients with serious hemodynamic compromise; dosages of induction agents should be appropriately reduced. Ketamine, because of its sympathomimetic effects, may be helpful in preserving heart rate and blood pressure response. It is not, however, a panacea and can induce hypotension in patients under maximal sympathetic stress. If on reopening the chest there is minimal fluid or if the patient shows little improvement, a thorough search for other causes of inadequate cardiac performance, such as clotted or kinked grafts, myocardial ischemia, or valve malfunction, is indicated.

Postoperative Pain Management

Early awakening and extubation have brought the problem of postoperative pain management in cardiac surgery into focus. The standard practice has been intravenous opioids given as needed followed by conversion to oral pain medications. However, the quest is on to find an ideal postoperative pain management technique to complement the goal of early extubation and maximize patient satisfaction. Several studies have shown the benefits of intrathecal

administration of opioids. The addition of nonsteroidal anti-inflammatory agents may play an increasing role. In cardiac patients with severe pain associated with sternal fractures due to the sternal retraction device during internal mammary harvest, epidural analgesia has been shown to be safe and effective, and results in improved postoperative pulmonary function.

ANESTHESIA FOR CHILDREN WITH CONGENITAL HEART DISEASE

Because "anatomy dictates physiology," the anesthetic management of children with congenital heart disease requires knowledge of anatomic defects, planned surgical procedures, and comprehensive understanding of the altered physiology. The overall incidence of congenital heart diseases varies between 4 and 12 per 1,000 live births.

The best way to understand the impact of a congenital defect and how anesthetic agents will interact with this defect is

to envision the path blood must follow to maintain flow to the pulmonary arteries and aorta. Congenital cardiac lesions can be cyanotic or acyanotic. Cyanotic lesions can be due a common mixing chamber, obstruction to pulmonary blood flow, or due to separation of the systemic and pulmonary circulation. Shunting of blood causes volume overload on the ventricle; and obstruction of blood flow causes pressure overload. Table 31-26 classifies various types of lesions by their physiologic impact. However, it must be remembered that there is often more than one defect present.

TABLE 31-26 Physiologic Effects of Congenital Cardiac Lesions

Volume Overload of Ventricle or Atrium Resulting in Increased Pulmonary Blood Flow
Atrial septal defect (high flow, low pressure)
Ventricular septal defect (high flow, high pressure)
Patent ductus arteriosus (high flow, high pressure)
Endocardial cushion defect (high flow, high pressure)
Cyanosis Resulting From Obstruction to Pulmonary Blood Flow
Tetralogy of Fallot
Tricuspid atresia
Pulmonary atresia
Pressure Overload to Ventricle
Aortic stenosis
Coarctation of the aorta
Pulmonary stenosis
Cyanosis Due to Common Mixing Chamber
Total anomalous venous return
Truncus arteriosus
Double outlet right ventricle
Single ventricle
Cyanosis Due to Separation of Systemic and Pulmonary Circulation
Transposition of the great vessels

Preoperative Evaluation

History

Symptoms. Infants who have heart failure present with feeding difficulties and symptoms of

respiratory distress, often take frequent small feeds, and rapidly become exhausted. Poor weight gain is often a consequence of this. In warmer climates infants may perspire profusely, particularly with feeds. Parents may notice that their baby is breathing rapidly and suffers from recurrent chest infections. Cyanosis may not be recognized until quite severe. The cyanosis may be continuous and unchanging or intermittent and progressive. Cyanotic episodes that are occurring more frequently and with less stimulation suggest the potential for rapid cardiorespiratory decompensation. In older children, heart failure manifests as breathlessness and exercise intolerance. This can be assessed by comparison with peers or by formal exercise testing. Orthopnea and nocturnal dyspnea indicate severe failure. Overt syncope or presyncope, light headedness, vertigo, and blurred vision may be the symptoms of an arrhythmia or, much less commonly, of significant outflow obstruction or myocardial dysfunction. The presence of an upper respiratory tract infection in a child may be associated with an increased incidence of postoperative respiratory complications and an extended stay in the ICU.[113]

Medications. It is important to obtain a detailed history of medications the patient is currently receiving and be aware of their potential interactions with anesthetic agents.

Previous Surgical Procedures. It is vital to understand the patient's original and "corrected" anatomy, as well as his or her response to previous surgery and anesthesia.

Physical Examination

The physical examination of a child should seek signs and symptoms of cardiac dysfunction and failure. Failure to thrive due to pulmonary hypertension, poor peripheral oxygenation, or metabolite delivery is a common finding. Obstructive lesions without congestive failure, such as coarctation, aortic stenosis, or pulmonary stenosis, are associated with normal growth. Patients with cyanotic lesions such as tetralogy of Fallot may exhibit generalized growth retardation; for those who have lesions associated with congestive heart failure, such as left-to-right shunts, weight is more often affected than height. Complete cessation of growth, even weight loss, is seen in patients with severe congestive heart failure.[114] The physical examination should seek to discover other signs of congestive heart failure, such as irritability, diaphoresis, rales, jugular venous distention, and hepatomegaly.

The possibility of associated congenital anomalies must be considered. The overall incidence of extracardiac anomalies among children with congenital heart disease may be as high as 20%.[115]

Assessment of extremities should include evaluation of cyanosis, clubbing, edema, pulse volume, and blood pressure. In children with Blalock-Taussig shunts, the pulse may be absent or reduced on the side of the shunt. It is important to measure blood pressure in the arms and in the legs in all patients in whom congenital heart disease is suspected; thus, coarctation of aorta will not be missed.

Auscultation of the heart in these patients can reveal different types of murmurs, depending on the lesions as shown in Table 31-27.

TABLE 31-27 Classification of Cardiac Murmurs

Systolic

- Stenotic semilunar valves
- Regurgitant atrioventricular valves
- Atrial septal defect
- Ventricular septal defect
- Coarctation of the aorta
- Still's murmur

Diastolic

- Regurgitant semilunar valves
- Stenotic atrioventricular valves
- Mitral flow rumble
- Tricuspid flow rumble

Continuous

- Patent ductus arteriosus
- Arteriovenous fistula
- Excessive bronchial collaterals
- Aortopulmonary window
- Venous hum
- Surgical shunt
- Severe peripheral pulmonic stenosis

All children undergoing cardiac surgery should have a complete examination of their airway. Presence of macroglossia, hypoplastic mandible, narrow palate, enlarged tonsils, and

laryngotracheal anomalies may compromise the anesthesiologist's ability to maintain a patent airway. This attention is particularly important in small children and in patients with compromised hemodynamic status because their small functional residual capacity, in combination with higher oxygen consumption, provides a mechanism for rapid desaturation and the potential for cardiovascular collapse.

Laboratory Evaluation

Hemoglobin. The presence of anemia in these patients may require priming of the extracorporeal circuit with red blood cells. Children with cyanotic lesions are polycythemic. Polycythemia results as a consequence of bone marrow stimulation (via release of erythropoietin from the kidneys) from arterial desaturation. This increase in red cell mass can lead to hyperviscosity. The increase in blood's viscosity predisposes to peripheral sludging and reduced oxygen delivery. The sludging is augmented by the presence of dehydration from preoperative fasting and by hypothermia from low ambient operating room temperatures. Children brought into the operating room with increased levels of hemoglobin are at risk for the development of a sudden hyperviscosity crisis that can lead to progressive acidosis, cardiovascular decompensation, and end-organ thrombosis. In patients with hematocrit of more than 70%, consideration should be given to preoperative electrophoresis if symptomatic hyperviscosity is present. Cyanotic children with low hematocrit may exhibit hypoxic spells more readily than if the oxygen-carrying capacity were normal.

Coagulation Profile. All children with congenital heart disease undergoing open heart surgical procedures are at risk for perioperative hemostatic derangements. Polycythemia can induce a low-grade disseminated intravascular coagulation with activation of fibrinolysis, degranulation of platelets, and consumption of coagulation factors.[116]

Newborns often have inadequate liver-dependent coagulation factors due to immaturity of hepatic function. A platelet count, prothrombin time, and partial thromboplastin time should be evaluated in every child.

Other Laboratory Evaluations. Children on diuretic therapy are at risk for hypokalemia, particularly if they are digitalized. Infants, particularly those in congestive heart failure, are also at risk for both hypoglycemia and hypocalcemia. Many children who have undergone major cardiac procedures earlier in their lives may have been exposed to blood or blood products. These children

are at increased risk of having abnormal serum antibodies to various blood antigens. Hence, samples of the child's blood should be sent to the blood bank for possible cross matching, which will allow proper identification of any abnormal antibodies.

Preoperative arterial blood gases obtained in patients with cardiorespiratory compromise indicate the amount of respiratory reserve present. Arterial PO_2 values of 30 to 40 mm Hg and peripheral O_2 saturations of less than 70% indicate a severe reduction of cardiovascular reserve to the point where progressive metabolic acidosis may be expected.

Chest Radiograph

The chest radiograph of a child with congenital heart disease should be evaluated for cardiac position, size, shape, abnormal vessels, right aortic arch, scimitar syndrome (hypoplasia/aplasia of one or more lobes of right lung and hypoplasia of right pulmonary artery), aberrant pulmonary vessels, abnormal position of bronchi, vascular rings, or associated pulmonary abnormalities (e.g., pneumonia, atelectasis, or emphysema).

Electrocardiogram

ECG should be reviewed for rate and rhythm abnormalities.

Echocardiography and Cardiac Catheterization

Echocardiography delineates most of the cardiac anatomy and permits noninvasive measurement of ventricular size and function, of cardiac output, and of the severity of valve dysfunction. Cardiac catheterization is reserved for patients with poor echocardiographic windows and when there is intervening bone or air-filled lung (e.g., scoliosis or abnormalities of the peripheral pulmonary arteries). The physiologic and anatomic data from echocardiography and cardiac catheterization provides invaluable insight into the formulation of the anesthetic plan.

Premedication

The primary purpose of the premedication is to calm the child without hemodynamic compromise. This will facilitate the separation of the child from the parents, as well as ease the fear and anxiety associated with the perioperative period. The choice of premedicant drug should be based on the child's physiology. The primary danger of premedication is oversedation, which leads to the loss of protective airway reflexes. Medications used for premedication include midazolam, fentanyl, ketamine, and atropine.

Small infants, particularly those scheduled later in the day, should not be kept without fluids while awaiting surgery.

Monitoring

Monitors typically used during the open heart procedures include ECG, peripheral and central temperatures, noninvasive and invasive blood pressure monitoring, central venous pressure monitoring (which can include right atrial and left atrial pressure lines placed by the surgeon intraoperatively), arterial oxygen saturation, and end-expiratory capnography. Intraoperative TEE has become an invaluable diagnostic and monitoring tool.

Induction

Inhalational agents hold a prominent place as induction agents for pediatric cardiac anesthesia and may also be continued for maintenance. Nitrous oxide can be used in conjunction with one of the potent inhalational agents. It does not increase pulmonary artery pressures except in those with preexisting pulmonary hypertension. The use of nitrous oxide in children with intracardiac shunts is primarily limited to the induction period because of the risk of enlarging bubbles of air. In addition, nitrous oxide has direct cardiac depressant effects that are more pronounced in infants and children than in adults.[117]

Ketamine has enjoyed some popularity as an induction agent in children with cyanotic lesions. Its popularity stems from its hemodynamic effects, combined with the facts that it can be given intramuscularly and spontaneous respiration can be maintained while intravenous and arterial cannulae are placed. In children studied postoperatively, ketamine was shown to have no significant effects on pulmonary vascular resistance as long as ventilation is preserved.[118] Ketamine is the agent of choice for induction of anesthesia in patients with cardiac tamponade. Ketamine usually produces a tachycardia and rise in blood pressure. Oxygenation is usually not impaired.

Maintenance

The choice of anesthetic agents following induction is governed by ventricular function, the use of CPB, and the anticipation of continued mechanical ventilation or tracheal extubation at the end of the case.

Intravenous Agents

Opioids are used routinely to eliminate the stress response in the prebypass phase of pediatric cardiac surgery. Stress responses to surgery (as measured by plasma concentration of epinephrine, norepinephrine, insulin, glucagons, and glucocorticoids) were blocked with high doses of fentanyl compared with surgery without fentanyl.[119] Large-dose synthetic opioid anesthesia with fentanyl 50 to 100 µg/kg is commonly used for neonates and infants undergoing congenital cardiac surgery, particularly if the patients have limited hemodynamic reserve, are at risk of pulmonary hypertension, or are expected to have a prolonged postoperative recovery. Sufentanil is similarly effective.[120] Remifentanil is a unique opioid allowing a rapidly titrable effect. In infants and children younger than 5 years of age, infusions of 1.0 µg/kg/min and greater can suppress glucose increase and tachycardia, and reduce plasma cortisol levels associated with the prebypass phase of cardiac surgery, whereas 0.25 µg/kg/min infusion does not. Remifentanil should be used with caution in neonates with complex congenital heart disease because it can be associated with severe bradycardia.[120] No specific relationship between opioid dose and stress response has been established. A balanced anesthetic technique containing fentanyl 25 to 50 µg/kg is sufficient to blunt hemodynamic and stress response to the prebypass phase of surgery. Higher doses of fentanyl 100 to 150 µg/kg offer little advantage over 50 µg/kg and can necessitate intervention to prevent hypotension.[121]

Inhalational Agents

Halothane depresses the cardiac output and blood pressure in a dose-dependent manner.[122] Halothane must be used cautiously in children with severe left ventricular failure or severe cyanosis because the myocardial depression from the drug may further compromise the already poorly contractile ventricle. Dose-dependent beta-blocking action of halothane may actually be beneficial in certain circumstances such as idiopathic hypertrophic subaortic stenosis or infundibular pulmonic stenosis.

Isoflurane causes a decrease in blood pressure that appears to be similar in magnitude to that caused by halothane when administered at equipotent doses. However, with isoflurane, myocardial function appears to be better preserved than with halothane.[123] Sevoflurane use may be associated with a decrease in blood pressure. The incidence of hypotension (defined as >30% decrease from baseline) at 1 MAC is highest in neonates and infants younger than 1 year of age. With incision, blood pressure tends to return toward baseline in all groups except neonates. Sevoflurane use is associated with a lower incidence of arrhythmias than is halothane. The ability to use sevoflurane for an inhalation induction, together with its lack of significant myocardial depression, makes it a good choice for induction when an inhalation agent is used.

Neuromuscular Blocking Drugs

Succinylcholine has often been used to facilitate tracheal intubation. Because infants have an

increased extracellular fluid space compared with adults and succinylcholine is distributed throughout this fluid space, a dose of 2 mg/kg is required to provide muscle relaxation for intubation in infants. The drug's major side effects are bradycardia and, very infrequently, asystole. These events are more common with repeated doses. Because of the potential for bradycardia and the ability to use other agents, succinylcholine should have little place in pediatric cardiac anesthesia.

A nondepolarizing relaxant can be used both to facilitate tracheal intubation and to provide muscle relaxation during the operative procedure. The choice among nondepolarizing relaxants is based on their hemodynamic effects and duration of action. When an increased heart rate would be beneficial, as in the case of a small infant, pancuronium is the preferred agent. The popularity of the intermediate-acting agents such as cis-atracurium and vecuronium has spilled over into cardiac anesthesia. They are more suitable for procedures where patients are expected to be extubated within a short postoperative period. Neuromuscular blocking agents should be titrated to effect. This is especially important in the case of a reoperation, in which the phrenic nerve may be encased in scar tissue. If excessive relaxants have been given and the diaphragm does not respond to electrical stimulation of the phrenic nerve, it is possible to transect the phrenic nerve with the electrocautery. In the small infant, loss of diaphragmatic activity can cause respiratory failure.

Cardiopulmonary Bypass

The many advances in the CPB, together with improved surgical and anesthetic techniques, have significantly improved the survival of children with congenital heart disease. Hemostatic derangement due to CPB is of particular significance in pediatric cardiac surgery and may result in a more pronounced bleeding tendency than that seen in adult patients. Specific influences include a greater degree of hemodilution, the use of deep hypothermic circulatory arrest, the influence of cyanosis on hemostasis and coagulation, and the immature coagulation system of the neonate. These factors can exacerbate activation of the hemostatic and inflammatory cascades and the impaired platelet function that result from a period of extracorporeal circulation. The protease inhibitor aprotinin has shown its capacity to block fibrinolysis in low doses and to attenuate contact activation in higher doses. Despite the proven efficacy of aprotinin to reduce bleeding and the need for blood and blood product transfusions in adult cardiac surgery, the results in pediatric cardiac surgery are conflicting.[124] Aprotinin has the ability to provoke an antibody response in the recipient, and children who are having repeat procedures are at risk for anaphylaxis, if aprotinin was used in previous operations.[125]

During the course of CPB, vasodilating agents may be employed to promote uniform cooling and rewarming. The adequacy of flow during CPB can be assessed by the difference between esophageal and rectal temperatures. If deep hypothermia is planned (temperature <20°C), a tympanic temperature probe may also be placed.

Separation from CPB will require pharmacologic inotropic and/or chronotropic support in some patients. Pacing should be employed in the presence of a heart rate that is slow for age. In lesions where the presence of increased pulmonary vascular resistance is known or suspected, the patient may benefit from addition of nitric oxide. Nitric oxide, a low molecular weight, lipophilic molecule with a rapid onset of action and a very short intravascular half-life, increases intracellular cyclic guanosine monophosphate, causing pulmonary vasodilation. The response among patients with pulmonary hypertension to inhaled NO (iNO) is variable. A favorable response is defined as a reduction in pulmonary arterial pressure and improvement in systemic arterial saturation (by virtue of increased pulmonary blood flow). Left ventricular filling and cardiac output may also

increase, and may be evidenced as an increase in urine output or a decrease in arterial base deficit. The presence of a dose-response relationship for iNO has been observed between the concentrations 2 and 80 ppm. Patients with higher pulmonary artery pressure or pulmonary vascular resistance have the most consistent and pronounced vasodilatory response. Nitric oxide is rapidly inactivated in the bloodstream by either binding to iron-rich oxyhemoglobin to form methemoglobin and nitrate or binding with oxygen to form nitrite. Methemoglobin is reduced by

methemoglobin reductase to its oxygen-carrying form, and nitrites and nitrates are excreted in the urine. Clinical use of iNO should include various precautionary measures. Because of the risk of nitrite production, the concentration of iNO should be titrated to the smallest concentration that achieves the desired clinical response. Concentrations of nitrites and methemoglobin levels should be monitored.[126]

Drugs useful in the postbypass period are listed in Table 31-28.

TABLE 31-28 Medications Given by Continuous Infusion

·DRUGS	·USUAL INITIAL DOSE (µg/kg/min)	·USUAL DOSE RANGE (µg/kg/min)
Amrinone[a]	2–5	2–20
Dobutamine	2–5	2–20
Dopamine	2–5	2–20
Epinephrine	0.01	0.01–0.1
Isoproterenol[b]	0.05–1	0.1–1
Lidocaine	20	20–50
Milrinone	50 µg/kg over 3 min	0.3–0.7
Nitroglycerin	0.5	0.5–5
Nitroprusside	0.5	0.5–5
Norepinephrine	0.1	0.1–1
Phentolamine	0.1–1	0.5–5
Phenylephrine	1	1–3
Prostaglandin E_1	0.05–0.1	0.05–0.2
Trimethaphan	5	5–10
Vasopressin	(1 µg–4 U)	0.0004

[a]Requires initial bolus of 750 µg/kg over 3 min before start of infusion.

[b]For chronotropic effect following cardiac transplantation, doses of 0.005 to 0.010 µg/kg/min are used.

Tracheal Extubation and Postoperative Ventilation

Children with simple lesions who have undergone surgery (atrial septal defect, ventricular septal defect without failure repaired across the tricuspid valve) that does not involve ventricular incisions can often be extubated at the conclusion of surgery, or shortly thereafter in the ICU.[127,128] Those with risk factors for ventilatory failure must fulfill traditional extubation criteria. Risks factors include complex surgery, circulatory arrest, pulmonary hypertension, and preexisting pulmonary disease.

Criteria for tracheal extubation following complex repairs are as follows: (1) ability to maintain oxygenation during spontaneous ventilation; (2) coordination of thoracic and abdominal components of respiration; (3) chest radiograph without significant atelectasis, effusions, or infiltrates; (4) short period of time without caloric input, or supplementation with enteral or intravenous feeding for patients requiring ventilation for a long period; and (5) stable inotropic support.

A thoracotomy incision in a young infant, for ligation of a patent ductus arteriosus or placement of a Blalock shunt, has been shown to decrease functional residual capacity in this population, and postoperative respiratory support is indicated. In some cases, nasal continuous positive airway pressure can be employed instead of mechanical ventilation.

The effects of mechanical ventilation on cardiac performance can be judged by changes in arterial oxygenation and right atrial (central venous) or mixed venous oxygenation.

In patients with Fontan physiology with passive pulmonary circulatory arrangement, decreasing pulmonary vascular resistance is of paramount importance, and very much depends on adequate ventilation, usually through mechanical ventilation. The potentially detrimental effects of endotracheal intubation and positive-pressure ventilation offset this. Positive-pressure ventilation is known to have a deleterious effect on pulmonary blood flow in patients with Fontan physiology. Resumption of pain-free spontaneous respiration does enhance hemodynamic performance in these patients.[129]

Chapter 32

Anesthesia for Vascular Surgery

John E. Ellis
Michael F. Roizen
Srinivas Mantha
Margaret L. Schwarze
James McKinsey
David A. Lubarsky
Charbel A. Kenaan

KEY POINTS

1	The heart is the major focus of the anesthesiologist's attention because myocardial dysfunction remains the single most important cause of morbidity following vascular surgery.
2	Excellent medical therapy, including use of antihypertensives such as beta-blockers and angiotensin-converting enzyme (ACE) inhibitors, statin drugs, aspirin, and control of hyperglycemia with hypoglycemics and/or insulin, may reduce perioperative morbidity and mortality in vascular surgery.
3	The multicenter Coronary Artery Revascularization Prophylaxis (CARP) trial randomized patients with coronary disease (except left main disease or ejection fraction <20%) before elective vascular surgery to either coronary revascularization or medical therapy. With state-of-the-art aggressive medical therapy (>80% of patients on beta-blockers, >70% on aspirin, and >50% on statins in both groups), they could find no benefit to coronary revascularization
4	Of the various risk-reducing strategies, evidence suggests that perioperative beta-blockade provides benefit in preventing cardiac morbidity and mortality.
5	Hypotension and hypoperfusion may not be the precipitating or sole cause of stroke after carotid endarterectomy (CEA); embolic events may be just as or even more important, and often occur postoperatively.
6	Phenylephrine doubles the incidence of wall motion abnormalities observed by echocardiography compared with the incidence in patients whose blood pressure is maintained simply by light anesthesia and endogenous vasoconstrictors.

7	The definitive preventive measures for spinal cord ischemia are short cross-clamping time, fast surgery, maintenance of normal cardiac function, and higher perfusion pressures. Other methods such as cerebrospinal fluid (CSF) drainage, distal perfusion, and hypothermia may be beneficial in high aortic clamping.
8	As opposed to elective aortic reconstruction, in which preserving myocardial function is the primary goal, in emergency resection of the aorta the crucial factor for patient survival is first rapid control of blood loss and reversal of hypotension, and then preservation of myocardial function.
9	Regional anesthesia may offer several advantages, including avoidance of hyperdynamic responses to tracheal intubation and extubation, reduced incidences of postoperative respiratory and infectious complications, and reduced postoperative hypercoagulability and graft thrombosis.

GOALS OF ANESTHESIA

The goals of anesthesia for vascular surgery are similar to those for any procedure: to minimize patient morbidity and maximize surgical benefit. In the current environment, we must also achieve these goals in the most cost-effective manner. The increasing age of the population in Western societies and our desire to restore functional status to the elderly will likely increase the number of vascular procedures performed in the United States. The morbidity from these procedures has decreased rapidly, from a 6-day mortality of >25% for major aortic reconstruction in the mid-1960s to as low as 3% mortality today. We believe that advances in preoperative preparation and anesthetic management are responsible for much of these improvements. The anesthesiologist may have a greater influence in reducing the morbidity and costs of vascular surgery than in any other surgical procedure.

1 This chapter begins with a discussion of the pathophysiology of atherosclerotic vascular disease and the general medical problems common in patients with peripheral vascular disease, particularly coronary artery disease (CAD). We believe the heart should be the major focus of the anesthesiologist's attention insofar as myocardial dysfunction remains the single most important cause of morbidity following vascular surgery. More recent studies have identified and emphasized the stressful nature of the postoperative period, whereas other workers have refined preoperative risk stratification and risk-reducing strategies. However, preservation of other organ systems (particularly renal and central nervous) is also crucial. Outcome after vascular surgery is determined essentially by patient factors, surgical factors, and institution-specific factors. The National Veterans Affairs Surgical Risk Study found that low serum albumin values and high American Society of Anesthesiologists (ASA) physical classification were among the best predictors of morbidity and mortality after vascular surgery (Table 32-1). Thus, this chapter reviews current controversies in the selection of anesthetic techniques, monitoring modalities, and organ protection strategies. The specific surgical goals, anatomy, and complications for cerebrovascular, thoracic aortic, visceral, abdominal aortic, and lower-extremity revascularization are placed in the context of optimal anesthetic management. New surgical techniques such as angioplasty and endovascular repair with the placement of stent grafts promise to further reduce morbidity and mortality.[1] The anesthetic implications of these new techniques are discussed. The different scenarios that lead to emergency surgery for these conditions and their appropriate management are also discussed.

TABLE 32-1 The 10 most important preoperative predictors of postoperative 30-day mortality after vascular surgery in veteran's affairs medical centers

▪PREDICTOR	▪ODDS RATIO
Ventilator dependent	2.71
ASA class	1.89
Emergency operation	2.40
DNR status	2.96
BUN >40 mg/dL	1.47
Albumin	0.61
Age	1.03
Creatinine >1.2 mg/dL	1.48
Esophageal varices	4.30
Operative complexity score	1.32
BUN, blood urea nitrogen; DNR, do not resuscitate.	
All variables are statistically significant ($P < .05$) and were selected after stepwise multivariable analysis.

VASCULAR DISEASE: EPIDEMIOLOGIC, MEDICAL, AND SURGICAL ASPECTS

Pathophysiology of Atherosclerosis

Atherosclerosis is a generalized inflammatory disorder of the arterial tree with associated endothelial dysfunction.[3] As a major regulator of vascular homeostasis, the endothelium exerts numerous vasoprotective effects such as vasodilation, suppression of smooth muscle cell growth, and inhibition of inflammatory responses. Many of these are mediated by nitric oxide, the most

potent endogenous vasodilator. Inflammatory and degenerative processes characterized by the formation of intimal plaques composed of oxidized lipid accumulation, inflammatory cells, smooth muscle cells, connective tissue fibers, and calcium deposits play an important role in the pathogenesis of atherosclerosis. Putative etiologies are endothelial damage caused by hemodynamic shear stress, inflammation from chronic infections, hypercoagulability resulting in thrombosis, and the destructive effects of oxidized low-density lipoproteins (LDLs). Disruption of the fibrous cap over a lipid deposit can lead to plaque rupture and ulceration. Vasoactive influences can result in spasm and acute thrombosis.

In atherosclerosis, the normal homeostatic functions of endothelium are altered, promoting an inflammatory response. In fact, chronic inflammation has been implicated at every stage of atherosclerosis, from initiation to progression and eventually, plaque rupture. Adhesion molecules expressed by inflamed endothelium recruit leukocytes, including monocytes which then penetrate into the intima, predisposing the vessel wall to lipid accretion and vasculitis. Markers of inflammation (e.g., acute-phase reactants such as high-sensitivity C-reactive protein [hs-CRP]) may be useful in predicting an increased risk of coronary heart disease. Predisposing risk factors for atherosclerosis include many aspects of the metabolic syndrome: abdominal obesity, atherogenic dyslipidemia, raised blood pressure, insulin resistance, proinflammatory state, and prothrombotic state.[4] Major risk factors also include cigarette smoking, elevated low-density lipoprotein cholesterol (LDL-C), low high-density lipoprotein (HDL), family history of premature coronary heart disease, and aging; emerging risk factors include elevated triglycerides, and small LDL particles. More recent recommendations for more aggressive treatment of hypertension reflect studies that suggest that this will delay the progression atherosclerotic disease; beginning at 115/75 mm Hg, cardiovascular disease risk doubles for each increment of 20/10 mm Hg throughout the blood pressure range.[5]

Morbidity associated with atherosclerosis arises from plaque enlargement and lumen obstruction (e.g., lower-extremity arterial occlusion with limb ischemia) or plaque ulceration, embolization, and thrombus formation (e.g., transient ischemic attacks in patients with carotid disease). Alternatively, atrophy of the media due to atherosclerotic disease may weaken the arterial wall, producing aneurysmal dilatation. The clinical expression of atherosclerosis tends to be focal, with clinical symptoms caused by localized interference with circulation occurring in several critical sites. Major arterial sites that are

particularly prone to the development of advanced atherosclerotic lesions include the coronary arteries, carotid bifurcation, infrarenal abdominal aorta, and iliofemoral vessels.

Natural History of Patients with Peripheral Vascular Disease

Atherosclerotic vascular disease (AVD) is one of the most important and common causes of death and disability in the United States and throughout the world. More than 25 million persons in the United States have at least one clinical manifestation of atherosclerosis. Throughout the last half of the twentieth century, coronary artery atherosclerosis has been a major focus for basic and clinical investigation. As a result, considerable strides have been made in the development of programs to prevent and treat the clinical manifestations of CAD. Yet atherosclerosis is a systemic disease with important sequelae in many other regional circulations, including those supplying the brain, kidneys, mesentery, and limbs. Elderly patients with symptomatic or even asymptomatic peripheral vascular disease have greatly increased mortality rates, particularly from cardiovascular causes (6- to 15-fold increases).

The prevalence of >25% carotid stenosis in patients older than 65 years of age was 43% in men and 34% in women in one of the Framingham studies. Patients with cerebral atherosclerosis are at increased risk for ischemic stroke. Stroke is the third leading cause of death and principal cause of long-term disability in the United States today, with 600,000 new or recurrent strokes occurring annually. Presence of carotid artery disease also identifies patients at risk for fatal and nonfatal myocardial infarction (MI). Stroke risk is most strongly associated with previous stroke history and greater degree of illness. The risk of stroke is relatively uncommon (0.4% to 0.6% of patients) after noncarotid peripheral vascular surgery, but when it does occur it is associated with

longer length of stay and higher mortality.[6] Patients with renal artery atherosclerosis are at risk for severe and refractory hypertension and renal failure. The principal clinical syndromes associated with aortic atherosclerosis are abdominal aortic aneurysms (AAAs), aortic dissection, peripheral atheroembolism, penetrating aortic ulcer, and intramural hematoma. Patients with atherosclerosis affecting the limb (i.e., peripheral arterial disease [PAD]) can develop disabling symptoms of claudication or critical limb ischemia and its associated threat to limb viability. The prevalence of claudication is 2% among older adults, but 10 times as many elderly patients have asymptomatic lower-extremity atherosclerosis, which can be detected by comparing blood pressure in the legs with blood pressure in the arms (ankle-brachial index). Moreover, once disease is apparent in one vascular territory, there is increased risk for adverse events in other territories. For example, patients with PAD have a fourfold greater risk of MI and a twofold to threefold greater risk of stroke than patients without PAD.

AAAs occur in up to 5% of men older than 65 years of age; most of them are small and require only infrequent follow-up. Data suggest that the risk of rupture is very low for AAAs 4.0 cm in diameter or less but rises exponentially for AAAs greater than 5 cm. AAAs between 4 and 5 cm in diameter should be followed every 6 to 12 months to determine whether they are increasing in size.

Medical Therapy for Atherosclerosis

2 The goals of medical therapy for atherosclerotic peripheral vascular disease are to improve functional status, prevent stroke, prevent limb loss, and reduce potential atherosclerotic progression and cardiovascular morbidity. Excellent medical therapy, including use of antihypertensives such as beta-blockers and angiotensin-converting enzyme (ACE) inhibitors, statin drugs, aspirin, and control of hyperglycemia with hypoglycemics and/or insulin, may reduce perioperative morbidity and mortality in vascular surgery. Prevention, including meticulous foot care in diabetic patients, is important to avoid infections and tissue loss. Lifestyle changes such as weight loss and exercise can forestall claudication. The use of statin drugs may reduce progression or even cause regression of atherosclerotic plaques, improve endothelial function, and reduce cardiovascular events in high-risk patients.[7] In the presence of oxidative stress, LDL particles can become oxidized to form a lipoprotein species that are particularly atherogenic and proinflammatory, and cause endothelial dysfunction as they readily accumulate within the arterial wall. Statins reduce the production of reactive oxygen species and increase the resistance of LDL to oxidation. The beneficial effects of statins on clinical events also involve other nonlipid mechanisms that modify endothelial function, inflammatory responses, plaque stability on the vascular wall, and thrombus formation. Patients with acute coronary events or undergoing major noncardiac surgery who received statins in the hospital were less likely to experience complications or die.[8] Statin use is also associated with improved graft patency, limb salvage, and decreased amputation rate in patients undergoing infrainguinal bypass for AVD.[9] The use of antioxidant vitamins such as C and E may also improve endothelial function, and folate supplementation may be of benefit for patients with hyperhomocysteinemia. Exercise programs improve vascular endothelial function and may delay the need for vascular surgery in those with claudication. ACE inhibitors have numerous beneficial effects in patients with AVD, including plaque stabilization, by increasing collagen synthesis in a thin, friable fibrous cap. Such action may explain beneficial effects of ACE inhibitors with regard to acute vascular events (e.g., stroke) that are independent of antihypertensive effect. ACE inhibitor use is also associated with decreased long-term mortality in patients undergoing infrainguinal bypass for AVD.[9] Cessation of smoking may be the most effective "medical" therapy. Cessation rates are approximately 25% after major surgery. Despite the low success rates, the benefits of smoking cessation are so great that such programs may be cost effective.[10] Our recommendations for management of concomitant medical therapy in the perioperative period are listed in Table 32-2.

TABLE 32-2 Concomitant Medical Therapy, Side Effects of Potential Concern Perioperatively, and the Authors' Current Recommendations

·MEDICATION OR DRUG CLASS	·SIDE EFFECT OF POTENTIAL CONCERN IN THE PERIOPERATIVE PERIOD	·RECOMMENDATION FOR PERIOPERATIVE USE
Aspirin	Platelet inhibition may increase bleeding; decreased GFR	Continue until day of surgery, especially for carotid and peripheral cases; monitor fluid and urine status
Clopidogrel	Platelet inhibition may increase bleeding Very rare thrombotic thrombocytopenic purpura	Hold for 7 d before surgery except for CEA and severe CAD. Consider additional cross-match of blood. Avoid neuraxial anesthesia if not held at least 7 d
HMG CoA reductase inhibitors (statins)	Liver function test abnormalities Rhabdomyolysis	Assess liver function tests and continue through morning of surgery Check CPK if myalgias
Beta-blockers	Bronchospasm Hypotension Bradycardia, heart block	Continue through perioperative period
ACE inhibitors	Induction hypotension, cough	Continue through perioperative period; consider one-half dose on day of surgery
Diuretics	Hypovolemia, electrolyte abnormalities	Continue through morning of surgery; monitor fluid and urine status
Calcium channel blockers	Perioperative hypotension, especially with amlodipine	Continue through perioperative period; consider withholding amlodipine on the morning of surgery
Oral hypoglycemics	Hypoglycemia preoperatively and intraoperatively Lactic acidosis with metformin	When feasible switch over to insulin preoperatively. Monitor glucose status perioperatively

ACE, angiotension-converting enzyme; CAD, coronary artery disease; CEA, carotid endarterectomy; CPK, creatine phosphokinase; GFR, glomerular filtration rate; HMG, 3-hydroxy-3-methylglutaryl–coenzyme A reductase.

Antiplatelet therapy is a mainstay of medical therapy for peripheral vascular disease. Chronic

therapy with aspirin or other anti-inflammatory drugs may retard the progression of atherosclerosis and prevent morbid cardiovascular events. Therefore, many patients presenting for vascular surgery will be taking aspirin, clopidogrel, ticlopidine, or COX-2 inhibitors. The benefits of aspirin in reducing heart attack and ischemic stroke after vascular surgery may outweigh the risks of gastrointestinal bleeding and hemorrhagic stroke. COX-2 inhibitors are useful in providing perioperative analgesia, and although they may reduce inflammation, their negative properties in vasculopathic patients include inhibition of prostacyclin production, increased blood pressure, and thrombotic potential. The use in COX-2 inhibitors of patients with AVD is controversial at present, with studies suggesting increased cardiovascular events leading to drug recall and black box warnings.[2] Clopidogrel irreversibly inhibits ADP-induced platelet aggregation, and reduces formation of both arterial and venous thrombi. Oral platelet glycoprotein IIb/IIIa inhibitors may also be used acutely during percutaneous coronary intervention and as adjunctive treatment of acute coronary syndromes. In general, we recommend that patients continue to take aspirin until the day of surgery for carotid and lower-extremity surgery, and individualize the choice for larger operations. In urgent

situations when patients develop acute ischemia, systemic anticoagulation may be instituted. The agents used may range from heparin, Coumadin, or thrombolytics. Therefore, when patients present to us for urgent surgery to reverse acute ischemia, we specifically ask them and their surgeons about recent or planned anticoagulation. If the answer is "yes," we almost always forego regional anesthesia. The implications of new antiplatelet agents on the use of regional anesthesia are unclear. However, the use of low-molecular-weight heparins (LMWHs) may be dangerous when combined with regional anesthesia, as discussed in this section.

A primary concern with the use of anticoagulation and antiplatelet therapy is the risk of spinal hematoma after spinal–epidural anesthesia. Therapeutic anticoagulation with intravenous heparin is routine during vascular surgery and may also be continued into the postoperative period. Concomitant use of other anticoagulants (antiplatelet medications, LMWH, and oral anticoagulants) is common. Guidelines have been proposed to improve safety in such situations. Spinal and epidural anesthesia may be safely performed in a patient undergoing subsequent therapeutic heparinization, provided that heparinization occurs at a minimum of 60 minutes after the needle placement. However, the authors of the most often quoted study (with ~3,100 patients) in support of such practice postponed surgery for 1 day for patients who had a "bloody tap" during attempted epidural catheterization.[11] The surgery was then subsequently performed under general anesthesia. In addition, some have suggested that heparin effect be monitored and maintained within acceptable levels (activated clotting time or activated partial thromboplastin time one and one-half to two times baseline), and indwelling catheters be removed at a time when heparin activity is low or completely reversed. More recently, concern has been growing about the use of LMWHs and the occurrence of spinal and epidural hematoma. In these cases, even when emergency decompressive laminectomy is performed to evacuate the hematoma, permanent neurologic deficit may occur (especially if diagnosis or surgical treatment is delayed). Factors suspected of predisposing patients to epidural hematoma include a dose of enoxaparin that exceeds the recommended dose (30 mg every 12 hours), use of indwelling epidural catheters, administration of concomitant medications known to increase bleeding, presence of vertebral column abnormalities, older age, and female gender. Because plasma half-life and bioavailability are higher for LMWHs as compared with conventional unfractionated heparin, the guidelines for spinal and epidural anesthesia are different. A single-dose spinal anesthetic may be the safest neuraxial technique in patients receiving preoperative LMWHs. Needle placement should occur at least 10 to 12 hours after the last dose of LMWH. Subsequent dosing of the anticoagulant should be delayed for at least 2 hours after the needle placement. Presence of blood during needle placement may warrant an additional delay in initiation of postoperative therapy. If a continuous technique is selected, the epidural catheter should be left indwelling overnight and removed the following day, with the first dose of LMWH administered 2 hours after catheter removal.[12] It is important to remember that not only the needle puncture, but also neuraxial catheter removal poses a potential risk for development of spinal–epidural hematoma in an anticoagulated patient.

We refer the reader to the guidelines produced by the Consensus Conference on Neuraxial

Anesthesia and Anticoagulation convened by the American Society of Regional Anesthesia and Pain Medicine (Table 32-3).[12] In summary, for any given scenario, concomitant use of other anticoagulants, including antiplatelet medications and dextran, increase the risk of spinal hematoma. It must be remembered that identification of risk factors and establishment of guidelines will not completely eliminate the complication of spinal hematoma. The type of analgesic solution should be tailored to minimize the degree of sensory and motor blockade. Vigilance in monitoring is critical to allow early evaluation of neurologic dysfunction

and prompt intervention. The guidelines focus not only on the prevention of spinal hematoma, but also optimization of neurologic outcome. Finally, it must be noted that the guidelines represent general recommendations, but in a given case, direct communication with the surgeon and specific risk–benefit decision about the management are warranted.

In patients who have previously undergone procedures during which heparin was administered, heparin antibodies may be present. When undiagnosed patients with heparin antibodies receive heparin, platelet counts may drop several days following surgery. In the most severe cases, thrombosis may occur due to platelet activation. Heparin-induced thrombosis (HIT) is one of the most common immune-mediated adverse drug reactions. HIT is caused by IgG antibodies that recognize complexes of heparin and platelet factor 4, leading to platelet activation via platelet Fc gamma IIa receptors. Two types of assays for HIT, washed platelet activation assays and commercial platelet factor 4/polyanion enzyme immunoassays, are sensitive for detecting clinically relevant HIT antibodies; thus, a negative test generally rules out HIT. However, weak antibodies can also be detected.[13] If HIT is suspected, heparin therapy should be stopped, including heparin in the "flush" of invasive monitors. Procoagulant, platelet-derived microparticles, and possibly the activation of endothelium cause thrombin generation in vivo. The central role of thrombin generation in this syndrome provides a rationale for the use of anticoagulants that inhibit thrombin (lepirudin and argatroban). Fondaparinux produces its antithrombotic effect through factor Xa inhibition. These drugs may be given to provide anticoagulation during surgery instead of heparin; however, their half-lives are longer than those of heparin, and their metabolism depends on renal (lepirudin) or hepatic (argatroban) function, which requires dose adjustment in the setting of end-organ dysfunction. Their interactions with regional anesthesia are unclear; we advise clinicians to limit regional anesthesia in their presence and to follow future Consensus Statements.

Chronic Medical Problems and Risk Prediction in Peripheral Vascular Disease Patients

Many disorders are associated with vascular disease; however, diabetes, smoking and its sequelae, chronic pulmonary disease, hypertension, renal insufficiency, and ischemic heart disease

are the most common. Understanding the end-organ effects of these diseases can guide appropriate perioperative therapy. It would be suboptimal to administer anesthesia to patients with uncontrolled medical conditions such as severe hypertension, a recent MI, uncontrolled diabetes and hyperglycemia, or untreated pulmonary infections. However, an expanding aneurysm, crescendo transient ischemic attacks, or threatened limb loss can force one's hand. In such situations, attempts to rapidly control chronically deranged blood pressure (which could precipitate cerebral ischemia) or electrolytes (which could, for example, result in accidental administration of a bolus of potassium) may be more hazardous than leaving the condition untreated or trying to control the abnormality slowly.

Whereas chronic medical conditions increase the likelihood of postoperative morbidity and mortality, postoperative complications have even greater predictive value for adverse outcomes. Other causes of morbidity following vascular surgery include bleeding, pulmonary infections, graft infections, renal insufficiency and failure, hepatic failure, cerebrovascular accidents, and spinal cord ischemia resulting in paraplegia. The incidence of these other causes of morbidity has declined substantially in the past 20 years; in particular, death from renal failure after abdominal aortic reconstruction has declined from 25 to <1% at present. Much of the decline in renal failure has been the result of better perioperative fluid management. Although multisystem organ failure may account for an increasing proportion of deaths after vascular surgery, we believe that maintaining adequate cardiac function and perfusion of vital organs remains a vital aspect of reducing perioperative mortality. The factors that limit patient prognosis after vascular surgery remain primarily related to the heart. We therefore more closely examine the effects of known or suspected CAD on patient management before, during, and after vascular surgery.

Coronary Artery Disease in Patients with Peripheral Vascular Disease

Hertzer et al.[14] performed coronary angiography in 1,000 consecutive patients presenting for vascular surgery and identified severe correctable CAD in 25% of the entire series. The incidence of significant CAD (stenosis >70%) detected by angiography was 78% in those with clinical indications of CAD and 37% in patients without any clinical indications. However, subsequent analysis demonstrated that clinical risk factors still predicted the severity of CAD (Fig. 32-1). The absence of severe coronary stenoses can be predicted with a positive predictive value of 96% for patients without diabetes, prior angina, previous MI, or congestive heart failure (CHF).

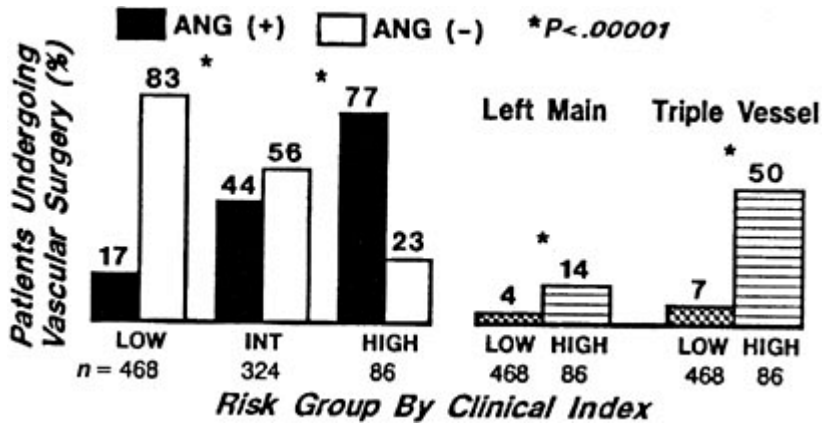

FIGURE 32-1. Clinical risk factors predict severe (left main or triple vessel) coronary artery disease. A preoperative clinical index (diabetes mellitus, prior myocardial infarction, angina, age older than 70 years, congestive heart failure) was used to stratify patients. ANG (+), angiogram positive for coronary artery disease; ANG (-), angiogram negative for coronary artery disease; INT, intermediate. (Based on data from Paul SD, Eagle KA, Kuntz KM *et al*:

Concordance of preoperative clinical risk with angiographic severity of coronary artery disease in patients undergoing vascular surgery. Circulation 94(7):1561, 1966; secondary analysis of data from Hertzer NR, Beven EG, Young JR *et al*: Coronary artery disease in peripheral vascular patients: A classification of 1000 coronary angiograms and results of surgical management. Ann Surg 199:223, 1984.)

Short-term postoperative morbidity and mortality after vascular surgery is higher than after other types of noncardiac surgery. Cardiac-related death, MI, cardiogenic pulmonary edema, unstable angina, and dysrhythmias may occur after vascular surgery. Complications after carotid endarterectomy (CEA) are generally less frequent, regardless of the presence or absence of known CAD. However, even after carotid surgery, cardiac causes produce 50 to 100% of the mortality encountered. Patients undergoing lower-extremity revascularization often have more severe medical conditions as a group than patients undergoing abdominal aortic surgery, resulting in equal aggregate risks for cardiac complications in one series.[15]

Long-term morbidity and mortality following vascular surgery are also greatly influenced by the presence of CAD. The presence of uncorrected CAD appears to double 5-year

mortality after vascular surgery. Coronary artery bypass graft (CABG) is associated with improved survival in peripheral vascular disease patients who have triple-vessel but not single-vessel or double-vessel CAD.[16] Previous percutaneous transluminal coronary angioplasty (PTCA) and stenting may or may not protect against perioperative cardiac events after vascular surgery. However, in the first 6 weeks after coronary stent placement, noncardiac surgery carries considerable risks. Because clopidogrel (Plavix) is usually prescribed to reduce stent thrombosis, clinicians are left with difficult choices: continue the clopidogrel and risk increased surgical bleeding, or stop it with an increased risk of acute perioperative coronary stent thrombosis and MI. Whenever possible, noncardiac surgery should be delayed until 6 weeks after coronary stent placement, by which time stents are generally endothelialized, and a course of antiplatelet therapy to prevent stent thrombosis has been completed.[17] Drug-eluting stents may simplify these problems in the future.

The prevalence of asymptomatic CAD and the substantial short-term and long-term cardiac morbidity and mortality in patients undergoing vascular surgery have led investigators and clinicians to propose and undertake extensive preoperative workups to detect underlying CAD. Controversy persists as to whether preoperative identification of patients most likely to have perioperative cardiovascular events related to myocardial ischemia benefits patients. Preoperative evaluation of the electrocardiogram (ECG) is more often abnormal than not in elderly patients and does not appear to be independently associated with adverse events, when ASA and heart failure status are considered.[18] Despite this, we continue to obtain an ECG before surgery to have a baseline with which to compare any ECGs obtained after surgery in the event of adverse outcomes. Invasive coronary interventions may benefit patients with vascular disease but are generally more risky than in other groups of patients. Many believe that preparatory coronary revascularization may be "survival tests" that are accompanied by increased short-term morbidity; others believe that these procedures lead to better long-term survival. In contrast, patients who have survived recent coronary revascularization (CABG <5 years, PTCA <2 years) have fewer cardiac complications after vascular surgery.

The timing and character of perioperative MI reported in the literature seems to have shifted from classical reports with a predominance of Q-wave MI peaking between postoperative days 2 and 3 with high mortality to more modern series with non–Q-wave MI occurring earlier (operative day/day 1 postsurgery) with lower mortality. In addition, MI occurring in the perioperative period is associated with sustained elevation of heart rate, absence of chest pain, and prolonged premonitory episodes of ST segment depression before overt MI.[19] The pathophysiology of perioperative MI differs somewhat from that of MI occurring in the usual nonoperative setting. In

the latter, rupture of a coronary atherosclerotic plaque leads to platelet aggregation and thrombus formation. In contrast, plaque rupture occurs only in about one-half of perioperative infarctions. The remainder is due to a prolonged imbalance between myocardial oxygen demand and supply in the setting of CAD. Myocardial oxygen supply may be diminished by anemia or hypotension, whereas oxygen demand may be increased by tachycardia and hypertension resulting from postoperative pain, withdrawal of anesthesia, or shifts in intravascular volume. Even small changes in cardiac troponin-I (cTn-I) or cardiac troponin-T (cTn-T) after surgery are associated with a worse perioperative and 6-month outcome, with a dose-response relationship.[20] This led to a shift in the current diagnostic definitions of MI with greater emphasis on elevation of cardiac troponins (either cTn-I or cTn-T).

Three essential purposes are served by preoperative cardiac risk stratification. The first would be to forego surgery or perform a more conservative surgical procedure in those at high risk. The second goal would be to determine which patients should undergo myocardial revascularization. This goal requires that we identify patients with left main CAD, as well as those with triple-vessel CAD and poor left ventricular function, because these patients are most likely to benefit from coronary revascularization in the long run. Finally, because most perioperative myocardial ischemia and MI occur early in the postoperative period, a third rationale for preoperative segregation of high-risk patients is to target those who might benefit from aggressive therapy in the first 24 to 72 hours after surgery. Risk-reducing interventions may include invasive monitoring in an intensive care unit (ICU), forced-air warming, stress-reducing anesthetic techniques, and/or perioperative beta-blockade. These attempts to reduce morbidity vary widely in cost, and their effectiveness is controversial. The choice of risk-reducing strategies depends on the surgical procedures, the discretion of the anesthesiologists and surgeons, and institutional protocols (clinical pathways).

The patient's history and bedside examination before vascular surgery serve not only to predict coronary anatomy, but also to provide important prognostic information. Studies have consistently identified CHF, previous MI, advanced age, severely limited exercise tolerance, chronic renal insufficiency, and diabetes as risk factors for the development of perioperative cardiac morbidity. The presence of three or more of these risk factors makes an individual patient "high risk." Patients who need emergency or urgent surgery are also at greatly increased risk for cardiac complications.

Previous work has suggested that risk of reinfarction depends primarily on the amount of time passed since infarction, with reduced reinfarction rate after 6 months. In the modern era, however, acute thrombolysis or angioplasty during MI reduces infarct size, as do ACE inhibitors and control of hyperglycemia. Therefore, given appropriate acute care of an MI, and subsequent risk stratification and quantification of ischemic burden with noninvasive testing (as described later in this seciton), we may identify patients who are at relatively low risk despite a recent infarction. In addition, studies using aggressive hemodynamic monitoring and intensive postoperative care suggest that the rate of reinfarction after a recent infarction is currently much lower in some centers. Thus, the long waiting period of 6 months after an MI before surgery may no longer apply to most patients. However, if coronary stenting has been performed, a 6-week wait would seem prudent if feasible.[17]

Exercise tolerance is also a useful prognostic indicator, although claudication, orthopedic problems, and frailty may limit a patient's capabilities. Patients with limited exercise capacity (<4 metabolic equivalents levels [METS]; 4 METS is represented by being able to do light household work such as dusting and washing clothes) have greatly increased perioperative risk. We believe that if patients can walk briskly for two blocks with neither angina nor dyspnea, and have no other indicators of CAD, they are very unlikely to have left main disease, triple-vessel disease, or severe left ventricular dysfunction. Such patients can probably undergo surgery without specialized noninvasive testing because they are unlikely to be at risk for adverse perioperative outcomes. However, because claudication and arthritis can limit the evaluation of functional capacity and CAD by conventional exercise testing, other noninvasive tests have become popular for cardiac risk stratification in the past two decades.

Routine coronary angiography is impractical to use routinely before vascular surgery because of the costs and risks involved. The use of screening tests has remained controversial, with some studies showing great prognostic value (Table 32-4) and others showing that these tests do not perform better than the basic clinical evaluation. In 2002, the American Heart

Association and American College of Cardiology (AHA/ACC) published revised guidelines for perioperative cardiovascular evaluation before noncardiac surgery.[21] The algorithm incorporates clinical history, exercise tolerance, and surgical procedure in the decision to perform further evaluation. Application of Bayes' theorem also suggests that as the prior probability of a disease in a population increases, the predictive value of a positive test increases and predictive value of a negative test decreases. The guidelines classified the clinical predictors of increased perioperative cardiovascular risk (MI, CHF, and death) as "major," "intermediate," and "minor." The major risk factors include acute MI (<7 days), recent MI (7 to 30 days), unstable angina, decompensated CHF, and significant arrhythmias. Major risk factors, when present, mandate intensive management, which may result in delay or cancellation of surgery unless it is emergent. "Intermediate risk factors" include current or prior angina pectoris, prior MI, CHF, advanced age (70 years or older), severely limited exercise tolerance, chronic renal insufficiency (serum creatinine >2.0 mg%), cerebrovascular accident, and diabetes (preoperative insulin therapy) as risk factors for the development of perioperative cardiac morbidity.[22] Generally, patients presenting for vascular surgery can be categorized by these clinical criteria as follows: at least 1 risk factor, "low risk"; 2 risk factors, "intermediate risk"; 3 or more risk factors, "high risk." The guidelines placed aortic and peripheral vascular surgery in the "high-risk" surgery category with an estimated cardiac risk (MI or cardiac-related death) exceeding 5%. CEA is regarded as the "intermediate-risk" category, with an estimated cardiac risk ranging from 1 to 5%. By applying the principles of Bayes' theorem, traditional recommendations made more than a decade ago proposed the use of noninvasive cardiac testing in patients with intermediate clinical risk category, "no testing" in low clinical risk category, and coronary angiography in high clinical risk category and in those tested positive by noninvasive test. However, the current recommendations seem to have shifted the paradigm toward perioperative drug therapy aimed at reducing the cardiac risk either with no noninvasive cardiac testing or only very highly selective noninvasive testing.[23] Studies where the AHA/ACC guidelines were used to guide preoperative testing have conflicted as to whether using the guidelines can improve outcome. Figure 32-2 summarizes our recommendations for vascular surgery patients.

From Kertai MD, Boersma E, Bax JJ, et al. A meta-analysis comparing the prognostic accuracy of six diagnostic tests for predicting perioperative cardiac risk in patients undergoing major vascular surgery. Heart. 2003 Nov;89(11):1327–34.

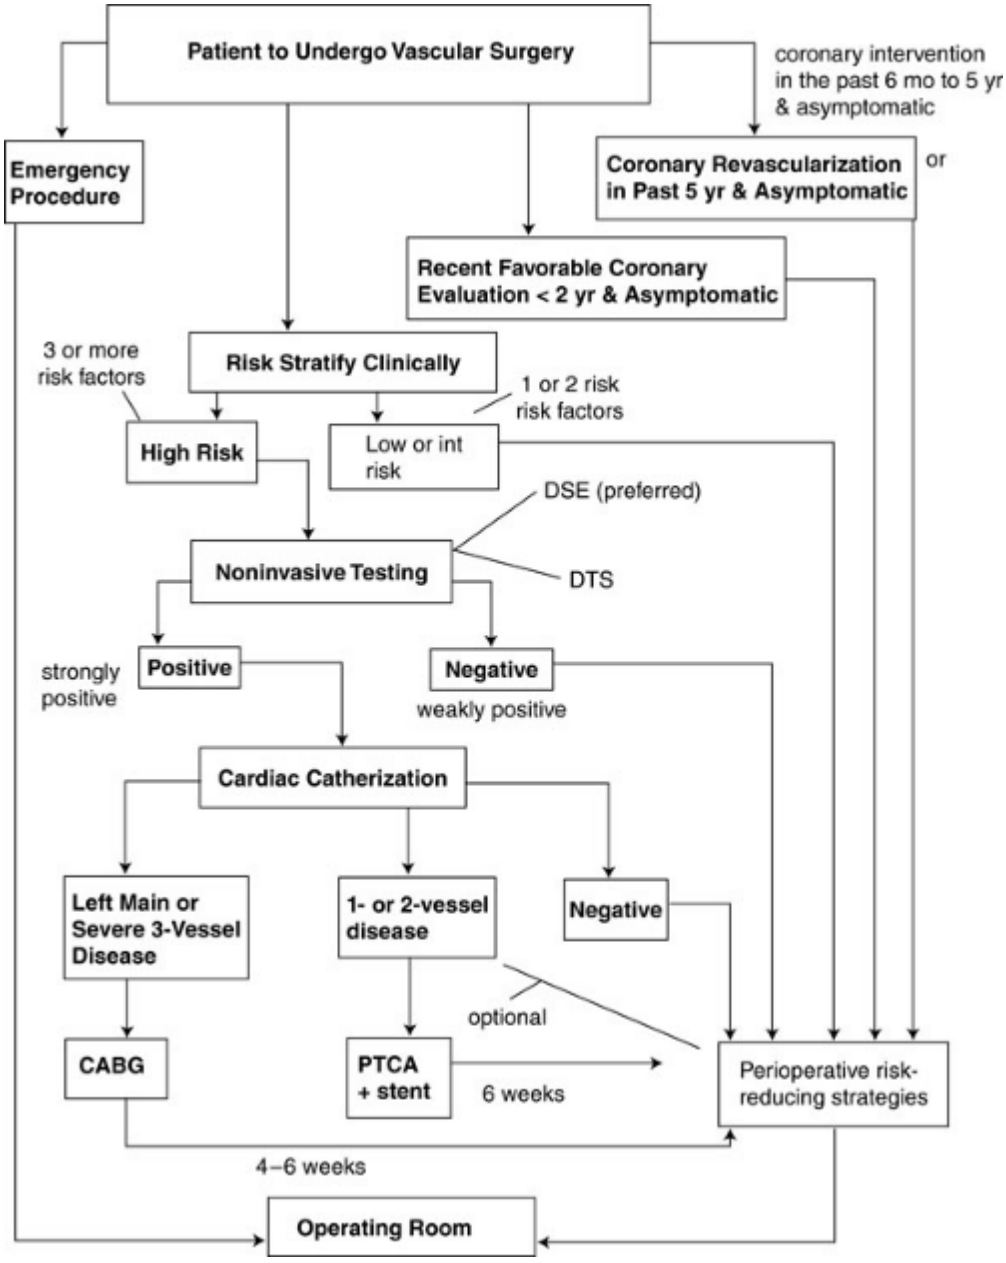

FIGURE 32-2. Our recommended algorithm for preoperative assessment. This may change as future randomized trials compare aggressive medical therapy with coronary revascularization. CABG, coronary artery bypass graft; DSE, dobutamine stress echocardiography; DTS, dipyridamole thallium scan; PTCA, percutaneous transluminal coronary angioplasty.

Dipyridamole-thallium scintigraphy is based on the principle of coronary steal. Dipyridamole is an antiplatelet drug and a coronary artery vasodilator. At rest, coronary arteries supplying the normal myocardium have a great vasodilatory reserve and are able to increase blood flow up to 10 times the normal to meet any extra demand. In the areas of critical stenosis, however, the coronary arteries are vasodilated in nonstressed state and have diminished reserve. Therefore, dipyridamole can vasodilate normal coronary arteries but cannot vasodilate those in areas with stenosis. When thallium radioisotope is injected, stenotic areas of myocardium will have lower concentration of the isotope (cold spot) after dipyridamole administration. When the effect of dipyridamole wears off, the isotope redistributes to ischemic zones. These areas with redistribution are considered ischemic but viable zones, whereas those with persistent defects with no redistribution are indicative of infarction. Both redistribution (reversible) and persistent (fixed) defects may be abnormal test results. Reversible defects are more important in risk stratification.

CHF is a strong predictor of morbid postoperative events. Determination of systolic left ventricular

function may therefore provide prognostic information. In the past, some clinicians would place a pulmonary artery catheter preoperatively to measure hemodynamics and perform risk stratification. This approach is rarely used today because catheter placement requires preoperative admission to an ICU, and most patients are now admitted on the day of surgery. In addition, preoperative transthoracic echocardiography can provide noninvasive preoperative evaluation of cardiac function. Pulmonary artery catheterization may still occasionally prove useful for preoperative optimization of unstable patients who require relatively urgent surgery; however, more recently, its use and safety have been increasingly questioned.

Radionuclide ventriculography can be used to define systolic and diastolic function. Our meta-analysis showed that patients who have an ejection fraction <35% by radionuclide ventriculography are 3.7 times more likely to have a postoperative cardiac event.[24] However, radionuclide ventriculography has generally been supplanted by echocardiography, which can define myocardial structure and function, and can also be combined with exercise or pharmacologic stress.

Dobutamine (5 to 30 μg/kg/min, with or without atropine) stress echocardiography (DSE) can produce changes in regional wall motion in patients with underlying CAD. In our meta-analysis, we found that a positive dobutamine stress test increased the risk of a postoperative cardiac event by 6.2-fold. Semiquantitative interpretation (high-risk, intermediate-risk, or low-risk results) of both dipyridamole-thallium scintigraphy and DSE may allow us to refer only high-risk patients for cardiac catheterization. By convention, marked changes in prior disease probability can be assumed in likelihood ratio (LR) for positive test exceeding 10.0 and LR for negative test falling below 0.1. Abnormality in five or more segments during DSE is considered as "strongly-positive" test result for risk stratification with a likelihood ratio of 13.09. Redistribution in >50% of the left ventricle during DTS has an LR of 11. Therefore, although severely positive patients might benefit from coronary angiography and revascularization, less severe cases of CAD identified by weakly positive (low-risk) results on these tests may benefit from current state-of-the-art perioperative care and risk reduction. However, these less severe cases will still require careful follow-up after surgery to look for progression of CAD. These results have been largely corroborated by another more recent meta-analysis, which suggests that DSE may be the best preoperative test.[25]

Endothelial dysfunction as evaluated preoperatively by noninvasive ultrasound assessment of brachial artery flow-mediated dilation is useful in predicting the short-term and long-term adverse cardiovascular outcomes following vascular surgery.[26] Decreased endothelium-dependent flow-mediated dilation reflects endothelial dysfunction in patients with AVD. Coronary calcium detected by CT is a hallmark of CAD and has been shown to predict MI following vascular surgery.[27]

One limitation of specialized testing, including coronary angiography, is the fact that MI and cardiac-related mortality are not necessarily due to severely narrowed coronary arteries. More recent evidence suggests that the rupture of previously nonocclusive lipid-laden, macrophage-rich coronary plaques can cause spasm and initiate unstable angina, acute MI, and sudden death. Therefore, testing that attempts to induce ischemia will miss some patients who have nonobstructive plaques that can rupture and cause transmural infarction; this appears to be the mechanism of a significant minority of perioperative MI.

Preoperative Coronary Revascularization

Myocardial revascularization may have long-term benefits in patients with triple-vessel coronary disease or poor left ventricular function. The range of options for preparatory coronary revascularization continues to expand. These include traditional surgical revascularization (CABG) with or without cardiopulmonary bypass (CPB), transmyocardial laser therapy, and PTCA with or without coronary stent placement. However, mortality rates associated with these techniques are

consistently higher in patients with peripheral vascular disease compared with those without.

Initial observational studies of PTCA performed before major noncardiac surgery suggest that patients who survive successful PTCA do well. Anticoagulation and antiplatelet therapy may be continued after these procedures and may preclude the use of regional anesthesia. Stent

thrombosis and increased surgical bleeding from clopidogrel are concerns in the patient with a recent coronary stent.

3 Whether preoperative coronary revascularization actually protects against the perioperative cardiac events is controversial. The benefits likely diminish as time goes on; CABG more than 5 years or PTCA more than 2 years before vascular surgery may actually be associated with a high risk of complications because CAD is a recurrent disease.[28] Even if one considers coronary revascularization to be protective, an obligate delay in performing the planned vascular surgical procedure must be considered. Once the patient has recovered from successful coronary revascularization (1 week after angioplasty and 6 to 8 weeks after coronary stenting or CABG, typically), peripheral vascular surgery is usually then performed. In some cases, CABG can be combined with vascular surgery, most commonly with CEA. However, patients with both symptomatic coronary and carotid disease are at high risk of both cardiac and neurologic complications following surgery, whether combined or staged; their management remains controversial.[29] The multicenter CARP trial randomized patients with coronary disease (except left main disease or ejection fraction <20%) before elective vascular surgery to either coronary revascularization or medical therapy. With state-of-the-art aggressive medical therapy (>80% of patients on beta-blockers, >70% on aspirin, and >50% on statins in both groups), they could find no benefit to coronary revascularization.[30] This trial may contribute further to the trend of aggressive prophylactic treatment rather than routine stress testing of vascular surgery patients.

Perioperative Cardiac Monitoring

The goals of perioperative cardiac monitoring are to detect myocardial ischemia and to identify abnormalities of preload,

afterload, and ventricular function. Such monitoring may prevent MI and allow better perfusion and preservation of other organs such as the liver, kidney, gut, and spinal cord.

Detection of Perioperative Myocardial ischemia

ECG monitoring remains the mainstay of perioperative detection of myocardial ischemia. ECG evidence of ST segment depression is a more common indicator of myocardial ischemia in vascular surgery patients than is ST segment elevation. ST segment depression occurs in 20 to 50% of patients undergoing vascular surgery. Landesberg et al. documented that a multilead system is required to detect ischemia (V3, V4, V5 for maximal detection). Further, leads V3 to V4 have a higher incidence and a greater degree of maximal myocardial ischemia than does lead V5.[31] Because clinicians often fail to detect intraoperative ischemic ECG changes when viewing oscilloscopes, automated ST segment monitors promise to increase the detection of such ECG changes. We have documented that the sensitivity of ST segment monitors for transesophageal echocardiography (TEE)-diagnosed myocardial ischemia is 40% and for ECG-diagnosed ischemia, 75%.[32] Although these monitors are not always accurate, we believe they are useful as alarms for busy clinicians.

Perioperative Holter monitoring has shown that the intraoperative period may be the least stressful for patients with CAD. Patients undergoing vascular surgery are most likely to manifest myocardial ischemia in the immediate postoperative period, with its associated pain, adrenergic stress, hypothermia, hypercoagulability, anemia, shivering, and sleep deprivation. Several studies have shown that postoperative myocardial ischemia begins earlier than previously believed, usually on the day of vascular surgery or the next day. At present, our clinical practice is to obtain a 12-lead ECG in the first 24 hours following surgery in high-risk patients, and then perhaps daily for the next 2 to 3 days. We believe such a strategy will detect most ischemia that is severe and protracted enough to represent a prodrome to infarction. Unfortunately, many vascular surgery patients will have baseline ECG abnormalities (left bundle branch block, paced rhythm, digoxin effect, left ventricular hypertrophy with strain) that preclude the detection of myocardial ischemia.

Other monitoring devices for detecting myocardial ischemia have been proposed. Pulmonary

capillary wedge pressure (PCWP) monitoring in patients undergoing vascular surgery has low sensitivity and specificity in detecting ischemia; most elevations in PCWP appear to be associated with tachycardia and hypertension, which suggests inadequate anesthesia. Our own group found that 90% of patients developed wall motion abnormalities on TEE when the aorta was cross-clamped above the celiac artery. However, the PCWP remained normal in >80% of these episodes.[33] We therefore do not routinely use PCWP as a monitor for myocardial ischemia, but we believe the pulmonary artery catheter provides useful information about a patient's intravascular volume status, myocardial performance, and organ perfusion.

TEE has also been proposed as a monitor for intraoperative myocardial ischemia. In animal studies and in models of coronary angioplasty during balloon inflation, mechanical dysfunction precedes surface ECG changes when myocardial ischemia is produced. Supporting these observations, Smith et al.[34] found that regional wall motion abnormalities were more sensitive than ST segment change on the ECG in detecting intraoperative ischemia in patients with CAD undergoing major vascular and coronary surgery. However, others have concluded that ischemia monitoring with TEE during noncardiac surgery appeared to have little incremental clinical value over preoperative clinical data and Holter monitoring in predicting perioperative ischemic outcomes.

Traditionally, creatine kinase myocardial band isoenzyme determination has been used to document myocardial damage after vascular surgery. Limitations of this method include false-positive results owing to skeletal muscle damage during surgery. The cardiac troponins appear to offer increased sensitivity, primarily because of their prolonged diagnostic window, and may offer enhanced specificity in patients with surgical skeletal muscle damage. Troponin leak after vascular surgery dramatically increases perioperative and 6-month MI and death risk, with a dose-response relationship; in this study, 12% of patients had postoperative cTnI > 1.5 ng/mL, which was associated with a 6-fold increased risk of 6-month mortality and a 27-fold increased risk of MI.[20]

Management of Perioperative Myocardial ischemia and Infarction in Vascular Patients

In the modern era, rates of MI in patients undergoing major vascular surgery can be reduced to <10%, but the rates are significantly lower for patients undergoing elective vascular repair. Perioperative myocardial ischemias (PMIs) are much more likely to occur in patients undergoing urgent or emergent surgery, who are presumably sicker and do not have the luxury of undergoing extensive preoperative evaluation and preparation. MIs in the modern era are more likely to occur in the first 24 hours following surgery. Badner et al. found that 5.6% of patients with known CAD undergoing major surgery had a PMI, of which 17% were fatal. Only 3 of 18 patients had chest pain, whereas 10 of 18 patients (56%) had other clinical findings. The PMIs occurred on the day of operation in nearly one-half the cases.[19] Patients who have PMIs after vascular surgery have a mortality of approximately 20% in a series at the Cleveland Clinic; Sprung et al. stated,

> The in-hospital cardiac mortality rate is high for patients who undergo vascular surgery and experience clinically significant PMI. Stress of surgery (increased intraoperative bleeding and aortic, peripheral vascular, and emergency surgery), poor preoperative cardiac functional status (CHF, lower ejection fraction, diagnosis of CAD), and preoperative history of coronary artery bypass grafting (protective) are the factors that determine perioperative cardiac morbidity and mortality rates.[35]

Stable coronary ischemic syndromes presumably occur with increased oxygen demand by the myocardium in a setting of fixed coronary plaques. Unstable syndromes are believed to be the result of active lesions caused by plaque rupture with local thrombus and vasoreactivity that produce intermittent critical decreases in coronary oxygen supply. The period following vascular surgery is characterized by adrenergic stress (Fig. 32-3).[36] The postoperative adrenergic response can predispose to myocardial ischemia in numerous ways, including tachycardia and decreased diastolic time, coronary vasoconstriction, and platelet aggregation. Factors increasing the likelihood of postoperative myocardial ischemia that the anesthesiologist can control include

tachycardia, hypertension, hypotension, anemia, hypothermia, shivering, endotracheal suctioning, and less than optimal analgesia. Other factors, such as postoperative hypercoagulability, rapid eye movement (REM) sleep rebound, and mild postoperative hypoxemia are more speculative culprits.

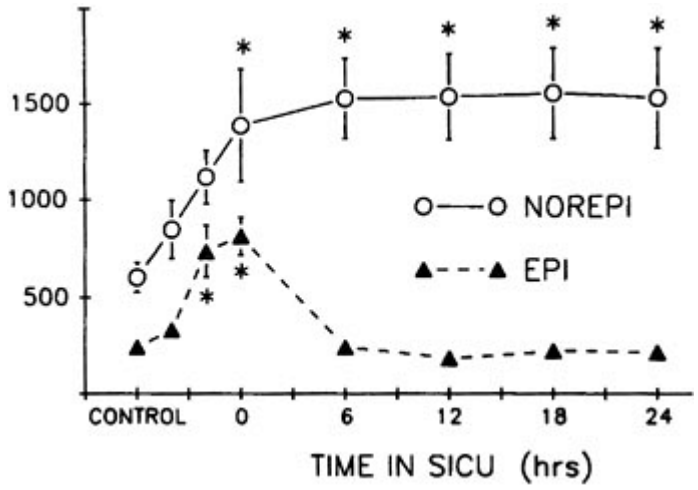

FIGURE 32-3. Aortic reconstructive surgery is associated with markedly elevated adrenergic tone. Epinephrine levels (pg/mL) rise with emergence from anesthesia but begin to fall by 6 hr after surgery. Norepinephrine levels (pg/mL) remain elevated for at least 1 day following surgery. SICU, Surgical ICU; NOREPI, norepinephine; EPI, epinephrine. (Reprinted with permission from Breslow MJ: The role of stress hormones in perioperative myocardial ischemia. Int Anesthesiol Clin 30:81, 1992.)

Postoperative myocardial ischemia confers increased risk to vascular surgical patients. Landesberg et al. found that patients experienced twice as much ischemia after vascular surgery than before or during.[37] Ischemia that lasted longer than 2 hours was associated with a 32-fold increase in the risk of postoperative morbid cardiac events. In this study, postoperative MI was usually preceded by long periods of severe ST segment depression. Aggressive efforts at prevention or treatment of ischemia

during these periods may improve patient outcome. We refer patients with documented severe postoperative myocardial ischemia (lasting longer than 2 hours; 2 mm ST segment depression) to a cardiologist because most adverse cardiac outcomes in a 2-year follow-up program were preceded by in-hospital postoperative ischemia.

Various strategies have been proposed to reduce cardiac morbidity during and after vascular surgery, including the prophylactic use of antianginal drugs and special anesthetic techniques. It is crucial that patients continue to receive their chronic antianginal and antihypertensive medications before and after surgery.

4 Of the various risk-reducing strategies (Table 32-5), growing evidence suggests that perioperative beta-blockade provides benefit in preventing cardiac morbidity and mortality.[38,39] Benefits of the therapy are best observed when oral preoperative therapy is extended to intraoperative and postoperative periods by intravenous therapy to titrate the heart rate $\leqslant$65 beats/minute. Typically, oral therapy has been initiated 7 to 30 days before surgery with either 50 to 100 mg atenolol daily or 5 to 10 mg of bisoprolol,[40] whereas intraoperative and postoperative periods are best managed by intravenous administration of 5 to 10 mg atenolol or metoprolol twice daily. Alternatively, esmolol 500 µg/kg may be given intravenously over 1 minute followed by infusion of 50 to 300 µg/kg per minute to achieve the target heart rate. In patients already taking beta-blockers, they are continued to the day of surgery followed by intravenous therapy to achieve the target heart rate as described previously. Although older literature warns

against use with any degree of reactive airway disease, insulin-dependent diabetes, and even peripheral vascular disease, newer data suggest that careful titration of β1-selective agents is well tolerated in many of these patients. However, severe asthma or a strong reversible component with chronic obstructive airway disease remains a major contraindication, as do cardiac conduction disease in the absence of a pacemaker and previous documented drug

sensitivities. It must be noted that hypovolemia can be poorly tolerated in the presence of beta-blockade and also that racial difference in response to beta-blockade can exist (Blacks may respond less favorably).[39]

TABLE 32-5 Pharmacologic Prophylaxis Against Acute Vascular Events in Patients Undergoing Vascular Surgery

·INTERVENTION	·REGIMEN AND REMARKS	·RECOMMENDATION[a]
Perioperative beta-blockade	Preoperative oral beta-1-selective beta-blocker (bisoprolol, metoprolol, or atenolol) initiated at least 30 d before surgery and IV therapy during intraoperative and postoperative period (metoprolol, atenolol, or esmolol).	Class I
Alpha-2-agonists	Pretreatment with oral clonidine 300 μg at least 90 min before surgery and therapy continued for 72 hr (oral or transdermal, 0.2 mg/d). IV clonidine 300 μg daily can also be administered for 72 hr.	Class IIa
Statin therapy	Typical dose of atorvastatin is 20 mg once daily initiated at least 45 d prior to surgery. Continued use after surgery for at least 2 wk. Statin use is also associated with improved graft patency, limb salvage, and decreased amputation rate in patients undergoing infrainguinal bypass for atherosclerotic vascular disease.	Class I
ACE inhibitors	Potential benefits include decreased stroke rate (e.g., ramipril), limitation of ventricular remodeling that follows acute ST elevation MI, decreased long-term mortality following infrainguinal bypass surgery, etc. Ability to stabilize the atherosclerotic plaque by upregulating type III collagen of the fibrous cap of the unstable plaque may explain some of these benefits.	Class IIb

Calcium channel blockers	Reduced perioperative adverse cardiac events; including supraventricular tachycardia in patients undergoing various types of noncardiac surgery (primarily diltiazem). Evidence limited in patients undergoing vascular surgery.	Class IIb
Nitroglycerin	Not indicated for myocardial ischemia prophylaxis or initial treatment. May be used to treat arterial hypertension or elevated cardiac filling pressures or suspected coronary vasospasm	Class III

ACE, angiotension converting enzyme; MI, myocardial infarction.

[a]Class I recommendation refers to conditions for which there is evidence or general agreement that a given procedure or treatment is useful or effective, class III refers to conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective or in some cases may be harmful. Class II recommendations fall in between and indicate conditions for which there is conflicting evidence or a divergence of opinion about the usefulness/efficacy of a procedure/treatment. Class IIa indicates that the weight of evidence/opinion is in favor of usefulness/efficacy. Class IIb indicates that the usefulness/efficacy is less well established by evidence/opinion. In simple terms, class I recommendations are the "dos," class III recommendations are "don'ts," and class II recommendations are the "maybes." Refer to Figure 32-2 for the algorithm. Calcium channel blockers and ACE inhibitors, although not recommended as independent agents for the purpose, should be continued if a patient is receiving them. Refer to Table 32-1 for suggestions for precautions on their perioperative use.

Alpha-2-adrenergic blockers (clonidine or mivazerol) have been in use aimed at controlling the perioperative cardiac morbidity and mortality for more than a decade. In our study, we used a regimen of a transdermal clonidine system (0.2 mg/day) the night prior to surgery, which was left in place for 72 hours, and 0.3 mg oral clonidine administered 60 to 90 minutes before surgery. Clondine not only reduced intraoperative myocardial ischemia, but also reduced catecholamine (adrenaline and noradrenaline) levels as measured on the first postoperative day.[41] More recently, a meta-analysis demonstrated beneficial effects of perioperative alpha-blockers with regard to cardiac morbidity and death in patients undergoing vascular surgery (evidence level B).[42] In addition, a randomized trial suggested that perioperative clonidine administration during high-risk noncardiac surgery reduces mortality[43] in a fashion similar to atenolol.

Interest has more recently focused on the use of statins aimed at controlling adverse cardiac events perioperatively and on those occurring during long-term follow-up for vascular surgery patients. A randomized trial demonstrated beneficial effects of statin use (atorvastatin 20 mg daily started 30 days before surgery and continued for roughly 2 weeks after surgery) with regard to primary end points (cardiac-related death, nonfatal MI, unstable angina, stroke) at 6-month follow-up.[44]

ACE inhibitors also have several beneficial actions with regard to acute vascular events independent of their antihypertensive action in patients with atherosclerotic vascular disease. Currently, there are no studies to provide evidence for their independent ability to reduce

perioperative cardiac problems for their therapy aimed at risk reduction. However, if a patient is already taking ACE inhibitors, he or she is best to continue, taking care to limit the morning dose of the drug.

A more recent meta-analysis suggested beneficial effects of calcium channel blockers in reducing perioperative adverse cardiac events (cardiac-related death, MI, ischemia, or supraventricular tachycardia) in patients undergoing different types of noncardiac surgery. The majority of these effects were attributable to diltiazem. Limited evidence was available from this meta-analysis for patients undergoing vascular surgery. Large randomized trials are required to establish their benefits in vascular surgery patients. Currently, we do not recommend their use as independent drug therapeutic modality for the perioperative cardiac risk reduction. Similarly, prophylactic intravenous nitroglycerin 0.9 μg/kg/min failed to reduce the incidence of PMI in patients with known or suspected CAD undergoing noncardiac surgery.[45] In this study, the preponderance of myocardial ischemia occurred during emergence from anesthesia, which is associated with acute increases in heart rate.

High-dose narcotic anesthetics reduce the stress response and may improve overall outcome after major surgery. Postoperative infusion of sufentanil 1 μg/kg/hr can reduce the severity of myocardial ischemia (ST segment changes) following CABG, although clinical outcome was not improved. High-dose narcotics may mandate overnight ventilation, which may not be cost effective. Another approach using intensive analgesia involves the use of epidural analgesia. Epidural local anesthetics may reduce perioperative myocardial ischemia because preload and afterload are reduced, the postoperative adrenergic and coagulation responses are reduced, and, with thoracic administration, the coronary arteries are dilated. Despite these effects on intermediate variables, improvement in cardiac outcomes has generally not been demonstrated in well-designed trials, suggesting that anesthetic technique does not affect cardiac outcome after abdominal aortic surgery, especially if heart rate is well controlled in the ICU.[46] Concerns about respiratory depression, neuraxial/epidural hematomas, and the expense and reimbursement for surveillance have limited the use of peridural narcotics in greater numbers of patients. Although epidural anesthesia may improve outcome in other organ systems, especially the lungs, its ability to reduce MI remains speculative. Last, a meta-analysis suggests that thoracic epidurals may reduce PMI.[47]

Given the prominent role of coronary thrombosis in causing acute coronary syndromes and the hypercoagulable state after vascular surgery, future development in the treatment of postoperative myocardial ischemia may include drugs with antiplatelet or anticoagulant effects, such as aspirin and newer platelet inhibitors, warfarin, or heparin. Increased postoperative hemorrhage, however, makes the use of anticoagulant therapy problematic in surgical patients. At present, we do not know how to balance these risks and benefits, or which patients might benefit most from such therapy.

Anemia (hematocrit <28%) may increase the incidence of postoperative myocardial ischemia and cardiac events in high-risk patients undergoing noncardiac surgery.[48] Therefore, we are more likely to transfuse high-risk patients, or those who demonstrate myocardial ischemia with packed red blood cells, to augment the hematocrit to 30%. We continue this practice, although some work in ICU patients (with a relatively low percentage of patients with CAD) suggests that lower transfusion thresholds may be beneficial.[49] Hypothermia is also associated with increased adrenergic tone and postoperative myocardial ischemia and events in vascular surgery patients.[50] We therefore aggressively warm patients and conserve heat during and after such surgery. Suctioning, extubation, and weaning from mechanical ventilation may also produce myocardial ischemia. Therefore, we attempt to extubate patients in the operating room with the same attention to the control of hemodynamics as during induction. If patients require postoperative ventilation, we provide adequate sedation, analgesia, and occasionally even paralysis (which can prevent shivering and its attendant increases in oxygen consumption). We treat tachycardia aggressively, most often with β-adrenergic blocking agents, while we attempt to correct other potential causes such as fever, pain, anemia, and hypovolemia.

Occasionally, in patients with evolving MI, we have resorted to using an intra-aortic balloon pump

(IABP) to improve coronary blood flow while decreasing workload. Definitive studies of its effectiveness are lacking, and IABP placement can be difficult and risky in patients with peripheral vascular disease. We have also referred some patients to interventional cardiologists immediately after surgery for emergent cardiac catheterization, selective thrombolysis, and PTCA for unstable angina or evolving postoperative MI.

Other Medical Problems in Vascular Surgery Patients

Hypertension occurs in the majority of vascular surgery patients and may produce end-organ damage to the heart and kidneys. One benefit of the modern system of same-day admission is that it allows us to interview many patients in a preanesthesia clinic a week or so before surgery. At that time, if hypertension is poorly controlled, we consult with the patient's internist or cardiologist and adjust or begin the antihypertensive regimen. Most often, this is accomplished with oral doses of atenolol or metoprolol 25 to 200 mg daily, which we may start in our clinic. Additional risk-reducing therapy prescribed more commonly by internists or cardiologists may include ACE inhibitors and statin drugs. Lowering blood pressure gradually in this way before surgery allows for restoration of normal intravascular volume and results in a more stable perioperative course. In the past few decades, many clinicians have chosen

to postpone surgery in patients with elevated blood pressure before surgery, regardless of whether they receive chronic treatment for hypertension. A more recent meta-analysis of 30 observational trials of cardiovascular outcomes after surgery in hypertensive patients suggests a statistically but "not clinically significant" increase in events.[51]

Diabetic patients have a greatly increased risk for peripheral vascular disease. Aggressive chronic treatment to maintain euglycemia promotes wound healing and forestalls retinopathy and the development of proteinuria, but its effects on the progression of large vessel peripheral vascular disease and CAD are unknown. Coronary disease is ubiquitous in diabetic patients requiring vascular surgery. Diabetic patients generally have higher risks of MI and wound infection compared with nondiabetics undergoing abdominal aortic aneurysm. The dramatic increase in the risk of postoperative death (7%) in diabetic patients with autonomic neuropathy suggests that simple tests to identify such patients might be part of the preoperative workup.[52] Patients with diabetes and severe CAD may live longer if they undergo CABG rather than PTCA. We are especially fastidious about glucose management during carotid and thoracic aortic procedures, where hyperglycemia may exacerbate neurologic injury. In addition, more recent randomized trials and large observational trials have suggested mortality reduction in surgical ICU patients and improved outcomes in cardiovascular surgery when insulin infusions are used to provide "tight" glucose control.[53] Possible mechanisms of these beneficial effects include reduced immunosupression, maintenance of ischemic preconditioning, improved cholesterol and fat metabolism, reduced inflammatory mediators, reduced free radical production, reduced nitric oxide scavenging and less hypercoagulability. More recent studies suggest that best results may be obtained by keeping glucose <110 mg/dL. Although in the past our practice was to give one-half the morning dose of insulin and treat with "sliding scale" insulin to keep glucose 150 to 200, we are now more likely to employ insulin infusions, usually at 1 to 2 U/hour, especially in those patients who will be in an ICU after surgery. We attempt to maintain a glucose <150 mg/dL. Frequent monitoring of glucose levels is required in patients receiving insulin infusions.

Patients with peripheral vascular disease may have hypercoagulable states. Hypercoagulable states are more common in younger patients presenting for vascular surgery and in those with vascular thrombosis in unusual locations. Hypercoagulable responses to surgery may also predispose patients to vascular graft occlusion after surgery. Postoperative abnormalities include elevated fibrinogen levels, antithrombin III deficiency, impaired fibrinolysis, protein C deficiency, and protein S deficiency. HIT can occur paradoxically on an immunologic basis (IgG) after several days of exposure to heparin.[13] Treatment includes cessation of all heparin, full anticoagulation with argatroban, and 3 weeks of Coumadin to prevent arterial thrombosis. Coumadin alone is not recommended as it depletes protein C and may increase thrombosis.

Patients with peripheral vascular disease have frequently abused tobacco. Preoperative spirometry

may help identify patients likely to have postoperative pulmonary complications. In vascular surgery patients, the incidence of postoperative pulmonary complications (pneumonia, ventilator dependence >48 hours, or the adult respiratory distress syndrome) may be significant. Patients with forced expiratory volume in 1 second (FEV_1) <2.0 L/sec have a much higher incidence of pulmonary complications. Not surprisingly, respiratory failure was much more common in patients undergoing repair of aortic aneurysm than surgery for lower-extremity occlusive disease or for carotid procedures. Chronic obstructive pulmonary disease (COPD) is more common in patients with aortic aneurysms than in patients presenting for other vascular surgery.[54]

Renal insufficiency or failure exists in many patients who present for arterial reconstruction. Patients with preexisting renal insufficiency have an increased risk of postoperative renal failure, as well as cardiac complications and death. Postoperative renal failure markedly increases the chance of death. If patients receive chronic dialysis treatments, we prefer that they receive dialysis on the day before or the same day as surgery. Some patients will actually be hypovolemic as a result, which can contribute to hypotension upon induction of general or regional anesthesia. Many dialysis patients receive recombinant erythropoietin, which normally increases the hematocrit to ~30%. Left ventricular hypertrophy and mitral annular calcification are more common in dialysis patients and may predispose to pulmonary edema in the perioperative period; ECG and echocardiography may help the clinician to make these diagnoses. In addition, we usually seek laboratory and electrocardiographic evidence of hyperkalemia, and avoid succinylcholine when possible if we suspect hyperkalemia. We are careful when positioning patients to avoid putting pressure on the arm used for hemodialysis; we also do not measure blood pressure in that arm. Vascular access may be difficult in patients who have had multiple arteriovenous fistulae placed for hemodialysis. Central venous access may be more difficult in those who have had multiple central venous dialysis catheters. We also anticipate a more difficult abdominal dissection in some patients who have received peritoneal dialysis.

CAROTID ENDARTERECTOMY

Anesthetic management of CEA involves attempts to optimize cerebral perfusion in patients with a high prevalence of CAD. During the period of interruption of flow to allow vascular repair, cerebral ischemia may occur. Approaches to this problem include preoperative testing to predict cerebral ischemic potential, routine shunting of every patient, neurologic monitoring of the awake patient, and specialized intraoperative testing. These specialized tests detect electrical integrity (electroencephalogram [EEG], somatosensory-evoked potential [SSEP], auditory-evoked potentials), flow velocities (transcranial Doppler), and perfusion (jugular vein oxygenation, stump pressure, and cerebral oximetry). Specialized testing or evaluation of the awake patient is undertaken in the hopes of limiting shunting to only those patients believed likely to benefit.

In addition to traditional CEA, carotid angioplasty and stenting (CAS) is increasingly used. The challenge for angioplasty is to limit stroke from distal embolization of plaque. It has been shown with transcranial Doppler that embolic events are far more common with angioplasty as compared with CEA[55] but may not be associated with increased rates of cognitive dysfunction.[56] "Umbrella" devices that allow capture of embolic particles may improve the results of angioplasty. The ischemic time for angioplasty and stenting, however, is much shorter than for CEA, which may have benefits. Large randomized trials have more recently been reported, with initial promising results for stenting compared with traditional CEA.

Carotid atherosclerosis is the leading cause of extracranial vascular cerebral events. Carotid disease is bilateral in about one-half of all cases. Atherosclerotic plaque usually develops at the lateral aspect of the carotid artery bifurcation (where shear stress is lowest), and commonly extends into the internal and external carotid arteries. The disease is primarily a problem of embolization and rarely occlusion or insufficiency. Plaque rupture or embolization can lead to transient ischemic attack (TIA)/cerebrovascular accident (CVA). Risk factors for carotid disease include advanced age, hypertension, and tobacco abuse. Elevated serum lipid levels and a history of diabetes mellitus are less powerful predictors. Patients with left main CAD and

other peripheral vascular disease are also more likely to have carotid disease.

Carotid disease may manifest itself only as an asymptomatic bruit, or as amaurosis fugax (transient attacks of monocular blindness) when the ophthalmic artery is embolized. Other patients may experience episodes of paresthesias, clumsiness of the extremities, or speech problems, which resolve spontaneously after a short period of time. These are the classic TIAs. The differentiation between a TIA and a reversible ischemic neurologic deficit (RIND) is one of degree and is somewhat arbitrary. A TIA resolves within 24 hours, whereas a RIND will last longer than 24 hours before complete resolution.

An isolated, cervical bruit in asymptomatic patients also seems to be associated with a higher risk of stroke, but the correlation between the location of the bruits and the type of subsequent stroke is poor. A bruit per se does not define the presence of a critical carotid lesion, nor are critical carotid lesions always associated with bruits. Therefore, a bruit may prompt further testing. The most common noninvasive test is the duplex scan, which combines B-mode anatomic imaging and pulse Doppler spectral analysis of blood flow velocity. The presence of high velocities and turbulent flow is used to predict the extent of carotid stenosis. The accuracy of duplex scanning reaches 95% in experienced hands when compared with angiography. Angiography provides measurements of the size and morphology of the atheromatous plaque and can also document aortic arch or intracranial disease, which may occur in conjunction with carotid disease and can cause strokes that are not prevented by CEA. Because of the risks of contrast angiography, most surgeons will now operate based on duplex findings and reserve angiography for special situations such as a string sign (pseudoocclusion of the extracranial internal carotid artery, a "diagnostic trap," often angiographically misdiagnosed as complete occlusion), or suspected proximal disease. Also, many surgeons use magnetic resonance angiography as the sole modality to detect disease.

There are pharmacologic and surgical treatments for carotid artery disease. Combined administration of aspirin and dipyridamole, when compared with placebo, reduces the incidence of TIAs more so than either drug alone.[57] More potent platelet inhibitors such a clopidogrel may offer further protection. Therefore, it is essential that patients presenting for CEA continue to receive aspirin and/or clopidogrel in the perioperative period. Discontinuation of these medications may promote perioperative thrombosis and stroke or other morbid cardiovascular events. In contrast, CEA, in conjunction with aspirin therapy, has proven superior to medical therapy alone in a large trial of symptomatic patients with a stenosis >70% in the North American trial (NASCET).[58] In this trial, major or fatal ipsilateral stroke was significantly reduced from 13.1% in the medical group to 2.5% in the surgical group. Estimates of the cumulative risk of any ipsilateral stroke at 2 years were 26% in the medical patients and 9% in the surgical patients. For asymptomatic patients with a stenosis of >60%, the Asymptomatic Carotid Atherosclerosis (ACAS) study also detected a substantial outcome benefit. However, the overall risk of stroke was lower in both medical and surgical groups than for symptomatic patients in NACSET. In ACAS, ipsilateral stroke and any perioperative stroke or death was estimated to be 11.0% for patients treated medically and 5.1% for surgical patients after 5 years.[59] Patients with ulcerated soft plaques seem to have a higher risk of stroke that approaches 7 to 8% per year. The serious nature of cerebrovascular disease is underscored by the fact that about one-third of all acute strokes are fatal and another third result in significant residual functional deficit. Of course, CEA is justifiable only if the operative morbidity and mortality are lower than the natural risk for ischemic events in the untreated patient. Also, repair of asymptomatic disease may not be beneficial in patients who do not have a reasonable chance of living 5 years. The number of asymptomatic patients who need to undergo CEA to prevent one stroke is approximately 20 to 40, leading some investigators to question its cost effectiveness in this setting. The guidelines published for CEA by the AHA were last revised in 1998.[60]

More recently, the SAPPHIRE trial of high-risk patients randomized to angioplasty plus stenting or traditional surgery reported noninferiority of stenting with a suggestion of important outcome benefits.[61] These benefits included a trend toward a lower cumulative incidence of a major cardiovascular event at 1 year—a composite of death, stroke, or MI within 30 days after the intervention or death or ipsilateral stroke between 31 days and 1 year. The primary end point occurred in 12.2% of patients randomly assigned to undergo carotid artery stenting and in 20.1%

of patients randomly assigned to undergo endarterectomy (P = .004 for noninferiority, and P = .053 for superiority of stenting). It is important to point out that these results were obtained with the use of "umbrella" devices to retrieve atheromatous debris. Previous series of angioplasty and stenting performed without such protection were associated with high rates of asymptomatic (detected by transcranial Doppler and/or postprocedure surveillance magnetic resonance imaging [MRI]) and symptomatic distal embolization.[55] Patients will generally receive clopidogrel and aspirin before stenting, plus periprocedural heparin to maintain the activated clotting time (ACT) at twice normal. Others have added glycoprotein IIb–IIIa receptor inhibitors to their antithrombotic "cocktails." To prevent bradycardia and hypotension during balloon inflation and stent deployment, prophylactic atropine is often administered as a routine, although some centers choose to treat only after a patient evidences bradycardia.[62]

Factors that consistently predict neurologic and cardiac morbidity and mortality after CEA include age ⩾75 years, experience of the surgeon, preoperative neurologic symptoms or previous stroke, history of angina, diastolic blood pressure >110 mm Hg, CEA performed in preparation for CABG, internal carotid artery thrombus, stenosis near the carotid siphon, or contralateral carotid occlusion. Patients undergoing CEA for lesions of the left carotid artery may suffer stroke more often, possibly due to technical difficulties, because most surgeons are right handed.

Preoperative Evaluation and Preparation

Although the most common cause of TIAs is occlusive carotid disease, other neurologic disease such as intracerebral tumor or cerebrovascular malformation may produce similar symptoms. Cardiac diseases also may produce neurologic symptoms, including atrial fibrillation, valvular heart disease, dilated cardiomyopathy, or an MI with akinetic ventricular segments leading to intracardiac thrombus formation and cerebral embolization. CAD is common in patients presenting for CEA. We are less likely to request special studies (DSE or dipyridamole-thallium scintigraphy) or cardiac catheterization before CEA than for other major vascular procedures. Our rationale is that CEA can prevent stroke, is less stressful, and does not result in death as frequently as other vascular operations. Indeed, it has been proposed that preoperative risk can be based not only on the presence of CAD, but also on the basis of exercise tolerance and extent of the surgical procedure.[21]

In the NASCET trial, the 30-day results were as follows: death, 1.1%; disabling stroke, 1.8%; nondisabling stroke, 3.7%; and cardiac death, 0.3%. These values are clearly lower than those reported for CABG, even in patients free of significant carotid disease. Therefore, it is difficult to recommend a CABG procedure to a patient with symptomatic carotid disease and stable coronary disease because the combined

mortality and stroke rate after CABG may be higher than that of an expertly performed CEA. Cerebrovascular disease is associated with increased mortality after CABG. In contrast, patients who have had previous CABG may have lower mortality following CEA.

We therefore usually undertake CEA in patients for whom the operation offers benefits, even if they have stable CAD. Our classification of stable CAD is based on a thorough history, physical examination, and review of basic laboratory tests, not specialized testing. We do not delay urgent surgery that might prevent a stroke for extensive cardiac evaluation in the patient with stable cardiac disease. However, the long-term risks of adverse cardiac events after CEA are related to progression of CAD. Identification and coronary revascularization or aggressive medical therapy of patients with triple-vessel or left main CAD and those with very low ejection fractions may prolong their lives.

The approach to patients with both severe CAD and carotid occlusive disease is controversial. The risk of stroke in patients with symptomatic carotid disease undergoing CABG surgery has been reported to range from 8.7 to 17%. Options include either a concurrent (performed under one anesthetic) operation or two separate, staged procedures. A medical record review of 10,561 CEA procedures randomly selected from Medicare patients undergoing CEA in 10 states found worse outcomes in 226 CEAs performed in combination with CABG in the same operative event.[29] The

combined stroke and death rate was 17.7%; 80% of the nonfatal strokes were disabling. Proximal aortic arch atherosclerosis and symptomatic carotid stenosis were associated with stroke ($P < .05$). Female gender, emergent operation, redo CABG, blood pressure on pump, total pump time, presence of left main disease, and number of diseased coronaries were associated with mortality ($P < .05$). The strokes appeared to be associated with the operative event, but diagnosis was delayed and postevent carotid patency was not documented. Operative strategies used in concurrent operations vary among surgeons. Some surgeons will begin with a simultaneous CEA and a saphenous vein harvest. After these procedures have been completed, coronary artery bypass is initiated. This technique avoids the potential threats posed to the brain by hypotension at the initiation of CPB or during cardiac manipulation during off-pump CABG. This strategy presumes hypoperfusion is the dominant mechanism of stroke after CABG. However, studies suggest that embolic events may predominate. Emboli may occur when the ascending aorta is cannulated or occluded with a cross-clamp and protruding aortic arch atheromas are dislodged; mobile atheromas are seen using TEE in 15% of patients with severe carotid artery disease. Therefore, other surgeons will perform a simultaneous correction of both the coronary and carotid arteries during the aortic cross-clamp period. They seek to protect the brain with systemic hypothermia of 20 to 25°C. With this strategy, several investigators have reported extremely low rates of perioperative strokes. Although these reports are encouraging, rigorous scientific proof for a preferred operative strategy in patients with severe coronary and carotid disease is not yet available.

Monitoring and Preserving Neurologic Integrity

The two main goals of intraoperative management are to protect the brain and to protect the heart, yet these two goals often conflict. For example, increasing arterial blood pressure to augment cerebral blood flow can increase afterload or myocardial contractility, thereby increasing the oxygen demand of the heart. Also, although hypothermia might provide effective cerebral protection, it also poses a significant challenge to myocardial well-being if patients wake up shivering. General approaches to myocardial protection have been summarized previously. Our approaches to neurologic and myocardial protection during CEA involve compromises that must be made if both organs are to be protected.

Routine aspects of anesthetic care that may affect cerebral outcome if hemispheric ischemia occurs during CEA include blood pressure augmentation, manipulation of $PaCO_2$, glucose management, and choice of intraoperative fluid administration. Whether further interventions to reduce cerebral metabolism and cerebral oxygen requirements are neuroprotective is controversial. More recent research suggests that the outcome of cerebral ischemia may be improved by antagonizing or modifying processes that normally occur after reperfusion rather than during ischemia. Shunts may be used if cerebral hypoperfusion is suspected. Percutaneous approaches using carotid stenting are no panacea; neurologic events also occur during and after these procedures.

5 The rationale behind maintaining a stable, high-normal blood pressure throughout the procedure is based on the assumption that blood vessels in ischemic or hypoperfused areas of brain have lost normal autoregulation. Flow in such areas is believed to be mainly pressure dependent. Under these circumstances, prolonged, severe hypotension may jeopardize the brain. Consequently, we maintain blood pressure in the patient's high-normal range. Nonetheless, hypotension and hypoperfusion may not be the precipitating or sole cause of stroke after CEA; embolic events may be just as or even more important, and often occur postoperatively (Fig. 32-4).[63] In addition, blood pressure augmentation with sympathomimetic drugs is not without risk to the heart. Indiscriminate use of phenylephrine to raise blood pressure during deep general anesthesia with a volatile anesthetic increases the incidence of intraoperative segmental wall abnormalities detected by TEE compared with light anesthesia without the use of phenylephrine. However, the judicious use of phenylephrine to raise blood pressure only in specific instances of EEG-detected reversible cerebral ischemia seems to be without detriment to the heart. Although phenylephrine lowers ejection fraction measured with TEE and causes cardiac dilatation in patients with CAD, norepinephrine maintains cardiac function while raising blood pressure. Phenylephrine

and norepinephrine both raise cerebral blood flow velocities to a similar extent, and the increase is proportional to increases in systemic blood pressure. Despite this, we almost never use norepinephrine during CEA due to

its potent effects and the possibility of raising blood pressure more than desired. Whatever the choice of vasopressor, we believe one benefit of EEG or other neurophysiologic monitoring is that it allows the anesthesiologist to use less vasopressor and to maintain a lower blood pressure during the period of temporary carotid occlusion than would be otherwise feasible. Thus, as long as the patient is without new neurologic deficits or the EEG or other neurophysiologic monitor is unchanged, the anesthesiologist may decrease the afterload in the patient who is at risk for myocardial ischemic events. Based on these studies, limited vasopressor use during hypotensive episodes associated with a change in neurophysiologic monitoring appears defensible, allowing the clinician to treat only those patients who might benefit most and sparing others from its risks.

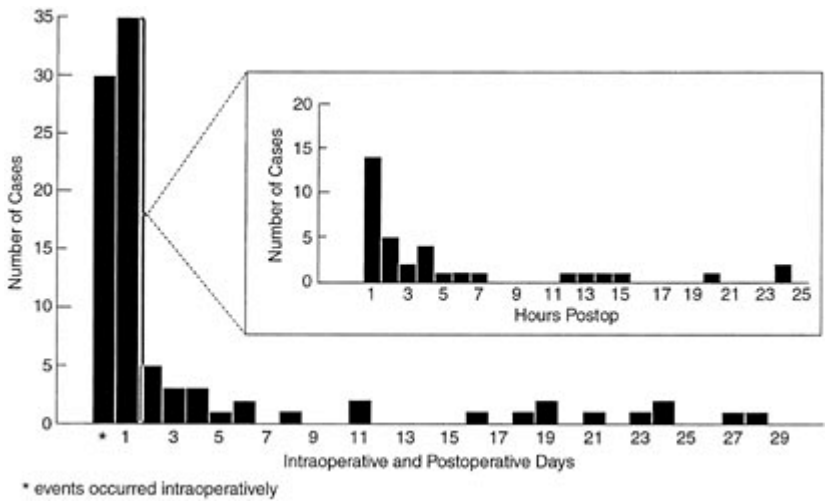

FIGURE 32-4. Data from the North American Symptomatic Carotid Trial (NASCET). Of the perioperative strokes, 35% (30/85) occurred intraoperatively, whereas 65% (55/85) occurred after the patient left the operating room (delayed events). The figure illustrates the time of onset of the 92 surgical outcome events.

Hypercapnia dilates cerebral blood vessels and thus increases cerebral blood flow. However, hypercapnia during CEA may be detrimental if it dilates vessels in normal areas of the brain while vessels in ischemic brain areas that are already maximally dilated cannot respond. The net effect, then, is a "steal" phenomenon (i.e., a diversion of blood flow from hypoperfused brain regions to normally perfused brain regions). Most authorities recommend the maintenance of normocarbia or moderate hypocarbia at best.

Moderate hyperglycemia may worsen ischemic brain injury. Increased cerebral lactic acidosis resulting from the anaerobic glycolysis of increased brain glucose stores is postulated to be directly or indirectly responsible for the adverse effect. Because of the neuroendocrine response to surgery, with its resultant breakdown of glycogen, and the relatively high incidence of diabetes in this patient population, blood sugar levels will often already be mildly elevated during CEA. The administration of dextrose-containing intravenous fluid may exacerbate hyperglycemia. A similar effect may result from lactated solutions because lactate is metabolized to dextrose. Although there is no proof that the focal neurologic injury that may follow CEA is actually augmented by hyperglycemia, we nonetheless prefer normal saline for intraoperative fluid substitution. Isovolemic hemodilution with dextran or hetastarch is of theoretical interest in cerebral ischemia because blood viscosity is reduced and attendant microcirculatory disturbances ameliorated.

Almost all commonly used anesthetic agents reduce cerebral metabolism, thereby decreasing the

brain's requirements for oxygen. It has been assumed that under anesthesia the brain's tolerance of temporary ischemia is enhanced. However, the notion that reduced cerebral metabolism is associated with cerebral protection has been challenged. Nonetheless, we believe that as long as this method of pharmacologic brain protection is not clearly refuted, there is no good justification to deny its potential benefits to a patient. The following section reviews the putative benefits of inhalational and intravenous anesthetic agents, as well as hypothermia in reducing cerebral metabolism.

Compared with older inhalational anesthetics, isoflurane may have more potential protective effect against cerebral ischemia, whereas compared with enflurane and halothane, isoflurane decreased the frequency of EEG-detected cerebral ischemic changes during CEA.[64] Nonetheless, clinical neurologic outcome was not different among the anesthetic groups. However, isoflurane's protective effects are maximal only at ~2 minimal alveolar concentrations (MAC). At this MAC level, systemic hypotension will occur in many patients; therefore, maximal protection may not be clinically achievable. Desflurane and sevoflurane also reduce cerebral oxygen requirements at MAC values comparable to those with isoflurane, resulting in faster emergence and recovery than isoflurane.[65]

Barbiturates may offer a degree of brain protection during periods of regional ischemia. Thiopental decreases cerebral metabolic oxygen requirements to about 50% of baseline. These maximally achievable reductions in oxygen requirements correspond to a silent (i.e., isoelectric) EEG. Beyond this point, additional doses of barbiturates are neither necessary nor helpful. In cases of massive global ischemia where basal cellular metabolism has already deteriorated, even high doses of barbiturates will not improve neurologic outcome. Therefore, some clinicians use thiopental not only for induction of anesthesia, but also for continuous infusion and/or as a 4 to 6 mg/kg bolus just before carotid occlusion. The cardiac depressant effects of the barbiturates may require inotropic support. Unfortunately, no rigorous proof is available that the use of barbiturates in the described manner can improve neurologic outcome after CEA. Excellent results have been obtained for CEA using high doses of barbiturates during carotid occlusion, without neurophysiologic monitoring or shunt placement; on average, tracheal extubation was delayed until 2 hours after surgery was completed.

Both etomidate and propofol decrease brain electrical activity and thus decrease cellular oxygen requirements. Etomidate preserves cardiovascular stability and may be beneficial in a patient population whose cardiac reserves are often limited. Propofol also allows rapid awakening of the patient and neurologic assessment at the end of surgery. Propofol may also be associated with a lower incidence of myocardial ischemia than is a volatile-based anesthetic but does not appear to affect overall clinical outcome.[66] Although the available evidence for the protective effects of etomidate or propofol during CEA is inconclusive, a small series in patients undergoing temporary ischemia for intracranial aneurysm clipping suggests that etomidate, propofol, or barbiturate use prolongs tolerable ischemia and reduces brain infarction.[67] Some animal studies have supported, and others refuted, the utility of α_2-agonists in reducing cereberal infarction in animal models.

Hypothermia can depress neuronal activity sufficiently to decrease cellular oxygen requirements below the minimum levels normally required for continued cell viability. In theory, hypothermia represents the most effective method of cerebral protection. Even a mild decrease in temperature of about 2 to 3°C at the time of arterial hypoxemia may reduce ischemic damage to the brain. The first reported CEA was performed with the patient's head covered by ice packs. Unfortunately, this method is cumbersome, unpredictable, and rarely used. We allow patients to cool passively in the operating room and avoid warming the operating suite, intravenous fluids, or inspired gases until the carotid repair has been completed. Afterward, forced-air warming may counteract the adrenergic response and increased incidence of myocardial ischemia associated with hypothermia in vascular surgery patients. We do not currently have clinical evidence to support the hypothesis that hypothermia protects the brain sufficiently to justify the myocardial risks imposed by hypothermia and shivering.

Effective pharmacologic brain protection is still theoretical. The outcome of cerebral ischemia may be improved by preventing activation of the neuron's excitatory amino acid receptor after

reperfusion. However, to date no conclusive data exist for use of this method in humans. Ischemia also leads to neuronal calcium overload, which in turn sets off a series of harmful biochemical intracellular events. Given early after the onset of stroke symptoms, nimodipine, a calcium channel blocker, may confer some benefit to patients. Nitric oxide synthesis and free-radical scavengers may also have important therapeutic roles. Volatile anesthetics may provide preconditioning and neuronal protection by inducing nitric oxide synthase.[68] Some centers still use intravenous steroids to protect the brain from the effects of hypoxia, as well as for prevention and treatment of hyperperfusion syndrome.

Temporary occlusion ("cross-clamping") of the carotid artery acutely disrupts blood flow, even if flow to the ipsilateral hemisphere of the brain was already markedly diminished by severe stenosis. Continued blood supply to the brain will

depend entirely on adequate collateral blood flow through the circle of Willis if no shunt is used. If carotid stenosis has worsened gradually before CEA is performed, collaterals from the circle of Willis may have had time to develop, and the cerebral circulation may not be compromised by carotid occlusion during surgery. However, if collateral flow is compromised because of occlusive disease of the contralateral carotid artery and/or the vertebral arteries, the chances are greater that marked hypoperfusion of the brain will occur during carotid clamping. Indeed, patients with bilateral carotid disease have a higher risk of perioperative stroke after CEA than patients with unilateral disease only.

There are practice variations among surgeons in the use of shunts in carotid surgery. Some surgeons never use shunts, others use them routinely, and still others use them only selectively. Surgeons who never use shunts usually rely on expedient surgery to avoid neurologic problems and do not report worse overall outcome statistics than those who do. The routine use of shunts is not risk free. Placement of a shunt is associated with an embolism-related stroke rate of at least 0.7% from the dislodgment and embolization of atheroma. The technical problems of shunting include air embolism, kinking of the shunt, shunt occlusion against the side of the vessel wall, and injury or disruption of the distal internal carotid artery. Patients with shunts may still develop EEG abnormalities; in these situations, we alert surgeons that shunt adjustments may be necessary. The shunt may impair surgical access to the artery, thereby increasing cross-clamp time. Most important, the use of a shunt is beneficial only if the cause of neurologic dysfunction is inadequate blood flow. However, the majority of studies suggest that as many as 65 to 95% of all neurologic deficits during CEA may be caused by thromboembolic events (see Fig. 32-4), which may occur when the carotid artery is dissected, at which point insertion of a shunt will not prevent a deficit. Not surprisingly, there is no rigorous proof that the routine insertion of a shunt reduces the incidence of postoperative neurologic deficits. In the NASCET trial, shunting (used in 41% of patients) was not associated with a change in risk of stroke.

Surgeons who use shunts selectively will need a monitoring device of cerebral perfusion to help them decide when to place the shunt. To this end, various cerebral perfusion monitors are used. Monitoring approaches include assessment of the awake patient, transcranial Doppler, SSEP, EEG, cerebral oximetry, and direct xenon cerebral blood flow measurement. In each case, the goal is to avoid routine shunting, which can cause air embolism and thromboembolism. Different techniques individually or in combination may be used by different centers.

Processed EEG monitoring is often used. However, as in all the previous techniques, its sensitivity in detecting perioperative stroke is limited by the fact that most strokes occur following surgery and are likely related to thromboembolic phenomena.[69] Rapid changes in anesthetic depth may also complicate interpretation.[70] This is particularly relevant in centers where barbiturates or propofol infusions are used to induce EEG suppression in hopes of reducing $CMRO_2$. In the North American trial, 93% of patients underwent CEA with general anesthesia; 51% of patients had intraoperative cerebral monitoring (31% EEG, 14% stump pressure, 7% evoked potentials, and 3% transcranial Doppler). However, the use of monitoring was not associated with reduced risk of stroke.[63] In summary, none of the previous procedures or neurophysiologic monitors has been shown to improve outcome. Because embolism, not hypoperfusion, is probably the most common cause of perioperative stroke, the real value of cerebral monitoring may lie in the avoidance of

interventions such as the placement of shunts (which can cause stroke) and blood pressure augmentation (with its detrimental effects on the heart).

The interpretation of the information gained from the scalp-recorded EEG has been simplified by the use of computerized data reduction methods. The EEG reflects the spontaneous electrical activity of cortical (surface) neurons. Increasing levels of ischemia lead to a decrease in recorded electrical activity. EEG deterioration begins usually below a cerebral blood flow rate of about 15 mL/min/100g brain tissue, but cellular metabolic failure does not seem to occur until blood flow falls below 10 to 12 mL/min/100g brain tissue.[71] Under conditions of focal cortical ischemia, the frequency of the recorded EEG waves over the affected area of the brain will slow significantly (i.e., >50%). In addition, the amplitude of the waves may decrease (attenuate) to a comparable extent. The appearance of a disorganized background rhythm may also be a sign of ischemia. Finally, as ischemia becomes severe, the EEG will become isoelectric. Ischemic EEG changes occur in 28% of all monitored patients during CEA.[72] When they occur, they define a patient subgroup with a significantly increased risk of perioperative stroke. The most common manifestations of EEG ischemia during CEA are ipsilateral attenuation, ipsilateral slowing with attenuation, and ipsilateral slowing without attenuation.

In practice, the EEG can be obtained using a 16-channel strip-chart recording or a processed EEG monitor with 2 or 4 channels. A 16-channel strip-chart EEG generally requires a technician to set up the monitor, and to monitor and interpret the large amount of (unprocessed) data generated. In contrast, a 2-channel or 4-channel processed EEG monitor provides less data but can be monitored more easily. Figure 32-5 shows a processed EEG reflecting acute cerebral ischemia following left carotid artery occlusion; the placement of a shunt in this case promptly reversed the ischemic changes.

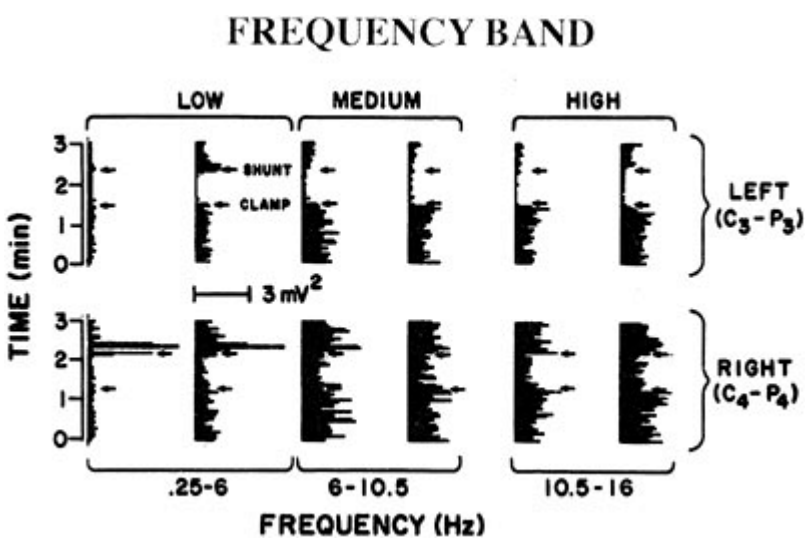

FIGURE 32-5. Acute cerebral ischemia following left carotid artery occlusion detected with processed electroencephalogram. The placement of a shunt in this case promptly reversed the ischemic changes. (Courtesy of Dr. Bruce L. Gewertz.)

However, EEG monitoring has several limitations. For one, deep brain structures are not monitored by EEG. Also, in patients with preexisting or fluctuating neurologic deficits the EEG may be false negative; that is, these patients can develop perioperative strokes despite the absence of major intraoperative EEG changes. In these patients, there may be cell populations that are electrically silent or immediately adjacent to regions of infarction, and therefore, not monitored by the EEG. The still viable regions may progress to irreversible deterioration in the course of the operative procedure. Furthermore, the EEG may not be an ischemia-specific monitor because decreases in temperature and blood pressure, as well as increases in the depth of anesthesia, produce EEG changes that mimic

ischemic changes. However, EEG changes secondary to anesthetics or hypothermia are more likely to be bilateral, whereas hemispheric ischemia is more likely to affect the electrical activity of only one side of the brain. Thus, we are compulsive in informing the encephalographer about adjustments to the anesthetic regimen.

Most importantly, the value of relatively costly EEG monitoring has not been rigorously established. Even if the advanced warning of an EEG can prevent some strokes, it would presumably do so only in the minority of patients who suffer strokes from intraoperative hypoperfusion (see Fig. 32-4).

Transcranial Doppler (TCD) measures middle cerebral artery blood flow velocities. TCD can also detect and quantify embolic signals, which almost always arise during dissection and/or angioplasty. A large series of 1,058 patients found the following TCD predictors of stroke after CEA: emboli during wound closure, >90% decrease of middle cerebral artery peak systolic velocity at cross-clamping, and >100% increase of the pulsatility index of the Doppler signal at clamp release. Emboli during dissection did not quite reach significance. The area under the ROC curve for stroke prediction was 0.69.[73] In a small case series, TCD predicted neurologic events despite a normal EEG.[74] However, compared with the awake patient as a gold standard, TCD may have a low positive predictive value for neurologic deficit accompanying carotid occlusion.[75] Other workers suggested that TCD is particularly useful in postoperative surveillance because most strokes occur after and not during CEA. TCD may also predict patients at risk of cerebral hyperperfusion syndrome following CEA/CAS.[76]

SSEP monitoring may be particularly useful in patients with cerebral ischemia in whom EEG interpretation is more difficult.[77] SSEP monitoring is based on the detection of cortical potentials after electrical stimuli are presented to a peripheral nerve. Detecting the potentials requires computer-assisted mathematic analysis and considerable expertise. In contrast to the EEG, which interrogates only cortical function, SSEP monitoring also evaluates deep brain structures. Any damage to these neural structures results in characteristic changes in the SSEP, usually in a decrease in amplitude and/or an increase in latency. If neural damage is severe, the cortical-evoked potential is completely abolished. Severe damage occurs at about one-third of normal cerebral blood flow (i.e., at 15 mL/min/100g brain tissue).

Whereas some studies have been optimistic about the value of SSEP monitoring in the detection of cerebral ischemia, other investigators have concluded that SSEP is neither sensitive nor specific for the detection of ischemic injury during CEA. Virtually all commonly used anesthetics lead to SSEP changes that mimic changes produced by cerebral hypoxia. Therefore, a constant light plane of anesthesia needs to be maintained if increased latencies and decreased amplitudes of evoked potentials are to be ascribed to inadequate cerebral perfusion. False-negative results may also occur. Based on the available data, we conclude that this monitoring system cannot yet be considered essential for a safe CEA.

Cerebral oximetry has had mixed results. One study of 100 patients suggests that "a 20% decrease in rSO_2 (regional frontal lobe saturation) reading from the preclamp baseline, as a predictor of neurologic compromise, resulted in a sensitivity of 80% and specificity of 82.2%. The false-positive rate using this cutoff point was 66.7%, and the false-negative rate was 2.6%, providing a positive predictive value of 33.3% and a negative predictive value of 97.4%." Monitoring rSO_2 with INVOS-3100 to detect cerebral ischemia during CEA has a high negative predictive value, but the positive predictive value is low.[78] With SSEP considered a "gold standard," the predictive value of cerebral oximetry was low, and "substantial interindividual variability of rSO_2 and derived change of rSO_2 did not allow the definition of a threshold value indicating need of shunt placement."[79] Others added that "relying on RSO_2 alone would increase the number of unnecessary shunts because of the low specificity. Accepting higher decreases in RSO_2 does not appear reasonable because it bears the risk of a low sensitivity."[80]

Anesthetic and Monitoring Choices for Elective Surgery

General discussions of cardiac function and myocardial ischemia monitoring can be found earlier in

this chapter. Our practice with patients undergoing CEA, summarized in this section, is somewhat different. Our intraoperative monitors include the usual monitors employed during all major, general, or regional anesthetics: temperature probe, blood pressure cuff, pulse oximeter, and an end-tidal carbon dioxide tension monitor. We routinely place an intra-arterial catheter for blood pressure monitoring so beat-to-beat changes in pressure are detected and treated promptly. However, in some patients, particularly elderly females, cannulation of the radial artery may be difficult. Before surgery, we also measure the blood pressures noninvasively in both arms because generalized peripheral vascular disease in this patient population can produce striking differences between the two upper extremities.

We routinely monitor leads II and V_5 of the ECG for ST-T segment changes because of the high incidence of perioperative myocardial ischemia after carotid reperfusion. In high-risk patients, we may rarely use TEE as an additional monitor, especially in those with acute stroke where source of embolus may be an issue. Rarely is it necessary to use a central venous or pulmonary artery catheter, even if TEE is not available. We seek to avoid central venous or pulmonary artery catheterization because of the risk of an accidental carotid artery puncture during cannulation of the internal jugular vein. We restrict the use of central venous access to the rare patient with uncompensated CHF undergoing urgent CEA, and then may insert it from the contralateral brachial or subclavian vein. Finally, in our experience, intravenous access for volume administration is generally sufficient with one well-secured and well-running, medium-bore, intravenous catheter because major blood loss or fluid shifts during CEA are rare.

For most patients, the assurance provided by the preoperative interview obviates the need for sedative drugs to prevent anxiety-induced myocardial ischemia. If sedatives are deemed indispensable, the smallest effective dose of midazolam is chosen for premedication to facilitate early perioperative neurologic assessment. Equally important, we obtain blood pressure and heart rate determinations from the preoperative clinic, other hospital or clinic visits, and at the time of admission, thus determining the range of a patient's acceptable values. We seek to maintain hemodynamics within this range intraoperatively. Chronic antianginal, antihypertensive, and aspirin medications are generally continued on the day of surgery. Patients who come to the hospital the same day as surgery must be reminded to take their medications at home. This is especially true for antiplatelet therapy. When patients forget to take their medications, we give them readily available oral or parenteral substitutes.

Our experience is that many patients present after an overnight fast slightly hypovolemic. They often present hypertensive despite having taken their morning antihypertensive and antianginal medications. These patients appear to be the most prone to hypotension after the induction of general anesthesia. For procedures performed under general anesthesia, we typically use propofol for induction, although thiopental or etomidate may be used. If thiopental is used, esmolol is particularly valuable to blunt hypertensive and tachycardic responses

to intubation. However, when a patient has a diastolic blood pressure >100 mm Hg in the operating room or is not well hydrated (often, both conditions exist simultaneously), induction of general anesthesia may result in hypotension. The clinician can anticipate this possibility and induce general anesthesia slowly, being prepared to use pharmacologic blood pressure augmentation if blood pressure decreases excessively. Despite this, in the operating room, we generally avoid administering more than 10 mL/kg of crystalloid in a typical 2-hour operation because fluid overload may contribute to postoperative hypertension. Diastolic filling abnormalities are common in elderly surgical patients,[81] and limiting fluid administration may also lessen symptoms of congestion following surgery.

Because the respiratory depression and sedation caused by opioids may persist into the postoperative period and may confound the results of early neurologic assessment, we generally restrict the use of opioids whenever possible (e.g., fentanyl $\leqslant$3 mg/kg) or use remifentanil. The combined use of a cervical plexus block and/or surgeon-administered local anesthetic helps considerably in almost eliminating opiate requirements.

We provide patients with a "light" general anesthetic that permits EEG monitoring and results in

blood pressures in the high range of normal. We may spray the trachea with 100 mg lidocaine to minimize stimulation by the endotracheal tube during surgery. Others have described the use of the laryngeal mask airway (LMA) during CEA, which may reduce hypertensive and tachycardic episodes. Anesthesia is maintained with 50% nitrous oxide in oxygen and light levels of a volatile anesthetic because of its salutary effects on the incidence of cerebral ischemia.[65] The newer volatile agents, desflurane and sevoflurane, may be used to facilitate rapid awakening and assessment of neurologic status.

We do not routinely use continuous infusions of vasopressors (e.g., phenylephrine) to augment blood pressure, but rather reduce the inhaled concentrations of volatile anesthetics and thereby rely on a patient's endogenous pressure-sustaining responses. Vasopressors are used to treat hypotension or EEG changes. Because sudden onset of bradycardia and hypotension may be caused by activation of baroreceptor reflexes with surgical irritation of the carotid sinus, some surgeons may infiltrate the carotid bifurcation with 1% lidocaine to attenuate this response. However, this practice may result in more postoperative hypertension. The vagal response may also occur during CAS, and atropine should be readily available. We typically use a medium-duration relaxant to provide muscle relaxation, although the choice of muscle relaxant depends on the heart rate we want to obtain. One of us administers no muscle relaxant except as necessary for intubation. Another usually gives an additional dose of muscle relaxant immediately before carotid occlusion when the concentration of volatile anesthetic is decreased to allow the blood pressure to rise. One limitation of this technique is that it lessens the potential neuroprotective effects of volatile anesthesia because the cerebral metabolic depression it produces is dose dependent. Our patients are almost always extubated at the end of the surgical procedure before or after we confirm neurologic integrity. In patients who were easy to intubate, we may perform a deep extubation in an attempt to limit the explosive hypertension that may accompany extubation. If this is done, we wait until neurologic integrity is verified before we leave the operating room. New neurologic deficits may lead to noninvasive imaging, contrast angiography, and/or surgical re-exploration. Our overall institutional results are good (mortality, 1%; stroke and MI, both 0.76%). Others achieved similar results using a nitrous oxide/opioid technique or a continuous infusion of thiopental. Intravenous techniques (propofol/remifentanil) may offer more hemodyanamic stability[82] than volatile anesthetic techniques. However, volatile anesthetic techniques allow easy titration of anesthetic depth and rapid awakening. In addition, animal and human studies suggest that volatile anesthetics may limit brain[83] and myocardial infarct[84] size at clinical doses. There is no proof that any one general anesthetic technique provides a superior outcome.

Regional anesthesia is used by many centers for CEA. The necessary sensory blockade of the C2 to C4 dermatomes can be achieved by superficial or deep cervical block or by subcutaneous infiltration of the surgical field. Superficial and deep plexus blocks appear to be equivalent in providing good surgical conditions and patient satisfaction; deep plexus blocks are more effective when a paresthesia is obtained.[85] Proponents of regional anesthetic techniques claim the following advantages: greater stability of blood pressure during surgery, inexpensive and easy cerebral monitoring, avoidance of tracheal intubation in patients with chronic obstructive lung disease, and avoidance of negative inotropic anesthetic agents in patients with limited cardiac reserves. The use of regional techniques appears to be associated with fewer episodes of EEG ischemia compared with general anesthesia.[86] In addition, overall hospital costs associated with the use of regional anesthesia may be lower. A systematic analysis has suggested lower stroke rates with regional anesthesia for CEA[87]; most published series are either not randomized and/or have too little power to detect outcome differences.

Disadvantages of regional anesthesia are that potential pharmacologic brain protection with anesthetics cannot be provided and that, in the case of panic, sudden loss of consciousness, or onset of seizures, control of the airway may be difficult. Although emergent intubation is uncommon, it may be difficult under these circumstances and complicate surgical management. Regional anesthesia requires that the patient remain highly cooperative throughout the operation, and sedation can be provided only to a limited extent during carotid occlusion. The NASCET study found no difference in event rate between regional and general anesthesia, although only 7% of

the 1,415 patients received a regional anesthetic. Based on the currently available evidence, the choice of anesthetic technique should take into account the preference of the surgeon and the experience and expertise of the anesthesiologist.

Initially, the internal carotid artery is isolated where the plaque or ulcerative lesion has been identified radiographically (usually starting near the bifurcation). Heparin is typically given in a dose of 50 to 100 U/kg. The surgeon isolates the diseased carotid segment with clamps or ties placed on the proximal and distal internal carotid artery and on the external carotid artery. After a period of test occlusion during which the adequacy of cerebral blood flow may be assessed with the modalities previously described, an incision is made into the artery. A shunt may be inserted at this time. The surgeon then endarterectomizes the ulcerated or plaque-containing area. Occasionally, a long or tortuous region is shortened by resection and reanastomosis, or if the remaining portion of the intima is too thin, a vein (often from the leg) or a Dacron patch is used. The use of a patch has been shown to improve long-term patency rates, particularly in women. Because suturing of the patch requires more time than suturing of the native vessel, an internal shunt is used more often during these procedures. Time is of the essence to help prevent neurologic deficits. If the shunt has been placed, it is then removed just prior to completing the repair. Shunt placement and removal usually takes between 1 and 4 minutes, and the total occlusion time rarely exceeds 40 minutes.

CAS may be performed by vascular surgeons, cardiologists, and/or radiologists. In some cases, this will involve sedation and monitoring provided by anesthesiologists; in other cases, no anesthesiologist will be involved. Adequate heparinization is crucial, with most protocols seeking to maintain ACT > 300 seconds. Both open CEA and CAS may cause blood pressure to fall immediately after reperfusion and into the postoperative

period, due to alterations in baroreceptor function.[88] Postoperative hypertension is common following CEA and may predispose to wound hematoma. Our experience has been that more aggressive antiplatelet therapy, especially with clopidogrel increasingly continued up until the time of surgery, is associated with greater bleeding in the Postanesthesia Care Unit (PACU). Wound hematoma may compromise the airway[89]; it is associated more with edema of the larynx than extrinsic compression and represents an emergency airway challenge.[90]

Postoperative Management

Common problems arising after CEA include the onset of new neurologic dysfunction, hemodynamic instability during emergence from general anesthesia, and respiratory insufficiency. Patients who have undergone general anesthesia may be awakened while still on the operating table to permit early neurologic evaluation. We may choose to extubate the trachea while the patient is breathing spontaneously but still anesthetized ("deep extubation"). We may do this in a patient who was easy to intubate, in an attempt to prevent emergence hypertension. However, even in these cases, we do not leave the operating room until the patient is awake enough to undergo neurologic assessment. A new neurologic deficit may demand immediate reexploration, or at least arteriography. A few surgeons routinely perform arteriography after restoring blood flow, but most believe that the complications of routine arteriography (emboli, allergic reactions, vasospasm, bleeding from the puncture hole, and stroke) are greater than its benefits (the detection of inadequate repairs, suture lines, or flow). With another method, duplex ultrasonography, the resutured vessel may be imaged at the end of surgery. The neurologic examination should also seek to identify cranial nerve (hypoglossal and facial) injuries arising from surgical manipulation.

Hyperperfusion syndrome is believed to result from blood flow to the brain that is greatly in excess of its metabolic needs following CEA. It may not occur until several days after surgery, when patients present with severe ipsilateral headache and can progress to develop signs of increased cerebral excitability or frank seizures. Transcranial Doppler may have a role in predicting which patients will develop this syndrome. Steroids may be used in the treatment of hyperperfusion syndrome.

Blood pressure abnormalities are common after CEA; hypertension is more common than hypotension. Severe hypertension seems to occur more often in patients with poorly controlled preoperative hypertension. Both acute tachycardia and hypertension may precipitate acute myocardial ischemia and failure, and hypertension may lead to cerebral edema and/or hemorrhage. Post-CEA hypertension is significantly associated with adverse events (stroke or death, with a statistical trend toward reduced cardiac complications), whereas postoperative hypotension and bradycardia do not appear to correlate with primary or secondary outcomes. We therefore routinely treat hypertension to reduce the work of the heart and in hopes of decreasing neck hematoma. Thus, having excluded and/or treated other causes of hypertension such as bladder distention, pain, hypoxemia, and hypercarbia, we lower systolic pressures of >140 mm Hg and diastolic pressures of >90 mm Hg to within the range of a patient's perioperative values. We write "as required" orders in the PACU, most often for labetalol in 5-mg increments; because labetalol is not beta-1-selective, we use other drugs in patients with reactive airways disease. Hyperdynamic responses accompanying emergence and extubation may be attenuated by prophylactic administration of intravenous lidocaine, esmolol, labetalol, or nitroglycerin. We prefer to use drugs with short half-lives that can be titrated to avoid undue hypotension. We believe that by supplementing with a regional anesthetic and/or tracheal lidocaine spray, these responses are suppressed. The incidence of myocardial ischemia is higher in the first few hours after CEA, even in patients who have been "awake" during CEA with a deep cervical block and prophylactic nitroglycerin infusions. Patients who undergo carotid artery stenting also manifest intraprocedural and postprocedural hemodynamic abnormalities similar to surgical patients. Bradycardia occurs frequently when right carotid lesions are angioplastied. The causes of postoperative hypertension are unclear. Our clinical experience suggests less postoperative hypertension when regional blocks are used, either alone or combined with a general anesthetic. Overzealous administration of intravenous fluid or surgical or chemical denervation of the baroreceptors of the carotid sinus nerve may also be responsible. Postoperative hypertension may be associated with an increased incidence of neurologic deficits. Usually, the hypertensive episode has its peak 2 to 3 hours after surgery, but in individual cases it may persist for 24 hours.

Postoperative hypotension and bradycardia after CEA are less frequent than hypertension. Surgical removal of the atheroma reexposes the baroreceptors of the carotid sinus nerve to higher levels of transmural pressure and causes brainstem-mediated vagal bradycardia and hypotension. Chemical denervation of the carotid baroreceptors with a local anesthetic by the surgeon results in fewer hypotensive patients but increases the incidence of postoperative hypertension. Over time, the baroreceptors seem to adjust and the hypotensive phase resolves within 12 to 24 hours. For patients who are hypotensive, some argue against any treatment as long as the ECG is unchanged and the patient's neurologic status is stable. Other clinicians, however, typically administer intravenous fluids and/or vasopressors such as ephedrine, dopamine, or phenylephrine to restore blood pressure to the low range of normal. Because significant hypertension and hypotension can be due to or caused by myocardial ischemia or infarction, we may obtain a 12-lead ECG in the recovery room in hemodynamically unstable patients.

Postoperative respiratory insufficiency may be caused by recurrent laryngeal nerve or hypoglossal nerve injury, a massive hematoma, or deficient carotid body function. Wound hematomas develop in up to 2% of patients after CEA. Whereas small hematomas caused by venous oozing usually can be treated by reversing residual heparin with protamine or by applying gentle digital compression for a few minutes, an expanding hematoma must be carefully and immediately evaluated because tracheal compression and loss of the airway may ensue rapidly. In some cases, evacuation of the hematoma may not relieve the airway obstruction if lymphatic obstruction has produced massive pharyngolaryngeal edema.[89,90] Indeed, four patients (0.3%) in the NASCET trial died directly due to neck hematomas. Risk factors for neck hematoma may also include failure to reverse heparin and the presence of an endotracheal tube beyond the end of surgery. Hematomas are more common and delayed if a patch angioplasty has been performed. Therefore, some clinicians routinely reverse heparin with protamine in patients who have had a patch angioplasty. Some studies, however, have suggested protamine may contribute to postoperative stroke. However, in the NASCET trial, heparin reversal using protamine (used in 40% of patients) was not associated

with a change in risk of stroke.[63]

Surgical manipulation may also damage the nerve supply to the carotid body. Although unilateral loss of carotid body function is unlikely to be significant, a bilateral loss may prevent the patient from increasing ventilation in response to a decrease in PaO_2. Therefore, supplemental oxygen should be routinely used in the recovery area. Similarly, drugs that depress respiratory drive should be avoided as much as possible in postoperative pain management. It is our experience that administration of acetaminophen constitutes effective pain

relief in most patients when skin infiltration or plexus block with local anesthetic was performed in the operating room.

In experienced centers, CEA causes only minor postoperative physiologic derangements in most patients. As a consequence, routine postoperative intensive care is unusual in our practice and has been questioned. In one study, postoperative intensive care surveillance was necessary only for patients with four or more of the following risk factors: stroke, CHF, chronic kidney failure, hypertension, arrhythmia, and MI. Equally important, all patients requiring interventions or with adverse outcomes could be identified by the eighth postoperative hour.[91] We believe routine admission of all patients to the ICU is probably not necessary and that intensive care surveillance can be limited to high-risk patients. Certain complications of CEA, such as hyperperfusion syndrome or bleeding after a patch angioplasty, may not occur until several days after CEA.

Management of Emergent Carotid Surgery

The patient who awakens with a major new neurologic deficit or who develops a suspected stroke in the immediate postoperative period represents a surgical emergency. Although postoperative neurologic deficits may be due to inadequate collateral flow, carotid thrombosis may cause postoperative stroke; prompt surgical reexploration can produce significant neurologic improvement. If a new neurologic deficit occurs in the postanesthesia recovery unit, most surgeons believe immediate reexploration is indicated, and logic would dictate utilization of pharmacologic methods of "cerebral protection;" however, this "logic" is controversial. Alternatively, if the deficit is deemed only focal and minor, it is most commonly due to microembolization. Consequently, noninvasive assessment of internal carotid flow and anticoagulation after exclusion of a hemorrhagic brain lesion usually constitute indicated treatment.

A patient undergoing emergency CEA may have a full stomach and thus may require protection against aspiration of gastric contents. The main goal is to minimize the hemodynamic stress of a rapid-sequence induction while maintaining adequate perfusion pressure across the stenotic lesion. General anesthesia is maintained with any of a variety of techniques aimed at attenuating hemodynamic fluctuations, achieving normocarbia (or a carbon dioxide level slightly below normal, as in elective operations), and maintaining adequate carotid artery perfusion pressure. An anesthetic technique similar to one for elective situations is used.

For patients undergoing neck exploration for a wound hematoma following CEA, oxygen is given at high concentration by face mask. In the event of acute airway obstruction, a high concentration of oxygen in the functional residual volume of the lung may provide additional protection against hypoxemia until the airway is secured by intubation or even by tracheostomy, or until the hematoma is evacuated surgically. A tracheostomy or cricothyroidotomy tray should be immediately available, as well as other devices for management of the difficult airway. It may be difficult to visualize the trachea because of edema or because of deviation caused by pressure of the hematoma.

If the hematoma does not obstruct the airway and the patient is not having difficulty breathing spontaneously, induction may be accomplished as in an elective procedure. If the airway appears compromised, topical anesthesia of the tongue, posterior pharynx, and epiglottis is provided. The larynx may then be visualized traditionally or with fiberoptic laryngoscopy. Esmolol is particularly useful to control hyperdynamic cardiovascular responses during awake intubation. If no difficulty with tracheal intubation is anticipated, induction is performed as described previously. However, if

any difficulty is expected, the wound is opened and drained externally, and tracheal intubation is performed before general anesthesia is induced.

AORTIC RECONSTRUCTION

In vascular surgery, understanding the pathophysiology of the disease and anticipating the surgical approach and techniques allow the anesthesiologist to serve the patient most effectively. The surgical goal in these operations is to create an enduring restoration of the normal circulation while minimizing the duration of ischemia to viscera, especially to the renal circulation. This goal is difficult to achieve: each possible surgical approach compromises some aspects while optimizing others. Surgery may be undertaken to correct aneurysmal or occlusive disease; sometimes the two coexist.

Aneurysmal Disease

Aneurysms pose an ever-present threat to life because of their unpredictable tendency to rupture or embolize. Mortality from rupture may be as high as 85%, and even patients who receive emergent surgery have mortality rates one-half that. Therefore, early recognition and aggressive surgical management are warranted, even in the absence of symptoms.

Epidemiology and Pathophysiology of Abdominal Aortic Aneurysm

There are approximately 200,000 new AAAs diagnosed annually with approximately 45,000 undergoing surgical repair per year in the United States. A population-based study in Norway in 1994 to 1995 used ultrasound to measure renal and infrarenal aortic diameters; an aneurysm was present in 263 (8.9%) of men and 74 (2.2%) of women ($P < .001$). Risk factors for aneurysm included advanced age, smoking >40 years, hypertension, low serum HDL cholesterol, high level of plasma fibrinogen, and low blood platelet count. This study indicates that risk factors for atherosclerosis are also associated with increased risk for AAA.[92] Thoracoabdominal aneurysms also occur in patients with hypertension or other risk factors for atherosclerotic disease.

AAA represents a dilatation of the abdominal aorta generally below the level of the renal arteries. The risk of rupture of the AAA is directly related to the luminal diameter of the aortic aneurysm. The aneurysm can develop an inner lining of mural thrombus, thereby decreasing the effective luminal diameter, but the size of the mural thrombus has not been shown to significantly decrease the risk of rupture. The risk of aortic rupture is only related to the absolute diameter of the aortic aneurysm sac. The risk of rupture increases once the aneurysm is greater than 4.5 to 5 cm in diameter. The size of the aneurysm is the most important predictor of subsequent rupture and mortality. A prospective study followed 300 consecutive patients (mean age 70 years; 70% men) who presented with AAA (average size, 4.1 cm) and were initially managed nonoperatively. The diameter of the aneurysm increased by a median of 0.3 cm per year. The 6-year cumulative incidence of rupture was 1% among patients with aneurysms <4.0 cm and 2% for aneurysms 4.0 to 4.9 cm in diameter. By comparison, the 6-year cumulative incidence of rupture was 20% among patients with aneurysms >5.0 cm in diameter.[93] Larger aneurysms expand even more rapidly. Patients with AAAs that do not undergo operation have an 80% 5-year mortality, predominantly owing to rupture. Generally, it has been recommended that in good-risk patients with aneurysms greater than 4.5 to 5 cm they should be considered for surgical repair.

Although traditional thinking has been that the lowered rate of mortality after elective AAA resection might justify elective repair of aneurysms as small as 4 cm, more recent evidence questions this practice. Although screening allows identification of larger numbers of patients with asymptomatic aneurysms, it also provides a mechanism for "watchful waiting." A randomized trial of 1,136 patients randomized to immediate repair versus surveillance with CT scanning and ultrasonography found similar survival in the two groups. In the immediate repair group, standard open repair was performed. In the surveillance group, patients were followed without repair until the aneurysm reached at least 5.5 cm in diameter or enlarged by at least 0.7 cm in 6 months or at least 1.0 cm in 1 year, or until symptoms developed that were attributed to the aneurysm. When

one of these criteria was met, open repair was to be carried out. The actual results showed that 80% of the "immediate" group had surgery within 6 weeks, while approximately 75% of patients in the "watchful waiting" group eventually had repair performed, but in this group it was delayed by an average of approximately 4 years after randomization. Although 11 patients in the surveillance group had rupture of AAAs (0.6% per year), resulting in seven deaths, the rate of hospitalization related to abdominal aortic aneurysm was actually 39% lower in the surveillance group.[94] This was true even though operative mortality was less than 3%. Therefore, these results may even be applicable to endovascular repair: watchful waiting may be preferable to repair in patients with AAAs of 4.0 to 5.4 cm in diameter.

The argument for aggressive surgical treatment is based on the fact that traditional surgery for ruptured AAA is still associated with mortality approaching 50%, roughly an order of magnitude greater than elective AAA surgery. Risk factors for mortality in patients with rupture include advanced age, APACHE (Acute Physiology and Chronic Health Evaluation) II score, initial hematocrit, and preoperative cardiac arrest. Unfortunately, in most patients with rupture, the diagnosis of AAA was unknown beforehand. These data reinforce the importance of screening of the high-risk population to permit elective repair.

Pathophysiology of Aortic Occlusion and Reperfusion

Aortic cross-clamping and unclamping is associated with complex cardiovascular, renal, humoral, and hemostatic changes. The intensity of these changes varies proportionally with the level of aortic clamping.

Cardiovascular Changes

The classic investigations of Gelman form the basis of our understanding of the pathophysiology of hemodynamic changes during aortic cross-clamping and unclamping.[95] Aortic cross-clamping increases mean arterial pressure and systemic vascular resistance up to 50%. This is attributed to a sudden increase in impedance to aortic flow (afterload); activation of renin; and release of cathecolamines, prostaglandins, and other active vasoconstrictors. Cardiac output initially decreases in the face of high systemic vascular resistance, and that decrease may be reinforced by the decrease in oxygen consumption below the aortic cross-clamp (Figs. 32-6 to 32-8 and Table 32-6). Some of the initial changes in hemodynamics associated with cross-clamping can be offset by boluses of a vasodilator

administered immediately prior to placement of the clamp (e.g., 0.3 to 0.7 mcg/kg of nitroprusside or milrinone 5 mcg/kg over 10 minutes). In this case, mechanical and pharmacologic actions cancel each other out while the body is allowed to adapt.

TABLE 32-6 Effect of Level of Aortic Occlusion on Changes in Cardiovascular Variables

▪CARDIOVASCULAR VARIABLE	▪% CHANGE IN VARIABLE, BY LEVEL OF AORTIC OCCLUSION		
	▪SUPRACELIAC	▪SUPRARENAL–INFRACELIAC	▪INFRARENAL
Mean arterial blood pressure	54	5[a]	2[a]
Pulmonary capillary wedge pressure	38	10[a]	0[a]

End-diastolic area	28	2[a]	9[a]
End-systolic area	69	10[a]	11[a]
Ejection fraction	-38	-10[a]	3[a]
Abnormal motion of wall, % of patients	92	33	0
New myocardial infarctions, % of patients	8	0	0

[a]Statistically different (P <.05) from group undergoing supraceliac aortic occlusion.

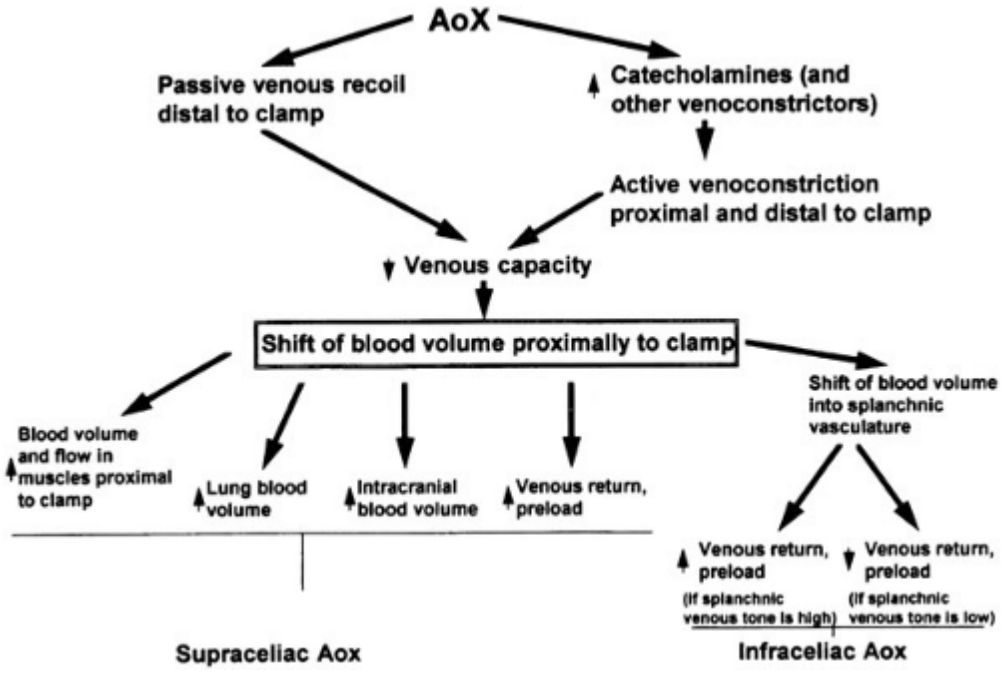

FIGURE 32-6. Blood volume redistribution during aortic cross-clamping. This schedule depicts the reason for the decrease in venous capacity, which results in blood volume redistribution from the vasculature distal to aortic occlusion to the vasculature proximal to aortic occlusion. If the aorta is occluded above the splanchnic system, the blood volume travels to the heart, increasing preload and blood volume in all organs and tissues proximal to the clamp. However, if the aorta is occluded below the splanchnic system, blood volume may shift into the splanchnic system or into the vasculature of other tissues proximal to the clamp. The distribution of this blood volume between the splanchnic and nonsplanchnic

vasculature determines changes in preload. AoX, aortic cross-clamping; ↑ and ↓, increase and decrease, respectively. (Reprinted with permission from Gelman S: The pathophysiology of aortic cross-clamping and unclamping. Anesthesiology 82:1026, 1995.)

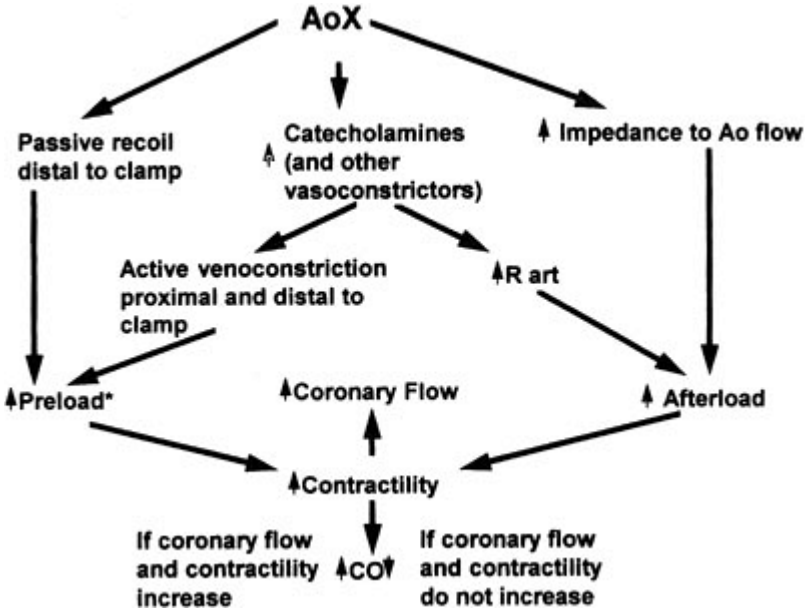

FIGURE 32-7. Systemic hemodynamic response to aortic cross-clamping. Preload does not necessarily increase. If during infrarenal aortic cross-clamping blood volume shifts into the splanchnic vasculature, preload does not increase (see Fig. 32-6). AoX, aortic cross-clamping; Ao, aortic; R art, arterial resistance; CO, cardiac output; ↑ and ↓, increase and decrease, respectively; *, different patterns are possible (see Fig. 32-6). (Reprinted with permission from Gelman S: The pathophysiology of aortic cross-clamping and unclamping. Anesthesiology 82:1026, 1995.)

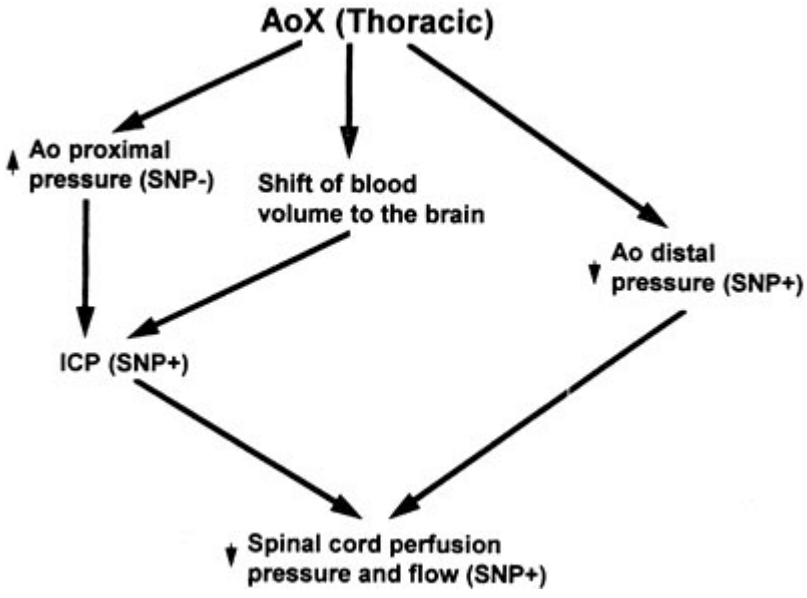

FIGURE 32-8. Spinal cord blood flow and perfusion pressure during thoracic aortic occlusion,

with or without sodium nitroprusside (SNP) infusion. The changes (*arrows*) represent the response to aortic cross-clamping per se. SNP+, SNP aggravates the effect of cross-clamping; SNP–, SNP counteracts the effect of cross-clamping; AoX, aortic cross-clamping; Ao, aortic; ICP, intercranial pressure; ↑ and ↓, increase and decrease, respectively. (Reprinted with permission from Gelman S: The pathophysiology of aortic cross-clamping and unclamping. Anesthesiology 82:1026, 1995.)

Preload changes are more variable than blood pressure changes. Higher central venous pressure (CVP) and pulmonary artery occlusion pressures do not accompany the decrease in cardiac index in the healthy heart. However, in those with CAD, myocardial dysfunction may be associated with cross-clamping and may lead to an increase in filling pressures as documented by TEE studies.[96]

The level of clamping affects hemodynamic response. Infrarenal aortic cross-clamping is well attenuated compared with suprarenal clamping, and during occlusive disease repair, aortic clamping usually has limited systemic hemodynamic effect. With lower clamping, blood volume from the infrasplanchnic vasculature may shift to the compliant splanchnic vasculature limiting preload changes, and vasodilation above the level of the clamp offsets the mechanical impedance to aortic flow. Clamping an occluded artery obviously is expected to have minimal effect. Existing collateral circulation remains intact during clamping and is responsible for maintaining lower body perfusion despite aortic cross-clamping. For higher clamps, nitrate therapy will not necessarily prevent wall motion abnormalities, and care should be exercised when using any vasodilator so perfusion pressure below the aortic cross-clamp remains at a level that will not potentiate visceral/spinal cord ischemia. It may be acceptable to allow a systolic blood pressure as high as 180 to 200 mm Hg as long as there is no other contraindication (e.g., intracerebral hemorrhage) and the surgeon has acceptable operating conditions. Even relative hypotension (<20% below resting pressure) probably should be avoided unless other means (shunts) are used to perfuse the lower part of the body.

Unclamping of the aorta can result in severe arterial hypotension unless aggressive therapy is undertaken prior to unclamping (Fig. 32-9). Various therapies are employed by anesthesiologists and surgeons, with no evidence one is superior to another. Most anesthesiologists employ some degree of fluid loading with or without vasoconstrictors such as neosynephrine (often 100 to 200 mcg) or drugs such as calcium chloride (300 to 500 mg) that can offset the negative inotropic/dromotropic effects of an acute potassium and acid load (and possibly other mediators) on the heart immediately following reperfusion. Much preferable to pharmacologic manipulation is gradual unclamping, which allows the body to adapt without much pharmacologic support. Whenever possible, unclamping should be gradual, either through actual staged release of the clamp, compression and gradual release of the femoral arteries by the surgical assistant, or restoring flow to one leg at a time in aortobifemoral grafts.

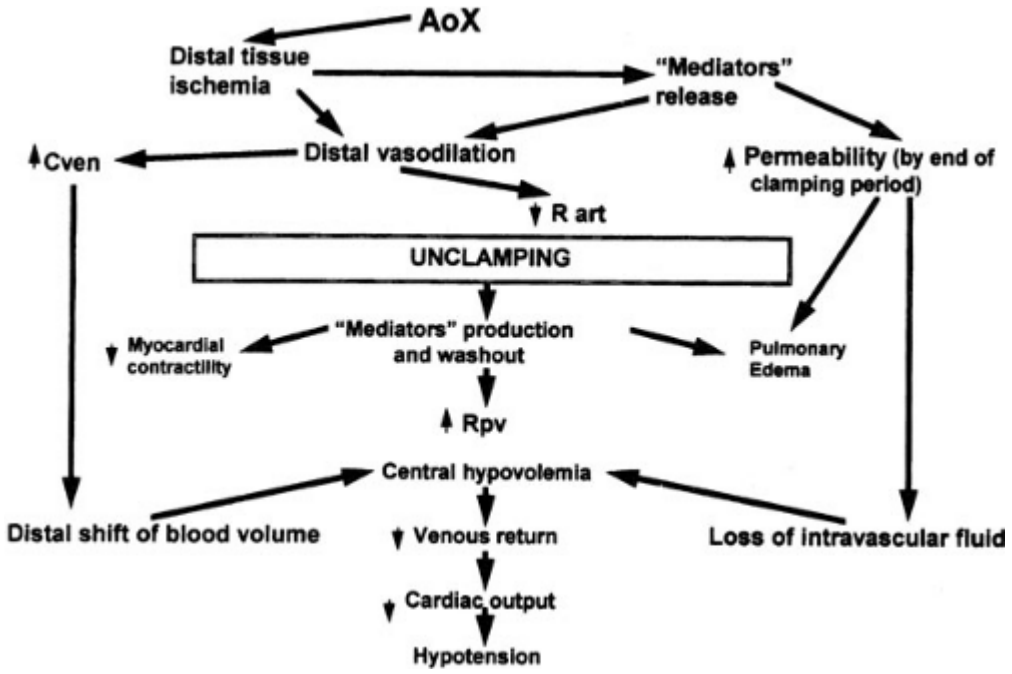

FIGURE 32-9. Systemic hemodynamic response to aortic unclamping. Preload does not necessarily increase. AoX, aortic cross-clamping; Cven, venous capacitance; R art, arterial resistance; Rpv, pulmonary vascular resistance; ↑ and ↓, increase and decrease, respectively. (Reprinted with permission from Gelman S: The pathophysiology of aortic cross-clamping and unclamping. Anesthesiology 82:1026, 1995.)

Renal Hemodynamics and Renal Protection

Renal protection is still a controversial topic, with no therapies proven to yield superior outcome. The level of aortic clamping is probably the most important of all the factors, as it markedly impacts renal blood flow. The incidence of acute renal failure is approximately 5% postinfrarenal clamping but approaches 13% postsuprarenal clamping. A major postoperative complication such as renal failure necessitating dialysis is probably the strongest predictor of mortality. Postoperative mortality is fourfold to fivefold higher in those who develop acute renal failure when compared with those who do not. It is imperative to understand routine regulation of renal perfusion (see Chapter 35), as well as the effect of aortic clamping on renal perfusion. With suprarenal occlusion, renal blood flow decreases by 80%. Blood flow is not only reduced with aortic cross-clamping, but also redistributed, favoring the cortical and juxtamedullary layers over the hypoxia-prone renal medulla.[97] Even with an infrarenal aortic clamping, renal blood flow is 45% lower during cross-clamping. Renal vascular resistance increases by almost 70%. Interestingly, these renal hemodynamic changes do not immediately revert after the release of cross-clamping and persisted for at least 30 minutes beyond the systemic cardiovascular return to baseline.

Many different methods of renal protection have been advocated, most of them centering on improving renal blood flow or glomerular flow. These include dopamine (dopaminergic receptor dose 2 to 3 mcg/kg per minute), fenoldopam,[98] ACE inhibitors, prostaglandins, thoracic epidurals for renal arterial sympatholysis,[99] vasodilators, isovolemic hemodilution (for increased blood flow in the face of increased vascular resistance), furosemide, and mannitol. Mannitol increases diuresis (although physiologically unimportant, it often satisfies the surgeon's need to hear that there is some urine output) and functions as a hydroxyl free radical scavenger. Outcomes have not been shown to improve with its use. Dopamine has been shown to lack specific renal hemodynamic effects and does not appear to improve postoperative renal dysfunction. Fenoldopam is gaining

more interest due to its specific DA-1 activity. Animal studies are promising, and human studies have shown better intermediate variables (e.g., creatinine clearance) but have not shown a reduction in need for dialysis.[98] One of the most important factors for preventing postoperative renal failure remains good hydration (as the most important factor for maintaining renal blood flow) during clamping and postclamp release.

Previous work from our group has shown that intraoperative urinary output is not predictive of postoperative renal function. In 137 patients undergoing aortic reconstruction (38 at the supraceliac level), we found no significant correlation between intraoperative mean urinary output, or lowest hourly urinary output, and changes from preoperative to postoperative levels of creatinine or blood urea nitrogen (Fig. 32-10).[100] Thus, urinary output, which is believed to be an index of perfusion and is therefore monitored routinely during surgery, was not predictive of postoperative renal function in normovolemic patients. When patients who underwent aortic occlusion at the suprarenal level were compared with those who underwent occlusion at the infrarenal level, there was no difference in postoperative renal function. Rather, preoperative renal dysfunction was the most powerful predictor of postoperative renal dysfunction. If prolonged renal ischemia is anticipated, selective

profound hypothermia and the direct intra-arterial infusion of mannitol into the kidneys may decrease the incidence of postoperative renal impairment.

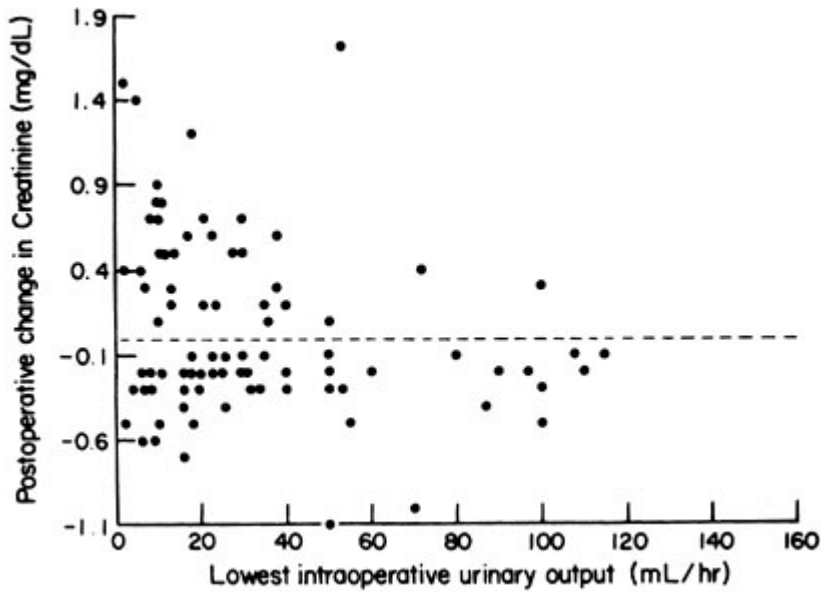

FIGURE 32-10. Lowest hourly intraoperative urinary output and maximal adverse change in renal function as assayed by change in creatinine from preoperatively to 7 days postoperatively. There was no correlation between lowest intraoperative urinary output and change in renal function postoperatively. (Modified with permission from Alpert RA, Roizen MF, Hamilton WK *et al*: Intraoperative urinary output does not predict postoperative renal function in patients undergoing abdominal aortic revascularization. Surgery 95:707, 1984.)

Humoral and Coagulation Profiles

Although the most evident factor contributing to hypotension is volume redistribution to the lower body after aortic cross-clamp release, many humoral mediators are released from the underperfused areas and contribute to the hemodynamic changes. Among the many factors described are renin, angiotensin, epinephrine, norepinephrine, PGI_2, endothelin, PGF-1, thromboxane A2 and B2, lactate, potassium, oxygen-free radicals, platelets activator, cytokines, activated complement (C3 and C4), and neutrophil sequestration. Administration of bicarbonate does not prevent immediate postunclamping hypotension and, in our anecdotal experience, can

exacerbate it, probably due to the initial increase in intracellular myocardial acidity. Mannitol administration before and after unclamping may be beneficial because of its function as a hydroxyl free radical scavenger. Nonsteroidal anti-inflammatory drugs may counteract the effect of prostaglandins; however, their use remains controversial due to their potential detrimental antiplatelet and renal perfusion effects. The use of COX-2 inhibitors augments postoperative pain control and avoids any platelet effect, but still may have some renal perfusion effects that have not been studied in this context. Regardless, we have used preoperative COX-2 inhibitors as part of a multimodal approach to postoperative pain control if a thoracic epidural is not employed, although more recent controversy suggests that COX-2 drugs may be contraindicated in patients with cardiovascular disease.

A high incidence (5 to 14%) of pulmonary complications is a fact in thoracoabdominal aneurysm repair. Sequestration of microaggregates and neutrophils contribute to postoperative pulmonary dysfunction. Aortic reperfusion may result in pulmonary vasoconstiction due to liberation of thromboxane A2 and other vasoactive substances. Increased permeability and pulmonary edema are not uncommon. As noted previously, mannitol may attenuate these responses.

Thirty minutes after aortic cross-clamping, t-PA and t-PA Ag levels in the peripheral vascular bed are increased. This reflects the increase in adrenergic state. TEG studies have documented an increase in clotting factor activity during cross-clamping and decreased speed of solid clot formation after unclamping. These changes, along with a low fibrinogen level, are consistent with clotting factor consumption rather than fibrinolysis.

Visceral and Mesenteric ischemia

As with postoperative renal failure, bowel ischemia is associated with a higher postoperative mortality rate, approaching 25%. Factors contributing to the pathogenesis of visceral ischemia include preexisting medical conditions, renal dysfunction, stage of aortic disease and level of aortic cross-clamping, perioperative hypotension, and last but not least the duration of cross-clamping.

Besides the acute ischemic injury to the organ, hypoxic insult to the intestines during aortic occlusion leads to gut permeability and bacterial translocation as evidenced by activation of polymorphonuclear leukocytes. This may predict respiratory and renal failure. Peak plasma level of tumor necrosis factor and interleukin-6 are significantly higher in hypotensive patients and in those who die. With endovascular repair, intestinal ischemic events seem less profound. High doses of methylprednisolone at induction of anesthesia may be beneficial in reducing the inflammatory response, including C-reactive protein and T-cell activation levels. Anesthetic techniques appear to minimally influence inflammatory cytokine stress responses, which correlate most with increasing operative times. Further research is needed to determine if anti-inflammatory therapy can reduce morbidity and mortality after aortic reconstructive surgery.

Cns and Spinal Cord ischemia and Protection

Few studies address the effect of abdominal aortic cross-clamping and unclamping on cerebral circulation. Middle cerebral artery blood velocity decreases during aortic occlusion. Unclamping is followed by a transient dilation of cerebral pial arterioles, followed by a sustained vasoconstriction. These changes are due to the hemodynamic changes, CO_2 accumulation and washout, decreased pH, and release of thromboxane A2, which is a powerful vasoconstrictor on cerebral vessels.

Spinal cord ischemia occurs in 1 to 11% of operations involving a distal aortic repair. The spinal cord is supplied by two posterior arteries; together, both supply 25% of spinal cord blood flow. The anterior spinal artery (Fig. 32-11), which supplies 75% of spinal cord blood flow, is the primary supplier to the anterolateral cord. The anterior spinal artery is fed by a series of radicular arteries arising from the aorta, and collateralization is poor. The blood supply to the thoracolumbar cord is derived from the radicular artery of Adamkiewicz. In 75% of cases, it joins the anterior spinal artery between T8 and T12, and in 10% it joins between L1 and L2. Much of the blood flow in the anterior spinal artery depends on the artery of Adamkiewicz. Because the flow in

the spinal arteries depends on collateralization and is often bidirectional, the blood supply to the spinal cord can be shunted to the rest of the body when perfusion pressures are low. Such a situation may arise when a single high aortic occlusion clamp is applied.

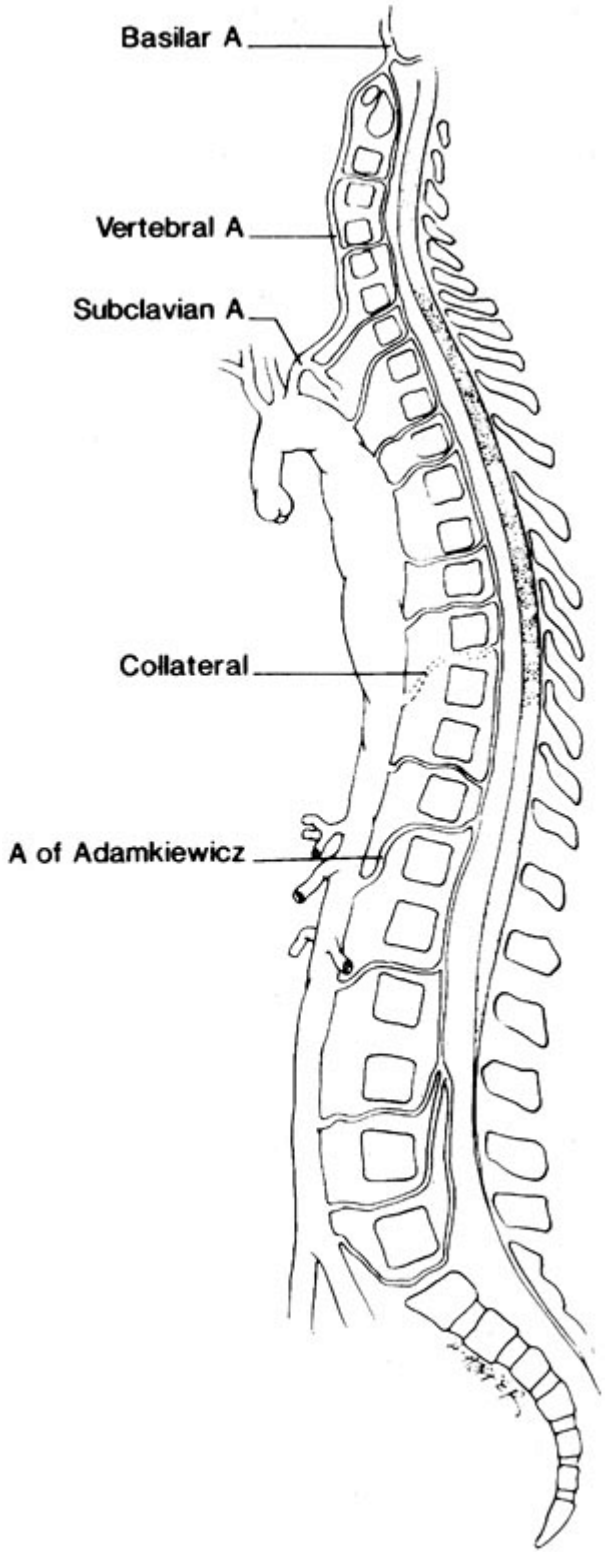

FIGURE 32-11. The artery of Adamkiewicz usually arises at the T11–T12 level and provides the blood supply to the lower spinal cord. Its variable location and the uncertainty of additional collateral blood supply explain, in part, the unpredictability of paraplegia following descending aortic surgery. (Reprinted with permission from Piccone W, DeLaria GA, Najafi H: Descending thoracic aneurysms. In Bergan JJ, Yao JST (eds): Aortic Surgery, p 249. Philadelphia, WB Saunders, 1989.)

6 The definitive preventive measures to spinal cord ischemia are short cross-clamping time, fast surgery, maintenance of normal cardiac function, and higher perfusion pressures. Other methods such as cerebrospinal fluid (CSF) drainage, distal perfusion, and hypothermia may be beneficial in high aortic clamping.

Surgical Procedures for Aortic Reconstruction

Perioperative (i.e., 30-day) mortality in elective aortic surgeries ranges between 0% and 12%, with a much higher probability

of death in emergent surgery especially in those situations where preoperative hypotension (systolic blood pressure (SBP) < 90 mm Hg) exists. Hypotension increases the risk by 3-fold, whereas preexisting heart disease including coronary artery disease (CAD) and congestive heart failure (CHF) increase the risk of mortality by 2.5- to 5-fold. Other identifiable risks for increased mortality are gender, with slight increase in female, serum creatinine above 2 mg/dL, and age older than 80 years. The size of an aneurysm does not appear to influence operative mortality by itself. Expeditious surgery with better graft materials, minimal clamp time, and blood conservation, along with better understanding of the pathophysiology of the disease, have made aortic surgery safer.

Arterial reconstruction surgery was developed based on normal anatomy. Although this is usually the easiest and best option, situations do occur that require circuitous revascularization procedures, such as axillofemoral or femoral-femoral bypass. These situations include graft infection, repeat surgery, and a hostile abdomen, such as one encounters with postradiation states, adhesions, sepsis, and malignancy. It should be emphasized that overall these procedures have lower long-term patency rates than anatomically correct procedures.

Approach

Abdominal aortic reconstruction can be performed through a transperitoneal or retroperitoneal exposure. In the first case, a thoracoabdominal midline incision is performed and the aorta is accessed through the peritoneum. This generous exposure is usually favored for complex aortic reconstruction or replacement. In the retroperitoneal approach, incision is made over the lateral border of the left rectus muscle, 2 cm below the umbilicus to the twelfth rib. This will allow the access to the aorta from the crux of the diaphragm to its bifurcation. The debate continues between advocates of transperitoneal versus the retroperitoneal approach. In more recent randomized studies, the retroperitoneal technique allowed a surgical exposure as good as the transperitoneal approach and was associated with less fluid shift, faster return of bowel function, lower pulmonary complications, shorter ICU stay, and lower overall hospital cost with an average savings of $4,000 to $5,000.[101] The retroperitoneal approach is considered by many to be more appropriate in cases of truncal obesity, serious COPD, hostile abdomen (e.g., previous surgeries), and juxtarenal aneurysm. However, the flank approach is not a panacea, as frequent chronic wound pain, incisional hernias, and abdominal bulges have been reported. Intraoperative blood loss during open AAA repair varies between 500 to several thousand milliliters of blood, depending on the size and complexity of the AAA. The postoperative course many times requires admission to the ICU for several days and hospital admission for 5 to 7 days. The postoperative recovery period after the open repair can be several months.

Clamp Level

Infrarenal aortic clamping carries the lowest risk for patients; supraceliac clamping carries the highest. Anesthesiologists should be aware that 10 to 20% of "infrarenal" aortic disease will actually involve the suprarenal portion of the aorta, necessitating suprarenal clamping. Ruptured aneurysms often must be controlled initially by supraceliac clamping. In these cases, great care must be taken so atheromatous material is not dislodged in the renal arteries during surgical manipulation and clamping.

Thoracic Aneurysm Repair

These operations are among the most challenging for anesthesiologists. Coincident CAD and COPD are common. Lung separation is required to facilitate surgical access to the aneurysm and to avoid an iatrogenic pulmonary contusion in the left lung. Lung separation may be provided with either double-lumen tubes or bronchial blockers. Bronchial blockers may be advantageous because they facilitate postoperative ventilation without the need to change a double-lumen tube at the end of surgery. Because of edema of the head and neck frequently occur after high cross-clamping (even with distal perfusion), reintubation may be difficult at the end of the procedure, and we have seen patients require emergent tracheostomy when an endotracheal tube could not be passed. Generous exposure of

the thoracic and abdominal aorta and its major branches can be obtained with a left thoracoabdominal incision and retroperitoneal dissection. The thoracoabdominal approach is favored for complex thoracoabdominal aortic replacement in the presence of stenotic or aneurysmal disease. The visceral branches are often excised from the parent aorta with a button of aortic wall. If the patient also has mesenteric occlusive disease, endarterectomy of these branch vessels is performed before they are attached as "buttons" to the graft at appropriate positions. If only mesenteric revascularization is to be performed and aortic replacement is not used, endarterectomy of any or all the major branches of the aorta may be performed with this exposure.

Aortomesenteric Revascularization

Chronic mesenteric ischemia occurs due to atherosclerosis or dissection. Surgical revascularization is indicated only in symptomatic disease. This will occur when two of the main mesenteric vessels become occluded. Elective surgery for asymptomatic occlusive disease is not justified because of the high risk of perioperative mortality, which can range from 7 to 18%. Cardiac events, hemorrhage, and bowel infarction are the most dreaded complications. In symptomatic cases, elective surgical reconstruction with or without concomitant aortic replacement remains the best choice because percutaneous transluminal angioplasty and stenting are associated with a significant incidence of recurrence and should be reserved to specific cases. Partial cross-clamping of the aorta is preferred if possible and may mitigate hemodynamic changes.

Acute mesenteric ischemia differs in its genesis. It is usually the result of an acute embolic event or trauma. The presence or absence of intestinal infarction plays a major role in the patient's overall prognosis in this setting. Endarterectomy of the mesenteric arteries may be performed through a transaortic access for isolated disease, or before the attachment of the vessels to the aortic graft at appropriate positions. If single-vessel endarterectomy is performed, it may be carried out for either the celiac axis or the superior mesenteric artery.

Aortorenal Revascularization

Renal artery revascularization can be performed by several surgical techniques. These techniques include endarterectomy, reimplantation, bypass, and ex vivo renal artery reconstruction. Extra-anatomical renal artery bypass may be the perfect choice in sick, debilitated patients who do not tolerate aortic clamping. Percutaneous approaches have largely replaced surgery for isolated renal artery revascularization.

Infrarenal Operations

Reconstruction of the infrarenal aorta is performed by exposing the relevant portion of the aorta and the iliac arteries. Heparin is commonly administered in a central line to reduce the risk of thromboembolic events before aortic clamping. Although it is generally recognized that distal ischemic complications are due to dislodgment of atheromatous material off the diseased aorta and that the systemic use of heparin in the absence of distal occlusive disease is unnecessary, many centers still religiously employ heparin before aortic clamping. Aortic repair is carried out by

interposition of a graft with an end-to-end anastomosis. Collagen impregnated polyester fibers (Dacron) grafts make the majority of implanted grafts. Dacron grafts appear to be associated with rare episodes of anaphylactic reactions, which may be related to the stabilizers used in their manufacture. Polytetrafluoroethylene (PTFE) grafts are less porous and are gaining more widespread use. Aortobiiliac, aortobifemoral, and aortoiliac/femoral grafts are used in most cases. Straight grafting constitutes approximately 30% of cases (see Fig. 32-12).

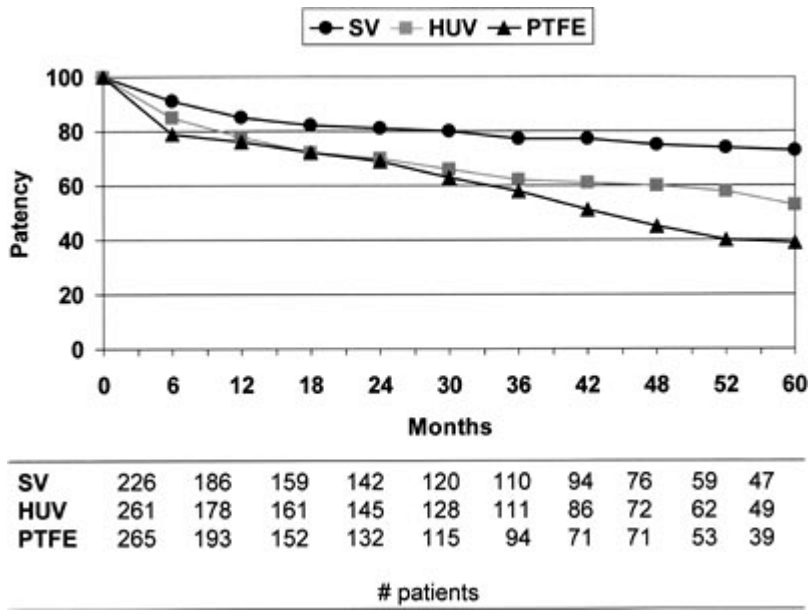

FIGURE 32-12. Superiority of saphenous vein bypass grafts for femorial-popliteal, above-knee bypass. Life table analysis for the patency of saphenous vein (SV), human umbilical vein (HUV), and polytetrafluoroethylene (PTFE). *N* represents the number of bypass grafts being observed for patency at that time. (Modified with permission from Johnson WC, Lee KK: A comparative evaluation of polytetrafluoroethylene, umbilical vein, and saphenous vein bypass grafts for femoral-popliteal above-knee revascularization: A prospective randomized Department of Veterans Affairs cooperative study. J Vasc Surg 32:268, 2000.)

Thoracic Aortic Surgery

Traditional surgery for thoracic aortic aneurysm continues to be associated with higher morbidity and mortality than infrarenal AAAs. The analysis of large databases suggests that population-based perioperative mortality is higher than that reported in series from selected institutions.[102] Mortality may approach 20%; risk factors include diabetes mellitus, cerebrovascular disease, and renal insufficiency. Median hospital charges ($64,000) are also high. Therefore, endovascular thoracoabdominal aortic aneurysm repair (endoTAAR) has been advocated as an alternative to open surgery with its stresses and frequent complications. Complications may be lower with endovascular approaches, with blood loss averaging only 450 cc and ICU stay 1 day in uncomplicated cases. Although paraplegia still may occur after endoTAAR, its incidence seems reduced compared with open abdominal aortic aneurysm repair (AAAR).[103] One approach to attempt to lessen paraplegia after endoTAAR has been to place a temporary stent under SSEP monitoring; if SSEP is unchanged, then the thinking goes, a permanent stent may be placed. However, motor evoked potential (MEP) monitoring would seem more appropriate for monitoring function of the anterior spinal column.[104] Drainage of CSF may be performed in attempt to rescue patients with paraplegia, as has been reported after open thoracoabdominal aortic aneurysm (TAAA) repair. Successful treatment of paraplegia with induced hypertension and CSF drainage following endoTAAR has been reported by several authors. The use of a single continuous subarachnoid catheter, first for local anesthetic injection to facilitate femoral or iliac arterial access in the groins, and later for prophylactic removal of CSF has been described during

endoTAAR.[105] Aspiration of CSF does not result in loss of the sensory or motor blockade if performed 15 to 20 minutes after local anesthetic instillation. Paraplegia has also been reported after endovascular repair of AAA (endoAAAR);

atheroembolization to the spinal cord appears to have been the underlying cause.

Endovascular Surgery of Aortic Aneurysms

There has been an explosion in the use of endovascular therapy of aortic and peripheral vascular disease. Approximately one-half of patients with AAA appear to be candidates for endoAAAR. Experienced centers have not noted a decrease in open AAA repair accompanying the growth of endoAAAR programs. This growth in endovascular repair has been occasioned by hopes of lower morbidity and mortality, shorter hospital stays and convalescence, and screening programs. In addition, manufacturers have driven the growth of endovascular procedures. Despite the shorter length of stay (LOS) after endoAAAR, the costs of the implant and radiologic procedures for follow-up actually may result in higher costs than open surgery; however, anesthesia costs are lower for endovascular repair. Vascular surgeons, cardiac surgeons, interventional radiologists, and/or cardiologists (with turf battles not uncommon) may perform procedures. When they are performed outside the main operating room (ours are performed by vascular surgeons in a specialized suite built in the ambulatory suite), appropriate equipment must be provided. This may include a blood refrigerator, the ability to obtain arterial blood gases and other labs, fluid warmers, forced-air warming, and so on. When faced with new technologies, clinicians caring for patients undergoing such procedures must exercise good judgment. That means being prepared for the rare disaster, especially during the "learning curves" of new practioners. It is also our experience that as technology is used for expanded indications and outside specialized centers and hospitals, complication rates may be higher.

In 1991, Juan Parodi, reported a small series of high-risk patients who underwent minimally invasive endoluminal repair of their aortic aneurysm through catheter delivery of grafts from remote cutdowns in the femoral arteries.[106] His initial report triggered significant interest within the vascular surgical community on the minimally invasive repair of AAAs. Initially, homemade devices were used to bridge the area of the aortic aneurysm with an expandable stent and Dacron-coated grafts. Commercially produced grafts initially started clinical trials in the United States in 1994. These grafts had hooks that were embedded with balloons into the aorta and iliac vessels, mimicking the effect of conventional surgical suturing. The body of the graft was unsupported, again consistent with the conventional open aortic aneurysm repair. Other graft designs quickly became available which involve the use of supported grafts with first expandable stainless steel stents and then the Nitinol stent that implemented the use the radial force of the stent to hold the stent graft in place. Generally, a neck below the renal arteries of approximately 15 mm is required for adequate fixation of the stent graft to the infrarenal aorta. The distal attachment of these grafts would either be to the distal abdominal aorta if an adequate neck was noted above the aortic bifurcation or, in most cases, into the common iliac vessels distal to the aneurysmal dilatation.

The technique for implantation of the endovascular aortic grafts generally requires bilateral common femoral artery or iliac artery cut down in the supine position. Arterial sheaths between 16F and 27F are then advanced into the iliac arteries and up into the AAA sac. This can be performed using local anesthetic, regional with epidural or general endotracheal anesthetic, as discussed later in this section. If the patient has small common femoral or external iliac arteries, the introducer sheath may be too large to safely advance to the abdominal aorta. In these cases, a retroperitoneal cutdown to the distal common iliac artery or the proximal external iliac artery can be performed to access a more suitable caliber vessel for graft implantation. This can be done with a small retroperitoneal incision, dissection down to the iliac vessels, and the suturing of a synthetic conduit onto the common iliac artery or the junction of the common and external iliac artery. The graft is then introduced through this conduit and deployed either into the common iliac artery or, in some cases, actually into the conduit itself. The conduit can then either be ligated or implanted into the femoral artery as an ileal femoral bypass graft. In isolated cases with extension

of the aneurysm to the bifurcation of the common iliac into the external and internal iliac artery, embolization of the internal iliac artery or reimplantation of the internal iliac artery into the external iliac artery by a retroperitoneal cutdown have been employed, as well as placement of the iliac stent graft into the external iliac artery.

Preimplantation calibrated angiography is required to identify the renal vessels, the potential for an accessory renal artery, the length from the renal arteries to the aortic bifurcation, and the distance from the aortic bifurcation to the bifurcation of the common iliac artery to the external and internal iliac artery. Dye loads may be considerable (100 to 250 cc); especially in diabetic patients, we may pretreat with N-acetyl cysteine, fluid loading (with bicarbonate added),[107] and/or mannitol in an attempt to reduce postoperative renal insufficiency. These measurements coupled with the diameter measurements allow the selection of the appropriate size endovascular stent graft. The device is then positioned just below the renal artery orifices and then fully deployed. Each type of stent graft has a unique method of deployment and specialized training is required for each device.

Major complications in endovascular stent grafting have included aneurysm rupture during the time of graft implantation, renal insufficiency secondary to contrast use, and the late complications include migration of the graft with changes in configuration of the aortic aneurysm sac, endoleak, or late AAA rupture.

Endoleak is defined as a persistent perfusion of the aneurysm sac through an attachment site leakage points (type 1 endoleak) or through lumbar or mesenteric artery branches (type 2 endoleak). A tear in the fabric of the aortic stent graft or a modular disconnect between the pieces of the endovascular aortic stent graft is classified as a type 3 endoleak. The significance of aortic endoleak is still uncertain. It has been shown that type 1 endoleaks have a high potential for aortic expansion or even rupture, and should be repaired with an additional stent, covered stent, or conversion to an open AAA repair. The significance of type 2 endoleak is uncertain. The general consensus is that in the presence of a type 2 endoleak the patient should be followed with serial CT scans and only intervened on if there are signs of progression or enlargement of the aortic aneurysm sac. Endoleaks may require subsequent repair in a significant percentage (up to 10%) of patients.

The potential for the need for retroperitoneal cutdown to the iliac arteries, or worst-case scenario, injury to the iliac vessels or the aortic aneurysm, necessitates that these procedures be performed in a setting that is suitable for urgent transfer to the operating facility or preferably within the operating room itself. This way, if either open aortic conversion or iliac repair is required, this can be accomplished with greatest efficiency and safety. One of the major U.S. Food and Drug Administration-approved device has shown that there is approximately a 0.8% risk of rupture in the perioperative or long-term postoperative period after aortic stent graft placement. Many of these cases are actually due to lack of follow-up and failure to intervene on changes of the aortic morphology that could have prevented AAA rupture.

Follow-up is critical in the patients undergoing endovascular aortic stent grafting. Generally, patients are followed with plain radiograph and serial CT scans at 1, 3, 6, 12, 18, and

24 months, and then yearly thereafter. This differs from the standard open aneurysm repair in which the patient may receive an ultrasound or no follow-up except for physical examination. The follow-up CT scan after endovascular aortic stent grafts is to detect signs of endoleak, aneurysmal sac enlargement, or graft migration. Graft migration can occur due to a technical problem with the stent graft itself or due to changes in the configuration of the aortic aneurysm as it decreases in size from lack of perfusion and then kinking or migration of the graft. Many late complications of aortic stent grafting can be repaired through endovascular techniques of embolization or addition of additional cuffs without necessitating open surgical conversion.

There are still many questions regarding the long-term patency and durability of endovascular aortic stent grafts,[108] but the preliminary data appear good. Changes in the design and configuration of aortic stent graft have shown significant improvement in the patency and ability to implant these devices into the abdominal aorta. As the grafts continue to progress into their

third and fourth generation, the authors are optimistic that this will continue to improve and become a safe and effective way of managing AAAs. A more recent randomized trial has confirmed what several large registries have shown: reduced combined mortality and severe complications, and reduced hospital length of stay with endovascular repair compared with traditional repair.[109]

Goals of Anesthesia for Endovascular Aneurysm Repair

As in open AAAR, the primary goal of perioperative management is to preserve organ function. This is particularly important, because endoAAAR patients may be sicker and have more end-organ disease than candidates for open repair. Even when performed under MAC, preparation for endoAAAR must anticipate significant blood loss and fluid requirements. In a series of 47 patients (from one of the most experienced centers in the United States), the average blood loss was 623 mL (range, 100 to 2,500 mL), and fluid requirements averaged 2,491 mL.[110] Therefore, the choice of a local or regional anesthetic may still require placement of invasive monitors in patients.

At the time of deployment, mild hypotension and lack of patient movement are important goals. In early series, induction of VF or atrioventricular block with adenosine was used to induce brief asystole. These are more feasible under general anesthesia (GA) compared with regional anesthesia (RA). However, more recently, mild hypotension is used, which can be induced with infusions of vasodilators such as nitroglycerin. In the patient receiving RA or monitored anesthesia MAC, brief induction of GA with a bolus of propofol and mask ventilation may accomplish these goals.

Managing Intraoperative Complications During Endovascular Thoracoabdominal Aortic Aneurysm Repair

EndoAAAR, although likely representing a significance advance, is not benign. Rupture may rarely occur during endoAAAR. In a case report, intraoperative monitored rupture, despite rapid inflation of a proximal balloon to effectively "cross-clamp" the aorta, was associated with hemorrhagic shock typical of ruptures occurring outside the hospital. In this patient, endotracheal intubation was performed after rupture because a regional anesthetic technique was originally chosen.[111] However, we are more likely to provide GA for patients with complicated anatomy (especially iliac arteries), where conversion might be more likely.

Misdeployment may result in immediate onset of visceral ischemia. Alternatively, atheroembolization may occur with resultant ischemic complications. Blood loss may be considerable in patients with severely diseased and tortuous femoral or iliac arteries. Injury to these arteries may require repair. A proactive approach in such a patient with severe iliac disease was described in a case report. In this report, an open iliac artery reconstruction (under RA) was initially performed, followed by stent deployment via the reconstructed artery. Other workers suggested arterial access via the brachial or carotid arteries.

Mortality in patients with ruptured AAA remains high after traditional surgery. More recently, reports suggest significantly better results with a novel, multifaceted approach, which includes endovascular repair with a proprietary device, balloon inflation above the site of rupture to mimic "cross-clamping," hypotensive hemostasis, limited fluid resuscitation, and monitored anesthesia care. Using this approach, 23 of 25 patients with ruptured aortoiliac aneurysms survived. Median hospital stay was 6 days, and the preoperative symptoms resolved in all patients. This approach tends to contradict traditional notions of the importance of aggressive volume resuscitation and normalization of blood pressure. However, this approach has been adapted from one shown successful in surgical patients suffering penetrating trauma.[112] The endovascular approach to patients with ruptured AAAs may be limited because of the need for time-consuming measurement (angiography) and the expense of keeping multiple-size grafts in inventory. Future studies will define the role of endovascular therapy in emergent and rupture situations.

Complications of Anesthetics

Various anesthetic techniques have been used for endoAAAR, including general, epidural, combined epidural/spinal, spinal, and continuous spinal. Because most endoAAAR are associated

with less hemodynamic stress, endocrine stress, cytokine release, decline in respiratory function, and prolonged convalescence compared with open repair, regional anesthesia might have less incremental benefit in endoAAAR. Of course, controversy persists even for open AAAR as to whether RA improves outcome.[113]

EndoAAAR is often advocated for patients with chonic obstructive pulmonary disease (COPD). Respiratory function and outcome is better after endoAAAR under GA compared with openAAA repair under GA. Although RA may or may not offer pulmonary benefits for patients undergoing open repair, it is not so clearly the case in endoAAAR. This may be because the hemodynamic[114] and endocrine metabolic response[115] to endoAAAR is far less than for open repair. Therefore, the potential amount of stress reduction produced by using RA for endoAAAR is likely to be much less than for openAAAR.

Local/sedation techniques have been be used successfully for endoAAAR and endoTAAR. It has been suggested that the use of epidural anesthesia, as opposed to local/sedation, may prolong stay and costs after ambulatory endovascular repair, perhaps because of greater administration of intravenous fluids in the epidural group.[116] However, interpretation of this and other retrospective studies may be confounded by the likely selection of epidural techniques for more extensive, complicated procedures and those earlier in the "learning curve." Similarly, the validity of retrospective studies of outcome after endoAAAR under GA versus RA techniques may be limited.

In traditional femoral-distal surgery, failure rates as high as 10% for spinal and 15% for epidural anesthesia have been reported.[117] Failure was defined as the need to convert to general aesthesia. In our experience, most conversions from regional to general have occurred either during long procedures when patients became restless or because of complications of
