wounds may be managed safely with an initial CT scan.[182] Patients with a negative study are observed, whereas those with positive findings undergo exploratory surgery. Equivocal CT results are followed by a laparoscopy and, if this is positive, by laparotomy.

TABLE 48-7 Diagnostic Tools in Abdominal Trauma: Strengths and Weaknesses

·DIAGNOSTIC TOOL	·STRENGTH	·WEAKNESS
Physical examination	Expeditious, safe, and inexpensive; potential for serial examination	Diagnosis of specific injury (e.g., diaphragm)
Diagnostic peritoneal lavage	Expeditious, safe, and inexpensive	Diagnosis of diaphragmatic injury, hollow viscus injury, retroperitoneal injury; can be oversensitive and nonspecific
Computed tomography	Evaluation of peritoneum and retroperitoneum	Diagnosis of diaphragmatic injury, hollow viscus injury

	Staging of solid organ injury	Expensive; controversial need for contrast
Ultrasonography	Expeditious, safe, and inexpensive; accurate for free peritoneal fluid	Diagnosis of diphragmatic injury, hollow viscus injury
	Potential for serial examinations	Less accurate in the presence of large retroperitoneal hematomas
Laparoscopy	Diagnosis of peritoneal penetration, diaphragmatic injury	Diagnosis of hollow viscus injury, retroperitoneal injury
	Evaluation of bleeding or solid organ injury	Expensive
	Potential for therapy	
Video-assisted thoracic surgery	Evaluation of lung, diaphragm, mediastinum, chest wall, and pericardium; potential for treatment	Requires operating room; expensive

Patients with blunt abdominal trauma are also evaluated by CT scan unless they are hemodynamically unstable and there are overt abdominal signs such as tenderness, guarding, and gross distention. Absence of abdominal distention, however, does not rule out intra-abdominal bleeding. At least 1 L of blood can accumulate before the smallest change in girth is apparent, and the diaphragm can also move cephalad, allowing further significant blood loss without any change in abdominal circumference.

In hemodynamically stable patients, there are two major diagnostic algorithms: focused approach with sonography for trauma (FAST; Fig. 48-4) and the conventional approach, without ultrasonography (Fig. 48-5). The diagnostic accuracy of these algorithms is similar, but FAST requires one-third of the time and is 3.5 times less expensive than the conventional approach.[183] Screening with abdominal ultrasonography is performed by placing a 3.0 to 5.0 MHz probe on four distinct areas of the abdomen: subxiphoid, to detect pericardial blood; right upper quadrant, for blood in the hepatorenal pouch; left upper quadrant, to detect perisplenic blood; and just above the pubic symphysis, for blood in the rectovesical pouch. FAST is accurate for detection of hemoperitoneum[183,184] and can also identify solid organ injuries, although experience with these is limited. It cannot reliably detect trauma to the intestines unless it is associated with bleeding.[184] Fortunately, isolated intestinal injuries are uncommon after blunt trauma. Depending on the results of FAST, patients are managed with observation, repeat FAST, DPL, abdominal CT, laparoscopy, or laparotomy.[183] Patients managed with the conventional algorithm are evaluated by

CT if they are stable, and DPL if they are hemodynamically or neurologically unstable. Depending on the results of these studies, they are observed or undergo surgery.[183]

J Trauma 47:632, 1999.)

Laparoscopy is an excellent screening tool in abdominal trauma patients. An analysis showed that it avoided laparotomy in 63% of patients and missed only 1% of the injuries.[181] It is also possible to repair diaphragmatic, bladder, and solid organ injuries with this technique. The complication rate of laparoscopy in trauma is approximately 1%, including pneumothorax, small bowel injury, intra-abdominal vascular injury, and extraperitoneal CO_2 insufflation.[181]

Fractures of the Pelvis

Pelvic fractures result in major hemorrhage in 25% and exsanguination in 1% of patients.[185] In most of these fractures,

bleeding results from disruption of veins by fragments of bone. Pelvic retroperitoneal bleeding is self-limited in most patients with venous injuries, except those with open fractures, in whom the tamponading effect does not occur. Approximately 18 to 20% of patients have arterial bleeding, which does not stop. The retroperitoneal space in these patients may serve as a distensible container, expanding superiorly and anteriorly toward the abdominal wall and totally obliterating the lower part of the abdominal cavity. Thus, DPL, as in pregnant trauma patients, should be performed above the umbilicus. Large retroperitoneal hematomas may also cause respiratory difficulty because of pressure on the diaphragm.

Following external pelvic fixation, which decreases the mobility of the bone fragments and thus helps control blood loss, angiography can indicate the type and location of bleeding. Arterial bleeding is treated with embolization; the angiography suite should be prepared in advance not only for anesthesia, but also for invasive monitoring and resuscitation. Pelvic fractures may also injure the bladder and the urethra. Thus, an urethrogram should be performed before insertion of a urinary catheter.

Extremity Injuries

Surgical repair of extremity fractures, whether they are open or closed, should be performed as soon as possible. Delayed fracture repair is associated with an increased risk of deep vein thrombosis (DVT), pneumonia, sepsis, and the pulmonary and cerebral complications of fat embolism. In open fractures, an additional important concern is infection. Wounds left unrepaired for more than 6 hours are likely to become septic.

Associated vascular trauma must be recognized early. Most vascular injuries exhibit at least some part of the classic syndrome of *pain*, *pulselessness*, *pallor*, *paresthesias*, and *paresis*. The definitive diagnosis is made with arteriography; in selected patients, a duplex ultrasound study may be used as a screening test.

Compartment syndrome, which is characterized by severe pain in the affected extremity, should be recognized early so emergency fasciotomy can be effective in preventing irreversible muscle and nerve damage. In unconscious patients, swelling and tenseness of the extremity indicate the presence of this complication. The definitive diagnosis is made by measuring compartment pressures, using a transducer attached to a fluid-filled extension tube and a needle inserted into the various compartments of the extremity. A pressure exceeding 40 cm H_2O is an indication for immediate surgery. Caution must be exercised when using epidural or nerve block analgesia for perioperative pain relief in the presence of extremity fractures. Absence of pain could delay the diagnosis of compartment syndrome.

Burns

Determination of the size and depth of a burn sets the guidelines for resuscitation, as well as the indications for surgical intervention.[186] A partial-thickness burn is red, blanches to touch, and is sensitive to painful stimuli and heat. Superficial partial-thickness (first-degree) burns involve the epidermis and upper dermis, and heal spontaneously. Deep partial-thickness (second-degree) burns involve the deep dermis, and require excision and grafting to ensure rapid return of function. A full-thickness (third-degree) burn does not blanch even with deep pressure and is

insensate. Complete destruction of the dermis requires wound excision and grafting to prevent wound infection that may lead to local sepsis and systemic inflammation. Fourth-degree burns involve muscle, fascia, and bone, necessitating complete excision and leaving the patient with limited function. The size of the burned area as a fraction of the total body surface area (TBSA) is estimated by the "rule of nines." In an adult, the head contributes to 9%; the upper extremities, 18%; the trunk, 36%; and the lower extremities, 36% of the TBSA. These proportions are somewhat different in children, depending on the age and size. To estimate the size of a burn, the palmar surface of a child (excluding the digits) represents about 0.5% of the TBSA over a wide range of ages.

12 Information about the mechanism of injury facilitates the diagnosis of associated clinical abnormalities. For example, thermal trauma caused by flames in a closed space is likely to be associated with airway damage. Burns resulting from motor vehicle, airplane, or industrial accidents may be complicated by other traumatic injuries. Finally, burns caused by electrocution may show little external evidence but may be associated with severe fractures, hematomas, visceral injury, and skeletal and cardiac muscle injury resulting in pain, myoglobinuria, and dysrhythmias or other ECG abnormalities.

Full-thickness burns involving >10% of the TBSA; partial-thickness burns covering >25% of TBSA in adults and over 20% at the extremes of age; burns involving the face, hands, feet, or perineum; inhalation, chemical, and electrical burns; and burns in patients with severe preexisting medical disorders are considered to be major burns.[186] A severe burn is a systemic disease that stimulates the release of mediators such as interleukins, tumor necrosis factor, and neopterins, locally—producing wound edema—and into the circulation, resulting in immune suppression, hypermetabolism, protein catabolism, sepsis, and multisystem organ failure.[186]

Airway Complications

Respiratory distress in the initial phase of a burn is usually caused by airway injury involving the pharynx or the trachea. Singed facial hair, facial burns, dysphonia or hoarseness, cough, soot in the mouth or nose, and swallowing difficulties in patients without respiratory distress should increase the suspicion of upper (frequent) and lower (occasional) airway injury. In the upper airway, glottic and periglottic edema and copious, thick secretions may produce respiratory obstruction. This may be aggravated by fluid resuscitation even in the absence of

significant inhalation injury.[187] In lower airway burns, decreased surfactant and mucociliary function, mucosal necrosis and ulceration, edema, tissue sloughing, and secretions produce bronchial obstruction, air trapping, and bronchopneumonia. The development of parenchymal lung injury takes approximately 1 to 5 days and presents with the clinical picture of adult respiratory distress syndrome. Pneumonia and pulmonary embolism (PE) are late complications that occur 5 or more days after burns. The presence of a lung injury markedly increases the mortality rate from thermal injuries.[188]

Administration of the highest possible concentration of O_2 by facemask is the first priority in moderately to severely burned patients with a patent airway. In patients with massive burns, stridor, respiratory distress, hypoxemia, hypercarbia, loss of consciousness, or altered mentation, immediate tracheal intubation is indicated.[189] The intubation technique selected depends on the operator's experience, the age of the patient, and the extent of airway compromise. In adults, awake fiberoptic intubation under adequate topical anesthesia is probably the safest approach, but other techniques (WuScope, intubating LMA, retrograde intubation, or transtracheal jet ventilation) may be used. In most pediatric patients, awake intubation is not possible. An inhalation induction with O_2 and sevoflurane, followed by intubation using a fiberoptic bronchoscope or conventional laryngoscope is appropriate.[186] A surgical airway entails a significant risk of pulmonary sepsis, late upper airway sequelae, and death in burned patients; it should be reserved for those whose airway management cannot be handled in any other way.[186,190] Immediately after securing the airway, ventilation with low levels of PEEP will prevent the pulmonary edema that may develop secondary to loss of laryngeal auto-PEEP in patients with significant airway obstruction before intubation.[191] Airway humidification, bronchial toilet, and

bronchodilators if needed for bronchospasm are also indicated.

The pediatric airway is particularly challenging because it may be occluded by minimal amounts of swelling due to its small diameter. Prophylactic intubation may therefore be required in children who are suspected of having an inhalation injury, even though they are not yet in respiratory distress. Prophylactic tracheal intubation may also be indicated in adults when the resources for careful follow-up are insufficient.[191] Information obtained from radiologic, ABG, and endoscopic examinations and pulmonary function testing may be useful to predict which patient will need tracheal intubation and possibly decrease the risks of airway manipulation.[189]

Fiberoptic laryngoscopy is easy to perform and can provide direct information about the glottic and periglottic structures. It may avoid tracheal intubation in patients who would otherwise be considered candidates for this procedure.[189] Fiberoptic bronchoscopy has the additional advantage of providing information about the lower airway, although it is more uncomfortable for the patient and requires topical anesthesia of the tracheobronchial tree.[192] These studies should be performed every 3 to 4 hours for the first 12 hours after injury. In cooperative patients, pulmonary function testing may aid in the evaluation of airway obstruction. A saw-toothed or flattened inspiratory flow and an extrathoracic obstruction pattern on the flow/volume loop suggest upper airway obstruction. Decreased peak expiratory flow, forced vital capacity and pulmonary compliance, and increased airway resistance suggest lower airway injury.

The chest radiograph, ABGs, and pulmonary function tests are usually normal in the immediate postburn period, even in patients with pulmonary complications. However, these tests should be performed at this time for later comparison. As expected, the more extensive the pulmonary edema, the more severe are the functional abnormalities of the lungs. The treatment of smoke inhalation in burns involves ventilatory management, intensive care, and treatment of carbon monoxide (CO) and cyanide (CN^-) toxicity.

Ventilation and Intensive Care

Hypoxemia may persist despite tracheal intubation, ventilation with PEEP, bronchodilators, and suction of airway secretions. In the first 36 hours, this is caused by acute pulmonary edema. From the second to the fifth day, hypoxia may result from atelectasis, bronchopneumonia, and airway edema following mucosal necrosis and sloughing, viscous secretions, and distal airway obstruction. Later there may be nosocomial pneumonia, hypermetabolism-induced respiratory failure, and acute respiratory distress syndrome. Treatment of these complications is individualized, using ventilatory maneuvers such as titrated PEEP, bronchoscopic lavage, antibiotics, chest physiotherapy, and other supportive measures. Lack of response to therapy because of severe ventilation–perfusion mismatching or shunt may be an indication for the use of nitric oxide, a potent, short-acting vasodilator, via the airway.[193] Prophylactic measures against DVT, gastric ulcers, and hypothermia should be used routinely.

Carbon Monoxide Toxicity

13 In burn victims, CO inhalation is almost always associated with smoke inhalation, which increases the morbidity and mortality compared with CO toxicity alone.[194] CO produces tissue hypoxia primarily by its 200-fold greater affinity for hemoglobin than oxygen and by its ability to shift the hemoglobin dissociation curve to the left, impairing O_2 unloading to the tissues. It also interferes with mitochondrial function, uncoupling oxidative phosphorylation and reducing ATP production, thus causing metabolic acidosis. Probably because of this effect on the mitochondria, CO can be a direct myocardial toxin, preventing survival in patients who suffer cardiac arrest, even though they have been resuscitated and treated with hyperbaric oxygen.[195]

A normal oxygen saturation on a pulse oximeter does not exclude the possibility of CO toxicity, although low arterial O_2 saturation measured by a cooximeter should raise the suspicion.[196] Similarly, the mixed venous oximeter catheters that are used for continuous in vivo measurement of

$\bar{v}$

O_2 overestimate oxyhemoglobin concentration in the presence of CO.[197] If CO toxicity is not

accompanied by a lung injury and thus by decreased PaO_2, tachypnea is absent; the carotid bodies are sensitive to the arterial O_2 tension and not to the O_2 content. The classic cherry-red color of the blood is also absent in most patients because it occurs only at carboxyhemoglobin (COHb) concentrations above 40%, and it may also be obscured by coexistent hypoxia and cyanosis.

The patient's inspired oxygen should be maintained at the highest possible concentration, even when there is no evidence of significant smoke-induced lung injury, until CO toxicity is ruled out by measurement of blood COHb. A high FIO_2 not only improves oxygenation, but also promotes elimination of CO; an FIO_2 of 1.0 decreases the blood half-life of COHb from the 4 hours seen in room air to 60 to 90 minutes, and to 20 to 30 minutes at 3 Atm in a hyperbaric chamber.[186]

The greater the blood concentrations of COHb, the more severe are the presenting symptoms (Table 48-8). Delayed neuropsychiatric disorders have been described in patients exposed to toxic levels of CO, and there is evidence to suggest that early hyperbaric O_2 treatment may prevent these symptoms.[186] The decision to institute this treatment should be based on comparing the risks of transport, decreased patient access, and delay in emergency treatment against the possible neurologic sequelae. Currently, hyperbaric O_2 is recommended for patients with COHb >30% at admission if the treatment of life-threatening problems—shock, neurologic injury, metabolic

acidosis, myocardial ischemia, infarction, or arrhythmias—will not be compromised.[198]

TABLE 48-8 Symptoms of Carbon Monoxide Toxicity as a Function of the Blood COHb Level

▪BLOOD COHb LEVEL (%)	▪SYMPTOMS
<15–20	Headache, dizziness, and occasional confusion
20–40	Nausea, vomiting, disorientation, and visual impairment
40–60	Agitation, combativeness, hallucinations, coma, and shock
>60	Death

COHb, carboxyhemoglobin.

Cyanide Toxicity

Another cause of tissue hypoxia in burned patients is CN^- toxicity. Cyanide or hydrocyanic acid is produced by incomplete combustion of synthetic materials, and may be inhaled or absorbed through mucous membranes. As in CO toxicity, the usual clinical presentation is unexplained metabolic acidosis. Nonspecific neurologic symptoms such as agitation, confusion, or coma are also common findings. Elevated plasma lactate levels in severe burns may result from hypovolemia, CO toxicity, or CN^- toxicity. However, lactic acidosis after smoke inhalation in a patient without a major burn suggests CN^- toxicity.[199] The definitive diagnosis can be made only by determination of the blood cyanide level, which is toxic above 0.2 mg/L and lethal at levels beyond 1 mg/L.[200] A spectrophotometric assay using methemoglobin as a colorimetric indicator provides a timely and reliable determination of blood CN^-.[201] The pulse oximetry reading will be accurate in the absence of CO toxicity and nitrate therapy-induced methemoglobinemia.[194]

Increased CN^- in the blood can cause generalized cardiovascular depression and cardiac rhythm disturbances, especially in patients with lactic acidosis. Fortunately, the half-life of CN^- is short (approximately 1 hour),[199] and rapid improvement of hemodynamics should be expected after rescue of the victim from the toxic environment. Immediate administration of O_2, which is required for all burn victims, may be lifesaving for this complication. Although there are specific therapies for CN^- toxicity (e.g., amyl nitrate, sodium nitrite, thiosulfate), given the short half-life of the ion, it is not clear whether these measures offer significant help to the patient whose blood CN^- usually decreases to low levels during transport from the field to the hospital.[202] Of course, if circumstances permit, hyperbaric O_2 treatment can be used for all the complications of thermal injury: CO and CN^- poisoning, smoke-induced lung damage, and cutaneous burns.[203]

Fluid Replacement

Immediately after a serious burn, microvascular permeability increases, causing the loss of a substantial amount of protein-rich fluid into the interstitial space. A major burn, a delay in initiation of resuscitation, or an inhalation injury increase the size of the leak.[186] Further, there seems to be a correlation between inhalation injury and cutaneous burns in the production of edema. Pulmonary edema increases cutaneous edema and vice versa.[194] If resuscitation is successful, edema formation stops within 18 to 24 hours.[194] This fluid flux is enhanced by increased intravascular hydrostatic and interstitial osmotic pressures and decreased interstitial hydrostatic pressure. In addition, cardiac contractility may decrease because of circulating mediators, a diminished response to catecholamines, decreased coronary blood flow, and increased systemic vascular resistance.[186] This may result in shock, whose origin is primarily hypovolemic and, to a much smaller extent, cardiogenic.[204] If the hypotension is treated appropriately with fluids, the hemodynamic picture is replaced within 24 to 48 hours by one resembling sepsis or septic shock, with increased cardiac output and diminished systemic vascular resistance caused by the release of inflammatory mediators.[186]

Fluid resuscitation is essential in the early care of the burned patient with an injury >15% of the TBSA. Smaller burns can be managed with replacement at 150% of the calculated maintenance rate and careful monitoring of fluid status. Intravascular volume should be restored with utmost care to prevent excessive edema formation in both damaged and intact tissues resulting from the generalized increase in capillary permeability caused by the injury. Edema from overaggressive resuscitation has many deleterious and potentially life-threatening effects. Mention has already been made of the facilitation of upper airway edema after rapid fluid infusion in large cutaneous burns with or without smoke inhalation.[187] Likewise, chest wall edema may develop after administration of large quantities of fluid, causing respiratory difficulties and necessitating excision of burned tissue from the anterior axillary line to improve breathing. Abdominal edema may also occur, and occasionally increase intra-abdominal pressure and impede venous return. This may be severe enough to produce abdominal compartment syndrome.[205] Edema formation may also increase the tissue pressure in the burned area, resulting in reduction of blood flow to distal sites. This, together with decreased tissue oxygen tension, may produce necrosis of damaged but viable cells, increasing the extent of injury and the risk of infection.

14 Crystalloid solutions are preferred for resuscitation during the first day following a burn injury; leakage of colloids during this phase may increase edema.[186] Nevertheless, crystalloid resuscitation, especially in children, may cause a rapid decline in plasma protein concentration and necessitate administration of 5% albumin in LR[206] after the first day following a >30% burn and/or significant inhalation injury, when the capillary leak stops.[207] It is believed that this will moderate the tendency to edema formation associated with the administration of large amounts of isotonic (0.9% saline or LR) solutions, even though a 6% increase in the risk of mortality has been reported with the use of colloids in patients who are critically injured and burned.[208,209] Alternatively, hypertonic saline solutions draw intracellular water into the bloodstream and thus decrease the fluid volume needed to maintain perfusion, maintain extracellular volume, and limit the severity of edema in patients with burns occupying >50% of the TBSA, circumferential extremity burns, or inhalational injury.[186] Unfortunately, hypertonic solutions cause hypernatremia and intracellular water depletion; patients and experimental animals receiving these fluids for

burn therapy often did not show an overall fluid sparing effect, and had an unacceptably high incidence of renal failure and death compared with those receiving LR.[210,211]

Of the many resuscitation formulas available, the Parkland (Baxter) and modified Brooke formulas are tailored to the clinical condition of the patient and are accepted in most centers[207] (Table 48-9). The addition of glucose is not necessary except in children, especially those weighing <20 kg. Albumin 5% may be administered after the first day following injury at a rate of 0.3, 0.4, or 0.5 mL/kg per %burn per 24 hours for burns of 30 to 50%, 50 to 70%, or 70 to 100% of TBSA, respectively. These formulas are guidelines only, and none can be expected to provide adequate restoration of intravascular volume in all burn victims, especially small children and patients with inhalation injuries. Therefore, administration of fluids during the

initial phase should be titrated to specific goals described in Table 48-9; and, if a pulmonary artery catheter is placed, acceptable cardiac output, filling pressures, and a mixed venous oxygen tension ($P_{\bar{v}}O_2$) of 35 to 40 mm Hg. Careful monitoring of the hematocrit may also guide fluid management. An increase in hematocrit during the first day suggests inadequate fluid resuscitation because hemolysis and sequestration are actually expected to cause a decrease in this parameter. Acute anemia, as may occur during excision and grafting of burns, is usually well tolerated. Blood replacement is usually not initiated until the hematocrit is below 15 to 20% in healthy patients requiring limited operations, approximately 25% in those who are healthy but need extensive procedures, and 30% or more when there is a history of preexisting cardiovascular disease.[212]

TABLE 48-9 Guidelines for Initial Fluid Resuscitation After Thermal Injury

Adults and children >20 kg
Parkland formula[a]
4.0 mL crystalloid/kg/% burn/first 24 hr
Modified Brooke formula[a]
2.0 mL lactated Ringer's/kg per % burn per first 24 hr
Children <20 kg
Crystalloid 2–3 mL/kg per % burn per 24 hr[a]
Crystalloid with 5% dextrose at maintenance rate
100 mL/kg for the first 10 kg and 50 mL/kg for the next 10 kg for 24 hr
Clinical end points of burn resuscitation
Urine output: 0.5–1 mL
Pulse: 80–140 per min (age dependent)
Systolic BP: 60 mm Hg (infants); children 70–90 plus 2x age in years mm Hg; adults MAP > 60 mm Hg
Base deficit: <2
BP, blood pressure; MAP, mean arterial pressure.
[a]50% of calculated volume is given during the first 8 hr, 25% is given during the second 8 hr, and the remaining 25% is given during the third 8 hr.

Although there is evidence that the standard clinical end points of resuscitation often provide inadequate information in major burns and that better information may be obtained from pulmonary artery catheter data,[213,214] there are also practical and methodological problems associated with the latter, especially the risks of infectious complications and the requirement for additional vascular access.

In Europe, the transpulmonary thermodilution technique, which relies on detecting cold fluid dilution in the descending aorta rather than in the pulmonary artery, has been used successfully to determine cardiac output.[215] This technique is less invasive because it uses the arterial and central venous (not pulmonary artery) catheters that are routinely inserted in major burn management. In addition, the double-indicator dilution technique can monitor intrathoracic blood volume—a better indicator of circulatory filling and volume status than central venous or PCWPs—and extravascular lung water.[216] It involves placement of a 5F femoral artery catheter equipped with fiberoptics and a thermostat tip advanced into the descending thoracic aorta, and injection via central venous catheter of 0.3 mg/kg indocyanine green mixed in 10 mL iced glucose, 5%. The resulting dilution curve is subjected to computerized analysis. Comparative studies suggest that this technique is a reliable preload indicator for volume resuscitation of major burn patients. The fluid volume administered with its guidance consistently exceeds that calculated by traditional burn formulas.[215,216]

When in rare instances fluid resuscitation fails despite administration of crystalloids in excess of 6 mL/kg per %TBSA, and invasive or semi-invasive monitoring suggests adequate intravascular volume, vasopressor and/or inotropic agents may be indicated. Dopamine in small doses (5µg/kg/min) and/or beta-adrenergic agents may improve urine output without further need for fluids.[207] Electrolyte abnormalities may occur after the first day for several reasons but are primarily a result of topical agents applied to control pain, decrease vapor loss, prevent desiccation, and slow bacterial growth.[207] Nonaqueous topicals (silver sulfadiazine), if administered without providing free water such as 5% dextrose, may result in hypernatremia and its central nervous system consequences, including intracranial bleeding. In contrast, aqueous topical agents such as 5% silver nitrate solution may cause hyponatremia and its consequences of cerebral edema and seizure secondary to electrolyte leaching. Central pontine demyelination may occur if the hyponatremia is corrected rapidly with salt solutions. Serum ionized calcium and magnesium should also be monitored.

OPERATIVE MANAGEMENT

15 Overall, nearly 25% of trauma patients present with preexisting conditions such as cirrhosis; cardiovascular, pulmonary, and renal diseases; coagulation disorders; diabetes; and alcohol or drug abuse that may increase trauma-related morbidity and mortality, and require additional care.[217] Premedication is rarely indicated, especially in those who are hypovolemic, head injured, or intoxicated. If needed, small doses of opioid (morphine, 1 to 2 mg; fentanyl, 25 to 50 µg) or sedative (midazolam, 0.5 to 1.0 mg) may be administered with close monitoring of vital signs. Regional analgesia may be provided for stable patients with skeletal injuries awaiting surgery. Femoral nerve block, for example, provides excellent analgesia for femoral shaft fractures. Evaluation of the multiple trauma patient emergently transported to the OR involves reviewing the vital signs, oxygenation, and preoperative fluid replacement, and confirmation of correct position and patency of a previously inserted endotracheal tube.

Monitoring

Table 48-10 lists monitoring techniques currently used in the OR and indicates their relative importance in the intraoperative care of the trauma patient. Clearly, valuable time can be lost if the placement of invasive monitors takes precedence over resuscitation.

TABLE 48-10 Techniques to Monitor Physiologic Parameters and their Importance in Intraoperative Management of the Trauma Patient

·PHYSIOLOGIC PARAMETER	·DEGREE OF IMPORTANCE	·MONITORING EQUIPMENT	·SPECIFIC INTRAOPERATIVE USES IN THE TRAUMA PATIENT

Cardiac rate, rhythm, and myocardial ischemia	Essential	Five-lead electrocardiogram system with oscilloscope, digital display, recorder, and printer (three-lead system can be used)	Routine
Arterial blood pressure	Essential	Indirect Blood pressure cuff Doppler system Programmable oscillometric system Direct Pressure transducer with calibrated oscilloscope and recorder	Routine
Central venous pressure	Useful	Pressure transducer with calibrated oscilloscope and recorder	Hypovolemia Pericardial tamponade, myocardial contusion Air embolism Pulmonary contusion
Pulmonary artery pressures	Essential in multiple trauma	Pressure transducer with calibrated oscilloscope and recorder	Blunt chest injury (pericardial tamponade, myocardial contusion) Adult respiratory distress syndrome Differentiation of low-pressure and high-pressure pulmonary edema; traumatic (cardiac contusion) or preexisting heart failure
Cardiac output	Useful in some patients	Thermodilution cardiac output computer with recorder and printer	Same as pulmonary artery pressure measurement
Cardiac wall motion abnormalities, myocardial	Useful in some patients	Transesophageal echocardiograph	Cardic contusion Coronary artery injuries? Septal injuries

ischemia, flow through valves or septal defects			Air embolism Thoracic aortic rupture Shock
Ventilation	Essential	End-tidal CO_2 monitor with waveform display and recording	Routine Head injury Air embolism
Arterial oxygenation	Essential	Airway pressure Pulse oximeter Arterial blood gases (intermittent or continuous)	Routine
Tissue oxygenation	Useful	Pulmonary artery catheter ($P\bar{v}O_2$) Arterial/venous lactate analyzer Base deficit $SLPCO_2$	Low perfusion states
Renal function	Essential	Foley catheter and graduated container	In all major trauma patients
Temperature	Essential	Esophageal or rectal probe	Routine
Neuromuscular function	Essential	Peripheral nerve stimulator Electromyograph	Head injury Open globe Sealed major vessel injury
Neurologic function	Useful	Intracranial pressure measurement with bolt, catheter, or fiberoptic sensor Jugular bulb O_2 saturation	Head injury
Depth of anesthesia		Bispectral index monitor	Intraoperative awareness
Blood coagulation	Useful	Prothrombin time/partial thromboplastin	Shock Massive transfusion Preexisting

		time/platelet count/fibrinogen, tube test, thrombelastograph	coagulation abnormalities

Hemodynamic Monitoring

Direct intra-arterial pressure monitoring, which permits beat-to-beat data acquisition and sampling for measurement of blood gases, should be in place before surgery. An ultrasound guided technique or a surgical cut-down may be necessary to facilitate access. The radial artery is the vessel of choice in abdominal or chest trauma in which the aorta may be cross-clamped, making a femoral or dorsalis pedis cannula nonfunctional. The right radial artery is preferred in cases of chest trauma in which cross-clamping of the descending aorta might result in occlusion of the left subclavian artery. In mechanically ventilated patients, the magnitude of systolic pressure variation (the difference between the maximum and minimum systolic pressure over the respiratory cycle) and its Δdown component (the difference between systolic pressure at end expiration and the lowest value during the respiratory cycle) can provide reliable information about the intravascular volume status (Fig. 48-6).

A systolic pressure variation >5 mm Hg and a Δdown >2 mm Hg suggest hypovolemia.[218] Delaying emergent surgery to place a central venous line is rarely indicated unless a large-bore catheter is needed for volume resuscitation. However, if the patient is elderly, there is a likelihood of myocardial damage, or if there is multiple organ damage with requirement for prolonged surgery and massive fluid replacement, early placement of a CVP or pulmonary artery catheter is indicated before the development of coagulopathy renders it hazardous.

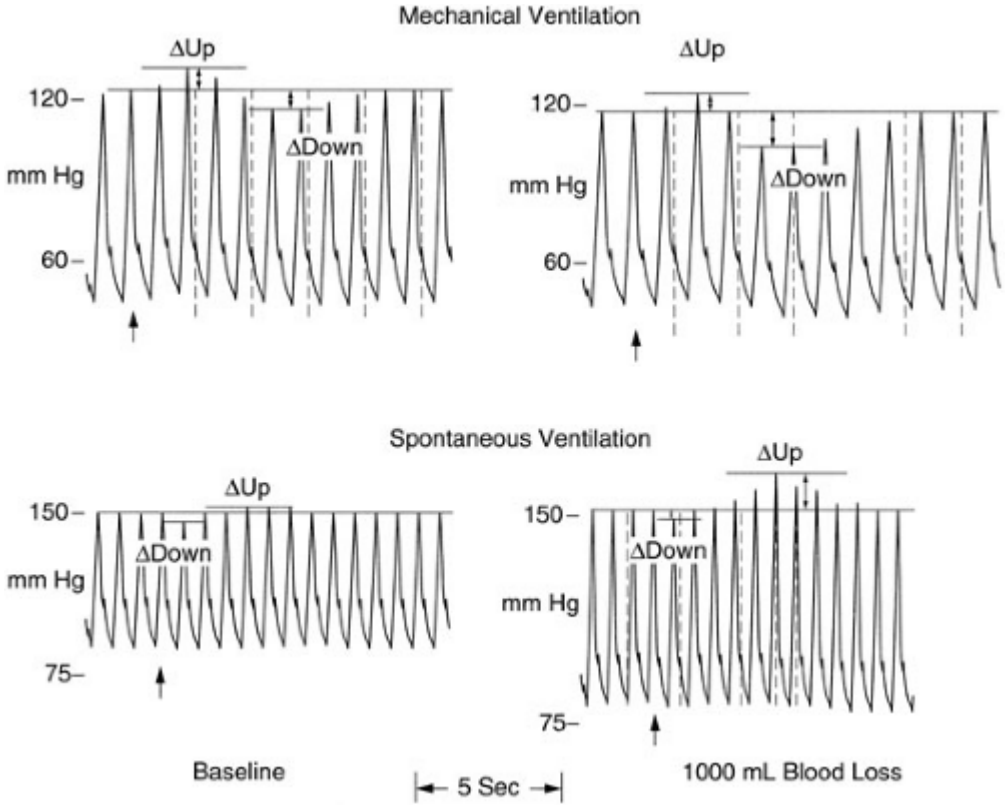

FIGURE 48-6. Arterial pressure records of a mechanically ventilated patient before (*left*) and after (*right*) 1,000 mL blood loss. Note the increase in systolic pressure variation and Δdown component following hemorrhage. Decrease in blood pressure occurs during exhalation with mechanical ventilation and inspiration in spontaneously breathing subjects (*upgoing arrow* defines inhalation). ΔUp is the difference between the end-expiratory systolic pressure and the maximum systolic pressure over a respiratory cycle. See text for definition of systolic pressure variation and Δdown component. (Reprinted with permission from Rooke GA, Schwid HA, Shapira Y: The effect of graded hemorrhage and intravascular volume replacement on systolic pressure variation in humans during mechanical and spontaneous ventilation. Anesth Analg 80:925, 1995.)

Volumetric assessment of preload appears to correlate better with cardiac index than the CVP or PCWP.[219,220] A pulmonary artery catheter equipped with a rapid-response thermistor and intracardiac electrodes is capable of measuring right ventricular (RV) cardiac output and ejection fraction, and calculating RV end-diastolic volume index. The latter appears to correlate with cardiac output better than CVP and PCWP in trauma patients. An RV end-diastolic volume index >130 mL/m^2 is considered optimal for organ perfusion.[219,220]

TEE provides valuable diagnostic information in blunt cardiac injury, cardiac septal or valvular damage, coronary artery injury, pericardial tamponade, and aortic rupture. It also permits assessment of cardiac function, including right and left ventricular volume, ejection fraction, wall motion abnormalities, pulmonary hypertension, and cardiac output, and detects acute ischemia more accurately than either ECG or pulmonary artery pressure monitoring. Monitoring left ventricular volume alone can provide information about the adequacy of the intravascular volume. This technique also allows visualization of fat and air entry into the right heart, or the left heart through a patent foramen ovale, during internal fixation of lower-extremity fractures.[221] In the trauma setting, it is possible that the TEE probe may be introduced into an unrecognized esophageal tear because the insidious nature of esophageal injury makes diagnosis difficult during the first 24 hours after trauma.

Urine Output

Urine output is routinely monitored as an indicator of organ perfusion, hemolysis, skeletal muscle destruction, and urinary tract integrity after trauma. Its reliability for perfusion is decreased by prolonged shock prior to surgery and osmotic diuresis caused by administration of mannitol or radiopaque dye. Dark, cola-colored urine in the trauma patient suggests either hemoglobinuria resulting from incompatible blood transfusion, or myoglobinuria caused by massive skeletal muscle destruction after blunt or electrical trauma. Although the definitive diagnosis is made by serum electrophoresis, rapid differential diagnosis can be made by centrifugation of a blood specimen. Pink-stained serum suggests hemoglobinuria, whereas unstained serum indicates myoglobinuria. Both of these conditions may result in acute renal failure. Prevention involves mannitol diuresis and, in myoglobinuria, alkalinization of the urine with sodium bicarbonate to pH levels above 5.6. Red-colored urine usually is caused by hematuria, which, in the traumatized patient, suggests urinary tract injury. It should be investigated with intravenous pyelography.

Organ Perfusion and Oxygen Utilization

As discussed previously, unrecognized hypoperfusion may lead to splanchnic ischemia with resulting acidosis in the intestinal wall, permitting the passage of luminal microorganisms into the circulation and release of inflammatory mediators, causing sepsis and multiorgan failure.[54,55,56,57] Oxygen transport variables, base deficit, blood lactate level, gastric intramucosal pH (pHi), and $SLPCO_2$ are considered acceptable markers of organ hypoperfusion in the *apparently* resuscitated patient and may be used to set the optimal end points of resuscitation.[57] Gastric intramucosal pH monitoring is too cumbersome to use during surgery and in the immediate postoperative period. Monitoring of base deficit, blood lactate level, and $SLPCO_2$ has already been discussed in the Management of Shock section.

Oxygen transport variables consist of oxygen delivery (DO_2), O_2 consumption (VO_2), and O_2 extraction ratio. A DO_2 index (DO_2I) of 500 mL/min/m^2 has been shown to be an acceptable goal for optimal shock resuscitation,[222] performing as effectively as the DO_2I of $\geqslant$600 mL/min/m^2 previously recommended by Bishop et al.[223] Selection of these specific numbers is based on the results of studies in which critically ill

patients who could increase DO_2I above this level survived. At $DO_2I \geqslant$ 500 mL/min/m^2, patients received approximately 30% less crystalloids and blood transfusions than were required to attain the higher level.[222] A computerized ICU bedside decision protocol developed to standardize shock resuscitation in some centers uses DO_2I >500 mL/min/m^2 as a goal.[222] This is a particularly useful end point because it integrates three important variables: hemoglobin concentration, arterial oxygen saturation, and cardiac output. The oxygen consumption index (VO_2I) is also an important variable. Subsequent organ failure may occur if it decreases below a value of 170 mL/min/m^2, indicating a flow-dependent phase of O_2 utilization.[57] Increasing DO_2I until VO_2I attains flow independence may prevent organ failure; however, this approach is not practical clinically, mainly because there are also DO_2I-independent regulators of VO_2.[222] Finally a global O_2 extraction ratio >0.25 to 0.3 suggests absence of dysoxia. However, it is possible that dysoxia may be present in an individual organ in the presence of a normal overall O_2 extraction ratio. Monitoring of O_2 transport variables, the most useful of which is DO_2I, is usually done in the ICU when invasive monitoring permits measurement of cardiac output and mixed venous O_2. These values can also be monitored in the OR whenever arterial and pulmonary artery lines are present.

A parameter that has been more recently used intraoperatively as a guide to resuscitation during emergency surgery for trauma patients is the end tidal–arterial CO_2 difference (Pa-ET) CO_2.[224] Values >10 mm Hg after resuscitation predict mortality.[224] It may also be useful in the decision about when to perform damage control surgery, and intraoperatively, in guiding resuscitation with fluids, inotropes, and vasopressors.

Coagulation

Conventional blood coagulation monitoring includes a baseline and subsequent serial

measurements of prothrombin time (PT), activated partial thromboplastin time (aPTT), platelet count, blood fibrinogen level, and fibrin degradation products (FDP). Although trauma center laboratories cannot provide results of the standard coagulation tests within an hour, a blood sample should be sent to the laboratory to determine, at least retrospectively, the etiology of any coagulation abnormality. The "tube test," which involves obtaining a tube of blood with no anticoagulant and observing coagulation, clot retraction, and clot lysis, is a practical intraoperative method of coagulation monitoring. If a good-quality clot does not form, or does so only after 10 to 20 minutes, clotting factor deficiency is the most likely cause. Failure of clot retraction within 1 hour after blood sampling suggests platelet depletion or dysfunction. Clot lysis earlier than 6 hours indicates fibrinolysis, which is infrequent in trauma patients.[225] Disseminated intravascular coagulation (DIC) occurs frequently after trauma and is associated with absence of spontaneous clotting in the tube test. In addition to causing bleeding, it may prevent typing and cross-matching of blood.[226]

Thrombelastography (TEG) is similar in principle to the tube test but provides a quantitative, graphic evaluation of clotting function.[227] TEG determines the time necessary for initial fibrin formation, the rapidity of fibrin deposition, clot consistency, the rate of clot formation, and the times required for clot retraction and lysis[227] (Fig. 48-7). Basically, the R and K values are indices of formation, buildup, and cross-linking of fibrin, and depend on the function of coagulation factors. The maximum amplitude (MA) corresponds to the widest portion of the curve and indicates the absolute strength of the fibrin clot. It represents platelet function. The *a* angle is the slope of the external divergence of the tracing from the R value point, indicating the speed of clot formation and fibrin cross-linking. The value of this index is determined by both coagulation factors and platelets. Hypothermia causes coagulopathy by interfering with both platelet and coagulation factor functions.[228,229,230] When the blood of a cold and coagulopathic patient is placed in the TEG cuvette, which is normally heated to 37°C, a near-normal trace may be obtained.[228] Newer TEG devices are temperature adjustable. Thus, the temperature in the cuvette can be adjusted to that of the patient.

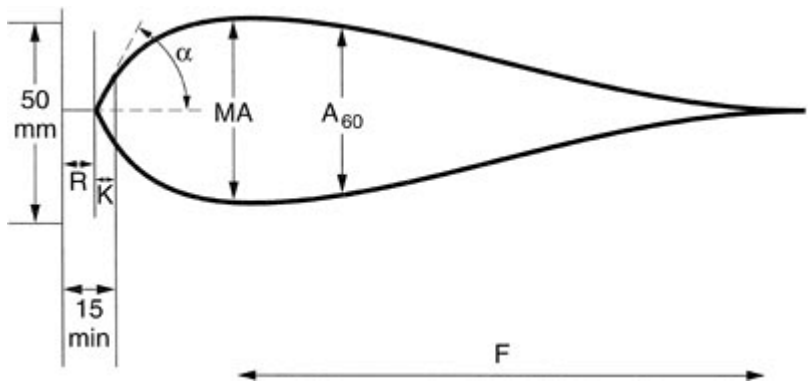

FIGURE 48-7. Thrombelastogram. R, interval from blood deposition in the cuvette to an amplitude of 1 mm on the thrombelastogram; K, time between the end of R and a point with an amplitude of 20 mm on the thrombelastogram; MA, maximum amplitude of thrombelastogram; α angle, slope of the external divergence of the tracing from the R value point; A_{60}, amplitude of thrombelastogram 60 min after maximum amplitude; F, time from MA to return to 0 amplitude (normal >300 min). In Capan LM, Miller SM, Turndorf H [eds]: Trauma: Anesthesia and Intensive Care, p 259. Philadelphia, JB Lippincott, 1991.)

Coagulation test results (PT, aPTT) are often abnormal in major trauma patients. However, these findings do not necessarily indicate that factor and platelet therapy should be initiated, unless there is a clinical indication to do so.[231] The administration of fresh frozen plasma (FFP) is generally recommended when PT and aPTT exceed 1.5 times control,[232] but treatment is based primarily on clinical bleeding (oozing from puncture sites and wound), the amount of blood lost, and the quantity transfused. The likelihood of bleeding, for example, after one blood volume is replaced, increases to 60%, so platelet and factor replacement becomes almost unavoidable once replacement exceeds this volume.[233,234] The results of coagulation tests have little primary impact on treatment. Nevertheless, they should be performed to determine the direction and extent of coagulation dysfunction over time.

Anesthetic and Adjunct Drugs

Apart from regional anesthesia techniques, which are used in patients with minor extremity injuries and stable hemodynamics, anesthetic and adjunct drugs for general anesthesia need to be tailored to five major clinical conditions. The varying contribution of these conditions to the clinical picture of a given patient necessitates priority-oriented planning.

Airway Compromise

Anesthetics and muscle relaxants should be avoided before the airway is secured if there is significant airway obstruction or if there is doubt as to whether the patient's trachea can be intubated because of anatomic limitations. If time permits, lateral neck radiographs, CT scanning, and endoscopy can be used to define the problem better. Topical anesthesia with mild sedation can be used with a flexible fiberoptic scope, Bullard blade,

WuScope, or other aids, and with surgical standby for cricothyroidotomy if intubation attempts are unsuccessful.[235]

Hypovolemia

16 Anesthetic agents not only have direct cardiovascular depressant effects, but also inhibit compensatory hemodynamic mechanisms such as central catecholamine output and baroreflex (neuroregulatory) mechanisms, which maintain systemic pressure in hypovolemia. Hemorrhage and hypovolemia lead to a higher blood concentration following a given dose of intravenous agents, increased sensitivity of the brain to anesthetics, preferential distribution of the cardiac output to the brain and the heart, cerebral hypoxia, dilutional hypoproteinemia, and acidosis, all of which increase the effects of drugs on the brain and the heart.[16] The pharmacokinetic and pharmacodynamic response of intravenous agents to experimental hemorrhagic shock varies. Because of the decrease in size of the central compartment and in systemic clearance, plasma concentrations of fentanyl and remifentanil are increased.[236] A decreased volume of distribution also increases the blood level of etomidate by 20% in shock,[237] and for propofol this effect is substantial.[238]

There is also variation in the extent of brain sensitivity to these agents. Although etomidate pharmacodynamics are unchanged,[237] a significant increase in the sensitivity of the brain and heart to propofol is noted in animals,[238] even after fluid resuscitation.[237] Based on these experimental findings, Shafer[239] calculated that in patients with shock, the dose of propofol should be only 10 to 20% of that given to a healthy patient. The etomidate dose, in contrast, does not require adjustment for shock. Of the opioids, the calculated dose for fentanyl and remifentanil is approximately one-half of that given to healthy patients[239] (Fig. 48-8). Thus, etomidate and fentanyl are the preferred drugs; propofol is not a desirable induction agent in patients with hemorrhagic shock. Of the remaining intravenous agents, thiopental and midazolam are also known to have significant cardiovascular depressant activity,[240,241] whereas ketamine has stimulatory effects when the autonomic nervous system is intact.[242]

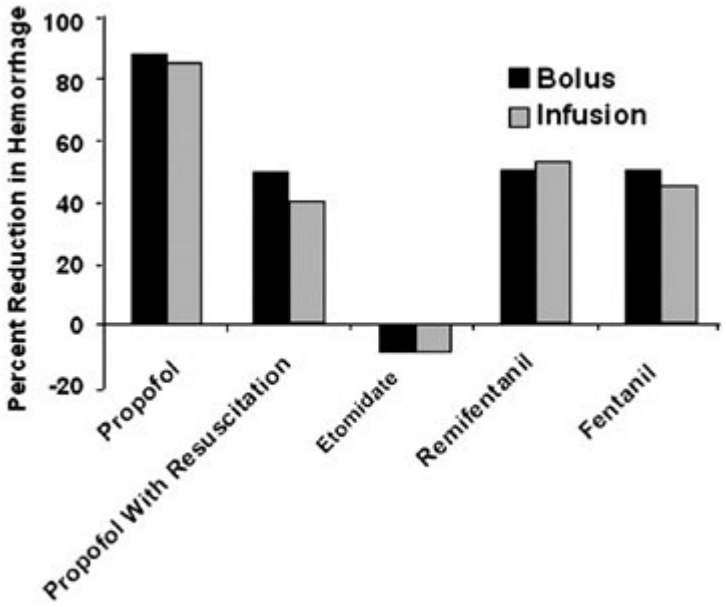

FIGURE 48-8. Calculated dose reduction of various anesthetics administered as a bolus or infusion in moderate hemorrhagic shock. Calculation is based on pharmacokinetic and pharmacodynamic studies performed in experimental hemorrhagic shock. (Reprinted with permission from Shafer SL: Shock values. Anesthesiology 101:567, 2004.)

There are also differences among anesthetics in the direction and extent of their effects on compensatory mechanisms. For example, the baroreceptor depression produced by intravenous agents is usually milder than that of inhalational agents. Data from animal and human studies have demonstrated that thiopental, propofol, and ketamine depress the baroreflex mechanism most and for approximately 10 minutes, whereas etomidate has little effect; the effects of midazolam, diazepam, and droperidol are intermediate.[243,244,245] Among inhalational agents, isoflurane has less of an inhibitory effect on the baroreflex mechanism than halothane or enflurane.[246] Opioid agents have little direct cardiovascular or baroreflex depressant effect; however, these agents can cause hypotension by inhibiting central sympathetic activity, especially in the hypovolemic trauma patient whose apparent hemodynamic stability is maintained by hyperactive sympathetic tone.[247]

Two important principles in the use of anesthetic agents are accurate estimation of the degree of hypovolemia and reduction of doses accordingly. The presence of hypotension suggests uncompensated hypovolemia, in which case anesthetics almost invariably produce further deterioration of systemic blood pressure and sometimes cardiac standstill. Intravascular volume, to the extent possible, must be restored before their use. When time constraints or continuing hemorrhage prevent restoration of blood volume, the airway must be secured without the benefit of anesthesia (perhaps using only rapidly acting muscle relaxants and small doses of opioids, etomidate, or ketamine), even though this approach may result in recall of induction and intraoperative events in up to 40% of patients.[248] Hypothermia, alcohol intoxication, drug use before anesthesia, and metabolic disturbances in the acute trauma patient cannot reliably prevent recall. However, scopolamine, 0.6 mg, given before airway management may decrease the likelihood of this complication. Intraoperative use of the bispectral index monitor and, whenever possible, titrating anesthetics to levels <60 may prevent recall in trauma patients.[249]

In normotensive but hypovolemic patients, restoration of volume and selection of an agent with the least cardiovascular depressant effect appears logical. Ketamine and etomidate are the preferred induction agents,[242,250] although at low doses other intravenous anesthetics are also unlikely to produce hypotension. Therefore, the use of any of these drugs in reduced doses is probably more important than the particular agent chosen.[251,252] These principles may become

especially important for the anesthesiologist if the concept of delayed fluid resuscitation, with hypovolemia prolonged until hemorrhage is controlled surgically, becomes widely accepted.[70]

Maintenance of anesthesia in the hypovolemic trauma patient raises concerns similar to those pertaining to induction. Although normally nitrous oxide's myocardial depressant effect is somewhat counterbalanced by its ability to increase sympathetic outflow, in acute hemorrhage there is already a dramatic increase in sympathetic activity and stimulation of baroreceptors. Under these circumstances, patients are unlikely to respond to the sympathetic effect of N_2O, and the cardiovascular depressant properties of the gas are unmasked; these may be similar to those of other inhalation agents.[253] In addition, by reducing FIO_2, N_2O incurs a risk of hypoxemia in patients with reduced cardiac output or pulmonary compromise. Despite causing little impairment of reflex tachycardia and having a vasodilatory action that preserves organ blood flow in normovolemic patients, isoflurane can impair cardiac output and organ blood flow in hypovolemia—that is, it can cause cardiovascular depression. Desflurane and sevoflurane are not significantly better than isoflurane in this regard. However, because of their low solubility in blood, severe hemodynamic depression produced by these agents can be rapidly reversed, preventing suboptimal perfusion for a significant period of time.[254]

In summary, in the hypovolemic patient all inhalational agents may reduce both global and regional blood flows, and therefore, should be used only in small concentrations

(<1 minimum alveolar concentration [MAC]). Opioid supplementation is usually well tolerated and often indicated.

Head and Open Eye Injuries

The importance of deep anesthesia and adequate muscle relaxation during airway management of patients with head or open eye injuries has already been discussed. Anesthetic agents selected for management of brain injury should produce the least increase in ICP, the least decrease in mean arterial pressure, and the greatest reduction in cerebral metabolic rate ($CMRO_2$). As demonstrated by intraoperative $SjvO_2$ measurements in patients with acute head injury, the most important factor in causing cerebral ischemia is increased ICP from intracranial hematoma.[255] Prompt decompression is the most crucial means of ensuring cerebral well-being. Hypotension caused by anesthetics or other factors contributes to the development or progression of cerebral ischemia. Utmost attention should be paid during anesthesia to avoidance of hypotension (mean arterial pressure <60 mm Hg) and, more important, if reliable $SjvO_2$ monitoring is in place, to avoid values <55 to 60%. With the possible exception of ketamine,[20] all intravenous anesthetics cause comparable degrees of cerebrovascular constriction.[20,256,257,258] Thiopental, midazolam, propofol, and etomidate therefore also produce a dose-dependent reduction in cerebrospinal fluid formation.[259] Again, with the exception of ketamine, $CMRO_2$ is also reduced by all the available intravenous anesthetics.[20,256,257,258] An important drawback to these agents is that their cardiovascular depressant effects may reduce CPP.[257,258,260] This problem can be ameliorated by administering pretreatment doses of opioids (fentanyl, 2 to 3 μg/kg), which permit reduction of the anesthetic dose. This may also prevent the myoclonic movements associated with etomidate and occasionally with propofol, and thus reduce the risks of ICP and IOP increase. Nevertheless, myoclonus is best prevented by careful timing of the dose of muscle relaxants.[261] Another measure to preserve CPP during anesthesia is to administer vasopressors, being aware that hypovolemia may be masked by their use.

Ordinarily, administration of succinylcholine should follow pretreatment doses of nondepolarizing agents to prevent fasciculation-induced elevation of ICP and IOP.[22,262] Avoiding succinylcholine usually does not alleviate the problem because laryngoscopy and tracheal intubation produce a greater and longer-lasting increase in IOP and ICP.[263] Rocuronium, at a dose of 0.9 to 1.2 mg/kg has an onset time comparable with that of succinylcholine.[264] Mivacurium has a longer onset time than rocuronium and, unlike rocuronium, can cause vasodilatation and hypotension.[265] None of the nondepolarizing muscle relaxants causes elevation of ICP or IOP in the absence of associated tracheal intubation.

All inhalation anesthetics may increase CBF, cerebral blood volume (CBV), and thus the ICP.[260] Cerebral autoregulation, CO_2 responsiveness, and $CMRO_2$ are reduced. Unlike thiopental, which decreases both CBF and $CMRO_2$ in parallel, inhalational anesthetics decrease $CMRO_2$ while increasing the CBF. The extent of this uncoupling varies with the agent and the dose. Isoflurane has the least vasodilatory effect and thus is the most widely used inhalation anesthetic, although desflurane and sevoflurane have comparable effects on the cerebral circulation.[292] In hyperventilated patients with cerebral tumors or mild edema, isoflurane does not raise the ICP if it is administered at an inspired concentration of <1 MAC.[266] In the presence of severe head injury, when cerebral autoregulation and CO_2 responsiveness are impaired, isoflurane has the potential to increase CBF and ICP even if it is given at levels below 1 MAC and with hyperventilation.[266] Therefore, it may be prudent not to use this agent at high concentrations in the presence of elevated ICP, at least until the skull is opened and the ICP is controlled. In these patients, anesthesia can be maintained initially with opioids plus thiopental, propofol, midazolam, or etomidate.

Nitrous oxide may increase CBF, CBV, and ICP when administered with inhalation anesthetics if the $PaCO_2$ is normal or increased.[267] This effect may be eliminated when this agent is administered with adequate doses of barbiturates or hyperventilation. The effect on $CMRO_2$ is variable: both an increase and a decrease have been observed. Thus, N_2O probably is not deleterious in patients with head injury with minimal ICP elevation, if it is used after a bolus dose or during infusion of intravenous anesthetics.

In a spontaneously breathing patient, opioids may produce hypoventilation with an associated increase in CBF and ICP; they should, therefore, be used only in mechanically ventilated patients with head trauma. Some reports suggest that opioids and, to a smaller extent, opiates may interfere with CPP by increasing ICP, decreasing mean arterial pressure, or both.[19,268] Fentanyl and sufentanil are most implicated, and it appears that this phenomenon occurs when the head injury is severe.[269,270] Although the clinical significance of these findings is not yet clear, it is prudent to administer fentanyl or its analogs slowly, when the arterial pressure is normal or slightly elevated, ensuring preservation of systemic blood pressure with vasoactive agents, if necessary.

Cardiac Injury

If there is pericardial tamponade, preload and myocardial contractility should be maintained. Any decrease in these parameters may exacerbate an already existing RV inflow occlusion. A decrease in heart rate should also be treated promptly to maintain adequate cardiac output. Because all the available anesthetics can depress myocardial contractility and cause vasodilation, it is preferable to administer these agents after evacuation of pericardial blood under local anesthesia. If general anesthesia is required to relieve the tamponade, induction should be delayed until the patient is prepared and draped. Both anesthetics and controlled ventilation, particularly with PEEP, impair cardiac output. Deep anesthesia and high airway pressures should be avoided before evacuation of the hemopericardium. In chronic pericardial effusion, ketamine supports the cardiac index better than diazepam.[271] In acute pericardial tamponade, even minor insults can bring cardiac activity to a halt. Ketamine thus remains the agent of choice. It should be given in small doses after adequate fluid infusion. Similar principles apply to the use of maintenance agents, which should be given in the smallest possible doses until the heart is decompressed. TEE monitoring may aid management between induction and pericardiotomy.

In blunt myocardial injury, the objective is not only to maintain cardiac contractility, but also to lower the elevated pulmonary vascular resistance that may result from concomitant pulmonary contusion or aspiration. All anesthetics should preferably be administered after restoration of intravascular volume and titrated to maintain adequate systemic blood pressure and cardiac output. If necessary, inotropes, preferably amrinone or milrinone, which produce some pulmonary vasodilation, may be used. Anesthetic maintenance by infusion of intravenous anesthetics and opioids to avoid the myocardial depression produced by inhalational agents should also be considered.

Burns

Extensive and repeated escharotomies may be required during the initial phase of convalescence after a burn injury, usually between the second day and the second week, often necessitating massive transfusion, temperature control, and management of fluid, electrolyte, and coagulation abnormalities. A

hypermetabolic state characterized by tachycardia, tachypnea, catecholamine surge, increased O_2 consumption, and augmented catabolism follows the initial few hours of a burn and continues into the convalescent phase, necessitating increased oxygen, ventilation, and nutrition.[186]

Anesthetic management of escharotomies presents several difficulties. Burned tissue may prevent access for ECG, pulse oximeter, neuromuscular function, and noninvasive blood pressure monitoring; needle electrodes or surgical staples, a reflectance pulse oximeter, and an arterial catheter may be necessary. Large-bore intravenous catheters are essential. Hyperthermia occurs, but hypothermia is more likely in the OR and is to be avoided. Exposure and evaporative fluid loss necessitate maintenance of the OR temperature between 28°C and 32°C, use of countercurrent fluid and blood warming devices, surface heating with forced dry, warm air, and humidified inspired gases. Blood loss can be controlled by restricting the escharotomy to 15 to 20% of TBSA, use of extremity tourniquets, applying dilute epinephrine solution topically (1:10,000) or by injection (0.5 mg per 1,000 mL), and using compression bandages. Epinephrine doses of up to 6.7 mg topically or 0.8 mg by injection into the surgical area are well tolerated;[272] the affinity of beta-adrenergic receptors to ligands is decreased after burns. The administration of a large amount of blood and blood products subjects the patient to complications of transfusion such as coagulopathy. Although citrate-induced hypocalcemia is a relatively rare complication of transfusion,[273] monitoring of Ca^{2+} and administration of calcium chloride (2.5 to 5.0 mg/kg) or gluconate (7.5 to 10.0 mg/kg) should be considered when blood products are administered rapidly.

Shock, hyperdynamic circulation, decreased serum albumin concentration, increased α_1-acid glycoprotein concentration, and altered receptor sensitivity alter the response to various drugs during the resuscitative and convalescent phases.[186] The doses of intravenous anesthetics should be reduced during the resuscitation phase to prevent excessive hemodynamic depression. Burn patients have excruciating pain and exceedingly high opioid requirements. A proven anesthetic regimen for excision and grafting of burns is isoflurane plus large doses of opioid. The response to depolarizing and nondepolarizing muscle relaxants remains unaltered during the first 24 hours after burn injury. However, after the first day, succinylcholine should be avoided for at least 1 year because it can result in a potentially lethal increase of serum K^+ when the burn size exceeds 10% of TBSA. Resistance develops to all nondepolarizing muscle relaxants, except mivacurium in patients with burns of >30% TBSA starting approximately 1 week and peaking 5 to 6 weeks after injury, probably from pharmacodynamic causes, such as an increased number of acetylcholine receptors in the muscle membrane under the burn site and in regions distant from the injury.[186] Increasing the dose can partly overcome this resistance. For instance, rocuronium, which is important for rapid-sequence induction and treatment of laryngospasm when succinylcholine is contraindicated, has an onset time delayed by 30% when a 0.9 mg/kg dose is used. The difference from normal is unchanged at a dose of 1.2 mg/kg, but the onset time is decreased by 30% in burned patients.[274]

For serial wound debridement, ketamine in intermittent doses, neuraxial or peripheral nerve blocks via an indwelling catheter, or sedation with opioids and intravenous agents may be employed.

Management of Intraoperative Complications

Persistent Hypotension

17 Persistent hypotension following trauma is usually the result of one of four mechanisms: bleeding, tension pneumothorax, neurogenic shock, and cardiac injury. Although many other

causes, such as citrate intoxication (hypocalcemia), hypothermia, coronary artery disease, allergic reactions, or incompatible transfusion, may be responsible for this complication, they occur infrequently.

Hypotension is most likely due to bleeding. The source may be obvious, such as external bleeding from the skull or an open vessel in the extremities, or hidden. The thoracic and abdominal cavities and the pelvic retroperitoneal space are the most common sites of occult hemorrhage that results in hypotension. Management includes early diagnosis and control of the bleeding site plus effective fluid resuscitation. The latter can best be accomplished using an infusion system with large-diameter tubing (5 mm) and a countercurrent heat exchanger. Up to 1,000 mL/min of crystalloid solution or 600 mL/min of packed cells can be given if a box-type pressure pump and a large-bore intravenous cannula are used.[275] The system should be connected to 14-gauge or larger cannulae, preferably inserted into veins both above and below the diaphragm. The rapid infusor system (Haemonetics, Braintree, MA), which consists of a reservoir, countercurrent heating system, and roller pump, is capable of delivering up to 1,600 mL/min of warm fluids once the rate of infusion is programmed. Although a powerful system, it is costly, difficult to assemble, and infrequently necessary in the trauma patient.

LR solution is the crystalloid of choice in most centers. However, it is slightly hypotonic (273 mOsm/L), acidic (pH 5.1), and contains a small amount of Ca^{2+}, which may counteract the citrate anticoagulant in PRBCs. Normal saline does not cause this problem, but its infusion in large quantities may result in hyperchloremic acidosis. Both Plasma-lyte A and Normosol-R have the advantages of a pH of 7.4, no Ca^{2+}, and a normal osmolarity (295 mOsm). Because of their prolonged intravascular retention and decreased tendency to produce edema, colloid solutions may be used in selected trauma patients such as those with head injury and those in whom edema develops due to inflammatory reactions or prior administration of large amounts of crystalloids. However, consistent evidence for the benefit of colloids over crystalloids is lacking.[208,276] Human serum albumin (5 and 25%) and hydroxyethyl starch are the most commonly used solutions. Hydroxyethyl starch may produce coagulation abnormalities primarily by reducing the levels of fibrinogen, factor VIII, and von Willebrand's factor, and by reducing platelet function. This is especially important in patients with head injury in whom fatal intracranial hemorrhage may develop.[277] The recommended safe dose of this agent as a component of therapy for surgical blood loss is 20 mL/kg, although a review suggests that there is little support for this recommendation.[277]

Neurogenic shock from spinal cord injury may be missed during initial evaluation, especially in unconscious patients. However, differentiation of neurogenic shock from hemorrhagic shock is important;[278] patients with spinal cord injury are often bradycardic and readily respond to catecholamine infusion. Misdiagnosing neurogenic shock for hemorrhagic shock may lead to excessive fluid infusion and pulmonary edema. The reverse error may also occur: depriving patients with hemorrhagic shock of fluids because of misdiagnosis of neurogenic shock.[278] Invasive central hemodynamic monitoring may be indicated in such patients.[153] In some patients, of course, hemorrhagic shock and neurogenic shock may coexist.

Cardiac causes of persistent hypotension include blunt cardiac injury and pericardial tamponade. Intraoperative TEE can be useful in the differential diagnosis. The RV is most commonly involved in blunt cardiac injury. If there is a concomitant increase in pulmonary vascular resistance (e.g., from an associated pulmonary contusion), the RV pressure increases while its output decreases, resulting in an increased CVP. The raised RV pressure causes the interventricular septum to shift toward the left, decreasing left ventricular

compliance, increasing its diastolic pressure, and decreasing cardiac output. These alterations in cardiac anatomy and ventricular dynamics can be displayed by TEE, information that can be useful during interpretation of elevated cardiac filling pressures.[279]

In the absence of TEE, a pulmonary artery catheter may be helpful. Equalization of pressures across the cardiac chambers during diastole suggests pericardial tamponade. A similar picture may also be seen in severe blunt cardiac injury, causing difficulty in differential diagnosis. This effect,

however, is rare and is usually associated with critical hemodynamic instability. Differential diagnosis in these instances can be established by pericardiocentesis. Septal encroachment into the left ventricle from RV contusion results in an increase in pulmonary artery wedge pressure. Decreasing the rate of fluid infusion in these patients results in a further decrease in cardiac output. Treatment includes fluid infusion, pulmonary vasodilators if the systemic blood pressure is normal, and inotropic support if the systemic blood pressure is low. Absence of response to this treatment is an indication for placement of an intra-aortic balloon pump. Pulmonary artery catheterization may also help detect an oxygen step-up from septal injury. During thoracotomy, a distended RV should also raise the suspicion of a septal defect.

Hypothermia

Shock, alcohol intoxication, exposure to cold, fluid resuscitation, and abnormalities in thermoregulatory mechanisms render the major trauma patient hypothermic during the initial phase of injury. The mortality rate after trauma increases with decreasing temperature. Severe hypothermia, which in the trauma patient is defined as core temperature below 32°C, was associated with a 100% mortality rate in one study.[280] The intraoperative risk of hypothermia is also higher for the trauma victim than for electively operated patients. Heat loss increases in patients with spinal cord, extensive soft-tissue, and burn injuries, and in those who consumed ethanol before surgery.

Hypothermia causes a reduction in cardiac output, cardiac conduction abnormalities, diminished cerebral and renal blood flows, decreased oxygen release from red cells caused by the leftward shift of the O_2 dissociation curve, altered platelet and clotting enzyme function, and abnormalities of K^+ and Ca^{2+} homeostasis.[229] These effects may further compromise poor organ perfusion, oxygenation, blood coagulation, and metabolism.

Aggressive therapy and correction of body temperature to normal within a short time appear to decrease mortality rate, blood loss, fluid requirement, organ failure, and length of ICU stay.[281] Convective warming with forced dry air at 43°C can prevent a temperature drop in most trauma victims but cannot effectively treat severe hypothermia; because of its low specific heat, air has little heat content to give to the cold trauma patient.[281] Airway rewarming can reduce heat loss caused by latent heat of vaporization, but this technique also transfers very little heat.[281] Administration of warm intravenous fluids is the most effective way to prevent and treat hypothermia in the trauma patient, provided that fluids are being administered at a relatively rapid rate. For each liter of fluid given at 40°C to a patient with a body temperature of 33°C, 7 kcal of heat energy is gained. Countercurrent heat exchanging systems are more effective than dry heat or still-water bath warmers. They warm the fluid to 40°C, and the delivered fluid temperature is not affected by rapid rates of administration.[275] The most effective method, however, is continuous arteriovenous rewarming, which can be achieved using a modified level 1 countercurrent system (Fig. 48-9). The blood exits the body from a percutaneously placed femoral arterial catheter at the

patient's own pressure, and then is warmed in the infusion system and returned to the body through a venous cannula. Because the circuit tubing is heparin bonded, there is no need for heparinization. Experience with this technique in the ICU has been encouraging.[281,282]

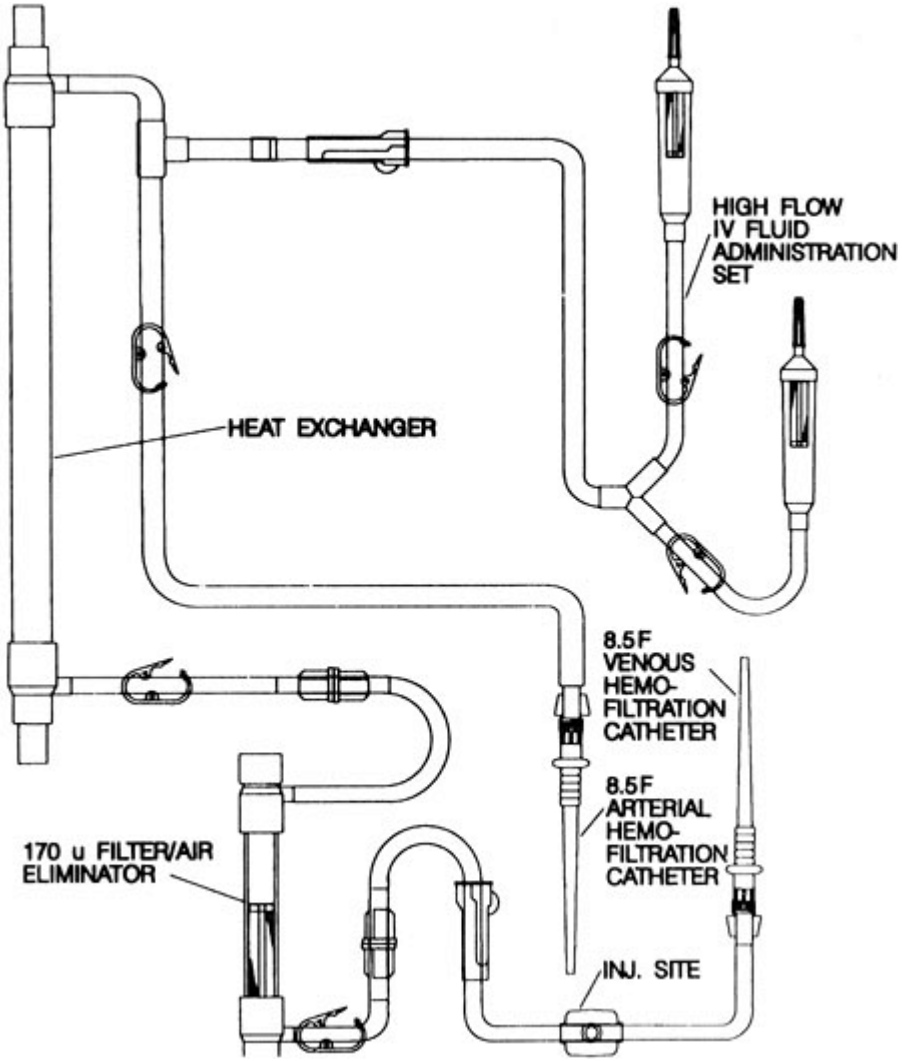

FIGURE 48-9. Schematic drawing of the system used for continuous arteriovenous rewarming. (Reprinted with permission from Gentilello LM, Cobean R, Offner PJ *et al*: Continuous arteriovenous rewarming: Rapid reversal of hypothermia in critically ill patients. J Trauma 32:316, 1992.)

Coagulation Abnormalities

In trauma, multiple factors may be responsible for coagulopathy: dilution of platelets and coagulation factors, hypothermia, acidosis, tissue hypoxia, and tissue thromboplastin release. Hypothermia and diminished tissue perfusion aggravate existing coagulation abnormalities,[283] and hypothermia by itself can cause clotting deficiencies in the absence of platelet or factor deficiency.[229] Hypothermia affects platelet morphology, function, and sequestration, and retards enzyme activity, slowing the initiation and propagation of both platelet plug and fibrin clot.[284] Decreased body temperature may also enhance fibrinolytic activity.[284]

The mechanism of hypothermia-induced coagulopathy is complex and depends on the extent of temperature decrease. Down to 33°C there is little alteration in coagulation enzyme activity, explaining the practically unchanged values reported for aPTT.[285] Within this temperature range, coagulopathy results from altered platelet aggregation/adhesion.[285] Both enzymatic activity and platelet aggregation are abnormal below 33°C.[285] Thus, the aPTT at temperatures from 33 to 37°C does not provide any meaningful information about coagulation status, even when the test is performed at the hypothermic patient's temperature, because it does not measure platelet adhesion. In contrast, thrombelastography at the patient's temperature may be reflective of the

degree of coagulopathy.

19 Perioperative diagnosis of coagulopathy is often made by observing bleeding from wounds or puncture sites, rather than by interpretation of laboratory tests. However, the differential diagnosis between consumptive and dilutional coagulopathy requires laboratory testing, although the results of these tests are usually delayed. In general, the inability to determine the type of coagulopathy does not present a problem because the initial treatment is similar for both conditions. Nevertheless, the diagnosis of DIC has prognostic significance because its treatment involves elimination of its causes. A blood sample without heparin should be sent for measurement of circulating fibrin degradation products (FDP/fdp). An FDP/fdp level >10 mg/mL is suggestive of DIC, whereas a value >40 mg/mL is diagnostic. In patients who have not received a large volume of blood products and other fluids, simultaneous determination of fibrinogen level, platelet count, and PT may be helpful in diagnosis of DIC. A fibrinogen level < 150 mg/dL, platelet count < 150,000, and PT > 15 seconds is highly suggestive. If only two of the three are abnormal, FDP/fdp should be measured.

Prompt platelet administration should always be considered once abnormal bleeding is noted. Each unit of platelet concentrate contains 55 billion platelets, which normally increase the platelet count by 5,000 to 10,000 per µL. If there is ongoing surgical bleeding, administration of platelets should perhaps be delayed until it is controlled; otherwise, they will be wasted. In contrast, severe thrombocytopenia may contribute to the bleeding. It has been shown that transfusion of PRBC in elective surgery results in earlier depletion of coagulation factors than of platelets.[232,286] Thus, it is not unreasonable to administer FFP or cryoprecipitate simultaneously with platelets in emergency trauma surgery. The minimum dose of FFP for adults is 2 U (~600 mL) given within less than 1 hour. Fibrinogen concentration <80 mg/dL is an indication for cryoprecipitate administration. Ten units increase plasma fibrinogen concentration by approximately 100 mg/dL.[233]

In the absence of abnormal bleeding, prophylactic administration of platelets, FFP, or cryoprecipitate is unwarranted, even if coagulation tests indicate platelet and factor depletion.[287] However, once transfusion of factor-deficient PRBC and fluids exceeds one blood volume, clinical coagulopathy is likely even in the absence of shock, hypothermia, or other aggravating factors.[233,234] Thus, in trauma patients who receive between one and two blood volume replacements, platelet or factor administration is almost always indicated. In hypothermic patients with clinical coagulopathy, the critical treatment is rewarming rather than platelet and coagulation factor administration, although circumstances may require both.[228,288] Some anecdotal reports suggest that factor VIIa may be useful as an adjunct for control of hemorrhage, especially in coagulopathic patients with liver injuries.[289]

Electrolyte and Acid-Base Disturbances

20 Intraoperative hyperkalemia may develop as a result of three mechanisms. First, in patients with irreversible shock, cell membrane permeability is altered so massive K^+ efflux results in severe hyperkalemia; in this situation, survival is unlikely. Second, after repair of a major vessel, subsequent reperfusion of the ischemic tissues results in a sudden release of K^+. Third, transfusion at a rate faster than 1 U every 4 minutes to an acidotic and hypovolemic patient may cause an increase in plasma K^+ levels.[290] Frequent monitoring of serum K^+, gradual and intermittent unclamping of vascular shunts, and avoiding transfusion at higher rates than needed helps reduce the rate of K^+ increase. If a rise in K^+ is detected, treatment with regular insulin, 10 U intravenously, with 50% dextrose, 50 mL, and sodium bicarbonate, 8.4%, 50 mL is indicated. If there is a dysrhythmia, $CaCl_2$, 500 mg should also be administered.[291] Insulin and dextrose can be repeated two or three times at 30- to 45-minute intervals, if necessary. Hemodialysis may be indicated in desperate situations.

Metabolic acidosis is caused by shock in most trauma patients. Other rare causes of metabolic acidosis in this population are alcoholic lactic acidosis, alcoholic ketoacidosis, diabetic ketoacidosis, and CO or CN^- poisoning after inhalation injuries. The differential diagnosis between hypovolemic, diabetic, and alcoholic acidosis, all of which have anion gaps, requires measurement

of blood lactate, urinary ketone bodies, blood sugar, and invasive monitoring to assess intravascular volume. Alcoholic ketoacidosis is treated with intravenous dextrose, whereas diabetic ketoacidosis is managed with insulin. No specific treatment except intravenous normal saline exists for alcoholic lactic acidosis.

Treatment of metabolic acidosis involves correction of the underlying cause: management of hypoxemia, restoration of intravascular volume, optimization of cardiac function, or treatment of CO or CN^- toxicity. Symptomatic treatment with sodium bicarbonate has serious disadvantages, including leftward shift of the oxyhemoglobin dissociation curve causing decreased O_2 unloading, a hyperosmolar state secondary to the excessive sodium load, hypokalemia, further hemodynamic depression, overshoot alkalosis a few hours after giving the drug, and intracellular acidosis if adequate ventilation or pulmonary blood flow cannot be provided. Nevertheless, because of the possibility that severe acidosis can cause dysrhythmias, myocardial depression, hypotension, and resistance to exogenous catecholamines, some clinicians administer bicarbonate to "buy time" if the pH is <7.2.

Intraoperative Death

Death is a much greater threat during emergency trauma surgery than it is in any other operative procedure. Approximately 0.7% of patients admitted for acute trauma die in the OR, accounting for approximately 8% of postinjury deaths.[292]

Uncontrollable bleeding is the cause of approximately 80% of intraoperative mortality; brain herniation and air embolism are the most common causes of death in the remaining patients.[292] A multicenter, retrospective study has defined certain features that increase the likelihood of OR death[292] (Table 48-11). Rapid transport to the OR, rapidly stabilizing life-threatening injuries while deferring definitive surgery ("damage control"), simultaneous thoracotomy and laparotomy for thoracoabdominal injuries, appropriate management of retroperitoneal hematoma, and early correction of hypothermia and shock may reduce intraoperative mortality rates.[292]

TABLE 48-11 Clinical Features Associated with Intraoperative Mortality

·CATEGORY	·CLINICAL FEATURES
Mechanism of injury	Gunshot wound Pedestrian injuries
Injury severity	Mean injury severity score >41 Mean revised trauma score >3.0
Preoperative physiologic profile	Mean BP in the field <50 mm Hg Mean BP on arrival to ED <60 mm Hg Best systolic BP in the ED <90 mm Hg Circulatory shock time >10 min Best mean pH <7.18 Mean preoperative crystalloid resuscitation >3,850 mL; mean red cell transfusion >834 mL
Type of injury	Significant head, chest, abdominal, and pelvic injuries individually or in combination after blunt trauma Significant chest and abdominal injuries individually

	or in combination after penetrating trauma
Organ injury	Brain Liver Aorta or other major vascular injury Cardiac injury
Operating room resuscitation and physiologic status	Systolic BP <90 mm Hg during first hour Systolic BP <90 mm Hg for >30 min Deterioration of mean pH from 7.19 to 7.01 Mean intraoperative blood loss 5,172 mL; mean blood replacement 4,541 mL Mean platelet transfusion 784 mL Mean fresh frozen plasma 1,418 mL Mean intraoperative temperature 32.2°C Intraoperative cardiac arrest
BP, blood pressure; ED, emergency department.	
Data from Hoyt DB, Bulger EM, Knudson MM *et al:* Death in the operating room: An analysis of a multi-center experience. J Trauma 37:426, 1994.	

Of these measures, the damage control principle has reduced not only the intraoperative, but also the overall mortality from trauma surgery.[293] Originally described in three stages, the current suggestion is that it should be managed in four phases.[293] In the first phase, in the emergency department attention is directed to recognition of the pattern of injury, as well as to the decision to initiate damage control by activating rewarming and blood component replacement. The second phase occurs in the OR where, in addition to efforts to maintain the patient's intravascular volume, near normal temperature, acid-base status, and coagulation, surgeons rapidly control bleeding and leave the abdominal cavity temporarily covered by a Vac-Pac dressing, which allows an enlarged space for edematous organs and controlled egress of fluid from the abdomen. The third phase occurs in the ICU where intravascular volume, hypothermia, acidosis, and coagulation abnormalities are corrected. In the fourth phase, the stabilized patient is returned to the OR for definitive surgery and abdominal closure.

EARLY POSTOPERATIVE CONSIDERATIONS

21 The concerns in the early postoperative period are similar to those of the intraoperative phase. Reevaluation and optimization of the circulation, oxygenation, temperature, CNS function, coagulation, electrolyte and acid-base status, and renal function are the hallmarks of postoperative management. Pain control in this group of patients may have more than a humanitarian purpose; it can improve pulmonary function, ventilation, and oxygenation in patients with chest injury or a long abdominal incision. For sedation in mechanically ventilated patients, both propofol (25 to 75 µg/kg/min) and midazolam (0.1 to 20 µg/kg/min) infusions alone or in combination are equally effective and safe, although wake-up time in patients receiving midazolam is longer (660 ± 400 minutes) than in those receiving propofol alone (110 ± 50 minutes) or in both agents combined (190 ± 200 minutes).[294] Morphine 0.02 to 0.04 mg/kg/hr or fentanyl 1 to 3 µg/kg/hr may be added for analgesia. Small boluses of midazolam (3 to 5 mg), propofol (50 mg), morphine (2 to 3 mg), or fentanyl (25 to 50 µg) may also be given as required.[294]

Acute Renal Failure

Acute renal failure is a possibility if prolonged shock or crush syndrome occur during early management. Following an episode of shock in patients who have not received an osmotic load (radiopaque material, mannitol) or diuretic, determination of 2- or 6-hour creatinine and free water clearances may help predict the development of posttraumatic renal dysfunction.[295] Creatinine clearance <25 mL/min and free water clearance ⩾ -15 mL/hr suggest the likelihood of acute renal failure. Decreased urine flow rate is not a good predictor, and the blood urea nitrogen does not rise until at least 24 hours after surgery or trauma.[295]

The cause of renal failure in crush syndrome is probably rhabdomyolysis-induced myoglobin release into the circulation. Serum CK levels increase in these patients; levels above 5,000 U/L are associated with renal failure.[296] The differentiation of myoglobinuria from hemoglobinuria is described in the Urine Output section. A clear supernatant suggests myoglobin, whereas a rose color indicates hemoglobin. The traditional prophylaxis for renal failure after rhabdomyolysis includes fluids, mannitol, and bicarbonate. However, more recent data suggest that bicarbonate and mannitol are ineffective.[296]

Abdominal Compartment Syndrome

Abdominal compartment syndrome results from intra-abdominal hypertension with organ dysfunction after major abdominal trauma and surgery (primary syndrome), although other patients may develop the syndrome without surgery, for example, during massive fluid resuscitation following major trauma or burns (secondary syndrome).[297,298,299,300] It frequently follows hemorrhage.[299] The syndrome results from massive edema of intra-abdominal organs produced by shock-induced inflammatory mediators, fluid resuscitation, and surgical manipulation. The significant cardiac, pulmonary, renal, gastrointestinal, hepatic, and CNS dysfunction caused by this syndrome results in a high mortality rate[298] (Fig. 48-10). A damage control procedure with towel-clip closure of the fascia after laparotomy may increase its incidence from the 17% seen with Bogata bag closure to 80%.[300]

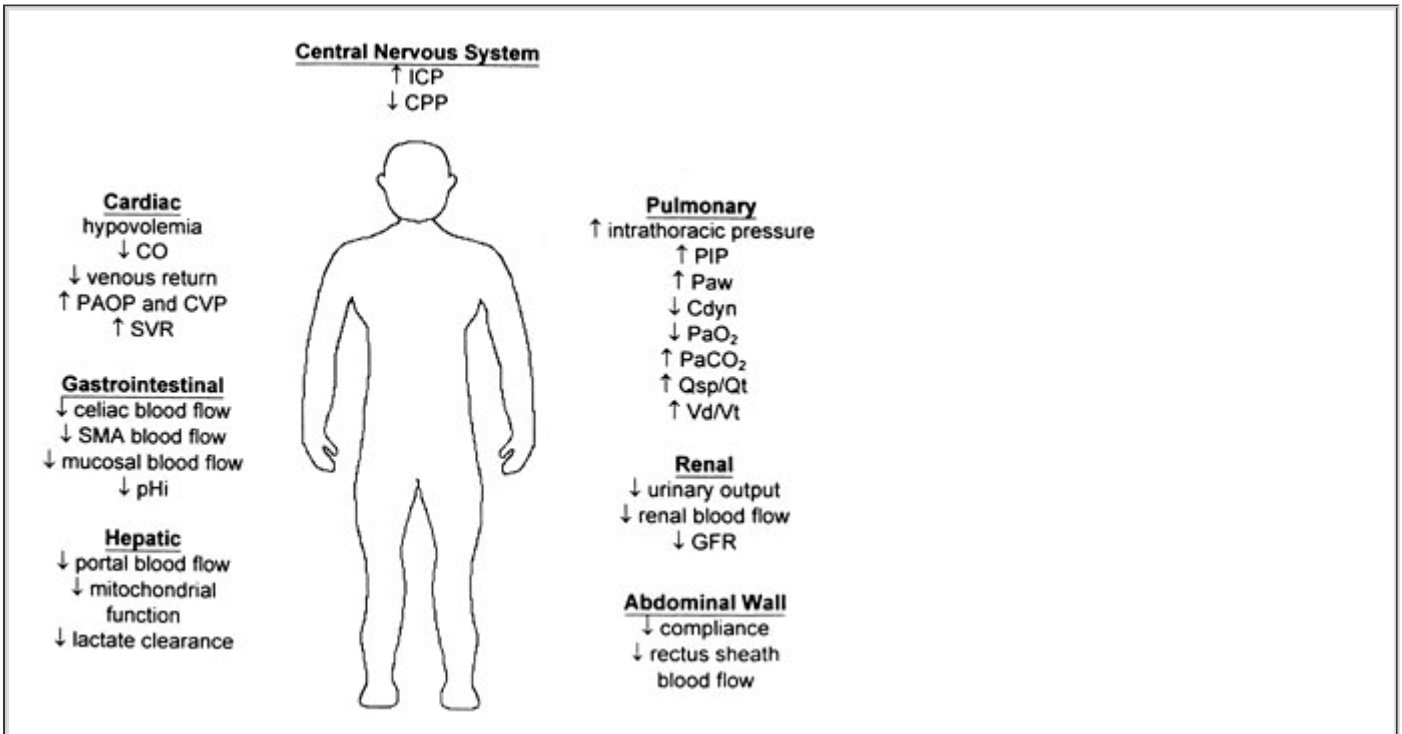

FIGURE 48-10. Physiologic effects of abdominal compartment syndrome. Cdyn, dynamic pulmonary compliance; CO, cardiac output; CPP, cerebral perfusion pressure; CVP, central venous pressure; GFR, glomerular filtration rate; ICP, intracranial pressure; PAOP, pulmonary artery occlusion pressure; Paw, mean airway pressure; pHi, intramucosal pH; PIP, peak

inspiratory pressure; Qsp/Qt, intrapulmonary shunt; SMA, superior mesenteric artery; SVR, systemic vascular resistance; Vd/Vt, dead space ventilation. (Reprinted with permission from Cheatham ML: Intra-abdominal hypertension and abdominal compartment syndrome. New Horiz 7:96, 1999.)

Clinically, a tense, distended abdomen should direct the clinician to measure the intravesical pressure (via Foley catheter), which reflects the intra-abdominal pressure (Fig. 48-11).[298] Values >20 to 25 mm Hg indicate inadequate organ perfusion and necessitate abdominal decompression, which, if delayed, results in progression to multiorgan failure and death.[297,300] Use of a volumetric pulmonary artery catheter for assessment of preload by left ventricular end-diastolic volume index determination may be more accurate than measuring CVP or PCWP in these patients.[298] Almost all these patients require mechanical ventilation. Attributing a relatively high PCWP to the ventilator and continuing high-volume fluid infusion may further increase intra-abdominal edema and increase mortality.[301] Interestingly, patients who will develop abdominal compartment syndrome often do not respond to fluid administration with elevated cardiac output despite an increasing PCWP.[301]

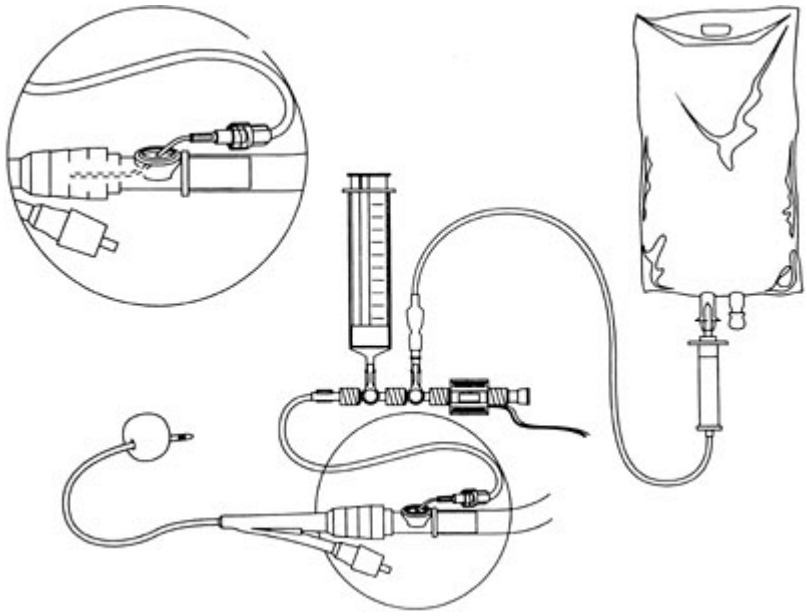

FIGURE 48-11. System used to measure intravesical pressure in abdominal compartment syndrome. (Reprinted with permission from Cheatham ML: Intra-abdominal hypertension and abdominal compartment syndrome. New Horiz 7:96, 1999.)

Thromboembolism

The overall incidence of DVT in the proximal femoral veins, the major source of PE, is approximately 18% in trauma patients.[302] However, DVT occurs in 24% of lower-extremity injuries, 27% of spine injuries, 20% of major head injuries, and 15% of serious injuries of the face, chest, or abdomen.[302] When injuries involve more than one of these high-risk regions, the likelihood of DVT is even higher.[302] Fortunately, only a relatively small fraction (approximately 0.3 to 2%) of severely injured patients have PE.[302,303] Almost half of all cases of PE occur within the first week, suggesting that DVT develops shortly after trauma.[303] In most instances, DVT is asymptomatic, and in many of those in whom leg swelling develops, concurrent lower-extremity injuries may be implicated. The diagnosis of proximal DVT in symptomatic patients can be made by duplex ultrasonography, but this method has low sensitivity in the absence of symptoms.[304]

can be performed in equivocal cases, although it is associated with complications and inherent logistical problems. Hypoxemia, especially when sudden and associated with dyspnea and hemodynamic abnormalities, is highly suggestive of PE. The definitive diagnosis is established by spiral CT and pulmonary angiography. In hemodynamically unstable patients, resuscitation takes precedence over radiologic diagnosis. Management is symptomatic, and includes tracheal intubation, positive pressure ventilation with FIO_2 of 1.0, administration of fluids and inotropes (amrinone or milrinone), and continuous arterial and CVP or pulmonary artery monitoring. TEE is helpful because it may demonstrate RV performance, tricuspid regurgitation, or, in some cases, the thrombus within the pulmonary artery, the right heart chambers, or in transit through a patent foramen ovale to the left atrium.

In patients with relatively minor injuries, PE is treated with anticoagulants. Low-molecular-weight heparin may be used if bleeding is unlikely to exacerbate the injury. Consideration should be given to placement of a vena cava filter if the risk of bleeding is unacceptably high. Removable vena cava filters are now available[305] and are likely to be used prophylactically in high-risk patients more often than permanent filters, which are associated with long-term complications. In patients with severe hemodynamic depression or cardiac arrest unresponsive to resuscitative measures, thrombolytic agents may be considered despite the risk of hemorrhage. The current recommendation for prophylaxis in most trauma patients is low-molecular-weight heparin.[304] Low-dose unfractionated heparin appears to be ineffective in trauma patients.[306] Mechanical devices such as sequential compression boots should be applied as early as possible after injury.

Chapter 49

The Allergic Response

Jerrold H. Levy

KEY POINTS

1	Anesthesiologists routinely manage patients during their perioperative medical care where they are exposed to foreign substances, including drugs (antibiotics, anesthetic agents, neuromuscular-blocking agents [NMBAs], sedative/hypnotics), polypeptides (i.e., protamine, aprotinin), blood products, and environmental antigens (i.e., latex).
2	Antibodies are specific proteins called immunoglobulins that can recognize and bind to a specific antigen.
3	Cytokines are inflammatory cell activators that are synthesized to act as secondary messengers and activate endothelial cells and white cells.
4	Immune competence during surgery can be affected by direct and hormonal effects of anesthetic drugs, by immunologic effects of other drugs used, by the surgery, by coincident infection, and by transfused blood products.
5	More than 90% of the allergic reactions evoked by intravenous drugs occur within 5 minutes of administration. In the anesthetized patient, the most common life-threatening manifestation of an allergic reaction is circulatory collapse, reflecting vasodilation with resulting decreased venous return.
6	Many diverse molecules administered during the perioperative period release histamine in a dose-dependent, nonimmunologic fashion.
7	A plan for treating anaphylactic reactions must be established before the event. Airway maintenance, 100% oxygen administration, intravascular volume expansion, and epinephrine are essential to treat the hypotension and hypoxia that result from vasodilation, increased capillary permeability, and bronchospasm.
8	After an anaphylactic reaction, it is important to identify the causative agent to prevent readministration.

9	Health care workers and children with spina bifida, urogenital abnormalities, or certain food allergies have been recognized as people at increased risk for anaphylaxis to latex.
10	NMBAs have several unique molecular features that make them potential antigens.

1 Allergic reactions represent an important cause of perioperative complications. Anesthesiologists routinely manage patients during their perioperative medical care where they are exposed to foreign substances, including drugs (i.e., antibiotics, anesthetic agents, neuromuscular-blocking agents [NMBAs], sedative hypnotics), polypeptides (protamine, aprotinin), blood products, and environmental antigens (i.e., latex). Anesthesiologists must be able to rapidly recognize and treat anaphylaxis, the most life-threatening form of an allergic reaction.[1]

The allergic response represents just one limb of the pathologic response the immune system that can mount against foreign substances. As part of normal host surveillance mechanisms, a series of cellular and humoral elements monitors foreign structures called *antigens* to provide host defense. These foreign substances (antigens) consist of molecular arrangements found on cells, bacteria, viruses, proteins, or complex macromolecules.[1,2,3,4] Immunologic mechanisms (1) involve antigen interaction with antibodies or specific effector cells; (2) are reproducible; and (3) are specific and adaptive, distinguishing foreign substances and amplifying reactivity through a series of inflammatory cells and proteins. The immune system serves to protect the body against external microorganisms and toxins, as well as internal threats from neoplastic cells; however, it can respond inappropriately to cause hypersensitive (allergic) reactions. Life-threatening allergic reactions to drugs and other foreign substances observed perioperatively may represent different expressions of the immune response.[1,2]

BASIC IMMUNOLOGIC PRINCIPLES

Host defense can be divided into cellular and humoral elements.[1,2,3,4] The humoral system includes antibodies, complement, cytokines, and other circulating proteins, whereas cellular immunity is mediated by specific lymphocytes of the T-cell series. Lymphocytes have receptors that distinguish between antigens of host and foreign origin. When lymphocytes react with foreign antigens, they respond to orchestrate immunosurveillance, regulate immunospecific antibody synthesis, and destroy foreign invaders. Individual aspects of the immune response and their importance are considered separately.

Antigens

Molecules capable of stimulating an immune response (antibody production or lymphocyte stimulation) are called *antigens.*[4] Only a few drugs used by anesthesiologists, such as polypeptides (protamine) and other large macromolecules (dextrans), are complete antigens (Table 49-1). Most commonly used drugs are simple organic compounds of low molecular weight (approximately 1,000 daltons). For such a small molecule to become immunogenic, it must form a stable bond with circulating proteins or tissue micromolecules to result in a complete antigen (hapten-macromolecular complex). Small molecular weight substances such as drugs or drug metabolites

that bind to host proteins or cell membranes to sensitize patients are called *haptens.* Haptens are not antigenic by themselves. Often, a reactive drug metabolite (i.e., penicilloyl derivative of penicillin) is believed to bind with macromolecules to become antigens, but for most drugs this has not been proved.

TABLE 49-1 Agents Administered During Anesthesia that Act as Antigens

·HAPTENS	·MACROMOLECULES
Penicillin and its derivatives	Blood products
Anesthetic drugs(?)	Chymopapain
	Colloid volume expanders
	Muscle relaxants
	Protamine
	Latex

Thymus-Derived (T-Cell) and Bursa-Derived (B-Cell) Lymphocytes

The thymus of the fetus differentiates immature lymphocytes into thymus-derived cells (T cells). T cells have receptors that are activated by binding with foreign antigens and secrete mediators that regulate the immune response. The subpopulations of T cells that exist in humans include helper, suppressor, cytotoxic, and killer cells.[5] The two types of regulatory T cells are helper cells (OKT4) and suppressor cells (OKT8). Helper cells are important for key effector cell responses, whereas suppressor cells inhibit immune function. Infection of helper T cells with a retrovirus, the human immunodeficiency virus, produces a specific increase in the number of suppressor cells. Cytotoxic T cells destroy mycobacteria, fungi, and viruses. Other lymphocytes, called natural killer cells, do not need specific antigen stimulation to initiate their function. Both the cytotoxic T cells and natural killer cells participate in defense against tumor cells and in transplant rejection. T cells produce a spectrum of mediators that influence the response of other cell types involved in the recognition and destruction of foreign substances.

B cells represent a specific lymphocyte cell line that can differentiate into specific plasma cells that synthesize antibodies, a step controlled by both helper and suppressor T-cell lymphocytes.[5] B cells are also called bursa-derived cells because in birds, the bursa of Fabricius is important in producing cells responsible for antibody synthesis.

Antibodies

2 Antibodies are specific proteins called *immunoglobulins* (Ig) that can recognize and bind to a specific antigen.[6] The basic structure of the antibody molecule is illustrated in Fig. 49-1. Each antibody has at least two heavy chains and two light chains that are bound together by disulfide bonds. The Fab fragment has the ability to bind antigen, and the Fc, or crystallizable, fragment is responsible for the unique biological properties of the different classes of immunoglobulins (cell binding and complement activation). Antibodies function as specific receptor molecules for immune

cells and proteins. When antigen binds covalently to the Fab fragments, the antibody undergoes conformational changes to activate the Fc receptor. The results of antigen-antibody binding depend on the cell type, which causes a specific type of activation (i.e., lymphocyte proliferation and differentiation into antibody-secreting cells, mast cell degranulation, and complement activation).

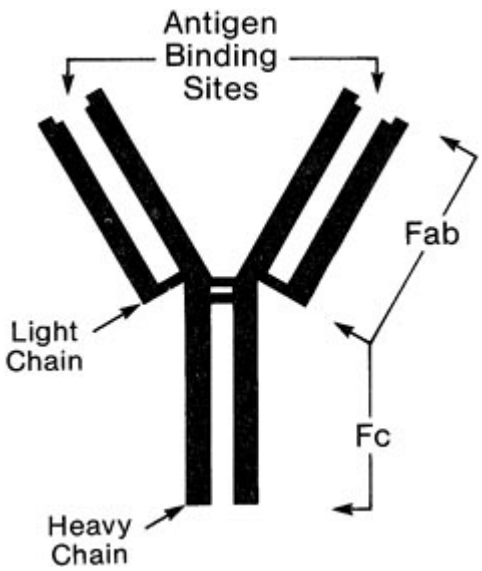

FIGURE 49-1. Basic structural configuration of the antibody molecule representing human immunoglobulin G (IgG). Immunoglobulins are composed of two heavy chains and two light chains bound by disulfide linkages (represented by *crossbars*). Papain cleaves the molecule into two Fab fragments and one Fc fragment. Antigen binding occurs on the Fab fragments, whereas the Fc segment is responsible for membrane binding or complement activation. (Reprinted with permission from Levy JH: Anaphylactic Reactions in Anesthesia and Intensive Care, 2nd ed. Boston, Butterworth-Heinemann, 1992.)

Five major classes of antibodies occur in humans: IgG, IgA, IgM, IgD, and IgE. The heavy chain determines the structure and the function of each molecule. The basic properties of each antibody are listed in Table 49-2.

TABLE 49-2 Biological Characteristics of Immunoglobulins

	·IgG	·IgM	·IgA	·IgE	·IgD
Heavy chain	γ	μ	α	ε	δ
Molecular weight	160,000	900,000	170,000	188,000	184,000
Subclasses	1,2,3,4	1,2	1,2		
Serum concentration, mg/dL	6–14	0.5–1.5	1–3	<-0.5 × 10^3	<0.1

Complement activation	All but IgG_4	+	-	-	-
Placental transfer	+	-	-	-	-
Serum half-life (days)	23	5	6	1–5	2–8
Cell binding	Mast cells (IgG_4)	Lymphocytes		Mast cells	Neutrophils
	Neutrophils			Basophils	Lymphocytes
	Lymphocytes			Lymphocytes

Effector Cells and Proteins of the Immune Response

Cells

Monocytes, neutrophils (polymorphonuclear leukocytes [PMNs]), and eosinophils represent important effector cells that migrate into areas of inflammation in response to specific chemotactic factors, including lymphokines, cytokines, and complement-derived mediators. The deposition of antibody or complement fragments on the surface of foreign cells is called *opsonization*, a process that facilitates the killing of foreign cells by effector cells. In addition, lymphokines and cytokines produce chemotaxis of other inflammatory cells in a manner described in the following sections.

Monocytes and Macrophages. Macrophages regulate immune responses by processing and presenting antigens to effect inflammatory, tumoricidal, and microbicidal functions. Macrophages arise from circulating monocytes or may be confined to specific organs such as the lung. They are recruited and activated in response to microorganisms or tissue injury. Macrophages ingest antigens before they interact with receptors on the lymphocyte surface to regulate their action. Macrophages synthesize mediators to facilitate both B-lymphocyte and T-lymphocyte responses.

Polymorphonuclear Leukocytes (Neutrophils). The first cells to appear in acute inflammatory reaction are neutrophils that contain acid hydrolases, neutral proteases, and lysosomes. Once activated, they produce hydroxyl radicals, superoxide, and hydrogen peroxide, which aid in microbial killing.

Eosinophils. The exact function of the eosinophil in host defense is unclear; however,

inflammatory cells recruit eosinophils to accumulate at sites of parasitic infections, tumors, and allergic reactions.[1]

Basophils. Basophils comprise 0.5 to 1% of circulating granulocytes in the blood.[1] On the surface of basophils are IgE receptors, which function similarly to those on mast cells.

Mast Cells. Mast cells are important cells for immediate hypersensitivity responses. They are tissue fixed and located in the perivascular spaces of the skin, lung, and intestine.[1] On the surface of mast cells are IgE receptors, which bind to specific antigens. Once activated, these cells release physiologically active mediators important to immediate hypersensitivity responses (see IgE-Mediated Pathophysiology section under Anaphylactic Reactions). Mast cells can be activated by a series of both immune and nonimmune stimuli.

Proteins

Cytokines/Interleukins. Cytokines are inflammatory cell activators that are synthesized by macrophages to act as secondary messengers and activate endothelial cells and white cells.[7] Interleukin-1 and tumor necrosis factor are examples of cytokines considered to be important mediators of the biological responses to infection and other inflammatory reactions. Liberation of interleukin-1 and tumor necrosis factor produces fever, neuropeptide release, endothelial cell activation, increased adhesion molecule expression, neutrophil priming, hypotension, myocardial suppression, and a catabolic state.[7] The term *interleukin* was coined for a group of cytokines that promotes communication between and among ("inter") leukocytes ("leukin"). Interleukins are a group of different regulatory proteins that act to control many aspects of the immune and inflammatory responses. The interleukins are polypeptides synthesized in response to cellular activation; they produce their inflammatory effects by activating specific receptors on inflammatory cells and vasculature. T-cell lymphocytes influence the activity of other immunologic and nonimmunologic cells by producing an array of interleukins that they secrete. Different interleukins of this class have been isolated and characterized; they function as short-range or intracellular soluble mediators of the immune and inflammatory responses. The interleukin family of cytokines has been rapidly growing in number because of advances in gene cloning.

Complement. The primary humoral response to antigen and antibody binding is activation of the complement system.[8] The complement system consists of approximately 20 different proteins that bind to activated antibodies, other complement proteins, and cell membranes. The complement system is an important effector system of inflammation. Complement activation can be initiated by IgG or IgM binding to antigen, by plasmin through the classic pathway, by endotoxin, or by drugs through the alternate (properdin) pathway[8] (Fig. 49-2). Specific fragments released during complement activation include C3a, C4a, and C5a, which have important humoral and chemotactic properties (see NonIgE-Mediated Reactions section). The major function of the complement system is to recognize bacteria both directly and indirectly by attracting phagocytes (chemotaxis), as well as the increased adhesion of phagocytes to antigens (opsonization), and cell lysis by activation of the complete cascade.

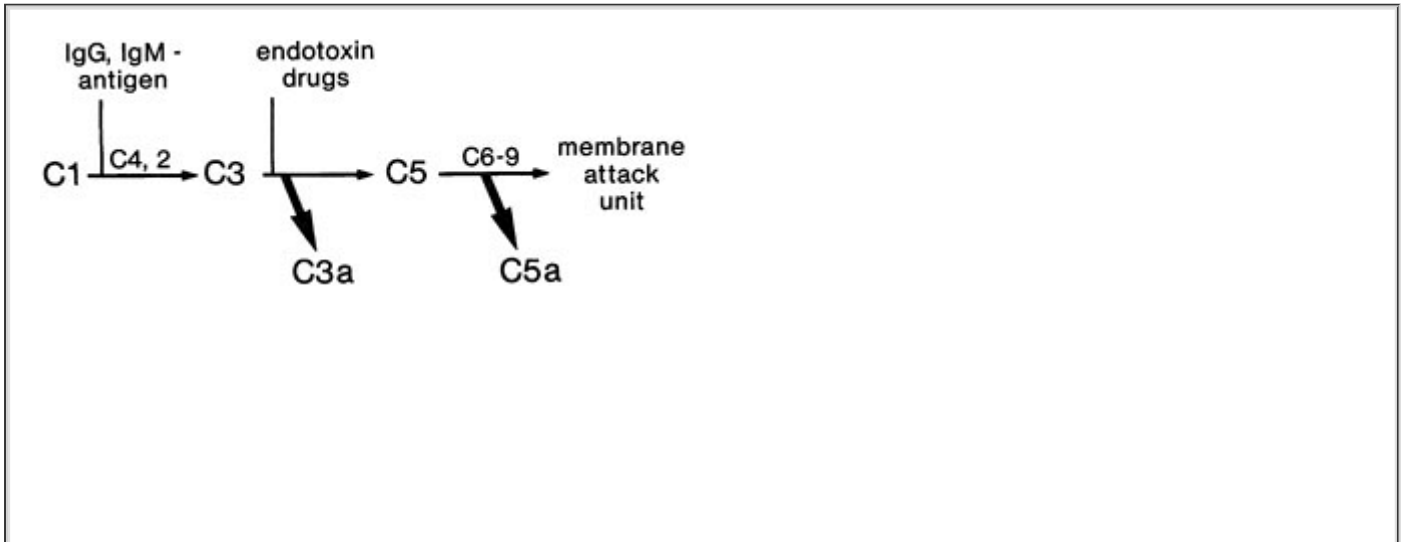

FIGURE 49-2. Diagram of complement activation. Complement system can be activated by either the classic pathway (IgG, IgM–antigen interaction) or the alternate pathway (endotoxin, drug interaction). Small peptide fragments of C3 and C5 called anaphylatoxins (C3a, C5a) that are released during activation are potent vasoactive mediators. Formation of the complete complement cascade produces a membrane attack unit that lyses cell walls and membranes. An inhibitor of the complement cascade, the C1 esterase inhibitor, ensures the complement system is turned off most of the time.

A series of inhibitors regulates activation to ensure regulation of the complement system. Hereditary (autosomal dominant) or acquired (associated with lymphoma, lymphosarcoma, chronic lymphatic leukemia, and macroglobulinemia) angioneurotic edema is an example of a deficiency in an inhibitor of the C1 complement system (C1 esterase deficiency). This syndrome is characterized by recurrent increased vascular permeability of specific subcutaneous and serosal tissues (angioedema), which produces laryngeal obstruction and respiratory and cardiovascular abnormalities after tissue trauma and surgery, or even without any obvious precipitating factor.[9] One of the important pathologic manifestations of complement activation is acute pulmonary vasoconstriction associated with protamine administration.[1]

Effects of Anesthesia on Immune Function

4 Anesthesia and surgery depress a spectrum of nonspecific host resistance mechanisms, including lymphocyte activation and phagocytosis.[6] Immune competence during surgery can be affected by direct and hormonal effects of anesthetic drugs, by immunologic effects of other drugs used, by the surgery, by coincident infections, and by transfused blood products. Blood represents a complex spectrum of humoral and cellular elements that may alter immunomodulation to various antigens. Although multiple studies demonstrate in vitro changes of immune function, no studies have ever proved their importance.[6] Besides, such changes are likely of minor importance compared with the hormonal aspects of stress responses.

HYPERSENSITIVITY RESPONSES (ALLERGY)

Gell and Coombs[3] first described a scheme for classifying immune responses to understand specific diseases mediated by immunologic processes. The immune pathway functions as a protective mechanism, but can also react inappropriately to produce a hypersensitivity or allergic response. They defined four basic types of hypersensitivity, types I to IV. It is useful first to review all four mechanisms to understand the different immune reactions that occur in humans.

Type I Reactions

Type I reactions are anaphylactic or immediate-type hypersensitivity reactions (Fig. 49-3). Physiologically active mediators are released from mast cells and basophils after antigen binding to IgE antibodies on the membranes of these cells. Type I hypersensitivity reactions include anaphylaxis, extrinsic asthma, and allergic rhinitis.

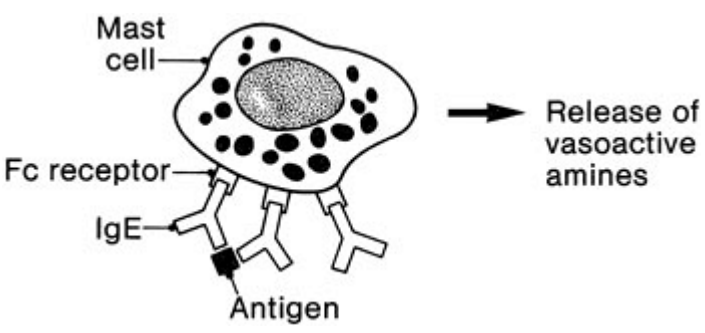

FIGURE 49-3. Type I immediate hypersensitivity reactions (anaphylaxis) involve IgE antibodies binding to mast cells or basophils by way of their Fc receptors. On encountering immunospecific antigens, the IgE becomes cross-linked, inducing degranulation, intracellular activation, and release of mediators. This reaction is independent of complement.

Type Ii Reactions

Type II reactions are also known as antibody-dependent cell-mediated cytotoxic hypersensitivity or cytotoxic reactions (antibody-dependent cell-mediated cytotoxic) (Fig. 49-4). These reactions are mediated by either IgG or IgM antibodies directed against antigens on the surface of foreign cells. These antigens may be either integral cell membrane components (A or B blood group antigens in ABO incompatibility reactions) or haptens that absorb to the surface of a cell, stimulating the production of antihapten antibodies (autoimmune hemolytic anemia). The cell damage in type II reactions is produced by (1) direct cell lysis after complete complement cascade activation, (2) increased phagocytosis by macrophages, or (3) killer T-cell lymphocytes producing antibody-dependent cell-mediated cytotoxic effects. Examples of type II reactions in humans are ABO-incompatible transfusion reactions,

drug-induced immune hemolytic anemia, and heparin-induced thrombocytopenia.

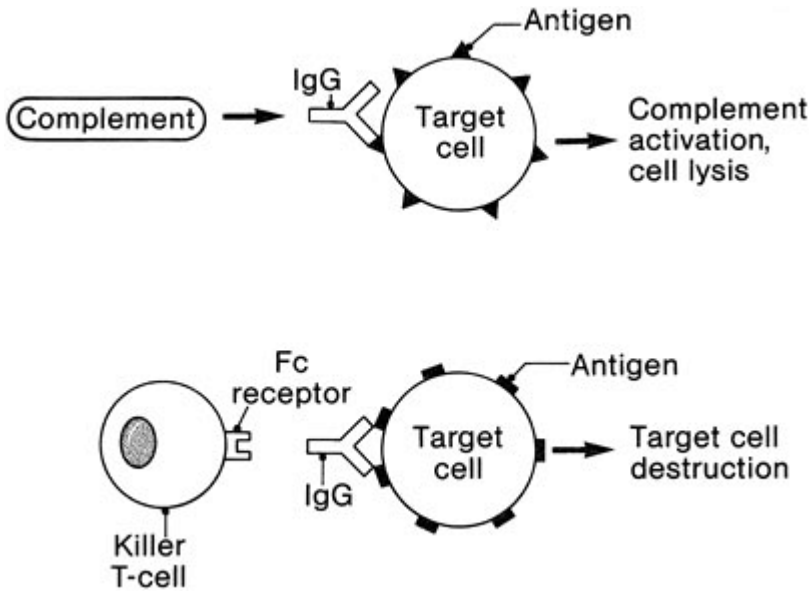

FIGURE 49-4. Type II or cytotoxic reactions. Antibody of an IgG or IgM class is directed against antigens on an individual's own cells (target cell). The antigens may be integral membrane components or foreign molecules that have been absorbed. This may lead to complement activation, including cell lysis (*upper figure*) or to cytotoxic action by killer T-cell lymphocytes (*lower figure*).

Type Iii Reactions (Immune Complex Reactions)

Type III reactions result from circulating soluble antigens and antibodies that bind to form insoluble complexes that deposit in the microvasculature (Fig. 49-5). Complement is activated, and neutrophils are localized to the site of complement deposition to produce tissue damage. Type III reactions include classic serum sickness observed after snake antisera or antithymocyte globulin, and immune complex vascular injury, and may occur through mechanisms of protamine-

mediated pulmonary vasoconstriction.[1]

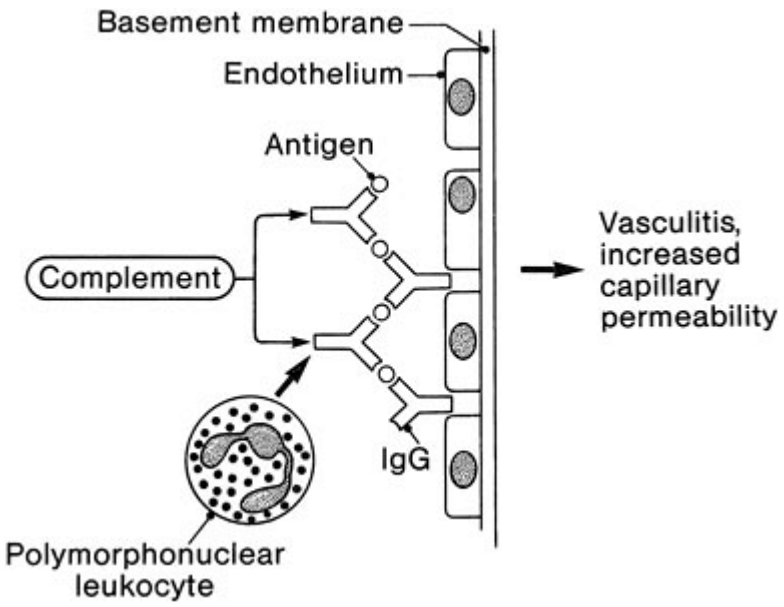

FIGURE 49-5. Type III immune complex reactions. Antibodies of an IgG or IgM type bind to the antigen in the soluble base and are subsequently deposited in the microvasculature. Complement is activated, resulting in chemotaxis and activation of polymorphonuclear leukocytes at the site of antigen-antibody complexes and subsequent tissue injury.

Type Iv Reactions (Delayed Hypersensitivity Reactions)

Type IV reactions result from the interactions of sensitized lymphocytes with specific antigens (Fig. 49-6). Delayed hypersensitivity reactions are mainly mononuclear, manifest in 18 to 24 hours, peak at 40 to 80 hours, and disappear in 72 to 96 hours. Antigen-lymphocyte binding produces lymphokine synthesis, lymphocyte proliferation, generation of cytotoxic T cells, and attracting macrophages and other inflammatory cells. Cytotoxic T cells are produced specifically to kill target cells that bear antigens identical with those that triggered the reaction. This form of immunity is important in tissue rejection, graft-versus-host reactions, contact dermatitis (e.g., poison ivy), and tuberculin immunity.

FIGURE 49-6. Type IV immune complex reactions (delayed hypersensitivity or cell-mediated immunity). Antigen binds to sensitized T-cell lymphocytes to release lymphokines after a

second contact with the same antigen. This reaction is independent of circulating antibody or complement activation. Lymphokines induce inflammatory reactions and activate, as well as attract, macrophages and other mononuclear cells to produce delayed tissue injury.

Intraoperative Allergic Reactions

5 Intraoperative allergic reactions occur once in every 5,000 to 25,000 anesthetics, with a 3.4% mortality rate.[10,11] More than 90% of the allergic reactions evoked by intravenous drugs occur within 5 minutes of administration. In the anesthetized patient, the most common life-threatening manifestation of an allergic reaction is circulatory collapse, reflecting vasodilation with resulting decreased venous return (Table 49-3). The only manifestation of an allergic reaction may be refractory hypotension.[12] Portier and Richet first used the word *anaphylaxis* (from *ana*, "against," and *prophylaxis*, "protection") to describe the profound shock and resulting death that sometimes occurred in dogs immediately after a second challenge with a foreign antigen.[13] When life-threatening allergic reactions mediated by antibodies occur, they are defined as anaphylactic. Although the term *anaphylactoid* has been used in the past to describe nonimmunologic reactions, this term is now rarely used.[14]

TABLE 49-3 Recognition of Anaphylaxis During Regional and General Anesthesia

▪SYSTEMS	▪SYMPTOMS	▪SIGNS
Respiratory	Dyspnea	Coughing
	Chest discomfort	Wheezing
		Sneezing
		Laryngeal edema
		Decreased pulmonary compliance
		Fulminant pulmonary edema
		Acute respiratory failure
Cardiovascular	Dizziness	Disorientation
	Malaise	Diaphoresis
	Retrosternal oppression	Loss of consciousness
		Hypotension

		Tachycardia
		Dysrhythmias
		Decreased systemic vascular resistance
		Cardiac arrest
		Pulmonary hypertension
Cutaneous	Itching	Urticaria (hives)
	Burning	Flushing

ANAPHYLACTIC REACTIONS

IgE-Mediated Pathophysiology

Antigen binding to IgE antibodies initiates anaphylaxis (Fig. 49-7). Prior exposure to the antigen or to a substance of similar structure is needed to produce sensitization, although an allergic history may be unknown to the patient. On reexposure, binding of the antigen to bridge two immunospecific IgE antibodies found on the surfaces of mast cells and basophils releases stored mediators, including histamine, tryptase, and chemotactic factors.[15,16,17] Arachidonic acid metabolites (leukotrienes and prostaglandins), kinins, and cytokines are subsequently synthesized and released in response to cellular activation.[18] The released mediators produce a symptom complex of bronchospasm and upper airway edema in the respiratory system, vasodilation and increased capillary permeability in the cardiovascular system, and urticaria in the cutaneous system. Different mediators are released from mast cells and basophils after activation.

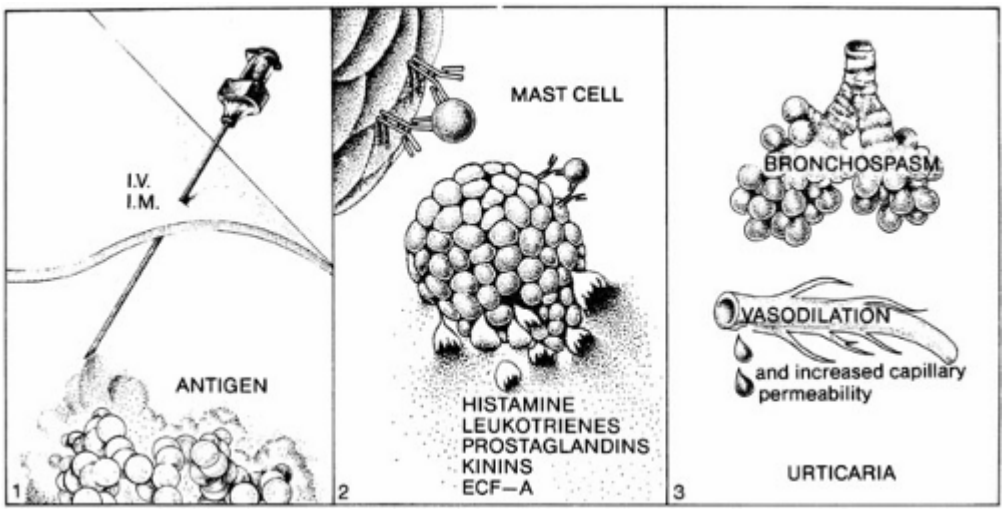

FIGURE 49-7. During anaphylaxis (type I immediate hypersensitivity reaction), (*1*) antigen enters a patient during anesthesia through a parenteral route. (*2*) It bridges two IgE antibodies on the surface of mast cells or basophils. In a calcium-dependent and energy-dependent process, cells release various substances—histamine, eosinophilic chemotactic factor of anaphylaxis, leukotrienes, prostaglandins, and kinins. (*3*) These released mediators produce the characteristic effects in the pulmonary, cardiovascular, and cutaneous systems. The most severe and life-threatening effects of the vasoactive mediators occur in the respiratory and cardiovascular systems. (Reprinted with permission from Levy JH: Identification and Treatment of Anaphylaxis: Mechanisms of Action and Strategies for Treatment Under General Anesthesia. Chicago, Smith Laboratories, 1983.)

Chemical Mediators of Anaphylaxis

Histamine stimulates H_1, H_2, and H_3 receptors. H_1 receptor activation releases endothelium-derived relaxing factor (nitric oxide) from vascular endothelium, increases capillary permeability, and contracts airway and vascular smooth muscle.[1,19,20] H_2 receptor activation causes gastric secretion, inhibits mast cell activation, and contributes to vasodilation.[19] When injected into skin, histamine produces the classic wheal (increased capillary permeability producing tissue edema) and flare (cutaneous vasodilation) response in humans.[21] Histamine undergoes rapid metabolism in humans by the enzymes histamine

N-methyltransferase and diamine oxidase found in endothelial cells.[1]

Peptide Mediators of Anaphylaxis

Factors are released from mast cells and basophils that cause granulocyte migration (chemotaxis) and collection at the site of the inflammatory stimulus.[18] Eosinophilic chemotactic factor of anaphylaxis (ECF-A) is a small molecular weight peptide chemotactic for eosinophils.[22] Although the exact role of ECF-A or the eosinophil in acute allergic response is unclear, eosinophils release enzymes that can inactivate histamine and leukotrienes.[18] In addition, a neutrophilic chemotactic factor is released that causes chemotaxis and activation.[18,23] Neutrophil

activation may be responsible for recurrent manifestations of anaphylaxis.

Arachidonic Acid Metabolites

Leukotrienes and prostaglandins are both synthesized after mast cell activation from arachidonic acid metabolism of phospholipid cell membranes through either lipoxygenase or cyclooxygenase pathways.[24,25] The classic slow-reacting substance of anaphylaxis is a combination of leukotrienes

C_4, D_4, and E_4.[25] Leukotrienes produce bronchoconstriction (more intense than that produced by histamine), increased capillary permeability, vasodilation, coronary vasoconstriction, and myocardial depression.[25] Prostaglandins are potent mast cell mediators that produce vasodilation, bronchospasm, pulmonary hypertension, and increased capillary permeability.[18,25] Prostaglandin D_2, the major metabolite of mast cells, produces bronchospasm and vasodilation.[25] Elevated plasma levels of thromboxane B_2 (the metabolite of thromboxane A_2), also a prostaglandin synthesized by mast cells as well as by PMNs, have been demonstrated after protamine reactions associated with pulmonary hypertension.[26,27]

Kinins

Small peptides called *kinins* are synthesized in mast cells and basophils to produce vasodilation, increased capillary permeability, and bronchoconstriction.[18,28] Kinins can stimulate vascular endothelium to release vasoactive factors, including prostacyclin, and endothelial-derived relaxing factors such as nitric oxide.[1]

Platelet-Activating Factor

Platelet-activating factor (PAF), an unstored lipid synthesized in activated human mast cells, is an extremely potent biological material, producing physiologic effects at concentrations as low as 10^{-10} M.[18] PAF aggregates and activates human platelets, and perhaps leukocytes, to release inflammatory products. PAF causes an intense wheal-and-flare response, smooth muscle contraction, and increased capillary permeability.[18]

Recognition of Anaphylaxis

The onset and severity of the reaction relate to the mediator's specific end-organ effects. Antigenic challenge in a sensitized individual usually produces immediate clinical manifestations of anaphylaxis, but the onset may be delayed 2 to 20 minutes.[29,30] The reaction may include some or all the symptoms and signs listed in Table 49-3. Individuals vary in their manifestations and course of anaphylaxis.[31,32] A spectrum of reactions exists, ranging from minor clinical changes to the full-blown syndrome leading to death.[31,33] The enigma of anaphylaxis lies in the unpredictability of happening, the severity of the attack, and the lack of a prior allergic history.

NonIgE-Mediated Reactions

Other immunologic and nonimmunologic mechanisms release many of the mediators previously discussed independent of IgE, creating a clinical syndrome identical with anaphylaxis. Specific pathways important in producing the same clinical manifestations are considered later.

Complement Activation

Complement activation follows both immunologic (antibody-mediated; i.e., classic pathway) or nonimmunologic (alternative) pathways to include a series of multimolecular, self-assembling proteins that release biologically active complement fragments of C3 and C5.[10,34] C3a and C5a are called *anaphylatoxins* because they release histamine from mast cells and basophils, contract smooth muscle, increase capillary permeability, and cause interleukin synthesis (Table 49-4). C5a interacts with specific high-affinity receptors on PMNs and platelets, causing leukocyte chemotaxis, aggregation, and activation.[35] Aggregated leukocytes embolize to various organs, producing microvascular occlusion and liberation of inflammatory products such as arachidonic acid metabolites, oxygen free radicals, and lysosomal enzymes (Fig. 49-8). Antibodies of the IgG class directed against antigenic determinants or granulocyte surfaces can also produce leukocyte aggregation.[36] These antibodies are called *leukoagglutinins.* Investigators have associated complement activation and PMN aggregation in producing the clinical expression of transfusion reactions,[36,37] pulmonary vasoconstriction after protamine reactions,[27] adult respiratory distress syndrome,[36] and septic shock.[38]

TABLE 49-4 Biological Effects of Anaphylatoxins

·BIOLOGICAL EFFECTS	·C32	·C52

Nonimmunologic Release of Histamine

6 Many diverse molecules administered during the perioperative period release histamine in a dose-dependent, nonimmunologic fashion[39,40,41,42,43] (Table 49-5 and Fig. 49-9). The mechanisms involved in nonimmunologic histamine release are not well understood, but represent selective mast cell and not basophil activation[43,44] (Fig. 49-10). Human cutaneous mast cells are the only cell population that releases histamine in response to both drugs and endogenous stimuli (neuropeptides).[1] Nonimmunologic histamine release may involve mast cell activation through specific cell-signaling activation[40] (Fig. 49-11). Different molecular structures release histamine in humans, which suggests that different mechanisms are involved. Histamine release is not dependent on the μ receptor because

fentanyl and sufentanil, the most potent μ receptor agonists clinically available, do not release histamine in human skin.[39] Although the newer muscle relaxants may be more potent at the neuromuscular junction, drugs that are mast cell degranulators are equally capable of releasing histamine.[39,40] On an equimolar basis, atracurium is as potent as *d*-tubocurarine or metocurine in its ability to degranulate mast cells.[40] Newer aminosteroidal agents such as rocuronium and rapacuronium at clinically recommended doses have minimal effects on histamine release.[44,45]

TABLE 49-5 Drugs Capable of Nonimmunologic Histamine Release

Antibiotics (vancomycin, pentamidine)
Basic compounds
Hyperosmotic agents
Muscle relaxants (*d*-tubocurarine, metocurine, atracurium, mivacurium, doxacurium)
Opioids (morphine, meperidine, codeine)
Thiobarbiturates

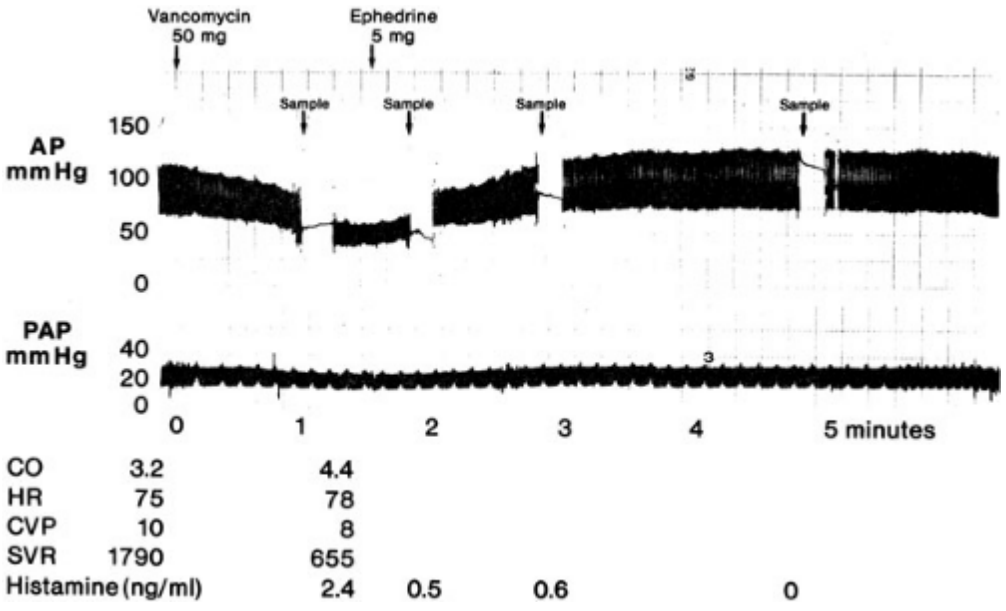

FIGURE 49-9. Example of an anaphylactic reaction after rapid vancomycin administration in a patient. Hypotension is associated with an increased cardiac output and decreased calculated systemic vascular resistance. Plasma histamine levels 1 min after the vancomycin administration were 2.4 ng/mL and subsequently decreased to zero. The patient was given ephedrine, 5 mg, and blood pressure returned to baseline values. (Reprinted from Levy JH, Kettlekamp N, Goertz P *et al:* Histamine release by vancomycin: A mechanism for hypotension in man. Anesthesiology 67:122, 1987.)

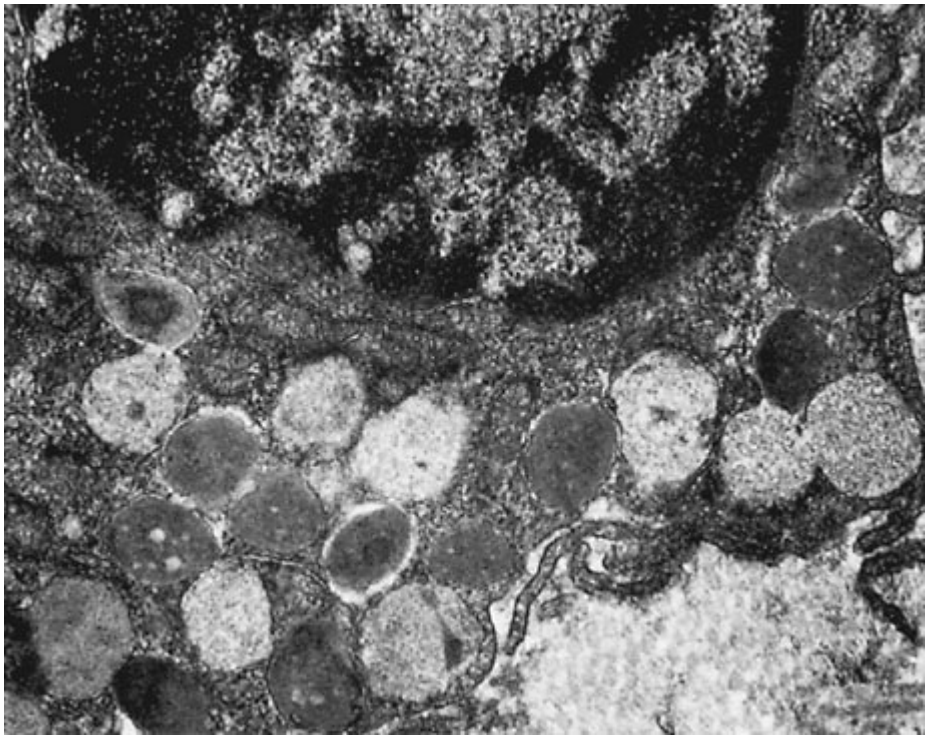

FIGURE 49-10. Electron micrograph of human cutaneous mast cell after injection of dynorphin, a κ opioid agonist. The cell outline is rounded and most of the cytoplasmic granules are swollen, exhibiting varying degrees of decreased electron density and flocculence consistent with ongoing degranulation. The perigranular membranes of the adjacent granules at the periphery of the cell are fused to each other and to plasma membrane. Original magnification ×72,000. (Reprinted from Casale TB, Bowman S, Kaliner M: Induction of human cutaneous mast cell degranulation by opiates and endogenous opioid peptides: Evidence for opiate and nonopiate receptor participation. J Allergy Clin Immunol 73:778, 1984.)

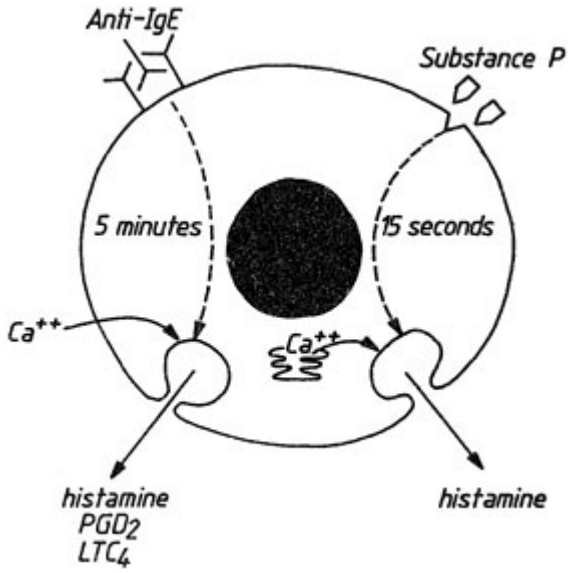

FIGURE 49-11. Different mechanisms of mediator release from human cutaneous mast cells stimulated immunologically by anti-IgE and by nonimmunologic stimuli with substance P. Anti-IgE stimulation, like antigen stimulation, initiates the release of histamine,

prostaglandin D_2 (PGD_2), or leukotriene C_4 (LTC_4) by a mechanism that takes 5 minutes to reach completion and requires the influx of intracellular calcium. Nonimmunologic activation with drugs or substance P releases histamine but not PGD_2 or LTC_4 by a mechanism that is complete within 15 seconds and uses calcium mobilized from intracellular sources. (Reprinted from Caulfield JP, El-Lati S, Thomas G, Church MK: Dissociated human foreskin mast cells degranulate in response to anti-IgE and substance P. Lab Invest 63:502, 1990.)

Antihistamine pretreatment before administration of drugs that are known to release histamine in humans does not inhibit histamine release; rather, the antihistamines compete with histamine at the receptor and may attenuate decreases in systemic vascular resistance.[1] However, the effect of any drug on systemic vascular resistance may depend on other factors in addition to histamine release.[46,47]

Treatment Plan

7 A plan for treating anaphylactic reactions must be established before the event. Airway maintenance, 100% oxygen administration, intravascular volume expansion, and epinephrine are essential to treat the hypotension and hypoxia that result from vasodilation, increased capillary permeability, and bronchospasm.[1] Table 49-6 lists a protocol for managing anaphylaxis during general anesthesia, with representative doses for a 70-kg adult. The treatment plan is the same for life-threatening anaphylactic or anaphylactoid reactions. Therapy must be titrated to needed effects with careful monitoring.[1] Severe reactions need aggressive therapy and may be protracted, with persistent hypotension, pulmonary hypertension, lower respiratory obstruction, or laryngeal obstruction that may persist 5 to 32 hours despite vigorous therapy.[48] All patients who have experienced an anaphylactic reaction should be admitted to an intensive care unit for 24 hours of monitoring because manifestations may recur after successful treatment.

TABLE 49-6 Management of Anaphylaxis During General Anesthesia

▪INITIAL THERAPY
1. Stop administration of antigen 2. Maintain airway and administer 100% O_2 3. Discontinue all anesthetic agents 4. Start intravascular volume expansion (2–4 L of crystalloid/colloid with hypotension) 5. Give epinephrine (5–10 µg IV bolus with hypotension, titrate as needed; 0.1–1.0 mg IV with cardiovascular collapse)
▪SECONDARY TREATMENT
1. Antihistamines (0.5–1 mg/kg diphenhydramine) 2. Catecholamine infusions (starting doses: epinephrine, 4–8 µg/min; norepinephrine, 4–8 µg/min; or isoproterenol, 0.5–1 µg/min as a drip; titrated to desired effects) 3. Aminophylline (5–6 mg/kg over 20 min with persistent bronchospasm) 4. Corticosteroids (0.25–1 g hydrocortisone; alternatively, 1–2 g methylprednisolone) [a] 5. Sodium bicarbonate (0.5–1 mEq/kg with persistent hypotension or acidosis)

6. Airway evaluation (before extubation)
IV, intravenous(ly).
[a]Methylprednisolone may be the drug of choice if the reaction is suspected to be mediated by complement.

Initial Therapy

Although it may not be possible to stop the administration of antigen, limiting antigen administration may prevent further mast cell and basophil activation.

Maintain Airway and Administer 100% Oxygen. Profound ventilation–perfusion abnormalities producing hypoxemia can occur with anaphylactic reactions.[49] Always administer 100% oxygen with ventilatory support as needed. Arterial blood gas values may be useful to follow during resuscitation.

Discontinue All Anesthetic Drugs. Inhalational anesthetic drugs are not the bronchodilators of choice in treating bronchospasm after anaphylaxis, especially during hypotension. These drugs interfere with the body's compensatory response to cardiovascular collapse, and halothane sensitizes the myocardium to epinephrine.

Provide Volume Expansion. Hypovolemia rapidly follows during anaphylactic shock.[50] Fisher[50] reported up to 40% loss of intravascular fluid into the interstitial space during reactions. Therefore, volume expansion is important with epinephrine in correcting the acute hypotension. Initially, 2 to 4 L of lactated Ringer's solution, or colloid or normal saline, should be administered, keeping in mind that an additional 25 to 50 mL/kg may be necessary if hypotension persists. Refractory hypotension after volume and epinephrine administration requires additional hemodynamic monitoring. The use of transesophageal echocardiography for rapid assessment of intraventricular volume and ventricular function, and to determine other occult causes of acute cardiovascular dysfunction, can be important for accurate assessment of intravascular volume and guidance of rational therapeutic interventions. Fulminant noncardiogenic pulmonary edema with loss of intravascular volume can occur after anaphylaxis. This condition requires intravascular volume repletion with careful hemodynamic monitoring until the capillary defect improves. Colloid volume expansion has not proved to be more effective

than crystalloid volume expansion for treating anaphylactic shock.

Administer Epinephrine. Epinephrine is the drug of choice when resuscitating patients during anaphylactic shock. α-Adrenergic effects vasoconstrict to reverse hypotension; β_2 receptor stimulation bronchodilates and inhibits mediator release by increasing cyclic adenosine monophosphate (cAMP) in mast cells and basophils.[32] The route of epinephrine administration and the dose depend on the patient's condition. Rapid and timely intervention is important when treating anaphylaxis. Furthermore, patients under general anesthesia may have altered sympathoadrenergic responses to acute anaphylactic shock, whereas the patient under spinal or epidural anesthesia may be partially sympathectomized and may need even larger doses of catecholamines.[51]

In hypotensive patients, 5- to 10-μg boluses of epinephrine should be administered intravenously

and incrementally titrated to restore blood pressure. (This dose of epinephrine can be obtained with 0.05 to 0.1 mL of a 1:10,000 dilution [100 µg/mL] or by mixing 2 mg epinephrine with

250 mL of fluid to yield an 8 µg/mL solution.) Additional volume and incrementally increased doses of epinephrine should be administered until hypotension is corrected. Although infusion is an ideal method of administering epinephrine, it is usually impossible to infuse the drug through peripheral intravenous access lines during acute volume resuscitation. With cardiovascular collapse, full intravenous cardiopulmonary resuscitative doses of epinephrine, 0.1 to 1.0 mg, should be administered and repeated until hemodynamic stability resumes. Patients with laryngeal edema without hypotension should receive subcutaneous epinephrine. Epinephrine should not be administered IV to patients with normal blood pressures.[52]

Secondary Treatment

Antihistamines. Because H_1 receptors mediate many of the adverse effects of histamine, the intravenous administration of 0.5 to 1 mg/kg of an H_1 antagonist such as diphenhydramine may be useful in treating acute anaphylaxis. Antihistamines do not inhibit anaphylactic reactions or histamine release, but compete with histamine at receptor sites. H_1 antagonists are indicated in all forms of anaphylaxis. The H_1 antagonists available for parenteral administration may have antidopaminergic effects and should be given slowly to prevent precipitous hypotension in potentially hypovolemic patients.[1] The indications for administering an H_2 antagonist once anaphylaxis has occurred remain unclear.

Catecholamines. Epinephrine infusions may be useful in patients with persistent hypotension or bronchospasm after initial resuscitation.[1] Epinephrine infusions should be started at 0.05 to 0.1 µg/kg/min (5 to 10 µg/min) and titrated to correct hypotension. Norepinephrine infusions may be needed in patients with refractory hypotension due to decreased systemic vascular resistance. It may be started at 0.05 to 0.1 µg/kg/min (5 to 10 µg/min) and adjusted to correct hypotension.

Aminophylline. Aminophylline, a nonspecific phosphodiesterase inhibitor, bronchodilates and decreases histamine release from mast cells or basophils in part by increasing intracellular cAMP. In addition, it increases right and left ventricular contractility, and decreases pulmonary vascular resistance. Aminophylline should be considered in patients with persistent bronchospasm and hemodynamic stability, although β_2-adrenergic drugs are the first-line drugs of choice. An intravenous loading dose of 5 to 6 mg/kg of aminophylline given over 20 minutes should be followed by an infusion of 0.5 to 0.9 mg/kg/hr.[1]

Corticosteroids. Corticosteroids have a series of anti-inflammatory effects mediated by multiple mechanisms, including altering the activation and migration of other inflammatory cells (i.e., PMNs) after an acute reaction.[53,54] Corticosteroids may require 12 to 24 hours to work and, despite their unproven usefulness in treating acute reactions, they are often administered as adjuncts to therapy when refractory bronchospasm or refractory shock occurs after resuscitative therapy.[55] Although the exact corticosteroid dose and preparation are unclear, investigators have recommended 0.25 to 1 g intravenously of hydrocortisone in IgE-mediated reactions. Alternately, 1 to 2 g of methylprednisolone (30 to 35 mg/kg) intravenously may be useful in reactions believed to be complement mediated, such as catastrophic pulmonary vasoconstriction after protamine transfusion reactions.[56] Administering corticosteroids after an anaphylactic reaction may also be important in attenuating the late-phase reactions reported to occur 12 to 24 hours after anaphylaxis.[48]

Bicarbonate. Acidosis develops rapidly in patients with persistent hypotension. This diminishes the effect of epinephrine on the heart and systemic vasculature. Therefore, with refractory hypotension or acidemia, sodium bicarbonate, 0.5 to 1 mEq/kg, may be given and repeated every 5 minutes or as dictated by arterial blood gas values.

Airway Evaluation. Because profound laryngeal edema can occur, the airway should be evaluated before extubation of the trachea.[29] Persistent facial edema suggests airway edema. The trachea of these patients should remain intubated until the edema subsides. Developing a significant air leak after endotracheal tube cuff deflation and before extubation of the trachea is useful in assessing

airway patency. If there is any question of airway edema, direct laryngoscopy should be performed before the trachea is extubated.

Refractory Hypotension. Based on the efficacy of arginine vasopressin in vasodilatory shock, it should also be considered in therapy of anaphylactic shock not responding to therapy. Vasopressin may attenuate pathologic-induced vasodilation. Further, additional monitoring, including echocardiography and preferably transesophageal, should be considered in patients with refractory hypotension to better evaluate cardiac function or hypovolemia.

PERIOPERATIVE MANAGEMENT OF THE PATIENT WITH ALLERGIES

Allergic drug reactions account for 6 to 10% of all adverse reactions.[57] DeSwarte[58] suggested that the risk of an allergic drug reaction occurring is approximately 1 to 3% for most drugs, and that around 5% of adults in the United States may be allergic to one or more drugs. Unfortunately, patients often refer to adverse drug effects as being allergic in nature. For example, opioid administration can produce nausea, vomiting, or even local release of histamine along the vein of administration. Patients will say they are "allergic" to a specific drug when in fact their adverse reaction is independent of allergy. Approximately 15% of adults in the United States believe they are allergic to specific medication(s) and therefore may be denied treatment with an indicated drug. To understand allergic reactions, the spectrum of adverse reactions to drugs needs to be considered.

Predictable adverse drug reactions account for approximately 80% of adverse drug effects. They are often dose dependent, related to known pharmacologic actions of the drug, and typically occur in normal patients. Most serious, predictable adverse drug reactions are toxic and are directly related to the amount of drug in the body (overdosage) or to an inadvertent route of administration (e.g., lidocaine-induced seizures or cardiovascular collapse). Side effects are the most common adverse drug reactions and are undesirable pharmacologic actions of the drugs occurring at usual prescribed dosages. Most anesthetic drugs present multiple side effects that can produce precipitous hypotension. For example, morphine dilates the venous capacitance bed, thereby decreasing preload; releases histamine from cutaneous mast cells, thereby producing arterial and venous dilation; slows the heart rate; and decreases sympathetic tone. However, the net effects of morphine on blood pressure and myocardial function depend on the patient's blood volume, sympathetic tone, and ventricular function. Hypotension rapidly develops in a volume-depleted trauma patient in pain who is given morphine. Drug interactions also represent important predictable adverse drug reactions. Intravenous fentanyl administration to a patient who has just received intravenous benzodiazepines, or other sedative-hypnotic drugs may produce precipitous hypotension that results from decreased sympathetic tone.[59] This represents a dose-dependent, predictable adverse drug reaction that is independent of allergy.

Unpredictable adverse drug reactions are usually dose independent and usually not related to the drug's pharmacologic actions, but are often related to the immunologic response (allergy) of the individual. On occasion, adverse reactions can be related to genetic differences (i.e., idiosyncratic) in a susceptible individual who has an isolated genetic enzyme deficiency. In most allergic drug reactions, an immunologic mechanism is present or, more often, presumed. Providing that the initiating event involves a reaction between the drug or drug metabolites with drug-specific antibodies or sensitized T lymphocytes is often impractical. In the absence of direct immunologic evidence, criteria that may be helpful in distinguishing an allergic reaction from other adverse reactions include the following: allergic reactions occur in only a small percentage of patients receiving the drug, and the clinical manifestations do not resemble known pharmacologic actions. In the absence of prior drug exposure, allergic symptoms rarely appear after less than 1 week of continuous treatment. After sensitization, the reaction develops rapidly on reexposure to the drug. In general, drugs that have been administered without complications for several months or longer are rarely responsible for producing drug allergy. The time span between exposure to the drug and noticed manifestations is often the most vital information in determining which drugs

administered were the cause of a suspected allergic reaction.

Although the reaction may produce a life-threatening response in the cardiopulmonary system (anaphylaxis), a variety of cutaneous manifestations, fever, and pulmonary reactions have been attributed to drug hypersensitivity. Usually, the reaction may be reproduced by very small doses of the suspected drug or other agents possessing similar or cross-reacting chemical structures. On occasion, drug-specific antibodies or lymphocytes have been identified that react with the suspected drug, although the relationship is seldom diagnostically useful in practice. Even when an immune response to a drug is demonstrated, it may not be associated with a clinical allergic reaction. As with adverse drug reactions in general, the reaction usually subsides within several days of discontinuation of the drug.

Immunologic Mechanisms of Drug Allergy

Different immunologic responses to any antigen can occur. Drugs have been associated with all the immunologic mechanisms proposed by Gell and Coombs.[3] Although more than one mechanism may contribute to a particular reaction, any one can occur. Penicillin may produce different reactions in different patients or a spectrum of reactions in the same patient. In one patient, penicillin can produce anaphylaxis (type I reaction), hemolytic anemia (type II reaction), serum sickness (type III reaction), and contact dermatitis (type IV reaction).[58] Therefore, any one antigen has the ability to produce a diffuse spectrum of allergic responses in humans. Why some patients have localized rashes or angioneurotic edema in response to penicillin whereas others sustain complete cardiopulmonary collapse is unknown. Most anesthetic drugs and agents administered perioperatively have been reported to produce anaphylactic reactions[31,39,40,41,42,43,44,45,60,61,62,63,64,65,66,67,68,69,70,71,72,73,74,75,76,77,78,79,80,81] (Table 49-7). Muscle relaxants are the most common drugs responsible for evoking intraoperative allergic reactions.[67] In this regard, there is cross-sensitivity between succinylcholine and the nondepolarizing muscle relaxants. Unexplained intraoperative cardiovascular collapse has been attributed to anaphylaxis triggered by latex (natural rubber), and certain patients, including those with a history of spina bifida, are at a greater risk for reactions.[1,68] Even vascular graft material has been reported as a cause of intraoperative allergic reactions.[69]

TABLE 49-7 Agents Implicated in Allergic Reactions During Anesthesia

- **ANESTHETIC AGENTS**

Induction agents (cremophor-solubilized drugs, barbiturates, etomidate, propofol)
Local anesthetics (para-aminobenzoic ester agents)
Muscle relaxants (succinylcholine, gallamine, pancuronium, *d*-tubocurarine, metocurine, atracurium, vecuronium, mivacurium, doxacurium)
Opioids (meperidine, morphine, fentanyl)

- **OTHER AGENTS**

Antibiotics (cephalosporins, penicillin, sulfonamides, vancomycin)
Aprotinin
Blood products (whole blood, packed cells, fresh frozen plasma, platelets, cryoprecipitate, fibrinin glue, gamma globulin)
Bone cement
Chymopapain
Corticosteriods
Cyclosporin
Drug additives (preservatives)
Furosemide
Insulin
Mannitol
Methylmethacrylate

Nonsteroidal anti-inflammatory drugs
Protamine
Radiocontrast dye
Latex (natural rubber)
Streptokinase
Vascular graft material
Vitamin K
Colloid volume expanders (dextrans, protein fractions, albumin, hydroxyethyl starch)

Reprinted with permission from Levy JH: Anaphylactic Reactions in Anesthesia and Intensive Care, 2nd ed. Boston, Butterworth-Heinemann, 1992.

Life-threatening allergic reactions are more likely to occur in patients with a history of allergy, atopy, or asthma. Nevertheless, because the incidence is low, the history is not a reliable predictor that an allergic reaction will occur and does not mandate that such patients should be investigated or pretreated, or that specific drugs be selected or avoided.[60] Although different mechanisms have been proposed, no one theory has been proved.[1] The drugs and foreign substances listed in Table 49-7 may have both immunologic and nonimmunologic mechanisms for adverse drug reactions in humans.

Evaluation of Patients with Allergic Reactions

Identifying the drug responsible for a suspected allergic reaction still depends on circumstantial evidence indicating the temporal sequence of drug administration. Conventional in vivo and in vitro methods of diagnosing allergic reactions to most anesthetic drugs are unavailable or not applicable. The most important factor in diagnosis is the awareness of the physician that an untoward event may be related to a drug the patient received. The physician must always be aware of the capacity of any drug to produce an allergic reaction. The history is important when evaluating whether an adverse drug reaction is allergic and whether the drug can be readministered. Although

a prior allergic reaction to the drug in question is important, this is rarely the case. Direct challenge of a patient with a test dose of drug is the only way to establish reaction, but this is potentially hazardous and not recommended. Although the anesthesiologist commonly gives small test doses of anesthetic drugs, these are pharmacologic test doses and have nothing to do with immunologic dosages. The demonstration of drug-specific IgE antibodies is accepted as evidence the patient may be at risk for anaphylaxis if the drug is administered.[58] Different clinical tests are available to confirm or diagnose drug allergy; several are considered in the following section.

Testing for Allergy

After an anaphylactoid reaction, it is important to identify the causative agent to prevent readministration. When one particular drug has been administered and there is a clear correlation between the time of administration and the occurrence of a reaction, testing may be unnecessary, and general avoidance of the drug should be instituted. However, when patients have simultaneously received multiple drugs (e.g., an opioid, muscle relaxant, hypnotic, and antibiotic), it is often difficult to prove which particular drug caused the reaction. Further, the reaction might have been caused by the vehicle or by one of the preservatives. For patients who want to know which drug was responsible and for patients scheduled for subsequent procedures, some degree of allergy evaluation should be undertaken to evaluate the drug at risk. Unfortunately, few *laboratory* tests exist for anesthetic drugs; therefore, the available allergy tests are discussed.

Leukocyte Histamine Release. Leukocyte histamine is performed by incubating the patient's leukocytes with the offending drug and measuring histamine release as a marker for basophil activation, although false-positive results can occur.[31] This test is not easy to perform, although variations allow the use of whole blood instead of isolated PMNs, and is generally not available.[76,82]

Radioallergosorbent Test. The radioallergosorbent test (RAST) allows *laboratory* detection of specific IgE directed toward particular antigens.[83] In this test, antigens are linked to insoluble material to make an immunoabsorbent.[83,84] When incubated with the serum in question, antibodies of different classes directed toward the antigen bind to it. After washing, the antigen-antibody complex on the immunoabsorbent is incubated with radiolabeled antibodies directed against human IgE, and counted in a scintillation counter. The concentration of specific IgE in the patient's serum directed toward the allergen is measured. The RAST is more quantitative than skin tests and avoids the potential of reexposure.[84] RAST testing has been used to detect the presence of antibodies to meperidine,[49] succinylcholine,[85] and thiopental.[86] Two major limitations to this test include the commercial availability of the drug prepared as an antigen and false-positive test results in patients with high IgE levels.[87]

Enzyme-Linked Immunosorbent Assay. The enzyme-linked immunosorbent assay (ELISA) measures antigen-specific antibodies. The basis of the ELISA is similar to that of the RAST; however, immunospecific IgE directed against the antigen in question is determined by the addition of an anti-IgE coupled to an enzyme such as peroxidase that acts as a chromogen.[5] A colorless substrate is acted on by peroxidase to produce a colored byproduct. The ELISA has been used to prove IgE antibodies to chymopapain and protamine, and has been developed to screen for other antibodies to diverse agents.

Intradermal Testing (Skin Testing). Skin testing is the method most often used in patients after anaphylactic reaction to anesthetic drugs after the history has suggested the relevant antigens for testing.[88,89] Within minutes after antigen introduction, histamine released from cutaneous mast cells causes vasodilation (flare) and localized edema from increased vascular permeability (wheal). Fisher[67,88] suggested that this is a simple, safe, and useful method of establishing a diagnosis in most cases of anaphylactic reactions occurring in the perioperative period. If the strict protocols established by Fisher[88] are used, intradermal reactions are helpful. Intradermal testing is of no value in reactions to contrast media or colloid volume expanders. Cross-sensitivity between drugs of similar structures can often be evaluated based on skin testing. Skin testing to local anesthetics is considered a direct challenge or provocative dose testing.[90] Local anesthetic drugs are injected in increasing quantities under controlled circumstances. This testing decides if the person can safely receive amide derivatives (e.g., lidocaine) and can also be used to decide if the person is sensitive to the paraaminobenzoic ester agents (e.g., procaine, tetracaine).

Agents Implicated in Allergic Reactions

Multiple agents, including antibiotics, induction agents, muscle relaxants, nonsteroidal anti-inflammatory drugs, protamine, colloid volume expanders, and blood products, are the etiologic agents often responsible for anaphylaxis in surgical patients.[1] However, any agent the patient receives as an injection, infusion, or environmental antigen has the potential to produce an allergic reaction.[1] Almost everything has been reported to produce an allergic reaction at some time, but usually from a case report or small series. The agents most often implicated include antibiotics, blood products, colloid volume expanders, latex, polypeptides, and NMBAs. If patients are allergic to a muscle relaxant, there is a potential for cross-reactivity because of the similarity of the active site, a quaternary ammonium molecule, among the different types of relaxants, and alternatives cannot be chosen without some degree of immunologic testing. Because of the ubiquity of latex as a perioperative environmental antigen, latex allergy is considered separately.

Latex Allergy

For the anesthesiologist, latex represents an environmental agent often implicated as an

important cause of perioperative anaphylaxis.[91,92,93,94,95,96,97,98,99] Latex is the milky sap derived from the tree *Hevea brasiliensis* to which multiple agents, including preservatives, accelerators, and antioxidants are added to make the final rubber product. Latex is present in a variety of different products. In March 1991, the U.S. Food and Drug Administration alerted health care professionals about the potential of severe allergic reactions to medical devices made of latex. The first case of an allergic reaction because of latex was reported in 1979 and was manifested by contact urticaria. In 1989, the first reports of intraoperative anaphylaxis due to latex were reported.

9 Health care workers and children with spina bifida, urogenital abnormalities, or certain food allergies have also been recognized as people at increased risk for anaphylaxis to latex.[91,92,93,94,95,96,97,98,99] Brown et al[95] reported a 24% incidence of irritant or contact dermatitis and a 12.5% incidence of latex-specific IgE positivity in anesthesiologists. Of this group, 10% were clinically asymptomatic, although IgE positive. A history of atopy was also a significant risk factor for latex sensitization. Brown et al[95] suggested that these people are in their early stages of sensitization and perhaps, by avoiding latex exposure, their progression to symptomatic disease can be prevented. Patients allergic to bananas, avocados, and kiwis have also been reported to have antibodies that cross-react with latex.[96,97] Multiple attempts are being made to reduce latex exposure to both health care workers and patients. If latex allergy occurs, then strict avoidance of latex from gloves and other sources needs to be considered, following recommendations as reported by Holzman.[91]

Because latex is such a common environmental antigen, this represents a daunting task.

More important, anesthesiologists must be prepared to treat the life-threatening cardiopulmonary collapse that occurs after anaphylaxis, as previously discussed. The most important preventive therapy is to avoid antigen exposure; although clinicians have used pretreatment with antihistamine (diphenhydramine and cimetidine) and corticosteroids, there are no data in the literature to suggest that pretreatment prevents anaphylaxis or decreases its severity.[1] Two patients in a series reported by Gold et al[93] were pretreated, yet still had life-threatening reactions to latex. Patients in whom latex allergy is suspected should be referred to an allergist for appropriate evaluation and potential in vitro testing (RAST) for definitive diagnosis. When this is not possible, patients should be treated as if they were latex allergic, and the antigen avoided. Patients with a documented history of latex allergy should wear Medic Alert bracelets.

Muscle Relaxants

NMBAs have several unique molecular features that make them potential allergens. All NMBAs are functionally divalent, and are thus capable of cross-linking cell-surface IgE and causing mediator release from mast cells and basophils without binding or haptenating to larger carrier molecules. NMBAs have also been implicated in epidemiologic studies of anesthetic drug-induced anaphylaxis. Epidemiologic data from France suggest that NMBAs are responsible for 62 to 81% of reactions, depending on the time period evaluated.[100,101,102,103,104,105]

In more recent years, NMBAs, especially steroid-derived agents, have been reported as potential causative agents of anaphylactic reactions during anesthesia. The data associating NMBAs in the most recent reports from France are mainly based on skin testing; however, studies have previously reported the steroidal-derived NMBAs and other molecules produce false-positive skin tests (i.e., weal and flare). One of the major problems is that anaphylaxis to NMBAs is rare in the United States, but has been reported more often in Europe.[105,106,107] Although suggestions have been made that this is because of underreporting, the severity of anaphylaxis and its sequelae to produce adverse outcomes clearly make this unlikely based on the current medicolegal climate that exists in the United States. One of the only ways to explain this widely divergent perspective is to understand how the diagnosis is made because the recommended threshold test concentrations have not been defined, resulting in unreliable results.

We previously reported in several studies that steroid-derived agents could induce positive weal and flare responses independent of mast cell degranulation, even at low concentrations, following

intradermal injection. This effect is likely because of a direct effect on the cutaneous vasculature that occurs for most NMBAs at concentrations as low as 10^{-5} M using intradermal skin tests in 30 volunteers. A positive cutaneous reaction without evidence of mast cell degranulation was noted at low concentrations (100 mcg/mL) of rocuronium in almost all the volunteers. We have used intradermal injections to compare cutaneous effects of anesthetic and other agents.[106]

Other investigators have also reported similar results. Because prick tests are often used for authenticating NMBAs as causative drugs, Dhonneur et al evaluated 30 volunteers, using prick testing. Each subject received a total of 10 prick tests (50 µL) on both forearms. The investigators studied the weal and flare responses to prick tests with rocuronium and vecuronium, using four dilutions (1/1,000, 1/100, 1/10, and 1) and two controls, and measured weal and flare immediately after and at 15 min. They noted 50 and 40% of the subjects had a positive skin reaction to undiluted rocuronium and vecuronium, respectively.[105] To avoid false-positive results, they suggested that prick testing with rocuronium and vecuronium should be performed in subjects who have experienced a hypersensitivity reaction during anesthesia, with concentrations below that commonly inducing positive reactions in anesthesia-naive, healthy subjects (i.e., for men in a dilution of 1/10 and for women in a dilution of 1/100). Guidelines for prick testing that are internationally agreed on need to be established. Many of these differences may explain the various incidences of allergy to NMBAs among countries. Concentration-skin response curves to rocuronium and vecuronium have showed that prick tests should be performed with dilution of the commercially available preparation. Female volunteers significantly ($P < .01$) reacted to lower vecuronium and rocuronium concentrations than males. In female subjects, positive skin reactions were reported with dilutions of 1/100 of both relaxants. In male subjects, positive skin reactions were noted with the undiluted concentration, except for one volunteer who reacted to rocuronium (1/10 dilution).

SUMMARY

Although the immune system functions to provide host defense, it can respond inappropriately to produce hypersensitivity or allergic reactions. A spectrum of life-threatening allergic reactions to any drug or agent can occur in the perioperative period.[100] The enigma of these reactions lies in their unpredictable nature. However, a high index of suspicion, prompt recognition, and appropriate and aggressive therapy can help avoid a disastrous outcome.

Chapter 50

Drug Interactions

Carl Rosow

Wilton C. Levine

KEY POINTS

1	Drug combinations are a useful and necessary part of anesthesia practice, but they are occasionally a source of morbidity. The qualitative nature of most anesthetic interactions is predictable even though the magnitude of the response might not be known with certainty. Drugs that interact to produce a totally unexpected or dangerous effect stand out because of their rarity.
2	A *pharmaceutical* interaction is a chemical or physical interaction that occurs before a drug is administered or absorbed systemically.
3	A *pharmacokinetic* interaction occurs when one drug alters the absorption, distribution, metabolism, or elimination of another.
4	A *pharmacodynamic* interaction occurs when one drug alters the sensitivity of a target receptor or tissue to the effects of a second drug. We commonly classify these interactions by their direction and intensity, that is, additive, antagonistic, or supra-additive (synergistic).
5	*Additive interactions* are most likely to occur when drugs with identical mechanisms are combined.
6	The most common *antagonistic interactions* are those involving deliberate reversal with competitive antagonists. Antagonism that is unintended is a much less common event.
7	*Synergistic interaction* is most likely to occur when drugs with different mechanisms are combined.
8	Most cardiovascular drug–drug interactions are simply extensions of the known pharmacology of the agents. With few exceptions, there is little reason to withhold most vasoactive medications before surgery.
	Combinations of central nervous system (CNS) depressants almost always

9	produce additive or synergistic increases in CNS effect. These interactions are usually useful and predictable.
10	Among the thousands of herbal preparations available, only a few have been documented to cause problems either through intrinsic toxicity or pharmacokinetic and pharmacodynamic interactions. There are no studies demonstrating specific adverse interactions between herbals and anesthetic drugs.

Modern drug regimens for medical ailments such as hypertension, angina, bronchospasm, or malignancy nearly always involve the use of multiple agents. This strategy is frequently successful because many medical conditions are responsive to groups of drugs that act by different mechanisms and have different dose-limiting toxicities. The goal in each case is to produce an increased therapeutic effect with decreased toxicity compared to treatment with individual agents. Unfortunately, the mixing of drugs is not without risk, and hundreds of research papers on the benefits and drawbacks of drug interactions appear every year. A sizable industry has now evolved to provide clinicians with reference books and computer databases on the subject.

Anesthesiologists face the same dilemma as all other physicians: drug combinations are a useful and necessary part of practice, but they are occasionally a source of morbidity. This chapter reviews the reasons that drugs are combined and the ways in which the combinations can alter either pharmacokinetics or pharmacodynamics. This is *not* a comprehensive list of anesthetic drug interactions—entire books have been devoted to the subject.[1] The examples included have been chosen largely on the basis of proven or likely clinical relevance and the strength of their documentation. When possible, prototypical interactions are illustrated with examples that have direct relevance to anesthesia, although in some cases no such examples are available. The emphasis throughout is on mechanism, but it will quickly be apparent that our understanding of mechanism is incomplete for many pharmacodynamic interactions. Finally, it is important to know how to read the relevant literature, and a short section is

devoted to some of the common ways interactions can be studied.

HISTORICAL PERSPECTIVE

Historically, anesthesiologists were trained to regard drug interactions as a danger and something to be avoided. The generations of clinicians who administered open-drop diethyl ether probably had good reason to limit the number of anesthetic drugs administered: ether by itself could produce hypnosis, reasonable levels of analgesia, and muscle relaxation. Ventilation and blood pressure were usually well maintained because ether has respiratory stimulant and sympathomimetic properties. Clinicians could adjust the dose of this single agent fairly accurately using Guedel's criteria for pupil size, respiratory pattern, muscle tone, and so forth. This meant that a patient requiring even major abdominal surgery could be anesthetized using nothing more than a can of ether and a simple mask.

Before World War II, endotracheal intubation and controlled ventilation were usually not options, and muscle relaxants had not been introduced. Clinicians in this era were well served to keep things simple: if an anesthesiologist chose to add morphine to an ether anesthetic, the pupil and respiratory signs would no longer be reliable, muscle relaxation would probably decrease, and ventilatory depression (if it occurred) could not be treated easily.

The introduction of muscle relaxants, opioid-based anesthesia, and modern intravenous and inhaled anesthetics completely changed these considerations. The signs and stages of ether anesthesia are no longer applicable, and controlled or assisted ventilation is often necessary because most of these drugs have profound effects on respiration. Most importantly, clinicians now realize that anesthetics are highly specific drugs, and no single agent can produce all the "desirable" components of anesthesia. There is good evidence that even the potent volatile anesthetics are not sufficient to produce optimal anesthetic conditions when given alone. Zbinden et al[2] showed that even moderately high concentrations of isoflurane in oxygen cannot suppress many cardiovascular responses to surgical stimuli. This finding is reflected in common clinical practice because isoflurane is routinely supplemented with opioids and other drugs to control blood pressure and heart rate.

Our views of what is desirable in anesthesia have also changed markedly. For example, most patients now expect and prefer an intravenous hypnotic, rather than a mask, for anesthetic induction. Similarly, the long emergence after ether is no longer expected or acceptable. A smooth recovery, free of pain or delirium, is now common within minutes after major surgical interventions. These goals are difficult to accomplish without using multiple drugs.

PROBLEMS CREATED BY DRUG–DRUG INTERACTION

There is almost no data on the true incidence of perioperative drug interaction, although there are data on general inpatient populations. It is logical that the probability of drug–drug interaction increases with the number of drugs administered.[3] Many patients are routinely taking three or four antihypertensives, antidepressants, or gastrointestinal drugs in the preoperative period. Most also receive 5 to 10 drugs during general anesthesia, but we do not normally hear about significant complications attributable to drug interaction. There are a number of possible explanations for this:

1. Interactions may occur, but they usually do not present a problem. Toxicity from a drug interaction is likely to become a source of morbidity primarily when it occurs in a setting where it is not rapidly recognized and treated. This happened when opioid and midazolam combinations were first used by nonanesthesia personnel for endoscopic and radiologic procedures. The unexpectedly large sedative and ventilatory effects led to numerous deaths.[4]
2. Many of the effects introduced by mixing drugs are hard to distinguish from clinical "noise." Variability in response to anesthetic drugs is the rule: the data on intravenous opioids[5] and hypnotics,[6] for example, show that different patients may have a three- to fivefold difference in the therapeutic and toxic effects of a given dose—even when the drug is given alone.

   1 The qualitative nature of most anesthetic interactions is predictable even though the magnitude of the responses might not be known with certainty. Combining two cardiovascular depressants will produce more hypotension; two central nervous system (CNS) depressants will produce more sedation, and so forth. Drugs that interact to produce a totally unexpected or dangerous effect stand out because of their rarity. A notorious example of such an idiosyncratic interaction is the CNS excitation that may occur when meperidine is administered to patients taking monoamine oxidase inhibitors (MAOIs).
3. Many intravenous anesthetic drugs (diazepam, fentanyl) have large safety margins—especially when respiration is supported—so changes in drug effect have few consequences. The mere fact that a measurable interaction exists does not mean it will cause a difference in outcome or the need for intervention. Dangerous interactions most often involve drugs such as warfarin, digoxin, and theophylline, agents with only small differences between therapeutic and toxic concentrations.
4. Finally, it is likely that many instances of anesthetic drug interaction go unrecognized. Excessive drug effects are often attributed to some ill-defined patient "sensitivity." When a drug *fails* to produce an effect, it is because the patient is "tolerant" or "resistant." It is

almost never considered a drug reaction or interaction.

WHY COMBINE DRUGS?

The goal of combining drugs is to decrease toxicity while maintaining or increasing efficacy. It is instructive to see how this principle has been applied in other areas of medicine:

1. Combination therapy can reduce toxicity. For example, a beta-adrenergic antagonist and a vasodilator have at least additive effects on blood pressure, but their side effects are different and (presumably) nonadditive. Lower doses of each drug may be used in combination so dose-related side effects are decreased.
2. Combination chemotherapy for malignancy can increase efficacy. To produce the maximum decrease in tumor burden, each chemotherapeutic drug is given at its maximally tolerated dose, an end-point determined by its toxic effects on some normal cell population. Drugs such as alkylating agents and vinca alkaloids are combined because they have different dose-limiting organ toxicities (bone marrow and nerve, respectively), so each drug can be given at a full tumor-suppressing dose.
3. Single-drug therapy is sometimes preferable. The mainstay drugs for prophylaxis of seizures (phenytoin, carbamazepine) have similar dose-limiting side effects such as

ataxia and drowsiness, so there is little to be gained by combining them.

PHARMACEUTICAL INTERACTIONS

2 A *pharmaceutical* interaction is a chemical or physical interaction that occurs before a drug is administered or absorbed systemically. The most obvious pharmaceutical interactions are the incompatibilities that can occur between drugs in solution:

- Precipitation of thiopental may occur when it is injected together with succinylcholine into the intravenous catheter line.
- Bicarbonate can decrease the solubility of bupivacaine and cause it to precipitate.
- Catecholamine solutions (norepinephrine, epinephrine) can be inactivated if they are alkalinized by the addition of sodium bicarbonate, a circumstance that could occur during cardiopulmonary resuscitation.

The number of these incompatibilities is large, and the anesthesiologist should avoid mixing drugs unless they are known to be compatible. Information on specific intravenous drug incompatibilities is readily available from most hospital pharmacists.

Occasionally, two drugs may interact chemically to form a toxic compound:

- The halogenated anesthetics—desflurane, enflurane, and isoflurane—have been shown to interact with dry soda lime or Baralyme to produce carbon monoxide.[7] Desiccation of soda lime is most likely to occur when oxygen has been left flowing through the canister overnight. Older anesthesiologists recall that trichloroethylene interacted with soda lime to produce the neurotoxin, dichloroacetylene.
- Nitric oxide (NO) is a selective pulmonary vasodilator that has been approved in the United States for treatment of primary pulmonary hypertension in the newborn.[8] If NO is allowed more than fleeting contact with oxygen, it forms nitrogen dioxide (NO_2). The latter compound can be quite toxic, and concentrations >10 ppm can produce pulmonary edema

and alveolar hemorrhage. The problem is circumvented by allowing oxygen and NO to mix in the breathing circuit just before administration.

PHARMACOKINETIC INTERACTIONS

3 A *pharmacokinetic* interaction occurs when one drug alters the absorption, distribution, metabolism, or elimination of another. Many of the basic pharmacokinetic principles underlying these interactions are reviewed in Chapter 11.

Absorption

Alteration of absorption may occur because of direct chemical or physical interaction between drugs in the body or because one drug alters the physiologic mechanisms governing absorption of the second:

- Orally administered tetracycline can be inactivated by chelation if it is given together with antacids containing polyvalent cations such as Mg^{2+}, Ca^{2+}, or Al^{3+}.
- Oral antidiarrheal drugs such as kaolin and pectin can physically adsorb digoxin and prevent it from being absorbed.
- The bile acid-binding resin, cholestyramine, can bind to warfarin and prevent its absorption. It can also reduce the absorption of vitamin K and other fat-soluble compounds.

Another interaction of significance to anesthesiologists is the delay of gastric emptying produced by medications such as opioids and anticholinergics. Opioids produce hypertonus of smooth muscle, reduction of peristalsis, and contraction of sphincters throughout the gastrointestinal tract, and it appears that both central and peripheral mechanisms play a role in this effect. Murphy et al[9] gave volunteers 500 mL of distilled water to drink and showed that 0.09 mg/kg of morphine increased the half-time for gastric emptying from 5.5 to 21 minutes. Morphine can also reduce the absorption of orally administered drugs because the primary site for absorption is the small intestine, and gastric emptying is rate limiting. Asai et al[10] demonstrated that morphine significantly reduces the absorption of oral acetaminophen in patients.

Changes in regional blood flow (vasodilators, vasoconstrictors) can affect the absorption of parenterally administered drugs. Shock or congestive heart failure decreases perfusion of peripheral tissues such as skin and muscle, so the onset and intensity of effect may become unpredictable for drugs given by intramuscular or subcutaneous injection:

- Local administration of epinephrine and other vasoconstrictors retard absorption of infiltrated local anesthetics and therefore prolong their effects.
- Drugs that decrease effective pulmonary ventilation have the potential to reduce the uptake of volatile anesthetics. Drugs that increase minute ventilation, reduce intrapulmonary shunting, or relieve bronchospasm can increase the uptake of volatile anesthetics even though the inspired concentration remains constant.
- The rapid uptake of nitrous oxide can increase the alveolar concentration of concomitantly administered volatile anesthetics (the "second gas effect").

Distribution

Many drug–drug interactions occur when one drug alters the distribution of a second. This may occur due to alterations in hemodynamics, drug ionization, or binding to plasma and tissue proteins. Much has been written about the involvement of these mechanisms in drug interactions

(particularly the last two), but there are few examples of proven relevance to anesthesia.

Drugs such as volatile anesthetics, beta-blockers, calcium channel blockers, and vasodilators can decrease cardiac output and produce significant changes in drug distribution. A decrease in cardiac output increases the arterial concentrations of other drugs in highly perfused tissues such as the brain and myocardium:[11]

- In a patient with depressed cardiac function, normal doses of intravenous agents such as propofol, thiopental, and remifentanil can produce substantially greater cardiovascular and CNS effects. This can be due to an increase in tissue drug concentrations or an increase in tissue sensitivity to the effects of the drug.[12,13,14]
- The same effect is seen with volatile anesthetics. Low cardiac output increases end-tidal concentrations and intensifies cardiovascular and CNS effects.

Drug-induced changes in pH in a particular body region or fluid compartment can alter the distribution of other drugs

by so-called "ion trapping." Most of our therapeutic agents are weak acids or bases that are partially ionized at normal body pH. It is only the nonionized fraction that can cross lipid membranes and come to equilibrium. The amount ionized can be determined for acids or bases from the general form of the Henderson-Hasselbach equation:

$$\frac{[\text{Protonated}]}{[\text{Unprotonated}]} = 10^{(pK_a - pH)}$$

Recall that an unprotonated acid is ionized, whereas an unprotonated base is nonionized. It is apparent from this relationship that a weak base (fentanyl, lidocaine) will be progressively ionized as the pH decreases, whereas a weak acid (aspirin, phenobarbital) will be more nonionized.

For certain membrane barriers, such as those in the stomach, placenta, or renal tubules, the pH on either side is very different, and this creates the necessary conditions for ion trapping. Consider the case of a weak acid (ionization constant [pK_a] = 3.4) that is distributing between stomach and blood. In stomach acid (pH 2.4),

$$\frac{[\text{Nonionized}]}{[\text{Ionized}]} = 10^{(3.4-2.4)} = 10$$

In blood (pH 7.4),

$$\frac{[\text{Nonionized}]}{[\text{Ionized}]} = 10^{(3.4-7.4)} = 0.0001$$

At equilibrium, the concentrations of nonionized drug must be the same on either side of the gastric membrane barrier. This means that a 10,000-fold concentration gradient is established for total drug (nonionized + ionized):

	·STOMACH (pH 2.4)	BLOOD (pH 7.4)
Nonionized drug	1	1
Ionized drug	0.1	10,000
Total drug	1.1	10,001

It is easy to see why weak acids such as aspirin are well absorbed from the stomach. The potential for drug interaction is great. Even moderate changes in pH can have large effects on this equilibrium: raising intragastric pH to 5.4 decreases the concentration gradient by 100-fold:

- Administration of antacids, histamine type 2 receptor antagonists, or proton pump inhibitors such as omeprazole can reduce the gastric absorption of some acidic drugs. Alteration of pH has been shown to change the oral bioavailability of ketoconazole[15] and midazolam.[16]
- Lipid-soluble basic drugs such as fentanyl and meperidine can diffuse *into* the stomach from the bloodstream. They become ionized and trapped in gastric acid only to be reabsorbed when they enter the more alkaline environment of the proximal jejunum. This gastric "recycling" is believed to be the basis for secondary increases in plasma concentrations of these opioids.[17]
- Alteration of urine pH can markedly affect the renal clearance of certain drugs (described in the Drug Elimination section).

Much has been written about the role of plasma protein binding in drug–drug interaction. The fraction of a dose that remains intravascular is either free or bound to circulating proteins. Acidic drugs usually bind to albumin and various globulin fractions. Many basic drugs such as meperidine, lidocaine, bupivacaine, and propranolol bind to α_1-acid glycoprotein, an acute-phase reactant. Drug binding by α_1-acid glycoprotein can increase after surgery and in certain other conditions such as burns, myocardial infarction, trauma, and malignancies. Conversely, hepatic cirrhosis and the nephrotic syndrome are often accompanied by hypoproteinemia and decreases in both albumin and globulin binding.

The extent to which drug is bound versus free is important because it is only the unbound fraction that is available for crossing membranes, entering tissues, and binding to receptors to produce the pharmacologic effect. Protein-bound drug is not filtered by a normal glomerulus and (for some drugs) is not acted on by drug-metabolizing enzymes. A drug that is highly bound to plasma protein effectively exists in a "depot," not unlike a drug given by deep intramuscular injection. The potential therefore exists that one drug could alter the disposition, clearance, or biological effect of another by affecting its binding:

- The classic example of such an interaction is drug displacement of bilirubin in infants. Premature infants have immature glucuronyl transferase and are unable to conjugate bilirubin formed by destruction of erythrocytes. Much of the load of unconjugated bilirubin is bound to albumin and thus prevented from entering tissues. Sulfonamides and other drugs can compete for albumin-binding sites, and the bilirubin they displace can enter tissues. Excessive levels of bilirubin in the brain can lead to kernicterus, a potentially fatal problem.

This effect was discovered accidentally in 1956 during a clinical drug trial. When premature infants were given a penicillin-sulfonamide mixture, the mortality rate increased, and many were found to have kernicterus at autopsy.[18]

- The same mechanism has been postulated for numerous drug–drug interactions. Highly bound, potentially toxic drugs such as warfarin and phenytoin may be displaced by other highly bound drugs. Warfarin is >98% bound to albumin, meaning that only 1 to 2% of the circulating drug accounts for the entire biological effect. Phenylbutazone is a nonsteroidal anti-inflammatory drug (NSAID) that competes effectively for the same binding sites. If phenylbutazone displaces only 2% of warfarin, this theoretically doubles the free (active) fraction and greatly increases the warfarin effect.

This type of drug–drug interaction has been dogma for years, but it is nearly impossible to find documented evidence that it causes harm:[19]

1. Most drugs are widely distributed in the body, so most of the administered dose is *extravascular*—two-thirds of the total dose in the case of warfarin. Even a large change in plasma unbound fraction (e.g., 10%) will therefore release only 3 to 4% of total warfarin in the body.
2. The body acts as a sink or buffer against large changes in unbound fraction (any unbound drug in plasma is rapidly distributed into peripheral tissues).

Some caution is still warranted for anesthesiologists and other clinicians who use intravenous drug regimens with doses often in the toxic range (e.g., high doses of opioids, hypnotics, and muscle relaxants). In these circumstances, it is possible that even a temporary change in free drug concentration can have clinical consequences.

Metabolism

There are numerous examples in anesthesia of drugs that increase or decrease the metabolism of others. Interactions may occur in extrahepatic or hepatic sites of metabolism.

Many drugs—especially those with ester linkages—undergo hydrolysis by specific or nonspecific esterases found in blood and peripheral tissues:

- Drugs given to inhibit acetylcholinesterase at the motor end plate usually inhibit butyrylcholinesterase (pseudocholinesterase) in plasma. Thus, administration of neostigmine or pyridostigmine intensifies and prolongs the effects of succinylcholine and can also theoretically affect ester local anesthetics (procaine, chloroprocaine, tetracaine, cocaine). Enzyme inhibition needs to be substantial (<20% of normal activity remaining) before the clinical effects of these local anesthetics become prolonged.[20,21] The prolongation of effect depends on the specific inhibitor. Neostigmine, for example, can prolong the effect of succinylcholine by several hours. The organophosphate, echothiophate, is a powerful miotic used topically for refractory glaucoma. This compound irreversibly inhibits pseudocholinesterase,[20,22] and the effect persists for weeks, so the risk for interaction is prolonged.
- Drugs such as esmolol and remifentanil are hydrolyzed by so-called "nonspecific" esterases in blood and peripheral tissues. These drugs are not good substrates for cholinesterases, so they are not subject to this interaction.[22] The nonspecific esterases constitute a large group of isozymes with extremely high capacity and low substrate specificity. This enzyme system is not likely to be involved in drug–drug interactions because inhibition of any one isozyme usually does not affect overall drug clearance.

Monamide Oxidase Interactions

The enzyme, monamide oxidase (MAO), is distributed throughout the body, with the largest amounts found in the liver, kidney, and brain. MAO is located on the outer surface of mitochondria in the presynaptic terminals of noradrenergic, dopaminergic, and serotonergic neurons in the CNS and periphery. It acts to regulate the presynaptic pool of norepinephrine, dopamine, epinephrine, and serotonin available for synaptic transmission (see Chapter 12). MAO exists in two isoforms: MAO-A predominates in the gut wall, whereas MAO-B is the major isoform in the CNS.

The MAOIs are used mainly for the treatment of refractory endogenous depression and certain other mood disorders. They have gained some notoriety in medicine because they are the cause of more clinically important drug–drug interactions than almost any other class of drugs. Many of the purported interactions are poorly documented, although they cannot be discounted completely.

There are currently only three MAOIs marketed in the United States. Phenelzine (Nardil) is an older, nonselective MAOI derived from hydrazine. It irreversibly inhibits the enzyme, and synthesis of new enzyme can take 10 to 14 days. Tranylcypromine (Parnate) is a slightly shorter-acting MAOI derived from amphetamine. The newest member of this class is selegiline (deprenyl, Eldepryl), which is used as an adjunct in the treatment of Parkinson's disease. In lower doses, selegiline is relatively selective for MAO-B. The antibiotic furazolidone and the chemotherapeutic drug procarbazine also cause substantial inhibition of MAO and can potentially cause many of the same interactions.

Reported MAOI interactions are broadly of two types: the first group involves drugs that affect sympathetic neurotransmission:

- The well-known interaction with indirect-acting sympathomimetic drugs (ephedrine, amphetamine) occurs because MAOI treatment increases the amount of presynaptic transmitter that can be released by these drugs. Normal doses of ephedrine have produced severe hypertensive crises, occasionally leading to cerebral hemorrhage and death.
- The "wine and cheese" reaction is essentially the same interaction. Many foods such as aged cheese contain tyramine, a phenylethylamine that has ephedrine-like actions at sympathetic nerve endings. Normally, exogenous tyramine is degraded by MAO-A in the gut wall and liver, but patients on an MAOI may achieve high systemic concentrations and consequently have hypertensive crises.
- Paradoxically, a patient who has been taking an MAOI for some time may actually have *decreased* adrenergic responsiveness (some of the older MAOIs were marketed as treatments for hypertension). Even with good dietary compliance, these patients absorb some tyramine. Chronic exposure to low levels of tyramine allows this compound to be taken up by adrenergic terminals (in place of tyrosine), where it is metabolized to octopamine (rather than norepinephrine). Octopamine is a "false transmitter" with little activity, so sympathetic nerve function may eventually be impaired.
- Because MAO plays only a small role in the metabolism of compounds in the synaptic cleft, the response to sympathomimetics that act directly on postsynaptic receptor sites (phenylephrine, norepinephrine, epinephrine) should be affected less by such interactions. In a small study of four healthy volunteers (two receiving tranylcypromine and two receiving phenelzine), there was a moderate (twofold) increase in the response to phenylephrine, but the responses to norepinephrine and epinephrine were not exaggerated.[24] This is reassuring, but any sympathomimetic drug should still be administered with caution to patients on an MAOI.
- Adverse interactions have been described with older MAOIs and levodopa, possibly because both drugs increase dopamine concentrations. Nevertheless, there is some experience that levodopa and selegiline may be combined safely in patients with Parkinson's disease. The MAOI is given in this case to prevent free radical formation believed to be involved in

neuronal degeneration.[25]

- Inhibition of norepinephrine reuptake by tricyclic antidepressants (TCAs) increases the amount of neurotransmitter in the synaptic cleft. This would seem to be a recipe for adverse interaction with MAOIs, but with careful monitoring, this combination has been used successfully for therapy.

The second group of MAOI interactions involves CNS depressants. As stated previously, some of these are poorly documented, and the mechanisms are unknown:

- The most important interaction is unquestionably with meperidine. When meperidine is given to a patient on an MAOI, a life-threatening reaction may occur, accompanied by excitation, hyperpyrexia, hypertension, profuse sweating, and rigidity.[26] This may progress to seizures, coma, and death. The reaction does not occur in every instance. It has also been described with selegiline,[27] and one or two case reports suggesting that a toxic interaction may occur with the antitussive, dextromethorphan,[28] and the analgesic, propoxyphene.[29] Other than some poorly documented case reports, the evidence suggests that morphine and fentanyl do not produce this interaction.[30] The mechanism of meperidine–MAOI interaction is unknown, but animal models suggest that it involves elevations in brain concentrations of serotonin.[31]
- Anecdotal reports have appeared regarding adverse MAOI interactions with other psychotropic drugs, including alcohol, phenothiazine, benzodiazepines, and

barbiturates,[32] but the evidence is weak. Some wines, such as Chianti, could be dangerous because they contain tyramine. It is possible (but probably not advisable) to use ketamine for induction of anesthesia in patients taking an MAOI.[33]

Should MAOIs be discontinued before elective surgery? The issue is still a matter of debate,[34] although drug package inserts usually advise an extremely conservative position (i.e., waiting 2 weeks for the enzyme to regenerate). Current clinical opinion probably favors continuing MAOI therapy up to the time of surgery, and our own experience supports this view. Most patients are receiving these drugs for moderate to severe psychiatric disorders that have not responded to other treatments. It is unpleasant and possibly risky for a patient with refractory depression to endure 2 to 3 weeks without effective therapy. If a general anesthetic is planned, it seems prudent to use the fewest possible drugs. Avoiding drugs with substantial sympathetic effects (e.g., pancuronium, cocaine, ketamine) probably makes sense.

There is little doubt that patients taking MAOIs have the potential for perioperative hemodynamic instability, yet beta-blockers, direct vasodilators, and direct-acting pressors appear to be safe and effective treatments in most circumstances. Roizen[35] concluded, "The major problem with continuing MAO inhibitors preoperatively is not the hemodynamic fluctuations that might occur … but rather the rare instance of hyperpyrexic coma following narcotic administration. …" Because opioids such as fentanyl appear safe and there are no major interactions with local anesthetics or NSAIDs, providing analgesia without meperidine should not be a hardship.

Hepatic Biotransformation

Many anesthetic drugs undergo oxidative metabolism by one of the isoforms of cytochrome P450 found in liver microsomes. The P450 isoforms have low substrate specificity, which means that drugs of diverse structures, such as general inhalation anesthetics, meperidine, barbiturates, and benzodiazepines, can be biotransformed by a single group of enzymes. It is not surprising that inhibitors or inducers of these enzymes can also affect the clearance of broad groups of drugs.

The removal of drug from the blood by hepatic biotransformation (hepatic clearance) is a function of two independent variables, the hepatic blood flow and the intrinsic clearance (the maximal ability of the liver to metabolize that drug). The intrinsic clearance is often expressed as the *extraction ratio* (ER)—the fraction of drug that can be metabolized in a single pass through the

liver (see Chapter 11).

$$ER = \frac{C_a - C_v}{C_a}$$

where C_a is the drug concentration coming to the liver (mixed portal vein + hepatic artery) and C_v is the drug concentration leaving (hepatic vein). So,

Hepatic clearance = ER × hepatic blood flow

Drugs may be classed broadly as "high extraction" and "low extraction," a distinction with important implications for drug interaction:

A high-extraction drug (e.g., lidocaine, propranolol) may have an ER of 0.7 to 0.8 or more (70 to 80% is cleared in one pass through the liver). For these drugs, hepatic blood flow is the rate-limiting factor in overall hepatic clearance, that is, the delivery of drug to the liver determines the amount cleared. Clearance is decreased by drugs or maneuvers that lower hepatic blood flow, such as beta-blockade, cimetidine, halothane, hypotension, and upper abdominal surgery. The clearance of these rapidly metabolized drugs is much less sensitive to changes in enzyme activity. Nor does plasma protein binding have a large effect: the enzymes are so active that a drug such as lidocaine is simply stripped off its binding proteins as it traverses the liver:

- Decreases in hepatic blood flow secondary to decreased cardiac output elevate lidocaine concentrations in humans.[36]
- Pressor administration can also accomplish the same thing. This effect was elegantly demonstrated by Benowitz et al[37] in rhesus monkeys (Fig. 50-1). Steady-state infusions of lidocaine were established, then hepatic blood flow was increased or decreased by infusions of isoproterenol or norepinephrine, respectively. During isoproterenol infusion, the concentration of lidocaine decreased, indicating increased clearance. During norepinephrine infusion, lidocaine concentrations increased.
- Lidocaine clearance is decreased and toxicity is increased when patients are treated chronically with cimetidine.[38] It is not clear whether single-dose premedication with cimetidine produces the same effect.
- Other high-extraction drugs, such as morphine and sufentanil, are affected the same way. The clearance of morphine may be very slow in a patient with decreased hepatic blood flow.

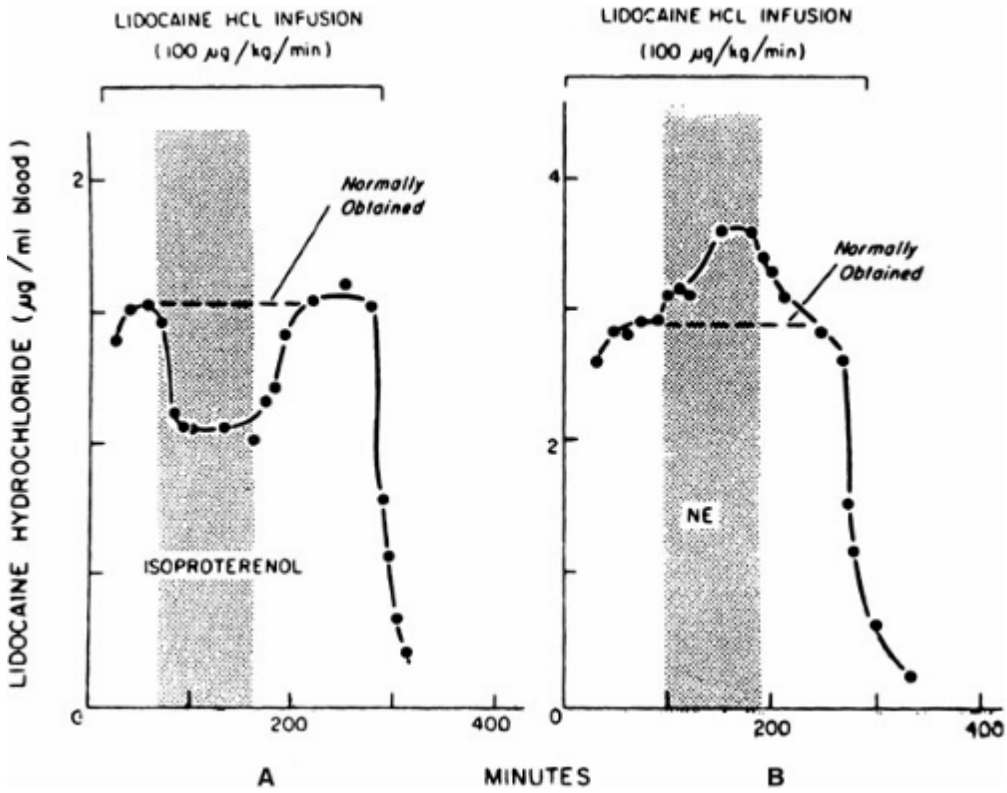

FIGURE 50-1. The effects of increasing or decreasing hepatic blood flow with isoproterenol **(A)** and norepinephrine (NE) **(B)** on steady-state arterial lidocaine concentrations in the rhesus monkey. The pressors were administered during the period indicated by the *shaded bar.* The *dashed lines* show the steady-state concentration expected in the absence of pressors. (Reprinted with permission from Benowitz NL, Forsyth RP, Melmon KL *et al*: Lidocaine disposition kinetics in monkey and man: II. Effects of hemorrhage and sympathomimetic drug administration. Clin Pharmacol Ther 16:99, 1974.)

Low-extraction drugs such as diazepam, alfentanil, or mepivacaine have ERs of 0.3 or less. These drugs behave quite differently because hepatic enzyme activity is rate limiting (hepatic clearance is limited by intrinsic clearance). Stimulation or inhibition of enzyme activity can have a large effect on overall pharmacokinetics. Protein binding is also more likely to affect clearance because the bound forms of these drugs are protected from hepatic metabolism. The most common reason for increased intrinsic clearance is enzyme induction. Many drugs of importance in anesthesiology are metabolized by the cytochrome P450 enzymes (so-called microsomal or CYP enzymes). Several families and numerous subfamilies of these enzymes have been identified based on the homology of their amino acid sequences. The most important subfamily appears to be CYP3A, which is found in greatest abundance in human liver and is responsible for the metabolism of a huge number of drugs. Other subfamilies play important roles in drug metabolism, such as CYP2C19 (diazepam) or CYP2E1 (defluorination of volatile anesthetics). There are hundreds of drugs and environmental toxins that can stimulate or "induce" microsomal enzymes. Typically, a single inducer can affect the products of several gene families. For example, phenobarbital can increase the amount of the P450 enzymes CYP2B, 2C, 2E, 3A, and 4B.[39] An increase in the quantity of enzyme protein can therefore increase the clearance of many drugs simultaneously. However, not all inducers affect the same enzymes.

Treatment with an enzyme inducer (Table 50-1) can make an otherwise stable drug regimen ineffective or inconsistently effective:

TABLE 50-1 Drugs that Induce or Inhibit Hepatic Drug Metabolism in Humans

·INDUCERS	·INHIBITORS
Phenobarbital	Cimetidine
Phenytoin	Ketoconazole
Rifampicin	Erythromycin
Carbamazepine	Disulfiram
Ethanol	Ritonavir

- A classic example is the interaction between phenobarbital and coumarin-type anticoagulants (Fig. 50-2). Increased metabolism may also result in the production of an active or toxic metabolite.
- In rat microsomal preparations, the liberation of inorganic fluoride by isoflurane, methoxyflurane, and enflurane can be increased by pretreatment with barbiturates,[40] but this interaction appears to be clinically

  important only for methoxyflurane.[41] In humans, phenobarbital does not induce defluorination of enflurane.
- Reductive pathways also involve P450 enzymes, and the production of toxic reduced intermediates has been postulated as a mechanism for "halothane hepatitis." In animal models, administration of halothane after enzyme inducers can lead to centrilobular necrosis.[42] The clinical relevance of this finding is unknown.

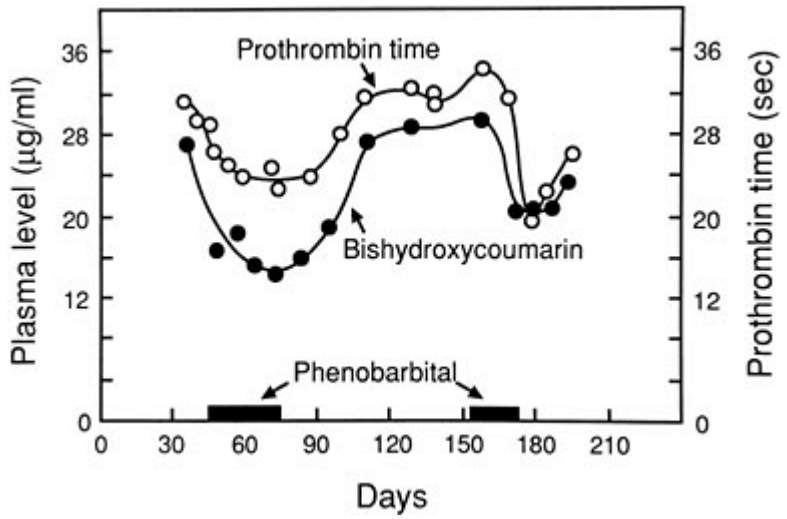

FIGURE 50-2. Effect of phenobarbital on plasma levels of bishydroxycoumarin. The anticoagulant was given at a dose of 75 mg/day. Phenobarbital, 65 mg/day, was given during the periods indicated on the *x*-axis. Induction of hepatic enzymes decreased anticoagulant concentrations and reduced the effect. (Reprinted with permission from Cucinell SA, Conney

AH, Sansur M *et al:* Drug interactions in man: I. Lowering effect of phenobarbital on plasma levels of bishydroxy coumarin [dicumarol] and diphenylhydantoin [Dilantin]. Clin Pharmacol Ther 6:420, 1965.)

There are many examples of drugs that inhibit the hepatic biotransformation of other drugs (see Table 50-1):

- When two drugs are substrates for the same P450 enzymes, they can interact competitively and reduce the clearance of both. For example, it has been demonstrated that midazolam and fentanyl are competitive inhibitors in vitro of metabolism by CYP3A4.[43] This pharmacokinetic interaction is probably far less important than the pharmacodynamic interaction between these drugs (described later).
- Another study concluded that propofol competitively inhibits CYP3A4, and it can reduce the clearance of midazolam by 37%.[44] Propofol itself appears to be metabolized by a different isoform, CYP2B6.[45]
- Alfentanil and erythromycin are both metabolized by CYP3A4, and the antibiotic greatly prolongs the effect of the opioid.[46] Sufentanil and fentanyl are also metabolized by CYP3A4,[47] but the clearance of sufentanil is not changed by erythromycin.[48] Perhaps this is because it is a high-clearance opioid.
- Cimetidine has an imidazole group that binds to the heme iron of cytochrome P450 and forms an inactive complex. Cimetidine inhibits the metabolism of many drugs, including warfarin, diazepam, phenytoin, and morphine. Several studies have demonstrated that coadministration

of cimetidine and diazepam causes clinically significant elevations in the concentration of both diazepam and its active metabolite.[49] As stated previously, cimetidine can decrease hepatic blood flow, so it can also decrease the clearance of high-extraction drugs.[38]

- Protease inhibitors such as saquinavir[50] and ritonavir[51] can inhibit the metabolism of midazolam and fentanyl, respectively, by inhibiting CYP3A4.
- Other imidazole drugs such as the antifungals, ketoconazole and itraconazole, can inhibit a wide variety of microsomal enzymes. They have been shown to decrease the clearance (and increase the toxicity) of glyburide, terfenadine, digoxin, midazolam, theophylline, and warfarin.
- The related benzimidazole, etomidate, blocks the synthesis of cortisol and aldosterone by inhibiting the P450-dependent mitochondrial enzymes, 17α-hydroxylase and 11β-hydroxylase.[52] Etomidate can inhibit the metabolism of other drugs, but the effects do not appear to be clinically important.

Drug Elimination

The final category of pharmacokinetic interaction is through alteration in drug elimination. These interactions usually involve altered renal clearance, but they may also involve changes in pulmonary excretion.

The mechanism for ion trapping was discussed earlier. Ion trapping can be the basis for large changes in renal drug excretion when the pK_a of the drug is close to the normal range of urine pH:

- A weak acid such as phenobarbital (pK_a = 7.4) is largely nonionized when the urine pH is

6.0. This means that much of the filtered drug is in a relatively lipid-soluble form and available for tubular reabsorption. If the urine pH is raised to 8 or 9 (e.g., with sodium bicarbonate), most of the phenobarbital becomes ionized, reabsorption decreases, and clearance increases. For a weak base, the reverse situation is true—excretion can be promoted when the urine is acidified. This type of interaction is used therapeutically in certain cases of drug overdose.

Organic anions and cations are actively secreted by separate transporters in the renal tubule. The cation system handles the elimination of atropine, isoproterenol, neostigmine, and meperidine. The anion system is involved in the excretion of salicylate, penicillins, cephalosporins, and most of the potent diuretics. The various anions and cations can compete for their respective transport sites:

- Probenecid inhibits the secretion of penicillin, increasing plasma concentrations and prolonging the duration of action.
- Quinidine has been shown to decrease both the volume of distribution and the renal clearance of digoxin, and plasma digoxin concentrations may increase by two- to fivefold.[53] The renal effect is believed to be due to a reduction in tubular secretion of digoxin.

PHARMACODYNAMIC INTERACTIONS

Up to this point, we have been discussing pharmacokinetic interactions that change the amount of active drug reaching receptor sites. A *pharmacodynamic* interaction occurs when one drug alters the sensitivity of a target receptor or tissue to the effects of a second drug. This means that the dose-response or concentration-response curve for one drug is shifted by another (Fig. 50-3). It is often difficult to assign a specific mechanism to these interactions. We commonly classify them by their direction and intensity, that is, additive, antagonistic, or supra-additive (synergistic).

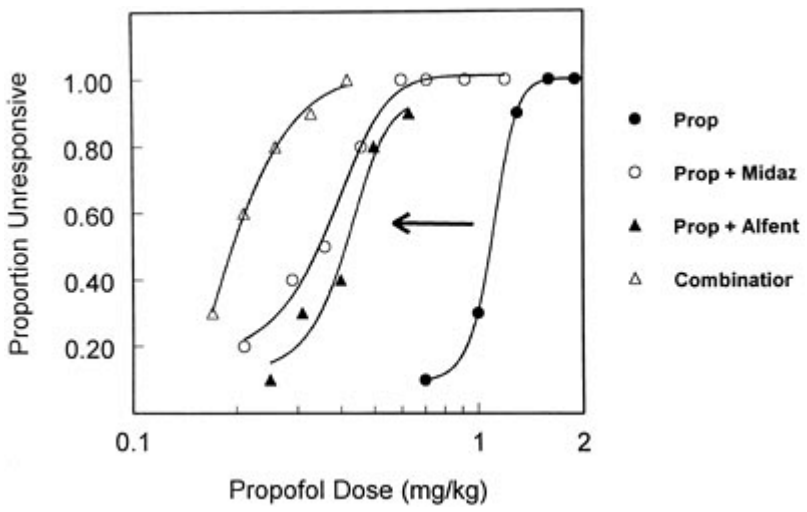

FIGURE 50-3. Dose-response curves for loss of consciousness after an intravenous bolus dose of propofol (Prop) alone, propofol plus midazolam (Midaz), propofol plus alfentanil (Alfent), or all three drugs. Drug combinations were given as constant ratios, based on the measured ED_{50}s of the individual drugs. Both the benzodiazepine and the opioid shifted the dose-response curve for propofol significantly to the left. (Redrawn, with permission, from data in Short TG, Plummer JL, Chui PT: Hypnotic and anaesthetic interactions between midazolam, propofol and alfentanil. Br J Anaesth 69:162, 1992.)

5 *Additive interactions* are most likely to occur when drugs with identical mechanisms are combined. The clinician normally expects additivity when combining two benzodiazepines, two fentanyl analogs, or two volatile anesthetics. Most additive interactions tend not to be particularly surprising, although some are clinically useful:

- The administration of two aminosteroid nondepolarizing muscle relaxants, such as rocuronium and vecuronium, gives an additive effect[54] (Fig. 50-4). Notably, the

  interactions between nondepolarizing relaxants of different chemical classes are often synergistic (see later).
- The interaction of two volatile anesthetics or nitrous oxide with volatile anesthetics is additive.[55,56,57]
- In animals, mixtures of lidocaine-tetracaine or lidocaine-etidocaine produce approximately additive CNS toxicity when given intravenously.[58]

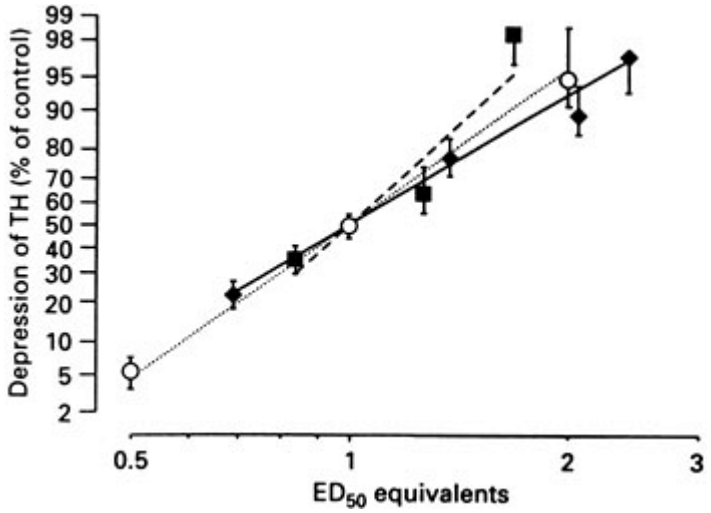

FIGURE 50-4. The interaction of rocuronium and vecuronium is additive in man. Log dose-probit graph plots twitch height (TH) as percentage of control value. Dose is given in terms of ED_{50} multiples. *Dark diamonds, dark squares*, and *open circles* represent rocuronium, vecuronium, and the combination, respectively. The dose–response curve for the combination cannot be distinguished from those of the individual drugs. (Reprinted with permission from Naguib M, Samarkandi AH, Bakhamees HS *et al:* Comparative potency of steroidal neuromuscular blocking drugs and isobolographic analysis of the interaction. Br J Anaesth 75:37, 1995.)

6 The most common *antagonistic drug interactions* in anesthesia are those involving deliberate reversal of effect with competitive antagonists such as neostigmine, naloxone, or flumazenil. Pharmacodynamic antagonism that is *unintended* is a much less common event:

- An antagonistic interaction occurs between succinylcholine and the nondepolarizing relaxants.[59]
- When epidural morphine or fentanyl is administered after establishing a block with 2-chloroprocaine, both the duration and the intensity of opioid analgesia are decreased.[60] The mechanism for this interaction is unclear.
- When butorphanol is combined with midazolam, the mixture increases sedation but has less anterograde amnestic effect than midazolam alone (Fig. 50-5). This illustrates the important concept that a drug combination may simultaneously be synergistic and antagonistic for different effects. In the case of the amnestic effect, butorphanol may simply be diluting the effects of midazolam.[61]

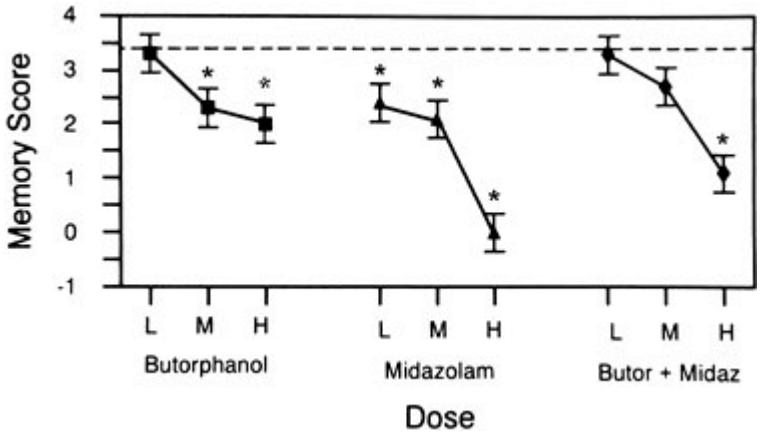

FIGURE 50-5. Memory scores of patients 5 minutes after receiving butorphanol, midazolam, or the combination. L, M, and H signify low, medium, and high doses (7.1, 22.5, and 71.4 µg/kg butorphanol; 4.3, 13.6, and 42.9 µg/kg midazolam; or 3.6 + 2.2, 11.3 + 6.8, and 35.7 + 21.5 µg/kg butorphanol and midazolam in combination). The *dashed line* indicates mean pretreatment value. Midazolam, but not butorphanol, produced a profound anterograde amnestic effect. Giving one-half the dose of each drug in combination produced an effect that was less than that after midazolam alone. (Reprinted with permission from Dershwitz M, Rosow CE, DiBiase PM *et al:* A comparison of the sedative effects of butorphanol and midazolam. Anesthesiology 74:717, 1991.)

7 The most interesting and clinically important interactions tend to be the *synergistic interactions*, in which small doses of two or more drugs can sometimes produce large effects. Synergy is most likely to occur when drugs of different classes, or even those with slightly different mechanisms, are used to produce the same effects:

- The potentiation of opioids by NSAIDs is a classic and useful interaction between analgesic drugs with completely different mechanisms.[62]
- The potentiation of nondepolarizing relaxants by the various volatile anesthetics is a useful interaction on a daily basis. The exact mechanism is unknown, but several theories have been proposed, including increased blood flow to muscle, depression of centrally mediated muscle tone, decreased neurotransmitter release, and decreased sensitivity of postjunctional or muscle membranes.
- A much more subtle supra-additive interaction occurs between aminosteroid and benzylisoquinolines. Pancuronium and *d*-tubocurarine were shown to produce a synergistic relaxant effect in combination,[63] and this is also seen with similar combinations across these two chemical classes (atracurium and vecuronium, *d*-tubocurarine and vecuronium, mivacurium and rocuronium). Various mechanisms have been proposed, including multiple binding sites[64] (presynaptic for aminosteroid versus postsynaptic for benzylisoquinolines) and allosteric interactions between separate agonist and antagonist binding sites.[65]
- Sedatives and hypnotics with related (but not identical) mechanisms of action usually interact synergistically to produce greater CNS depression. This is discussed in more detail later in this chapter.

STUDYING DRUG INTERACTIONS

As already discussed, a study that demonstrates that a drug–drug interaction exists does not necessarily establish its mechanism, its magnitude, or its clinical relevance. What information is needed to conclude that an interaction is pharmacodynamic rather than pharmacokinetic? How do we know it is really synergistic? Let us consider four clinical experiments to study the interaction of midazolam and thiopental. Given the different mechanisms for these two drugs, we might predict a synergistic interaction: benzodiazepines increase neuronal chloride conductance by facilitating GABA action, whereas barbiturates bind to a separate site and affect the chloride channel more directly:

1. In the simplest study design, two groups of patients are randomly assigned to receive midazolam-thiopental or placebo-thiopental. The percentage that becomes unresponsive in each group is assessed at a standard time after thiopental administration. The data show that midazolam increases the percentage unresponsive.

   Such a study is severely limited: it tells us that an interaction has occurred, but the results cannot be generalized beyond the conditions examined (a single dose of midazolam, a single dose of thiopental). Nothing may be inferred about mechanism.

2. A more complex (but more useful) experiment would be to study a thiopental dose-response curve in the presence and absence of midazolam. This would show that the dose of thiopental required to produce hypnosis in half the patients (ED_{50}) is decreased by midazolam.

   These results allow us to conclude that the interaction occurs over a range of thiopental doses relevant to clinical practice. The data still apply only to a single dose of midazolam, and they tell us nothing about the mechanism of the interaction.

3. A useful modification of this experiment is to administer the thiopental by a constant-rate infusion (with or without midazolam) and measure its concentration over time. The data show that concentrations of thiopental rise at the same rate in both groups, but midazolam decreases the concentration needed to produce hypnosis in 50% of the patients (the EC_{50}).

   This tells us that midazolam has not changed the pharmacokinetics of thiopental, so the interaction must have a pharmacodynamic mechanism.

4. Finally, there are a number of experimental designs for demonstrating synergy, and these have been reviewed

   in the clinical literature.[66] Two of the most common techniques used by experimental pharmacologists are algebraic (fractional)[67] and isobolographic[68,69] analysis, and clinical anesthesia studies using these methods have been appearing frequently. The interaction of thiopental and midazolam was studied with an isobolographic technique, and the results are shown in Fig. 50-6.[70] In general, this analysis requires a minimum of *three* dose-response experiments, one with each drug alone and one with the drugs in combination. The drug combination can be studied as a fixed ratio, or one of the drugs can be given at a fixed dose and the dose of the second drug varied. From these experiments, three estimates of ED_{50} are made, and an isobologram is constructed as shown in Fig. 50-6. The ED_{50}s for thiopental and midazolam alone are graphed on the two axes, and these points are connected by the theoretic "line of additivity." If the two drugs are simply additive when combined, we would expect the ED_{50} of the mixture to fall somewhere along this line. Because the actual ED_{50} of the mixture is significantly less than predicted by this line, the interaction is synergistic (an ED_{50} greater than predicted would signify antagonism).

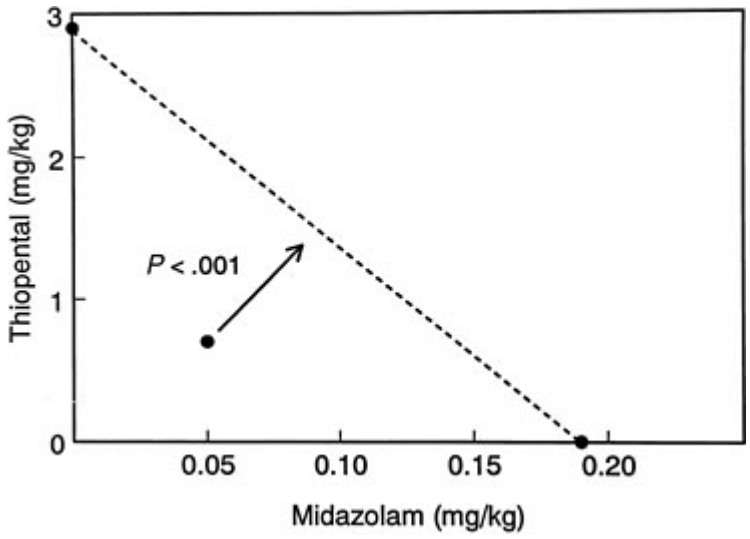

FIGURE 50-6. Isobolographic analysis of the interaction between midazolam and thiopental in humans (see text for details). The ED_{50} of the combination was significantly less than predicted by the dotted "line of additivity." (Redrawn from data of Tverskoy M, Fleyshman G, Bradley EL Jr, Kissin I: Midazolam-thiopental anesthetic interaction in patients. Anesth Analg 67:342, 1988, with permission.)

PHARMACODYNAMIC INTERACTIONS AFFECTING HEMODYNAMICS

The treatment of hypertension, angina, dysrhythmias, and congestive heart failure involves the use of drugs with powerful effects on autonomic function and cardiovascular homeostasis. Until the 1970s, the teaching was generally that cardiovascular depressant or stimulant medications should be discontinued before surgery because they interfered with protective responses to the trauma of anesthesia and surgery. Some older antihypertensives like reserpine and α-methyl dopa altered the depth of anesthesia, and this was believed to be undesirable. There is now a substantial body of evidence showing that most cardiovascular medications need not and should not be stopped before surgery. Hypertensive patients who remain well controlled are less likely to have wide swings in pressure during surgery. Even small doses of beta-blockers given before surgery can reduce the incidence of myocardial ischemia and improve outcome.[71,72] One week of perioperative treatment with atenolol can produce long-term benefits.[73,74] Conversely, the abrupt discontinuation of vasoactive medications can actually increase cardiovascular instability, and in the case of beta-blockers and clonidine, the rebound hypertension and dysrhythmias may be dangerous.

8 Given the foregoing observations, it is fortunate that most cardiovascular drug–drug interactions are simply extensions of the known pharmacology of the agents (Table 50-2). In short, the hypotensive effects of general or regional anesthesia may be increased by all antihypertensive medications. Using similar logic, antidysrhythmic drugs such as amiodarone or procainamide increase the possibility of bradycardia, hypotension, and decreased cardiac output.

TABLE 50-2 Effects of Antihypertensive Drugs during Anesthesia

·CLASS	·DRUGS	·CLASS EFFECTS

Alpha-blockers	Phenoxybenzamine Phentolamine Prazosin	Hypotension/vasodilation Reflex tachycardia
Beta-blockers	Propranolol Metoprolol Atenolol	Hypotension Decreased contractility Bradycardia AV block
Mixed alpha-/beta-blocker	Labetalol	Hypotension/vasodilation Bradycardia AV block
Calcium channel blockers	Verapamil Diltiazem Nifedipine Nicardipine	Hypotension/vasodilation Decreased contractility Bradycardia AV block
Direct vasodilators	Nitroglycerin Isosorbide Hydralazine	Hypotension/vasodilation Reflex tachycardia
Angiotensin-converting enzyme inhibitors	Captopril Enalapril Lisinopril	Hypotension/vasodilation Hyperkalemia
Angiotensin II blocker	Losartan Valsartan	Hypotension/vasodilation Hyperkalemia
Diuretics	Thiazides Furosemide Bumetanide	Hypovolemia Hypokalemia Possible vasodilation

AV, atrioventricular.

With few exceptions, there is little reason to withhold most vasoactive medications before surgery. It may be prudent to stop diuretic treatment before procedures with large anticipated fluid requirements or significant use of nephrotoxic antibiotics. Some studies suggest that continuation of the angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) leads to a high incidence of severe, sometimes refractory hypotension during induction of general anesthesia.[75,76] These drugs decrease afterload, and they also potentiate anesthetic-induced reduction in preload. The effect on preload may be quite important in hypertensive patients who have preexisting diastolic dysfunction.

Like the baroreceptor reflexes, the renin-angiotensin system is an important way the body can respond to hypovolemia or hypotension. Within minutes after a pressure decrease is sensed by the juxtaglomerular apparatus, angiotensin II causes vasoconstriction by both central and peripheral

actions. Chronic blockade of this system not only inhibits the angiotensin response, but it also reduces the vasoconstrictor response to norepinephrine.[77] This may explain why ACEI-induced and ARB-induced hypotension can be so resistant to sympathetic drugs such as phenylephrine, ephedrine, and norepinephrine.[78] Vasopressin and various vasopressin analogs can restore sympathetic response[79] and may be useful pressors in cases of refractory hypotension.

There is currently no consensus on the preoperative management of patients taking ACEI or ARB. Withholding them for 24 hours may decrease hypotension but also make blood pressure extremely labile during surgery. Some have found them to be beneficial during surgery.[80] The considerations are probably different for patients receiving ACEIs for chronic congestive heart failure. ACEIs are given to these patients for afterload reduction; they improve baroreceptor sensitivity, reduce ventricular remodeling, and decrease the mortality rate. Perioperative use of ACEIs in this population may not increase the already high incidence of hypotension during induction.[81]

Most perioperative hemodynamic interactions involve the use of cardiovascular depressants. It is also useful to consider several groups of patients who are treated (or who "self-treat") before surgery with cardiovascular *stimulants*:

1. Patients with bronchospasm may require treatment with rapid-acting β_2 agonists (albuterol, terbutaline), anticholinergics (ipratropium), or phosphodiesterase inhibitors (theophylline). These patients are at increased risk for tachydysrhythmias and ectopic rhythms. Similar considerations apply to the patient receiving the intravenous β_2 agonist, ritodrine, for premature labor.
2. Patients who receive TCAs such as imipramine, desipramine, amitriptyline, and nortriptyline present several possible scenarios for adverse drug interaction. These drugs work by blocking presynaptic reuptake of

   norepinephrine or serotonin, so they can theoretically increase the effects of direct-acting or indirect-acting agonists at these synapses. Most TCAs also have prominent anticholinergic effects. In overdose situations, TCAs can create the entire range of cardiovascular toxicity, including myocardial infarction and sudden death. In spite of this, hypotension and tachydysrhythmias are not common intraoperative problems for patients taking these older antidepressants. It is still reasonable to minimize the use of pancuronium, halothane, ketamine, and other agents with the potential to increase the incidence of dysrhythmias. If TCA-induced hypotension occurs, there is disagreement about the best way to treat it.[82] One case report[83] describes a patient on chronic nifedipine and nortriptyline therapy who had hypotension that was resistant to ephedrine, phenylephrine, and dopamine (norepinephrine was eventually successful).
3. Finally, we must all be prepared to treat patients who are acutely or chronically intoxicated with cocaine. In addition to its local anesthetic properties, cocaine decreases norepinephrine reuptake, like TCAs. Acute intoxication presents a particular challenge. Young, otherwise healthy people may present with fulminant hypertension, tachycardia, and myocardial ischemia (the latter may be severe because cocaine can also induce a thrombotic diathesis). Management of the acute cardiovascular effects is similar to that for pheochromocytoma: these patients need both vasodilators and beta-blockers. A beta-blocker should not be given alone because unopposed α-adrenergic stimulation can cause a further increase in systemic vascular resistance. Patients with chronic cocaine intoxication are less of a problem, but they are still at risk for dysrhythmias (avoiding halothane, pancuronium, atropine, and sympathomimetics still seems like a good idea). Chronic cocaine exposure increases halothane minimum alveolar concentration (MAC) in dogs[84] and isoflurane MAC in sheep,[85] but it may increase the sedative effects of benzodiazepines in humans.[86] This is an interesting contrast to chronic treatment with amphetamine, which appears to decrease MAC in dogs.[87] It might be believed that the adrenergic overactivity induced by cocaine would produce receptor downregulation over time, but several animal studies suggest that chronic cocaine treatment does not decrease brain catecholamine content or sympathetic

responsiveness.[88,89] The relevance of these data to human cardiovascular responses remains to be proven.

PHARMACODYNAMIC INTERACTIONS AFFECTING ANALGESIA OR HYPNOSIS

Combinations of CNS depressants almost always produce additive or synergistic increases in CNS effect. These interactions are usually useful and predictable. All the common intravenous and inhaled anesthetic agents have been tested in combination in humans. The following sections highlight some of the most important interactions.

Opioid–Hypnotic Interactions

This is arguably the most commonly used synergistic combination in intravenous anesthesia:

- Fentanyl and alfentanil have been shown to reduce the requirement for barbiturates, and there is some evidence that the interaction is beneficial. Reducing the total dose of thiopental[90] or thiamylal[91] during short procedures decreases the time to awakening and orientation.

- Opioids also potentiate propofol, but it has been much more difficult to show that the combination improves recovery compared with propofol alone. Short et al[92] found that a small dose of alfentanil can reduce the induction dose of propofol by 50% (see Fig. 50-3). During total intravenous anesthesia, infusions of remifentanil or alfentanil tremendously reduce the infusion rate of propofol needed to suppress response to voice and movement responses to surgical stimuli.[93,94] Target effect-site concentrations of only 1 to 2 µg/mL of propofol produce adequate anesthesia in many cases. These are routinely achieved with propofol doses used for conscious sedation (25 to 50 µg/kg per minute).

Opioid–Benzodiazepine Interactions

This important interaction was alluded to earlier, and it illustrates why opioids are so commonly used in combination with diazepam or midazolam. Opioids are highly selective CNS depressants; they can produce sedation, but they are relatively weak hypnotics. Even huge doses of fentanyl and its congeners do not dependably produce sleep by themselves.[95] For example, alfentanil doses as high as 100 to 200 µg/kg cannot always induce unconsciousness in unpremedicated patients.[96] Such opioid doses uniformly produce apnea, rigidity, and profound analgesia.

Kissin and coworkers[97] found, however, that a tiny dose of alfentanil (3 µg/kg) is sufficient to reduce the hypnotic ED_{50} of midazolam by 50%. This dose is subanalgesic and subhypnotic when given alone. This means that a small dose of opioid (50 µg fentanyl, 500 µg alfentanil) may have almost no hypnotic effect by itself, but can still be an extremely effective potentiator of other hypnotics. It also means that when fentanyl and midazolam are combined for conscious sedation, the opioid is producing sleep as well as analgesia.

Benzodiazepine–Hypnotic Interactions

The theoretical basis for the interaction between barbiturates and benzodiazepines was discussed earlier, and the thiopental–midazolam interaction is shown in Fig. 50-6.

- Thiopental–midazolam interaction has been studied in humans, and the combination was found to have 1.8 times the expected potency of the individual agents.[70,98] Similar results have been described with the combination of midazolam and methohexital.[99]
- Propofol also acts by modulation of GABA neurotransmission, and its hypnotic effects are

potentiated when it is combined with midazolam.[92]

The clinical benefits of benzodiazepine premedication are most obvious during the preoperative period. Intraoperative benefits (i.e., increased efficacy or reduced toxicity) of benzodiazepine–hypnotic combinations have not been demonstrated. The patient premedicated with midazolam needs less thiopental or propofol for induction (or maintenance), but it has not been established that this results in a smoother anesthetic or more rapid awakening.

Volatile Anesthetic–Opioid Interactions

Opioids produce dose-dependent and concentration-dependent decreases in MAC for all the inhalation anesthetics:

- A steady-state plasma fentanyl concentration of 1.67 ng/mL decreases human isoflurane MAC by 50%[100] (Fig. 50-7).
- Opioid partial agonists such as nalbuphine and butorphanol produce smaller reductions in MAC.[101]
- Animal data consistently show that an approximately 70% reduction in MAC is the maximum effect obtainable with a full agonist like fentanyl.[102] The mechanism for this interaction is unknown, but Licina et al[103] showed that administration of lumbar intrathecal morphine (15 µg/kg) does not alter halothane MAC in humans. This suggests that the effect may be due to supraspinal opioid actions. These findings are particularly interesting in view of the work by Rampil et al[104] who showed that MAC in the rat is not altered when the cerebral cortex and all other precollicular brain structures are removed. MAC therefore appears to reflect an action of the volatile anesthetics on the spinal cord, whereas MAC reduction by opioids is most likely to be mediated by structures in the brainstem or higher. One possible site for interaction is the locus coeruleus.

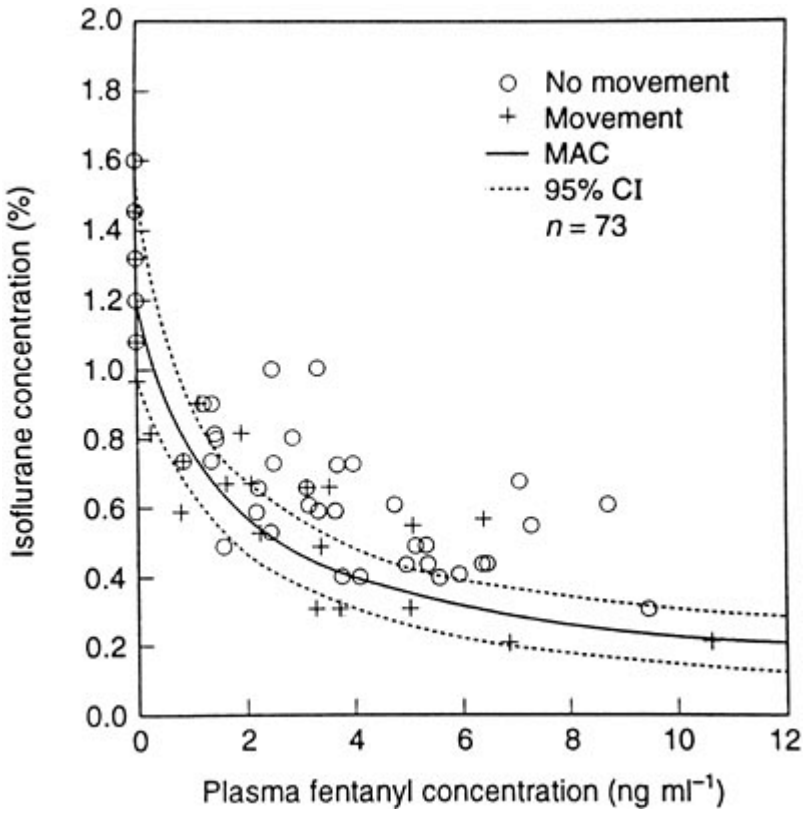

FIGURE 50-7. The interaction between fentanyl and isoflurane. The *solid line* represents the

concentration of the two drugs that prevents movement in 50% of patients. MAC, minimum alveolar concentration; CI, confidence interval. (Reprinted with permission from McEwan AI, Smith C, Dyar O *et al*: Isoflurane minimum alveolar concentration reduction by fentanyl. Anesthesiology 78:864, 1993.)

Opioids and volatile agents are often combined to smooth the intraoperative and postoperative course. In some patients, the combination of opioid and volatile agent is hemodynamically better tolerated than the volatile agent alone. Addition of an opioid may also reduce the incidence of emergence delirium.

Is there any evidence that the combination speeds awakening? Reduction of MAC clearly leads to lower end-tidal concentrations at the end of surgery. Faster emergence occurs only if the concentration of inhaled agent that produces hypnosis (i.e., "MAC awake," the concentration at which 50% of subjects respond to voice) is not reduced by a comparable amount. A few data indicate that MAC awake is not decreased by opioids, suggesting that the combination improves recovery.[105,106]

There have been no studies specifically designed to test this hypothesis.

Other intravenous agents such as lidocaine,[107] midazolam,[108] and α_2 agonists have been shown to decrease MAC in experimental animals. For lidocaine and midazolam, the plasma concentrations required to produce a meaningful decrease in MAC are so high that the interaction is unlikely to have clinical utility. There is some evidence that the simultaneous use of volatile anesthetics and benzodiazepines causes increased cortical binding of the latter.[109]

α_2-AGONIST INTERACTIONS

It has long been known that drugs that depress CNS sympathetic function can produce sedation and potentiate anesthesia. Older antihypertensives such as reserpine and α-methyldopa can produce drowsiness and reduce halothane MAC.[110] The newer autonomic modulators—α_2 agonists such as clonidine or dexmedetomidine—are powerful sedatives and analgesics in humans.

- In animals, dexmedetomidine produces marked potentiation of opioid analgesia and benzodiazepine-induced hypnosis.[111]
- Dexmedetomidine also lowers halothane MAC by nearly 100% through a specific postsynaptic α_2 mechanism.[112]

Dexmedetomidine interacts with both presynaptic and postsynaptic α_2-adrenergic receptors to decrease central sympathetic tone. Its hypnotic effect is due largely to depression of function in the locus coeruleus (LC), the main adrenergic nucleus in the brain.[113] There is evidence to suggest that the LC is an important site for control of sleep, attention, memory, analgesia, and autonomic function.[114] The LC contains receptors for glutamate, GABA, acetylcholine, opioids, and benzodiazepines, and experimental evidence suggests that it may be the site for some important anesthetic drug effects and interactions:

1. The LC is the rostral portion of an important descending inhibitory pathway, which plays a part in the production of opioid analgesia.[115]
2. In the rat, destroying the LC produces a state of narcolepsy and decreases halothane MAC by 30 to 40%.[116]
3. Agonists at GABA, opioid, and α_2 receptors are all inhibitory when injected into the LC. These drugs all have sedative-hypnotic properties, and all of them lower the requirement for

volatile anesthetics.

4. Acetylcholine and glutamate receptor agonists are excitatory in the LC, and antagonists at these receptors (e.g., scopolamine, ketamine) are hypnotics. Some glutamate effects are mediated by NO, and inhibitors of neuronal NO synthase can decrease the requirement for halothane[117] and isoflurane.[118]

Three-Way Interactions

In clinical practice, it is common to combine more than two drugs with sedative-hypnotic effects. We have relatively little information on what happens when a third drug is added to two that already have synergistic effects:

- Short et al[92] performed a clinical study of hypnotic interactions among propofol, midazolam, and alfentanil (see Fig. 50-3). Propofol requirement was reduced by 82% with the three-way combination, but it produced less potentiation than would have been predicted by adding the effects of the two-way combinations.
- Vinik et al[119] studied the same combination and also found profound hypnotic synergism: the dose of propofol could be decreased by 86% in the presence of alfentanil and midazolam. The data also suggested that the interaction between midazolam and alfentanil was a marked potentiation, but the addition of propofol did not produce significant additional change. Figure 50-8 shows the data from this experiment analyzed with a three-way isobologram.
- A three-way interaction involving enflurane, dexmedetomidine, and fentanyl was investigated in dogs. Salmenpera et al[120] found that each of the two intravenous agents lowered enflurane MAC, and combining the three drugs produced a MAC reduction that was probably greater than predicted by simple additivity. In this case, the three-way combination produced more bradycardia than enflurane alone.

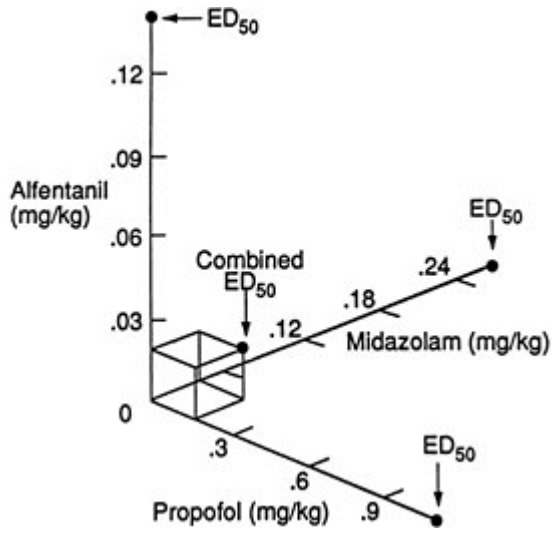

FIGURE 50-8. ED_{50} isobolograms for the three-way hypnotic interactions among midazolam, alfentanil, and propofol. The reader can imagine a triangular "plane of additivity" with its corners at the individual ED_{50} values. The ED_{50} for the triple combination was significantly lower than predicted by additivity. (Reprinted with permission from Vinik HR, Bradley EL Jr, Kissin I: Triple anesthetic combination: Propofol-midazolam-alfentanil. Anesth Analg 78:354, 1994.)

Herbal Preparations and Drug Interactions

Americans are increasingly using herbal, vitamin, and over-the-counter preparations in an attempt to treat various ailments. In 2003, over-the-counter sales of herbals and vitamins were approximately $62.9 billion, an 8% growth from 2002.[121] A survey of 3,842 patients during preoperative evaluations found that 22% used herbal medications and 51% used vitamins. The most likely patients to use these products were women ages 40 to 60 years.[122] Another survey of 1,017 patients found 32% used one or more herb-related compounds, and 70% did not report this information when asked during routine preanesthetic assessment.[123]

Herbal preparations are classified as dietary supplements in the Dietary Supplement Heath and Education Act of 1994.[124] By this act, herbal preparations are exempt from the safety and efficacy requirements and regulations that prescription and over-the-counter drugs must fulfill. Instead, the U.S. Food and Drug Administration (FDA) must prove lack of safety.[125] There is no regulatory oversight of the specific contents of the herbal preparations, and different batches or brands of the same herbal often do not contain equal amounts of the active compound.

The *Physicians' Desk Reference (PDR) for Herbal Medicines* is now in its third edition,[126] but there is still relatively little peer-reviewed literature addressing herbals and dietary supplements with specific reference to perioperative care. Among the thousands of herbal preparations available, only a few have been documented to cause problems either through intrinsic toxicity or through pharmacokinetic and pharmacodynamic interactions.[127,128,129] The herbals most commonly cited are echinacea, ephedra (ma huang), garlic, gingko, ginseng, kava, and St. John's wort. As Fugh-Berman noted, many of the papers on herbals contain significant errors and unsubstantiated conclusions.[130] Some commonly mentioned herbal-based interactions are listed in Table 50-3, along with an assessment of the strength of the evidence. We were unable to find clinical trials proving that there are specific adverse interactions between herbals and anesthetic drugs.

TABLE 50-3 Published Evidence for Herbal Toxicity

·NAME(S)	·COMMON USE	·CLAIMED TOXICITY[127,129,130,132]	·PUBLISHED EVIDENCE[a]
Ephedra Ma huang Ephedrine Chinese joint fir	Weight loss Antitussive Bacteriostatic	Halothane: arrhythmias MAOI: enhanced sympathetic effects Oxytocin: hypertension Stroke, hypertension, cardiac arrest	Intravenous ephedrine well characterized Inadequate data on specific interactions with oral ephedra. Oral ephedra known to cause adverse CNS and cardiac events[133]
Echinacea Purple cone flower	Common cold prevention Wounds and burns Urinary tract infections Coughs and bronchitis	Hepatotoxicity Decrease corticosteroid effect	No evidence of hepatotoxicity[130] Lab evidence of macrophage activation and enhanced natural killer cell activation[134,135]

Garlic Ajo	Lipid lowering Hypertension Antiplatelet, antioxidant	Potentiate warfarin	No evidence of interaction with warfarin[136] Decreased platelet aggregation in vitro[137,138,139,140,141,142]
Ginger	Nausea Antispasmodic	Inhibit thromboxane synthetase	In vitro evidence of thromboxane synthetase inhibition144, 145,146 No effect on platelet function with 2 g, but inhibition with 5 g[147],[148]
Ginkgo Maidenhair tree Fossil tree	Circulatory stimulant	Inhibit PAF	Case reports of increased bleeding in humans[149] In vitro evidence of PAF inhibition[150],[151]
Goldenseal Orange root Yellow root Ground raspberry Tumeric root Eye root	Diuretic Anti-inflammatory Laxative Hemostatic	Oxytocic Paralysis in overdose Edema Hypertension	No evidence
Kava Ava/ava pepper Kawa	Anxiolytic	Hepatotoxicity Potentiate barbiturates, benzodiazepines	Case reports of hepatotoxicity[152],[153] Clinical and animal studies demonstrating sedation and anxiolysis[154],[155]
Licorice Sweet root	Gastric/duodenal ulcer Gastritis Cough and bronchitis	Hypertension Hypokalemia Edema	Licorice abuse can cause hypokalemia Uncontrolled, studies show reductions in ADH, aldosterone, and plasma renin activity[156],[157]
St. John's wort Hardhay	Depression	Decreased digoxin level Enzyme induction	Clinical data show decreased digoxin level[158]

Amber Goat weed		Prolonged anesthesia	Clinical evidence for P-glycoprotein and CYP induction[158] Case reports of prolonged emergence, cardiovascular toxicity[159],[160]
Valerian All-heal Setwall Vandal root	Sedative Anxiolytic	Potentiate barbiturates	Small controlled clinical trial showed decreased sleep latency[161],[162]
Vitamin E	Antiaging Prevent stroke, pulmonary emboli Prevent atherosclerosis Promote wound healing	Increased bleeding Increased hypertension	Decreased platelet aggregation in vitro163,164,165 Small clinical trial shows reduction in platelet aggregation[166] No evidence for hypertension

ADH, antidiuretic hormone; CNS, central nervous system; MAOI, monamide oxidase inhibitors; PAF, platelet activating factor;

MODELS FOR THE FUTURE: DRUG INTERACTION DURING TOTAL INTRAVENOUS ANESTHESIA

Anesthesia must always be titrated to effect, but the clinician usually begins dosing each drug with some notion of a "normal" dose range and a reasonable incremental dose. As

additional drugs are added to the anesthetic, these doses need to be modified. Are there any reliable data to guide the administration of anesthetic drugs in combination? The answer for most routine balanced anesthetics is probably "no." As we have seen, almost all anesthetic drugs interact in a nonlinear, synergistic fashion, and the magnitude of the interaction depends on the specific doses of each agent. If the drugs are given by bolus injection or variable-rate infusion, the interaction changes constantly with time. Predicting anesthetic interaction, then, is like aiming at a moving target. Even a relatively simple anesthetic seems to require the analysis of an impossibly large number of potential variables.

In spite of the obstacles, there have been some attempts to apply quantitative models to total intravenous anesthesia (TIVA). The TIVA technique offers several advantages in this regard:

1. Anesthesia is often induced and maintained with only two drugs, a rapid-acting hypnotic (e.g., propofol) and a rapid-acting opioid (e.g., alfentanil, remifentanil). The pharmacokinetics and pharmacodynamics of these drugs are exceptionally well studied.

2. The drugs have pharmacokinetics well suited to administration by continuous infusion with microprocessor-driven pumps. During anesthesia, plasma concentrations of the drugs may be held relatively constant, so blood and brain attain pseudoequilibrium. The researcher may vary the infusion of each drug independently and relate stable plasma concentrations to clinical effects.

In a frequently cited study, Vuyk and colleagues[93] gave computer-controlled infusions of propofol and alfentanil to women undergoing lower abdominal surgery. First, the target concentration of alfentanil was held constant and propofol was varied; then, the reverse experiment was done. The onset of sleep and the time to awakening were measured, as was presence or absence of somatic and hemodynamic responses to laryngoscopy, intubation, incision, and opening of peritoneum. Arterial blood samples were collected, and the EC_{50} of alfentanil for each clinical end point was related to blood propofol concentration. As expected, the data showed that propofol potentiated the analgesic effects of alfentanil, and alfentanil potentiated the hypnotic effects of propofol. More importantly, the authors were able to relate various concentrations of each agent to a given end point.

The interest in these data lie in the way they can be used to model drug interactions.[131] In Fig. 50-9, Vuyk et al simulated the time to regain consciousness at different ratios of propofol and alfentanil. The graph is somewhat complex, but it is worth considering for a few moments. Vuyk and colleagues assume that a 180-minute anesthetic has been given with propofol and alfentanil targeted at various concentrations. Regardless of the ratio of the two drugs, the resulting anesthetic is sufficient to prevent the response to intraabdominal surgery in 50% of patients. The three-axis graph relates the concentrations of each drug to the time after discontinuation of the infusions. At time 0 (the floor of the graph), we see the steady-state concentrations just when the infusions are stopped. The disappearance of both drugs is shown, and the family of plasma decay curves (all possible combinations of propofol and alfentanil) is depicted on the graph surface. The curved line that crosses the time versus concentration surface identifies the time at which a patient has a 50% probability of awakening. The fastest emergence (10 minutes) occurs when propofol and alfentanil are targeted at concentrations of 3.5 µg/mL and 85 ng/mL, respectively. Emergence is significantly longer if the anesthetic is mostly propofol or mostly alfentanil.

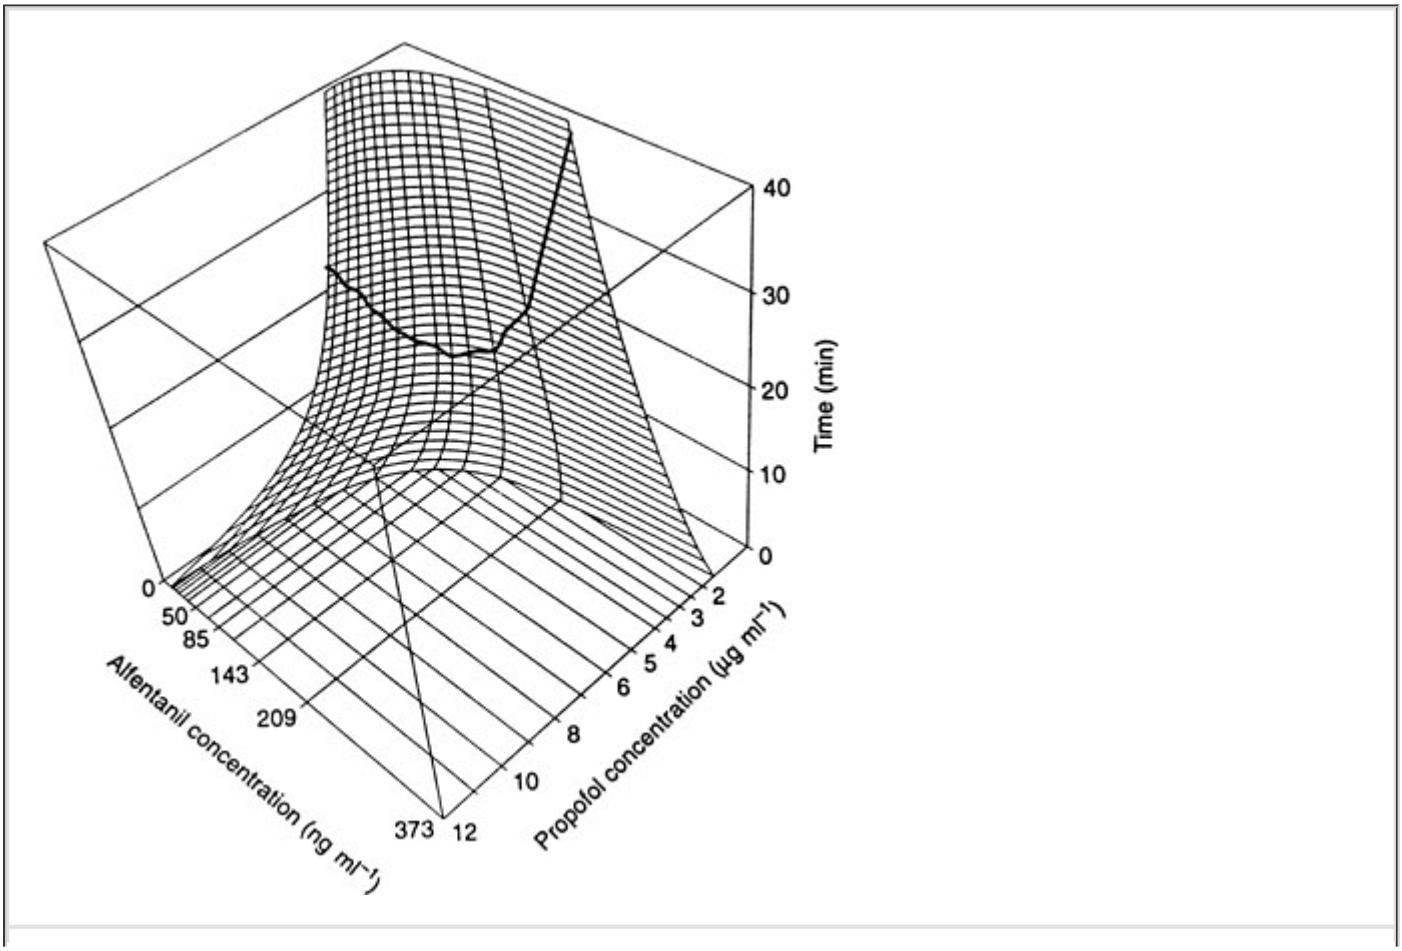

FIGURE 50-9. Computer simulation of the decay in blood propofol and plasma alfentanil concentrations during the first 40 minutes after the termination of a computer-controlled infusion (see text for details). (Reprinted with permission from Vuyk J, Lim T, Engbers FHM *et al*: The pharmacodynamic interaction of propofol and alfentanil during lower abdominal surgery in women. Anesthesiology 83:8, 1995.)

How will these data help anyone give an anesthetic? What if the infusion is much shorter or longer than 180 minutes? What if the patients are old and sick? What if the anesthesiologist does not have a computer or an infusion pump? The answer could be another set of questions: "What is the value of knowing that the MAC of halothane is 0.74 vol%, the induction dose of propofol is 2.5 mg/kg, or the analgesic dose of morphine is 0.1 mg/kg?" We all understand that the value of such numbers is to give us a frame of reference for titrating the agents. The value of Vuyk and colleagues' model is not as a "recipe" for a good intravenous anesthetic—it is a way to think about dosing guidelines for two or more drugs simultaneously. It is not farfetched to imagine that the FDA will someday require information on "optimal combinations" for each new pharmacologic agent.

Chapter 51

Anesthesia Provided at Alternate Sites

Karen J. Souter

KEY POINTS

1	Alternate sites are locations remote from the operating room.
2	The number of requests for anesthetic services in alternate sites is increasing.
3	A three-step approach is useful in considering an anesthetic at an alternate site: the patient, the procedure, and the environment.
4	The American Society of Anesthesiologists (ASA) has defined guidelines to be applied to the administration of anesthesia at nonoperating room locations.
5	Environmental considerations include hazards such as radiation and the side effects of contrast media.
6	Procedural considerations are both general (e.g., duration, position, and level of discomfort) and specific to individual specialties.
7	Patient considerations include whether the patient will tolerate sedation or require general anesthesia, the ASA grade, significant comorbidities, and the level of monitoring.
8	Patients should receive the same standard of care at an alternate site as they do in the operating room.
9	The anesthetic and monitoring equipment must meet the same standards as equipment provided in the operating room.
10	Following anesthesia at an alternate site, the patient should be transported to an appropriate postanesthesia care unit, accompanied and monitored by anesthesia personnel.

To better understand and develop a systematic approach to providing anesthesia at alternate sites, this chapter discusses the challenges facing the anesthesiologist regarding the procedures, the patients, and the environment. This chapter also describes the special considerations that apply to administering anesthesia at sites other than in the operating room. These sites may be located within a large hospital, such as in a radiology department or endoscopy suite, where the resources of the operating rooms are within the same facility, but are not close at hand. Or, they may include a stand-alone facility such as an office or dental clinic that is remote from the backup of a full surgical hospital. Only the former locations are considered in this section. Office-based anesthesia is described in Chapter 52.

GENERAL PRINCIPLES

In more recent years, the number of anesthetics being delivered to patients in areas other than the operating room has steadily increased. This is mainly due to the development of large, complex equipment for both diagnostic and therapeutic procedures that cannot be transported to the operating room. Standards introduced by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) require that the anesthesia service of a hospital participates with other departments in setting up a uniform quality of care for patients undergoing sedation in all parts of the hospital.[1,2]

Anesthesiologists undertake most of their training in the operating room, surrounded by familiar equipment and staff experienced in the care of the anesthetized patient. Away from the operating room, the anesthesiologist may not have this support. A simple three-step paradigm can be used to approach an anesthetic assignment in an alternate site (Fig. 51-1 and Table 51-1).

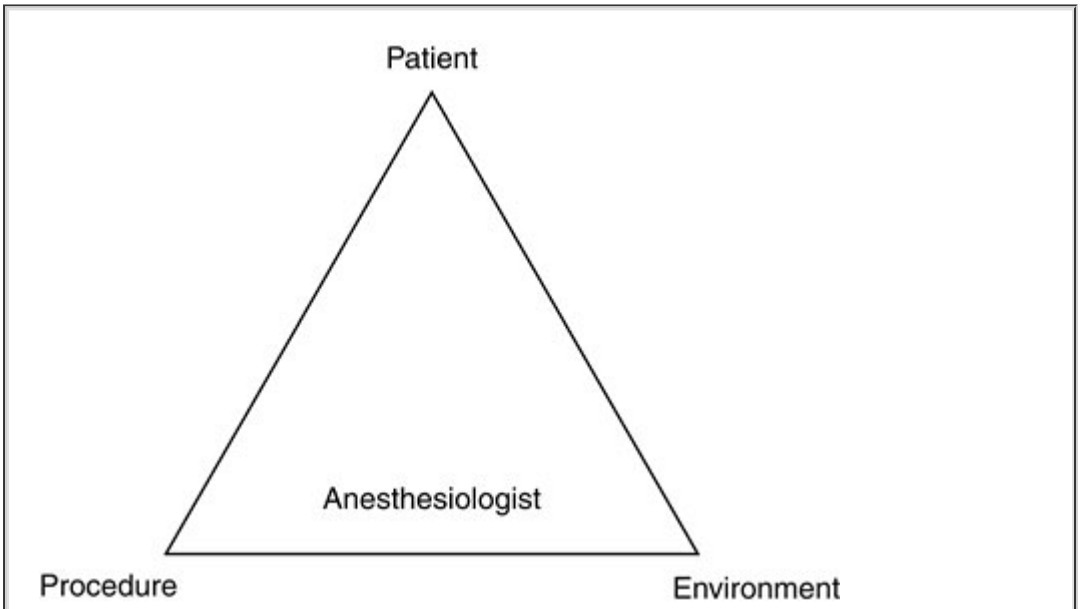

FIGURE 51-1. A three-step paradigm for anesthesia at alternate sites.

The Environment

The American Society of Anesthesiologists (ASA) has developed standards to apply to anesthesia in remote locations[3] (Table 51-2). Before commencing an anesthetic in an alternate site, it is vital to confirm the presence and proper functioning of all equipment an anesthesiologist would expect to have in the operating room. This equipment includes a central oxygen supply, spare oxygen cylinders, wall suction, overhead lighting, gas scavenging systems, and electrical outlets. Replacement batteries should be available for any equipment that is battery powered. The location of immediately available resuscitation equipment should be noted and plans formulated with the local staff for emergency resuscitation procedures, including cardiopulmonary

resuscitation and the management of anaphylaxis.

TABLE 51-1 A Three-Step Approach To Anesthesia At Alternate Sites

1. Environment	Anesthetic equipment Anesthesia monitors Suction Resuscitation equipment Personnel Technical equipment Radiation hazard Magnetic fields Ambient temperature Warming blankets
2. Procedure	Diagnostic or therapeutic Duration Level of discomfort/pain Position of patient Special requirements (e.g., functional monitoring) Potential complications Surgical support
3. Patient	Ability to tolerate sedation versus general anesthesia ASA grade and comorbidity Airway assessment Allergies—IV contrast Monitoring requirements—simple versus advanced

ASA, American Society of Anesthesiologists; IV, intravenous(ly).

TABLE 51-2 American Society of Anesthesiologists Guidelines for Nonoperating Room Anesthetizing Locations

1. Oxygen
    - Reliable source
    - Backup E cylinder—full
2. Suction
    - Adequate and reliable
3. Scavenging system if inhalational agents are administered
4. Anesthetic equipment
    - Backup self-inflating bag to deliver positive-pressure ventilation
    - Adequate anesthetic drugs and supplies
    - Anesthesia machine with equivalent function to those in the operating rooms and maintained to the same standards
    - Adequate monitoring equipment to allow adherence to the ASA Standards for

Basic Monitoring[9]

5. Electrical outlets
    - Sufficient for anesthesia machine and monitors
    - Isolated electrical power or ground fault circuit interrupters if "wet location"
6. Adequate illumination
    - Battery-operated backups
7. Sufficient space for
    - Personnel and equipment
    - Easy and expeditious access to patient, anesthesia machine, and monitoring
8. Resuscitation equipment immediately available
    - Defibrillator
    - Emergency drugs
    - Cardiopulmonary resuscitation equipment
9. Adequately trained staff to support anesthesia team
10. All building and safety codes and facility standards should be observed
11. Postanesthesia care facilities
    - Adequately trained staff to provide postanesthesia care
    - Appropriately equipment to allow safe transport to main postanesthesia care unit

From American Society of Anesthesiologist (ASA): Standards for postanesthesia care. In ASA Directory of members. Park Ridge, IL, ASA, 2003

Anesthesia Equipment and Monitors. In some alternate sites, anesthesia machines and monitors are provided; in others, it may be necessary to bring anesthesia equipment to the location. Both situations can present problems. Anesthesia machines and monitors that remain in an outside location need to be routinely serviced, as does anesthesia equipment used in the main operating rooms. This equipment is not often used on a daily basis; therefore, before using the equipment, it is vital to conduct a thorough check. For example, attention should be paid to the freshness of the soda lime and whether any pieces of equipment or monitors have been removed or misplaced. Monitoring equipment found in alternate sites is often used by the staff to monitor patients who are not being anesthetized. These monitors may be malfunctioning or different from monitors

used in the operating room. Anesthesiologists should be aware of these differences. If more advanced monitors (e.g., an arterial line, central venous pressure or intracranial pressure [ICP] monitoring) are required, these devices should be available to be brought to the alternate site. Small portable anesthesia machines and monitors are available that may be useful to bring into an outside location. A pre-prepared cart containing essential equipment that is checked and restocked after each case is recommended to eliminate the need for anesthesia personnel to move between locations to collect equipment that has been forgotten or that is urgently needed.

Technical Equipment. The complex technical equipment used in alternate sites, particularly in the radiology suites, is often bulky and fixed to the floor so the anesthesia team has to work around it. Ionizing radiation related to both imaging and therapeutic procedures is a hazard to both staff and patients. Magnetic resonance imaging (MRI) creates its own environmental concerns related to magnetic fields. In all these areas, the equipment is kept at low temperatures, and patients may easily develop hypothermia. Warming blankets should be available. Radiotherapy rooms are heavily shielded, and staff are excluded from the room during treatment, requiring the anesthesiology team to monitor patients remotely, often with surveillance cameras.[4]

Procedures

6 Common procedures carried out in alternate sites for which the patient may require anesthesia or sedation are listed in Table 51-3. It is vital for the anesthesiologist to understand the nature of the procedure, the position of the patient, how painful the procedure will be, and how long the procedure will last. This will allow the development of an anesthesia plan to provide safe patient care and facilitate the procedure. Discussions with physicians, dentists, and others performing interventional procedures must include contingencies for adverse outcomes.

TABLE 51-3 Common Procedures Requiring Anesthesia At Alternate Sites

Radiology

- Computed tomography
- Magnetic resonance imaging
- Interventional radiology (vascular and nonvascular)
- Interventional neuroradiology
- Functional brain imaging

Radiotherapy

- Radiation therapy
- Intraoperative radiotherapy
- Radiosurgery

Gastroenterology

- Upper gastroenterology endoscopy
- Endoscopic retrograde cholangiopancreatography
- Colonoscopy
- Liver biopsy
- Transjugular intrahepatic portosystemic shunt

Cardiology

- Cardiac catheterization
- Radiofrequency ablation
- Cardioversion
- Transesophageal echocardiography

Psychiatry

- Electroconvulsive therapy

Patients

7 Patients may require anesthesia at alternate sites for a number of reasons (Table 51-4). The patient may have been unable to tolerate the procedure without sedation or has failed with simple sedation administered by a nonanesthesiologist. Children represent a special group of patients who are more likely to require sedation or anesthesia for various diagnostic and therapeutic procedures. Another group is patients who are too ill to tolerate a major surgical procedure, but who may be able to undergo palliative, less invasive procedures at alternate sites.

These patients require a thorough preanesthetic assessment and often need invasive monitoring.

TABLE 51-4 Patient Factors Requiring Sedation or General Anesthesia At Alternate Sites

Anxiety and panic disorders
Claustrophobia
Developmental delay and learning difficulties
Cerebral palsy
Seizure disorders
Movement disorders
Severe pain
Acute trauma with unstable cardiovascular, respiratory, or neurologic function
Significant comorbidity
Child

ANESTHESIA CARE

8 The terms *anesthesia*, *sedation*, *conscious sedation*, and *deep sedation* are commonly used. They span a continuum that starts with a fully awake patient with a protected, patent airway and ends with general anesthesia and the need for interventions to protect and secure the airway. JCAHO defines *anesthesia care* as the administration of intravenous, intramuscular, or inhalational agents that may result in the loss of the patient's protective reflexes. Patients who receive anesthesia or sedation at alternate sites should expect the same standard of care that they would receive in the operating room. The ASA has published guidelines and standards of care, including those for preanesthesia and postanesthesia care, as well as monitored anesthesia care,[5,6,7] and definitions of general anesthesia and levels of sedation[8] (Table 51-5). A patient's level of sedation frequently varies during the course of a procedure, and it is important that individuals administering a given level of sedation are able to rescue the patient whose level becomes deeper than initially intended. The ASA basic standards of monitoring should be adhered to in any location where anesthesia or sedation is being performed.[9] Standard I requires a qualified anesthesia provider to be present in the room throughout the conduct of anesthesia.

9 Standard II calls for continual evaluation of the patient's oxygenation, ventilation, circulation, and temperature. The degree of invasive monitoring that should be used will depend on the patient's status and the procedure being undertaken.

TABLE 51-5 Definition of General Anesthesia and Levels of Sedation/Analgesia

	▪Minimal sedation "Anxiolysis"	▪Moderate sedation/analgesia "Conscious sedation"	▪Deep sedation/analgesia	▪General anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful response to verbal or tactile stimulation	Purposeful response following repeated or painful stimulation	Unarousable even with painful stimulus

Airway	Unaffected	No intervention required	Intervention may be required	Intervention required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

10 At the conclusion of the procedure, patients should recover from anesthesia or sedation in a postanesthesia care unit (PACU) or similar setting. Care should be supervised by personnel who are trained to take care of unconscious patients, and with appropriate monitoring and resuscitation equipment immediately at hand.

RADIOLOGY AND RADIATION THERAPY

Developments in technology have meant that interventional radiologists now perform an increasing number of procedures that were once in the domain of surgeons. Anesthesiologists are increasingly required to take care of patients undergoing both diagnostic and therapeutic interventional procedures. Two important aspects of the radiological environment are the side effects of contrast media, which are commonly used to enhance radiological images, and the hazards of ionizing radiation.

Intravenous Contrast Agents

Intravenous contrast agents are iodinated compounds used for many radiological procedures.[10] MRI contrast media are also now widely used; these agents are chelated metal complexes containing gadolinium, iron, and manganese.

Contrast media are eliminated via the kidneys, and contrast-induced nephropathy is a concern. This condition accounts for 10% of hospital-acquired renal failure[11] and is more likely to occur in patients with preexisting renal insufficiency, diabetes, and those taking nonsteroidal anti-inflammatory drugs.[12] Adequate hydration, careful monitoring of urine output, and the use of low-osmolarity contrast media[13] help reduce the risk of contrast-induced nephropathy. A randomized controlled trial has demonstrated the efficacy of sodium bicarbonate in preventing contrast-induced nephropathy when given by intravenous infusion 1 hour before contrast.[12] In procedures lasting several hours, a urinary catheter is recommended to monitor urine output and prevent restlessness due to a full bladder. Low-osmolarity, nonionic compounds with osmolarities ranging from 290 to 650 mOsm/kg have a lower incidence of adverse reactions compared with the older, high-osmolarity agents.[14,15] The overall incidence of adverse drug reactions with nonionic contrast media is reported as 3.13%, and the incidence of severe reactions is 0.04%.[15] These are shown in more detail in Table 51-6. Reactions are described as mild (e.g., urticaria, chills, fever, facial flushing, nausea, vomiting), moderate (e.g., edema, bronchospasm, hypotension seizures), and severe (e.g., dyspnea, prolonged hypotension, cardiac arrest, loss of consciousness, anaphylactic reactions). Patients with atopy or allergy to shellfish are more prone to contrast-related adverse reactions.[16] Pretreatment with oral methylprednisolone prior to intravenous administration of contrast medium[17] can reduce the incidence of adverse reactions. Treatment of severe reactions should include discontinuing the causative agent and supportive therapy, such as oxygen administration, securing the airway, and cardiovascular support with fluids, vasopressors, and

inotropes. Bronchospasm should be treated with appropriate bronchodilators. Adverse reactions to MRI contrast media are similar to those with other contrast media and have a similar incidence.[18] In some cases, there is cross-sensitivity between gadolinium-containing agents and iodinated ones.

TABLE 51-6 Incidence of Contrast-Related Adverse Reactions

▪IODINATED CONTRAST MEDIA		
▪HIGH-OSMOLARITY CONTRAST MEDIA (%)	**▪ADVERSE REACTIONS**	**▪LOW-OSMOLARITY CONTRAST MEDIA (%)**
6.0	Nausea and vomiting	1.0
3.0	Urticaria	0.5
2.6	Hoarseness, sneezing, cough, dyspnea, facial edema	0.5
0.1	Hypotension	0.01
▪MAGNETIC RESONANCE IMAGING CONTRAST MEDIA		
▪CONTRAST MEDIA	▪ADVERSE REACTIONS	▪INCIDENCE (%)
Gadolinium chelates	Mild (nausea and/or vomiting)	2.0
	Moderate	0.1
	Severe	0.01
Ferrous oxide	Aching muscles	8.0
	Others (including allergic-like reactions)	3.0
Manganese fodipir	Injection site discomfort	67.0
	Nausea and/or vomiting	14.0
	Headache	5.0

	Others	<1.0

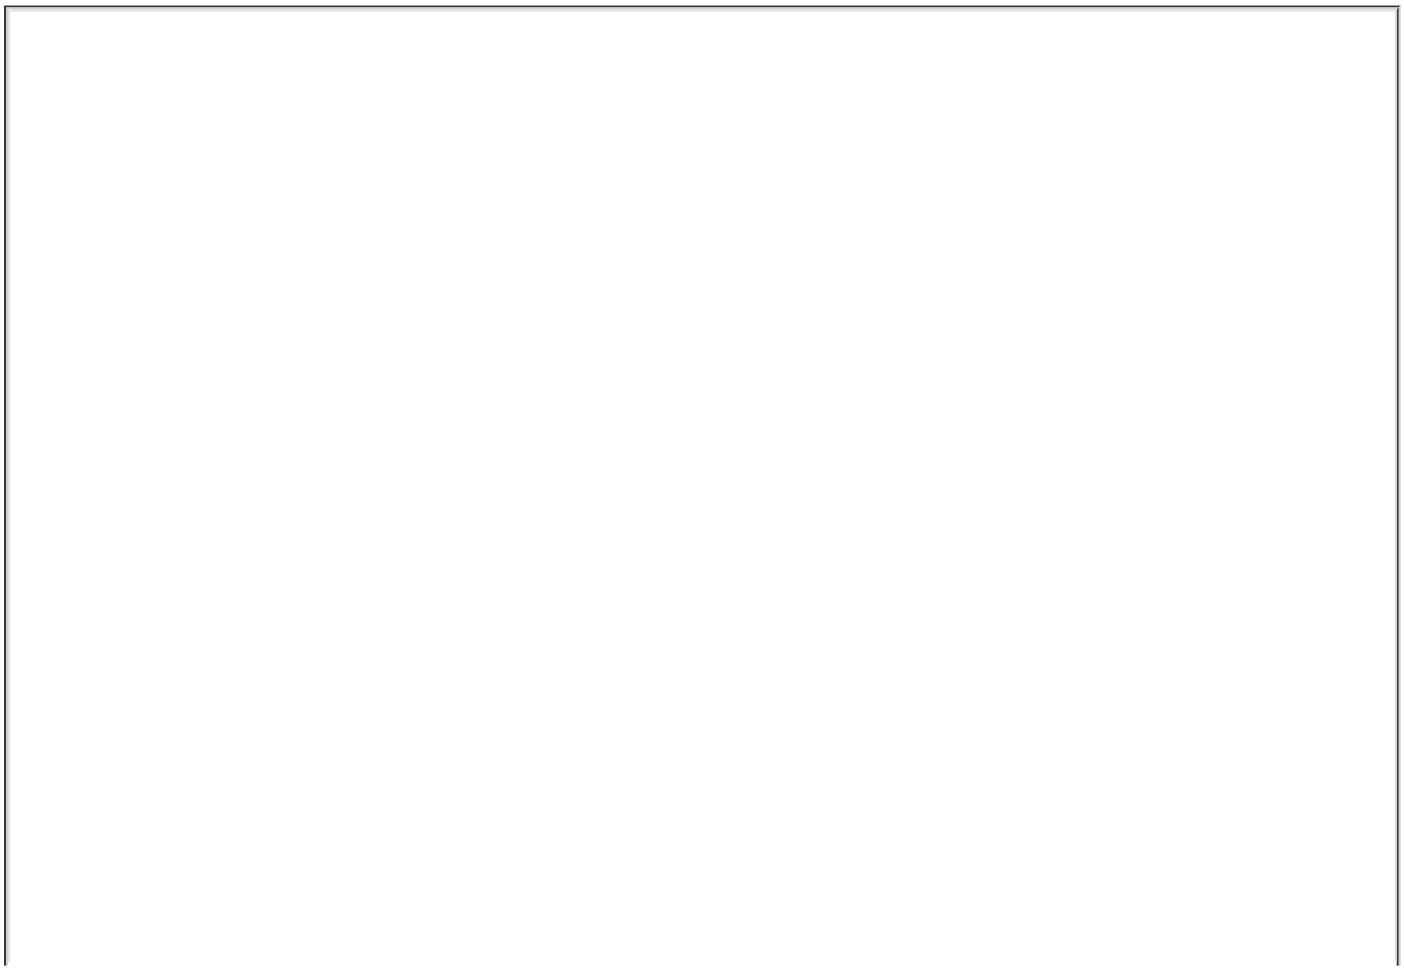
Protection From Ionizing Radiation

Patients, physicians, and other health care workers are frequently exposed to ionizing radiation, usually in the form of x-rays. Exposure to gamma radiation, or, rarely, alpha or beta radiation from radioactive isotopes, may also occur during implantation or removal procedures. Ionizing radiation exposure may occur directly from the source, as leakage from the ionizing device, or as scatter from the equipment. Direct exposure must be avoided. A *rad* (radiation-absorbed dose) is a measure of an absorbed dose of radiation. The total dose of x-rays is measured in roentgens, and a *rem* (roentgen-equivalent-man) is the dose of ionizing radiation with the same biological tissue effect as 1 rad of x-rays.[19] The dose of radiation received during a chest radiograph is in the order of 8 mrem, a head computed tomography (CT) scan is 170 mrem, and an abdominal CT is 680 mrem.[20] Radiation exposure with fluoroscopy may be greater than 75,000 mrem.[19] The effective dose received by the patient during intraoperative digital subtraction angiography was calculated as 76.7 mrem.[20] The exposure of health care workers to the radiation emitted from x-ray equipment is several orders of magnitude lower.[20] The National Council on Radiation Protection and Measurements has established guidelines governing medical radiation.[21] The recommended annual occupational exposure is 5,000 mrem. With the routine use of a lead apron, protective goggles, and thyroid shield, exposure to radiation can be kept to a low level. However, this protective clothing is cumbersome, and can result in fatigue and discomfort, which can distract from patient care.

SPECIFIC RADIOLOGICAL PROCEDURES



Cerebral and spinal angiography cause minimal discomfort and may be performed under local anesthesia with or without light sedation administered by nonanesthesiologists. Patients are required to remain completely motionless during these

procedures, which may be lengthy, particularly spinal angiography. Neurologic disorders such as recent subarachnoid hemorrhage, stroke, and depressed level of consciousness or raised ICP may make it impossible for patients to tolerate these procedures. Deep sedation or general anesthesia with airway protection is often required. Angiography is usually performed via the femoral artery; the femoral vein may also be accessed when imaging arteriovenous malformations or dural venous abnormalities. Liberal use of local anesthetic at the puncture site precludes the need for intravenous analgesia. The injection of contrast media into the cerebral arteries may cause discomfort, burning, or pruritus around the face and eyes. Hypotension and bradycardia may also occur. Complications following angiography are described as neurologic and nonneurologic, and vary between 1 and 2.5%.[22] During cerebral angiography, the patient is placed on a moving gantry, and the radiologist positions the patient to track catheters as they pass from the groin into the cerebral vessels. It is vital to have extensions on all anesthesia breathing circuits, infusion lines, and monitors to prevent these from being accidentally dislodged as the radiologist

swings the x-ray table rapidly back and forth. Care should be taken with positioning of radiopaque pieces of equipment. The electrocardiogram (ECG) electrodes may interfere with imaging during spinal angiography, and little metallic springs in the cuffs of endotracheal tubes can cause interesting and annoying artifacts if they lie over the area being imaged.

Interventional Neuroradiology

A number of neurosurgical conditions may be treated by interventional neuroradiological (INR) techniques.[23] The diseases amenable to endovascular treatment may be classified as emergent or elective; hemorrhagic or occlusive; and definitive, adjunctive, or palliative. Endovascular treatment of intracranial aneurysms with detachable platinum coils (Guglielmi detachable coils)[24] has become an acceptable alternative to surgery for reducing the risk of spontaneous recurrent hemorrhage following subarachnoid hemorrhage.[25] Endovascular treatment avoids the need for craniotomy and is often offered to patients with significant comorbidity or poor prognoses;[26,27] it may also reduce cognitive impairment and frontotemporal brain damage associated with craniotomy.[28] Arteriovenous malformations (AVMs) are increasingly being treated endovascularly, either as the sole therapy or in conjunction with surgical resection or stereotactic radiosurgery.[29] Materials used for INR include occlusive agents; detachable balloons, polyvinyl alcohol particles, coils (pushable, flow directed, and detachable), and liquid agents; and acrylic glues (N-butyl cyanoacrylates), nonadhesive polymerizing agents, and sclerosing agents.[29] For most INR procedures, arterial access is gained using a 6 or 7F sheath via the femoral or, rarely, the carotid or axillary artery[29,30] (Fig. 51-2). The umbilical vessels are an alternative route in neonates. A continuous infusion of heparinized saline is infused into the sheath via a side arm during the procedure. Continuous monitoring of blood pressure and sampling of arterial blood may be performed via the sheath, although most anesthesiologists prefer to insert a dedicated arterial catheter for monitoring the patient. The radiological imaging techniques include high-speed fluoroscopy and digital subtraction angiography. Once the sheath is in place, a guide catheter is advanced through the sheath and a "road mapping" technique is employed, whereby a bolus of contrast medium is injected to outline the vascular anatomy. This image may be superimposed onto the live fluoroscopic imaging to guide the advancement of the microcatheters for placement of embolic materials into an aneurysm or the feeding vessels of an AVM.

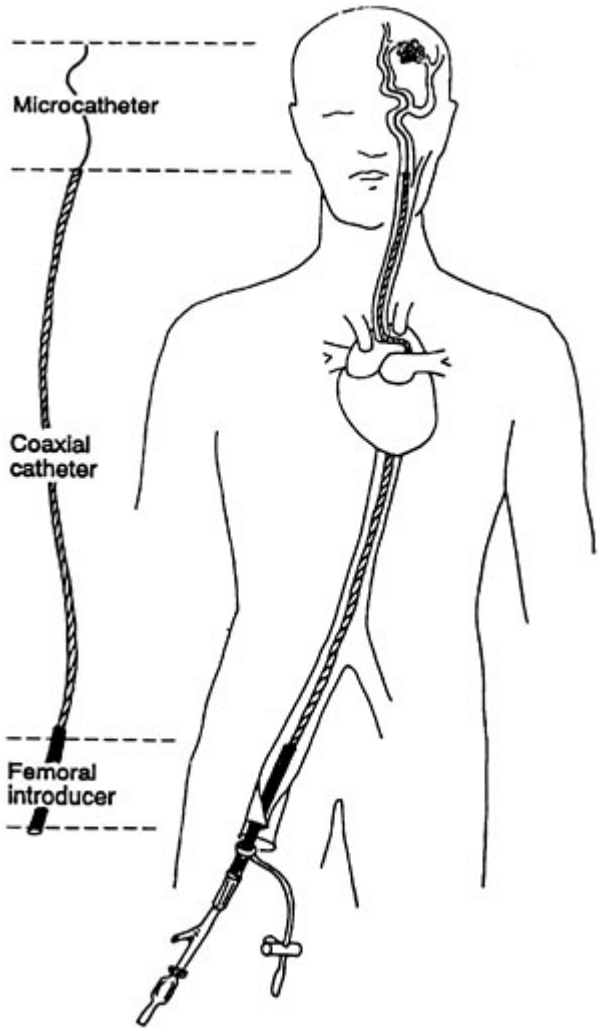


FIGURE 51-2. Representation of a superselective catheter. (Reprinted with permission from Young WL, Pile-Spellman J: Anesthetic considerations for interventional neuroradiology. Anesthesiology 80:427, 1994.)

Anticoagulation

Anticoagulation with heparin is required during and up to 24 hours after interventional radiological procedures to prevent thromboembolism. The usual dose is between 3,000 and

5,000 U as an initial bolus, and 1,000 U/hour to maintain the activated clotting time at about 2.5 times the patient's baseline.

Complications

Interventional neuroradiological procedures are nonstimulating and generally well tolerated. Particular care should be exerted to prevent air embolism via the femoral sheath. Hematoma or hemorrhage may result from femoral artery puncture. There have also been reports of pulmonary embolic phenomena due to acrylic glues.[31] During angioplasty or stenting of carotid artery stenosis, the anesthesia team should be prepared to treat severe bradycardias or transient asystole. The two most catastrophic complications that can occur are intracranial hemorrhage or thromboembolic stroke. The incidence of these during coiling of cerebral aneurysms is 2.4 and 3.5%, respectively.[32] During embolization of AVMs, the incidence of catastrophic complications is between 1 and 8%.[33] The anesthesia team is vital in the expedient treatment of these life-threatening events (Table 51-7).

TABLE 51-7 Acute Management of Neurologic Catastrophes

Initial resuscitation
- Communicate with radiologists
- Call for assistance
- Secure the airway and hyperventilate with 100% O_2
- Determine if problem is hemorrhagic or occlusive
  - Hemorrhagic: immediate heparin reversal (1 mg protamine for each 100 units heparin given) and low normal pressure
  - Occlusive: deliberate hypertension, titrated to neurologic examination, angiography, or physiologic imaging studies (e.g., TCD, CBF)*

Further resuscitation
- Head up 15° in neutral position
- Titrate ventillation to a $PaCO_2$ of 26–28 mm Hg
- 5 g/kg mannitol, rapid intravenous infusion
- Anticonvulsants: dilantin (give slowly, 50 mg/min) and phenobarbitol
- Titrate thiopental infusion to electroencephalogram burst suppression
- Allow body temperature to fall as quickly as possible to 33–34°C

Consider dexamethasone 10 mg

*TCD, Transcranial Dopples; CBF, Cerebral blood flow.

Reprinted from Young WL, Pile-Spellman J: Anesthetic considerations for interventional neuroradiology. Anesthesiology 80:427, 1994.

Anesthetic Technique

Neuroradiologists are increasingly requesting general anesthesia for interventional procedures.[27,32,34] Anesthetic complications are quite low, although the incidence of complications related to the procedure has been reported as 20%.[34]

General anesthesia is usually conducted with endotracheal intubation and intermittent positive-pressure ventilation, although the laryngeal mask airway is a suitable alternative.[32] Propofol and thiopental are the most commonly used induction agents. Conscious sedation techniques vary. Combinations of a benzodiazepine (usually midazolam) and opioid (usually fentanyl) are popular, as are propofol infusions.[34] Droperidol and dimenhydrinate are less frequently used alternatives. Invasive monitoring is used less often in patients undergoing INR compared with those having neurosurgical procedures.[27] The anesthesia team may facilitate the neuroradiologist in a number of ways by manipulating systemic blood pressure and controlling end-tidal $PaCO_2$.[30,32] Controlled hypotension is often requested to facilitate embolization of AVMs. Esmolol, labetalol, metoprolol, and hydralazine are commonly used. Moderate hypertension may help reduce cerebral ischemia by maintaining cerebral perfusion; in this case, phenylephedrine is the agent of choice.

Certain procedures require patients to be awake at least for part of the procedure. A superselective anesthesia functional examination, or SAFE,[30] may be performed prior to therapeutic embolization to determine whether the catheter has been placed in a vessel that supplies an eloquent area of the brain or spinal cord, such as speech or language areas. Following baseline neurologic examination, amobarbital 30 mg (for investigating the gray matter areas) or lidocaine 30 mg (to evaluate the integrity of the white matter tracts) mixed with contrast agent is injected via the catheter. The patient is then reassessed for neurologic deficits in the areas at risk; if the assessment is negative, embolization may proceed. A "sleep-awake-sleep" anesthetic technique using a propofol infusion allows the patient to be rapidly awakened for appropriate

neurologic testing; once this is complete, the patient is once again sedated or anesthetized while the definitive procedure is carried out.

Computed Tomography and Magnetic Resonance Imaging

CT scanning and MRI are used for a wide array of diagnostic imaging and an increasingly large number of therapeutic procedures. The procedures are similar in that they are relatively painless and most adults can tolerate them without the

need for sedation or anesthesia. There is, however, an absolute requirement for the patient to remain motionless while the study is being performed. Children and adults with a variety of psychological or neurologic disorders may require sedation or anesthesia to enable them to tolerate the procedures (see Table 51-4).

Patients with acute thoracic, abdominal, and head trauma often require urgent imaging to facilitate diagnosis. It is not unheard of for these patients to develop hemorrhagic shock, raised intracranial pressure (ICP), depression of consciousness, and cardiac arrest in the CT scanner. Patients must be adequately resuscitated and stabilized before transportation to the radiology department.

Computed Tomography

Modern CT scanners obtain a cross-sectional image in just a few seconds, and spiral scanners can image a slice of the body in less than 1 second, minimizing the problems with motion artifacts. Stereotactic-guided surgery is performed using CT scanning to minimize injury to adjacent structures. Most of these procedures involve biopsy or aspiration of intracranial masses. A radiolucent frame is placed around the head and held in place by pins inserted directly into the skull. This aspect of the procedure is painful. Transient deep sedation or general anesthesia may be necessary in combination with the injection of local anesthetic at the pin insertion sites. Sedation must be used with caution in patients with suspected intracranial hypertension. The frame may completely occlude the patient's airway, so the anesthesia team should have a plan for rapid airway control should the need arise. Such a plan may involve removal of the frame or fiberoptic-assisted tracheal intubation.

Magnetic Resonance Imaging

The physical principles of MRI are described in depth elsewhere.[35] Briefly, when atoms with an odd number of protons in their nuclei, notably hydrogen, are subjected to a powerful static magnetic field, they align themselves with the magnetic field. If they are then intermittently exposed to a radiofrequency wave, the nuclei change their alignment. As the radiofrequency pulses are discontinued, the protons return to their original alignment (i.e., they "relax") within the original magnetic field and, as they do, they release energy. The release of energy over time (the relaxation time) is specific for given tissues and is used to generate the MRI signal. The magnetic field strengths are measured in tesla (T; 1 T = 10,000 gauss). The earth's magnetic field is approximately 0.5 gauss. MRI scanners used for clinical purposes generate a field of 0.15 to 2.0 T,[36] and machines generating magnetic fields from 4 to 8 T are used in research. Despite extensive review,[37] no adverse effects have been described due to human exposure to magnetic fields. Deaths and adverse outcomes in MRI scanners are entirely due to the presence of ferrometallic foreign bodies such as cerebral aneurysm clips or implanted devices such as pacemakers. Before entering the vicinity of the magnet, patients and staff need to complete a rigorous checklist to ensure they have no ferrometallic objects in their bodies. The magnetic field takes several days to establish and is constantly present. It decreases in strength with distance from the center of the magnet, quantified as a number of concentric rings termed "gauss lines." This peripheral or fringe field around the magnet is responsible for malfunction of electrical equipment. The 5 gauss line, for example, is the point beyond which pacemakers will malfunction. Ferromagnetic anesthetic gas cylinders, if brought within the 50 gauss line, become potentially lethal projectiles, and a number of near-miss incidents have been documented.[38] MRI-compatible anesthesia machines and monitors are available, but it is still important to check exactly how

close this equipment can be brought to the magnetic field.[39] Standard pulse oximeters will work in the MRI scanner but have been reported to produce burns,[40] and nonferrous or fiberoptically cabled pulse oximeters should be used. The ECG is sensitive to the changing magnetic signals, and it is nearly impossible to eliminate all artifacts. The electrodes should be placed close together and toward the center of the magnetic field. The leads should be insulated from the patient's skin because they may heat up and cause thermal injury. All cables and wires should run a straight path and not be wound in loops to avoid induction heating effects. Noninvasive blood pressure monitors and transducers for invasive pressure monitoring are available. In the absence of MRI-compatible monitors, long sampling tubes can be connected to standard capnographs and anesthetic agent monitors. Most infusion pumps can be used outside the 30 gauss line,[41] and extra lengths of extension tubing should be available. MRI takes upward of 30 minutes, and many patients find it difficult to stay still for long periods. It may become very warm within the coil of the magnate, often reaching 80°F, adding to patient discomfort. The MRI scanner emits a considerable amount of noise, up to 90 dB, and both the patient and the anesthesia team should wear hearing protection. It is important to remember that once a scan sequence is initiated, no one may enter or leave the scan room. In the case of an emergency, the MRI technicians should be notified, the scan sequence stopped, and the patient rapidly removed. Resuscitation attempts should take place outside the scanner because laryngoscopes, oxygen cylinders, cardiac defibrillators, and so on cannot be taken close to the magnet.

Anesthetic Techniques

Thirty percent of adult patients experience some degree of anxiety during MRI scanning,[42] and up to 10% experience severe panic and claustrophobia. Four percent of adult patients will terminate the procedure prematurely,[43] whereas 14% require some form of sedation to tolerate MRI scanning.[44] In most cases, this may be provided as either oral sedation with benzodiazepines or intravenous sedation administered under the supervision of the radiologist. Anesthesiologists are usually only involved with more complex patients, such as those with obesity, obstructive sleep apnea, raised ICP, movement disorders, developmental delay, and the potential for a difficult airway.

Most children younger than the age of 5, and many as old as age 11,[45] require sedation or general anesthesia to tolerate MRI and CT scanning. Twenty-two percent of children undergoing sedation for MRI or CT scans have been found to experience some sort of adverse event; oxygen desaturation occurred in 2.9%, and in 15%, sedation was inadequate.[46] Adverse events are more common in children with higher ASA grades who are undergoing sedation, and preselecting children who are unsuitable for oral sedation improves the efficiency of oral sedation programs. Oral sedation techniques, if appropriately administered, have a success rate of 93%.[45,46] Children who undergo general anesthesia for scans have a very low incidence of adverse reactions (<0.7%).[45,46] Oral chloral hydrate is a popular agent for sedation by nonanesthesiologists, and doses between 80 and 100 mg/kg have shown to be effective for children younger than 3 years of age who are undergoing CT scan.[47] Chloral hydrate can cause excessive sedation, agitation,[48] and respiratory depression; it may also have a prolonged effect in neonates.[49] Benzodiazepines such as midazolam administered either orally (0.25 to 0.75 mg/kg) or intravenously (0.05 to 0.15 mg/kg) are also commonly used for sedation. Deep sedation with propofol infusion, oxygen administration via nasal cannula, and end-tidal CO_2 monitoring are successful techniques.[45] Children are initially sedated with incremental propofol boluses up to 3 mg/kg with or without midazolam, 0.2 to 0.5 mg/kg, and then maintained with an infusion rate of propofol, -1 to 3 mg/kg/hr with supplemental boluses of 1 mg/kg for movement.

Radiation Therapy

Two different types of radiation therapy commonly require anesthesia care—external beam radiation treatments, usually for children with malignancies, and intraoperative radiation to tumor masses that cannot be completely resected. Radiosensitive malignancies occurring in children are shown in Table 51-8.

TABLE 51-8 Common Radiosensitive Tumors

Primary CNS tumor—neuroblastoma, medulloblastoma Acute leukemia—CNS leukemia Radiosensitive ocular tumors—retinoblastoma Intraabdominal tumors—Wilms' tumor Rhabdomyosarcoma Other tumors—Langerhans' cell histiocytosis
CNS, central nervous system.

Tumors may involve a variety of vital areas, including the airway, thorax, mediastinum, and heart. Patients with central nervous system (CNS) tumors should be assessed for signs of raised ICP. Many children receive cytotoxic or immunosuppressive chemotherapy, as well as radiotherapy. This may result in increased risk of sepsis, thrombocytopenia, and anemia. Patients are typically scheduled for a series of treatments over several weeks. Radiation doses are high, in the range of 180 to 250 cGy, and all medical personnel must leave the room during the actual treatment. Direct observation of the patient is not possible, and an interfaced system of closed-circuit television and telemetric microphones is used with standard monitoring.[4] In the event of a problem, shutdown of the radiation beam and immediate access to the patient are crucial (within 20 to 30 seconds).

The goals of anesthesia for pediatric radiotherapy have been defined as[50]

1. Assurance of immobility
2. Rapid onset
3. Brief duration of action
4. Not painful to administer
5. Prompt recovery
6. Minimal interference with eating or drinking and playing
7. Avoidance of tolerance to the anesthetic agents
8. Maintenance of a patent airway in a variety of body positions

General anesthesia[50] or deep sedation techniques with propofol are preferable to prevent patient movement. The first treatment planning simulation usually lasts 2 hours; following that, treatments usually take 30 minutes several times per week. Most children will have indwelling intravenous access, avoiding the need for repeated intravenous puncture and inhalational induction. Extremely high radiation levels are used as palliation for a variety of tumors.

Intraoperative radiation therapy treatments are provided after the masses are exposed to view. Patients with pancreatic, colon, and rectal cancers; radiation-sensitive sarcomas; and specific types of ovarian cancers receive this form of treatment. Doses of 5,000 to 6,000 cGy may be used during a single, intraoperative treatment. These patients typically suffer from advanced cancers, and may have the attendant nutritional deficiency, dehydration, electrolyte imbalances, and coagulopathies that can complicate anesthetic management. Some hospitals are equipped with

combination radiation therapy/operating room suites; however, most centers require that surgical exploration be performed in the traditional operating room. The anesthetized patient is subsequently transported to the radiology suite, which may be at a considerable distance. Portable monitors and methods for delivery of oxygen and agents to maintain general anesthesia during transport are required.[51] Requirements for patient monitoring for intraoperative radiation are comparable to those described for external beam radiation. Personnel must leave the room during the actual treatment. After treatment, patients must be transported back to the operating room for surgical closure. Occasionally, closure can be performed in the radiology suite and the patient taken directly to the PACU.

CARDIAC CATHETERIZATION

Procedures that may require anesthesia in the cardiac catheterization laboratory[52] include diagnostic cardiac catheterization and therapeutic procedures such as percutaneous transluminal coronary angioplasty with coronary stenting, carotid stenting, atherectomy, and valvuloplasty. Electrophysiologic (EP) mapping and ablation studies are also performed. Most adults can tolerate these procedures under light sedation. More complex procedures include laser extraction of automatic implantable cardioverter-defibrillators (AICDs), as well as endovascular stenting of thoracic and abdominal aortic aneurysms. These procedures usually require more invasive monitoring and general anesthesia.

Cardiac catheterization is performed in children with congenital heart disease for both hemodynamic assessment and interventional procedures.[53] Careful cardiac assessment is essential, and the presence of a trained pediatric anesthesiologist is desirable. Patients often present with cyanosis, dyspnea, congestive heart failure, and intracardiac shunts. Hypoxia, hypercarbia, and sympathetic stimulation as a result of anxiety may exacerbate cardiopulmonary abnormalities. In patients with a patent ductus arteriosis, high oxygen tension can lead to premature closure and should be avoided. Prostaglandin infusions are often used to maintain duct patency. Meticulous attention must be paid to preventing air bubbles entering intravenous lines because they may cross to the arterial circulation via a right-to-left shunt. Diagnostic, noninterventional studies are often performed with sedation, and local anesthetic is injected at the site of femoral puncture. Oral sedation techniques include chloral hydrate 75 to 100 mg/kg, or a mixture of meperidine, promethazine, and chlorpromazine.[53] Intravenous agents include midazolam, morphine, and ketamine. General anesthesia is necessary when children cannot tolerate sedation techniques and/or have significant cardiac or other morbidity, and when the procedure involves severe hemodynamic disturbances such as ventricular septal defect occlusion. Ketamine is useful in children with myocardial depression and can be used as an infusion together with propofol.[54] Fentanyl, midazolam, and etomidate are alternatives.

Electrophysiologic Procedures

EP studies and ablation of abnormal conduction pathways are performed for treatment of dysrhythmias caused by aberrant conduction pathways. Cardiac catheters are inserted via the femoral and sometimes internal jugular routes, and multiple stimulations of the cardiac conducting system are carried out. Once identified, the abnormal conduction pathways are ablated using radiofrequency techniques. The volatile anesthetic agents and propofol have been shown not to interfere with cardiac conduction during these procedures.[55] EP studies are lengthy and can be painful; children usually require general anesthesia. Children undergoing radiofrequency ablation

experience a high incidence of nausea and vomiting,[56] and this may be reduced using a propofol infusion technique rather than volatile anesthesia. The patient's antidysrhythmic therapy is stopped prior to the procedure, and cardiac dysrhythmias generated by the procedure are usually terminated using overdrive pacing via the catheters or, if unsuccessful, by external cardioversion. External pads should be applied before the procedure.

Automatic Implantable Cardioverter-Defibrillators

In the late 1990s, a number of trials proved the benefit of AICDs in reducing mortality of patients

with ventricular tachyarrhythmias and left ventricular dysfunction following myocardial infarction or cardiac arrest.[58,59] AICDs are usually implanted in the EP lab rather than in the operating room, under general anesthesia or sedation. The procedure itself is not particularly painful; however, ventricular fibrillation is induced to test the device during implantation, which is distressing for the patient.

CARDIOVERSION

Atrial fibrillation (AF) affects approximately 0.4% of the general population, its prevalence increasing with age.[60] AF is associated with a number of conditions, particularly hypertension, chronic heart failure, and valvular and ischemic heart disease, and is a frequent sequelal of cardiothoracic surgery.[61] Transthoracic cardioversion is an accepted, often used treatment for atrial fibrillation and atrial flutter.[62] AF is associated with significant morbidity and mortality from thromboembolic stroke. Two strategies are employed to prevent thromboembolism following cardioversion in patients who have been in AF for longer than 48 hours. The conventional approach is to initiate anticoagulation 3 weeks before cardioversion, usually with Coumadin and to continue for 4 weeks after cardioversion.[62,63] More recently, transesophageal echocardiography (TEE) has been recommended to determine whether patients are at low or high risk of thromboembolism.[64,65] In low-risk patients, the dose of anticoagulants can be reduced, whereas in patients considered to be high risk, cardioversion may be postponed to allow adequate anticoagulation.[66] Cardioversion is a brief but distressing procedure that should be carried out using sedation.[67] When TEE is being performed prior to cardioversion, the procedure may take 15 to 30 minutes. Elective cardioversion is often performed in areas near the operating room, usually in the PACU. Alternatively, there may be a requirement for the anesthesia team to provide sedation in the intensive care unit (ICU) for urgent cardioversion in an unstable patient.

The usual anesthetic technique for cardioversion is a small bolus of intravenous induction agent. All currently available induction agents are effective. Propofol produces hypotension more often than etomidate,[68] although this can be attenuated by using an infusion[69] or smaller doses of propofol (1 mg/kg).[70] Etomidate causes a high incidence of myoclonus, which can render interpretation of the ECG difficult.[68,69] Recovery after midazolam tends to be longer than after the other agents, although this may be reversed with flumazenil.[71] Propofol administered by a target-controlled infusion has been compared with inhalational anesthesia with sevoflurane.[72] Sevoflurane was found to provide greater hemodynamic stability than propofol. However, this technique is only practical if there is easy access to a sevoflurane vaporizer and an anesthesia machine. Fentanyl 1.5 mg/kg may also be administered 3 minutes before induction.[68] When TEE is being performed before cardioversion, the patient needs to remain sedated for longer, and a propofol infusion may be useful. In general, patients do not require intubation for cardioversion unless there is a risk of regurgitation. During TEE, local anesthetic is sprayed into the oropharynx to allow easy passage of the TEE probe. A bite block is inserted to prevent the patient from biting down on the probe, damaging both their teeth and the probe. The anesthesiologist can often assist the cardiologists by deepening the level of sedation in the initial stages to allow the TEE probe to be inserted more easily.

GASTROENTEROLOGY

The gastroenterology suite is another location where technology is expanding, and where an increasing number of diagnostic and therapeutic procedures are being performed. Procedures commonly performed in the gastrointestinal (GI) endoscopy suite are shown in Table 51-9.

TABLE 51-9 Common Gastroenterological Procedures

Upper endoscopy
Sigmoidoscopy

Colonoscopy
Endoscopic retrograde cholangiopancreatography
Esophageal dilatation
Esophageal stenting
Percutaneous endoscopic gastrostomy tube placement
Transjugular intrahepatic portosystemic shunt

In the majority of cases, gastroenterologists provide their own sedation for GI endoscopy. Sedation techniques include combinations of benzodiazepine, midazolam, or diazepam with or without an opioid, fentanyl, alfentanil, or meperidine.[73] A greater incidence of side effects is seen when a combination of a benzodiazepine and opioid is used or when patients have significant comorbidity.[74] The incidence of serious cardiorespiratory side effects and death have been reported as 5.4 and 0.3 per 1,000 procedures, respectively.[75] Propofol has been used by gastroenterologists and found to provide excellent conditions for GI endoscopy[76] and endoscopic retrograde cholangiopancreatography (ERCP);[77] however, many gastroenterologists believe it should only be administered by trained anesthesia providers.[78,79]

Upper Gastrointestinal Endoscopy

Upper GI endoscopy is performed for diagnostic procedures, such as biopsy, and for therapeutic procedures, such as retrieval of foreign bodies, treatment of esophageal varices with sclerotherapy or band ligation, dilation of esophageal strictures, and placement of a percutaneous endoscopic gastrostomy. Patients may have a number of comorbidities, including disease of the esophagus and stomach, with a risk of reflux, biliary and hepatic disease with esophageal varices, hepatic dysfunction, coagulopathy, and ascites. The procedure is tolerated without sedation in 66 to 81% of patients,[80] and in the rest, conscious sedation is usually sufficient. With general anesthesia, patients usually require endotracheal intubation to protect the airway and facilitate passage of the endoscope. The laryngeal mask airway has also been used successfully in adults[81] and children[82] as an alternative device for airway management. Local anesthetic is sprayed into the oropharynx to facilitate passage of the

endoscope; this can abolish the gag reflex, increasing the risk of aspiration. A bite block is inserted to prevent the patient from biting down on the endoscope and damaging both their teeth and the endoscope. If the patient has received general anesthesia, care must be taken that the bite block and endoscope do not dislodge or obstruct the endotracheal tube. Procedures are performed in the prone or semiprone position with the patient's head rotated to the side. This position makes the airway less accessible. Care and attention should also be paid to pressure areas, particularly the eyes, lips, and teeth. Extreme rotation of the neck should be avoided. Most procedures are brief, lasting 10 to 30 minutes, and are generally painless.

Endoscopic Retrograde Cholangiopancreatography

ERCP is important in the diagnosis and treatment of both biliary and pancreatic disease. During the procedure, the endoscope is advanced via the mouth into the stomach, and then into the duodenum where the ampulla of Vater is visualized. The biliary and pancreatic duct systems may then be instrumented, and therapeutic maneuvers such as the passage of stents or removal of stones carried out. Sphincter of Oddi manometry (SOM) may also be performed. Patients usually experience discomfort during ERCP, particularly with instrumentation and stenting of the biliary

and pancreatic ducts. Conscious or deep sedation techniques are recommended.[83] Only 5 to 8%[81,84] of patients require general anesthesia. The procedure usually lasts between 20 to 80 minutes.[83] The airway and patient positioning considerations are similar to those for GI endoscopy. If SOM is being performed, glycopyrrolate, atropine, and glucagon should be avoided[84] because they effect sphincter pressure. Opioids, particularly morphine[85] and fentanyl, cause spasm of the sphincter of Oddi, which may be relieved with naloxone.[86] Meperidine, in contrast, reduces the frequency of sphincter of Oddi contractions.[85]

Patients presenting for emergency ERCP may have significant comorbidity,[84] including acute cholangitis with septicemia, jaundice with liver dysfunction and coagulopathy, bleeding from esophageal varices resulting in hypovolemia, or biliary stricture following major hepatobiliary surgery, including liver transplantation. Transient bacteremia may occur during endoscopy, and antibiotic prophylaxis is recommended for patients with cardiac valvular abnormalities.

Antispasmodics

Gastroenterologists frequently use antispasmodics to improve operating conditions during endoscopy.[78,87] Intravenous hyoscyamine given as a 0.5-mg bolus before the procedure has been shown to reduce the incidence of spasm, shorten the procedure, and improve patient comfort;[87] however, it can also cause sinus tachycardia.

Transjugular Intrahepatic Portosystemic Shunt

The transjugular intrahepatic portosystemic shunt (TIPS) is created via a catheter inserted in the internal jugular vein and directed into the liver. It connects the right or left portal vein through the liver parenchyma to one of the three hepatic veins.[88] The TIPS functions to decompress the portal circulation in patients with portal hypertension and is often performed in patients who have failed to respond to medical therapy. The TIPS has been found to be equally effective as other therapies in the secondary prophylaxis of bleeding varices and control of refractory cirrhotic ascites,[89] but with no improvement in mortality and an increased risk of development of encephalopathy. The TIPS has been used in children and found to be feasible and safe in providing temporary relief of portal hypertension while awaiting liver transplantation.[90] The TIPS procedure causes minimal stimulation, lasts between 2 to 3 hours, and may be performed under sedation or general anesthesia.[91] Patients presenting for a TIPS procedure, in general, have significant hepatic dysfunction and require careful preoperative assessment. Considerations are outlined in Table 51-10. Chronic liver disease has a number of effects on the pharmacokinetics of anesthetic agents,[91] and the response to anesthetic agents may be unpredictable. Volume of distribution is increased, and protein binding, drug metabolism, and elimination are all decreased. CNS sensitivity is variably affected. Patients need careful monitoring; the use of an arterial catheter to monitor blood pressure, and to allow frequent blood gas and chemistry analysis, is recommended. Blood glucose should be monitored frequently because patients with hepatic disease are at risk for hypoglycemia due to depleted liver glycogen stores. Preoperative use of diuretics and intraoperative fluid shifts make these patients vulnerable to electrolyte abnormalities. Urine output should be closely monitored to prevent worsening of renal function and development of the hepatorenal syndrome.

TABLE 51-10 Preoperative Considerations in Patients Presenting for the Transjugular Intrahepatic Portosystemic Shunt Procedure

Airway—risk of aspiration	Recent gastrointestinal bleeding Raised intragastric pressure due to ascites Decreased level of consciousness due to hepatic encephalopathy

Respiratory system	Decreased functional residual capacity due to ascites Pleural effusion Intrapulmonary shunts Pneumonia
Cardiovascular system	Associated alcoholic cardiomyopathy Altered volume status Acute hemorrhage from esophageal varices Intraperitoneal hemorrhage
Hematologic system	Coagulopathy Thrombocytopenia
Neurologic system	Hepatic encephalopathy

ELECTROCONVULSIVE THERAPY

Electroconvulsive therapy (ECT) has had an important role in the management of psychiatric disorders since the 1930s. ECT is used to treat depression, mania, and affective disorders in schizophrenic patients, as well as a number of other psychiatric disorders. Its use in the United States is increasing.[92] Typically, ECT is performed three times per week for 6 to 12 treatments, followed by weekly or monthly maintenance therapy to prevent relapses.[93]

Physiologic Response to Electroconvulsive Therapy

The physiologic response to an electrical current applied to the brain includes generalized motor seizures and an acute

cardiovascular response. The grand mal seizure lasts several minutes and includes a short, 10- to 15-second tonic phase, followed by a more prolonged clonic phase, lasting 30 to 60 seconds. A minimum seizure duration of 25 seconds is recommended to ensure adequate antidepressant efficacy.[92,94] The cardiovascular response includes increased cerebral blood flow and ICP. Generalized autonomic nervous system stimulation results in an initial 10 to 15 seconds of bradycardia and occasional asystole, followed by a more prominent sympathetic response of hypertension and tachycardia. Occasionally, cardiac dysrhythmias, myocardial ischemia, infarction, or neurologic vascular events may be precipitated. Short-term memory loss is also common following ECT. Other sequelae include muscular aches, fracture-dislocations, headache, emergence agitation, status epilepticus, and sudden death.

Anesthetic Considerations

ECT is usually carried out in the PACU near the operating room; alternatively, psychiatric institutions may have an area set aside for treatments. Psychiatrists place scalp electrodes to monitor the electroencephalogram during the seizure, and a blood pressure cuff is applied to an extremity and inflated before the muscle relaxant is administered to monitor the seizure. Patients with depression presenting for ECT are often elderly with a number of coexisting conditions; therefore, a thorough preoperative assessment and workup should be performed before the patient begins treatment.[95] First-line pharmacotherapeutic agents for the treatment of depression include tricyclic antidepressants, monoamine oxidase inhibitors (MAOIs), and selective serotonin-reuptake inhibitors (SSRIs). Patients may be taking a variety of drugs, which can have important interactions with the anesthetic agent. The MAOIs have the most significant interactions, although

more modern drugs are superseding these. The anesthetic requirements for ECT include amnesia, airway management, prevention of bodily injury from the seizure, control of hemodynamic changes, and a smooth, rapid emergence.[93,95] Most of the intravenous induction agents have been used to induce anesthesia for ECT. Methohexital (1 to 1.5 mg/kg) is considered the "gold standard,"[93] although it decreases seizure duration in a dose-dependant way.[96] Etomidate (0.15 to 0.3 mg/kg) is generally associated with longer seizure duration, myoclonus, and delayed recovery,[96] and is useful in patients who experience short seizures.[97] However, etomidate does not depress the cardiovascular system, so hypertensive and tachycardic responses may be accentuated.[93] Propofol is more effective at attenuating the acute hemodynamic responses to ECT,[98] and recovery is rapid. Propofol, however, has anticonvulsant effects, although with a small dose (0.75 mg/kg) seizure duration is usually acceptable,[96] and studies have found that reduction in seizure duration by propofol does not adversely affect the outcome of ECT therapy.[99] Most other induction agents decrease seizure activity. The short-acting opioids alfentanil[100] and remifentanil can be used to decrease the dose of induction agent and prolong seizure duration without reducing the depth of anesthesia.[101] Muscle relaxants are used to prevent musculoskeletal complications such as fractures or dislocations during the seizure. Succinylcholine 0.75 to 1.5 mg/kg is the most commonly used agent and is preferable to the longer-acting nondepolarizing agents.[93] Anesthesia is induced, and the patient is ventilated with 100% oxygen using an oral airway and a self-inflating bag and mask. Moderate hyperventilation is beneficial prior to the ECT to improve the quality and duration of seizures,[97] and it has been suggested that the laryngeal mask airway may be useful to improve ventilation during ECT.[102] Before administrating the seizure, a bite guard is placed to protect the teeth. In younger patients, 15 to 30 mg of intravenous ketorolac helps to reduce ECT-induced myalgia. Older patients, or those in whom ketorolac is contraindicated, may receive aspirin or acetaminophen orally before their treatment.[93] The parasympathetic effects of ECT, salivation, transient bradycardia, and asystole can be prevented by premedication with glycopyrrolate or atropine. Of the two, glycopyrrolate is associated with less tachycardia.[93] A number of drugs have been used to attenuate the hypertensive and tachycardic responses that accompany ECT. Labetalol (0.3 mg/kg) and esmolol (1 mg/kg) both ameliorated the hemodynamic responses, although esmolol has a lesser effect on seizure duration than labetalol.[103] The calcium channel antagonists nifedipine, diltiazem, and nicardipine all attenuate the hemodynamic responses to ECT, particularly in combination with labetalol. Clonidine is also effective in controlling blood pressure without affecting seizure duration.[93]

DENTAL SURGERY

Most dental procedures are performed in the office with no sedation and only local anesthesia. General anesthesia may be required during more complicated or prolonged cases and when patients are uncooperative, phobic, or mentally challenged. Patients may also present for dental clearance prior to undergoing cardiac surgery or heart transplantation with severe cardiomyopathy or valvular abnormalities. A number of genetic diseases result in mental deficiency, psychiatric diagnoses, and aberrant behavior. These patients commonly require sedation or general anesthesia to tolerate dental procedures. Genetic diseases are commonly associated with other medical problems, particularly those related to the cardiovascular system and the airway.[104] Down syndrome is commonly encountered, and the anesthesiologist should be aware of cardiac abnormalities, including conduction abnormalities and structural defects; the risk of atlantooccipital dislocation; and a variety of potential airway problems, including macroglossia, hypoplastic maxilla, palatal abnormalities, or mandibular protrusion. If the patient is positioned head-up in the dental chair, vasodilation and myocardial depressant effects of anesthetics can be pronounced, especially in patients with cardiovascular diseases. Patients with neuromuscular diseases may have a history of aspiration and episodes of chronic recurrent pneumonitis that must be addressed before dental surgery. The most challenging part of anesthesia for dental surgery is induction. Many patients, particularly children, are unable to cooperate due to learning disabilities or mental retardation. Ketamine is a useful induction agent. It may be given by a variety of routes alone or in combination with atropine and midazolam.[105] Doses are as follows: intravenously, 1 to 2 mg/kg; orally, 5 to 10 mg/kg; and intramuscularly, 2 to 4 mg/kg, with an onset time of 5 to 10 minutes. The rectal and intranasal routes have also been used. Ketamine is also advantageous in

that it does not abolish upper airway reflexes. Oral midazolam is also popular. A dose of 0.5 mg/kg is dissolved in a small amount of liquid. In children and needle-phobic adults, the use of local anesthetic cream facilitates the placement of intravenous lines. Alternatively, a gaseous induction may be attempted. During and after dental surgery blood, saliva and dental debris are present in the upper airway. A throat pack is used to help protect the airway, and this must be removed at the end of surgery. Tracheal intubation, often via the nasal route is required to protect the airway, although more recently the laryngeal mask airway has been used successfully for both adults[106] and children[107] undergoing dental surgery. Anesthesia can be maintained with intravenous infusions or inhalation anesthesia. Patients need close observation during emergence and recovery. The immediate postoperative complications include bleeding, airway obstruction, and laryngeal spasm. Later complications in ambulatory patients include drowsiness, nausea and vomiting, and pain.[108]

TRANSPORT OF PATIENTS

Patients who receive anesthesia or sedation at alternate sites may need to be transported to the PACU at the end of the procedure; this may be some distance away. During transport, patients should be accompanied by a member of the anesthesia team who should continue to evaluate, monitor, and support the patient's medical condition.[9] Other patients transported within a hospital may require the care of an anesthesiologist for a variety of reasons. For example, surgery patients may be transferred to the ICU or the radiology department for imaging at the end of surgery, or critically ill patients may be transferred to the operating room from the ICU or the emergency room for urgent surgery. In these situations, the anesthesiologist should monitor the patients closely. These patients are often ventilated and receiving a number of drug infusions for both sedation and hemodynamic support. Portable ventilators are useful for transport; however, these are often oxygen powered and adequate supplies of oxygen must be available for the transfer, as well as a manual self-inflating bag to allow hand ventilation in the event of ventilator failure. Similarly, the infusion pumps and portable monitors should have adequate battery power to allow them to continue working in transit. The anesthesiologist should carry spare anesthetic and emergency drugs, equipment for intubation or reintubation, portable suction, and, if the patient's condition requires, a portable defibrillator. It is useful to notify the destination that the patient is in transit so appropriate preparations to receive the patient can be made in advance. It is also useful to send personnel ahead to secure the elevators to prevent delays during transfer.

SUMMARY

The number and complexity of procedures that are performed at alternate sites is steadily increasing. This had led to an expansion of anesthesia services in areas remote from the operating room that may not be familiar to anesthesia providers. In preparing to administer anesthesia or sedation in an alternate site, a simple three-step approach can be followed. This involves giving careful consideration to the needs of the patient, the particular problems posed by the procedure, and the hazards and limitations of the environment. In all cases, the standards of anesthesia care and monitoring should be no different than those provided in the conventional operating room.

Chapter 52

office-Based Anesthesia

Laurence M. Hausman

Meg A. Rosenblatt

KEY POINTS

1	Prior to administering an anesthetic, the anesthesiologist must determine whether a patient and procedure are appropriate for an office-based setting.
2	Both the surgeon and the anesthesiologist must be appropriately trained and have the proper credentials.
3	Continued medical education, peer review, and performance improvement are critical to the office-based practitioner.
4	An office must be properly designed, constructed, equipped, and staffed to house an office-based anesthetic.
5	All American Society of Anesthesiologists (ASA) standards for preoperative evaluation, and intraoperative and post-operative care and monitoring, must be applied to the office-based practice.
6	Several major organizations currently accredit office-based practices.
7	Many states have laws and regulations in place regarding an office-based anesthetic. The practitioner must be knowledgeable regarding the laws in his or her state of practice.
8	An office-based anesthetic can range from monitored anesthesia care to regional and/or general anesthesia.
9	Anesthetics used should be short acting and have a high safety profile.

Office-based anesthesia (OBA) has become an intrinsic and vital part of our specialty. An office-based anesthetic is one that is performed in a location, such as an office or procedure room, that is not accredited by a state agency as an ambulatory surgery center (ASC) and may, in some

states, have no accreditation. In addition, the office must also house nonsurgical activities such as patient consultation and practice administration.

During the 1970s, less than 10% of all surgical and/or diagnostic procedures were performed on an ambulatory basis, and virtually all these were performed in hospitals. In 1987, approximately 25 million procedures, or 40% of all procedures, were performed on an ambulatory basis. In the United States between 1984 and 1990, the number of office-based procedures increased from 400,000 to 1.2 million, and by 1994, 8.5% of all procedures were performed in offices.[1] In the same year, a survey of the membership of the American Society of Plastic Surgeons (ASPS) revealed that 55% of the respondents performed the majority or all their procedures in an office.[2] By the year 2000, approximately 75% of all procedures were performed on an outpatient basis; 17% in freestanding ASCs, and 14 to 25% (approximately 8 to 10 million) in physicians' offices.[3,4,5] It is estimated that by 2005 approximately 82% of all procedures will be outpatient and, of these, 24% will be office based.[3,6]

Although an OBA practice may be an exciting alternative to the traditional hospital-based one, it requires the anesthesiologist to expand his or her role. Along with providing safe anesthetics across the spectrum of healthy to medically challenged patients undergoing increasingly complex procedures, the anesthesiologist must understand office safety and policy, as well as legal and financial issues such as billing and collection.[5,7]

ADVANTAGES AND DISADVANTAGES

There are several advantages to an office-based procedure when compared with a traditional hospital-based one, the most obvious being cost containment. Several components comprise the cost of a given procedure. In addition to surgical and anesthesia fees, which are usually negotiated prior to an elective procedure, there is a facility fee. This fee covers the associated costs to the office, including equipment and staff, and often constitutes a large component of the patient's overall charge. In an office, this amount is easily predicted and frequently minimized, whereas in a hospital, because of greater overhead costs, it can be both enormous and unpredictable.[3,4,8,9] In 1994, Schultz determined the cost of a laparoscopic inguinal hernia repair, when done in a hospital, to be $5,494.00. When the same procedure was performed in an office, the price decreased to $1,533.84. Similarly, the average cost of an in-hospital open inguinal hernia repair was $2,237.00, whereas the same procedure performed in a private office cost only $894.79.[9] It has been reported that office-based ocular surgery performed

under monitored anesthesia care (MAC) can cost 70% less than similar procedures performed in a hospital.[10] Some insurance companies now offer incentives to surgeons who use an office as their surgical venue.[11] Other advantages of office-based procedures over ASCs or traditional hospital-based settings include ease of scheduling, patient and surgeon convenience, a decrease in patient exposure to nosocomial infections, and improved patient privacy and continuity of care because an office is usually staffed by a small and consistent group of personnel.[4,5,7,12,13]

There are potential disadvantages to office-based surgery. These usually relate to issues regarding patient safety and peer review. In most states, no regulations exist regarding certification for the surgeon or anesthesiologist's capabilities, the surgical office's peer review policy, documentation, policies and procedures, and reporting of adverse outcomes. These issues must be considered before selecting an office facility in which to deliver anesthetic care.

OFFICE SAFETY

The earliest questions regarding the safety of office-based procedures were raised by media reports and newspaper articles.[7,14,15] An examination of the data reveals that injuries and deaths occurring in offices are often multifactorial in their causation. Reasons include overdosages of local anesthetics, prolonged surgery with occult blood loss, accumulation of multiple anesthetics, hypovolemia, hypoxemia, and the use of reversal drugs with short half-lives.[14] Both the Anesthesia Patient Safety Foundation and the American Society of Anesthesiologists (ASA) have emerged as leaders in the field of OBA safety and have advocated that the quality of care in an

office-based practice be no less than that of a hospital or ASC.[16,17] Thus, it is imperative to ensure all safety precautions one may take for granted in a hospital are present in the surgical office.[14]

In 1990, the mortality rate from anesthesia was approximately 1/10,000. By the year 2000, the rate had decreased to 1/250,000 in hospitals and 1/400,000 in freestanding ASCs.[5,14,18] This can be attributed, in part, to improvements in the training of the anesthesia providers, the safety profiles of the newer anesthetics, and intrinsic safety mechanisms in place within the anesthetizing location. Because the majority of office-based patients are young and healthy, one would expect that an anesthetic performed in an office would be at least equally as safe as an anesthetic performed in a hospital. However, reports of morbidity and mortality within office-based practices vary dramatically. In 1997, Morello et al conducted a survey querying 418 accredited plastic surgeons' offices.[19] They had a 57% response rate and found that, during a 5-year period, 400,675 office procedures were conducted—63.2% cosmetic and 36.8% reconstructive. Several outcomes were reviewed including hemorrhage, hypertension, hypotension, wound infection, need for hospital admission, and reoperation. There was an overall complication rate of 0.24%, and seven deaths occurred. The causes of mortality were both surgery and anesthesia related. They included two cases of myocardial infarction (one following an augmentation mammoplasty, the other one 4 hours after a rhinoplasty), one case of cerebral hypoxia during an abdominoplasty, a tension pneumothorax during a breast augmentation, a cardiac arrest during carpal tunnel surgery, a stroke 3 days following a rhytidectomy and brow lift, and one unexplained death.[19] This represents an overall mortality rate of 1 in 57,000. A report by Hoefflin et al found no complications after 23,000 procedures that occurred in an office under general anesthesia.[20] Similarly, Sullivan et al[21] retrospectively reviewed the results in an office performing more than 5,000 surgical procedures by five independent surgeons. The anesthesia during this time period consisted of deep sedation in conjunction with local anesthesia or regional block, and was performed by an anesthesiologist supervising a certified registered nurse anesthetist (CRNA). No mortalities occurred during the 5-year period. Bitar et al[22] retrospectively studied adverse outcomes in 3,615 consecutive patients undergoing 4,778 procedures in offices between 1995 and 2000, employing MAC with midazolam, propofol, and an opioid. During this time period, no deaths were reported. Dyspnea occurred in 0.05% of patients, and nausea and vomiting occurred in 0.2%. There was a 0.05% rate of hospital admissions.

Other data reveal a significant risk associated with an office-based procedure. Rao et al reported that, according to closed malpractice claims in Florida, 830 deaths and 4,000 injuries were associated with OBA between 1990 and 1999. These claims accounted for 30% of all malpractice claims in that state.[23] In a hospital operating room, the risks of an anesthetic are usually limited to the underlying medical condition of the patient, whereas in an office they may be increased because of factors such as inadequate standards and safeguards.[14] The challenge of acquiring accurate morbidity and mortality data for OBA is complicated by the fact that many offices are not required to report adverse events. In addition, although an anesthesiologist may not even be administering the anesthetic in an office, many complications may still be reported as anesthetic related.[24]

Traditional credentialing procedures, such as board certification and the granting or renewing of hospital privileges based on proficiency and proof of continuing medical education, may not be required in an office.[18] Within and among offices, health care providers of anesthesia may have varying degrees of education and expertise. The provider may be an anesthesiologist, a nurse anesthetist, a dental anesthetist, or a surgeon with little or no training in anesthesia.[25] Furthermore, safety within an anesthetizing location depends on the patient monitoring capabilities that have become the standard of care within hospital operating rooms.[22] There are reported cases of injuries to patients in offices resulting from obsolete and malfunctioning anesthesia machines, as well as resulting from alarms that have not been serviced and/or are not functioning properly.[4] The ASA has created guidelines for defining obsolete anesthesia machines. These guidelines prohibit the use of any anesthesia machine that lacks essential safety features (e.g., oxygen ratio device, oxygen pressure failure alarm), has the presence of unacceptable features (e.g., copper kettles, vaporizers with rotary concentration dials that increase vapor concentration when the dial is turned clockwise), or for which routine maintenance is no longer

possible.[26]

A review of ASA Closed Claims Project data reveals safety concerns in office-based practices are more than theoretical.[18] The Closed Claims database incorporates information from 35 liability insurers, which in turn indemnify approximately 50% of the practicing anesthesiologists in the United States. As of 2001, in the Closed Claims Project database there were 753 (13.7%) claims for ambulatory procedures and 14 (0.26%) for office-based ones. This small number of claims is most likely due to the 3- to 5-year time lag in reporting to the Closed Claims Project database.[18] ASA physical status 1 or 2 females who had undergone elective surgery under general anesthesia comprise the majority of claims filed. This statistic parallels the profiles of trends seen in operating rooms and freestanding ASCs. The injuries that occur in offices tend to be of greater severity than those that occur in ASCs. Twenty-one percent of the reported injuries sustained in offices were temporary and nondisabling in nature, and 64% were permanent or led to death, whereas 62% of the injuries sustained in ASCs were temporary and nondisabling, and only 21% were permanent or led to death.[18] A study by Coté et al revealed that the causes for injuries in an office ranged from human error to machine and equipment malfunction (Table 52-1).[27,28]

TABLE 52-1 Causes of Injury in the Office-Based Practice

Inadequate resuscitation equipment
Inadequate monitoring
Most commonly no pulse oximetry
Inadequate preoperative or postoperative evaluation
Human error
Slow recognition of an event
Slow response to an event
Lack of experience
Drug overdosage

Data from Coté CJ, Karl HW, Notterman DA, *et al*: Adverse sedation events in pediatrics: Analysis of medications used for sedation. Pediatrics 106:633, 2000; Coté CJ, Notterman DA, Karl HW, *et al*: Adverse sedation events in pediatrics: A critical incident analysis of contributing factors. Pediatrics 105:805, 2000.

According to the Closed Claims Project database, injuries during office-based procedures occur throughout the

perioperative period and are multifactorial in etiology. The majority, 64%, occurred intraoperatively, whereas 14% occurred in the postanesthesia care unit (PACU) and 21% after discharge.[18] Many of these adverse events (50%) were respiratory in nature and included airway obstruction, bronchospasm, inadequate oxygenation and ventilation, and unrecognized esophageal intubation. The second most common events were drug related, occurring 25% of the time. These events included incorrect agent or dosage, allergy, and malignant hyperthermia. Cardiovascular injuries and equipment-related injuries each occurred in 8% of incidents.[18]

An important point to consider when looking at adverse events is whether they were preventable. Thirteen percent of the events that occurred in ASCs were considered to have been preventable, whereas 46% of the office-based events were deemed so. Furthermore, all the adverse respiratory events that occurred in the PACU of offices could have been prevented if pulse oximetry had been used. Care was considered to be substandard in 50% of OBA claims and in 34% of ASC ones. Claims originating from an office-based procedure resulted in a monetary award 92% of the time, with a median payment of $200,000 (ranging between $10,000 and $2,000,000), whereas claims originating from ASC-based procedures were compensated only 59% of the time with a median

payout of $85,000 (ranging between $34 and $14,700,000).[18]

The question of how to make an office-based practice safe has become critical. After several highly publicized office liposuction injuries and deaths in August 2000, the State of Florida attempted to address this problem by placing a 90-day moratorium on all office-based procedures that used anesthetic depths greater than conscious sedation. During that time period, a safety panel that comprised surgeons, anesthesiologists, and other health care professionals was formed and charged with the task of developing recommendations to improve the safety record of office-based procedures. The panel's recommendations concern factors such as patient selection, preoperative evaluation and testing, procedures to be excluded, surgeon qualification, and facility standards.[13,29] Other major organizations that have played a leading role in developing standards for the office-based practitioner include the ASA, the ASPS, the American Association of Nurse Anesthetists, and the American Medical Association.[13,16,25,29,30,31]

PATIENT SELECTION

1 Prior to presenting for an office-based procedure, the patient must be medically optimized. The patient should have a preoperative history and physical examination recorded within 30 days, all pertinent laboratory tests, and any medically indicated specialist consultation(s). Consent for the procedure and the anesthetic must be in the chart. The anesthesiologist should have access to all this information preoperatively, and when possible, he or she should contact the patient prior to the scheduled procedure. If a patient is an ASA physical status 1 or 2, the surgeon's office should arrange the surgery as per office protocol. However, if a patient has significant comorbid conditions, a preoperative anesthesiology consultation should be obtained before scheduling the patient for surgery.

Patient selection remains a controversial topic among practicing office-based anesthesiologists because little morbidity and mortality data exist to support the inclusion or exclusion of specific patient populations. A study by Meridy in 1982 concluded that patients should not be excluded from undergoing ambulatory procedures based solely on their age, the type of procedure, or the duration of the planned procedure.[32] Similar data are yet to exist regarding office-based practices; however, some recommendations have been made. The ASPS has acknowledged that the ideal patient for an office-based procedure has an ASA physical status of 1 or 2. They recommended that ASA physical status 3 patients undergo an office procedure only after an anesthesia consultation, and patients assigned an ASA physical status greater than 3 should only have an office-based procedure performed under local anesthesia without sedation.[13] The ASA also has developed recommendations regarding patient selection.[33] When determining whether a patient is suitable for OBA it is important to realize that the location is often remote, and the anesthesiologist may be unable to get assistance if required. Anticipated anesthetic problems must be avoided **(**Table 52-2**).** Individual anesthesiologists should therefore consider excluding certain patients with significant comorbid conditions to avoid unanticipated problems.[14,34]

TABLE 52-2 Comorbidities That Can Preclude Patients Being Good Candidates For an Office-Based Procedure

Expected significant blood loss or postoperative pain
History of substance abuse
Seizure disorder
Malignant hyperthermia susceptibility
Potential difficult airway
Morbid obesity
Obstructive sleep apnea syndrome
NPO less than 8 hours
No escort

Previous adverse outcome from anesthesia Significant drug allergies Pulmonary aspiration risk
NPO, nothing by mouth.

The morbidly obese patient and patients with obstructive sleep apnea syndrome (OSAS) present unique and increasingly frequent challenges to the office-based practitioner. Indeed, they are usually the same population, with estimates of 60 to 90% of all OSAS patients being obese (body mass index greater than or equal to 0.30).[35,36,37] Confounding this problem is that the majority of the patients with OSAS have not been formally diagnosed.[38,39] These patients are likely to present major anesthetic problems throughout the perioperative period.[40] There may be failure to intubate the trachea or ventilate the lungs, or they may have respiratory distress soon after tracheal extubation or suffer from respiratory

arrest with preoperative sedation or postoperative analgesia.[35] These patients tend to be exquisitely sensitive to the respiratory depressant effects of even small dosages of sedation or analgesics.[37,40,41] Furthermore, respiratory depression may not be reversible with pharmacologic antagonism.[42] One of the first steps in the ASA algorithm for management of the difficult airway is to call for help. In an office, there is usually little or no help available. It has been recommended that an observational unit with close monitoring of oxygen saturation or an intensive care unit setting be used for monitoring the OSAS patient postoperatively.[43] It has also been suggested that outpatient facilities develop specific policies regarding acceptable patients for the outpatient setting, possibly excluding patients with OSAS.[38]

As office-based surgery continues to gain popularity, more subspecialty physicians will begin to perform office-based procedures and older, sicker patients will present for anesthesia. The anesthesiologist must be the patient's advocate in the matter of safety.

SURGEON SELECTION

The relationship between the surgeon and anesthesiologist must be one of mutual trust and understanding. Because the surgeon performing the procedure may also own the office, he or she must not pressure the anesthesiologist to perform an anesthetic if the anesthesiologist believes the patient or procedure is not appropriate for the office-based setting.

2 The surgeon must have a valid medical license and Drug Enforcement Administration (DEA) number. He or she should be either board eligible or board certified by a recognized member of the American Board of Medical Specialties,[29] and either have privileges to perform the proposed procedure in a local hospital or have training and documented proficiency comparable to a practitioner who does have such privileges. Although this may sound intuitive, there have been cases reported of surgeons performing procedures for which they have little or no training.[4] In addition, the surgeon must have adequate liability insurance, at least equal to that carried by the anesthesiologist. If a lawsuit should arise and the surgeon is inadequately insured, the anesthesiologist may be held financially responsible and become the “deep pocket.” Similarly, the facility itself should have adequate liability insurance.

In addition, there should be a system in place for monitoring continuing medical education, as well

as peer review and performance improvement, for both the surgeon and anesthesiologist: this is often missing in the office-based practice.[4] If an anesthesia group provides care at more than one office, an overall peer review may be used; however, it does not need to be specific to each office. Solo anesthesia practitioners should not be exempt from this process. They need to align themselves with the offices in which they provide services and either participate in the office's process or help organize an ongoing one. The peer review committee should include surgeons, anesthesiologists, and nursing staff. It should meet regularly and maintain a written record of minutes and recommendations. Similarly, continuing medical education should also be documented and, at a minimum, should be sufficient to meet relicensing requirements.

3 When formulating a quality assurance program, there should be certain sentinel events that trigger a case review (Table 52-3). It is imperative that this review be an open forum to ensure continued quality improvement of care, and not be biased or hindered by fear of litigation. Legal counsel should be sought to determine whether information disclosed at these meetings is discoverable in a court of law if a malpractice claim should arise.

TABLE 52-3 Sentinel Events That Should Trigger a Chart Review and Be Presented At a Performance Improvement/Quality Assurance Meeting

Dental injury
Corneal abrasion
Perioperative myocardial infarction or stroke
Pulmonary aspiration
Reintubation of the trachea
Return to the operating room
Peripheral nerve injury
Adverse drug reaction
Uncontrolled pain or nausea and vomiting
Unexpected hospital admission
Cardiac arrest
Death
Incomplete charts
Controlled substance discrepancy
Patient complaints

OFFICE SELECTION

4 The anesthesiologist should ensure patients are anesthetized only in a safe location.[25] The office needs to be appropriately equipped and stocked to perform a general anesthetic (Table 52-4). All supplies must be age and size appropriate for the patient population. If an anesthesia machine or ventilator is present, it must be up to date, and regularly maintained and calibrated. If potent inhaled volatile agents or N_2O are used, there must be a functioning waste gas scavenging system. This waste gas system may be exhausted via a window or roof vent. The exhaust must not be vented back into the office or into any other inhabited space and be in accordance with Occupational Safety and Health Administration standards. Air testing

should also be done on a regular basis. In an office without an exhaust system for waste gases, total intravenous anesthesia techniques should be considered. Similarly, all medical and hazardous waste must be disposed of in accordance with state and local laws.

TABLE 52-4 Equipment Required For Safe Delivery Of Office-Based Anesthesia

Monitors Noninvasive blood pressure with an assortment of cuff sizes
  Heart rate/electrocardiogram
  Pulse oximeter
  Temperature
Airway supplies
  Nasal cannulas
  Oral airways
  Facemasks
  Self-inflating bag-mask ventilation device
  Laryngoscopes multiple sizes and styles
  Various sizes of tracheal tubes
  Intubating stylettes
  Emergency airway equipment (laryngeal mask airways, cricothyrotomy kit, transtracheal jet ventilation)
Suction catheters and suction equipment
Cardiac defibrillator
Emergency drugs
  Advanced cardiac life support drugs
  Dantrolene and malignant hyperthermia supplies
Anesthetic drugs
Vascular cannulation equipment

All offices, especially those without ventilators or anesthesia machines, require a method to deliver positive-pressure ventilation to the patient's lungs. This can be achieved using a self-inflating resuscitation device. An adequate supply of compressed oxygen must be present, as well as a backup supply for use in an emergency. In offices that do not have a pipeline supply of oxygen, H cylinders are usually used, with several E cylinders kept in reserve. A policy must be in place describing the transport and storage of gases, consistent with state and local laws. All equipment described in the ASA algorithm for management of the difficult airway should be present.[44] An available means to create an emergency surgical airway and jet ventilation capability may be lifesaving.

5 Perioperative monitoring must adhere to the ASA standards for basic anesthetic monitoring.[45,46] These include continuous monitoring of heart rate and oxygen saturation, intermittent noninvasive blood pressure monitoring, and the capacity for both temperature and continuous electrocardiogram monitoring. In addition, there must exist a way to monitor respiration either by rate, auscultation, or end-tidal CO_2 ($ETCO_2$). $ETCO_2$ must be monitored in all cases of general anesthesia. Monitors must be routinely serviced, calibrated, and repaired as necessary.

All emergency drugs appearing on the American Heart Association advanced cardiac life support (ACLS) protocol should be available. The expiration dates for these agents should be checked on a regular basis, and outdated drugs replaced. A cardiac defibrillator should also be immediately available and routinely checked, as should a source of suction, including a pharyngeal suction catheter. The office-based anesthesiologist should be prepared to begin the initial treatment of malignant hyperthermia (MH), which requires having at least 12 bottles of dantrolene. A complete listing of MH supplies is available via the Internet at http://www.mhaus.org.

A protocol for the delivery and secure storage of controlled substances must be in place. A licensed anesthesiologist may supply these drugs in accordance with DEA regulations, as may any licensed physician with a current DEA registration certificate. Instead of transporting drugs, it is often more convenient to store them in the surgeon's office. In this situation, they must be stored in a double-locked storage cabinet, installed in a secure location. Drug accounting must be performed in accordance with state and federal regulations. Individual states have different

provisions and regulations regarding the dispensing of controlled substances, and it is the responsibility of the dispensing physician to ensure the office-based practice is in compliance.

A medical director responsible for overall operations should be identified for every office. There must also be a policy and procedures manual that outlines the responsibilities of each staff member, including nurses (circulating/scrub and postop), physician assistants, surgical technicians, and office administrators. The manual should include a description of the infection control policy. All nurses should be licensed by the state and have training and education consistent with their responsibilities. Basic life support certification should be mandatory, and ACLS certification is preferable. In addition, either the anesthesiologist or the physician who supervises the anesthesia care provider must be ACLS or pediatric advanced life support certified, depending on the patient population.

Emergencies can, and do, occur in an office-based setting (Table 52-5**)**. Each office must have a plan in place delineating the responsibilities of each staff member, in the event of such an occurrence. The physical structure of the office is an important consideration. There should be a clear egress that would easily accommodate a stretcher carrying a mechanically ventilated patient. Adequate clearance and room for transport in an elevator must also be considered.

TABLE 52-5 Emergencies That May Occur Within an Office That Require Contingency Plans

Fire
Bomb/bomb threat
Power loss
Equipment malfunction
Loss of oxygen supply pressure
Cardiac or respiratory arrest in the waiting room, operating room, or postanesthesia care unit
Earthquake
Hurricane
External disturbance such as a riot
Malignant hyperthermia
Massive blood loss
Emergency transfer of patient to a hospital

Destinations for a patient in need of hospital admission must be identified. Developing this type of relationship is challenging because hospitals may be reluctant to be involved in office mishaps. However, it is of utmost importance to have a formal written arrangement with a nearby hospital. Telephoning the emergency services number (911) is an acceptable plan for transportation, provided the response time is rapid. If emergency resuscitation personnel are unavailable in a specific city or the response time is slow, the office should have a contractual agreement with an ambulance company.

Ideally, a 1-hour firewall should be in place to provide enough time to awaken and escort a patient to safety in the event of a fire. If a 1-hour firewall is not present, the office should, at a minimum, be in compliance with local fire codes. In addition, the office must be in compliance with commercial construction codes and with maximum occupancy regulations.

There must be contingency plans in the event of a power supply interruption or electrical failure. Each office should have an emergency generator capable of running necessary equipment and monitors; monitors should have battery backup power that is routinely checked. Battery reserve power will usually last for 1.5 hours, but this needs to be verified for each piece of electrically powered equipment.

The office should keep patient records (including anesthesia record) in accordance with local laws, which is usually for a minimum of 5 years. Similarly, the anesthesiologist should maintain his or her own records, which include the preanesthesia history and physical, informed consent, intraoperative documentation, and postoperative care record, as well as discharge orders.

Accreditation

6 One way to objectively evaluate an office is to have it accredited by a nationally recognized agency. The ASA has developed a classification of offices that stratifies them by the level of anesthetic depth that may be offered (Table 52-6**)**.[33] Presently, several states require offices to be accredited, and more are following suit. In states that do not require accreditation of an office, there are benefits to voluntarily obtaining it. Often, this accreditation will allow the facility fee to be reimbursed by a third-party payer in medically necessary procedures.[47] In addition, the patient may be more comfortable undergoing a

procedure in an office that has been accredited. Finally, as more states require accreditation, if a surgeon's office proactively becomes accredited in a state that subsequently requires it, there would be no interruption of services.[7]

TABLE 52-6 American Society Of Anesthesiologists Classification Of Surgical Offices According To the Anesthesia and Surgical Procedures Performed

Class A
Minor surgical procedures
Local, topical, or infiltration of local anesthetic
No sedation preoperatively or intraoperatively
Class B
Minor or major surgical procedures
Sedation via oral, rectal, or intravenous sedation
Analgesic or dissociative drugs
Class C
Minor or major surgical procedures
General anesthesia
Major conduction block anesthesia

Adapted from ASA Committee on Ambulatory Surgical Care and ASA Task Force on Office-Based Anesthesia: Office-based anesthesia: Considerations for anesthesiologists in setting up and maintaining a safe office anesthesia environment. Available at: http://www.asahq.org/publicationsAndServices/office.pdf . Accessed March 28, 2005.

Currently, there are three major accrediting bodies for office-based surgery offices, although several other agencies are also recognized. The Accreditation Association for Ambulatory Health Care (AAAHC) was the first major accrediting body, offering certification since 1998. The American Association for Accreditation of Ambulatory Surgical Facilities (AAAASF), originally the Accreditation Association for Ambulatory Plastic Surgical Facilities (AAAPSF), was the second, followed by the Joint Commission for Accreditation of Healthcare Organizations (JCAHO). To date, the most active organization is the AAAASF. Its requirements are simpler than those of AAAHC and JCAHO, and accreditation is less expensive; however, changes are underway to allow AAAHC and JCAHO to be more competitive.[7] Each agency has different criteria for eligibility and different accreditation cycles pertaining to the time limit of a certificate.[48] The agencies deal with issues ranging from office design to patient positioning (Table 52-7**)**. In addition, the AAAHC can accredit not only the surgical office, but also an anesthesia group that provides OBA.

TABLE 52-7 Factors Considered By Accrediting Agencies Before Accrediting an Office

Physical layout of the office Environmental safety and infection control Patient and personnel records Surgeon qualification   Training   Local hospital privileges (surgical and admission) Office administration Anesthesiologist requirements Staffing intraoperatively and postoperatively Monitoring capabilities, both intraoperatively and postoperatively Ancillary care Equipment Drugs (emergency, controlled substances, routine medications) Basic life support and/or advanced cardiac life support/pediatric advanced life support certification Temperature Neuromuscular functioning Patient positioning Preanesthesia and postanesthesia care and documentation Quality assurance/peer review Liability insurance Postanesthesia care unit evaluation Discharge evaluation Emergency procedure (e.g., fire/admission/transfer)
A complete listing of criteria can be obtained from the individual agencies.

The accrediting agencies were developed, in part, to reduce some of the variability that exists among offices in regard to safety issues. Several professional societies are encouraging their members to perform procedures only in accredited facilities. The Society for Aesthetic Plastic Surgeons mandates that all its members perform procedures only in offices that have either been accredited by one of the nationally recognized accrediting agencies, have been certified to participate in the Medicare program under Title XVIII, or are licensed by the state. The actual improvement in safety conferred by performing surgery in an accredited office has yet to be determined, and there are those who suggest that it provides no advantage.[19,49] As long as there is no mandatory reporting system in place, it will be impossible to determine true morbidity rates associated with an office-based practice. Clearly, safety in an office depends on more than just accreditation; there must be constant vigilance by all members of the health care team.

PROCEDURE SELECTION

Early in the development of office-based surgery, procedures were generally noninvasive and of short duration. However, as newer surgical and anesthetic techniques have evolved, longer and more invasive procedures have been successfully performed.[25,50,51,52,53,54,55,56] Suitable office-based procedures range from incision and drainage of abscesses to microlaparoscopies. There are few data regarding procedure length and suitability for an office; however, the ASPS has recommended that procedures not exceed 6 hours in duration and be completed by 3 PM to allow for recovery time.[29] In addition, when determining the suitability of a procedure one must consider the possibility of hypothermia, blood loss, or significant fluid shifts.[29]

Specific Procedures

Liposuction

Liposuction is the most commonly performed plastic surgery procedure and is performed primarily by plastic surgeons and dermatologists.[57] Liposuction is accomplished by inserting hollow rods into small incisions in the skin and suctioning subcutaneous fat into an aspiration canister. Superwet and tumescent techniques, introduced in the mid-1980s, use large volumes (1 to 4 cc) of infiltrate solution for each 1 cc of fat to be removed. This infiltrate solution consists of 0.9% saline or Ringer's lactate with epinephrine 1:1,000,000 and lidocaine 0.025 to 0.1%. Blood loss is generally 1% of the aspirate with these techniques.[58] The peak serum levels of lidocaine occur 12 to 14 hours after injection and decline over the subsequent 6 to 14 hours.[59,60] Although the maximum dose of lidocaine

has been traditionally limited to 7mg/kg, 35 to 55 mg/kg doses have been used safely because the tumescent technique results in a single compartment clearance similar to that of a sustained-release medication.[60,61]

Liposuction is not a benign procedure. In 2000, a census survey of the 1,200 members of the American Society of Aesthetic Plastic Surgeons (ASAPS) revealed an overall mortality rate of 19.1 per 100,000 liposuction procedures, with pulmonary embolism the diagnosis in 23.1% of deaths. Other causes of mortality included abdominal viscus perforation, anesthesia “causes,” fat embolism, infection, and hemorrhage; 28.5% of all deaths in this study were reported as unknown or confidential.[62] Risk factors identified included the use of multiliter wetting solution infiltration, large volume aspiration causing massive third spacing, multiple concurrent procedures, anesthetic sedative effects yielding hypoventilation, and permissive discharge policies. The management of the postoperative period, with attention to fluid and electrolyte balance and pain control, is critical to an optimal outcome after liposuction. Generally, it is recommended that an office liposuction be limited to 5,000 mL of total aspirant, which includes supernatant fat and fluid.[29]

Iverson et al developed the following considerations and recommendations regarding office-based liposuction:[13,29]

1. Plastic surgeons should follow the current ASA Guidelines for Sedation and Analgesia.
2. General anesthesia can be used safely in the office setting.
3. General anesthesia has advantages for more complex liposuction procedures that include precise dosing, controlled patient movement, and airway management.
4. Epidural and spinal anesthesia in the office setting is discouraged because of the possibility of vasodilatation, hypotension, and fluid overload.
5. Moderate sedation/analgesia augments the patient's comfort and is an effective adjunct to the anesthetic infiltrate solutions.

Two hundred sixty-one respondents to a survey sent to the membership of The American Society for Dermatologic Surgery reported no mortalities among 66,570 liposuction procedures performed in hospitals, ASCs, and offices. The authors reported adverse events, which mirrored those in the ASAPS survey. They found that serious adverse events occurred more frequently with procedures performed in hospitals and ASCs than those in offices. This may be due to the fact that in hospitals liposuction is performed on sicker patients or that the procedures are associated with removal of a larger amount of fat. Interestingly, 71% of the offices surveyed were nonaccredited. Further, the authors reported that morbidity correlated better with the area of the body suctioned (abdomen and buttocks), than the facility in which the procedure took place.[63]

Aesthetics

Many facial aesthetic procedures such as blepharoplasty, rhinoplasty, and meloplasty are routinely performed in the office, usually under varying depths of MAC, but occasionally under general anesthesia. Facial plastic procedures that require use of a laser, such as facial resurfacing, pose a problem for the anesthesiologist. The use of supplemental nasal oxygen to maintain adequate SpO_2 in patients receiving sedation is a potential fire hazard. Any supplemental oxygen must be turned off during periods of laser or electrocautery use about the face, and this requires vigilance by the anesthesiologist who must be in constant communication with the surgeon. Methods for delivering supplemental oxygen to a patient having a facial procedure include nasal cannula, an oxygen hood, or placement of an oxygen cannula in an oral airway. The latter usually requires a deeper level of sedation.

Breast

Procedures such as breast biopsy or augmentation, implant exchanges, and completion of transverse rectus abdominal muscle flaps are performed in office settings. Breast augmentation entails separating the pectoralis muscles from the chest wall, which is painful and usually requires general anesthesia. This can be accomplished by using either a laryngeal mask airway or tracheal tube. It is likely that patients undergoing breast surgery will require antiemetic medication and postoperative analgesics.[64]

Gastrointestinal Endoscopy

Procedures performed by gastroenterologists include esophageal, gastric, and duodenal endoscopies and colonoscopies. This patient population tends to be older, with significant comorbid conditions. Upper gastrointestinal (GI) procedures rarely require endotracheal intubation because, although many of these patients have gastroesophageal reflux, the stomach is emptied under direct visualization. The endoscopist does require patient participation to aid in insertion of the endoscope, which can usually be accomplished with sedation using midazolam and small doses of propofol.

Colonoscopy is painful secondary to the insertion and manipulation of the endoscope, and may be associated with cardiovascular effects, including dysrhythmias, bradycardia, hypotension, hypertension, myocardial infarction, and death. The mechanism of these cardiovascular effects is not known, but there is evidence that they may be mediated by the autonomic nervous system when stimulated by anxiety or discomfort.[65] Adding an opioid to midazolam during colonoscopy has been shown to improve patient tolerance of the procedure and decrease pain without increasing the frequency of respiratory events.[66] Interestingly, anesthetic techniques consisting of midazolam,[67] remifentanil/propofol, and fentanyl/propofol/midazolam[68] potentiate the low-frequency components of heart rate variability, which reflects sympathetic activation as seen on continuous electrocardiography, and may contribute to the number of cardiovascular events that occur during colonoscopy.

Dentistry and Oral and Maxillofacial Surgery

Nitrous oxide has been used for most of the world's office-based dental anesthetics since 1884, when Horace Wells, himself a dentist, had nitrous oxide administered for a wisdom tooth extraction by a colleague. It was Harry Langa, another dentist, who pioneered the concept of using lower concentrations of nitrous oxide in combination with local anesthetics. This idea of “relative analgesia” was the forbearer of “conscious sedation.”[69]

The American Association of Oral and Maxillofacial Surgeons designed a prospective cohort study of patients who underwent oral and maxillofacial surgery (OMS) surgery between January and December 2001. Of the 34,191 patients included, 71.9% received deep sedation/general anesthetics, 15.5% conscious sedations, and 12.6% local anesthesia. The operating surgeon provided anesthesia services in 96% of cases, and anesthesia-specific hospitalization rate was 4 per 100,000, with no reported mortalities. This high level of safety is attributed to the use of pulse oximetry, blood pressure and ventilation monitoring, and administration of supplemental oxygen.[70] As anesthesiologists increase their presence in the dental/OMS arena, one can expect an

increased utilization of nontraditional agents for procedures.

Orthopaedics and Podiatry

The orthopaedic office provides an excellent location for the anesthesiologist who practices regional anesthesia. Although

knee arthroscopies can be performed with intra-articular local anesthesia and MAC, a three-in-one block of the lumbar plexus with bupivacaine or ropivacaine, supplementing the intra-articular local anesthetic in an arthroscopically assisted anterior cruciate ligament repair will provide long-acting postoperative analgesia. Brachial plexus (interscalene and axillary) regional anesthetics avoid airway manipulations in patients undergoing upper-extremity procedures, whereas ankle blocks or blocks of the sciatic nerve in the popliteal fossa provide anesthesia for operations on the lower extremity. All these blocks can be supplemented with short-acting anxiolytic agents.

Spinal anesthetics in the office-based setting must be of short duration, secondary to limited PACU space. Lidocaine, which provides reliable short-acting analgesia, may be associated with an increased risk of transient neurologic symptoms in the ambulatory patient population,[71] whereas using procaine-fentanyl spinals is associated with nausea and vomiting and pruritus.[72] When the neuraxial anesthetic wears off, issues of postoperative pain management arise; therefore, peripheral regional techniques or general anesthetics may be preferable in this arena.

Gynecology and Genitourinary

Many procedures, such as dilation and curettage, vasectomy, and cystoscopy, have been performed in offices for many years. More recently, there has been an increase in more invasive procedures such as minilaparoscopies, ovum retrieval, prostate biopsies, and lithotripsy, necessitating an anesthesiologist's expertise. A variety of anesthetic options are available for these procedures and the anesthetic choice depends on the surgeon, patient, and anesthesiologist's preferences.

Ophthalmology and Otolaryngology

Ophthalmologic procedures suitable for the office include cataract extraction, lacrimal duct probing, and ocular plastics. Topical anesthesia or periorbital and retrobulbar blocks are frequently used to provide analgesia. Supplemental sedation may be required. Otolaryngology procedures include endoscopic sinus surgery, turbinate resection, septoplasty, and myringotomy. Again, combinations of topical and regional nerve blocks with supplemental sedation are commonly employed, but occasionally general anesthesia is used.

Pediatrics

Although no minimum age requirement for a child to undergo an office-based anesthetic has been established, patients older than 6 months of age and ASA physical status 1 or 2 may be reasonable candidates.[73] Usual OBA pediatric cases are dental. Chloral hydrate with nitrous oxide is the anesthetic choice of many dentists. The use of these agents is associated with significant morbidity. Ross et al found that in children between the ages of 1 and 9 years, 70 mg/kg of chloral hydrate with 30% nitrous oxide resulted in hypoventilation in 94% of patients, which increased to 97% of patients when the chloral hydrate was combined with 50% nitrous oxide.[8] This is significant in view of the findings of Coté et al, who reviewed 95 adverse sedation-related events in pediatric patients. In the 93% of these cases that resulted in permanent neurologic injury or death, the anesthetic was delivered by either an oral surgeon, periodontist, or certified registered nurse anesthetist supervised by a dentist.[27,28]

There are increasing numbers of ophthalmologic (exam under anesthesia, lacrimal duct probing), otolaryngology (myringotomy), cast/dressing changes, and minor plastics procedures being performed on children in offices. The American Academy of Pediatrics, Section on Anesthesiology, has developed guidelines for the pediatric perioperative environment, which should be adhered to

in the OBA setting[74] (Table 52-8).

TABLE 52-8 Guidelines For The Pediatric Perioperative Anesthesia Environment

▪PATIENT CARE FACILITY AND MEDICAL STAFF POLICIES
Designation of operative procedures Categorization of pediatric patients undergoing anesthesia Annual minimal case volume to maintain clinical competence
▪CLINICAL PRIVILEGES OF ANESTHESIOLOGISTS
Regular privileges Special clinical privileges Pain management
▪PATIENT CARE UNITS
Preoperative evaluation and preparation units Operating room Anesthesiologists Other health care providers involved in perioperative care Clinical laboratory and radiologic services availability and capabilities Pediatric anesthesia equipment and drugs, including resuscitation cart Postanesthesia care unit Nursing staff Anesthesiologist and physician staff Pediatric anesthesia equipment and drugs
▪POSTOPERATIVE INTENSIVE CARE

ANESTHETIC TECHNIQUES

The ASA recommends that anesthetics be provided or supervised by a fully licensed anesthesiologist.[33] If an anesthesiologist is directing anesthesia care, he or she must be immediately available throughout the entire perioperative period. Regulations in several states have questioned the need for this level of anesthesia training in the delivery of OBA. Some states allow for an anesthetic to be performed by a nonphysician anesthesia provider supervised by a licensed physician. In this situation, the supervising physician must be qualified to perform a preanesthetic focused history and physical examination, as well as be immediately available throughout the perioperative period. He or she must know how to handle anesthetic-related emergencies and complications. The supervising physician must be ACLS certified.

8 OBA may entail any type of anesthesia from MAC through regional and general anesthesia.[75] Anesthesia is, however, a continuum, and it is often impossible to predict how a patient will react. The ASA has developed definitions regarding depths of anesthesia (Table 52-9). The anesthesia provider or supervisor must be able to rescue a patient from a deeper level of anesthetic than is anticipated.

TABLE 52-9 Definitions Of Levels Of Sedation and Analgesia By the American Society Of Anesthesiologists

▪MINIMAL SEDATION (ANXIOLYSIS)
Drug-induced sedation Patient responds normally to verbal commands Cognitive and motor function may be impaired Ventilatory and cardiovascular function maintained normally
▪MODERATE SEDATION/ANALGESIA (CONSCIOUS SEDATION)
Drug-induced sedation Patient responds purposefully to verbal commands either alone or with light tactile stimulation Patient maintains a patent airway and spontaneous ventilation Cardiovascular function maintained
▪DEEP SEDATION/ANALGESIA
Drug-induced sedation Patient not easily aroused but can respond purposefully to repeated or painful stimulation Ventilatory function may be impaired, requiring assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate Cardiovascular function usually maintained
▪GENERAL ANESTHESIA
Drug-induced loss of consciousness Patients not aroused by painful stimulation Ventilatory function often impaired; patient may require assistance in maintaining a patent airway Spontaneous ventilation and neuromuscular functioning may be impaired Positive-pressure ventilation often required Cardiovascular function may be impaired
Adapted from ASA 2001 Directory of Members, p 513. Park Ridge, IL: ASA, 2001.

When formulating an anesthetic plan, one must consider that all agents and techniques used should be short acting, and the patient should be ready for discharge home soon after the completion of the procedure.[5,75] Furthermore, any agents used should have a high safety profile and be cost effective.[76] In choosing MAC over general anesthesia, one must not be under the false impression that MAC anesthesia is inherently safer than general anesthesia. In 1988, Cohen et al reviewed

the data from 100,000 anesthetics. They found that the group with the greatest number of

mortalities had undergone procedures with MAC, whereas MAC constituted only 2% of all cases.[77] The complication rate related to MAC anesthetics is increasing as its use expands. The ASA Closed Claims Project database reveals that in the 1970s, MAC cases accounted for 1.6% of the claims; in the 1980s, 1.9%; and by the 1990s, 6%. The injuries sustained in patients receiving MAC ranged from emotional distress to death (Table 52-10). The percentage of claims resulting from mortality was identical for both MAC and general anesthesia cases. When injuries other than death occurred during MAC anesthetics, they were more likely to be permanent, whereas injuries occurring during general anesthetics were more frequently temporary.[78] MAC anesthetics also tend to lead to litigation. Suits were filed in 90% of the MAC claims, 65% were settled, 20% went to judgment, and 15% were discontinued. The range of payout was $2,000 to $6,300,000 with a median of $75,000.[78]

TABLE 52-10 Patient Injuries Occur During Monitored Anesthesia Care According To The Closed Claims Project Database

▪PATIENT INJURY	▪PERCENTAGE
Death	34%
Brain damage	19%
Nerve damage	7%
Eye damage	12%
Myocardial infarction	4%
Stroke	4%
Burn	4%
Emotional distress	4%
Aspiration	4%

Anesthetic Agents

Intravenous sedation (propofol, barbiturates, midazolam, fentanyl, meperidine) is the most often used anesthetic technique in the OBA setting.[25] When selecting anesthetics for an office-based procedure, one must consider factors such as duration of action, cost effectiveness, and safety profile. The drugs should have a short half-life, be inexpensive, and not be associated with undesirable side effects such as nausea and vomiting. Remifentanil, when combined with propofol for conscious sedation, has been shown to provide discharge readiness within 15 minutes after

colonoscopy, which is a marked reduction from the 48 to 80 minutes reported after the traditional meperidine/midazolam technique.[79] Remifentanil, an ultra–short-acting opioid, is an ideal drug for use during many office-based procedures such as facial cosmetic procedures. Facial surgery can be quite painful while the local anesthetic is being injected, after which it is relatively painless. An important caveat to the use of remifentanil is that it may cause nausea and vomiting, in addition to the respiratory depression characteristic of all opioids.

Ketamine has increased in popularity over the past several years in office-based practice.[8] The use of ketamine-propofol sedation has been described as an excellent way to provide a relaxed surgical field in a quiet, immobile patient.[80] Ketamine, a phencyclidine derivative, functions as both an anesthetic and an analgesic. It is particularly useful in that it does not depress respirations and will increase laryngeal reflexes, thus decreasing the risk of aspiration. Furthermore, it is not associated with nausea and vomiting.[81] Ketamine can, however, cause an increase in secretions and cause hallucinations. The latter can be decreased or eliminated by adding propofol and midazolam.[81,82,83,84] Glycopyrrolate can be used as an antisialagogue. Another advantage of ketamine is that it is relatively inexpensive.

Clonidine has also been found to be useful in an office. It has long been appreciated that it will help with blood pressure control throughout the perioperative period, thus potentially minimizing blood loss.[85,86] In addition, it may decrease the total propofol usage.[84]

General anesthesia can be administered in an office setting safely. Hoefflin et al reported their 18-year experience using general anesthesia for 23,000 surgical procedures in an accredited office-based plastic surgery facility. There were no intraoperative or postoperative deaths or significant complications.[20] They asserted that general anesthesia decreases the risk of intraoperative airway obstruction, allows the surgeon to focus wholly on the procedure without the distraction of patient movement, and eliminates the “seesaw effect” of intravenous sedation. The inhalational anesthetic agent of choice in their office was desflurane, with or without nitrous oxide. The pharmacokinetics and pharmacodynamics of desflurane and sevoflurane render them good potent inhaled agents for an office-based procedure, although the ability of anesthesia machines to deliver desflurane must be considered. Inhaled anesthetics with

poor solubility in blood can be used safely and provide a rapid recovery.

Depth of anesthesia monitoring via a processed electroencephalogram has been shown to decrease the time to tracheal extubation and discharge readiness.[87,88,89] A depth of anesthesia monitor has been described as useful in the office during MAC procedures, with a possible decrease in total propofol usage.[90] Whether this type of monitoring will prove to be cost effective in the office-based situation remains to be seen.

POSTANESTHESIA CARE UNIT

Following an office-based procedure, it is expected that the patient will be able to sit in a chair or ambulate to an examination room to dress almost immediately. A formal PACU may not be present, and the patient may recover in the surgical suite. Regardless of where the patient recovers, it is important to adhere to all ASA standards for monitoring and documentation throughout the postoperative period.[46] Staffing in the recovery area must be adequate, and the use of a pulse oximeter is imperative.[18,91]

Because PACU space in an office is often limited and the anesthesiologist may have multiple locations to attend in a single day, problems of postoperative nausea and vomiting (PONV) and pain may become particularly troublesome. PONV or pain are not only problems for the patient and anesthesiologist, but they can also have a profound economic impact on an office surgical unit.[92] It is imperative that every anesthetic administered be designed to maximize patient alertness and mobility, and minimize the risks of the need for a prolonged PACU stay.[25] It has been recommended that the postanesthesia discharge scoring system and clinical discharge criteria used in ambulatory surgery are also used in the office-based setting.[93] Interestingly, there is a trend to discharge patients, particularly after colonoscopy, without escorts. This has been sanctioned in some states. In New York, regulations require that all patients undergoing a

procedure with anesthesia be “discharged in the company of a responsible adult, unless exempted by a physician”.[94] Specific data confirming the safety of this practice do not exist.

Local anesthesia, conscious sedation supplemented by wound infiltration with local anesthetics, or nerve blocks often form the basis for a multimodal strategy for postoperative pain management. These effective pain relief techniques not only decrease the anesthetic and analgesic requirements during surgery, but also reduce the need for more opioid analgesics in the postoperative period, thus facilitating the recovery process.[95] Opioid analgesics are commonly associated with nausea, vomiting, sedation, dysphoria, pruritus, constipation, urinary retention, and respiratory depression. Nonopioid analgesics (e.g., acetaminophen) and nonsteroidal anti-inflammatory drugs (e.g., ketorolac) are routinely used. Ketorolac for postoperative pain decreases the incidence of PONV; patients tolerate oral fluids and meet discharge criteria earlier than those receiving opioids.[96] In an effort to minimize the potential for postoperative bleeding and risk of GI complications, more specific cyclooxygenase-2 inhibitors may be used as nonopioid adjuvants for minimizing postoperative pain.[97] (Recently, some cyclooxygenase-2 inhibitors have been withdrawn from the market in the United States).

An optimal antiemetic regimen for OBA has yet to be established; however, because the causes of PONV are multifactorial, combination therapies may be more beneficial in high-risk patients. Many of the traditional first-line therapies are associated with sedation, drowsiness, and extrapyramidal side effects, and have been supplanted by 5-HT_3 antagonists such as ondansetron, dolasetron, and granisetron.[98] Dexamethasone has been shown to improve the efficacy of both 5-HT_3 antagonists[99] and dopamine antagonists.[100] Routine prophylaxis, though, has not been shown to offer any advantage over symptomatic treatment[101] and has direct costs associated with it. Ensuring adequate hydration (up to 20 mL/kg) to avoid orthostatic hypotension and thus prevent the release of emetogenic chemicals by decreased blood flow to the midbrain emetic centers is an intervention that may be useful in the prevention of PONV.[98]

REGULATIONS

Governmental oversight of office-based surgery varies among states; currently, regulations exist in many states, and others are following (Table 52-11). Whereas accreditation is usually a voluntary certification of an office, regulations are governmental mandates imposed by the local or state government. It is imperative that anesthesiologists embarking on an office-based practice familiarize themselves with any rules and regulations that govern practice in their particular state.

TABLE 52-11 States In Which Office-Based Surgery and Anesthesia are Currently Regulated

California	North Carolina
Colorado	Ohio
Connecticut	Oklahoma
Florida	Pennsylvania
Illinois	Rhode Island
Massachusetts	South Carolina
Mississippi	Texas
New Jersey	Virginia

This list is growing, and it is imperative that the anesthesiologist who is considering beginning an office-based practice be familiar with the regulations in place in his or her state.

In 1994, California was the first state to adopt legislation regarding office-based anesthesia,

followed by New Jersey.[4] A closer look at these two states gives an example of the varied requirements being enforced by states throughout the country. California's regulations pertain to patients undergoing a general anesthetic, and do not address procedures performed under local, peripheral nerve block, or sedation/anxiolysis administered in doses that do not affect a patient's life-preserving reflexes.[102] The regulations deal with issues ranging from office policy and mandatory reporting of adverse outcomes to surgeon and anesthesia provider qualifications.[103] California Health and Safety Code 1248-1248.85 mandates that surgical procedures occur only in offices that have been accredited or have been certified to participate in the Medicare Program under Title XVIII (42 U.S.C. Sec. 1395 et seq.) with few exceptions.[104] In addition, the office must have a written plan in place that deals with issues regarding emergency admissions. The surgeon must have admitting privileges at a local licensed or accredited acute care hospital or have a written transfer agreement with a physician who does have such privileges. The office must have an agreement with the hospital for the admission, in accordance with the hospital's system of quality assurance and peer review. California law also requires that offices have adequate patient monitoring throughout the perioperative period, and have a system in place for the storage and maintenance of patient records. An office that fails to comply with the regulations in place risks sanctions ranging from reprimand with or without monetary penalties through criminal prosecution.

New Jersey's administrative Code 13:35-4A.1-13:35-4A.18 develops criteria for patient selection. Only ASA physical status 1 and 2 patients may undergo general or regional anesthesia. ASA physical status 3 patients can undergo only conscious sedation. The provider of general anesthesia must have the credentials to do so by a hospital, and only a physician with the appropriate credentials may supervise a certified registered nurse anesthetist. New Jersey law establishes guidelines regarding mandatory monitoring, emergency supplies that must be present, physician credentialing, and peer review. In contrast to California, New Jersey's regulations pertain to all patients undergoing a surgical procedure, regardless of the anesthetic depth. However, similar to California, violations may result in fines ranging from reprimand to license revocation and criminal prosecution.[105]

Although many states have regulations in place regarding office-based surgical procedures, the majority have none. Consequently, any physician who holds a valid medical license may perform any procedure, he or she so chooses, within an office. A surgeon may perform a procedure for which he or she may have had little to no training, and may sedate a patient without any training in anesthesia or airway management. In fact, there have been reported cases of patients undergoing a procedure without a preoperative evaluation, pertinent labs, informed consent, intraoperative or postoperative monitoring, or operative report, and without regard for sterile technique.[4]

Business and Legal Aspects

It is in the anesthesia provider's best interest to seek legal counsel before embarking on a career in OBA. Many OBA groups have formed either professional corporations or limited liability companies. Although not eliminating the need for liability insurance, both of these arrangements serve to protect the private assets of the anesthesiologist in the case of a malpractice claim.[7] Legal counsel will also prove to be beneficial in formulating business plans that follow all state and federal laws regarding billing/collection and antitrust. It is important to have an aboveboard and legal relationship with every office in which one administers anesthesia.

Billing strategies must be legal. In this complex environment of third-party payers, it is quite easy to make errors. Ignorance of the law offers no protection or excuse, and one should seek the advice of expert billing agencies even if one chooses not to outsource this responsibility. In planning prices, one must include all overhead charges such as drugs, equipment, time, and business expenses, including malpractice insurance. A pricing structure with the surgeon must exist before embarking on a business relationship. One must outline specifically what will be provided by the office (e.g., intravenous equipment, antibiotics, monitors) and what will be

supplied by the anesthesiologist.

CONCLUSION

OBA continues to rapidly expand and pose unique challenges to anesthesiologists, who must not only provide medical care in new environments, but must also have good business sense and an understanding of operating room management. Although regulations have not kept pace with the growth of OBA, providers must make it their responsibility to ensure every possible safety measure is afforded to their patients. Decisions about appropriate patient selection and equipping anesthetizing locations must be made in conjunction with surgeons, and anesthetics chosen with consideration for the need for rapid turnover and limited PACU availability. The multiple advantages afforded by office-based surgery are fueling its evolution, and as more complex procedures are conducted on patients with increasing numbers of comorbidities, the anesthesiologist's role as patient advocate is vital.

Chapter 53

Anesthesia for Organ Transplantation

Marie Csete

Kathryn Glas

KEY POINTS

1	Brain death is declared when the clinical picture is consistent with irreversible cessation of all brain function.
2	The preoperative assessment of the donor should include the declaration of brain death, consent for donation, and the donor blood type.
3	The mainstay of donor management is maintenance of euvolemia, oxygenation, perfusion, and normothermia.
4	Immune suppression is associated with severe, life-threatening infections (including recurrence of hepatitis after liver transplantation), increased risk of tumors, and progressive vascular disease.
5	Patients on chronic steroid therapy do not necessarily require large doses of perioperative steroids to cover their stress response, especially for small or local surgical procedures.
6	During transplant evaluation, in addition to history and physical exams, patients are generally screened with electrocardiogram, echocardiography, and pulmonary function tests.
7	For renal transplantation, the major anesthetic consideration is maintenance of renal blood flow. Typical hemodynamic goals during transplant are systolic pressure > 90 mm Hg, mean systemic pressure > 60 mm Hg, and central venous pressure > 10 mm Hg.
8	A kidney graft is defective in concentrating urine and reabsorbing sodium, so attention to electrolytes is important.
9	Patients with end-stage liver disease have multisystem dysfunction with common cardiac, pulmonary, and renal compromise because of their liver

	disease.
10	Liver transplantation is a complex surgical procedure, traditionally described in three phases: dissection, anhepatic, and neohepatic phases, with reperfusion of the graft marking the start of the neohepatic phase.
11	A major hurdle for small bowel and multivisceral transplantation is line placement adequate for transfusion of blood products and fluids, which may be substantial during these long cases.
12	Use of nitric oxide (NO) for lung transplantation is associated with risks of methemoglobinemia, NO metabolite-related lung injury, and decreased sensitivity of exhaled NO monitoring as a diagnostic tool for acute lung rejection.
13	For nontransplant surgery in solid organ recipients, evaluation of patients is centered on function of the grafted organ.
14	For all transplant recipients, antibiotic, antiviral, antifungal, and immune suppression regimens should be disrupted as little as possible in the perioperative period.

Transplantation is a growth industry in developed countries, and increasingly performed throughout the world. About 87,000 patients are on transplant waiting lists in the United States. As transplant waiting lists grow, organ donation has not increased to meet demand. Consequently, living-related organ donation is increasingly common, and 2001 was the first year in which the number of living-related kidney donors exceeded the number of cadaveric donors in the United States. In addition, use of organs once considered marginal is on the rise, increasing the difficulty of anesthetic management of organ recipients.

The United Network of Organ Sharing (UNOS; http://www.unos.org) is an important source of information related to organ transplantation for patients and physicians. UNOS was created by the 1984 National Organ Transplant Act to operate the organ procurement and transplant network for efficient and equitable distribution of donated organs. To address local concerns and optimize organ allocation, the United States is divided into 11 regions for purposes of organ distribution, each with its own regional review board. Some 259 transplant centers in the United States perform about 13,000 transplants per year.

Anesthesiologists are involved in the care of organ donors, perioperative management of transplant recipients, and, in major transplant centers, anesthesiologists with special expertise actively participate in the preoperative assessment and optimization of patients for major organ transplant procedures.

ANESTHETIC MANAGEMENT OF ORGAN DONORS

Brain Dead Donors

1 Brain dead heart-beating donors present challenging, unfamiliar management issues to

anesthesiologists. Brain death is declared when the clinical picture is consistent with irreversible cessation of all brain function.[1] Legal and medical brain death criteria can differ from state to state and over time, but all require evaluation of both cerebral and brainstem function. Physicians involved in the transplant recipient process should not be involved in declaration of brain death of the donor. Potentially reversible causes of coma or unresponsiveness must be ruled out (hypothermia, hypotension, drugs, or toxins) before declaration of brain death. Brain dead donors are unresponsive to verbal or painful stimuli, and the clinical exam is confirmed by transcranial Doppler or angiography showing no blood flow to the brain. Flat electroencephalogram is consistent with brain death. All brainstem reflexes must be absent, including ventilatory drive with apnea testing.

2 The preoperative assessment of the donor should include the declaration of brain death, consent for donation, and the donor blood type. Brain dead patients may have intact spinal reflexes and some movement, and so may require neuromuscular blockade.

Brain death is associated with hemodynamic instability, hormonal chaos, and diffuse inflammatory changes, all of which may negatively impact donor organ function.[2] Adrenergic surges can cause ischemia. Vasodilation, loss of temperature control, and diabetes insipidus are also surprisingly difficult management issues. Because of the scarcity of randomized controlled trials in brain dead donors, uniform guidelines for managing donors simply are not available. Anesthetic management during organ harvest is guided by the needs of the teams harvesting organs and personnel from organ procurement networks, who may come from several centers, and have discrepant requests, depending on the organs procured. UNOS has created a resource for managing organ donors, in an effort to improve their care, and therefore the function of donated organs (see the Critical Pathway for the Organ Donor form on the Internet at http://www.unos.org/resources/pdfs/CriticalPathwayPoster.pdf).

In addition, it is advisable to contact the local representative of the regional organ procurement agency before managing any organ donor in the operating room. The professionals in organ management are aware of the latest management strategies, as well as local preferences and research protocols.

Extrapolation of data from animal models and small clinical studies suggests that donated organs are protected by hormone therapy,[3,4] especially when thoracic organs are procured. A typical regimen is tri-iodothyronine (4 µg intravenously then 3 µg/hour), methylprednisolone 15 mg/kg intravenously q 24 hr, DDAVP 1 U then 0.5 to 4 U/hour to maintain systemic vascular resistance (SVR) at 800 to 1,200 dyne * seconds/cm^5, and insulin infusion to maintain blood glucose 120 to 180 mg/dL.[4] Other medications that should be available are broad spectrum antibiotics, albumin, mannitol and loop diuretics, heparin, dopamine, and norepinephrine.

3 The mainstay of donor management is maintenance of euvolemia. Packed cells are used to maintain hematocrit of 30%, while fresh frozen plasma (FFP) is used to maintain the international normalized ratio (INR) <1.5. Arterial catheters and central venous catheters are used to guide fluid and vasopressor therapies. In general, central venous pressure (CVP) is maintained at 6 to 12 mm Hg, and when pulmonary artery catheters are used to assess cardiac function, pulmonary capillary wedge pressure (PCWP) is maintained at <12 mm Hg. The goals of volume and hormonal therapies are to minimize the use of vasopressors. Surgeons procuring the lungs will want to keep central filling pressure low and diuretics may be requested just prior to collection of the lungs, whereas those procuring kidneys will request high filling pressures. Obviously, the job of the anesthesiologist is to maintain the donor oxygenation, perfusion, and normothermia, but the targets of therapies require coordination with the various procurement teams, and good communication is essential. Efforts should be made to keep serum Na < 150 mEq/L, and generally arterial pCO_2 is maintained at 30 to 35 mm Hg. Transport of ventilated patients often requires positive end-expiratory pressure (PEEP) valves attached to the ambu bag to maintain oxygenation of the donor. Peak airway pressures should be kept below 30 mm Hg.

Prior to lung removal, surgeons will perform bronchoscopy. An adapter, such as the Portex fiberoptic bronchoscopic swivel adapter (SIMS Portex, Inc., Keene, NH, USA), facilitates ventilation during the procedure. Glucocorticoids are usually administered, and on occasion,

prostaglandin E_1 is requested to improve circulation of the preservation solution. Surgical techniques have been developed to allow three recipients from one thoracic donor: two single lung transplants

and a heart transplant.[5] The heart is removed first, leaving a small cuff of left atrium attached to the lungs. The harvesting team will ask for systemic heparinization just prior to exsanguination and excision. Cardioplegia is administered, the heart stops ejecting, and the heart is removed. The trachea is transected and the lungs removed en bloc for later separation.

Donor lungs are more susceptible to injury in brain dead patients before procurement than are other organs, likely from contusion, aspiration, or edema with fluid resuscitation. Consequently, only 20% of multiorgan donors meet the current strict criteria for lung donors. These criteria are listed in Table 53-1. A more recent review published by the Pulmonary Council of the International Society for Heart and Lung Transplantation discusses the scientific basis for these criteria.[6] Lungs once considered marginal are being used increasingly because of a severe shortage of donor lungs. Exclusion of donors based on blood gas[7] or CXR findings[6] (see Table 53-1) are based on small single-center trials. With experience, lung transplantation using donors outside these boundaries does not negatively impact the recipient, and most centers rely on bronchoscopy to determine lung suitability for transplantation.[8] A more recent study suggested that aspiration on bronchoscopy, bilateral pulmonary infiltrates, or persistent purulent secretions are criteria for donor exclusion.[9] There is also uniform agreement that advanced donor age (>55 years), together with long ischemic time (>6 hours), is associated with poor transplant outcome. Donors and recipients are matched based on height and/or total lung capacity (TLC) compatibility.

TABLE 53-1 Ideal Cadaveric Lung Donor

Age younger than 55 years
ABO compatibility
Clear chest radiograph
PaO_2 >300 on FIO_2 = 1.0, PEEP 5 cm H_2O
Tobacco history <20 pack-years
Absence of chest trauma
No evidence of aspiration or sepsis
Negative sputum Gram's stain
Absence of purulent secretions at bronchoscopy

Adapted from www.unos.org , August 2004.

A consensus conference was convened in 2002 in an effort to improve evaluation and utilization of cardiac donors.[10] Mortality on the heart transplant waiting list is 17%, compounded by a donor "yield" of only 42%. The ideal heart donor is younger than 50 years old, and hemodynamically stable. Presence of major chest trauma, known cardiac disease, active infection, prolonged cardiac arrest, malignancy, HIV or HBV positive, or intracardiac injections moves the donor from ideal to marginal status. Overall, health status of the donor prior to determination of brain death can facilitate a directed laboratory evaluation. Electrocardiogram (ECG) is often abnormal in the setting of brain injury/death, and further evaluation with transthoracic echocardiography (TTE) is often necessary. Cardiac catheterization is sometimes requested in older donors, and those with significant personal or family history of coronary artery disease (CAD). Marginal donors are typically used only for high-risk recipients who are at increased risk of waiting list mortality. In recipients with pulmonary hypertension, younger donors, short ischemic time, low donor inotrope requirement, and oversized organs are preferred.

Non–heart-beating donors have been used mostly for kidney transplantation, more recently for

livers and islet transplants, and even for lungs.[11,12,13] These donors usually have severe brain damage but are not brain dead, and death is defined by cessation of cardiac and respiratory function. Life support measures are used to control the timing of death and organ procurement. Guidelines for non–heart-beating donor management, and ethical considerations are available in a study conducted by the Institute of Medicine.[14] Depending on the local hospital protocol, anesthesiologists may not be involved in the care of non–heart-beating donors. The donor may be declared dead just outside the operating room (OR), then quickly taken into the OR for organ procurement without an anesthesiologist in attendance. Other hospitals have developed protocols that involve preparation of the patient in the OR with an anesthesiologist present, and the anesthesiologist may be responsible for removing the patient from ventilatory support and for declaration of death. Despite concerns that non–heart-beating organ donors should be managed throughout by the primary care team without anesthesiologists involved,[15] current federally based recommendations and the success of transplantation using organs from these donors, along with applied research in this area, make it likely that non–heart-beating organ donation will increase. Anesthesiologists should be involved in the design of protocols in their local institution, if they are to be involved in the process.

Living Kidney Donors

Living donors have no significant cardiopulmonary, neurologic, or psychiatric disease, diabetes, obesity, hypertension, history of renal stones, or proteinuria. Renal function must be normal. Living donors are, by definition, quite healthy, and these volunteers deserve exquisite attention to safety and pain management. Historically, open nephrectomy involved a long flank incision and rib resection, a painful procedure. The traditional open procedure was modified to reduce the size of incision, making rib resection unnecessary.[16] The open procedure is still painful, usually requiring postoperative patient-controlled opioid analgesia for at least a day. General anesthesia is used in many centers, but epidural and combined epidural-spinal techniques (supplemented with intravenous propofol) have also been used successfully.[17] For the open procedure, the patient is positioned in the lateral decubitus position with the bed flexed to expose and arch the flank.

Laparoscopic (versus open) donor nephrectomy is increasingly the norm and is generally better tolerated by donors in terms of comfort and shorter hospital stay.[18] However, anesthesiologists must be aware that mastering the technique takes a while, and the first procedures performed by surgeons tend to be long. Anesthetics and insufflation of the peritoneum with CO_2 decrease renal blood flow so fluid repletion is important to maintaining renal perfusion. A reasonable protocol is to administer crystalloid at 10 cc/kg per hour above calculated losses and to maintain urine output at about 100 cc/hour;[19] however, local protocols may rely on CVP for fluid administration or mandate set amounts of fluid. Central venous lines are generally placed after induction of anesthesia for patient comfort.

Virtually all donor tracheas can be extubated in the operating room. Patient-controlled analgesia is common after donor surgery. Some centers admit donors to a step-down or medical intensive care unit (ICU) for a day after surgery, but the total hospital stay is usually only 2 to 4 days. A bladder catheter is removed on postop day 1. Patients should be advised that full recovery (i.e., feeling normal) takes 4 to 6 weeks.

Complications after living donor nephrectomy include atelectasis of the lungs, pneumothorax, arrhythmias, wound pain or infection, urinary tract infection, and mental status changes.[20] Perioperative mortality is rare but cannot be denied as a possible outcome during preoperative patient discussions.[21]

Living Liver Donors

Left lobe liver donation is usually done in the context of parent-to-child donation. Although left lateral segmentectomy is a big operation, it is generally well tolerated. Right lobectomy by comparison is a larger procedure and carries significant risk. Mortality of right liver resection for donation is estimated at 0.4 to 1%.[22,23] A more recent living related donor death that received considerable public scrutiny[24] and the report of the first Japanese donor death[25] highlight the

enormity of this operation, the need for experienced teams to manage the patients, and the often neglected need for long-term follow-up of donors. Nonetheless, as donor shortages become more desperate, it is likely that adult-to-adult living related transplantation will be in more demand. Other reported complications of this surgery include air embolism, atelectasis, and pneumonia.[26]

Large liver resections may require virtually complete hepatic venous exclusion (cross-clamping of the hepatic pedicle usually without cava clamping). Not unexpectedly, venous return falls by about 50%. Without the collaterals developed by patients with liver disease, normal donors may experience significant hypotension when the cava or even just the portal vein is cross-clamped. Blood pressure is maintained largely through reflex increases in endogenous vasopressin and norepinephrine levels.[27] For these reasons, volume loading seems a reasonable preparation (often albumin) just prior to clamping and is the practice at our institution. However, some authors have argued that blood loss is reduced if the CVP is kept low during resections.[28] These reports have prompted some centers to not only keep CVP <5 mm Hg by limiting fluids, but also by adding vasodilators and diuretics.[29] Sufficiently powered studies to prove that low CVP benefits (less blood transfusion) outweigh risks (renal compromise and air embolism) are unlikely to be performed, and institutional practices vary widely. If vasopressors are needed, vasopressin and norepinephrine are reasonable choices to enhance normal endogenous reflexes. Most donors do not require vasopressors.

Isovolemic hemodilution has been reported to reduce allogeneic red cell requirements in major hepatic resections.[30] At experienced centers, blood loss is usually less than 1 L, with 20 to 40% of donors requiring transfusion.[31,32,33] Transesophageal echocardiography, if expertise is available, is ideal and obviates central line placement. Blood salvage is useful, and some centers offer autologous donation programs for donors; both can reduce the need for allogeneic blood transfusions.[34]

The trachea of most donors can be extubated safely in the operating room. Hypothermia is a common reason for not extubating in the OR. Postoperative pain management in these patients is a matter of controversy. Some institutions successfully place epidural catheters, providing excellent analgesia without reported complications.[35] However, with right liver resection, INR rises significantly after surgery, peaking a few days after surgery along with a fall in platelet counts, just when the catheter is usually removed.[32,36] For this reason, many centers will not place epidural catheters in these patients, and rely on intravenous patient-controlled analgesia.

Living Lung Donors

As of March 2004, only 234 living donor lobar lung transplantation (LDLLT) procedures have been reported by UNOS. LDLLT is typically reserved for critically ill recipients unlikely to survive until a cadaveric donor becomes available. Given this, as in all living donors, the inherently coercive conditions must be balanced by numerous visits to review the procedure, allowing the donors multiple opportunities to withdraw from participation. Selection criteria for donors are listed in Table 53-2.[37] No donor mortality has been reported to date, and morbidity remains low. If two donors are used for one recipient, scheduling difficulties are considerable. The surgical procedure is performed in three operating rooms simultaneously, one for each donor and the recipient. Donors receive a general anesthetic with epidural analgesia.

TABLE 53-2 Living Lung Donor Criteria

Member of extended family
Age 18–55 years
No prior thoracic surgery on donor side
Good general health

Taller than recipient preferred
ABO compatible
FVC and FEV_1 >85% predicted
pO_2 >80 mm Hg on room air
No chronic viral diseases
Normal electrocardiogram and echocardiogram
Normal stress test in donors older than 40 years old

Adapted from www.unos.org , August 2004.

IMMUNOSUPPRESSIVE DRUGS

The long-term goal of transplant immunologists is to create recipient tolerance to grafts, but the complexity of immune responses means this goal will be difficult to achieve. Nonetheless, efforts to create hematopoietic chimerism are a major research focus in transplantation. For now, suppression of immune responses is used to blunt reaction to allografts, and drugs powerful enough to suppress the immune system are associated with significant side effects. Immunosuppressed patients who are undertreated can reject an organ. Immune suppression is associated with severe, life-threatening infections (including recurrence of hepatitis after liver transplantation), increased risk of tumors, and progressive vascular disease. Immunosuppression regimens differ considerably from center to center, and anesthesiologists must communicate with the transplant team to obtain the schedule and dose of immunosuppressive agents used for each patient. Considerable variability between patients in intestinal absorption, and genetic and induced differences in metabolism of these drugs require precise individualization of immunosuppressive regimens. It is particularly important to review drug regimens with transplant coordinators when posttransplant patients are scheduled for surgery because the transplant team is likely to have information about peak and trough drug levels that may not be accessible on the hospital chart.

All immunosuppression regimens carry major risks: infection and malignancy. Thus, immune-suppressed patients coming to the OR deserve special attention to sterile technique and maintenance of antibiotic/antifungal/antiviral regimens during the perioperative period. Complications of immunosuppression are summarized in Table 53-3. Both a review of immunologic mechanisms of rejection and the various immunosuppressive regimens used for each organ transplant are beyond the scope of this chapter. Rather, the mechanism of each drug's action and information about its use pertinent to anesthesiologists are outlined here.

TABLE 53-3 Multisystem Complications Of Chronic Immune Suppression

·SYSTEM	·COMPLICATION
Central nervous system	Lowered seizure threshold
Cardiovascular	Diabetes

	Hypertension
	Hyperlipidemia
Renal/electrolyte	Decreased glomerular filtration rate
	Hyperkalemia
	Hypomagnesemia
Hematologic/immune	Increased risk of infections
	Increased risk of tumors
	Pancytopenia
Endocrine/other	Osteoporosis
	Poor wound healing
Adapted from www.unos.org , August 2004.	

Calcineurin Inhibitors

The modern transplant era began with the introduction of *cyclosporine*, a calcineurin inhibitor, into the marketplace. These drugs remain a major part of immunosuppression for solid organ transplant recipients.[38] Cyclosporine is still used, but other calcineurin inhibitors are used increasingly in its place. *Tacrolimus* has been particularly important for kidney transplant recipients because of its potency in preventing acute rejection (within 6 months of transplantation), long-term graft survival, and relative lack of side effects compared with historical regimens.[39] Cyclosporine binds cellular cyclophilins and tacrolimus binds the FK binding protein, and these bound complexes interact with the phosphatase, calcineurin. Calcineurin, among other effects, in turn modifies NFAT (nuclear factor of activated T-cells) and frees NF-kB to translocate to the nucleus, where they enhance transcription of T-cell interleukin-2 (IL-2).[40] The (simplified) mechanism of action of calcineurin inhibitors is that they inhibit T-lymphocyte differentiation and cytokine elaboration.

Calcineurin is involved in diverse cellular processes in addition to immune function, and therefore, inhibition of calcineurin is associated with significant side effects. These include hypertension (often requiring therapy), hyperlipidemia, ischemic vascular disease (including in heart recipients), diabetes, and nephrotoxicity.[41] Ischemic cardiac disease is the leading cause of death of kidney transplant recipients, in part due to underlying disease that preceded transplantation, but use of calcineurin inhibitors can exacerbate risk factors for coronary artery disease.[42] It is important to note that end-stage liver disease (ESLD) does not confer protection from coronary artery disease, and liver transplant patients are also at risk for progression of ischemic cardiac disease after transplantation. Neurologic side effects are also common. Most of the side effects of

these drugs are dose related, and patients typically require quite a bit of dosage adjustment after transplantation.

An old retrospective review and occasional case report suggested that cyclosporine may prolong the action of pancuronium,[43,44] but these reports have not been followed by clinical experience, suggesting that inability to reverse neuromuscular blockade is common in cyclosporine-treated patients. Cyclosporine increases MAC in rats, but similar studies have not been reported in humans.[45] To switch from oral to intravenous dosing of cyclosporine, usually about one-third the oral dose is used. Usual doses of tacrolimus are 0.15 to 0.3 mg/kg per day given in two doses. To switch from oral to intravenous tacrolimus, a starting dose of about one-tenth the oral dose can be used. For optimal perioperative management, the precise doses of drugs given in the OR should be clearly communicated to the primary care team so immunosuppression is minimally disrupted.

5 Corticosteroids disrupt expression of many cytokines in T-cells, antigen-presenting cells, and macrophages. These drugs are used both for maintenance immunosuppression and in pulse dosing for acute rejection. Especially for children, corticosteroid-sparing regimens are increasingly popular because growth is negatively affected by steroids and because the drugs are generally not tolerated well. Well-known side effects are hypertension, diabetes, hyperlipidemia, weight gain (including Cushingoid features), and gastrointestinal (GI) ulceration. Patients on chronic steroid therapy do not necessarily require large doses of perioperative steroids to cover their stress response, especially for small or local surgical procedures.[46] Again, communication with the primary transplant service is important in determining steroid coverage that least impacts the delicate balance of immunosuppression.

Antiproliferative drugs rely on the fact that immune activation implies explosive proliferation of lymphocytes. Side effects occur because other proliferating cells (GI tract, bone marrow) are also affected.

mTOR (mammalian target of rapamycin) inhibitors are often used in combination with calcineurin inhibitors to decrease the complications of dose-related side effects ("calcineurin sparing regimens") such as nephrotoxicity.[47] TOR is involved in complex signaling processes that promote synthesis of proteins, including several that regulate cellular proliferation. Thus, mTOR inhibitors such as rapamycin (sirolimus) are antiproliferative, used both in immunosuppression and increasingly in cancer therapies. Similar to cyclosporine and tacrolimus, sirolimus is metabolized in liver via P450CYP3A isoenzymes, but coadministration of sirolimus and a calcineurin inhibitor does not increase calcineurin inhibitor drug requirements. In fact, the combination may be synergistic.[48] Everolimus is a new drug in this category.[49]

Azathioprine is hydrolyzed in blood to 6-mercaptopurine, a purine analog and metabolite with the ability to incorporate into DNA during the S phase of the cell cycle. Because DNA synthesis is a necessary prerequisite to mitosis, azathioprine exerts an antiproliferative effect. The major side effect of azathioprine is repression of bone marrow cell cycling, which can cause pancytopenia. Cardiac arrest and severe upper airway edema are rare complications.[50] The intravenous dose is about half the oral dose.

Mycophenolate mofetil is metabolized into a molecule that inhibits purine synthesis. It too can cause leukopenia and thrombocytopenia as side effects, as well as red cell aplasia.[51] Usual oral dose is 1 to 1.5 g two times a day.

Monoclonal and Polyclonal Antibodies

OKT3 antibody is directed against a component of the T-cell receptor complex and affects immunosuppression by blocking T-cell function. Acute administration of OKT3 in awake patients (especially first administration) may result in generalized weakness, fever, chills, and some hypotension. More severe hypotension, bronchospasm, and pulmonary edema have been reported.[52] Anesthesiologists administering the drug should note that formulations of OKT3 may require filtering before administration (and a syringe filter is supplied with the drug).

"Humanized" antibodies are used with increasing frequency. These are antibodies engineered to contain human constant regions in the immunoglobulin so patients do not develop an antimouse

immunologic response against a mouse monoclonal antibody. Muromonab-CD3 is a humanized form of OKT3,[53] usually used for acute rejection. Basiliximab and daclizumab are newer humanized antibodies. These antibodies are both directed against a portion of the IL-2 receptor and work by blocking IL-2-mediated T-cell activation. GI upset is the most commonly cited side effect of these drugs. However, basiliximab was more recently implicated in three cases of pulmonary edema in young renal transplant patients.[54]

Polyclonal antibodies (directed against more than one protein epitope) include *antithymocyte globulin*, used to deplete T-cells from the circulation. Side effects include a serum sickness syndrome, leukopenia and thrombocytopenia, and fever.

RENAL TRANSPLANTATION

Preoperative Considerations

6 An enormous variety of diseases are treated with renal transplants (Table 53-4). Many of these underlying diagnoses are also risk factors for coronary artery disease, so preoperative evaluation is focused on cardiovascular function. About half the mortality of patients on dialysis is due to heart failure,[55] and

cardiovascular complications are a leading cause of death after renal transplantation. Therefore, cardiovascular risk factor modification is imperative before and after transplantation.[56] During transplant evaluation, in addition to history and physical exams, patients are generally screened with ECG, echocardiography, and pulmonary function tests (PFTs), which should be reviewed by the anesthesiologist. In addition, patients will be screened for tumors (mammography, Pap test, colonoscopy) and infection (dental evaluation, viral serologies). Patients should have good control of their diabetes before transplantation and have an evaluation for psychiatric stability. Severe heart, lung, or liver disease; most malignancies; and active or untreatable infections such as tuberculosis (TB) are exclusion criteria for renal transplantation. With obesity at epidemic proportions, renal transplantation is commonly performed in obese patients. These patients are at increased risk of surgical complications, including delayed graft function and wound infection.[57]

TABLE 53-4 Diagnoses Of Adults Awaiting Renal Transplants

▪DISEASE CATEGORY AND EXAMPLES	▪% OF PATIENTS ON LIST
Glomerular disease	
Chronic glomerulonephritis	4.1
IgA nephropathy	2.3
Systemic lupus erythematosus	2.9
Alport's syndrome	0.5
Membranous nephropathy	1.4
Hemolytic uremic syndrome	0.1

Membranous glomerulonephritis	1.4
Diabetes	
Type 1	6.1
Type 2	20.4
Polycystic kidney disease	5.3
Hypertensive nephrosclerosis	16.4
Renovascular disease	
Malignant hypertension	4.6
Focal glomerular sclerosis	2.8
Polyarteritis	0.03
Scleroderma	0.08
Congenital/metabolic	
Obstructive uropathy	0.5
Cystinosis	0.02
Tubular/interstitial nephritis	0.7
Acquired obstructive nephropathy	0.3
Drug-induced nephropathy	
Analgesics	0.2
Antibiotics	0.03
Cyclosporine	0.05

Chronic pyelonephritis	0.8
Acute tubular necrosis	0.04
Renal graft failure	12.7
Adapted from www.unos.org , August 2004.	

Dialysis-dependent patients should be dialyzed before surgery. Cadaveric grafts can be safely transplanted after 24 hours of cold ischemia time, and up to 36 hours, allowing scheduling of preoperative dialysis. With preoperative dialysis, severe hyperkalemia during surgery is unusual.

Intraoperative Protocols

Renal transplantation is generally done under general anesthesia, although small studies have suggested good outcomes with epidural anesthesia.[58] Rapid sequence induction is indicated in diabetic patients with gastroparesis[59] (preceded by oral sodium bicitrate). In general, concerns over uremic platelet dysfunction and residual heparin from preoperative dialysis have limited use of regional anesthesia for kidney transplantation. Before incision, antibiotics are given. A central venous catheter (usually triple lumen) is placed for CVP monitoring and drug administration, and a bladder catheter is placed.

Incision is usually in the lower right abdomen to facilitate placement of the graft in the iliac fossa. The recipient iliac artery and vein are used for graft vascularization, followed by connection of the ureter to recipient bladder. If the kidney is too large for the iliac fossa, it can be positioned in the retroperitoneal space; iliac vessels may be used for anastomoses, or the aorta and inferior vena cava may be required.

7 The major anesthetic consideration is maintenance of renal blood flow. No data are available to determine whether inhaled versus intravenous techniques are better at preserving (graft) renal flow. So typical hemodynamic goals during transplant are systolic pressure >90 mm Hg, mean systemic pressure >60 mm Hg, and CVP >10 mm Hg. These goals are usually achieved without use of vasopressors, using isotonic fluids and adjustment of anesthetic doses. (In reality, CVP goals vary considerably from center to center. Some surgeons aim for CVP of about 10 mm Hg, others prefer CVP of about 20 mm Hg, and still others request specified amounts of intravenous fluids and ignore the CVP. Similarly, some programs prefer high mean systemic pressures of 80 to 100 mm Hg.) Because hemodynamic goals vary widely from center to center, close communication between surgeon and anesthesiologist is imperative. If rapid resuscitation of intravascular volume depletion is needed, low molecular weight hydroxyethyl starch is generally recommended by nephrologists and does not compromise coagulation if less than 33 mL/kg are given.[60] Neuromuscular blockade is usually accomplished with cisatracurium.

8 Once the first anastomosis is started, a diuresis is initiated (mannitol and furosemide are often both given). Heparin and verapamil should also be available in the operating room, and in some centers, anesthesiologists are asked to administer the first doses of immunosuppression. A kidney graft is defective in concentrating urine and reabsorbing sodium, so attention to electrolytes is important. For patients with diabetes, intraoperative administration of insulin to normalize blood glucose has not been formally studied for improving outcome. However, more recent studies in ICU patients suggest that outcome is significantly improved when glucose is tightly controlled.[61] Therefore, optimal management of glucose (80 to 110 mg/dL) seems a

reasonable anesthetic goal during renal transplantation. The entire surgery should take about 3 hours. Patient-controlled analgesia is a good choice for postoperative pain management. Nonsteroidal anti-inflammatory agents are contraindicated. Transplant recipients are generally discharged from the hospital within a week of surgery.

Transfusion is rarely required in the OR, although renal transplant patients are often anemic coming to surgery (and may be receiving erythropoietin). Because of immunosuppression, if cytomegalovirus (CMV)-negative patients receiving a CMV-negative organ are to receive transfusion, CMV-negative blood is preferred. Leukocyte filters are also effective in preventing CMV transmission but are probably inferior to CMV-negative blood.[62]

Most surgical complications of renal transplantation are not recognized in the operating room. The common (postoperative) complications are ureteral obstruction and fistulae, vascular thromboses, lymphoceles, and wound complications.[63] Rare complications from self-retaining retractors are bowel perforation and femoral neuropathy.[64]

Pediatric renal transplantation is associated with somewhat lower rates of success than adult transplantation, with vascular thromboses of the grafts more common in young children. Size mismatch may also be a consideration in some small children

during the operation. Adult donors to small children require the graft placement in the retroperitoneum. Although chronic peritoneal dialysis may help expand the abdominal volume,[65] attention to peak inspiratory pressures at closure is important and increased pressures should be reported to the surgical team.

LIVER TRANSPLANTATION

Preoperative Considerations

9 Patients with ESLD have multisystem dysfunction with common cardiac, pulmonary, and renal compromise because of their liver disease (Table 53-5). Anesthesiologists should be consulted about liver transplant recipients before they are listed to help surgeons assess candidacy for transplant and to help optimize organ function prior to transplant. Common indications for adult liver transplantation are hepatitis C, Laennec's cirrhosis, and autoimmune diseases.

TABLE 53-5 Multisystem Complications of End-Stage Liver Disease

▪SYSTEM	▪CONSEQUENCE
Central nervous system	Fatigue
Encephalopathy (confusion to coma)	Blood-brain barrier disruption and intracranial hypertension (acute liver failure)
Pulmonary	Hypoxemia/hepatopulmonary syndrome
Respiratory alkalosis	
Pulmonary hypertension	

Cardiovascular	Reduced systemic vascular resistance
Hyperdynamic circulation	
Diastolic dysfunction	
Prolonged QT interval	
Blunted responses to inotropes	
Blunted responses to vasopressors	
Gastrointestinal	Gastrointestinal bleeding from varices
Ascites	
Delayed gastric emptying	
Hematologic	Hypersplenism (pancytopenia)
Decreased synthesis of clotting factors	
Impaired fibrinolytic mechanisms	
Renal	Hepatorenal syndrome
Hyponatremia	
Endocrine	Glucose intolerance
Osteoporosis	
Nutritional/metabolic	Muscle wasting and weakness
Poor skin integrity	
Increased volume of distribution for drugs	
Decreased citrate metabolism	

In an effort to minimize deaths on the liver transplant waiting list with objective factors (rather than "degree of ascites") and to develop a better method for predicting survival after transplantation, the scoring system for allocation of livers was changed in February 2002. Instead of Child's class, adult patients are tracked by the MELD (model for ESLD):[66]

MELD Score = $0.957 \times \text{Log}_e$ (creatinine in mg/dL)

$+ 0.378 \times \text{Log}_e$ (total bilirubin in mg/dL)

$+ 1.12 \times \text{Log}_e$ (INR)

+ 0.643

and pediatric patients using the pediatric end-stage liver disease score (PELD):

PELD Score = (0.463[age[a]] - $0.687 \times \text{Log}_e$ [albumin g/dL]

$+ 0.480 \times \text{Log}_e$ [total bilirubin mg/dL] + 1.857

$\times \text{Log}_e$ [INR] + 0.667 [growth failure[b]]) × 10

These scoring systems were adapted from analysis of survival in patients with ESLD independent of transplantation. Ongoing analysis of the MELD/PELD as predictors of transplant survival suggests that this new scoring system helps minimize death on the waiting list.

For adult patients, a major change with MELD is the priority given to patients with renal failure. The hope is that patients will be transplanted at a time when liver transplant can reverse hepatorenal syndrome, and before combined liver-kidney transplantation (associated with poor outcome) is necessary. Nonetheless, because poor renal function is a major risk factor for poor liver transplant outcome,[67] ongoing studies are needed to determine the utility of MELD in prioritizing patients for transplantation. The new system is also designed so ongoing evaluation of MELD/PELD scores is mandated. For example, the sickest patients are required to get laboratory studies for scoring every 48 hours.

Difficult decisions about patient candidacy are common in evaluating liver transplant candidates. Several are discussed here to highlight the need for regular involvement of a transplant anesthesiologist in the candidacy evaluation process. Liver disease does not protect patients from coronary artery disease. Most patients are screened for cardiac problems using dobutamine stress echocardiography.[68] Patients with inducible ischemia are generally evaluated with cardiac catheterization in an effort to identify lesions that can be fixed with percutaneous angioplasty. Patients with severe coronary artery disease are generally not candidates for liver transplantation. (Increasingly, cardiologists are using cardiac positron emission tomography scanning for the evaluation of ischemic disease in transplant candidates.) Significant aortic stenosis also presents a difficult dilemma pretransplant.[69] Because cardiac surgery is considered risky in a patient with ESLD, a new approach is to optimize valve area using valvuloplasty before liver transplantation. Then, after the liver graft is stable, aortic valve replacement can be considered.

Another difficult lesion for which echocardiography is a useful screening tool is portopulmonary hypertension.

If screening echo suggests moderate to severe pulmonary hypertension (estimated systolic pulmonary artery [PA] pressure >50 mm Hg), right heart catheterization is suggested to document the severity of disease.[70] Multiple case reports and small retrospective reviews demonstrate that patients with portopulmonary hypertension are at substantial risk of perioperative death. There is general agreement that mean PA pressure >50 mm Hg is an absolute contraindication to liver transplantation. Patients with PA pressures between 35 and 50 mm Hg and pulmonary vascular resistance (PVR) >250 dynes·seconds·cm^{-5} are also likely at increased risk, and should be treated to lower PA pressure before proceeding with transplantation.[71] Epoprostenol is the usual first-line therapy for portopulmonary hypertension and is effective in lowering PA pressures significantly in many patients,[72] but requires home intravenous delivery in the United States. Sildenafil is an alternative for preoperative treatment of portopulmonary hypertension.[73]

PFTs are also used for screening liver transplant candidates. Severe hypoxemia in the setting of liver disease (hepatopulmonary syndrome or HPS) was once a contraindication to liver transplantation. However, if transplants are performed before anatomic changes of the lung are fixed, liver transplantation may cure HPS.[74] Inhaled NO[75] and transjugular intrahepatic portosystemic shunt (TIPS)[76] may help bridge patients with severe HPS to transplantation. (TIPS is also used to stabilize renal dysfunction, severe ascites, and variceal hemorrhages, but similar to surgical shunting, is associated with worsening of encephalopathy.) If HPS is severe and completely unresponsive to oxygen, transplantation is risky because the immediate perioperative period may be complicated by frank graft hypoxia and failure. Fortunately, most patients with HPS have some element of physiologic V/Q mismatch, are oxygen responsive, and with this "room to move" can be safely transplanted.

Intraoperative Procedures

Management of these patients has progressed substantially in the last 5 years with collected experience of transplant teams, such that intraoperative extubation of some patients is routine in busier centers. Nonetheless, intensive preparation for surgery is important because it is difficult to predict which patients are at risk for massive blood loss. We place invasive lines and monitors after induction of general anesthesia. Rapid sequence induction of general anesthesia is indicated because patients with ESLD often have gastroparesis[77] in addition to increased intra-abdominal pressure from ascites. We place two arterial catheters, one in the left radial and one in the right femoral artery. Although venovenous bypass is now rarely used in our center, the left radial catheter serves as a monitor of disruption of arterial flow if the axillary vein is used for bypass, and the right femoral arterial line leaves the left groin free for surgical bypass access. Pulmonary artery catheters or continuous echocardiography are used for monitoring volume status, and at least two large-bore catheters are placed for rapid intravenous infusions (9F each). In many centers, anesthesiologists also place percutaneous lines that can be modified and used for bypass, if necessary.[78,79] Bladder catheters and nasogastric tubes are placed in all patients. A rapid infusion system with the ability to deliver at least 500 mL/minute warmed blood is primed and in the room. Before surgical incision, blood product availability is confirmed and some blood products are in the room and checked (routinely 10 U red cells and 10 U FFP). Normothermia, essential for optimal hemostasis, is maintained with convective warming blankets over the legs and over the upper chest, arms, and head.

10 Liver transplantation is a complex surgical procedure, traditionally described in three phases: dissection, anhepatic, and neohepatic phases, with reperfusion of the graft marking the start of the neohepatic phase. During the dissection phase of surgery, blood loss may be high. The major anesthetic goals of this phase are correction of coagulopathies and maintenance of intravascular volume for renal protection.

Coagulation Management

Similar to any other surgical procedure, FFP is used to maintain INR $\leqslant$1.5 in any patient with anticipated or ongoing bleeding.[80] With rapid infusion of FFP, citrate binding of ionized calcium often requires treatment. A low dose infusion of $CaCl_2$ is better at maintaining constant Ca^{++} levels than are intermittent boluses (usually 0.5 g $CaCl_2$/hour). Platelet transfusion is used to maintain platelet count higher than 50,000/mm^3. In addition, we use cryoprecipitate concentrates to maintain fibrinogen >150 mg/dL. Cell saver blood may also be used to limit allogeneic transfusions.

Despite the complex coagulopathy in ESLD that makes intraoperative hemostasis difficult, many patients with liver disease simultaneously have a hypercoagulable state. For example, patients with autoimmune liver diseases may have antiphospholipid antibodies (and many other causes of hypercoagulable states are possible in ESLD). So, in addition to monitoring discrete parts of the coagulation profile to guide transfusion therapies, it is important to look at a measure of entire clotting mechanism. Many centers use thrombelastography,[81] others use bedside Lee-White clotting times. Using these tests, normal or hypernormal whole clotting in the presence of high INR, low platelets (and usually elevated D-dimers) should be taken as a caution that the patient

may have a clinically significant hypercoagulable state. Under these circumstances, our approach is to maintain transfusion therapies as noted previously and to avoid pharmacologic procoagulant drugs. For the majority of patients with synthetic dysfunction, thrombocytopenia, and hypofibrinogenemia, clotting is delayed. In these patients, many centers supplement transfusion therapy with antifibrinolytic agents.

Worldwide, considerable center-dependent variation in the antifibrinolytic and dose of drug used makes generalizations difficult. The majority of adult patients in our center receive epsilon-aminocaproic acid (EACA; 5 g load and 1 g/hour infusion) to support hemostasis during surgery.[82] Other centers use considerably less drug, less often. Many centers, particularly in Europe, use aprotinin routinely during liver transplantation,[83] but several case reports of fatal pulmonary embolism associated with aprotinin use[84] have made many U.S. centers shy away from the drug during liver transplantation. Fibrinolysis acutely worsens immediately after reperfusion to varying degrees, depending largely on the amount of tissue plasminogen activator (tPA) released from the graft.[85] A (re)bolus of EACA (again doses are highly variable) is helpful to maintain hemostasis once this postreperfusion exacerbation of fibrinolysis is documented.

Activated factor VII (NovoSeven, Novo Nordisk, Copenhagen, Denmark) is approved in Europe and appears to be a safe hemostatic agent during liver transplantation.[86] When this drug is given, INR rapidly normalizes,[87] even though the amount of circulating clotting factors does not change. Although no literature has commented on this resultant inability to use the prothrombin time (PT) to guide FFP transfusion, it must be kept in mind that significant synthesis of coagulation factors may take days after liver transplantation, and a normal PT in this setting does not imply normal coagulation factor reserve. In our center, acute NovoSeven administration has been useful for surgical hemostasis for placement of intracranial pressure monitors in patients with acute liver failure and for selected patients undergoing liver transplantation with difficult red cell cross matches.

Perioperative renal dysfunction is a major problem in liver transplantation, so protection of the kidneys is a critical feature of managing liver transplant patients. Virtually all anesthetics reduce renal blood flow, and it is not uncommon for urine output to decrease dramatically in these patients with induction of anesthesia. Creatinine levels may grossly underestimate the degree of renal dysfunction, especially in ESLD patients with significant muscle wasting.[88] Hepatorenal syndrome (HRS) is a functional renal disorder associated with liver disease and categorized as type 1 (acute severe decompensation, creatinine >2.5 mg/dL), which is usually fatal, and type 2 (chronic, moderate renal failure with Cr >1.5 and GFR <40 mL/min). More recent evidence suggests that albumin may

play a role in preventing and treating HRS in the setting of spontaneous bacterial peritonitis.[89] In addition, large volume (>5 L) drainage of ascites with incision is really a paracentesis that should be accompanied by albumin therapy to prevent renal decompensation, with recommended albumin doses of 6 to 8 g/L of ascites drained.[90] Terlipressin (not available in the United States) is a new option for treating HRS.[91] This drug is metabolized into lysine-vasopressin, and for this reason, if hemodynamic support is needed in the setting of HRS, low-dose vasopressin may be a good choice. Other studies suggest that norepinephrine is also well-tolerated and may even improve renal function in patients with type 1 HRS,[92] and for this reason, we use norepinephrine as vasopressor of choice during liver transplantation. There are no prospective trials to support use of one vasopressor over another during transplantation, and anesthesiologists are obligated for now to keep pace with the ICU literature concerning the best treatment for patients with HRS. The most important consideration is to ensure adequate volume replacement before instituting diuresis in the OR.

The *anhepatic phase* begins when the liver is functionally excluded (clamped) from the circulation. Traditionally, the vena cava is clamped above (suprahepatic anastomosis) and below (infrahepatic anastomosis) the liver, the portal vein, and hepatic artery are clamped. With complete cava cross-clamp, venous return falls by 50 to 60%, often resulting in hypotension. Venovenous bypass may be used to increase venous return, improve systemic hemodynamics, increase renal perfusion pressure, and decompress portal pressures for a better surgical field.[93] Venovenous bypass

certainly facilitated teaching of a generation of liver transplant surgeons, but experienced centers tend to use it increasingly less. Most patients can be managed without venovenous bypass using some volume loading (vasopressors are rarely required), but other anesthesiologists use vasopressors to support pressures during bypass. Bypass carries potential complications, including arm lymphedema, air embolism, and vascular injury, and its benefit is limited when anhepatic times are short,[94] but it is still used for selected patients in many centers. Furthermore, modification of the surgical technique to preserve caval flow (piggyback technique)[95] clearly results in more stable hemodynamics during the anhepatic period, and venovenous bypass is not needed when this surgical technique is used.

Reperfusion of the graft is the most treacherous time of the liver transplant. Communication between the surgical and anesthesia teams is essential in preparing for reperfusion. Caval clamps are removed first, and the integrity of the caval anastomoses are assured. Caval reperfusion is usually hemodynamically well tolerated. However, portal vein reperfusion (despite flushing of the graft) can often result in hemodynamic instability. The original descriptions of reperfusion syndrome emphasized (often severe) hypotension and bradycardia with portal reperfusion.[96] Now, with flushing techniques that precede reperfusion[97] and changes in preservation solution, bradycardia is uncommon. Typically, reperfusion is associated with hypotension (further drop of already low SVR and increase in CO), which may or may not require treatment.

Our preparation for reperfusion is to give sodium bicarbonate just before unclamping (50 mEq) to meet the acid load from the graft, and 500 mg $CaCl_2$ exactly simultaneous with portal unclamping to counteract the effects of potassium on the heart. If, despite this preparation, T waves (ECG) become elevated, the same treatment is repeated. Other anesthesiologists wait to see T-wave changes before treating. Lidocaine, atropine, and norepinephrine are also available at the time of reperfusion in case of ventricular arrhythmias, bradyarrhythmias, and severe hypotension. Hepatic artery unclamping is usually not hemodynamically significant.

Neohepatic Period

After hemodynamic stability is achieved, the calcium infusion is stopped. One early indication of graft function is the lack of a calcium requirement even when FFP is being infused rapidly. Usually within 30 minutes, the base deficit improves with graft metabolism of citrate. Within the first hour, the CO decreases and SVR increases as the graft metabolizes vasoactive substances. These are early signs of good graft function. In addition, the graft appearance should be noted. It should have a smooth edge, no evidence of engorgement, and bile is made in the first half-hour after reperfusion. Often, renal function improves after reperfusion, probably due to graft metabolism of renal vasoconstrictors.

During the neohepatic period, biliary anastomoses are completed, and sources of surgical bleeding are corrected. Drains are placed, and the abdomen closed. Fast-tracking protocols for liver transplant patients are common in experienced centers.[98]

Pediatric Liver Transplantation

Indications for pediatric liver transplantation differ considerably from adults, with inherited disorders dominating the preop diagnoses (Table 53-6). Children younger than 1 year of age with inherited liver disease are often very small for age. In addition, such a wide variety of metabolic diseases mandates that anesthesiologists consult specialty textbooks for medical management of children with unusual disorders. In small children, a radial artery catheter and at least one large (18 g) peripheral intravenous line are placed after induction of anesthesia. Surgeons may place tunneled central lines before incision, useful for postoperative administration of drugs as well as CVP monitoring during surgery. Children with previous Kasai operations for biliary atresia may have massive bleeding due to adhesions in the dissection phase. Small children receiving large grafts may have respiratory compromise with abdominal closure. Because hepatic artery thrombosis (HAT) is a more common complication in children than adults, some centers choose to have INR at the end of surgery in the 1.8 to 2 range. HAT is

generally recognized to be a technical issue related to the small diameter of arteries in children,[99] and intraoperative reanastomosis may be required if flow is inadequate through the artery. Aortic cross-clamping may be required for these anastomoses.

TABLE 53-6 Diagnoses Leading To Liver Transplantation In Children

▪DIAGNOSIS	▪% OF WAITING LIST
Biliary atresia	23.8
Other cholestatic diseases	
Alagille's syndrome	3.8
Inherited metabolic diseases	
α-1-antitrypsin deficiency	2.9
Wilson's disease	1.2
Tyrosinemia	1.1
Glycogen storage diseases	0.6
Acute (fulminant) liver failure	3.1
Chronic active hepatitis	
Neonatal hepatitis	0.6
Autoimmune cirrhosis	3.7
Tumors	
Cystic fibrosis	
Total parenteral nutrition/hyperalimentation	8.0
Adapted from data from UNOS (www.unos.org).	

Acute Liver Failure

Anesthetic considerations for both adults and children with acute liver failure are focused on protection of the brain. Patients with acute or fulminant hepatic failure may have a rapidly progressive course of elevated intracranial pressure (ICP), leading to herniation and death. Intracranial pressure monitoring is useful in managing these patients but risks intracranial bleeding. Vasodilating anesthetics (all inhalation agents) are to be avoided, especially without ICP monitoring. In our experience, pentothal infusion is a good maintenance anesthetic, and acute rises in ICP can be managed with etomidate. When antihypertensive therapy is required, labetalol does not cause significant cerebral vasodilation in these patients.[100] Management of intracranial hypertension is discussed in greater detail in Chapter 27.

PANCREAS AND ISLET TRANSPLANTATION

The majority of pancreas transplants (about three-fourths) are done as simultaneous pancreas/kidney transplants from a single cadaveric donor. Pancreata grafted in these procedures have the best long-term survival, compared with grafts done after kidney transplantation, or (independent) pancreas grafts. Independent pancreas grafts are usually performed for patients with type I diabetes who have frequent metabolic complications (hypoglycemia) but preserved renal function. Living donor partial pancreas grafts are not commonly performed, with the largest ongoing experience at the University of Minnesota.[101]

The preoperative assessment of pancreas transplant recipients focuses on the end-organ complications of diabetes reviewed in Chapter 41. Monitoring will depend on cardiac status, but generally patients do not require PA catheters, and have been evaluated for risk of intraoperative cardiac complications as part of the transplant workup. Nonetheless, cardiovascular disease is present in many patients undergoing pancreas transplantation.

The major difference between pancreas transplantation and other procedures is that strict attention to control of blood glucose is indicated to protect newly transplanted beta cells from hyperglycemic damage. No formula for controlling blood glucose has emerged as a standard of intraoperative management. In general, if adult patients arrive with glucose >250 mg/dL, 10 U of insulin can be given intravenously, followed by an infusion of insulin. The infusion starting rate varies, depending on the initial blood glucose level. Once blood glucose levels are controlled (<150 mg/dL), intravenous 5% dextrose (about 100 mL/hour) should also be infused as the insulin infusion is continued. The most important issue is to check the response to insulin frequently and adjust infusions as necessary. No literature exists for a patient with an implanted insulin pump, but it seems reasonable to continue to use the pump at basal rates in these patients as long as its operation is reviewed[102] and blood glucoses are monitored regularly during surgery.

Islet transplants were revived by the Edmonton protocol, published in 2000.[103] The major changes introduced included a glucocorticoid-free immunosuppression regimen and immediate transplantation of islets after isolation. Because processing of islets takes only a few hours, the new protocols mean little flexibility in timing islet transplants—the sooner the islets are transplanted, the better they will function. Islets are generally infused into the portal circulation. Acute portal hypertension is a feared complication.[104]

SMALL BOWEL AND MULTIVISCERAL TRANSPLANTATION

In 2003, the American Gastroenterological Association published a medical position statement concerning indications for intestinal transplantation (http://0-www.guideline.gov.innopac.up.ac.za:80/summary/summary.aspx?ss=15&doc_id=3795&nbr=3021#s23). Indications for intestinal transplantation include impending liver failure in patients with intestinal failure (or short gut syndromes requiring total parenteral nutrition [TPN]), frequent severe dehydration in patients with intestinal failure, and severe complications of central lines for TPN (sepsis, thrombosis of central veins). Patients who develop liver failure from TPN for intestinal failure are candidates for combined liver-intestine transplantation. In these cases, liver failure should be irreversible, and biopsy findings are often required for this conclusion in patients without overt ESLD,[105] especially because isolated intestinal transplantation may have better results than the combined procedure.[106] In general,

intestinal transplantation should only be considered in patients with life-threatening complications of their intestinal failure.

For anesthesiologists, a major hurdle for these transplants is line placement adequate for transfusion of blood products and fluids, which may be substantial during these long cases. Anesthesiologists should review angiographic studies to determine patency before attempting central line placement. Ultrasound devices are helpful in identifying the known patent vessels for cannulation, but surgical cutdowns for venous access may be necessary, including transhepatic or intraoperative renal vein catheterization.[107] Superior vena cava or inferior vena cava obstruction may require preoperative intervention (surgical and/or lytic) so adequate vascular access for surgery is possible.[108] Antibiotic regimens should be continued during the surgery. Nitrous oxide, as in liver transplantation, is avoided.

Common complications of intestinal failure include dehydration and electrolyte abnormalities, gastric acid hypersecretion, pancreatic insufficiency, bone disease, and TPN-induced liver failure.[109] Because electrolyte abnormalities are common, they should be monitored continuously during surgery and appropriate replacement instituted. Because enteral feeding will not be possible until weeks after surgery, TPN should be continued in the perioperative period.

Like reperfusion of liver grafts, intestinal reperfusion is associated with an acute release of acid and potassium from the graft. Anticipatory bicarbonate and $CaCl_2$ administration is used to counteract the effects of acid and potassium on the heart. After reperfusion, coagulopathy may worsen, usually managed by reassessment of INR, fibrinogen and platelet counts, and correction with blood products.

LUNG TRANSPLANTATION

Lung transplantation is now accepted therapy for end-stage pulmonary and pulmonary vascular disease, building on successful case series from the early 1980s.[110,111] UNOS reports more than 11,000 lung transplant procedures since 1995, but more than 3,000 patients have died awaiting transplant in this same time frame, due to the shortage of suitable organs. The Registry of the International Society for Heart and Lung Transplantation (ISHLT) lists chronic obstructive pulmonary disease, idiopathic pulmonary fibrosis, cystic fibrosis (CF), and

α_1-antitrypsin deficiency as the most common preoperative diagnoses.[112]

Surgical options for lung transplantation are single lung transplant, en bloc double and sequential double transplants, and heart-lung transplantation. Single and sequential double lung transplants can be performed without cardiopulmonary bypass (CPB), although CPB is often used, especially for recipients with pulmonary hypertension. Bilateral lung transplantation is most commonly used in patients with associated pulmonary vascular disease and CF-related bronchiectasis. Single lung transplantation for emphysema gained favor based on good short-term outcomes, with the added advantage of leaving a donor lung for another recipient. Lung transplant centers vary in their use of single or double lung transplant for varying diagnoses, and the better procedure based on recipient preoperative status and diagnosis is still debated.[113] It is generally agreed that double lung transplantation is indicated in the presence of pulmonary infection (CF), severe bullous emphysema, and primary pulmonary hypertension (PPH). Eisenmenger syndrome is managed with single or bilateral lung transplantation.

Recipient Selection

International Guidelines for the Selection of Lung Transplant Candidates were published in 1988 by consensus agreement of several thoracic societies (summarized in Table 53-7).[114] In general, patients should be considered for lung transplantation if they exhibit decline in pulmonary function, despite maximal medical therapy, and expected life span is only 2 to 3 years. Contraindications to lung transplantation are based on their impact on long-term survival. Symptomatic osteoporosis, thoracic musculoskeletal abnormalities, corticosteroid use, nutritional status (<70% or >130% of ideal body weight), active addiction or psychiatric conditions, mechanical ventilation, and colonization with resistant organisms are relative contraindications.

Absolute contraindications are significant dysfunction of other organs particularly kidney and heart, HIV or chronic hepatitis B or C, and malignancy (other than basal cell or squamous cell skin carcinoma). Patients with significant cardiac disease can be considered for heart-lung transplantation, but are not candidates for isolated lung transplant.

TABLE 53-7 Lung Recipient Selection Guidelines

▪GENERAL INDICATIONS	
End-stage lung disease	
Failed maximal medical treatment of lung disease	
Age within limits for planned transplant	
Life expectancy <2–3 yr	
Ability to walk and undergo rehabilitation	
Sound nutritional status (70–130% of ideal body weight)	
Stable psychosocial profile	
No significant comorbid disease	
▪DISEASE-SPECIFIC INDICATIONS	
COPD	FEV_1<25% of predicted value after bronchodilators
	and/or $PaCO_2$ = 55 mm Hg
	and/or pulmonary hypertension (especially with cor pulmonale)
	Chronic O_2 therapy
Cystic fibrosis	FEV_1 <30% predicted
	Hypoxemia, hypercapnia, or rapidly declining lung function
	Weight loss and hemoptysis

	Frequent exacerbations, especially young females
	Absence of antibiotic-resistant organisms
Idiopathic pulmonary fibrosis	Vital capacity <60–65% of predicted
	Resting hypoxemia
	Progression of disease despite therapy (steroids)
Pulmonary hypertension	NYHA functional status class III or IV, despite prostacyclin therapy
	Mean right atrial pressure >15 mm Hg
	Mean pulmonary artery pressure >55 mm Hg
	Cardiac index <2 L/min per m^2
Eisenmenger's syndrome	NYHA class III or IV, despite optimal therapy
Pediatric	NYHA class III or IV
	Disease unresponsive to maximal therapy
	Cor pulmonale, cyanosis, low cardiac output
COPD, chronic obstructive pulmonary disease; FEV_1, forced expiratory volume in 1 sec; NYHA, New York Heart Association.	

As for other transplants, patients are screened for malignancy (mammography, Pap test, colonoscopy). Systemic disease processes such as diabetes and hypertension are not considered contraindications, as long as they are clinically stable and medically optimized. Lung transplantation has not been advocated for acute disease processes, such as acute respiratory distress syndrome. PFTs, left and right heart catheterization, and transthoracic echocardiography are routinely used for evaluating recipients. Survival is inversely correlated with patient age, and for these reasons, recommended age limits are

- Heart-lung transplant: 55 years
- Double lung transplant: 60 years
- Single lung transplant: 65 years

A voluntary survey of current clinical practices in North America found remarkable concordance among transplant centers in their patient selection criteria,[115] similar to criteria listed in Table 53-7.

CF is associated with complex pulmonary infections that clearly impact transplant outcomes.[116,117] Patients infected with *Burkholderia cepacia* have poor outcome, and many U.S. centers consider this infection (or some subtypes of the organism) a contraindication to transplantation.[117,118] Twenty-year data by the Toronto group found better long-term survival in CF patients free of *B. cepacia* than in similar patients who were infected.[119]

Preanesthetic Considerations

Medical evaluation prior to listing a patient for transplantation encompasses many specialties. Unfortunately, anesthesiologists are not always included in this process. If the patient has been on the waiting list for an extended period, it is important to review lab and functional data because diagnostic testing was performed for transplant listing. It is critical to confirm ABO compatibility of donor and recipient prior to surgery. By definition, lung transplant candidates have poor pulmonary status and are frequently receiving multiple therapies, including oxygen, inhaled bronchodilators, steroids, and vasodilators. These medications should be continued in the perioperative period. Because of the short ischemic times needed for optimal organ function, the procedure must be performed as soon as an organ becomes available, precluding delay of cases for full stomachs.

Although patients are understandably anxious, they also have minimal pulmonary reserve, and sedation must be done carefully under monitored conditions. After determining oxygen saturation, slow, incremental dosing of a short-acting

benzodiazepine (0.25 to 1.0 mg midazolam) is used for anxiolysis. Narcotic premedication must be given with extreme care in hypercarbic patients. Premedication with a combination of metoclopramide, histamine-2 antagonists, and a nonparticulate antacid is usually warranted. Many patients are not able to rest supine or in the Trendelenburg position for placement of central access. Placement of large-bore peripheral intravenous catheter and arterial access is usually adequate for initiation of the anesthetic, with central access placed after induction. Placement of a PA catheter with continuous cardiac output and mixed venous oxygenation monitoring provides both rapid assessment of cardiopulmonary status changes and minimizes the fluid administration necessary for frequent cardiac output determinations. Epidural catheters are placed preoperatively at some centers, especially in patients who are believed unlikely to require CPB. (It is not always possible, however, to determine need for CPB preoperatively.) The American Society for Regional Anesthesia Consensus statement on regional anesthesia in the anticoagulated patient[120] states that there is currently insufficient evidence to determine the risk of neuraxial hematoma in patients receiving neuraxial anesthesia and full systemic anticoagulation. Another option is to place the epidural in the early postoperative period after coagulopathies are corrected. This can be done in the lightly sedated patient during weaning of the ventilator, allowing better neurologic monitoring and optimizing pain control prior to extubation. It is currently recommended that recipients receive antibiotics based on donor Gram's stain results, with alteration of therapy as necessary after receipt of culture data.[121]

Intraoperative Management: Single Lung Transplantation

Lung transplant recipients tend to be chronically intravascularly volume depleted, and anesthetic induction can be associated with hypotension. Because fluid restriction is beneficial for postoperative management, small fluid boluses and slow induction with etomidate and narcotics are prudent. These patients remain intubated for hours to days postoperatively, so a fast-track anesthetic technique is unnecessary. A balanced technique combining narcotic and inhalational anesthetics is preferred. Muscle relaxation can be maintained with any nonhistamine-releasing agent. Nitrous oxide is rarely an anesthetic option due to bullous emphysematous disease, pulmonary hypertension, or intraoperative hypoxemia. Lung isolation, preferably with a double-lumen endotracheal tube, is necessary for single and bilateral sequential lung transplantation. The

double-lumen endotracheal tube facilitates suctioning of secretions and improved deflation of the operative lung during the initial dissection. A bronchial blocker is more easily dislodged with surgical manipulation, may not provide isolation of the right upper lobe, and requires repositioning midsurgery in the case of a bilateral sequential procedure. Left-sided endotracheal tubes are preferred, due to ease of positioning within the left main-stem bronchus.

A single lung transplant can be performed via posterolateral thoracotomy position. If the surgeon is concerned about possible need for CPB, then the patient must be positioned to allow rapid access to either the aorta and right atrium or the femoral artery and vein. This can be accomplished via either anterior thoracotomy with partial sternotomy or posterolateral thoracotomy with decreased angulation of the hips to allow access to the femoral vessels. Determination of operative side is based on preoperative ventilation-perfusion studies and prior thoracic surgeries. The lung with poorer function is typically the one replaced.

During one-lung ventilation, hypoxemia is common. Strategies to improve oxygenation and ventilation are the same as those discussed in Chapter 29. Introduction of anesthesia machines with pressure-controlled ventilation has diminished the need for ICU ventilators during the operative procedure. Although an ICU ventilator can provide improvement in oxygenation and ventilation, it does not allow concomitant use of inhalational anesthetic, an option available on the newer anesthesia machines.

12 Lung recipients are susceptible to development of pulmonary hypertension and right ventricular (RV) dysfunction or failure during one-lung ventilation. Optimizing oxygenation and ventilation does not always improve RV function, and vasodilator and/or inotropic support may be required. Some anesthesiologists use inhaled nitric oxide (INO) routinely for lung transplantation,[122] whereas others[123] believe the potential adverse side effects mean its use should be more restricted. Proponents argue that use of INO in the recipient, and possibly even the donor, takes advantage of immunomodulatory and antimicrobial activities of NO that reduce recipient lung injury.[122,124] Opponents argue INO use should be limited to the population at risk for needing CPB during lung transplantation and to patients with reperfusion injury. They cite risks of methemoglobinemia, NO metabolite-related lung injury, and decreased sensitivity of exhaled NO monitoring as a diagnostic tool for acute lung rejection. Further study is needed to confirm the findings in a small cohort suggesting that INO is safe and effective in lung transplantation patients.[125]

NO has an extremely short duration of action in vivo, rapidly inactivated by reacting with heme, producing methemoglobin. INO therapy is used to decrease pulmonary vascular resistance and improve oxygenation. Because INO is preferentially delivered to ventilated areas, vascular relaxation in these areas leads to improved blood flow, and hence improvements in ventilation-perfusion mismatch and improved oxygenation. Rapid inactivation of INO in the pulmonary vasculature prevents systemic vasorelaxation and resulting systolic hypotension.

NO activates NOS in other tissues to produce other clinically beneficial actions. NO activates guanylate cyclase in platelets to attenuate platelet aggregation and adhesion.[126] NO can potentiate microbial killing.[127] INO can thus decrease pulmonary vascular resistance, improve oxygenation, decrease inflammatory response to surgery or trauma, impede microbial growth, and have an effect limited only to the pulmonary system. Its use in successful management of lung transplant patients is well documented.[122,124,125]

CPB is indicated during lung transplantation if adequate oxygenation cannot be maintained, despite ventilatory and pharmacologic maneuvers and PA clamping by the surgeons. Inability to ventilate or development of RV dysfunction is also an indication for CPB. After pneumonectomy, the surgeon will size the donor vascular tissue to the recipient vessels, and sequentially anastomose the atrial/pulmonary vein patch, bronchus, and pulmonary artery. The lung is kept cool with packed ice in the field until reperfusion. Circulation is restored to the donor lung, suture lines are checked for hemostasis, and then ventilation is begun. Systemic hypotension can occur during reperfusion, but it is not as significant as that seen with liver graft reperfusion. Hyperkalemia is also not a common reperfusion event. There can, however, be reperfusion injury to the lung presenting as pulmonary edema. PEEP is useful in this scenario. Bronchoscopy to

suction secretions and blood is recommended to improve ventilation and oxygenation, and to examine bronchial suture lines.

Intraoperative transesophageal echocardiography (TEE) has become a valuable tool in the assessment of lung transplant patients. A comprehensive TEE exam should be performed after induction of anesthesia with attention focused on biventricular function, presence of valvular regurgitation, patent foramen ovale (PFO) or atrial septal defect (ASD), and pulse wave Doppler flow patterns in the pulmonary veins. Significant RV

dysfunction, valvular regurgitation, or intraatrial shunt may lead the surgeon to plan the operation with CPB. TEE can be helpful in monitoring RV function during initial clamping of the PA for a procedure done without CPB. After reperfusion, another comprehensive TEE exam should be performed. Pulmonary vein anastomotic obstruction can be diagnosed with careful Doppler exam of the pulmonary venous inflow. Because this condition leads to a high incidence of acute graft failure, rapid diagnosis and treatment in the OR are beneficial.

At the completion of the procedure, the patient should be evaluated for exchange of the double-lumen endotracheal tube to a large (8 mm ID or larger) single-lumen endotracheal tube. Significant oropharyngeal edema or high PEEP requirement justify leaving the double-lumen tube in place for 24 hours to allow improvement in clinical status.

Double Lung Transplantation

Bilateral lung transplant is performed in the supine position via the clamshell incision. The arms can be suspended on a padded bar above the patient or tucked at the sides. These cases can also be performed with sternotomy. En bloc double lung transplant requires CPB, and a single-lumen endotracheal tube is sufficient. Bilateral sequential transplantation requires lung isolation, preferably via a double-lumen endotracheal tube. Bilateral sequential transplant is now the preferred procedure because a tracheal anastomosis is unnecessary, and surgical bleeding is less. Most centers electively institute CPB for this procedure in the presence of preoperative pulmonary hypertension, and urgent CPB for indications discussed previously. Serial implantation implies longer ischemic time for the second lung, but this has not adversely affected outcome. The clamshell incision is extensive and can cause significant postoperative pain. Thoracic epidurals are often used to provide pain relief.

Pediatric Lung Transplantation

The Registry of the International Society for Heart and Lung Transplantation Pediatric Report indicates that transplantation of very young children is becoming increasingly uncommon.[128] Instead, adolescents are being transplanted, and the most common diagnoses are cystic fibrosis (CF), congenital heart disease, and primary pulmonary hypertension. Congenital heart disease is the most common indication in infants. Survival is worse for pediatric than for adult lung transplant recipients, and has not improved significantly since 1992, with 5-year survival about 40%. Patients receiving bilateral lung transplants have a better outcome than those receiving single lung transplantation. Only 634 pediatric lung transplants are reported in the UNOS database, and 93 of these are living-related donor lung transplant (LRDLT). The literature regarding pediatric lung transplantation suggests a small increase in life span and an increase in quality of life in the majority of the survivors at 3 years. Cautious optimism appears to be the current status of this procedure.

Most pediatric patients receive double lung transplantation with CPB. Single lung procedures are reserved for larger adolescents with CF. A single-lumen endotracheal tube is adequate. The clamshell incision is used. Central and arterial access is necessary for perioperative monitoring purposes.

Heart-Lung Transplant (Adult and Pediatric)

Heart-lung transplantation is the least common intrathoracic transplant procedure. UNOS lists 834

total procedures to date, with 146 in the pediatric age group. Only 10 cases were reported worldwide in 2001.[128] Bilateral sequential lung transplant has largely replaced heart-lung transplantation, combined with advances in the pharmacologic management of pulmonary hypertension and RV failure. PPH and pulmonary hypertension associated Eisenmenger syndrome are the most common indications for heart-lung transplant. CF is the third most common diagnosis, with the CF native heart usually given to another recipient (domino procedure). Patients with Eisenmenger syndrome have the best survival rates in the adult population (ISHLT adult 2003).[129] Anesthetic management of these patients is similar to that of isolated heart or lung transplantation. Because a tracheal anastomosis is performed, a single-lumen endotracheal tube is adequate. The endotracheal tube is either removed or withdrawn above the suture line during CPB. Inotropes may be needed for RV dysfunction immediately postbypass. Pulmonary reperfusion injury can also occur, requiring PEEP and suctioning, as during isolated lung transplantation.

HEART TRANSPLANTATION

Since Christian Barnard performed the first successful heart transplant in South Africa in 1967, the procedure has moved into the realm of acceptable practice for treatment of heart failure recalcitrant to medical therapy. More than 36,000 individuals have received heart transplants in the United States since 1988. Unfortunately, more than 6,000 patients died while waiting for a donor during that time. Currently, more than 3,000 patients await heart transplants (http://www.unos.org). Overall, 1-year survival has improved from 74% in the early 1980s to 86% in the late 1990s.[130] Ten-year survival was 40% in one study.[131]

The most common diagnoses leading to transplantation are ischemic and idiopathic dilated cardiomyopathies. Less common diagnoses include viral, infiltrative, postpartum, and congenital heart disease-related heart failure.[129] Due to the limited availability of donor organs, technologies that can extend the life of patients waiting for donors have developed. Temporary implantation of a ventricular assist device can provide circulatory support to critically ill patients. Newer versions of the left ventricular assist devices (LVADs) are small enough that some centers are using these devices as permanent treatment for heart failure.[132] Totally implantable artificial hearts are not currently used because of technical issues. Heterotopic heart transplantation has been virtually abandoned.

Recipient Selection

In 1996, the 5-year survival for CHF was reported to be less than 30%.[133] Medical therapy of CHF has improved dramatically in the past 10 years. Current pharmacologic therapy includes angiotensin-converting enzyme (ACE) inhibitors, beta-blockers (specifically carvedilol), diuretics, and digoxin. Cardiac resynchronization therapy can also improve symptoms, exercise tolerance, and quality of life in properly selected patients;[134] however, long-term survival data are not yet available. More than 2 million Americans have CHF, with the incidence increasing with age. Of these, only about 6,000 per year are listed for heart transplantation.

Consensus guidelines for selection criteria were last published in 1993[135] with some recent modifications.[130,136] Patients referred for transplant evaluation should have New York Heart Association class III or IV heart failure, despite optimal medical therapy. Surgical correction of coronary artery disease or valvular heart disease should be undertaken prior to listing. Patients with severe mitral regurgitation and low ejection fraction should be considered for mitral valve repair

instead of transplantation because survival is better than with transplantation.[136] Most candidates have severe left ventricular systolic dysfunction; however, transplantation is occasionally indicated for treatment of refractory angina, unmanageable arrhythmias, or diastolic heart failure.

Prognosis in patients with CHF has been linked to functional capacity. Maximal exercise testing with oxygen uptake (VO_2) is an excellent method to determine functional capacity.[136] In patients on a stable medical regimen, maximal VO_2 less than 10 mL/kg/min is associated with a poor prognosis. Patients with VO_2 greater than 10 mL/kg/min have a better 1-year prognosis with

medical therapy than transplantation. Patients with Holter monitor evidence of asymptomatic, significant ventricular ectopy should be considered for transplantation to reduce the risk of sudden death.

Pulmonary hypertension is associated with increased perioperative mortality, so severe, irreversible pulmonary hypertension is a contraindication to transplant. Right heart catheterization is performed to determine transpulmonary gradient (the difference between mean PA and PCWP) and pulmonary arteriolar resistance. Transpulmonary gradient >12 indicates significant pathology. Pulmonary arteriolar resistance (the ratio of transpulmonary gradient to cardiac output, expressed as Wood units) >2.5 also indicates a high risk of perioperative RV failure. Patients with elevated transpulmonary gradient or pulmonary arteriolar resistance require management with sodium nitroprusside, prostacyclin, dobutamine, or milrinone in an attempt to decrease pulmonary resistance. Patients unresponsive to these therapies are often considered too high risk for transplantation and may be candidates for LVAD insertion as definitive therapy or bridge to transplant.

Contraindications to cardiac transplantation include significant noncardiac diseases. Because immunosuppressive agents have renal and hepatic side effects, the presence of intrinsic renal or hepatic disease increases perioperative risk of organ dysfunction or failure. Some patients with multiorgan disease can be considered for combined heart-kidney or heart-liver transplant in these cases. Patients with FEV_1 <50% predicted, despite optimal management of CHF, are at increased risk for ventilatory failure and respiratory infections posttransplant. The presence of significant atherosclerosis is a contraindication due to the increased perioperative morbidity and mortality of atheroembolic phenomenon.

Preanesthetic Considerations

Donor heart function worsens with ischemic times above 6 hours. For this reason, transplantation must occur when the donor surgery can be performed, frequently during night hours. Preoperative evaluation and preparation of the patient must be done quickly. Close communication between the donor and recipient teams facilitates optimal use of donor organs. The goal is to minimize organ ischemic time. Optimally, the recipient heart will be excised when the donor heart arrives. Induction of anesthesia and surgical incision of the recipient begin when the donor team has evaluated the donor and made the final determination that the organ is acceptable. Timing decisions are based on distance and time necessary to transport the donor organ, as well as time it will take to prepare the recipient. History of prior sternotomy or difficult airway can increase recipient preparation time.

When evaluating the recipient, a few issues need special attention: NPO (nothing by mouth) status, level of cardiovascular support (inotropic infusions, chronic medications for heart failure, presence of LVADs), and presence of hemodynamic monitoring lines or antiarrhythmic devices, such as pacemaker or defibrillator. A pacemaker or defibrillator needs to be interrogated and reprogrammed to a mode that will not be affected by electrocautery interference. Due to the emergency nature of these cases, it is common that the patient has recently eaten, and rapid sequence induction may be necessary. Patients are frequently taking ACE inhibitors, which could increase the risk of intraoperative hypotension, or coumadin, which can increase the risk of bleeding. Vasopressin infusions can be beneficial for treatment of ACE inhibitor-induced hypotension, and FFP should be ordered if the INR is elevated. If cardiac status has deteriorated recently, the patient may be receiving infusions of inotropes, such as dobutamine or milrinone. On occasion, patients are receiving chronic dobutamine therapy as outpatients. If patients have had multiple central lines, ultrasound evaluation of the central vessels may be helpful to determine vessel patency. Recent chest films and laboratory studies must be reviewed to assess pulmonary, hepatic, and renal compromise associated with CHF.

Many anesthetic management issues related to the heart transplant patient are similar to those for open heart surgeries (see Chapter 31). The notable differences are strictest attention to sterility and immunosuppression, poorer hemodynamic status of transplant candidates, and issues related to early donor heart function and denervation. The surgical team will request antibiotics specific to

donor and recipient infectious patterns, and immunosuppressive medications are given prior to incision.

Placement of the PA catheter prior to anesthetic induction is favored by many centers. Mixed venous saturation (SvO_2) PA catheters are optimal because they provide continuous assessment of CO and SvO_2. If the patient cannot lie flat for central line placement, cautious induction can proceed, but arterial catheters should always be used for blood pressure monitoring during induction. Large-bore intravenous access is necessary for administration of resuscitation medications if no central line is present during induction. Inotropes should be readily available prior to induction. Dobutamine, epinephrine, milrinone, norepinephrine, dopamine, vasopressin, and phenylephrine have all been used effectively in the perioperative management of heart transplant patients.

Presence of an LVAD or prior sternotomy increases the length and the risks associated with the procedure. Aprotinin reduces allogeneic transfusion requirements in patients undergoing repeat sternotomy.[137] Aprotinin has also been used extensively for high-risk procedures, such as LVAD insertion. Where possible, old medical records should be reviewed to determine use of aprotinin during prior operations. Aprotinin is a foreign protein, and its use is associated with anaphylaxis if reexposure occurs within 6 months.[138,139,140] If aprotinin has been used recently or exposure is uncertain, the test dose should not be administered until such time that the surgeons could rapidly institute CPB for management of hemodynamic collapse. Four units of blood should be immediately available prior to sternotomy for all repeat procedures. Availability of FFP, platelets, and cryoprecipitate should be confirmed at the start of the procedure.

Intraoperative Management

Anesthetic induction in patients with poor ventricular function can be complicated by hemodynamic instability. Instituting inotropes, or increasing those already infusing, can be beneficial in these cases. Choice of anesthetic technique should be focused on minimizing cardiovascular complications. High-dose narcotic techniques have been used for induction and management of cardiac transplantation patients for many years with good results.[139] Balanced anesthetic techniques, using lower doses of narcotics and inhalation anesthetics, can also be used.[136] Neuromuscular blockade with a nondepolarizing agent is recommended. Hypotension may not respond to ephedrine or

phenylephrine, and inotrope use should be rapidly instituted or increased if response to phenylephrine is inadequate.

TEE should be performed intraoperatively if there are no contraindications to the procedure. The recipient heart can be monitored prior to CPB for changes in ventricular function or increase in valvular regurgitation. Early diagnosis of deterioration can facilitate rapid therapy and hemodynamic stability. The risk of intracardiac thrombus is increased in the recipient heart. The left atrium and ventricle should be carefully examined. Manipulation of the heart is minimized prior to aortic cross-clamping if thrombus is noted. TEE is also beneficial for evaluation of the donor heart during and after CPB.

Incision is via median sternotomy for orthotopic heart transplantation. The recipient heart is excised, except for the left atrial tissue encompassing the pulmonary veins. In the classic approach, the atria are transected at the grooves. The biatrial approach totally excises both atria, mandating bicaval anastomosis. The biatrial approach is preferred in pediatric recipients.

Heparin dosing is similar to that of other CPB procedures. Cannulation of the aorta is performed high along the ascending aorta, near the aortic arch. The superior and inferior vena cavae are cannulated individually. By encircling the cavae with tourniquets, all blood flow is directed through the cannula into the bypass circuit, and the surgical field is bloodless. Prior to resection of the native heart, the PA catheter should be withdrawn from the surgical field. The catheter can be readvanced after removal of the superior caval cannula. Maintenance of CPB, and weaning from CPB, are associated with the same issues as for other cardiac surgical procedures. Ischemic time for the donor heart starts with aortic cross-clamp during the harvest and ends with removal of the

cross-clamp from the recipient aorta. Air should be evacuated prior to weaning from CPB.

Prior to weaning from CPB, the heart is reevaluated with TEE, looking at ventricular and valvular function. Intracardiac shunts should be ruled out. Because the donor heart is denervated, normal physiologic feedback loops controlling inotropy and chronotropy are lost. Isoproterenol is used frequently for its direct effects on cardiac beta-receptors to increase graft heart rate. Use of temporary epicardial pacing is sometimes needed until isoproterenol has had adequate time to reach maximal effect. (Vasoactive drug effects in heart transplantation are reviewed in Table 53-8.) Residual atrial tissue may continue to have electrical activity, seen clinically as two P waves on ECG. The native P wave has no physiologic activity on the donor heart.

TABLE 53-8 Effect Of Denervation On Cardiac Pharmacology

·SUBSTANCE	·EFFECT ON RECIPIENT	·MECHANISM
Digitalis	Normal increase of contractility, minimal effect on atrioventricular node	Direct myocardial effect, denervation
Atropine	None	Denervation
Adrenaline	Increased contractility	Denervation
	Increased chronotropy	hypersensitivity
Noradrenaline	Increased contractility	Denervation
	Increased chronotropy	No neuronal uptake
Isoproterenol	Normal increase in contractility, normal increase in chronotropy	
Quinidine	No vagolytic effect	Denervation
Verapamil	Atrioventricular block	Direct effect
Nifedipine	No reflex tachycardia	Denervation
Hydralazine	No reflex tachycardia	Denervation
Beta-blocker	Increased antagonist effect	Denervation

Inotrope selection for weaning from CPB is similar to other cardiac surgical procedures. Special consideration should be given to recipients with preoperative pulmonary hypertension, donor hearts with a long ischemic time, or those that were believed to be marginal organs at time of

harvest. The risk of donor right heart failure is increased in these cases. The donor right heart is not accustomed to high pulmonary resistance and may fail acutely. Therapy for graft right heart failure is similar to therapy for right heart failure in other cardiac cases. The goal is to improve contractility and decrease pulmonary vascular resistance. If intravenous agents are not adequate support to wean from CPB, inhaled NO and inhaled prostacyclin (Iloprost) have been shown to be beneficial in this population.[141,142,143,144]

Pediatric Heart Transplantation

UNOS reports 4,054 pediatric heart transplants performed since 1988. Sixty percent are performed on children younger than 1 year of age or children older than 11 years of age. The pretransplant diagnosis was congenital heart disease or idiopathic/viral cardiomyopathy in 75% of these patients. Eight hundred fifty children have died while waiting for a suitable organ. Extracorporeal membrane oxygenation is used as a bridge to transplant at some centers, although it is acknowledged to be only a short-term option.[145] Marginal donors are, not surprisingly, also being used for pediatric heart grafts, including size mismatches of more than three times recipient body weight, high donor inotrope requirement, prolonged ischemic time, and ABO mismatch. (LVADs are currently not available for pediatric patients.) Although ABO incompatible transplantation is contraindicated in the adult population, it is more successful in infant recipients.[146,147] Hyperacute rejection does not occur due to the immaturity of the immune system, and absence of antibodies to various antigens, including blood group antigens. For ABO mismatched grafts, recipient isohemagglutinin titers are obtained pretransplantation, and then plasma exchange is performed during CPB. Four-year follow-up data show similar morbidity and mortality compared with ABO-compatible recipients. Furthermore, waiting list survival is improved due to expansion of the donor pool.

Preoperative evaluation focuses on cardiopulmonary status, and the particulars of the cardiac physiology in congenital heart disease patients. Palliative procedures may have been performed prior to transplant, and reoperation increases surgical risk. Central venous catheters and intraarterial catheters are placed routinely, although frequently after induction. After an inhalation induction, anesthetic management frequently involves high-dose narcotics and intermittent benzodiazepines.

Anesthetic Management of the Transplant Patient for Nontransplant Surgery

As the population of transplant recipients increases, the incidence of elective or emergent nontransplant surgery in this group will also increase.[148] These patients cannot always return to the transplant facility for surgery, so it is incumbent on

all anesthesiologists to review perioperative issues associated with transplantation.[149]

13 For solid organ recipients, evaluation of patients is centered on function of the grafted organ. In renal transplant patients, the level of renal dysfunction will determine choice of drugs, particularly neuromuscular blockers, and dose modification of drugs dependent on renal excretion such as antibiotics. Table 53-9 lists medications that can cause renal dysfunction when administered to a patient receiving immunosuppressive agents. A major consideration for renal transplant recipients is maintenance of renal perfusion with adequate volume replacement. Thus, CVP monitoring is useful for preventing prerenal damage to transplanted kidneys, but CVP lines must be placed using strict aseptic technique.

TABLE 53-9 Drugs That May Cause Renal Dysfunction When Coadministered With Calcineurin Inhibitors

Amphotericin	Cotrimoxazole
Cimetidine	Vancomycin
Ranitidine	Tobramycin
Melphalan	Gentamicin
Nonsteroidal anti-inflammatory drugs

Similarly failing, rejecting, or reinfected liver grafts are often accompanied by deterioration of renal function. Protection of the kidneys is a central part of anesthesia plans, and CVP or TEE is useful to guide fluid replacement, especially in cases where large fluid shifts are anticipated.

14 For all transplant recipients, antibiotic, antiviral, antifungal, and immune suppression regimens should be disrupted as little as possible in the perioperative period. This may require coordination with the transplant center. Complications of immune suppression are reviewed in Table 53-3, and important drug interactions with calcineurin inhibitors are reviewed in Table 53-10.[149] Significant intraoperative fluid shifts can cause acute decrease in cyclosporine or tacrolimus blood levels, and in these cases, consideration should be given to repeat testing of drug levels during the day of surgery.[149] Nonsteroidal anti-inflammatory medications should be avoided for a number of reasons. First, many patients have underlying renal dysfunction related to immunosuppressives. Second, the risk of GI hemorrhage is increased in patients already at risk for gastritis due to chronic steroids.

TABLE 53-10 Drugs Affecting Cyclosporine Or Tacrolimus Blood Levels

·INCREASE BLOOD LEVELS	·DECREASE BLOOD LEVELS
Bromocriptine	Carbamazepine
Chloroquine[a]	Octreotide[a]
Cimetidine[b]	Phenobarbital
Clarithromycin	Phenytoin
Cotrimoxazole	Rifampin

Danazole	Ticlopidine
Erythromycin	
Fluconazole	
Itraconazole	
Ketoconazole	
Metoclopramide	
Nicardipine	
Verapamil	
[a]Reported with cyclosporine; may not interact with tacrolimus.	
[b]May not interact with cyclosporine.	

Patients who present for surgery with signs of acute rejection or infection may benefit from delay of surgery to optimize status. Both rejection and infection in the face of surgery are associated with increased risk of morbidity and mortality.[149] Regional and general anesthetic techniques have been used successfully in posttransplant patients. In addition to the standard ASA monitors, invasive monitors should be used if warranted based on surgical procedure and general health status of the patient. Invasive monitoring is not indicated solely on the basis of prior transplantation. Nasal intubation should be avoided, due to the potential risk for infection presented by nasal flora.

Lung Transplant Recipients

If the patient had a lung transplant that included a tracheal anastomosis, denervation has occurred below the level of the suture line, and the cough reflex is diminished or absent. These patients are at increased risk of retained secretions and pneumonia, and have an increased airway hyperreactivity and bronchospasm. Because most lung transplants are now being done with bronchial instead of tracheal anastomoses, the risk of tracheal suture line stenosis or disruption with manipulation are markedly diminished. Advantages of regional anesthetic techniques in lung transplant patients include minimization of airway manipulation and decreased infectious risk.

Comparison of preoperative PFT, arterial blood gas (ABG), and chest radiograph (CXR) results with prior studies can help diagnose acute infection or rejection. Significant decreases in FEV_1, vital capacity (VC), and total lung capacity (TLC) and an obstructive pattern may indicate acute rejection. ABG in the presence of rejection will show an increased A-a gradient from stable baseline gases, along with perihilar infiltration on CXR. However, rejection and infection can be difficult to distinguish clinically. If the patient is suspected of having an active pulmonary process, consultation with pulmonary medicine for a possible diagnostic bronchoscopy should be considered

prior to surgery.

Heart Transplant Recipients

Denervation of the heart has a significant clinical impact on perioperative management. The transplanted heart cannot respond to indirect acting agents, such as ephedrine and even dopamine, or to peripheral attempts to induce hemodynamic changes, such as carotid massage, Valsalva maneuver, or laryngoscopy. Beta effects of epinephrine and norepinephrine are exaggerated in heart transplant recipients (versus alpha effects). Isoproterenol is the mainstay of chronotropic therapy in these patients. ECG analysis may show two P waves, one from the native atrium and one from the implanted atrium. The native P wave will not conduct to the implanted heart, and these nonconducted P waves should not be confused with complete heart block. Isoproterenol should be available as an inotrope and chronotrope. Dobutamine can also be helpful; norepinephrine and epinephrine should be reserved for refractory cardiogenic shock. Because the denervated heart does not reflexively compensate for hemodynamic changes induced by regional anesthetics, general anesthesia is usually preferred.

Preoperative evaluation should focus on cardiac functional status. Significant rejection will present with symptoms of heart failure. All heart transplant patients should be evaluated with ECG and TTE prior to surgery. New findings should be discussed with the cardiology consultant to determine need for stress testing or myocardial biopsy. Invasive monitors should be placed only when warranted by the clinical status and surgical procedure. Use of either TEE or CVP monitoring can be helpful in managing fluid resuscitation and inotropic support.

Chapter 54

Postoperative Recovery

Roger S. Mecca

KEY POINTS

1	Choosing a postanesthesia setting based on each patient's individual need can reduce cost, enhance patient satisfaction, and optimize use of scarce postanesthesia care unit (PACU) resources. If doubt exists about the safety of a lower-intensity setting, admit to a "full-service" PACU.
2	Anesthesiology personnel should manage a patient until a PACU nurse secures admission vital signs and attaches appropriate monitors. Ensure a succinct but thorough report is documented that includes sufficient information to allow rapid evaluation and intervention for postoperative complications.
3	Postoperative analgesia remains a top priority for patients and providers. Careful assessment of individual analgesic requirements and implementation of a planned, multimodal approach provides seamless pain control through and beyond the PACU interval.
4	Ideally, an anesthesiologist should evaluate each patient for discharge using a consistent set of criteria. Consider the severity of underlying disease, the anesthetic and recovery course, the likelihood of complications, and the level of care available at the destination
5	Hypovolemia is a common postoperative problem. Evaluate and actively manage intravascular volume status throughout the PACU interval, considering preoperative status, type and duration of surgery, estimated blood loss, fluid replacement, and hemostasis.
6	Risk of postoperative myocardial ischemia and infarction remains high. Control of precipitating factors, as well as timely therapy with analgesia and aggressive use of beta-adrenergic blocking agents and nitrates when appropriate, helps decrease morbidity.
7	In PACU patients, elevated $PaCO_2$ and respiratory acidemia do not necessarily indicate inadequate postoperative ventilation. During early recovery from

	anesthesia, residual anesthetics, opioids, and sedatives blunt the ventilatory responses to both hypercarbia and hypoxemia.
8	One cannot predict which postoperative patients will become hypoxemic or when hypoxemia will occur. Supplemental oxygen helps prevent or treat hypoxemia; however, oxygen does not address underlying causes of hypoxemia in postoperative patients, and its use does not guarantee that hypoxemia will not occur.
9	The incidence of serious aspiration is relatively low in PACU patients, but the risk is still significant. Preventing aspiration is critical because effective therapy is limited.
10	The ability to void should be assessed because opioids and autonomic side effects of regional anesthesia interfere with sphincter relaxation and promote urine retention.
11	Moderate postoperative hyperglycemia (200 to 300 mg/dL) resolves spontaneously and has little adverse effect. Higher glucose levels cause glycosuria with osmotic diuresis and interfere with serum electrolyte determinations.
12	Avoiding postoperative nausea and vomiting is a high priority. The most effective medications for prophylaxis and treatment are serotonin blocking agents, dexamethasone, and droperidol.
13	Hypothermia complicates care in the PACU. Average PACU stay is increased by 40 to 90 minutes for hypothermic patients
14	A high percentage of elderly patients experience some degree of postoperative confusion, delirium, or cognitive decline.

An individualized, problem-oriented approach to the assessment of surgical patients is essential to optimize outcome and to minimize risk and expense during postoperative recovery.

ASSESSING THE VALUE OF POSTANESTHESIA CARE

Indicators of quality in postanesthesia care now include not only clinical results and patient satisfaction, but also the "value" of the care provided, loosely defined as the improvement in postoperative outcome per dollar spent. The actual impact that postanesthesia care has on clinical outcomes in a surgical population varies with incidence and severity of underlying illness; the frequency, urgency, and type of surgical procedures; and the blend of surgical and anesthetic techniques used. Training, skill, and preferences of surgeons, anesthesia providers, and nurses also affect how important a postanesthesia care unit (PACU) admission is to a patient. The effectiveness with which PACU staff recognize complications, the quality of diagnostic and consultative services, and the efficiency with which physicians institute therapy are also important.

Actual cost of PACU care incorporates costs of staffing, space, and hardware. Triage, admission, and discharge policies affect how many admissions occur and what resources each admission consumes. Nurse staffing is the largest direct cost in the PACU. Mix of nursing staff (e.g., amount of training and experience, salaries and benefit levels), the staffing ratios (e.g., number of patients per caregiver, number of support staff), and the duration of PACU stay affect the overall personnel cost per admission. The level of monitoring provided affects capital expenditure for equipment and operating expenditure for disposable items. Expenditures for staffing, and for equipment such as intravenous pumps and ventilators, are also affected by patient mix. The type of physician coverage (e.g., dedicated versus on-demand coverage, response times) impacts the efficiency of care. Routine postoperative diagnostic testing increases costs for securing, processing, and professionally interpreting tests. Finally, routine use of therapies (e.g., antiemetics, respiratory treatments) increases the expenditure per patient for drugs and disposable items, and can add to the staffing resources required per patient.

Value comparisons among institutions are difficult because factors affecting impact and cost are facility specific and vary over time. Regulatory requirements, standards of care, and medicolegal climates also differ among regions or between facilities in the same locale. Attempts to establish national benchmarks of the "cost effectiveness" of postanesthesia care are fraught with inaccuracy. Despite this complexity, emphasis on reducing health care costs forces each surgical facility to evaluate the value of its PACU care to individual patients.

Innovative PACU practices help postanesthesia care unit directors maintain safe care, optimize clinical outcomes, minimize cost, and fulfill regulatory requirements. Inappropriate PACU admissions should be eliminated. Medical leaders must also identify those interventions that have yield versus those that are "wasteful." The actual impact of many PACU interventions on clinical outcome is not substantiated by controlled scientific analysis, so avoid inappropriate use of expensive therapies or testing. However, using a more expensive therapy can sometimes generate real savings by decreasing length of stay, or avoiding complications or hospital admission. Integration of the PACU service with other elements in the surgical continuum is essential. The most important interface is between the PACU and the intraoperative anesthesiology service. Consumption of PACU resources is definitely linked to anesthetic duration and technique. In one study, 22.1% of 37,000 patients had a minor anesthesia-related event or complication that prolonged PACU stay and consumed PACU resources.[1]

It is important to distinguish between potential and actual cost savings. Improvements in care might create an opportunity to shorten length of stay in the PACU or discharge unit, but the realized change is frequently reduced by transportation delays, persistence of pain or nausea, waiting for space, or surgeon discharge delays.[2] Also, beware of cost-saving measures in other areas that increase the cost of PACU care. For example, use of a cheaper, longer-acting muscle relaxant might trim cost in anesthesiology but increase length of stay, complication rates, and cost in the PACU. Finally, savings are illusory unless an operational change yields a decrease in expenditures for staff, supplies, or equipment. For example, bypassing the PACU creates a savings opportunity that is realized only if paid nursing hours are reduced or if more surgical cases are covered with the same hours. If ineffective scheduling or low-yield clerical or maintenance tasks consume excess staffing hours, then no savings are realized. Finally, trimming costs sometimes entails an increase in risk. Differentiating between cost-effective postanesthesia care and unsafe clinical practice must remain a matter of professional judgment.

SELECTING THE APPROPRIATE LEVEL OF POSTOPERATIVE CARE

1 For both ambulatory and inpatient surgery, the level of postoperative care that a patient requires is determined by the degree of underlying illness, the duration and complexity of anesthesia and surgery, and the risk of postoperative complications. Less invasive surgical techniques and shorter-duration anesthetic regimens facilitate high levels of arousal and minimal cardiovascular or respiratory depression at the end of surgery. Choosing a less intensive postanesthesia setting based on each patient's individual need can reduce cost of a surgical procedure and allow utilization of scarce PACU resources for patients with greater needs. Also,

each patient's impressions during recovery have a major impact on his or her perception of the entire surgical episode. Patients are more satisfied when spared unnecessary assessments and the potentially upsetting environment of intensive PACU care. Earlier reunion with family in a lower-intensity recovery setting that offers amenities such as recliners, reading material, television, music, and food improves perceptions without affecting quality or safety.

Patients must be carefully triaged to receive an appropriate level of postoperative care by evaluating clinical condition and the potential for complications inherent in the specific procedure. Do not use artificial triage categories based on age, American Society of Anesthesiologists (ASA) classification, ambulatory versus inpatient status, or type of insurance. Similarly, the level of postanesthesia care required should not vary depending on where surgery is performed. An individual patient undergoing a specific procedure should receive the same appropriate level of postoperative care whether the procedure is performed in a hospital operating room, an ambulatory surgical center, an endoscopy room, an invasive radiology suite, or an outpatient office. Preserve a wide margin of safety, and observe applicable PACU guidelines when appropriate[3,4]. If doubt exists about the safety of a lower-intensity setting, admit the patient to a "full-service" PACU or provide equivalent services. Always err for patient safety, regardless of cost.

Healthy patients can almost always recover safely with less intensive monitoring and coverage after procedures using local anesthetic infiltration, minor blocks with sedation, or even major plexus anesthesia. Selected ambulatory patients who meet the PACU discharge criteria at the end of general anesthesia can also bypass the PACU and be admitted directly to a discharge area. Use of short-acting anesthetics and bispectral index monitoring help facilitate this fast-track postoperative care.[5] However, inadequate control of pain or postoperative nausea and vomiting (PONV) often derails PACU bypass and reduces potential resource savings. PACU bypass increases capacity and monitoring requirements, as well as workload and complexity of nursing interventions in the phase II discharge area.[6]

Requirements of state and national agencies sometimes impede the implementation of innovative postanesthesia care policies. Regulations are sometimes outdated or poorly substantiated. Flexibility and evidence-based logic need to be incorporated into regulations for complete evolution of postanesthesia care to occur. Also, full-intensity PACU care must always be available, given the unavoidable incidence of complications after anesthesia and surgery.[7]

SAFETY IN THE POSTANESTHESIA CARE UNIT

The PACU medical director must ensure the PACU environment is as safe as possible for both patients and staff. Beyond usual safety policies, maintain staffing and training to ensure appropriate coverage and skill mix are available to deal with unforeseen crises. Incidence of adverse events in the PACU correlates with nursing workload and staff availability.[8] Ideally, all staff should have PACU certification, and staffing ratios should never fall below acceptable standards.[3] Less skilled staff must be appropriately supervised, and a sufficient number of certified personnel must always be available to handle worst-case scenarios.

The PACU staff protects patients who are temporarily incompetent and preserves patients' rights to observance of advanced directives and to informed consent for additional procedures. The staff is obligated to optimize each patient's privacy and dignity, and to minimize the psychological impact of unpleasant or frightening events. Observance of procedures for hand washing, sterility, and infection control should be assiduous.[9] Medical directors must safeguard against potential for personal assault of patients during recovery. Access to the PACU should be strictly controlled, and unobserved coverage of a PACU patient by one staff member for prolonged periods should be avoided, especially if there is a gender difference.

The PACU environment must also be safe for professionals. Air handling should guarantee that personnel are not exposed to unacceptable levels of trace anesthetic gases, although trace gas monitoring is not necessary. Ensure staff members receive appropriate vaccinations, including that for hepatitis B. Practitioners must adhere to policies for radiation safety, infection control,

disposal of sharps, universal precautions for bloodborne diseases, and safeguarding against exposure to pathogens such as methicillin-resistant *Staphylococcus* or tuberculosis. Always keep masks, gloves, eye protection, and appropriate personal respiratory equipment available. Ensure sufficient help is available to avoid injury while lifting and positioning patients or while dealing with emergence reactions. Compulsive documentation and clear delineation of responsibility protect staff against unnecessary medicolegal exposure.

ADMISSION TO THE POSTANESTHESIA CARE UNIT

Every patient admitted to a PACU should have heart rate and rhythm, systemic blood pressure, airway patency, oxygen saturation, ventilatory rate and character, and level of pain recorded and periodically monitored.[4] Assessment with contemporaneous recording every 5 minutes for the first 15 minutes and every 15 minutes thereafter is a prudent minimum. Document temperature, level of consciousness, mental status, neuromuscular function, hydration status, and degree of nausea on admission and discharge, and more frequent if appropriate. Every patient should be continuously monitored with a pulse oximeter and a single-lead electrocardiogram (ECG). Capnography is necessary only for patients receiving mechanical ventilation or those at risk for compromised ventilatory function. Transduce and record the output from invasive monitors such as central venous, systemic, or pulmonary arterial catheters. Order diagnostic tests only for specific indications.

2 Anesthesiology personnel should manage the patient until a PACU nurse secures admission vital signs and attaches appropriate monitors. A succinct but thorough report that includes sufficient information to allow rapid evaluation and intervention for postoperative complications (Table 54-1) must be legibly recorded using a standardized format printed on the PACU record. Document the time and amount of all neuromuscular relaxants, respiratory depressant medications, and reversal agents. Outline orders, specific therapeutic end points, and how to contact the responsible anesthesiologist. Never transfer responsibility to PACU personnel until the patient's airway status, ventilation, and hemodynamics are appropriate. Check the function of indwelling cannulae, intravenous catheters, and monitors before leaving.

TABLE 54-1 Components Of a Postanesthesia Care Unit Admission Report

·PREOPERATIVE HISTORY
• Medication allergies or reactions • Pertinent earlier surgical procedures • Underlying medical illness • Chronic medications • Acute problems (e.g., ischemia, acid-base status, dehydration) • Premedications • NPO status
·INTRAOPERATIVE FACTORS
• Surgical procedure • Type of anesthetic • Relaxant/reversal status • Time and amount of opioids administered • Type and amount of intravenous fluids administered • Estimated blood loss • Urine output

- Unexpected surgical or anesthetic events
- Intraoperative vital sign ranges
- Intraoperative laboratory findings
- Drugs given (e.g., steroids, diuretics, antibiotics, vasoactive medications)

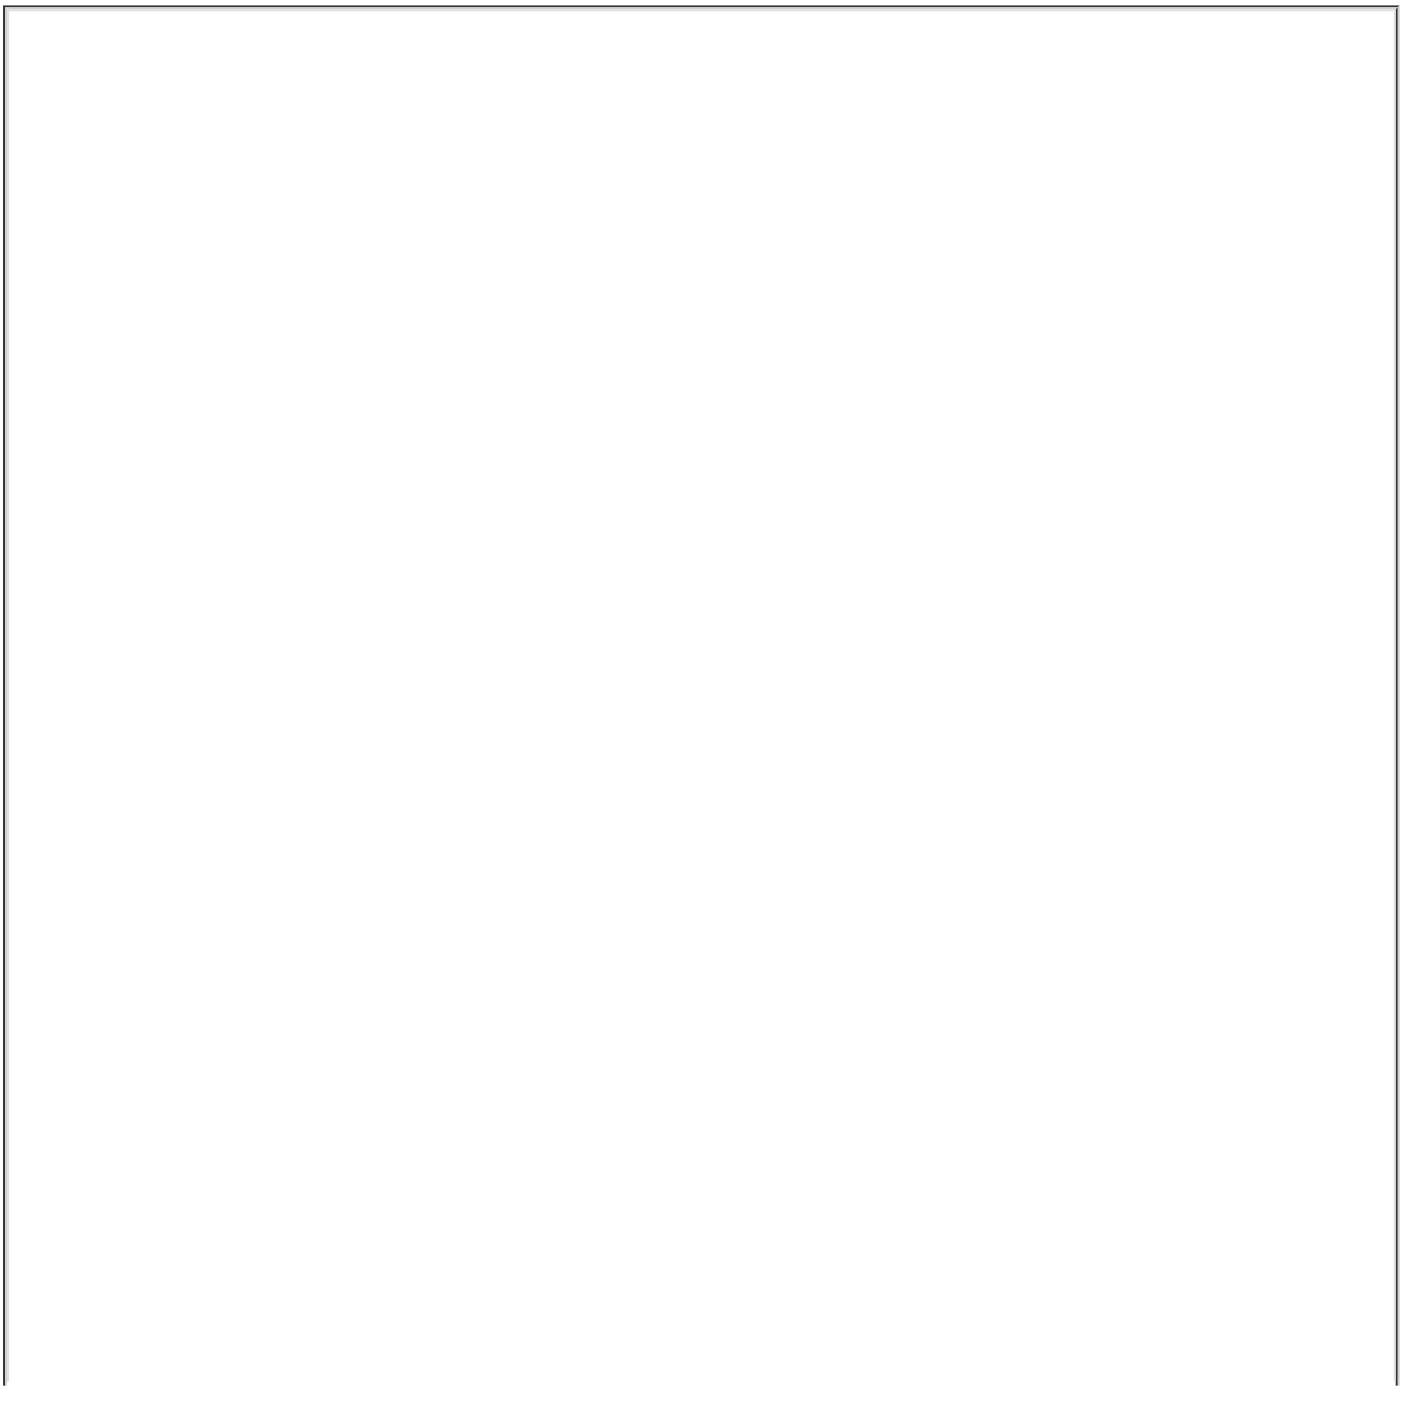
·ASSESSMENT AND REPORT OF CURRENT STATUS

- Airway patency
- Ventilatory adequacy
- Level of consciousness
- Level of pain
- Heart rate and heart rhythm
- Endotracheal tube position
- Systemic pressure
- Intravascular volume status
- Function of invasive monitors
- Size and location of intravenous catheters
- Anesthetic equipment (e.g., epidural catheters)
- Overall impression

·POSTOPERATIVE INSTRUCTIONS

- Expected airway and ventilatory status
- Acceptable vital sign ranges
- Acceptable urine output and blood loss
- Surgical instructions (e.g., positioning, wound care)
- Anticipated cardiovascular problems
- Orders for therapeutic interventions
- Diagnostic tests to be secured
- Therapeutic goals and end points before discharge
- Location of responsible physician

NPO, nothing by mouth.



POSTOPERATIVE PAIN MANAGEMENT

3 Relief of surgical pain with minimal side effects is a high priority during PACU care,[4,10,11,12] so periodically assess and document level of pain throughout recovery (see Chapter 55). Inadequate postoperative analgesia is a major source of preoperative fear and postoperative dissatisfaction for surgical patients. In addition to improving comfort, analgesia reduces sympathetic nervous system (SNS) response and helps avoid hypertension, tachycardia, and dysrhythmias. In hypovolemic patients relying on SNS activity for cardiovascular homeostasis, analgesics can precipitate hypotension, especially if direct or histamine-induced vasodilation occurs. Assess a tachycardic patient with low or normal blood pressure who complains of pain carefully before giving analgesics that might precipitate or accentuate hypotension.

The actual degree of postoperative pain can be difficult to establish. Severity of pain varies among surgical procedures and anesthetic techniques. Staff members are relatively ineffective at

quantifying level of discomfort. Inexperienced nurses overestimate a patient's pain, whereas more experienced nurses tend to underestimate.[13] Either error leads to inappropriate treatment. Use of a quantitative pain scale yields more reliable results. A wide divergence can exist between a patient's cognitive perception of pain and SNS response, related to psychological, cultural, and cardiovascular differences among individuals. Some patients perceive severe pain with minimal SNS activity, whereas others exhibit hypertension and tachycardia with minimal complaint of discomfort. The best barometer of analgesia is the patient's perception.

Careful identification of patient subgroups, assessment of individual analgesic requirements, and implementation of a planned, multimodal approach will provide seamless pain control through and beyond the PACU interval.[14] In a study of postoperative pain in 10,008 ambulatory patients, only 5.3% related severe pain in the PACU and 1.7% in the discharge area (Fig. 54-1). However, a much higher percentage of patients relate that moderate to severe pain recurs after discharge.[15,16] To avoid masking signs of an unrelated condition or a surgical complication, ascertain that the nature and intensity of pain are appropriate for the surgical procedure. The central nervous system (CNS) signs of hypoxemia, acidemia, or cerebral hypoperfusion often mimic those of pain, especially during emergence. Administration of parenteral analgesics or sedatives can acutely worsen hypoventilation, airway obstruction, or hypotension, causing sudden deterioration. Evaluating orientation, the level of arousal, and cardiovascular or pulmonary status usually identifies such patients.

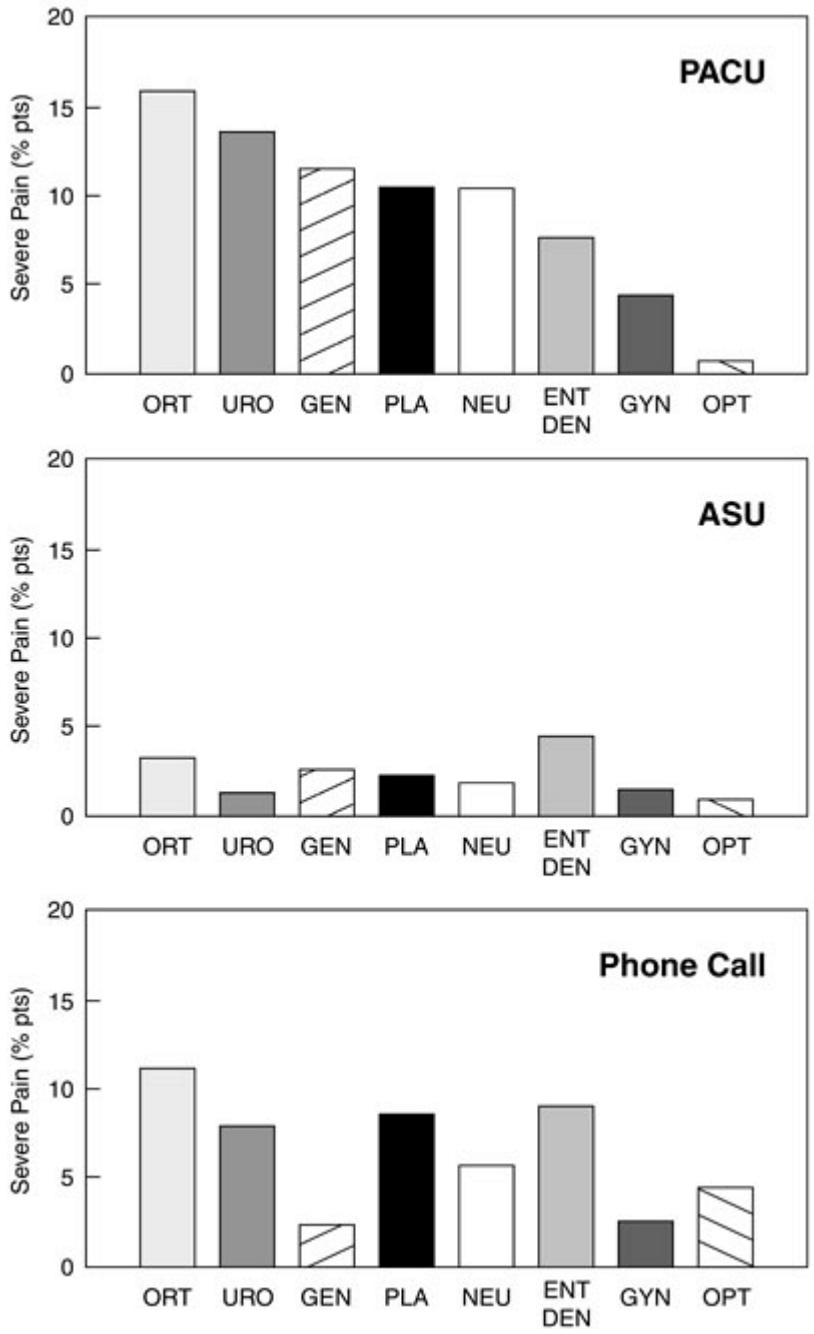


FIGURE 54-1. Percentage of patients experiencing severe pain in the postanesthesia care unit (PACU), the ambulatory surgery unit (ASU), and during a postanesthesia phone call at 24 hours. (Reprinted with permission from Chung F, Ritchie E, Su J: Postoperative pain in ambulatory surgery. Anesth Analg 85:808, 1997.)

Incisional pain can be effectively treated with intravenous opioids as part of a planned analgesic continuum that begins prior to the induction of surgical anesthesia and continues

throughout the postoperative course. Sufficient analgesia is the end point, even if large doses of opioids are necessary in tolerant patients. Short-acting opioids are useful to expedite discharge and minimize nausea in ambulatory settings,[17] although duration of analgesia can be a problem. During intravenous titration of opioids, assess for incremental respiratory or cardiovascular depression. Disadvantages of intramuscular administration include larger dose requirements, delayed onset, and unpredictable uptake in hypothermic patients. Oral and transdermal analgesics have a limited role in the PACU but are helpful for ambulatory patients after PACU discharge. Rectal analgesics are sometimes useful in small children.

Perioperative oral or intravenous administration of cyclooxygenase-2 (COX-2) inhibitors seems to offer a promising adjunctive therapy that augments postoperative analgesia, probably by reducing the inflammatory components of postoperative pain.[18] Unfortunately, more recent concern about negative cardiac side effects of COX-2 inhibitors, culminating in the withdrawal of rofecoxib, has clouded the overall appropriateness of this approach. Ibuprofen or acetaminophen are also effective, especially when administered orally before surgery. Preoperative administration likely augments the overall level of analgesia rather than offering a substantial preemptive advantage.[19] Ketorolac is an effective analgesic and anti-inflammatory that lowers opioid requirements, although possibility of hemorrhage due to its antiplatelet properties limits its use. Ketorolac might also decrease ischemic events in patients with coronary artery disease through analgesic and antiplatelet actions. Use of clonidine to supplement analgesia is effective but can cause hypotension. Agonist–antagonist analgesics offer little advantage. Interventions such as repositioning, reassurance, or extubation also help minimize discomfort.

Other analgesic modalities provide pain relief in and beyond the PACU.[20] Intravenous opioid loading in the PACU is important for smooth transition to intravenous patient-controlled analgesia. Injection of opioids into the epidural or subarachnoid space during anesthesia or in the PACU yields prolonged postoperative analgesia in selected patients.[21,22] Nausea and pruritus are troubling side effects, and immediate or delayed ventilatory depression can occur, related to vascular uptake and cephalad spread in cerebrospinal fluid. Nausea resolves with antiemetics, whereas pruritus and ventilatory depression often respond to naloxone infusion. Addition of local anesthetic or clonidine enhances analgesia and decreases the risk of side effects from epidural opioids, although local anesthetics add risk of hypotension or motor blockade. Epidural analgesia is effective after thoracic and upper abdominal procedures and helps wean patients with obesity or chronic obstructive pulmonary disease (COPD) from mechanical ventilation. Whether epidural analgesia improves surgical outcomes is debatable.

Placement of long-acting regional analgesic blocks reduces pain, controls SNS activity, and often improves ventilation.[20] After shoulder procedures, interscalene block yields almost complete pain relief with only moderate inconvenience from motor impairment. Paralysis of the ipsilateral diaphragm can impair postoperative ventilation in patients with marginal reserve, although the impact is small in most patients.[23] Suprascapular nerve block might be an alternative to avoid this potentially serious side effect. Percutaneous intercostal blocks reduce analgesic requirements after thoracic or high abdominal incision, although beneficial effects on postoperative pulmonary function are questionable. Caudal analgesia is effective in children after inguinal or genital procedures, whereas infiltration of local anesthetic into joints, soft tissues, or incisions decreases the intensity of pain. Instillation of opioids or neostigmine into joints is also analgesic. Other modalities, such as positive suggestion, hypnosis, transcutaneous nerve stimulation, "white noise," or acupuncture have limited utility for surgical pain.

Use of patient-controlled analgesia, spinal opioids, or neural blockade mandates anticipation of risk beyond the PACU. Plan for extended postoperative analgesia before induction of surgical anesthesia, and orient the anesthetic and PACU care toward that plan. If one analgesic modality proves inadequate, take particular care when implementing a second technique.

Fear, anxiety, and confusion often accentuate postoperative pain during recovery, especially after general anesthesia. Titration of an intravenous sedative such as midazolam attenuates this psychogenic component, although analgesic requirements may increase slightly because benzodiazepines interact with γ-aminobutyric acid receptors. It is important to distinguish between requirements for analgesia and for sedation. Opioids are poor sedatives, whereas benzodiazepines are poor analgesics.

DISCHARGE CRITERIA

When possible before discharge from postoperative care, each patient should be sufficiently oriented to assess his or her physical condition and summon assistance. Airway reflexes and motor function must be adequate to maintain patency and prevent aspiration. Ensure ventilation and oxygenation are acceptable, with sufficient reserve to cover minor deterioration in unmonitored

settings. Blood pressure, heart rate, and indices of peripheral perfusion should be relatively constant for at least 15 minutes and appropriately near baseline. Achieving normal body temperature is not an absolute requirement, but resolution of shivering is. Acceptable analgesia must be achieved and vomiting appropriately controlled. Patients should be observed for at least 15 minutes after the last intravenous opioid or sedative is administered to assess peak effects and side effects. After reinforcement of regional anesthetics, longer observation could be appropriate. Monitor oxygen saturation for 15 minutes after discontinuation of supplemental oxygen to detect hypoxemia. Assess likely complications of surgery (e.g., bleeding, vascular compromise, pneumothorax) or of underlying conditions (e.g., hypertension, myocardial ischemia, hyperglycemia, bronchospasm). Document a brief neurologic assessment of orientation, eye signs, facral synmetry, and extramity movement. Review results of diagnostic tests. If these generic criteria cannot be met, postponement of discharge or transfer to a specialized unit is advisable.

4 There is no demonstrable benefit from a mandatory minimum duration of PACU care. Rather, observe patients until they meet discharge criterion and are no longer at increased risk for cardiorespiratory depression.[4] Fixed PACU discharge criteria must be used with caution because variability among patients is tremendous. Scoring systems that quantify physical status or establish thresholds for vital signs are useful for assessment but cannot replace individual evaluation.[24,25] Ideally, each patient should be evaluated for discharge by an anesthesiologist using a consistent set of criteria (Table 54-2), considering the severity of underlying disease, the anesthetic and recovery course, and the level of care at the destination (see Chapter 46). Plan for the continued management of likely postdischarge symptoms such as pain, nausea, headache, dizziness, drowsiness, and fatigue.[16]

TABLE 54-2 Guidelines For Discharge Evaluation From Postanesthesia Care Unit

▪GENERAL CONDITION

- Oriented to time, place, and surgical procedure
- Responds to verbal input and follows simple instructions
- Acceptable color without cyanosis, splotchiness, or paleness
- Adequate muscular strength and mobility for minimal self-care
- Absence or control of specific acute surgical complications (e.g., bleeding, edema, neurologic weakness, diminished pulse)
- Suitable control of nausea and emesis
- Destination unit appropriate for patient's status

▪SYSTEM BLOOD PRESSURE

- Within ±20% of resting preoperative value
- Heart rate and rhythm relatively constant for at least 30 min
- Resolution of any new dysrhythmia
- Acceptable intravascular volume status
- Any suspicion of myocardial ischemia rectified

▪VENTILATION AND OXYGENATION

- Ventilatory rate >10, <30 breaths/min
- Forced vital capacity approximately twice tidal volume
- Adequate ability to cough and clear secretions

- Qualitatively acceptable work of breathing

▪AIRWAY MAINTENANCE

- Protective reflexes (swallow, gag) intact
- Absence of stridor, retraction, or partial obstruction
- No further need for artificial airway support

▪CONTROL OF PAIN

- Ability to localize and identify intensity of surgical pain
- Adequate analgesia, at least 15 min since last opioid
- Safe, appropriate orders for postdischarge analgesics

▪RENAL FUNCTION

- Urine output >30 mL/h (catheterized patients)
- Appropriate color and appearance of urine, evaluation of hematuria
- Follow-up orders in regard to output if spontaneous voiding has not occurred

▪METABOLIC/LABORATORY

- Acceptable hematocrit level in view of hydration, blood loss, and potential for future losses
- Suitable control of blood glucose
- Appropriate electrolyte homeostasis
- Evaluation of chest radiograph, electrocardiogram, and other tests as appropriate

▪AMBULATORY PATIENTS

- Ability to ambulate without dizziness, hypotension, or support
- Suitable control of nausea and vomiting after ambulation

Not all criteria will be satisfied by every patient, especially if discharge is to a critical care unit. Clinical judgment must always supersede established guidelines if the patient's condition is less than optimal in a given area. Whenever doubt exists about diagnosis or patient safety, discharge should be delayed.

CARDIOVASCULAR COMPLICATIONS

Postoperative Hypotension

5 Systemic hypotension, a common postoperative complication, can cause hypoperfusion of vital organ systems. Consequent tissue hypoxia promotes inefficient anaerobic metabolism and lactic acidemia. During hypotension, the SNS diverts blood

flow to preserve the brain, heart, and kidneys, so symptoms of hypoperfusion referable to these organs (e.g., disorientation, nausea, loss of consciousness, angina, reduced urine output) indicate that compensatory mechanisms have been exhausted. Complications of hypotension include ischemia or infarction of the myocardium, cerebrum, renal tubules, spinal cord, or bowel. Reduced venous flow rate increases risk of deep vein thrombosis and pulmonary embolism. Decreased hepatic oxygen delivery might change metabolic pathways for drugs or cause hepatic damage by toxic metabolites. The degree of postoperative hypotension at which risk of complications increases varies with the baseline blood pressure, and is higher in patients with arteriosclerotic disease, stenotic vascular lesions, chronic hypertension, increased intracranial pressure, or renal failure.

Spurious Hypotension

Identifying spurious hypotension avoids unnecessary treatment and iatrogenic hypertension. A blood pressure cuff that is too large yields falsely low values. A transducer system that is improperly zeroed or excessively damped by air bubbles or catheter obstruction yields artificially low readings from an arterial catheter. Arterial constriction caused by hypothermia or alpha-adrenergic agonist drugs can reduce radial or brachial blood pressure below aortic pressure.

Hypovolemia

A reduction in circulating intravascular volume ("absolute" hypovolemia) decreases ventricular filling and cardiac output. SNS-mediated tachycardia, increased systemic vascular resistance (SVR), and venoconstriction might compensate for a 15 to 20% loss of intravascular volume. Greater deficits cause hypotension.

Failure to replace preoperative fluid deficit and fluid or blood lost during surgery frequently causes absolute hypovolemia. In the PACU, ongoing hemorrhage, sweating, and exudation of fluid into tissues (third-space losses) exacerbate hypovolemia. Blood loss is often occult, as with retroperitoneal bleeding, oozing related to coagulopathy, or hemorrhage into muscle after trauma or orthopaedic procedures. Third-space losses can continue for up to 48 hours after surgery and can be massive during high-permeability pulmonary edema or accumulation of ascites. In a hypothermic, venoconstricted patient, a low intravascular volume might maintain cardiac output on PACU admission but cause hypotension when venous capacity increases during rewarming.

Sometimes, a "normal" intravascular volume is inadequate to maintain blood pressure (relative hypovolemia). Sudden decreases in endogenous SNS activity caused by relief of pain or vasovagal responses can acutely increase venous capacity, as can medications that mimic alpha-adrenergic receptor blockade (droperidol, chlorpromazine), release histamine (morphine), or directly dilate veins (nitrates, furosemide). Spinal or epidural anesthesia interferes with SNS regulation of venous tone, increasing venous capacitance and preventing constriction of veins in response to hemorrhage or positional changes. Compression of thoracic veins from positive intrathoracic pressure during mechanical ventilation impedes venous return, as does inferior vena caval compression from a gravid uterus or increased intra-abdominal pressure. Pericardial tamponade or air embolism also impedes ventricular filling.

Evaluate each patient's hydration status on admission and throughout the PACU stay,[4] considering preoperative status, type and duration of surgery, estimated blood loss, fluid replacement, and hemostasis. Monitoring urine output as an index of intravascular volume can be misleading. Surgery and anesthesia impair renal tubular concentrating ability, and glycosuria causes osmotic diuresis, each falsely indicating that intravascular

volume is adequate. The variation of systolic blood pressure seen on an arterial catheter or pulse oximeter trace during positive-pressure ventilation provides a qualitative warning of hypovolemia in some patients. Central venous pressure (CVP), pulmonary artery (PA) pressure, or transesophageal echocardiography (TEE) monitoring helps clarify volume status. Manage intravascular volume actively during recovery.

Ventricular Dysfunction

Postoperative hypotension caused by ventricular dysfunction usually indicates that baseline ventricular contractility is reduced. Such patients often need high left ventricular end-diastolic pressure and elevated SNS activity to maintain cardiac output. Excessive fluid administration causes ventricular dilation, decreased cardiac output, and hypotension, often complicated by hydrostatic pulmonary edema. Overhydration may not be evident. If sympathetic blockade during spinal or epidural anesthesia is treated with excessive fluids, ventricular filling pressures can be normal during early recovery, despite hypervolemia. When SNS blockade resolves, a characteristically high level of SNS outflow mobilizes large fluid volumes to the central circulation, precipitating ventricular failure. Depression from residual inhalational anesthetics and opiates contributes to decreased SNS outflow, reducing ventricular contractility during early recovery. Profound metabolic or respiratory acidemia reduces ventricular performance by interfering with catecholamine–receptor interaction and by depressing central SNS outflow. Low ionized calcium levels caused by dilution, chelation, or acute alkalemia also reduce ventricular contractility. Right ventricular dysfunction caused by pulmonary thromboembolism often presents with systemic hypotension.

Myocardial ischemia

6 Among patients with coronary disease, risk of postoperative myocardial ischemia and infarction is higher for those with a history of congestive heart failure, valvular disease, low ejection fraction, smoking, anemia, and probably hypertension, and those having emergency surgery.[26,27] Patients are at significant risk after both general and regional anesthetics. Ischemia is often initiated in high-risk patients by tachycardia that reduces diastolic filling time. Postoperative tachycardia is caused by pain, hypotension, acidemia, anxiety, or medications. Diastolic hypotension from hypovolemia, bradycardia, or vasodilation can also precipitate ischemia by decreasing the pressure gradient for coronary perfusion. Increased ventricular wall tension secondary to overhydration, hypertension, or increased SNS activity increases myocardial oxygen consumption. Severe hypoxemia, anemia, or carbon monoxide (CO) poisoning generates ischemia independent of coronary perfusion. The lowest tolerable oxygen saturation value varies among individuals but is usually higher in patients with vascular disease. Postoperative ischemia is often silent and more frequently leads to non–Q-wave infarction. Risk of early morbidity is still high.[28] Postoperative anginal chest pain might be overshadowed by pain from surgical incisions and gastric distention, or masked by analgesia from residual anesthetics or opioids. The incidence of ischemic dysrhythmias is difficult to determine, given the high incidence of benign postoperative dysrhythmias. Hypotension caused by ischemic ventricular dysfunction can quickly cause irreversible infarction. Close evaluation of the hemodynamic responses to fluid challenge, the ST segment and T-wave morphology on the ECG, and the PA pressures can sometimes uncover ischemia before hypotension occurs (Fig. 54-2). However, the predictive value of these indices is controversial. Control of precipitating factors and timely therapy with analgesia, aggressive use of beta-adrenergic blocking agents, and nitrates when appropriate helps decrease morbidity.[29,30,31] Postoperative use of short-acting beta-adrenergic blockers is generally safe in patients with bronchospastic disease or decreased ventricular contractility. Efficacy is significant even with nearly baseline heart rates and may reflect other benefits of beta-blockade beyond rate control.

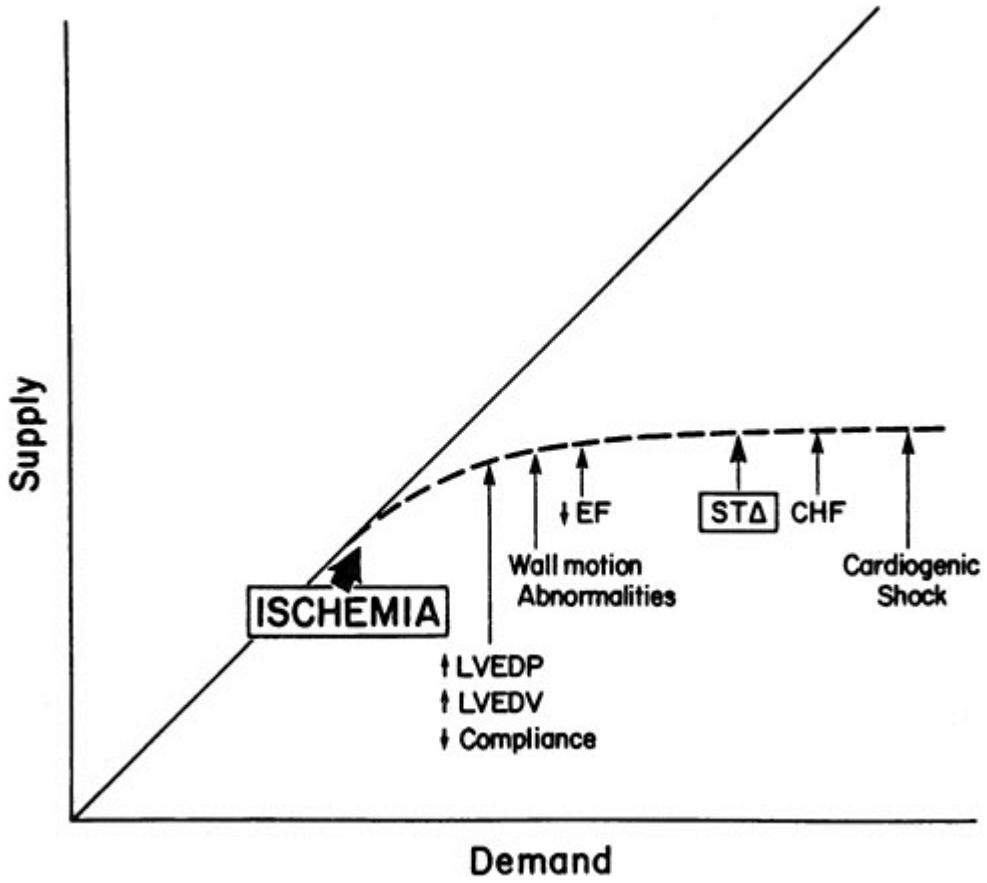

FIGURE 54-2. Physiologic consequences of myocardial ischemia. Note that changes in ventricular pressure and compliance may precede electrocardiographic changes (ST segment). LVEDP, left ventricular end-diastolic pressure; LVEDV, left ventricular end-diastolic volume; EF, ejection fraction; ST, ST segment change; CHF, congestive heart failure. (Reprinted with permission from Barash PG: Monitoring myocardial oxygen balance: Physiologic basis and clinical application. In Barash PG, Deutsch S, Tinker J [eds]: Refresher Courses in Anesthesiology, vol 13, p 21. Philadelphia, JB Lippincott, 1985.)

Cardiac Dysrhythmias

Preexisting myocardial disease or rhythm disturbances increase the risk of postoperative hypotension caused by cardiac dysrhythmias. Sinus or nodal bradycardia with ventricular rates below 40 beats/min decreases cardiac output and blood pressure, as do slow ventricular rhythms associated with complete heart block. A tachydysrhythmia that generates ventricular rates of 140 to 150 beats/min can decrease cardiac output because ventricular filling time is compromised. Ventricular fibrillation, asystole, or electromechanical dissociation causes life-threatening reductions of output. Swings in autonomic nervous system activity place patients with critical valvular abnormalities at particular risk of hypotension from rate or rhythm changes. An increased heart rate in patients with aortic stenosis reduces systolic ejection time, whereas tachycardia in patients with mitral stenosis impedes ventricular filling. Both decrease cardiac output and cause hypotension.

Decreased Systemic Vascular Resistance

Hypotension associated with regional anesthesia, alpha-adrenergic receptor blocking drugs, blood components, warming, or systemic sepsis is caused by decreased SVR and by reduced venous return. Severe systemic acidemia decreases SVR by directly dilating vessels and by interfering with the catecholamine–alpha-receptor interaction. Decreased SVR often generates a high-output,

low-resistance hypotension.

Postoperative hypotension is occasionally caused by the effects of anesthesia or surgery on baroreceptor function or by intracranial disease. Rarely, hypotension reflects steroid deficiency in patients whose adrenal axis is suppressed by exogenous steroid use. Hypotension secondary to steroid deficiency is often preceded by lethargy, fever, or nausea and by hyponatremia, hyperkalemia, and hypoglycemia.

Treatment of Postoperative Hypotension

In general, symptoms of vital organ hypoperfusion or a 20 to 30% reduction in systolic pressure from preoperative levels is an indication to treat. If risk for complication from hypotension is high, tighter limits for pressure and heart rate should be defined during PACU admission. A low blood pressure determination should be quickly validated. Auscultation of heart sounds and palpation of carotid or femoral pulses are useful qualitative indicators of central blood pressure. Check breath sounds and the cardiac rate and rhythm, and administer supplemental oxygen. Evaluate recent drug administration, and stop infusions that might cause vasodilation. A 12-lead ECG, arterial blood gas, or chest radiography might be indicated.

Direct therapy toward the etiology of reduced blood pressure. Simple maneuvers such as reducing airway pressure, placing pregnant patients in a lateral tilt position, or placing patients with orthostatic changes in a supine position should be used when appropriate. Tension pneumothorax must be evacuated. Increase the intravenous infusion rate to maximum because hypovolemia is the most common etiology. If hypotension is spurious or caused by a reduced SVR or ischemia, the amount of excess fluid infused while these diagnoses are established is usually inconsequential. Infusion of crystalloid solutions is usually sufficient to treat hypovolemia, although plasma expanders or blood facilitate more rapid volume expansion. Sympathomimetic alpha-adrenergic pressors such as phenylephrine that increase SVR and venous return will temporarily maintain systemic pressure until sufficient volume can be infused. Ephedrine is less desirable because increased heart rate and contractility are usually unnecessary.

If fluid administration (300 to 500 mL) does not improve hypotension, myocardial dysfunction should be considered. If hypotension is caused by ischemia, resolution of the ischemia usually restores baseline cardiac function. Heart rate control with analgesics, sedatives, and especially beta-receptor blockers is important. Support of aortic diastolic pressure with an alpha-receptor agonist and reduction of left ventricular end-diastolic pressure with nitroglycerin help maximize the coronary artery pressure gradient. Accurate diagnosis of ischemia is critical because therapy for ischemia can worsen hypotension caused by hypovolemia or other causes. PA catheterization or TEE might be useful to estimate left ventricular filling and cardiac output, although the value of PA readings is questionable. For dysfunction not related to ischemia, drugs that augment contractility, perhaps in conjunction with systemic vasodilators, restore cardiac output and systemic pressure.

If hypotension is caused by metabolic acidemia, intravenous bicarbonate or another alkalinizing agent helps restore pH until the underlying cause is remedied. Hypotension from severe hypoxemia or respiratory acidemia mandates tracheal intubation and mechanical ventilation with supplemental oxygen. Sinus bradycardia unrelated to hypoxemia usually responds to intravenous atropine, glycopyrrolate, or ephedrine. Refractory bradycardia caused by sinus node disease or complete heart block is managed with intravenous epinephrine or isoproterenol, or with cardiac pacing. Beta-adrenergic or calcium channel blockade reduces the ventricular rate from acute-onset atrial fibrillation, whereas reentrant paroxysmal atrial tachycardia often disappears with beta-adrenergic blockade or with maneuvers or drugs that change cardiac conduction rates. If hypotension is severe, immediate low-energy, direct-current cardioversion is indicated.

Hypotension caused by a low SVR is treated with an alpha-adrenergic agent. Sympathectomy from regional anesthesia responds to low levels of alpha stimulation. During advanced sepsis or catecholamine depletion, norepinephrine infusions may be required. If decreased SVR is caused by acidemia, correction of pH is necessary before pressor therapy will be effective.

Postoperative Hypertension

A moderate elevation in systemic blood pressure is common and acceptable in well-hydrated postoperative patients.[7] However, excessively high blood pressure can cause hemorrhage and third-space losses, and might disrupt vascular suture lines. High ventricular intracavitary pressure might lead to myocardial fiber stretch and increased wall tension, precipitating ischemia or dysrhythmias. Elevated intraocular or intracranial pressure, cerebral edema, and intracranial hemorrhage also potentially increase morbidity.

A blood pressure cuff that is too small yields erroneously high readings, especially in obese or very muscular patients. A transducing system that is improperly zeroed or exhibits excessive resonance overestimates systolic pressure. Overshoot does not significantly change the accuracy of diastolic readings. Patients with preexisting hypertension exhibit exaggerated blood pressure responses because they have noncompliant vasculature, elevated peripheral vascular tone, and high levels of baseline endogenous SNS activity. Baroreceptor control of heart rate may be impaired, especially after carotid endarterectomy or anticholinergic administration during reversal of neuromuscular relaxation.

Enhanced SNS activity frequently causes hypertension in PACU patients. Peripheral arteriolar and venous constriction mediated by alpha-adrenergic stimulation increases SVR and venous return, whereas increased β_1 receptor stimulation increases ventricular contractility and heart rate. SNS outflow most often reflects an appropriate response to noxious stimuli or adverse physiologic conditions (Table 54-3). SNS activity might also result from exogenous sympathomimetics, monoamine oxidase inhibition, or pheochromocytoma. Intravascular volume expansion and hypothermia accentuate the

effect of SNS activity on blood pressure. Cerebral vascular accidents, hypoxic encephalopathy, increased intracranial pressure, or osmotic changes can interfere with central SNS regulation and cause autonomic dysfunction and severe hypertension.

TABLE 54-3 Factors That Increase Postoperative Sympathetic Nervous System Activity

▪FACTORS INCREASING SYMPATHETIC ACTIVITY
Noxious stimuli Pain, anxiety, cranial stimulation, full bladder, tracheal intubation Adverse physiologic conditions Hypercarbia/acidosis, hypoxemia, hypotension, hypoglycemia, congestive heart failure, increased intracranial pressure, myocardial ischemia Medications Beta-mimetic pressors, ephedrine, isoproterenol, epinephrine Dopamine, dobutamine Bronchodilators Terbutaline, aminophylline Antihypertensives Hydralazine, nitroprusside Anesthetics Ketamine, isoflurane
▪FACTORS DECREASING PARASYMPATHETIC ACTIVITY

Medications
Parasympatholytics
Atropine, glycopyrrolate
Relaxants
Pancuronium

Indications for treatment of postoperative hypertension include a systolic or diastolic pressure 20 to 30% above baseline, signs or symptoms of complications (e.g., headache, bleeding, ocular changes, angina, ST segment depression), or an unusual risk of morbidity (e.g., increased intracranial pressure, mitral regurgitation, open eye injury). In patients with chronic hypertension, achieving a "normal" systemic pressure could promote vital organ hypoperfusion so blood pressure should be reduced toward preoperative levels. Orient therapy toward causes of increased SNS activity. Administering analgesics or sedatives, correcting acidemia or hypoxemia, and ensuring ability to void are helpful. If hypertension persists, intravenous antihypertensive medications such as labetalol, esmolol, hydralazine with propranolol, or nicardipine yield temporary control. Incorporation of clonidine into the overall regimen may augment analgesia, control blood pressure, and blunt the postoperative SNS response to stimuli. Potent vasodilators (nitroprusside, nitroglycerin) are reserved for refractory or profound hypertension.

Cardiac Dysrhythmias in the Postoperative Period

Asymptomatic Electrocardiographic Abnormalities

General anesthesia causes ECG changes in axis, intraventricular conduction, P-wave and T-wave morphology, and ST segments that are not related to cardiac abnormality (see Appendix – Electrocardiography). These changes reflect electrophysiologic effects of hypothermia, inhalation anesthetics, autonomic nervous system imbalance, and mild electrolyte abnormalities. Changes usually resolve within 3 to 6 hours. If persistent ECG changes indicate ischemia, optimize myocardial oxygen supply and demand, follow serial ECG and enzyme determinations, and monitor as appropriate.

Bradycardia

In the PACU, increased parasympathetic nervous system (PNS) or decreased SNS activity influence promotes sinus bradycardia (Table 54-4). Sick sinus syndrome, sinoatrial nodal ischemia, or severe hypoxemia also reduce sinus rate. Sinus bradycardia is benign unless it causes hypotension, usually when the rate falls below 40 to 45 beats/min. Therapy involves restoring SNS/PNS balance to normal. Bradycardia caused by excess PNS activity usually responds to muscarinic blocking drugs such as atropine or glycopyrrolate. Decreased SNS activity usually responds to a beta-mimetic drug such as ephedrine.

TABLE 54-4 Factors That Increase Postoperative Parasympathetic Nervous System Activity

▪FACTORS INCREASING PARASYMPATHETIC ACTIVITY
Vagal reflexes Carotid sinus massage, Valsalva maneuver, gagging, rectal examination, increased ocular pressure, bladder distention, pharyngeal stimulation Parasympathomimetic medications Acetylcholinesterase inhibitors Neostigmine, edrophonium Alpha-adrenergic drugs Neo-Synephrine, norepinephrine Opioids Morphine, fentanyl Succinylcholine
▪FACTORS DECREASING SYMPATHETIC ACTIVITY
High spinal or epidural anesthesia Withdrawal of stimulus, extubation, emptying bladder Severe acidemia/hypoxemia Sympatholytic medications Beta-receptor blockers (propranolol) Opioids/sedatives/general anesthetics Ganglionic blockers Local anesthetics

Emergence of a nodal pacemaker in the lower atrioventricular (AV) node or the bundle of His is also usually caused by autonomic imbalance. Factors that stop sinus impulses from reaching the ventricle also promote nodal rhythms. Nodal rhythms are benign unless a low ventricular rate or lack of coordinated atrial contraction reduces cardiac output and blood pressure. If hypotension occurs, atropine or beta-mimetic medications can restore a sinus rhythm. These measures sometimes only increase nodal rate, necessitating support of blood pressure until spontaneous resolution occurs.

Risk of developing complete heart block in patients with bifascicular block or left bundle-branch block is small but real. Idioventricular bradycardia seldom generates adequate cardiac output, and usually indicates life-threatening heart block, hypoxemia, acidemia, or myocardial ischemia. Atropine might improve AV nodal conduction enough to allow supraventricular impulses to reach the ventricles with acute third-degree AV nodal block. Atropine does not increase rate of ventricular pacemaker cells because they lack PNS innervation, but epinephrine, isoproterenol, or cardiac pacing will accelerate the ventricular rate.

Tachycardia

Postoperative sinus tachycardia is nearly always associated with a physiologic increase in SNS influence (see Table 54-3). Tachycardia is usually harmless, but it can precipitate acute myocardial ischemia in patients with coronary artery disease. Sinus tachycardia seldom interferes with ventricular filling but compromises cardiac output in patients with stenotic valvular lesions. Tachycardia exacerbates hypertension and might indicate acidemia, hypoxemia, or malignant hyperthermia. Sinus tachycardia is treated by addressing the underlying cause. Giving analgesics for pain, intravenous fluids for hypovolemia, or sedatives to calm anxiety is usually sufficient.

Decompressing a full bladder is helpful. Tachycardia caused by sympathomimetic drugs resolves as drug levels fall. If SNS activity is beyond control or tachycardia presents a threat, beta-blockade helps control rate. Digoxin is ineffective unless ventricular failure is the underlying cause.

Overall incidence of postoperative supraventricular arrhythmia after noncardiac surgery can approach 6%, with atrial fibrillation twice as common as supraventricular tachycardia.[32] Sudden-onset atrial fibrillation sometimes generates ventricular rates greater than 150 beats/min and might appear as a fast, nearly regular tachycardia on the ECG. Patients recovering from thoracic surgical procedures or those with mitral valvular disease or pulmonary emboli have a higher incidence. Rapid ventricular rate might cause hypotension or myocardial ischemia. Once aggravating factors are resolved, control of rate with beta-adrenergic or calcium channel blockers is appropriate to decrease the number of impulses that traverse the AV node per minute. For acute postoperative atrial fibrillation, rate control is more effective than rhythm conversion. Be cautious using aderosine, beta-blockers, digoxin, or calcium channel blockers if there is a possibility that the dysrhythmia is caused by Wolfe-Parkinson-White syndrome. Digoxin should be used for patients who will benefit from increased contractility. If hypotension is serious, direct-current cardioversion can convert fibrillation to sinus rhythm.

Atrial flutter is uncommon in postoperative patients. Treatment decreases the ventricular rate and regularizes atrial electrical activity. Paroxysmal atrial tachycardia usually reflects either circus reentry in a loop of conduction tissue, or discrete, rapidly firing atrial cells causing junctional, ectopic, or multifocal atrial tachycardia. Rapid rates can interfere with ventricular filling and compromise cardiac output. Treatment involves slowing conduction velocities to interrupt reentrant synchrony by increasing PNS influence (see Table 54-4). Beta-adrenergic or calcium channel blockers are useful for rate control, whereas slowing conduction velocities by increasing PNS influence (see Table 54-4) can interrupt reentrant synchrony. Junctional, ectopic or multifocal atrial tachycardices initially slow with adenosine and are subsequently treated with beta-blockers, Ca^{++} channel blockers, or amiodarome. They are not amenable to cardioversion.

Postoperative ventricular tachycardia or fibrillation almost always reflects severe myocardial ischemia, systemic acidemia, or hypoxemia, although reentrant ventricular tachycardia does occur. Cardiopulmonary resuscitation, beta-mimetic pressors, cardioversion, and control of ventilation, oxygenation, and serum pH help restore a synchronized rhythm.

Premature Contractions

An aberrant impulse arising in the atrium, AV node, or upper bundle of His generates an atrial premature contraction (APC), causing an early but otherwise normal QRS complex that is often not preceded by a P wave. In postoperative patients, APCs usually reflect increased SNS activity and seldom cause hemodynamic compromise. Control of stimuli causing increased SNS activity often eliminates APCs (see Table 54-3).

Ventricular ectopy present before surgery usually reappears in the PACU and does not predict postoperative outcome.[33] In postoperative patients, many high-amplitude, wide, and bizarre QRS complexes represent benign, aberrantly conducted APCs or reentrant beats rather than abnormal impulses that originate in the ventricle. If an early supraventricular impulse enters the ventricular conduction system before all pathways have fully recovered excitability, it will generate asynchronous ventricular depolarization and a wide, high-amplitude ECG complex. This aberrantly conducted APC is sometimes preceded by an abnormal P wave, often exhibits a noncompensatory pause, and frequently resembles normal complexes in general shape. If a sinus impulse is delayed in a ventricular conduction pathway long enough to encounter tissue that has recovered excitability, the impulse redepolarizes this tissue and spreads through the entire heart a second time. This “reentrant” depolarization generates uniform, wide, high-amplitude QRS complexes that manifest full compensatory pauses, follow the preceding normal complex by a constant interval (fixed coupling), and often appear in a bigeminal pattern. Delayed recovery of excitability after general anesthesia and increased SNS tone favor both aberrant conduction and reentry.

In postoperative patients, most actual premature ventricular contractions (PVCs) are caused by nonthreatening conditions. PVCs usually occur at varying intervals from a previous normal QRS

and often exhibit a full compensatory pause. Benign PVCs often accompany excessive PNS or SNS activity. Increased PNS influence allows emergence of ventricular escape beats. Increased SNS activity accelerates ventricular automatic cells, promoting depolarization between supraventricular impulses, and fosters emergence of parasystolic foci. PVCs resolve when autonomic nervous system balance is restored. Benign postoperative PVCs can also be generated by stretch of myocardial fibers from hypertension and by mechanical stimulation from central vascular catheters. PVCs that reflect myocardial ischemia, electrolyte disturbances, or digitalis toxicity are rare but serious.

If frequent ectopic beats compromise cardiac output, control of autonomic nervous system imbalance usually suffices. Antidysrhythmics are seldom necessary, although beta-receptor blockade might be useful. Elimination of factors that cause conduction delay or nonuniform recovery of excitability will often abolish reentrant impulses.

POSTOPERATIVE PULMONARY DYSFUNCTION

Mechanical, hemodynamic, and pharmacologic factors related to surgery and anesthesia impair ventilation, oxygenation, and airway maintenance.[34] Heavy smoking, obesity, sleep apnea, severe asthma, and COPD increase the risk of postoperative ventilatory events.[35] Preoperative pulmonary function testing has limited predictive value for postoperative complications,[36] perhaps with the exception of postoperative bronchospasm in smokers.[37]

Inadequate Postoperative Ventilation

7 In PACU patients, mild respiratory acidemia is expected, so elevated $PaCO_2$ does not necessarily indicate inadequate postoperative ventilation. Inadequate ventilation should be suspected when (1) respiratory acidemia occurs coincident with tachypnea, anxiety, dyspnea, labored ventilation, or increased SNS activity; (2) hypocarbia reduces the arterial pH below 7.30; or (3) $PaCO_2$ progressively increases with a progressive decrease in arterial pH.

Inadequate Respiratory Drive

During early recovery from anesthesia, residual effects of intravenous or inhalational anesthetics blunt the ventilatory responses to both hypercarbia and hypoxemia. Sedatives augment depression from opioids or anesthetics and reduce the conscious desire to ventilate (a significant component of ventilatory drive). Residual neuromuscular relaxants might also depress cholinergic portions of the hypoxic drive neural arc.

Hypoventilation and hypercarbia can evolve insidiously during transfer and admission to the PACU. Although effects of intraoperative medications are usually waning, but the peak depressant effect of intravenous opioid given just before transfer occurs in the PACU. Coincident depression of medullary centers that regulate the SNS can blunt signs of acidemia or hypoxemia such as hypertension, tachycardia, and agitation, concealing hypoventilation. Patients might communicate lucidly and even complain of pain still while experiencing significant opioid-induced hypoventilation. A balance must be struck between an acceptable level of postoperative ventilatory depression and a tolerable level of pain or agitation. Patients with abnormal CO_2/pH responses from morbid obesity, chronic airway obstruction, or sleep apnea are more sensitive to respiratory depressants.[38] Risk for apnea after anesthesia in preterm infants depends on type of anesthetic, postconceptual age, and preoperative hematocrit. Preterm infants should be monitored for at least 12 hours (see Chapter 43). Children with active or recent upper respiratory infection are more prone to breath holding, severe cough, and arterial desaturations below 90% during recovery, especially if they have a history of reactive airway disease or secondhand smoke exposure or have undergone intubation and/or airway surgery.[39] If hypoventilation from opioids is excessive, forced arousal and titration of intravenous naloxone reverses respiratory depression without affecting analgesia. Flumazenil directly reverses depressant effects of benzodiazepines on ventilatory drive but is usually unnecessary.

The abrupt diminution of a noxious stimulus (e.g., tracheal extubation, placement of a postoperative block) may promote hypoventilation or airway obstruction by altering the balance between arousal from discomfort and depression from medication. Intracranial hemorrhage or edema sometimes presents with hypoventilation, especially after posterior fossa craniotomy. Bilateral carotid body injury after endarterectomy can ablate peripheral hypoxic drive. Chronic respiratory acidemia from COPD alters CNS sensitivity to pH and makes hypoxic drive dominant, but hypoventilation from supplemental oxygen rarely occurs.

Increased Airway Resistance

High resistance to gas flow through airways increases work of breathing and CO_2 production. If inspiratory muscles cannot generate sufficient pressure gradients to overcome resistance, alveolar ventilation fails to match CO_2 production and progressive respiratory acidemia occurs.

In postoperative patients, increased upper airway resistance is caused by obstruction in the pharynx (posterior tongue displacement, change in anteroposterior and lateral dimensions from soft tissue collapse), in the larynx (laryngospasm, laryngeal edema), or in the large airways (extrinsic compression from hematoma, tumor, or tracheal stenosis). Weakness from residual neuromuscular relaxation[40] or myasthenia gravis can contribute, but it is seldom the primary etiology of airway compromise. If the airway is clear of vomitus or foreign bodies, simple maneuvers such as improving the level of consciousness, lateral positioning, chin lift, mandible elevation, or placement of an oropharyngeal or nasopharyngeal airway usually relieve obstruction. A nasopharyngeal airway is better tolerated with functional gag reflexes. Acute extrinsic upper airway compression (e.g., an expanding neck hematoma) must be relieved.

During emergence, stimulation of the pharynx or vocal cords by secretions, foreign matter, or extubation generates laryngospasm.[41] Laryngeal constrictor muscles occlude the tracheal inlet and reduce gas flow. Patients who smoke or are chronically exposed to smoke, have irritable airway conditions, have copious secretions, or have undergone upper airway surgery are at higher risk.[34,39] Laryngospasm can usually be overcome by providing gentle positive pressure in the oropharynx with 100% O_2. Prolonged laryngospasm is relieved with a small dose of succinylcholine (e.g., 0.1 mg/kg). An intubating dosage of succinylcholine should not be used to break postoperative laryngospasm, especially if the alveolar partial pressure of oxygen (PAO_2) is decreased by hypoventilation. Unless assisted ventilation is provided, declining PAO_2 causes serious hypoxemia before spontaneous ventilation resumes[42] (Fig. 54-3). If the functional residual capacity (FRC) is abnormally reduced, the decreased volume of O_2 available in the lungs accelerates the development of hypoxemia. Severe

laryngeal obstruction can occur secondary to hypocalcemia after parathyroid excision.

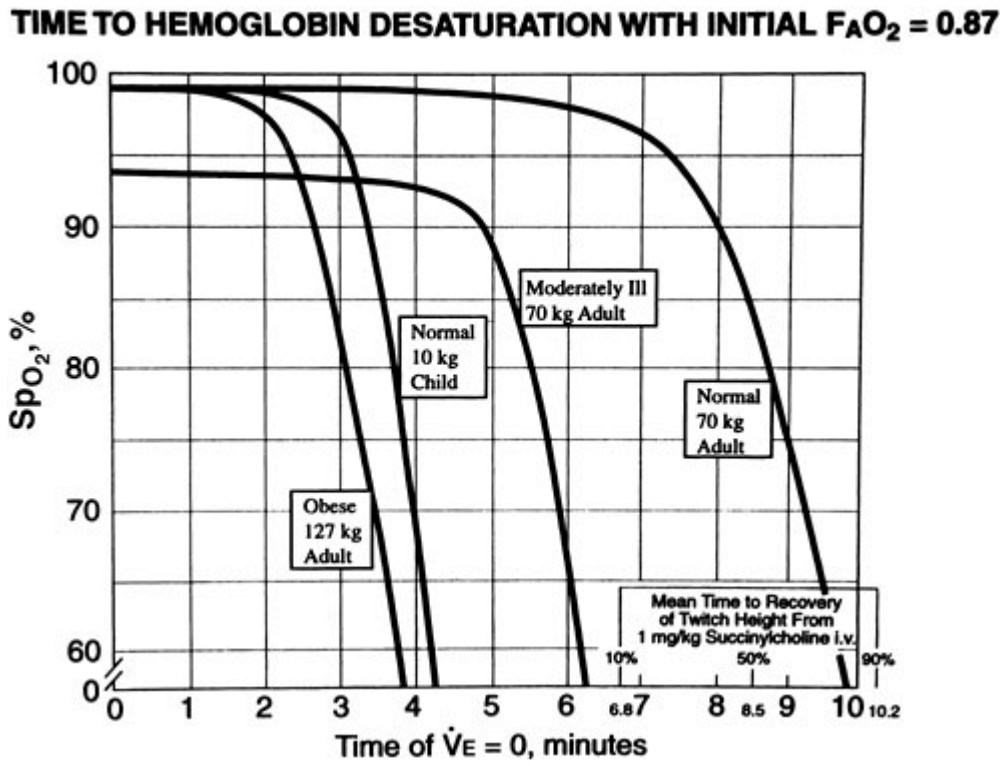

FIGURE 54-3. Rate of SpO_2 decline after onset of apnea. (Reprinted with permission from Benumof JL, Dagg R, Benumof R: Critical hemoglobin desaturation will occur before return to an unparalyzed state following 1 mg/kg intravenous succinylcholine. Anesthesiology 87:979, 1997.)

Soft-tissue edema worsens airway obstruction, especially in children and adults recovering from procedures on the neck. Nebulized vasoconstrictors help somewhat, but steroids have little effect. Patients with C1 esterase inhibitor deficiency can develop severe angioneurotic edema after even slight trauma to the airway. Pathologic airway obstruction (e.g., severe edema, epiglottitis, retropharyngeal abscess, encroaching tumors) might require emergency tracheal intubation, but airway manipulation is dangerous because minor trauma from intubation attempts can convert a marginal airway into a total obstruction. Sedatives or muscle relaxants used to facilitate intubation can worsen obstruction by compromising the patient's volitional efforts to maintain the airway and by eliminating spontaneous ventilation. Equipment and personnel necessary for emergency cricothyroidotomy or tracheostomy should be available. Cricothyroidotomy using a 14-gauge intravenous catheter or a commercially available kit permits oxygenation and marginal ventilation until the airway is secured (Fig. 54-4), especially if jet ventilation with 100% oxygen is used.

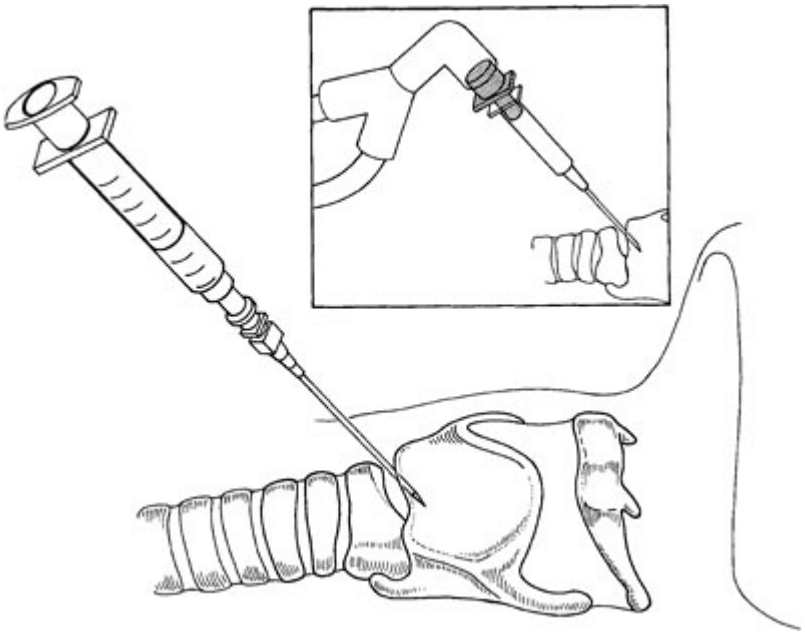

FIGURE 54-4. Cricothyroidotomy using a large-bore (14-gauge) intravenous catheter attached to syringe. After entry into the trachea, the needle is directed toward the carina.

Reduction of cross-sectional area in small airways increases overall airway resistance because resistance varies inversely with the fourth power of radius during laminar flow and with the fifth power during turbulent flow. Pharyngeal or tracheal stimulation from secretions, suctioning, aspiration, or a tracheal tube can trigger a reflex constriction of bronchial smooth muscle in emerging patients with reactive airways. Histamine release precipitated by medication or allergic reactions also increases airway smooth muscle tone. Decreased radial traction on small airways reduces cross-sectional area in patients with COPD or with decreased lung volume secondary to obesity, surgical manipulation, excessive lung water, or splinting. Preoperative spirometric evidence of increased airway resistance predicts an increased risk of postoperative bronchospasm.[37] Smokers and patients with bronchospastic conditions are at highest risk.[43] If ventilatory requirements are increased by warming, hyperthermia, or work of breathing, high flow rates convert laminar flow to higher-resistance turbulent flow. Prolonged expiratory time or audible turbulent air flow (wheezing) during a forced vital capacity expiration often unmasks subclinical airway resistance. (Resistance is higher during expiration because intermediate-diameter airways are compressed by positive intrathoracic pressure.) High airway resistance does not always cause wheezing because flow might be so impeded that no sound is produced. Signs of increased resistance mimic those of decreased pulmonary compliance. Spontaneously breathing patients exhibit accessory muscle recruitment, labored ventilation, and increased work of breathing with either condition. Mechanically ventilated patients exhibit high peak inspiratory pressures.

The treatment of small airway resistance is directed at an underlying etiology. Eliminate laryngeal or airway stimulation. Patients often respond to their preexisting regimen of albuterol, pirbuterol, or salmeterol inhalers. Isoetharine or metaproterenol nebulized in oxygen resolves postoperative bronchospasm with minimal tachycardia. Intramuscular or sublingual terbutaline can be added. Administration of steroid therapy offers little acute improvement. Adverse side effects of intravenous aminophylline have led to its replacement by other agents. Bronchospasm that is resistant to β_2-sympathomimetic medication may improve with an anticholinergic medication such as atropine or ipratropium. If bronchospasm is life threatening, an intravenous epinephrine infusion yields profound bronchodilation. Increased small airway resistance caused by mechanical factors (e.g., loss of lung volume, retained secretions, pulmonary edema) usually does not resolve with bronchodilators. Restoration of lung volume with incentive spirometry or deep tidal

ventilation increases radial traction on small airways. Reducing left ventricular filling pressures might relieve airway resistance caused by increased lung water, although interstitial fluid accumulation can persist. Also, extended contraction of airway smooth muscle obstructs venous and lymphatic flow, leading to airway wall edema that resolves slowly.

Decreased Compliance

Reduced pulmonary compliance accentuates the work of breathing. In the extreme, low compliance causes progressive respiratory muscle fatigue, hypoventilation, and respiratory acidemia. Parenchymal changes also affect compliance. Reduction of FRC leads to small airway closure and distal lung collapse, requiring greater energy expenditure to reexpand the lung. Pulmonary edema increases the lung's weight and inertia, and elevates surface tension by interfering with surfactant activity, making expansion more difficult. Pulmonary contusion or hemorrhage interferes with lung expansion, as do restrictive lung diseases, skeletal abnormalities, intrathoracic lesions, hemothorax, pneumothorax, or cardiomegaly. Obesity affects pulmonary compliance, especially when adipose tissue compresses the thoracic cage or increases intra-abdominal pressure in supine or lateral positions. Extrathoracic factors such as tight chest or abdominal dressings and gas in the stomach or bowel reduce compliance. An intra-abdominal tumor, hemorrhage, ascites, bowel obstruction, or pregnancy impairs diaphragmatic excursion and reduces compliance.

Work of breathing is improved by resolving problems that reduce compliance. Allowing patients to recover in a semisitting position (rather than supine or full sitting) reduces work of breathing. Incentive spirometry and chest physiotherapy help restore lung volume, as does positive end-expiratory pressure (PEEP) or continuous positive airway pressure (CPAP). In patients with COPD and highly compliant lungs, positive airway pressure might force the rib cage and diaphragms toward their excursion limits, accentuating inspiratory muscular effort.

Neuromuscular and Skeletal Problems

Postoperative airway obstruction and hypoventilation are accentuated by incomplete reversal of neuromuscular relaxation. Residual paralysis compromises airway patency, ability to overcome airway resistance, airway protection, and ability to clear secretions.[44] In the extreme, paralysis precludes effective spontaneous ventilation. Intraoperative use of shorter-acting

relaxants might decrease the incidence of residual paralysis but does not eliminate the problem. Marginal reversal can be more dangerous than near-total paralysis because a weak, agitated patient exhibiting uncoordinated movements and airway obstruction is more easily identified. A somnolent patient exhibiting mild stridor and shallow ventilation from marginal neuromuscular function might be overlooked, allowing insidious hypoventilation and respiratory acidemia or regurgitation with aspiration to occur. Beware of patients who have received nondepolarizing muscle relaxants but no reversal agents because they often exhibit low levels of residual paralysis.[45] Safety of techniques designed to avoid reversal of short and intermediate duration relaxants has not been substantiated, and reversal of nondepolarizing relaxants is recommended.[4] Patients with neuromuscular abnormalities such as myasthenia gravis, Eaton-Lambert syndrome, periodic paralysis, or muscular dystrophies exhibit exaggerated or prolonged responses to muscle relaxants. Even without relaxant administration, these patients can exhibit postoperative ventilatory insufficiency. Medications potentiate neuromuscular relaxation (e.g., antibiotics, furosemide, propranolol, phenytoin), as does hypocalcemia or hypermagnesemia.

Diaphragmatic contraction is compromised in some postoperative patients, forcing more reliance on intercostal muscles and reducing the ability to overcome decreased compliance or increased ventilatory demands. Impairment of phrenic nerve function from interscalene block, trauma, or thoracic and neck operations can "paralyze" one or rarely both diaphragms.[23] Adequate ventilation will normally be maintained with only one diaphragm and marginal ventilation by external intercostal muscles alone. However, with high work of breathing, muscle weakness, or increased ventilatory demands, a nonfunctional diaphragm impairs minute ventilation. Thoracic spinal or epidural blockade interferes with intercostal muscle function and reduces ventilatory reserve, especially in patients with COPD. Abnormal motor neuron function (e.g., Guillain-Barré syndrome,

cervical spinal cord trauma), flail chest, or severe kyphosis or scoliosis can cause postoperative ventilatory insufficiency.

Simple tests help assess mechanical ability to ventilate. The ability to sustain head elevation in a supine position, a forced vital capacity of 10 to 12 mL/kg, an inspiratory pressure more negative than −25 cm H_2O, and tactile train-of-four assessment imply that strength of ventilatory muscles is adequate to sustain ventilation. However, none of these clinical end points reliably predicts recovery of airway protective reflexes,[45] and failure on these tests does not necessarily indicate the need for assisted ventilation.

Occasionally, a clinical picture suggests ventilatory insufficiency when ventilation is adequate. Voluntary limitation of chest expansion to avoid pain (splinting) causes labored, rapid, shallow breathing characteristic of inadequate ventilation. Splinting seldom causes actual hypoventilation and usually improves with analgesia and repositioning. Ventilation with small tidal volumes due to thoracic restriction or reduced compliance seems to generate afferent input from pulmonary stretch receptors, leading to dyspnea, labored breathing, and accessory muscle recruitment in spite of appropriate minute ventilation. (This also occurs during mechanical ventilation with low volumes.) Occasional large, "satisfying" lung expansions often relieve these symptoms. Finally, spontaneous hyperventilation to compensate for a metabolic acidemia might generate tachypnea or labored breathing, which is mistaken for ventilatory insufficiency.

Increased Dead Space

Ventilation of unperfused dead space or of poorly perfused alveoli with high ventilation/perfusion ($\dot{V}/\dot{Q}$) ratios is less effective in removing CO_2. Expansion of dead space volume or reduction of tidal volume increases the fraction of each breath wasted in dead space ($\dot{V}_D/\dot{V}_T$) and the amount of CO_2 from the previous exhalation that is rebreathed. A proportionally larger increase in total minute ventilation is required to meet any increase in CO_2 production. Patients with high $\dot{V}_D/\dot{V}_T$ are at greater risk for postoperative ventilatory failure.

Occasionally, an acute increase in dead space contributes to respiratory acidemia in postoperative patients. Although upper airway dead space is reduced after tracheal intubation and tracheostomy, excessive tubing volume or valve reversal in breathing circuits promotes rebreathing of CO_2. PEEP or CPAP elevates anatomic dead space, especially in patients with high pulmonary compliance. Pulmonary embolization with air, thrombus, or cellular debris increases physiologic dead space, although impact on CO_2 excretion is often compensated by accelerated minute ventilation from hypercorbic and hypoxic drives or reflex responses. Pulmonary hypotension can transiently increase $\dot{V}_D/\dot{V}_T$ by decreasing perfusion to well-ventilated, nondependent lung. Irreversible increases in dead space occur if adult respiratory distress syndrome (ARDS) related to sepsis, massive transfusion, or hypoxia destroys pulmonary microvasculature. Dead space may appear high if an inhalation interrupts the previous exhalation and spent alveolar gas is retained. This "gas trapping" occurs when high airway resistance lengthens the time required to exhale completely, or if improper inspiration/expiration ratios or high ventilatory rates are used during mechanical ventilation.

Increased Carbon Dioxide Production

Carbon dioxide production varies directly with metabolic rate, body temperature, and substrate availability. During anesthesia, CO_2 production falls to approximately 60% of the normal 2 to 3 mL/kg/min as hypothermia lowers metabolic activity and neuromuscular relaxation reduces tonic muscle contraction. Therefore, during recovery, metabolic rate and CO_2 production can increase by 40%. Shivering, high work of breathing, infection, SNS activity, or rapid carbohydrate metabolism

during intravenous hyperalimentation accelerate CO_2 production even more. Malignant hyperthermia generates CO_2 production many times greater than normal that rapidly exceeds ventilatory reserve and causes severe respiratory acidemia. Even mild increases of CO_2 production can precipitate respiratory acidemia if low compliance, airway resistance, or neuromuscular paralysis interferes with ventilation. With the exception of adjusting hyperalimentation, improving work of breathing, reducing shivering, or treating hyperthermia, there is little yield from addressing CO_2 production in PACU patients.

Inadequate Postoperative Oxygenation

Systemic arterial partial pressure of oxygen (PaO_2) is the best indicator of pulmonary oxygen transfer from alveolar gas to pulmonary capillary blood. Arterial hemoglobin saturation monitored by pulse oximetry yields less information on alveolar-arterial gradients and is not helpful in assessing impact of hemoglobin dissociation curve shifts or carboxyhemoglobin.[46] Evaluation of metabolic acidemia or mixed venous oxygen content yields insight into peripheral oxygen delivery and utilization. Adequate arterial oxygenation does not mean that cardiac output, arterial perfusion pressure, or distribution of blood flow will maintain tissue oxygenation. Sepsis, hypotension, anemia, or hemoglobin dissociation abnormalities can generate tissue ischemia despite adequate oxygenation.

In postoperative patients, the acceptable lower limit for PaO_2 varies with individual patient characteristics. A PaO_2 below 65 to 70 mm Hg causes significant hemoglobin desaturation, although tissue oxygen delivery might be maintained at lower levels. Maintaining PaO_2 between 80 and 100 mm Hg (saturation 93 to 97%) ensures adequate oxygen availability. Little benefit is derived from elevating PaO_2 above 110 mm Hg because hemoglobin is saturated and the amount of additional oxygen dissolved in plasma is negligible. During mechanical ventilation, a PaO_2 above 80 mm Hg with 0.4 FIO_2 and 5 cm H_2O PEEP or CPAP usually predicts sustained adequate oxygenation after tracheal extubation.

Distribution of Ventilation

Loss of dependent lung volume commonly causes $\dot{V}/\dot{Q}$ mismatching and hypoxemia. A reduction in FRC decreases radial traction on small airways, leading to collapse and distal atelectasis that can worsen for 36 hours after surgery.[47] Reduced ventilation in dependent lung is particularly damaging because gravity directs pulmonary blood flow to dependent areas. Obese patients sustain large decreases in FRC during surgery. Older patients normally exhibit some airway closure at end expiration, and those with COPD have more severe closure that is exacerbated by small reductions in FRC. Retraction, packing, manipulation, or peritoneal insufflation during upper abdominal surgery reduces FRC, as does compression from leaning surgical assistants.[48] Prone, lithotomy, or Trendelenburg positions are disadvantageous, especially in obese patients. Right upper lobe collapse secondary to partial right main-stem intubation is a frequently overlooked cause. During one-lung anesthesia, the weight of unsupported mediastinal contents, pressure from abdominal contents on the dependent diaphragm, and lung compression all reduce dependent lung volume. Gravity and lymphatic obstruction promote interstitial fluid accumulation and further $\dot{V}/\dot{Q}$ mismatching. This "down lung syndrome" may appear as unilateral pulmonary edema on the chest film.

Postoperatively, acute pulmonary edema from overhydration, ventricular dysfunction, or increased capillary permeability leads to hypoxemia by interfering with both $\dot{V}/$

matching and diffusion of oxygen. Strong inspiratory efforts against an obstructed airway decrease FRC and promote negative-pressure pulmonary edema. Small airway occlusion from compression, retained secretions, or aspiration leads to distal hypoventilation and hypoxemia, as does main-stem intubation. Pneumothorax or hemothorax also reduce lung volume.

Conservative measures that restore lung volume often improve oxygenation. If possible, patients should recover in a semisitting position to reduce abdominal pressure on the diaphragms. Pain with ventilation encourages shallow breathing, so analgesia helps maintain FRC, especially with upper abdominal or chest wall incisions. Deep ventilation, cough, chest physiotherapy, and incentive spirometry seem to help expand FRC, mobilize secretions, and accustom a patient to incisional discomfort, but actual efficacy is debated.[49,50] For serious postoperative reduction of FRC, positive pressure is effective. CPAP (5 to 7 cm H_2O) can be delivered by facemask for several hours until factors promoting loss of lung volume resolve. If hypoxemia is severe or patient acceptance of mask CPAP is poor, tracheal intubation is usually required. Intubation for delivery of CPAP does not mandate positive-pressure ventilation. Ventilatory requirements should be assessed independently, considering $PaCO_2$, arterial pH, and work of breathing. Usually, 5 to 10 cm H_2O of CPAP or PEEP improves PaO_2 without risking hypotension, increased intracranial pressure, or barotrauma. If PaO_2 does not improve, reevaluate the etiology. During routine postoperative care, airway pressure >10 cm H_2O is transmitted more to thoracic veins and increases incidence of barotrauma. An occasional patient with ARDS or pulmonary contusion might require higher pressures for improved oxygenation.

Tracheal intubation eliminates normal expiratory resistance and the "physiologic PEEP" (2 to 5 cm H_2O) that helps maintain lung volume during spontaneous ventilation. Exposing an intubated trachea to ambient pressure may cause a gradual reduction in FRC. Healthy, slender patients will often tolerate short periods of intubation without positive pressure, but generally it is prudent to allow intubated postoperative patients to exhale against a slight degree of CPAP.

Distribution of Perfusion

Poor distribution of pulmonary blood flow also interferes with $\dot{V}/\dot{Q}$ matching and oxygenation. Flow distribution is primarily determined by hydrodynamic factors (PA and venous pressures, vascular resistance), which are affected by gravity, airway pressure, lung volume, and cardiac dynamics. Flow distribution is modulated by hypoxic pulmonary vasoconstriction (HPV), which diverts flow from air spaces that exhibit low PaO_2. In postoperative patients, position affects oxygenation if gravity forces blood flow to areas with reduced ventilation. Placing a poorly ventilated lung in a dependent position can reduce PaO_2. Postoperative changes in PA pressure, airway pressure, and lung volume also have complex effects on blood flow distribution that can adversely affect $\dot{V}/\dot{Q}$ matching. Residual inhalational anesthetics, vasodilators, and sympathomimetics directly affect vascular tone and HPV, partially explaining larger alveolar-arterial oxygen gradients after general anesthesia. (Changes in distribution of ventilation also contribute.) Patients with liver cirrhosis exhibit poor $\dot{V}/\dot{Q}$ matching caused by circulating humoral substances related to abnormal hepatic metabolism. Circulating endotoxin impairs HPV, contributing to hypoxemia in septic patients.

In the PACU, few interventions are useful to improve $\dot{V}/\dot{Q}$

matching by changing pulmonary blood flow. Maintain PA and airway pressures within an acceptable range. When possible, avoid placing an atelectatic or diseased lung tissue in a dependent position. Placing poorly ventilated parenchyma in a nondependent position could improve $\dot{V}/\dot{Q}$ matching, but positioning a diseased lung in an "up" position may promote drainage of purulent material into the unaffected lung. Avoiding beta-mimetic or vasodilatory medications may improve PaO_2 but benefits from the medication usually outweigh drawbacks of impaired HPV.

INADEQUATE ALVEOLAR PAO_2

Postoperative hypoxemia is occasionally caused by a global reduction of PAO_2, usually from inadequate ventilation. If oxygen uptake from alveoli exceeds delivery by ventilation, PAO_2 decreases. Hypoventilation must be severe to cause hypoxemia based on a reduction in oxygen delivery to alveoli. Complete apnea or airway obstruction by a foreign body, soft-tissue edema, or laryngospasm leads to rapid depletion of alveolar oxygen, as does very high small airway resistance, which precludes effective ventilation. If cessation of ventilation does occur, the rate of PAO_2 decline varies with age, body habitus, degree of underlying illness, and initial PAO_2[42] (see Fig. 54-3). Hypoxemia might also occur if opioids or residual anesthetic levels severely depress ventilatory drives. Partial airway obstruction does not usually reduce PAO_2, especially when patients are receiving supplemental oxygen. Increasing the

oxygen content of the FRC with supplemental oxygen safeguards against hypoxemia from hypoventilation or airway obstruction. Rarely, excessive concentrations of other gases reduce PAO_2. After general anesthesia, rapid outpouring of nitrous oxide displaces alveolar gas and can lower PAO_2 if a patient is hypoventilating or breathing ambient air, but this "diffusion hypoxia" would usually occur before PACU admission. Volume displacement of oxygen could also occur during severe hypercarbia in a patient breathing ambient air, although acidemia is often a greater problem.

REDUCED MIXED VENOUS PO_2

Systemic venous partial pressure of oxygen ($P\bar{v}O_2$) is affected by arterial oxygen content, cardiac output, distribution of peripheral blood flow, and tissue oxygen extraction. If arterial oxygen content decreases or tissue extraction increases, $P\bar{v}O_2$ falls. The lower the $P\bar{v}O_2$ in blood that is shunted or flows through low $\dot{V}/\dot{Q}$ units, the greater the reduction of PaO_2. Blood with a low $P\bar{v}O_2$ also extracts larger volumes of oxygen from alveolar gas, amplifying the effect of hypoventilation or airway obstruction on PAO_2. Very low $P\bar{v}O_2$ increases the risk of resorption atelectasis in poorly ventilated alveoli. In postoperative patients, shivering, infection, and hypermetabolism lower $P\bar{v}O_2$ by increasing peripheral oxygen extraction. Low cardiac output or hypotension also lower $P\bar{v}O_2$ by decreasing tissue oxygen delivery. Supplemental oxygen reduces the impact of low $P\bar{v}O_2$ on alveolar oxygen extraction and on arterial oxygenation.

Carbon Monoxide Poisoning

Carbon monoxide (CO) reversibly binds to hemoglobin with 200 times the affinity of oxygen, reducing oxygen-carrying capacity by impeding both the binding and the dissociation of oxygen. Trauma or burn patients might be poisoned prior to emergency surgery. Patients can also be exposed to CO generated by a reaction between inhalation anesthetics and dry CO_2-absorbing agents during general anesthesia. Risk of intraoperative exposure is low but increases during first cases of the day, especially those performed in peripheral locations. Moderate CO poisoning is difficult to recognize in postoperative patients because symptoms such as headache, nausea, vomiting, irritability, and altered visual or motor skills are nonspecific and common during recovery. CO seldom causes cyanosis and the PaO_2 is often high, although SpO_2 is low and metabolic acidemia is significant. A pulse oximeter interprets carboxyhemoglobin as oxyhemoglobin, so SpO_2 reads falsely high. (A cooximeter is required to differentiate.) Thus, a postoperative patient with CO poisoning can be hypoxemic yet appear well oxygenated. One hundred percent oxygen displaces CO from hemoglobin and accelerates CO elimination. Hyperbaric oxygen therapy may be indicated for severe cases.

Anemia

Preoperative hematocrit and intraoperative hemorrhage determine a patient's red cell mass and oxygen-carrying capacity after surgery. Reduction of hematocrit caused by dilution has less impact. The hematocrit at which oxygen delivery becomes insufficient to match tissue needs varies with cardiac reserve, oxygen consumption, hemoglobin dissociation, PaO_2, and blood flow distribution. Each patient has a minimum hematocrit below which tissues use inefficient anaerobic metabolism, generating a lactic acidemia. Patients with vascular disease are at increased risk of vital organ ischemia as hematocrit falls.

Supplemental Oxygen

8 The incidence of hypoxemia in postoperative patients is high. In PACU patients placed on room air, 30% of patients younger than 1 year of age, 20% ages 1 to 3 years, 14% ages 3 to 14 years, and 7.8% of adults had hemoglobin saturations fall below 90%, with many falling below 85%[51] (Fig. 54-5). Clinical observation and assessment of cognitive function do not accurately screen for hypoxemia, so monitoring with oximetry is essential throughout the PACU admission.[46] One cannot predict which patients will become hypoxemic or when hypoxemia will occur. Patients with lung disease or obesity, those recovering from thoracic or upper abdominal procedures, and those with preoperative hypoxemia are at increased risk.[52] Postoperative hypoxemia occurs in children, especially those with respiratory infections or chronic adenotonsillar hypertrophy. Hypoxemia occurs frequently after regional anesthesia.[22]

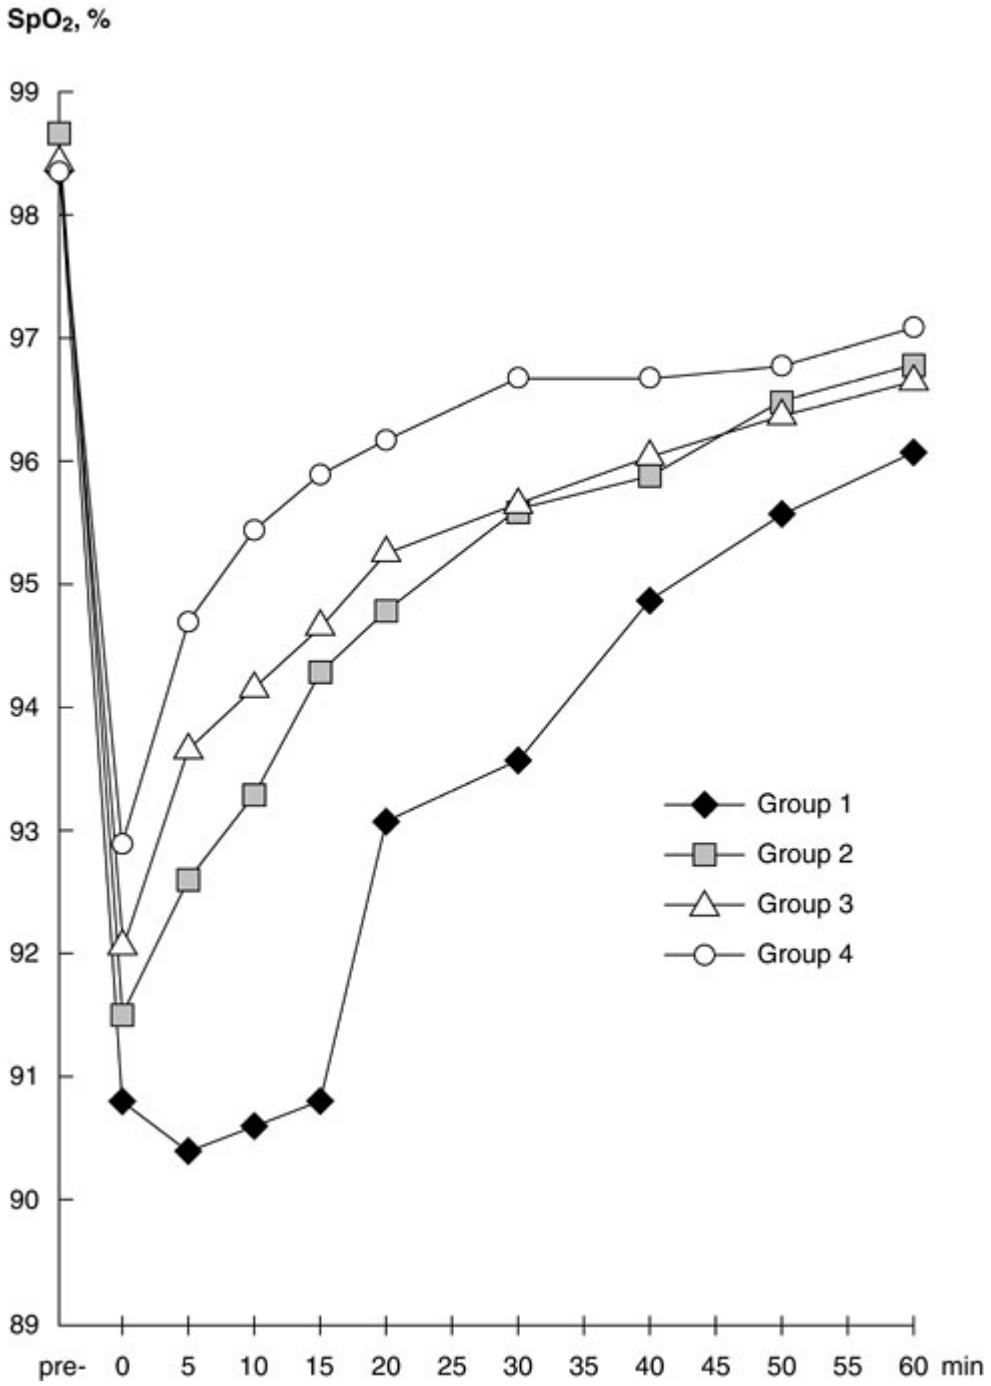

FIGURE 54-5. SpO_2 versus postanesthesia care unit time in patients spontaneously ventilating on room air after general anesthesia (group 1, 0–1 year of age; group 2, 1–3 years; group 3, 3–14 years; group 4, 14–58 years). (Reprinted with permission from Xue FS, Huang YG, Tong SY *et al:* A comparative study of early postoperative hypoxemia in infants, children, and adults undergoing elective plastic surgery. Anesth Analg 83:709, 1996.)

Supplemental oxygen could be administered only to patients at high risk of hypoxemia or with low SpO_2 readings. However, if a patient qualifies for PACU admission, he or she should probably receive oxygen during initial recovery and perhaps during transport to the PACU.[4] Supplemental oxygen improves PaO_2 and helps prevent or treat hypoxemia, although its efficacy is variable. However, oxygen does not address underlying causes of hypoxemia in postoperative patients, and its use does not guarantee that hypoxemia will not occur.[53] If hypoxemia is caused by low

$\dot{V}$

/

$\dot{Q}$

, increasing oxygen content in marginally ventilated air spaces improves arterial saturation. Oxygen has a negligible effect on hypoxemia caused by shunting because shunted blood is not exposed to increased FIO_2, whereas blood passing ventilated alveoli is already saturated. Increased oxygen content in the FRC delays the onset of serious hypoxemia during airway obstruction or hypoventilation. Cost of supplemental oxygen is minimal, inconvenience to patients is minor, and risk is small. Although oxygen might cause minor mucosal drying, routine humidification is of little benefit unless intubation bypasses natural humidification. Oxygen apparatus might cause corneal abrasion during emergence. An $FIO_2 > 0.8$ promotes resorption atelectasis as inert nitrogen is replaced with oxygen in poorly ventilated alveoli. Inspiration of 100% oxygen for 24 to 36 hours generates early signs of pulmonary oxygen toxicity. Toxicity is accelerated by hyperbaric oxygen therapy. Previous carmustine therapy might increase risk at oxygen toxicity but bleomycin therapy does not.

Perioperative Aspiration

During anesthesia, depression of airway reflexes places patients at risk for intraoperative pulmonary aspiration that causes symptoms in the PACU or for aspiration during recovery. Pulmonary morbidity from perioperative aspiration varies with the type and volume of the aspirate. Although aspiration of gastric contents is most widely feared, surgical patients also experience other aspiration syndromes.

Aspiration of clear oral secretions during induction, facemask ventilation, or emergence is common and usually insignificant. Cough, mild tracheal irritation, or transient laryngospasm are immediate sequelae, although large-volume aspiration predisposes to infection, small airway obstruction, or pulmonary edema. Aspiration of blood secondary to trauma, epistaxis, or airway surgery generates marked changes on the chest radiograph that are out of proportion with clinical signs. Aspirated "sterile" blood causes minor airway obstruction but is rapidly cleared by mucociliary transport, resorption, and phagocytosis. Massive blood aspiration or aspiration of clots obstructs airways, interferes with oxygenation, and leads to fibrinous changes in air spaces and to pulmonary

hemochromatosis from iron accumulation in phagocytic cells. Secondary infection is a threat, especially if tissue or purulent matter is also aspirated.

Aspiration of food, small objects, pieces of teeth, or dental appliances causes persistent cough, diffuse reflex bronchospasm, airway obstruction with distal atelectasis, or pneumonia. Complications are often localized and treated with antibiotics and supportive care once the foreign matter is expelled or removed. Secondary thermal, chemical, or traumatic airway injury from aspirated objects can occur. Of course, complete upper airway or tracheal obstruction by an aspirated object is a life-threatening emergency.

Aspiration of acidic gastric contents during vomiting or regurgitation causes chemical pneumonitis characterized initially by diffuse bronchospasm, hypoxemia, and atelectasis.[54] The morbidity increases directly with volume and inversely with the pH of the acidic aspirate. Aspiration of partially digested food worsens and prolongs pneumonitis, especially if vegetable matter is present. Food particles mechanically obstruct airways and are a nidus for secondary bacterial infection. In serious cases, epithelial degeneration, interstitial and alveolar edema, and hemorrhage into air spaces rapidly progresses to ARDS with high-permeability pulmonary edema. Destruction of pneumocytes, decreased surfactant activity, hyaline membrane formation, and emphysematous changes can follow, leading to

$$\dot{V}$$

/

$$\dot{Q}$$

mismatching and reduced compliance. Destruction of microvasculature increases pulmonary vascular resistance and

$$\dot{V}_D/\dot{V}_T$$

.

9 The incidence of serious aspiration is relatively low in PACU patients, but the risk is still significant. Frequency of postoperative vomiting remains high, especially if gas has

accumulated in the stomach. Protective airway reflexes such as cough, swallowing, and laryngospasm are suppressed by depressant medications such as inhalation anesthetics, barbiturates, and opiates, so observe patients with decreased levels of consciousness carefully. Persisting effects of laryngeal nerve blocks or topical local anesthetics used to reduce airway irritability decrease postoperative airway protection, as does residual sedation. Reflexes are also impaired by residual neuromuscular paralysis.[44,45] Patients can sustain airway patency and spontaneous ventilation, pass a head lift test, have a tactile train-of-four T4/T1 ratio greater than 0.7, and still have impaired airway reflexes from residual paralysis. The T4/T1 ratio might need to exceed 0.9 before reflexes are completely competent.[55] Risk of aspiration also increases if reversal is omitted. Hypotension, hypoxemia, or acidemia cause both emesis and obtundation, increasing aspiration risk.

Preventing aspiration is critical because effective therapy is limited.[56] For patients at high risk, preoperative administration of nonparticulate antacids such as sodium citrate increases

the pH of gastric fluid without excessively increasing volume. Avoid particulate antacids. Histamine type 2 receptor blockers such as cimetidine or ranitidine reduce the volume and increase the pH of gastric secretions. Metoclopramide increases gastroesophageal sphincter tone and accelerates gastric emptying. Inserting a nasogastric tube is often ineffective to remove particulate matter and interferes with gastroesophageal sphincter integrity.

In the PACU, vigilance against aspiration is important. Trendelenburg position might promote regurgitation but aids in airway clearance if regurgitation or vomiting occurs. Head elevation in unconscious patients should be avoided because it creates a gravitational gradient from pharynx to lung. High-risk patients should not have the trachea extubated until airway reflexes are fully restored. Aspiration of acidic fluid can still occur around an inflated tracheal tube cuff, so frequently monitor the upper airway for secretions or vomitus. Avoid cuff deflation until extubation because the rigid tube impairs laryngospasm, swallowing, and other protective reflexes. Suction the pharynx completely and extubate at end inspiration with positive airway pressure to promote expulsion of material trapped below the cords but above the inflated cuff. Observation is essential after extubation because airway reflexes might be temporarily impaired. Anatomic distortion in the airway from soft-tissue trauma or surgical intervention interferes with airway protection. Mandibular fixation makes expulsion of vomitus, blood, or secretions difficult, so have equipment for release of mandibular fixation available and ensure patients demonstrate cognitive and physical ability to clear the airway before the trachea is extubated.

Discovery of gastric secretions in the pharynx mandates immediate lateral head positioning (assuming cervical spine integrity) and suction of the airway. If airway reflexes are compromised, tracheal intubation is often appropriate. After intubation, the trachea is suctioned through the tracheal tube before positive-pressure ventilation; this avoids widely disseminating aspirated material into distal airways. Instillation of saline or alkalotic solutions is not recommended. Assessing the pH of tracheal aspirate is useless because buffering is immediate. Checking pharyngeal aspirate pH is more accurate but of little practical value. Suspicion that aspiration has occurred mandates 24 to 48 hours of monitoring for development of aspiration pneumonitis. If the likelihood of aspiration is small in an ambulatory patient, outpatient follow-up can be done, assuming hypoxemia, cough, wheezing, or radiographic abnormalities do not appear within 4 to 6 hours. Give the patient explicit instructions to contact a medical facility at the first appearance of malaise, fever, cough, chest pain, or other symptoms of pneumonitis. If likelihood of aspiration is high, the patient should be admitted to the hospital. Observation includes serial temperature checks, white blood cell counts with differential, chest radiograph, and blood gas determination or pulmonary function testing, if appropriate. Chest physiotherapy, incentive spirometry, and restarting medications for preexisting pulmonary conditions minimize the loss of lung volume,

$\dot{V}$

/

$\dot{Q}$

mismatching, and infection. Fluffy infiltrates may appear on the chest radiograph any time within 24 hours. Hypoxemia might develop quickly or evolve insidiously as injury progresses, so frequent

pulse oximetry monitoring is important.

If hypoxemia, increased airway resistance, consolidation, or pulmonary edema evolves, support the patient with supplemental oxygen, PEEP, or CPAP. Mechanical ventilation is often necessary. Steroids yield little improvement. Bacterial infection does not always follow aspiration, so prophylactic antibiotics merely promote colonization by resistant organisms. If bacterial infection appears, institute antibiotic therapy based on culture results. If cultures are equivocal, use broad-spectrum antibiotics with coverage for gram-negative rods and anaerobes, including *Bacteroides fragilis.* Overall therapy is similar to that for ARDS. Pulmonary edema from increased capillary permeability should not be treated with diuretics unless high filling pressures or hypervolemia exist. Fluid losses into the lung necessitate aggressive hydration.

POSTOPERATIVE RENAL COMPLICATIONS

Ability to Void

10 The ability to void should be assessed because opioids and autonomic side effects of regional anesthesia interfere with sphincter relaxation and promote urine retention. Urinary retention is common after urologic, inguinal, and genital surgery, and frequently delays discharge.[57] Neither the patient nor staff can accurately estimate bladder volume through sensation or palpation, respectively. Avoid the archaic practice of "straight catheterization." An ultrasonic bladder scan helps assess bladder volume before discharge. It is reasonable to discharge selected ambulatory patients from the facility and inpatients to a floor before they void.[4,58,59] However, ensure urination is monitored after discharge to avoid urinary retention. Give ambulatory patients who are discharged without voiding a specific time interval in which to void (i.e., 10 to 12 hours after discharge). If retention persists, the patient must contact a health care facility. High return rates after urologic procedures are related to urinary retention.[60]

Renal Tubular Function

Analysis of urine yields information about postoperative renal tubular function. Urine color is not useful for assessing concentrating ability, but it does assist recognition of hematuria, hemoglobinuria, or pyuria. Urine osmolarity (reflecting the number of particles in solution) is a more reliable index of tubular function than specific gravity, which is affected by molecular weight of solutes. An osmolarity >450 mOsm/L indicates intact tubular concentrating ability. A urine sodium concentration far below or a potassium concentration above serum concentrations also indicates tubular viability, as does acidification or alkalinization of urine. Osmolarity, electrolyte, and pH values close to those in serum may indicate poor tubular function or acute tubular necrosis.

Inorganic fluoride released during metabolism of certain inhalation anesthetics can cause a transient reduction of tubular concentrating ability after long anesthetics. Higher fluoride levels cause renal tubular necrosis. Interaction of sevoflurane with dry carbon dioxide absorbents (often found in first cases or peripheral locations) generates compound A, a vinyl ether that degrades to release inorganic fluoride. Although transient impairment of protein retention and concentrating ability may occur, use of sevoflurane does not seriously affect renal function.

Oliguria

Oliguria (⩽0.5 mL/kg/h) occurs frequently during recovery and usually reflects an appropriate renal response to hypovolemia. However, decreased urine output might indicate abnormal renal function. The acceptable degree and duration of oliguria vary with baseline renal status, the surgical procedure, and the anticipated postoperative course. In patients without catheters, assess interval since last voiding and bladder volume to help differentiate oliguria from inability to void. Check indwelling urinary catheters for kinking, for obstruction

by blood clots or debris, and for the catheter tip being positioned above the urinary level in the bladder. Aggressively evaluate oliguria if intraoperative events could jeopardize renal function

(e.g., aortic cross-clamping, severe hypotension, possible ureteral ligature, massive transfusion). Systemic blood pressure must be adequate for renal perfusion, based on preoperative pressures. Administration of desmopressin for hematologic purposes seldom affects postoperative urinary output. After urine is sent for electrolyte and osmolarity determinations, a 300- to 500-mL intravenous crystalloid bolus helps assess whether oliguria represents a renal response to hypovolemia. If output does not improve, consider a larger bolus or a diagnostic trial of furosemide, 5 mg intravenously. Furosemide increases urine output if oliguria reflects tubular resorption of fluid. Patients on chronic diuretic therapy might require a diuretic effect to maintain postoperative urine output.

Persistence of oliguria despite hydration, adequate perfusion pressure, and a furosemide challenge increases the likelihood of acute tubular necrosis, ureteral obstruction, renal artery or vein occlusion, or inappropriate antidiuretic hormone (ADH) secretion. Cystoscopy, intravenous pyelography, angiography, or radionuclide scanning may help clarify renal status. Osmotic or loop diuretics may be useful to attenuate renal damage. The efficacy of low-dose dopamine or dobutamine is questionable. Consultation with a nephrologist is prudent.

Polyuria

Relying on high postoperative urinary output to gauge intravascular volume status or renal viability can be misleading. Profuse urine output often reflects generous intraoperative fluid administration, but osmotic diuresis caused by hyperglycemia and glycosuria is another common cause, particularly if glucose-containing crystalloid solutions are infusing. Polyuria might also reflect intraoperative diuretic administration. However, sustained polyuria (4 to 5 mL/kg/h) can indicate abnormal regulation of water clearance or high-output renal failure, especially if urinary losses compromise intravascular volume and systemic blood pressure. Diabetes insipidus occurs secondary to intracranial surgery, pituitary ablation, head trauma, or increased intracranial pressure. The diagnosis is made by comparing urine and serum electrolytes with osmolarity. Diagnostic or therapeutic administration of vasopressin is useful.

METABOLIC COMPLICATIONS

Postoperative Acid-Base Disorders

Categorization of postoperative acid-base abnormalities into primary and compensatory disorders is difficult because rapidly changing pathophysiology often generates two or more primary disorders.

Respiratory Acidemia

Respiratory acidemia is frequently encountered in PACU patients because anesthetics, opioids, and sedatives promote hypoventilation by depressing CNS sensitivity to pH and CO_2. In awake, spontaneously breathing patients with adequate analgesia, hypercarbia and acidemia are usually mild ($PaCO_2$ 45 to 50 mm Hg, pH 7.36 to 7.32). Deeply sedated patients exhibit more profound acidemia unless supplemental ventilation is administered. Patients with residual neuromuscular paralysis, increased airway resistance, or decreased pulmonary compliance might not sustain adequate ventilation despite an intact CNS drive, especially if CO_2 production is elevated by fever, shivering, or hyperalimentation. The kidneys require hours to generate a compensatory metabolic alkalosis, so compensation for acute postoperative respiratory acidemia is limited.

Symptoms of respiratory acidemia include agitation, confusion, ventilatory dissatisfaction, and tachypnea. SNS response to low pH causes hypertension, tachycardia, and dysrhythmias. Respiratory acidemia caused by CNS depression often produces less intense signs of SNS activity. In patients with head injury, intracranial tumors, or cerebral edema, respiratory acidemia increases cerebral blood flow and intracranial pressure. At very low pH, catecholamines cannot interact with adrenergic receptors, so heart rate and blood pressure decrease precipitously. Treatment consists of correcting the imbalance between CO_2 production and alveolar ventilation. Raising the level of consciousness and judicious reversal of opioids improves ventilatory drive.

Improving airway resistance, neuromuscular function, or ventilatory mechanics is useful. If spontaneous ventilation cannot maintain CO_2 excretion, tracheal intubation and mechanical ventilation are necessary. Reducing CO_2 production by controlling fever or shivering may be helpful.

Metabolic Acidemia

Evaluation of acute postoperative metabolic acidemia is relatively straightforward. Occasionally, ketoacidosis occurs in diabetic patients. Serum glucose levels are elevated, and ketones are detectable in blood or urine. Patients with renal failure or renal tubular acidosis usually exhibit a preoperative metabolic acidemia. Excessive saline infusion during surgery can generate a mild hyperchloremic, metabolic acidemia, but use of lactated Ringer's solution avoids this problem. Rarely, a patient manifests acidemia from toxic ingestion of phenformin, aspirin, or methanol. Once these unusual causes are excluded, postoperative metabolic acidemia almost always represents lactic acidemia secondary to insufficient delivery or utilization of oxygen in peripheral tissues. Peripheral hypoperfusion is often caused by low cardiac output (hypovolemia, cardiac failure, dysrhythmia) or decreased SVR (sepsis, catecholamine depletion, sympathectomy). Arteriolar constriction from hypothermia or pressor administration reduces tissue perfusion, as does poor distribution of blood flow. Hypoxemia, severe anemia, impaired hemoglobin dissociation, CO poisoning, and inability to use oxygen in the mitochondria (cyanide or arsenic poisoning) also generate lactic acidemia.

A spontaneously breathing patient will hyperventilate and quickly generate a respiratory alkalosis to compensate for metabolic acidemia, but anesthetics and analgesics interfere with this ventilatory response. The sympathetic response to acute postoperative metabolic acidemia is often milder than the response to respiratory acidemia because hydrogen and bicarbonate ions cross the blood-brain barrier with more difficulty than CO_2. Treatment consists of resolving the condition causing accumulation of metabolic acid. Ketoacidosis is treated with intravenous potassium, insulin, and glucose. Improving cardiac output or systemic blood pressure will reduce lactic acid production, as will rewarming. If conditions causing lactate accumulation are improved and acidemia is mild, renal excretion of hydrogen ions will restore normal pH. For severe or progressive acidemia, intravenous bicarbonate or calcium gluconate helps restore pH.

Respiratory Alkalemia

Pain or anxiety during emergence causes hyperventilation and acute respiratory alkalemia. Excessive mechanical ventilation also generates respiratory alkalemia, especially if hypothermia or paralysis has decreased CO_2 production. Pathologic causes of "central" hyperventilation include sepsis, cerebrovascular accident, or paradoxical CNS acidosis (an imbalance of

bicarbonate concentration across the blood-brain barrier caused by prolonged hyperventilation). Acute respiratory alkalemia generates confusion, dizziness, atrial dysrhythmias, or abnormal cardiac conduction. Alkalemia decreases cerebral blood flow, causing hypoperfusion and even stroke in patients with cerebrovascular disease. If the alkalemia is severe, reduced serum ionized calcium concentration precipitates muscle fasciculation or hypocalcemic tetany. Very high pH depresses cardiovascular, CNS, and catecholamine receptor functions. Metabolic compensation for acute respiratory alkalemia is limited because time constants for bicarbonate excretion are large. Treatment necessitates reducing alveolar ventilation, usually by administering analgesics and sedatives for pain and anxiety. Rebreathing of CO_2 has little application in the PACU.

Metabolic Alkalemia

Metabolic alkalemia is rare in PACU patients unless vomiting, gastric suctioning, dehydration, alkaline ingestion, or potassium-wasting diuretics caused an alkalemia that existed before surgery. Excessive intraoperative bicarbonate administration causes postoperative metabolic alkalemia, but alkalemia from metabolism of lactate or citrate usually does not appear within the first 24 hours. Respiratory compensation through retention of CO_2 is rapid but limited because hypoventilation eventually causes hypoxemia. Hydration and correction of hypochloremia and

hypokalemia allow the kidney to excrete excess bicarbonate.

Glucose and Electrolyte Disorders

Serum glucose determination is superior to urine glucose measurement for managing blood sugar abnormalities. However, urine glucose concentration helps assess osmotic diuresis and estimate renal transport thresholds by comparison with serum levels.

Hyperglycemia

Glucose infusions and stress responses commonly elevate serum glucose levels after surgery. During anesthesia, the value of including glucose in maintenance intravenous solutions is questionable. Moderate postoperative hyperglycemia (150–250 mg/dL) resolves spontaneously and has little adverse effect. Higher glucose levels cause glycosuria with osmotic diuresis and interfere with serum electrolyte determinations. Severe hyperglycemia increases serum osmolality to a point that cerebral disequilibrium and hyperosmolar coma occur. In diabetic patients, hyperglycemia may indicate insulin deficiency and potential for ketoacidosis. Incremental titration or infusion of intravenous regular insulin adjusts serum glucose rapidly. Potassium replacement and serial blood glucose determinations are essential.

Hypoglycemia

Hypoglycemia in the PACU can be caused by endogenous insulin secretion or by excessive or inadvertent insulin administration. Serious postoperative hypoglycemia is rare and easily treated with intravenous 50% dextrose followed by glucose infusion. Either sedation or excessive SNS activity masks signs and symptoms of hypoglycemia during recovery.

Hyponatremia

Postoperative hyponatremia occurs if free water is infused intravenously during surgery or if sodium-free irrigating solution is absorbed during transurethral prostatic resection or hysteroscopy. Accumulation of serum glycine or its metabolite, ammonia, might exacerbate symptoms. Free water retention is also caused by inappropriate ADH secretion, prolonged labor induction with oxytocin, or respiratory uptake of nebulized droplets. Theoretically, excessive infusion of isotonic saline leads to excretion of hypertonic urine, desalination, and iatrogenic hyponatremia. Symptoms of moderate hyponatremia include agitation, disorientation, visual disturbances, and nausea, whereas severe hyponatremia causes unconsciousness, impaired airway reflexes, and CNS irritability that progresses to grand mal seizures. Therapy includes intravenous normal saline and intravenous furosemide to promote free water excretion. Infusion of hypertonic saline may be useful for severe hyponatremia. Monitor serum sodium concentration and osmolarity.

Hypokalemia

Postoperative hypokalemia is often inconsequential but might generate serious dysrhythmias, especially in patients taking digoxin. A potassium deficit caused by chronic diuretic therapy, nasogastric suctioning, or vomiting often underlies hypokalemia. Urinary and hemorrhagic losses, dilution, and insulin therapy generate acute hypokalemia that worsens during respiratory alkalemia. Excess SNS activity, infusion of calcium, or beta-mimetic medications exacerbates effects of hypokalemia. Adding potassium to peripheral intravenous fluids often restores serum concentration, but concentrated solutions infused through a central catheter may be necessary.

Hyperkalemia

A high serum potassium raises the suspicion of spurious hyperkalemia from a hemolyzed specimen or from sampling near an intravenous catheter containing potassium or banked blood. Postoperative hyperkalemia occurs after excessive potassium infusion or in patients with renal failure or malignant hyperthermia. Acute acidemia exacerbates hyperkalemia. Succinylcholine

given in the PACU to patients with burns, severe trauma, or chronic neurologic injuries could increase serum potassium. Treatment with intravenous insulin and glucose acutely lowers potassium, whereas intravenous calcium counters myocardial effects. Beta-mimetic medications might also have a role.

Calcium and Magnesium

Although underlying parathyroid disease or massive fluid replacement reduces total body and ionized calcium, symptomatic hypocalcemia seldom occurs in the PACU. A rare patient might exhibit upper airway obstruction from hypocalcemia after parathyroid excision. Reduction of the ionized fraction by acute alkalemia may cause myocardial conduction and contractility abnormalities, decreased vascular tone, or tetany. Transfusion of blood containing chelating agents (e.g., citrate) rarely causes symptomatic hypocalcemia. Administration of calcium chloride or calcium gluconate to hypocalcemic patients improves cardiovascular dynamics.

Magnesium plays a key role in restoration of neuromuscular function after surgery and in maintenance of cardiac rhythm and conduction.

MISCELLANEOUS COMPLICATIONS

Nausea and Vomiting

12 Avoiding PONV is a high priority for physicians and patients,[10] yet PONV remains a significant problem. Aside from unpleasantness for the patient and staff, PONV poses medical risks. Increased intra-abdominal pressure and forceful vomiting

jeopardize abdominal or inguinal suture lines and risks esophageal rupture, whereas elevated CVP increases morbidity after ocular, tympanic, or intracranial procedures. Risk of aspirating gastric contents increases, especially if airway reflexes or ability to expel secretions are impaired. SNS response elevates heart rate and systemic blood pressure, increasing the risk of myocardial ischemia or dysrhythmias. Movement during PONV worsens postoperative pain and accentuates autonomic responses. Gagging and retching might also elicit PNS responses with bradycardia and hypotension. Finally, PONV delays discharge or necessitates admission of ambulatory patients. Assess the degree of PONV periodically throughout recovery.[4]

The incidence of PONV varies with many factors.[7,61,62] Reported incidence is lower in the PACU than over 24 to 48 hours. A high percentage of patients experience postdischarge PONV,[63] and 36% of those do not experience PONV prior to discharge.[16] Delayed emesis may reflect timing of oral intake, waning effects of antiemetics, or greater postdischarge pain. Risk is low in children younger than age 2, increases thereafter until puberty, and then decreases 13% per decade of age. Women have a higher incidence than men. Ear-nose-throat and dental procedures entail a high risk, followed by orthopaedic and cosmetic surgery. The risk of PONV is also high after procedures involving extraocular muscle traction, middle ear manipulation, peritoneal or intestinal irritation, or testicular traction. However, the predictive value of procedure type is questionable.[64] A history of postoperative emesis or motion sickness predicts PONV. Nonsmokers have a significantly higher risk of PONV than smokers.[65]

Perioperative factors such as starvation, autonomic imbalance, pain, and effects of anesthetics on the chemotactic center probably contribute to emergence of PONV. Conditions that affect the gastroesophageal junction (obesity, hiatal hernia) may increase the likelihood of emesis in the PACU. Swallowed blood or secretions promotes PONV, as does gas in the stomach from facemask ventilation, esophageal intubation, or nitrous oxide diffusion. Incidence of PONV is lower after regional than general anesthesia, although this difference narrows when epinephrine or long-acting axial opioids are included, or once parenteral opioids are needed to control postoperative pain.[66] Exclusion of nitrous oxide from an anesthetic appears to reduce the incidence of PONV.[67,68] The incidence of nausea does not differ greatly among inhalation anesthetics, although desflurane and sevoflurane might generate slightly higher rates. Barbiturate induction seems less offensive than etomidate or ketamine, whereas propofol offers a still lower risk. Use of "pure" inhalational

techniques and administration of opioid analgesics increases the incidence PONV, especially after ambulatory surgery. Small doses of shorter-acting opioids might decrease incidence, but short duration of analgesia offsets this advantage. Supplementation with nonopioid analgesics such as ketorolac, acetaminophen, or ibuprofen might reduce the frequency of emesis. It is unclear whether administration of neostigmine or the choice of anticholinergic used to reverse neuromuscular relaxation also increases the incidence.

Several algorithms have been recommended to prevent or treat PONV.[61,64] Evacuation of stomach contents with an orogastric tube is of questionable value. Use of high concentrations of supplemental oxygen and hydration appear to reduce the incidence of PONV, but postoperative drinking is often a triggering event. Need to drink prior to discharge should be determined on a case-by-case basis, so children or high-risk patients can be appropriately discharged before they take oral fluids.[4,68] Whether this decreases incidence of PONV or merely delays onset is unclear. Limiting vestibular stimulation by minimizing brisk head motion seems helpful.

Studies of medications for prophylaxis and treatment of PONV reveal that serotonin blocking agents, dexamethasone, and droperidol are probably equal in efficacy, cost effectiveness, and patient satisfaction.[61,64] Guidelines on postoperative care from the ASA endorse the use of serotonin blocking agents and dexamethasone, and of multiple agents.[4] These antiemetics have different sites of action, so combination therapy might generate better results by simultaneously treating two or more precipitating factors, although their effects appear merely additive rather than synergistic.[64] Prophylaxis should only be used in patients at medium or high risk of emesis, but the unreliability of risk scoring systems mandates use of clinical judgment.

Serotonin receptor blockers are useful in this class for treating PONV, but it is not clear that any particular drug is superior. Optimum intravenous adult dosage of ondansetron, the most widely studied of these drugs, seems to be 4 mg administered near the end of surgery.[69] Serotonin blockers have few side effects and appear to be particularly useful for PONV related to stimulation of gastric enterochromaffin cells. Bothersome headache occurs after intravenous administration, and transient liver enzyme elevation is seen in a small percentage of patients. Serotonin blockers are cost effective if use shortens PACU length of stay, avoids admission, and improves patient satisfaction. However, their cost effectiveness as first-line agents is debatable.

Dexamethasone is a potent agent for PONV prophylaxis, especially during procedures where an inflammation may contribute to postoperative nausea. A dose of 0.05 to 0.1 mg/kg (4 to 8 mg in adults) given intravenously before induction of anesthesia is effective, and offers a low cost and a mild side effect profile. Dexamethasone may be a valuable first-line drug for prophylaxis.

Droperidol decreases the incidence and severity of PONV, although efficacy varies among procedures and patients. A total intravenous dose of 1 to 2 µg/kg (0.625 to 1.25 mg in adults) seems optimal. Droperidol also effectively treats breakthrough nausea after prophylaxis. Although mild sedation might delay discharge slightly, delay from untreated PONV is usually greater. Transient restlessness and rare extrapyramidal side effects are usually inconsequential. The alpha-adrenergic blocking properties of droperidol can precipitate hypotension in hypovolemic patients. Concerns about isolated cases of Q-T interval prolongation and cardiac dysrhythmia have decreased the use of this valuable agent, but the actual risk at doses used for PONV is likely overemphasized. However, the U.S. Food and Drug Administration has issued a "black box warning" relating to Q-T interval prolongation.

Other agents exhibit antiemetic properties. Propofol likely has short-term antiemetic properties and is useful for anesthesia in patients at high risk for PONV, but it does not compare with the three first-line antiemetics. Cimetidine, ranitidine, metoclopramide, dimenhydrinate, and thiethylperazine are relatively ineffective. Intravenous scopolamine causes unacceptable psychogenic reactions, whereas transdermal scopolamine causes postoperative visual disturbances. Efficacy of ephedrine for PONV related to ambulation or motion is unclear. The antiemetic effect of midazolam in children is likely related to the relationship between crying, fear, or agitation and vomiting. P6 acupuncture or acupressure seems a useful adjunct to pharmacologic therapy, especially for cases of refractory nausea.[70,71]

Before treating PONV, serious causes of nausea and emesis such as hypotension, hypoxemia, hypoglycemia, intracranial pressure, or gastric bleeding should be excluded.

Incidental Trauma

Each patient admitted to the PACU should be carefully evaluated for traumatic complications. Discovery of a complication necessitates careful documentation, notification of physicians

responsible for extended care, consultation with specialists, and follow-up.

Ocular Injuries and Visual Changes

Corneal abrasion caused by drying or inadvertent eye contact during facemask ventilation or intubation is a common postoperative eye injury. Corneal abrasion occurs more frequently in elderly patients, after long cases, with lateral or prone positioning, and after head or neck surgery.[72] Corneal injury occurs in the PACU if a rigid oxygen facemask rides up on the eye or if the eye is rubbed with a digital pulse oximeter probe. Abrasion causes tearing, decreased visual acuity, pain, and photophobia. Fluorescein staining aids diagnosis. Abrasion usually heals spontaneously within 72 hours without scarring, but severe injury can cause cataract formation and impair vision. Symptomatic treatment includes artificial tears and eye closure.

Visual acuity is often impaired after anesthesia. Autonomic side effects of medications impair accommodation, and residual ocular lubricant clouds vision. Impairment of retinal perfusion by ocular compression generates postoperative visual disturbances ranging from loss of acuity to permanent blindness.[73,74] Ischemic optic atrophy also occurs in the absence of external compression.[75] Risk is higher after long procedures in the prone position, as well as in patients with vascular disease and anemia. A significant percentage of postoperative patients suffer deficits in acuity unrelated to ocular trauma, some of which require permanent refractive adjustment.[76] Be alert for visual impairment and check acuity when assessing patients at higher risk for ischemic optic atrophy.

Hearing Impairment

Hearing impairment after anesthesia and surgery is relatively common.[77] Although impairment is often subclinical, patients sometimes experience decreased auditory acuity, tinnitus, or roaring. Incidence of detectable hearing impairment is particularly high after dural puncture for spinal anesthesia (8 to 16%), and varies with needle size, needle type, and patient age. Impairment can be unilateral or bilateral and usually resolves spontaneously. Hearing loss also occurs after general anesthesia for both noncardiac and cardiac surgery, and is often related to disruption of the round window or tympanic membrane rupture. Eustachian tube inflammation and otitis secondary to endotracheal intubation can also impact hearing.

Oral, Pharyngeal, and Laryngeal Injuries

Laryngoscope blades, surgical instruments, rigid airways, and dentition can all cause trauma of oral soft tissues. Lip, tongue, or gum abrasions are treated with an ice pack and analgesia. Penetrating injuries caused by tissue entrapment between teeth and rigid devices may require topical antibiotics. After a traumatic tracheal intubation, hematoma or edema might cause partial upper airway obstruction. Nebulized racemic epinephrine often improves stridor. Dental damage can occur during airway manipulations or during emergence if a patient bites on a rigid oral airway or forcefully clenches his or her teeth. Document tooth or dental appliance damage, obtain a dental consultation, and observe for signs of foreign body aspiration.[78]

Sore throat and hoarseness after tracheal intubation occur in 20 to 50% of patients, depending on the degree of trauma during laryngoscopy and oropharyngeal suctioning, the duration of intubation, and the type of tube (see Chapter 22). Mucosal irritation also presents as an unquenchable dryness in mouth and throat. The use of local anesthetic ointments to lubricate endotracheal tubes may cause additional mucosal irritation. Topical viscous lidocaine attenuates

irritation from nasogastric tubes but may increase risk of aspiration during recovery. In children, the severity of postextubation laryngeal edema or tracheitis varies with age, intubation duration, and degree of trauma or tube movement. Most recover with cool mist therapy, but nebulized racemic epinephrine and dexamethasone are also effective. Laryngoscopy and intubation can also cause hypoglossal, lingual, or recurrent laryngeal nerve damage, vocal cord evulsion, desquamation of laryngeal or tracheal mucosa, edema or ulceration, and tracheal perforation. Postoperative sore throat and dysphagia also occurs without intubation, related to use of laryngeal mask airways,[79] oral airways, trauma from suctioning, or drying from unhumidified gases. Neck and jaw soreness are common after facemask anesthetics.

Nerve Injuries

Nerve injuries caused by improper positioning during anesthesia generate serious long-term complications (see Chapter 23).[80] Spinal cord injury can be caused by positioning for intubation or by hematoma accumulation after placement of regional anesthetics. Peripheral nerve compression during general or regional anesthesia sometimes causes permanent sensory and motor deficits, as do stretch injuries from hyperextension of an extremity.[81] Any bruising or skin breakdown noted postoperatively should prompt evaluation for underlying nerve damage. Many postoperative neuropathies have no identifiable cause. This is particularly true for ulnar neuropathy, which may be related to subtle positioning problems, preexisting impairment, or sensitivity of the nerve to ischemia.[82] Every complaint of nonsurgical pain, numbness, or weakness from a postoperative patient should be carefully evaluated.

Postdural puncture headache sometimes first emerges in the PACU. Headache is more frequent after difficult subarachnoid anesthetics with multiple attempts and after dural puncture during attempted epidural placement. Subarachnoid air bubbles from loss-of-resistance testing may contribute. In the PACU, treatment is supportive with hydration, analgesics, and positioning. In severe cases, an early epidural blood patch might be considered. Nerve injury secondary to needle contact or intraneuronal injection during placement of regional anesthesia is rare but does occur.[81,83] In one study, 6.3% of 4,767 patients experienced paresthesia during placement of spinal anesthesia, but only 0.126% had persisting symptoms.[84] In the PACU, patients complain of pain, focal numbness, residual paresthesia, or dysesthesia. Symptoms are usually transient. Administer analgesia, reassure the patient, document findings, and follow for the possibility of an evolving neurologic deficit.

During recovery from spinal anesthesia, some patients exhibit lower-extremity discomfort, buttock pain, and other signs of sacral or lumbar neurologic irritation. This problem is more common in obese patients, after procedures in lithotomy position, and after spinal anesthesia with 5% lidocaine.[83] Symptoms are transient and treated supportively. Rarely, a patient exhibits headache and meningeal signs caused by chemical meningitis after injection of a spinal drug that is contaminated or outside the acceptable pH range.

Soft-Tissue and Joint Injuries

If pressure points are improperly padded during long procedures, soft-tissue ischemia and necrosis occur, especially with lateral or prone positioning. Prolonged scalp pressure causes localized alopecia, whereas entrapment of ears, breasts, genitalia, or skin folds causes inflammation or necrosis. Regional ischemia from major arterial compression is rare. Thermal, electrical, or chemical burns from cautery equipment, preparatory solutions, or adhesives also occur. Extravasation of intravenous medications or fluids can cause sloughing, localized chemical neuropathy, or compartment syndromes. Excessive joint or muscle extension leads to postoperative backache, joint pain, stiffness, and even joint instability.

Skeletal Muscle Pain

Postoperative muscle pain is caused by many intraoperative factors. Prolonged lack of motion or unusual muscle stretch during positioning often contributes to muscle stiffness and aching.

Fasciculation during depolarizing blockade has implicated succinylcholine as a cause of postoperative myalgias. Acute myalgia also occurs after administration of other relaxants and in patients receiving no relaxant. Delayed-onset muscle fatigue can appear days after surgery and resolve spontaneously.

Hypothermia and Shivering

Although intraoperative temperature maintenance is a standard, patients still exhibit postoperative hypothermia. During anesthesia, heat is redistributed and also lost by evaporation during skin preparation, by humidification of dry gases in the airway, and by radiation and convection from the skin and wound. Temperature reduction is accelerated by cold intravenous fluids and low ambient temperatures. The thermoregulatory threshold, below which humans actively regulate body temperature, is decreased during general anesthesia and is less effective under anesthesia. Ability to maintain body temperature is also compromised because paralysis and anesthesia impair shivering and thermoregulatory vasoconstriction, and because nonshivering thermogenesis is ineffective in adults. Rate of heat loss is similar during general or regional anesthesia, but rewarming is slower after regional anesthesia because residual vasodilation and paralysis impede heat generation and retention. Cachectic, traumatized, or burned patients experience greater temperature reduction, as do infants because of a low ratio of body mass-to-surface area.

13 Hypothermia complicates care in the PACU.[85] Average PACU stay is increased by 40 to 90 minutes for hypothermic patients.[86] Postoperative hypothermia increase SNS activity, elevates peripheral vascular resistance, and decreases venous capacitance. Risk of myocardial ischemia[87] and dysrhythmia from mechanical myocardial stimulation is increased. Vasoconstriction interferes with the reliability of pulse oximetry and intra-arterial pressure monitoring. Hypoperfusion jeopardizes marginal tissue grafts, and promotes tissue hypoxia and metabolic acidemia. The alveolar-arterial oxygen gradient increases, and high avidity of hemoglobin compromises oxygen unloading to hypothermic tissues. Platelet sequestration, decreased platelet function, and reduced clotting factor contribute to coagulopathy. Moderate hyperglycemia occurs, cellular immune responses are compromised, and postoperative infection rates increase. A decrease in the minimal alveolar concentration of inhalation anesthetics (5 to 7% per 1°C cooling) accentuates residual sedation. Low perfusion and impaired biotransformation might increase the duration of neuromuscular relaxants and sedatives. Severe hypothermia interferes with cardiac rhythm generation and impulse conduction. On ECG, the PR, QRS, or QT intervals lengthen, and J waves appear. Spontaneous ventricular fibrillation occurs at temperatures <28°C.

During emergence, hypothalamic regulation generates shivering to increase endogenous heat production.[88] Shivering increases the risk of incidental trauma, disrupts medical devices, and interferes with ECG and pulse oximetry monitoring. Oxygen consumption and CO_2 production increase by up to 200%. Associated increases in minute ventilation and cardiac output might precipitate ventilatory failure in patients with limited reserve or myocardial ischemia in those with coronary artery disease.[87] Shivering is accentuated by tremors related to emergence from inhalation anesthesia. Tremors exhibit clonic and tonic components, and likely reflect decreased cortical influence on spinal cord reflexes.

Restoration of normothermia is an important goal during recovery. Forced-air warming devices are most useful for treating hypothermia. For most patients, shivering from mild to moderate hypothermia is uncomfortable but self-limited, and needs no treatment other than rewarming and reassurance. Many medications have been recommended to suppress shivering, but meperidine is most efficacious in conjunction with treatment of hypothermia with rewarming.[4] Other opioid agonists or agonist–antagonists may be useful if meperidine is contraindicated. Withholding reversal of relaxants in ventilated, sedated patients attenuates shivering but increases rewarming time. If temperature is near normal (>96 to 97°F) and shivering is resolved, transfer from PACU to an inpatient floor or a discharge area is acceptable.

Hyperthermia

Hyperthermia is relatively uncommon in the PACU. Occasionally, a patient exhibits short-lived hyperthermia from close draping or aggressive intraoperative heat preservation. Postoperative fever sometimes reflects a preexisting infection (e.g., sinusitis, upper respiratory or urinary tract infection) or an infection exacerbated by the surgical procedure (e.g., resection of infected tonsils or appendix, abscess drainage, urinary tract manipulation). Atelectasis secondary to loss of lung volume, retained secretions, or aspiration is another cause, although fever often appears after PACU discharge. Elevated temperature might indicate a drug or transfusion reaction. Muscarinic blocking agents such as atropine interfere with cooling and might contribute to fever, but they are seldom the cause. Other hypermetabolic states such as thyroid storm must be considered. High fever occurs with malignant hyperthermia, but signs such as tachycardia, muscle rigidity, dysrhythmia, hyperventilation, and acidemia establish the diagnosis first.

Ambient cooling, chest physiotherapy, incentive spirometry, and antipyretics are usually sufficient to treat postoperative fever. Withhold offending medications or blood products if a drug or transfusion reaction is suspected. Notify the physician responsible for extended care to ensure postdischarge evaluation. Therapy for thyroid storm or malignant hyperthermia is well described elsewhere.

Persistent Sedation

Because 90% of patients regain consciousness within 15 minutes of admission to the PACU, unconsciousness persisting for a greater period is considered *prolonged*.[89] Even a highly susceptible patient should respond to a stimulus within 30 to 45 minutes after a reasonably conducted anesthetic. In a patient with prolonged sedation, research the level of preoperative responsiveness to uncover intoxication with drugs and alcohol or preexisting mental dysfunction. Note the time and amount of preoperative and intraoperative sedative medications, and review any unusual intraoperative events. The rate and character of spontaneous ventilation helps judge residual anesthesia depth, whereas the heart rate, rhythm, and blood pressure qualitatively indicate adequacy of cerebral perfusion. Physical assessment should include a tactile stimulus such as a light skin pinch. This elicits greater arousal than verbal stimulation, perhaps because sensory input is amplified through the reticular activating system. Diagnostic value of pupillary size and response is low.

Residual sedation from inhalation anesthetics might cause prolonged unconsciousness, especially after long procedures, in obese patients, or when high concentrations are continued

through the end of surgery. This is less likely after anesthesia with low solubility agents such as sevoflurane or desflurane. Long-acting sedatives used for premedication (e.g., pentobarbital, hydroxyzine, promethazine, droperidol, lorazepam, scopolamine) contribute to postoperative somnolence. Sedation from intraoperative opioid or sedative administration is dose related. To assess sedation from opioids, administer low-dose intravenous naloxone (0.04-mg increments every 2 minutes, up to 0.2 mg). With careful titration, respiratory depression and sedation are reversed without dangerous reversal of analgesia. If unconsciousness is related to residual opioid effects, ventilatory rate and arousal will increase with 0.2 mg or less of intravenous naloxone, unless a patient has received a massive opioid overdose. Flumazenil (0.2 mg intravenously per minute to a total of 1.0 mg), a competitive benzodiazepine antagonist, differentiates sedation from midazolam and diazepam, although duration of action is short. Neither naloxone nor flumazenil should be used as a routine element of postoperative care.[4] Administer reversal only for specific indications in individual patients. Administration of intravenous physostigmine (1.25 mg) counteracts but does not reverse sedation caused by inhalation anesthetics and other sedatives. If administration of naloxone, flumazenil, or physostigmine does not elicit a response, unconsciousness is most likely not related to residual anesthetic medications. However, it is still possible that an unrecognized, preoperative overdose with depressant oral drugs is responsible.

Profound residual neuromuscular paralysis might rarely mimic unconsciousness by precluding any motor response to stimuli. This could occur after gross overdosage, if reversal agents are omitted, in patients with unrecognized neuromuscular disease, or with phase II blockade from succinylcholine use in a patient with pseudocholinesterase deficiency. Observation of purposeful

motion, spontaneous ventilation, or reflex activity eliminates residual paralysis as an explanation. CNS depression secondary to intravenous local anesthetic toxicity or inadvertent subarachnoid injection can mimic postoperative coma. Children who were exhausted before surgery are often difficult to arouse after anesthesia, especially if sleep patterns are disrupted by emergency surgery at night. Hypothermia below 33°C impairs consciousness and increases the depressant effect of medications. Core temperatures below 30°C can cause fixed pupillary dilation, areflexia, and coma. Check a serum glucose level to eliminate severe hypoglycemia or hyperglycemic, hyperosmolar coma as causes. Suspicion that unresponsiveness is caused by hypoglycemia indicates an immediate empiric trial of intravenous 50% dextrose. Hyposmolar states (<260 mOsm/L) such as acute hyponatremia (Na < 125 mEq/L) are ruled out by checking serum electrolyte and osmolarity. Arterial blood gas analysis reveals CO_2 narcosis ($PaCO_2$ > 200 to 250 mm Hg). A patient may also be feigning unresponsiveness or having a hysterical reaction that presents as unconsciousness.

If a diagnosis remains elusive, consult a neurologist for a thorough neurologic evaluation. Occasionally unresponsiveness reflects subclinical grand mal seizures secondary to delirium tremens or an underlying seizure disorder. Cerebral anoxia from intraoperative hypotension, hypoxemia, or CO poisoning must be considered. In injured patients or those recovering from intracranial surgery, evaluate for unrecognized head trauma, intracerebral hemorrhage, or increased intracranial pressure. Patients sometimes awaken very slowly after long intracranial procedures.[90] Cerebral thromboembolism is another possibility in patients who have undergone internal jugular or subclavian cannulation. Patients with atrial fibrillation, carotid bruits, or hypercoagulable states are also at increased risk of thromboembolism. Paradoxical air or fat embolism through a right-to-left intracardiac shunt should be considered. After cardiac, proximal major vascular, or invasive neck surgery, risk of postoperative stroke ranges from 2.2 to 5.2%.[91] Postoperative cerebrovascular accidents in other patients are rare (0.08 to 0.4%) and usually become evident after the PACU interval.

Altered Mental Status

Recovering patients sometimes exhibit inappropriate mental reactions, ranging from lethargy and confusion to physical combativeness and extreme disorientation.

Emergence Reactions

Aside from the disturbance to staff and other patients, a stormy emergence reaction has significant medical consequences. The risk of incidental trauma increases, including contusion or fracture, corneal abrasion, and sprains from struggling. Thrashing jeopardizes suture lines, orthopaedic fixations, vascular grafts, drains, tracheal tubes, and vascular catheters. Agitated patients manifest high levels of SNS tone, tachycardia, and hypertension. Least appreciated is the risk of injury to PACU staff struggling to protect a combative patient.

For a short period after regaining consciousness, some patients appear unable to appropriately process sensory input. Most exhibit somnolence, slight disorientation, and sluggish mental reactions that rapidly clear. Others experience wide emotional swings such as weeping or escalating resistance to positioning and restraint. Predicting which patients will have adverse psychological reactions is difficult. Emergence reactions are prevalent in children and young adults, especially after anesthesia with sevoflurane and desflurane and after ear-nose-throat procedures. In young children, anxiety is heightened by parental separation. Very young children may react inappropriately to sound when hearing acutely improves after myringotomies. Patients with mental retardation, psychiatric disorders, organic brain dysfunction, or hostile preoperative interactions manifest those problems after surgery. Inability to speak secondary to oral fixation or tracheal intubation generates frustration or fear that exaggerates emergence reactions. Ethnic, cultural, and psychological characteristics play some role. A language barrier or a new postoperative hearing impairment accentuates an emergence reaction because input from PACU staff might not be understood. The incidence of stormy emergence is probably higher after procedures with high emotional significance. Recall of intraoperative events can generate severe panic and anxiety during emergence.[92] In patients who abuse alcohol, opioids, cocaine, or other

illicit drugs, intoxication or withdrawal elicits bizarre emergence behavior. Disorientation, paranoia, and combativeness occur after use of scopolamine as a premedication or antiemetic. This can be treated with intravenous physostigmine. Ketamine or droperidol can cause dysphoria and hallucination, although acute reactions are rare. Etomidate contributes to restlessness.

Pain amplifies agitation, confusion, and aggressive behavior during emergence;[93] therefore, it is helpful to ensure adequate postoperative analgesia early in the PACU course. Urinary urgency or gastric distention from trapped gas generates discomfort and agitation, as do tight dressings, painful phlebotomy, and poor positioning. Endotracheal or nasogastric tubes and urinary catheters are equally discomforting. Check for unusual pain sources such as corneal abrasion, entrapment of body parts, infiltrated vascular catheters, or small devices left beneath a patient. Nausea, dizziness, and pruritus are distressing during emergence. Some patients struggle to move from a supine into a more comfortable semisitting or lateral position, especially those with gastroesophageal reflux, pulmonary congestion, or obesity. Emerging patients often resist physical restraint. Residual paralysis elicits agitation or uncoordinated motions that make a patient appear disoriented and combative. Observation of weakness or a peculiar flapping nature of

voluntary motion help in the diagnosis. However, patients can appear fully recovered by head lift and train-of-four monitoring but still perceive impaired swallowing, visual acuity, and sense of strength.[94]

Combativeness, confusion, or disorientation might reflect respiratory dysfunction. Moderate hypoxemia often presents with clouded mentation, disorientation, and agitation resembling that caused by pain. Respiratory acidemia elicits profound agitation, although acidemia caused by ventilatory center depression generates less agitation because higher CNS functions are also depressed. Hypercarbia without acidemia is usually asymptomatic. Limitation of inspiratory volume by chest dressings, gastric distention, or splinting causes a vague dissatisfaction with lung inflation similar to air hunger. This also occurs during mechanical ventilation with low delivered volumes and is probably mediated by stretch receptors in the lung. Inability to generate a forceful cough or clear secretions causes distress, as does high work of breathing. Interstitial pulmonary edema elicits symptoms of air hunger before airway flooding occurs. Agitation can be profound, even with adequate ventilation and oxygenation.

Metabolic abnormalities interfere with lucidity. Lactic acidemia causes anxiety and mild disorientation, acute hyponatremia clouds the sensorium, and hypoglycemia causes first agitation and then diminished responsiveness. Seizure activity might mimic agitation and combativeness. Suspect seizures in patients with epilepsy, head trauma, and chronic alcohol or cocaine abuse. Cerebral hypoperfusion can produce disorientation, agitation, and combativeness. This is a medical emergency that requires aggressive resolution.

There are few interventions that prevent "stormy" emergence reactions.[95] Use of preoperative sedatives in children does not decrease the incidence of emergence delirium, and preoperative suggestion or reassurance seems ineffective. Altered mental status is treated supportively because most emergence reactions disappear within 10 to 15 minutes. Verbal reassurances that surgery is completed and that the patient is doing well are invaluable. Use the patient's and the surgeon's name frequently, and stress the time and location. When practical, allow patients to choose their own position. Provide adequate analgesia. In selected cases, parenteral sedation relieves fear or anxiety and smooths emergence. Identifying whether a patient is reacting to pain or to anxiety is important. Benzodiazepines and barbiturates are ineffective analgesics, whereas opioids are poor sedatives. Do not administer sedative or analgesic medications if altered mental status might reflect a physiologic abnormality such as hypoxemia, hypoglycemia, hypotension, or acidemia. Use restraint only if a patient's safety is jeopardized.

Delirium and Cognitive Decline

14 A high percentage of elderly patients (5 to 50%) experience some degree of postoperative confusion, delirium, or cognitive decline.[96,97] Patients exhibit fluctuations in level of consciousness and orientation, or deterioration of memory, mental functions, and acquisition of

new information. The problem may be related to exacerbation of central cholinergic insufficiency by narcotics, sedatives, or anticholinergics. However, stress of surgery, fever, pain, emesis, sleep deprivation, and loss of routine undoubtedly contribute. Presence of preexisting dementia, cognitive abnormalities, organic brain syndrome, or hearing and visual impairment predicts postoperative delirium, as does evidence of physical infirmity such as high ASA physical status or lack of stress response to surgery. Cognitive dysfunction also occurs at lower incidence (15% greater than control) in younger patients, more frequently resolves within 3 months, and may be related to inactivity during recuperation.[98] Although signs often appear on the first to third postoperative day, onset is sometimes evident in the PACU.

Overall, recovery of cognitive function is slower in the elderly.[99] Because older patients are often skilled at concealing declining capabilities, careful assessment of preoperative capabilities helps identify deficits that affect postoperative status. Postoperative lethargy, clouded sensorium, or delirium sometimes reflect an acute physiologic change. Hyperosmolarity from hyperglycemia or hypernatremia clouds consciousness, as does hyponatremia. Cerebral fluid shifts with decreased mentation occur in patients on dialysis and after rapid correction of severe dehydration. Patients receiving atropine premedication or chronic meperidine therapy might exhibit anticholinergic-induced delirium. Disorientation or clouded sensorium can reflect chronic use of psychogenic drugs, premedication with long-acting sedatives, or unrecognized intoxication. Life-threatening conditions such as seizures, hypoxemia, hypoglycemia, hypotension, acidemia, or cerebrovascular accident sometimes present with confusion, disorientation, inability to vocalize, or reduced level of consciousness, especially if earlier premonitory signs and symptoms are misinterpreted.

Chapter 55

Management of Acute Postoperative Pain

Timothy R. Lubenow

Anthony D. Ivankovich

Robert L. Barkin

KEY POINTS

1	Modulation of pain occurs in the brain, spinal cord, and periphery. There are alterations in the excitability of spinal cord neurons as peripheral firing increases.
2	The neurophysiologic response to pain involves endocrine, respiratory, cardiovascular, gastrointestinal, genitourinary, neurologic components, and other organ system such as the coagulation and immune systems.
3	Thoracic epidural analgesia has been shown to diminish cardiovascular and other thrombotic complications after major surgery.
4	Human peripheral nerves that are chronically inflamed synthesize opioid ligands in the dorsal root ganglia and transport them down the nerve axion to the inflamed tissue. This allows opioids to have a local anesthetic type of effect in the periphery.
5	Continuous epidural infusion of an opioid-local anesthetic mixture minimizes side effects and fosters more efficient titration of analgesia.
6	Polymodal pharmacotherapies are designed in a patient specific manner including decisions focused at renal function, liver function, age, comorbidites social history and CYP450 system.

Acute postoperative pain is a complex physiologic reaction to tissue injury, visceral distention, or disease. It is manifested by of autonomic, psychological, and behavioral responses that result in patient-specific unpleasant, unwanted sensory and subjective emotional experience. Patients often perceive postoperative pain as one of the more ominous aspects of undergoing surgical procedures. In the past, the treatment of postoperative pain was given a low priority by both surgeons and anesthesiologists, and pain was considered a requisite part of the comprehensive postoperative experience.

With the development of an expanding awareness of the epidemiology and pathophysiology of pain, more attention has been focused on the polymodal management of pain in an effort to improve quality of life, augment functionality, enhance activities of daily living, and reduce physiological and emotional morbidity. The natural progression of this focus was the formation of the postoperative analgesia service or acute pain service, involving a multidisciplinary group of clinicians who specialize through training and education in pain management and who apply an ever-increasing array of modalities to attenuate postoperative pain. This chapter reviews the pathophysiology of pain; examines some pharmacologic considerations; and compares the use of oral, parenteral, central neuraxial analgesics, and adjuvant pharmacotherapies. Peripheral nerve blocks that have application for postoperative pain relief and some nonpharmacologic interventions are described. Incorporation of this knowledge into clinical practice is the basis and the rationale for the effective management of acute postoperative pain.

FUNDAMENTAL CONCEPTS

Nociception

Nociception refers to the detection, transduction, and transmission of noxious stimuli. Stimuli generated from thermal, mechanical, or chemical tissue damage may activate nociceptors, which are free nerve endings. Nociceptors can be further classified into exteroceptors, which receive stimuli from skin

surfaces, and interoceptors, which are located in the walls of viscera or deeper body structures. Although nociceptors are free nerve terminals, they are adjacent to small blood vessels and mast cells, with which they operate as a functional unit.[1] In addition to nociceptors, the skin is richly innervated by specialized somatosensory receptors that are sensitive to other forms of stimulation (Table 55-1). Each sensory unit includes an end-organ receptor, accompanying axon, dorsal root ganglion, and axon terminals in the spinal cord. In contrast to other special somatosensory receptors, nociceptors exhibit high response thresholds and persistent discharge to suprathreshold stimuli without rapid adaptation and are associated with small receptive fields and small afferent nerve fiber endings.

TABLE 55-1 Somatosensory Receptors

▪RECEPTOR	▪SENSATION PERCEIVED
Nerve fibers on hair follicles	Touch
Merkel's disks	Touch
Meissner's corpuscles	Touch
Free nerve endings (nociceptors)	Pain
Krause's end bulbs	Cold
Ruffini's endings	Heat
Pacinian corpuscles	Pressure

Golgi-Mazzoni endings	Pressure

Peripheral Nerve Afferent Fibers

Nerve fibers were first described according to their type of covering and the presence or absence of myelination. Neural fibers may be covered with neurolemma or myelin, or both. Speed of conduction is determined by fiber size and the presence or absence of myelination. Small, unmyelinated fibers transmit at slower speed than larger myelinated afferent fibers.

With the invention of the oscilloscope, Erlanger and Gasser[2] were able to describe a more functional classification of peripheral nerve fibers. Nerve fibers were categorized into three classes (A, B, and C), depending on size, degree of myelination, rapidity of conduction, and distribution of fibers. A refinement of this classification is the functional subdivision of the class A fibers into the subtypes of alpha, beta, gamma, and delta.[3]

Class A. These neurons, composed of large myelinated fibers, exhibit a low threshold for activation, conduct impulses at a speed of 5 to 100 m/sec, and measure 1 to 20 µm in diameter. Class A delta fibers mediate pain sensation, whereas class A alpha fibers transmit motor and proprioceptive impulses. Class A beta and gamma fibers are responsible for cutaneous touch and pressure, as well as regulation of muscle spindle reflexes.

Class B. These neurons constitute the medium-size myelinated fibers with a conduction velocity ranging from 3 to 14 m/sec and a diameter less than 3 µm. They have a higher threshold (lower excitability) than class A fibers but a lower threshold than class C fibers. The postganglionic sympathetic and visceral afferents belong to this class.

Class C. These fibers are unmyelinated or thinly myelinated and have conduction velocities in the range of 0.5 to 2 m/sec. This class is composed of preganglionic autonomic fibers and pain fibers. Approximately 50 to 80% of class C fibers modulate nociceptive stimuli.

An additional classification of afferent muscle nerve fibers used by neurophysiologists divides the large myelinated fibers into three functional groups (Ia, Ib, II), placing the thinly myelinated (III) and unmyelinated fibers (IV) into separate groups. The muscle afferents of Erlanger and Gasser's class A alpha fibers are subdivided into two groups, Ia and Ib. Fibers from the annulospiral endings of the muscle spindles compose the Ia group, whereas group Ib fibers emanate from the Golgi tendon organs. Group II consists of the tactile and proprioceptive fibers of classes A beta and gamma, respectively, whereas the primary nociceptive nerve fibers of classes A delta and C are equivalent to groups III and IV, respectively, within this classification.[4]

Spinal Cord and Brain Pathways

The peripheral afferent neuron, termed the *first-order neuron*, has its cell body located in the dorsal root ganglion and sends axonal projections into the dorsal horn and other areas of the spinal cord. At this point, a synapse occurs with a second-order afferent neuron, which can be

categorized depending on the afferent input it receives, as a nociceptive-specific or wide dynamic-range neuron. Nociceptive-specific neurons process afferent impulses only from nociceptive afferent fibers, whereas A beta, A delta, and C fibers communicate with wide dynamic-range neurons. In the dorsal horn, further synaptic connections occur between first-order and regulatory internuncial neurons. First-order neurons also communicate with the cell bodies of the sympathetic nervous system and ventral motor nuclei, either directly or through the internuncial neurons.[5] The cell body of the second-order neuron lies in the dorsal horn, and axonal projections of this neuron cross to the contralateral hemisphere of the spinal cord (Fig. 55-1). This second-order afferent neuron ascends from that level in the lateral spinothalamic tract to synapse in the thalamus. Along the way, this neuron divides and sends axonal branches that synapse in the regions of the reticular formation, nucleus raphe magnus, periaqueductal gray, and other areas in the brainstem. In the thalamus, the second-order neuron synapses with a third-order afferent neuron, which sends axonal projections into the sensory cortex.

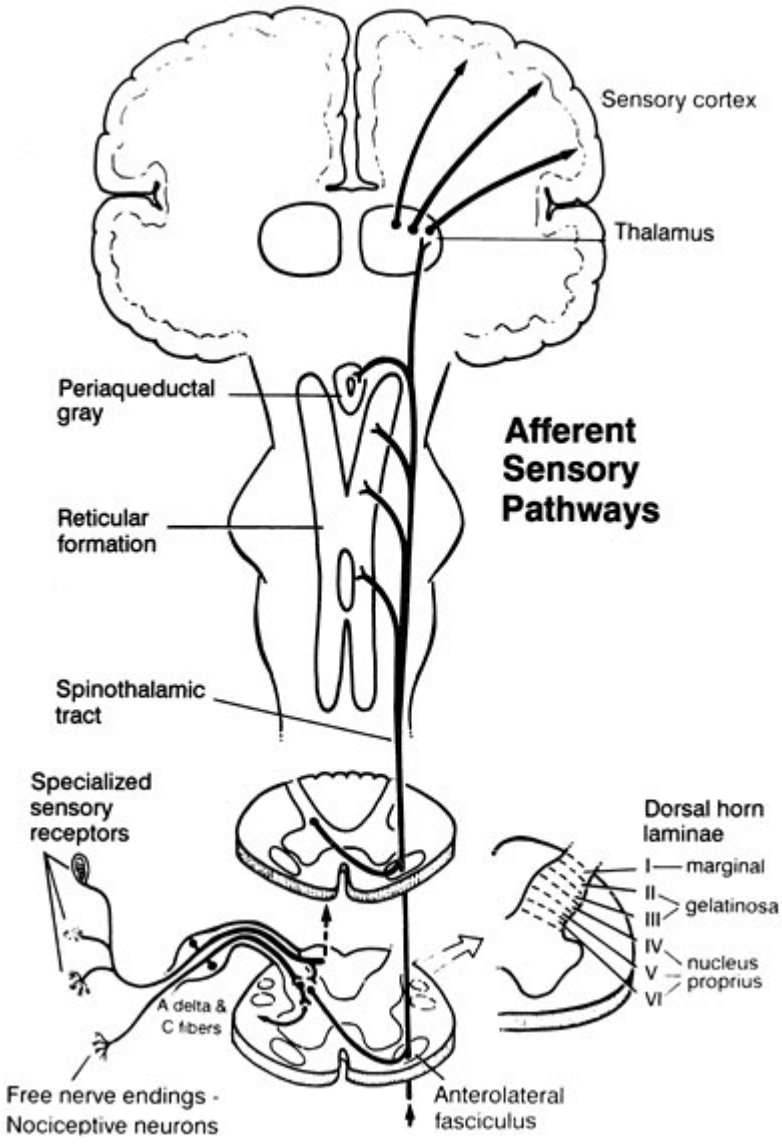

FIGURE 55-1. Afferent sensory pathways for detection and transmission of nociceptive impulses.

Modulation of Nociception

1. Even though nociceptors and the afferent sensory neural pathways detect and transmit noxious stimuli reliably, modulation occurs at several levels in the pathway before perception

of the signal at the cortical levels. Modulation can occur either in the periphery or at any point where synaptic transmission occurs.

Peripheral Modulation

Peripheral modulation occurs either by the liberation or elimination of allogeneic substances in the vicinity of the nociceptor. Tissue injury activates nociceptors in the periphery by causing the release of neurotransmitters such as substance P and glutamate, which directly activate nociceptors. Other allogenic mediators—such as potassium and hydrogen ions, lactic acid, serotonin, bradykinin, histamine, and the prostaglandins—further sensitize and excite nociceptors and act as mediators of inflammation. The sources of these substances include ischemic damaged cells and mast cells in the area of the injury, as well as plasma and platelets in the microcirculation surrounding the nociceptors.[1] Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), and specific cyclooxygenase-2 (COX-2) inhibitors exert an analgesic effect by inhibiting prostaglandin synthesis and reducing prostaglandin E_1-mediated and prostaglandin E_2-mediated sensitization of peripheral nociceptors. Peripheral terminals of nociceptive sensory neurons contain an excitatory ion channel and are sensitive to heat and the compound capsaicin. This calcium channel receptor, known as the vanilloid or TRPV 1 receptor, is involved in pain sensation and hypersensitivity to noxious stimuli following tissue injury and inflammation.[6] There are also tetrodotoxin-insensitive sodium channels, designated $NA_V1.8$ and $NA_V1.9$, in pain sensing neurons. These channels modulate increased pain hyperexcitability following inflammation, and this may contribute to the effectiveness of use-dependent sodium channel blockers (e.g., local anesthetics) in the treatment of pain.[7,8,9]

Spinal Modulation

Modulation in the spinal cord results from the action of neurotransmitter substances in the dorsal horn or from spinal reflexes, which convey efferent impulses back to the peripheral nociceptive field. The excitatory amino acid transmitters L-glutamate and aspartate, and several neuropeptides, including vasoactive intestinal peptide, calcitonin gene-related peptide, and neuropeptide Y, are found in central terminals of the first-order neurons and have been shown to modulate transmission of nociceptive afferent signals.[10] Substance P, which is found in the synaptic vesicle of unmyelinated C fibers, is also an important neuromodulator that can enhance or aggravate pain.[11] Prostaglandins produced in response to inflammation play a role in inflammation-evoked central sensitization of spinal cord neurons.[12] The mechanism by which prostaglandin E2 increases inflammatory pain sensitization in the dorsal horn is by decreasing the activity of the α3 subunit of the glycine receptor.[13]

Inhibitory substances involved in the regulation of afferent impulses in the dorsal horn include GABA, glycine, enkephalins, beta-endorphins, norepinephrine, dopamine, and adenosine.[10] Somatostatin, a neuropeptide found in cells that do not contain substance P, may represent another inhibitory neuropeptide involved in afferent modulation. Acetylcholine is also involved in afferent signal processing. Muscarinic receptors of the M_1 and M_2 subtypes have been identified on the nerve terminals of the first-order neurons in laminae II and III of the spinal cord.[14] Cell bodies staining for choline acetyltransferase have been found in laminae III, IV, and V,[15] with dendritic projections into laminae I, II, and III, sites that are primarily involved in processing of nociceptive impulses.[16] Cholinergic agonists have been demonstrated to produce analgesia,[17] as has neostigmine, which inhibits the breakdown of the endogenous neurotransmitter acetylcholine.[18] Acetylcholine acts at muscarinic (M_1 or M_3) receptors that appear to mediate spinal antinociception.[19] The analgesic efficacy of modulating the cholinergic system depends on the tonic release of acetylcholine at muscarinic receptors involved in afferent signal processing because acetylcholine has actions at other spinal sites (inhibition of motor neuron activity, excitation of sympathetic outflow) that produce unwanted side effects.[18]

Afferent modulating mechanisms at the spinal level may also involve spinal reflexes in which afferent signals directly evoke somatic or sympathetic efferent impulses. These impulses discharge in the area of the efferent nociceptive signal. For example, skeletal muscle spasm in an injured area is part of a somatic efferent reflex that is induced as a result of nociceptive afferent signals.

Increased skeletal muscle tone initiates more nociceptive signals in a positive feedback loop system from the muscles (Fig. 55-2). In addition, spinal reflexes may involve the discharge of efferent sympathetic signals evoked from the nociceptive impulse (see Fig. 55-2). Efferent sympathetic signals emanate from cell bodies located in the intermediolateral column of the spinal cord. These cell bodies receive internuncial projections from the dorsal horn of the gray matter. This sympathetic reflex produces smooth muscle spasm, vasoconstriction, and liberation of norepinephrine in the vicinity of the wound, thereby generating more pain. Release of norepinephrine has been shown to produce or augment pain after injury.

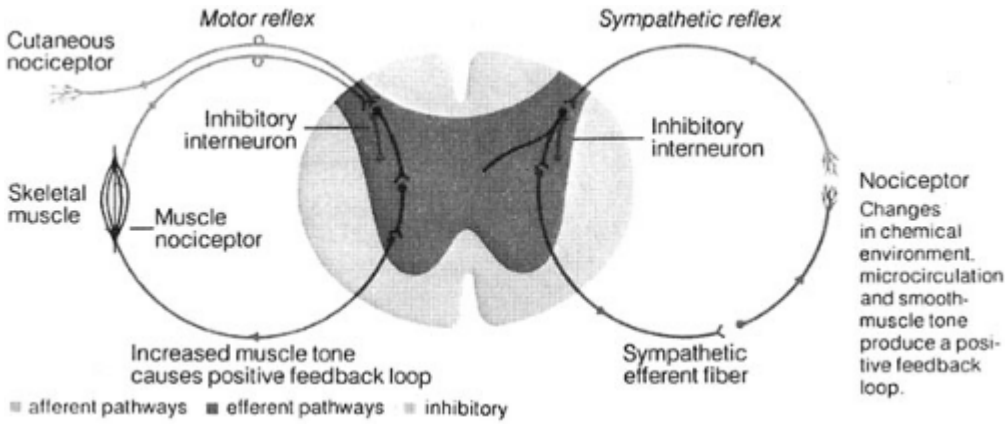

FIGURE 55-2. Schematic representation of spinal reflexes involved in pain modulation. (Reprinted with permission from Bonica JJ, Liebeskind JC, Albe-Fessard DG [eds]: Advances in Pain Research and Therapy, p 3. New York, Raven Press, 1979.)

Neuroplasticity: The Dynamic Modulation of Neural Impulses. The preceding description of the neurophysiology of afferent signal transmission and processing is based on the

concept that neural connections involve isolated, unaltered transmission of a single impulse or group of impulses between neurons. Using this model, modulation of noxious afferent signals could be described by gating mechanisms, which formed the initial basis for therapeutic analgesic interventions. Subsequently, however, the description of neural activity-dependent plasticity has enhanced our understanding of the dynamic nature of the nociceptive response to injury. As peripheral nociceptors are sensitized by local tissue mediators of injury (potassium, prostaglandins, and bradykinins), the excitability and frequency of neural discharge increase. This primary hyperalgesia permits previously subnoxious stimuli to generate action potentials and be transduced orthodromically in the spinal cord (Fig. 55-3). The facilitation of impulse transduction in the first-order neuron is partially mediated by noxious substances released from damaged tissues. In addition, axonal reflexes exaggerate this response by releasing substance P. This produces vasodilation and mast cell degranulation, liberating histamine and serotonin, as well as effectively enlarging the peripheral receptive field to include adjacent noninjured tissue, resulting in secondary hyperalgesia.[20]

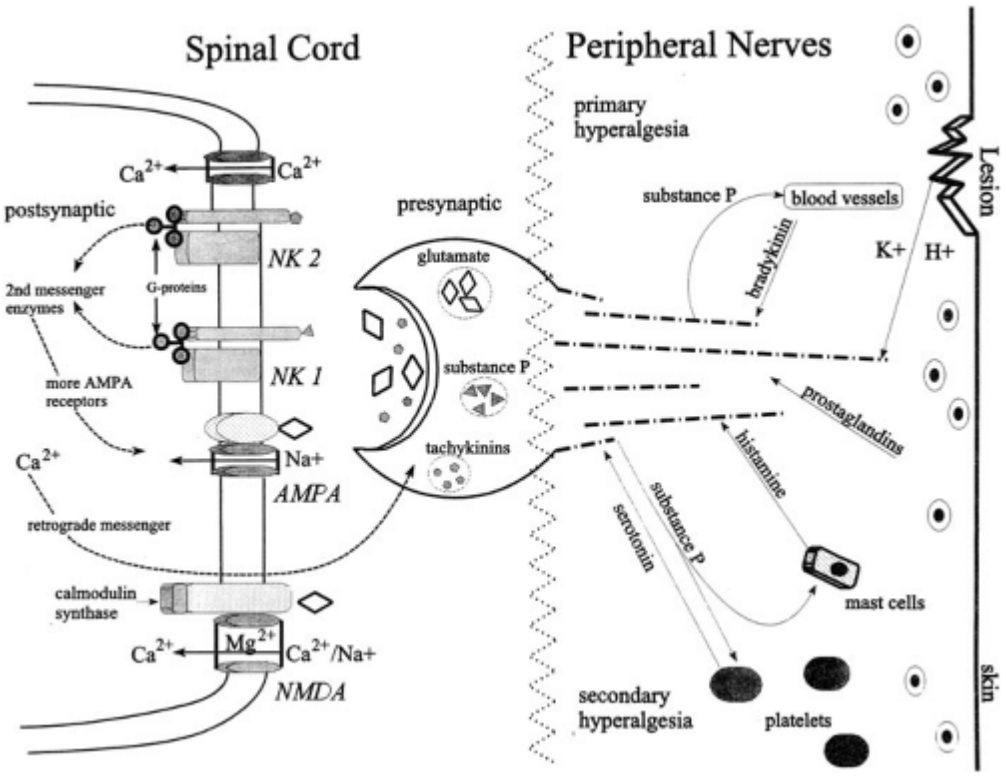

FIGURE 55-3. Schematic representation of peripheral and spinal mechanism involved in neuroplasticity. Primary hyperalgesia results from tissue release of toxic substances. These toxic substances spread to adjacent tissues, prolonging the hyperalgesic state (secondary hyperalgesia). As C fiber terminals increase in frequency of release of neurotransmitters, such as glutamate, substance P, tachykinins, brain-derived neurotrophic factor, and calcitonin gene-related peptide, the effects of these neurotransmitters are summated, resulting in prolonged depolarizations of second-order neurons ("windup"). Function changes at the second-order neuron occur as a result of neurotransmitter binding to postsynaptic receptors, which results in activity-dependent plasticity of the spinal cord. See text for details. AMPA, *a*-amino-3 hydroxy-5-methyl-4-isoxazole propionic acid; NK, neurokinin; NMDA, N-methyl-D-aspartate.

The increased frequency of impulse transmission to the dorsal horn reduces the gradient between the resting and the critical threshold potential of second-order neurons in the spinal cord. As peripheral nerve firing increases, other changes also occur in the excitability of spinal cord neurons, altering their response to afferent impulses. This central sensitization to afferent impulses results from a functional change in spinal cord processing, termed *neuroplasticity* (see Fig. 55-3). The temporal summation of the number and duration of action potentials elicited per stimulus that occurs in dorsal horn neurons (or in the motor neurons of the ventral horn) has been referred to as the *windup phenomenon.*[21] In general, the windup phenomenon requires a minimum stimulus frequency of 0.5 Hz, arising from C fibers. Once the stimulus frequency reaches a critical threshold, the postsynaptic depolarizing responses of these second-order afferent neurons summate to produce bursts of action potential discharges instead of a single action potential. The windup phenomenon results in a persistence of action potentials for up to 60 seconds after the discontinuance of the stimulus, and results in a change in spinal cord processing that can last for 1 to 3 hours.[22] As this process repeats, more permanent changes in these second-order neurons occur and have been termed *long-term potentiation.*

The cellular mechanisms of spinal cord sensitization involve the relatively slow-onset and long-duration synaptic potentials elicited by A delta and C fibers in dorsal horn neurons.[16] These potentials persist up to 20 seconds (approximately 2,000 times longer than the fast potentials of A

beta fibers). These slow potentials are mediated via release by the afferent axon of the

excitatory neurotransmitter glutamate, and the neuropeptides substance P and neurokinin A[21,23] (see Fig. 55-3). As peripheral afferent nerve activity increases, progressively more and longer-lasting second-order neuron depolarizations occur because of the accumulation of these excitatory neurotransmitters and summation of these slow potentials. The net result is that a few seconds of C fiber activity can result in several minutes of postsynaptic depolarization.

Spinal cord synaptic plasticity involves the binding of glutamate to the N-methyl-D-aspartate (NMDA) receptor, as well as binding of substance P and neurokinins to tachykinin receptors.[21,24] High-frequency presynaptic activity causes release of glutamate and tachykinins from presynaptic vesicles. Binding of glutamate to NMDA receptors alters a magnesium-dependent block of ion channels, subsequently increasing cellular permeability to all cations, especially calcium and sodium. Glutamate also activates the *a*-amino-3 hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) and metabotropic receptors on the postsynaptic cell. AMPA receptors control depolarization primarily through modulation of sodium influx into the cell. Neurokinins and substance P, through G protein-linked receptors, increase enzymatic activity, resulting in augmented depolarization and increases in stores of secondary neurotransmitters. Calcitonin gene-related peptide (CGRP) acting through CGRP receptors is involved in central sensitization and mechanical hyperalgesia, although the second-messenger systems have not been clearly identified.[25] Brain-derived neurotrophic factor is released by primary sensory neurons, and its activation of the TrkB receptor mediates postsynaptic excitability.[26,27] In aggregate, stimulation of these receptor groups enhances the excitability of the second-order neuron (see Fig. 55-3).

In addition to modulating augmented excitability, these transmitter and cellular mechanisms mediate changes in the postsynaptic cell, leading to more permanent changes in nerve conduction or long-term potentiation.[22] Extracellular calcium influx enhances release of intracellular calcium stores, initiating a series of intracellular events that include calcium-dependent enzymatic reactions mediated by protein kinase C, calcium-calmodulin, and cyclic adenosine monophosphate-dependent protein kinase A. These enzymes phosphorylate membrane proteins, namely, receptors and ion channels on the postsynaptic cell, which further increases excitability. AMPA receptor density increases on the postsynaptic cell membrane, and a retrograde factor is released that diffuses back to the presynaptic cell, augmenting neurotransmitter release in response to a given presynaptic action potential. Finally, changes in second messengers also activate immediate early gene products, transcription factors that can alter the expression of particular genes, which in turn can result in more persistent changes in neural processing.

Although much of the preceding discussion of altered spinal cord processing in response to nociceptive input has been derived from the study of chronic pain, similar changes in spinal cord processing occur even after a minor surgical incision.[28] These changes result in an increase in primary hyperalgesic response to noxious stimulus that persists for many days in the area of the incision and secondary hyperalgesia of shorter duration in surrounding tissues.[29]

Supraspinal Modulation

Brainstem. Descending inhibitory tracts at the brainstem level originate from cell bodies located in the region of the periaqueductal gray, reticular formation, and nucleus raphe magnus. These inhibitory tracts descend into the dorsolateral fasciculus and synapse in the dorsal horn. Neurotransmitters act presynaptically on the first-order neuron and postsynaptically on the second-order neuron of the spinothalamic tract or on the internuncial neuron pool. Internuncial neurons can be inhibitory and can regulate synaptic transmission between primary and secondary afferent neurons in the dorsal horn. At least two groups of nerve fibers have been identified as participants in this inhibitory modulation. One group of fibers involves the opioid system and contains the neurotransmitters beta-endorphin and the enkephalins, as well as other neuropeptides. Analgesia is produced during electrical stimulation of the periaqueductal gray, and this effect is blocked by naloxone.[30] These opioid projections from the nucleus raphe magnus and reticular formation interface presynaptically with the first-order afferent neurons. Neurotransmitters released from these projections hyperpolarize class A delta and C fibers, which

serve to negate or shunt out the depolarizing current that approaches the terminal end plate, thereby diminishing the release of neurotransmitters such as substance P[31] (Fig. 55-4). In addition to this presynaptic modulation, exogenously applied opioids inhibit L-glutamate–evoked discharge of dorsal horn neurons, suggesting that opioids exert a direct postsynaptic effect.[32] In summary, opioids modulate transmission of afferent impulses in the dorsal horn presynaptically at the level of the first-order neuron. The enkephalinergic transmitter that is released from the descending inhibitory pathways hyperpolarizes the afferent terminals to block neurotransmitter release. Opioids also exert a direct inhibitory effect on the postsynaptic membrane potential (see Fig. 55-4).

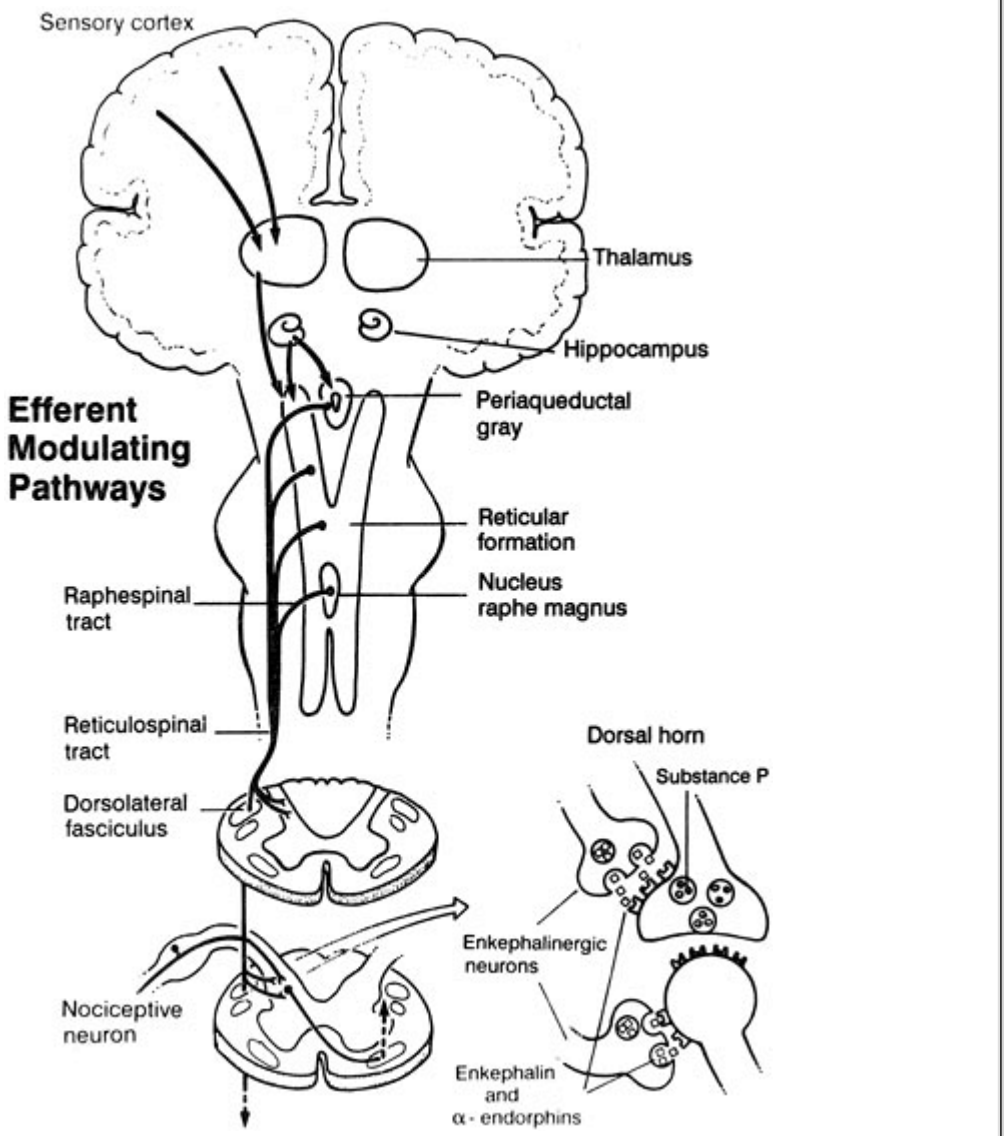

FIGURE 55-4. Efferent pathways involved in nociceptive regulation.

In addition to the opioid descending inhibitory pathway, a monoamine pathway also originates from locations in the periaqueductal gray and reticular formation. Stimulation of these pathways inhibits synaptic transmission in the dorsal

horn, similar to the inhibiton produced by the opioid system. Electrical stimulation of these pathways and intracerebral injections of α_2-adrenergic agonists can inhibit spinal nociceptive reflexes, and this effect can be antagonized by intrathecally administered α_2-adrenergic antagonists.[33] Further evidence of a monoamine pathway stems from the observation that the intrathecal administration of α_2-adrenergic agonists produces analgesia, implying that α_2 adrenoreceptors are responsible for this antinociceptive effect.[34] These fibers descend into the

dorsolateral fasciculus, in a manner similar to that of the opioid fibers, and synapse in the substantia gelatinosa region of the dorsal horn. Norepinephrine is released from these nerve terminals and produces hyperpolarization of the first-order neurons, internuncial neurons, and wide dynamic-range neurons in the spinothalamic tract. In addition, there are α_2-adrenoreceptor projections into the ventral gray matter area of the motor nuclei.

The opioid and the α_2 receptors share a common mechanism of action. At the cellular level, these receptors belong to a family of receptors that are coupled to a G protein[35] (Fig. 55-5). The G protein exerts its membrane function through a secondary messenger protein capable of converting guanosine triphosphate to guanosine diphosphate. When the receptor is occupied, the α subunit of the G protein releases from the β and γ subunits and modulates cellular functions, such as ion exchange, adenyl cyclase, and phospholipase C activity. Hyperpolarization of the nerve results in decreased transmission of the action potential and decreased release of stored neurotransmitter. Hyperpolarization of the nerve most likely occurs because of the opening of potassium channels and the inhibition of calcium movement.[35,36]

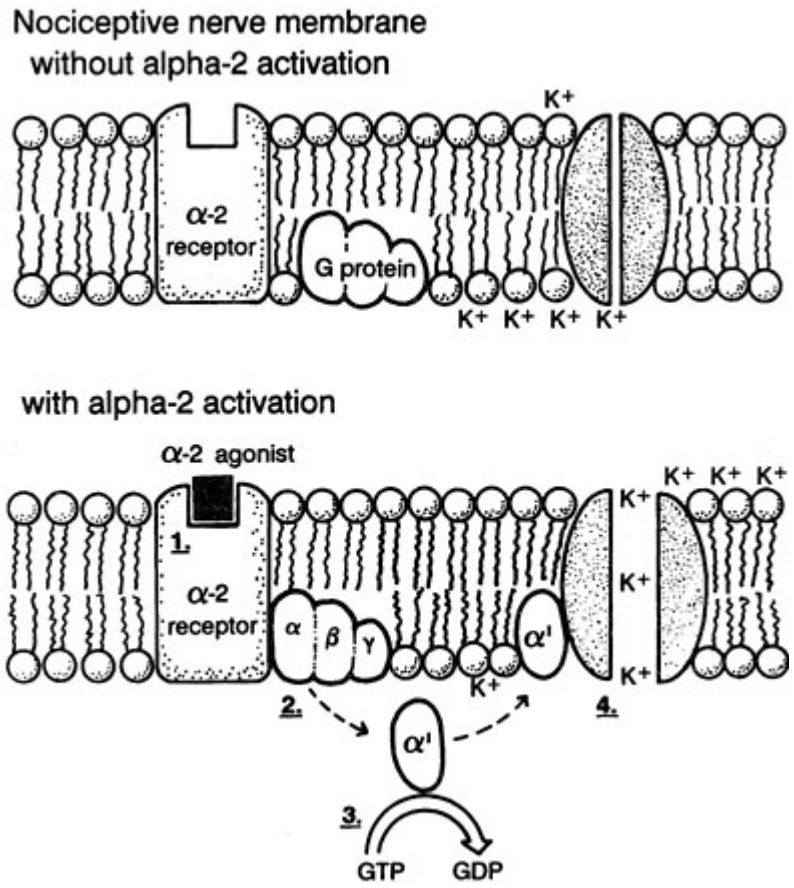

FIGURE 55-5. Schematic representation of cellular mechanisms of G-protein–linked receptor, depicted as an α_2-adrenergic receptor. Binding of agonist at receptor causes conformational change in G protein, allowing for cleavage of α subunit. Activation of α subunit occurs by hydrolysis of guanosine triphosphate (GTP) to active state α', which is capable of increasing K^+ movement and resulting in membrane hyperpolarization. GDP, guanosine diphosphate. (Adapted with permission from Maze M: Alpha-2 adrenoreceptor agonists: Defining the role in clinical anesthesia. Anesthesiology 74:581, 1991.)

Higher Central Nervous System. A basic review of the dimensions of perceptual psychology is required to understand the role of higher cortical function. Perception is the phenomenon by which noxious stimuli reach consciousness. Input from the cerebral cortex is necessary to provide interpretation and to give meaning to the stimuli. Perception can be subdivided into two categories: cognition and attention. Cognitive functions are those abilities that recognize,

discriminate, memorize, or judge afferent information that stems from external stimuli. Therefore, cognitive modulation of pain involves the patient's ability to relate a painful experience to another event. For example, pain experienced in a pleasant environment elicits a less intense response than pain experienced in a setting of depression. The other area of perception is attention. Attention operates on the premise that only a fixed number of afferent stimuli can reach cortical centers. If a patient in pain concentrates on a separate and unrelated image, it is possible to reduce the effect of a painful sensation. The positive impact on pain from biofeedback or hypnosis operates on this principle.

PATHOPHYSIOLOGY OF PAIN

Components of the Surgical Stress Response

2 It has been well established that surgical patients receiving routine, intermittent, on-demand opioid analgesics remain in moderate to severe pain. Provision of effective postoperative analgesia is important not only for humanitarian reasons, but also because of the deleterious effects of postoperative pain on specific organ systems and the negative impact on postoperative recovery (Table 55-2).

TABLE 55-2 Adverse Physiologic Sequelae Of Pain

·ORGAN SYSTEM	·CLINICAL EFFECT
·RESPIRATORY	
Increased skeletal muscle tension	Hypoxemia
Decreased total lung compliance	Hypercapnia
	Ventilation-perfusion abnormality
	Atelectasis
	Pneumonitis
·ENDOCRINE	
Increased adrenocorticotropic hormone	Protein catabolism
Increased cortisol	Lipolysis
Increased glucagon	Hyperglycemia
Increased epinephrine	

Decreased insulin	
Decreased testosterone	Decreased protein anabolism
Increased aldosterone	Salt and water retention
Increased antidiuretic hormone	
Increased cortisol	Congestive heart failure
Increased catecholamines	Vasoconstriction
Increased angiotensin II	Increased myocardial contractility
	Increased heart rate
·CARDIOVASCULAR	
Increased myocardial work(mediated by catecholamines, angiotensin II)	Dysrhythmias
	Angina
	Myocardial infarction
	Congestive heart failure
·IMMUNOLOGIC	
Lymphopenia	Decreased immune function
Depression of reticuloendothelial system	
Leukocytosis	
Reduced killer T-cell cytotoxicity	
·COAGULATION EFFECTS	

Increased platelet adhesiveness	Increased incidence of thromboembolic
Diminished fibrinolysis	phenomena
Activation of coagulation cascade	
·GASTROINTESTINAL	
Increased sphincter tone	Ileus
Decreased smooth muscle tone	
·GENITOURINARY	
Increased sphincter tone	
Decreased smooth muscle tone	Urinary retention

Neuroendocrine

Surgical stress and pain elicit a consistent and well-defined metabolic response, involving release of neuroendocrine hormones and cytokines, which leads to a myriad of detrimental effects.[33] In addition to the rise in catabolically active hormones such as catecholamines, cortisol, angiotensin II, and antidiuretic hormone, stress causes an increase in adrenocorticotropic hormone, growth hormone, and glucagon.[38] The stress response results in lower levels of anabolic hormones, such as testosterone and insulin. Epinephrine, cortisol, and glucagon produce hyperglycemia by promoting insulin resistance and gluconeogenesis. They induce protein catabolism and lipolysis to provide substrates for gluconeogenesis. The stress response causes a negative postoperative nitrogen balance. Aldosterone, cortisol, and antidiuretic hormone influence water and electrolyte reabsorption by promoting Na^+ and water retention, while expending potassium. This contributes to increases in the extravascular fluid compartment both peripherally and within pulmonary parenchymal tissue. Local release of cytokines such as interleukin-2, interleukin-6, and tumor necrosis factor may contribute to abnormal physiologic responses such as alterations in heart rate, temperature, blood pressure, and ventilation.[39] Finally, catecholamines sensitize peripheral nociceptive endings, which serve to propagate more intense pain and may contribute to a vicious pain–catecholamine release–pain cycle.[40] The magnitude of these neuroendocrine and cytokine responses is related to the severity of tissue injury and correlates with outcome after injury.[41,42]

Cardiovascular

The cardiovascular effects of pain are initiated by the release of catecholamines from sympathetic nerve endings and the adrenal medulla, of aldosterone and cortisol from the adrenal cortex, and of antidiuretic hormone from the hypothalamus,

as well as by activation of the renin-angiotensin system. These hormones have direct effects on the myocardium and vasculature, and they augment salt and water retention, which places a

greater burden on the cardiovascular system.

Angiotensin II causes generalized vasoconstriction, whereas catecholamines increase heart rate, myocardial contractility, and systemic vascular resistance. The sympathoadrenal release of catecholamines and the effects of angiotensin II may result in hypertension, tachycardia, and dysrhythmias and may lead to myocardial ischemia in susceptible patients as a consequence of increased oxygen demand. In addition, a significant proportion of perioperative myocardial ischemia is related to reductions in myocardial oxygen supply without hemodynamic aberrations. Activation of the sympathetic nervous system may trigger coronary vasoconstriction, which may result in myocardial ischemia in the presence of atherosclerotic coronary artery disease. This may occur through direct activation of cardiac sympathetic nerves,[43] as well as through circulating catecholamines that may contribute to hypercoagulability, a known mediator of adverse outcome in patients with ischemic heart disease. Salt and water retention secondary to aldosterone, cortisol, and antidiuretic hormone, in combination with the previously described effects of catecholamines and angiotensin II, can also precipitate congestive heart failure in patients with limited cardiac reserve.

Respiratory

Increases in extracellular lung water may contribute to ventilation-perfusion abnormalities. For surgical procedures performed on the thorax and abdomen, pain-induced reflex increases in skeletal muscle tension may lead to decreased total lung compliance, splinting, and hypoventilation. These changes promote atelectasis, contribute to further ventilation-perfusion abnormalities, and result in hypoxemia. In major surgical procedures or in high-risk patients, these respiratory effects of pain may lead to a significant reduction in functional residual capacity ranging from 25 to 50% of preoperative values.[44] Hypoxemia stimulates increases in minute ventilation. Although tachypnea and hypocapnia are common initially, prolonged increases in the work of breathing may result in hypercapnic respiratory failure. Pulmonary consolidation and pneumonitis may occur because of hypoventilation and further aggravate the clinical scenario. These sequelae are especially significant in patients with preexisting pulmonary disease, upper abdominal and thoracic incisions,[45] advanced age, or obesity.[44]

Gastrointestinal

Pain-induced sympathetic hyperactivity may cause reflex inhibition of gastrointestinal function.[46] This promotes postoperative ileus, which contributes to postoperative nausea, vomiting, and discomfort, and delays resumption of an enteral diet. Failure to resume early enteral feeding may be associated with postoperative morbidity, including septic complications and abnormal wound healing.[47]

Genitourinary

An increase in sympathetic activity responses to pain causes reflex inhibition of most visceral smooth muscle, including urinary bladder tone. This can result in urinary retention with subsequent urinary tract infections and related complications.

Immunologic

The pain-related stress response suppresses both cellular and humoral immune function[48,49] and results in lymphopenia, leukocytosis, and depression of the reticuloendothelial system. In addition, some anesthetic agents reduce chemotaxis of neutrophils and may be one factor involved in the reduction of monocyte activity. Many known mediators of the stress response are potent immunosuppressants, and both cortisol and epinephrine infusions decrease neutrophil chemotaxis.[50] These effects can lower resistance to pathogens and may be key factors in the development of perioperative infectious complications.[51] When surgical manipulation of neoplasms causes release of tumor cells, the postoperative stress response may reduce the cytotoxicity of killer T cells. Increases

in catecholamines, glucocorticoids, and prostaglandins in response to stress may impair immunologic responses important for patients with neoplasms.[52]

Coagulation

Stress-related alterations in blood viscosity, platelet function, fibrinolysis, and coagulation pathways have been described.[53,54,55,56] These stress-mediated effects include increased platelet adhesiveness, diminished fibrinolysis, and promotion of a hypercoagulable state. When these effects are coupled with the microcirculatory effects of catecholamines and immobilization of the patient in the postoperative period, thromboembolic events are more likely to occur.

General Well-Being

Pain increases skeletal muscle tone in the area of the surgical field. This postoperative impairment of muscle function may lead to physical immobility and a delayed return to normal function. Poorly controlled pain also contributes to insomnia, anxiety, and a feeling of helplessness. These psychological factors, coupled with the immobilization that occurs because of the increased skeletal muscle tone, create a postoperative scenario feared by many patients.

Attenuation of Central Sensitization and the Stress Response

As discussed earlier, acute tissue injury results in peripheral and central neural sensitization. It is also evident that acute nociceptive stimulation can result in neuroplastic responses that compound the intensity of pain perception in concert with other deleterious systemic effects, including those modulated as part of the stress response. Because most of these events are not manifest until after surgery, most efforts to attenuate the cascade of events precipitated by intraoperative trauma have focused on the postoperative period. These efforts are well founded because of the need to interrupt and limit central sensitization propagated by ongoing tissue injury. However, perioperative anesthetic and analgesic strategies must also consider the temporal relation of nociceptive stimulation to the initiation of central sensitization. The ideal perioperative intervention should focus on preventive, rather than primarily therapeutic measures to control the adverse sequelae of central sensitization and the stress response. Our current understanding of the pathophysiologic consequences of tissue injury has therefore prompted the application of preoperative and intraoperative techniques that prevent or minimize this postinjury hypersensitivity, and has fostered the concept of preemptive analgesia.

The relative importance of preemptive analgesia in preventing adverse sequelae depends on several factors, including preoperative patient status, as well as the magnitude and site of the surgical intervention. It is widely believed that preemptive analgesia has a greater impact in patients with impaired physiologic reserve than in healthier patients who can better tolerate the perturbations induced by surgery. Minor, peripheral surgical procedures performed with the use of local anesthesia usually produce minimal systemic or central neuraxial changes. The more extensive the surgical procedure, the greater the magnitude of the neuroendocrine stress response. Procedures associated with greater degrees of surgical trauma may also contribute to greater central sensitization than less invasive procedures.

From the previous discussion, it is apparent that postoperative physiologic changes are not homeostatic mechanisms but are reproducible adverse responses to tissue injury that result in a myriad of adverse physiologic events that likely modulate perioperative outcome. Research efforts have therefore been focused on the effectiveness of various anesthetic and analgesic strategies targeted to modify the adverse neural and systemic derangements commonly observed after surgery.

Influence of Anesthesia on the Surgical Stress Response and Outcome

General Anesthesia

It has been demonstrated that general anesthesia, either with intravenous or inhalational anesthetics, does not effectively attenuate the neuroendocrine stress response.[57] One exception to this assertion is the administration of high-dose opioid anesthesia. Extremely high doses of certain opioids can inhibit some aspects of the stress response, but lower doses of opioids usually are unable to hinder the neuroendocrine effects of stress.[58,59] The effect of opioids on immune function is controversial because both immune-suppressing and immune-enhancing effects have been described.[60] High doses of inhalational agents (1.5 times minimum alveolar concentration) may suppress the intraoperative catecholamine response but do not diminish the catecholamine response that develops after surgery.

Regional Anesthesia and Analgesia

Mitigation of nociception at the peripheral and central level may be accomplished through a variety of techniques. A regional anesthetic or analgesic modality is ideally suited to produce this desired effect because it diminishes the intensity of afferent impulses reaching the spinal cord. Regional anesthesia and analgesia have been shown to reduce catecholamine and other stress hormone responses during the perioperative period for certain surgical procedures.[38,55,61] The finding that regional anesthesia and analgesia can ablate the neuroendocrine stress responses is not universal. Some studies have demonstrated that central neuraxial techniques have no significant influence on cortisol release. The differing results may be related to the level of the afferent neural blockade. Another confounding variable is the region of the body where the surgical procedure was performed. In studies where regional anesthesia did not have an influence on the cortisol response, surgery was performed in the upper abdomen, whereas in most studies that demonstrate inhibition, surgery was performed on a lower extremity or the lower abdomen. Sensory blocks below L1 usually have no effect on cortisol response. To prevent a cortisol response to surgery, all afferent pathways from the surgical site must be blocked.[62]

Besides reducing the neuroendocrine stress response, regional anesthesia can reduce myocardial work and oxygen consumption by reducing heart rate, arterial pressure, and left ventricular contractility. Left ventricular ejection fraction is not significantly affected by epidural anesthesia in normal patients, whereas patients with chronic stable angina experience a modest but significant improvement in left ventricular ejection fraction and left ventricular wall motion, provided that volume loading is limited.[63] In patients with unstable angina that is refractory to treatment with nitrates, beta-blockers, and Ca^{2+} antagonists, thoracic epidural analgesia alleviates chest pain without changing coronary perfusion pressure, cardiac output, or systemic vascular resistance.[64] Studies evaluating regional myocardial blood flow distribution in intact animals indicate that epidurally administered local anesthetics can improve endocardial-to-epicardial blood flow ratios, shifting blood flow to the area of myocardium at greatest risk of ischemia and infarction.[65] A reduction in infarct size in experimental models of acute coronary occlusion has also been demonstrated.[65]

Administration of epidural local anesthetics or opioids in the postoperative period can reduce the incidence of

myocardial ischemia and dysrhythmias compared with systemic opioids.[66,67] Beneficial effects of epidural anesthesia and analgesia on cardiac outcomes have been demonstrated only in high-risk populations undergoing major operations, perhaps because such patients experience a high incidence of complications which may show allowing differences to be detected in relatively small samples. Epidural anesthesia and analgesia was associated with both statistically and clinically significant reductions in serious cardiovascular morbidity when compared with general anesthesia with on-demand opioid analgesia alone in a population of patients undergoing major intrathoracic, intra-abdominal, or vascular surgery,[68] as well as in a series of patients undergoing major peripheral vascular surgery (approximately 45% of operations involving the abdominal aorta).[53] Another study in abdominal aortic reconstructive surgery comparing general anesthesia with combined epidural anesthesia and general anesthesia found no differences in cardiovascular or other outcomes, although postoperative analgesia techniques were not controlled or randomized.[69] In aggregate, these findings are consistent with the hypothesis that outcome improvement

requires that intraoperative initiation of central neuraxial blockade be accompanied by postoperative continuation of this modality. Other studies investigating lower-risk patient populations,[70] or less invasive surgical procedures (infrainguinal revascularizations)[71] with a lesser magnitude of surgical insult, had lower incidences of cardiac morbidity and could not demonstrate significant effects on cardiac morbidity, despite other beneficial effects of epidural anesthesia and analgesia. Therefore, the benefits of epidural analgesia on cardiac morbidity remain controversial, and formation of definitive conclusions has been hindered by the absence of studies with sufficient numbers of patients and the multifactorial causation of cardiac morbidity, which mandates a tightly controlled study design. Most studies with negative results have not consistently continued the intraoperative epidural technique for postoperative analgesia.

3 The beneficial effects of epidural anesthesia and analgesia on some aspects of cardiovascular outcome may be intimately related to modulation of the hypercoagulable state that occurs and persists after major surgical trauma, especially in patients with atherosclerotic vascular disease and others with a predisposition to hypercoagulability.[72] General anesthesia with parenteral opioid analgesia has little effect on postoperative hypercoagulability.[53,54,71,73] Epidural anesthesia using local anesthetics with or without opioids enhances fibrinolytic activity,[54,74] hastens the return of antithrombin III from elevated to normal levels, and attenuates postoperative increases in platelet activity. These effects probably occur through multiple mechanisms, including block of sympathetic efferent nerves, reduced levels of circulating catecholamines, and anticoagulant properties of even low levels of systemically absorbed local anesthetics. These reductions in postoperative hypercoagulability appear to reduce the incidence of thromboses of vascular grafts in patients undergoing lower-extremity revascularization,[53,71] and also reduce the incidence of deep venous thromboses and risk of pulmonary thromboembolism in patients undergoing total hip replacements. The reduced incidence of thrombotic phenomena in these settings may be related to an inhibitory effect on platelet aggregation and to improvements in lower limb blood flow.[75] Similar reductions in thromboembolic complications have been reported with the use of epidural anesthesia and analgesia (with local anesthetics) after other procedures, including knee arthroplasty[76] and open prostatectomy.[77] The differences in coagulability associated with epidural anesthesia and analgesia have been observed only in patients inherently at high risk for vaso-occlusive events.

Epidural analgesia is associated with improved pulmonary function after surgery compared with intramuscular and intravenous opioid.[44,78,79,80,81] Diaphragmatic function is commonly impaired after abdominal or thoracic surgery, probably as a result of reflex inhibition of phrenic nerve activity.[82,83] Although analgesia provided by parenterally or epidurally administered opioids alone does not significantly improve this dysfunction,[84] thoracic epidural analgesia with local anesthetic may improve postoperative diaphragmatic function by neural blockade of the inhibitory reflex[82,83] and by changing chest wall compliance.

Although epidural and parenteral opioids are associated with similar frequencies of episodic postoperative hypoxemia,[85] epidural analgesia with local anesthetics reduces the frequency and severity of early postoperative hypoxemia. It is likely that reductions in the work of breathing and other beneficial effects of improved analgesia, such as enhanced ability to cough and facilitation of chest physiotherapy, also play an important role in preventing postoperative respiratory complications. The former effects may be related to improved analgesia during activity, particularly when epidural local anesthetics and opioid are combined.[86]

Several studies have demonstrated reductions in the incidence of postoperative pneumonia and respiratory failure in high-risk patients undergoing thoracic or abdominal operations.[44,53] Similar differences in pulmonary morbidity between parenteral postoperative opioids and epidural analgesia have not been observed in healthy patients undergoing low-risk operations or when postoperative analgesia was not managed using well-defined protocols.[63,87,88,89]

In summary, epidural anesthesia and analgesia can reduce the frequency and severity of postsurgical stress-induced physiologic perturbations. The effect of epidural anesthesia and postoperative analgesia on mediators of the stress response appears to have the greatest impact on perioperative outcome in patients at high risk of complications. The relative importance of

preemptive intraoperative initiation compared with postoperative application of epidural local anesthetics (versus opioid alone or in combination), as well as the cost effectiveness of these analgesic techniques compared with other modalities for management of postoperative pain, depends on the patient's preoperative status and the specific operative procedure.

PHARMACOLOGY OF POSTOPERATIVE PAIN MANAGEMENT

Drugs administered orally, parenterally, transdermally, transmucosally, and transnasally for postoperative pain management may be grouped by their mechanism of effect as nonopioid or opioid analgesics and adjuvant pharmacotherapeutic agents.

Nonopioid Analgesics

Nsaids, Cox-1 and Cox-2 Inhibitors, and Acetaminophen

Aspirin (ASA), acetaminophen (APAP), the NSAIDs, and the selective COX-2 inhibitors ("coxibs") are the principal nonopioid analgesics used to treat minor or moderate acute postoperative pain (Table 55-3). Although these compounds represent diverse chemical entities, their common mechanism of action is inhibition of prostaglandin-mediated amplification of chemical and mechanical irritants on the sensory pathways peripherally and centrally. Although sensitization or intensification of painful stimuli is mediated by the prostaglandins and lowers the threshold for further activation of the nociceptors, the prostaglandins directly evoke little painful response.

TABLE 55-3 Pharmacokinetic Parameters and Maximum Dosage Recommendations Of Nonnarcotic Analgesics

	▪ROUTE	▪TIME TO PEAK LEVELS (hr)	▪HALF-LIFE (hr)	▪ANALGESIC ACTIONS (hr)		▪MAXIMUM RECOMMENDED DAILY DOSE (mg)
				▪ONSET	▪DURATION	
▪SALICYLATES

[i]Daily recommended dose for oral dosing.

Two phases of nociceptor sensitization are mediated with the release of potassium, prostaglandin, bradykinins, and substance P from tissues surgically damaged. These substances excite nociceptors and increase their pain sensitivity-hyperalgesia. Substance P, released by axon reflex, induces vasodilation and mast-cell degranulation, leading to histamine and serotonin release. These inflammatory agents sensitize damaged surgical tissue and surrounding nociceptors, further prolonging the hypersensitivity state (secondary hyperalgesia).

Aspirin and Other Nonsteroidal Drugs

Most of these agents modulate prostaglandin synthesis through inhibition of the action of the enzyme prostaglandin endoperoxide synthase (COX-2), which is one of the first steps in the conversion of arachidonic acid into the prostaglandins, thromboxanes, and prostacyclin. By reducing prostaglandin synthesis from tissue damage during surgery, cyclooxygenase inhibitors block the nociceptive response to endogenous mediators of

inflammation such as prostaglandins, bradykinin, substance P, potassium, acetylcholine, and serotonin. Such mediators augment nociception and painful sensations up the spinal cord to the brain and pain sensitivity at the surgical site. Although the exact mechanism for the participation of endogenous substances such as prostaglandins in the generation and transduction of nociceptive stimuli is unknown, the effect is greatest in tissues that have been subjected to trauma and inflammation.[90] The prostaglandins represent a diverse group of compounds that mediate many cellular and subcellular functions. The order of the sensitizing or hyperalgesic effect that is usually observed with this group is $PGE_1 > PGE_2 > PGF_{2a}$, whereas PGA_1, PGB_2, and PGI_2 exhibit little sensitizing effect.

Although mediation of the peripheral inflammatory response is an important component of pain, modulation by this group of drugs and inhibition of central mechanisms of hyperalgesia is likely.[91,92] Acetaminophen, ketorolac, and rofecoxib are cyclooxygenase inhibitors that are equipotent to aspirin in inhibiting prostaglandin synthesis in the central nervous system but vastly differ in inhibiting prostaglandin synthesis at peripheral sites. The site of activity of these agents reflects pharmacokinetic factors such as drug distribution, but more important, it reflects differences in the cyclooxygenase enzyme systems throughout the body. Studies in mammalian cells indicate that COX exists as three unique isoenzymes. The most recognized are PGH synthase-1 (COX-1) and PGH synthase-2 (COX-2).[93] Major differences between these isoenzymes involve dissimilar regulation and expression, with COX-1 (PGHS-1) constitutive regulation found in most tissues, especially platelets, stomach, vascular endothelial cells, and renal collecting tubules. Unlike COX-1, under basal conditions COX-2 has inducible regulation and is usually undetectable in most tissues except prostate, central nervous system (CNS), activated macrophages, fibroblasts, synoviocytes, and renal cortex, with expression capability in many tissues by stimulation or induction.[94] The COX-1 isoform primarily produces prostaglandins that regulate renal, gastric, and vascular homeostasis. In the presence of inflammation or tissue injury, inflammatory cytokines induce the expression of the COX-2 enzyme, which generates the prostaglandins involved in pain. Both isoforms of the enzyme are membrane associated and have a long, narrow channel into which arachidonic acid is drawn for conversion to a prostaglandin. NSAIDs block the channel at approximately its midpoint. Although the enzymes are not selective for substrate, a valine amino acid substitution (for isoleucine) in the COX-2 isoform allows for the synthesis of isoform-specific inhibitors. The smaller valine amino acid exposes an area in the channel into which larger side-chain substitutions of the enzyme inhibitor can engage. Because of these bulkier side groups, these same drugs have much less COX-1 activity, resulting in analgesic/anti-inflammatory properties with diminished effects on platelet, gastric mucosal, and renal functions.[95]

Because not all NSAIDs block COX to the same degree, membrane stabilization has also been attributed to these drugs.[96] Membrane stabilization may account for decreased prostaglandin release seen at drug concentrations that are lower than those needed for effective COX inhibition. This theory is supported by the correlation of analgesic potency with the octanol/water partition coefficient in this group.[97] Corticosteroids, which are membrane stabilizers, are known selectively to inhibit the expression of COX-2 during inflammation. NSAIDs, tricyclic antidepressants, and local anesthetics may also function through this mechanism of action, which explains some of their beneficial effects when they are used for acute pain management. Prostaglandin synthesis is known to be catalyzed by not less than 2-cyclooxygenase forms that convert arachidonic acid to multiple prostaglandins. Eiconside synthesis is initiated with arachidonate release from membrane phospholipids by the activity of phospholipase A2 (PLA_2).

Acetaminophen (Paracetamol-Apap)

APAP provides analgesic and antipyretic benefits but in overdose is associated with potentially fatal hepatic necrosis. Analgesic mechanisms of APAP are in part a function of COX-3 inhibition. In certain patients (chronic ethanol users, malnutrition, fasting patients), repeating therapeutic or slightly excessive doses may precipitate hepatotoxicity. A dose of 2,600 to 3,200 mg per day may represent a safer chronic daily dose in the authors' experience. Toxic doses may be a function of baseline glutathione levels and other dose-related factors. APAP is completely and rapidly absorbed following the oral route. Peak serum concentrations are achieved within 2 hours of a therapeutic dose, and therapeutic serum concentrations are 10 to 20 mcg/mL. The t½β (half-life) is 2 to 4 hours when used for acute postoperative pain. About 90% of APAP is hepatically metabolized to sulfate and glucuronide conjugates for renal excretion with a small amount secreted unchanged in the urine. An important minor pathway is phase one metabolism by cytochrome P450 (CYP450, 2E1, 1A2, 3A5). The fraction metabolized by CYP450 produces a reactive intermediate metabolite, N-acetyl-p-benzoquinoneimine (NAPQI), which arylates, binding covalently with hepatocytes, producing oxidative hepatocellular necrotic injury. This CYP450 pathway is engaged during toxicity when NAPQI accumulates, producing hepatic insult. Consumption of three or more alcoholic drinks daily may increase risk of hepatic damage with acetaminophen.

Clinical Uses

Unlike the opioid analgesics, the mechanism of analgesia of the nonopioid analgesics do not specifically involve interrupting the transmission of the nociceptive stimulus. The effectiveness of these agents depends on their ability to modulate the prostaglandin-dependent central and peripheral inflammatory responses to surgical or traumatic tissue injury. They have little or no inhibitory effect on classic catabolic stress hormones, acute-phase proteins, and other immunologic responses.[60] Nonetheless, incorporation of theses drugs into a polymodal, polypharmacotherapeutic pain treatment plan is clinically beneficial. The reduction in prostaglandin-mediated inflammatory response can serve to enhance analgesia when these agents are combined with opioids. Based on their pharmacologic mechanisms, it is predictable that the analgesic effect of nonopioid analgesic drugs are within narrow therapeutic ranges, above which there is little enhancement of analgesia but an increase in end-organ toxicity. Doses of APAP exceeding 3,200 mg chronically may be associated with hepatic toxicity, especially in elderly alcohol users or fasting patients due to glutathione depletion. To reduce the postoperative amplification of the nociceptive response to tissue injury, the most efficacious use of these agents would be presurgical or perisurgical. This is because the effect of COX-2 can last for many hours, and the sensitizing effects of circulating prostaglandins are not completely reversed by COX inhibitors. Unlike the COX-1 agents that affect platelets, the COX-2 agents have no platelet effects, do not increase surgical bleeding and do not have to be discontinued prior to surgery. These agents also appear to be more effective in procedures involving musculoskeletal, post-traumatic, and inflammatory pain, and in conditions such as dysmenorrhea, migraine headache, renal colic, and biliary obstruction, in which prostaglandins are known to be involved in the pathogenesis of the pain. The COX-2 agents additionally have a postoperative opioid-sparing effect. Perioperative administration of a COX-2 inhibitor is an integral component in polymodal analgesic treatment plans. This approach has been shown to improve range of motion after total knee replacement and diminish opioid utilization, pain, and opioid-induced iatrogenic effects such as emesis and insomnia.[98] The COX-2 and COX-1 agents have a dose ceiling effect beyond which there are no

therapeutic benefits. A pharmacokinetic comparison of the COX-2 agents is provided in Table 55-4.

TABLE 55-4 Pharmacokinetic Properties of COX-2 Inhibitors

The FDA asked manufactures of prescription and OTC NAIDs (COX1/COX2) to revise labeling to include a boxed warning and patient medication guide with more specific information about cardiovascular and gastrointestinal bleeding risks.

Opioid Analgesics

Mechanism of Analgesic Effects

4 Morphine and related compounds act as agonists, producing their biologic effects by interacting with stereoselective and saturable membrane-bound receptors that are nonuniformly distributed throughout the CNS. The major sites of opioid activity in the CNS include the periaqueductal and periventricular gray, nucleus reticularis gigantocellularis, medial thalamus, mesencephalic reticular formation, lateral hypothalamus, raphe nuclei, and spinal cord. The endogenous neuromodulating peptides of the enkephalin and beta-endorphin classes also bind to this family of receptors, which are collectively referred to as the *opioid receptors.* The unique properties of the individual drugs of this group are a result of their specific receptor activity and affinity. Three well-characterized classes of opioid receptors have been identified (μ, μ_1, μ_2; κ; δ). Human peripheral nerves contain endogenic opioid ligands and opioid receptors. A peripheral effect of opioids that results in "local analgesia" is more pronounced in chronically inflamed tissues,[99,100] where opioid receptors that are synthesized in the dorsal root ganglia have been transported and activated on primary afferent neurons in response to inflammation.[101] The local analgesic effects of opioids such as morphine have been clinically useful after surgery. Application of morphine at the nerve terminal (e.g., intra-articular injections after orthopaedic procedures) often produces effective, long-lasting analgesia of similar potency to conventional local anesthetics.[102,103,104,105,106,107] Peripherally acting μ-receptor agonists that do not cross the blood-brain barrier are being investigated.[108]

Affinity and activity at all three of the opioid receptor classes (μ, δ, κ) are responsible for the organ specific pharmacologic effects of the opiates (Table 55-5). The enkephalins and opiates have affinity and activity at the μ_1 receptor, which mediates supraspinal analgesia, prolactin release, and euphoria. Opiate-selective μ_2 receptors appear to mediate respiratory depression and physical dependence. The δ and κ receptors are at least partially responsible for spinal analgesia. Miosis and sedation are a result of κ-receptor activity. Pure opioid agonists (Table 55-6) have affinity, and exhibit at least moderate activity at the μ_1, μ, δ, and κ receptors, which explains their central and spinal analgesic effect, as well as their dose-related side effects and addictive potential. The differences in potency and side effects among drugs in this class are a result of receptor selectivity, affinity, and lipophilicity of the drug.

[a]Intravenous route usually used for antagonist properties.

Adapted from Intrurrsi DE, Foley KM: Narcotic analgesics in the management of pain. In Kuhar M, Pasternak G (eds): Analgesics Neurochemical, Behavioral and Clinical Perspectives, p 257. New York, Raven Press, 1984.

Raven Press, 1984.

Tramadol, a synthetic cyclohexanol, 4-phenyl-piperidine chiral racemate analog of codeine, is a centrally acting analgesic that possesses weak affinity for the μ opioid receptor (L-isomer) and modifies transmission of nociceptive impulses through inhibition of monoamine (norepinephrine and serotonin) reuptake (D-isomer), but not production. Receptor-blocking studies have demonstrated that these mechanisms work synergistically to produce the therapeutic analgesic effects of tramadol.[109,110,111] Tramadol is approximately one-tenth as potent an analgesic as morphine in treating moderately severe pain. At similar analgesic doses, tramadol has less effect on the respiratory center than morphine and has not been associated with a high abuse potential.[112] Analgesic effects are comparable to codeine, hydrocodone, oxycodone, and propoxyphene.

The pharmacologic properties of the mixed agonist–antagonist analgesics are also a result of their affinity for the opioid receptors. Unlike pure agonists, however, not all these agents produce an agonist effect when they interact with the receptor. There are two distinct groupings of the agonist–antagonist drugs based on their receptor affinity and activity. The first of these groups is characterized by high μ receptor affinity with activity less than or similar to that of morphine.

Agents in this partial agonist category (see Table 55-5) include buprenorphine. The second group of agonist–antagonist analgesics includes pentazocine, butorphanol, and nalbuphine. This group possesses only moderate affinity without activity at the μ receptor, high affinity with at least moderate activity at the κ receptor, and at least moderate affinity and some activity at the *σ* receptor, which accounts for the highly sedative effects and potential for psychomimetic reactions seen with these drugs. In addition, because of the affinity of both of these classes for the μ receptor, with activity less than that of the pure agonists, the mixed agonist–antagonist drugs have the potential for reversing the effect of an agonist, including precipitation of withdrawal symptoms.

Absorption/Biotransformation/Elimination

Although opioid analgesics are well absorbed from the gastrointestinal tract, differences in analgesic equivalence between oral and parenteral doses result from significant first-pass metabolism by the gut, liver, and lungs (fentanyl). Codeine, oxycodone, and hydrocodone do not undergo extensive first-pass hepatic metabolism owing to the methoxy-substitution of the phenolic component of the phenanthrene ring. These drugs are cytochrome CYP450 2D6 substrates, and they have greater oral-to-parenteral equivalency than morphine. Parenteral administration results in a more rapid onset of effect compared with oral and rectal administration. Fentanyl has a greater lipophilicity than morphine, and consequently, rapidly redistributes to highly perfused tissue (rather than to adipose tissue) and skeletal muscle. Extensive pulmonary first-pass uptake accounts for about 75% of the fentanyl dose absorption. These factors account for the longer duration of action, despite a relatively short elimination half-life ($t_{1/2\beta}$). Following redistribution, the slow release into plasma is culminated by CYP450 3A4 hepatic metabolism. Distribution

depends on the lipophilicity of the drug; smaller amounts of the more hydrophobic morphine equilibrate in the brain as opposed to more lipophilic agents, such as methadone, meperidine, and codeine. Biotransformation followed by renal elimination of conjugated metabolites is the primary mode of elimination. Active metabolites of morphine (morphine-6-glucuronide, M-3 glucuronide), codeine (morphine), meperidine (normeperidine), hydrocodone (hydromorphone), oxycodone (oxymorphone), and propoxyphene (norpropoxyphene) also contribute to the primary pharmacologic effect. Some of these metabolites (normeperidine, norpropoxyphene) also produce organ-specific toxicity. Morphine is metabolized by phase II glucuronidation yielding both M-3-G (up to 85%) and M-6-G (up to 10%). The active metabolite M-6 glucuronide accumulates with renal compromise (Clcr $\leqslant$ 30 mL/min) and necessitates cautious utilization of morphine in such patients.

Metabolism of tramadol by CYP450 2D6, including production of its primary metabolite *O*-dimethyl tramadol and its conjugates, is influenced by debrisoquine polymorphism.[113] This metabolite has a greater affinity for opioid receptors than the parent drug; however, the elimination half-life of this metabolite is not significantly greater than that of tramadol itself.[114] Methadone, a diphenylhetane, is a chiral compound and the S (+) enantiomer is either inactive or less active (weak) at opioid at receptors; however, it is also an NMDA receptor antagonist that blocks morphine tolerance development. The d-isomer and l-isomer of methadone bind to noncompetitive

sites on the NMDA receptor. The d-methadone blocks morphine tolerance and NMDA-induced hyperalgesia.

Renal elimination of the opioids and their metabolites is primarily by glomerular filtration. Only small fractions of the drugs and metabolites are excreted in the feces.

Adverse Effects

With short-term, moderate-dose therapy, CNS and gastrointestinal side effects predominate. Sedation, dizziness, lightheadedness, miosis, nausea, vomiting, and constipation are extensions of the pharmacologic actions of these drugs and occur in dose-dependent fashion. Tolerance to the sedative and other CNS effects develops rapidly over the first few days of therapy or after an increase in dosage. Tolerance to opioids and α_2 agonists may be a paradoxical sensory hypersensitivity that is blocked by NMDA receptor antagonism. Tolerance to the euphorigenic effects of drugs of abuse (prescribed and nonprescribed) develops more insidiously than to the proposed therapeutic effects of these pharmacotherapies. Constipation is a result of decreased bowel peristalsis and decreased secretory actions of the stomach, biliary tract, and pancreas. Spasm of the sphincter of Oddi can increase pressure in the common bile duct and contribute to epigastric distress. This effect may persist for up to 24 hours after a single therapeutic dose of an opioid. Low doses of naloxone and vasodilating agents have been used to relieve this discomfort. Biliary colic tends to occur similarly in patients after morphine administration or after meperidine administration, each producing a similar increase in biliary pressure. The partial agonist–antagonists tend to produce less of a rise in biliary pressure than pure agonists. Stool softeners and colon-specific laxatives may be beneficial if initiated prophylactically to avert severe constipation with opioid therapy. Urinary retention may also result from an increase in sphincter tone. Physical dependence and analgesic tolerance are usually not clinical problems during short-term use, but they may occur following chronic opioid therapy. Unlike the NSAIDs, opioid analgesics do not directly interfere with renal processes or gastric mucosa. Ventilatory depression, apnea, cardiac arrest, circulatory collapse, coma, and death can occur after large

parenteral doses. The cardiovascular and hemodynamic opioid effects are not uniform. Opioids may produce dose-dependent bradycardia as a function of vagal nucleus control stimulation that is attenuated by anticholinergic activity. Meperidine has an atropine-like effect that produces tachycardia, and it also has negative inotropic effects. Some opiates (morphine, meperidine, codeine) elicit histamine release that leads to vasodilation-induced hypotension. Clinically significant histamine release is rare with fentanyl, sufentanil, or alfentanil. The propoxyphene metabolite norpropoxyphene produces arrhythmias, QTc prolongation, and pulmonary edema. QTc

prolongation is additionally reported with methadone doses (260 mg).

Opioids initially decrease the respiratory rate without affecting tidal volume. Tidal volume diminishes with linear increase of opiate doses, and large doses may precipitate apnea episodes. In general, opioids shift the CO_2 response curve to the right, indicating that a higher serum concentration of CO_2 is required to stimulate ventilatory response.

Clinical Uses

Opioids remain the primary pharmacologic therapy for moderate to severe postoperative pain. Analgesia is achieved by blunting the central response to noxious stimuli without loss of consciousness or affecting tactile, visual, or auditory sensation. Dose-limiting side effects such as nausea, vomiting, constipation, urinary retention, and ventilatory depression can be overcome by proper selection of the agent and route of administration. Sedation and euphoria may be desired in the immediate postoperative period. Analgesic potency is not necessarily of major importance, because at equianalgesic doses there are parallel increases in side effects. Partial agonists and agonist–antagonists can be effective analgesics in the postoperative period and have a ceiling effect for ventilatory depression. Unfortunately, dose escalations with these agents may also produce a ceiling for analgesic effects, while enhancing sedative and dysphoric properties.

Therapeutic approaches using patient request for nursing on-demand administration have been largely replaced with continuous or regularly scheduled dosing methods, and patient-controlled and patient-facilitated analgesia. As postoperative analgesic requirements diminish, the transition from parenteral to oral opioid or transdermal analgesia usually involves replacing the parenteral opioid with oral opioid, NSAID, APAP, and patient-specific adjuvant pharmacotherapy. Tramadol (325 mg)/APAP (325 mg) is indicated for acute pain and may be used in chronic pain (moderate to severe). Codeine, hydrocodone, and oxycodone drug formulations that also contain NSAID or APAP in combination are limited in their analgesic efficacy because of the high incidence of side effects and end-organ toxicities related to the latter coanalgesic components. Meperidine and propoxyphene use is decreasing because of recognition of the potential for neurotoxicity and cardiac/pulmonary toxicity, respectively. Alternative delivery techniques have evolved that may supplant the oral or intravenous delivery of opioids in certain clinical circumstances. Oxymorphone, sufentanil, fentanyl, and morphine dosage forms are being developed to provide greater long-acting analgesic postoperative opportunities. Oral slow release long-acting opioids (e.g., morphine, oxycodone, oxymorphone) that have long been used for chronic pain are finding a role in acute postoperative pain.[115,116]

NEW METHODS OF OPIOID ADMINISTRATION

Fentanyl patient-controlled transdermal analgesia (PCTA) can provide needleless analgesia for moderate to severe pain for ⩾24 hours, including the postoperative period. A credit card-size PCTA device can deliver up to 80 doses of 40 mcg (μg), each for 10 minutes over a 24-hour period. Fentanyl is embedded in a hydrogel reservoir and delivered transdermally using low-intensity direct current. Due to lack of needle tubing, this delivery system has many potential applications in postoperative pain settings.[117]

Sufentanil (Chronogesic) is currently under investigation for use as a small subcutaneous continuous delivery system with a titanium rod implant that provides up to 90 days of this agent by osmotic pump. This delivery system could prove useful for patients with acute postoperative pain superimposed on chronic pain syndromes.

DepoDur (morphine) is a single 15- to 25-mg epidural injection of sustained release (SR) morphine providing analgesia over 48 hours. The extended release (ER) mechanism is a function of a liposome-capsulated, morphine-based delivery system impregnated within naturally occurring lipid particles (10- to 30-μm diameter) suspended in saline. The lipid particles contain discrete, water-filled chambers dispersed through the synthetic lipid matrix, with activation on metabolism to release morphine.[118]

Oxymorphone is a semisynthetic μ-specific opioid agonist used for moderate to severe pain. This

opioid has an oral 12-hour SR dosage form and an immediate release (IR) dosage form available to complement the parenteral and rectal dosage form. The oxymorphone molecule stays in the aqueous phase of the CNS and is highly μ-receptor (especially μ_1) specific. The SR dosage form contains a hydrophilic matrix polysaccharide gel that provides a linear release of oxymorphone without peaks and valleys of blood concentration. Unlike other agonists, the cytochromes CYP450 3A4 and CYP450 2D6 do not significantly metabolize oxymorphone, and there is no oxymorphone induction inhibition of other agents. Uniquely, there appears to be little analgesic tolerance, even after 1 year of administration. The dose-dependent side effects are similar to other opioids. The t½β half-life is 2 hours, and steady-state concentration (Css) is reached in 3 to 4 days for the ER form. The metabolites are 6-OH-oxymorphone and oxymorphone-3-glucuronide. Single dose data reflect dose proportional linear increases for the mean area under the curve (AUC) and Cmax. The median time to maximum concentration (Tmax) for IR is 6.5 hours and 2.5 to 4 hours for the ER version. Clinically, the IR form is administered every 6 hours with low fluctuations in drug levels, whereas the SR form produces consistent drug concentrations over a 12-hour time interval.

Clinical Dosing End Point

Serum concentrations that produce either therapeutic or side effects are a function of multiple dynamic processes that include preoperative opioid tolerance, CYP450 inhibition or induction, plasma albumin binding (acidic drug binding site), α_1 acid glycoprotein binding (basic drug binding site), aging process of essential organs (brain, heart, lung, kidney, liver, hematologic), multiple concurrent disease states, comorbidity, and extent of surgical trauma. Typical therapeutic end points include decreased pain (quality and intensity), increased functionality, and improved activities of daily living. Observing improvements in function is often more useful than analyzing subjective pain scores when titrating opioid and other adjuvant pain medications.

During periods of acute postoperative pain, scheduled administration of opioids, NSAIDs, antiepileptic drugs, antidepressants, lidocaine patch, sedatives, hypnotics, and centrally acting tramadol and acetaminophen are typically more effective than use on an as-needed (PRN) basis. This approach facilitates transition from inpatient to outpatient status in a more

time-efficient manner. The addition of a well-structured narrow limit for PRN dosing to treat breakthrough pain may be beneficial.

Adjuvant Analgesia

Lidocaine Topical Patch

Lidocaine topical patch 5% provides relief for some acute postoperative painful conditions, including incisional site pain, and can be useful in combination with polymodal pharmacotherapy for neuropathic and nociception pain states in the immediate postoperative period. No serious systemic adverse effects or drug–drug interactions have been evident with such use. Mechanisms of action include sodium channel blockade, modulation of A delta and C fibers, and inhibition of both nitric oxide expression and T-cell release of proinflammatory cytokines. The patch can be placed 3 inches from intact wound site perimeters (both sides of wound site) and remains in place continuously. The most common side effects are mild local skin reactions (erythema, edema) without sensory changes. Systemic events are unlikely due to minimal absorbed active drug (i.e., one-sixth of concentration for cardiac events, one-twentieth of concentration of toxic events).[119,120] The clinical experience of the authors' indicates that the lidocaine patch can provide an opiate-sparing effect.

METHODS OF ANALGESIA

Pain relief may involve administration of analgesic drugs by various routes or nonpharmacologic application of mechanical, electrical, or psychological techniques. In any patient, the optimal combinations of these techniques depend on the type and degree of pain, the patient's perception of the pain, and the underlying medical, social, emotional, and environmental conditions in which

the pain is managed.

Routes of Analgesic Delivery

Oral

Oral analgesics are usually considered less than optimal for moderate to severe acute postoperative pain management because of their lack of immediate titratability and prolonged time to peak effect, and because they require a functional gastrointestinal system. In general, hospitalized inpatients receive systemically administered opioids and then are converted to long-acting and/or short-acting oral or transdermal analgesics when the therapeutic need for rapid adjustments in the level of analgesia has diminished. However, with the focus on more rapid hospital discharge, early use of longer-acting, potent oral opioids facilitates transition of patients from parenteral opioids to oral therapy. Both nonopioid and opioid analgesic agents are available for oral administration, alone or in combination.

Transepithelial (Transdermal, Transmucosal)

With the increased number and complexity of surgical procedures being performed in the outpatient setting, there is a growing need for efficacious analgesic regimens for moderate to severe acute postoperative pain in this subset of patients. Methods of drug delivery such as transdermal[121] or transmucosal[122] administration are available as alternatives to oral analgesics on a patient-specific basis. These techniques permit delivery of potent analgesics that would be less effective when administered orally because of significant first-pass metabolism. Pharmacokinetic characteristics, primarily related to absorption, confer important clinical differences to these routes of administration. For example, to achieve optimal analgesic efficacy, transdermal fentanyl must be applied several hours prior to discontinuation of parenteral analgesics or patient-controlled analgesics. Transmucosal fentanyl is more rapidly absorbed but requires multiple titrations and is not indicated for postoperative pain. As with the oral route, titratability can be problematic and there may be unpredictability of drug absorption. Although transdermal fentanyl combined with patient-controlled analgesia (PCA) using morphine can reduce the number of demand doses, total opioid requirements and side effects are not decreased.[123] The new dosing method of fentanyl (E-Trans) described previously and involving PCTA is gaining increased use for postoperative pain following major surgery.

Parenteral

Parenteral administration of opioid analgesics remains the primary pharmacologic route for the treatment of moderate to severe postoperative pain. The use of computerized, patient-controlled delivery systems has played an important role in refining this method of delivery and reducing side effects of parenterally administered drugs.

Intramuscular. Intramuscular administration of postoperative analgesics produces a more rapid onset and time to peak effect than oral administration. It is also simple to administer analgesics by this route because no special infusion device is needed. However, pain at the injection site, patient apprehensiveness of needle sticks, the potential for delayed ventilatory depression, and wide variability in drug serum concentrations limit the viability of this route. Absorption from intramuscular sites depends on the lipophilicity of the agent and blood flow in the area of the injection. After intramuscular injections of morphine or meperidine, plasma concentrations may vary as much as threefold to fivefold, and time to peak concentration may vary from 4 to 108 minutes.[124] Another limitation is that administration efforts may not actually achieve the intramuscular site but may be deposited in a less perfused adipose tissue site. Conversely, with intramuscular administration, there is less variability in the minimum analgesic plasma concentration for an individual patient.[125] Small changes in plasma concentrations (10 to 20%) for a patient may represent a spectrum of effects from inadequate analgesia to complete pain relief.[126]

The relationship between plasma concentrations, effect, and time is depicted in Fig. 55-6. Plasma

concentrations after intramuscular administration of large doses of an opioid analgesic such as morphine at long dosing intervals establish a cyclic pattern of sedation, analgesia, and ultimately inadequate analgesia. When morphine is administered by this route with a 3- or 4-hour dosing interval, plasma concentrations exceed or meet analgesic requirements for only approximately 35% of the dosing interval because of the delayed absorption and narrow therapeutic window. This situation is exacerbated by the patient-specific dynamic nature of analgesic requirements. PCA and continuous epidural infusions, as well as patient-controlled epidural infusions, circumvent many of the challenges of intramuscular administration and may provide more effective analgesia with fewer side effects by maintaining a more uniform control of plasma levels.

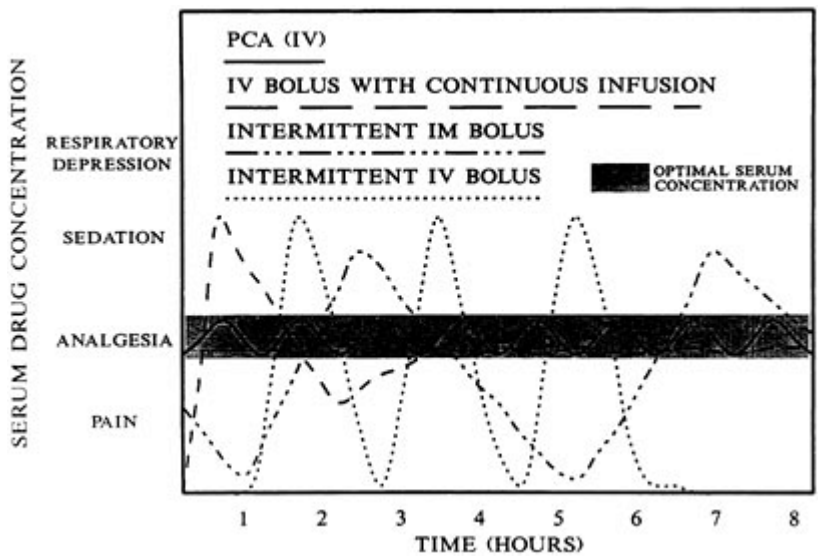

FIGURE 55-6. Relationship between serum drug concentration, pharmacologic effect, and method of administration. IM, intramuscular(ly); IV, intravenous(ly); PCA, patient-controlled analgesia. (Reprinted with permission from Tuman KJ, McCarthy RJ, Ivankovich AD: Pain control in the postoperative cardiac surgery patient. Hosp Formul 23:580, 1988.)

Most opioids can be administered by the parenteral route; however, a few NSAIDs, parecoxib, a valdecoxib prodrug, and ketorolac are designed for parenteral injection to manage postoperative pain.

Intravenous. Intermittent intravenous bolus infusions of opioids can be administered in situations when close

continuous monitoring of the patient is feasible. With a small intravenous bolus, the delay until analgesic effect and the variability in plasma concentrations seen with intramuscular administration can be reduced. Rapid redistribution of the drug shortens the duration of effect after a single intravenous administration compared with intramuscular injections. The numerous personnel needed to supervise frequent administration of boluses and monitoring of responses related to the fluctuations in plasma concentrations in the individual patient has led to the use of continuous intravenous infusions.

Continuous intravenous infusions offer the advantages of maintaining nearly constant plasma drug concentrations and reducing the peak-and-valley effect inherent in intermittent injections. Without the use of an initial bolus loading injection, continuous infusion techniques are inadequate because of the long time required for the drug to reach steady state (four to five elimination half-lives, t½β). Initiating therapy with a loading dose eliminates this problem but still does not allow for rapid dosage adjustments as analgesic requirements change.

Patient-Controlled Analgesia. By combining the advantages of a continuous infusion with the flexibility of interposing small bolus and patient-initiated doses as analgesic requirements vary,

PCA appears to effectively address many patients' analgesic needs. This method has evolved as advances in computer technology have met the needs for improved drug delivery. Early PCA devices permitted a patient to titrate analgesic needs by activating a switch to deliver a small bolus dose of an opioid such as morphine sulfate. Limits could be placed on the number of activations per unit time the patient was allowed, as well as the minimum time that would have to elapse between activations (lockout interval). Refinements of this system permit administration of a continuous background infusion superimposed on patient-controlled boluses. Background infusion concomitant with intermittent PCA boluses is advantageous in maintaining serum drug levels within the analgesic range and further attenuates fluctuations in levels, resulting in improved analgesia and patient satisfaction without producing excessive additional unwanted side effects.[127] In addition to combining infusion and bolus dosing, current devices record a profile of the drug administration, including number and time of bolus delivery, number of activations that did not result in drug delivery, and total amounts of the agent that were administered per unit time. Only the patient should be permitted to initiate a bolus dose from a PCA device.

Compared with traditional methods of on-demand analgesic delivery, PCA has been shown to provide superior analgesia, with less total drug use, less sedation, fewer nocturnal sleep disturbances, and a more rapid return to physical activity.[128] Most patients tend to titrate PCA to a level of pain at which they are comfortable and taper their dosage requirements as they convalesce.[129] In addition, patient acceptance of PCA is high because patients believe they have significant control over their therapy.[130]

One limitation to PCA therapy is the selection of agents available for use in the PCA devices (Table 55-7). Ideally, a drug administered by PCA should be highly efficacious, have a rapid onset of action and a moderate duration of effect, should not accumulate or change pharmacokinetic properties with repeated administration, and should have a large therapeutic window. Morphine and fentanyl are the drugs most widely prescribed by this route. The partial agonist and mixed agonist–antagonist drugs are far from ideal, and limitations imposed by the pharmacology of the agonist–antagonist group have made their use in these devices disappointing. Despite theoretic advantages, the use of fentanyl for PCA has not been shown to be a clearly superior analgesic to morphine,[131] although it may improve the initial PCA demand-to-delivery ratio.[132]

TABLE 55-7 Common Bolus Dosages, Lockout Intervals, and Continuous Infusions For Various Parenteral Analgesics When Using a Patient-Controlled Analgesia System

▪DRUG	▪BOLUS DOSE (mg)	▪LOCKOUT INTERVAL (min)	▪CONTINUOUS INFUSION (mg/hr)	▪4-hr LIMIT (mg)
▪AGONISTS				
Fentanyl citrate	0.015–0.05	3–10	0.02–0.1	0.2–0.4
Hydromorphone hydrochloride	0.10–0.5	5–15	0.2–0.5	200–300

Pentazocine hydrochloride	5–30	5–15		
[a]For pediatric dosing, see text.				

Other problems encountered with PCA therapy are primarily a result of operator or mechanical errors.[133] Because patients titrate their own therapy and not third "nonmedical" parties (i.e., family, friends), it is requisite that the patient is capable of understanding the concepts of the device, able to activate the trigger, and willing to participate. This makes the use of PCA devices more difficult in pediatric patients, as well as in patients who are older and debilitated or patients who are cognitively impaired.

Optimum results from PCA therapy are obtained only when the patient's analgesic needs can be met within the prescribed parameters set on the device. The patient's age, end-organ function, surgical procedure, need for a continuous background infusion, number and amount of boluses allowed, and total analgesic requirements are considered. Anesthesiologists must incorporate some flexibility into protocols for ordering PCA therapy to account for the variability introduced by these and other patient-specific factors. Further, the patient's prehospital analgesic burden should be considered in any postoperative analgesic treatment plan. Factors influencing postoperative opiate dosing include use of "recreational" drugs, ethanol use history, pharmacotherapy affecting the cytochrome CYP450 system, and genetic polymorphism.

Genetic Polymorphism. The cytochrome P450 used for metabolism of most pharmacotherapeutic agents has become a clinical challenge. The potential of substrate induction and inhibition by certain drugs used by the patient can importantly influence postoperative analgesic therapy. This is compounded by genetic polymorphism with a CYP450 enzyme deficit and the effect on patient-specific individual pharmacokinetic and pharmacodynamic variances among the extensive metabolites. Genetic polymorphism is displayed primarily by CYP450 2C9, 2C19, 2D6, and 3A4. These account for 80% of the CYP450-mediated reactions. Genetic polymorphism is the presence in the general population of more than one allele at the same locus with the least frequent allele

occurring more frequently than can be accounted for by mutation alone. The implication for pharmacotherapeutic dosing and response includes increased risk of therapeutic failure, adverse drug reactions (ADRs), and drug toxicity.

In general, CYP450 induction produces a decrease of therapeutic efficacy, whereas CYP450 inhibition produces an increase in AUC, a decrease in clearance, increase in plasma level

and potential for ADRs, and toxicity of a given substrate drug. This highlights the importance of CYP450 substrate modulation because of concomitant pharmacotherapy. Reduced drug metabolism is associated with genetic polymorphism at the 2C9 allele (6 to 8% Caucasian), 2C19 allele (3 to 5% Caucasian and 12 to 23% Asian), and 2D6 allele (6 to 10% Caucasian, 2 to 5% African American, 1% Asian).

Preoperative Alcohol and Controlled Substance History. Preoperative alcohol, recreational or illicit drug use, and prescription controlled substance use (e.g., opiates, benzodiazepines), as well as history of adverse drug reactions or episodes of abstinence or withdrawal of these agents, are important to assess. Preoperative alcohol, opioid, and benzodiazepine use are factors in postoperative therapeutic selection and in averting withdrawal postoperatively. Alcohol withdrawal may be confused with inappropriate analgesia based on cognitive, behavioral, and other physiologic manifestations. Alcohol and other recreational drug withdrawal may present as autonomic hyperactivity as is seen with inadequate pain relief or side effects of pharmacotherapies (hand tremors, insomnia, psychomotor agitation, nausea, vomiting, anxiety, transient hallucinations, or seizures).

Central Neuraxial Analgesia

5 The technique of spinal analgesia was described by Bier and Tuffler in 1898, and that of sacral epidural analgesia by Sicard and Cathelin in 1901. In 1949, a major advance in the application of central neuraxial analgesia was the description by Cleland[134] of the use of a continuous catheter epidural infusion for postoperative analgesia. Analgesia was maintained for 1 to 5 days after surgery by administering intermittent bolus doses of a local anesthetic. Although effective analgesia was obtained, a significant sympathetic block accompanied the analgesia, and all patients required at least one dose of a vasopressor. Additional shortcomings of this technique, as with any intermittent dosing regimen, were the fluctuating levels of analgesia that occur as the effect of the bolus dissipates and the requirement of the medical staff to reinject the patient every several hours.

Because of the shortcomings of intermittent dosing, the continuous infusion of local anesthetics along the central neuraxis was subsequently recommended as an alternative to the intermittent bolus technique. The continuous infusion of local anesthetics simplifies maintenance of analgesia, but the use of local anesthetics in concentrations sufficient to produce pain relief usually results in sensory and occasional motor blockade. These are unwanted effects in the postoperative period because sensory and, more importantly, motor blockade prohibit ambulation, an important factor in postoperative convalescence.

Although it has long been recognized that application of local anesthetic agents along the spinal canal could provide effective analgesia, the demonstration that opioids could produce analgesia by this route has been responsible for the widespread application of the practice of central neuraxial analgesia. The enthusiasm for this route of administration has also been a direct result of the shortcomings of intramuscular and intravenous therapies. By interrupting pain pathways at the level of communication between the first-order neurons and the second-order neurons, this method can provide effective analgesia without the associated CNS depression and cyclical nature of pain associated with other parenteral routes of administration.

Intrathecal. The intrathecal administration of opioids has the advantage of providing long-lasting analgesia after a single injection. The onset of analgesic effect after the intrathecal administration of an opioid is directly proportional to the lipid solubility of the agent, whereas the duration of the effect is longer with more hydrophilic compounds. Morphine, for example, produces peak analgesic effects in 20 to 60 minutes that last for 2 to 12 hours when doses ranging from 0.25 to 4 mg are

administered intrathecally to adults.[135,136] In routine clinical practice, 0.25 to 1 mg morphine can be expected to provide effective analgesia, whereas doses in the range of 0.25 to 0.5 mg generally maintain analgesic efficacy while minimizing the potential for ventilatory depression.[135]

Intrathecal bolus injections share many of the problems of other intermittent techniques, including lack of titratability and extensive time requirements for monitoring and reinjection. In addition, the potential for infection, a greater risk of ventilatory depression owing to rostral spread of the drug, and a higher incidence of side effects make this technique less desirable than epidural administration (Table 55-8). Widespread clinical experience has shown that continuous epidural infusions may be preferable to intrathecal techniques for central neuraxial

analgesia. The practical aspects of maintaining a catheter in the intrathecal space for a prolonged period and reports of cauda equina syndrome after continuous spinal anesthesia also may favor the continuous epidural technique.[137] Although intrathecal analgesic techniques are infrequently used outside the setting of labor analgesia, the combination of spinal anesthesia followed by continuous epidural analgesia has gained increasing popularity because it provides the advantages of spinal anesthesia (rapid onset, dense neural blockade), while facilitating the transition to an effective and titratable postoperative analgesia method after major surgery.[138]

TABLE 55-8 Complications of Neuraxial Opioids

▪COMPLICATION	▪REPORTED INCIDENCE (%)[a] ▪SPINAL	▪EPIDURAL	▪TREATMENT
Respiratory depression	5–7	0.1–2	Support ventilation, naloxone
Pruritus	60	1–100	Antihistamine, naloxone
Nausea and vomiting	20–30	20–30	Antiemetic, transdermal scopolamine, naloxone
Urinary retention	50	15–25	Catheterize, naloxone

[a]Reported incidences vary widely, appear to be related to dose, and are higher with spinal than with epidural administration.

Epidural. Epidural administration of opioids and local anesthetics has evolved in parallel with intrathecal techniques. As noted, the advantages of epidural administration of drugs such as opioids and local anesthetics include the reduced incidence of side effects and a diminished propensity for opioid-induced ventilatory depression compared with the intrathecal route. When a drug is placed in the epidural space, it must first cross the dura before it can reach the spinal cord. Besides the physical barrier presented by the dura, the epidural space is highly vascularized, and a significant redistribution of drug to the systemic circulation occurs. The epidural space also

contains fat, connective tissues, a lymphatic network, and the dorsal and ventral roots of the spinal nerves, all of which can serve as a repository for lipophilic agents.[139]

The influence of these factors can be demonstrated by an examination of the pharmacokinetics of epidurally administered hydrophilic (morphine) and lipophilic (fentanyl) opioids. Ten milligrams of morphine, given either intravenously or epidurally, produce peak serum levels and decay curves that are nearly identical (Fig. 55-7). Whereas the duration of pain relief from intravenous administration is short lived (1 to 2 hours), epidural morphine can provide 12 or more hours of analgesia. This indicates that, although much of an epidural dose is absorbed into the systemic circulation, a small fraction of the morphine dose (~2 to 10%) diffuses across the dura to bind spinal opiate receptors and produce analgesia. In contrast, when epidural fentanyl 200 µg is given in a similar manner, peak serum levels are only approximately 50% of those after a similar intramuscular injection. However, serum levels of fentanyl 24 hours after a continuous rate epidural infusion are similar to those obtained from a similar intravenous infusion.[140] This implies that with the initial bolus of fentanyl, there is redistribution of the drug to lipophilic tissues, which become saturated after continuous administration. Therefore, only a small fraction of a typically administered epidural dose is necessary to produce spinally mediated analgesia.

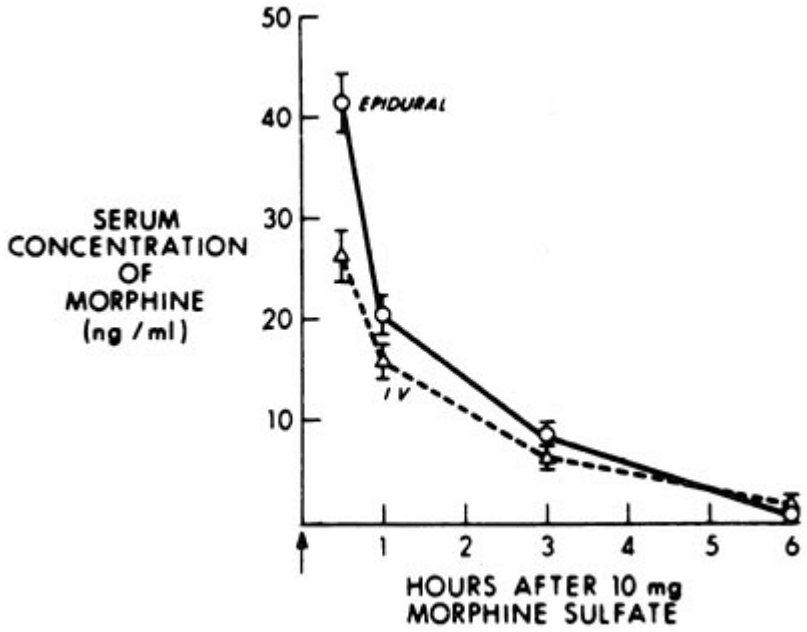

FIGURE 55-7. Serum concentration of morphine (mean ± SEM) after intravenous and lumbar epidural administration of 10 mg of morphine sulfate in 10 subjects. Triangles, intravenous; circles, epidural. (Reprinted with permission from Bromage PR, Camporesi EM, Durant PAC, Nielsen CH: Nonrespiratory side effects of epidural morphine. Anesth Analg 61:490, 1982.)

Because the diffusion of drugs across the dura is both concentration and time dependent, it is necessary to administer significantly larger amounts of drugs than those that effectively saturate spinal opiate receptors. These higher doses are more likely to produce unwanted side effects from systemic and rostral distribution of the drug, but fewer than those associated with equianalgesic intrathecal doses. When these factors are considered, the margin of therapeutic safety and the decrease in side effects with epidural administration make this route preferred for postoperative analgesia.

Intermittent epidural bolus doses of morphine sulfate (⩽15 mg over 24 hours) have been used for postsurgical analgesia.[80] Although this method of administration provides excellent analgesia for up to 12 hours, side effects associated with these bolus doses limit the widespread application of this technique. An intermittent bolus technique also has the disadvantage of limiting the number of usable opioids to the longer-acting drugs (e.g., morphine and hydromorphone).

In an effort to mitigate the frequency and severity of opioid-induced side effects associated with bolus techniques, El-Baz

et al[141] described the use of a continuous epidural morphine infusion (100 µg/h) and found equivalent analgesia and fewer side effects than after epidural boluses of either bupivacaine (0.5%) or morphine (5 mg) (Fig. 55-8 and Table 55-9). It is now well accepted that continuous epidural infusions of opioids provide effective analgesia while reducing the side effects associated with bolus administration.[142,143,144]

TABLE 55-9 Side Effects With Postoperative Epidural Analgesia

▪SIDE EFFECT	▪GROUP A (BUPIVACAINE 25 mg/5 mL, 0.5%, EPIDURAL BOLUS)	▪GROUP B (MORPHINE 5 mg, EPIDURAL BOLUS)	▪GROUP C (MORPHINE 100 µg/hr EPIDURAL INFUSION)

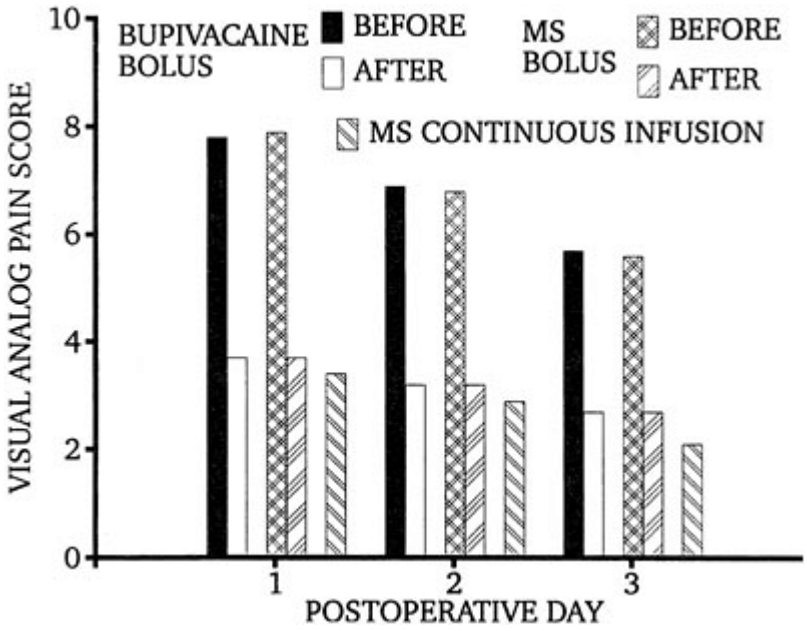

FIGURE 55-8. Analgesic effectiveness of continuous morphine epidural infusion compared with epidural bolus doses of morphine sulfate (MS) or bupivacaine. See text for details. (Adapted from El-Baz NI, Faber LP, Jensik RJ: Continuous epidural infusion of morphine for treatment of pain after thoracic surgery: A new technique. Anesth Analg 63:757, 1984.)

Because the laws of mass action apply to diffusion of drugs out of the epidural space to their sites of action, several hours are often required to achieve adequate analgesia when using continuous infusions alone. Effective analgesia with epidural infusions administered at a continuous rate may take as long as 3 to 4 hours to achieve. Delay in onset of effective analgesia can be reduced by adjusting the infusion rate to provide the equivalent of a small (5 to 10 mL) bolus of the epidural solution over 5 to 15 minutes before beginning the maintenance infusion. This allows an adequate concentration of the analgesic drug(s) to be present at their site(s) of action in a shorter time.

In addition to a reduction in adverse effects, another advantage of a continuous epidural infusion over an epidural bolus injection is the ability to titrate the amount of analgesia (Table 55-10). Although morphine usually provides 12 hours of pain relief after a single epidural injection, wide variability has been reported in the duration of effective analgesia (4 to 24 hours), depending on the site and extent of surgical trauma and age of the patient. Because of this variability, it becomes difficult to titrate uniform levels of analgesia. A continuous infusion provides easier analgesic titration, particularly when shorter-acting opioids such as fentanyl are used. Fentanyl has an onset of action within 4 to 5 minutes and a peak effect within 20 minutes.[145,146] Because of the rapid onset, it becomes much easier to adjust dosage, observe the desired effect, and titrate to an optimal intensity of analgesia. Morphine, in contrast, has an onset time of 30 minutes with a time to peak effect ranging from 60 to 90 minutes.

TABLE 55-10 Comparison of Epidural Analgesia Administration Techniques

·ADVANTAGES	·DISADVANTAGES
·CONTINUOUS EPIDURAL INFUSIONS	

1. Less rostral spread so side effects are minimized 2. Provides continuous analgesia avoiding the peaks and nadir seen with intermittent bolus 3. Allows for concomitant use of dilute local anesthetic solutions 4. Allows the use of shorter-acting opiates such as fentanyl or sufentanil 5. Less potential risk of contamination for injection because the catheter system has fewer breaks in sterile technique 6. Simple and easy maintenance; removes the need for anesthesia personnel to inject patients periodically	1. Need for sophisticated infusion device
·INTERMITTENT EPIDURAL BOLUS	
1. Simple (providing resident or nursing staff accepts the responsibility of epidural catheter injections) 2. No need for infusion devices	1. Limited number of suitable opioids 2. Higher incidence of side effects 3. Extra effort to inject catheter every 8–12 hr 4. Excludes the use of local anesthesia 5. More difficult to titrate dose

Mirroring the evolution of PCA, a refinement in delivery of analgesics by the epidural route is the use of superimposed patient-controlled bolus doses with a continuous basal infusion. Early application of this technique for delivery of epidural analgesia used relatively large intermittent demand doses alone or combined with a low-rate continuous infusion, and the intermittent demand doses provided the preponderance of analgesia. This dosing paradigm has reduced efficacy because of fluctuations in analgesia occurring as a consequence of large intermittent bolus dosing. Using higher basal infusion rates and smaller patient-activated bolus doses, the continuous infusion maintains a more constant intensity of analgesia, whereas the bolus doses provide supplemental analgesia for transient increases in analgesic requirements[147] (Table 55-11). Patient-controlled epidural analgesia is particularly useful to manage dynamic changes in pain related to patient activity (e.g., coughing, chest physiotherapy).[148] The development of new infusion devices has allowed such combined modes of administration of epidural analgesia to be readily delivered (Appendix 55-1).

Initiation and maintenance of therapy. Based on the preceding considerations, achievement of optimal results with a continuous epidural analgesia technique requires appropriate perioperative planning and assessment. This strategy includes identifying patients who may benefit from epidural analgesia and scheduling the epidural catheter placement as part of the anesthetic plan. At the authors' institution, epidural catheters for postoperative analgesia are commonly placed immediately prior to induction of operative anesthesia. This practice allows the anesthesiologist to administer a test dose of local anesthetic to evaluate while the patient is still awake. The application of bolus administration followed by a continuous infusion mandates that the test dose be administered to an awake patient. This facilitates diagnosis of intrathecal, intravascular, or subdural catheter placement, and allows confirmation of segmental epidural analgesia when the test dose of local anesthetic is administered. This practice also allows the continuous

epidural infusion to be started during surgery. Solutions of morphine (0.1 mg/mL) with bupivacaine (1 mg/mL) or fentanyl (10 µg/mL) with bupivacaine (1 mg/mL) are most commonly used. Concentrations of opioid are reduced for patients with increased risk of serious opioid-induced side effects. The infusion is begun during surgery at a rate of 4 to 6 mL/h, augmenting the general anesthetic and providing sufficient time to achieve good analgesia and smooth emergence. If the surgical procedure is relatively short (1 to 2 hours), a 5- to 10-mL bolus of the epidural solution may be given as a rapid infusion as described previously to hasten the onset of analgesia. As an alternative, the patient may be given an epidural bolus of 0.5% bupivacaine combined with either fentanyl (50 to 100 µg) or morphine (2 to 5 mg). If the surgical procedure is expected to exceed 3 to 4 hours, bolus dosing may not be needed because sufficient time is allowed for continuous epidural

infusion alone to achieve analgesia at the time of the patient's awakening.

Placement of epidural catheter. Hydrophilic compounds such as morphine, when injected epidurally, result in cerebrospinal fluid concentrations of the drug that allow it to saturate more rostral portions of the spinal cord[149] (Fig. 55-9). Because of this property, epidural morphine may be infused at a lower lumbar level and still provide analgesia for surgical procedures performed on the upper abdomen and thorax. Lipophilic drugs such as fentanyl tend to provide more of a segmental analgesic effect.[150] This may in part be the result of the lipophilic compounds partitioning into lipid compartments in the spinal canal, such as epidural fat and the spinal cord. This segmental nature of analgesia mandates the need to place an epidural catheter in a location to cover the dermatomes included in the surgical field. A general guideline for the catheter locations in various types of surgery is as follows: thoracic surgery—upper to lower thoracic; upper abdominal and renal surgery—low thoracic to high lumbar; orthopaedic procedures of the lower extremities and lower abdominal and gynecologic surgery—lumbar region. Alternatively, catheter placement should be approximately at the dermatomal level that corresponds to a point intersecting the upper one-third and lower two-thirds of the surgical incision. In general,

placement of the epidural catheter at a level lower than that described previously necessitates increased epidural drug dosing to achieve effective analgesia, especially when lipophilic opioids are used, and this may lead to an increase in side effects.

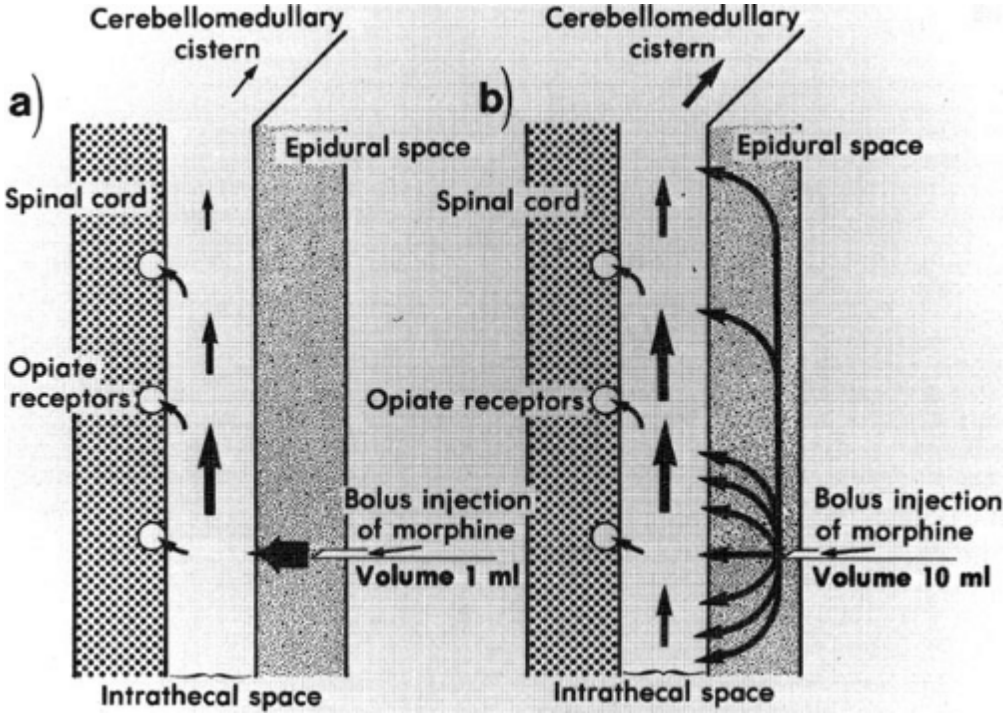

FIGURE 55-9. Rostral spread of central neuraxial morphine. **a**. Spread in small injection volumes of 1 mL after dura penetration into the intrathecal space. **b**. Spread in high injection volumes of 10 mL in the intrathecal and epidural space. (Reprinted with permission from Chrubasik J: Investigations on respiratory repression. In Chrubasik J [ed]: Spinal Infusions of Opiates and Somatostatin, p 19. Obersul, Germany, Verlag Hygeineplan, 1985.)

Selection of analgesics. The differences among the opioids used for epidural analgesia relate to their duration of action and propensity to produce side effects. Patient factors such as advanced age, small body habitus, morbid obesity, history of sleep apnea, and general debilitation should be considered when initiating epidural analgesia because these conditions are associated with a greater propensity for respiratory complications. Reduced concentrations of opioids should be used when initiating epidural analgesia in such patients (Appendices 55-1 to 54-3).

Pain relief lasts longer with hydrophilic agents such as morphine than with the more lipid-soluble hydromorphone or fentanyl (see Table 55-11). The relatively long duration of action of epidural or intrathecal morphine allows it to be used effectively as an intermittent bolus given every 12 hours, whereas because of a shorter duration of analgesia, fentanyl is better suited for continuous epidural infusions. Morphine can be used as a continuous epidural infusion and has been associated with reduced side effects compared with epidural bolus injections.[141] Hydromorphone, which has a lipid solubility between that of morphine and fentanyl, is 7 to 10 times as potent as morphine. Intermittent epidural bolus administration of hydromorphone provides effective analgesia for 7 to 12 hours, with a reduced incidence of pruritus and nausea compared with morphine.[151]

Lipophilic compounds such as fentanyl, sufentanil, and, to a lesser extent, hydromorphone partition into the spinal cord and lipid structures in the epidural space more than hydrophilic agents, which remain in the cerebrospinal fluid to a greater extent. Therefore, it may be preferable to use lipophilic opioids such as fentanyl, rather than the more hydrophilic morphine, to produce a more segmental level of analgesia. Although the tendency of hydrophilic drugs for rostral ascension facilitates the dermatomal distribution of analgesia, it also can result in a higher

incidence of some side effects.[149]

Epidural coadministration of opioids with local anesthetics takes advantage of the desirable properties of each drug. The desired result of these combinations is achievement of potentiated analgesia at lower opioid doses with a concentration of a local anesthetic that does not produce significant motor blockade. This potentiation may be a result of antinociception at different sites in the spinal cord.[152] Opioids produce analgesia by binding to opiate receptors in the substantia gelatinosa, whereas local anesthetics block transmission of afferent impulses at the nerve roots and dorsal root ganglia.[153] Another advantage of the combination using reduced doses is the concomitant decrease in the incidence and severity of side effects. Despite wide acceptance, not all studies have demonstrated analgesic potentiation when bupivacaine and fentanyl have been used in combination.[154]

Adrenergic receptors of the α_2 class modulate nociceptive impulses in the dorsal horn of the spinal cord and throughout the CNS. Agonists of these receptors produce antinociception

with minimal ventilatory depression compared with opioids.[155] Clonidine has been the most widely used α_2 agonist for epidural analgesia, producing dose-dependent analgesia when given as a bolus.[156,157] Epidural clonidine has been associated with hypotension and with bradycardia because of inhibition of preganglionic sympathetic fibers. This is most prevalent at smaller doses, whereas large doses normalize blood pressure because of systemic vasoconstriction that overrides the central hypotensive effect. Although epidural clonidine has been used as a single agent to provide postoperative analgesia,[158] it has more frequently been used in combination with local anesthetics[159] or opiates[160,161] to potentiate analgesia and minimize side effects. Optimal ratios for combining α_2 agonists with opioid or local anesthetics are yet to be defined[162] because these drugs exhibit nonlinear synergism.[163] Other α_2 agonists that have been used for pain management include dexmedetomidine and tizanidine.[164] Dexmedetomidine is an α_2 agonist with a very high α_2-to-α_1 selectivity (ratio of 1,600) compared with clonidine (ratio of 200).[165] Tizanidine, an analog of clonidine, produces analgesia in a manner similar to clonidine but has fewer cardiovascular effects.[164,166]

Management of inadequate analgesia. Although epidural analgesia is usually effective, patients may occasionally experience inadequate pain relief. A systematic approach is necessary to evaluate and manage inadequate epidural analgesia. The initial step in this process is verification of the integrity of the catheter system, followed by a bolus (5 to 7 mL) of the epidural solution (typically a combination of dilute local anesthetic with opioid), with analgesic assessment after a short interval (15 to 30 minutes). If analgesia remains inadequate, a test dose of a local anesthetic solution, such as 2% lidocaine with 1:200,000 epinephrine, can then be given to evaluate epidural catheter location (Fig. 55-10). The test dose usually yields one of three results. If bilateral sensory block occurs in a few segmental dermatomes, epidural catheter location is confirmed. In this case, volume of the infusion was likely insufficient for adequate dermatomal coverage, resulting in inadequate analgesia, and increasing the rate of infusion may produce effective analgesia. A unilateral sensory block after administration of a test dose of local anesthetic is suggestive of the catheter tip residing laterally in or near a neuroforamen. Withdrawal of the catheter 1 to 2 cm is usually associated with a bilateral sensory block after a subsequent test dose. Once bilateral sensory blockade has been documented, adequate analgesia can be maintained with bolus administration of the epidural solution followed by adjustments of the continuous epidural infusion or patient-controlled epidural infusion parameters.

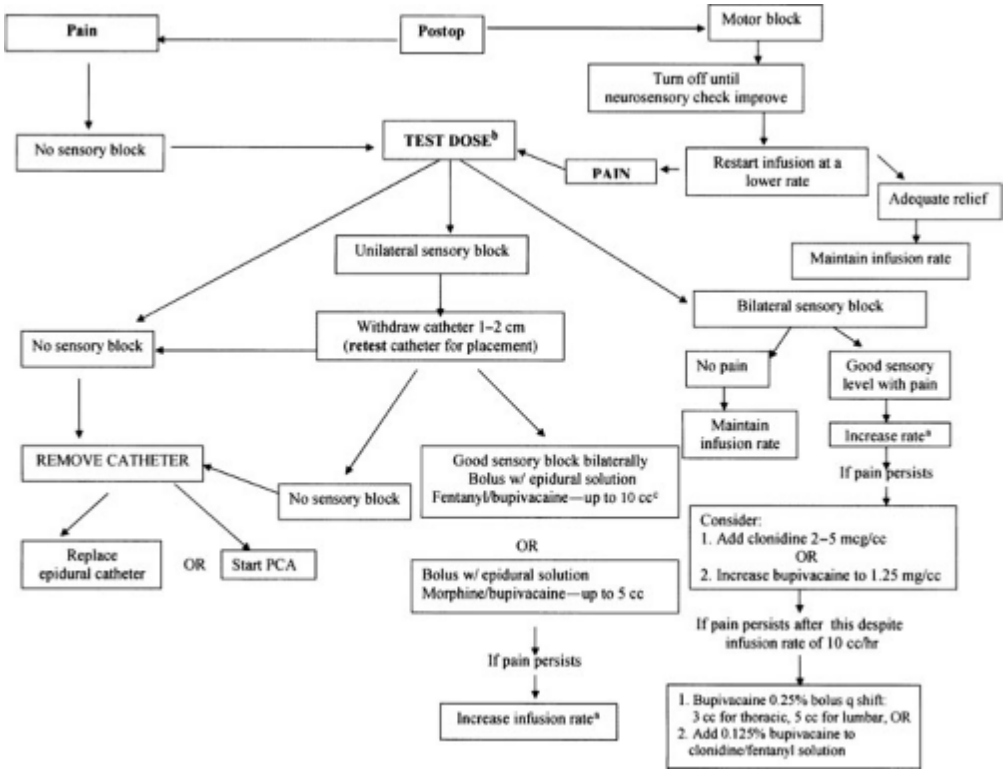

FIGURE 55-10. Postoperative epidural management algorithm. The test dose, given by anesthesia personnel, is 2% lidocaine with epinephrine 1:200,000 (5 mL for lumbar catheters; 3 mL for thoracic catheters). PCA, patient-controlled analgesia. [a]Not to exceed 10 cc/degree with fentanyl or morphine. [b]Test dose: 3 cc 2% lidocaine with epinephrine 1:200,000 for thoracic catheter. Test dose: 5 cc 2% lidocaine epinephrine 1:200,000 for lumbar catheter.

Finally, a lack of sensory blockade after test dose administration indicates that the epidural catheter does not reside in the epidural space. In this situation, the catheter is removed, and the patient is given the option of having another epidural catheter placed or switching to PCA therapy.

Safety considerations. Serious complications that can occur with a continuous epidural technique include accidental intrathecal administration of drug, infection-related problems, epidural hematoma, and ventilatory depression. To decrease the incidence of these complications, the authors propose the

following guidelines:

1. A low concentration of local anesthetic (e.g., 0.1% bupivacaine) in combination with an opioid analgesic allows subarachnoid catheter migration to be identified earlier by the onset of progressive sensory blockade. Low concentrations of local anesthetics do not interfere with neurologic assessments because they do not usually produce significant sensory or motor block when administered epidurally. If sensory or motor deficits are present, discontinuation of the infusion should allow for regression of these anesthetic effects within 2 to 4 hours. Persistent impairment of sensory or motor function should prompt appropriate evaluation to identify potentially serious causes of neurologic dysfunction, especially in anticoagulated patients (see Fig. 55-10).
2. Catheter sites should be examined daily, temperature curves monitored, and the patient periodically evaluated for signs of meningism. Symptoms of epidural abscess include neurologic deficits, elevated body temperature, and back pain, although meningitis is

uncommon.[167] If any findings consistent with infection are present, the catheter is removed and cultures performed. In the authors' experience of more than 30,000 cases of postoperative epidural analgesia, only a single case of epidural abscess has been encountered, and this patient was successfully treated without neurologic compromise. In a small number of patients, infections limited to the cutaneous structures have developed and resolved with conservative therapy.

3. Epidural catheters should be placed at least 1 hour before intravenous heparinization in patients without preoperative coagulation defects but requiring intraoperative anticoagulation with unfractionated heparin. At least one published series has shown that if epidural catheters are placed at least 1 hour before heparinization, the incidence of clinically significant epidural hemorrhage does not appear to increase.[168]

4. The risk of epidural hematoma formation related to epidural catheter placement in patients receiving certain forms of perioperative anticoagulation is controversial. Historically, concern for epidural hematoma formation with epidural catheterization has been generated primarily in the setting of intraoperative anticoagulation with unfractionated heparin. With the introduction of low-molecular-weight heparins (LMWHs), increased risk of epidural hematoma formation related to epidural catheterization has been attributed to the perioperative use of such fractionated heparin compounds. Similar to unfractionated heparin, LMWH binds to antithrombin III; however, the resulting complex also diminishes thrombin generation by inhibiting factor Xa. In contrast to unfractionated heparin, the anticoagulating effects of LMWH are of longer duration and not effectively monitored with the activated clotting time or activated partial thromboplastin time.[169] Based on consensus opinion, after assessing the risks and benefits of epidural anesthesia/analgesia on an individual patient basis, it has been recommended that epidural catheterization (as well as removal of epidural catheters) be performed at least 10 to 12 hours after a dose of LMWH.[170] In addition, dosing of LMWH should not occur for at least 2 hours after removal of an epidural catheter to avoid manipulation during the peak anticoagulant effect.[170] Although some clinicians remove epidural catheters before postoperative initiation of LMWH, others continue postoperative epidural analgesia for longer than 24 hours in some patients. In such instances, LMWH administration may be delayed or alternative methods of thromboprophylaxis selected. The risks of spinal hematoma are incrementally increased when LMWH is used concomitantly with other drugs that affect hemostasis, including antiplatelet drugs, standard heparin, and dextran. The entire patient care team must be cognizant of this whenever postoperative epidural analgesia is used, and the postoperative analgesia service should interface with other managing clinicians to determine the optimal management of patients with these considerations. Whenever perioperative anticoagulation is used in patients managed with epidural analgesia, monitoring of anticoagulation and neurologic status is imperative.

5. With appropriate monitoring of coagulation status, epidural catheters may be inserted safely in patients who receive perioperative warfarin.[171] In patients with international normalized ratio values exceeding 1.5, neurologic checks should be continued for at least 24 hours after epidural catheter removal.[172]

6. Respiratory rates and level of sedation should be monitored every hour for the first 24 hours of the epidural infusion and every 4 hours thereafter. Apnea monitors can be used to supplement, but cannot replace, direct patient observation. Patients at increased risk for respiratory compromise include the elderly and those with sleep apnea or any debilitating disease. In the authors' institution, an apnea monitor is commonly used for the first 24 hours when epidural bolus doses of morphine 2 mg or greater are given as loading doses.

   It has become increasingly evident that the patient with obstructive sleep apnea (OSA) is at a greater risk of respiratory depression from opioids, regardless of the route of administration. The expanding knowledge base of OSA also suggests that it is more common than previously appreciated.[173] Patients with a constellation of symptoms (e.g., excessive snoring, hypertension, daytime somnolence) and who have physical findings consistent with OSA should probably be considered to have a provisional diagnosis of OSA and thus managed

with appropriate precautions. Patients with sleep apnea should have continuous pulse oximetry monitoring to promote early detection of respiratory depression, and they may benefit from nasal continuous positive airway pressure (NCPAP) after extubation and during periods of sleep.[174]

In summary, a continuous infusion technique alone or in combination with patient-controlled epidural boluses simplifies maintenance of epidural analgesia and allows greater analgesic titratability than intermittent epidural bolus dosing. Proper patient selection, catheter placement, and methods to identify and treat inadequate analgesia are important aspects of postoperative pain management. Patient safety is paramount and guidelines should be established within each facility for prevention, early diagnosis, and treatment of complications.

Caudal. Caudal nerve blocks play a minor role in acute postoperative pain management in adults. Because they are technically more difficult to perform in adults than other efficacious forms of lumbar epidural blocks, they are used less frequently in adults than in the pediatric population. Continuous caudal analgesia for postoperative pain has a limited utility because of the difficulty of securing a catheter, but it may have a role in select patients such as those who have had extensive lumbar or thoracic spine surgery. In those unusual situations where continuous caudal analgesia is used, the standard solutions for lumbar epidural analgesia may be used, although infusion rates may need to be higher than those with a lumbar epidural infusion.

Pediatric ("kiddie") caudals have become popular for intraoperative supplementation and postoperative pain relief. Palpation of the sacral hiatus is much easier in the pediatric population, and a distinct "pop" can be heard as the needle pierces the sacrococcygeal membrane. A short, 22- or 23-gauge

needle should be used; the block is usually performed with the child in the lateral position. After needle insertion, needle aspiration should be performed to avoid inadvertent injection into the intrathecal or vascular space. Volumes of local anesthetic ranging from 0.75 to 1 mL/kg body weight of 0.25% bupivacaine should provide analgesia to the T10 level, which is sufficient for procedures in the groin and lower extremities. Although bupivacaine usually provides 4 to 6 hours of effective pain relief, children receiving caudal nerve blocks at the time of surgery exhibit better pain relief and use significantly fewer supplemental opioids during the first 12 postoperative hours.

As with other combined regional and general techniques, a relatively lighter plane of general anesthesia is required to maintain adequate surgical anesthesia when this block is instituted before the surgical incision, and this may represent an advantage over the use of a caudal block placed at the conclusion of the procedure. Blocks placed before surgical incisions also allow the patient to awaken more quickly and to benefit from a smoother emergence from general anesthesia.

Peripheral Nerve Blocks

General Considerations. Peripheral application of local anesthetics to block nociceptive neural transmission can be a useful adjunct in the treatment of acute postoperative pain. Although peripheral neural blocks are simple to perform and have a historical record of safety, the relatively short duration of analgesia and the selective nature of these blocks preclude their general application to all patient populations. With proper selection of the patient and the local anesthetic, the pain relief afforded by regional nerve blocks may be superior to that achievable with systemic opioids.

Mechanism of Action of Local Anesthetics. The electrophysiology of local anesthetics is described in detail elsewhere in this textbook (see Chapter 17). Local anesthetics produce their neuronal blocking effect by diffusing across the nerve membrane and inhibiting sodium channels, thereby preventing the normal influx of sodium ions necessary for depolarization and nerve transmission. Thus, the membrane remains in its normal polarized state, and neither local miniature endplate

potentials nor action potentials are generated.

Local Infiltration. Local infiltration, the instillation of local anesthetics in the vicinity of the surgical incision, is a simple technique for providing postoperative analgesia for the first several hours after a minor surgical procedure. Needle aspiration before injection should be performed to avoid intravascular injection or perforation of deep vascular structures. Even when blood has not been aspirated before injection, it is still possible for local anesthetic to be delivered intravascularly during a local infiltration. In addition to intravascular injection, exceeding recommended total volume and dosages of local anesthetic is another factor that can be responsible for untoward reactions.

The primary advantages of the local infiltration technique are simplicity and the ability to block afferent nerve activity in the area of the incision without affecting the general sensorium. A major disadvantage is the limited duration of analgesia, which usually lasts only several hours. The most commonly used local anesthetics for this procedure are bupivacaine and ropivacaine because of their long duration of effect compared with most other local anesthetics.

A special type of local infiltration is the intra-articular injection of local anesthetics after arthroscopic procedures. This technique decreases postoperative discomfort and facilitates postsurgical recuperation.[175] Bupivacaine is the most commonly used local anesthetic, with doses of 100 mg providing effective analgesia while maintaining serum concentrations below toxic levels.[175,176]

Intercostal. Intercostal nerve blocks are useful for providing analgesia after operations of the thorax and upper abdomen. A 22- or 25-gauge needle is advanced at the midaxillary or postaxillary line until a rib is contacted. The needle is then walked off the inferior border and advanced 1 mm. When performing intercostal blocks for large thoracic incisions, it is important to identify the sensory dermatomes supplying the surgical incision so each can be blocked. Dermatomes that supply the area where thoracostomy drainage tubes may be inserted should also be blocked. When abdominal incisions are large and lie in or extend across the midline, a large volume of local anesthetic is needed for optimal pain relief. Providing adequate analgesia for these types of incisions usually requires multiple bilateral intercostal nerve blocks. In general, postoperative pain management for abdominal surgery is better conducted with continuous epidural infusion of opioids or with opioid and local anesthetic solutions. An additional problem with intercostal nerve blocks is the potential for pneumothorax and respiratory compromise. Bupivacaine or bupivacaine with epinephrine is recommended for postsurgical pain relief with an intercostal nerve block. Intercostal blocks should be performed in the midaxillary or posterior axillary line. The site of the injection must be proximal or more posterior to the area of incision. This may occasionally present technical difficulties because the ribs tend to project more anteriorly as they approach the posterior midline. Adequate analgesia for a surgical incision usually requires application of local anesthetic to a minimum of two intercostal segments, and optimal analgesia usually requires that a minimum of three segments be blocked.

An alternative to the injection of local anesthetic on the intercostal nerve is the use of a cryoprobe, which is designed to produce local intercostal nerve freezing (cryoanalgesia).[177] This technique has been reported to produce reversible nerve disruption while preserving intraneural and peridural connective tissues. For optimal results, the cryoprobe should be applied on the intercostal nerve from within the chest by piercing the parietal pleura, and two to three levels above and below the incision should be blocked. Two to 3 weeks after cryoanalgesia, nerve function and structure begin to recover, with complete recovery occurring within 1 to 3 months. Advantages reported with this technique include a low incidence of neuritis or neuroma formation. Because of the extended period of postoperative analgesia, this technique is advantageous when prolonged effective postoperative analgesia is desirable, such as in the patient with chest trauma or significantly limited respiratory function.[178]

Ilioinguinal. An ilioinguinal nerve block is useful for pain relief after inguinal or femoral herniorrhaphy, appendectomy, or procedures involving the scrotum. A simple technique to perform ilioinguinal nerve block involves palpation of the anterior superior iliac spine.[179] Next, a position is located two fingerbreadths medial and two fingerbreadths superior until an imaginary line drawn

from the anterosuperior iliac spine to the umbilicus is reached. At this point, a 22-gauge, 8.75-cm spinal needle is advanced perpendicular to the skin. The needle is advanced slowly and bounced every several millimeters until a paresthesia is elicited. This is indicative of needle contact with the fascia immediately outside the external oblique muscle pierced by the ilioinguinal nerve on its path to more superficial structures. Once the needle is in this location, 10 to 15 mL of local anesthetic is injected after aspiration. The needle is then withdrawn by several centimeters and redirected laterally until the tip reaches the medial edge of the anterior superior iliac spine. An additional 10 to 15 mL of local anesthetic solution is then injected. Complications of ilioinguinal nerve blocks include hemorrhage and hematoma at the injection site. Occasionally, numbness in the distribution of the lateral femoral cutaneous nerve can be demonstrated. Ilioinguinal nerve blocks are useful for acute postoperative analgesia after outpatient procedures such as inguinal herniorrhaphy.

Femoral Nerve Block/Fascia Iliaca Blocks

The increased use of new anticoagulant drugs following joint replacement has prompted the use of alternative peripheral regional nerve block techniques. The techniques of femoral nerve block (FNB) and fascia iliaca block (FIB) are particularly useful for managing pain from total knee arthroplasty. Either FNB or FIB technique may be used as a single injection or continuous catheter technique. The FIB is performed with the patient in the supine position. The site of needle entry is typically 1 cm below the junction of the lateral one-third and medial two-thirds of the inguinal ligament (running between the anterior superior iliac spine and the pubic symphysis medially). A 22-gauge, B bevel-type needle is advanced until two "pops" are felt as the needle traverses first the fascia lata and then fascia iliaca (Fig. 55-11). A volume of 20 to 30 mL of local anesthetic is injected after needle aspiration. The technique for a continuous FIB catheter technique is similar to the single injection technique, except that an 18-gauge epidural needle is advanced with a slight cephalad direction after the second "pop" is felt. A catheter is then threaded through the needle and advanced 5 to 6 cm. A stimulating catheter may aid in directional placement. Infusion of 0.2% ropivacaine or 0.25% bupivacaine (with or without clonidine 1.5 to 2 mcg/kg) up to 10 to 15 mL/hour generally provides adequate analgesia.

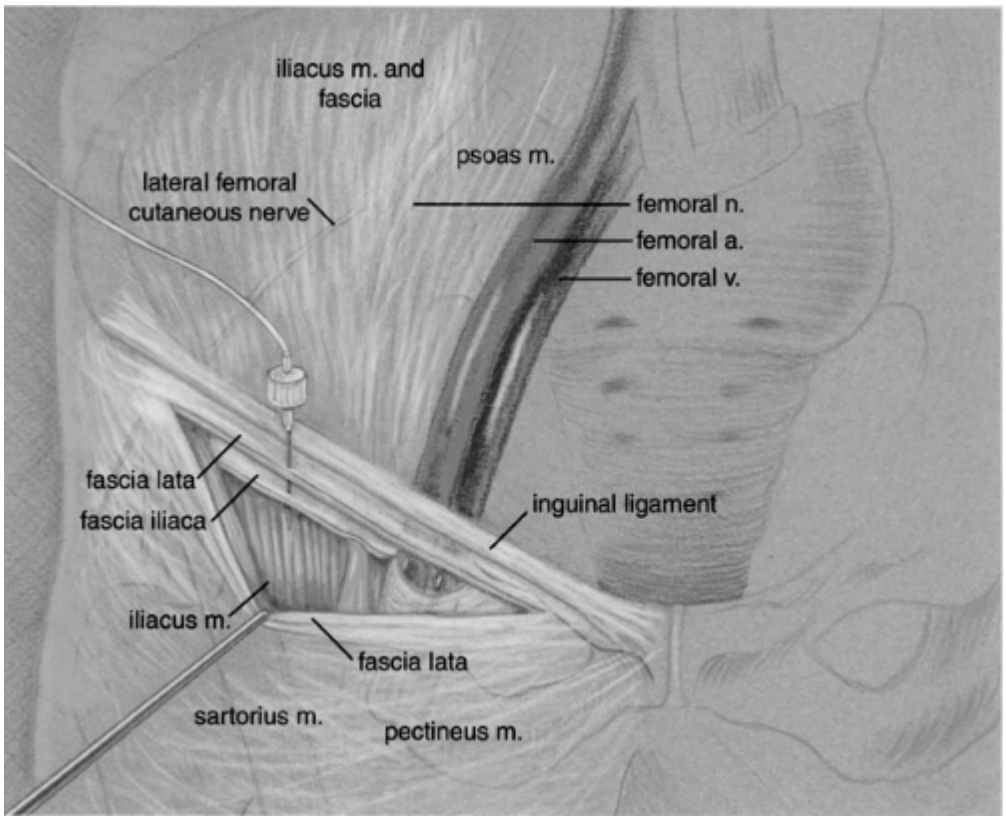

FIGURE 55-11. Anatomic relationships during fascia iliaca block.

Penile. A penile nerve block performed with 0.25% bupivacaine can provide effective analgesia after circumcision or orchiopexy. Two techniques are described for performing this block. One involves injecting half of the volume of local anesthetic at the 10 o'clock position at the base of the penis, with the remainder at the 2 o'clock position. An alternative involves placing the local anesthetic in a ring of the subcutaneous tissue 360 degrees around the base of the penis. Epinephrine-containing local anesthetic should not be used for penile blocks because of the risk of vasoconstriction and ischemic necrosis of the skin.

Brachial Plexus. Continuous postoperative brachial plexus analgesia can be achieved using catheters placed by the infraclavicular, supraclavicular, axillary, or interscalene approach. A catheter-over-needle technique using an 18-gauge, 5-cm Teflon-coated intravenous catheter threaded over a 22-gauge, 8.75-cm spinal needle is one method. A nerve stimulator is essential to elicit paresthesias and identify when the neurovascular bundle is contacted. Another method for catheter placement uses the Seldinger technique. With this technique, the needle is positioned with the aid of a nerve stimulator, and after paresthesias are elicited, a guidewire is passed through the needle. Sterile alligator clips connected to the nerve stimulator can then be placed on the guidewire after the needle has been removed to confirm that the guidewire is still contacting the brachial plexus. A 20-gauge catheter is passed over the guidewire, which is then removed. For rapid sequential confirmation of correct catheter placement, the guidewire can be reinserted through the catheter at any time and a nerve stimulator used to determine if paresthesias can be elicited.

Postoperative brachial plexus analgesia has been described using bupivacaine 0.25% at rates ranging from 6 to 10 mL/hr. When infusion rates are maintained in this range, toxic serum levels are unlikely to occur. Application of this regimen does not preclude the use of any commonly used doses and volumes of local anesthetics currently recommended for surgical anesthesia with brachial plexus blockade. Patient-controlled interscalene brachial plexus analgesia has also been used in patients after shoulder surgery.[180] One disadvantage to this technique is postoperative catheter migration, and the infraclavicular and interscalene approaches may be better suited to continuous postoperative analgesia of the upper extremity because there tends to be less catheter migration than with the axillary approach.

Intrapleural. Intrapleural regional analgesia involves the percutaneous placement of a catheter in the thoracic cage between the visceral and parietal pleurae. The procedure is usually performed with the patient in the lateral decubitus

position. An intercostal space between the fifth and tenth ribs is usually chosen, and a 17-gauge Touhy needle is inserted in the posterior axillary line over the superior aspect of the rib. A saline-lubricated glass syringe filled with 3 to 4 mL of air is attached to the needle, and the syringe and needle unit is advanced with the needle bevel directed in a cephalad direction. Once the pleural space is entered, the negative interpleural pressure draws the syringe plunger down in a manner analogous to the hanging drop technique of Gutierrez used for locating the epidural space. An epidural catheter may then be advanced 6 cm into the pleural space, rapidly to prevent the development of a clinically significant pneumothorax. If patients are mechanically ventilated, positive-pressure ventilation should be interrupted while the needle and catheter are being inserted to prevent injury to the pulmonary parenchyma. When patients are breathing spontaneously, the needle and catheter procedure should be performed during end exhalation.

Local anesthetics placed in the pleural cavity diffuse across the parietal pleura to the intercostal neurovascular bundle, producing a unilateral intercostal nerve block at multiple levels. A more extensive block may be achieved with placement of two catheters in the interpleural space. Interpleural analgesia using intermittent boluses of local anesthetic may be used to provide postoperative analgesia after upper abdominal surgical procedures, such as open cholecystectomy

with subcostal incision and laparoscopic cholecystectomy. Effective postoperative pain relief requires intermittent intrapleural injections every 6 hours with approximately 20 mL of 0.25 to 0.5% bupivacaine. As in other intermittent bolus techniques, peaks and valleys in intrapleural analgesia occur when sequential doses are separated by hours.

Intrapleural analgesia may be less effective for postthoracotomy pain than after other procedures in which the pleura is intact, and there are no pleural drainage tubes to divert the local anesthetic from its site of action. Certain intercostal incisions, particularly those used for anterior thoracotomies, require that pleural drainage tubes be clamped for a short time after each intermittent local anesthetic injection to allow the local anesthetic to cross the parietal pleura and provide effective analgesia. Intermittent clamping of the pleural drainage tube after injection of the local anesthetic may not be tolerated in patients with a moderate or large air leak from the pulmonary parenchyma after thoracotomy. The risk of pneumothorax and the problems of fluctuating levels of analgesia with intermittent dosing of intrapleural catheters suggest that other techniques, such as continuous thoracic epidural analgesia, may be preferable after thoracotomy when there is an anterior intercostal incision.[181,182]

Other Modalities

Psychological Interventions for Postoperative Analgesia

The use of various analgesic techniques involving nerve blocks and opioids applied to the central neuraxis and administered by intravenous infusions has produced dramatic changes in the management of pain. Nevertheless, it is sometimes necessary to augment these techniques with various psychological interventions. Psychological interventions are used widely in the treatment of chronic pain, and the benefit of these behavioral strategies for the management of acute pain is now recognized. This often involves approaching the treatment of pain on a cognitive basis and using interventions such as distraction or imagery that attempt to focus attention away from the painful event. Other, simpler methods consist of educating patients about their surroundings, disease state, treatment plans, and the hospital environment in an effort to reduce fear and anxiety about unknown events or situations in the perioperative period. Despite the banality of this approach, it is a frequently overlooked element when dealing with patients who often are unfamiliar with the hospital environment. Other psychological interventions that may be effective are relaxation techniques such as deep breathing exercises or muscle relaxation training, which can reduce anxiety and muscle tension.

ORGANIZATION OF A POSTOPERATIVE ANALGESIA SERVICE

With the increasing number and complexity of modalities for treating postoperative pain, it is logical that an organized, systematic approach involving all members of the health care team has evolved in the form of the postoperative analgesia service. The anesthesiologist is uniquely qualified to lead this team because of his or her knowledge of the neurophysiology, pathophysiology, pharmacology, and anatomic pathways involved in the modulation of acute pain. Furthermore, with the postoperative analgesia service under the direction of the anesthesiologist, continuity of pain care management is enhanced because the anesthesiologist is routinely involved in the preoperative assessment, intraoperative management, and postoperative follow-up of surgical patients. Because anesthesiologists are the logical choice for managing the postoperative analgesia service, it is desirable that each department of anesthesiology assume responsibility for organizing and maintaining efficient operation of the service.

When initiating a postoperative analgesia service (e.g., physician, pharmacologist, nursing, psychologist), it is essential that the department of anesthesiology have one or more members who will assume the position of director or codirector. This ensures at least one person will be responsible for communication with the pharmacy, nursing, and surgical departments, development of policy and procedural protocols, and departmental representation when issues concerning postoperative pain management arise.

The delivery of central neuraxial opioid analgesia requires cooperation among the anesthesiology,

nursing, surgery, and pharmacy staffs. Success of such an interdisciplinary program for postoperative analgesia often requires significant flexibility to satisfy the needs of all parties concerned. Each institution must identify the approach that is practical and most beneficial for its patients after considering available resources. With these considerations, protocols that reflect individual practice patterns can be effectively developed. These protocols should include written policy and procedure manuals for nursing staff (see Appendices 55-2 and 55-4), as well as preprinted epidural analgesia orders (see Appendix 55-3). Postoperative pain relief has generated intense interest and fostered the introduction of several new analgesic modalities. Although these techniques have been shown to provide better pain relief than conventional intramuscular administration of opioids, the complexity of these modalities requires the use of an organized approach to maximize efficacy while minimizing potentially adverse effects. The transition phase from the operating room to the recovery area, and then to the patient ward, is a crucial period for intervention by the postoperative analgesia service. Optimization of analgesia (while the effects of anesthesia are dissipating) and potential reduction in the incidence or severity of side effects requires proactive evaluation and management in the recovery area by personnel trained and dedicated to these aspects of patient care.

When formulating the strategy for development and initiation of an epidural analgesia service, consideration must be given to the choice of continuous infusion techniques, intermittent bolus regimens, or combinations of these methods. In

addition, with the use of PCA devices, similar protocols outlining the initial parameters for starting therapy should be established to facilitate effective use when these devices are prescribed (see Table 55-7).

The basic goals of the postoperative analgesia service are (1) administering and monitoring postoperative analgesia, and (2) identifying and managing complications or side effects of postoperative analgesic techniques. Implicit in these goals is the inclusion of an active quality assurance program directed at maintaining high-quality patient care while minimizing complications. When the postoperative analgesia service is managed by anesthesiologists, quality assurance monitoring can be applied to the heterogeneous surgical population so the goals of pain management can be refined for the individual patient. This is much more difficult to achieve when individual surgical services are charged with the management of postoperative pain. Nonetheless, successful implementation of these principles requires the cooperation and involvement of health care providers outside the department of anesthesiology, such as surgeons, nurses, and pharmacy personnel.

The foundation of an effective postoperative analgesia service is based on education of all members of the interdisciplinary health care team. This educational process must begin within the department of anesthesiology and, optimally, be directed by physicians with special qualifications in pain medicine and regional anesthesia. A corollary of this educational process is the use of a standardized approach to the initiation of pain management, which may include choices among fixed medication protocols, algorithms to identify and treat inadequate analgesia, and preprinted postoperative orders. The use of such methods increases efficiency, serves as a guideline for health care providers involved with the postoperative analgesia service, and gives the postoperative analgesia service team the flexibility to individualize therapy. This approach also facilitates the education of ancillary personnel, such as nursing staff, necessary to the functioning of the service.

Ideally, all members of each anesthesia department should become well versed in the basic principles necessary for the day-to-day operation of the postoperative analgesia service. Although its management usually is the responsibility of a limited number of anesthesia personnel, education of all members of the department ensures the smooth operation of the service when those key individuals are not available after hours or on weekends. Although patients receiving postoperative analgesia should be seen on a regular basis by the anesthesiologist, it may be necessary for nurse clinicians or anesthesiology residents to assist in performing these functions if the service is very large. It is the responsibility of the anesthesiologist to educate these individuals in the principles of pain management. Nurse clinicians often have excellent rapport

with other nursing staff and can act as effective liaisons. In addition, nurse clinicians can facilitate the operation of the postoperative analgesia service by performing tasks such as charting daily progress notes, inspecting epidural catheter sites, removing epidural catheters when therapy is discontinued, notifying the anesthesiologist of any problems pertaining to pain management, and collecting patient data to facilitate quality assurance. The participation of anesthesiology residents in the postoperative analgesia service allows them to gain knowledge and expertise in this area of perioperative care. Depending on the size of the surgical population and the scope of the service, additional support may be required from clinical pharmacologists, nurse anesthetists, psychologists, or other physicians. Developing this solid foundation is an important consideration when establishing a postoperative analgesia service.

In addition to 24-hour per day support from the anesthesia department, a successful postoperative analgesia service requires the cooperation and education of nursing staff so they are responsive to the needs of the patients. In-service training of hospital nurses requires instruction in the principles of analgesic techniques, including appropriate aspects of neuroanatomy, neuropsychopharmacology, side effects and their treatment, monitoring skills, analgesia assessment, and the technical aspects of the operation of PCA and epidural infusion devices. This instruction should also be conducted under the supervision of the anesthesiologist in charge of the postoperative analgesia service, but may also involve a clinical nurse specialist, trained by the anesthesiology department, who may assist in solving nursing problems related to the operation of the service. To minimize dosing and medication errors, and to improve patient comfort by early treatment of inadequate analgesia and complications such as pruritus, nurses must understand the use of the standardized protocols.

One additional benefit of such a model is the ability to transition patients from epidural or PCA techniques to oral or other analgesia delivery systems, facilitating postoperative discharge. This can usually be accomplished for most surgical patients by converting from the parenteral techniques to an orally administered acetaminophen–hydrocodone or acetaminophen–codeine preparation. However, some patients experience difficulty with transition from parenteral therapy and require more potent opioids and other nonopioid adjuvants. Such patients have typically received opioids chronically for pain and have higher analgesic requirements to achieve satisfactory postoperative pain control.[165] Because of their experience with the principles and use of the more potent, longer-acting oral opioid preparations (in the setting of chronic pain management), anesthesiologists can facilitate the management of this complicated set of patients. For example, combining sustained-release forms of long-duration drugs such as oxycodone or morphine sulfate every 6 to 12 hours can be effective in the transition from parenteral analgesic therapy. Using such an approach, this transition may be accomplished more efficiently and potentially hastens postsurgical discharge in patients who have received opioids chronically for pain.

Another key aspect to the initiation of a postoperative analgesia service is the identification of patient populations that are most likely to benefit from improved postoperative pain management. Patients undergoing thoracic and upper abdominal procedures, major orthopaedic operations such as hip surgery, and high-risk vascular surgical procedures are examples of groups in whom effective postoperative pain management produces the most rewarding results. It is often useful to consider a pilot program using PCA or epidural analgesia when surgeons are doubtful or hesitant about the efficacy of these methods. After the utility of the postoperative analgesia service has been demonstrated to surgeons, referring physicians, and others, the service can expand logically to patient populations in which improved analgesia will be obvious, but in which the effects on outcome may be more subtle. Initiation of the service in any subset of patients also requires the education of surgical staff regarding (1) the advantages to their practice of being able to offer patients surgery with less postoperative discomfort, and (2) the potential differences in outcome when using certain methods of postoperative analgesia. Despite the lack of large-scale, randomized studies to demonstrate that improved postoperative analgesia (especially the use of epidural analgesia in high-risk patients) is definitively associated with improved outcomes (such as shorter, less expensive hospital stays, with fewer major complications), there is more than enough evidence currently in the literature to support the important role of epidural

anesthesia and analgesia in clinical practice. Surgeons must understand that their patients will receive attentive care and that an essential element of the postoperative analgesia service is the maintenance of a cooperative spirit among disciplines.

Once the appropriate subsets of patients have been identified and educated, the physicians in charge of initiating the

postoperative analgesia service must make plans for the provision of the capital resources necessary to operate the service. Plans must be made regarding types of equipment needed for continuous or patient-controlled intravenous catheter or epidural analgesia, whether such devices are to be rented or purchased, types of monitoring equipment deemed necessary, any pharmacy-related factors necessary to prepare solutions of drugs for administration, and the printing of standard orders for the postoperative management of pain and treatment of complications. Decisions regarding funding sources for these capital expenses often must involve discussions with hospital administrators. In the present medical-economic climate, hospital administrators may be opposed to the purchase of new equipment if old methods appear to be functional. It is important to educate administrators who are reluctant to support the concept of a postoperative analgesia service about the potential benefits to some patients in terms of shorter, less complicated, less expensive hospital stays. Not only can the service be cost effective, but sometimes it can be used by hospital administrators as a marketing tool to attract surgical patients. Preprinted order forms usually require approval from the hospital's medical records/forms department. Job descriptions and resources are necessary to define and fund support staff such as nurse clinicians, psychologists, or clinical pharmacologists. Thus, a significant degree of planning, effort, and commitment is necessary to initiate a properly functioning postoperative analgesia service. When such efforts are expended, the establishment of such a service allows the anesthesiologist to play an important role in the postoperative period and to provide a valuable service to patients.

SPECIAL CONSIDERATIONS IN PEDIATRIC ACUTE PAIN MANAGEMENT

Acute pain management in the pediatric patient poses a unique challenge to the anesthesiologist. It is often more difficult to evaluate pain intensity in children because the expression of pain is manifested over a broad emotional spectrum. For instance, some children withdraw and become nonverbal with the onset of pain, whereas others become emotionally labile, with crying, screaming, and violent behavior. Psychological distress is often compounded in children by separation from their parents and by inadequate understanding of their disease and its treatment. Furthermore, depending on age, lack of cognitive development makes it more difficult to communicate relevant concepts to children. In view of these difficulties, a useful monitor of analgesic efficacy in children is behavior observation. Some behavior such as crying can be easily understood, but social withdrawal and the inability to be distracted often indicate that a young patient has distressing pain.

The selection and dosing of analgesic agents also requires special attention in the pediatric patient (Table 55-12). Neonates and infants, because of immature hepatic function and reduced plasma proteins and plasma protein-binding capacity, exhibit a higher fraction of free drug in the central compartment. This effect is offset to some degree by the higher total body water and extracellular fluid, and larger blood volume in this group compared with adults. Increased susceptibility to the respiratory depressant component of opioids may be a result of the increased fraction of cardiac output to the developing brain or of reduced metabolic pathways, leading to accumulation of opioids and their metabolites. Morphine exhibits an increase in half-life and respiratory depressant effect in infants younger than 1 month of age, owing to immature glucuronidation pathways. The half-lives of meperidine and fentanyl are similarly increased during the first 3 months of life. The pharmacokinetics of local anesthetics exhibit a similar pattern of development in neonates and infants. Free fractions of local anesthetics approach those seen in adults by 6 months of age (Table 55-13).

TABLE 55-12 Pharmacologic Considerations For Pediatric Patients

·DRUG	·DOSE (Age > 6 mo)[a]	·INTERVAL (hr)	·ROUTE	·COMMENTS
·NONOPIOID				
Acetaminophen	5–15 mg/kg	4–6	PO	Overdose may cause hepatotoxicity
Ibuprofen	20 mg/kg	4–6	Rectal	
Naproxen	8 mg/kg	6	PO	
	5 mg/kg	8–12	PO	
·OPIOID				
Codeine	0.5–1 mg/kg	4–6	PO	Most commonly combined with acetaminophen
Oxycodone	0.005–0.15 mg/kg	4–6	PO	Similar to codeine
		3–4	IM	May cause less constipation, ileus, and urinary retention than morphine
Meperidine	1–1.5 mg/kg	2–3	IV	
	0.8–1 mg/kg	3–4	IM	
Morphine	0.1–0.15 mg/kg	2	IV	
	0.08–0.1 mg/kg	12–24	IV	
	0.05–0.06 mg/kg	12–24	EPI	

	50 µg/kg	12–24	EPI	Continuous infusion
	120–150µg/kg	1–2	Caudal	Abdominal surgery
	50–100 µg/kg		IV	Thoracic surgery
Fentanyl	1–1.5 mg/kg 2–4 µg/kg/hr		IV	Diluted in equal volume of normal saline Minimum age, 1 yr Continuous infusion
[a]Fractionation of dose is recommended for age < 6 mo.				
Caudal, S4–S5; EPI, epidural (L3–L5); IM, intramuscular; IV, intravenous: PO, by mouth.				

TABLE 55-13 Maximum Local Anesthetic Doses In Infants and Children

·DRUG	·INFANT DOSE (mg/kg): AGE	·CHILD DOSE (mg/kg)

Oral Analgesics

Nonopioid

NSAIDs are useful oral drugs for acute postoperative pain management in the pediatric population. Ibuprofen can be administered at 6- to 8-hour intervals in doses of 8 mg/kg. Contraindications to the use of NSAIDs in the pediatric population are similar to those in adults. The most frequently encountered adverse effects are gastrointestinal. Platelet function alteration can occur with non–COX-2 agents, but this is usually not a significant clinical problem after short-term administration in the postoperative period. Acetaminophen has fewer side effects than ibuprofen and can be administered in doses of 5 to 15 mg/kg orally or 20 mg/kg rectally every 4 to 6 hours. Ketorolac in doses of 0.4 to 1.0 mg/kg is also useful for mild to moderate postoperative pain in children when parenteral administration is desirable, but may be associated with a greater incidence of vomiting than morphine.[183,184]

Opioid

Codeine in combination with acetaminophen is a commonly used oral preparation for moderate postoperative pain in the pediatric population. The recommended oral dosage range is 0.5 to 1 mg/kg every 4 to 6 hours. Internationally, tramadol 1 to 2 mg/kg every 6 hours PRN has been used for pain in pediatric patients.

Patient-Controlled Analgesia

PCA is an opioid delivery system that has been used with increasing frequency to treat acute postoperative pain in children. Morphine sulfate given as a loading dose of 0.1 to 0.2 mg/kg and administered as small incremental boluses of 0.01 to 0.03 mg/kg can be used to initiate PCA therapy. After this, maintenance doses of morphine sulfate (0.01 to 0.015 mg/kg) given every 6 to 10 minutes with a 4-hour limit of 0.25 mg/kg are appropriate. Incorporation of a continuous infusion (0.01 to 0.015 mg/kg/h) into the regimen may be beneficial.[185] Smaller doses of morphine may be used if ketorolac is used in conjunction with PCA.[186] Meperidine maintenance doses of 0.15 to 0.20 mg/kg with a 4-hour limit of 2 to 3 mg/kg has been used but may be associated with neurotoxic side effects.

Epidural Opioids

Similar to other methods of pain control, the use of epidural opioids has not been extensively studied in the pediatric population. Lumbar epidural analgesia has been used for young patients undergoing abdominal, urologic, or orthopaedic procedures. Because lumbar epidural catheters may be more difficult to place in the pediatric patient than in adults, an alternative is to perform a "kiddie caudal" with a mixture of local anesthetic and opioid for postoperative analgesia. Morphine is the preferable drug for single-injection techniques and can be administered as a 0.05 mg/kg bolus in volumes appropriate for the age and weight of the child.[175] Additional information on caudal analgesia is reported in earlier sections of this chapter.

RELATIONSHIP BETWEEN ACUTE (EUDYNIA) AND CHRONIC PAIN (MALDYNIA)

For an individual patient, the development of a chronic pain syndrome may simply be the extension of inadequately treated acute pain after trauma or surgery. Differentiation between acute (eudynia as a symptom) and chronic pain (maldynia as a syndrome) is important in clinical practice because therapy usually is vastly different. Pain persisting longer than 30 days can be viewed as chronic pain. Acute pain management techniques usually are not effective and may cause other problems when applied to chronic pain. For instance, systemic opioids for long-term use are often associated with the development of tolerance and, occasionally, drug dependency. Chronic pain is not simply the extension of acute pain as an isolated entity but involves multiple

additional factors such as altered mechanisms of nociceptive modulation, and centralization and amplification of neural responses that account for the differences in clinical presentation and, more importantly, in choice of therapeutic modality.

SUMMARY

This chapter reviews the physiology of nociception and the production of acute postoperative pain, as well as compares and contrastes various methods for analgesia. In addition, the rationale behind the development of a multidisciplinary team of health care personnel aimed at managing postoperative pain has been addressed. Postoperative pain management requires continued study to refine, explore, and open new avenues for further improvement of current techniques.

APPENDIX

APPENDIX 55-1 Solutions and Rates of Patient-Controlled Epidural Analgesia

STANDARD FENTANYL SOLUTIONS

Fentanyl 3,000 µg with bupivacaine 300 mg in 300 mL normal saline (NS)—adults <70 yr, >50 kg

Fentanyl 1,500 µg with bupivacaine 300 mg in 300 mL NS—adults ⩾70 yr, ⩽50 kg, history of sleep apnea

Maximum continuous rate 10 mL/hr for lumbar epidural catheters (total infusion rate ⩽40 mL/4 hr)

Examples of Continuous and Demand Dosing Combinations for Fentanyl Solutions

- 4 mL/hr continuous, demand mode 1 mL q10min, 40 mL/4 hr lockout
- 4 mL/hr continuous, demand mode 2 mL q20min, 40 mL/4 hr lockout
- 5 mL/hr continuous, demand mode 1 mL q12min, 40 mL/4 hr lockout

- 6 mL/hr continuous, demand mode 1 mL q15min, 40 mL/4 hr lockout
- 6 mL/hr continuous, demand mode 2 mL q30min, 40 mL/4 hr lockout
- 7 mL/hr continuous, demand mode 1 mL q20min, 40 mL/4 hr lockout
- 8 mL/hr continuous, demand mode 1 mL q30min, 40 mL/4 hr lockout
- 8 mL/hr continuous, demand mode 2 mL q60min, 40 mL/4 hr lockout
- 9 mL/hr continuous, demand mode 1 mL q60min, 40 mL/4 hr lockout
- 10 mL/hr, no demand mode

Morphine Solutions

Morphine 30 mg with bupivacaine 300 mg in 300 mL NS—adults <70 yr, >50 kg

Morphine 15 mg with bupivacaine 300 mg in 150 mL NS—adults ⩾70 yr, ⩽50 kg, history of sleep apnea

Maximum continuous rate 6 mL/hr for lumbar or thoracic epidural catheters (total infusion rate ⩽ 24 mL/4 hr)

Examples of Continuous and Demand Dosing Combinations for Morphine Solutions

- 3 mL/hr continuous, demand mode 1 mL q20min, 24 mL/4 hr lockout
- 4 mL/hr continuous, demand mode 1 mL q30min, 24 mL/4 hr lockout
- 5 mL/hr continuous, demand mode 1 mL q60min, 24 mL/4 hr lockout
- 6 mL/hr continuous, no demand mode

Appendix 55-2 Policy and Procedures for Initiation and Nursing Care of Patients with Postoperative Epidural Analgesia

I. Purpose

   A. To list guidelines for initiating and monitoring patients receiving postoperative epidural analgesia and to provide quality assurance and patient safety

II. Candidates

   A. Postsurgical patients who have no previous history of allergy to the ordered analgesics

   B. Patients must not have any contraindications to the placement of an epidural catheter (e.g., sepsis, severe coagulation abnormality, hypovolemia, head injury)

III. Equipment

   A. Epidural infusion pump

   B. Cassette tubing

   C. Epidural catheter tray

   D. Micropore tape

   E. Tegaderm dressing

   F. Apnea monitor (if required)

   G. Naloxone 0.4 mg/mL—two ampules

   H. 3-mL syringes with needles

   I. Alcohol wipes

   J. Epidural solution

      1. Fentanyl 0.001%/bupivacaine 0.1%—300 mL (age <70 yr)

2. Fentanyl 0.0005%/bupivacaine 0.1%—300 mL (age ⩾70 yr, ⩽50 kg, history of sleep apnea)
3. Morphine 0.01%/bupivacaine 0.1%—300 mL (age <70 yr)
4. Morphine 0.005%/bupivacaine 0.1%—300 mL (age ⩾70 yr, ⩽50 kg, history of sleep apnea)

IV. Treatment initiation and guidelines

A. Placement of epidural catheter is performed by the anesthesiologist.

B. Epidural order sheet must be completed by the anesthesiologist.

1. Anesthesiologist's written order for epidural solution to include the name and amount of fluid, rate of infusion, name and dosage of any medications added, and supplemental intravenous/intramuscular pain medications as required.

C. Epidural solution must be administered via designated infusion pump.

D. Baseline blood pressure and respiratory rate must be documented before initiating epidural infusion.

E. Blood pressure, heart rate, level of consciousness, and temperature are to be monitored every 4 hours for the first 24 hours of the epidural infusion.

F. Respiratory monitoring

1. An apnea monitor is required for patients who received epidural narcotic bolus of MSO_4 ⩾2 mg. Patients may receive an epidural bolus of fentanyl 50 to 150 µg without the routine use of an apnea monitor.
2. Respiratory rate to be monitored every hour for the first 24 hours of the epidural infusion.

a. Naloxone, syringe, and needle are to be readily available at all times.

G. The epidural solution bag and volumetric pump cassette are not changed unless otherwise ordered.

V. Nursing responsibilities

A. Record vital signs (blood pressure, level of consciousness, ambulation, temperature) every 4 hours for first 24 hours of epidural infusion, then as ordered.

B. Record respiratory rates every 1 hour for the first 24 hours of the epidural infusion and every 4 hours thereafter.

1. If the respiratory rate falls below 8 per minute, notify the postoperative analgesia service (PAS) and administer naloxone as ordered.

C. Record all analgesic medications administered on the medication record.

D. Using the visual analog scale, record patient's subjective level of pain with vital signs on flow sheet.

1. Scale for pain: 0 to 10, with 0 = no pain and 10 = worst pain ever.

E. Assess epidural catheter integrity, and check dressing for wetness every shift and as needed.

1. Reinforce with dry 4 × 4 gauze if dressing is wet.
2. Cover with clear plastic tape.
3. Notify PAS if excessive wetness or integrity of catheter is in question.

a. If epidural catheter becomes dislodged or disconnected:

i. Notify PAS.

ii. If catheter is disconnected, cover end of catheter with sterile 4 × 4 gauze (do not reconnect).

iii. If catheter becomes dislodged, keep for inspection by anesthesiologist.

F. Assess and document signs and symptoms of side effects.

1. Pruritus with and without rash
2. Nausea or vomiting
3. Paresthesia, numbness, motor weakness

4. Headache
5. Backache
6. Signs of infection around catheter site
7. Urinary retention

G. Assess and document the following if patient is on anticoagulation medication:

1. Notify PAS if patient receiving warfarin has an international normalized ratio (INR) >1.8.
2. Notify PAS if a second anticoagulant is ordered.

H. Record any prescribed treatment administered for side effects or supplemental analgesics on patient care record.

VI. Postoperative analgesia service responsibilities

A. Team members will see patients daily and chart progress notes documenting adequacy of pain relief and the occurrence of side effects or problems associated with epidural use; will adjust therapy or institute test dose algorithm if current protocol is associated with inadequate analgesia, side effects, or complications; and will collect and maintain data for review by anesthesiologist on a weekly basis.

B. Organize and conduct inservice training of hospital nursing staff.

C. Review epidural medication record to ensure adequate documentation of use and disposal of medications.

D. Evaluate and make recommendations regarding new equipment for epidural analgesia.

E. Analyze data, identify problems, propose changes, if any, and evaluate changes for quality assurance purposes.

F. Review anticoagulation medication taken along with coagulation status before epidural catheter removal.

1. The epidural catheter should not be removed for at least 4 hours after the previous dose of subcutaneous standard heparin or discontinuation of intravenous heparin infusion. The next subcutaneous dose or the resumption of the intravenous infusion should be at least 2 hours after catheter removal.
2. The epidural catheter should not be removed for at least 10 hours after the previous dose of a low-molecular-weight heparin. The next dose should not be given for at least 2 hours after catheter removal.
3. Patients receiving warfarin should not have the epidural catheter removed until INR <1.8 and platelet count >80,000 per mm^3. After epidural catheter removal in

patients with INR >1.5, order neurosensory assessments to be made every 4 hours for the next 24 hours.

VII. Pharmacy responsibilities

A. Daily log of all patients receiving epidural analgesia with type of solution and amount dispensed.

B. Computer printout of all patients started on epidural analgesia in the last 24 hours. Printout should be available in pharmacy at 8 AM Monday through Saturday. Patients started on epidural analgesia on Saturday or Sunday will be on the Monday morning printout. This list will be picked up by the PAS personnel to aid in identifying those patients started on epidural analgesia.

C. Collaborate with PAS personnel in quality assurance matters.

VIII. Termination

A. Epidural infusions ordinarily will be terminated by the PAS in conjunction with the primary surgical service using guidelines established for the type of surgical procedure and patients' analgesic requirements.

IX. Questions/problems

A. Any questions or problems regarding epidural drip or catheter are referred to the PAS between 8:00 AM and 4:30 PM, or to the anesthesiologist on call after 4:00 PM and weekends.

Appendix 55-3 Postoperative Epidural Analgesia Order Sheet

(PLEASE CIRCLE ORDERS TO BE IMPLEMENTED AND COMPLETE BLANKS WHERE APPROPRIATE)

(DATE AND TIME FOR EACH PROCEDURE IS TO BE NOTED)

1. Admit to PACU or SICU, routine PACU or SICU VS.
2. Discharge from PACU per anesthesia care team.
3. On floor (circle):
    a. Monitoring
        1. Apnea monitor
        2. Telemetry
        3. Pulse oximetry
    b. VS q4hr, respiratory rate q1hr for the first 24 hours.
    c. Tape two ampules of naloxone with syringe and needle at bedside.
    d. If respiratory rate <8 per minute, give 0.4 mg naloxone intravenously stat and call anesthesia.
4. Epidural solution (circle one):
    a. Morphine 15 mg with bupivacaine 300 mg in 300 mL NS, rate _____ mL/hr (age ⩾70 yr, ⩽50 kg, history of sleep apnea)
    b. Morphine 30 mg with bupivacaine 300 mg in 300 mL NS, rate _____ mL/hr

c. Fentanyl 1,500 µg with bupivacaine 300 mg in 300 mL NS, rate _____ mL/hr (age ⩾70 yr, ⩽50 kg, history of sleep apnea)

d. Fentanyl 3,000 µg with bupivacaine 300 mg in 300 mL NS, rate _____ mL/hr

e. PATIENT-ASSISTED EPIDURAL MODE _____ mL q _____ min, with _____ mL/4 hr lockout

5. Supplemental medications (circle):

   a. Morphine 2 mg intravenously, intramuscularly, or sq q2–4hr PRN VAS > _____

   b. Metoclopramide 10 mg intramuscularly q4–6hr PRN for nausea

   c. Nalbuphine 10 mg intramuscularly or sq q4–6hr PRN for pruritus

   d. Ketorolac 30 mg intramuscularly q6hr × 48 hr PRN for pain; if patient >65 yr or <65 kg, give 15 mg intramuscularly q6hr × 48 hr PRN for pain

6. Nursing staff on floor call postoperative analgesia service × 24 hours per day if any problems arise or if catheter needs to be discontinued.

7. All other preoperative orders, medications, and diet per service with the exception of opioids and sedatives.

Signed _____, MD Date _____

Appendix 55-4 Patient-Controlled Analgesia Service Protocol for Postsurgical Pain Relief

I. Purpose

   A. To list guidelines to follow when PCA is ordered and to provide quality assurance and patient safety

II. Candidates

   A. Postsurgical patients who have no previous history of allergy to the ordered analgesics

   B. Patients must be mentally alert, understand basic instructions, and be physically capable of operating the PCA infusion device

III. Treatment initiation

   A. Treatment may be initiated by any surgical service and by anesthesia personnel. PCA treatment initiated by surgical services must conform to the guidelines listed as follows.

IV. Postoperative PCA guidelines

   A. The physician's order for PCA must include the following:

      1. Drug (Only morphine and meperidine are available for routine use for postsurgical pain. Fentanyl and other drugs may be used only with the approval of the postoperative analgesia service [PAS] physician or anesthesiologist on call when the PAS service is not available.)

      2. Loading dose (if patient has pain when PCA is ordered)

      3. Maintenance infusion (if desired)

4. Incremental or maintenance dose
5. Lockout interval
6. 4-hr limit
7. Mode of operation—PCA

B. Recommended starting parameters

1. Loading dose, morphine 1–4 mg, meperidine 10–40 mg
2. Maintenance dose, morphine 1 mg, meperidine 10 mg
3. Lockout interval, 6–10 min
4. 4-hr limit, morphine 20 mg, meperidine 200 mg
5. Mode of operation—PCA

V. Surgical staff

A. Initiate preprinted order sheet.

B. Evaluate adequacy of therapy.

C. Contact PAS personnel if inadequate pain relief or patient has requirements for more complex PCA dosing.

D. Monitor for complications.

VI. Nursing responsibilities

A. Obtain and assure prompt delivery of PCA morphine/meperidine vials from pharmacy to nursing units.

B. Verify proper and patent intravenous line.

C. Monitor and record vital signs per orders.

D. Reinforce patient teaching on use of PCA, if needed.

E. Assess pain level and effectiveness of PCA.

F. Change PCA tubing every 48 hours.

G. Document accurate dosage of narcotic used or wasted in separate PCA medication sheets (two signatures needed for drug wasted).

H. Verify that PCA is programmed to deliver dosage as ordered.

I. At the change of shift, the incoming and outgoing nurses will check the PCA flow sheet, the pump readout, and the labeled syringe. The amount of drug administered in the previous 8 hours will be recorded on the PCA medication sheet.

J. Notify PAS personnel and primary surgical service if the patient experiences side effects, complications, or inadequate analgesia.

K. Assess and document signs and symptoms of side effects.

1. Pruritus with and without rash
2. Nausea or vomiting
3. Sedation/decreased mentation
4. Decreased respiration
5. Ileus/constipation

6. Signs of infection or infiltration around catheter site
7. Urinary retention

L. Record any prescribed treatment administered for side effects or supplemental analgesics on patient care record.

VII. Postoperative analgesia service responsibilities

A. Instruct patients on the use of PCA when ordered by anesthesia and provide additional teaching if PCA is ordered by surgical service.

B. Team members will see patients daily and chart progress notes documenting adequacy of pain relief and the occurrence of side effects or problems associated with PCA use. Will adjust therapy or substitute with a new protocol if current therapy is associated with inadequate analgesia, side effects, or complications. Will collect and maintain data for review by anesthesiologist on a weekly basis.

C. Organize and conduct inservice training of hospital nursing staff.

D. Review PCA medication record to ensure adequate documentation of use and disposal of medications.

E. Evaluate and make recommendations regarding new equipment for PCA.

F. Analyze data, identify problems, propose changes, if any, and evaluate changes for quality assurance purposes.

VIII. Pharmacy responsibilities

A. Daily log of all patients receiving PCA with type of solution and amount dispensed.

B. Computer printout of all patients started on epidural analgesia in the last 24 hours. Printout should be available in pharmacy at 8 AM Monday through Saturday. Patients started on PCA on Saturday or Sunday will be on the Monday morning printout. This list will be picked up by the PAS personnel to aid in identifying those patients started on epidural analgesia.

C. Collaborate with PAS personnel in quality assurance matters.

IX. Termination

A. PCA ordinarily will be terminated by the PAS in conjunction with the primary surgical service using guidelines established for the type of surgical procedure and patients' analgesic requirements.

X. Questions/problems

A. Any questions or problems regarding PCA are referred to the postoperative analgesia service between 8:00 AM and 4:30 PM or to the anesthesiologist on call after 4:00 PM and weekends.

Chapter 56

Chronic Pain Management

Stephen E. Abram

KEY POINTS

1	Persistent activation of peripheral nociceptors produces sensitization of spinal cord pain transmission systems that is triggered by the prolonged release of glutamate, substance P, and other peptides, and mediated through N-methyl-D-aspartate (NMDA) receptor-dependent mechanisms.
2	Tissue inflammation, nerve injury, and central nervous system (CNS) injury or infection can activate glial cells in the CNS and glia-like elements in peripheral nerves. Activated glia release proinflammatory cytokines and other substances that increase the sensitivity of surrounding neurons to both noxious and nonnoxious stimulation.
3	Central sensitization, whether triggered by neuronal or glial mechanisms, leads to reduced responsiveness to both endogenous and exogenous opioids. Prolonged opioid administration, even in the absence of nerve or tissue injury, can produce central sensitization and hyperalgesia through both NMDA-mediated neuronal mechanisms and glial activation.
4	Interactions between the sympathetic nervous system and pain projections systems can add to the sensitized state of the nervous system seen in a number of chronic pain syndromes. Complex regional pain syndromes are seen in both the presence and absence of significant nerve injury and may or may not have a component of sympathetically mediated pain.
5	Low back pain and cervical pain are associated with multiple physical pain mechanisms, including discogenic, radicular, arthropathic, and myofascial syndromes. Most patients with chronic back or neck pain have more than one active pain mechanism. This is particularly true of patients who have failed multiple surgical procedures.
6	Medication management of chronic pain patients can provide substantial pain reduction for some patients, but rarely produces complete or near-complete relief. Long-term opioid administration should be continued only when there is substantial pain reduction, significant improvement in physical function, minimal dose escalation over time, and minimal side effects.

7	Cancer pain needs to be addressed promptly and aggressively with management, based on careful determination of the site and mechanism of pain. Opioids should be given in adequate doses throughout the course of the disease. Spinal drug administration and neuroablative procedures are considered when tolerance and side effects limit the ability of systemic medications to provide significant pain relief.
8	The great majority of chronic pain patients have significant disability related to loss of physical conditioning and psychopathological changes. Any management program that fails to include rehabilitation, patient education, and psychological therapy will provide suboptimal treatment to most chronic pain patients.
9	New, invasive, and often expensive techniques have expanded the ability of physicians to provide effective nonsurgical treatment of painful conditions. It is essential that these technologies be critically assessed and that they are applied only to those conditions that have a high likelihood of success.

Perhaps the most common factor associated with treatment failure of chronic pain is the assumption that treatment principles that apply to acute pain management are appropriate for chronic pain. It is often assumed that if we can find the source of the pain, the "pain generator," and remove it, denervate it, or modify the pathologic process, the pain will go away. Similarly, we assume the pharmacologic approaches that work for acute pain also apply to chronic pain. For many, perhaps most chronic pain patients, such approaches will invariably fail.

Persistent pain, especially pain associated with nerve injury, produces significant and often permanent changes in the way the nervous system processes sensory information. Activation of peripheral nociceptors, nerve injury, tissue inflammation, and infection can produce dramatic changes in firing thresholds for neurons in the peripheral and central nervous system (CNS). Activation of glial cells leads to the production of substances that greatly enhance the responses to both painful and nonpainful tissue stimulation. Persistent firing of nociceptive afferent fibers leads to high levels of excitatory amino acids in the CNS, which can cause injury to neurons that normally inhibit pain projection neurons.

Persistent pain can also lead to anatomic changes in both the peripheral and CNS. Following nerve injury, a variety of neuronal plasticity changes occur, such as sprouting of dendrites on neurons projecting to the dorsal horn or ingrowth os sympathetic fibers into the dorsal root ganglia. These anatomic deviations undoubtedly produce some of the functional changes characteristic of chronic pain states.

Opioids, the mainstay of acute pain management, behave very differently when given chronically. Daily opioid administration to intact animals consistently produces hyperalgesia within 1 week. This phenomenon occurs more rapidly and more profoundly in animals subjected to peripheral nerve injury. The neurophysiologic mechanisms of these changes are now well characterized. These data lead to concern about the advisability of long-term administration of opioids to those patients who experience minimal relief from high doses.

These recently characterized physiologic changes represent only a portion of the story. Persistent pain leads to inactivity, deconditioning, muscle and tendon shortening and fibrosis, and joint dysfunction. It is also associated with behavioral changes that lead to dramatic and often devastating deterioration in function, and decreased participation in vocational, social, and recreational activities. Depression, which occurs in the majority of patients with chronic pain, can

be even more debilitating than the original painful condition.

No two patients share the same constellation of pathologic, physiologic, physical, and psychological changes. Each patient deserves assessment based on a careful medical, social, and psychological evaluation. Evaluation should include both a psychological and a functional assessment, as well as a plan for rehabilitative therapies. This can only be accomplished in a health care environment that includes close cooperation among multiple disciplines. At minimum, medical, rehabilitation, psychological, and social services should be provided in a coordinated fashion. The picture is further complicated by the presence in the chronic pain patient population of individuals whose complaints are related to addiction rather than pain. The practitioner must also confront the reality that drug diversion is a source of income for some individuals whose pain complaints serve only to provide a steady source of medications for resale on the street. Resources should therefore be readily available for identifying and treating addiction.

PAIN PATHWAYS AND MECHANISMS

Pain is most often experienced as a result of injury. Its survival value to an organism is based on the fact that it is initiated by tissue injury or by stimuli that threaten damage, and that it produces sufficient arousal and distress so as to unlikely be ignored. It is tempting to envision pain as a straightforward receptive system, with transducers that respond to intense, tissue-threatening stimuli and neurons that project to areas of the brain capable of processing pain information. Unfortunately, such a view of pain perception fails to explain the tremendous variation in pain sensitivity between individuals or the dramatic shifts in sensitivity that can occur in a single individual. It also fails to explain chronic pain that is experienced without any noxious stimulation. Oversimplified anatomic concepts also predispose to simplistic therapeutic interventions, such as neurectomy or rhizotomy, that may intensify pain or create new and often more distressing pain.

In reality, the nociceptive system is highly complex and highly adaptable. Sensitivity of most of its components can be reset by a variety of physiologic and pathologic conditions. Injury to neural elements may result in loss of ability to perceive pain or may cause spontaneous pain or heightened pain sensitivity.

To understand the pathophysiologic mechanisms involved in chronic pain, it is important to have a sound understanding of acute pain pathways and mechanisms. This requires knowledge of the physiology of receptors that respond to tissue-threatening stimuli, the anatomy of peripheral and CNS pathways that are activated, and the mechanisms by which various components of the pain projection system can be acutely sensitized or suppressed. Mechanisms of chronic pain are even more complex. Chronic injury may lead to irreversible alterations in nociceptor sensitivity, to spontaneous firing of peripheral or central pain projection fibers, and to dramatic changes in the reaction of the CNS to sensory inputs. This section provides an overview of the anatomic pathways, the physiologic modulating mechanisms, and the pathologic alterations that are important to the perception of pain.

ANATOMIC PATHWAYS

Nociceptors

Receptors that respond exclusively to intense, potentially tissue-damaging stimuli are well characterized. Cutaneous nociceptors have been extensively studied. Considerably less is known about receptors responsive to intense stimuli found in deep somatic structures, and still less is known about the physiology of visceral pain.

Cutaneous Nociceptors

Most cutaneous nociceptors respond to both intense mechanical stimulation and to high temperatures and are termed mechanoheat nociceptors.[1] These nociceptors do not respond to low-threshold mechanical stimulation (light touch, pressure) or to warm temperatures below the

noxious range. C fiber mechanoheat (CMH) nociceptors respond to temperatures above 43°C. Firing frequency increases in a roughly linear fashion as skin temperature is increased within the noxious range. Repeated or prolonged exposure to suprathreshold stimuli may lead to a reduction in response, or habituation. However, under certain circumstances, previous exposure to a noxious stimulus may lead to an enhanced response (sensitization).

There are two types of A fiber mechanoheat (AMH) nociceptors. Type I AMHs have a very high threshold to thermal stimuli (53°C or greater) and are considered by some investigators to be mechanical nociceptors, or high-threshold mechanoreceptors. These nociceptors are found principally in glabrous skin. Although most have afferent fibers with conduction velocities

in the A-delta range (~30 m/sec), some have conduction velocities as high as 55 m/sec, and would be considered A-b fibers. Type II AMHs are activated by temperatures below activation thresholds of type I AMHs and conduct at about 15 m/sec. These nociceptors also have a much shorter delay between stimulus onset and receptor activation. They are generally found in hairy skin and on the face.

The receptive fields for mechanical and thermal nociception are essentially identical for both CMHs and AMHs. However, there may be differences in the transducer mechanisms for mechanical versus thermal nociception. For instance, application of capsaicin to the skin produces analgesia to noxious thermal, but not mechanical stimulation. Cutaneous AMHs and CMHs are poorly responsive to cooling stimuli, and there is some evidence that afferent fibers from vascular structures are capable of signaling cold pain.[2]

A number of chemical mediators that are released following injury are capable of either activating or sensitizing both CMHs and AMHs. These substances include bradykinin, serotonin, prostaglandins, leukotrienes, histamine, and substance P (SP). Bradykinin, which is released locally following tissue injury, is capable of evoking

pain on intradermal injection, and has been shown to activate both CMHs and AMHs when administered within a nerve's receptive field. In addition, bradykinin produces hyperalgesia to heat stimuli through receptor sensitization. Serotonin can activate nociceptors and potentiates bradykinin-induced pain. Low pH is also capable of producing pain, both by nociceptor activation and by sensitization to mechanical stimuli.[1]

Nociceptors in Other Somatic Structures

A large number of A-delta and C fibers found in muscle, fascia, and tendons are poorly responsive to normal stretching or contraction and are probably nociceptive in function. Many of the C fibers are responsive to chemical irritants, heat, and strong pressure.[3] A few respond to strong contraction and to ischemia, whereas others fire in response to muscle stretching. Some A-delta fibers in muscle have relatively low sensitivity to mechanical stimuli, responding best to chemicals, such as bradykinin. Others, which tend to be arranged near muscle–tendon junctions, respond to local pressure, stretch, and contractions.[3]

Nociceptors in joints are located in the joint capsule, ligaments, periosteum, and articular fat pads, but probably not in cartilage. Small myelinated and unmyelinated fibers terminate in free nerve endings in joints, and A-delta fibers form a widespread plexus in capsules, fat pads, and ligaments.[4] Some of the A-delta axons respond to noxious stimuli. Intracapsular bradykinin in animals produces generalized nociceptive responses that are enhanced by prostaglandins.

Corneal sensitivity serves a primarily protective function, and most stimuli to corneal epithelium are sensed as pain. Innervation is mainly from A-delta fibers, with fine terminals devoid of Schwann cell covering.[3] These fibers have activation thresholds similar to low-threshold mechanoreceptors in skin,[5] but low-intensity stimulation is capable of evoking pain. Tooth pulp afferents respond to a variety of chemical stimuli, strong heating, cooling, and pressure. Electrical stimulation produces almost exclusively painful sensations.[3]

Visceral Pain Receptors

Because of the infrequency with which visceral structures are exposed to potentially damaging events, it would not seem efficient to provide these structures with receptors designed solely to detect intense stimuli in the environment. Although severe pain of visceral origin is a common clinical phenomenon, there is little evidence that specialized pain receptors exist in visceral structures. Many damaging stimuli, such as cutting, burning, or clamping, produce no pain when applied to visceral structures. In contrast, inflammation, ischemia, mesenteric stretching, or dilation or spasm of hollow viscera may produce severe pain. These stimuli are usually associated with pathologic processes, and the pain they induce may serve a survival function by promoting immobility.

For almost all intrathoracic, intra-abdominal, and pelvic viscera, pain perception is a function of visceral afferent (sometimes termed sympathetic afferent) nerve activity.[3] These neurons accompany sympathetic afferent axons in the sympathetic chain and intra-abdominal and intrathoracic plexuses; but most, like other afferent fibers, have their cell bodies in the dorsal root ganglia and synapse with dorsal horn neurons.

Pain Perception in the Gut

It has been widely accepted that nociceptive-specific fibers do not exist in the gut. Pain is believed to result from intense activation of afferent fibers that serve other functions, such as stretch receptors. High-frequency activation of these visceral afferents in turn activates dorsal horn pain projection neurons, producing pain perceived within cutaneous referral sites. This referred pain is probably the result of viscerosomatic convergence, the phenomenon of a single spinothalamic tract (STT) neuron that can be activated by either visceral or somatic stimuli. Another type of convergence, reported by Bahr et al,[6] is based on the existence of afferent neurons with two sensory branches, one visceral (sympathetic afferent) and one somatic. It is not possible to locate the site of a painful stimulus to the gut with any accuracy because stimulation of widely distant sites can give rise to the same referred sensations.

Cardiac Pain

Cardiac afferent fibers, conducting in the C and A-delta range, have been shown to fire at high rates in response to coronary occlusion or intracoronary bradykinin.[7] However, to designate these nerves as nociceptors, they should respond only to noxious stimuli and should exhibit no background discharge. Malliani[7] showed that these putative nociceptors are tonically active, demonstrate mechanosensitivity, and respond to normal hemodynamic events. It is likely that cardiac afferents that are responsive to tissue-threatening stimuli have physiologic functions under normal circumstances, but give rise to volleys of activity that can cause poorly localized pain referred to somatic structures. Viscerosomatic convergence probably occurs with these fibers.

Other Visceral Structures

Pain associated with gallbladder disease is similar in character and location to angina pectoris.[8] Mechanical stimulation of the gallbladder or the application of chemical stimuli can affect the electrical activity and contractility of the heart.[9] Stretching of the bile ducts and gallbladder activates two populations of afferent fibers, one responding to small changes in pressure and the other responding only to high pressures (>25 mm Hg).[10] The high-threshold stretch receptors may have a nociceptive function. Gallbladder distension activates spinothalamic cells in the T1–T5 portion of the cord, cells that are also activated by cardiac afferents and somatic afferents from the medial aspect of the arm and the chest wall.

Pain from the upper portions of the esophagus is most likely caused by activation of vagal afferents.[3] Heartburn pain may be a vagally mediated phenomenon, but little study of the activation of pain by acids in the esophagus has been carried out.

Distension of the renal pelvis or ureters is known to produce pain, but few studies have

characterized afferent responses from the urinary tract. Pain of urethral origin is probably transmitted via sacral nerve roots rather than through sympathetic afferents. Urinary bladder distension is capable of producing cardiovascular responses, but, unlike gallbladder distension, is associated with reduced heart rate and contractility.

Dorsal Horn Mechanisms

The spinal dorsal horn and its analog in the medulla are exceedingly complex sensory processing areas. They contain the central terminals of peripheral afferent fibers, projection neurons of spinothalamic and other ascending tracts, local neurons that activate or inhibit projection neurons, and axon terminals of descending brainstem fibers.

As nerve roots approach the dorsal horn, segregation of fibers according to size takes place, with large myelinated afferents becoming arranged medially and small unmyelinated and thinly myelinated fibers arranged laterally. Most large myelinated fibers enter the cord medial to the dorsal horn. Many of these axons bifurcate, sending one branch rostrally in the dorsal columns. The other branch enters deeper layers of the dorsal horn, sending terminals into laminae IV and V and extensive arborizations into the substantia gelatinosa (laminae II and III).

Most unmyelinated or thinly myelinated afferents pass directly through the outer layer of lamina I, where they synapse with marginal layer cells and send a few branches into the underlying substantia gelatinosa. Some axons pass ventrally through these outer layers to terminate in laminae V and X.[11]

There are two groups of cells in the dorsal horn that respond to noxious stimulation in the periphery. One group, located mainly in lamina I, responds exclusively to noxious stimulation. Most of these cells, termed nociceptive specific, have relatively limited receptive fields, confined to some fraction of a dermatome. The second group of cells, termed wide dynamic range neurons, can be activated by either tactile or noxious stimuli. Most of these cells are located in lamina V. They have large, complex receptive fields that often have a central area of responsiveness to either noxious or tactile stimulation, surrounded by an area of responsiveness only to noxious stimulation. Stimulation just outside the entire receptive field may produce inhibition. It is generally accepted that wide dynamic range neurons contribute to pain perception and that their selective activation is sufficient to cause pain. It is likely that many of the neurons in laminae I and V that respond to noxious stimuli are STT neurons.

Activation of the Dorsal Horn Projection System

There is considerable evidence that excitatory amino acids (EAAs) such as glutamate and aspartate are the principal neurotransmitters responsible for activation of dorsal horn neurons following noxious stimulation. Evidence for this conclusion is based on localization of these substances in nerve terminals in the dorsal horn, detection of release of EAAs following noxious stimulation, and behavioral evidence of hyperalgesia following intrathecal (IT) administration of EAAs in animals.[12]

Several types of EAA receptors are involved in the initiation of neuronal excitation that leads to the transmission of pain information. The AMPA receptor responds briefly (tens of milliseconds) and unconditionally to the release of glutamate.[13] Activation of the N-methyl-D-aspartate (NMDA) receptor results in postsynaptic potentials that may last much longer, on the order of seconds to minutes. The NMDA receptor is normally unresponsive to EAAs because of a voltage-dependent block that occurs at normal resting membrane potentials and physiologic concentrations of Mg^{2+}. Following a period of depolarization of the AMPA receptor or activation of neurokinin (NK-1) receptors by SP (which is released from nociceptive afferent terminals following intense activation), the NMDA receptor becomes responsive to EAAs and produces a relatively prolonged postsynaptic response (Fig. 56-1). In such a way, the brief response to a short-lived stimulus is converted to a prolonged response, one likely to be perceived as pain, following prolonged repetitive stimulation. The phenomenon of "windup,"[14] the progressive increase in response to repetitive, brief C fiber intensity stimulation, appears to be NMDA receptor mediated, and can be blocked by pretreatment with NMDA receptor antagonists. It has been proposed that the NMDA

receptor is principally activated by aspartate released from excitatory interneurons in the dorsal horn, whereas the AMPA receptor is usually activated by glutamate released directly from afferent nerve terminals.

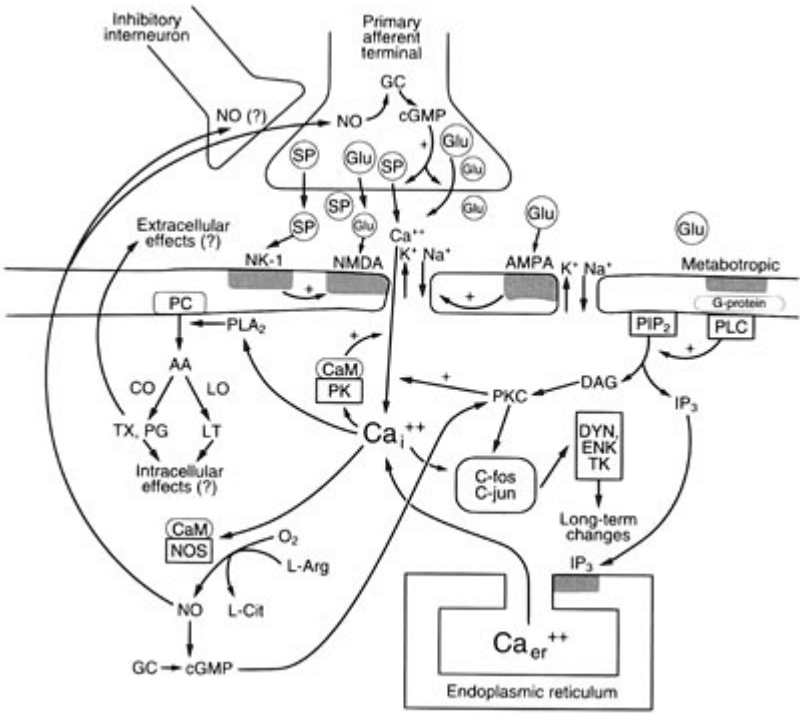

FIGURE 56-1. Sequence of events leading to sensitization of dorsal horn neurons following injury and intense nociceptive stimulation. Intense activation of primary afferent neuron stimulates release of glutamate (Glu) and substance P (SP). The NMDA receptor, at physiologic Mg^{2+} levels, is initially unresponsive to Glu. However, following depolarization of the AMPA receptor by Glu on the metabotropic receptor, it stimulates G protein-mediated activation of phospholipase C (PLC), which catalyzes hydrolysis of phosphatidylinositol 4, 5-biphosphate (PIP_2) to produce inositol triphosphate (IP_3) and diacylglycerol (DAG). DAG stimulates production of protein kinase C (PKC), which is activated in the presence of high levels of intracellular Ca^{2+} (Ca^{2+}). IP_3 stimulates release of intracellular Ca^{2+} from intracellular stores within the endoplasmic reticulum (Ca^{2+}_{er}). Increased PKC induces a sustained increase in membrane permeability and, in conjunction with increased intracellular Ca^{2+}, leads to increased expression of protooncogenes such as *c-fos* and *c-jun.* The proteins produced by these protooncogenes encode a number of neuropeptides, such as enkephalins (ENK), dynorphin (DYN), and tachykinins (TK). Increased Ca^{2+}_{i} also leads to activation of phospholipase A_2 (PLA_2) and to activation of nitric oxide synthase (NOS) through a calcium/calmodulin mechanism. PLA_2 catalyzes the conversion of phosphatidyl choline (PC) to prostaglandins (PG) and thromboxanes (TX), and by lipoxygenase (LO) to produce leukotrienes (LT). NOS catalyzes the production of protein kinases, such as PKC, and alterations in gene expression. NO diffuses out of the cell to the primary afferent terminal, where, through a GC/cGMP mechanism, it increases the release of glutamate. It is speculated that NO may interfere with release of inhibitory neurotransmitters from inhibitory neurons. (From Hogan QH, Abram SE: Diagnostic and prognostic neural blockade. In Cousins MJ, Bridenbaugh PO [eds]: Neural Blockade in Clinical Anesthesia and Management of Pain, p 837. Philadelphia, Lippincott-Raven, 1998.)

There is evidence for still more prolonged increases in sensitivity of spinal cord neurons to sensory inputs occurring in response to ongoing nociceptor activation. Changes in dorsal horn neural function known as long-term potentiation can occur in the spinal cord and may last

hours to days. It has been shown that prolonged excitation and release of EAAs in certain areas of the CNS can lead to damage or loss of neurons, and that such neurotoxicity is mediated at least in part by the NMDA receptor.[15] Following some types of peripheral nerve lesions in animals, the appearance of small darkly staining neurons in the substantia gelatinosa occurs coincidentally with the development of thermal hyperalgesia.[16] It has been proposed that these cells represent degenerating inhibitory interneurons (e.g., GABAergic or glycinergic cells) damaged by the large amounts of EAAs released by barrages of neural discharge from the injured nerve segment.[13]

Several neuropeptides that are released in the dorsal horn in response to noxious stimulation, including SP, neurokinin A, somatostatin, calcitonin gene-related peptide, and galanin, are believed to play a role in modulating the neural responses of dorsal horn cells sensory inputs.[16] The role of SP is perhaps best understood. It activates a postsynaptic NK-1 receptor, resulting in reduction of K^+ efflux (μ-opioids and α_2-adrenergic agonists enhance K^+ efflux), thereby increasing neuronal excitability. Its activity is limited by rapid enzymatic degradation. Neurokinin A also acts as an NK-1 receptor agonist, but it is more slowly broken down and may actively enhance dorsal horn transmission for a period of many minutes to a few hours following injury.[17]

1 Intense or prolonged noxious stimulation produces sustained depolarization of dorsal horn neurons leading to a series of intracellular events that alter cellular responsiveness to subsequent sensory input. Ca^{2+} influx into dorsal horn cells is generated by both membrane depolarization and NMDA receptor activation. Ca^{2+} influx then results in a series of intracellular events. These include the activation of phospholipase A_2 (PLA_2), as well as increased production of intracellular arachidonic acid and the products of the prostaglandin cascade. The resultant spinal cord accumulation of prostaglandins augments the hyperalgesic state through mechanisms not yet identified. Evidence for this proposal is provided by the fact that IT prostaglandins are indeed capable of inducing a hyperalgesic state[18] and that hyperalgesia induced by IT NMDA is inhibited by IT administration of nonsteroidal anti-inflammatory drugs (NSAIDs).[19]

Another mechanism by which Ca^{2+} influx enhances responsiveness to noxious stimulation is through an increase in the production of intracellular nitric oxide (NO). Intracellular Ca^{2+} activates the enzyme nitric oxide synthase through a calcium-calmodulin mechanism. NO is produced by the action of the enzyme on L-arginine. NO, which is rapidly diffusible both within and outside the cell, activates protein kinases through a cyclic guanosine monophosphate (cGMP) mechanism, leading to enhanced release of neurotransmitters from primary afferent terminals and enhanced responsiveness of the NMDA receptor in postsynaptic neurons. IT administration of substances that block the synthesis NO has been shown to inhibit nociceptor-induced spinal sensitization.[20]

Still other intracellular events, triggered by the action of EAAs and neuropeptides on metabotropic receptors, may lead to enhanced sensory processing. The activation of intracellular phospholipase C (PLC) stimulates the formation of inositol triphosphate (IP_3) and diacylglycerol (DAG). IP_3 stimulates release of intracellular Ca^{2+} stores, whereas DAG leads to increased production of protein kinase C (PKC). PKC further enhances NMDA receptor excitation and increases the expression of protooncogenes such as *c-fos* and *c-jun*, which control transcription of genes encoding a variety of neuropeptides that modulate responses to noxious stimuli.[16] Agents that inhibit production of PLC (e.g., neomycin) or PKC (e.g., H-7) reduce the delayed hyperalgesic response to subcutaneous formalin injection in rats (see Fig. 56-1).[21]

PKC is involved in the development of opioid tolerance.[22] Following prolonged occupation of opioid receptors on postjunctional dorsal horn neurons, there is translocation and activation of PKC, which in turn may uncouple the G protein that activates the potassium channel from the opioid receptor, producing tolerance. Thus activated, PKC may also enhance calcium influx through the NMDA receptor, producing sensitization of the cell as described previously. In addition, PKC activated by the activity of EAAs on the NMDA receptor is capable of uncoupling the opiate receptor mechanism, reducing opioid responsiveness (see Fig. 56-1). Thus, prolonged opioid administration can lead to spinal sensitization, and prolonged EAA release, as occurs with neuropathic pain states, and can reduce responsiveness to opioids.[22]

2 More recently, considerable research has been performed to characterize the role of glial, as opposed to neuronal cells, in the processes involved in sensitization of pain projection

systems. Glial cells (microglia, astrocytes, oligodendrocytes) represent nearly three-fourths of all the cells in the CNS. It was originally believed that the sole function of these cells was to provide physical support for neurons. It is now known that they have important neuromodulatory and neurotrophic effects, and that they are extremely important in providing immune functions following injury, inflammation, or infection.[23]

Following nerve injury, there is rapid activation of glial cells within the CNS. Microglias, which are normally quiescent, are the first to respond. A triggering mechanism for glial activation is stimulation of toll-like receptors, which respond to membrane proteins of various viral and bacterial pathogens. One of these receptors, TLR4, can respond to substances produced during nerve injury in the absence of pathogens.[23] Following TLR4 upregulation, microglia then exhibit a change in morphology to an amoeboid form, they hypertrophy and proliferate, and they release substances that subsequently activate astrocytes (Fig. 56-2). Microglias initiate the immune response, and astrocytes maintain it. Both types of cells produce proinflammatory cytokines, including the interleukins IL-1β and IL-6 and tumor necrosis factor (TNF), which can diffuse throughout the region and produce functional changes in the surrounding neuronal cells.

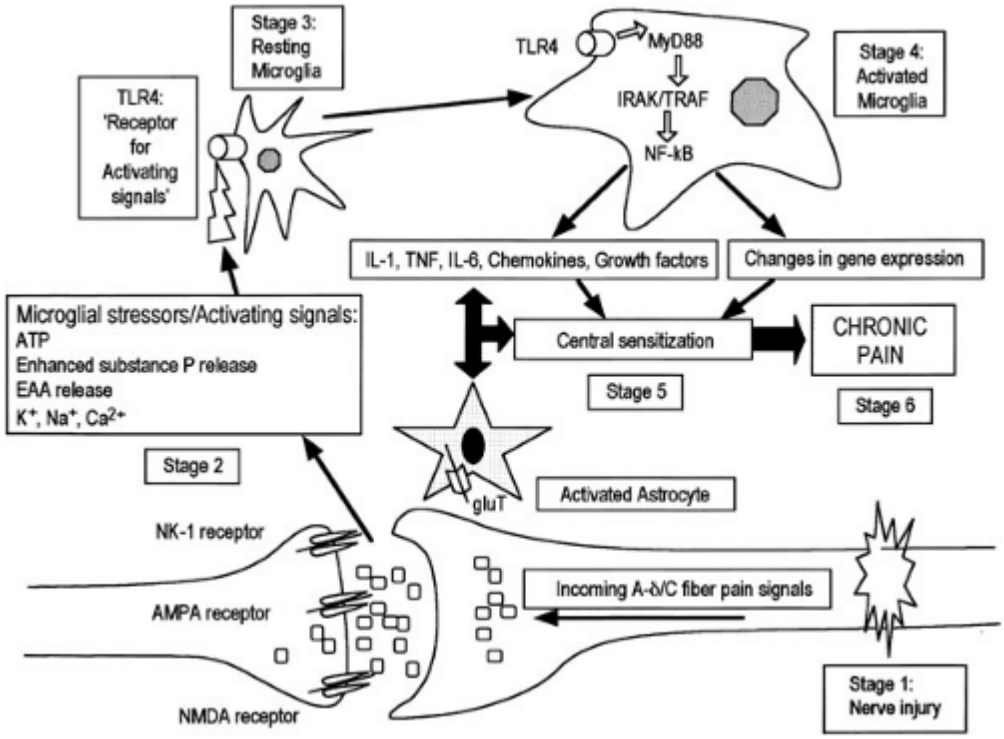

FIGURE 56-2. Proposed schema of TLR4-"receptor for activating signals" cascade in relation to the generation of chronic pain states. Under normal conditions, microglia are quiescent and highly ramified (stage 3). Upon nerve injury (stage 1), "pain" signals arriving from the periphery along a-δ and C fibers cause the release of substance P, excitatory amino acids (EAAs), adenosine triphosphates (ATPs), extracellular ions, and so on (stage 4). The stimulation of TLR4 leads to microglial activation, the recruitment of adaptor proteins (MyD88 and IRAK/TRAF6), the release of growth factors, and proinflammatory cytokines that trigger further cytokine and chemokine transcription and release. Upon release, cytokines contribute to activating astrocytes, which may decrease the efficiency of glutamate transporters (GluT, important for uptake of excess synaptic glutamate), and cause further release of additional cytokines and other algesic mediators. The release of these mediators leads to central sensitization (stage 5) and the clinical manifestation of chronic pain (stage 6). (Reprinted with permission from Deleo JA, Tanga FY, Tawfikk VL: Neuroimmune activation and neuroinflammation in chronic pain and opioid tolerance/hyperalgesia. Neuroscientist 10:40, 2004.)

Cytokines induce the release of a variety of substances that participate in the sensitization of sensory neurons. These include cyclooxygenase 2 (COX-2), inducible nitric oxide synthase (iNOS), and SP. They also activate chemokines in macrophages and endothelial cells, which initiate extravasation of leukocytes from the blood. Activated glial cells also release glutamate, NO, reactive oxygen species, eicosanoids, and other substances that act via the NMDA receptor to produce spinal sensitization.

A variety of stimuli have been shown experimentally to induce glial activation and the release of proinflammatory cytokines. These include nerve injury, nerve root ligation, tissue inflammation, arthritis, infection, and HIV antigen. Agents that prevent glial activation or that block the effect of cytokines have been shown to reliably prevent the development of hyperalgesia and allodynia in a number of experimental models.[24]

3 A particularly important part of the glial activation story is the observation that neuroimmune activation can occur following the induction of opioid tolerance.[25] Glial activation and upregulation of IL-1β, IL-6, and TNF-α were observed in the lumbar spinal cord of rats after 5 days of twice daily morphine but not saline injections. In addition, hyperalgesia and allodynia occurred following withdrawal of morphine. Chronic administration of morphine to nerve-injured rats produced more rapid development of allodynia and hyperalgesia, as well as greater cytokine production, than was seen in animals exposed to nerve injury but not morphine. The spinal administration of substances that inhibited cytokines restored the antinociceptive

effects of morphine and reversed the morphine-induced allodynia and hyperalgesia in both nerve-injured and sham-operated animals.[25] One proposed mechanism of opioid-induced hyperalgesia involves direct interference with glutamate transporter mechanisms on primary afferent nerve terminals and glial cells, blocking reuptake of excitatory amino acids and increasing their synaptic levels[23,26] (Fig. 56-3).

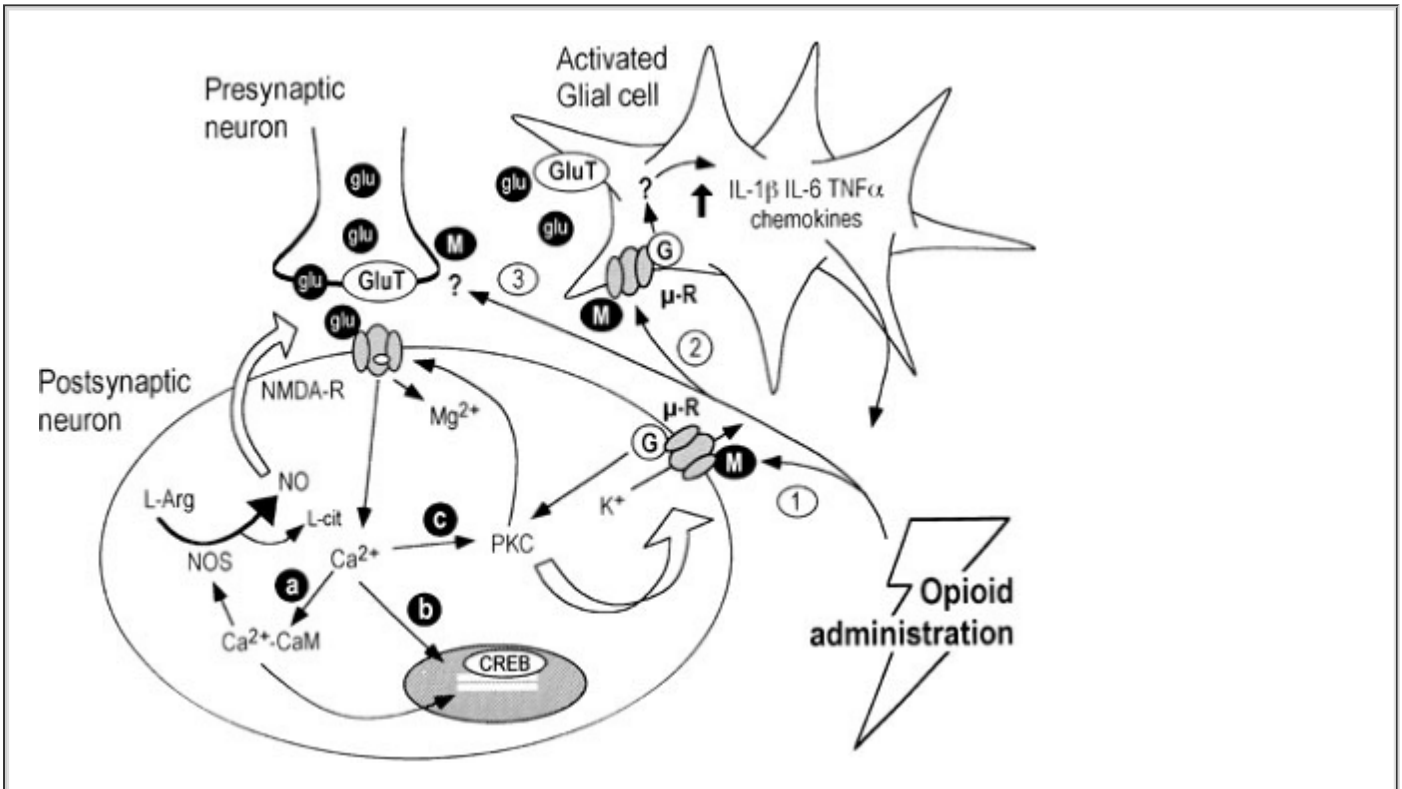

FIGURE 56-3. Cellular mechanisms of morphine tolerance/hyperalgesia. An opioid may act on the postsynaptic neuron (1), on the glial cell network (s), or on the presynaptic neuron (3). On the presynaptic neuron (1), opioid binding (represented by morphine, M) to the neuronal μ-receptor (μ-R) activates G protein-mediated protein kinase C (PKC) translocation and activation promoting removal of the NMDA receptor MG^{2+} plug. The ionotropic NMDA-R then responds to glutamate released from the presynaptic cell by allowing Ca^{2+} influx. This increase in intracellular Ca^{2+} leads to several downstream effects, including activation of

Ca^{2+}-CaM (a), changes in gene expression (b), and further activation of PCK (c). Ca^{2+}-CaM in turn initiates the conversion of L-arginine to nitric oxide (NO) by nitric oxide synthase (NOS). NO may then act as a retrograde messenger to enhance glutamate release from the presynaptic neuron. With continual activation of these pathways by opioid receptor occupation, PKC may uncouple the G protein from the μ-R, preventing any downstream signaling upon ligand binding. Chronic opioid administration can act through the μ-R (2) on astrocytes to increase the production and secretion of cytokines and chemokines, or it can act directly on glial and neuronal glutamate transporters (Glu-T) to alter synaptic glutamate levels (3). Once released, cytokines may then act on the presynaptic or postsynaptic neurons to induce tolerance/hyperalgesia, or on the glial cells to promote further neuroimmune activation. G, G protein; glu, glutamate; Ca^{2+}-CaM, calcium-calmodulin. (Reprinted with permission from Deleo JA, Tanga FY, Tawfikk VL: Neuroimmune activation and neuroinflammation in chronic pain and opioid tolerance/hyperalgesia. Neuroscientist 10:40, 2004.)

There are several systems capable of suppressing activity in STT neurons. There is substantial evidence that both descending and segmental neuronal inputs can inhibit activation of nociceptive-specific and wide dynamic-range neurons. The amino acids glycine and γ-aminobutyric acid (GABA) are known to be inhibitors of synaptic transmission, and there is some speculation that they are important mediators of segmental inhibition of nociception. There are two known GABA recognition sites: $GABA_A$, for which muscimol and isoguvacine are agonists, and $GABA_B$, for which baclofen is an agonist. Benzodiazepines act to enhance the effect of GABA on $GABA_A$ receptors. When administered spinally, they produce a mild analgesic effect and inhibit sympathetic response to noxious stimuli.

Two pentapeptides, leucine enkephalin and methionine enkephalin, appear to be important spinal cord inhibitors of nociception. STT neurons in laminae I and V receive input from enkephalin-containing cells in the dorsal horn. It has been proposed that enkephalins are released in proximity to primary afferent terminals in the dorsal horn, activating presynaptic opiate receptors that prevent release of SP. However, the presence of direct synaptic contact between enkephalin-containing cells and STT neurons suggests that their inhibitory mechanism is, at least in part, postsynaptic. Enkephalins are found in highest concentrations in laminae I and II but are also present in deeper laminae. Most dorsal horn enkephalins originate from intrinsic neurons.

It is not clear whether dorsal horn enkephalins function in a tonic fashion or whether their activity is stimulated for the most part by descending or peripheral segmental activity. If there is significant tonic inhibition by enkephalins, administration of naloxone should markedly increase activity in STT neurons. There is only equivocal evidence for such disinhibition. Release of enkephalins in response to descending neural activity has not been well documented. There is, however, evidence of enkephalin release in response to segmental activity.[27]

Serotonin, or 5-hydroxytryptamine (5-HT), produces analgesia when injected intrathecally, and its antagonist methysergide attenuates the analgesia produced by certain pharmacologic interventions. It is likely that this neurotransmitter is involved in descending control mechanisms that originate in the midbrain and medulla. It has been speculated that the analgesic effect of some of the tricyclic antidepressants may be related to an increase in serotonin availability in the CNS. However, the class of antidepressants known as serotonin-specific reuptake inhibitors (SSRIs) appears to have little or no

beneficial effect on those conditions that typically respond to tricyclics.

Norepinephrine is also an important neurotransmitter in descending inhibitory pathways. Spinally administered adrenergic agonists, such as epinephrine, have been shown to have analgesic effects in animals. This analgesic effect is mediated by α_2-adrenergic receptors. Evidence for this is provided by the fact that α_2 agonists such as clonidine and dexmedetomidine produce analgesia

when injected spinally and that α_2 antagonists such as yohimbine and idazoxan block their analgesic effects. IT clonidine is now in use for the treatment of intractable cancer pain. It appears to be helpful in some opioid-tolerant patients.

Adenosine receptors appear to play a role in the modulation of nociceptive transmission in the dorsal horn. There are two receptor subtypes: A_1, which inhibits adenyl cyclase activity, and A_2, which stimulates it.[28] Adenosine receptors may play a role in the analgesia provided by transcutaneous electrical stimulation because it has been demonstrated that dorsal horn inhibition induced by high-frequency stimulation is blocked by methylxanthines, which antagonize adenosine receptor activity. The adenosine receptor may also play a role in the mediation of analgesia induced by spinally administered opiates. Adenosine agonists have been shown to reduce the tactile hyperesthesia induced by low-dose spinal strychnine, a glycine receptor antagonist, and may prove to be effective in certain hyperalgesic states.

In summary, the dorsal horn functions as a relay center for nociceptive and other sensory activity. The degree of activation of ascending pain projection systems depends on the degree of activation of segmental and descending inhibitory neurons in the dorsal horn, the preexisting concentration of excitatory neurotransmitters, the level of activation of inhibitory neurotransmitters, the intensity of the noxious stimulus, and the degree of sensitization of nociceptors in the periphery.

Ascending Pathways

The STT has been considered for many years to be the most important pathway transmitting nociceptive stimuli to the brain. Although it is important to normal perception of pain, it is by no means the only pathway with that function. The ability of patients to perceive pain following spinothalamic tractotomy provides evidence that other pathways are involved.

Many of the neurons in laminae I and V that respond to noxious stimulation are probably cells of origin of the STT. The majority of STT fibers cross near their level of origin. There are

believed to be two functionally distinct divisions of the STT: the neospinothalamic tract, whose fibers tend to be more lateral, and the paleospinothalamic tract, located in the medial portion of the pathway. The phylogenetically newer neospinothalamic tract projects to posterior nuclei of the thalamus, such as the ventral posterolateral nucleus, and is believed to be involved with discriminative functions (e.g., location, intensity, and duration of noxious stimulation).[29] The paleospinothalamic tract projects to medial thalamic nuclei, and its activation, is probably associated with autonomic and unpleasant emotional aspects of pain. This older portion of the STT is likely to be important in pain associated with denervation dysesthesia. Stimulation of the thalamic projections of the paleospinothalamic tract in patients with denervation dysesthesia reproduces the burning pain these patients experience spontaneously.[30]

The spinoreticular tract is likely to play a role in pain perception. Its cells of origin are unknown. It is believed to produce arousal associated with pain perception, and probably contributes to neural activity underlying motivational, affective, and autonomic responses to pain.[31] The spinomesencephalic tract projects to the midbrain reticular formation. It probably evokes nondiscriminative painful sensations and may be important in the activation of descending antinociceptive pathways.[31]

Following bilateral spinothalamic tractotomy, it is still possible for patients to perceive pain from peripheral stimulation. There must necessarily be pathways in the dorsal portions of the spinal cord that are capable of producing pain perception. The spinocervical tract is a likely candidate for such a function. It is located in the dorsolateral funiculus. Its fibers ascend uncrossed to the lateral cervical nucleus, which serves as a relay, sending fibers to the contralateral thalamus.[31] There is also evidence that some fibers in the dorsal columns are responsive to noxious stimuli.

Descending Control

In the early 1970s, several reports showed that electrical stimulation of the periaqueductal gray (PAG) area of the midbrain could produce widespread analgesia in animals and humans. The PAG

was later found to have high concentrations of endogenous opiates and to be rich in opiate receptors. Microinjection of small quantities of morphine into that area produces generalized analgesia. Anatomic connections from the PAG area to the nucleus raphe magnus and to the medullary reticular formation were subsequently described. From the nucleus raphe magnus, serotoninergic fibers descend via the dorsolateral funiculus to spinal cord dorsal horn cells. It is not clear whether serotoninergic fibers produce a direct, postsynaptic inhibition of STT neurons or whether they act by activation of inhibitory neurons that release enkephalins or GABA.

There are also adrenergic fibers that descend in the dorsolateral funiculus that are believed to be inhibitors of pain. The cells of origin of these descending adrenergic pathways are believed to lie in the locus ceruleus and parabrachial regions of the medulla. Stimulation of spinal α_2-adrenergic receptors produces analgesia through G protein-mediated K^+ channel activation.

Multiple environmental factors appear to activate descending pain control mechanisms. Nociceptive inputs and various types of stress can produce generalized increases in pain threshold. Anxiety, depression, and emotional distress can reduce pain threshold. The descending control mechanisms described may respond to such factors. Under normal circumstances, inhibitory and pronociceptive neurons located in the midbrain periaqueductal gray rostral ventromedial medulla (RVM) play an important role in integrating and coordinating behavioral and autonomic responses to noxious stimuli.[32] Following a brief noxious stimulus, certain cells, known as "off-cells," in the RVM abruptly cease firing. It is believed that these cells produce tonic inhibition of nociceptive reflexes, and their cessation is associated with loss of such inhibition. Other cells, known as "on-cells," show a sudden burst of activity just before a behavioral response to a noxious stimulus. Their activation appears to produce a facilitatory influence on nociceptive transmission. At least some on-cells are GABAergic and exert an inhibitory influence on descending inhibitory neurons, including off-cells. On-cell activity is inhibited by local application of opioids, which block their inhibitory effect on pain-inhibitory pathways.

Pain and Nerve Injury

Spontaneous discharge of injured peripheral nerves was demonstrated by Wall and Gutnick,[33] who reported spontaneous neural activity originating from experimentally induced neuromas. It was later demonstrated that sympathetic stimulation or norepinephrine infusion could increase such abnormal firing.[34] There is now considerable evidence that changes in ion channel configuration and distribution are responsible for functional changes in the behavior of injured axons. Following nerve injury, there is an increase in the occurrence of large intramembranous particles, which represent surface proteins such as receptors and channel proteins. In addition, the membrane properties of a regenerating nerve tip differ from those of intact nerves. There is disappearance of the sodium-dependent action potential and an increase in conductance to Na^+, K^+, and Ca^{2+}.[35]

In addition to impulse generation originating from the site of injury, there is considerable evidence that impulse generation occurs at points of membrane instability proximal to the injury. Wall and Devor[36] reported spontaneous discharge originating from dorsal root ganglia in sciatic nerve-sectioned rats. They proposed that the dorsal root ganglia impulses could contribute to pain after peripheral nerve injury.

Another possible mechanism for chronic pain following peripheral nerve lesions involves the short circuiting of action potentials (ephaptic transmission, cross-talk) across demyelinated segments. Several possible types of interaction might exist. Demyelination of large afferent fibers could cause activation of nociceptors at the site of injury in response to stimulation of mechanoreceptors by nonnoxious stimuli. Injury of motor fibers could cause nociceptor activation in response to motoneuron activation. Loss of Schwann cell protection of postganglionic sympathetics could produce nociceptor firing in response to sympathetic discharge.

Intact peripheral nerve pathways are essential for normal function of pain projection neurons and inhibitory interneurons in the dorsal horn. Following loss of peripheral nerve activity, there may be an increase in sensitivity or onset of spontaneous activity in STT neurons. It has been postulated that disruption of large afferents, which send extensive arborizations into the

substantia gelatinosa, decreases the activity of inhibitory neurons in those areas.

Spontaneous activity or heightened sensitivity of neurons is also believed to occur at more central locations within the pain projection system. Thalamic cells may undergo such changes following cord injury or some cerebrovascular accidents. Sensitization of central neurons may also occur some time after peripheral nerve injuries.

Sympathetically Maintained Pain

4 There are several mechanisms by which the sympathetic nervous system influences the perception of pain. Interactions between sympathetic outflow and spontaneous depolarization of

injured nerve segments have already been discussed. Following trauma, surgery, and certain illnesses, a syndrome of pain, hyperalgesia, autonomic dysfunction, and dystrophy, known as complex regional pain syndrome (CRPS), can occur. A common explanation is that there is interference with the normal regulatory function of the sympathetics to the affected area induced by pain or injury, hence the former name of the syndrome, reflex sympathetic dystrophy (RSD). Periods of heightened sympathetic activity are believed to result in vasoconstriction, ischemia, changes in interstitial environment, and, perhaps, release of prostaglandins, bradykinin, and other pain-sensitizing substances. This explanation is highly simplistic and is contradicted by several clinical findings: (1) early in the course of the syndrome, the affected limb is usually warm and erythematous; (2) microneurographic recording studies have failed to demonstrate alterations in sympathetic outflow in the affected limb; and (3) venous catecholamine levels in the affected limb are not elevated. However, there may be central dysregulation of autonomic function in these patients. Experimental evidence for interference with sympathetic regulatory function following injury was provided by Blumberg and Janig,[37] who demonstrated loss of the normal reciprocity between skin and muscle vasoconstrictors in animals with peripheral nerve lesions. Skin vasoconstrictors are normally under the influence of hypothalamic centers. They are important in thermoregulation and tend to be inhibited by stimuli that activate muscle vasoconstrictors, which are under medullary control. Following peroneal nerve lesions, skin vasoconstrictors begin to respond like muscle vasoconstrictors and appear to be under medullary control.[37]

Another possible interaction between sympathetic activity and pain perception involves ephaptic transmission, or "cross-talk," between different fiber types at injured nerve segments. Segmental loss of myelin or protective Schwann cell sheaths could lead to depolarization of nociceptor fibers by efferent sympathetic transmission. Although such segmental demyelination has been demonstrated anatomically, physiologic evidence for the phenomenon is scant.

Another proposal is the direct sensitization of nociceptor nerve endings by sympathetic nerve terminals. Again, there is little evidence that such nociceptor sensitization occurs. There is, however, considerable evidence that sympathetic fibers are in direct contact with mechanoreceptors and that sympathetic activity can sensitize mechanosensitive afferents. Roberts[38] proposed that a combination of sensitization of mechanoreceptors plus disinhibition of wide dynamic-range neurons could occur in certain posttraumatic states. Such a situation would lead to high-frequency firing of STT neurons and pain perception in response to nonnoxious mechanical stimulation.

Several studies have demonstrated sprouting of sympathetic neurons following nerve injury. These neurons proliferate to form elaborate arborizations, known as baskets, surrounding neuronal cell bodies.[39] It is not known as yet whether there is synaptic contact between the sympathetic fibers and the cell bodies, nor have the types of afferents whose somata are invaded by sympathetic sprouts been characterized. Nerve growth factor (NGF) and the cytokines leukemia inhibitor factor and IL-6 appear to contribute to the initiation of sympathetic sprouting. There is considerable speculation, although so far no proof, that the interactions between sympathetic sprouts and DRG cell bodies are responsible in part for sympathetically maintained pain in some clinical states.

PSYCHOLOGICAL MECHANISMS

No discussion of chronic pain is complete without some consideration of the psychological factors that are related to pain. In 1986, the International Association for the Study of Pain published a taxonomy of pain-related terms to promote uniformity of usage and to enhance accurate reporting of clinical and experimental phenomena.[40] Pain was defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage." The salient features of that definition are that (1) pain is unpleasant, which is no surprise to most; (2) it may have a sensory component, also not surprising; (3) it has an emotional component, which distinguishes it from other sensory experiences such as touch, pressure, and vibration; and, most important, (4) it is an experience and, as such, is subjective, personal, private, and verifiable only by report of the individual suspected of suffering from pain. This last point cannot be overemphasized. Although much of what a physician does when dealing with pain patients is objectively verifiable by monitors, touch, or direct vision, these clinical tools only allow us to make inferences about another's suffering. The gold standard for determining if a patient is in pain is to ask the patient if he or she hurts. Other observations may aid in formulating a diagnostic impression, but only the patient can tell you if he or she has pain.

Psychological mechanisms can contribute to the pain experience in two general ways. A direct influence is exemplified by a situation in which psychological factors are entirely the cause of a report of pain. An example of this is psychogenic pain, which is considered to be rare. The psychological construct that is invoked to explain this involves the production of a perception of pain as a result of purely psychological factors, such as the need to suffer, a means of assuaging guilt, or a way to resolve some other intrapsychic conflict. This type of condition does exist but is frequently overdiagnosed. In fact, the likelihood of diagnosing psychogenic pain is inversely proportional to the skill and expertise of the physician examining the patient. The histories of these patients present no clear patterns or similarities, making a neat diagnostic algorithm impossible. Dramatic presentations, or conversely, apparent indifference, are not pathognomonic.[41]

Other direct psychological influences are found in the somatization disorders. These are a group of psychiatric disorders that are typified by a preoccupation with bodily function or symptoms. Hypochondriasis is a condition in which the individual is preoccupied with the notion that he or she is sick, despite continual reassurance from physicians. The exact psychological mechanism is not well understood, but this condition should be treated by a psychologist or psychiatrist. In suspecting this diagnosis, it is wise to remember that the term arose from patients describing pain below the right costal margin (hypochondriac) at a time when cholecystitis was not recognized as a bona fide medical entity. Patients with fears or convictions that they are ill do, on occasion, turn out to be right, so a careful history and physical examination coupled with performance of clearly indicated tests is advisable.

Somatization disorder is characterized by an onset of physical symptoms before the age of 30 years and includes at least 12 (for men) or 14 (for women) of 37 symptoms involving various organ systems. These symptoms are of sufficient severity to cause the individual to seek medical attention, to take medicines, or to otherwise alter his or her lifestyle. These patients typically have undergone extensive investigations, usually from multiple physicians, all of which have yielded negative, equivocal, or conflicting results. Frequent surgeries, usually of an exploratory nature, are a common historical feature. These features are superimposed on any genuine somatic diseases suffered by the person, presenting a complex clinical picture. The mechanism for this disorder is not proved, but it is suspected that these persons come from families in which little credence or attention is given to display of emotion, yet care and attention are provided in response to physical symptoms. Thus, the theory goes, the patient learns that the exhibition of a physical symptom results in attention to the patient's needs.

This modus operandi becomes ingrained on a subconscious level and then becomes part of the person's psychic constitution. This condition is not nearly as rare as psychogenic pain and, therefore, is likely to be seen with some frequency by a physician treating patients presenting with pain.

Factitious disorders (Munchausen syndrome) present with reporting of symptoms and the

intentional creation of signs that are intended to lead a physician to suspect a medical or surgical disorder. Patients have been known to instrument their urethra to cause hematuria and complain of flank pain or to use tourniquets to induce edema of the limb. The motivation for this behavior appears to be to occupy the role of a patient. The reasons for this goal are poorly understood.

Another similar condition is malingering, which is differentiated only by motivation. In this case, the motivation to assume the role of a patient is driven by the desire to avoid some other alternative that the individual believes is distasteful, such as military service or apprehension by the police, or to achieve financial gain. Fortunately, these charades are usually transparent to the astute physician. The incidence of this disorder in pain clinics is probably low.

Indirect psychological effects that influence the pain experience are common in chronic pain syndromes. At its most basic level, the presence of an ongoing nociceptive process that is not well relieved and produces continual suffering is bound to have some psychological sequelae that will color the whole pain experience. Such secondary effects as sleep deprivation, fatigue, irritability, and anger are commonly observed.[42]

The issue of depression and pain has been discussed by several authors.[41,43] It is not surprising that most patients with chronic pain are likely to show signs of depression. It is difficult at times, however, to clarify the distinction between a set of depressive features that are reactive to having chronic pain and an episode of major depression because there can be so much overlap in symptoms.[43] The *Diagnostic and Statistical Manual of Mental Diseases*[44] includes many somatic and related symptoms in its criteria for diagnosing major depression. Most chronic pain patients will have several of these, but the genesis of the symptom (e.g., insomnia) may be due to the pain itself rather than depression. It is clear, however, that a negative affective state such as depression serves to enhance the suffering of a person with chronic pain.

Another indirect influence is that of pain behavior. Pilowsky et al[45] described the concept of illness behavior as it applies to pain patients. Simply stated, an illness is the individual's reaction or response to a disease. Illness behaviors arise from the patient's underlying physical condition and may consist of active behaviors, such as taking pills and visiting physicians, or passive behaviors, such as not working and lying down or sitting much of the day. In many chronic pain patients, the illness behaviors must become a focus of treatment.

Behaviors of any type are subject to influence by operant factors. Operant conditioning states that the likelihood of a behavior being expressed in a given situation can be altered by the consequences of the behavior. In chronic pain, for example, pain behavior (moaning) may be unwittingly reinforced by a spouse (showing attention), resulting in an increased frequency of the behavioral expression in the presence of the spouse. This is an example of positive reinforcement. By rewarding the behavior, its frequency is increased. The term *secondary gain* is often used to describe the type of paradigm wherein the individual, despite suffering with pain, does receive some benefit from it. Negative reinforcement increases the frequency of the behavior by removing a noxious condition from the environment in response to the behavior. Avoiding taking the garbage out by complaining of back pain is an example. Punishment, or the provision of undesirable consequences in response to a behavior, and extinction, the provision of no consequences, lead to decreased frequency of a behavior.

Cognitive factors also influence a pain experience. The belief that a person has about the meaning of his or her pain can substantially alter the actual perception of the pain. An important issue in this regard is the perceived degree of control over the pain. Using this fact, it is common practice for dentists to tell patients to raise their finger if anything hurts during the procedure. This granting of control allows patients to tolerate procedures with greater comfort. Contrast this with a patient suffering from poorly controlled cancer. Here, every time a pain is experienced, it reminds the patient of the cancer and the likelihood of an imminent and probably painful death.

MANAGEMENT OF COMMON CHRONIC PAIN SYNDROMES

It is beyond the scope of this chapter to consider the entire spectrum of long-term pain problems. Instead, the medical management of several painful conditions that are likely to respond to

regional analgesic techniques or other modalities that anesthesiologists are likely to use is discussed. In addition, this section presents, in general terms, the use of some pharmacologic agents that are helpful in certain pain syndromes and provides a brief overview of the psychological principles that are important in managing chronic pain.

Low Back Pain

5 Several low back structures are innervated by nociceptors and act as sources of pain under certain pathologic conditions. The outer third of the annulus of the intervertebral disc has sensory innervation. Pain associated with annular tears is generally thought of as occurring only in the back; however, during discography, distension of the annulus commonly produces pain in the thigh and lower leg.[46] There is also evidence that, in the presence of chronic degenerative or inflammatory conditions, the vertebral bodies and vertebral end plates may become sources of pain.[47] Facet joints receive sensory innervation and, particularly if there are inflammatory changes in the joint, mechanical stimulation or injection of the joint may result in pain that may be localized to the back or may radiate to the buttock, thigh, and lower leg. A study using saline-controlled diagnostic local anesthetic injections of the facet joint indicated that in 40% of patients the facet joint was a source of low back pain.[48] Similarly, the sacroiliac (SI) joint is a source of pain in some patients, and injection of the joint reproduces back and lower-extremity pain in some patients who have evidence of SI joint pathology. Using a rigorous paradigm requiring pain relief after two separate joint injections, Maigne et al[49] concluded that only 20% of patients with clinical symptoms compatible with SI arthropathy had pain of SI joint origin. Mechanical compression or traction on a normal nerve root produces painless paresthesias. However, similar stimulation of a chronically injured or inflamed nerve root produces sciatica or pain in the normal sensory distribution of that nerve root.[50]

Lumbosacral Radiculopathy

Mechanical nerve root compression was originally presumed to be the cause of pain in discogenic radiculopathy. The lack of uniform success with surgical decompression and the fact that many asymptomatic patients demonstrate substantial disc protrusion on myelography or on subsequent postmortem examination suggests that other mechanisms must also be operative. Following a period of mechanical nerve root compression, an acute inflammatory process may ensue, leading to intraneural accumulation of serum proteins and fluid, raised intraneural pressure, ischemia, and axonal degeneration.[51] There is

considerable evidence that the contents of the intervertebral disc can produce severe inflammation in the spinal canal. Gertzbein et al[52] found that patients with lumbar disc disease in which sequestration of nucleus pulposus occurred were highly likely to exhibit cellular immune responses to homogenates of lumbar disc material, whereas patients who did not show sequestration were less likely to show such a response. These findings led the authors to propose an inflammatory autoimmune mechanism for the radicular pain associated with disc rupture. Marshall and Trethwie[53] demonstrated the production of antibodies to glycoproteins from nucleus pulposus among patients who suffered from acute lumbar disc disease. They also demonstrated severe inflammatory reaction to nuclear glycoproteins following pulmonary arterial injection in a guinea pig heart-lung preparation.

A different line of evidence for the development of inflammation in response to disc rupture was presented by Saal et al.[54] They collected human disc samples removed at surgery from patients with symptomatic radiculopathy and analyzed the material for PLA_2 activity. They found extremely high levels in this material, 20- to 100-fold higher than activity from human inflammatory synovial effusion. They concluded that the high PLA_2 activity leads to inflammation at the site of disc herniation by action of the enzyme to liberate arachidonic acid from cell membranes.

Cytokines, including interleukins, NGF, interferons, and tumor necrosis factor alpha (TNF-α), are believed to play an important role in the pathophysiology of radiculopathic pain. Intrathecal administration of IL-6 can produce touch-evoked allodynia in rats, and substances that block the effects of TNF-α are capable of blocking the hyperalgesic effect of experimental mononeuropathy

or endotoxin.[55]

It has been proposed that epidural or subarachnoid injection of corticosteroids provides beneficial effects by reducing the inflammation initiated by either mechanical or chemical insult to the nerve root.[56] The earliest use of epidural steroids was published by Lievre et al[57] in 1957, who reported good to excellent results in 50% of patients following injection of cortisone acetate plus radiographic dye. Most subsequent series of epidural steroid injections used a combination of local anesthetic and suspensions of insoluble steroids. To determine whether local anesthetic alone provided benefit for patients with sciatica, Coomes[58] compared patients receiving bed rest plus epidural injections of procaine with patients treated with bed rest alone. He found that patients treated with procaine became ambulatory in 11 days, whereas it took the noninjected patients an average of 31 days to regain ambulation. Swerdlow and Sayle-Creer,[59] in a nonrandomized study, found consistently better results among chronic pain patients treated with epidural lidocaine and methylprednisolone than for patients treated with epidural saline or lidocaine injections. There was no difference in success rates among the three treatment groups for patients with acute or recurrent sciatica. Winnie et al[60] compared patients treated with epidural methylprednisolone with patients treated with local anesthetic combined with the steroid. Success was close to 100% in both groups, suggesting that the steroid, rather than the local anesthetic, was providing the benefit.

Reports on more than 7,000 patients appear in the English language literature attesting to the beneficial effects of epidural steroid injections for the treatment of sciatica. However, although there have been anecdotal reports or noncontrolled case series attesting to the beneficial effect of epidural steroids in several thousand patients, only 13 controlled, randomized studies of the use of caudal or lumbar epidural steroid injections have been published. Koes et al[61] found that more than half of these controlled studies had substantial methodologic flaws. Of four studies that had reasonable methodologies, two reported positive (beneficial) results and two reported negative results. Watts and Silagy[62] performed a meta-analysis of nearly the same group of studies (11 randomized studies with 907 patients). In assessing the rate of treatment success, defined as >75% improvement for up to 60 days, they found the odds ratio for success in the steroid treatment group to be 2.61 (95% confidence interval [CI] 1.90 to 3.77). For long-term (>12 months) treatment success, the odds ratio for the steroid treatment group was 1.87 (95% CI 1.31 to 2.68). There was no significant difference in outcomes between the caudal and lumbar route of injection. A more recent controlled study, not included in either of the previous reviews, compared epidural methylprednisolone acetate with epidural saline.[63] The steroid-treated group experienced more improvement in sensory function and flexibility, but only at the 3-week assessment.

Few studies have evaluated the long-term effects of epidural steroids. Abram and Hopwood[64] compared the long-term responses of patients who initially experienced a favorable response to epidural steroid injections to those of patients who were considered treatment failures. After 6 months, patients in the initial success group were significantly more likely to rate their pain level lower, had significantly less sleep disruption, and were significantly less likely to be unemployed as a result of their pain when compared with initial failure patients.

The L5 and S1 nerve roots are most commonly affected by disc disease. Those roots pass through a narrow lateral bony recess as they exit the spinal canal, a circumstance that increases the likelihood of root compression.[65] Symptoms of lumbosacral radiculopathy consist of varying degrees of low back pain, pain radiating a varying distance into the lower extremity, and, in more severe cases, motor and sensory loss consistent with damage to the affected root. Typical signs and symptoms are listed in Table 56-1. As noted previously, the pain typically associated with nerve root pathology is often in the

same distribution as pain associated with lumbosacral or facet arthropathy or with annular tears without nerve root pathology. The presence of sciatic stretch signs (positive straight leg raising, Lasegue's sign) or single segment sensory, motor, or reflex changes increase the likelihood that the pain is related to radiculopathy.

TABLE 56-1 Pain Distribution and Physical Signs Associated with Acute Disc Herniation

·LEVEL OF HERNIATION	·PAIN DISTRIBUTION	·NUMBNESS	·WEAKNESS	·REFLEX CHANGES
L3–L4 disc (L4 root)	Low back, buttock, lateral thigh, anterior calf, ankle, and occasionally big toe	Lower anterior thigh and patella	Mid (quadriceps)	Diminished (knee jerk)
L4–L5 disc (L5 root)	Low back, buttock, lateral thigh, calf, ankle, big toe	Lateral calf, web space of first and second toe	Foot (dorsiflexion)	None
L5–S1 disc (S1 root)	Low back, buttock, posterior thigh, and calf	Posterior calf, lateral heel, and foot	Foot (plantar flexion)	Diminished or absent (ankle jerk)

If bowel and bladder dysfunction are present, indicative of a large midline disc, prompt surgical intervention may be indicated. Otherwise, initial treatment of acute discogenic radiculopathy consists of short periods (a few days) of immobilization and mild analgesics followed by gradual resumption in physical activity. Prolonged immobilization has been shown to be counterproductive. If severe pain persists after reasonable trials of conservative management, epidural steroids may be used.

Methylprednisolone acetate is the most commonly used preparation. The usual dose is 80 mg, but smaller amounts should be considered in diabetic patients. Injections are generally performed as close to the affected nerve root as possible. Injection of a small volume (3 to 4 mL) of local anesthetic (preferably short acting, e.g., 1% lidocaine) will produce considerable analgesia if it reaches the affected nerve root, confirming proper drug placement. The anesthetic may be injected first as a test dose to rule out intrathecal placement. In occasional patients, particularly those with S1 pathology, the drug will not spread adequately to the affected root. In that situation, caudal injection may result in better drug access to the injured nerve.

Fluoroscopic guidance is often used to ensure the drug reaches the target nerve root. For the interlaminar approach, the patient is positioned prone and the appropriate interspace is identified. The needle is introduced slightly off the midline on the affected side, at the lower border of the interlaminar space, and directed slightly cephalad. It is advanced until the ligamentum flavum is engaged, and a loss of resistance technique is used to initially identify the epidural space (Fig. 56-4). A small volume of nonionic radiographic dye is injected "live," and both AP and lateral images are observed (Fig. 56-5). Intravascular injection can be readily identified as the dye is quickly carried away from the injection site. Following observation of appropriate spread of dye, the steroid is injected, either with or without anesthetic. If dye does not spread to the affected nerve root, another approach is attempted, either at a different level or via a transforaminal

technique.

FIGURE 56-4. Fluoroscopic translaminar approach to the epidural space at the L5–S1 level.

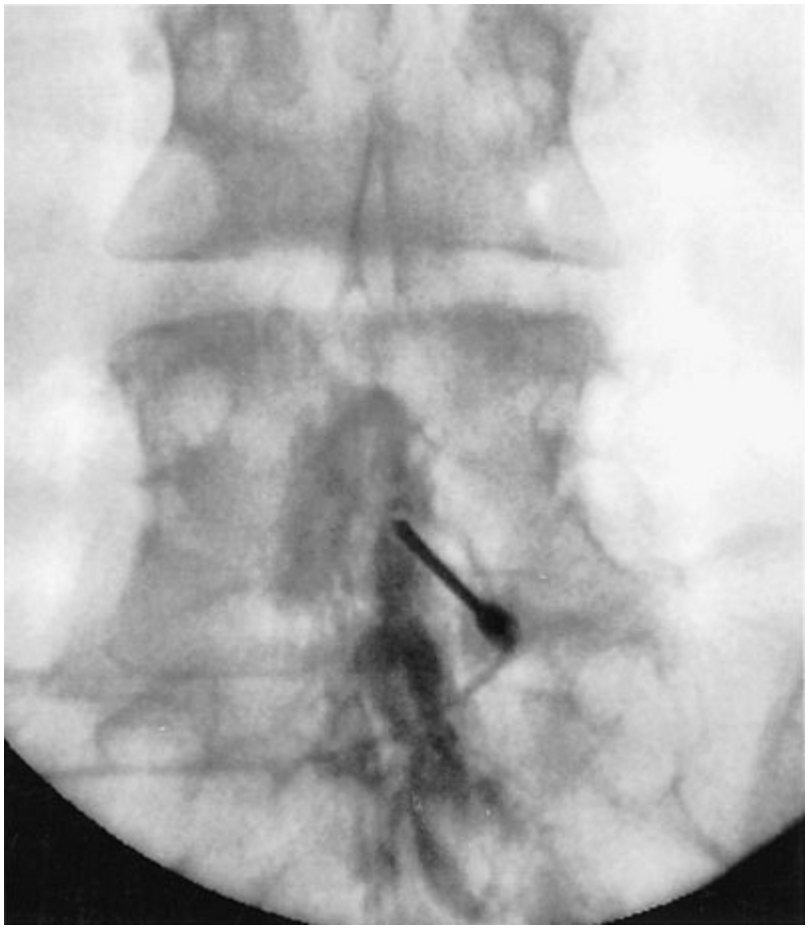

FIGURE 56-5. Epidural injection of 2 mL nonionic radiopaque dye via the L5–S1 interlaminar space.

The transforaminal approach involves placement of a needle at the exit site of the affected nerve root from the foramen. Using an oblique view (left anterior oblique for a right-sided block), the needle is positioned against the posterolateral aspect of the vertebral body, just below the pedicle. Injection in this so-called "safe triangle" will reduce the risk of intraneural injection, which can result in intrathecal drug spread.[66] Nonionic radiographic dye is injected "live," and should be seen to spread both centrally into the epidural space and peripherally along the nerve root (Fig. 56-6). Careful observation during injection will help rule out intra-arterial injection. Injection of the particulate steroid into a radicular artery could theoretically produce spinal cord or nerve root injury. A small amount of local anesthetic (1 to 2 mL) should be injected to determine if the target nerve root is indeed a pain generator. The usual dose of methylprednisolone acetate is 20 to 40 mg.

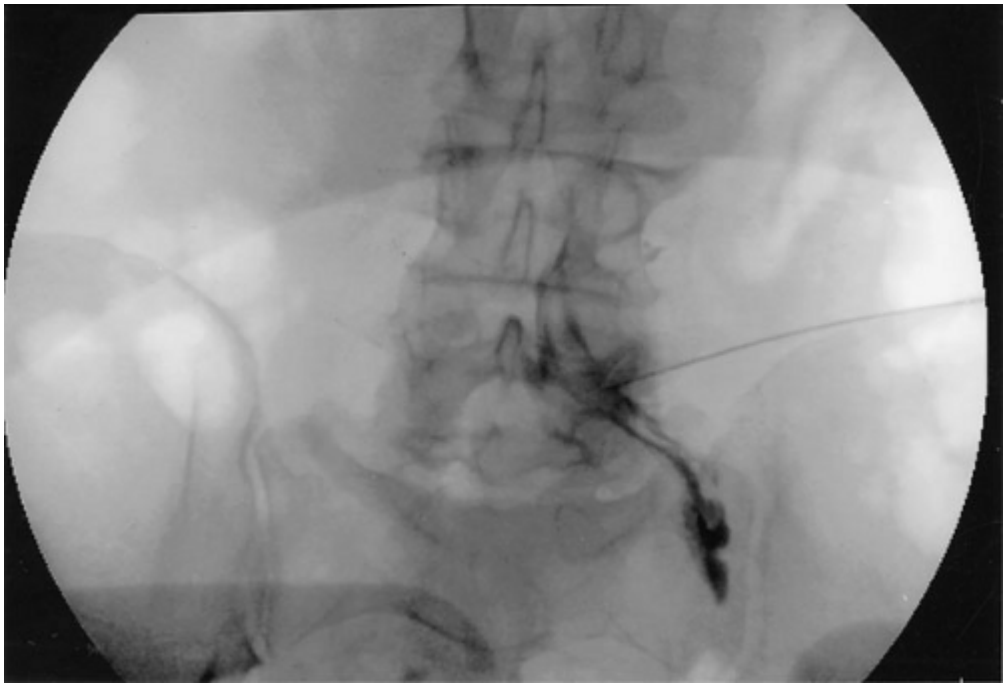

FIGURE 56-6. Right transforaminal epidural injection. Injection of 2 mL nonionic radiopaque dye demonstrates spread of injectate proximally into the epidural space and distally along the nerve root. The nerve root can be visualized as lucency outlined by the dye.

Another approach involves passage of a radiopaque caudal catheter under fluoroscopic control. The catheter is advanced epidurally to the foramen of the target nerve root. Injection should be carried out in the same manner as for transforaminal injection.

The fluoroscopically controlled techniques are especially indicated for patients who have had previous surgery or who have anatomic conditions that are likely to make a blind epidural difficult. Although a growing number of physicians use fluoroscopy for all epidural steroid injections, standard techniques may be reasonable for patients who have relatively normal anatomy.

Reassessment should be carried out 1 to 2 weeks after the initial treatment. If the patient has little or no pain at the time

of the return visit, repeating the injection is relatively unlikely to be of benefit. However, if it was believed that the drug may not have reached the affected root at the time of the initial injection, a repeat procedure is a reasonable option. If symptoms are improved at the time of the follow-up visit, but some pain is still present, it is likely that a repeat injection will produce further improvement. A third block can be performed 1 to 2 weeks later if some symptoms persist. An algorithm for epidural steroid treatment is shown in Fig. 56-7.

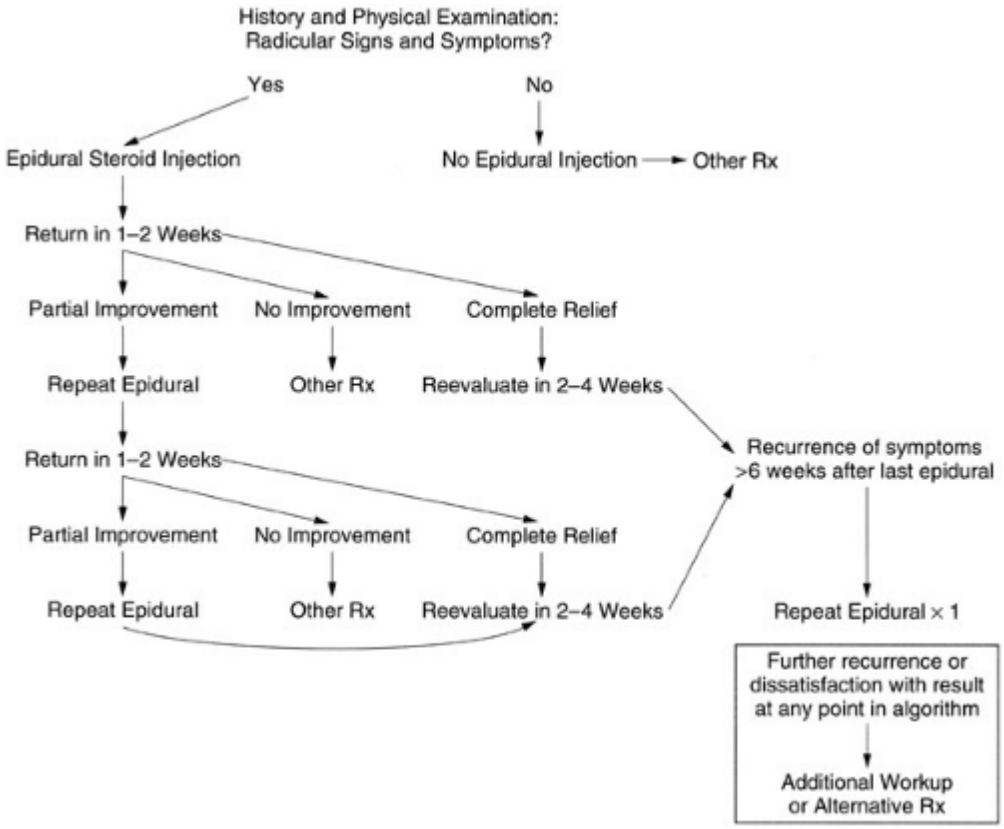

FIGURE 56-7. Algorithm for treatment of sciatica with epidural steroid injections.

There appears to be extremely little risk of serious complications associated with the use of epidural steroid injections. Animal studies tend to confirm the safety of neuraxial administration of depo steroids.[67,68] Allegations that the 3% polyethylene glycol vehicle of methylprednisolone acetate (MPA) and triamcinolone diacetate (TD) is capable of producing neurologic damage[69] are based on studies of high concentrations of propylene glycol (80 to 100%), and appear to be unfounded. The doses of corticosteroids commonly used for the treatment

of sciatica are capable of producing adrenal suppression for up to several weeks, and there are occasional reports of cushingoid side effects, sometimes lasting for weeks or longer. For example, a single injection of triamcinolone into the epidural space for the treatment of low back pain in adult patients has been shown to acutely suppress the hypothalamic-pituitary-adrenal (HPA) axis as reflected by decreased plasma cortisol and adrenocorticotrophic hormone levels in response to a provocative stimulus.[70] When three epidural triamcinolone injections were administered at 7-day intervals, the median suppression of the HPA axis was less than 1 month following the last injection, and all patients had recovered by 3 months. Sedation with midazolam in conjunction with the epidural steroid injection accentuates the suppression of the HPA axis.[70] These observations suggest the possible need for exogenous steroid coverage in patients undergoing major stress during the period that the HPA axis may be suppressed by epidural steroids. Epidural steroid injections should be used with caution in diabetic patients, who may be at added risk for epidural infections, and whose glucose control may be compromised. Of the several cases of epidural abscess reported following epidural steroids, most occurred in diabetic patients.[71] Because of the immunosuppression associated with the steroid, aseptic technique should be meticulous.

Most of the literature documenting the safety of epidural steroids comes from reports on the use of a small number of injections, usually one to three, and with modest doses, usually 40 to 80 mg MPA or 50 mg TD. There are few data to support the safety of this treatment when higher doses

are used.

There is some evidence that complications can occur following intrathecal steroid injections. Accidental injection of substantial doses of local anesthetic can result in high or total spinal. No cases of death or brain damage were reported following epidural steroid injections by the ASA Closed Claims Project,[72] all of which undoubtedly involved intrathecal local anesthetic placement. Aseptic meningitis[73] and bacterial meningitis[74] appear to be uncommon but real risks. Arachnoiditis[75] and cauda equina syndrome[76] have been reported, but these cases are rare and have occurred after multiple injections over a prolonged time interval. Nevertheless, it may be reasonable to use a test dose of local anesthetic prior to injection of steroid, or to use fluoroscopy and radiographic dye to rule out intrathecal placement of the needle.

Patients with chronic radicular low back pain are much less likely to benefit from epidural steroid injections than are patients with more acute symptoms. Abram and Anderson[77] reported in a retrospective study that patients with long-standing symptoms were much less likely to experience even transient relief from epidural steroid injections. Similar findings were seen in a subsequent prospective study.[64] Patients who had undergone previous back surgery also had a much lower success rate. Several mechanisms may lead to chronic radicular pain that is unresponsive to steroid injections. Spontaneous activity or ephaptic transmission may occur from the injured, demyelinated root. Scarring of the root, with replacement of neural elements with fibrous tissue, causes inelasticity of the nerve. The nerve root can no longer stretch with leg motion, and chronic mechanical irritation ensues.[51] Loss of large afferent fibers may lead to disruption of dorsal horn gating mechanisms and disinhibition of spinothalamic projection cells. Loss of disc height following herniation can lead to narrowing of intervertebral foramina, with subsequent root irritation laterally, or may cause redundancy and buckling of the posterior longitudinal ligament, which can effectively narrow the spinal canal. Loss of disc height can lead to facet joint subluxation and degeneration, producing pain from the joint itself and to osteophyte formation, which can narrow foramina or the central canal. Injury to the vertebral plate, the cartilaginous portion of the vertebral body adjacent to the disc, often accompanies disc disease and may lead to osteophytic growth into the central canal.

Some patients with chronic radicular pain do experience relief for several weeks to months after epidural steroids, and a growing number of physicians are willing to repeat the injections at 3- to 4-month intervals. Such treatment appears to be relatively safe, although no prospective studies have been carried out in this treatment population.

Lumbosacral Arthropathies

Degeneration and inflammation of the lumbar facet joints and sacroiliac joints can produce low back pain that is often difficult to distinguish from radicular pain. Both conditions may cause pain that radiates to the lower extremities. Computed tomography scanning is a fairly reliable method of demonstrating pathology in these joints. Bone scans, particularly single-photon emission computed tomography (CT) scanning, may also be useful diagnostically.

When facet arthropathy is the suspected cause of low back pain, the diagnosis can be confirmed by injection of local anesthetic into the facet joint. The procedure can be done easily under fluoroscopic control. The patient is placed prone, and the affected side is tilted upward until the joint space is visualized. Proper needle placement can be confirmed by injection of 0.5 to 1 mL of nonionic contrast (Fig. 56-8). The injection should transiently reproduce the patient's pain, and the dye will outline the extent of the capsule. Injection of 0.5 mL of local anesthetic should produce dramatic relief of arthropathic pain. Injection of a small volume of insoluble corticosteroid into an affected joint has been reported to produce analgesia lasting 6 months or longer in about one-third of patients who experience relief from the local anesthetic. NSAIDs may be of some benefit.

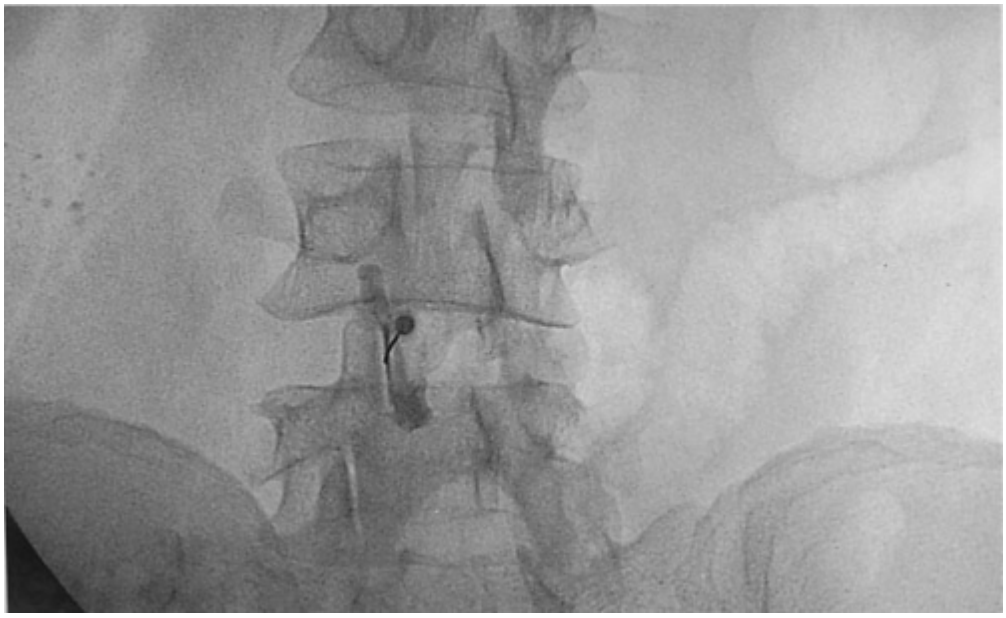

FIGURE 56-8. Left L4–L5 facet injection. Injection of 0.5 mL nonionic radiopaque dye demonstrates the extent of the joint capsule.

When sacroiliac pathology is demonstrated, injection of the joint with local anesthetic will help confirm the diagnosis. In an uncontrolled study, we found that 25 of 35 patients with suspected sacroiliac disease experienced pain relief from local anesthetic injection of the joint. After injection of triamcinolone diacetate, 7 of 20 patients who were followed long-term experienced at least 6 months of moderate to complete pain relief (Abram SE, unpublished data, 1982). As noted previously, a more rigorous local anesthetic treatment paradigm showed only a 20% response to local anesthetic injection.[49] Injection is performed in the lower one-third of the joint, within the diarthrodial portion. A slightly posterior oblique view permits alignment of the anterior and posterior joint lines, giving a view along the plane of the joint. Correct positioning of the needle can be confirmed with the injection of a small volume of dye, which will be seen spreading along the joint space (Fig. 56-9).

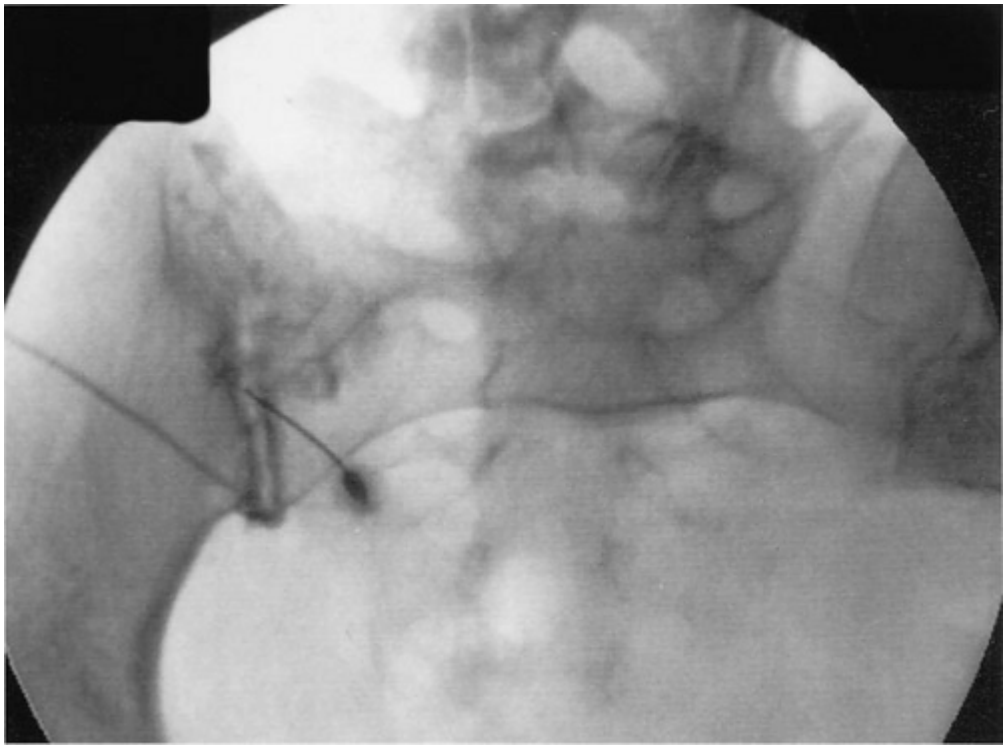

FIGURE 56-9. Sacroiliac joint injection. Radiopaque dye injection outlines the cartilaginous portion of the joint.

Myofascial Pain

The myofascial syndrome is an extremely common cause of somatic pain. It is associated with marked tenderness of discrete points (trigger points) within affected muscles, pain that is referred to areas some distance from the trigger point, and the appearance of tight, ropy bands of muscle. Autonomic changes, such as vasoconstriction and skin conductivity changes, may occur some distance from the affected muscle.[78] Biopsies of trigger points have been reported to show little or no change or to show degenerative changes, the severity of which corresponds to the intensity of the symptoms.[78] Although the pathophysiology of the condition has not been clearly defined, Travell and Simons[78] proposed the following explanation: acute muscle strain causes disruption of sarcoplasmic reticulum and release of calcium, which in turn produces sustained or

repeated contraction and fatigue. Blood flow becomes inadequate for the degree of metabolic activity occurring locally. Adenosine triphosphate becomes depleted, preventing release of myosin from actin, causing sarcomeres to become rigid and affected muscles to become taut. Nociceptor-sensitizing substances, such as prostaglandins, bradykinin, and serotonin, are released from platelets and mast cells, causing increased firing of muscle nociceptors.

Many of the commonly affected muscles, the sites of their trigger points, and their zones of referred pain have been mapped out. The scapulocostal syndrome, one of the most common patterns of myofascial pain, is characterized by a trigger point located just medial and superior to the upper portion of the scapula and pain that can radiate to the occipital region, shoulder, medial aspect of the arm, or anterior chest wall.[79] Myofascial pain involving gluteal muscles produces pain referred into the posterior thigh and calf, mimicking S1 radiculopathy. Myofascial pain involving the piriformis muscle, which overlies the sciatic nerve, can produce sciatic irritation and, occasionally, hypoesthesia, again resembling radiculopathy.

The most important aspect of treatment for myofascial pain is to regain muscle length and elasticity. This is best done by maneuvers that gently stretch affected muscles. Because of the sensitization of muscle afferents, appropriate physical therapeutic maneuvers are often painful

and may reinitiate muscle contraction. Therapy aimed at reducing muscle pain and sensitivity should therefore be employed before stretching exercises. Trigger point injection, infiltration of local anesthetic directly into the trigger point, is a valuable initial therapy. Pain relief following injection confirms the diagnosis of myofascial

syndrome, and a series of several injections performed daily or every several days can markedly reduce muscle sensitivity. Fairly vigorous therapy can be carried out during the analgesic period after each injection. Ultrasound therapy applied over the affected muscle may also produce periods of analgesia.

Trigger point injections and ultrasound require the participation of trained personnel, precluding their use on a frequent regular basis (e.g., several times per day). Several treatment modalities can be used by the patient alone or with the help of family members. Transcutaneous electrical nerve stimulation (TENS), applied directly over the trigger points, may produce analgesia during stimulation and often for some time afterward. Stimulation should be carried out for 20 to 30 minutes prior to stretching exercises. Some patients who do not respond to the usual high-frequency TENS may benefit from a brief period (about 5 to 10 minutes) of low-frequency (2 to 4 Hz), high-intensity TENS. The current should be high enough to cause muscle contraction and mild discomfort. Vapocoolant spray (e.g., fluoromethane) sprayed over the affected muscle may produce transient analgesia sufficient to facilitate physical therapy. Massage of the affected muscle with ice may also be of some benefit.

Injection of myofascial trigger points with botulinum toxin, which produces a long-lasting block of acetylcholine release from peripheral nerves, has been shown to provide lasting pain relief in myofascial syndrome.[80] Pain relief begins within 1 to several days after injection and generally lasts several weeks. The principal side effect is weakness in the injected and adjacent muscles.

Myofascial pain often develops in patients whose response to stress is an increase in muscle tone. This mechanism frequently contributes to the pathophysiology of tension headache. Surface measurement of electromyography in such patients will often demonstrate extremely high activity at rest. Electromyographic biofeedback is a useful added therapy for such patients and appears to be helpful in preventing future painful episodes for patients with recurrent problems.

Complex Regional Pain Syndromes

The term *reflex sympathetic dystrophy* (RSD) has been widely used to describe a group of conditions associated with burning pain in an extremity; dystrophic changes in skin, hair, nails, and joints; allodynia; and signs of autonomic dysfunction, including skin temperature changes and alterations of sweat gland activity. The term *causalgia* has been used to describe a syndrome with similar clinical features following injury to a major nerve trunk. The term *sympathetically maintained pain* (SMP) has been used synonymously with both of these syndromes, implying that the autonomic nervous system is somehow involved in the pathophysiology of these conditions. Although autonomic dysfunction is clearly evident in some cases of causalgia and RSD, it is not a prominent feature in some cases, and many patients with these conditions fail to respond to blockade or ablation of sympathetic fibers. Therefore, the term *complex regional pain syndrome* (CRPS) has become widely accepted.[81] Complex regional pain syndrome type I (CRPS-I) has replaced the term RSD, and CRPS-II is now used in place of the term causalgia. SMP describes that component of pain that is initiated or maintained by activity in the sympathetic nervous system, including both efferent sympathetic nervous system activity and circulating catecholamines. Painful conditions that are not typical of CRPS may have a sympathetically mediated component. Patients with certain types of neuropathic pain do not exhibit the typical clinical features of CRPS and yet experience significant pain relief following sympathetic blockade. Likewise, some patients with typical features of CRPS experience no relief from sympathetic denervation. Pain that does not appear to be sympathetically mediated is termed *sympathetically independent pain*.

Crps-I

Common antecedents to the development of this syndrome include crush injuries, lacerations, fractures, sprains, and burns. Many postoperative cases occur after surgery involving the median nerve distribution, such as carpal tunnel release or palmar fasciectomy. The syndrome occasionally occurs after cerebrovascular accident or myocardial infarction. The pain is usually burning in quality and is often accompanied by diffuse tenderness and pain on light touch. The hand or foot are commonly the major sites of pain. The pain and hypersensitivity often spread beyond the original sites of pain.

Autonomic dysfunction is manifested as changes in skin temperature, cyanosis, edema, and hyperhydrosis. The skin may be warm and erythematous, with occasional to frequent bouts of intense vasoconstriction. In more severe, rapidly progressive cases the involved extremity is predominantly cool and pale or cyanotic. The vascular phase of bone scanning often demonstrates differences in flow between the normal and the affected extremity. Thermography or local measurement of skin temperature using surface thermistors is useful in documenting differences in skin blood flow.

Dystrophic changes become increasingly evident with time if the condition is untreated. Skin of the affected area becomes smooth and glossy. Bone demineralization takes place to a much greater extent than would be expected on the basis of reduced activity. Joints in the affected extremity become stiff and painful as a result of synovial edema, hyperplasia, fibrosis, and perivascular inflammation.

Local anesthetic blockade of the sympathetic chain is useful diagnostically, particularly when only a portion of the spectrum of possible symptoms is present. Cervicothoracic sympathetic block is usually carried out by injection of local anesthetic on the anterior tubercle of C6 (see Fig. 56-10) or on the medial portion of the transverse process of C7. Unfortunately, a moderate number of patients experience Horner's syndrome but fail to demonstrate evidence of sympathetic denervation of the upper extremity. Using magnetic resonance imaging (MRI) scans, Hogan et al[82] demonstrated that solutions injected paratracheally at the C6 or C7 anterior tubercle often fail to spread to the stellate ganglion. Subsequently, he and his colleagues described a CT-guided technique for direct injection of the stellate ganglion just anterior to the head of the first rib.[83] Using this technique, evidence of sympathetic denervation of the extremity is often seen after injection of as little as 1 mL of local anesthetic. Lumbar sympathetic block is

performed by injecting local anesthetic at the anterolateral aspect of the lumbar spine (see Fig. 56-11). Placement of the needle at the lower border of the L2 vertebral body minimizes needle contact with the nerve root and places the needle tip in the plane of the sympathetic chain.

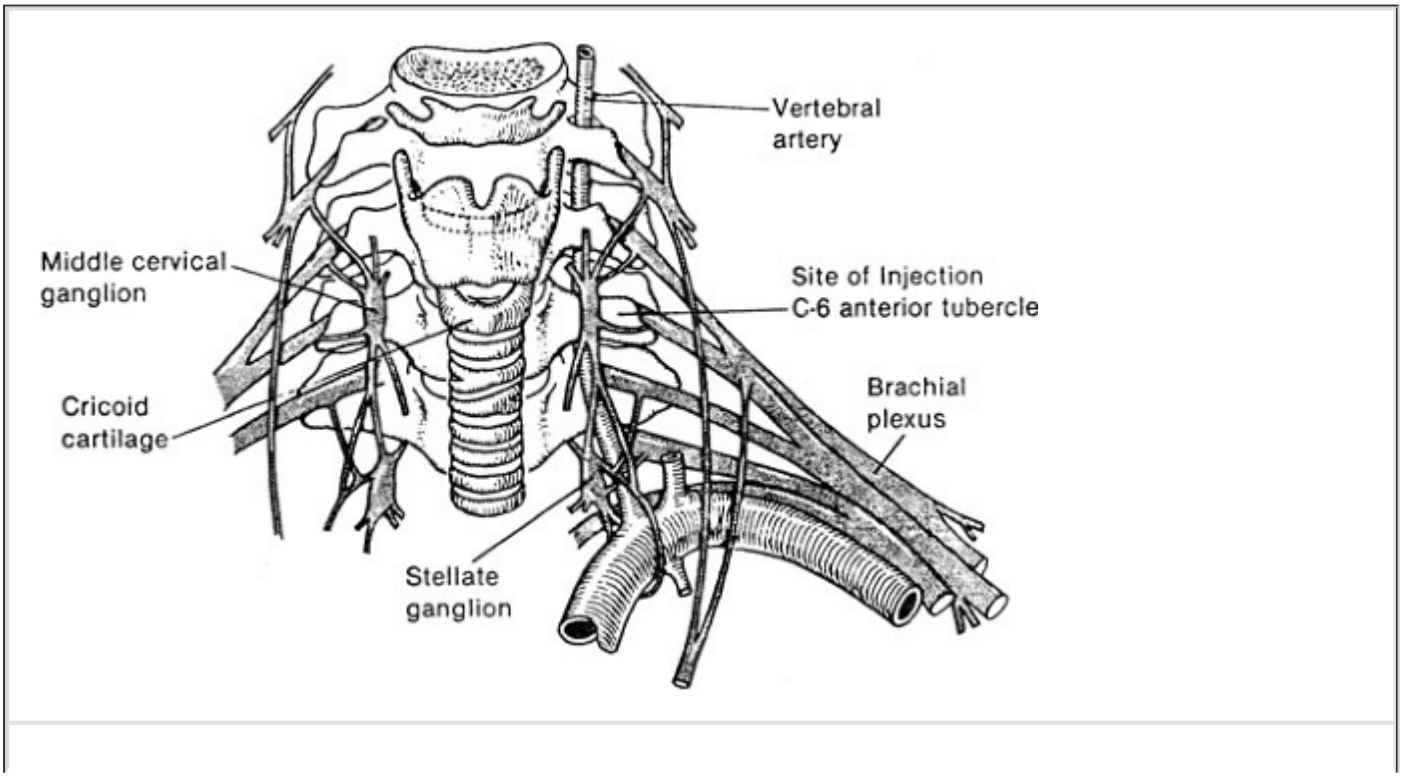

FIGURE 56-10. Site of injection for the C6 paratracheal approach to the cervicothoracic sympathetic chain. (From Abram SE, Boas RA: Sympathetic and visceral nerve blocks. In Benumof JL [ed]: Clinical Procedures in Anesthesia and Intensive Care, p 787. Philadelphia, JB Lippincott, 1992.)

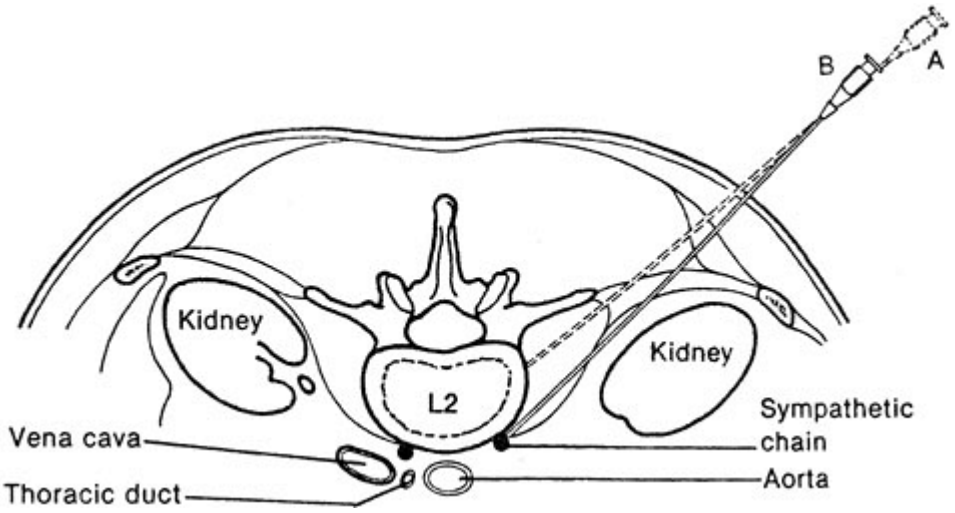

FIGURE 56-11. Initial needle position **(A)** and final needle position **(B)** for lumbar sympathetic block. Contact should be made at the lower portion of the L2 vertebral body, just cephalad to the L2–L3 disc. (Reprinted with permission from Stanton-Hicks M, Abram SE, Nolte H: Sympathetic blocks. In Raj PP [ed]: Practical Management of Pain, p 674. Chicago, Year Book, 1986.)

Pain relief following sympathetic blockade does not guarantee that there is a sympathetically mediated component to the patient's pain. Pain relief may be the result of a placebo effect, spread of anesthetic to somatic afferent fibers, blockade of afferent fibers located in the sympathetic chain, or the systemic effect of absorbed local anesthetic.[84] Similarly, failure to achieve pain relief following sympathetic block does not guarantee that the pain is not sympathetically mediated. There may be sympathetic efferent fibers to the limb that do not travel with that portion of the sympathetic chain that has been interrupted.[84]

Once it has been established that there is a sympathetically mediated component to the patient's pain, treatment consists of a series of local anesthetic sympathetic blocks. For patients with lower-extremity pain, if lumbar sympathetic block is technically difficult or is particularly painful to the patient, repeated or continuous lumbar epidural blockade can be used instead. Injections are generally continued until symptoms are minimal or until there is no further progression of benefit. Physical therapy, consisting of desensitizing techniques and active or active-assisted range of motion, is usually indicated and should be carried out immediately after each sympathetic block. Vigorous passive range of motion and heavy weights should be avoided because they may retrigger symptoms. Patients whose condition is diagnosed and treated early are more likely to respond to sympathetic blocks. Success rates of 90% or more have been reported.[85] Unfortunately, few if any controlled studies documenting the long-term effects of sympathetic blockade exist, and the high success rates associated with early intervention may simply reflect the natural history of the process.

The use of systemic sympathetic blocking drugs is occasionally useful clinically. Prazosin and phenoxybenzamine, both α-adrenergic blocking agents, provide partial symptomatic relief in some patients, particularly those patients exhibiting signs of vasoconstriction.[86] Intravenous

phentolamine, given in small incremental doses up to 30 mg maximum, is helpful in predicting response to oral α-adrenergic blockers.[87] Oral and transdermal clonidine are also occasionally useful. Other systemic medications that have been used with variable success include calcium channel blockers, tricyclic antidepressants, and anticonvulsants. Gabapentin has been used with some success and is better tolerated than most of the older anticonvulsants.

Kozin et al[88] reported substantial benefit from treatment of RSD with a brief course of high-dose corticosteroids. Their success rate was 82%, which is particularly impressive in that many of their patients had experienced long-term symptoms. However, it is not clear whether improvement was permanent in these patients. In addition, their criteria for diagnosing RSD were somewhat vague and did not include response to sympathetic block, allodynia, hyperpathia, or burning pain. Side effects from high-dose systemic steroids are often troublesome. An alternative treatment is the intravenous regional injection of soluble steroids in the affected limb.[89] TENS can be a useful adjunctive treatment for CRPS-I. Increased skin temperature during stimulation has been documented in patients who experience pain relief following treatment,[90] and TENS has been reported to provide substantial clinical benefit when used as the sole therapy.[91]

Patients with long-standing symptoms of CRPS-I, who develop dystrophic changes and, frequently, the behavioral and psychological profiles typical of chronic pain patients, are extremely resistant to the types of intervention described previously. Surgical or neurolytic sympathectomy has been suggested as a treatment for patients who respond only transiently to sympathetic blocks. It is the authors' experience, however, that most patients with chronic CRPS-I get no relief or only a few days to weeks of benefit from sympathetic ablation. Therapy instead should be directed toward extinguishing pain behavior, increasing strength and mobility, and developing coping strategies.

Crps-Ii

The term *causalgia*, which has been used to indicate a specific syndrome of burning pain and autonomic dysfunction associated with major nerve trunk injury,[85] has been replaced by the term *complex regional pain syndrome type II* (CRPS-II). Most cases of CRPS-II are caused by gunshot wounds. Rapid, violent deformation of the nerve seems to play a major pathophysiologic role. Most cases involve partial injury to the brachial plexus, median nerve, or tibial division of the sciatic nerve proximal to the elbow or knee. Pain often begins immediately after injury and may spread to involve previously unaffected areas. There is usually severe burning pain, allodynia, and hyperpathia, often accompanied by deep shooting, crushing, or stabbing pains. The pain is aggravated by movement or any physical stimulation, such as light touch or pressure. Stimuli that increase sympathetic activity, such as a loud noise, a flash of light, or anxiety, often increase the severity of the pain. Pain may persist for many years in inadequately treated patients. There is usually evidence of reduced sympathetic activity in the affected extremity, which is generally warm, dry, and venodilated. Vasoconstriction, hyperhydrosis, cyanosis, and edema are occasionally seen. Dystrophic changes of skin, bone, and joints, similar to those encountered in CRPS-I patients, often begin early.

Reports on the therapy of causalgia from the early 1900s described surgical destruction of peripheral nerves, which was uniformly unsuccessful. Opioid analgesics were likewise ineffective. In 1930, Spurling[92] published encouraging results of treatment with sympathetic ganglionectomy. Since then, numerous reports have documented the efficacy of such treatment. Mayfield[93] reported complete relief of symptoms in 91% of 105 causalgia victims treated with surgical sympathectomy. Bonica,[85] in a review of 500 cases, found that 80% of patients responded to sympathectomy.

More recently, less invasive therapy has been undertaken in the management of CRPS-II. Neurolytic lumbar sympathetic block has been proposed as an alternative to surgical lumbar sympathectomy and has been shown to produce long-term sympathetic denervation in the large majority of patients.[94] Aggressive treatment with local anesthetic sympathetic blockade has met with some success. Bonica[85] reported success in 10 of 17 causalgia patients managed with

frequent local anesthetic blocks. The authors have treated three patients with early, severe causalgia who responded dramatically to continuous-infusion lumbar epidural blockade or continuous-infusion brachial plexus block that was maintained for 5 to 7 days (unreported findings Abram SE, 1986).

Herpes Zoster

Herpes zoster is caused by the varicella zoster virus, which, following a chickenpox infection, lies dormant in dorsal root ganglia. As immunity to the virus declines with advancing age or immunosuppression, the virus becomes active again. In patients with normal immune systems, the infection is confined to a single dermatomal segment. In immunocompromised patients, multiple segments may be involved.

Herpes zoster most commonly involves the thoracic and trigeminal dermatomes, with the ophthalmic division of the trigeminal nerve being second most common.[95] Autopsy studies have shown evidence of viral DNA in trigeminal ganglia in 87% of patients and in thoracic dorsal root ganglia in 53% of patients.

The incidence of herpes zoster in the general population is 1 to 2/1,000 per year. It is higher among older patients, whose incidence is 5 to 10/1,000 per year. Postherpetic neuralgia has been defined as pain persisting well beyond healing of the skin rash (4 weeks to 6 months). Overall incidence among patients with herpes zoster infection has been reported to range from 9 to 34%.[96] Incidence is considerably higher in older patients (16% in patients younger than 60 years of age, 47% in patients older than 60 years of age).[97] Patients with severe pain during the acute phase of the disease are more likely to develop postherpetic neuralgia.

As the latent virus in the sensory ganglion becomes active, it causes a vesicular skin eruption characterized by inflammation, intranuclear inclusion bodies, and giant cell formation. Severe inflammation, hemorrhage, and necrosis occur in the dorsal root ganglia, dorsal horn, and adjacent meninges. Changes in the peripheral nerve include demyelinization, Wallerian degeneration, fibrosis, and cellular infiltration.[98] Noordenbos proposed that pain of postherpetic neuralgia is associated with loss of large afferent fibers with relative preservation of C fibers.[99] In subsequent studies, however, examination of biopsy and autopsy specimens from patients with or without persistent pain failed to show differences in populations of different fiber types.[98,100] Some specimens showed predominantly large fiber loss, but this was seen in patients with and without postherpetic neuralgia. In contrast, atrophy of the dorsal horn appears to be a regular autopsy feature in patients who had postherpetic neuralgia at the time of death. Persistence of inflammatory cells has been described in patients with long-standing postherpetic pain.[100]

Because of anecdotal evidence that sympathetic blocks provide lasting pain relief in patients with acute herpes zoster,[101] there has been speculation that intense sympathetic stimulation initiated by the virus is, at least in part, responsible for the pathologic changes that lead to postherpetic neuralgia. Winne[102] proposed that the increased sympathetic discharge initiated by the virus produces perineural ischemia that results in loss of large afferent fibers and persistence of small, unmyelinated neurons. There are several problems with the theory, including a lack of evidence that there is a local increase in sympathetic activity or that neural ischemia results from sympathetic discharge. In addition, the Noordenbos theory that pain is associated with small fiber predominance does not appear to be valid, nor is there substantial evidence that early sympathetic blockade reduces the incidence of postherpetic neuralgia.

A variety of treatments have been advocated for managing patients with acute herpes zoster. The goal of management is to control the pain associated with the acute eruption and, if possible, prevent the occurrence of persistent pain or postherpetic neuralgia. Antiviral agents have been advocated for management of the acute stage of the disease. Acyclovir has been widely used and has been shown to modestly accelerate the rate of cutaneous healing and to reduce the severity of the acute pain, but there is little evidence that it reduces the incidence of postherpetic neuralgia.[103] In contrast, one of the newer antiviral agents, famciclovir, does appear to reduce the incidence and severity of postherpetic neuralgia if initiated soon after the eruption begins.[104]

Corticosteroids have enjoyed some popularity for the treatment of the pain of acute herpes zoster. Eaglestein,[105] in a double-blind, controlled study, demonstrated that systemic triamcinolone reduced the duration of acute pain in patients older than 60 years of age. Several other studies have failed to demonstrate a reduction in the incidence of postherpetic neuralgia. Likewise, subcutaneous steroid infiltration[106] and epidural steroid injection[107] have been shown to reduce the acute pain intensity and/or duration, but there have been no controlled trials to determine whether they influence the incidence of postherpetic neuralgia. Although there is some concern over the possibility that steroids may increase the risk of dissemination of the virus, there is little evidence that this is likely to occur.[95]

Rosenak[108] was the first to report a beneficial effect of local anesthetic blocks on the pain of herpes zoster infection. He found that paravertebral sympathetic blocks or gasserian ganglion blocks with procaine resulted in dramatic relief of pain and rapid drying of vesicles. A number of subsequent uncontrolled studies also attest to the beneficial effect of sympathetic blockade. A single controlled study[109] attests to the ability of sympathetic blocks done early in the acute stage to prevent postherpetic neuralgia. The study contained only 10 patients in each treatment arm, and there have been no subsequent controlled studies to confirm these findings.

There is substantial evidence that local anesthetic blocks are ineffective in the management of postherpetic neuralgia. At best, they provide temporary relief, often only for the duration of the anesthetic agent. Winnie[102] more recently confirmed this observation in a study that showed a low incidence of lasting benefit from sympathetic blocks instituted more than a few months after the eruption. It is unclear whether the apparently favorable response to blocks instituted early in the course of the disease represents a real benefit from treatment or simply the natural history of the disease in the majority of patients.

The management of postherpetic neuralgia is often frustrating because some patients respond poorly to nearly every therapy provided. Tricyclic antidepressants provide the best chance of relief with the fewest side effects, although drowsiness, xerostomia, dysphoria, arrhythmias, and ataxia are potential problems. The onset of analgesia is slow (often requiring 2 to 3 weeks) and the relief is rarely complete, so many patients fail to realize they are experiencing much relief until they discontinue the drug and the pain returns to its former intensity. The addition of a second drug, such as an anticonvulsant (carbamazepine, valproic acid, phenytoin), may provide some additional benefit, but one must follow patients closely for the possibility of liver dysfunction or bone marrow depression. Gabapentin has been shown to be significantly more effective than placebo for the management of postherpetic neuralgia.[110] The majority of patients required 3,600 mg per day. Side effects of gabapentin are usually mild, there are few significant drug interactions, and it does not carry the risk of organ dysfunction seen with older anticonvulsants. Opioids rarely provide dramatic relief and cause major problems with constipation in older patients. Most studies fail to show much benefit from spinal cord stimulation. TENS may help in occasional patients, but cause aggravation of pain in patients with severe allodynia, and is not beneficial if there is considerable cutaneous sensory loss. Topical capsaicin is occasionally helpful, but can aggravate the pain in some individuals. Transdermal lidocaine patches can be helpful in some patients.

PHARMACOLOGIC TREATMENT OF CHRONIC PAIN

6 The long-term use of systemic opioids in patients who have noncancer pain continues to cause concern for many physicians. Although most pain management physicians are comfortable with the use of opioids for patients who do not have a terminal illness, there is much disagreement regarding appropriate dosage, patient selection, and choice of drug. Among primary care practitioners, there remains much resistance to prescribing opioids for noncancer pain for a variety of reasons. These include the following concerns:

1. Addiction will occur.
2. Tolerance will develop, leading to loss of efficacy and increasing drug side effects.

3. Drug regulatory agencies will take action against the prescribing physician.
4. Patients may be diverting (selling) drugs.

The reality is that certain patients experience good pain control over long periods of time with minimal tolerance and few side effects. Others have pain that is poorly controlled by opioids or have rapid reduction in efficacy requiring substantial dose escalation and eventual treatment failure. Although it is difficult to predict response to opioids in a given patient, there are some predictors of poor response. Patients with neuropathic pain are less likely to experience good pain control, and phasic pain (e.g., incident pain) is more difficult to control than constant or tonic pain. Patients with cognitive impairment or high levels of psychological distress are more likely to experience suboptimal pain control from opioids. A history of substance abuse is associated with a high risk of treatment failure and is believed by some physicians to represent a contraindication to opioid use.

The decision to prescribe opioids for patients with chronic pain should be based on the answers to three questions:

1. Is there a history of significant substance abuse?
2. Is there a good therapeutic effect? The selected medication should provide complete or substantial analgesia. There should be minimal dose escalation over time, and there should be measurable improvement in functional activity.
3. Are there substantial side effects? These should be minimal or tolerable.

Side effects should be monitored closely. Cognitive impairment is often insidious and may not be recognized by the patient or family members during treatment, but becomes obvious when the medication is withdrawn. Sedation, nausea, constipation, insomnia, and sexual dysfunction are common problems.

As noted in the section on pain mechanisms, there is substantial theoretical evidence that chronic opioid use may lead to a state of hyperalgesia or sensitization of spinal pain projection systems. Persistent opioid administration may lead to loss of responsiveness to both endogenous and exogenous opioids, as well as to hypersensitivity of systems that respond to noxious stimulation. Therefore, it is reasonable to withdraw and discontinue opioid administration for those patients who have evidence of central facilitation (allodynia, hyperalgesia, hyperpathia) and who exhibit poor responsiveness to opioids. Occasionally, such patients experience gradual improvement in pain, generally beginning a few weeks after drug withdrawal. Often, they will experience a reduction in adverse effects, especially cognitive impairment, sedation, constipation, and sexual dysfunction. Opioid withdrawal is commonly incorporated into chronic pain rehabilitation programs. All but 3 of 135 patients who had been on chronic opioid therapy were able to discontinue opioids during a comprehensive pain rehabilitation program at the Mayo Clinic.[111] The group demonstrated significant reduction in pain ratings, affective distress and depression, and increases in activity despite the discontinuation of opioids. Patients who had been on high doses did as well as those on low doses.

Few patients with chronic pain are addicted to opioids. Addiction is defined as compulsive use of a drug or substance resulting in physical, psychological, or social harm to the user, and continued use despite that harm.[112] It may be difficult to recognize addiction in patients with persistent pain. Signs of addiction include:

1. Intense desire for the drug and unfounded concerns over availability
2. Unsanctioned dose escalation
3. Use of drug when pain is absent or treatment of nonpain symptoms (anxiety, depression)

4. Aberrant drug-related behaviors

Drug diversion, or sale of drugs for recreational or street use, is difficult to document or to disprove. Occasionally, an

acquaintance or a family member will report such activity. Documentation depends on a negative drug screen. The patient is asked whether he or she has taken the prescribed drug in the past several hours. If the answer is yes, a urine sample is obtained immediately and analyzed for the prescribed drug. If it is absent, diversion is likely.

When opioids are prescribed over long intervals, there should be an agreement, either informal or written, outlining the physician's obligation to continue treatment and the patient's obligation to meet several expectations of behavior. For patients who have previously failed to meet behavioral expectations, a written agreement, or "opioid contract," may be helpful. Under such a contract, the patient agrees to obtain prescriptions from one physician source and to fill prescriptions at one pharmacy, and to discontinue use if there is rapid tolerance development, minimal therapeutic effect, substantial side effects, or failure to achieve improved physical function. The patient agrees to take medications only as prescribed and is not to request early refills. The patient agrees that no prescription will be issued in the event that drugs are lost, stolen, or accidentally destroyed. The physician, however, should be willing to adjust dosage as needed, within reason, particularly in the early stages of treatment. The patient should agree to unannounced random drug screening and to allow the physician access to all other medical records. The patient understands that violation of this agreement could result in discontinuation of opioid therapy and/or referral to an addiction specialist.

Adjuvant Analgesics

Imipramine was shown to be useful in treating chronic pain in 1960.[113] Since then, the tricyclic antidepressants have come into widespread use in the management of certain chronic pain conditions, particularly neuropathic pain. The most popular explanation of the analgesic property of these drugs is that reuptake inhibition of serotonin and norepinephrine increases the levels of these inhibitory neurotransmitters in the brainstem and spinal cord.

The clinically relevant benefits to be expected from judicious use of these drugs in patients with chronic pain syndromes are normalization of sleep patterns, reduction in anxiety and depression (if present), and reduction of the patient's perception of pain. Although the antidepressant and pain-relieving effects are often delayed in onset, the improvement in sleep patterns provided by these drugs usually occurs promptly, often with the initial dose. Tricyclics suppress rapid eye movement sleep, and abrupt cessation can be associated with rebound in the form of restless sleep, with excessively vivid and pervasive dreams.

The common side effects of the tricyclics include the antimuscarinic effects of xerostomia, impaired visual accommodation, urinary retention, and constipation. Antihistaminic effects occur via blockade of both H_1 and H_2 receptors, and include sedation and an increase in gastric pH. Orthostatic hypotension is mediated through the blockade of peripheral α_1-adrenergic receptors. Cardiac conduction effects mimic the actions of quinidine but in general are of little clinical relevance, except in the case of overdosage. The lethal potential of these drugs in overdose is substantial, especially when doses exceed 2,000 mg of amitriptyline or the equivalent.

Most studies of efficacy of these drugs in pain syndromes are open and are not controlled for placebo effects or for the presence of depression. Since the first double-blind placebo-controlled study by Watson et al in 1982,[114] several well-designed studies have been conducted. They studied the effects of gradually increasing doses of amitriptyline in patients suffering from postherpetic neuralgia. After 3 weeks, 16 of 24 patients had obtained good to excellent relief, with doses below the norm for treatment of depression and with no change in a standard psychometric instrument assessing the presence and severity of depression. Getto et al[115] reviewed 24 studies and found 19 to report some degree of benefit. Four double-blind placebo studies with a combined enrollment of 107 subjects yielded a 68% response rate with the active drug, as compared with a

13% response with placebo. Studies of a double-blind placebo crossover design included 140 subjects in five reports and revealed an aggregate response rate of 61%.

Beginning in 1987, Max et al[116,117] published a series of double-blind, placebo-controlled trials that assessed the efficacy of antidepressants in certain painful syndromes. They showed that tricyclic antidepressants had analgesic effects independent of their effects on mood in neuropathic pain states (diabetic neuropathies and postherpetic neuralgia), although not all subjects had a beneficial response.

With the introduction of the SSRI fluoxetine, there was hope that the new class of drugs would provide pain relief at least comparable to the tricyclics. Clinical experience and research into this have yielded mixed results. In 1989, Diamond and Freitag reported their somewhat positive experience with the use of fluoxetine in the treatment of headache.[118] This prompted numerous reports of fluoxetine use in pain, some of which purport to demonstrate some benefit.[119,120] Max compared desipramine, amitriptyline, fluoxetine, and placebo in the treatment of diabetic neuropathy pain and found that, whereas both amitriptyline and desipramine were beneficial, fluoxetine had no more effect than placebo.[121] Paroxetine has, however, been shown to be of benefit in the treatment of diabetic neuropathy pain.[122]

As noted previously, the pain-relieving effect of antidepressants has been attributed to the ability to block reuptake of serotonin and norepinephrine. Because serotonin is believed to be an important inhibitory neurotransmitter in descending pain inhibitory pathways, it was anticipated that the SSRIs would be at least as effective as the tricyclics, but with fewer side effects. This has not generally been the case. It is now postulated that the tricyclic antidepressants may exert their analgesic and antihyperalgesic effects through other mechanisms. These drugs have been shown to bind at NMDA receptors and can block NMDA-mediated synaptic activity.[123] This property, which may not be shared by many of the SSRIs, may be the principal mechanism of analgesic action.

Another class of agents said to have some efficacy in the treatment of chronic pain syndromes are the anticonvulsants. Unlike the antidepressants and neuroleptics, the pharmacology of this group varies substantially from one drug to another. The older members of this class that have some benefit in pain patients are phenytoin, valproic acid, carbamazepine, and clonazepam. The first three affect sodium, potassium, or calcium flux across the neuronal membrane, whereas clonazepam is a benzodiazepine and works via the benzodiazepine-GABA-chloride channel receptor complex.

The side effect profiles of these drugs are also variable, with nausea and ataxia being commonly seen with any of them. Phenytoin can cause vitamin D and K and folate deficiencies, hirsutism, and gingival hyperplasia. Valproic acid use is associated with hepatic enzyme elevations, rare but occasionally fatal hepatic necrosis in children, and significant gastrointestinal effects that can be modified by the use of the enteric-coated form of the drug. Carbamazepine can cause a clinically significant decrease in any of the blood elements selectively or can induce pancytopenia. Clonazepam is occasionally associated with disinhibition, leading to hostility and aggression or emotional lability.

Several newer anticonvulsants appear to have some efficacy in treating painful conditions, particularly neuropathic pain. Gabapentin has been shown to provide significant pain relief for patients with reflex sympathetic dystrophy,[124] diabetic neuropathy,[125] and postherpetic neuralgia.[110] It has

antihyperalgesic effects in rat mononeuropathy models when administered spinally.[126] Although it is a structural analog of GABA, its action does not appear to be limited to its effects on GABA receptors. Inhibition of voltage-gated calcium currents may be an important mechanism. It may also have anti-inflammatory properties.[127] It has fewer side effects and drug interactions than most of the older anticonvulsants, but somnolence, dizziness, ataxia, and peripheral edema are occasional problems.

Lamotrigine acts by inhibition of a sodium channel subtype and has been shown to inhibit glutamate release. Although there are a few reports of beneficial effects on neuropathic pain,[128]

there are few controlled studies demonstrating efficacy. Rashes are fairly common and can progress to Stevens-Johnson syndrome or toxic epidermal necrolysis.

The mechanism of topiramate has not been fully investigated. Proposed mechanisms of action include sodium channel blockade, GABA potentiation, and blockade of some excitatory amino acid receptors. There are anecdotal reports of beneficial effects in a variety of neuropathic pain states. Weight loss is a common side effect.

Oxcarbazepine has mechanisms of action similar to those of carbamazepine, including sodium channel blockade and suppression of synaptic transmission. It is better tolerated than carbamazepine and appears to lack the potential for producing blood dyscrasias. It has been proposed as a first-line drug for treating trigeminal neuralgia. Its benefits in other neuropathic pain states are not as well documented.

Other drugs that are being used with increasing frequency in the management of neuropathic pain include zonisamide, levetiracetam, pregabalin, and tiagabine. There have been few studies comparing efficacy of the large number of antidepressants currently available, and there are essentially no studies that have examined the combined effects of multiple drugs. Although there appears to be some rationale for switching to another drug following the failure of the first anticonvulsant, the process so far has been totally empirical.

Use-dependent sodium channel blocking drugs have a role in the management of neuropathic pain. Systemically administered lidocaine is capable of suppressing spontaneous activity originating from experimentally induced neuromas at blood levels that produce no adverse effects.[129] Intravenous lidocaine and oral mexiletine have analgesic properties in some patients with neuropathic pain.[130] The analgesic effects of lidocaine are generally transient unless a continuous infusion is used. Lidocaine is commonly used to predict response to oral mexiletine, although its prognostic utility has not been well established. Lidocaine is given as a slow intravenous bolus at 1.5 mg/kg over 5 minutes followed by an infusion of 50 µg/kg/min. The infusion is adjusted downward if symptoms of systemic toxicity become evident.

CANCER PAIN

In assessing patients with malignant disease who seek treatment for pain, it is essential to determine the specific site and mechanism of their pain. It is not enough to make a diagnosis of cancer pain. The entire range of acute and chronic pain mechanisms is encountered among patients with malignancy. It is also essential to know the stage of the patient's malignant disease. The approach to a given pain for a terminal patient may vary greatly from the approach to the same type of pain in a patient whose cancer is curable.

It is useful to determine whether the patient's pain is acute or chronic, and whether it is related to tumor progression, therapeutic intervention, or, as is occasionally the case, factors unrelated to the patient's malignant disease (arthritis, herniated disc, etc.). It is also useful to know whether the patient has a history of chronic pain or drug abuse predating the onset of malignant disease. Pain caused by tumor progression can result from compression or infiltration of peripheral nerves, nerve root, or spinal cord; infiltration of bone and soft tissue; obstruction or distension of visceral structures; and vascular occlusion. Surgical intervention may lead to scar pain, neuroma formation, sympathetic dystrophy, and venous or lymphatic obstruction. Chemotherapy may be associated with peripheral neuropathies. Therapy with steroids can cause aseptic bony necrosis or rheumatoid-like symptoms when therapy is withdrawn. Herpes zoster is associated with agents that suppress immune function. Radiation therapy sometimes results in esophagitis, plexopathy and myelopathy, and bone necrosis.

7 A substantial range of therapeutic options is available to the cancer patient. A major consideration in approaching the patient with severe pain is when to institute a particular modality. It is generally advisable to consider less invasive, lower-risk options initially, progressing to procedures that are more invasive, more painful to perform, and carry a higher risk of complications only when the more benign procedures are ineffective. Occasionally, it is prudent to select a more invasive procedure early in the course of management if it is believed that it will

provide the patient maximum comfort or if the patient's pain level has progressed to a crisis state.

Pharmacologic Therapy

The use of oral analgesic agents is the mainstay of treatment for cancer pain. Adequate analgesia can be achieved in the large majority of patients with cancer-related pain if sound pharmacologic principles are employed. Several guidelines are essential to cancer pain management:

1. *Use agents appropriate for the nature and severity of the patient's pain*. Weaker opioids such as codeine may be adequate for mild to moderate pain. For severe pain, more efficacious agents such as morphine, hydromorphone, or methadone should be employed. Agonist–antagonist agents such as pentazocine and buprenorphine have a ceiling effect on their analgesic efficacy and are generally effective only for mild to moderate pain. Meperidine is a poor drug for repetitive dosing because accumulation of its metabolite normeperidine can cause CNS stimulation manifested as anxiety, tremors, or seizures. Be aware of the oral bioavailability of the drug used. The oral dose of morphine, for instance, is about three times the parenteral dose. When peripheral nociceptive processes are involved (e.g., bony or soft-tissue invasion), the addition of NSAIDs may be helpful.
2. *Use adequate doses*. The dose of opioid analgesic should be escalated until satisfactory analgesia occurs (usually the case) or until problematic side effects occur. The dose required varies tremendously. It is not unusual for cancer patients to require 100 to 200 mg of oral morphine or its equivalent every 3 to 4 hours.
3. *Maintain steady blood and tissue levels of analgesic*. All analgesics should be given by the clock. As-needed administration may result in periods of inadequate relief. The time interval for administration should be consistent with the duration of action of the drug. When possible, use long-acting agents. Methadone, whose plasma half-life is 24 to 36 hours, can be given twice per day, avoiding the need for nighttime awakening for analgesic administration. Morphine is available in a time-release form that can be administered once or twice per day. Transdermal fentanyl provides prolonged, steady release that achieves fairly constant blood levels.

4. *Consider the use of adjuvant drugs*. Tricyclic antidepressants are frequently beneficial for postherpetic neuralgia, may be helpful for some patients with other types of neuralgic pain or denervation dysesthesia, and can be effective for treating concomitant depression. Some anticonvulsants may be beneficial for neuralgic pain. Phenothiazines or butyrophenones have been shown to reduce symptoms of nausea, agitation, and pain when used in conjunction with narcotic analgesics. Corticosteroids should be considered for increased intracranial pressure, cord compression, severe bone pain, or pain from liver metastases. Calcitonin is effective in some patients with bone pain.
5. *Anticipate and promptly treat side effects*. Constipation, which may become a major problem, occurs in most patients on opiates. Prophylactic management is essential. Nausea is a common opiate side effect, and concomitant administration of antiemetics may be necessary. Respiratory depression is unusual in tolerant patients. When it occurs in opioid-naive patients, it should be treated with small incremental doses of intravenous naloxone (e.g., 0.05 to 0.1 mg) until the respiratory rate increases to an acceptable range. Large doses precipitate withdrawal, reverse much of the patient's analgesia, and initiate vomiting. Patients who are unable to take analgesics orally can often be satisfactorily managed with parenteral opiate administration. Some patients who do not achieve satisfactory analgesia with oral drugs may have adequate control with parenteral agents, possibly because enteric absorption is poor. When the parenteral route is chosen, a constant-infusion technique or infusion plus patient-controlled analgesia (PCA) is usually superior to intermittent intramuscular injections. Many cancer patients have long-term venous access ports for chemotherapy that can be used for narcotic infusion.

When beginning opiate infusions, it is generally prudent to start with a relatively low-dose bolus injection and a modest infusion rate. If analgesia is inadequate after 1 to 2 hours, a small bolus is repeated, and the infusion rate is increased. The process is repeated until the infusion rate is adequate. An alternative, less labor-intensive method is to use a PCA device. Once the daily opiate requirement is established, the patient can be switched to a portable, battery-powered, constant-infusion device or portable PCA. When venous access is not available, portable external infusion devices can be used to deliver opiates subcutaneously through a "butterfly"-type needle. The infusion site is changed every few days or when soreness occurs. When large doses are required, the use of a concentrated preparation of hydromorphone (10 mg/mL) allows for longer intervals between refilling the portable infusion pump and reduces the mass of fluid injected.

Patients may experience diminishing analgesic effects from oral or parenteral opioids, either from tolerance development or from increasing noxious stimulation related to tumor spread. A study by Collin et al[131] suggests that increasing dose requirement is nearly always associated with spread of disease. In either event, there may be a rationale for changing from morphine to a more potent drug such as fentanyl or sufentanil. This rationale is related to the concept of intrinsic activity (IA) of analgesics (i.e., the fractional receptor occupancy [FRO]) required to produce a given effect. A drug with relatively low IA, such as morphine or meperidine, requires a higher FRO than a drug with a high IA, such as fentanyl or sufentanil. Under conditions of tolerance, some receptors become unresponsive, and a drug with low IA may not be capable of interacting with enough of the remaining receptors to achieve adequate analgesia. Likewise, if the level of noxious stimulation increases, a greater number of receptors must be activated to produce a given analgesic effect, and a drug with a low IA may not interact with sufficient receptors to provide a reasonable analgesic response. Chronic infusion of morphine or meperidine in animals is associated with rapid development of tolerance to subsequent doses of morphine or meperidine, but not fentanyl or sufentanil.[132]

Transdermal fentanyl offers an alternative to parenteral opioids for patients who are unable to take medications orally. It is available in four dosage forms, which deliver 25, 50, 75, or 100 µg/hr of fentanyl. The continuous use of the 100-µg/hr form offers roughly the same analgesia as 360 mg of oral morphine or 60 mg of parenteral morphine per 24 hours. If higher delivery rates are required, multiple patches can be used simultaneously. Several hours are required for analgesia to develop following application of the transdermal patch and for analgesia to dissipate following its removal. An oral transmucosal preparation of fentanyl is available in doses up to 1,600 µg. The onset of analgesia is much more rapid with this form of administration, with peak levels occurring at about 20 minutes.

Intraspinal Opioids

Some cancer patients do not achieve satisfactory analgesia with systemic opiates without pushing the doses to the point of marked sedation or confusion. Less conventional methods of opiate administration may be effective for some of these patients. The discovery of spinal cord opiate receptors led to speculation regarding the feasibility of intraspinal administration of opioids. Most experience with chronic intraspinal opioid administration has been with morphine, probably because it has a long duration, allowing bolus and continuous administration, and because it has been approved by the U.S. Food and Drug Administration (FDA) for intraspinal use. The use of intraspinal opioids in patients who had not previously been on systemic opioids (e.g., postoperative patients and volunteers) was associated with nausea and vomiting, urinary retention, pruritus, and respiratory depression. As more experience with cancer patients accumulated, it became evident that these problems were, indeed, uncommon in this population, probably because the patients had been on systemic opioids chronically and had become tolerant to these side effects.

Intraspinal opioids have been chronically administered by both the epidural and IT routes. IT administration has the advantage of allowing use of much lower doses, potentially minimizing systemic side effects, but carries the risks of cerebrospinal fluid leak, headache, meningitis, and arachnoiditis. With either epidural or IT administration, the drug may be administered as a bolus,

by infusion via an external pump, or by infusion via a totally implanted pump.

Percutaneous placement of an epidural catheter followed by bolus administration of opioid constitutes the simplest method of administration. The principal drawback of this technique is the risk of infection, which may spread to the epidural space. Such a technique is useful as a temporary measure to evaluate efficacy of epidural narcotics and is a reasonable method of administration for patients whose life expectancy is relatively short. The simple expedient of tunneling the catheter subcutaneously to the flank decreases the incidence of catheter dislodgment, allows the patient access to the catheter exit site to facilitate dressing changes, and may reduce the risk of epidural infection.

The decision to use an external pump is based on pharmacokinetic, technical, and financial considerations. There is some evidence that lower doses of morphine can be employed when using a continuous infusion. Coombs et al[133] were able to provide good analgesia for a group of cancer pain patients using a mean dose of 2 mg/day initially and

6.6 mg/day at the end of 12 weeks. Reports of studies that use bolus injection describe much higher daily doses. Bolus injection produces much higher peak cerebrospinal fluid levels,[134] which may predispose to more cephalad migration of the drug. Another advantage to continuous-infusion techniques is the lower incidence of catheter occlusion. Inability to inject is a fairly common problem with bolus injection technique. When an obstructed catheter is removed, it is common to find fibrin material in the lumen. However, the use of large-bore silicone rubber catheters should minimize that possibility. Patients with epidural metastases may have severe pain with bolus injection but tolerate continuous infusion well. Perhaps the biggest drawback to continuous-infusion techniques is the expense. Portable pumps cost up to several thousand dollars, and the use of implantable systems adds several thousand dollars in additional physician and operating room expenses.

The totally implantable infusion pump is the most elegant and expensive drug delivery system. The Infusaid pump is a freon-driven device with a 50-mL, percutaneously filled drug chamber and a constant infusion rate. Pumps with a 2 to 3 mL/day flow rate will run for 15 to 20 days between refills. Daily dose is adjusted by changing the drug concentration. A separate drug injection septum allows injection directly into the catheter, bypassing the drug chamber. The technique is most appropriate for patients with a relatively long life expectancy (months rather than weeks). Medtronic produces an electronically driven, externally programmable implanted pump that allows variations in rate plus the administration of intermittent bolus injections.

Perhaps the most frustrating problem associated with intraspinal opioid administration is the development of marked resistance or tolerance to the medication. Although most patients develop tolerance slowly and to a limited degree, some demonstrate rapid escalation of doses. Woods and Cohen[135] reported a patient who had been on 280 mg of morphine intravenously and 90 mg of methadone orally per day who was initially comfortable on 5 mg/day of epidural morphine. However, by the fifth day of epidural morphine administration, the dose had increased to 7 to 10 mg/hr. One of the reported side effects of such high doses, particularly with high-dose IT morphine, is the paradoxical development of segmental allodynia, which has been reported in patients[136] and in animal studies.[137]

Neuraxial administration of nonopioid analgesics, either alone or in combination with opioids, may be effective when opioids alone are ineffective. Limited trials of the α_2-agonist clonidine injected epidurally and intrathecally have proved at least temporarily effective. Animal studies suggest that there is a synergistic interaction between spinally administered α_2-adrenergic agonists and opioids. Eisenach et al[138] found a dose-related analgesic effect from epidural clonidine in a series of nine cancer patients. They reported dose-related decreases in heart rate and blood pressure, as well as somnolence. Seven patients were maintained on clonidine plus morphine infusions at home for periods of up to 5 months. These patients reported satisfactory analgesia, as well as less nausea and sedation than they experienced with systemic morphine. There was minimal escalation of either clonidine or morphine during the combined infusions.

The intrathecal administration of baclofen has been used to treat patients with spasticity

associated with multiple sclerosis and spinal cord injury. However, baclofen appears to have some potential as a spinal analgesic in patients without increased muscle tone who are resistant or tolerant to opioids. Intrathecal L-baclofen is antinociceptive in several animal models at doses that produce no discernible motor blockade.[139] It has been shown to produce substantial lasting analgesia in opioid-tolerant patients with neuropathic and radiculopathic pain at doses devoid of motor effects.[140]

Another approach to the patient who has become resistant to neuraxial opioids is to use combinations of opioids and dilute local anesthetics. The combined use of these agents makes sense because the local anesthetic, even at subblocking concentrations, can reduce the maximum firing rates of nociceptor fibers, and the opiate reduces the sensitivity of wide dynamic-range and nociceptive-specific neurons in the dorsal horn to activation by nociceptors. Hogan et al[141] found that 10 of 16 patients, selected from a total of 1,205 cancer admissions, required local anesthetic infusions along with epidural morphine to achieve satisfactory analgesia. Du Pen et al[142] found that 68 of 375 patients (18%) failed to achieve satisfactory analgesia with neuraxial opioids alone. Sixty-one of those 68 patients experienced satisfactory analgesia with the addition of local anesthetics.

Nonneurolytic Nerve Blocks

Myofascial pain is common among cancer patients. It is often associated with bony infiltration, neural compression, or visceral pain. Local anesthetic injections of trigger points may be surprisingly effective. Fluoromethane spray of trigger points combined with gentle stretching of affected muscles can be helpful. TENS is also likely to be of benefit.

Tumor compression of nerve roots, brachial or femoral plexus, or peripheral nerves sometimes responds dramatically to perineural injection of insoluble steroids. Pain relief can be achieved for up to 1 month in many instances. When radicular pain is caused by epidural tumor spread, epidural injections of triamcinolone diacetate are likely to be of benefit. Tumor compression of the brachial plexus may respond to brachial plexus block with a combination of depo steroid and local anesthetic. The interscalene, supraclavicular, infraclavicular, or axillary approaches may all be used, the choice depending on the site of pathology. Femoral plexopathy can be treated with a paravertebral approach (psoas compartment block) to the femoral plexus, again using depo steroids and local anesthetic. Steroid local anesthetic blocks of peripheral nerves that are irritated or compressed by tumor are occasionally beneficial, particularly if they are performed reasonably soon after the onset of pain. Patients with severe neurogenic pain should be warned that if the injections are successful in producing pain relief, they are likely to be left with some numbness, not from the injections, but from the already present neural pathology.

Acute herpes zoster is a relatively common and often debilitating source of pain in patients with malignancy. There is some evidence that local anesthetic blockade of sympathetic fibers, using either paravertebral sympathetic blocks or epidurals, will promptly relieve pain and may shorten the acute phase of the illness.[109] Even if the overall course of the illness is not dramatically affected, patients are usually extremely grateful for any respite from the severe pain associated with this condition.

Occasionally, patients with severe cancer pain are refractory to any opioid intervention. These patients may progress to psychological decompensation without reasonably prompt intervention. The use of continuous-infusion local anesthetic blockade may be the best answer for patients who reach such a crisis. Continuous epidurals with dilute local anesthetics can be performed at any level of the neuraxis. When upper thoracic or cervical approaches are used, close monitoring of blood pressure and respiratory function is necessary.

Neurolytic Blocks

There is a much greater willingness among anesthesiologists to perform neurolytic blocks for terminal cancer patients with pain than for patients with nonmalignant causes of pain.

Reluctance to use neurolytic blocks for noncancer pain is certainly justified. The extent and

duration of analgesia from neurodestructive procedures is limited by regrowth of axons and development of central pain mechanisms (denervation dysesthesia). Although neurolytic blocks can produce dramatic relief for some cancer pain patients, there are some serious potential drawbacks to the technique, and overzealous use of neurodestructive procedures should be avoided.

The principal disadvantage of neurolytic blocks is the inability to precisely control the spread of the destructive agents. Loss of motor function and inability to control bowel or bladder function following neurolysis can be devastating to a patient and will greatly impair the quality of remaining life. The expected analgesia may not always result from destruction of the intended neural structures, even when prognostic local anesthetic blocks have been performed. If CNS mechanisms play a major role in a patient's pain, neurolysis is unlikely to be of benefit. In some cases, tumor progression rapidly produces pain beyond the confines of the block. With the advent of improved methods of cancer therapy, more patients survive well beyond the efficacy of the block. Overall, the incidence of fair to good results following neurolytic blockade is estimated at 50 to 60%.

Alcohol and phenol are the agents most commonly used for prolonged interruption of neural function. There is relatively little difference in overall efficacy between these agents, but there are major differences in the initial responses. Phenol produces no pain on injection, has an initial anesthetic effect, and takes about 15 minutes to exert its neurolytic effect. Alcohol causes significant pain on injection and produces neurolysis promptly. When used for IT neurolysis, alcohol is hypobaric, whereas phenol in glycerine, the usual IT preparation, is hyperbaric.

IT neurolysis with small volumes of alcohol or phenol requires careful positioning to place the affected sensory root uppermost (for alcohol) or in the most dependent position (for phenol). In such a way, only the involved sensory roots are affected. Patient movement during or shortly after injection can produce spread of drug to the cord, other dermatomes, or motor roots. Papo and Visca[143] published results in a large series of patients who underwent phenol rhizotomy. They reported good results (pain free until death) in 40% of 290 patients and fair results (reduced analgesic requirements or temporary complete relief) in 35%. Patients whose pain was localized to sacral dermatomes had the best results, whereas patients with pain in the upper thoracic area or upper or lower extremities had poor analgesia and more frequent complications. Swerdlow[144] reviewed 13 reports of the results of phenol and alcohol rhizotomies and found good relief of pain in about 60% of patients. In reviewing results on his own patients, he found that analgesia lasted less than 2 months in 50% the patients and less than 1 month in 25% of patients. Complications lasting longer than a week occurred in 15% of patients.

Patients with severe, localized perineal pain are likely to experience relief with IT blocks with phenol in glycerine. Phenol 7% in glycerine is injected in 0.25-mL increments up to a maximum of 2 mL, with the patient in the sitting position. Injection is stopped at a lower dose if the patient experiences any lower-extremity sensory changes. This treatment is limited to patients who have undergone fecal and urinary diversion procedures.

Celiac plexus block for pain associated with upper abdominal malignancy is the most successful and rewarding of the neurolytic blocks. Thompson et al[145] reported that 94% of 97 patients who underwent celiac plexus block for pain of upper abdominal cancer had good-to-excellent pain relief. Injections were performed with 50 mL of 50% alcohol. Survival from the cancer ranged from 2 days to 14 months. Fourteen patients required repeat injections for recurrent pain. Ten patients experienced transient orthostatic hypotension, and one patient had partial motor loss in one leg.

The classical technique for percutaneous injection of the celiac plexus involves bilateral placement of block needles just anterior to the body of L1, and posterior to the aorta and diaphragmatic crura. More recently, techniques have been described that involve more anterior positioning of the needle tip with CT assistance so it lies anterior to the diaphragmatic crura.[146] The injected solution can be seen to spread more anteriorly, surrounding the aorta. There is much less tendency of the injected solution to spread posteriorly to the paravertebral nerve roots or sympathetic chain, minimizing risk of paresis or orthostatic hypotension. Ischia et al,[147] using

such a technique, reported 93% success in relieving pain in 28 patients with cancer pain. Similar placement can be achieved with the use of biplane fluoroscopy. Five-inch 22-gauge needles are advanced from both sides at a point 7 cm from the midline, at the lower border of the twelfth rib toward the midpoint of the L1 vertebral body, and advanced under anteroposterior fluoroscopy until they are just past the lateral border of the body. Under lateral fluoroscopy, the right-sided needle is advanced 1 cm beyond the anterior border of the body. It will probably lie between the aorta and vena cava. The left-sided needle is advanced the same distance, but it will usually enter the aorta at this point. If so, it is advanced through the aorta until negative aspiration occurs. Half the total alcohol dose is then injected through each needle (see Fig. 56-12). Alternatively, deafferentation of the upper abdominal viscera can be accomplished with the use of splanchnic block. With this technique, the neurolytic agent is injected over the anterolateral surface of the T12 and/or T11 vertebral body (see Fig. 56-12). This technique may be more effective than the transcrural approach if there is dense, widespread tumor invasion around the celiac plexus.

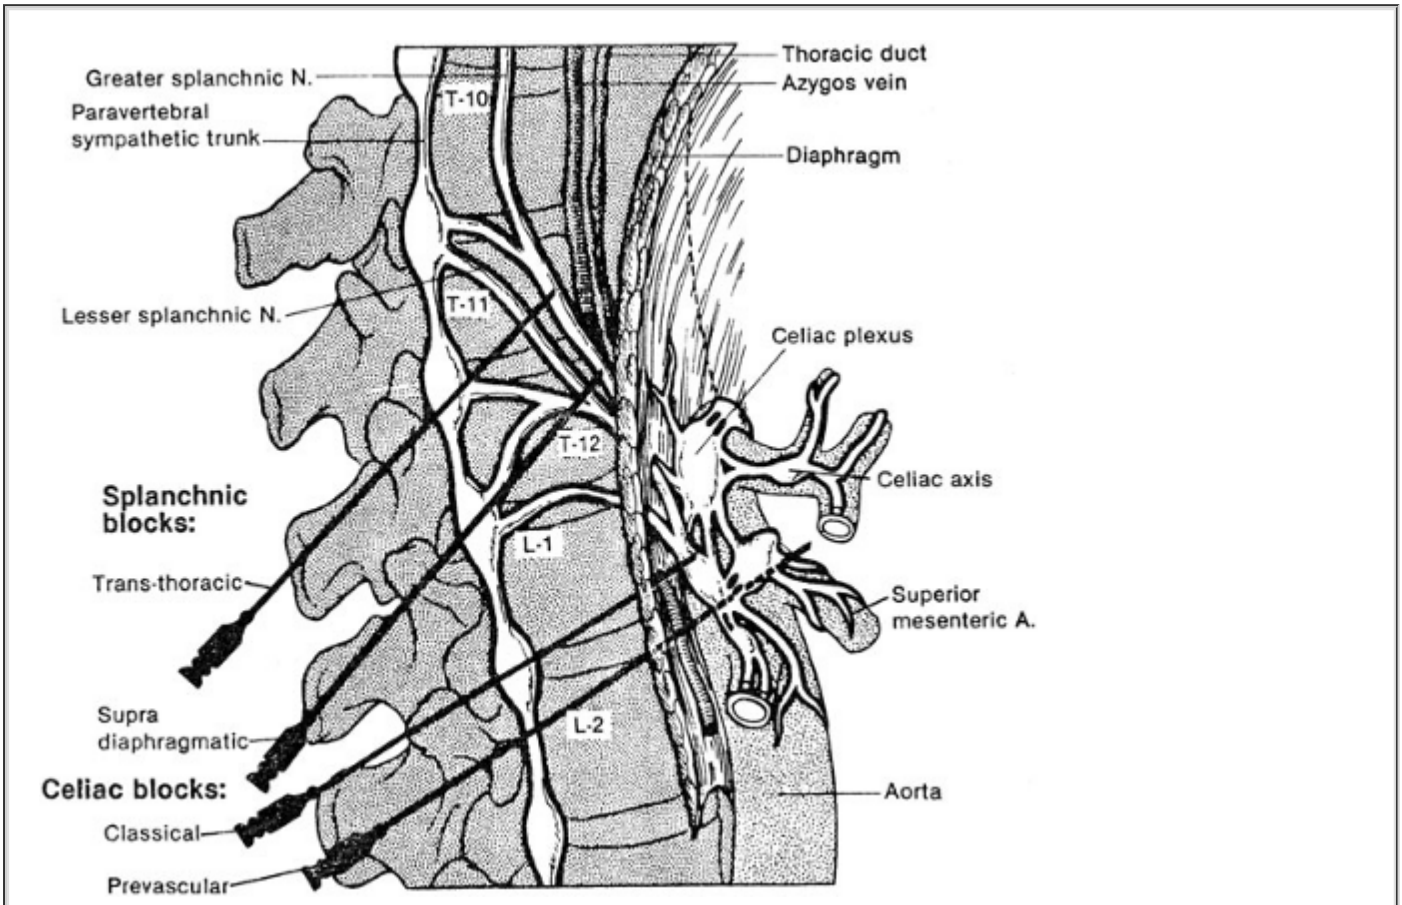

FIGURE 56-12. Lateral projection showing the splanchnic nerves and celiac plexus in relation to the diaphragm, vertebrae, and aortic vessels. Placement of needles for two approaches to the celiac plexus and two approaches to the splanchnic nerves is shown. (From Abram SE, Boas RA: Sympathetic and visceral nerve blocks. In Benumof JL [ed]: Clinical Procedures in Anesthesia and Intensive Care, p. 787. Philadelphia, JB Lippincott, 1992.)

Patients with pelvic pain associated with gynecologic, rectal, and genitourinary malignancies may benefit from interruption of pelvic visceral innervation at the level of the superior hypogastric plexus. The technique of needle placement just anterior to the upper portion of the sacrum originally described by Plancarte et al[148] allows for interruption of afferents from the pelvic viscera with minimal risk of somatic blockade. The block is performed by introducing bilateral needles medially and caudally through the space between the L5 spinous process and the upper border of the sacrum under fluoroscopic control. Eight milliliters of phenol introduced through each needle is generally sufficient to provide reduction in pain and opioid requirement[149] (see Fig. 56-13). Bladder pain and spasm have been successfully treated with transsacral phenol injections.[150] If

blocks are confined to one or two roots, there is little risk of disrupting bladder function.

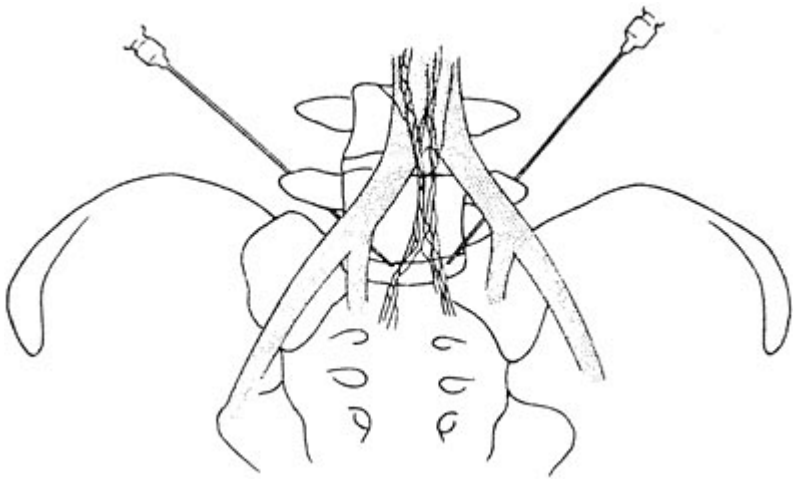

FIGURE 56-13. Anterior view of the pelvis showing location of the hypogastric plexus and suggested bilateral needle placement. (Reprinted with permission from Plancarte R, Amescua C, Patt RB, Aldrete A: Superior hypogastric plexus block for pelvic cancer pain. Anesthesiology 73:236, 1990.)

Other Modes of Therapy

There are a number of therapeutic options that are relatively specific for the type of malignancy with which one is dealing. When dealing with tumors that are extremely radiosensitive, radiation therapy is often the most effective form of intervention. If chemotherapeutic options are available, they may provide analgesia through reduction of tumor mass. Pain caused by hormonally sensitive tumors may be best treated by appropriate manipulation of the patient's hormonal environment. Surgical debulking of a large tumor will sometimes relieve pain of obstruction or abdominal distension. Stabilization of an isolated pathologic fracture can be an extremely effective pain-relieving procedure. Certain neurosurgical procedures, such as spinal cord stimulation, cordotomy, or hypophysectomy, may afford months of profound relief in certain types of cases. Some patients benefit considerably from psychological interventions

such as hypnosis or other cognitive strategies. With the complexity of the disease processes involved with cancer-related pain and the number of pain mechanisms and therapeutic interventions that are possible, it is essential that the full range of medical and behavioral science disciplines be made available to this group of patients.

PAIN IN HIV/AIDS

Knowledge of the syndromes in HIV disease is the fundamental prerequisite for diagnosis of HIV disease pain. HIV disease pain can be divided into three classifications: nociceptive pain, neuropathic pain, and idiopathic pain. The most common pain sources associated with HIV disease-related pain are abdominal pain 26%, peripheral neuropathy 25%, throat pain 20%, HIV disease-related headaches 17%, AZT-induced headache 16%, arthralgia 5%, back pain 5%, and herpes zoster 5%.[151]

Pain in HIV disease varies, depending on the stage of HIV disease progression with acute phase evidenced by mononeuritides, brachial plexopathy, and acute demyelinating polyneuropathy, such as Guillain-Barré syndrome. As the disease progresses, pain will be associated with chronic inflammatory demyelinating polyneuropathy, herpes zoster, and mononeuritis multiplex. Late-stage HIV disease pain arises out of sensory polyneuropathy, cytomegalovirus polyradiculopathy,

progressive mononeuritis multiplex, aseptic meningitis, lymphomatous meningitis, and nucleoside toxicity. As discussed earlier in this chapter, sensitization of neurons and activation of glial cells in the CNS undoubtedly play a major role in the pathophysiology of AIDS neuropathy. For instance, HIV envelope proteins have been shown to induce glial activation. Much clinical research is now focused on drugs that inhibit glial activation or that block the effects of proinflammatory cytokines.

Pain at any stage is influenced by perception, and by psychological, social, and even spiritual anxieties.[152] The psychological sequelae of HIV disease pain are essentially similar to cancer pain, where there is the constant threat of severity and persistence. Optimal HIV disease treatment should incorporate psychological treatment strategies because patient mood, depression, and beliefs about pain, as well as the significance (meaning) of pain influence pain perception.

Pharmacologic treatment for HIV disease pain should follow the World Health Organization analgesic pain treatment protocol developed for cancer, beginning with acetaminophen and NSAIDs, with appropriate caution related to possible drug interaction with acetaminophen and AZT. Weak opioids are then used, including codeine, oxycodone, and hydrocodone added to acetaminophen. Concerns over use of opioid

treatment in substance abusers presents difficulties that require firm limits and contractual, written agreement on the use of narcotic analgesics.

The overall course of treatment and ability of the patient to cooperate in treatment may be compromised by the impact of HIV disease dementia. As the disease progresses, the risks of associated pain and dementia increase. Some studies have found that dementia is the initial AIDS-defining illness, viz. 4% followed by an increased incidence of 7% after a second AIDS-defining illness and a cumulative risk of 25%.[153] Nonpharmacologic treatment such as physical therapy and psychological interventions may be difficult in the presence of apathy, psychomotor retardation, decreased attention span, and short-term memory loss.

Nerve blocks, including injection of local anesthetic or neurolytic agents, are not typically applicable to HIV disease pain. However, temporary relief from pain may facilitate physical therapy, and frequently, sympathetic or somatic blocks may result in relief of pain that exceeds the actual anesthetic action.

PSYCHOLOGICAL INTERVENTIONS FOR CHRONIC PAIN

Psychological input into the diagnosis and treatment of chronic pain has become an accepted part of any comprehensive team approach to the management of this class of patients. Because the psychological influences on pain experiences are myriad, the regular consultation of a specialist in behavioral medicine is invaluable. In addition to helping understand some of the psychological influences mentioned earlier, the psychologist has at his or her disposal a number of specific techniques that prove useful as part of a multidisciplinary treatment plan for chronic pain management.

8 Psychodynamic approaches to the patient in chronic pain are typified by an attempt to understand the patient in terms of personality structure, biological drives, social contexts, desires, and expectations. This leads to a psychodynamic formulation that posits a relationship between any or all these factors and the presenting problem. Therapy is usually done on an individual basis and is aimed at establishing a therapeutic alliance with the patient, providing an interpretation of relevant symptoms, leading the individual to new levels of understanding about the derivation of their symptoms, and enhancing symptom resolution through the patient–therapist relationship, with termination of that relationship as the ultimate goal. To engage in this sort of approach requires a knowledge of fundamental psychoanalytic and therapeutic principles, training in the particulars of psychotherapy with chronic pain patients, and the time to engage in weekly or more frequent sessions with the patient for months to years of therapy. Clearly, this is out of the realm of expertise or desire of most anesthesiologists, and is typically so labor intensive that it is not practical for many psychologists. In general, a small proportion of patients in a given clinic population would be either amenable or appropriate to involvement in this style of

therapy.

Much more common is the use of cognitive therapies. This group of strategies focuses on the cognitive or thought processes that are found in chronic pain patients. Often, the thinking style of an individual has a great deal of effect on how he or she copes with pain. As mentioned earlier, the meaning of the pain experience can greatly influence the suffering. A classic example of this is the often quoted observation by Beecher[154] that injured soldiers on the battlefront in World War II often complained of pain far less than would be expected from the severity of their wounds. When they were safely behind the lines, however, they would complain just as loudly as anyone else when multiple venipunctures or other mildly painful procedures were required, disproving the notion that these people were stoic by nature. Beecher[154] reasoned that the meaning of the pain was making the difference in that a significant injury meant that one would be taken back home and, therefore, would survive the war. A common clinical example in a pain clinic would be the individual who is convinced that he or she cannot cope with a flare-up of pain. Such an individual will frequently think catastrophic thoughts such as "If this pain gets real bad, I don't know what I'll do!" These thoughts can become the focus of treatment and can, with motivation and practice on the part of the patient, be changed to more adaptive thoughts. This in time will give the individual some degree of control over the situation and will prevent him or her from engaging in self-defeating destructive thought patterns. Coping ability is thereby improved.[155]

Behavioral therapies involve efforts to reshape behaviors, rather than the sensory or emotional conditions that underlie them. This is a direct outgrowth of the work of Fordyce et al,[156] who adapted B. F. Skinner's operant model of behavior to the human pain patient. As previously discussed, this model states that behaviors can be cued by certain stimuli and can be modified by conditions that follow the emission of the behavior. Taking this antecedent-behavior-consequence paradigm view of pain behaviors, such as limping, groaning, seeking dependence on others, and taking inappropriate analgesics, Fordyce and colleagues imposed strict control on the environment into which the chronic pain patient was placed. No reinforcement of pain behaviors was forthcoming from the staff (extinction), and positive reinforcement for wellness behaviors was instituted. This resulted in a significant decrease in pain behaviors. A critique of this method was that only the behaviors were decreased, but Fordyce et al argued that many patients state that after a largely behavioral treatment program they perceive less pain.[157] The principles of behavior modification extend to the staff of a pain clinic, the patient's workplace, and the home, in that solicitous responses from a spouse in response to pain behaviors by the patient may sabotage an otherwise intact and appropriate treatment plan.

Biofeedback is the providing of information to an individual about bodily functions that are commonly held to be inaccessible to the conscious mind. Commonly used devices measure surface electromyographic activity, temperature, or electrodermal activity. When feedback from these systems is provided, a patient can frequently be taught to control those functions at will. Originally, the logical assumption was made that teaching an individual to reduce muscle tone in a specific muscle would reduce the pain by the mechanism of muscle relaxation. Although the outcome is generally that which is expected, the mechanism is not universally accepted to be reduction in muscle tone, leading to decreased activation of muscle nociceptive afferent neurons. The same statement can be made for the other modes of biofeedback. This does not, however, detract from the usefulness of the techniques, and they remain a valuable psychological intervention for some patients.

Numerous strategies have evolved for the induction of a state of relaxation in chronic pain. The theory is that relaxation induces both positive mental and physical changes in the individual that promote a sense of well-being, decrease muscle tone, and enhance coping. Jacobson[158] developed the first standardized approach to relaxation using the progressive contraction and relaxation of muscle groups in an ascending sequence from feet to head. There have been numerous procedures since then that can be learned to induce relaxation. These techniques rely on conscious manipulation of the body to induce a relaxed state, not merely getting comfortable on the couch and propping up one's feet. Benson[159] studied the physiologic concomitants of a relaxed state and found commonalities to the conditions induced by a variety of methods. These included a

decrease in sympathetic tone, regularity in respiratory pattern, decreased skeletal muscle tone, and a feeling of well-being. He termed this physiologic pattern the *relaxation response*, postulated that the means of achieving it was unimportant, and developed a simple and straightforward induction method. This and similar techniques find great applicability to chronic pain patients, especially those with muscular involvement such as myofascial pain syndromes.

Hypnosis has long been used to help alleviate surgical and other acute pains. It also has some utility in the chronic pain population. For an individual to become hypnotized, several conditions must exist: (1) an ability to concentrate, (2) a belief in the process, and (3) some motivation for the process to ensue. The trance state is believed to be a naturally occurring phenomenon in most people, although there is great variability in the population with regard to frequency and ease of occurrence. Trance state can be defined as an altered state of awareness characterized by extremely focused attention, relaxation, and responsiveness to suggestion. It is believed by most modern practitioners that the hypnotist does not hypnotize the subject but rather facilitates entry into trance by directing and guiding the individual's attention. The use of hypnosis can, in the properly selected individual, be a useful adjunct to therapy of chronic pain. It has found particular utility in the treatment of patients with cancer pain, possibly because these patients are so profoundly motivated. The mechanism of analgesia associated with hypnosis is unclear, but it does not appear to be due to endogenous opiates or to be solely due to placebo effect.

Group therapy, supportive therapy, education, and family therapy are other types of psychological interventions that have utility in the management of chronic pain patients. A skilled practitioner of behavioral medicine will aid the anesthesiologist in the diagnosis, conceptualization, and treatment of patients presenting with chronic pain by selecting evaluation and therapeutic strategies that are tailored to each individual's presentation.

INTERVENTIONAL PAIN MANAGEMENT

Over the past two decades, there has been rapid technological development in the field of pain management. Reliable and sophisticated intraspinal drug delivery devices can provide complex patterns of infusion over long periods of time. Totally implanted spinal cord stimulation devices can now access multiple electrodes simultaneously. Techniques for radiofrequency denervation have been developed for many neurologic structures. Miniaturized endoscopic devices permit more accurate perineural injection of medications within the spinal canal. Systems have been developed for thermocoagulation of annular tears of intervertebral discs and for stabilization of vertebral compression fractures. Although these interventional techniques are not appropriate for the majority of patients with chronic pain, they have extended our capability for managing some of the most intractable problems. The following discussion describes a few of these systems.

Intrathecal Drug Delivery Devices

The discovery of opioid receptors and endogenous opioids in the late 1970s[160] led to early experiences with intraspinal opioids in animals[161] and eventually patients with chronic pain.[162] The original research with spinal opioids was fueled by the search for alternatives to irreversible neurodestructive techniques. The advantage of spinal opioid analgesia was believed to lie in the potential for obtaining more potent analgesia and fewer side effects due to higher drug concentrations at spinal opioid receptors. What made intraspinal opioids suited for continuous administration and eventually outpatient use was the selective nature of its action compared with local anesthetics, avoiding sensory, motor, and sympathetic blockade.

The original use of spinal narcotics for continuous drug delivery focused on cancer pain, proving its safety and efficacy in multiple studies.[163,164] A subsequent development was the successful utilization of intrathecal baclofen for the treatment of spasticity and rigidity in patients with spinal cord injuries.[165] Utilization of spinal opioids for nonmalignant pain remains controversial but is gaining acceptance. More recent studies in this patient population seem to suggest a lower incidence of tolerance and iatrogenic addiction than first feared.[166]

Opioids administered by the spinal route act preferentially on receptors in the dorsal horn. Pain relief is produced through modulation of incoming A-delta and C fiber sensory input.[167] In part,

opioids also travel rostrally and act on supraspinal opiate receptors.

In selecting patients for chronic intrathecal opioid therapy, one must distinguish between neuropathic and nociceptive pain syndromes. Nociceptive pain is generally opioid responsive; neuropathic pain, however, may not respond or may require much larger opioid doses.[168] The latter may respond to the spinal administration of α_2-receptor agonists such as clonidine or local anesthetic/opioid combinations. Although intrathecal baclofen is currently used mainly for the treatment of spasticity, it has been shown to provide persistent pain relief in patients who have failed intrathecal morphine treatment.[169] Success has been reported among patients with persistent postlaminectomy pain[140] and CRPS-I.[170]

Selection of patients with nonmalignant pain for chronic spinal drug administration remains difficult, with no clear selection criteria identified. Prior to considering these patients for candidacy, every effort must be made to establish a diagnosis of the pain syndrome at hand. All available surgical and medical alternatives should be explored, including trials of long-acting opioids. These should be escalated until side effects are encountered or inadequate benefit is established. Psychological evaluation and psychometric testing should be considered to investigate the possibility of primary psychological pain states. Contraindications to the placement of implantable infusion devices include, among other things, the presence of sepsis, anticoagulation, severe immune suppression, and drug addiction.

Morphine continues to be the most widely used agent for long-term spinal administration. It remains the only FDA-approved intraspinal analgesic. Its high water solubility and receptor affinity provide for prolonged duration predictability and a widespread distribution throughout the cerebrospinal fluid compartment. Substances with higher lipid solubility, such as fentanyl, sufentanil, and meperidine, not only reduce supraspinal effects through limited spread, but also require accurate catheter placement adjacent to the spinal cord level associated with the specific pain syndrome. Opioid rotation is commonly done in long-term use because tolerance and drug side effects can develop. Owing to the phenomenon of incomplete cross-tolerance among opioids, a lower dose of a different opioid can often be substituted.

Efficacy trials are essential to pump implantation. Different methods are in clinical use, ranging from single-shot outpatient drug administration to titration of a continuous epidural or intrathecal infusion in the inpatient setting. Prior oral or systemic opioid needs will determine trial doses of intrathecal drugs. The patient is then observed for analgesic efficacy and drug side effects. The minimum analgesic response is controversial, but often a minimum of 50% reduction in pain scores and duration twice the half-life of the agent is sought. Response to placebo injections should be compared with responses to active drug. The development of early side effects such as

intractable pruritus or nausea is often discouraging, even though tolerance to them may develop with longer-term administration. Efficacy of intrathecal baclofen for treatment of spasticity is assessed using the Ashworth muscle rigidity/tone scale.

Intrathecal drug delivery systems vary from simple percutaneous catheters to totally implantable and programmable infusion pumps. Implanted systems have gained in popularity for long-term infusions, both in cancer pain states with long survival times and in nonmalignant pain states. These systems provide for a broad range of delivery rates and modes, and hence flexibility. Refill periods range from weeks to months, depending on drug concentrations and tolerance.

Examples of postoperative complications include bleeding, infection, seroma formation, and cerebrospinal fluid leakage. Infection is usually localized; however, epidural or intrathecal sepsis is disastrous, requiring the removal of all hardware and administration of systemic antibiotics.[171] Long-term complications related to the implanted equipment include catheter disconnects, obstruction, or breakage as well as pump failure among other things. Pump malfunction is uncommon, but errors in refilling and reprogramming have resulted in serious morbidity and mortality.[172]

A serious potential complication reported with the use of high doses of spinal morphine or hydromorphone is the formation of intrathecal mass lesions. North et al[173] first reported this

complication in a 42-year-old woman who had been receiving 25 mg/day of IT morphine (50 mg/mL) for 2 months and who presented with paraplegia and incontinence. At laminectomy, a soft-tissue mass containing chronic inflammatory cells surrounding the catheter tip was found and removed, but the patient remained paraplegic.

Coffey and Burchiel[174] provided a review of the known cases of this complication in 2002. They found 41 cases, most of whom were receiving >10 mg/day morphine at concentrations of 25 to 50 mg/mL or >10 mg/day hydromorphone at concentrations of 10 to 100 mg/mL. Most had been receiving IT medications for more than 6 months. Seven patients presented with new or increased pain complaints, whereas 34 presented with neurologic dysfunction. Thirty patients underwent surgical resection, nine of whom had persistent neurologic defects. The pathologic diagnosis in most cases was granuloma. No cases have been reported in patients receiving baclofen alone.

Spinal Cord Stimulation

The gate control theory, introduced by Melzack and Wall in 1965, provided the theoretical foundation for the use of implanted electrical stimulation. Several years later, Shealy[175] was the first to describe what was initially known as dorsal column stimulation and eventually spinal cord stimulation (SCS). Electrical stimulation in proximity of the dorsal columns through epidural lead placement was believed convenient because sensory pathways there are segregated from motor pathways. Initially, however, poor patient selection and technological limitations led to disappointing results. Patient selection improved through work done in the late 1980s and early 1990s.[176] At the same time, new technology became available, including the arrival of multichannel leads, dual-lead configurations, totally implantable generators, and expanded programming options. The specific mechanism of action of SCS remains elusive. Neural and neurochemical changes, perhaps resulting from stimulation in the dorsal roots, dorsal root entry zone, or dorsal columns, have been implicated.[177] The efficacy of SCS is greatest for certain types of ischemic and neuropathic pain syndromes with primarily causalgic and dysesthetic features.[178]

Conditions that have favorably responded to SCS include lumbosacral fibrosis and arachnoiditis,[179] complex regional pain sydromes,[180] and more recently, pain associated with peripheral vascular disease[181] and angina pectoris.[182] Failed back surgery patients with predominantly radicular pain elements have shown response rates of 50 to 60% at 5 years in more recent studies.[183,184] Patients with peripheral vascular disease have also responded favorably, with significant limb salvage rates reported.[181,185] Patients with medically refractory angina pectoris who were not candidates for revascularization have experienced pain relief and improvement in cardiac function and stress testing.[182] Significant improvement in anginal symptoms and improvement in functional class was shown to occur in more than 70% of patients with severe coronary artery disease and intractable angina.[186]

The most critical issues in patient selection consist of identifying a well-founded diagnosis and the presence of specific neuropathic or ischemic pain states. A multidisciplinary approach including a psychological evaluation is recommended. High scores on the Minnesota Multiphasic Personality Inventory's depression scale have been associated with SCS failure.[187] Other contraindications such as the presence of localized infection, systemic sepsis, severe immune suppression, and coagulopathy are similar to other implantable devices.

The systems in current use employ a totally implantable generator system that employs an implantable receiver and external transmitter. Either system is adaptable to multiple leads, depending on the need for bilateral extremity stimulation or wider unilateral coverage. Similarly, different electrode configurations exist, varying in number and spacing of electrodes. One can also take advantage of complex programming options to fine-tune or change stimulation patterns.

Prior to permanent placement, a trial stimulation is performed. Generally, temporary percutaneous stimulator leads are used for this purpose. Once an appropriate stimulation pattern is produced, most protocols will require at least a 50% improvement in pain scores. The length of trial screening is controversial, varying from days to weeks.

Lead migration and breakage are common problems with long-term stimulation. Lead migration

may produce unwanted paresthesias or diminish benefit in the original area of stimulation. This can sometimes be overcome by reprogramming of the electrode but may require lead replacement. Serious infection, bleeding, and nerve injury are uncommon complications.[183] Generator or transmitter failure is unlikely; however, fully implantable generators will require replacement, depending on use.

Radiofrequency Lesioning

Radiofrequency (RF) technology was first used to produce nervous system lesions in the 1950s. The technique was further refined in the 1970s by the invention of the RF probe, leading to the technique of facet joint denervation. Modern RF thermocoagulation has been used to ablate pain pathways in the spinal cord, dorsal root entry zone, dorsal root ganglion, trigeminal ganglion, sympathetic chain, and peripheral nerves.

An insulated probe with an uninsulated tip is placed in proximity of the target tissue and RF current is allowed to flow from a generator. As the current encounters resistance in the tissue, heat is generated, creating a lesion. Lesion size is directly proportional to tissue temperature at thermal equilibrium between the probe tip and the surrounding tissue. This equilibrium is generally achieved in 1 minute. Prior to lesioning, the target structure must be localized. This is accomplished by electrical stimulation. High frequencies and lower voltages are used to elicit a paresthesia in the desired distribution, whereas low frequencies and higher voltages are used to test for motor stimulation. Temperatures specific for the target nerve can be selected.

Patient selection requires a firm diagnosis verified by prognostic blocks with local anesthetics. RF lesioning is by definition neurodestructive and can be considered only after more conservative options have failed. Patients may require psychological screening and should be aware of all potential adverse sequelae, including neurologic impairment. Thorough knowledge of neuroanatomy and the use of fluoroscopy are mandatory for the pain physician.

The lumbar spine is an area where RF lesioning is often applied. Specific techniques have been developed for pain originating from the facet joints, nerve roots, annulus fibrosis, and sacroiliac joints. Approximately 50 to 60% of carefully selected patients with mechanical low back pain due to facet arthropathy achieve at least moderate reduction in pain following RF lesioning of the medial branches of the posterior primary divisions (i.e., the nerves that supply the facet joints).[188] A randomized, double-blind, controlled trial of RF facet denervation versus a sham procedure using no RF current showed a significantly better response in the RF group 8 weeks after the procedure. Ten of 15 RF subjects and 6 of 16 control subjects met criteria for treatment success.[189]

Lesions for discogenic pain are performed at the ramus communicans and intradiscally.[198] Owing to the complexity of disc innervation and disc pathology, this procedure is not nearly as successful as for medial branch denervation. RF applications for cervical spine pain are primarily oriented toward facet joint denervation, and results are similar to those for lumbar facet arthropathy. Lesions of the sphenopalatine and trigeminal ganglia[190] have been successfully used for select patients for the treatment of migraine headaches and trigeminal neuralgia, respectively. RF neurolysis of the sympathetic chain, although not in widespread use, has been helpful in some patients with type II complex regional pain syndrome and vasoocclusive disorders.

Patients can experience postoperative pain or dysesthesia for days to weeks after the procedure as a result of low-level heat injuries to tissue. Subsequently, judging the efficacy of the procedure is often difficult in the short term. More permanent nerve injuries and disc infections have been described.[191] Duration of benefit from RF lesioning is usually no more than 6 to 8 months because nerve regeneration usually occurs, but the procedure may offer more prolonged analgesia than nerve blocks. For patients who experience several months of relief from facet joint steroid injections, repeating that procedure may be a more appropriate alternative.

Minimally Invasive Treatment for Disc Pathology

Discography

Discography is a purely diagnostic procedure that incorporates provocative injection to determine whether a particular disc is a source of pain with radiographic imaging using radiographic dye. Using a combination of oblique, PA and lateral views, a needle is placed into the central portion of the disc. A two needle technique is often used to reduce the risk of bacterial discitis, advancing a larger needle into close proximity to the disc and passing a finer needle through it into the disc. A small volume (0.5 to 3 mL) is slowly injected until resistance to injection or pain is elicited. Anteroposterior and lateral views are observed for the pattern of dye spread. Commonly seen defects include annular tears and extravasation into the epidural space. Subsequent CT scan provides more detailed imaging of anatomic defects. Often, an adjacent, presumably normal disc is injected. Concordant pain in the affected disc and lack of pain in the adjacent, normal disc helps confirm the abnormal disc as the source of pain.

Percutaneous Annuloplasty

Intradiscal electrothermal therapy (IDET) is a treatment system that permits the controlled delivery of electrothermal heat to the intervertebral disc via a thermal resistive coil. The electrode is navigated circumferentially around the inner surface of the disc annulus. By then heating the electrode, annular collagen is denatured and nerve endings innervating the disc are coagulated. A similar system uses RF heating of the annulus. The target diagnoses for these procedures are discogenic pain with internal disc disruptions secondary to small contained disc herniations, posterior annular fissures, and degenerated disc with relatively preserved disc height. Patients with these diagnoses are likely to fail conservative therapy, whereas discectomy and fusion surgery have shown mixed results. MRI evidence of disc disruption and a positive discogram are usually required for patient selection. A review of the available literature published in 2002 indicated that several prospective studies showed significant improvement lasting a year or longer.[192] One nonrandomized study that compared IDET with a control group treated with a physical rehabilitation program showed better outcomes after 1 year in the IDET group.[193] Randomized controlled trials are needed.

Percutaneous Disc Decompression

Several minimally invasive techniques have been introduced that are designed to reduce intradiscal pressure, thus reducing tension on the outer layers of the annulus fibrosus and decreasing compression of the adjacent nerve root. Chymopapain chemonucleolysis was first used in the 1960s. Although successful in some patients, the process was not controllable, and resulted in overdecompression with disc collapse and spine instability in some individuals. In addition, there were a number of reports of serious complications, including anaphylaxis and transverse myelitis.[194] Percutaneous laser discectomy has had limited success, and may produce complications related to overdecompression and injury to surrounding tissues, especially nerve roots, because of the high temperatures generated.

Nucleoplasty is a newer technology that produces vaporization of small volumes of material in the nucleus followed by RF thermocoagulation. Relatively low temperatures are used, and small amounts of tissue are eliminated, making it a fairly safe procedure.[194] A similar decompressive procedure involves the use a small percutaneous motorized augur, which removes measurable amounts of nuclear tissue percutaneously. For both procedures, treatment appears to be more useful for radiculopathy associated with disc bulge than for discogenic pain. Neither procedure has been subjected to randomized controlled trial.

CONCLUDING REMARKS

During the 1970s and 1980s, there was dramatic evolution of pain management toward a multidisciplinary approach. The biopsychosocial model was introduced, combining medical and behavioral and management, while addressing important issues regarding financial, vocational, recreational, and social aspects of the patient's life. There was a strong emphasis on reducing or eliminating opioid and sedative medications. Although these programs were expensive, results

were often dramatic. Few such programs exist any longer. Perhaps the primary reason has been the devolution of much of the health insurance industry to programs that require participation of separate, selected providers for medical, psychological, and rehabilitation

services. The opportunities for obtaining reimbursement for all three types of services in a coordinated fashion within a single institution are almost nonexistent. At the same time, new technologies have been introduced that, while apparently beneficial for selected individuals, are rarely of lasting benefit for patients with truly chronic pain. Nevertheless, the same third-party payers that fail to reimburse a multidisciplinary approach that addresses the entire spectrum of a chronic pain patient's needs may provide payment for expensive interventions or surgeries without hesitation.

Above all, the practice of pain medicine requires a comprehensive and meticulous assessment of all aspects of each patient's problem. There are indeed problems that can be managed expeditiously, particularly for patients whose duration of symptoms has been relatively short and for whom specific procedures can be of substantial benefit. However, the patient who has had back and leg pain for 7 years, is unemployed, has had five back surgeries, and is on three opioid medications is unlikely to experience a quick cure from an injection, a device, or another operation. Such a patient requires the services of multiple health care professionals who can address his medical, behavioral, and rehabilitation needs.

Chapter 57

Anesthesia and Critical Care Medicine

Miriam M. Treggiari

Steven Deem

KEY POINTS

1	Administration of high-dose corticosteroids to patients presenting with traumatic brain injury is associated with a 20% increase in the relative risk of death.
2	Administration of thrombolytic therapy (rt-PA) to patients presenting within 3 hours of onset of acute ischemic stroke results in improved neurologic outcome.
3	Patients who are resuscitated from cardiac arrest due to ventricular fibrillation have improved neurologic outcome and possibly reduced mortality when treated with mild therapeutic hypothermia (32 to 34°C) for 12 to 24 hours after hospital admission.
4	In patients with severe sepsis or septic shock, activated protein C is associated with a 6% absolute 28-day mortality reduction, and early goal-directed therapy, targeting an $ScvO_2$ >70% in the first 6 hours after admission to the emergency department, has been associated with an even greater reduction in mortality.
5	Separation from mechanical ventilation in patients who are recovering from respiratory failure is accelerated by respiratory therapy-driven protocols and daily trials of spontaneous breathing.
6	Ventilation with low tidal volume (6 mL/kg) in patients with acute lung injury and acute respiratory distress syndrome reduces mortality, compared with traditional tidal volumes (12 mL/kg).
7	Tight glycemic control using intensive insulin therapy (goal glucose <110 mg/dL) reduces intensive care unit (ICU) mortality by approximately 50% compared with more conventional therapy (goal glucose <215).
8	Red blood cell transfusion in the ICU should be restricted (transfusion threshold hemoglobin <7 g/dL) with the possible exception of patients with a diagnosis of active bleeding, early septic shock, acute myocardial infarction or unstable

	angina, or with primarily neurologic or neurosurgical problems.
9	Nurse-driven sedation protocols and daily interruption of sedative infusions reduce the duration of mechanical ventilation and ICU length of stay.
10	The incidence of ventilator-associated pneumonia (VAP) can be reduced with strict hand washing during patient care and semirecumbent positioning of the patient. Antibiotic therapy of VAP should use a "deescalating" strategy and can be limited to an 8-day course in uncomplicated cases.

ANESTHESIOLOGISTS AND CRITICAL CARE MEDICINE

Historically, critical care medicine evolved as a specialty nearly simultaneously in Europe and North America, but it has followed strikingly different models in regard to the involvement of anesthesiologists. The first intensive care unit (ICU) in Europe may have been located in Denmark in the 1950s, and concurrently, the first critical care physician, or "intensivist," may well have been an anesthesiologist.[1] Anesthesiologists continued to play a defining role in the development of critical care

medicine in most of Europe, Australia, New Zealand, Japan, and elsewhere, and comprise the majority of intensivists in many countries around the world today. In North America, anesthesiologists were also integral to the development of critical care medicine as a specialty. However, in contrast to other countries, in the United States anesthesiologists have played an ever-diminishing role in the specialty, and today comprise a small minority of the intensivist workforce.[2]

Although it has been suggested that the first ICU in North America was established at Johns Hopkins in 1923 to care for postoperative neurosurgical patients, it was not until the late 1950s and early 1960s that true multidisciplinary ICUs began to appear. The driving forces behind ICU development included advances in surgical techniques; polio epidemics, which resulted in widespread respiratory failure; and later the recognition of acute respiratory distress syndrome (ARDS). Anesthesiologists played a natural role in the evolution of ICUs, given their familiarity with surgical resuscitation and mechanical ventilation. Early on, however, the concept of "intensivists" did not exist, and patients were often managed by their primary physician (be it surgeon or internist) and nurses, with formal or informal consultation given by specialists, including anesthesiologists.

In the early 1960s, the first critical care medicine training program was established at the University of Pittsburgh under the direction of an anesthesiologist, Peter Safar. At this point, the concept of "intensivist" was born; as defined by Dr. Safar, the qualities and qualifications of such an individual should include inquisitiveness, thoughtfulness, high motivation level, action orientation, diplomacy, and scientific training. In the late 1960s, a group that included Dr. Safar and another anesthesiologist, Ake Grenvik, were instrumental in inaugurating the Society of Critical Care Medicine (SCCM). Anesthesiologists working through SCCM were instrumental in developing the board certification process for critical care medicine, and in 1986, the first critical care medicine certification examination was administered by the American Board of Anesthesiology.[3] From the 1960s until now, numerous anesthesiologists made important contributions to the development of the specialty, to critical care-related research, and to improvements in the care of critically ill patients. However, as of 2004, only about 1,100 anesthesiologists had completed the certification process in critical care medicine in the United

States.[4]

Anesthesiology and Critical Care Medicine: The Future

Although it seems certain that anesthesiologists will continue to play an important role in critical care medicine worldwide, in the United States, anesthesiology is currently at a crossroads in regard to its continued involvement in critical care medicine. There are several forces that will shape the evolution of the specialty of critical care medicine as a whole and the contribution that anesthesiologists will make to this evolution. These forces are (1) quality of care issues and the contribution of intensivists to improved ICU outcomes, (2) business/economic factors, and (3) the aging population and increasing demand for critical care services.

Intuitively, the involvement of intensivists in the management of critical illness makes sense. This has become increasingly clear as advances in medical and surgical therapeutics have increased the complexity of care for an aging and increasingly ill population of patients. However, debates over loss of physician autonomy, economic and training considerations, and a lack of hard evidence of the benefit of intensivists has hindered the development of an intensivist-centered ICU paradigm in the United States. More recently, however, several studies have suggested that mortality and other intermediate endpoints such as ICU length of stay can be reduced when "high-intensity" physician staffing models that mandate management or comanagement by intensivists are used.[5] These studies, as summarized in a meta-analysis by Pronovost et al,[5] have provoked a reconsideration of the ideal staffing model for ICUs in the United States, particularly among the business community.

The Business Roundtable, a national association of CEOs of Fortune 500 companies, formed the Leapfrog Group in 1999. The Leapfrog Group is a coalition of more than 150 purchasers and providers of health care benefits, including large companies such as General Motors, Motorola, and Merck, and insurers such as Aetna. The stated goal of the Leapfrog Group is to improve health care, in particular by reducing deaths due to medical error. To accomplish this aim, the group formulated the Leapfrog Initiative, which includes a series of "safety standards" that health care providers (largely meaning hospitals) should strive for if they are to provide care for Leapfrog Group employees. Prompted by the more recent data associating intensivists with improved outcomes, the Leapfrog Initiative included an ICU physician staffing (IPS) standard that promotes the continuous involvement of intensivists in the care of critically ill patients (Table 57-1). Given that only an estimated 10% of hospitals met this standard when it was initially published, the Leapfrog Initiative has moved the discussion of ICU staffing models from academic debate to the administrative boardroom. Although many hospitals may be able to meet the IPS standards by simple reconfiguration of current care models, meeting the standards in full will certainly increase the demand for intensivists.

TABLE 57-1 Leapfrog Intensive Care Unit Physician Staffing Standard

Hospitals fulfilling the IPS standard will operate adult and/or pediatric ICUs that are managed or comanaged by intensivists who

1. Are present during daytime hours and provide clinical care exclusively in the ICU and,
2. At other times can, at least 95% of the time,
    i. Return ICU pages within 5 minutes
    ii. Arrange for a FCCS-certified nonphysician effector to reach ICU patients within 5 minutes

IPS, intensive care unit physician staffing; ICU, intensive care unit; FCCS, fundamental

critical care support (course training sponsored by the Society of Critical Care Medicine to prepare nonintensivists to manage the first 24 hours of critical illness).

Data from http://www.leapfroggroup.org/for_consumers/hospitals asked what

A final, important force driving the evolution of critical care medicine in the United States is the aging population, which will place increasing demands on the health care system. Increased demand will result in a shortage of intensivists starting in 2007 that will grow to a greater than 20% deficit by the year 2020, given current training levels.[2] This prediction does not take into account any additional demands placed on the health care system, if any, by the Leapfrog Initiative, and thus is likely an underestimate of the true future need for intensivists.

Given the previous observations, it is clear that opportunities for careers in critical care medicine will be amply available in the coming years. Anesthesiology as a specialty would seem ideally suited to help satisfy the increasing demand for intensivists. Anesthesiologists are hospital based; have sound fundamental training in physiology, pharmacology, and invasive procedures and monitoring; and have excellent historical and concurrent (see Europe, etc.) role models for the anesthesiologist as intensivist. However, economic and lifestyle incentives

have recently dissuaded residents from pursuing further training and careers in critical care medicine. Critical care services are currently not reimbursed at rates commensurate with surgical anesthesia, and critical care practice is accurately perceived as more time-consuming and unpredictable than an operating room-based practice. However, these factors may change in the coming years, as reimbursement for surgical anesthesia and critical care services equalize and the lifestyle constraints associated with critical care are moderated by creative organizational strategies, including the use of physician extenders and other mechanisms for reducing the "24-7" workload. Last, more recent proposals to expand the anesthesiology residency training requirement to include 6 months of intensive care may imbue trainees with a greater interest in critical care medicine as a career choice. As stated previously, anesthesiology in the United States is at a crossroads—with the proper imagination, emphasis, support, and training, the specialty can reassert itself as a leader in the field of critical care medicine. The alternative is that the percentage of anesthesiologists involved in critical care medicine will continue to decline and anesthesiology will become little more than a historical footnote in this field.

Critical Care Medicine: A Systems and Evidence-Based Approach

Critical care encompasses all disciplines of medicine. It is clearly beyond the scope of a single chapter to provide detailed coverage of all aspects of critical illness, including physiology, pathophysiology, mechanisms, and management of disease. In addition, many critical care issues are commonly faced by anesthesiologists that practice solely in the operating room, and are covered in detail elsewhere in this text. Thus, this chapter focuses on issues that are relatively unique to the ICU, on therapeutic approaches, and on practices for which strong evidence exists. Where appropriate, the level of evidence supporting treatment regimens is graded according to commonly accepted methodology (Table 57-2).[6]

TABLE 57-2 Evaluating Evidence for Medical Therapies

·LEVELS OF EVIDENCE

I. Large, randomized trials with clear-cut results; low risk of false-positive (alpha) error or false-negative (beta) error
II. Small, randomized trials with uncertain results; moderate-to-high risk of false-positive (alpha) and/or false-negative (beta) error
III. Nonrandomized, contemporaneous controls
IV. Nonrandomized, historical controls and expert opinion
V. Case series, uncontrolled studies, and expert opinion

·GRADES OF RECOMMENDATION BASED ON EXPERT CONSENSUS[a]

A. Supported by two or more level I studies
B. Supported by only one level I study
C. Supported by level II studies
D. Supported by level III studies
E. Supported by level IV or V studies

[a] The grades assigned in this chapter are taken directly from consensus conference statements. However, consensus grading systems are not consistent between conferences. This grading scale is one that is objective and widely used, but it may not directly reflect the criteria used to derive the individual grades reported here.

NEUROLOGIC AND NEUROSURGICAL CRITICAL CARE

Neuromonitoring

Several neuromonitoring devices used in the ICU setting may help in assessing pathophysiologic processes and adjusting therapy. The following section discusses some commonly used neuromonitoring devices, including transcranial Doppler ultrasonography, brain tissue oxygenation, and microdialysis. Intracranial pressure (ICP) monitoring and jugular venous oximetry are discussed in chapters on monitoring the anesthetized patient, anesthesia for neurosurgery, and burns and trauma, and are not discussed in detail here.

Transcranial Doppler Ultrasonography

Transcranial Doppler (TCD) measures mean, peak systolic, and end-diastolic flow velocities, and indirectly estimates cerebral blood flow (CBF). In patients with subarachnoid hemorrhage or traumatic brain injury (TBI), TCD can be used as a tool to identify vasospasm. Despite some technical limitation due to the quality of the bone window and the fact that increased velocity needs to be interpreted either in the context of vasospasm or hyperdynamic flow patterns, TCD remains a valuable monitoring device to follow trends over time. In patients with TBI, flow velocities are depressed, and impaired autoregulation and vascular reactivity are common. In these patients, monitoring of TCD and jugular venous oxygen saturation (SjO_2) may be used to

define the optimum cerebral perfusion pressure (CPP) level.[7] Patients with subarachnoid hemorrhage are at high risk of cerebral vasospasm, and serial TCD can monitor changes in blood velocities, detecting occurrence of ischemic flow patterns.

Brain Tissue Oxygenation

Brain tissue oxygen pressure ($PbrO_2$) measurements are performed by introducing a small, oxygen-sensitive catheter into the brain tissue. The device monitors a very local area of the brain tissue, and this technique is increasingly used for evaluation of cerebral oxygenation (normal $PbrO_2$ values: 25 to 30 mm Hg).[8] Monitoring may be performed in relatively undamaged parts of the brain or, preferably, in the penumbra region of an intracerebral lesion. Various studies have shown that an increase in ICP and a decrease in CPP or arterial oxygenation, as well as hyperventilation, may result in decreased $PbrO_2$. In patients with TBI, ischemic episodes defined as $PbrO_2$ <10 mm Hg for longer than 15 minutes in the first week after the injury were found to be associated with unfavorable neurologic outcome. CPP >60 mm Hg has been identified as the most important factor determining sufficient brain tissue oxygenation.

Microdialysis

Microdialysis uses a probe as an interface to the brain to continuously monitor the chemistry of a small focal volume of the cerebral extracellular space. This method uses internally perfused semipermeable membrane probes, which allow neurochemical water-soluble substances to be collected outside the brain for further analysis. Microdialysis monitoring in neurointensive care allows measurement of chemical substances such as lactate, pyruvate, glucose, glutamate, glycerol, and metabolites of several biochemical pathways and electrolytes, and thus provides insight into the bioenergetic status of the brain. Increased lactate, decreased glucose, and an elevated lactate/glucose ratio indicate accelerated anaerobic glycolysis. This metabolic pattern commonly occurs with cerebral ischemia or hypoxia, and

increased glycolysis in this setting is associated with a poor outcome. Extracellular excitatory amino acids such as glutamate may provide a marker for secondary brain insults, as indicated by elevation during periods of hypoxia and intracranial hypertension. However, metabolism can be altered without changes of cerebral oxygenation and may not correlate with high ICP or low CPP.[9] In addition, lack of equilibration with the extracellular space may introduce sampling error.

Diagnosis and Clinical Management of the Most Common Types of Neurologic Failure

Traumatic Brain Injury

1 TBI is the leading cause of death from blunt trauma, with an incidence of approximately 10 per 100,000 per year. With a proportion of 20% of deaths occurring in patients between the age of 5 and 45 years, TBI represents the leading cause of death in this age group. The most powerful predictors of poor outcome from injury through resuscitation are age older than 55 years, poor pupillary reactivity, postresuscitation Glasgow Coma Scale (GCS), hypotension, hypoxia, and unfavorable intracranial diagnosis as established by radiologic features (computed tomography [CT] scan). In addition, early hyperglycemia (>200 mg/dL) is a reliable independent predictor of poor outcome.

The GCS (see Chapter 48) is the most widely used clinical measure of injury severity in patients with TBI. The advantages of this scale are that it provides an objective method of measuring consciousness, it has high intrarater and interrater reliability across observers with a wide variety of experience, and it has an excellent correlation with outcome. However, the GCS is unmeasurable in up to 25 to 45% of the patients at admission and is inaccurate when only the partial score is used, such as in patients with endotracheal intubation whose verbal response cannot be assessed. TBI qualifies as severe when the GCS is 8 or less after cardiopulmonary resuscitation. The predictive value of the GCS at admission is about 69% for good neurologic

outcome and 76% for unfavorable outcome. After 7 days, these figures approximate 80% for both favorable and unfavorable outcome.[10]

Pupillary dilatation and light reactivity are also useful predictors of neurologic outcome. When both pupils are dilated and unreactive, the likelihood of poor neurologic outcome or death is as high as 90 to 95%. When both pupils are reactive, the likelihood of poor neurologic outcome is approximately 30 to 40%, whereas the probability of good outcome is 50 to 70%.

Hypotension is a strong predictor of poor outcome in TBI. Chesnut et al reported that there was a 15-fold increased risk of mortality in patients with early hypotension and an 11-fold increase in mortality in patients with late hypotension.[11]

Radiologic imaging is important in the diagnosis and in assessing the prognosis of patients with TBI. Based on the CT scan, TBI can be classified according to the severity of the intracranial lesion: diffuse injury I (no visible intracranial pathology); diffuse injury II (cisterns are present with midline shift 0 to 5 mm, no high-density or mixed-density lesion >25 cc); diffuse injury III (swelling; cisterns are compressed or absent with midline shift 0 to 5 mm, no high-density or mixed-density lesion >25 cc); diffuse injury IV (shift; midline shift >5 mm, no high-density or mixed-density lesion >25 cc); evacuated mass lesion (any lesion surgically evacuated); nonevacuated mass lesion (high-density or mixed-density lesion >25 cc, not surgically evacuated). The CT classification of TBI is correlated with neurologic outcome, with diffuse injury I having a 38% rate of unfavorable (death, vegetative, or severe disability) outcome, increasing to a 94% rate in patients with a grade IV diffuse injury. In addition, it should be noted that about one-third to one-half of the patients present with no lesion at admission and develop new lesions secondarily, which is associated with substantially worse neurologic outcome.

The goal of resuscitation in TBI and other types of brain injury is to prevent continuing cerebral insult after a primary injury has already occurred. The extent of the primary cerebral injury is usually determined by the mechanism of the trauma, the cause, and duration of cerebral ischemia. A primary insult is often associated with intracranial hypertension and systemic hypotension, leading to decreased cerebral perfusion and brain ischemia. Concomitant hypoxemia aggravates brain hypoxia, especially in the presence of hyperthermia, which increases brain metabolic demand. The combined effect of these factors leads to secondary brain injury characterized by excitotoxicity, oxidative stress, and inflammation. The resulting cerebral ischemia may be the single most important secondary event affecting outcome following a cerebral insult. Prevention of secondary injury is the main goal of resuscitative efforts.

Traumatized areas of the brain manifest impaired autoregulation, with increased dependency of flow on perfusion pressure, and disruption of the blood-brain barrier. If space-occupying lesions or edema are present, they will contribute to reduced brain compliance, leading to increased ICP and consequent deleterious effect on CBF. The rationale for attempting to optimize CPP arises from the fact that cerebral regions surrounding the primary lesion may be close to the ischemic threshold. Therefore, the goals of neuroresuscitation are oriented at restoration of CBF by maintenance of adequate CPP, reduction of ICP, evacuation of space-occupying lesions, and initiation of therapies for cerebral protection and avoidance of hypoxia.

Unfortunately, the ICU treatment of TBI is hindered by a lack of rigorous, randomized, controlled trials to prove benefit, or lack thereof, for many of the management strategies used today. Thus, treatment is based largely on pathophysiologic principles and uncontrolled trials (level III evidence or less). A general guideline for management of patients with severe TBI appears in Table 57-3. Basic principles of management of acute TBI, including osmotherapy, are discussed further in Chapter 48, whereas sedation, hyperventilation, hypothermia, corticosteroids, and antiseizure prophylaxis are discussed in further detail in this chapter.

TABLE 57-3 Intensive Care Unit Management of Patients with Severe Traumatic Brain Injury

Basic principles applied to all patients, assuming initial surgical management	• Head elevation 30–45°[a] • CPP > 60 mm Hg ○ Euvolemia, vasopressors as needed • ICP < 20 mm Hg ○ Mannitol, hypertonic saline ○ CSF drainage • SaO_2 ⩾95%; $PaCO_2$ 35–40 mm Hg • Temperature ⩽37°C • Glucose < 180 mg/dL[b] • Sedation and analgesia • Early enteral nutrition • Seizure, stress ulcer, and DVT prophylaxis
Refractory intracranial hypertension Consider one or all these interventions, depending on individual circumstances	• Optimized hyperventilation with SjO_2 and/or $PbrO_2$ monitoring • Barbiturate coma • Mild therapeutic hypothermia (33–35°C) • Decompressive craniectomy
CSF, cerebrospinal fluid; CPP, cerebral perfusion pressure; DVT, deep venous thrombosis; ICP, intracranial pressure.	
[a]Unless contraindicated by spine injury, hemodynamic instability, or otherwise.	
[b]Consider intensive control (glucose < 110 mg/dL).[96]	

Sedation of neurologically impaired patients should typically be achieved with short-acting sedatives to allow for frequent assessment of neurologic examination.[12] Although no studies have investigated the effect of sedation on outcome in patients with neurologic disorders, a common practice is to provide sedation with propofol or benzodiazepines in patients following TBI. These agents have favorable effects on cerebral oxygen balance, although propofol is more potent in this regard. Undesirable effects of sedatives are those leading to a reduction in CPP due to hemodynamic depression, or to an increase in CBF accompanied by a simultaneous increase in ICP, a condition occurring, for example, with the use of ketamine.

Propofol rapidly penetrates the central nervous system and has rapid elimination kinetics. Despite the induction of systemic hypotension, propofol decreases cerebral metabolism resulting in a coupled decline in CBF, with consequent decrease in ICP. Propofol's favorable pharmacologic and neurophysiologic profile has lead to its widespread use in neurointensive care, and high-dose propofol has been advocated as a substitute for barbiturate therapy in patients with refractory intracranial hypertension. However, prolonged (>24 hours), high-dose (>80 μg/kg per minute) propofol administration has been associated with lactic acidosis, cardiac failure, and death (propofol infusion syndrome) in children and adults with TBI.[13] Thus, the use of high-dose propofol to control refractory intracranial

hypertension is not recommended, and barbiturates should be considered if ICP is not controlled

by moderate doses of propofol.

The mechanisms by which barbiturates exert their cerebral protective effect appear to be mediated by a reduction in ICP via alteration in vascular tone, reduction of cerebral metabolic rate, and inhibition of free radical peroxidation. Although barbiturates are effective at reducing ICP, their routine use in TBI does not appear beneficial, and may in fact result in excess mortality in patients with diffuse brain injury (level II evidence).[14,15] This effect may in part relate to the profound cardiovascular depressant effects of barbiturates. Based on one small randomized trial, barbiturates do appear to reduce mortality in patients with refractory high ICP (level II evidence).[16] Thus, high-dose barbiturate therapy may be considered in hemodynamically stable severe TBI patients with intracranial hypertension refractory to maximal medical and surgical ICP-lowering therapy. In some patients, pentobarbital may induce hypoxia by reducing CBF in excess of metabolism, and therefore, SjO_2 monitoring should be considered during barbiturate therapy.

Although neuromuscular blockade may result in a fall in ICP, the routine use of neuromuscular blockade is discouraged because its use has been associated with longer ICU course, a higher incidence of pneumonia, and a trend toward more frequent sepsis without any improvement in outcome.

Hyperventilation effectively reduces ICP by reducing CBF. However, the role that hyperventilation should play in routine management of TBI is not clear. Primarily, this is related to concerns that hyperventilation may lead to dangerously low CBF, resulting in worsening cerebral ischemia.[17] In small randomized trials, prophylactic hyperventilation has not proven to be beneficial in TBI.[18] In contrast, it has been proposed that "optimized hyperventilation" in the presence of "luxury perfusion" (excess CBF) may increase global cerebral oxygen metabolism and help normalize global cerebral glucose extraction. Cruz reported that an optimized hyperventilation strategy resulted in a reduction in mortality compared with CPP management in concurrent matched control patients, although this was not a randomized trial (level III evidence).[19] Based on the available evidence, prolonged or prophylactic hyperventilation should be avoided after severe TBI. Hyperventilation may be necessary for brief periods to reduce intracranial hypertension refractory to sedation, osmotic therapy, and CSF drainage, and should be guided by SjO_2 and/or $PbrO_2$. A marked fall in either of these values suggests a harmful effect of hyperventilation, and it should be discontinued.

Experimentally, hypothermia causes a reduction in cerebral metabolism by decreasing all cell functions, both related to neuronal electric activity and those responsible for cellular integrity. In addition, mild hypothermia has been shown to decrease the release of substrates associated with tissue injury such as glutamate and aspartate. A meta-analysis of eight randomized trials using mild hypothermia (33 to 35°C) in 748 patients with TBI indicated that, despite a marginal improvement in poor neurologic outcome, there was no mortality advantage and an increased risk of pneumonia.[20] Therefore, there is insufficient evidence to provide recommendations for the use of moderate hypothermia in patients with TBI. In patients with TBI, mild iatrogenic hypothermia should be differentiated from spontaneous hypothermia, which indeed carries a poor prognosis, and is characterized by markedly abnormal brain metabolic indices. In contrast, immediate rewarming of TBI patients with spontaneous hypothermia may further worsen outcome.[21]

Corticosteroids to reduce posttraumatic inflammatory injury in TBI have been advocated for 30 years or more, but without convincing evidence of benefit. However, a more recent large, prospective, randomized trial confirms that corticosteroids in this setting are harmful. The CRASH study randomized more than 10,000 patients presenting with acute TBI to receive high-dose methylprednisolone or placebo for 48 hours after hospital admission. Methylprednisolone administration was associated with an approximately 20% increase in the relative risk of death at 2 weeks in the entire cohort, and detriment was evident across subgroups divided by severity and type of injury (level I evidence).[22] Thus, high-dose corticosteroids should not be administered as therapy for acute TBI.

Antiseizure prophylaxis is not recommended for preventing posttraumatic late seizures. Anticonvulsants may be used to prevent early posttraumatic seizures following head trauma. However, the evidence does not indicate that prevention of early seizures improves outcome

following TBI.[23]

Subarachnoid Hemorrhage

The incidence of subarachnoid hemorrhage (SAH) in the United States varies from 7.5 to 12.1 cases per 100,000 population. SAH is most commonly caused by the rupture of an intracranial aneurysm. Other causes of SAH include trauma, vertebral and carotid artery dissection, dural and spinal arteriovenous malformations, mycotic aneurysms, sickle cell disease, cocaine abuse, coagulation disorders, and pituitary apoplexy. SAH is associated with considerable morbidity and mortality, with only one-third of the patients suffering from SAH being functional survivors. The leading causes of death and disability are the direct effect of the initial bleed, cerebral vasospasm, and rebleeding. The Report of the Cooperative Study of Intracranial Aneurysms and SAH estimated that 33% of the patients would die before receiving medical attention. Another 27% would either die during hospitalization or become severely disabled, leaving only about 30% to survive without major disability.[24,25] Severity of the initial bleed is the most important determinant of SAH outcome.

At the time of aneurysm rupture, there is a critical reduction in CBF due to increase in ICP toward arterial diastolic values. The persistence of a no-flow pattern is associated with acute vasospasm and swelling of perivascular astrocytes, neuronal cells, and capillary endothelium. After SAH, injury to the posterior hypothalamus may stimulate release of norepinephrine from the adrenal medulla and sympathetic cardiac efferent nerves. The release of norepinephrine has been associated with ischemic changes in the subendocardium (neurogenic stunned myocardium), cardiac dysrhythmias, and pulmonary edema.

In survivors of the initial bleed, emphasis has been placed on early aneurysm securing with either surgery or interventional neuroradiology (coiling). Approximately 10 to 23% of unsecured aneurysms will rebleed in the first 2 weeks, most within the first 6 to 12 hours after the initial hemorrhage, and rebleeding is associated with mortality approximating 80%. Early aneurysm occlusion substantially reduces the risk of this complication. However, with the improvement of the operative management, delayed complications have become increasingly important causes of death and disability.

Cerebral vasospasm after SAH, consisting of intracerebral arterial narrowing, has been identified by angiography in up to 60% of patients, and is correlated with the amount and location of subarachnoid blood. A reduction in CBF is ultimately responsible for the appearance of *delayed ischemic neurologic deficits (DINDS)*. DINDS occur in approximately one-third of patients suffering from SAH. In a systematic review of the literature, Dorsch et al found an overall death rate of 31% (versus 17% in patients without vasospasm), permanent deficits in 35%, and good outcome in 34% of the patients who developed symptomatic vasospasm.[26] DINDS typically presents as alteration in consciousness and/or transient focal neurologic deficits that rarely occur within the first 3 days after aneurysm rupture, typically peak in 7 to 10 days, and resolve over 10 to 14 days. If severe, vasospasm can result in cerebral infarction and persistent neurologic deficits, which contribute to considerable long-term morbidity.

TCD has been used to identify and quantify cerebral vasospasm on the basis that velocity profiles increase as the diameter of the vessel decreases. Changes in measured velocities over time may be more reliable than absolute values in predicting symptomatic vasospasm. Velocities greater than 200 cm/second have been associated with a high risk of infarction, but there is a poor correlation between the TCD velocities and angiographic findings, especially for the anterior cerebral artery and the posterior circulation. Single photon emission CT may provide a more accurate means of identifying patients at risk for delayed ischemia.

Oral nimodipine (60 mg every 4 hours for 21 days) as prophylaxis for cerebral vasospasm is recognized as an effective treatment in improving neurologic outcome (reduction of cerebral infarction and poor outcome) and mortality from cerebral vasospasm in patients suffering from SAH (level I evidence).[27] Although angiographic studies did not demonstrate a difference in the frequency of vasospasm compared with a placebo treated group, the benefits of nimodipine have

been attributed to a cytoprotective effect related to the reduced availability of intracellular calcium and improved microvascular collateral flow. No other pharmacologic therapies to prevent or treat cerebral vasospasm have demonstrated effective results in clinical trials.

Hypervolemic/hypertensive and hemodilution (triple H) therapy is one of the mainstays of treatment for cerebral ischemia associated with SAH-induced vasospasm, despite the lack of evidence for its effectiveness, especially for its prophylactic use.[28] The rationale for this therapy is that hypovolemia is present because of blood loss, and also induced by hypothalamic dysfunction and secretion of natriuretic peptides. Volume expansion is therefore considered beneficial to optimize the hemodynamic profile. The rationale for hypertension derives from the concept that a loss of cerebral autoregulation associated with vasospasm results in pressure-dependent blood flow. Finally, hemodilution is a consequence of hypervolemic therapy, and is believed to optimize the rheologic properties of the blood, thereby improving microcirculatory flow. There is no consensus with regard to the goals of therapy, and it is unclear which component of this therapy is necessary or sufficient to treat vasospasm. Common complications of treatment are pulmonary edema and myocardial ischemia. Because the blood-brain barrier may be disrupted, aggravation of vasogenic edema or hemorrhagic infarction have also been described.[29]

Interventional neuroradiology with the use of balloon angioplasty can reverse or improve vasospasm-induced neurologic deficits. Patients treated within 6 to 12 hours after the development of ischemic symptoms have better results than those receiving delayed intervention. The risks of angioplasty include intimal dissection, vessel rupture, ischemia, and infarction.

Hydrocephalus is another cause of neurologic dysfunction after SAH, occurring in 25% of patients surviving the hemorrhage. The presence of blood in the ventricular system obstructs ventricular drainage and CSF absorption sites (subarachnoid villi). Ventricular drainage is usually successful in improving neurologic symptoms due to hydrocephalus. A minority of patients will require a permanent ventriculoperitoneal shunt. Seizures occur in 13% of patients with SAH, and are more common in patients with a neurologic deficit; thus, prophylactic anticonvulsant therapy is recommended.

A relatively common complication after SAH (10 to 34%) is hyponatremia. Hyponatremia usually develops several days after the hemorrhage, and is attributed to two main causes: (1) a syndrome of inappropriate antidiuretic hormone (SIADH), which is associated with euvolemia or mild hypervolemia and an excess of free water; or (2) cerebral salt wasting, which is marked by depletion of sodium and water. The differentiation of these two entities can be difficult but is theoretically important, in that SIADH is treated by free water restriction, and cerebral salt wasting with volume expansion and sodium administration. Thus, assessment of intravascular volume status is a key component when deciding on the treatment regimen for hyponatremia associated with SAH. Other medical complications of SAH include pneumonia, neurogenic pulmonary edema and acute lung injury, sepsis, gastrointestinal (GI) bleeding, deep venous thrombosis (DVT), and pulmonary embolism (PE).

Acute ischemic Stroke

Although evidence indicates that the incidence of stroke has declined during the past 30 years, stroke remains one of the leading causes of disability and death in the United States. More than one-half of all strokes can be attributed to a thrombotic mechanism. Other major causes of stroke are embolism, lacunar infarct, cerebellar infarction, and hemorrhage. Transient ischemic attacks may precede stroke and thus should be considered a warning sign. The prognosis of stroke patients varies, depending on the size of the lesion. In patients with acute ischemic stroke, the duration of coma appears to be the most important predictor of outcome and successful therapy.

2 Rapid clot lysis and restoration of circulation have been proposed as measures to limit the extent of brain injury and improve outcome after stroke. In accordance with the American Heart Association guidelines, systemic thrombolysis using alteplase (rt-PA) should be provided within 3 hours of stroke onset (level I evidence, grade A recommendation).[30] Thrombolytic therapy has been shown to recanalize both the carotid and the vertebrobasilar territories in 21 to 93% of cases when provided within 3 hours after the onset of symptoms, and to improve 24-hour and 3-

mortality. A more recent placebo-controlled study provided evidence of a sustained benefit at 1 year from systemic thrombolysis in patients with acute ischemic stroke. The overall rate of recurrent stroke was 6.6%, and the transient ischemic attack rate 3.3% at 1 year. Regional or local intra-arterial administration of a thrombolytic agent within 6 hours of symptom onset demonstrated a high recanalization rate, but a potential limitation to the use of intra-arterial treatment is the time required to mobilize a team to perform angiography (level II evidence). There is no evidence that intra-arterial thrombolysis is superior or inferior to intravenous administration. Intravenous streptokinase is not indicated for the management of ischemic stroke (grade A recommendation).

Concerns persist regarding the safety of rt-PA therapy for acute ischemic stroke, primarily related to hemorrhage. The symptomatic intracerebral hemorrhage rate has been reported to be around 5 to 6%, and is greater than in patients receiving thrombolytic therapy for management of myocardial ischemia (level I evidence).[31] Patients receiving systemic rt-PA should not receive aspirin, heparin, warfarin, ticlopidine, or other antithrombotic or antiplatelet aggregating drugs within 24 hours of treatment (grade A recommendation).

Unfractionated and low-molecular-weight heparin(LMWH) have not been shown to prevent progression or reduce the rate of stroke recurrence when administered within 48 hours of the acute event; therefore, their use is not recommended (grade A recommendation). In general, heparin is only recommended for early secondary prophylaxis in patients with suspected cardiac embolism. Aspirin (160 to 325 mg/day) has been shown to reduce the risk of early recurrent ischemic stroke when given within 48 hours of stroke onset, but increases the risk of hemorrhagic stroke. The frequency of deep venous thrombosis (DVT) in acute stroke is reduced by anticoagulants, especially LMWH, but not by antiplatelet agents. However, it is unclear if the frequency of pulmonary embolism (PE) is also reduced.

The majority of patients with acute ischemic stroke present with severe arterial hypertension. If intracerebral hemorrhage is excluded, treatment of hypertension should be delayed because reduction of the perfusion pressure could compromise the viable brain surrounding the ischemia (ischemic penumbra). However, severe hypertension (systolic blood pressure >220 mm Hg, or mean arterial blood pressure of >130 mm Hg, or diastolic >120 mm Hg) should be controlled because of increased risk of hemorrhagic transformation in anticoagulated patients or after thrombolysis. Although there is no evidence for an optimal level of blood pressure, there is general consensus that the systolic pressure should not be lowered below 150 to 160 mm Hg. If the event is accompanied by raised ICP due to cerebral edema, the principles of treatment of raised ICP discussed previously with regard to TBI similarly apply. Cytotoxic brain edema usually occurs 24 to 96 hours after acute ischemic stroke, and osmotherapy constitutes the basis of ICP reduction. Steroids are of no value in the treatment of ischemic stroke. Because hyperglycemia is associated with poor outcome in ischemic stroke, tight glucose control is recommended.

Space-occupying middle cerebral artery (malignant MCA syndrome) and cerebellar infarctions have a high mortality rate and, in selected cases where signs of intractable intracranial hypertension are present, hemicraniectomy or decompressive surgery of the posterior fossa, respectively, could be lifesaving and improve outcome.

Anoxic Brain Injury

Anoxic brain injury most commonly occurs as a result of cardiac arrest, either in-hospital or out-of-hospital. Of patients who survive their initial cardiac arrest, in-hospital mortality ranges from approximately 50 to 90%, and a high percentage of survivors suffer brain injury with significant long-term disability. The pathophysiology of anoxic brain injury is multifactorial and includes excitatory neurotransmitter release, accumulation of intracellular calcium, and oxygen-free radical generation. Unfortunately, pharmacologic therapies aimed at several of these pathways, including barbiturates, benzodiazepines, corticosteroids, calcium channel antagonists, and free radical scavengers have failed to improve the outcome of anoxic brain injury.

3 A strong experimental literature supports a role for mild therapeutic hypothermia in anoxic brain injury. Two more recently published prospective, randomized trials of mild hypothermia (temperature 32 to 34°C) in survivors of out-of-hospital ventricular fibrillation have provided some encouragement for survivors of cardiac arrest.[32,33] Hypothermia was associated with a relative increase in patients with a favorable neurologic outcome (moderate disability or less) of 40 to 50%, and in one study was also associated with relative 6-month mortality reduction of approximately 25% (level II evidence).[32] Thus, mild therapeutic hypothermia should be routinely applied to comatose survivors of out-of-hospital cardiac arrest due to ventricular fibrillation; it should also be considered in other scenarios, including in-hospital cardiac arrest and cardiac arrest due to asystole and pulseless electrical activity.

CARDIOVASCULAR AND HEMODYNAMIC ASPECTS OF CRITICAL CARE

Principles of Monitoring and Resuscitation

Shock states are associated with impairment of adequate oxygen delivery resulting in decreased tissue perfusion and tissue hypoxia. It is important to emphasize that global hemodynamic monitoring may not reflect regional perfusion or the peripheral tissue energy status. Occasionally, despite increased cardiac output and oxygen delivery, peripheral tissues suffer from hypoxia due to blood flow maldistribution, as well as uncoupling between oxygen delivery and oxygen utilization from mitochondrial dysfunction and energetic failure.

Invasive monitoring in shock states provides insight into the circulatory status, organ perfusion, tissue microcirculation, and cellular metabolic status of the critically ill patient. Hemodynamic monitoring ranges from the simple monitoring of electrocardiogram and pulse oximetry, to continuous arterial pressure via an arterial catheter and the monitoring of cardiac filling pressures with central venous or pulmonary artery catheters, to cardiac echocardiography. Several experimental monitoring devices detecting microenvironmental conditions at the tissue level are under continuous investigation.

Functional Hemodynamic Monitoring

Pulmonary Artery Catheter

The pulmonary artery catheter (PAC) measures hemodynamic indices, including central venous pressure (CVP), pulmonary artery pressure and occlusion pressure (PaOP), cardiac output (thermodilution method), systemic and pulmonary vascular resistances, and mixed venous oxygen saturation (SvO_2), and provides data for deriving oxygenation variables (oxygen delivery [DO_2], consumption [VO_2], and extraction [O_2ER]). The information provided by the PAC may assist in the differentiation of cardiogenic and noncardiogenic circulatory and respiratory failure, and help guide fluid, inotropic, and

vasopressor therapy. The technical and physiologic principles of the PAC are discussed in detail in other chapters in this text.

Despite the theoretical benefits of pulmonary artery catheterization, there are few data to support a positive effect of the PAC on mortality or other substantive outcome variables, leading some experts to call for a moratorium in PAC use until more definitive evidence of benefit is made available. In a retrospective analysis using propensity scores, Connors et al suggested that the use of the PAC within 24 hours following ICU admission was associated with increased mortality, length of stay, and health care costs in postoperative patients.[34] However, this study may have overestimated the mortality in the group with the PAC because of residual confounding despite patient matching. Vieillard-Baron et al. suggested that right heart catheterization may be associated with increased mortality, but after adjustment for the use of vasopressors, there was no increased mortality associated with the use of the PAC.[35] As a consequence of these studies questioning the benefits of the PAC, the frequency of use of the PAC has substantially decreased

in the management of patients with cardiogenic shock and in other ICU settings.[36] More recently, a randomized controlled trial assigning patients with shock, ARDS, or both to receive a PAC or not did not find any differences in mortality, organ system failures, renal support, and use of vasoactive agents between the two groups.[37] Similarly, there was no benefit to therapy directed by PAC over standard therapy in elderly, high-risk surgical patients requiring intensive care.[38]

Some or all the following factors may be responsible for the observed lack of benefit associated with PAC use: (1) device or procedure-related complications, (2) inaccurate data, (3) fundamentally incorrect assumptions about the meaning of the measured data, (4) inappropriate decisions resulting from misinterpretation of the data, and (5) harmful effects of well-intended therapies. As an example of the third factor, there is increasing evidence that CVP and pulmonary artery pressure do not predict the hemodynamic response to intravenous fluid administration in normal subjects or patients with shock.[39,40] As an example of the fifth factor, the ability to increase DO_2 with fluid resuscitation and inotropic therapy in patients with septic shock identifies a better prognosis. This observation led to a therapeutic strategy known as "supraphysiologic resuscitation" to defined end points (cardiac index >4.5 L/min, DO_2 >600 mL/m^2 per minute, and VO_2 >170 mL/m^2 per minute) in patients with septic and surgical/trauma-related shock. However, a large, randomized, prospective study found that this approach was associated with increased mortality in patients with septic shock.[41] As a result, supraphysiologic resuscitation has generally fallen out of favor, although it is still used in some centers. However, this example shows how information derived from the PAC can lead to patient harm, despite the best of intentions.

In summary, although the PAC remains a commonly used tool in critical care medicine, the evidence supporting its benefit is scant. A consensus conference on the use of the PAC concluded that the catheter should only be used when noninvasive methods are not available to provide the information required.[42] The decision to insert a PAC must weigh the risks of monitoring versus the potential benefits in terms of adaptation of treatment to the information obtained from the monitoring. In this regard, the PAC may be most useful as a tool to allow interpretation of the relationship between cardiac output and the peripheral demand for oxygen, and to direct therapy accordingly, rather than as a measure of intravascular volume status. Clearly, further research is necessary to establish the utility, if any, of the PAC in critically ill patients.

A somewhat less invasive and less costly alternative to placing a PAC for the measurement of SvO_2 is to measure central venous oxygen saturation ($ScvO_2$) via a fiberoptic central venous catheter. $ScvO_2$ is typically approximately 5 mm Hg higher than SvO_2, but it appears to correlate well with SvO_2 during changes in hemodynamic status.[43] Targeting an $ScvO_2$ >70% as a component of early goal-directed therapy in patients with septic shock has been associated with a reduction in mortality.[44]

Arterial Pressure Waveform Analysis

In addition to static pressure measurements such as CVP and PaOP, dynamic indicators of preload include respiratory variation in systolic pressure and pulse pressure, both of which can be derived from the analysis of the waveform generated by a peripherally placed arterial catheter. In addition, techniques for deriving stroke volume, cardiac output, and intrathoracic blood volume have more recently become available. These techniques present a less invasive and perhaps superior approach to hemodynamic monitoring of critically ill patients.

The variation in systolic blood pressure and pulse pressure during positive-pressure ventilation is highly predictive of the response to intravascular fluid administration in both normal subjects and critically ill patients. During positive-pressure ventilation, there is an inspiratory reduction in right ventricular stroke volume due to decreased venous return and a subsequent reduction in left ventricular end-diastolic volume appearing during the expiratory phase of the respiratory cycle. Therefore, the left ventricular stroke volume varies cyclically with ventilation, and is paralleled by a similar variation in systolic blood pressure and pulse pressure. These effects are exaggerated during absolute and relative hypovolemia. Systolic and pulse pressure variation are superior predictors of fluid responsiveness (compared with static measures such as CVP and PaOP) in patients with a variety of critical illnesses, including septic shock, acute lung injury, and following

cardiac surgery.[45]

Analysis of the systemic arterial pulse contour allows derivation of cardiac output after initial calibration using an indicator dilution technique. Two commercially available devices use either lithium (injected through a peripheral intravenous catheter; LiDCO) or thermal dilution (injected through a central venous catheter; PiCCO) for initial calibration. Cardiac output derived using pulse contour analysis correlates well with thermodilution cardiac output in a variety of conditions and has the advantage of providing continuous measurement without necessitating the placement of a PAC. The PiCCO device also allows for measurement of intrathoracic blood volume using transpulmonary thermodilution; the latter may be a more accurate reflection of preload than static central pressure measurements. Although further validation of these techniques in critically ill patients is necessary, the use of pulse contour analysis may potentially obviate the need for pulmonary artery catheterization to measure cardiac output, particularly if combined with the measurement of $ScvO_2$ as an indicator of the balance between oxygen delivery and consumption.

Echocardiography

An even less invasive hemodynamic monitoring tool is echocardiography. Transthoracic and transesophageal echocardiography provide accurate diagnostic information with regard to right and left ventricular function, valve function, pericardium anatomy, traumatic vascular injury, and PE (direct and indirect signs). Transesophageal echocardiography can also be used to assess volume status or preload via measurement of left ventricular end-diastolic volume and/or area. The major limitation of echocardiography is that it does not provide continuous monitoring, is associated with high initial cost, and requires a high standard of training and experience.

Transesophageal Doppler sonography using a small probe in a large nasogastric tube (6 mm) monitors descending aortic flow velocity continuously and allows noninvasive monitoring of cardiac output. The disadvantages of this technique are that it is inaccurate if not positioned correctly, ideally at

an angle with the aorta of 45 degrees (minimal error in flow measurement), and that it does not measure the supra-aortic output or the aortic cross-sectional area, which is determined using a nomogram and assumed to remain constant throughout the systole.[46] Two cases of intrabronchial displacement of the probe have been reported.

Although the role of echocardiography in routine critical care management remains undefined, it has been suggested that this technique can replace pulmonary arterial catheterization in the ICU without adversely affecting outcomes.[47]

Definition and Types of Circulatory Failure

The common denominator of shock is circulatory instability characterized by severe hypotension and inadequate tissue perfusion. Shock states are classified according to the primary cause of circulatory failure. Distributive or vasodilatory shock results from a reduction in systemic vascular resistance, often associated with an increased cardiac output, whereas cardiogenic (left or right cardiac failure) and hypovolemic shock are low cardiac output states usually characterized by increased peripheral resistance. The most common forms of shock encountered in the ICU are cardiogenic, septic, and hypovolemic shock. Despite extensive research and aggressive management, the mortality from shock remains staggeringly high; approximately 35 to 40% of patients die within 28 days of the onset of septic shock, and the mortality rate is 70 to 80% for patients with cardiogenic shock. The mortality from hypovolemic shock is highly variable and depends on the etiology and the rapidity of recognition and treatment. Cardiogenic and septic shock are discussed in more detail in the following section; the causes and treatment of traumatic shock, including hypovolemic shock, are discussed in Chapter 48.

Cardiogenic Shock

The initiating event in cardiogenic shock is a primary pump failure. Heart failure may result from

extensive myocardial infarction, cardiomyopathy, arrhythmias, mechanical complications (mitral regurgitation, ventricular septal defect), tamponade, and so on. The pathophysiologic characteristics include reduction in contractility, usually accompanied by dilatation of cardiac cavities and venous congestion. Absence of pulmonary congestion at initial clinical evaluation does not exclude a diagnosis of cardiogenic shock due to predominant left ventricular failure and is not associated with a better prognosis. The onset of pump failure is associated with two compensatory mechanisms: (1) a reflex vasoconstriction in systemic vessels, causing an increase in left ventricular workload and myocardial oxygen demand; and (2) a redistribution of blood volume toward the heart and the lungs. However, cardiogenic shock developing within 36 hours of an acute myocardial infarction has been associated with variably decreased systemic vascular resistances, possibly mediated by the presence of a systemic inflammatory response.

Several studies demonstrated that the incidence and severity of left ventricular failure complicating acute myocardial infarction were directly related to the extent of ventricular mass necrosis. Consequently, therapy should minimize myocardial oxygen demand and raise oxygen delivery to the ischemic area; this goal is complicated by the fact that many resuscitative approaches to correct hypotension (preload augmentation, inotropes, and vasopressors) increase myocardial oxygen consumption. In patients without hypotension, pharmacologic vasodilatation using nitrates or sodium nitroprusside may reduce myocardial oxygen consumption and improve ventricular ejection by reducing left ventricular afterload, and possibly produce a shift of blood from the lungs to the periphery by reducing venous tone. B-type natriuretic peptide (human recombinant form of BNP, nesiritide) and fenoldopam have similar effects, and have an additional beneficial diuretic effect.[48] When pharmacologic interventions are not sufficient to restore hemodynamic stability, the use of mechanical support with the insertion of intra-aortic balloon pump counterpulsation and ventricular assist devices can help unload the ventricles.

In patients with myocardial infarction, coronary reperfusion can be achieved with thrombolysis or, preferably, primary percutaneous coronary intervention (PCI). A randomized trial comparing emergency revascularization with primary PCI or coronary artery bypass surgery to a regimen of thrombolysis did not demonstrate a mortality difference at 30 days. However, at 6 months and 1 year, there was a significant mortality reduction with emergency revascularization in patients younger than 75 years of age.[49] The use of primary PCI in patients younger than 75 years with acute ST elevation and myocardial infarction complicated by cardiogenic shock who can be treated within 18 hours of the onset of shock is a grade A recommendation.

Septic Shock

Septic shock is a form of distributive shock associated with the activation of the systemic inflammatory response, and is usually characterized by a high cardiac output, low systemic vascular resistance, hypotension, and regional blood flow redistribution, resulting in tissue hypoperfusion. Other forms of distributive shock include pancreatitis, burns, fulminant hepatic failure, multiple traumatic injuries, toxic shock syndrome, anaphylaxis and anaphylactoid reactions, and drug or toxin reactions, including insect bites, transfusion reactions, and heavy metal poisoning. In patients with systemic infections, the physiologic response can be staged on a continuum from a systemic inflammatory response syndrome (SIRS), to sepsis, severe sepsis, and septic shock (Table 57-4). The hemodynamic profile of septic shock is influenced by several sepsis-induced physiologic changes, including hypovolemia and vasodilation, in addition to cardiac depression. Sepsis is associated with a global decrease in cardiac contractility, and echocardiographic measurements of the left ventricle size demonstrate an inability of the ventricle to dilate in septic patients.[50]

TABLE 57-4 Definitions of Sepsis and Organ Failure

Clinical evidence of infection:

Infection: Microbial phenomenon characterized by an inflammatory response to the presence of microorganisms or the invasion of normally sterile tissue by those organisms.
Bacteremia: The presence of viable bacteria in the blood.
Systemic inflammatory response syndrome (SIRS): Systemic inflammatory response to a variety of severe clinical insults. The response is manifested by two or more of the following conditions: Core temperature <36°C or >38°C
Tachycardia >90 beats/min
Tachypnea >20 breaths/min while breathing spontaneously, or $PaCO_2$ <32 mm Hg
White blood count >12,000 cells/mm^3, <4,000 cells/mm^3, or >10% immature forms
Sepsis: The systemic response to infection. This systemic response is manifested by three or more of the conditions described previously (SIRS) and presented clinical or microbiological evidence of infection.
Severe sepsis: Sepsis associated with organ dysfunction, hypoperfusion, or hypotension. Hypoperfusion and perfusion abnormalities may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status.
Septic shock: Sepsis with hypotension, despite adequate fluid resuscitation, along with the presence of perfusion abnormalities that may include, but are not limited to, lactic acidosis, oliguria, or an acute alteration in mental status. Patients who are on inotropic or vasopressor agents may not be hypotensive at the time perfusion abnormalities are measured.
Sepsis-induced hypotension: A systolic blood pressure of <90 mm Hg or a reduction of >40 mm Hg from baseline in the absence of other causes for hypotension.
Multiple organ dysfunction syndrome: Presence of several altered organ function in an acutely ill patient, such that homeostasis cannot be maintained without intervention.

American College of Chest Physicians/Society of Critical Care Medicine Consensus Conference: Definitions for sepsis and organ failure and guidelines for the use of innovative therapies in sepsis. Crit Care Med 20:864, 1992.

In endotoxemia and sepsis, metabolic needs are increased, and the ability of the tissues to extract and use oxygen may be impaired. Thus, a metabolic acidosis may be present despite normal levels of oxygen transport. A decrease in cellular O_2 extraction capacity may result from factors other than hypoperfusion, such as direct cellular damage by toxins and/or mediators or maldistribution of blood flow. The impact of impaired perfusion on organ function depends on individual susceptibility to hypoxia. The peculiar anatomy and the microcirculatory structure of intestinal villi with their countercurrent flow mechanism render the superficial layers of the mucosa particularly vulnerable to ischemia. The GI tract has been implicated as the "motor" of multiple organ dysfunction syndrome (MODS), and "splanchnic resuscitation" has been advocated as a central objective in patients with septic shock. Intramucosal pH and PCO_2 monitoring has been proposed as a technique to assess the splanchnic metabolic state.

Although hypoperfusion is the dominant cause of lactic acidosis in sepsis, various degrees of intermediary metabolic alterations may contribute to the increased lactate production independent of perfusion. Normally, lactate is cleared by the liver metabolic activity via the Cori cycle. Subsequently, with the development of liver perfusion impairment, this organ may turn to a net lactate producer. Furthermore, the increase in the rate of glucose metabolism may also occur due to inhibition of the step-limiting enzyme, pyruvate dehydrogenase, for pyruvate to enter the Krebs cycle. An increase in the relative proportion of

inactive to active enzyme results in pyruvate accumulation and lactate production.

MODS refers to the presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention.[51] The exact pathophysiology of MODS is not yet fully understood, although alterations in systemic hemodynamics, organ perfusion, and tissue microcirculation resulting in tissue hypoxia play a role in initiating and maintaining the syndrome. MODS accounts for most deaths in the ICU.

Although organ failure only qualifies a dichotomous event that is either present or absent, organ dysfunction represents a continuum of physiologic derangements. Different severity scores have been proposed to quantify the range of severity of MODS. A commonly used score that correlates with a higher mortality in the ICU was developed by Marshall et al.[52] This scoring system assigns increasingly high values based on markers of increasing respiratory, renal, cardiovascular, hepatic, hematologic, and central nervous system dysfunction.

Based on the etiology, MODS can be classified as either primary or secondary. Primary MODS is the result of a well-defined insult in which a primary organ dysfunction occurs early and can be directly attributable to the insult itself (e.g., ARDS due to pulmonary contusion). Secondary MODS represents an abnormal host response (e.g., ARDS in patients with sepsis) and is the result of a systemic inflammatory response initiated by a primary insult involving another organ system.

Clinical Management of Shock/Circulatory Failure Based on Hemodynamic Parameters

The mainstay of treatment of hemodynamic instability is correction of hypotension and restoration of regional blood flow with intravascular volume expansion and vasopressors, and/or inotropes. Adequacy of regional perfusion is usually assessed by evaluating indices of organ function, including myocardial ischemia, renal dysfunction (urine output and renal function tests), arterial lactate levels as an indicator of anaerobic metabolism, central nervous system dysfunction as indicated by abnormal sensorium, and hepatic parenchymal injury by liver function tests. However, these functional assessments of satisfactory organ perfusion may not allow rapid adjustments in therapy compared with more direct continuous monitoring of global and/or regional perfusion. Therefore, additional end points of treatment consist of mean arterial pressure and DO_2, or some surrogate of the latter (SvO_2 or $ScvO_2$).

Management of Hypotension with Fluid Replacement Therapy

Intravascular volume expansion is the first line of therapy in all forms of shock. Clinical indicators of the response to a fluid challenge (bolus fluid therapy of 250 to 1,000 mL crystalloids over 5 to 15 minutes) are heart rate, blood pressure, and urine output, as well as invasively acquired measures, including CVP, PaOP, systolic and pulse pressure variation, and cardiac output. An increase in cardiac output following volume expansion unmasks an absolute or relative hypovolemic state (preload dependency). Lack of change or a decrease in cardiac output following volume expansion suggests a euvolemic status, volume overload, or cardiac failure.

The choice of crystalloids versus colloids for volume expansion has been debated for decades, without clear resolution. Two meta-analyses examined how the choice of crystalloid or colloid solutions affects survival in critically ill patients. Results from these analyses were conflicting, demonstrating either noninferior or increased mortality with the use of albumin-containing fluids.[53,54] A more recent multicenter, randomized, double-blind trial compared the effect of fluid resuscitation with albumin or saline on mortality in ICU patients.[55] The study indicated that use of either 4% albumin or normal saline for fluid resuscitation resulted in similar outcomes at 28 days (level II evidence).

Management of Shock with Vasopressors/Inotropes

If patients remain persistently hypotensive despite volume expansion and markers of adequate preload, the use of vasopressors is indicated. Pharmacologic agents include adrenergic agonists with inotropic and vasoconstrictor effects (norepinephrine, dopamine, dobutamine, epinephrine,

phenylephrine); other vasoconstrictors are vasopressin and nitric oxide synthase inhibitors. Select agents are discussed in the following sections.

Norepinephrine. Norepinephrine (NE) increases systemic arterial pressure, with variable effects on cardiac output and heart rate. This effect is mainly mediated by α-adrenergic and β-adrenergic receptor agonism. Studies comparing the hemodynamic and splanchnic effects of NE to dopamine in patients with sepsis indicate that NE improves organ perfusion

by an increase in systemic vascular resistance and oxygen consumption accompanied by a decrease in lactate levels, whereas dopamine acts largely by increasing cardiac performance, with an unfavorable effect on the oxygen delivery and consumption relationship.[56,57]

A concern that NE may compromise renal perfusion has led to some hesitancy to use this drug; however, the majority of available evidence suggests that NE improves renal function in volume-resuscitated, hypotensive patients with septic shock. It is worth noting that the combination of excessively high doses of NE with inadequate effective plasma volume expansion may reduce organ perfusion and should be avoided.

In summary, provided adequate fluid replacement therapy, NE restores perfusion pressure, improves organ function, and corrects splanchnic ischemia in hypotensive patients. Because of its favorable hemodynamic profile, NE is the drug of first choice in the management of septic shock.[56,57] In addition, in the only large, prospective evaluation of vasopressor therapy for septic shock, norepinephrine administration was associated with a reduction in mortality compared with dopamine or epinephrine, although this was not a randomized or blinded trial (level III evidence).[58]

Dopamine. Dopamine raises mean arterial pressure by increasing cardiac index and, to a lesser degree, systemic vascular resistance. Dopamine does not have selective dopaminergic effects on renal blood flow, but rather improves urine output by either by improving overall hemodynamics, a direct diuretic effect, or by decreasing the release of antidiuretic hormone via baroreceptor responses.[56] Further, a large randomized trial and a meta-analysis comparing low-dose dopamine to placebo in critically ill patients found no differences in either renal function tests or survival, and the use of low-dose dopamine is therefore not recommended (level II evidence, grade B recommendation).[59] In addition, dopamine may have detrimental effects on the splanchnic circulation. Marik et al showed that dopamine increased splanchnic oxygen consumption, which was not compensated by an increase in oxygen delivery and therefore resulted in increased oxygen debt, and suggested that dopamine might redistribute flow within the intestinal wall and ultimately reduce mucosal blood flow.[57] Last, the response to receptor activation by dopamine administration is highly unpredictable at any dopamine dosage. In patients with septic shock, even low doses of dopamine have consistent inotropic effects and, despite an increased oxygen transport, dopamine may adversely affect gastric mucosal perfusion.

Dobutamine. Dobutamine is a β-1 and β-2 receptor agonist that demonstrates potent inotropic and chronotropic effects, as well as mild peripheral vasodilatation, with the ultimate effect of increasing oxygen delivery and consumption. Dobutamine is the drug of choice in patients with circulatory failure primarily due to cardiac pump failure (cardiogenic shock). However, dobutamine should not be used as first-line single therapy when hypotension is present. In patients with septic shock, dobutamine may be useful in the presence of impaired cardiac contractility with resulting inadequate cardiac output and oxygen delivery. Several studies show that dobutamine alone or added to standard vasopressor regimens increases both oxygen delivery and consumption in septic and elderly septic patients.[60] In patients with septic shock, the combination of NE plus dobutamine resulted in increased gastric mucosal perfusion compared with NE alone.[61] Other studies comparing the effects of NE plus dobutamine versus epinephrine or dopamine alone suggested an improved balance between oxygen delivery and consumption with the combination therapy.

Despite these physiologic benefits of dobutamine in septic shock, detrimental effects have been observed when therapy is oriented to supranormal cardiac output, DO_2 and VO_2 in critically ill patients, as discussed previously.[41] Based on this and other studies, the use of aggressive strategies, such as high-dose dobutamine to drive cardiac index above a predefined

supraphysiologic level, is not recommended as routine therapy in the critically ill (grade A recommendation). In contrast, a more recent clinical trial of early goal-directed therapy during the first 6 hours of septic shock to maintain central venous oxyhemoglobin saturation ($ScvO_2$) of 70% or greater with volume resuscitation, packed red blood cell transfusion to a hematocrit of 30%, and, if not sufficient, with dobutamine up to 20 μg/kg per minute demonstrated a 16% absolute reduction in 28-day mortality compared with standard therapy (level II evidence).[44] It is not clear whether the observed benefits of early goal-directed therapy were due to the early initiation of treatment, achievement of the goal end points, or specific elements of treatment (e.g., blood transfusion or dobutamine). However, this early approach of increasing oxygen delivery in septic shock patients by targeting an indicator of supply–demand relationship is substantially different from the supraphysiologic resuscitation in general ICU populations previously described.

In summary, dobutamine treatment is the first line of treatment in patients with shock and decreased cardiac contractility and performance. In patients with septic shock, dobutamine may be useful as a second-line agent, after adequate fluid resuscitation and if introduction of vasopressors has not restored sufficient levels of oxygen delivery, reflected by an $ScvO_2$ of >70% (which approximates a mixed venous oxygen saturation, SvO_2, of >65%) and increased lactate clearance. However, further corroborating data are necessary to determine the true benefits of early optimization of oxygen delivery. Targeting supranormal levels of oxygen delivery and consumption is not recommended.

Epinephrine. Epinephrine increases cardiac index by increasing contractility and heart rate, and also increases systemic vascular resistance. The response to stepwise dose increments of epinephrine on hemodynamic variables confirms that this drug is a strong inotropic agent even in patients with septic shock, and increases mean arterial blood pressure, cardiac output, DO_2, and VO_2. Epinephrine also increases VO_2 via activation of metabolic pathways.

In patients with septic shock, epinephrine may reduce splanchnic perfusion despite an increase in global hemodynamic and oxygen transport.[62,63] In addition, epinephrine therapy consistently increases plasma lactate levels in septic shock. Whether this reflects a reduction in vital organ perfusion with resulting anaerobic metabolism, increased production consequent to a thermogenic effect in skeletal muscle, or reduced clearance remains to be defined. However, epinephrine treatment at best brings no additional benefit to other catecholamine therapy in the management of patients with septic shock.

Vasopressin. Vasopressin is a potent vasoconstrictor when administered in low doses to patients in shock, particularly those with distributive shock due to sepsis or hepatic failure, or with circulatory failure following cardiopulmonary bypass.[64] This may be in part related to a relative deficiency of vasopressin in these settings. Vasopressin may also be useful in resuscitation from cardiac arrest, particularly if due to asystole, and is offered as an option in the current advanced cardiac life support algorithm for treatment of ventricular fibrillation (level II evidence).[65]

Vasopressin administration during shock typically results in dramatically increased systemic blood pressure, with either no effect or a mild decrease in cardiac output, little change in heart rate, and no effect on pulmonary vascular resistance. Although vasopressin has the potential to reduce mesenteric and renal blood flow, it does not appear to do so when administered at low dose during vasodilatory shock.[66,67] In addition, vasopressin and its analogs have been shown to improve urine output in the hepatorenal syndrome, supporting a positive effect of vasopressin on renal blood flow in vasodilatory states. However, because there are no outcome data to suggest the

superiority of vasopressin in the management of septic shock at this time, its use should be reserved for cases of catecholamine refractory shock; in addition, it should be used as a fixed, low-dose infusion (0.01 to 0.1 U/minute) to avoid possible deleterious vasoconstrictor effects associated with higher doses.[64]

Additional Treatment Considerations for Critically Ill Patients with Septic Shock

Activated Protein C. Clinical or subclinical manifestations of intravascular disseminated coagulation and consumption coagulopathy (increase in D-dimers, decreased protein C, thrombocytopenia, and increased prothrombin time) are present in essentially all patients with septic shock. The activation of protein C is believed to be an important mechanism for modulating sepsis-induced consumption coagulopathy. Activated protein C works as an antithrombotic agent by inactivating factors Va and VIIIa. Activated protein C also facilitates clot lysis by inhibiting plasminogen activator inhibitor 1. In patients with sepsis, inflammatory cytokines (TNF-α, IL-1β) downregulate two key components of the protein C activation complex, thrombomodulin and the endothelial cell protein C receptor, resulting in decreased protein C activation. In addition, activated protein C inhibits the generation of inflammatory cytokines from monocytes, and reduces the expression of adhesion receptors and inflammatory mediators from the endothelium. The rationale for replacing activated protein C relates to its anticoagulant and profibrinolytic properties, which interrupt the consumption coagulopathy and are particularly effective at preventing microvascular thrombosis. Drotrecogin-alfa, a human recombinant-activated protein C, administrated intravenously for 96 hours at the rate of 24 μg/kg per hour to patients with severe sepsis, has been investigated in a large randomized trial.[68] Infusion of activated protein C decreased the circulating D-dimers and decreased IL-6 levels. The study showed a 6.1% absolute 28-day mortality reduction (30.8% versus 24.7%). Given the risk of drug-induced bleeding, activated protein C is only approved in patients with severe sepsis and high risk of death as indicated by an APACHE II score >25 (grade B recommendation). In addition to the latter indication, small reports suggest that protein C supplementation can be beneficial in treating purpura fulminans-associated meningococcemia.

Corticosteroids. Although high-dose corticosteroids for the treatment of septic shock are of no benefit, more recent evidence suggests that lower doses, on the order of hydrocortisone 200 to 300 mg per day, can reduce dependency on vasopressors and confer a mortality benefit (level II evidence);[69] this issue is discussed in depth in the Endocrinology section.

Treatment of Infection. Identifying the source of the infection, source control, and early initiation of appropriate antibiotic therapy are critical priorities in addition to hemodynamic support. Appropriate cultures should always be obtained before antimicrobial therapy is initiated. At least two blood cultures (one drawn percutaneously and one drawn through a vascular access device), and cultures of respiratory secretions, urine, cerebrospinal fluid, wounds, or fluid collection should be obtained as indicated by the clinical scenario (grade D recommendation). Diagnostic studies should be performed promptly to assist with the identification of the source of infection and the causative organism, especially for foci amenable to source control measures (e.g., abscess drainage) (grade E recommendation). Empiric antibiotic therapy should be started as soon as possible after appropriate culture collection (grade E recommendation). Initial empiric therapy should be broad enough, and should include one or more drugs that have activity against the likely pathogens and that penetrate into the presumed site of infection. After antibiotic susceptibility testing is available, restricting the number of antibiotics and narrowing the spectrum of antimicrobial treatment is appropriate. For a more detailed discussion and specific sites of infection, see the Nosocomial Infections section.

ACUTE RESPIRATORY FAILURE

Acute respiratory failure is a generic term that encompasses the need for mechanical ventilation and/or airway intubation, independent of cause. Indeed, in some cases respiratory failure may be caused by nonrespiratory issues (e.g., coma that results in the inability to protect the airway). Acute respiratory failure is a relatively common phenomenon; depending on the type of ICU, the majority of patients may be mechanically ventilated at any given time, and virtually all critically ill patients are mechanically ventilated for some portion of their ICU stay. Suffice it to say that the treatment of acute respiratory failure is primarily supportive, and the need for mechanical ventilation and airway intubation typically resolves when the initiating condition is adequately treated. The following sections discuss basic principles of mechanical ventilation, some of the more challenging types of respiratory failure, and potential therapeutic approaches to respiratory failure.

Principles of Mechanical Ventilation

Mechanical ventilation in the ICU is provided through the application of positive pressure to the airway; commonly, a preset tidal volume and rate are provided, and any breathing that the patient does above this set minute ventilation is either supported (assist control or AC) or not (intermittent mandatory ventilation or IMV). However, beyond this simplest level, ICU ventilators have become increasingly powerful and complex, and are high-flow capacity, microprocessor-based systems that offer multiple modes of ventilation and computer-compatible monitoring or control. Thus, ventilatory modes used today (in addition to the traditional "volume" modes AC and IMV) include pressure support ventilation, pressure control ventilation, volume support ventilation, pressure-regulated volume control, high-frequency ventilation, proportional assist ventilation, and airway pressure release ventilation. In reality, there is little evidence to suggest that the mode of mechanical ventilation contributes significantly to any major outcome measure, and the choice of mode is at this point one of clinician preference. Thus, this discussion does not dwell on specific modes of ventilation.

As indicated previously, mechanical ventilation is a supportive therapy that is applied until the initiating cause of respiratory failure improves sufficiently such that the patient can breathe unassisted. Moreover, more recent evidence suggests that mechanical ventilation may be injurious in certain settings. Traditionally, tidal volumes of 10 to 15 mL/kg have been routinely used to ventilate patients in the ICU. The use of such supraphysiologic tidal volumes (normal resting tidal volumes are 5 to 7 mL/kg) evolved from the observation that the use of smaller-size volumes was associated with the development of atelectasis and hypoxemia in anesthetized patients in the operating room. However, in certain patients, large tidal volumes can result in cardiovascular compromise, barotrauma, ventilator-induced lung injury (VILI) or ventilator-associated lung injury (VALI), and excess mortality.

Positive-pressure ventilation results in increased intrathoracic pressure, which reduces venous return, and in turn results in reduced cardiac output and blood pressure. In addition, positive-pressure ventilation can result in alveolar overdistention and alveolar rupture, which manifests as pneumothorax and pneumomediastinum (barotrauma). Both these effects are amplified in patients with obstructive lung disease (asthma and

chronic obstructive lung disease [COPD]). In these patients, limitation of expiratory flow leads to air trapping and the development of intrinsic positive end-expiratory pressure, or auto-PEEP. Air trapping results in alveolar overdistention and increases the risk of barotrauma, and auto-PEEP can contribute substantially to increased intrathoracic pressure and cardiovascular depression. Auto-PEEP cannot be detected without holding exhalation for a prolonged interval (expiratory pause), with both inspiratory and expiratory ventilator valves closed; thus, auto-PEEP may not be appreciated unless actively looked for.

The development of air trapping and auto-PEEP leads to significant morbidity and mortality in patients with obstructive lung disease. Thus, the ventilatory strategy in these patients should focus on prolongation of expiratory time by limiting minute ventilation by using low tidal volumes ($\leqslant$6 to 8 mL/kg) and a low rate (8 to 12 breaths per minute), and by reducing the inspiratory time of the respiratory cycle. Low minute ventilation is often associated with hypercapnia and respiratory acidosis (permissive hypercapnia); however, this does not appear to be harmful, and the benefits of reduced air trapping and auto-PEEP far outweigh any possible detriment. The reduction of inspiratory time is accompanied by increasing inspiratory flow; this results in increased peak airway pressure. However, most of the peak pressure is dissipated in the endotracheal tube and large airways, and more important, end-expiratory, static or plateau, and mean airway pressures will fall with increased expiratory time. To accomplish the previous goals, deep sedation is often required, and rarely, neuromuscular blockade must be used. The adoption of this type of ventilatory strategy in the 1980s and 1990s was associated with a dramatic reduction in mortality due to acute, severe asthma and respiratory failure, from as high as 23% to less than 5% (level IV evidence).[70]

In contrast to barotrauma, VILI or VALI refers to microscopic injury to the lung due to

overdistention and cyclic reopening of alveoli. VALI has been well-demonstrated in numerous experimental models, and is histologically similar to the features seen in acute lung injury of other causes, with diffuse alveolar damage and increased microvascular permeability.[71] In addition, VALI is associated with the systemic release of inflammatory mediators that may contribute to multiple organ failure. Clinically, patients believed to be at risk for VALI are those with abnormally low recruitable lung volumes, in particular those with acute lung injury (ALI) and ARDS. Thus, a "lung-protective" ventilatory strategy using low tidal volume ventilation has been proven to save lives when applied to patients with ALI/ARDS.

In summary, although tidal volumes of 10 to 12 mL/kg may still be appropriate for some patients, the choice of tidal volume should be carefully individualized, and volumes as low as 4 mL/kg may be appropriate in some cases. In addition, because lung volumes correlate with height rather than weight, tidal volume selection should be based on predicted body weight (PBW) or ideal body weight, rather than on actual weight, to avoid lung overdistention. PBW can be calculated from the following formula:

PBW = 50 + 2.3(height [in.] - 60) (males), or

45.5 + 2.3(height [in.] - 60) (females)

Although mechanical ventilation generally implies airway intubation, either translaryngeal or via tracheotomy, noninvasive positive-pressure ventilation (NPPV) or continuous positive airway pressure (CPAP) can be delivered via a tight sealing nasal or full facemask. NPPV is applied using either standard ICU ventilators (typically set to pressure support or pressure control modes, with or without positive end-expiratory pressure [PEEP]), or specially designed ventilators that deliver CPAP or bilevel positive airway pressure (Bi-PAP). These dedicated noninvasive ventilators generate high gas flow, can cycle between a high inspiratory pressure and a lower expiratory pressure, and can sense and respond to patient inspiratory effort. Originally developed for home ventilation in patients with obstructive sleep apnea and chronic respiratory failure, newer models are targeted for use in the ICU by incorporating monitoring packages that allow assessment of delivered tidal volumes and respiratory patterns. However, there is no evidence that the type of ventilator used for NPPV affects patient outcome, and the choice of equipment is typically based on availability and familiarity.

NPPV compared with standard therapy has been associated with improved outcomes in a variety of causes of respiratory failure, including cardiogenic pulmonary edema, COPD, and acute lung injury in immunosuppressed patients (level II evidence).[72,73] Improved outcomes include the avoidance of endotracheal intubation; a reduction in complications associated with intubation, including ventilator-associated pneumonia; and reduced mortality. However, NPPV is not without risk and has been associated with increased complications in some studies, including a higher rate of myocardial infarction in patients with cardiogenic pulmonary edema and increased mortality in patients with respiratory failure after extubation.[74,75] Therefore, NPPV is best and most safely used when patient characteristics are ideal, including an awake, cooperative patient (with the exception of rapidly reversible obtundation due to high PCO_2), a low risk for regurgitation and aspiration of gastric contents, and a high likelihood that the process resulting in respiratory failure is rapidly reversible. Further research including larger, randomized trials of NPPV is necessary to better define the particular subgroups of patients who will benefit from this approach.

5 Weaning from mechanical ventilation is better termed "liberation" or "separation" from ventilation because "weaning" implies that ventilation must be gradually withdrawn to allow respiratory muscle and patient adaptation to the process. In reality, separation from mechanical ventilation is more a function of the resolution of the cause of respiratory failure, rather than the technique used to withdraw ventilatory support. This is supported by a study showing that daily trials of unassisted ventilation (T-piece trials) resulted in more rapid separation from ventilation than other more gradual approaches, in particular, IMV weaning (level I evidence).[76] In addition, so-called "weaning parameters" are inadequate predictors of the success or failure of withdrawal of ventilatory support, adding little to routine management. Thus, the process of separation from mechanical ventilation is expedited when respiratory therapy-driven protocols are used that focus

on daily assessment of the ability to breath without assistance, assuming improvement of the inciting process, adequate oxygenation, and hemodynamic stability (grade A recommendation).[77] Once the patient can breath comfortably for 30 to 120 minutes without support, the trachea can be extubated, assuming there are no other precluding factors such as airway abnormalities, coma, etc.

Acute Lung Injury and Acute Respiratory Distress Syndrome

ALI and ARDS are syndromes of acute, hypoxemic respiratory failure marked pathologically by diffuse alveolar damage (DAD), with resulting increased lung permeability and diffuse alveolar edema.[78] ARDS can occur as a result of direct injury to the lung (e.g., aspiration or pneumonia) or in association with extrapulmonary infection (sepsis) or injury (e.g., multiple trauma). ARDS/DAD are associated with an inflammatory cell infiltration of the lung; increased systemic markers of inflammation; and progression through exudative, fibroproliferative, and fibrotic phases of injury over days to weeks.

To better standardize the definition of ARDS for epidemiologic and research purposes, in 1994, a joint American–European conference proposed criteria for characterizing ARDS according to the severity of gas exchange abnormality.[79] Despite some controversy, these criteria have been generally accepted (Table 57-5).[78] Thus, ALI is identical to ARDS in all aspects, except for the ratio of PaO_2 to FIO_2 (P/F ratio) at the time of diagnosis. The rationale for characterizing ALI/ARDS according to gas exchange abnormality was that this might allow identification of patients at lower and higher risk of death. However, this does not appear to be the case, because more recent evidence suggests that the P/F ratio is not a risk factor for mortality in ARDS, and mortality in ARDS and ALI appear to be similar.[80]

TABLE 57-5 Consensus Criteria for the Diagnosis of Acute lung injury and Acute respiratory distress syndrome

1. Identifiable cause
2. Acute onset
3. Hypoxemia[a]
4. Diffuse, bilateral radiographic opacities
5. PaOP $\leqslant$18, or no clinical evidence of left atrial hypertension

PaOP, pulmonary artery occlusion pressure.

ALI/ARDS is highly prevalent in the ICU population. A more recent prospective, multicenter study of ICUs in France found that patients with ALI/ARDS comprised approximately 9% of all ICU patients and approximately 40% of all patients with hypoxemic respiratory failure.[81] Of predisposing factors, sepsis carries the highest risk (approximately 30%) and is the most common cause of ALI/ARDS. Mortality associated with ARDS has fallen substantially since the mid-1980s, and is currently in the 30 to 40% range overall. However, ARDS mortality varies greatly with the

population of patients studied (e.g., ARDS mortality in trauma patients is in the 10 to 15% range, whereas mortality in medical ICU patients is as high as 60%). Moreover, patients with ARDS continue to die primarily as a result of associated conditions (e.g., sepsis, multiple organ failure), and uncommonly die of hypoxemia per se.

Clinically, ARDS and ALI are characterized by reduced static thoracic (lung and chest wall) compliance and severe impairment of gas exchange, including high intrapulmonary shunt and dead space fraction. These mechanics and gas exchange abnormalities create a challenge in terms of optimizing mechanical ventilation because maintenance of adequate oxygenation and CO_2 elimination are both problematic. In addition, although the P/F ratio does not appear to predict mortality, high dead space fraction does, and may reflect the extent of pulmonary vascular injury.[82] Pulmonary hypertension often develops as the syndrome progresses and can complicate hemodynamic management.

Although ALI/ARDS appears to be a diffuse process by chest radiography, lung opacification is surprisingly heterogeneous when the lung is imaged by CT. Areas of dense opacification are frequently confined to the posterior, dependent portion of the lung, leaving a small, relatively normal, recruitable volume available for ventilation. This low recruitable lung volume has been termed the "baby lung" and has important implications for ventilatory management in ARDS.[71]

6 The treatment of ALI/ARDS is largely supportive, and includes aggressive treatment of inciting events, avoidance of complications, and mechanical ventilation. In regard to the latter, it is critical that tidal volumes and static ventilatory pressures are minimized to avoid further injury to the remaining relatively uninjured lung (VALI). A more recent large, randomized, prospective trial found that a strategy that used tidal volumes of 6 mL/kg or less and maintained static (plateau) airway pressure at $\leqslant$30 cm H_2O resulted in a relative mortality reduction of 22% when compared with a control group ventilated with tidal volumes of 12 mL/kg (level I evidence).[83] This is the only intervention that has been unequivocally proven to reduce mortality in patients with ARDS.

Because ARDS is marked by high intrapulmonary shunt, hypoxemia is relatively unresponsive to oxygen therapy. Thus, strategies to recruit collapsed lung are necessary. This is most commonly achieved by using PEEP. The optimal balance between PEEP and FIO_2 has been long debated, but at this point there is no strong evidence to favor either a "high PEEP, low FIO_2" versus a "minimal PEEP, high FIO_2" strategy (level II evidence).[84] Other maneuvers to promote recruitment of lung include the use of intermittent, high-level, end-expiratory pressure or sigh breaths, pressure-controlled ventilation, inverse ratio ventilation (prolonged inspiratory time), prone positioning, and high-frequency ventilation. However, although each intervention has been temporally associated with improved oxygenation, none have been shown to result in significant outcome differences when compared with standard approaches (level II and III evidence).

Inhaled nitric oxide (iNO) also variably and transiently improves oxygenation in ALI/ARDS by improving blood flow to ventilated alveoli. However, several randomized, prospective trials have failed to show any relevant long-term outcome benefits associated with iNO administration to patients with ALI/ARDS (level I evidence).[85,86] iNO may still be useful as "rescue" therapy in selected patients with severe, refractory hypoxemia, although its benefits in this setting have not been rigorously tested.

Given that ALI/ARDS are marked by high-permeability pulmonary edema, it is intuitive that administration of excessive fluids be avoided. However, the correct balance between adequate resuscitation and aggressive diuresis is controversial. Furthermore, the level of hemodynamic monitoring, specifically the utility of the PAC, in the management of patients with ARDS is the subject of great debate. These issues are addressed in an ongoing prospective, randomized, multicenter trial sponsored by the National Institutes of Health.

Multiple therapies have been tested in an effort to halt the inflammatory and proliferative phases of injury, with little success. Yet, although corticosteroid administration early in the course of ARDS is of no benefit or even harmful, administration during the fibroproliferative phase (day 3 and beyond) has been associated with reduced mortality in small trials (level II evidence).[87]

Preliminary results from a large, multicenter randomized trial of corticosteroid therapy for "late-phase" ARDS are less encouraging, however.

ACUTE RENAL FAILURE

Acute renal failure (ARF) is reported to occur in as many as 25% of critically ill patients. Unfortunately, the true incidence is difficult to pinpoint due to variability in patient populations and the use of multiple diagnostic criteria. More recently, a consensus group proposed standard criteria for the diagnosis of renal risk, injury, and failure, which is expected to improve the ability to identify, study, and treat renal failure in the ICU.[88]

Despite these caveats regarding the diagnosis of ARF, since the mid-1980s, the incidence appears to be fairly stable.[89]

Moreover, the mortality associated with ARF requiring dialysis has remained approximately 60% since the mid-1950s. [89] This is discouraging when one considers reductions in mortality in association with other organ failures over the same time interval. The reasons for the lack of improvement in outcome are unclear, but likely include insensitive means for identifying patients with incipient renal failure, and lack of effective preventive and therapeutic measures.

In the ICU, ARF occurs due to prerenal causes and tubular injury (acute tubular necrosis) in the vast majority of cases.[89] Other potential causes of ARF in the ICU include glomerulonephritis, vasculitis, interstitial nephritis, macrovascular and microvascular disease (e.g., thrombotic thrombocytopenic purpura), toxins (e.g., nonsteroidal anti-inflammatory drugs, cisplatin, aminoglycosides, myoglobin, hemoglobin), and urinary tract obstruction. The initial evaluation of ARF should focus on identifying easily correctable causes; thus, urine sodium concentration and fractional excretion of sodium can help identify prerenal azotemia, urinalysis can identify possible glomerulonephritis or interstitial nephritis, and ultrasonography can rule out postrenal or obstructive sources of ARF (Table 57-6).

In incipient and established ARF, supportive care is the rule, with the focus on maintenance of euvolemia, avoidance of renal toxins, adjustment of medication doses, and monitoring of electrolytes and acid-base status. Pharmacologic approaches to the prevention and treatment of ARF have been uniformly disappointing; these include low-dose dopamine[59] (level II evidence), anaritide (recombinant atrial natriuretic peptide) (level I evidence), and diuretics. More recent evidence suggests that diuretics may in fact be harmful in early ARF, and their use should probably be restricted to the treatment of hypervolemia prior to the institution of dialysis or ultrafiltration (level III evidence).[90] Although N-acetylcysteine has been advocated for the prevention of contrast-induced nephropathy, the evidence supporting significant benefit for this agent is limited, and there is no evidence that this drug prevents ARF in the ICU.

Although hemodialysis (renal replacement therapy or RRT) is typically considered a supportive measure in ARF, more recent interest has focused on the potential for RRT to improve renal recovery and reduce mortality. Research on RRT in the ICU has focused on the type and intensity or dose of dialysis. Although the timing of initiation of RRT is also of interest, it has not been rigorously studied in this setting.

The intensity of RRT is determined by both the frequency of treatment and the degree of solute clearance per time. Increased intensity of dialysis improves outcome in patients with end-stage renal disease, and more recent studies suggest similar benefits in ARF. Daily dialysis has been associated with reduced mortality and faster recovery of renal function compared with alternate day dialysis in ARF (level II evidence).[91] Likewise, increased clearance during continuous RRT (CRRT) is also associated with reduced mortality (level I evidence).[92]

CRRT (including continuous venovenous hemofiltration and hemodialysis) has been long known as a useful technique when hemodynamic instability is present; in contrast to intermittent hemodialysis, effective solute removal is possible with CRRT in the presence of arterial hypotension. However, given the previous considerations regarding dialysis dose, the routine use of CRRT to increase the intensity of dialysis in ARF has been proposed as a means of improving outcome. Studies comparing CRRT to intermittent RRT have been inconclusive, although meta-analyses suggest a mortality benefit and a trend toward improved recovery of renal function with CRRT (level II evidence).[93] CRRT is used much more commonly than intermittent hemodialysis for ARF in Europe and Australia compared with the United States. Additional large, randomized trials are necessary to determine whether CRRT is indeed associated with the outcome benefits suggested in meta-analyses. In the interim, the weight of evidence supports an increased intensity

of dialysis, using either daily standard hemodialysis, CRRT, or extended daily hemodialysis (slow dialysis).

ENDOCRINE ASPECTS OF CRITICAL CARE MEDICINE

Glucose Management in Critical Illness

Hyperglycemia is commonly encountered in critically ill patients, and occurs in both diabetics and nondiabetics. Hyperglycemia results primarily because of increased glucose production and insulin resistance caused by inflammatory and hormonal mediators that are released in response to injury. Hyperglycemia may also be aggravated by various therapeutic and supportive interventions, including the use of corticosteroids

and total parenteral nutrition. Although the risks of hyperglycemia for patients with diabetes who are ketosis prone have long been appreciated, mounting evidence suggests that hyperglycemia is detrimental to critically ill patients in a broader sense. Hyperglycemia is associated with increased risk of postoperative wound infection, and poor outcome in patients with stroke or TBI.[94] In addition, the blood glucose level is a risk factor for mortality in diabetic patients admitted with acute myocardial infarction.[95]

7 Strict glycemic control in critically ill patients is likely to confer substantial outcome benefits. A more recent prospective, randomized trial in surgical patients found that intensive insulin therapy (goal glucose <110 mg/dL) reduced ICU mortality by approximately 50% compared with more conventional therapy (goal glucose <215) (level I evidence).[96] The benefit was most pronounced in patients who were in the ICU for more than 5 days. Intensive insulin therapy reduced multiple organ failure, bloodstream infection, the need for dialysis, and the incidence of polyneuropathy. A later retrospective analysis of the data generated from this study suggested that the mortality and morbidity benefits occurred because of blood glucose reduction, rather than insulin administration per se.[97] Another study found a significant long-term mortality reduction when diabetic patients with acute myocardial infarction were managed with intensive insulin therapy.[98] Thus, although questions remain as to the optimal goal glucose threshold and whether intensive insulin therapy confers similar benefits to a general population of medically ill patients, the data clearly favor an aggressive approach to blood glucose control in the ICU.

Adrenal Function in Critical Illness

The stress response to injury includes an increase in serum cortisol levels in most critically ill patients.[99] However, adrenal insufficiency may also occur in critically ill patients for several reasons, including inhibition of adrenal stimulation or corticosteroid synthesis by drugs or cytokines, and direct injury to or infection of the pituitary or adrenal glands.[100] Thus, adrenal insufficiency has been reported to occur with increased frequency in critically ill patients with trauma, burns, sepsis, and other conditions in comparison with the general population.

The diagnosis of adrenal insufficiency in critical illness is complicated by limitations of commonly used tests of adrenal function. Cortisol is highly protein bound, and serum proteins, including albumin, are commonly depressed in critically ill patients. A more recent study found that although total serum cortisol levels are low in critically ill patients with hypoproteinemia, free cortisol levels are elevated.[101] This suggests that earlier reports that used total serum cortisol levels in critically ill patients may have overestimated the incidence of adrenal insufficiency. However, until free cortisol assays are more widely available, the diagnosis of adrenal insufficiency in critical illness must be based on clinical suspicion and total cortisol levels.

In addition to absolute adrenal insufficiency (low baseline cortisol and poor response to adrenocorticotropic [ACTH] administration/stimulation), a condition of relative adrenal insufficiency (poor response to ACTH independent of the baseline cortisol level) has been described in patients in septic shock. In these patients, both a high baseline cortisol level and a poor response to ACTH are predictors of increased mortality, with a combination of the two being

particularly ominous.[102]

Although high-dose corticosteroids for the treatment of septic shock are of no benefit, more recent evidence suggests that lower doses, on the order of hydrocortisone 200 to 300 mg per day, can reduce dependency on vasopressors and confer a mortality benefit (level II evidence). A more recent prospective, randomized trial suggests that these benefits are limited to those patients with relative adrenal insufficiency, defined as an increase in serum cortisol of ⩽9 μg/dL after ACTH administration.[69] Although the precise role of corticosteroid administration in septic shock and other acute conditions remains undefined, adrenal insufficiency should be considered in all critically ill patients with pressor-dependent shock. A reasonable approach in these patients is to administer "stress-dose" corticosteroids to such patients while awaiting results of adrenal testing (baseline and ACTH-stimulated serum cortisol levels), and continue steroids in only those patients with confirmed absolute or relative adrenal insufficiency. However, this approach has not been prospectively tested.

Thyroid Function in Critical Illness

Measures of thyroid function, including levels of thyrotropin (TSH), T_3, and T_4, are deranged in the majority of critically ill patients. Depression of T_3 occurs within hours of injury or illness and can persist for weeks. TSH levels may be normal initially, but they fall to inappropriately low levels as illness progresses. T_4 levels are also often low, but they can be normal or high. Low hormone levels may occur for a variety of reasons, including altered binding and metabolism early in the course of illness, and depressed neuroendocrine function with more prolonged courses. In addition, certain drugs, in particular the vasopressor dopamine, can depress thyroid function through central mechanisms.[103] Low thyroid hormone levels, particularly for T_3, correlate with the severity of illness and are associated with an increased risk of death.[99]

It is controversial as to whether the observed abnormalities in thyroid hormones represent an appropriate response to illness or true hypothyroidism; thus, the terms "euthyroid sick syndrome" or "nonthyroidal illness" have been coined to describe thyroid function abnormalities in critical illness.[104] Furthermore, it is not clear whether replacement of thyroid hormones is indicated or beneficial in critical illness. T_3 administration to brain dead organ donors appears to improve hemodynamic stability (level IV evidence), although randomized trials found minimal or no benefit to T_3 or T_4 administration in patients undergoing cardiopulmonary bypass and cardiac surgery (level II evidence).[105] In addition, several small studies have found no benefit to T_3 or T_4 administration to patients with a variety of critical illnesses (level II evidence). Larger, randomized prospective trials are necessary to define the role of routine thyroid hormone supplementation in nonthyroidal illness.

Importantly, true hypothyroidism may be present in the critically ill, particularly in the geriatric population, and should be considered in the face of refractory shock, adrenal insufficiency, unexplained coma, and prolonged, unexplained respiratory failure. True hypothyroidism is marked by an elevation of TSH (usually >25 mU/L) in the face of a low T_4 level.

Somatotropic Function in Critical Illness

Growth hormone (GH) levels are low in prolonged critical illness, and it has been conjectured that deficiencies of GH and insulin-like growth factor-1 (IGF-1) contribute to the muscle wasting seen in acute illness.[99] However, although small trials have found that GH administration can attenuate muscle catabolism in critical illness, a large, randomized prospective trial found that administration of large doses of GH to critically ill patients resulted in increased mortality (level I evidence).[106] Thus, GH administration during critical illness cannot be advocated at this time, although further exploration of the benefits of smaller doses of GH may be warranted.

ANEMIA AND TRANSFUSION THERAPY IN CRITICAL ILLNESS

Anemia is a frequent, if not obligate, accompaniment of critical illness. The vast majority of

patients admitted to the ICU are anemic at some point in their hospital stay, and more than one-third of them will receive transfused blood.[107,108] Importantly, both anemia (Hb <9 g/dL) and the amount of transfused blood are independently associated with mortality.[107,108] This association does not denote cause and effect, however, particularly for anemia, which may just be a marker of the severity of illness.

The cause of anemia in critical illness is multifactorial, and related to blood loss from the primary injury or illness, iatrogenic blood loss due to daily blood sampling, and nutritional deficiencies.[109] Given that approximately 13% of ICU patients may have iron, folate, or vitamin B12 deficiencies, these parameters should be checked prior to blood transfusion.

8 Treatment of anemia in critical illness is the source of considerable debate. In unstressed subjects, severe anemia (Hb of ⩽5 g/dL) is amazingly well tolerated due to physiologic compensations that maintain oxygen delivery and extraction. However, it has long been assumed that critically ill patients have less efficient compensatory mechanisms and reduced physiologic reserve, and thereby require a higher Hb concentration than unstressed individuals. Historically, this has translated to a transfusion threshold at an Hb concentration of approximately 10 g/dL. However, a large, randomized, prospective trial of transfusion requirements in critical illness (the TRICC study) found that 30-day mortality was not affected when a restrictive transfusion threshold (Hb <7 g/dL) was used, compared with a more conventional threshold of <10 g/dL (level I evidence).[110] Furthermore, a trend in mortality reduction favored the restrictive group, and various subgroups of patients (younger than 55 years of age and less severely ill by APACHE scoring) had a significantly lower mortality when they were transfused using the restrictive strategy. These data strongly suggest that routine transfusion of critically ill patients is not necessary and may be harmful unless the Hb concentration is less than 7 g/dL. Unfortunately, data collected from ICUs at multiple centers in the United States since the publication of the TRICC study suggests that the transfusion threshold remains substantially higher, at a mean Hb of 8.6 g/dL.[107]

There are multiple possible reasons for the persistence of a high transfusion threshold in the ICU. Although the TRICC study included a broad spectrum of critically ill patients, some groups were excluded (active bleeding) or underrepresented (neurologic or neurosurgical injury). Furthermore, although a retrospective analysis of the TRICC data suggested that patients with coronary artery disease did not benefit from more liberal transfusion unless they had unstable angina or acute myocardial infarction, concern remains about the tolerance for anemia in this group of patients. Last, Hb is an important determinant of oxygen delivery (DO_2), and transfusion is an integral component of goal-directed therapeutic strategies that aim to optimize DO_2 in early shock states.[44] In the absence of these possible exclusions (active bleeding, acute neurologic injury, active myocardial ischemia, or the early resuscitation of septic shock), restriction of blood transfusion to a threshold of <7.0 g/dL should be considered the standard of care and as potentially lifesaving.

Alternatives to the transfusion of red cells for treatment of anemia are not currently available for widespread use. Several hemoglobin-based oxygen carriers (HBOCs) have been studied in clinical trials involving trauma and surgery, but results have been mixed, and none are currently U.S. Food and Drug Administration (FDA) approved for use. Compassionate use of HBOCs in patients that have refused blood transfusion for religious reasons has been reported.

Prevention of anemia in critical illness is an appealing alternative to transfusion. One simple and potentially cost-saving approach is to reduce the volume and frequency of blood draws in the ICU. As noted earlier, iatrogenic blood loss is a major factor in the development of anemia of critical illness. Another potential approach is the administration of recombinant erythropoietin and iron. A more recent large, randomized, prospective trial found that administration of erythropoietin to critically ill patients on day 3 of ICU stay and every week thereafter reduced transfusion requirements significantly, without affecting mortality or other outcome variables (level I evidence).[111] However, the threshold for transfusion in this study was high (Hb of 8.5) and the mean amount of transfused blood saved per patient was quite small (approximately 0.5 U); it is possible that with a lower transfusion threshold there would have been no difference between

groups. Given the current high cost of erythropoietin, it is not a cost-effective alternative at this time.

NUTRITION IN THE CRITICALLY ILL PATIENT

Critical illness can lead to hypermetabolic states and if nutritional support is inadequate or delayed, patients are at immediate risk of malnutrition. Poor nutritional status is associated with increased mortality and morbidity among critically ill patients. Therefore, appropriate nutrition is an important aspect of critical care, and adequate nutritional support should be considered a standard of care. The American College of Chest Physicians recommends that the daily caloric intake be based on the patient's ideal body weight (25 kcal/kg or 27.5 kcal/kg in the presence of SIRS), of which 15 to 20% should be represented by proteins (1.5 to 2 g/kg per day).

Patient metabolic requirements should be established early after ICU admission and, enteral feeding tolerance evaluated without delay (within 24 hours of admission). A more recent small randomized trial indicated that early enteral nutrition (EN) initiated within 4.4 hours after ICU admission resulted in less organ dysfunction than delayed feeding (36.5 hours after ICU admission) (level II evidence).[112] Feeding intolerance due to high gastric residual volume can be improved by the administering gastric prokinetic agents, and positioning the tube postpyloric. However, a systematic review comparing gastric versus postpyloric feeding did not suggest a clinical benefit from postpyloric tube feeding with regard to pneumonia, ICU length of stay, and mortality.[113] Because gastric feeding was initiated sooner, no advantages in terms of overall caloric goal achievement were observed.

Most of the trials evaluating parenteral nutrition (PN) do not demonstrate any favorable impact on outcome (level II evidence). More recent reviews suggest that enteral nutrition is associated with lower infection risk, and that PN is associated with increased rates of complications and death. Animal studies show that endotoxin-induced ischemia can be prevented by early EN, and adding EN to parenteral nutrition has favorable effects on bacterial translocation and nitrogen balance, independent of total energy and protein intake. Therefore, EN is preferred over PN whenever possible because of its lower cost, and less frequent complications. Although not rigorously investigated, PN is preferable to no nutrition in patients who cannot tolerate enteral feedings. However, it is unclear how long of a delay in initiating PN is acceptable, assuming EN is contraindicated or not tolerated despite vigorous attempts.

Complications associated with enteral feedings include aspiration of gastric feeding, diarrhea, and fluid and electrolyte imbalance. To prevent aspiration with gastric feeding, the head of

the patient's bed should be raised 30 to 45 degrees during feeding; jejunal access can be considered in patients with recurrent tube feeding aspiration. Diarrhea is a common complication during enteral feeding associated with many potential causes, including medications (antibiotics or sorbitol-containing products), altered bacterial flora (*Clostridium difficile*), formula composition (including osmolality), infusion rate, hypoalbuminemia, bacterial contamination of the enteral fluid, and the patient's related conditions. To prevent or reduce diarrhea, all potential etiologies should be considered and corrected. Exchanging a polymeric formula with fiber with a more expensive elemental amino acid diet may improve feeding tolerance. However, animal studies demonstrated that elemental diets promote bacterial overgrowth and may result in greater bacterial translocation (level V evidence).

Among special formulations, immunonutrition has been hypothesized to influence infectious morbidity and mortality in critically ill patients via a beneficial effect on GI immunologic function. Specific enteral formulations, particularly those with high concentrations of branch chain amino acids (isoleucine, leucine, valine), arginine, glutamine, nucleotides, or omega-3 fatty acids, have been suggested to improve mortality and decrease infectious complications in burn and postoperative cancer patients.[114] A more recent meta-analysis indicates that immune-enhancing diets may be beneficial for elective surgical patients but have no demonstrated benefit and may be deleterious in critically ill patients (level II evidence).[115] Use of special formulations may be beneficial in patients with renal or liver disease.

SEDATION OF THE CRITICALLY ILL PATIENT

Critically ill patients are often deeply sedated, in part due to concerns for patient comfort, but also because of potential benefits afforded by a reduction in the sympathoadrenal response to injury. In addition, complications associated with undersedation include ventilator dyssynchrony, patient injury, agitation, anxiety, stress disorders, and, possibly, unplanned extubation.

9 Several more recent studies have tempered the enthusiasm for deep sedation in the ICU. In a prospective cohort study, Kollef et al observed that patients who received continuous infusions of sedatives had nearly twice the duration of mechanical ventilation compared with patients not receiving continuous intravenous sedation (level III evidence).[116] Furthermore, the implementation of nurse-driven sedation protocols that discourage the use of continuous infusions has been demonstrated to reduce the duration of mechanical ventilation, the ICU length of stay, and the requirement for tracheostomy (level I evidence).[117] In a randomized trial of critically ill patients receiving continuous sedative and analgesic drug infusions, daily interruption of these infusions was effective in reducing the length of mechanical ventilation and length of ICU stay (level I evidence).[118] Length of ICU stay was reduced by 3.5 days, and no incremental complications were observed in the intervention group. Beyond longer duration of mechanical ventilation, other complications are associated with oversedation, such as excessive cardiovascular and respiratory depression, as well as infectious complications.[119]

The depth of sedation may also play a role in long-term outcomes after discharge from the ICU and hospital. Increasing evidence suggests that patients admitted to the ICU are at risk of developing symptoms of posttraumatic stress disorder and of experiencing delusional memories. More recently, Kress et al followed-up long-term psychological effects in those subjects that were enrolled in the daily sedative interruption trial. Although the loss to follow-up was negligible and the design was exploratory in nature, the study suggested that daily interruption of sedation tended to be protective for subsequent development of posttraumatic stress disorder, or at least did not result in adverse psychological outcomes (level III evidence).[120]

Several factors such as interindividual variability, changes over time, severity of disease, intensity of painful stimuli, drug interactions, and organ dysfunction influence the analgesic and sedative needs of ICU patients. Therefore, it is important to titrate medications according to established therapeutic goals and to reevaluate the sedation requirements frequently. Several scales are available to assess sedation levels over time. The most commonly used scales are the Ramsay sedation scale, the sedation-agitation scale, and the Richmond agitation-sedation scale. Common features to all these scales are the grading of sedation over different depths and allowance for indicators of agitation. There is no evidence that one scale is superior to another at this time.

Confusion and agitation are common in ICU patients and could have unfavorable consequences on patient outcome. Patients experiencing agitation have been reported to have a higher incidence of major complications, higher admission to rehabilitation centers, and increase duration of hospital stay. Agitation is also a predictive factor for mortality. Agitation needs to be distinguished from delirium, which is relatively common in ICU patients and equally associated with increased length of stay, morbidity, and mortality.[121] Delirium can be difficult to diagnose in ICU patients because features of delirium, such as altered status of consciousness, are shared with several disorders typical of ICU patients. The distinguishing characteristics of delirium include acute onset and fluctuating course, inattention, disorganized thinking, and altered level of consciousness. An ICU delirium diagnostic scale (CAM-ICU scale) has been more recently proposed and is a valid instrument to diagnose delirium in the ICU.[122]

Nonpharmacologic and pharmacologic means can be used to provide comfort and safety to ICU patients. The former include communication and frequent reorientation, maintenance of a day–night cycle, noise reduction, and ensuring ventilation synchrony. Pharmacologic agents include hypnotics-anxiolytics, opioids, and antipsychotics. Hypnotics most commonly used are propofol, midazolam, and lorazepam; each drug has its own particular advantages, but there are insufficient data at this time to suggest a difference in relevant patient outcomes among them. A prospective, randomized, nonblinded trial compared a continuous infusion of lorazepam, midazolam, and

propofol in trauma patients.[123] Midazolam appeared to be the most titratable drug, with the lowest incidence of oversedation and undersedation. Lorazepam was the most cost-effective choice for sedation, despite the observation that oversedation occurred twice as often with lorazepam than with propofol or midazolam. A meta-analysis including 27 randomized trials comparing propofol versus midazolam suggested that extubation occurred earlier with the use of propofol for patients that were ventilated for less than 36 hours.[124] However, no differences were found with regard to the ICU length of stay or mortality. Greater levels of hypotension and elevated triglyceride levels were observed with the use of propofol.

Adverse effects unique to hypnotic-anxiolytic drugs include a hyperosmolar acidosis due to the diluent mixed with lorazepam (propylene glycol), and the potentially lethal "propofol infusion syndrome" (for more details, see Traumatic Brain Injury section).[13] Both complications can be avoided by minimizing the administered dose of the respective agent.

Dexmedetomidine is a unique sedative agent for several reasons: (1) mechanistically, it is an α-2 adrenergic receptor agonist, similar to clonidine; (2) it provides sedation without inducing unresponsiveness or coma; (3) it has some analgesic effect; and (4) it has little effect on respiratory drive. Dexmedetomidine has been effectively used as a single agent or in

combination with other drugs in postsurgical and medical ICU patients. Although, the acquisition costs of dexmedetomidine are high, it is currently FDA approved for use for only up to 24 hours, and there is insufficient evidence to recommend its routine use at the current time.[125]

Morphine and fentanyl are the most commonly used opioids to provide analgesia in the ICU. Morphine should be avoided in patients with renal failure due to active metabolites that accumulate in the presence of impaired renal elimination.

Delirium in the ICU is commonly treated with antipsychotic agents such as haloperidol, and more recently, newer antipsychotics such as olanzapine and risperidone. However, none of these agents has been proven effective for the treatment of ICU-associated delirium in a randomized, placebo-controlled trial, and it is not clear that the newer agents, which are also more expensive, are more effective than haloperidol.

Neuromuscular blockade may be occasionally indicated in ICU patients with severe TBI or respiratory failure, but routine use is discouraged because of concerns that this practice may predispose to critical illness polyneuropathy and myopathy (see Acquired Neuromuscular Disorders in Critical Illness section), and because of an increased risk of nosocomial pneumonia in patients receiving these agents.

In summary, sedation and analgesia should be provided in the ICU population to ensure patient comfort and safety. In establishing treatment algorithms, analgesia should be prioritized over sedation. Titration and assessment of analgesia and sedation should be an integral part of the ICU monitoring so oversedation and undersedation can be avoided. The establishment of nurse-guided sedation protocols and daily interruption of sedation have been shown to be effective in reducing the length of mechanical ventilation and ICU stay.

COMPLICATIONS IN THE ICU: DETECTION, PREVENTION, AND THERAPY

Nosocomial Infections

Nosocomial infections are a major source of morbidity and mortality in the critically ill. At some level, nosocomial infections are unavoidable and occur because of the nature of intensive care: patients are critically ill with altered host defenses; they require invasive devices (e.g., endotracheal tubes, intravascular catheters) for support, monitoring, and therapy that provide portals of entry for infectious organisms; and they receive therapies that increase the risk of infection (glucocorticoids, parenteral nutrition). In contrast, many nosocomial infections are preventable with relatively simple interventions.[126]

Several types and sources of infections are relatively unique to ICU care and should be included in the differential diagnosis when signs suggestive of infection arise. These infections include sinusitis, ventilator-associated pneumonia, intravascular catheter-associated bacteremia, catheter-associated urinary tract infection, and invasive fungal infection. The diagnosis, prevention, and treatment of these infections are discussed in this section.

Sinusitis

Radiographic sinusitis is common in critically ill patients with indwelling oral and nasal tubes. Nasal intubation confers a greater risk than oral intubation of radiographic sinusitis, occurring in approximately 95% and 25% of patients with nasal and oral tubes after 1 week of intubation, respectively.[127] Approximately 10% of radiographically diagnosed sinusitis is infected as determined by quantitative cultures, with the cultured organisms representing those that are responsible of other nosocomial infections, particularly ventilator-assisted pneumonia (VAP) (*Staphylococcal* species, enteric Gram-negative bacteria, nonlactose fermenting Gram-negative rods such as *Pseudomonas* and *Acinetobacter*). Bacterial sinusitis may predispose to the development of VAP, possibly because of microaspiration of infected secretions.

Prevention of sinusitis should focus on efforts to improve sinus drainage, including semirecumbent positioning and avoidance of nasal tubes. Bacterial sinusitis should be considered in patients with unexplained fever and leukocytosis in the ICU. If radiographic sinusitis is documented, any nasal tubes should be removed, and nasal irrigation and short-term administration of nasal decongestants should be considered. If the patient is severely ill, broad-spectrum antibiotic coverage should be considered. If these maneuvers do not result in resolution of signs and symptoms of infection in 2 to 3 days, and in the absence of infection elsewhere, otolaryngologic consultation and consideration of sinus drainage procedures should be undertaken.

Ventilator-Associated Pneumonia

Endotracheal intubation and mechanical ventilation increase the risk of nosocomial pneumonia, in this situation termed VAP. The likelihood of developing VAP increases with the duration of mechanical ventilation, although the incremental risk may fall over time from a high of 3% per day in the first week of intubation/ventilation, to 1% per day after 15 days in the ICU.[128] The quoted incidence of VAP depends on the criteria used to diagnose pneumonia (clinical versus invasive technique); traditional clinical criteria are likely to be both insensitive and nonspecific, and may lead to a falsely high or low incidences of VAP. For example, in a more recent study comparing an invasive diagnostic technique with traditional clinical criteria in patients suspected of having VAP, only 50% of the patients in the invasive group met criteria for VAP compared with the clinical diagnostic group.[129] Given this caveat, studies that solely or primarily relied on invasive techniques to diagnose VAP suggest an incidence greater than 15% at 1 week of ICU stay and greater than 20% at 2 weeks.[128]

Although the mortality in patients with VAP ranges between 30 to 70%, the attributable mortality—the number of patients who die because of VAP rather than with VAP—is more difficult to pinpoint. This may be due to differences in the type of ICU, patient factors, diagnostic techniques across studies or differences in the virulence of the causative pathogens. Thus, some investigators have been unable to find any mortality attributable to VAP, whereas others have suggested a rate greater than 40%.[130]

VAP can be categorized as "early onset," occurring within the first 48 to 72 hours of intubation/ventilation, or "late onset," occurring thereafter. Early-onset VAP is generally caused by organisms such as *Haemophilus influenza*, *Streptococcus pneumonia*, methicillin-sensitive *Staphylococcus aureus*, and other relatively antibiotic-sensitive oral flora that enter the trachea around the time of intubation. Late-onset VAP is associated with more virulent and antibiotic-resistant organisms such as methicillin-resistant *S. aureus*, *Pseudomonas aeruginosa*, and *Acinetobacter*. In general, early-onset organisms are associated with zero or low attributable mortality, whereas late-onset organisms, particularly *Pseudomonas* and *Acinetobacter* species, are associated with high mortality.[130]

There are a number of interventions that can reduce the incidence of VAP, some of which are relatively simple and inexpensive, and others of which are more costly and/or associated with some risk. The simplest and least expensive, yet very effective, interventions are strict hand washing between patients, and semirecumbent positioning of the patient (head height at 30 degrees or greater from horizontal) (level II evidence). These

practices should be rigorously applied in all ICUs (granted that semirecumbent positioning is not possible in all patients).

A somewhat more controversial subject involves the use of prophylaxis to prevent GI bleeding. As mentioned previously, acid-suppression therapies have been associated with an increased risk of VAP because they allow bacterial overgrowth in the stomach. Further, the risk of significant GI bleeding is low in the ICU, even in high-risk patients (those with coagulopathy or those on mechanical ventilation). Thus, GI prophylactic therapy should be reserved for only these high-risk patients, and sucralfate should be considered as an alternative agent to acid-suppressive regimens despite its potentially reduced effectiveness.

Somewhat more expensive interventions to reduce VAP that may be useful in certain patients include subglottic suctioning and oscillating beds.[131] Intermittent subglottic suctioning using specially designed tracheal tubes has been shown to reduce the incidence of VAP in two small studies (level II evidence). However, these tubes are more expensive than conventional tracheal tubes, and their cost effectiveness has not been established, particularly if their use is instituted in all intubated patients. Oscillating beds have been shown to reduce the incidence of VAP in surgical populations and patients with neurologic injury (level II evidence). However, these beds are quite costly and cannot be recommended for routine use.[131] In patients who do not tolerate semirecumbent positioning because of fractures, hemodynamic instability, etc, the use of oscillating beds should be considered.

Given that gastric and oropharyngeal colonization with resistant organisms appears to be a risk factor for the development of VAP, intervention to "decontaminate" these sites have been investigated. Selective digestive decontamination (SDD) typically involves the application of a mix of nonabsorbable antimicrobial agents, such as polymyxin, amphotericin, and aminoglycoside, in paste form to coat the oropharynx, and as an elixir applied orally and via a nasogastric tube to decontaminate the GI tract, with or without the concomitant administration of systemic antibiotics. SDD does reduce the incidence of VAP and has been associated with variable mortality reduction in some studies (level II evidence). However, SDD is also associated with the development of antibiotic resistance, and concerns regarding the long-term impact of resistance have limited the widespread adoption of SDD.[131]

An additional and important approach to reduce the overall mortality from VAP involves refinement of the diagnostic process and limitation of antibiotic therapy to avoid the development of antibiotic resistance. As mentioned previously, an invasive diagnostic strategy is likely more accurate than traditional clinical criteria to diagnose VAP. Invasive strategies typically involve collection of bronchial-alveolar specimens using lavage or protected brushes, and then quantitating bacterial growth in the laboratory. Thus, VAP is diagnosed only when bacteria are seen within bronchoalveolar cells microscopically, or when bacterial growth exceeds specific thresholds ($\geqslant 10^4$ colony-forming U/mL for bronchoalveolar lavage and $\geqslant 10^3$ colony-forming U/mL for protected brush specimens). Specimens have typically been obtained bronchoscopically, although more recent data suggest that specimens obtained by direct aspiration through the tracheal tube are comparable to bronchoscopic specimens, suggesting it is quantitation of bacterial growth rather than the "invasiveness" of the technique that is important (level II evidence).[132] The important adjunct to this diagnostic approach is that although antibiotics may be started at the time clinical criteria for pneumonia are met and quantitative cultures are sent, they are stopped if the threshold values for VAP are not reached.

A more recent, moderately sized, randomized, prospective trial of invasive versus noninvasive strategies to diagnose and treat VAP found that the invasive approach resulted in a mortality reduction at 14 days and a trend toward mortality reduction at 28 days (level II evidence).[129] In

addition, the invasive strategy was associated with less multiple organ failure and reduced antibiotic use. Surprisingly, the invasive strategy did not result in a reduced incidence of emergence of resistant bacteria, although the incidence of *Candida* growth was reduced. However, these data suggest that an invasive strategy to diagnose VAP should be used when and if possible.

It is clear that delay in treatment of nosocomial infections, including VAP is associated with increased mortality. Thus, treatment should not be delayed pending diagnostic evaluation; rather treatment should be started after culture specimens are sent if the clinical suspicion of VAP is high. Antibiotics can then be narrowed in spectrum or discontinued, depending on the results from quantitative cultures after 48 to 72 hours. This approach is known as "deescalating therapy", and is designed to ensure adequate antibiotic treatment up front but avoid overuse of antibiotics in the long run.[130] Antibiotic selection should be predicated on hospital bacterial growth and resistance patterns. In general, for patients with early-onset VAP, antibiotics can be relatively narrow in spectrum and limited to a single agent. For late-onset VAP, broader spectrum antibiotics should be initiated. These should include agents from two different classes directed toward resistant Gram-negative organisms, and in many cases, an agent directed against methicillin-resistant *S. aureus* (Table 57-7).

TABLE 57-7 Empiric Therapy of Ventilator-Associated Pneumonia

·COMMON ORGANISMS	·ANTIBIOTICS
·EARLY-ONSET VAP	
Enteric Gram-negative rods •*Escherichia coli* •*Enterobacter* species •*Proteus* species •*Klebsiella* species •*Haemophilus influenzae* •Methicillin-sensitive *Staphylococcus aureus* •*Streptococcus pneumoniae*	β-lactam/β-lactamase inhibitor combination, *or* second-generation cephalosporin, *or* fluoroquinolone
·LATE-ONSET OR SEVERE EARLY-ONSET VAP	
Above, plus •*Pseudomonas aeruginosa* •*Acinetobacter* species •Methicillin-resistant *S. aureus*	β-lactam/β-lactamase inhibitor combination, *or* third-generation or fourth-generation cephalosporin, *or* fluoroquinolone *plus* aminoglycoside, *or* second, structurally unrelated agent with antipseudomonal activity *plus*, vancomycin or linezolid[a]
VAP, ventilator-assisted pneumonia.	
[a]If likelihood of methicillin-resistant *S. aureus* is high.	

10 The optimal duration of antibiotic therapy for VAP is not well defined. A more recent, moderately sized, prospective, randomized trial found that 8 days of antibiotic therapy was comparable for treatment of VAP in terms of mortality and recurrent infections, and resulted in

more antibiotic-free days (level II evidence).[133] However, patients who had VAP caused

by nonlactose fermenting Gram-negative rods (including *Pseudomonas*) had a higher infection recurrence rate if they received an initial 8-day course of therapy. It is unclear whether intermediate courses of therapy would have avoided infection recurrence. Thus, it is reasonable to choose an 8-day course of therapy for many patients with VAP; however, if there is an inadequate early clinical response or infection with nonlactose fermenting Gram-negative rods a longer course should be considered.

Intravascular Catheter-Associated Bacteremia

Intravascular catheter-associated bacteremia as strictly defined by the Centers for Disease Control and Prevention (CDC) includes the following criteria: (1) clinical suspicion of catheter-related infection (including low likelihood of infection elsewhere); (2) positive culture of blood drawn from the catheter or of a segment of catheter; and (3) matching positive blood culture drawn from another site, preferably by direct venotomy or arterial puncture. Given this strict definition, the incidence of catheter-associated bacteremia is less than 5% in most studies. However, the incidence of bacteremia is affected by several factors, including the conditions and technique of insertion, type and location of catheter, and the duration of catheterization, and can vary widely from study to study. The attributable mortality of catheter-associated bacteremia is approximately 11%, which is much lower than that for primary bacteremia or bacteremia associated with another site of infection.[134]

Catheter infection is more likely when placement occurs under emergency conditions and is reduced by the use of strict aseptic technique with full barrier precautions. This includes preinsertion hand washing, full gown and gloves, and the use of a large barrier drape.[135] In addition, skin cleansing with chlorhexidine is more effective than other agents at reducing catheter-related infection. These simple interventions should be considered as standards of care and are recommended by the CDC.

Catheter-related infection and bacteremia increase with the duration of catheterization, particularly for durations of greater than 2 days. However, routine catheter replacement at 3 or 7 days does not reduce the incidence of infection and results in increased mechanical complications. Thus, routine guidewire change of catheters is not recommended.

Catheters coated with either antiseptics (chlorhexidine and silver sulfadiazine) or antibiotics (rifampin and minocycline) reduce catheter-related infection and bacteremia (level I evidence).[135] Antibiotic-coated catheters appear to be more effective than antiseptic-coated catheters at reducing infection and bacteremia (level I evidence).[136] Coated catheters are relatively expensive compared with conventional catheters, but they should be considered when insertion is predicted to be for longer than 2 days.

Catheter-related infection is insertion site dependent, increasing in frequency from subclavian to internal jugular to femoral vein sites, respectively. In addition, infection appears to be less likely for arterial versus venous catheters. Thus, the subclavian site should be used when possible if the duration of catheterization is predicted to be longer than 2 days.[135]

Catheter-related venous thrombosis occurs commonly and is associated with an increased risk of infection. Routine flushing of catheter ports with heparin reduces both the incidence of thrombosis and infection (level II evidence).[135]

Organisms commonly responsible for catheter-related bacteremia include *Staphylococcus epidermidis* and *S. aureus*, enteric Gram-negative bacteria, *P. aeruginosa*, *Acinetobacter*, and occasionally, *Enterococcal* species. When catheter-related bacteremia is confirmed, the offending catheter should be removed and appropriate antibiotics continued for a minimum of 7 days; longer courses should be considered for *S. aureus* bacteremia, given the predilection for this organism to cause endocarditis. Suspected catheter-related infections can be addressed by sending screening cultures drawn through the catheter and from a peripheral site; guidewire exchange of the catheter with culture of the intracutaneous segment and tip can also be considered in this

situation. Depending on the patient's severity of illness, a strong suspicion of catheter-related bacteremia should trigger the institution of broad-spectrum antibiotic coverage, including coverage for methicillin-resistant *Staphylococcal* species and nonlactose fermenting Gram-negative rods until culture results return, with subsequent deescalation of therapy. Similar to VAP, early appropriate antibiotic coverage of catheter-related bacteremia will likely reduce mortality, although this has not been systematically studied.

Urinary Tract Infection

The urinary tract is the second most common source of infection in the ICU, with infections occurring in up to one-third of patients. The incidence of urinary tract infection (UTI) increases with the duration of bladder catheterization.[126,137] The responsible organisms are similar to those causing other nosocomial infections, and include *Staphylococcal* species, *Enterococcus*, enteric Gram-negative bacteria, and nonlactose fermenting Gram-negative bacteria such as *Pseudomonas*. Bacteruria is associated with bacteremia about 5% of the time. Similar to other ICU-acquired infections, UTIs are associated with increased mortality, although the attributable mortality is not clear.

Prevention of ICU-acquired UTIs includes using careful hand washing and aseptic technique during catheter insertion and minimization of catheterization duration. The use of silver-alloy and antibiotic-coated catheters may also reduce the incidence of UTI, although the evidence is insufficient at this point to recommend general use of coated catheters.[126,137]

Invasive Fungal Infections

Invasive fungal infection in non-neutropenic patients is caused by *Candida* species in the vast majority of cases. It is increasingly common in the ICU population, and accounts for 5 to 10% of all bloodstream infections in the ICU.[134,138] Other than neutropenia, risk factors for *Candida* bloodstream infection include the presence of central venous catheters; uremia and dialysis-dependent renal failure; and administration of parenteral nutrition, multiple broad-spectrum antibiotics, and steroids. In addition, colonization of multiple sites by *Candida* is a risk factor for the development of fungemia.[139] The attributable mortality due to *Candida* bloodstream infection is high, approaching 40%, and mortality appears to be much higher in medical versus surgical ICU patients. Invasive *Candida* infection is also associated with increased duration of mechanical ventilation, as well as with ICU and hospital length of stay.

In addition to simple bloodstream infection, *Candida* species are associated with UTI, postoperative peritonitis, and disseminated bloodborne infection. *Candida* is frequently cultured from the urine of catheterized patients, and candiduria is associated with the development of bloodstream infection. True *Candida* peritonitis is also difficult to separate from contamination of culture specimens, but given that the mortality associated with *Candid*a peritonitis is approximately 50%, treatment is warranted if clinical signs suggest infection. Disseminated bloodborne infection can result in endophthalmitis, endocarditis, and hepatic and pulmonary abscesses; is likely to occur when initial treatment of candidemia is delayed; and is associated with a high mortality. Last, although *Candida* is frequently grown from sputum cultures, true *Candida* pneumonia

is unlikely. However, sputum colonization is a risk factor for bloodstream infection.

Candida albicans is responsible for approximately 50% of invasive *Candida* infections in critically ill patients. *Candida tropicalis*, *Candida parapsilosis*, *Candida glabrata*, and *Candida krusei* account for the remainder, in descending order of frequency. Speciation is important because *C. glabrata* and, particularly, *C. krusei* are resistant to treatment with the most commonly used therapeutic agent, fluconazole.

Prevention of invasive *Candida* infection involves avoidance of risk factors, including limitation of intravascular catheterization, parenteral nutrition, and antibiotic regimens. Prophylactic therapy with fluconazole is effective at reducing the risk of invasive *Candida* infection in high-risk patients, but this strategy has been studied most extensively in the neutropenic population.

Prophylactic fluconazole appears to increase the incidence of invasive infection with more resistant species, such as *C. glabrata* and *C. krusei*; thus, prophylactic therapy should be reserved for only the highest risk patients.[140]

Candida grows slowly in blood culture medium, and invasive infection can be indolent, making diagnosis of invasive candidiasis difficult. Serologic and molecular tests for *Candida* infection are not currently clinically available. Thus, a high level of suspicion for invasive *Candida* infection in critically ill patients is necessary, particularly in patients with multiple risk factors, including multiple site colonization. While awaiting blood culture results, "preemptive" therapy should be considered in patients with a high likelihood of invasive *Candida* infection because delay in treatment is associated with increased mortality. Unfortunately, many cases of invasive candidiasis are identified only at autopsy.[138]

Documented *Candida* bloodstream infection should be treated aggressively, with therapy started promptly (or preemptively, as described previously) and continued for at least 2 weeks after the last positive blood culture. An ophthalmologic exam is warranted in patients with documented or suspected bloodstream infection because patients with endophthalmitis may require longer courses of therapy. Intravascular catheters that are potential sources of bloodstream infection should be removed.

It is not clear that routine treatment of candiduria is warranted because it often clears without treatment or with discontinuation of the bladder catheter; in addition, candiduria often recurs after initially successful antifungal therapy.[140] However, if candiduria is associated with signs of systemic infection, antifungal treatment should be considered; a similar approach can be taken when *Candida* is cultured from the peritoneal space.

Organisms sensitive to the azole derivative fluconazole cause the majority of invasive *Candida* infections in the ICU, and fluconazole is the first-line treatment given its reasonable efficacy and limited toxicity. Infections caused by resistant organisms such as *C. glabrata* and *C. krusei* may respond to newer-generation azoles such as voriconazole, although there are limited data on these agents at present. Caspofungin is another new antifungal agent with broad-spectrum activity and seemingly limited toxicity that is a reasonable alternative for infection due to resistant species. Amphotericin B is generally reserved for refractory, life-threatening infections due to its toxicity. The reader is directed elsewhere for a more detailed discussion of antifungal agents.[140]

Stress Ulceration and Gastrointestinal Hemorrhage

Gastric mucosal breakdown with resulting gastritis and ulceration (often called stress ulceration) can lead to GI bleeding in the ICU. Clinically significant GI bleeding is that which results in hemodynamic instability and/or a sudden fall in hematocrit that results in blood transfusion. The incidence of clinically significant stress-related GI bleeding was once believed to be quite high (20% or greater), but large studies from the past 10 years suggest that the incidence is much lower at less than 5% in high-risk patients and less than 1% in low-risk patients.[141] The major risk factors for stress-related GI bleeding are mechanical ventilation and coagulopathy; secondary risk factors among mechanically ventilated patients include renal failure, thermal injury, and possibly head injury, although the latter two factors have not been recently evaluated.[141,142,143] Enteral nutrition may protect against significant GI bleeding.[143]

Agents used to prevent stress ulceration and GI bleeding include methods to suppress acid production (H_2 blockers and proton pump inhibitors [PPIs]) and cytoprotective agents (sucralfate). However, the agent of choice—and whether any prophylaxis is beneficial or indicated—is somewhat controversial for the following reasons. Although ranitidine was shown to be more effective than sucralfate in preventing clinically significant GI bleeding in high-risk patients in a large, randomized prospective trial (level I evidence), the incidence of bleeding with both agents was quite low (1.7 vs. 3.8%).[144] Furthermore, a more recent meta-analysis suggests that neither ranitidine nor sucralfate are superior to placebo in reducing clinically important bleeding.[145] Acid suppression may favor gastric colonization with enteric flora, which may in turn increase the risk of nosocomial pneumonia. Multiple small, randomized trials suggested a higher incidence of VAP when ranitidine was compared with sucralfate, and in the previously quoted large trial, there was

a trend toward increased VAP in the ranitidine group (level II evidence). It appears that stress ulcer prophylaxis is more widely used than necessary, is often administered to low-risk patients, and results in an overall cost that may be higher than the benefit. Thus, although stress ulcer prophylaxis, predominantly with ranitidine, is commonly used in critically ill patients, the utility of this intervention is unclear.

PPIs are quite effective at suppressing gastric acid production and have been shown to be as effective as ranitidine at reducing stress ulcer-related bleeding in the ICU. In addition, PPIs may be more effective than ranitidine in preventing rebleeding due to stress ulceration (level II evidence).[146] However, PPIs cannot be recommended for routine use as prophylactic agents due to insufficient data and cost considerations. In addition, PPIs have the potential to increase the risk of VAP, given their effective suppression of gastric acid secretion.

Venous Thromboembolism

Venous thromboembolism (VTE) occurs frequently in critically ill patients, with incidences of DVT of 10 to 30% and of PE of 1.5 to 5%. However, the reported incidence varies widely, depending on study design, tests used to detect DVT, and the patient population studied. Virtually all critically ill patients have one or more risk factors for VTE. Risk factors can be grouped according to their importance, as described by Anderson and Spencer (Table 57-8).[147] Determination of VTE risk is important in that it will help in choosing prophylactic therapy and in determining the level of suspicion for VTE in individual patients.

TABLE 57-8 Risk Factors for Venous Thromboembolism

Strong risk factors (odds ratio >10)
Fracture (hip or leg)
Hip or knee replacement
Major trauma
Spinal cord injury
Moderate risk factors (odds ratio 2–9)
Arthroscopic knee surgery
Central venous lines
Chemotherapy
Congestive heart or respiratory failure
Hormone replacement therapy
Malignancy
Oral contraceptive therapy
Paralytic stroke
Pregnancy/postpartum
Previous venous thromboembolism
Thrombophilia
Weak risk factors (odds ratio <2)
Bed rest >3 days
Immobility due to sitting (e.g., prolonged car or air travel)
Increasing age
Laparoscopic surgery (e.g., cholecystectomy)
Obesity
Pregnancy/antepartum
Varicose veins

Reprinted with permission from Anderson FA Jr, Spencer FA: Risk factors for venous thromboembolism. Circulation 107:19, 2003.

In addition to classic lower-extremity DVT, upper-extremity DVT occurs with increased frequency in the ICU population. This is directly associated with the use of central venous catheters in the subclavian and internal jugular sites. Upper-extremity DVT can result in PE in up to two-thirds of cases, with occasional fatalities. Catheter-related thrombosis is also associated with increased risk of catheter-associated infection and bacteremia. Finally, upper-extremity DVT is associated

with considerable long-term morbidity, particularly related to postthrombotic syndrome.[148]

The literature supporting prophylactic measures to prevent VTE in the ICU population is relatively poor and marked by small, heterogeneous studies. In addition, studies supporting VTE prophylaxis in the ICU generally show differences only in intermediate end points, such as asymptomatic DVT, with no differences in the incidence of PE or death. This is particularly true for VTE prophylaxis in patients with traumatic injury and makes evidence-based recommendations for prophylaxis difficult. Finally, the risks of VTE prophylaxis, including heparin-induced thrombocytopenia and bleeding, must be weighed when considering prophylaxis in the ICU population. Nonetheless, it is generally agreed that high-risk patients without contraindications should receive prophylaxis with LMWH, and that patients with low-to-moderate risk should receive low-dose unfractionated heparin (UFH) (see Table 57-8). Patients with contraindications to LMWH or UFH should probably receive prophylaxis with mechanical devices (serial compression devices), although there is no compelling evidence to suggest that they are effective in the ICU population.[149] Fondaparinux has not been studied in critically ill patients, and there is no evidence to support the preventive placement of

vena cava filters in the critically ill. To reduce central venous catheter-associated thrombosis and infection, catheter tips should be positioned in the superior vena cava, and catheters should be flushed with a dilute heparin solution (level II evidence). Heparin bonding of catheters may also reduce local thrombosis. Importantly, it should be recognized that the incidence of VTE in patients receiving pharmacologic prophylaxis remains substantial, ranging between 5 to 30%, depending on the therapy and population studied.

Given the high incidence of asymptomatic DVT in critically ill patients, a high index of suspicion for VTE must be maintained in the ICU. However, despite the high incidence of DVT, routine screening studies for DVT do not appear to improve clinical outcomes in the ICU. Thus, VTE should be considered in critically ill patients in the face of relatively nonspecific findings, such as unexplained tachycardia, tachypnea, fever, asymmetric extremity edema, and gas exchange abnormalities, including high dead space ventilation. Compression Doppler ultrasonography is the most commonly used test for diagnosis of DVT, and has good positive and negative predictive value compared with contrast venography.[150] Helical CT has supplanted radionuclide ventilation-perfusion scanning as the primary test for the diagnosis of PE.[151] CT scanning can also be extended to include the extremities to diagnose DVT. However, ventilation-perfusion scanning and/or pulmonary angiography may have utility in specific circumstances, including in the presence of renal insufficiency (concerns about contrast-induced nephrotoxicity) or equivocal results on CT scan. In addition, pulmonary angiography may be the test of choice when the likelihood of PE is high and anticoagulation is contraindicated, necessitating immediate placement of a vena cava filter. Although low D-dimer levels have a high negative predictive value in ruling out venous thromboembolism in outpatients, this test appears to have less utility in the ICU setting due to the frequent occurrence of high levels in critically ill patients.[152]

The mainstay of treatment for VTE is heparin, which should be started prior to confirmatory studies if clinical suspicion is high. LMWH may be superior to UFH in efficacy, with comparable rates of bleeding for the treatment of VTE (level II evidence). The choice of drug should be based on clinical circumstances and availability. The advantage of UFH in the ICU population is its titratability and rapid reversibility, which may be desirable in patients at high risk for bleeding. In patients with PE and hemodynamic instability, thrombolytic therapy should be considered if not contraindicated. Although the data supporting thrombolytic therapy for treatment of PE are limited, patients with massive PE and/or shock are likely to benefit from thrombolysis; patients with more subtle signs of instability, including right ventricular dilation may also benefit.[153]

For patients who have contraindications to anticoagulation or who have recurrent PE despite anticoagulation, vena cava filters can be placed in the SVC or IVC, depending on DVT location. Ultimately, given the long-term thrombotic complications associated with these devices, patients with vena cava filters should be anticoagulated when no longer contraindicated. Another attractive option is to place a retrievable vena cava filter and remove it once anticoagulation can be started.[153] The timeframe for safe removal varies with filter type; they can remain permanently, if necessary.

Acquired Neuromuscular Disorders in Critical Illness

Neuromuscular abnormalities developing as a consequence of critical illness can be found in the majority of patients hospitalized in the ICU for 1 week or more. The spectrum of illness ranges from isolated nerve entrapment with focal pain or weakness, to disuse muscle atrophy with mild weakness, to severe myopathy or neuropathy with associated severe, prolonged weakness. In particular, so-called critical illness polyneuropathy and myopathy (CIPNM) and a similar and likely related disorder, acute quadriplegic myopathy (AQM), produce significant morbidity and are associated with increased mortality in critically ill patients.[154]

CIPNM is the most common acquired neuromuscular disorder in the ICU. Prospective studies have shown that 25 to 36% of patients receiving intensive care are weak by clinical evaluation. Electrodiagnostic studies (nerve conduction and electromyography) suggest that CIPNM is present in 42 to 47% of

patients in the ICU for 7 days or more, and in 68 to 100% of patients with sepsis or the SIRS. In addition to sepsis, factors associated with the development of CIPNM include duration of illness, hyperglycemia, and corticosteroid and neuromuscular blocking drug administration.

AQM was initially described in asthmatics with respiratory failure that were receiving high-dose corticosteroids and neuromuscular blocking drugs, but has since been described in other patients receiving similar therapeutic regimens. It is likely that the combination of these two drugs, in addition to as yet undefined patient factors, results in toxic injury to muscle that can range from a mild myopathy to rhabdomyolysis. It is also likely that CIPNM and AQM overlap, and it is often difficult to differentiate one from the other in published studies.

CIPNM and AQM can result in severe weakness with flaccid quadriplegia that lasts for weeks or months. It is likely that CIPNM and AQM prolong the duration of mechanical ventilation, ICU stay, and hospitalization, and provide a significant impediment to long-term functional recovery from critical illness.[154,155] In addition, acquired weakness in the ICU may be a significant contributor to ICU and hospital mortality.

Prevention of acquired neuromuscular disorders in the ICU centers on avoidance or minimization of contributory risk factors, including high-dose steroids, prolonged administration of neuromuscular blockade, and hyperglycemia. In regard to the latter, the only prospectively proven intervention for prevention of CIPN is tight glycemic control using intensive insulin therapy (goal glucose <110 mg/dL).[96] In addition, efforts to reduce the risk of infection and ICU length of stay, including rigorous hand washing and infection control procedures, semirecumbent positioning, careful aseptic technique and barrier protection for central venous catheter placement, and lung protective ventilation, will likely result in a reduction in the incidence and ramifications of CIPNM.

The diagnosis of CIPNM and/or AQM should be entertained in all critically ill patients with unexplained weakness. Electrodiagnostic studies can help confirm the diagnosis and rule out other, potentially treatable causes of weakness such as Guillain-Barré syndrome. Muscle biopsy is confirmatory in cases of myopathy, but given its invasive nature, biopsy is not warranted outside research settings. Unfortunately, no treatment for either CIPNM or AQM has been identified; avoidance of potentially contributing agents and aggressive physical therapy are warranted. Discharge planning should include the potential need for long-term nursing and rehabilitative care.

Chapter 58

Cardiopulmonary Resuscitation

Charles W. Otto

KEY POINTS

1	Early uninterrupted basic life support and rapid defibrillation are necessary to obtain the best possible rates of resuscitation.
2	For arrests due to ventricular fibrillation/tachycardia, ventilation is probably not necessary for the first 10 minutes. Bystanders should be encouraged to provide chest compressions with or without mouth-to-mouth ventilation.
3	No alternative method of closed-chest compression has been shown to improve outcome from cardiac arrest when compared with the standard technique.
4	Restoration of spontaneous circulation depends on restoring oxygenated blood flow to the myocardium. Arterial diastolic pressure of 40 mm Hg and/or end-tidal carbon dioxide of >10 mm Hg indicate adequate blood flow for resuscitation, and should be used to guide resuscitation efforts whenever possible.
5	Public access defibrillation improves outcome from cardiac arrest by allowing definitive treatment of ventricular fibrillation within the first few minutes of collapse. If more than 4 to 5 minutes have elapsed since collapse, 2 to 3 minutes of chest compressions should be performed before defibrillation.
6	Epinephrine aids resuscitation through its alpha-adrenergic effects, causing vasoconstriction leading to increased coronary perfusion pressure and myocardial blood flow. Experimentally, all strong vasoconstrictors are equally effective.
7	High-dose epinephrine and vasopressin have not been found superior to epinephrine in aiding resuscitation from cardiac arrest.
8	Amiodarone, when administered during out-of-hospital cardiac arrest resistant to initial defibrillation, has been shown to improve initial resuscitation but not to improve survival to discharge from the hospital.

9	Comatose survivors of cardiac arrest had improved neurologic outcome when mild therapeutic hypothermia (32 to 34°C) was induced for 24 hours. No specific pharmacologic agent has been found to improve neurologic outcome following cardiac arrest.

Treatment of cardiac and respiratory arrest is an integral part of anesthesia practice. The American Board of Anesthesiology indicates in its *Booklet of Information* that the "clinical management and teaching of cardiac and pulmonary resuscitation" are some of the activities that define the specialty of anesthesiology. The cardiopulmonary physiology and pharmacology that form the basis of anesthesia practice are applicable to treating the victim of cardiac arrest. However, there is specialized knowledge relating to blood flow, ventilation, and pharmacology under the conditions of a cardiac arrest that must be understood to maintain leadership of the modern cardiopulmonary resuscitation (CPR) team. This chapter concentrates on those aspects of CPR that are different from the more common circumstances requiring cardiovascular support (e.g., shock, dysrhythmias).

HISTORY

Anesthesiologists have contributed many of the elements of modern CPR and continue to be active investigators and teachers in the field. Discoveries leading to current CPR practice have a long history recorded in many famous works.[1,2] The earliest reference may be the Bible story of Elisha breathing life back into the son of a Shunammite woman (II Kings 4:34). In 1543, Andreas Vesalius described tracheotomy and artificial ventilation.[3] William Harvey's manual manipulation of the heart is well known. Early teaching of resuscitation was organized by the Society for the Recovery of Persons Apparently Drowned, founded in London in 1774. The combined techniques of modern CPR developed primarily from the

fortuitous assemblage of innovative clinicians and researchers in Baltimore in the 1950s and early 1960s. Building on the long history of contributions from around the world, these investigators laid the framework for current CPR practice. In the late 1950s, mouth-to-mouth ventilation was established as the only effective means of artificial ventilation.[4,5,6,7] The internal defibrillator was developed in 1933,[8] but it was not applied successfully until 1947.[9] It was another decade before general use was made possible by the development of external cross-chest defibrillation.[10,11] Despite these advances, widespread resuscitation from cardiac arrest was not possible until Kouwenhoven et al described success with closed-chest cardiac massage in a series of patients.[12] The final major component of modern CPR was added in 1963, when Redding and Pearson described the improved success obtained by administering epinephrine or other vasopressor drugs.[13]

SCOPE OF THE PROBLEM

Cardiovascular disease remains the most common cause of death in the industrialized world. Although cardiovascular mortality has been declining in the United States since the mid-1960s, nearly 50% of all deaths are due to cardiovascular causes.[14] Of the 1 million annual cardiovascular deaths, approximately half are related to coronary artery disease and the majority of these are

sudden deaths. Thus, CPR teaching and research tend to focus on myocardial ischemia as the primary cause of cardiac arrest. However, anesthesiologists are more likely than other practitioners to deal with etiologies other than myocardial infarction. CPR is symptomatic therapy, aimed at sustaining vital organ function until natural cardiac function is restored. The details of effective resuscitation technique are important. However, search for a remediable cause of the arrest must not be lost in excessive attention to mechanics.

Brain adenosine triphosphate (ATP) is depleted after 4 to 6 minutes of no blood flow. It returns nearly to normal within 6 minutes of starting effective CPR. Studies in animals suggest that good neurologic outcome may be possible from 10- to 15-minute periods of normothermic cardiac arrest if good circulation is promptly restored.[15,16] In clinical practice, the severity of the underlying cardiac disease is the major determining factor in the success or failure of resuscitation attempts. Of those factors under control of the rescuers, poor outcomes are associated with long arrest times before CPR is begun, prolonged ventricular fibrillation without definitive therapy, and inadequate coronary and cerebral perfusion during cardiac massage. Survival from out-of-hospital cardiac arrest is improved when CPR is begun by bystanders.[17] Optimum outcome from ventricular fibrillation is obtained only if basic life support is begun within 4 minutes of arrest and defibrillation applied within 8 minutes.[18,19] The importance of early defibrillation has been known for some time and is emphasized in CPR practice.[20,21] What is not as well recognized is the tendency to interrupt chest compressions frequently during a resuscitation attempt. Studies of emergency medical systems suggest that chest compressions are performed for less than 50% of the time during a typical out-of-hospital resuscitation, being interrupted for pulse checks, intubations, starting intravenous catheters, defibrillation attempts, and moving the victim. Because blood flow falls rapidly with cessation of compressions and resumes slowly with reinstitution of compressions, these interruptions undoubtedly contribute to the poor survival rates.

With an effective rapid response emergency medical system, initial resuscitation rates of 40% and survival to hospital discharge of 10 to 15% are reported after out-of-hospital arrests.[19,21] A better outcome might be expected for in-hospital arrests because of rapid response times and expert personnel. However, overall rates for initial resuscitation and survival to discharge from in-hospital arrest are about 40% and 10%, respectively.[22] Intercurrent illnesses of hospitalized patients reduce the likelihood of survival and the arrest victim is more likely to be elderly, a factor that may reduce survival. Within the hospital, the operating room is the location where CPR has the highest rate of success. Cardiac arrest occurs approximately 7 times for every 10,000 anesthetics.[23] The cause for the arrest is anesthesia related, ~4.5 times for every 10,000 anesthetics, but mortality from these arrests is only 0.4 per 10,000 anesthetics. Thus, resuscitation is successful ~90% of the time in anesthesia-related cardiac arrests. Outside the operating suite, the best initial resuscitation rates are found in the intensive care unit (ICU), whereas the best survival rates are for patients arresting in the emergency department.[22]

ORGANIZING A SOLUTION

Since the mid-1970s, CPR has become widely practiced, facilitated by the efforts of the American Heart Association, the International Red Cross, the European Resuscitation Council, and many other organizations around the world. Specific guidelines for the teaching and practice of CPR are published periodically.[24] These guidelines were developed because numerous individuals with varying levels of expertise (laypersons, emergency personnel, nurses, and physicians) need to be trained if CPR is to be effective in saving lives. For training to be effective, a standardized approach is needed (Table 58-1). The organizations also develop and sponsor courses at different levels of complexity for teaching CPR. The two levels of CPR care are referred to as basic life support (BLS) for ventilation and chest compressions without additional equipment, and advanced cardiac life support (ACLS) for using all modalities available for resuscitation. Medical personnel need to be well versed in both levels of care. BLS is also appropriate for laypersons.

TABLE 58-1 Standard Approach to the Unconscious Patient

1. Determine unresponsiveness.
2. Activate emergency medical services or team.
3. Position victim supine on firm surface.
4. Open airway.
5. Determine absence of breathing.
6. Perform ventilation by giving 2 breaths.
7. Determine absence of pulse.
8. Initiate chest compressions.
9. Alternate 15 compressions with 2 breaths.

The American Heart Association, in conjunction with the International Liaison Committee on Resuscitation (ILCOR), periodically coordinates an International Conference on CPR and emergency cardiac care, during which worldwide experts evaluate the scientific data regarding CPR. The recommendations resulting from the conference comprise the most complete compilation of guidelines for CPR practice.[24] International contributions to the most recent conferences in 1992 and 2000 produce similar CPR practices worldwide. However, no common infrastructure exists that allows adoption of true international guidelines for CPR. The algorithms for approaching the patient with cardiac arrest published in the guidelines are familiar to all physicians and are reproduced throughout this chapter. However, the major purpose of this chapter is not

to reiterate the standard approach but to provide the scientific background, where it exists, that led to adoption of the standard approach; to point out areas of continuing controversy; and to suggest areas of possible future development.

ETHICAL ISSUES: DO NOT RESUSCITATE ORDERS IN THE OPERATING ROOM

Institution of CPR is standard medical care when an individual is found to be apparently dead. In more recent years, terminally ill patients have become increasingly concerned about inappropriate application of life-sustaining procedures, including CPR. Through living wills and other instruments, patients have begun placing limitations on medical treatment to include do not resuscitate (DNR) orders. Such requests are generally accepted, even welcomed, by health care workers. However, the operating room is one area of the hospital where DNR orders continue to cause ethical conflicts between medical personnel and patients.[25,26] There are ethically sound arguments on both sides of the issue as to whether DNR orders should be upheld in the operating room.

The patient's right to limit medical treatment, including refusing CPR, is firmly established in modern medical practice based on the ethical principle of respect for patient autonomy. A terminally ill patient can reject heroic measures such as resuscitation and still choose palliative therapy. If a surgical intervention will ameliorate symptoms or cure a problem that improves quality of life, there is no reason to withhold this treatment. During surgery, the patient reasonably may want to maintain the DNR status to avoid heroic measures that serve only to prolong death. Operative intervention increases the risk of cardiac arrest, and the patient may not want the burden of surviving in a worse condition than previously. Thus, the time that the DNR order provides the greatest protection against unwanted intervention is during surgery. The possibility of death under anesthesia may be viewed as especially peaceful.

Despite these rather strong arguments for treating a DNR status in the operating room the same way it is treated elsewhere in the hospital, most operating room personnel are at least a little uneasy caring for these patients. Many surgeons require that DNR orders be suspended during the

perioperative period or assume consent to surgery includes such suspension. There are multiple reasons for the reluctance to accept DNR status during surgery and anesthesia. Approximately 75% of cardiac arrests in the operating room are related to a surgical or anesthetic complication, and resuscitative attempts are highly successful.[23] Ethically, surgeons and anesthesiologists feel responsible for what happens to patients in the operating room: primum non nocere (first, do no harm). Although the physicians are highly diligent in monitoring and managing changes in the patient's status, complications and arrests do occur. Honoring a DNR under these circumstances is frequently viewed as failure to treat a reversible process, and hence, tantamount to killing. This is an ethically sound view if the cause of arrest is readily identifiable and easily reversible, and if treatment is likely to allow the patient to fulfill the objectives of coming to surgery.[25]

Institutionally, these ethical conflicts should be addressed by adoption of clear policies by hospitals.[27] For the individual patient, conflicts can be resolved by communication among the patient, family, and caregivers. A mutual decision can often be reached to suspend or severely limit a DNR order in the perioperative period if the patient understands the special circumstances of perioperative arrest, that interventions are brief and usually successful, and that the physicians support the patient's goals in coming to surgery and values in desiring not to prolong death. Many interventions commonly used in the operating room (mechanical ventilation, vasopressors, antidysrhythmics, blood products) may be considered forms of resuscitation in other situations. The only modalities that are not routine anesthetic care are cardiac massage and defibrillation. Therefore, the specific interventions included in a DNR status must be clarified with specific allowance made for methods necessary to perform anesthesia and surgery.

BASIC LIFE SUPPORT

BLS consists of those elements of resuscitation that can be performed without additional equipment: basic airway management, rescue breathing, and manual chest compressions. Common practice is to approach a victim with the airway, breathing, and circulation (ABC) sequence, although the circulation, airway, and breathing (CAB) sequence has been used in some countries with comparable results. Table 58-1 itemizes the standard approach to an unconscious victim.

Airway Management

The problem of airway obstruction by the tongue in the unconscious patient is familiar to the anesthesiologist. The techniques used for airway maintenance during anesthesia are applicable to the cardiac arrest victim. The primary method recommended to the public is the same "head tilt–chin lift" method commonly employed in the operating room.[28] The head is extended by pressure applied to the brow while the mandible is pulled forward by pressure on the front of the jaw, lifting the tongue away from the posterior pharynx. The "jaw thrust" maneuver (applying pressure behind the rami of the mandible) is an effective alternative. Properly inserted oropharyngeal or nasopharyngeal airways can be useful before intubation, recognizing the danger of inducing vomiting or laryngospasm in the semiconscious victim. Tracheal intubation provides the best airway control, preventing aspiration and allowing the most effective ventilation. Intubation is indicated in any resuscitation lasting more than a few minutes, but it should not be performed until adequate ventilation (preferably with supplemental oxygen) and chest compressions have been established. A number of alternative airways designed for blind placement by individuals who are not skilled laryngoscopists have been described.[24] These include the laryngotracheal mask, pharyngotracheal lumen airway, esophageal obturator airway, esophageal gastric tube airway, and combination esophageal tracheal tube. None ensures airway control as well as an endotracheal tube. When other methods of establishing an airway are unsuccessful, translaryngeal ventilation or tracheotomy by cricothyroid puncture may be necessary.

Foreign Body Airway Obstruction

It is estimated that foreign body airway obstruction accounts for 1% of all sudden deaths (~3,900 deaths in the United States in 1989).[24] Airway occlusion by a foreign object must be considered in any victim who suddenly stops breathing and becomes cyanotic and unconscious. It occurs most commonly during eating and is usually due to food, especially meat, impacting in the laryngeal

inlet, at the epiglottis or in the vallecula. Sudden death in restaurants from this cause is frequently mistaken for myocardial infarction, leading to the label "cafe coronary." Poorly chewed pieces of food, poor dentition or dentures, and elevated blood alcohol are the most common factors contributing to choking. The signs of total airway obstruction are the lack of air movement despite respiratory efforts and the inability of the victim to speak or cough. Cyanosis,

unconsciousness, and cardiac arrest follow quickly. Partial airway obstruction will result in rasping or wheezing respirations accompanied by coughing. If the victim has good air movement and is able to cough forcefully, no intervention is indicated. However, if the cough weakens or cyanosis develops, the patient must be treated as if there were complete obstruction.

Mothers and friends have been pounding on the backs of choking victims for centuries. In 1974, Heimlich proposed abdominal thrusts as a better method of relieving airway obstruction and, in 1976, Guildner et al reported that sternal thrusts were just as effective.[29,30] Subsequently, there were multiple studies of these maneuvers. In clinical practice, Redding[31] observed that no maneuver was always successful and that each occasionally was successful when another had failed. To minimize confusion from teaching multiple techniques (especially to the lay public), the American Heart Association has elected to emphasize the abdominal thrust maneuver (with chest thrusts as an alternative for the pregnant and massively obese) and the finger sweep.[24] This recommendation is made on the twofold premise that the abdominal thrust is at least as effective as other techniques and that teaching one method simplifies education.

For the awake victim, abdominal thrusts are applied in the erect position (sitting or standing). The rescuer reaches around the victim from behind, placing the fist of one hand in the epigastrium between the xiphoid and umbilicus. The fist is grasped with the other hand and pressed into the epigastrium with a quick upward thrust. In the unconscious, thrusts are applied by kneeling astride the victim, placing the heel of one hand in the epigastrium and the other on top of the first. Care must be taken to ensure the xiphoid is not pushed into the abdominal contents and that the thrust is in the midline. Sternal thrusts are valuable in the massively obese or in women in advanced pregnancy. In the erect victim, the chest is encircled from behind as in the abdominal maneuver but the fist is placed in the midsternum. For the unconscious, thrusts are applied from the side of the supine victim with a hand position the same as for external cardiac compression. Back blows are applied directly over the thoracic spine between the scapulae. They must be delivered with force. Placing the victim in a head-down position (e.g., leaning over a chair) may help move the obstruction into the pharynx.

Whatever technique is used, each individual maneuver must be delivered as if it will relieve the obstruction. If the first attempt is unsuccessful, repeated attempts should be made because hypoxia-related muscular relaxation may eventually allow success. Complications of thrust maneuvers include laceration of the liver and spleen, gastric rupture, fractured ribs, and regurgitation.

In the unconscious victim, if these maneuvers are unsuccessful, manual dislodgment of the obstruction should be tried. The mouth is opened, and the tongue and jaw are grasped between the thumb and fingers and pulled forward. A finger of the other hand is inserted along the buccal mucosa, attempting to dislodge the object laterally. Care must be taken not to push the foreign body deeper into the larynx. Direct visualization of the object may also be successful. In the absence of a laryngoscope and Magill forceps, ordinary instruments (e.g., a tablespoon and ice tongs) may be used. However, blind grasping with instruments is rarely successful and may cause damage to tonsils or other tissue. Finally, if the object cannot be dislodged, a cricothyroidotomy can be lifesaving.

Ventilation

2 The standard approach to the unresponsive victim is to follow opening the airway with ventilation (see Table 58-1). If the airway remains patent, chest compressions cause substantial air exchange. Early studies in anesthetized humans suggested that the airway would not remain open in the unconscious,[6,7] leading to the teaching that airway control and artificial

ventilation must accompany chest compressions. However, data from the Belgian CPCR Registry have demonstrated that 14-day survival and neurologic outcome are the same if bystanders initiate full BLS or do only chest compressions. Both lead to substantially better survival than if the bystanders do only mouth-to-mouth ventilation or do not attempt CPR.[32,33] Studies in the more controlled setting of the animal laboratory also raise questions about the importance of ventilation during assisted ventilation during the first 10 minutes of BLS. A cumulative series of more than 170 swine in ventricular fibrillation have been studied, and no differences in 24- to 48-hour survival or neurologic outcome have been found between those provided with assisted ventilation and those not provided with assisted ventilation during simulated bystander CPR prior to the application of ACLS.[34,35,36,37] Another study using an asphyxial cardiac arrest model found a markedly improved 24-hour outcome when ventilation was added to chest compressions during BLS.[38] These observations suggest that when arrest is witnessed, likely to be of cardiac (rather than respiratory) cause, and when intubation is available within a short time, closed-chest compressions alone may be as efficacious as compressions and mouth-to-mouth ventilation. If these preliminary studies are confirmed, BLS teaching could be considerably simplified, potentially resulting in improved rates of bystander CPR because studies show that many people are reluctant to provide mouth-to-mouth ventilation.[39,40,41] Currently, airway management and ventilation remain the standard first steps of CPR. Mouth-to-mouth or mouth-to-nose ventilation is the most expeditious and effective method immediately available. Although inspired gas with this method will contain ~4% carbon dioxide and only ~17% oxygen (composition of exhaled air), it is sufficient to maintain viability.

Physiology of Ventilation During Cpr

In the absence of an endotracheal tube, the distribution of gas between the lungs and stomach during mouth-to-mouth or mask ventilation will be determined by the relative impedance to flow into each (i.e., the opening pressure of the esophagus and the lung-thorax compliance). It is likely that esophageal opening pressure during cardiac arrest is no more than that found in anesthetized individuals (~20 cm H_2O), and lung-thorax compliance is likely reduced. To avoid gastric insufflation, inspiratory airway pressures must be kept low.

Insufflation of air into the stomach during CPR leads to gastric distension, impeding ventilation and increasing the risk of regurgitation and gastric rupture. Avoiding gastric insufflation requires that peak inspiratory airway pressures stay below esophageal opening pressure. Partial airway obstruction by the tongue and pharyngeal tissues is a major cause of increased airway pressure contributing to gastric insufflation during CPR. Meticulous attention to airway management is necessary during rescue breathing. Recommended tidal volumes to cause a noticeable rise in the chest wall in most adults is 0.8 to 1.2 L. To achieve these tidal volumes with low inspiratory pressures, a slow inspiratory flow rate and long inspiratory time are needed, even with an open airway. Therefore, rescue breaths should be given over 1.5 to 2 seconds during a pause in chest compressions.

A useful adjunct for preventing gastric insufflation during positive-pressure ventilation without an endotracheal tube is cricoid pressure (Sellick maneuver).[42] Properly applied pressure to the anterior arch of the cricoid causes the cricoid lamina to seal the esophagus and can prevent air from entering the stomach at airway pressures up to 100 cm H_2O.[43] Pressure on the thyroid cartilage is useless. Cricoid pressure should be used during rescue breathing without an endotracheal tube, but this inevitably involves the need for an additional rescuer.

Techniques of Rescue Breathing

While maintaining an open airway with the head tilt–jaw lift technique, the hand on the forehead pinches the nose, the rescuer takes a deep breath and seals the victim's mouth with the lips and exhales, watching for the chest to rise, indicating effective ventilation. For exhalation, the rescuer's mouth is removed from the victim, listening for escaping air and taking a breath. When both hands are being used in the jaw thrust maneuver of opening the airway, the cheek is used to seal the nose. For mouth-to-nose ventilation, the rescuer's lips surround the nose and the victim's

lips are held closed. In some patients, the mouth must be allowed to open for exhalation with this technique. On initiation of resuscitation, two consecutive breaths should be given and breathing continued at a rate of 10 to 12 minutes^{-1}. During a one-rescuer CPR, a pause for two breaths should be made after each 15 chest compressions. When there are two rescuers, a 1.5- to 2-second pause after every fifth chest compression will allow a breath to be given. Exhalation can occur during subsequent compressions.

Several adjuncts to ventilation are available. An oropharyngeal airway with mouthguard and external extension mouthpiece has been used, but obtaining a good mouth seal is often difficult. Perhaps the most useful adjunct is a common mask, such as that used for anesthesia. The mask can be applied to the face and held in place with the thumbs and index fingers while the other fingers are used to apply jaw thrust. Breathing into the connector port of the mask provides ventilation. Mouth-to-mask ventilation may be more aesthetic than mouth-to-mouth ventilation and can be just as effective in trained hands. Masks are also available with one-way valves that direct the victim's exhaled gas away from the rescuer. Masks with integral nipple adapters are useful for providing supplemental oxygen. An oxygen flow of 10 L/min can raise the inspired concentration to 50%.

The self-inflating resuscitation bag and mask are the most common adjuncts used in rescue vehicles and hospitals. Although these devices have the advantages of noncontact and ability to use supplemental oxygen, they have been shown to be difficult for a single rescuer to apply properly, preventing substantial gas leak while maintaining a patent airway.[44] Tidal volumes with mouth-to-mouth and mouth-to-mask ventilation are often greater than with the resuscitation bag. It is now recommended that if this device is to be used, two individuals manage the airway: one to hold the mask and maintain head position, and one to squeeze the bag using both hands.[45] Finally, tracheal intubation provides the best control of ventilation. With a tube in place, breathing can proceed without concern for gastric distension or synchronizing ventilation with chest compressions. Blood flow during CPR slows rapidly when chest compressions are stopped and recovers slowly when they are resumed. Consequently, following intubation, no pause should be made for ventilation, and ventilation should be delivered without regard for the compression cycle.

Circulation

Physiology of Circulation During Closed-Chest Compression

Two theories of the mechanism of blood flow during closed-chest compression have been suggested.[12,46] They are not mutually exclusive, and which theory predominates in humans continues to be the subject of controversy.

Cardiac Pump Mechanism. The cardiac pump mechanism was originally proposed by Kouwenhoven et al.[12,47] According to this theory, pressure on the chest compresses the heart between the sternum and the spine. Compression raises the pressure in the ventricular chambers, closing the atrioventricular valves and ejecting blood into the lungs and aorta. During the relaxation phase of closed-chest compression, expansion of the thoracic cage causes a subatmospheric intrathoracic pressure, facilitating blood return. The mitral and tricuspid valves open, allowing blood to fill the ventricles. Pressure in the aorta causes aortic valve closure and coronary artery perfusion.

Thoracic Pump Mechanism. In 1976, Criley et al[48] reported a patient undergoing cardiac catheterization who simultaneously developed ventricular fibrillation and an episode of cough-hiccups. With every cough-hiccup, a significant arterial pressure was noted. This observation of self-administered "cough CPR" prompted further investigations on the mechanism of blood flow, and these studies produced the theory of a thoracic pump mechanism for blood flow during closed-chest compressions.[46] According to this theory, blood flows into the thorax during the relaxation phase of chest compressions in the same manner as that described for the cardiac pump mechanism. During the compression phase, all intrathoracic structures are compressed equally by the rise in intrathoracic pressure caused by sternal depression, forcing blood out of the chest. Backward flow through the venous system is prevented by valves in the subclavian and internal

jugular veins, and by dynamic compression of the veins at the thoracic outlet by the increased intrathoracic pressure. Thicker, less compressible vessel walls prevent collapse on the arterial side, although arterial collapse will occur if intrathoracic pressure is raised enough.[49] The heart is a passive conduit with the atrioventricular valves remaining open during chest compression. Because there is a significant pressure difference between the carotid artery and jugular vein, blood flow to the head is favored. The lack of valves in the inferior vena cava results in less resistance to backward flow, and pressures in the arteries and veins below the diaphragm are nearly equal. This is consistent with the fact that there is little blood flow to organs below the diaphragm.[50,51]

It seems clear that fluctuations in intrathoracic pressure plays a significant role in blood flow during CPR. It is also likely that compression of the heart occurs under some circumstances. Factors that influence the mechanism probably include the compliance and configuration of the chest wall, size of the heart, force of the sternal compressions, duration of cardiac arrest, and other undiscovered factors. Which mechanism predominates varies from victim to victim and even during the resuscitation of the same victim.

Distribution of Blood Flow During Cpr. Whatever the predominant mechanism, total body blood flow (cardiac output) is reduced to 10 to 33% of normal during experimental closed-chest cardiac massage. Similar severe reductions in flow are likely during clinical CPR in humans. Nearly all the blood flow is directed to organs above the diaphragm.[50,51] Myocardial perfusion is 20 to 50% of normal, whereas cerebral perfusion is maintained at 50 to 90% of normal. Abdominal visceral and lower-extremity flow is reduced to 5% of normal. Total flow tends to decrease with time during CPR, but the relative distribution is not altered. Changes in CPR technique and the use of epinephrine may help sustain cardiac output over time.[51] Epinephrine improves flow to the brain and heart, whereas flow to organs below the diaphragm is unchanged or further reduced.

Gas Transport During Cpr. During the low flow state of CPR, excretion of carbon dioxide (CO_2) (mL of CO_2/minute in exhaled gas) is decreased from prearrest levels to approximately the same extent as cardiac output is reduced. This reduced CO_2 excretion is due primarily to shunting of blood flow away from the lower half of the body. The exhaled CO_2 reflects only the metabolism of the part of the body that is being perfused. In the nonperfused areas, CO_2 accumulates during CPR. When normal circulation is restored, the accumulated CO_2 is washed out, and a temporary increase in CO_2 excretion is seen.

Although CO_2 excretion is reduced during CPR, measurement of blood gases reveals an arterial respiratory alkalosis and a venous respiratory acidosis with a markedly elevated arteriovenous CO_2 difference.[52,53] The primary cause of these changes is the severely reduced cardiac output. Two factors account for the elevation of the venous partial pressure of CO_2 ($PvCO_2$). Buffering acid causes a reduction in serum bicarbonate so the same blood CO_2 content results in a higher $PvCO_2$. In addition, the mixed venous CO_2 content is elevated. When flow to a tissue is reduced, all the CO_2 produced fails to be removed and CO_2 accumulates, raising the tissue partial pressure of CO_2. This allows more CO_2 to be carried in each aliquot of blood and mixed venous CO_2 content increases. If flow remains constant, a new equilibrium is established where all CO_2 produced in the tissue is removed but at a higher venous CO_2 content and partial pressure. In contrast to the venous blood, arterial CO_2 content and partial pressure ($PaCO_2$) are usually reduced during CPR. This reduction accounts for most of the observed increase in arteriovenous CO_2 content difference. Even though venous blood may have an increased CO_2, the marked reduction in cardiac output with maintained ventilation results in efficient CO_2 removal.

Decreased pulmonary blood flow during CPR causes lack of perfusion to many nondependent alveoli. The alveolar gas of these lung units has no CO_2. Consequently, mixed alveolar CO_2 (i.e., end-tidal CO_2) will be low and correlate poorly with arterial CO_2. However, end-tidal CO_2 does correlate well with cardiac output during CPR. As flow increases, more alveoli become perfused, there is less alveolar dead space, and end-tidal CO_2 measurements rise.

Technique of Closed-Chest Compression

In an unconscious apneic patient, cardiac arrest must be assumed in the absence of a pulse in a major artery (carotid, femoral, axillary). Because a systolic pressure of ~50 mm Hg is necessary for a palpable pulse, some circulation may remain in the "pulseless" patient with primary respiratory arrest. Opening the airway and ventilation may be sufficient for resuscitation in such circumstances. Therefore, further search for a pulse should always be made following artificial ventilation and before beginning sternal compressions.

Important considerations in performing closed-chest compressions are the position of the rescuer relative to the victim, the position of the rescuer's hands, and the rate and force of compression. The victim must be supine, the head level with the heart, for adequate brain perfusion. The victim must be on a firm surface. The rescuer should stand or kneel next to the victim's side. Compressions are performed most effectively if the rescuer's hips are on the same level, or slightly above the level of, the victim's chest.

Standard technique consists of the rhythmic application of pressure over the lower half of the sternum. The heel of one hand is placed on the lower sternum, and the other hand is placed on top of the first. Great care must be taken to avoid pressing the xiphoid into the abdomen, which can lacerate the liver. Even with properly performed CPR, costochondral separation and rib fractures are common. Applying pressure on the ribs by improper hand placement increases these complications and risks puncturing the lung. Pressure on the sternum should be applied through the heel of the hand only, keeping the fingers free of the chest wall. The direction of force must be straight down on the sternum, with the arms straight and the elbows locked into position so the entire weight of the upper body is used to apply force. During relaxation, all pressure should be removed from the hands, but they should not lose contact with the chest wall.

The sternum must be depressed 3.5 to 5.0 cm in the average adult. Occasionally, deeper compressions are necessary to generate a palpable pulse. The duration of compression should be equal to that of relaxation, and the compression rate should be 80 to 100 times/min. This rate seems to be optimal for both possible mechanisms of blood flow. The faster rate makes it easier to maintain a 50% compression–relaxation ratio, important in the thoracic pump mechanism. It also requires a rapid, more forceful compression that may be important in the cardiac pump mechanism.[70] A fast rate also allows time to pause for ventilations. With a single rescuer, two ventilations should be given following every 15 compressions. With two rescuers, a 1.5- to 2.0-second pause for ventilation should occur every 5 compressions. With an endotracheal tube in place, ventilations at a rate of 12 breaths/min should be interposed between compressions without a pause.

Alternative Methods of Circulatory Support

3 As currently practiced, CPR has limited success, with only ~40% of victims being admitted to the hospital and 10% surviving to discharge. Despite the occasional success of prolonged resuscitation, standard CPR will sustain most patients for only 15 to 30 minutes. If return of spontaneous circulation has not been achieved in that time, the outcome is dismal. Recognition of these limits and improved understanding of circulatory physiology during CPR have led to several proposals for alternatives to the standard techniques of closed-chest compression. Most, but not all, are based on the thoracic pump mechanism of blood flow. The goals of the new methods are to provide better hemodynamics during CPR and thus improve survival and/or to extend the duration during which CPR can successfully support viability. Unfortunately, none of the alternatives has proved reliably superior to the standard technique.

Simultaneous Ventilation–Compression Cpr and Abdominal Binding. According to the thoracic pump theory, elevation of intrathoracic pressure during chest compression should improve blood flow and pressure.[49] Initial studies with techniques that raise intrathoracic pressure (abdominal binding, simultaneous ventilation/compression) were encouraging because the increased aortic pressure suggested better myocardial and cerebral perfusion.[54,55] Subsequent investigations have demonstrated that right atrial pressure and intracranial pressure are elevated as much as, or more than, the arterial pressures.[56,57,58,59] Thus, no improvement in myocardial or cerebral blood flow is found. Most important, survival from cardiac arrest is not improved when

these techniques are compared with standard CPR in experimental animals or limited human trials.[59,60,61,62,63]

Interposed Abdominal Compression Cpr. Interposed abdominal compression (IAC) is fundamentally different from abdominal binding. With this technique, an additional rescuer applies abdominal compressions manually during the relaxation phase of chest compression.[64] Abdominal pressure is released when chest compression begins.[65] One large randomized trial of out-of-hospital cardiac arrest with IAC CPR found no improvement in survival compared with standard CPR,[66] but a subsequent in-hospital study demonstrated improved outcome.[67] The safety of IAC CPR has been established and is recommended as an alternative to standard CPR for in-hospital resuscitation. Further studies will be needed to establish out-of-hospital efficacy.

Pneumatic Vest Cpr. Following the description of "cough CPR" and the development of the thoracic pump theory, a pneumatic vest device was developed that would simulate the events of vigorous coughing.[68,69] With the original method, thoracic and abdominal vests containing pneumatic bladders inflate simultaneously with positive-pressure ventilation. The technique continues to be investigated with a number of modifications from the original method. In a preliminary clinical study, aortic and coronary perfusion pressure was better with

the vest than with standard CPR, but survival was not significantly improved.[70] Randomized human trials are now being conducted.

Active Compression–Decompression Cpr. The newest proposed alternative technique developed from the anecdotal report of CPR performed with a plumber's helper applied to the anterior chest wall.[71] This suggested that active decompression of the chest wall might reduce intrathoracic pressure during the relaxation phase of chest compressions, leading to improved venous return, increased stroke volume with compression, and better blood flow. A suction device that can be applied to the chest wall to enable active compression and decompression was developed.[72] Hemodynamic studies in animals and humans with this technique have shown that coronary and cerebral perfusion may be somewhat improved with this method compared with standard CPR, although when epinephrine is used there is no difference between techniques.[72,73] Early clinical trials of this technique were discouraging, but more recent reports have had conflicting results.[74,75,76] A large randomized trial in France found improved outcome in out-of-hospital arrest.[77] However, a large study in Canada involving in-hospital and out-of-hospital arrests found no difference in immediate resuscitation or survival.[78]

Invasive Techniques. In contrast to the closed-chest techniques, two invasive methods have been able to maintain cardiac and cerebral viability during long periods of cardiac arrest. In animal models, open-chest cardiac massage and cardiopulmonary bypass (through the femoral artery and vein using a membrane oxygenator) can provide better hemodynamics, as well as better myocardial and cerebral perfusion, than closed-chest techniques.[57,79] Preliminary trials of percutaneous cardiopulmonary bypass for refractory human cardiac arrest have been reported.[80,81,82] Prompt restoration of blood flow and perfusion pressure with cardiopulmonary bypass can provide resuscitation with minimal neurologic deficit after 20 minutes of fibrillatory cardiac arrest in canines.[15] However, these techniques must be instituted relatively early (probably within 20 to 30 minutes of arrest) to be effective.[16,83] If open chest massage is begun after 30 minutes of ineffective closed-chest compressions, survival is no better even though hemodynamics are improved.[84] The need to apply these maneuvers early in an arrest obviously limits the application. Before invasive procedures play a greater role in modern CPR, a method must be developed to predict, early in resuscitation, which patients will and will not respond to closed-chest compressions.

Assessing the Adequacy of Circulation During Cpr

The adequacy of closed-chest compression is usually judged by palpation of a pulse in the carotid or femoral vessels. The palpable pulse primarily reflects systolic pressure. Cardiac output correlates better with mean pressure and coronary perfusion with diastolic pressure. In the femoral area, the palpable pulse is as likely to be venous as arterial. Despite these shortcomings,

palpating the pulse remains the only monitor available during BLS.

4 Return of spontaneous circulation with an arrested heart greatly depends on restoring oxygenated blood flow to the myocardium. In experimental models, a minimum blood flow of 15 to 20 mL/min/100 g of myocardium has been shown to be necessary for successful resuscitation.[85] Obtaining such flow depends on closed-chest compressions developing adequate cardiac output and coronary perfusion pressure. Similar to the beating heart, coronary perfusion during CPR occurs primarily in the relaxation phase (diastole) of chest compressions. In 1906, Crile and Dolley suggested that a critical coronary perfusion pressure was necessary for successful resuscitation.[86] This concept has been confirmed in numerous other reports.[51,85,86,87,88,89,90,91,92,93,94,95] During standard CPR, critical myocardial blood flow is associated with aortic diastolic pressure exceeding 40 mm Hg. Because right atrial pressure can be elevated with some techniques, the aortic diastolic pressure minus the right atrial diastolic pressure is a more accurate reflection of coronary perfusion pressure. The critical coronary perfusion pressure is 15 to 25 mm Hg. When invasive monitoring is available during CPR, adjustments in chest compression technique and epinephrine should be used to ensure critical perfusion pressures are exceeded. Damage to the myocardium from underlying disease may preclude survival no matter how effective the CPR efforts. However, vascular pressures below critical levels are associated with poor results even in patients who may be salvageable (Table 58-2).

TABLE 58-2 Critical Variables Associated with Successful Resuscitation

▪VARIABLE	▪AMOUNT
Mycocardial blood flow (mL/min/100 g)	>15–20
Aortic diastolic pressure (mm Hg)	>40
Coronary perfusion pressure (mm Hg)	>15–25
End-tidal carbon dioxide (mm Hg)	>10

Although invasive pressure monitoring may be ideal, it is rarely available during CPR. End-tidal CO_2 also has been found to be an excellent noninvasive guide to the adequacy of closed-chest compressions.[96] Carbon dioxide excretion during CPR with an endotracheal tube in place is flow dependent rather than ventilation dependent. Because alveolar dead space is large in low-flow states, end-tidal CO_2 is very low (frequently <10 mm Hg). If blood flow improves with better CPR technique, more alveoli are perfused and end-tidal CO_2 rises (usually to >20 mm Hg with successful CPR). The earliest sign of return of spontaneous circulation is frequently a sudden increase in end-tidal CO_2 to >40 mm Hg. Within a wide range of cardiac outputs during CPR, end-tidal CO_2 correlates well with cardiac output,[97] coronary perfusion pressure,[98] and initial resuscitation.[99] End-tidal CO_2 correlates with survival in human CPR and can predict outcome.[100,101] Patients with end-tidal CO_2 <10 mm Hg will not be resuscitated successfully. In the absence of invasive monitoring, end-tidal CO_2 should be used to judge the effectiveness of chest compressions, whenever possible.[102] Attempts should be made to maximize the measured end-tidal CO_2 by alterations in technique or drug therapy. It should be remembered that sodium bicarbonate administration liberates CO_2 into the blood and causes a temporary increase in end-tidal CO_2. The elevation returns to baseline within 3 to 5 minutes of drug administration and end-tidal CO_2 monitoring can again be used for monitoring effectiveness of closed-chest compressions.

ADVANCED CARDIAC LIFE SUPPORT

ACLS encompasses all the cognitive and technical skills that are necessary to restore spontaneous circulatory function when simple support does not result in resuscitation. In addition to BLS skills, it includes use of adjunctive equipment and techniques for assisting ventilation and circulation, electrocardiogram (ECG) monitoring with dysrhythmia recognition and defibrillation, establishment of intravenous access, and pharmacologic therapy. A number of aspects of ACLS have been discussed in previous sections. The following sections concentrate on electrical and drug treatment, as well as the generalized

ACLS algorithms. Figure 58-1 demonstrates the universal algorithm for adult emergency cardiac care.

2000.)

Defibrillation

Electrical Pattern and Duration of Ventricular Fibrillation

Ventricular fibrillation is the most common ECG pattern found during cardiac arrest in adults. The only consistently effective treatment is electrical defibrillation. The most important controllable determinant of failure to resuscitate a patient with ventricular fibrillation is the duration of fibrillation.[103] Other important factors, such as underlying disease and metabolic status, are largely beyond the control of rescuers. The fibrillating heart has high oxygen consumption, increasing myocardial ischemia and decreasing the time to irreversible cell damage. The longer ventricular fibrillation continues, the more difficult it is to defibrillate and the less likely is successful resuscitation.[83,104] If defibrillation occurs within 1 minute of fibrillation, CPR is unnecessary for resuscitation. Initial resuscitation success following out-of-hospital fibrillation and survival to hospital discharge are improved the earlier that defibrillation is accomplished.[18,20,105]

The coarseness of the fibrillatory waves on the ECG may reflect the severity and duration of the myocardial insult, and thus, have prognostic significance.[106] However, the fibrillation amplitude seen on any one ECG lead varies with the orientation of that lead to the vector of the fibrillatory wave.[107] If the lead is oriented at right angles to the fibrillatory wave, a flat line can be seen. For this reason, the trace from a second lead or from a different position of paddle electrodes should always be inspected before a decision is made not to defibrillate. Low-*amplitude* fibrillatory waveforms are less likely to be associated with successful resuscitation and more likely to convert to asystole following defibrillation.[106] Similarly, low-*frequency* fibrillatory waveforms are associated with poor outcome, and the median frequency of the waveform correlates with myocardial perfusion during CPR and with success of defibrillation.[108,109] Catecholamines with β-adrenergic activity increase the vigor of fibrillation and the amplitude of the electrical activity, leading to the practice of administering epinephrine to make it "easier" to defibrillate. However, experimental work has shown that manipulation of the electrical pattern with epinephrine does not influence the success of defibrillation or reduce the energy needed for defibrillation.[104,110] Consequently, defibrillation should not be delayed for drug administration. The algorithm for managing ventricular fibrillation–tachycardia is illustrated in Fig. 58-2.

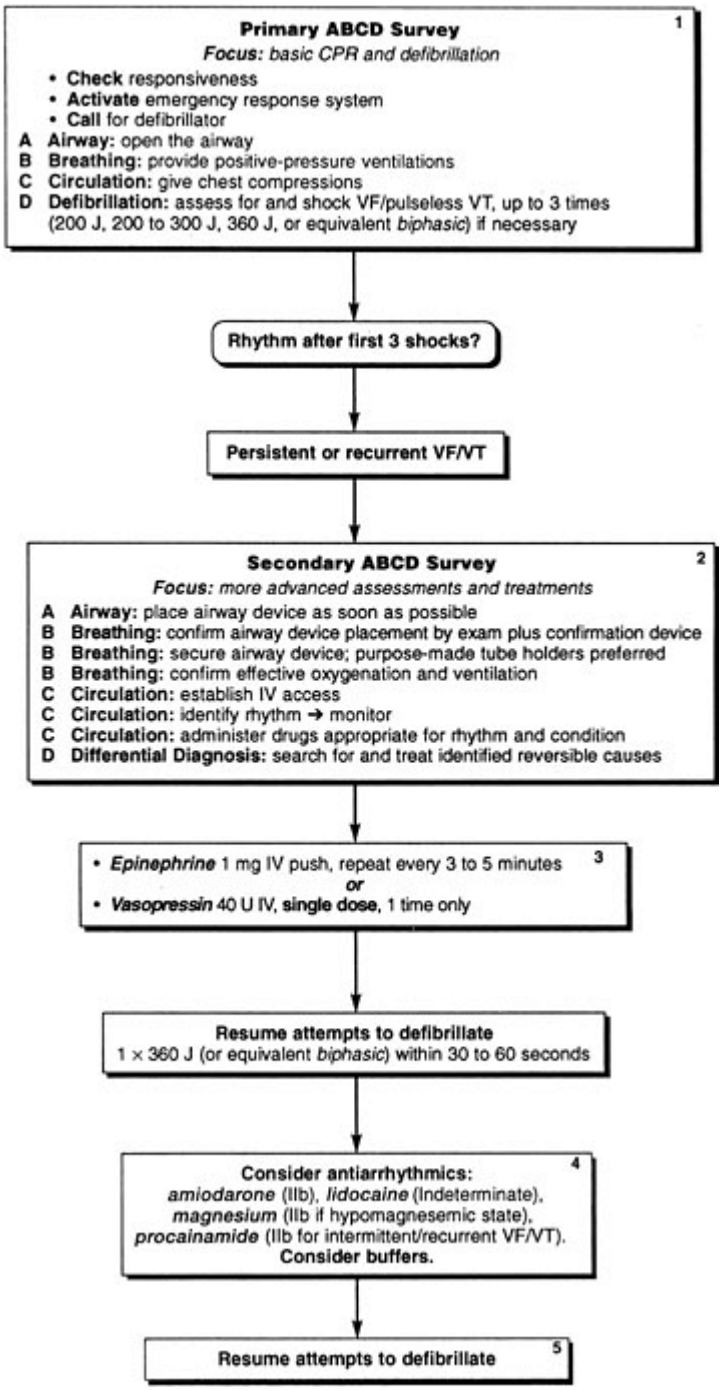

FIGURE 58-2. Ventricular fibrillation (VF)/pulseless ventricular tachycardia (VT) algorithm. CPR, cardiopulmonary resuscitation; IV, intravenous(ly). (Reprinted with permission from American Heart Association: Guidelines 2000 for cardiopulmonary resuscitation and emergency cardiovascular care: International consensus on science. Circulation 102:I-147, 2000.)

Current CPR guidelines recommend that defibrillation should not be postponed for any other therapy but should be carried out as soon as fibrillation is diagnosed and the equipment is available. The application of this principle has been made much easier by the development of automatic external defibrillators that recognize ventricular fibrillation, charge

automatically, and give a defibrillatory shock.[111] This device has allowed the introduction of public access defibrillation because minimally trained individuals can incorporate defibrillation into BLS skills, improving survival in out-of-hospital arrest by reducing time to delivery of the first shock.[18,19,20,21,112] The algorithms these devices use to detect ventricular fibrillation are accurate

with nearly perfect specificity. They will not defibrillate a nonfibrillatory rhythm. Sensitivity rates are somewhat lower. They sometimes have trouble recognizing low-amplitude ventricular fibrillation and can misinterpret pacemaker spikes as QRS complexes. Unfortunately, rhythm analysis can require up to 90 seconds during which chest compressions are not being given. This may adversely influence outcome in some circumstances. The improved success with public access defibrillation was dramatically demonstrated by the results of installing automatic external defibrillators (AEDs) in Chicago airports where, over the first 2 years, there was a 55% 1-year neurologically intact survival.[113] Similarly, when AEDs were installed in Las Vegas casinos and security personnel instructed in their use, there was a 53% survival to discharge (74% in patients who received the shock within 3 minutes of collapse).[114]

5 However, what if defibrillation is not really applied early after collapse? In the usual out-of-hospital rescue with emergency medical technicians or paramedics doing the defibrillation, a rapid response is to apply the first shock in 6 to 7 minutes and frequently it may be more than 10 minutes. In Seattle, it has been noted that patients who had CPR prior to defibrillation had a better survival, and the improvement was accounted for by better results in the group of patients in whom the response time was greater than 4 minutes.[115] In a randomized trial of 200 out-of-hospital cardiac arrests in Oslo, there was a highly significant improvement in outcome if CPR was provided before defibrillation when the response time was greater than 5 minutes.[116] Consequently, it now appears that immediate defibrillation is only effective if applied within 4 to 5 minutes of collapse. Otherwise, a brief period of 2 to 3 minutes of chest compressions before defibrillation is necessary. The precordial thump, although rarely successful, can be tried while awaiting a defibrillator. It should not be used for the conscious patient with ventricular tachycardia unless a defibrillator is immediately available. It is as likely to induce fibrillation as normal rhythm. Blind defibrillation should no longer be necessary because modern defibrillators have built-in monitoring capability using the paddles as electrodes.

Defibrillators: Energy, Current, and Voltage

Defibrillators derive power from a line source of alternating current or an integral battery. The typical defibrillator consists of a variable transformer that allows selection of a variable voltage potential, an AC/DC converter to provide a direct current that is stored in a capacitor, a switch to charge the capacitor, and discharge switches to complete the circuit from capacitor to electrodes. Until more recently, the current waveform of most clinically used defibrillators was a damped half-sinusoid, although some delivered trapezoidal or near-square waves. Implantable defibrillators use multipulse, multipathway defibrillation, but such techniques have had conflicting results in transthoracic defibrillation. Many newer defibrillators deliver a biphasic, truncated, exponential waveform for transthoracic defibrillation. This is the waveform used in AEDs and allows successful defibrillation at lower energies than MDS waveforms.[117]

Defibrillation is accomplished by current passing through a critical mass of myocardium causing simultaneous depolarization of the myofibrils. However, the output of most defibrillators is indicated in energy units (joules or watt-seconds), not current (amperes). The relationships among energy, current, and impedance (resistance) are given by the following equations (standard units are indicated):

$$\text{Energy (joules)} = \text{Power (watts)} \times \text{Duration (seconds)} \tag{58.1}$$

$$\text{Power (watts)} = \text{Potential (volts)} \times \text{Current (amperes)} \tag{58.2}$$

$$\text{Current (amperes)} = \text{Potential (volts)/Resistance (ohms)} \tag{58.3}$$

$$\text{Current (amperes)} = \{\text{Energy (joules)/[Resistance (ohms)} \times \text{Duration (seconds)]}\}^{1/2} \tag{58.4}$$

From these equations, it can be determined that as the impedance between the paddle electrodes increases, the delivered energy will be reduced. Because internal resistance is low, the primary determinant of delivered energy will be transthoracic impedance. For consistency, the energy level indicated on most commercially available defibrillators is the output when discharged into a 50-

ohm load. When transthoracic impedance is higher than that standard, actual delivered energy will be lower. Even at a constant delivered energy, Eq. (58-4) indicates

that delivered current (the critical determinant of defibrillation) will be reduced as impedance increases. At high impedance and relatively low energy levels, current could be too low for defibrillation. Optimal success of defibrillation is obtained by keeping impedance as low as possible.

Transthoracic Impedance

Transthoracic impedance has been measured between 15 to 143 ohms in human defibrillation.[118] Many of the important factors in minimizing transthoracic impedance are under the control of the rescuers. Resistance decreases with increasing electrode size, and studies suggest that optimal paddle size may be 13 cm in diameter.[119,120] Concern has been expressed that a paddle this large may diffuse the current over too great an area for effective defibrillation. The most common paddle size remains 8 to 10 cm in diameter. The high impedance between metal electrode and skin can be reduced somewhat by use of saline-soaked gauze pads or creams, such as those used for recording ECGs. However, resistance is least when a gel or paste specifically designed to conduct electricity in the defibrillation setting is used.[119,120] Self-adhesive defibrillation/monitor pads also work well when carefully applied. When paste is used, it should be applied liberally to the paddle surface, especially the edges, to prevent burns and to obtain the maximum reduction in impedance. In experimental models, transthoracic impedance decreases with successive shocks.[121] Although the clinical significance has been questioned,[118] this factor may partially explain why an additional shock of the same energy can cause defibrillation when previous shocks have failed. Transthoracic impedance is slightly, but significantly, higher during inspiration than during exhalation.[122] Air is a poor electrical conductor. Firm paddle pressure of at least 11 kg reduces resistance by improving paddle-to-skin contact and by expelling air from the lungs.[118]

The average transthoracic impedance in human defibrillation is 70 to 80 ohms. Resistance is probably of little clinical significance when reasonably proper technique and high energy (300 J) shocks are used. For lower energy shocks, great care should be taken to minimize resistance. Defibrillators have been developed that measure transthoracic impedance prior to the shock by passing a low-voltage current through the chest during the charge cycle.[123,124] This allows the use of low-energy shocks in appropriate patients and identification of victims needing higher energy. Although not widely used, this technology allows current-based defibrillation by adjusting the delivered energy for the measured resistance.[125]

Adverse Effects and Energy Requirements

Repeated defibrillation with high energy in animals can be associated with dysrhythmias, ECG changes suggesting myocardial damage, and morphologic evidence of myocardial necrosis.[126,127] Whether similar injuries occur in humans is less certain. Slight elevations in creatine kinase MB fractions have been measured in patients following cardioversion with high energies.[128] A higher incidence of atrioventricular block has been observed in patients receiving high-energy shocks than in patients receiving low-energy shock.[129] It seems likely that high-energy shocks, especially if repeated at close intervals, may result in myocardial damage. Therefore, it would be prudent to keep energy levels as low as possible during defibrillation attempts. However, if energy is too low, the delivered current may be insufficient for defibrillation, especially when transthoracic impedance is high.

When using monophasic waveforms, there is a general relationship between body size and energy requirements for defibrillation. Geddes et al observed that the current necessary for defibrillation in animals increased with increasing body mass.[130] Children need less energy than adults, perhaps as low as 0.5 J/kg,[131] although the recommended dose is 2.0 J/kg.[24] However, over the size range of adults, weight variability is not clinically significant and other factors are more important.[132] Multiple studies have demonstrated high rates of successful defibrillation using relatively low levels (160 to 200 J) of delivered energy.[133,134,135,136] Studies of out-of-hospital and in-hospital arrests have demonstrated equal success when using $\leqslant$200 J initial energy compared with

administering all shocks at energies ⩾300 J.[129,137] Therefore, when using defibrillators with a monophasic waveform, current recommendations are to use 200 J for the initial shock followed by a second shock at 200 to 300 J if the first is unsuccessful. If both fail to defibrillate the patient, additional shocks should be given at 300 to 360 J (see Fig. 58-2).[24] When using defibrillators with a biphasic waveform, 150 J shocks provide similar success to the escalating energies used with monophasic waveforms. It is not yet clear if escalating biphasic energies improve success in difficult defibrillation.

Pharmacologic Therapy

This discussion of drug therapy is confined to the use of drugs during CPR attempts to restore spontaneous circulation. The use of drugs to support the circulation when there is mechanical cardiac function is discussed elsewhere (see Chapters 12 and 32). During cardiac arrest, drug therapy is secondary to other interventions. Chest compressions, airway management, ventilation, and defibrillation, if appropriate, should take precedence over medications. Establishing intravenous access and pharmacologic therapy should come after other interventions are established. The most common drugs and the appropriate adult doses are shown in Table 58-3. Of the drugs given during CPR, only vasopressors are usually acknowledged as being helpful in restoring spontaneous circulation.[138] Asystole and pulseless electrical activity (PEA), also called electromechanical dissociation (EMD), are circumstances in which drugs are

most frequently given. The standard algorithms for management of these types of cardiac arrest are shown in Figs. 58-3 and 58-4. In addition, the algorithms for the American Heart Association protocols for bradycardia, tachycardia, shock, and synchronized cardioversion are included (Figs. 58-5 to 58-8).

TABLE 58-3 Adult Advanced Cardiac Life Support Drugs And Doses (Intravenous)

	·DOSE	·INTERVAL	·MAXIMUM
Epinephrine	1 mg	Every 3–5 min	None
If dose fails, consider	3–7 mg	Every 3–5 min	None
Amiodarone	300 mg	Repeat in 3–5 min	2 g
Lidocaine	1.5 mg/kg	Repeat in 3–5 min	3.0 mg/kg
Bretylium tosylate	5 mg/kg	Repeat in 5 min	10 mg/kg
Atropine	1 mg	Every 3–5 min	0.04 mg/kg
Sodium bicarbonate	1 mEq/kg	As needed	Check pH

Routes of Administration

The preferred route of administration of all drugs during CPR is intravenous. The most rapid and highest drug levels occur with administration into a central vein. However, peripheral intravenous administration is also effective. The antecubital and external jugular veins are the sites of first choice for starting an infusion during resuscitation because inserting a central catheter usually necessitates stopping CPR. Because of poor blood flow below the diaphragm during CPR, drugs administered in the lower extremity may be extremely delayed or not reach the sites of action. Even in the upper extremity, drugs may require 1 to 2 minutes to reach the central circulation. Onset of action may be speeded if the drug bolus is followed by a 20- to 30-mL bolus of intravenous fluid. If intravenous access cannot be established, the endotracheal tube is an alternative route for administration of epinephrine, lidocaine, and atropine. (Sodium bicarbonate should not be given endotracheally.) The time to effect and drug levels achieved are inconsistent using this route during CPR. Better results may be obtained by administering 5- to 10-mL volumes. It is unclear whether deep injection is better than simple instillation into the endotracheal tube. Doses 2 to 2.5 times higher than the recommended intravenous dose should be administered when this route is used.

Catecholamines and Vasopressors

6 **Mechanism of Action.** Epinephrine has been used in resuscitation since the 1890s and has

been the vasopressor of choice in modern CPR since the studies of Redding and Pearson in the 1960s.[13,139] The efficacy of epinephrine lies entirely in its α-adrenergic properties.[92] Peripheral vasoconstriction leads to an increase in aortic diastolic pressure, causing

an increase in coronary perfusion pressure and myocardial blood flow.[51,140,141] All strong α-adrenergic drugs (epinephrine, phenylephrine, methoxamine, dopamine, norepinephrine), regardless of β-adrenergic potency, are equally successful in aiding resuscitation, as are strong nonadrenergic vasopressors (vasopressin, endothelin-1).[13,139,142,143] β-Adrenergic agonists without α activity (isoproterenol, dobutamine) are no better than placebo. α-Adrenergic blockade precludes resuscitation, whereas *β*-adrenergic blockade has no effect on the ability to restore spontaneous circulation.[89,90]

The *β*-adrenergic effects of epinephrine are potentially deleterious during cardiac arrest. In the fibrillating heart, epinephrine increases oxygen consumption and decreases the endocardial–epicardial blood flow ratio, an effect not seen with methoxamine. Myocardial lactate production in the fibrillating heart is unchanged after epinephrine administration during CPR, suggesting that the increased coronary blood flow does not improve the oxygen supply–demand ratio. Large doses of epinephrine increase deaths in swine early after resuscitation due to tachyarrhythmias and hypertension, an effect partially offset by metoprolol treatment. Despite these theoretical considerations, survival and neurologic outcome studies have shown no difference when epinephrine is compared with a pure α-agonist (methoxamine or phenylephrine) during CPR in animals[139,144] or humans.[145]

Epinephrine. When added to chest compressions, epinephrine helps develop the critical coronary perfusion pressure necessary to provide enough myocardial blood flow for restoration of spontaneous circulation. With invasive monitoring present during CPR, an arterial diastolic pressure of 40 mm Hg or coronary perfusion pressure of 20 mm Hg must be obtained with good chest compression technique and/or epinephrine therapy (see Table 58-2). In the absence of such monitoring, the dose of epinephrine must be chosen empirically. For many years, the empiric standard intravenous dose used has been 0.5 to 1.0 mg. However, animal studies in the 1980s suggested that higher doses of epinephrine in human CPR might improve myocardial and cerebral perfusion, and improve success of resuscitation. Case reports and a series of children with historical controls were published of return of spontaneous circulation when large doses (0.1 to 0.2 mg/kg) of epinephrine were given to patients who had failed resuscitation with standard doses.

Subsequent outcome studies have not demonstrated conclusively that higher doses of epinephrine will improve survival. Eight adult prospective randomized clinical trials involving more than 9,000 cardiac arrest patients have found no improvement in survival to hospital discharge or neurologic outcome, even in subgroups, when initial high-dose epinephrine (5 to 18 mg) is compared with standard doses (1 to 2 mg).[146,147,148,149,150,151,152,153] Some of the studies (and the cumulative data) suggest that there may be an improvement in immediate resuscitation with high-dose epinephrine. None of the studies found improvement in survival to hospital discharge. Retrospective studies of epinephrine dosing have suggested that higher doses may be associated with impaired postresuscitation

cardiovascular function and worse neurologic outcome.[154,155] None of the prospective studies found lower survival or worse neurologic outcome with higher epinephrine dosing.

7 It should be noted that these outcome studies used high-dose epinephrine as initial therapy. High doses apparently are not needed early in most cardiac arrests and could be deleterious under some circumstances. The successful case reports were in patients who had failed conventional treatment. The high doses were given late in prolonged CPR when the vasculature may not be as responsive to catecholamines. Although the use of high-dose epinephrine as rescue therapy when standard doses have failed has not been rigorously studied, this may be its appropriate place in CPR practice. Current recommendations are to give 1 mg intravenously every 3 to 5 minutes in the adult. If this dose seems ineffective, higher doses (3 to 8 mg) should be

considered (see Figs. 58-2 to 58-4).

Vasopressin. The newest addition to the pharmacologic armamentarium in CPR is arginine vasopressin. It is currently recommended as an alternative to epinephrine in a dose of 40 units intravenously one time only. If additional vasopressor doses are needed, epinephrine should be used. Vasopressin is a naturally occurring hormone (antidiuretic hormone) that, when administered in high doses, is a potent nonadrenergic vasoconstrictor, acting by stimulation of smooth muscle V_1 receptors. It is usually not recommended for conscious patients with coronary artery disease because the increased peripheral vascular resistance may provoke angina. The half-life in the intact circulation is 10 to 20 minutes and longer than epinephrine during CPR. Animal studies have demonstrated that vasopressin is as effective as or more effective than epinephrine in maintaining vital organ blood flow during CPR. Repeated doses during prolonged CPR in swine were associated with significantly improved rates of neurologically intact survival compared with epinephrine and placebo. Postresuscitation myocardial depression and splanchnic blood flow reduction are more marked with vasopressin than epinephrine, but they are transient and can be treated with low doses of dopamine.[156] Preliminary clinical studies indicate that vasopressin is as effective as epinephrine, but have not definitively shown it to be superior. A small randomized, blinded study comparing vasopressin and standard dose epinephrine in 40 patients with out-of-hospital ventricular fibrillation found improved 24-hour survival with vasopressin, but no difference in return of spontaneous circulation or survival to hospital discharge.[157] A larger,

clinical trial of 200 in-patients found no difference between the drugs in survival for 1 hour or to hospital discharge.[158] In this study, response times were short, indicating that CPR outcome achieved with both vasopressin and epinephrine in short-term cardiac arrest may be comparable. The hemodynamic effects of vasopressin, compared with epinephrine, are especially impressive during long cardiac arrests. Thus, vasopressin may find most use in CPR during prolonged resuscitation. A multicenter, randomized study of 1,186 patients comparing vasopressin 40 U and epinephrine 1 mg for the first two doses of vasopressor during resuscitation from out-of-hospital cardiac arrest found no overall difference in survival to hospital admission (36% versus 31%) or discharge (10% versus 10%).[159] However, in subgroup analysis, in patients presenting in asystole, there was a significant improvement in survival to hospital admission (29% versus 20%) and discharge (4.7% versus 1.5%). In those patients who did not resuscitate following two doses of study drug, approximately 60% received additional epinephrine. In these difficult to resuscitate patients, irrespective of presenting rhythm, those that received vasopressin followed by epinephrine had better outcomes than those that received only epinephrine, suggesting that the combination of the drugs may have advantages. Overall, evidence currently suggests that, like other potent vasopressors, vasopressin is equivalent to but not better than epinephrine for use during CPR.

Amiodarone and Lidocaine

8 After epinephrine, the most effective drugs during CPR are those that help suppress ectopic ventricular rhythms. Amiodarone and lidocaine are used during cardiac arrest to aid defibrillation when ventricular fibrillation is refractory to electrical countershock therapy or when fibrillation recurs following successful conversion. Bretylium used to be included in this category but is no longer available for clinical use. Lidocaine, primarily an antiectopic agent with few hemodynamic effects, tends to reverse the reduction in ventricular fibrillation

threshold caused by ischemia or infarction. It depresses automaticity by reducing the slope of phase 4 depolarization and reducing the heterogeneity of ventricular refractoriness. Amiodarone is a pharmacologically complex drug with sodium, potassium, calcium, and α-adrenergic and β-adrenergic blocking properties that is useful for treatment of atrial and ventricular arrhythmias. Amiodarone can cause hypotension and bradycardia when infused too rapidly in patients with an intact circulation.[160] This can usually be prevented by slowing the rate of drug infusion, or it can be treated with fluids, vasopressors, chronotropic agents, or temporary pacing. There are two randomized, blinded, placebo-controlled clinical trials in shock-resistant cardiac arrest victims demonstrating improved admission alive to hospital with amiodarone treatment, although there

was no difference in survival to discharge.[161,162] Although weak, this is more evidence of efficacy than exists for lidocaine.

When ventricular fibrillation or pulseless ventricular tachycardia is recognized, defibrillation should be attempted as soon as possible (see Fig. 58-2). No antiarrhythmic agent has been shown to be superior to electrical defibrillation or more effective than placebo in the treatment of ventricular fibrillation. Consequently, defibrillation should not be withheld or delayed to establish intravenous access or to administer drugs. When ventricular tachycardia or ventricular fibrillation has not responded to or recurred following BLS, epinephrine, and defibrillation, amiodarone should be administered. In cardiac arrest, amiodarone is initially administered as a 300-mg rapid infusion. Supplemental infusions of 150 mg can be repeated as necessary for recurrent or resistant arrhythmias to a maximum total daily dose of 2 g. (For dysrhythmias with an intact circulation, amiodarone is usually administered as 150 mg intravenously over 10 minutes, followed by 1 mg/min infusion for 6 hours and 0.5 mg/min thereafter.) Lidocaine is an alternative therapy in refractory fibrillation. To rapidly achieve and maintain therapeutic blood levels during CPR, relatively large doses are necessary. An initial bolus of 1.5 mg/kg should be given and additional boluses of 0.5 to 1.5 mg/kg can be given every 5 to 10 minutes during CPR up to a total dose of 3 mg/kg. Only bolus dosing should be used during CPR, but an infusion of 2 to 4 mg/min can be started after successful resuscitation.

Sodium Bicarbonate

Although sodium bicarbonate was used commonly during CPR in the past, little evidence supports its efficacy. Use of sodium bicarbonate during resuscitation has been based on the theoretical considerations that acidosis lowers fibrillation threshold[163] and impairs the physiologic response to catecholamines.[164] But most studies have failed to demonstrate improved success of defibrillation or resuscitation with the use of bicarbonate.[165,166,167] The lack of effect of buffer therapy may be partially explained by the slow onset of metabolic acidosis during cardiac arrest. As measured by blood lactate or base deficit, acidosis does not become severe for 15 or 20 minutes of cardiac arrest.[52,53,168]

In contrast to the lack of evidence that buffer therapy during CPR improves survival, the adverse effects of excessive sodium bicarbonate administration are well documented. In the past, metabolic alkalosis, hypernatremia, and hyperosmolarity were common after administration of bicarbonate during resuscitation attempts.[168,169] These abnormalities are associated with low resuscitation rates and poor outcome. However, if sodium bicarbonate is given judiciously according to standard recommendations, no significant metabolic abnormalities should occur.[170]

Intravenous sodium bicarbonate combines with hydrogen ion to produce carbonic acid that dissociates into CO_2 and water. The PCO_2 in blood is temporarily elevated until the excess CO_2 is eliminated through the lungs. Tissue acidosis during CPR is caused primarily by the low blood flow and accumulation of CO_2 in the tissues.[52,53] Therefore, concern has been expressed that the liberation of CO_2 by bicarbonate administration would only worsen the existing problem. This is of particular concern within myocardial cells and the brain. Carbon dioxide readily diffuses across cell membranes and the blood-brain barrier, whereas bicarbonate diffuses much more slowly. Thus, it is possible that sodium bicarbonate administration could result in a paradoxical worsening of intracellular and cerebral acidosis by further raising intracellular and cerebral CO_2 without a balancing increase in bicarbonate. Direct evidence for this effect has not been found. One study demonstrated an elevation in cerebral spinal fluid PCO_2, and reduction in pH could occur when very large doses of bicarbonate were given.[171] However, with clinically relevant doses, another study found no changes in spinal fluid acid-base status.[172] Measurement of myocardial intracellular pH during bicarbonate administration has also not detected a worsening in acidosis.[173] Therefore, paradoxical acidosis from sodium bicarbonate therapy remains a concern primarily on theoretical grounds.

Current practice restricts the use of sodium bicarbonate primarily to arrests associated with hyperkalemia, severe preexisting metabolic acidosis, and tricyclic or phenobarbital overdose. It may be considered for use in protracted resuscitation attempts after other modalities have been

instituted and failed. When bicarbonate is used during CPR, the usual dose is 1 mEq/kg initially with additional doses of 0.5 mEq/kg every 10 minutes. However, dosing of sodium bicarbonate should be guided by blood gas determination whenever possible.

Atropine

Atropine sulfate enhances sinus node automaticity and atrioventricular conduction by its vagolytic effects. Although atropine is frequently given during cardiac arrest associated with an ECG pattern of asystole or slow PEA, neither animal nor human studies provide evidence that it actually improves outcome from asystolic or bradysystolic arrest.[174,175] The predominant cause of asystole and EMD is severe myocardial ischemia. Excessive parasympathetic tone probably contributes little to these rhythms during cardiac arrest in adults. Even in children, it is doubtful that parasympathetic tone plays a significant role during most arrests. Therefore, the most important treatment for asystole and EMD is effective chest compressions, ventilation, and epinephrine to improve coronary perfusion and myocardial oxygenation. However, cardiac arrest with these rhythms has a poor prognosis.[24] Because atropine has few adverse effects, it is recommended in arrest with asystole or PEA and refractory to epinephrine and oxygenation. The dose is 1.0 mg intravenously, repeated every 3 to 5 minutes up to a total of 0.04 mg/kg, which is totally vagolytic.[176] Full vagolytic doses may be associated with fixed mydriasis, following successful resuscitation confounding neurologic examination. Occasionally, a sinus tachycardia following resuscitation may be due to the use of atropine during CPR.

Calcium

With normal cardiovascular physiology, calcium increases myocardial contractility and enhances ventricular automaticity. Consequently, it has been advocated as a treatment for asystole and PEA. Early animal studies showed moderate success with calcium chloride in asphyxial arrest, although vasopressors were better.[13] In 1981, Dembo reported dangerously high serum calcium levels (up to 18.2 mg/dL) during CPR and questioned the efficacy of calcium in cardiac arrest.[177] Subsequently, several retrospective studies and prospective clinical trials during out-of-hospital cardiac arrest showed that calcium was no better than placebo in promoting resuscitation and survival from asystole or EMD.[178,179,180,181,182,183] Consequently, because of potentially deleterious effects, calcium is not recommended during CPR unless specific indications exist. Calcium may prove useful if hyperkalemia, hypocalcemia, or calcium channel blocker toxicity is present. There are no other indications for its use during CPR. When calcium is administered, the chloride salt is recommended because it produces higher and more consistent levels of ionized calcium than other salts. The usual dose is 2 to 4 mg/kg of the 10% solution administered slowly intravenously. Calcium gluconate contains one-third as much molecular calcium as does calcium chloride and requires metabolism of gluconate in the liver.

PEDIATRIC CARDIOPULMONARY RESUSCITATION

The principles of CPR discussed previously apply to the child in cardiac arrest. Arrest is less likely to be a sudden event and more likely related to progressive deterioration of respiratory and circulatory function in the pediatric age group. Airway

and ventilation problems lead to asystole and PEA as the most common presenting rhythms. However, the consequences of myocardial and cerebral ischemia are the same as for the adult. The basic approach to the arrest victim is the same (see Table 58-1). The specific anatomic and physiologic considerations necessary for the child will be familiar to anesthesiologists. The special circumstance of neonatal resuscitation has been discussed in other chapters.

The problem of airway management in the infant is well known to the anesthesiologist. Effective ventilation is especially critical because respiratory problems are frequently the cause for arrest. Mouth-to-mouth or mouth-to-nose and mouth (for infants) can be used as well as bag-valve-mask devices until intubation is possible. Cardiac compression in the infant is provided with two fingers

on the midsternum or by encircling the chest with the hands and using the thumbs to provide compression. For the small child, compression can be provided with one hand on the midsternum.

The algorithm for ACLS in the pediatric patient is shown in Figs. 58-9 and 58-10. Although defibrillation is less frequently necessary in children, the same principles apply as in the adult. However, the recommended starting energy is 2 J/kg, which is doubled if defibrillation is unsuccessful. Considerations for drug administration are the same as for the adult, except that the interosseous route in the anterior tibia provides an additional option in small children. Drug therapy is similar to the adult but plays a larger role because electrical therapy is less often needed (see Figs. 58-9 and 58-10; Table 58-4).

TABLE 58-4 Pediatric Advanced Life Support Medication For Cardiac Arrest And Symptomatic Arrhythmias

▪DRUG	▪DOSAGE (PEDIATRIC)	▪REMARKS
Adenosine	0.1 mg/kg	Rapid IV/IO bolus
	Repeat dose: 0.2 mg/kg	Rapid flush to central circulation
	Maximum single dose: 12 mg	Monitor ECG during dose.
Amiodarone for pulseless VF/VT	5 mg/kg IV/IO	Rapid IV bolus
Amiodarone for perfusing tachycardias	Loading dose: 5 mg/kg IV/IO	IV over 20 to 60 min
	Maximum dose: 15 mg/kg per day	Routine use in combination with drugs prolonging QT interval is *not* recommended. Hypotension is most frequent side effect.
Atropine sulfate[a]	0.02 mg/kg	May give IV, IO or ET
	Minimum dose: 0.1 mg	Tachycardia and pupil dilation may occur but *not* fixed dilated pupils.
	Maximum single dose: 0.5 mg in child, 1.0 mg in adolescent. May repeat once.	
Calcium chloride 10% =100 mg/mL (=27.2 mg/mL elemental Ca)	20 mg/kg (0.2 mL/kg) IV/IO	Give slow IV push for hypocalcemia, hypermagnesemia, calcium channel blocker toxicity, preferably via central

		vein. Monitor heart rate; bradycardia may occur.
Calcium gluconate 10%= 100 mg/mL (=9 mg/mL elemental Ca)	60–100 mg/kg (0.6–1.0 mL/kg) IV/IO	Give slow IV push for hypocalcemia, hypermagnesemia, calcium channel blocker toxicity, preferably via central vein.
Epinephrine for symptomatic bradycardia[a]	IV/IO: 0.01 mg/kg (1:10,000, 0.1 mL/kg) ET: 0.1 mg/kg (1:1,000, 0.1 mL/kg)	Tachyarrhythmias, hypertension may occur.
Epinephrine for pulseless arrest[a]	First dose: IV/IO: 0.01 mg/kg (1:10,000, 0.1 mL/kg) ET: 0.1 mg/kg (1:1,000, 0.1 mL/kg)	
	Subsequent doses: Repeat initial dose or may increase up to 10 times (0.1 mg/kg, 1:1,000, 0.1 mL/kg) Administer epinephrine every 3 to 5 min. IV/IO/ET doses as high as 0.2 mg/kg of 1:1,000 may be effective.	
Glucose (10% or 25% or 50%)	IV/IO: 0.5–1.0 g/kg	For suspected hypoglycemia; avoid hyperglycemia.
	•1–2 mL/kg 50%	
	•2–4 mL/kg 25%	
	•5–10 mL/kg 10%	
Lidocaine[a]	IV/IO/ET: 1 mg/kg	Rapid bolus
Lidocaine infusion (start after a bolus)	IV/IO: 20–50 µg/kg per minute	1 to 2.5 mL/kg per hour of 120 mg/100 mL solution or use "rule of 6"
Magnesium sulfate (500 mg/mL)	IV/IO: 25–50 mg/kg. Maximum dose: 2 g per dose	Rapid IV infusion for torsades or suspected hypomagnesemia; 10- to 20-min infusion for asthma that responds poorly to β-adrenergic agonists.

Naloxone[a]	⩽5 years of ⩽20 kg: 0.1 mg/kg	For total reversal of narcotic effect. Use small repeated doses (0.01 to 0.03 mg/kg) titrated to desired effect.
	>5 years or >20 kg: 2.0 mg	
Procainamide for perfusing tachycardias (100 mg/mL and 500 mg/mL)	Loading dose: 15 mg/kg IV/IO	Infusion over 30 to 60 min; routine use in combination with drugs prolonging QT interval is *not* recommended.
Sodium bicarbonate (1 mEq/mL and 0.5 mEq/mL)	IV/IO: 1 mEq/kg per dose	Infuse slowly and only if ventilation is adequate.

ECG, electrocardiogram; ET, endotracheal; IO, intraosseous; IV, intravenous; VF, ventricular fibrillation; VT, ventricular tachycardia.

[a]For endotracheal administration use higher doses (2 to 10 times the IV dose); dilute medication with normal saline to a volume of 3 to 5 mL and follow with several positive-pressure ventilations.

POSTRESUSCITATION CARE

The major factors contributing to mortality following successful resuscitation are progression of the primary disease and cerebral damage suffered as a result of the arrest. There is growing awareness that any cardiac arrest, even of brief duration, causes a generalized decrease in myocardial function similar to the regional hypokinesis seen following periods of regional ischemia. This is usually referred to as global myocardial stunning and can be mitigated with inotropic agents, if necessary. Active management following resuscitation appears to mitigate

post-ischemic brain damage and improve neurologic outcome.[184] Although a significant number of patients have severe neurologic deficits following resuscitation, aggressive brain-oriented support does not seem to increase the proportion surviving in vegetative states. Most severely damaged victims die of multisystem failure within 1 to 2 weeks.

When flow is restored following a period of global brain ischemia, three stages of cerebral reperfusion are seen in the ensuing 12 hours. Immediately following resuscitation, there are multifocal areas of the brain with no reflow. Within 1 hour, there is global hyperemia followed quickly

by prolonged global hypoperfusion. Elevation of intracranial pressure is unusual following resuscitation from cardiac arrest. However, severe ischemic injury can lead to cerebral edema and increased intracranial pressure in the ensuing days.

Postresuscitation support is focused on providing stable oxygenation and hemodynamics to minimize any further cerebral insult. A comatose patient should be maintained on mechanical ventilation for several hours to ensure adequate oxygenation and ventilation. Restlessness, coughing, or seizure activity should be aggressively treated with appropriate medications, including neuromuscular blockers, if necessary. Arterial PaO_2 should be maintained above 100 mm Hg, and hypocapnia ($PaCO_2$ <30 mm Hg) should be avoided. Blood volume should be maintained normal, and moderate hemodilution to a hematocrit of 30 to 35% may be helpful. A brief, 5-minute period of hypertension to mean arterial pressure of 120 to 140 mm Hg may help overcome the initial cerebral no reflow. This frequently occurs secondary to the effects of epinephrine given during CPR. Because cerebral autoregulation of blood flow is severely attenuated, both prolonged hypertension and hypotension are associated with a worsened outcome. Therefore, mean arterial pressure should be maintained at 90 to 110 mm Hg. Hyperglycemia during cerebral ischemia is known to result in increased neurologic damage. Although it is unknown if high serum glucose in the postresuscitation period influences outcome, it seems prudent to control glucose in the 100 to 250 mg/dL range. Specific pharmacologic therapy directed at brain preservation has not been shown to have further benefit. Some animal trials of barbiturates were promising, but a large multicenter trial of thiopental found no improvement in neurologic status when this drug was given following cardiac arrest.[184] Similar results were found with calcium channel blockers. Animal studies were encouraging, but a clinical trial found no improvement in outcome.[185]

9 In contrast to pharmacologic therapy, two more recent studies have demonstrated improved neurologic outcome when mild therapeutic hypothermia (32 to 34°C) was induced for 12 to 24 hours in cardiac arrest survivors who remained comatose after admission to the hospital.[186,187] Both investigations studied only patients whose initial rhythm was ventricular fibrillation, and the larger of the trials included only witnessed arrests. Nevertheless, these are the first studies to document improved neurologic outcome with a specific postarrest intervention. ILCOR now recommends "unconscious adult patients with spontaneous circulation after out-of-hospital cardiac arrest should be cooled to 32 to 34°C for 12 to 24 hours when the initial rhythm was ventricular fibrillation. Such cooling may also be beneficial for other rhythms or in-hospital cardiac arrest."

Prognosis

For the comatose survivor of CPR, the question of ultimate prognosis is important. One retrospective study demonstrated that the admission neurologic examination of comatose victims is highly correlated with the likelihood of awakening.[188] If there were no pupillary light response and no spontaneous eye movement, and if the motor response to pain were absent or extensor posturing, there was only a 5% chance the patient would ever awaken. A companion study demonstrated that the chance of ever awakening fell rapidly in the days following arrest.[189] If the patient was not awake by 4 days following arrest, the chance of ever awakening was 20%, and all those awakening had marked neurologic deficits. Most patients who completely recover show rapid improvement in the first 48 hours. There is also a high correlation between severity of neurologic injury and the level of creatine kinase-BB found in the cerebrospinal fluid.[190,191] Peak values of $\geqslant$ 25 IU are associated with severe neurologic damage and are reached 48 to 72 hours following

arrest.

Chapter 59

Disaster Preparedness and Weapons of Mass Destruction

Michael J. Murray

KEY POINTS

1	Emergency preparedness is a way of life in many countries. It needs to become much more a part of life in the United States than it is today. What we need to do as healthcare leaders is to call the first meeting to prepare a community response, or if it already exists, become familiar with the community's response plan.
2	When caring for patients with severe acute respiratory syndrome in both Canada and in several countries in Asia, not only many healthcare providers become patients, but several also became fatalities. To maintain surge capacity, it is imperative that each healthcare provider recognize the importance of protecting himself or herself.
3	The reality is that we are far more likely to have to manage patients and healthcare facilities that are victims of natural and unintentional disasters. These are most often related to extreme weather, earthquakes, and industrial accidents.
4	Physicians avoided neuromuscular blockade to intubate the tracheas of patients with inhalation injuries and were glad they did because several patients had significant airway edema that may have made intubation difficult, if not impossible.
5	The Federal Emergency Management Agency is the lead agency for management assistance to state and local governments, providing emergency relief to affected individuals and businesses, decontaminating affected areas, and helping ensure public health safety.
6	The anesthesiologist, depending on where he or she practices, may be called on to manage situations that are unimaginable by current standards. However, with their basic understanding of physiology and pharmacology, their airway skills, their fluid-resuscitation expertise, and their ability to manage ventilators and to provide anesthesia in the field environment, emergency department, operating

	room, and intensive care units will be invaluable.
7	The experience from Chernobyl should indicate the kind of injuries and results that anesthesiologists can anticipate from nuclear accidents, including radiation burns, bone marrow suppression, the destruction of the lining of the gastrointestinal tract, gastrointestinal bleeding with translocation of bacteria, infection, sepsis, septic shock, and death.
8	Because of the possibility of exposure to ionizing radiation from nuclear power plants and so on, the American Academy of Pediatrics has recommended that at least two tablets of potassium iodide be available for all inhabitants within 10 miles of any nuclear power plant.
9	With any nuclear explosion, many individuals will be injured or die from building collapse or the thermal pulse. Patients could have burn, crush, radiation injury, or any combination thereof.
10	Influenza has killed more people in the 20th century than any other infectious disease. There have been three large pandemics, including one in 1918 when an avian virus infected humans, creating the deadliest outbreak of disease in U.S. history.
11	In the event of a documented case of smallpox, the Centers for Disease Control and Prevention has plans to quarantine the patient and then immunize immediate contacts of patients within a certain geographic radius.

Since antiquity, physicians have cared not only for individuals, but also for the welfare of the state. In the former role, they functioned not only as doctors, but also as priests. Because so little was known of science, supernatural forces were often invoked to help heal the patient. In the latter role, as the guardian and advisor to state and public health issues, the same was often true. During the Middle Ages, physicians became more focused on science and less on the supernatural. After September 11, 2001, however, physicians have been faced with a prospect that challenges their scientific training. Although, during war, catastrophic events occur on a daily basis, we are now in an era in which the unimaginable can happen at any time. We must confront the possibility that terrorists can attack our cities with conventional, nuclear, biological, and chemical weapons. As anesthesiologists, we must now be prepared at any time to care for the victims of such assaults and to protect our own welfare so that we do not become casualties and an additional burden to the healthcare system. We must use our scientific training to manage events that will likely evoke widespread fear and panic.

JOINT COMMISSION ON ACCREDITATION OF HEALTHCARE ORGANIZATIONS

Following the events of September 11, 2001, and subsequent anthrax attacks, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) published a "white paper" to help hospitals develop systems to create and sustain community-wide emergency preparedness.[1] The JCAHO recognizes that there has been a change in healthcare delivery in the United States over the last several years and decades, reflective of similar problems faced worldwide, that has

left the healthcare system underfunded with limited resources[2] and ever-increasing demand. However, the JCAHO also recognizes that despite the best effort of law enforcement, fire and rescue, and emergency medical agencies, hospitals will continue to play a vital role in helping communities respond to catastrophic events, whether natural, unintentional, or terrorist initiated. The JCAHO's initiative was proactive in recognition of the fact that, "It is no longer sufficient to develop disaster plans and dust them off if a threat appears imminent. Rather, a system of preparedness across communities must be in place everyday."[1] The JCAHO acknowledged the need, despite decreasing healthcare resources, for what it describes as "surge capacity" within healthcare systems to handle the potentially hundreds, if not thousands or more, of patients who might be victims of catastrophic events. By being prepared, the JCAHO wants to reduce the appeal to terrorists of using weapons of mass destruction as an effective means of warfare and to help communities to better respond to natural disasters. The JCAHO white paper focuses on three major areas:

1. *Enlisting the community* to develop the local response
2. *Focusing on the key aspects of the system* that prepares the community to mobilize to care for patients, protect its staff, and serve the public
3. *Establishing* the accountability, oversight, leadership, and sustainability of *a community-preparedness system*

Although JCAHO guidelines are just that—guidelines that are not mandatory or required by law—all hospitals aspire to have JCAHO accreditation. From that perspective, the white paper is an important step in helping prepare the medical community to deal with catastrophic events that could inundate the healthcare system. It is incumbent on physicians to be familiar with what their hospital has done to comply with the JCAHO standards, in anticipation of what their roles may be.

ENLISTING THE COMMUNITY

In the past, the JCAHO required that hospitals test their disaster plans twice per year. Often, organizations went through the motions without truly embracing the idea of planning for a catastrophe; however, even these minimal events did have benefit if the hospital was confronted with an actual disaster. However, with the World Trade Center and Pentagon bombings and the anthrax attacks, the JCAHO recognized how deficient most hospitals' plans were. By serendipity, prior to the events of 2001, the JCAHO had been reworking its disaster preparedness standards. Their requirements were introduced in January 2002 and have been updated since then (Table 59-1). Central to these is the recognition that the response needs to be a local response; most hospitals and communities may have to deal with whatever they are confronted with during the first 24 to 72 hours. In addition, there needs to be a better framework for integrating community resources.

TABLE 59-1 2004 Emergency Management Standards of the Joint Commission on Accreditation of Healthcare Organizations Hospital Accreditation Standards

1. Develop a management plan that addresses emergency management (Standards EC.4.10–4.110). The four phases of emergency management activities are as follows:
    - Mitigation
    - Preparedness
    - Response
    - Recovery
2. Perform a hazard vulnerability analysis.

- Establish emergency procedures in response to a hazard vulnerability analysis.
- Define the organization's role with that of other community agencies.
- Notify external authorities of emergencies.
- Notify hospital personnel when emergency procedures are initiated.
- Assign available personnel to cover necessary positions.
- The following activities must be managed:
  - Patient/resident activities
  - Staff activities
  - Staff/family support
  - Logistics of critical supplies
  - Security
  - Evacuation of the facility, if necessary
- Establish internal/external communication systems
- Establish an orientation/education program
- Monitor ongoing drills and real emergencies
- Determine how an annual evaluation will occur
- Provide alternate means of meeting essential building and utility needs
- Identify radioactive and biological isolation decontamination sites
- Clarify alternate responsibility of personnel

3. Involve community-wide response.
4. Reestablish and continue operations following a disaster.

The aforementioned terrorist events of 2001 and 2002, the 2001 Houston flood experience, and the 2004 Florida hurricane experiences underscored the fact that healthcare-provider organizations need to communicate more effectively with one another. There has traditionally been poor communication between law enforcement agencies, fire and rescue services, and emergency medical services. The medical community does no better in its interactions with the public health

community. They have different priorities—the medical community focuses on the individual, and public health personnel focus on the community at large. As is often the case, rarely have these five "agencies" come together to prepare a community-wide response, often expecting the local, state, or federal government to provide coordination. However, there is a fundamental need to formalize an organization of community resources of which hospitals and physicians are but one component.

Community-wide emergency response plans are in place in some large cities. However, the majority of metropolitan areas do not have such an organizational structure, and many hospitals and physicians are waiting for someone to take the first step in organizing such a response plan. The JCAHO, in publicizing its white paper, wanted to stimulate hospitals and hospital leadership to initiate a discussion of the responsibility of "the community" in preparing a response and to stimulate hospitals and healthcare providers to forge new partnerships in addressing this critical need.

In New York City, the Greater New York Hospital Association took a leadership role in forging a cross-disciplinary, cross-jurisdictional partnership to prepare an integrated response plan to any future disaster. Obviously, New York City had a vested interest in doing so, but the entire world watched the World Trade Center buildings collapse, and the anthrax attacks affected people in several states and received widespread media coverage.

Although the average layperson may conclude that the healthcare system seemed to respond adequately to the events of September 11 and the anthrax attacks, but in essence the healthcare system was not significantly challenged. Both New York City and Oklahoma City (with the bombing

of the Federal Building on April 19, 1995) had a much higher fatality rate than is normal for mass casualties in which the ratio is between 5 and 10 casualties to 1 fatality. In both New York City and Oklahoma City, the ratio was reversed, with approximately 10 fatalities for every 1 casualty. In the post-hoc analysis, there were multiple problems identified to which the revised New York City disaster plan responded in anticipation of what the future might hold. Communications were one major problem that needed resolution. In New York City on September 11, pilots in helicopters recognized shortly after the South Tower collapsed that the North Tower would also collapse and radioed that warning to rescuers on the ground 21 minutes before the building fell. The message was relayed to police over their radios, and most managed to escape. Unfortunately, firefighter radios used a different frequency and did not pick up the warning, and at least 121 firefighters died because of the telecommunication breakdown.[3]

As the building fell, the entire telecommunications infrastructure in the area became nonfunctional. Communication throughout most of lower Manhattan had to be person-to-person or with hand-delivered notes within hospitals.

However, communication involves not only communicating within the hospital when a healthcare facility is inundated with casualties, but it also involves communication with other hospitals and healthcare and government agencies before and after a disaster. The anthrax letters of October 2001 were the first bioterrorism attack in this country to which the Centers for Disease Control and Prevention (CDC) had to respond. Twenty-two cases were confirmed or suspected—11 inhalation and 11 cutaneous attacks with 5 deaths. The first diagnosis of anthrax was made by a physician who suspected the disease, with confirmation by a laboratory technician who had trained in bioterrorism preparedness. But the general unfamiliarity of many healthcare professionals with biological agents contributed to misdiagnoses and delayed treatment for some patients. Even when the diagnosis was made, there was reluctance of hospitals and healthcare agencies to notify others. After the Brentwood postal worker was diagnosed at a hospital in the District of Columbia and the case was reported to public health care officials, the latter did not immediately act to notify other area hospitals.[4] It seems incredible that just months after the attacks on the World Trade Center that people were still doubtful that the United States could be attacked in yet another format.

1 Whereas emergency preparedness is a way of life in many countries, it very much needs to become much more a part of life in the United States than it is today. What we need to do as healthcare leaders is to call the first meeting to prepare a community response, or if it already exists, become familiar with the community's response plan. Community planning needs to occur, and the results of that planning need to be widely disseminated to as many potential partners in implementing the plan as possible.

FOCUSING ON THE KEY ASPECTS OF THE SYSTEM

To respond to a mass casualty event, an emergency medical system must be able to assess and expand its surge capacity—the ability to provide care for and transport countless numbers of patients to facilities with appropriate capacity, resources, and staff. To anticipate surge capacity, one must know which beds are available for patients, if there is space available for triaging and decontaminating patients, and if there are personnel available to provide first aid and more-comprehensive care. Because many emergency departments are already overwhelmed and there are fewer hospitals today than there were 10 years ago, the U.S. healthcare system has less surge capacity. However, we need to be proactive, recognize that standards may change, and plan accordingly. Patients may be cared for in hallways, and decontamination may not even take place in the hospital. It may be best done outside the hospital (e.g., near a loading dock or in an emptied parking lot between two fire trucks).

2 To preserve the functionality of the system, the staff must also protect themselves. In the Tokyo sarin attacks of 1995, several healthcare providers were contaminated with sarin when they cared for patients who had not been decontaminated,[5] thereby becoming patients themselves and further burdening the health care system. Similarly, when caring for patients with severe acute respiratory syndrome (SARS) in Canada and in several countries in Asia, not only did many

healthcare providers not only became patients,[6] but also several became fatalities. To maintain surge capacity, it is imperative that every healthcare provider recognize the importance of protecting himself or herself.

Also in these situations, one cannot forget about the patients for whom one is already caring. Patients who are healthy enough need to be discharged immediately, but more critically ill patients may need to be moved to other hospitals. This may occur if a hospital is inundated with patients from a disaster or as a result of the hospital being affected by the catastrophe such as occurred in Houston during the 2001 flood[7] or in Florida in 2004 when some hospitals lost power and patients had to be transported elsewhere.

After having established the basics, the most important aspect of managing a mass casualty event, again whether it is natural, unintentional, or intentional, is having a command and control structure with which everyone is familiar. In the Northridge, California, earthquake in 1994, many healthcare providers coming into the hospital, which lacked electricity and was severely damaged itself, had difficulty finding the command and control center. As a result, efforts were not coordinated and were slow to be implemented.

Healthcare providers also need to be concerned not only about their personal safety, but also about their psychological

safety. That is, they should have plans in place for their families if they are required to stay at hospitals for an extended length of time. Because of natural catastrophes that have occurred throughout the United States with hurricanes, floods, tornados, earthquakes, and so on, most healthcare providers have had the opportunity to establish a plan for their families while they provide care during mass casualty situations.

Finally, in addressing these issues, the public must be mobilized to participate in the response. As part of this response, the health care system and its leaders must identify communication and information needs. During the synagogue and business bombings in Istanbul, Turkey, in 2003, the hospital at which most victims were admitted was ill prepared to handle the information needs of multiple governments, their healthcare agencies, and their intelligence and law enforcement agencies.

Hospital and healthcare providers must be able to manage not only the external, but also the internal communication needs of the hospital and have a plan to address them, especially if any aspect of the system fails, as occurred at the World Trade Center site on September 11, 2001. Finally, one must test, learn, improve, and be ready to address deficiencies in the plan. JCAHO requires two drills annually, with one of them expected to be a community-wide drill. These situations provide healthcare providers an opportunity to hone their skills and anticipate problems they might confront in the future in dealing with natural disasters and terrorist attacks.

ESTABLISHING A COMMUNITY-PREPAREDNESS SYSTEM

At this level, most of the responsibility for preparedness is with local, state, and federal governments inconjunction with hospitals and hospital organizations. As physicians, we should be familiar with the clinical competencies for emergency preparedness in bioterrorism developed through the Association of Teachers of Preventive Medicine in collaboration with the Center for Health Policy, Columbia University School of Nursing (Table 59-2).[8]

TABLE 59-2 Clinical Competencies for Clinicians and Emergency Preparedness

Clinicians should be able to

- Describe their role in the emergency response.

- Respond to an emergency event within the emergency management system.
- Recognize an illness or injury as potentially resulting from exposure to weapons of mass destruction.
- Institute appropriate steps to limit the spread of the offending agent.
- Report identified cases or events through the public health care system.
- Initiate patient care within their professional skill.[a]
- Use reliable information sources.
- Provide reliable information to others.
- Communicate risks and actions to patients.
- Identify and manage expected stress and anxiety.
- Participate in postevent feedback (after action report).

[a]Remember that anyone can provide rudimentary first aid if the situation warrants.

DISASTER PREPAREDNESS

3 Although we recognize the critical importance for planning and preparing to deal with the use of weapons of mass destruction, the reality is that we are far more likely to have to manage patients and healthcare facilities that are victims of natural and unintentional disasters. These are most often related to extreme weather, earthquakes, and industrial accidents (Table 59-3).

TABLE 59-3 Disasters That Result In Mass Casualties

Natural
- Hurricanes
- Tornados
- Floods
- Earthquakes
- Fires

Unintentional
- Public transportation accident
- Boat accident
- Nuclear accident
- Industrial accident
- Building collapse/sports stadium disaster

Intentional
- Bombing
- Nuclear
- Biological
- Chemical

Among weather-related events, hurricanes, tsunamis, tropical storms, and tornadoes are the most

likely to wreak havoc, creating mass casualty situations (Table 59-4). Hurricane Andrew, which came ashore in south Florida on August 24, 1992, killed 40 people, injured scores more, left 250,000 people homeless, and severely compromised the ability of hospitals to provide care because healthcare workers were unable to get to work, electricity and water supplies were jeopardized, and many hospitals suffered direct damage.[9] Similar events occurred in Houston in June 2001 when tropical storm Allison destroyed the ability of many hospitals to provide care. Hospitals had to be evacuated, with critically ill patients going to other facilities, many of which were attempting to deal with the city's "normal", if not increased, number of emergencies.[7]

TABLE 59-4 Fatalities From Natural Disasters

▪NATURAL DISASTER	▪DATE	▪NO. OF FATALITIES
Galveston hurricane	September 8, 1900	6,000
Bangladesh floods	November 12, 1970	300,000
Mount St. Helen's volcanic eruption	May 18, 1980	57
Bam, Iran earthquake	December 26, 2003	41,000
Indian Ocean tsunami	December 26, 2004	155,000

Although many die in such catastrophic events, the sequelae to survivors are often unimaginable. The Indian Ocean tsunami of December 26, 2004, killed many healthcare workers and destroyed countless numbers of healthcare facilities, and surging flood water with huge debris crushed and fractured extremities, resulting in many amputations. Survivors had to contend with lack of potable water, sanitation issues, rotting corpses, and incipient disease. Cholera, typhoid, and other communicable diseases were rampant in multiple countries.

Hospitals are often destroyed or, if not, need to evacuate because of an earthquake. In the January 17, 1994, earthquake affecting Northridge, California, 8 of 91 acute care hospitals had to be evacuated. Six of the hospitals evacuated within the first day because of water damage and loss of electrical power. Two of the eight hospitals evacuated within 72 hours when major structural damage was found, despite the fact that

initial inspections of the hospitals did not reveal significant damage. Both hospitals ultimately had to be demolished and rebuilt.[10]

Much can be learned in preparing for disaster management from a risk assessment of major earthquakes. The Marmara earthquake that struck northwest Turkey on August 17, 1999, killed approximately 16,000 people, injured 44,000 (many healthcare workers were killed or injured), and demolished the majority of healthcare facilities. Patients had to be taken from Marmara to 35 hospitals outside the earthquake zone that were not affected. Of the thousands of injuries, there were many patients who were crushed and lay in the rubble for hours to days. Surprisingly, the time under the rubble did not correlate with morbidity and mortality. Most of these patients had amputations, but the incidence of renal failure did not increase as the time under the rubble increased.[11] Individuals involved in management of the disaster concluded that rescuers should try to find and uncover victims for at least 5 days after an earthquake.[11]

The earthquake that struck Bam, Iran, on December 26, 2003, killed 41,000 people and tens of

thousands were injured. Because so many medical facilities were destroyed, Iran relied on 40 international teams to help provide search-and-rescue services, as well as evacuation and treatment of casualties. Mortuary teams had to deal with thousands of corpses, and public health agencies addressed sanitation needs and had to provide potable water, food, and shelter.[12]

4 Most casualties in earthquakes are from crush injuries, but a number of patients will also experience burn injuries. Obviously, the greatest likelihood of dealing with patients with burns involves fires, as evidenced from the Rhode Island nightclub fire on February 20, 2003, that killed 100 people immediately and left more than 200 injured. There are important lessons from that fire, especially for anesthesiologists, because one of the greatest challenges faced by physicians and healthcare workers at the small community hospital only 2 miles away was how to manage the airway. Physicians avoided neuromuscular blockade to intubate the tracheas of patients with inhalation injuries and were glad they did because several patients had significant airway edema that may have made intubation difficult, if not impossible. Several patients were given local nerve blocks with small amounts of sedatives and intubated awake.[13]

In situations in which area hospitals are completely destroyed or nonfunctional, the government may have to establish healthcare facilities such as field hospitals[14] or, if close to a body of water, bring in one of the U.S. Navy's hospital ships as they did in New York City after the World Trade Center collapsed.

Finally, healthcare facilities near large industrial complexes must anticipate chemical injuries, explosions, and fires. The Bhopal gas tragedy of December 3, 1984, is but one example. Methyl isocyanate gas leaked from a tank, killing approximately 3,800 people and injuring several thousand.[15] Four years later, an independent investigation concluded that the event could have only been the result of sabotage; that is, a person or persons deliberately attached a water hose to the gas storage tank, initiating a massive chemical reaction.[15]

ROLE OF GOVERNMENT

The initial response to any disaster, whether natural, unintended, or terrorist initiated, begins at the local level and involves law enforcement agencies, especially if there is criminal activity suspected; firefighters; and paramedics. Depending on the nature of the disaster, local passersby might also become involved, as is often the case. Fire departments are trained to deal with toxic chemicals, and, depending on the size of the municipality, many have hazardous materials teams, which are trained to deal with chemical and toxic agent spills. Unfortunately, many other first responders may not have had such training and are at risk of becoming casualties themselves, as has happened several times in the past.

If the incident is more than local agencies can handle, not only from a government perspective but also from the hospitals perspective, then state emergency management systems are called into play. The governor of the state could call up the National Guard to provide medical decontamination, transportation, and other services. Within the National Guard, there are a total of 32, with 11 more planned, chemical defense units stationed around the United States. Unfortunately, these units require many hours to mobilize and deploy to a site.[16] The Marine Chemical Biological Incident Response Force at Camp LeJuene, North Carolina, could likewise be activated.[17]

5 If the event supersedes the state's ability to respond, the federal government would become involved. The federal government's actions are predicated on multiple presidential decision directives, many of which have been established following September 11.[18] The Federal Bureau of Investigation has the responsibility for domestic terrorism and crisis management, investigating and preparing documentation for any criminal proceedings that might be conducted within the judicial system. The Federal Emergency Management Agency (Fema) is the lead agency for management assistance to state and local governments, providing emergency relief to affected individuals and businesses, decontaminating affected areas, and helping ensure public health safety.[19]

In addition to Fema, the Department of Health and Human Services is the lead agency under the

federal response plan to help provide health and health-related services, as well as medical services.[20] The Public Health Service would, in turn, activate the National Disaster Medical System,[21] which helps prepare direct relief to disaster survivors in the field. The National Disaster Medical System has three components—prehospital treatment, hospital evacuation, and in-hospital care. The prehospital treatment is provided by disaster medical assistance teams,[22] which are teams of about 40 individuals to include

physicians, nurses, paramedics, and so on, who are responsible for first aid, casualty-clearing medical station, and field surgical intervention. As with the National Guard, however, these activities take a minimum of 12 to 24 hours to organize and implement. The Department of Health and Human Services has a number of other specialized teams that help respond.

The Department of Defense (Dd) is also in a position to assist with incidents of biological or chemical terrorism, providing technical assistance, bomb disposal, decontamination, security, and other services to federal, state, and local authorities. The Dod can assign a military support liaison officer who works with Fema to coordinate interagency efforts between Fema and the branches of the Armed Forces.[23,24]

What the anesthesiologist in his or her worksite needs to know is that while he or she is managing a disaster, there are a number of local, state, and federal agencies that are mobilizing to help him or her handle the situation, depending on the gravity and number of casualties. The individual physician-anesthesiologist needs to focus his or her activities on dealing with individual patients, as outlined in this section.

The Cdc has established a National Pharmaceutical Stockpile program as a national repository of antibiotics, chemical antidotes, life-support medications, intravenous administration and airway maintenance supplies, and medical/surgical items. There are two phases to this program. The first phase is the provision of eight separate, yet identical, prepackaged caches of medical materials called 12-hour "push packages," which are deployed throughout the United States. The second phase is, if the incident requires a larger response, that vendor management inventories are sent to arrive within 24 to 36 hours after the initial cache of materials arrives. Unfortunately, as with many of these initiatives, there are problems with the adequacy of the response plan.[25]

Military installations have also developed, and have provided when asked by Fema, critical incident stress management teams, as they did following the attacks on the World Trade Center on September 11, 2001. These teams are designed to help individuals, both patients and healthcare providers, cope with traumatic stress and provide grief management.[26]

ROLE OF ANESTHESIOLOGIST IN MANAGING MASS CASUALTIES

It is probably difficult to anticipate all the ways in which anesthesiologists could be asked to assist in managing mass casualty situations. For example, on October 26, 2002, terrorists held 750 hostages at the Nord-Ost theater in Moscow. Many believe that the authorities instilled nebulized or volatile carfentanil into the air ducts of the opera house, thereby immobilizing the terrorists.[27] Unfortunately, because of the incapacitating effect of carfentanil, the hostages also became victims. Patients were transported from the theater to hospitals without any treatment prior to arrival. Ideally, anesthesiologists or other healthcare providers with an opioid antagonist such as naloxone should have been readily available and present at the site to manage both hostages and the terrorists themselves. Unfortunately, this was not the case.

6 As unusual as this scenario is, the anesthesiologist, depending on where he or she practices, may be called to manage situations that are unimaginable by current standards. However, with their basic understanding of physiology and pharmacology, their airway skills, their fluid-resuscitation expertise, and their ability to manage ventilators and to provide anesthesia in the field environment, in the emergency department, in the operating room, and in intensive care units (Icus) will be invaluable. In these mass-casualty situations, many patients suffer burns, fractures, lacerations, soft-tissue trauma, and amputations that will require triage, stabilization in the emergency room or in some other facility near the emergency room, and more-definitive

treatment in the operating room or Icu.

In previous industrial accidents and fires, appropriate management of the airway has been critical. Patients with large-area burns will require establishment of intravenous access for provision of intravascular volume resuscitation. Depending on the event (burn versus a crush injury—protocols for fluid resuscitation vary), in patients with extensive soft-tissue and skeletal muscle damage, alkalinization of the urine with volume resuscitation and diuresis may be organ saving and life saving.[28,29]

If chemical weapons are also used, again depending on the severity of the injury, not only may tracheal intubation be required, but ventilator management may also be necessary. The correct antidotes for managing patients who are victims of industrial chemical accidents and/or chemical warfare agents are discussed subsequently.

NUCLEAR ACCIDENTS

The likelihood of dealing with patients who are exposed to ionizing radiation—from most likely to least likely—would be from a nuclear power plant or reactor accident, terrorist action, and detonation of a nuclear bomb (Table 59-5). Unfortunately, this has happened too often in the past, with Chernobyl being the best example. On April 26, 1986, workers at the Chernobyl nuclear power plant did not recognize or respond to evidence of one of the reactors malfunctioning, with loss of cooling capacity and an explosion of the nuclear reactor.[30] Two workers died as a direct effect of the explosion, whereas those who remained in shielded areas survived unless they went to fight the fire, in which case they eventually died of radiation exposure. Short-term gamma and beta emissions from the explosion, as well as subsequent gamma and beta radiation from the reactor-core debris, killed many more and caused long-term health effects to the entire community. Because of a lack of protective clothing and respirators, the radioactive material that exploded into the atmosphere rained down for several hours and days, affecting many more workers and thousands of civilians. Primary sources of radiation were iodine-131, strontium-90, and cesium-137. During the next 24 hours, 140,000 people were evacuated, and potassium iodide tablets were distributed to as many people in the area as possible. Two hundred and thirty patients were subsequently hospitalized, with many patients succumbing to infections because of bone marrow suppression; and, in those patients in whom bone marrow transplantation was attempted, 17 of 19 died because of associated radiation burns. All told, radiation burns caused 21 deaths. Oropharyngeal burns occurred in 28 patients.

TABLE 59-5 Nuclear Threats In Decreasing Order Of Probability

Accidents (nuclear power plants, reactors)
Terrorist action
Single nuclear bomb detonation
Theater nuclear war
Strategic nuclear war

7 Over the next several years, the average exposure around Chernobyl was four times normal due to residual ground contamination. Almost two decades later, the effects of Chernobyl

continue to be felt in the immediate vicinity and in the area downwind from the reactor site.[30,31] The experience from Chernobyl should indicate the kind of injuries and results that anesthesiologists can anticipate from nuclear accidents, including radiation burns, bone marrow suppression, the destruction of the lining of the gastrointestinal (Gi) tract, Gi bleeding with translocation of bacteria, infection, sepsis, septic shock, and death. The sequelae of infection and sepsis are best managed using the evidence-based medicine guidelines promulgated by 11 international groups.[32] As evidenced by the experiences in Chernobyl, potassium iodide is indicated to protect the thyroid gland from taking up iodine-131 and the use of other drugs are being considered, such as 5-androstenediol.

There have also been other situations, from which we can learn, during which people have been exposed to ionizing radiation. On March 28, 1979, at the Three Mile Island nuclear power plant, the number 2 nuclear reactor overheated, and, because the pressure-relief valve failed to close, radioactive coolant was released into the containment facility.[33] As is often the case, there were numerous communication missteps, which resulted in the release of inconsistent information, generating genuine fear among individuals living nearby the nuclear power plant. There were no biological effects of the event, but severe psychological sequelae did result.

On September 13, 1987, in Goiania, Brazil, a lead canister containing between 1,400 and 1,600 curies of cesium-137 was opened, contaminating 250 people. Four people died, but multiple individuals had short-term and long-term health sequelae.[34] Mitigation efforts required the removal of 6,000 tons of clothing, furniture, dirt, trees, and other materials.[35] The cesium had been left in a building in a lead canister when it was abandoned by its occupants; the canister was taken and opened by looters, and children played with the material.

8 Because of the possibility of exposure to ionizing radiation from nuclear power plants and so on, the American Academy of Pediatrics has recommended that at least two tablets of potassium iodide be available for all inhabitants within 10 miles of any nuclear power plant.[36]

POTENTIAL SOURCES OF IONIZING RADIATION EXPOSURE

We are exposed to radiation on an annual basis from cosmic radiation, radon, medical devices, and in multiple stores, factories, and so on. Even an air flight is associated with cosmic radiation exposure. A chest radiograph leads to 5 to 10 mrem of exposure, whereas a computed tomography scan can lead to up to 5,000 mrem of exposure.[37]

9 Obviously, the greatest concern is the exposure to ionizing radiation that is unintentional, such as occurred at the Chernobyl nuclear power plant, or intentional. Intentional threats are the result of military conflict or terrorism, two occurres of intental exposure were in Hiroshima and Nagasaki in 1945. It is important to remember that in Hiroshima, the bomb ("little boy") was only a 12.5-kiloton bomb, which killed an estimated 66,000 people and injured 69,000 more.[38] The bomb that fell at Nagasaki ("fat boy") was a 22-kiloton plutonium implosion-type bomb, which killed between 39,000 and 74,000 people, with 75,000 people sustaining severe injuries.[38] We learned in that experience that the majority of casualties are from the initial blast, from fire, and from the collapse of buildings. Radiation exposure subsequently kills many more. With any nuclear explosion, then, many individuals will be injured or die from building collapse or the thermal pulse. Patients could have burn, crush, or radiation injury, or any combination thereof.

More recently, we recognize that exposure to ionizing radiation may be as a result of terrorism. The most likely event will be the use of a dispersion device such as a conventional weapon (i.e., a bomb), surrounded with radionuclides such as cesium or strontium. In fact, in 1987, Iraq tested a one-ton "dirty" bomb, and, in 1996, Islamic terrorists in Chechnya placed a bomb packed with cesium-137 that did not explode in a Moscow park.[39] Although a radiologic dispersion device remains the most likely event, terrorists could also target a nuclear power plant using a commercial jet, munitions, or internal sabotage.

Although a blast, crush, or thermal injury is readily apparent, the effects of ionizing radiation are usually not apparent. Individuals should be familiar with types of ionizing radiation that include alpha particles, beta particles, gamma rays, x-rays, and neutrons (Table 59-6).[40] It is also helpful

to understand how radiation is measured (Table 59-7). There are several methods that take into account the decay rate of a radioactive isotope (becquerel or a curie) or the dose absorbed, usually quantified as the amount absorbed by any type of tissue or material. The radiation-absorbed dose (rad) = 0.01 Gray (Gy), which is the international system of units (Si) for denoting the amount of energy deposited in joules per kilogram. One Gy equals 100 rad. A Sievert (Sv) is the Si unit for measurement of *human* exposure to radiation in joules per kilogram, with 1 Sv = 100 rem, the latter being a roentgen equivalent for man (rem).

TABLE 59-6 Types Of Radiation

▪TYPE	▪DESCRIPTION
Ionizing radiation	A high-frequency, low-amplitude form of radiation that interacts significantly with biological systems.
Alpha particle (α-particle)	A particle emitted from the nucleus of an atom. It contains two protons and two neutrons and is identical to the nucleus of a helium atom, without the electrons. Having a very large mass, α-particles have poor penetration and pose little hazard after external exposure but can produce tissue injury when inhaled or ingested.
Beta particle (β-particle)	A high-speed particle, identical to an electron, emitted from the nucleus of an atom.
Neutrons	A powerful but uncommon type of radiation, emitted only after a nuclear detonation. Neutrons are highly destructive, producing 10 times more tissue damage than gamma rays.
Gamma rays (γ-rays)	A form of ionizing radiation having no mass. Like visible light, γ-rays are made of photons, have significant penetrance, and are the most important external radiation hazard after a radiation disaster. γ–Rays are emitted from nuclei.
X-rays	Like γ-rays, x-rays have no mass; their energy is emitted from electrons.

TABLE 59-7 Radiation Exposure Terms

▪TERM	▪DEFINITION	▪COMPARISON
Becquerel (Bq)	International system of units (Si) measurement of radioactivity, defined as decay events per second	1 Bq = 1 disintegration/sec

Curie (Ci)	Traditional measure of radioactivity, as measured by radioactive decay	1 Ci = 2.7×10^{10} disintegrations/sec
Radiation-absorbed dose (rad)	Energy deposited by any type of radiation to any type of tissue or material	1 rad = 0.01 Gy
Gray (Gy)	Si unit for the energy deposited by any type of radiation, in joules per kilogram	1 Gy = 100 rad
Roentgen equivalent man (rem)	Unit of *human* exposure to radiation	1 rem = 0.01 Sievert
Sievert (Sv)	Si unit for measurement of *human* exposure to radiation, in joules per kilogram	1 Sv = 100 rem

In a nuclear accident or catastrophe, patients could have several types of radiation exposure, such as external radiation from an x-ray–emitting device or from gamma rays or beta particles. They can also be contaminated with debris-emitting ionized radiation, or they can inhale or ingest gaseous

radioactive material. Some of this material can become incorporated into tissue, such as with radioactive iodine isotopes. To protect individuals, the distance from the source or explosion is the amount of shielding, the time one is exposed, and the amount of radioactive material to which one is exposed are important. Human tissue will block alpha particles (although, if inhaled, alpha particles can penetrate up to 50 μm into the pulmonary epithelium material, leading to the development of lung cancer) but will not stop beta particles or gamma rays. Beta particles can be stopped by aluminum shields, but gamma rays can penetrate even concrete walls, and, from that perspective, therefore, lead is required to shield for both gamma rays and x-rays.

The most likely injury from ionizing radiation is to those tissues that have the greatest turnover rate (i.e., the sensitivity of tissues to radiation is greatest for lymphoid tissues and greater for Gi, reproductive, dermal, bone marrow, and nervous system tissue than for other types of tissue). In reality, the response of lymphoid and bone marrow to ionizing radiation causes the most problems. The thrombocytopenia, granulocytopenia, and Gi injury lead to bleeding and bacterial translocation across the Gi epithelium, the net result of which is sepsis and bleeding, the hallmarks of acute radiation syndrome, which lead to death.

Because ionizing radiation is invisible, individuals may appear normal or may present with nausea, vomiting, diarrhea, fever, hypotension, erythema, and central nervous system (Cns) dysfunction. Patients who present with nausea, vomiting, diarrhea, and fever are likely to have severe acute radiation syndrome. Hypotension, erythema, and Cns dysfunction will manifest later. "Short-term" effects such as these, however, may not appear until days to weeks after the exposure, depending on the amount of exposure (as little as 0.75 to 1.0 Gy), whereas hematopoietic syndrome (severe lymphoid and bone marrow suppression) results from exposure to 3 to 6 Gy and may lead to death within 8 to 50 days.[39] Long-term effects include thyroid cancer and psychologic injury, as has been documented many times in the past.

MANAGEMENT OF IONIZING RADIATION EXPOSURE

If a radiation disaster occurs, it would be followed by a huge coordinated local, state, and federal response, which, at the federal level, would include the U.S. Department of Homeland Security, the Department of Energy, the Department of Justice, Fema, the Environmental Protection Agency, and the Nuclear Regulatory Commission.

Of most importance, depending on the type of event, would be the immediate evacuation of the area. If evacuation is impossible, a safe place should be sought within the home or building. The principle of disaster management always involves containment (avoid bringing patients with material emitting ionizing radiation to the hospital). Therefore, as part of the containment process—to the extent possible—patients should be decontaminated at the site of exposure. Removal of clothing is important. Beta and gamma rays and neutrons will be gone unless there is still material emitting this radiation on patients' clothing. Rather than guess, it is best to disrobe. In previous mass casualty situations, maintenance of patients' privacy has been a concern, but not one that is readily solved, depending on the number of casualties. Afterward, patients' skin should be washed with warm soapy water. Depending on the number of casualties, decontamination areas may have to be set up outside hospitals, with care taken to isolate belongings. The same consideration must also be given to biological fluids as for clothing, including saliva, blood, urine, and stool, because they may be contaminated with radioisotopes and require special handling precautions.

As mentioned earlier, potassium iodide can prevent radiation-induced thyroid effects but must be given as quickly as possible; within 24 hours, if not given it has little protective effect.[36] Other drugs under investigation for prophylaxis of radiation-induced injuries include vitamin E, 5-androstenediol, nitroxides,[41,42,43] and a new compound, He2100, which is a naturally occurring synthetic adrenal steroid hormone that has been found to have protective effects against radiation injury in nonhuman primates.[44] Currently, though, treatment is largely supportive because these patients will develop, based on their acute exposure, acute radiation syndrome manifested by bleeding and sepsis.

Treatment guidelines for management of postirradiation sepsis have been developed and advocated by the military.[45] The use of granulocyte colony-stimulating factor and so on may be of benefit.[39] Other treatments would include oral and Gi decontamination using nasopharyngeal lavage, oral lavage and brushing; early stomach lavage; or administration of emetics and osmotic laxatives. Blocking agents include potassium iodide and strontium lactate. Mobilizing agents include ammonium chloride, calcium gluconate, and diuretics, which may enhance renal excretion. Chelation therapy that has been recommended includes calcium diethylenetriamine pentaacetic acid (Dtpa) as an initial dose and then zinc Dtpa.[46] The use of granulocyte macrophage colony-stimulating factor and thrombopoietin or interleukin 11, although postulated, has not been proven to be of benefit. For individuals with a contaminated Gi tract, selective decontamination may be helpful although, again, has not been demonstrated to be of benefit in this situation.[46]

Unfortunately, because of the possibility of blast, thermal, and crush injury, along with the radiation injury, the care of the injured may require the care of patients who have multiple combined injuries. The initial response should be as per the advanced trauma life support guidelines, which include an assessment of the airway, breathing, and circulation, as well as extent of trauma, and then decontamination of the patient, after which the patient is stabilized and further evaluated. Wounds must be considered contaminated. “Dirty wounds” should not be closed but cleaned and débrided, excised, and observed. Unfortunately, in this situation, there is also the possibility that there may be the combined effects of a radiation-releasing event and the use of chemical or biological weapons.[47]

BIOLOGICAL DISASTERS

Although the threat of biological warfare has existed for some time, following the anthrax attacks of 2001 and 2002, we have had to confront the specter of terrorists using biological weapons to

attack the United States, creating widespread panic and, based on what they used and how it was dispersed, large numbers of casualties and deaths.

10 Even with this heightened awareness of biological terrorism, as in every other area, the reality is that anesthesiologists need to be familiar with contagious diseases that are not initiated by terrorist groups (i.e., influenza, severe acute respiratory syndrome (Sars), West Nile virus). Influenza has killed more people in the twentieth century than any other infectious disease. There have been three large pandemics, including one in 1918 when an avian virus infected humans, creating the deadliest outbreak of disease in U.S. history. Somewhere between 25 and 50 million people, if not more, died, half of whom were otherwise healthy young adults. There were so many deaths in some communities that mass graves were dug to accommodate all the corpses.[48]

The Spanish flu was caused by a subtype of influenza A (there are three types of human influenza viruses: A, B, and C). Only subtypes of influenza A virus normally infect people: H1N1, H1N2, H3N2, H2N2, and now H1N5. All subtype of influenza A viruses infect birds, although birds. Typically, birds do not get sick when they are infected, but avian viruses can transform and infect humans, with subsequent human to human transmission in which case a pandemic could result. Alternately, current human influenza A viruses could have antigenic drift or shift, in which case a virus for which there is already a vaccine could transform such that populations would be naive and another pandemic would develop. This was the case in 1957 and 1958, when the Asian flu (H2N2) caused some 70,000 deaths in the U.S., and in 1968 to 1969, when the Hong Kong flu (H3N2) caused approximately 34,000 deaths in the United States.[49] Usually, the new pathogenic virus is detected several months in advance of major outbreaks and, hopefully, could allow sufficient time for the preparation of vaccines for entire populations. However, currently in the U.S., there is a shortage of vaccines, a shortage that is unlikely to be resolved because of manufacturing liability issues, in which case the government may have to become more involved. There are four antiviral drugs that currently have benefit in patients with the flu, including amantadine, rimantadine, zanamivir, and oseltamivir. If there were another flu pandemic, the World Health Organization (Who) acknowledges that it could kill up to 50 million people worldwide.[49a] Because of their airway and ventilator-management skills, anesthesiologists will be involved in providing care for many of these patients.

Of greater worry is a recurrence of Sars. This is a viral illness, a coronavirus, that first presented in February 2003, infecting thousands of people worldwide, and almost 1,000 died (almost a 10% fatality rate).[50] Healthcare workers were significantly at risk, especially because they were called on to manage these patients in emergency departments, operating rooms, and Icus. Because the virus was airborne and some healthcare workers wore ineffective isolation equipment, such as standard facemasks and so on, some of these individuals inhaled virions, became sick, and died.[51] Entire hospitals had to be quarantined, with no individuals allowed to leave or enter for fear of spreading the virus. Although this seems draconian, the action of several governments in enforcing this strict quarantine was one of the most important ways that the disease was limited. At this time, treatment of Sars is supportive, without any definitive therapy. In 2004, there were several isolated cases reported, but, as of December 2004, no further cases are currently being reported.[52]

The West Nile virus, a mosquito-borne encephalitis, had killed 87 of 2,432 infected people in 2004.[53] The death rate was relatively high, although the number of individuals infected was relatively small. The reason to highlight the West Nile virus is to underscore the importance of public health measures in controlling mosquito-borne diseases.

Biological Terrorism

History

Infectious agents have been used as biological weapons since the dawn of history. Ghengis Khan is reported to have used cats infected with fleas bearing the plague to destroy towns in his conquest of Asia. British forces distributed blankets that had been used by smallpox patients to Native

Americans, killing more than 50% of the infected tribes.[54] In World War Ii, Unit 731, a Japanese military unit, is reported to have dropped plague-infected fleas over populated areas of China, causing outbreaks of plague and killing several hundred thousand people.[54]

The ideal biological agent is one that has the greatest potential for adverse public health impact, generating mass casualties and with potential for easy large-scale dissemination that could cause mass hysteria and civil disruption.[55] Such weapons should be relatively easy to produce, inexpensive, highly infectious, and contagious, resulting in widespread morbidity and mortality. To be effective, there needs to be no natural immunity, which is currently the case with diseases such as smallpox, for which we no longer routinely vaccinate individuals, except in the military and in high-risk public-health areas. There are three categories of biological weapons (Table 59-8). Category A are those weapons that are highly contagious and that fit all the characteristics of a relatively ideal biological agent.

TABLE 59-8 Biological Agents Used For Warfare

▪CATEGORY A	▪CATEGORY B	▪CATEGORY C
Bacillus anthracis (anthrax)	*Coxiella brunetti* (Q fever)	Various equine encephalitic viruses
Variola major (smallpox)	*Vibrio cholerae* (cholera)	
Yersinia pestis (plague)	*Burkholderia mallei* (glanders)	
Clostridium botulinum (botulism)	Enteric pathogens (*Escherichia coli* O157:H7, salmonella, shigella)	
Francisella tularensis (tularemia)	Cholera, cryptosporidium	
Viral hemorrhagic fever (Ebola, Lassa, Marburg, Argentine)	Various encephalitic viruses	
	Various biological toxins	

Smallpox

The last case of naturally occurring smallpox in the world was reported in 1977 in Somalia.[56] In 1978, two laboratory workers in the United Kingdom were infected with smallpox.[56] In 1980, the Who announced that the world was free of this scourge. In 1972, routine vaccination for smallpox was discontinued in the United States.[56] it is precisely because of this that we are at most risk for terrorists using smallpox as a biological weapon. Forty percent to 80% of patients exposed to the smallpox virus will come down with the disease. Smallpox is highly infective, requiring only 10 to 100 organisms to infect an individual. The mortality rate is approximately 30% in unvaccinated patients, and as high as 50% if smallpox occurs in communities that have no native immunity against smallpox. The protective effect of the smallpox vaccine decreases with time, but, even at

20 years, the vaccine would provide some protection.

When an unvaccinated person is initially infected, he or she develops a prodrome of malaise, headache, and backache with the onset of fever to as high as 40°C. The fever decreases over the next 3 or 4 days, at which time a rash develops. This is in contradistinction to chickenpox, in which the rash develops at the same time as the fever. Unlike chickenpox, smallpox has a predilection for the distal extremities and face, although no part of the body is spared (Fig. 59-1). Also, all lesions in a patient with smallpox are at the same stage, whereas, with chickenpox, lesions are at multiple stages, including papules, vesicles, pustules, and scabs (Table 59-9). Most cases of smallpox are transmitted through aerosolized droplets that are inhaled, but clothes and blankets that have come in contact with pustules, until the scab falls off, are infectious; the organism can be transmitted in these linens.

TABLE 59-9 Differential Of Pustular Lesions

	·SMALLPOX	·CHICKENPOX
Fever	2–4 days before rash	Simultaneous with rash
Rash	All lesions have same-stage development	Lesions at various stages (papules, pustules, scabs all present)

FIGURE 59-1. Smallpox.

Smallpox has probably been present in humans since 10,000 BC. It is transmitted human to human, and, if used as a bioterrorism agent, would likely be dispersed by aerosols in the

environment with the hope that multiple humans would be infected and would transmit it to other humans. There is evidence that the former Soviet Union has developed transgenic smallpox viruses that are very infectious and for which the U.S. vaccine may not be completely protective. The onset of such a virus might be very short. Currently, there are only two Who-approved depositories of smallpox, at the Cdc in Atlanta, Georgia, and at the Institute of Virus Preparations in Russia. With the collapse of the Soviet Union, there was concern that some stores of smallpox made it into rogue countries that may have developed their own biological weapons.

A look at how the Who eradicated smallpox might be helpful in understanding how the United States has prepared to respond to smallpox as a biological weapon. It must be remembered that, in the eighteenth century, 400,000 Europeans per year were dying from smallpox. Although only 1% of patients who survive smallpox become blind, it accounted for one third of all cases of blindness in Europe. The Who eradicated smallpox by identifying patients with smallpox and placing them in strict quarantine. Such patients are readily identified because of the presence of smallpox lesions on the face. Not only were patients isolated, but all their contacts were vaccinated because there was a 3- to 7-day window with the naturally occurring virus before the patient developed symptoms and signs of smallpox.[57]

11 Vaccination against smallpox is controversial. The vaccine is made from a live vaccinia virus developed in calf lymph, but it is not an attenuated smallpox virus itself. Smallpox is a member of the *Orthopox* genus of the *pox varidae* family of double-stranded Dna viruses that also contain cowpox, monkeypox, vaccinia, and so on. In the event of a documented case of smallpox, the Cdc has plans to quarantine the patient and then vaccinate immediate contacts of patients within a certain geographic radius. There are stockpiles of vaccines placed strategically throughout the U.S. for just such an event. A bifurcated needle is dipped into the reconstituted vaccine and then 10 to 15 jabs are made into the dermis of the upper deltoid. Because of the side effects of smallpox vaccinations, people with immunologic disorders or eczema (active or with a history of severe eczema) and pregnant or nursing women will not be administered the vaccine. As of 2003, with the use of

vaccination in the U.S. Armed Forces and for healthcare workers, the Cdc reported several nonserious adverse events such as fever, rash, and malaise, and two cases of cardiomyopathy.[58] Because of this, there is no plan to routinely vaccinate the U.S. population. The Cdc and the state departments of health will implement their quarantine and vaccination plans should an index case or several cases (a cluster) occur.

Anthrax

Bacillus anthracis (anthrax) was probably used as a biological weapon in the Middle Ages when troops laying siege to a town would catapult infected animal carcasses over the ramparts and into the inhabited areas. For reasons discussed later, this was not a particularly effective way of infecting the native population. During the 20th century, several countries, including the U.S., Great Britain, Russia, and Iraq, studied ways to weaponize anthrax. Anthrax has appeal as a bioterrorism agent because, if it can be "weaponized" (normally, if anthrax spores are inhaled, they clump in the nasal pharynx), *B. anthracis* must be finely ground so it readily aerosolizes and can get to and deposit in the terminal bronchioles and alveoli.[59] Inhalation anthrax, which was relatively uncommon in the past, has an 80% fatality rate. One of the letters that was mailed in the anthrax attacks of 2001 contained 2 g of weapons-grade anthrax. With an Ld50 of 1,000 spores under optimum conditions, this was enough material to infect 50 million individuals. Most countries that have weaponized anthrax would either aerosolize it using airplanes or deliver it through a dispersion device mounted on top of a missile. The attacks on North America in 2001, as well as the dispersion of anthrax spores from the accidental release at a biological facility in the city of Sverdlovsk in the former Soviet Union in 1979, are illustrative of the potential of anthrax as a weapon. In the U.S., 5 of 11 cases died (50% mortality rate); in the former Soviet Union, 66 of 77 died (86% mortality rate).[60] The Aum Shinrikyo also released anthrax spores in Tokyo in 1993. Fortunately, they used a nonpathogenic strain of anthrax and so there were no casualties.[59] As demonstrated in 2001 in the U.S., smarter terrorists will be far more successful in using

infectious weapons-grade anthrax. Such attacks, even if detected, create mass hysteria and greatly impact the public healthcare system.[61]

Anthrax is a Gram-positive, spore-forming bacillus that is transmitted to humans from contaminated animals, their byproducts, or their carcasses. Spores may persist in soil for years. The disease is all but gone from North America, but it is still prevalent in many developing countries, and herbivores, especially cattle, usually die within 24 to 48 hours of contracting the disease. The dead carvs has such a huge number of organisms that humans, who are relatively resistant to infection, can be exposed and contract the disease.[62]

There are three primary types of anthrax infection: cutaneous, inhalation, and Gi. Ninety-five percent of cases are cutaneous. From a public-health perspective, we are worried most about inhalation anthrax, which worldwide usually affects 2,000 to 20,000 people per annum. People can be exposed through contact with animals in an agricultural setting or in an industrial setting (e.g., a rendering plant or tanning facility) or, as mentioned previously, in the production of biological weapons.[63]

Anthrax has additional appeal to bioterrorists because inhalation anthrax is hard to detect. It manifests as an influenza-like disease with fever, myalgias, malaise, and a nonproductive cough with or without chest pain.[64] After a few days, the patient appears to get better, but then a couple of days later the patient becomes much sicker with dyspnea, cyanosis, hemoptysis, stridor, and chest pain. The most notable finding on physical examination and laboratory testing is a widened mediastinum. Usually, when a patient develops profound dyspnea, death ensues within 1 to 2 days. In the past, penicillin G was the treatment of choice, but, because weaponized anthrax has been engineered to be resistant to penicillin G, ciprofloxacin or doxycycline is more commonly used. In the outbreaks in Florida; and New Jersey, the District of Columbia contacts of infected patients or people exposed to the spores were treated with ciprofloxacin or doxycycline.

Plague

The oldest cases of *Yersinia pestis* (plague) were documented in China in the third century. It created multiple epidemics throughout the world in subsequent years. In the 14th century alone, plague killed one third of the European population. The first documented use of plague as a biological weapon was in 1346 when the Tartars in their siege of the fortress at Kaffa catapulted infected corpses into the city.[54] The plague was used by Unit 731 to infect large areas of China, and as many as 200,000 Chinese may have died. More recently, the U.S. and Russia have studied *Y. pestis* as a bioagent, examining ways to aerosolize it and ways to distribute it. It is viable for approximately 60 minutes after being distributed, and, if spread by an airplane, could remain viable on wind currents for up to 10 km from the dispersion site.

Y. pestis is a nonmotile, Gram-positive bacillus.[55] Rodents and fleas are its natural hosts, and they reinfect each other by fleas biting infected rodents, or, because the soil can be contaminated, rodents can acquire the disease simply by digging in an infected area. Humans are an accidental host, and they acquire the disease usually from a flea bite, although rarely there can be direct inoculation of infected material into a person. Direct person-to-person transmission occurs with pneumonic plague.

There are two types of plague: bubonic and pneumonic. With bubonic plague, after a flea bite, there is a 2- to 6-day incubation period, at which time there is the sudden onset of fever, chills, weakness, and headache. Intense painful swelling occurs in the lymph nodes, usually in the groin, axilla, or neck. This swelling or buboes is typically oval in nature, 1 to 10 cm in diameter and extremely tender. Up to 25% of patients will have pustules, papules, or skin lesions near this buboe. Without treatment, patients become septic and develop septic shock with cyanosis and gangrene in peripheral tissues, leading to the "black death" descriptor that was used during the epidemics in Europe. As mentioned, material from these buboes is infective only if inoculated into human tissue. However, patients who have bubonic plague can seed their lungs, in which case they develop pneumonic plague. During coughing, they aerosolize *Y. pestis*, which is highly contagious. Mortality for either form of the disease is more than 50%. Diagnosis is made with a

Gram stain or culture of organisms from blood, sputum, or buboe.

The treatment of choice is streptomycin, but chloramphenicol and tetracycline are acceptable alternatives. These patients with pneumonic plague should be managed as one would manage a patient with drug resistance to tuberculosis because the respiratory secretions are highly infectious.

There was one formal and fixed whole organism vaccine that has been removed from the market, but the U.S. government continues to develop vaccines to *Y. pestis.*[65]

Tularemia

Francisella tularensis (tularemia) has some similarities to anthrax and plague, but it is not nearly as dangerous. It was studied as a biological weapon in the 20th century because it is highly infectious, requiring an inoculum of perhaps as small as only 10 organisms.[66] During World War Ii, tularemia developed in soldiers along the German-Russian front that was

believed secondary to the use of *F. tularensis* as a biological weapon. The fact that both armies were infected underscores one of the dangers of using infectious agents as biological weapons. Often these are dispersed with aerosols, and, despite the best predictions of air currents, they are notoriously unpredictable; with the shifting air currents, one's own troops could become infected. Unit 731 of the Japanese army also studied the use of *F. tularensis* as a biological weapon, and the U.S. and Russia were known to have grown large quantities of *F. tularensis* and stored it.

F. tularensis is a gram-negative, pleomorphic rod.[55] There are several animal hosts, with the cotton-tailed rabbit being one of the most susceptible. Normally, humans acquire *F. tularensis* with direct contact with an infected animal or from the bite of an infected tick or deerfly.[66] Occasionally, the ingestion of infected food or inhalation of a small amount of aerosol will initiate the disease. There are two strains of *F. tularensis*, Jellisoni A and B, with the B strain being relatively innocuous, and, in North America, the A strain is quite virulent. Normally, a patient will develop a cutaneous ulcer at the site of entry after contact with an animal. As few as 10 or 50 organisms can invade the body, either through hair follicles or miniabrasions. The incubation period is 2 to 6 days, at which time there is swelling and ulceration at the site of entry. As the swelling continues, the skin eventually breaks and creates an ulcer, which develops a necrotic base that becomes black as it scars.

It is most likely that *F. tularensis* would be delivered from an aerosol via an airplane, in which case, following inhalation, there is a 3- to 5-day incubation period, and then the onset of disease is marked with fever, pharyngitis, bronchitis, pneumonia, pleuritis, and hilar lymphadenopathy. Mortality rate for pneumonic tularemia is 5 to 15%.[67]

The treatment of choice for tularemia is streptomycin, although gentamicin, tetracycline, and chloramphenicol have been used. There is concern that the former Soviet Union, and perhaps the U.S. and terrorists, have engineered *F. tularensis* to be resistant to a number of agents. Prophylaxis with streptomycin, ciprofloxacin, or doxycycline has been recommended in the past for individuals exposed to the organism. There was a vaccine that was comprised of an attenuated whole organism strain, but it is no longer available. The U.S. Army Medical Research Institute of Infectious Diseases continues to work on vaccines to tularemia.[68]

Botulism

The first known work with *Clostridium botulinum* (botulism) as a biological weapon was in World War Ii. Both the Germans and Japanese military and scientific communities experimented with *C. botulinum*. Unit 731 fed pure cultures of *C. botulinum* to Chinese captives with devastating effects. Both the United States and the former Soviet Union are known to have produced large quantities of *botulinum* toxin, as has Iraq, Iran, Syria, and North Korea. In fact, after the first Gulf War, Iraq admitted to having more than 19,000 L of concentrated *botulinum* toxin, of which almost half was loaded on military weapons.[69] Nineteen thousand liters of *botulinum* toxin is enough to kill the world's population three times over. More recently, the Aum Shinrikyo cult in

Japan dispersed aerosols of *C. botulinum* toxin on three different occasions in their country. Fortunately, their dispersal methods and the agent were associated with multiple problems, and no one was injured. Of concern is if a terrorist organization working with a rogue state acquired and used *C. botulinum* as a bioterrorist weapon.

Botulism is a neuroparalytic disease caused by the toxin from *botulinum*. Unlike all the other bioterrorist agents mentioned previously, it is not caused by a live organism and is, therefore, not contagious. The organism from which *botulinum* toxin is derived is a gram-positive spore, which is an obligatory anaerobe widely distributed in nature in soil and in marine and agriculture products. Humans ingest *C. botulinum* without apparent effects. It is the toxin that produces toxicity. *C. botulinum* has seven distinct toxins, and, once ingested or inhaled, the toxins are distributed in the bloodstream to the cholinergic receptor, where they block the release of acetylcholine by inhibiting the intracellular fusion of the acetylcholine vesicle to the membrane for release. Victims develop progressive weakness, a flaccid paralysis that begins in the extremities and progresses until the respiratory muscles are paralyzed. Of note, *C. botulinum* toxin is the most potent poison known to humans; the Ld100 dose is only 1 picogram.[70]

Shortly after ingestion or inhalation of the toxin, the incubation period is between 2 hours and 8 days but most commonly between 12 and 36 hours.[71] It is manifested, as muscles become weak as diplopia, dysphonia, dysarthria, dysphagia, and eventually dyspnea and frank paralysis. Along with the effects in the skeletal muscular system caused by dysfunction of the nicotinic receptor, muscularinic blockade results in decreased salivation, ileus, and urinary retention. The toxin can be removed through gastric lavage, and the use of cathartics with enemas. The treatment of patients includes the use of a trivalent antitoxin. Patients with profound respiratory embarrassment should have their trachea protected and mechanical ventilation initiated. Without the use of antitoxin, it takes the patient 2 to 8 weeks to recover. From past experience, the mortality rate is quoted as 5 to 10%.

Hemorrhagic Fevers

There are a number of viral hemorrhagic fevers that are listed as category A agents, including the arena viruses (e.g., Lassa fever), bunya viruses (e.g., Hanta), flaviruses (e.g., Dengue), and filoviruses (e.g., Ebola, Marburg). There are at least 18 viruses that cause human hemorrhagic fevers, which form a special group of viruses characterized by viral replication in lymphoid cells, after which patients develop fever and myalgia with an incubation of anywhere from 2 to 18 days, depending on the agent itself and the amount of the agent that is inhaled or inoculated across the dermis.[70] They encompass syndromes that vary from febrile hemorrhagic fever with edema to distributive shock, which rapidly leads to death. Both the U.S. and the former Soviet Union have experimented with and weaponized several of these viruses. Studies in nonhuman primates suggest that the agents are highly infectious, requiring only a few virions to produce illness.[71] As mentioned, several governments have weaponized hemorrhagic fever viruses, and the Aum Shinrikyo cult in Japan went to Africa in the 1990s to try to obtain an Ebola virus that they could weaponize. There is no known incident in which these agents have been used as a biological weapon, but there is clear interest and potential for this use.

The viruses are single-stranded, Rna viruses that have a rodent or insect reservoir and are communicated to humans by inhalation of an aerosol or, as mentioned, contact with an infected animal or through a bite. Humans are not a reservoir for the virus but become infected through contact with infected animals or the bite of an infected insect. The diseases are contagious, and person-to-person transmission in Africa has been documented with several of these viruses.[68] As mentioned, the incubation period is within several days of contact or inhalation of the agent, at which time patients present with fever, myalgia, and evidence of capillary leak (peripheral or pulmonary edema), disseminated intravascular coagulation, and thrombocytopenia, which is one of the hallmarks of the illnesses. The fatality rate, depending again on the specific virus used, is anywhere from 2 to 60%.[68] There are no specific antiviral therapies for this class of viruses, but there have been anecdotal reports of ribavirin, interferon-alpha, and hyperimmune

globulin as being protective, but there is simply not enough experience to know for sure.

There is a live attenuated virus vaccine for yellow fever, but there are none for any of the other agents, although there is extensive, ongoing testing with the development of vaccines for several of these most dangerous viruses.

Role of the Anesthesiologist in Bioterrorism

It is unlikely that an Icu physician or anesthesiologist would be at the initial site of origin of a biological attack, but it could happen. Most likely, they will become involved if the hospital at which they work ends up providing care for a number of these patients.[55] As in the previous situations, anesthesiologists could find themselves being involved in triage in the emergency room, operating room, or Icu.[72] As suggested for several of these situations, airway management and ventilator management may be critical, as would the establishment of intravascular access and volume resuscitation. There is anecdotal evidence from Asia that, with infectious agents, healthcare workers are better protected if they use a neuromuscular blocker when intubating the trachea for the obvious reason that when the anesthesiologist intubates the trachea, they are less likely to be subjected to any aerosolized particles (S. F. Yim, personal communication June 1, 2003). However, this argument is somewhat specious because, whenever dealing with a patient with a suspected pulmonary contagious disease such as anthrax, plague, hemorrhagic virus, tularemia, or drug-resistant tuberculosis, anesthesiologists must protect themselves by using 100% effective respiratory protection, going so far as to consider an oxygen-rebreathing system. (With a burn injury to the airway, however, neuromuscular blockers are not recommended in managing the casualties of a major disaster.)

Obviously, it is critical to have a high index of suspicion if you are managing the index case or two or more patients with presenting signs and symptoms that are suggestive of the use of a biological weapon. The individual who is the point of contact for the index case should notify the hospital infectious disease specialist and the local and state health departments. Factors that might indicate the intentional release of a biological agent would include unusual temporal or geographic clustering of cases, an uncommon age distribution, or a significant number of cases (more than one) of acute flaccid paralysis that might suggest use of *botulinum* toxin.

If called to the hospital to be involved in managing such a catastrophe, the anesthesiologist must review basic decontamination and isolation techniques and, as commented previously, must follow those guidelines scrupulously.

CHEMICAL

Emergency management teams in the U.S. have traditionally prepared to respond to chemical spills and industrial accidents. Many communities have hazardous materials teams that would respond to a chemical spill and exposure at an industrial or commercial site, and communities that have large industrial/chemical plants have emergency plans and systems in anticipation of an accident in their community. It is more difficult to prepare for accidents that involve derailments of railroad tank cars containing chemical agents, but, in this circumstance, state and federal agencies would respond in assisting local communities.

Prior to the mid-1980s, it was unthinkable that chemical agents would be used by rogue states or terrorists, but much has changed. In the 20th century, during World War I, more than 1 million soldiers and civilians were exposed to chemical (gas) injuries, with more than 100,000 of them dying. In 1935, Italy invaded Abyssinia (Ethiopia) and, during that invasion, sprayed mustard gas from aircraft. When Japan invaded China, mustard gas, phosgene, and hydrogen cyanide were used. In that same year, German chemical laboratories produced the first nerve agent, tabun. From 1963 to 1967, Egypt used phosgene and mustard agents in support of South Yemen during the civil war in that country. When Iraq attacked Iran in the 1980s, mustard gas and nerve agents were used. In all these examples,[73] chemical agents were used by the military during armed conflict. In 1994 and 1995, the use of nerve agents by the Japanese cult Aum Shinrikyo was a major turning point.[74] As outlined previously in this chapter, the cult had tried to use anthrax and *botulinum* spores and, as noted, tried to obtain specimens of hemorrhagic viruses for use as

biological weapons. They were not successful with any of these enterprises, but it was their use of sarin in Tokyo that had major healthcare consequences and far-reaching ramifications. As a result of the attack, more than 5,000 persons required emergency medical evaluation, with approximately 1,000 of them likely exposed to the agent, resulting in at least 11 deaths.

Since then, and because of the events of September 11 and the anthrax attacks of 2001, we have had to prepare for the possibility that terrorists would use chemical weapons to attack the United States. Chemical weapons make sense because they are relatively inexpensive compared with conventional and nuclear weapons, they are relatively easy to use, and when used against a population, create major fear and panic and incredible demands on healthcare systems.[73] A well-planned attack would severely cripple a U.S. city, as well as inflict considerable morbidity and mortality. In this section, we discuss some of the different chemical agents that have been developed (Table 59-10).

TABLE 59-10 Potential Chemical Weapons

Nerve
GA (tabun)
GB (sarin)
GD (soman)
GF
VX
Pulmonary
Chlorine
Phosgene
Blood
AC (hydrogen cyanide)
CK (cyanogen chloride)
Vesicants
H, HD (sulfur mustard)
HN_1, HN_2, HN_3 (nitrogen, mustard)
Lewisite (chlorovinyldichloroarsine)

Nerve Agents

The nerve agents are chemicals that affect nerve transmission by inhibiting acetylcholinesterase so that acetylcholine accumulates at the muscarinic and nicotinic acetylcholine receptor and within the CNS. Their effects are due to excess catecholamine. Examples of nerve agents that anesthesiologists use on a regular basis are the carbamates, which include physostigmine, neostigmine, and pyridostigmine. Savin is a carbamate compound that is an insecticide. The rest of the anticholinesterases are the organophosphates, which include the insecticides malathion and diazinon and the nerve agents.

Nerve agents were developed by Germany before World War II but were not used in World War II. They include GA, GB, GD,

GF, and VX in increasing potency and toxicity. These five agents are clear, colorless liquids, which vaporize at room temperature and can then penetrate skin, clothing, or the epithelium of the lung or GI tract. As the agents bind to acetylcholinesterase, acetylcholine accumulates, and one sees the sequelae of excess acetylcholine.

With muscarinic receptor activation, patients experience airway, pupillary, and GI constriction; bradycardia; and activity of the glands within the eyes, nose, and mouth and sweat glands. Nicotinic stimulation leads to tachycardia and hypertension from stimulation at the preganglionic

site and, from stimulation of the nicotinic acetylcholine receptor on the neuromuscular junction, fasciculations, twitching, fatigue, and flaccid paralysis. Excess parasympathetic activity leads to miosis and loss of accommodation, so patients complain of blurred vision. Within the respiratory system, the increased parasympathetic activity leads to bronchospasm, dyspnea, and rhinorrhea. The agent on the skin will produce localized sweating, and fasciculations can be observed. Within the cardiovascular system, activity within the muscarinic system leads to bradycardia, and, at the nicotinic site, preganglionic nodes and increase in heart rate. The net effect is difficult to anticipate; the patient's heart rate may be low, normal, or high. Within the GI tract, the increased parasympathetic activity leads to nausea, vomiting, diarrhea, and incontinence. This overall unopposed parasympathetic activity leads to a pneumonic of DUMBELS (diarrhea, urination, miosis, bronchorrhea and bronchoconstriction, emesis, lacrimation, and salivation).

The toxicity of the nerve agents depends on the compound delivered, the dose that is delivered, and the time that an individual is exposed to that dose. Toxicity of the compounds is demonstrated in Table 59-11, where LCt_{50} is a measure of the concentration versus the time (Ct) of exposure. For example, a patient exposed to 10 mg/m^3 of an agent for 10 minutes would have a Ct of 100 mg/min per m^3. The same could be achieved by being exposed to a concentration of 100 mg/m^3 for only 1 minute.

TABLE 59-11 Toxicity of Nerve Agents

	·LCT_{50} mg/min per m^3	·LD_{50} mg/70 kg
GA	400	1,000
GB	100	1,700
GD	70	50
GF	50	30
VX	10	10

The treatment for nerve agent poisoning is one with which every anesthesiologist is familiar. Atropine is a competitive muscarinic blocker. Pralidoxime chloride is the better long-term treatment because it reactivates acetylcholinesterase by removing the organophosphate compound. Atropine is administered at a dose of 2 to 6 mg or more and is repeated every 5 to 10 minutes until secretions begin to decrease (the patient is not salivating) and ventilation is improved. In severe casualties, 15 to 20 mg would not be unusual, and some casualties have required over 1000 mg of atropine.[75] The U.S. military travels with automatic injectors containing 2 mg of atropine and 600 mg of 2-PAM CL (pyridostigmine) or pralidoxime chloride.

Depending on the extent of exposure, treatment is different. For minimal exposure, often seen with brief exposure to nerve agent vapor, patients may complain of headache and tightness in the chest and manifest miosis, rhinorrhea, and salivation. Individuals must be removed from further exposure, clothing removed, topical atropine instilled in the eye if pain is significant, and wet decontamination provided if there was any liquid exposure. With moderate exposure, the same signs are present, but now the patient demonstrates more severe rhinorrhea, complains of dyspnea, and on examination, there is evidence of bronchospasm and muscular fasciculations. Patients should now be treated with atropine and 2-PAM CL intramuscularly. Casualties again must have their clothing removed, and, if they were exposed to liquid nerve agent, they need to go

through a wet decontamination process. With severe exposure, the same symptoms as mentioned previously are present, but now the patient manifests severe respiratory compromise, flaccid paralysis, incontinence, convulsions, and arrhythmias. The patient should receive aggressive atropine, along with 2-PAM CL to a maximum of 1,500 mg intravenously or intramuscularly, and the patient should go through a wet decontamination, with ventilatory assistance provided if necessary.

For situations in which one is anticipating nerve agent exposure, pyridostigmine is a long-acting agent that binds with acetylcholinesterase, allowing the enzyme to spontaneously regenerate. It does not cross the blood-brain barrier and, if used, must be taken more than 30 minutes prior to exposure.

With nerve injury casualties, decontamination is critical. It needs to be done as quickly as possible, first as mentioned previously by leaving the area of exposure, whether to liquid or vapor. As commented on at the beginning of this chapter, healthcare and emergency workers in Japan became victims themselves by standing unprotected in the subway cars in which there was liquid sarin with some vapor.[5] Patients are decontaminated by removing their clothing and by pouring on them copious amounts of water in 5% hypochlorite (household bleach). The bleach is not as critical as washing with copious amounts of water. Depending on the number of casualties, emergency departments have plans in place to set up fire trucks side by side, with a "chamber" established between the two trucks in which individuals would disrobe as they came into the chamber and be exposed to water sprays as they walked through the chamber to the other side.[76] From there, depending on the severity of the symptoms, they would receive atropine, 2-PAM CL, and further treatment (e.g., assisted ventilation, benzodiazepines, oxygen procedures).

Pulmonary Agents

The pulmonary or choking agents were probably the first chemicals to be used in warfare during World War I. On April 22, 1915, near Ypres, Belgium, the Germans released about 160 tons of chlorine gas from 6,000 pressurized cylinders along their lines with the wind blowing toward the Allies. The chlorine floated on huge clouds toward the Allied lines, causing eye, nose, and throat burning and, as it was inhaled, created pulmonary edema. Casualties began to cough up yellow-tinged pulmonary secretions. Approximately 5,000 soldiers died in that attack, and 2 days later, in a second attack, another 500 soldiers died. In all, more than 15,000 men were wounded. By late 1915, chlorine was replaced by phosgene, which was more deadly than the chlorine gas previously used.[77] During World War II, no chemical weapons were used, but, as mentioned previously, prior to the war, the Germans discovered the chemical weapons known as nerve agents. Following the war, both the Allies and the former Soviet Union used German chemists to develop their own chemical weapons programs.

There are primarily four pulmonary agents: chloropicrin, chlorine, phosgene (CG), and diphosgene. Phosgone is a prototypical agent because, as stated, it is deadlier than any of the other compounds.[78] Its chemical formula is $COCL_2$ with a molecular weight of 98 and a boiling point of 8.2°C. It is a colorless gas and has an odor of recently cut hay at 22 to 28°C and normal pressure conditions. Because of a vapor density of 3.4, it stays in the air for a long period of time, congregating in low-lying places. It is highly soluble in lipids and, therefore, can easily penetrate pulmonary epithelium and the cells lining

the alveoli. Although it is very lipid soluble, it reacts rapidly with water to form hydrochloric acid and carbon dioxide. This may explain how it works because, when it reaches the alveoli, it may produce hydrochloric acid, which is itself extremely toxic to tissues, causing a capillary leak and the development of acute lung injury, which would progress to acute respiratory distress syndrome. Depending on the amount of gas inhaled, hypoxia from low FIO_2 would also complicate this picture. Immediately on exposure to phosgene, patients begin coughing because of the noxious nature of the gas and also exhibit nausea, vomiting, choking, and chest tightness. Following the initial exposure, depending on the amount of gas inhaled, there is a 1- to 24-hour period in which the individual seems relatively free of abnormalities, but during this period of time

the pulmonary capillary membranes are being injured with leakage of fluid into the alveoli.

For individuals who are exposed, gas masks provide the best protection. If gas masks are not available, individuals need to remove themselves from exposure as quickly as possible. For those individuals who inhale sufficient quantities of gas who then develop acute lung injury or acute respiratory distress syndrome, the management is similar to patients who develop this syndrome for other reasons. In this circumstance, the anesthesiologists should be relatively at ease because this is a situation in which they have the physiologic and pharmacologic experience to manage the airway, ventilators, and hemodynamic monitoring to optimize care for patients with noncardiogenic pulmonary edema.

Blood Agents

The so-called blood agents are cyanogens, which are inhaled and release hydrogen cyanide, which impairs cytochrome oxidase and aerobic metabolism at the level of the mitochondria. The blood agents are hydrogen cyanide (AC), hydrocyanic acid, cyanogen chloride, and arsine.[78] At 22 to 27° C, AC is a colorless liquid and can be taken up through the skin as a liquid or inhaled. Its boiling point is 25.7°C, and it is difficult to use as a biological weapon because it is so highly volatile and, therefore, is not persistent. If released in an open area, high concentrations are hard to obtain. In a closed area, high concentrations, which are lethal, can readily be obtained. It is lethal because it interferes with cytochrome oxidase and cellular respiration. Patients quickly develop metabolic acidosis and all the sequelae associated with cellular hypoxemia.

Patients who present with AC exposure have a variety of symptoms, depending on the amount to which they were exposed, the root of poisoning, and as in previous examples, the exposure time. The patient will appear restless, tachypneic, and occasionally will complain of headaches, palpitations, and dyspnea. As time progresses, depending on the severity of the inhalation, nausea, vomiting, convulsions leading to coma, and respiratory failure manifest themselves. If the AC dosage is high, patients may not have any of these symptoms and simply collapse within seconds to minutes of exposure, which would be followed within 1 to 2 minutes by convulsions and cardiac arrest.

Treatment for AC toxicity is another problem for which anesthesiologists are quite familiar because of their use of nitroprusside, which at high doses and for extended periods of time also releases cyanide ions that can poison the cellular respiration. Cyanide ions are normally metabolized by the body by the rhodanese enzyme in the liver, which is a sulfur-requiring step that leads to the bioformation of methemoglobin. Often, there is an insufficient quantity of sulfur present for rhodanese to operate efficiently; therefore, treatment involves the administration of sodium thiosulfate, with supportive care in terms of tracheal intubation, ventilation, 100% oxygen, and cardiac support with ionotropes and vasopressors. If the number of casualties is too great and there is insufficient means to manage casualties, then mortality could be quite high.

Again, for the reasons mentioned, it would be difficult to use AC as an effective chemical weapon by terrorists that would affect large numbers of persons in civilian areas. It is mentioned primarily because of its historical interest and because there may be situations in which in could be used in the future.

Vesicants

During World War I, not only were chlorine and phosgene used, but sulfur mustard was also widely used on both sides of the conflict. Sodium mustard and related compounds such as nitrogen mustard, phosgene oxime, and lewisite, also known as "blister agents," get their names from the burns and blisters produced by these compounds on contact with the skin. Although these blisters are the most readily apparent manifestations, these compounds are also inhaled and can inflict severe damage to the respiratory system and the eyes and produce multiple organ dysfunction syndrome. Vesicants are often used by warring factions to force enemy troops to wear protective equipment, which makes them less mobile and able to fight less efficiently.[78] Blister agents are colorless and almost odorless. if the temperature is high enough, an odor that smells like rotten

onions or mustard is present.

Sulfur mustard is a bifunctional alkylating agent that contains two reactive chloroethyl moieties. These chloroethyl compounds are extremely reactive and allow them to bind to other substances such as nucleic acids, proteins, and nucleotides. For individuals exposed to sulfur mustard, it readily penetrates clothing and infiltrates the skin and the eyes. As it volatilizes, it can be inhaled or ingested through the Gi tract. Symptoms of sulfur poisoning do not show up for 1 to 24 hours after the initial exposure occurs, depending on the amount of material to which an individual is exposed. By this point in time, the majority of damage has already been done. Mild poisoning with sulfur mustard results in such symptoms as eye pain with extensive tearing, erythema and inflammation of the skin, irritation of the mucous membranes, cough, sneezing, and hoarseness. Mild poisoning does not warrant anything other than supportive care and will pass with time.

Exposure to larger amounts of sulfur mustard cause considerable dysfunction, incapacitating individuals and requiring emergency medical care. Individuals often lose their sight, as was common in World War I. Lines of soldiers were led around by one individual with good vision at the front and subsequent individuals in the chain following the soldier ahead of them, with one arm extended onto the shoulder of the soldier in front of them. Nausea, vomiting, and diarrhea develop along with severe respiratory difficulty because the same thing that happens to the skin can occur to the pulmonary epithelium.

A nuclear-biological-chemical protective suit and gas mask provide the best protection against sulfur mustard. Individuals who are exposed should be decontaminated as they would be

if they were exposed to a nerve agent (i.e., clothing is removed and they are washed with warm soapy water with or without 0.5% hypochlorite). Those patients who develop respiratory compromise are managed as they would be with the inhalation of a pulmonary agent.

CONCLUSION

It is difficult to anticipate the role anesthesiologists might play in managing patients who are victims of natural disasters or casualties of a terrorist attack with weapons of mass destruction. What is clear is that anesthesiologists have the requisite training and experience to be of vital importance in managing such casualties. However, based on their training, they may not be emotionally prepared to manage these patients. They must remember that, unlike in their normal practice, they may have to triage patients, accept the fact that the standard of care may be changed, and focus their efforts on interventions that will carry the greatest benefit for the greatest number of casualties (Table 59-12).

TABLE 59-12 Anesthesia and Mass Casualties

- Consider injuries that are or will become life threatening if untreated.
- Aim for anesthesia and surgery that are quick and effective.
- Perioperative deaths are to be expected.
- Many patients are at high risk.
- The usual standard of care is likely to be impossible.
- A vaporizer is unnecessary if total intravenous anesthesia is used. A draw over vaporizer is the most versatile inhalation device.

This process begins when the anesthesiologist receives the call at home or in the hospital of an

impending mass casualty. He or she must first report to the command and control center and, although will most likely work in the operating room, he or she could also be used in the triage area in the emergency department or in the ICU (Table 59-13). Of utmost importance is familiarity with the hospital's disaster plan. The anesthesiologist, like other healthcare personnel, must also develop their own family care plan in anticipation of absence from the home for extended periods of time. Ensuring the safety of healthcare personnel through the appropriate use of protective devices to serve as barriers against radiologic, biological, and chemical weapons is also of vital importance.

TABLE 59-13 Functions of Anesthesiologist at Command and Control Center During Impending Mass Casualty

Report to command and control center (may be difficult to get to, hospital may be secure) and perform the following functions:

- Decontamination
- Triage
  - Dead
  - Expectant
  - Minor
  - Operating room
  - Stabilize—floor
  - Intensive care unit (ICU)—to operating room later
- Operating room—intervention
- ICU—burns, flail chests, traumatic amputations

ELECTROCARDIOGRAM

Lead Placement		
	·ELECTRODE	
	·POSITIVE	·NEGATIVE
BIPOLAR LEADS		
I	LA	RA
II	LL	RA
III	LL	LA
AUGMENTED UNIPOLAR		
aVR	RA	LA, LL
aVL	LA	RA, LL
aVF	LL	RA, LA
	·POSITION	
PRECORDIAL		
V_1	4 ICS–RSB	
V_2	4 ICS–LSB	

V_3	Midway between V_2 and V_4
V_4	5 ICS–MCL
V_5	5 ICS–AAL
V_6	5 ICS–MAL

Three-Lead Systems

·BIPOLAR LEAD SYSTEM	·ELECTRODE PLACEMENT	·ECG LEAD*	·ADVANTAGE
II	RA R–clavicle	II (II)	Dysrhythmias
	LA L–10th rib (midclavicular line)		
	LL Ground		
MCL 1	RA Ground LA L–clavicle LL V_1	III (V_1)	Dysrhythmias and conduction defects
CS 5	RA R–clavicle LA V_5	I (V_5)	Precordial ischemia
	LL Ground		
CB 5	RA R–scapula LA V_5 LL Ground	I (V_5)	Precordial ischemia and dysrhythmias

MCL = modified central lead; CB = central back; CS = central subclavian.

*Selected lead on monitor: ( ) = simulated ECG lead.

THE NORMAL ELECTROCARDIOGRAM—CARDIAC CYCLE

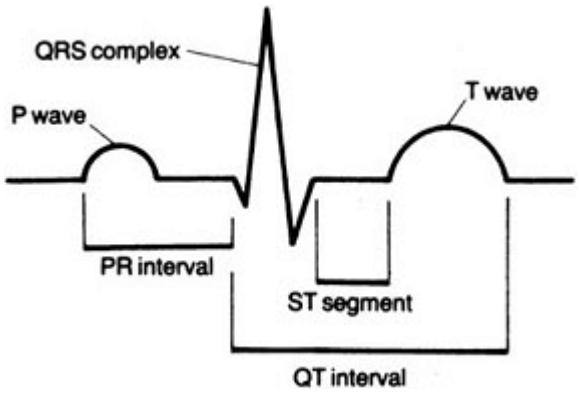

Figure. No Caption Available.

In this section the ECG complex is divided into the atrial (PR interval) and ventricular (QT interval) components.

ASHMAN BEATS

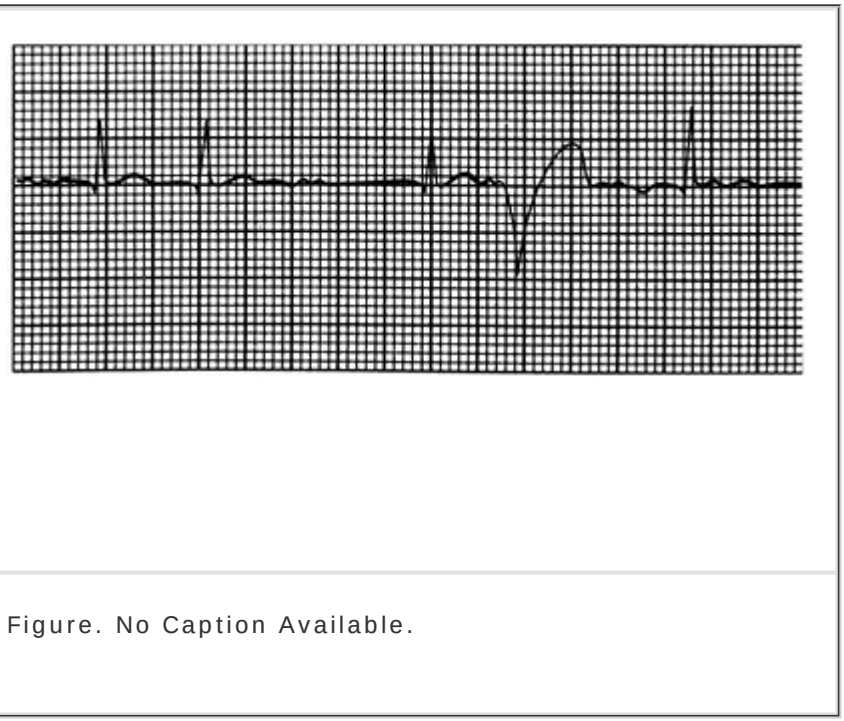

Figure. No Caption Available.

Rate: Variable.

Rhythm: Irregular.

PR interval: P wave may be present if supraventricular premature beat.

QT interval: QRS prolonged (>0.12 s) and altered, revealing bundle-branch pattern, most commonly right bundle. ST segment abnormal.

Note: Ashman beats are often confused with ventricular premature contractions. Ashman beats, usually seen with atrial fibrillation, have no compensatory pause and are a benign ECG finding requiring no treatment.

ATRIAL FIBRILLATION

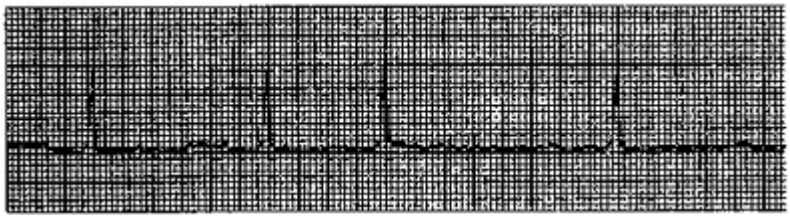

Figure. No Caption Available.

Rate: Variable (~150–200 beats/min).

Rhythm: Irregular.

PR interval: No P wave, and PR interval not discernible.

QT interval: QRS normal.

Note: Must be differentiated from atrial flutter: (1) absence of flutter waves and presence of fibrillatory line; (2) flutter usually associated with higher ventricular rates (>150 beats/min). Loss of atrial contraction reduces cardiac output (10–20%). Mural atrial thrombi may develop. Considered controlled if ventricular rate <100 beats/min.

ATRIAL FLUTTER

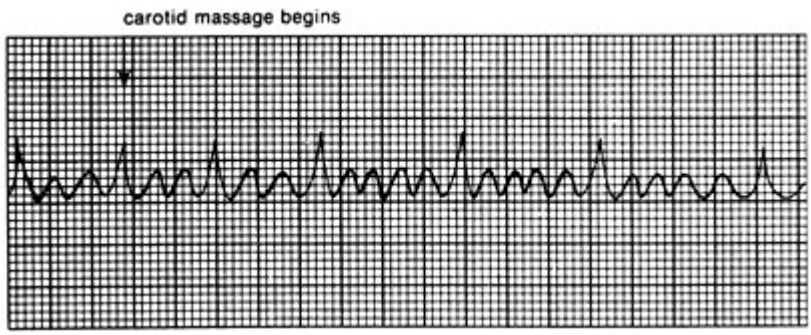

Figure. No Caption Available.

Rate: Rapid, atrial usually regular (250–350 beats/min); ventricular usually regular (<100 beats/min).

Rhythm: Atrial and ventricular regular.

PR interval: Flutter (F) waves are saw-toothed. PR interval cannot be measured.

QT interval: QRS usually normal; ST segment and T waves are not identifiable.

Note: Carotid massage will slow ventricular response, simplifying recognition of the F waves.

ATRIOVENTRICULAR BLOCK (FIRST-DEGREE)

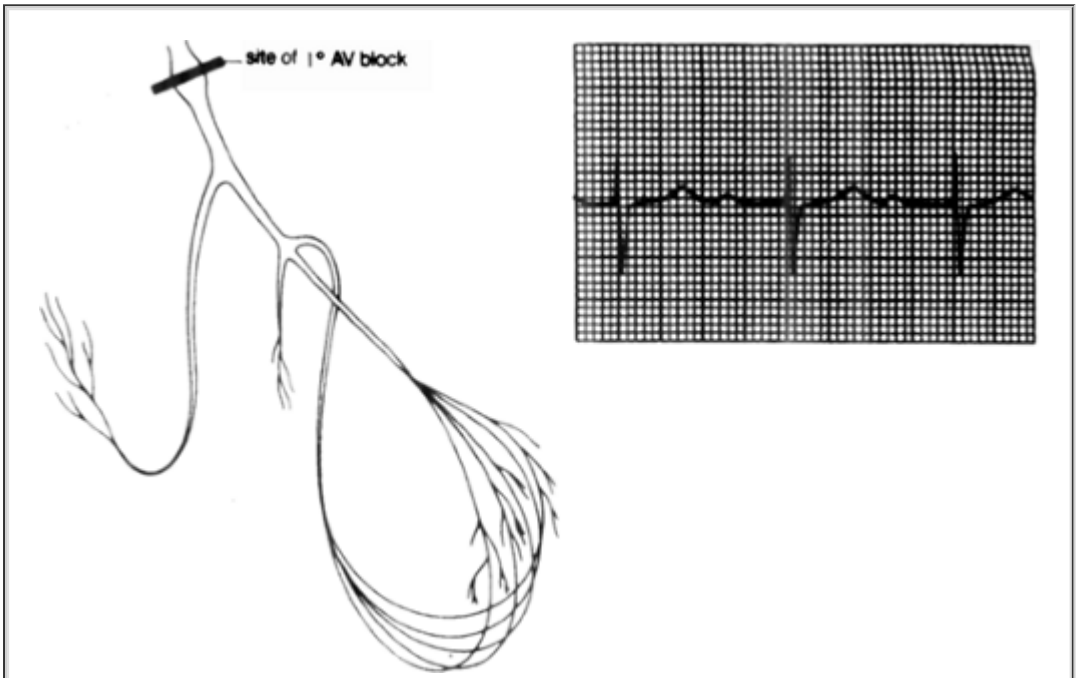

Figure. No Caption Available.

Rate: 60–100 beats/min.

Rhythm: Regular.

PR interval: Prolonged (>0.20 s) and constant.

QT interval: Normal.

Note: Usually clinically insignificant; may be early harbinger of drug toxicity.

ATRIOVENTRICULAR BLOCK (Second-Degree), Mobitz Type I Wenckebach Block

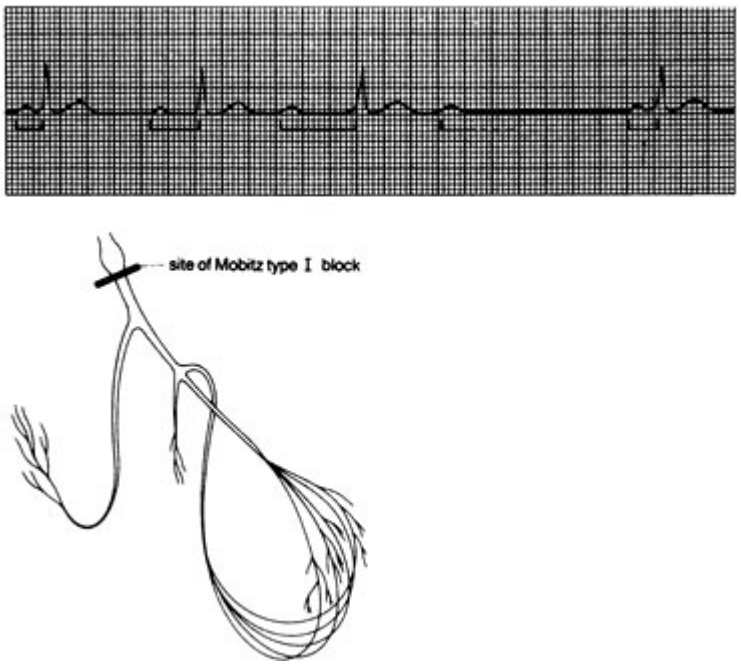

Figure. No Caption Available.

Rate: 60–100 beats/min.

Rhythm: Atrial regular; ventricular irregular.

PR interval: P wave normal; PR interval progressively lengthens with each cycle until QRS complex is dropped (dropped beat). PR interval following dropped beat is shorter than normal.

QT interval: QRS complex normal but dropped periodically.

Note: Commonly seen (1) in trained athletes and (2) with drug toxicity.

ATRIOVENTRICULAR BLOCK (Second-Degree), Mobitz Type II

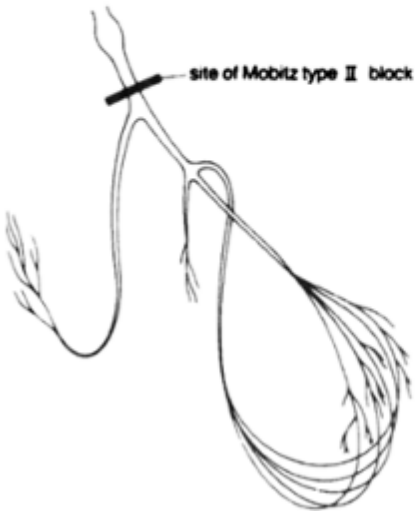

Figure. No Caption Available.

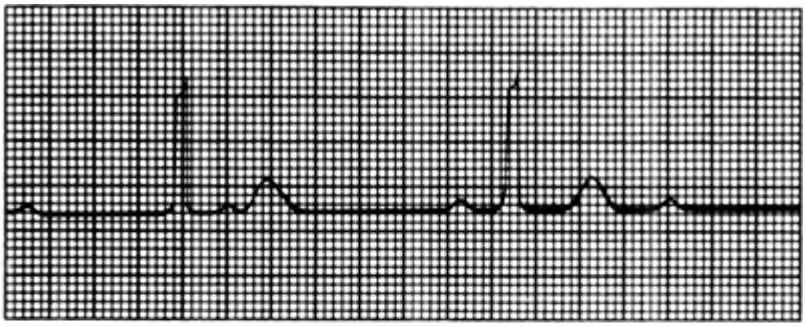
Rate: <100 beats/min.



Rhythm: Atrial regular; ventricular regular or irregular.

PR interval: P waves normal, but some are not followed by QRS complex.

QT interval: Normal but may have widened QRS complex if block is at level of bundle branch. ST segment and T wave may be abnormal, depending on location of block.

Note: In contrast to Mobitz type I block, the PR and RR intervals are constant and the dropped QRS occurs without warning. The wider the QRS complex (block lower in the conduction system), the greater the amount of myocardial damage.

ATRIOVENTRICULAR BLOCK (Third-Degree), Complete Heart Block

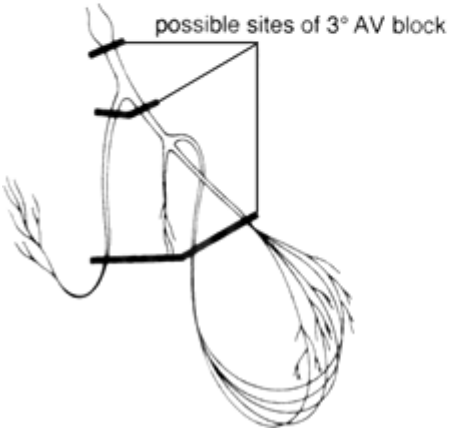


Figure. No Caption Available.

Rate: <45 beats/min.

Rhythm: Atrial regular; ventricular regular; no relationship between P wave and QRS complex.

PR interval: Variable because artia and ventricles beat independently.

QT interval: QRS morphology variable, depending on the origin of the ventricular beat in the intrinsic pacemaker system (atrioventricular junctional versus ventricular pacemaker). ST segment and T wave normal.

Note: Immediate treatment with atropine or isoproterenol is required if cardiac output is reduced. Consideration should be given to insertion of a pacemaker. Seen as a complication of mitral valve replacement.

ATRIOVENTRICULAR DISSOCIATION

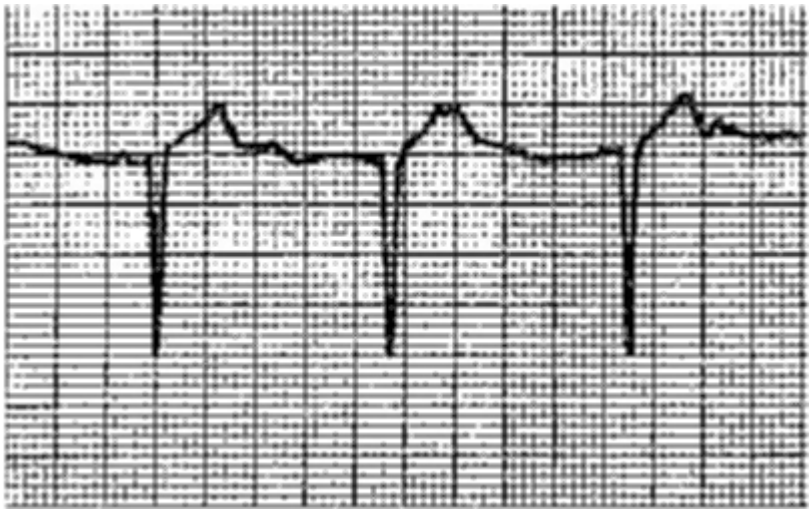

Figure. No Caption Available.

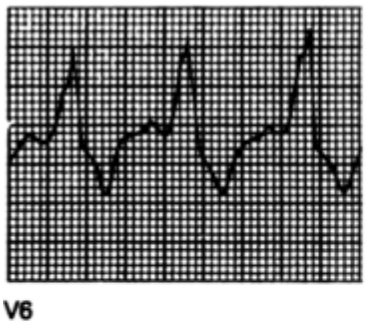
Rate: Variable.



Rhythm: Atrial regular; ventricular regular; ventricular rate faster than atrial rate; no relationship between P wave and QRS complex.

PR interval: Variable because atria and ventricles beat independently.

QT interval: QRS morphology depends on location of ventricular pacemaker. ST segment and T wave abnormal.

Note: Digitalis toxicity can present as atrioventricular dissociation.

BUNDLE-BRANCH BLOCK—LEFT (LBBB)

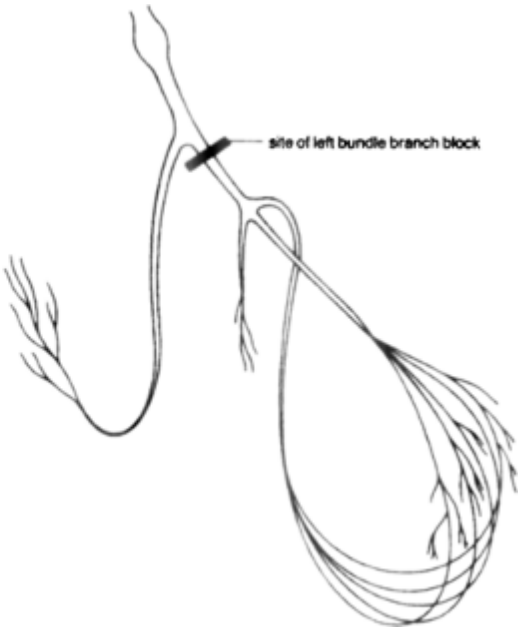


Figure. No Caption Available.

Rate: <100 beats/min.

Rhythm: Regular.

PR interval: Normal.

QT interval: Complete LBBB (QRS >0.12 s); incomplete LBBB (QRS = 0.10–0.12 s); Lead V_1 negative rS complex; I, aVL, V_6 wide R wave without Q or S component. ST segment and T wave defection opposite direction of the R wave.

Note: LBBB does not occur in healthy patients and usually indicates serious heart disease with a poorer prognosis. In patients with LBBB, insertion of a pulmonary artery catheter may lead to complete heart block.

BUNDLE-BRANCH BLOCK—RIGHT (RBBB)

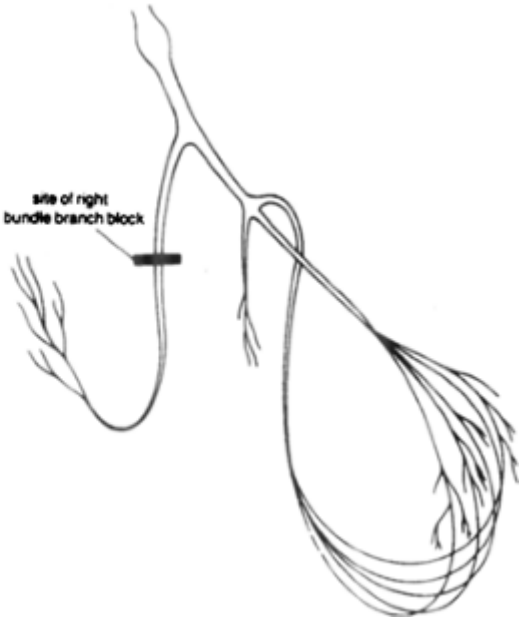

Figure. No Caption Available.

Rate: <100 beats/min.

Rhythm: Regular.

PR interval: Normal.

QT interval: Complete RBBB (QRS >0.12 s); incomplete RBBB (QRS = 0.10–0.12 s). Varying patterns of QRS complex; rSR (V_1); RS, wide R with M pattern. ST segment and T wave opposite direction of the R wave.

Note: In the presence of RBBB, Q waves may be seen with a myocardial infarction.

Electrolyte Disturbances

	▪↓ Ca^{2+}	▪↑ Ca^{2+}	▪↓K^{+}	▪↑K^{+}
Rate	<100 beats/min	<100 beats/min	<100 beats/min	<100 beats/min
Rhythm	Regular	Regular	Regular	Regular
PR interval	Normal	Normal/increased	Normal	Normal
QT interval	Increased	Decreased	T flat U wave	T peaked QT decreased

Note: ECG changes usually do not correlate with serum calcium. Hypocalcemia rarely causes dysrhythmias in the absence of hypokalemia. In contrast, abnormalities in serum potassium concentration can be diagnosed by ECG.

DIGITALIS EFFECT

Figure. No Caption Available.

Rate: <100 beats/min.

Rhythm: Regular.

PR interval: Normal or prolonged.

QT interval: ST segment sloping (“digitalis effect”).

Note: Digitalis toxicity can be the cause of many common dysrhythmias (*e.g.*, premature ventricular contractions, second-degree heart block). Verapamil, quinidine, and amiodarone cause an increase in serum digitalis concentration.

CORONARY ARTERY DISEASE—Ischemia

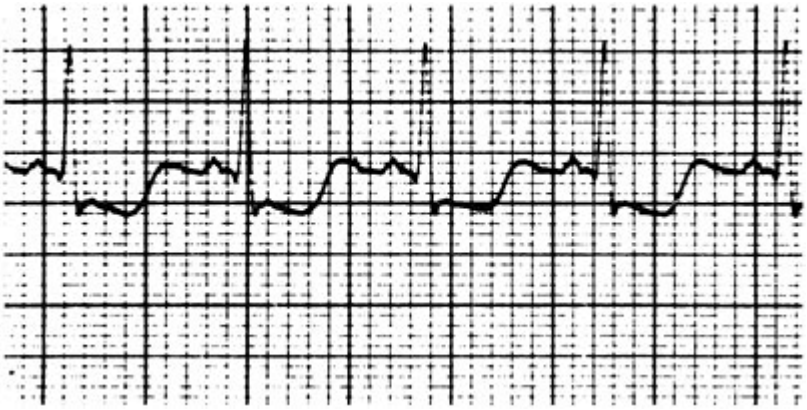

Figure. No Caption Available.

Rate: Variable.

Rhythm: Usually regular, but may show atrial and/or ventricular dysrhythmias.

PR interval: Normal.

QT interval: ST segment depressed; J point depression; T-wave inversion; conduction disturbances. Coronary vasospasm (Prinzmetal) ST segment elevation.

Note: Intraoperative ischemia is usually seen in the presence of "normal" vital signs (*e.g.*, ±20% of preinduction values).

Coronary Artery Disease—Myocardial Infarction

▪ANATOMIC SITE	▪LEADS	▪ECG CHANGES	▪CORONARY ARTERY
Inferior	II, III, aVF	Q, ST, T	Right
Lateral	I, aVL, V_5–V_6	Q, ST, T	Left circumflex
Anterior	I, aVL, V_1–V_4	Q, ST, T	Left
Anteroseptal	V_1–V_4	Q, ST, T	Left anterior descending

SUBENDOCARDIAL MYOCARDIAL INFARCTION (SEMI)

Persistent ST segment depression and/or T-wave inversion in the absence of Q wave. Usually requires additional laboratory data (*e.g.*, isoenzymes) to confirm diagnosis.

TRANSMURAL MYOCARDIAL INFARCTION (TMI)

Q waves seen on ECG useful in confirming diagnosis. Associated with poorer prognosis and more significant hemodynamic impairment; dysrhythmias frequently complicate course.

PAROXYSMAL ATRIAL TACHYCARDIA (PAT)

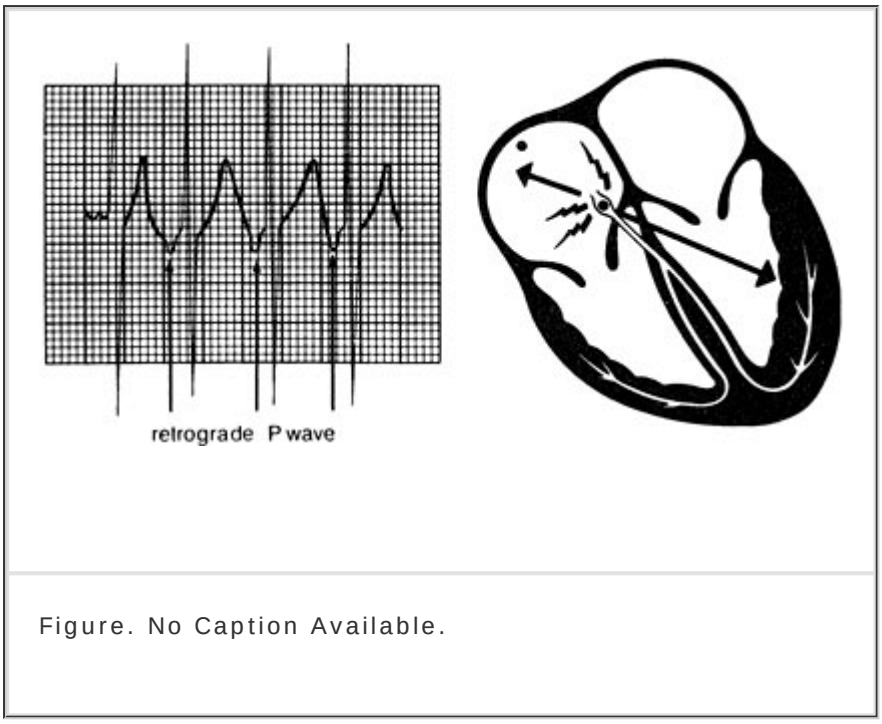

Figure. No Caption Available.

Rate: 150–250 beats/min.

Rhythm: Regular.

PR interval: Difficult to distinguish because of tachycardia obscuring P wave. P wave may precede, be included in, or follow QRS complex.

QT interval: Normal, but ST segment and T wave may be difficult to distinguish.

Note: Therapy depends on degree of hemodynamic compromise. In contrast to management of PAT in awake patients, synchronized cardoversion rather than pharmacologic treatment is preferred in hemodynamically unstable anesthetized patients.

PREMATURE ATRIAL CONTRACTION (PAC)

Figure. No Caption Available.

Rate: <100 beats/min.

Rhythm: Irregular.

PR interval: P waves may be lost in preceding T waves. PR interval is variable.

QT interval: QRS normal configuration; ST segment and T wave normal.

Note: Nonconducted PAC appearance similar to that of sinus arrest; T waves with PAC may be distorted by inclusion of P wave in the T wave.

PREMATURE VENTRICULAR CONTRACTION (PVC)

Figure. No Caption Available.

Rate: Usually <100 beats/min.

Rhythm: Irregular.

PR interval: P wave and PR interval absent; retrograde conduction of P wave can be seen.

QT interval: Wide QRS (>0.12 s); ST segment cannot be evaluated (*e.g.*, ischemia); T wave opposite direction of QRS with compensatory pause (*A*). Bigeminy: every other beat a PVC (*B*); trigeminy: every third beat a PVC. R-on-T occurs when PVC falls in the T wave and can lead to ventricular tachycardia or fibrillation.

Note: If compensatory pause is not seen following an ectopic beat, the complex is most likely supraventricular in origin.

SINUS TACHYCARDIA

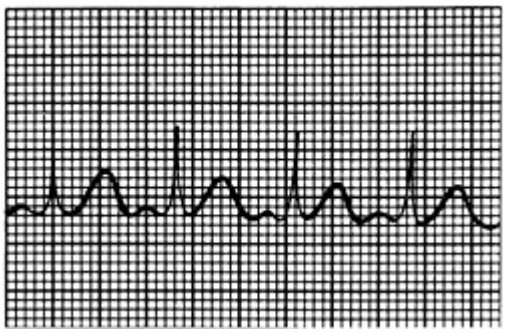

Figure. No Caption Available.

Rate: 100–160 beats/min.

Rhythm: Regular.

PR interval: Normal; P wave may be difficult to see.

QT interval: Normal.

Note: Should be differentiated from paroxysmal atrial tachycardia (PAT). With PAT, carotid massage terminates dysrhythmia. Sinus tachycardia may respond to vagal maneuvers but reappears as soon as vagal stimulus is removed.

TORSADES DE POINTES

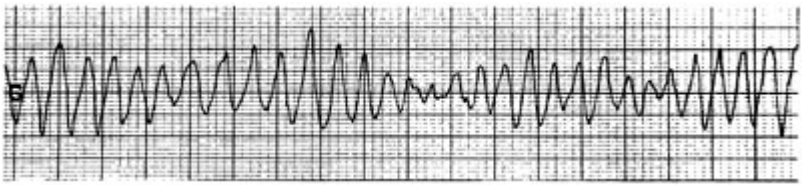

Figure. No Caption Available.

Rate: 150–250 beats/min.

Rhythm: No atrial component seen; ventricular rhythm regular or irregular.

PR interval: P wave buried in QRS complex.

QT interval: QRS complexes usually wide and with phasic variation twisting around a central axis (a few complexes point upward then a few point downward). ST segments and T waves difficult to discern.

Note: Type of ventricular tachycardia associated with prolonged QT interval. Seen with electrolyte disturbances (*e.g.*, hypokalemia, hypocalcemia, and hypomagnesemia) and bradycardia. Administering standard antidysrhythmics (lidocaine, proeain-amide, etc.) may worsen Torsades de Pointes. Treatment includes increasing heart rate pharmacologically or by pacing.

VENTRICULAR FIBRILLATION

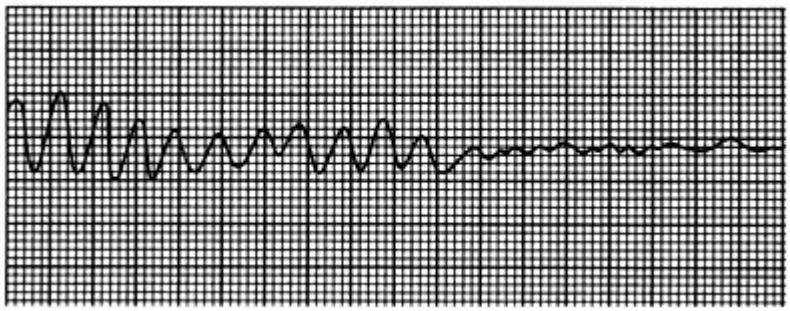

Figure. No Caption Available.

Rate: Absent.

Rhythm: None.

PR interval: Absent.

QT interval: Absent.

Note: "Pseudoventricular fibrillation" may be the result of a monitor malfunction (*e.g.*, ECG lead disconnect). Always check for carotid pulse before instituting therapy.

VENTRICULAR TACHYCARDIA

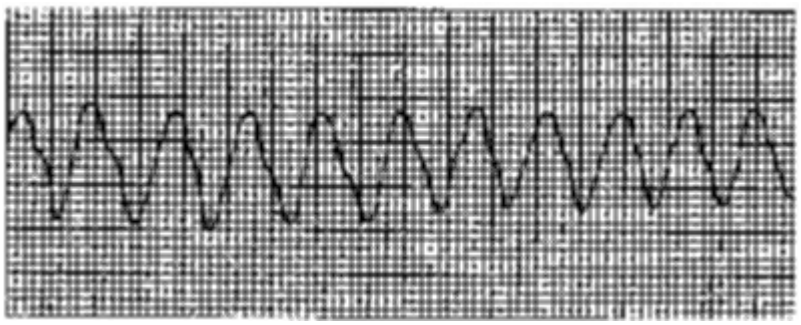

Figure. No Caption Available.

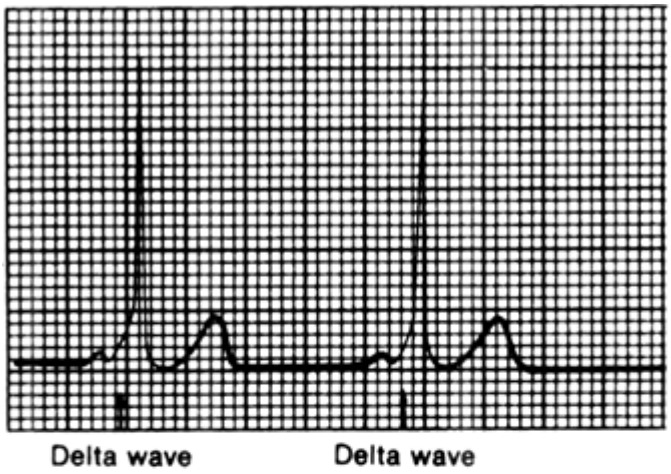
Rate: 100–250 beats/min.



Rhythm: No atrial component seen; ventricular rhythm irregular or regular.

PR interval: Absent; retrograde P wave may be seen in QRS complex.

QT interval: Wide, bizarre QRS complex. ST segment and T wave difficult to determine.

Note: In the presence of hemodynamic compromise, immediate DC synchronized cardioversion is required. If the patient is stable, with short bursts of ventricular tachycardia, pharmacologic management is preferred. Should be differentiated from supraventricular tachycardia with aberrancy (SVT-A). Compensatory pause and atrioventricular dissociation suggest a PVC. P waves and SR' (V_1) and slowing to vagal stimulus suggest SVT-A.

WOLFF-PARKINSON-WHITE SYNDROME (WPW)

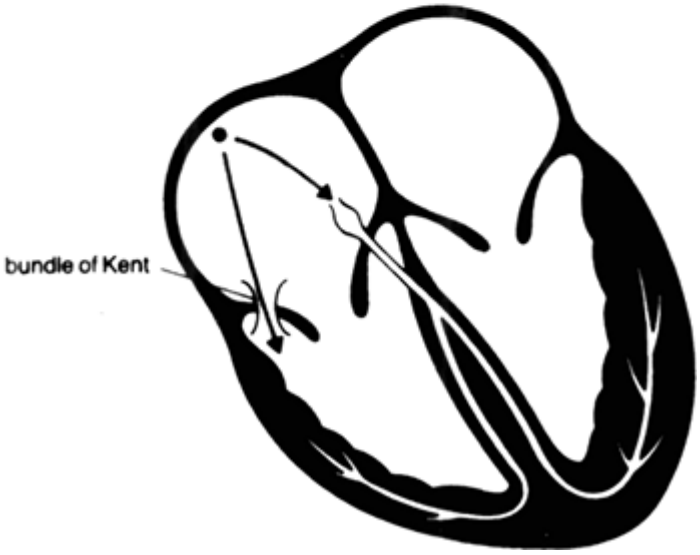


Figure. No Caption Available.

Rate: <100 beats/min.

Rhythm: Regular.

PR interval: P wave normal; PR interval short (<0.12 s).

QT interval: Duration (>0.10 s) with slurred QRS complex. Type A has delta wave, RBBB, with upright QRS complex V_1. Type B has delta wave and downward QRS-V_1. ST segment and T wave usually normal.

Note: Digoxin should be avoided in the presence of WPW because it increases conduction through the accessory bypass tract (bundle of Kent) and decreases atrioventricular node conduction; consequently, ventricular fibrillation can occur.

PACEMAKER

Generic Pacemaker Code (NBG*): NASPE/BPEG Revised (2002)

·POSITION I, PACING CHAMBER(S)	·POSITION II, SENSING CHAMBER(S)	·POSITION III, RESPONSE (S) TO SENSING	·POSITION IV, PROGRAMMABILITY	·POSITION V, MULTISITE PACING
O = none	O = none	O = none	O = none	O = none
A = atrium	A = atrium	I = Inhibited	R = rate modulation	A = atrium
V = ventricle	V = ventricle	T = triggered		V = ventricle
D = dual (A+V)	D = dual (A+V)	D = dual (T+I)		D = dual (A+V)

ICD, implanted cardioverter defibrillator.

*NBG: N refers to North American Society of Pacing and Electrophysiology (NASPE), now called the Heart Rhythm Society (HRS), B refers to British Pacing and Electrophysiology Group (BPEG), and G refers to generic.

From practice advisory for perioperative management of patients with cardiac rhythm management devices: Pacemakers and implantable cardioventer defibrillators. Anesthesiology, 103:186, 2005.

Generic Defibrillator Code (NBD): NASPE/BPEG

·POSITION I, Shock Chamber(s)	·POSITION II, Antitachycardia Pacing Chamber(s)	·POSITION III, Tachycardia Detection	·POSITION IV,* ANTIBRADYCARDIA PACING CHAMBER(S)
O = none	O = none	E = electrogram	O = none
A = atrium	A = atrium	H = hemodynamic	A = atrium
V = ventricle	V = ventricle		V = ventricle
D = dual (A+V)	D = dual (A+V)		D = dual (A+V)

*For robust identification, position IV is expanded into its complete NBG code. For example, a biventricular pacing–defibrillator with ventricular shock and antitachycardia pacing functionality would be identified as VVE-DDDRV, assuming that the pacing section was programmed DDDRV. Currently, no hemodynamic sensors have been approved for tachycardia detection (position III).

From practice advisory for perioperative management of patients with cardiac rhythm management devices: Pacemakers and implantable cardioventer defibrillators. Anesthesiology, 103:186, 2005.

Example of a Stepwise Approach to the Perioperative Treatment of the Patient with a Cardiac Rhythm Management Device (CRMD)

▪PERIOPERATIVE PERIOD	▪PATIENT/CRMD CONDITION	▪INTERVENTION
Preoperative evaluation	Patient has CRMD	• Focused history
		• Focused physical examination
	Determine CRMD type (pacemaker, ICD, CRT)	• Manufacture's CRMD identification card • Chest x-ray studies (no data available) • Supplemental resources*
	Determine whether patient is CRMD-dependent for pacing function	• Verbal history • Bradyarrhythmia symptoms • Atrioventricular node ablation
		• No spontaneous ventricular activity †
	Determine CRMD function	• Comprehensive CRMD evaluation ‡
		• Determine whether pacing pulses are present and create paced beats
Preoperative preparation	EMI unlikely during procedure	• If EMI unlikely, special precautions are not needed

	EMI likely: CRMD is pacemaker	• Reprogram to asynchronous mode when indicated
		• Suspend rate-adaptive functions[§]
	EMI likely: CRMD is ICD	• Suspend antitachyarrhythmia functions
		• If patient is dependent on pacing function, after pacing functions as above
	EMI likely: all CRMD	• Use bipolar cautery; ultrasonic scalpel • Temporary pacing and external cardioversion–defibrillation available
	Intraoperative physiologic changes likely (*e.g.*, bradycardia, ischemia)	• Plan for possible adverse CRMD–patient interaction
Intraoperative management	Monitoring	• Electrocardiographic monitoring per ASA standard • Peripheral pulse monitoring
	Electrocautery interference	• CT/CRP—no current through PG/leads
		• Avoid proximity of CT to PG/leads
		• Short bursts at lowest possible energy
		• Use bipolar cautery; ultrasonic scalpel
	Radiofrequency catheter ablation	• Avoid contact of radiofrequency catheter with PG/leads
		• Radiofrequency current path far away from PG/leads

		• Discuss these concerns with operator
	Lithotripsy	• Do not focus lithotripsy beam near PG
		• R wave triggers lithotripsy? Disable atrial pacing[||]
	MRI	• Generally contraindicated
		• If required, consult ordering physician, cardiologist, radiologists, and manufacturer
	RT	• PG/leads must be outside of RT field
		• Possible surgical relocation of PG
		• Verify PG function during/after RT course
	ECT	• Consult with ordering physician, patient's cardiologist, a CRMD service, or CRMD manufacturer
Emergency defibrillation–cardioversion	ICD: magnet disabled	• Terminate all EMI sources • Remove magnet to reenable therapies • Observe for appropriate therapies
	ICD: programming disabled	• Programming to reenable therapies or proceed directly with external cardioversion–defibrillation
	ICD: either of above	• Minimize current flow through PG/leads
		• PP as far as possible from PG
		• PP perpendicular to major axis PG/leads

		• To extent possible, PP in anterior–posterior location
	Regardless of CRMD type	• Use clinically appropriate cardioversion/defibrillation energy
Postoperative management	Immediate postoperative period	• Monitor cardiac R&R continuously • Backup pacing and cardioversion/defibrillation capability
	Postoperative interrogation and restoration of CRMD function	• Interrogation to assess function • Setting appropriate?[#] • Is CRMD an ICD?** • Use cardiology/pacemaker–ICD service if needed

*Manufacturer's databases, pacemaker clinic records, cardiology consultation.

[†]With cardiac rhythm management device (CRMD) programmed WI at lowest programmable rate.

[‡]Ideally CRMD function assessed by interrogation, with function altered by reprogramming if required.

[§]Most times this will be necessary; when in doubt, assume so.

[||]Atrial pacing spikes may be interpreted by the lithotriptor as R waves, possibly inciting the lithotriptor to deliver a shock during a vulnerable period in the heart.

[#]If necessary, reprogram appropriate setting.

**restore all antitachycardia therapies.

CRP, current return pad; CRT, cardiac resynchronization therapy; CT, cautery tool; ECT, electroconvulsive therapy; EMI, electromagnetic interference; ICD, internal cardioverter–defibrillator; MRI, magnetic resonance imaging; PG, pulse generator; PP, external cardioversion–defibrillation pads or paddles; R&R, rhythm and rate; RT, radiation therapy.

From practice advisory for perioperative management of patients with cardiac rhythm management devices: Pacemakers and implantable cardioventer defibrillators. Anesthesiology, 103:186, 2005.

Treatment of Pacemaker Failure

▪RATE	▪POSSIBLE RESPONSE
Adequate to maintain blood pressure	1. Oxygen, airway control 2. Place magnet over pacemaker 3. Atropine if sinus bradycardia
Severe bradycardia and hypotension	1. Oxygen, airway control 2. Place magnet over pacemaker 3. Other types of pacing if magnet does not activate the pacemaker (transcutaneous, esophageal, or transvenous) 4. Atropine if sinus bradycardia 5. Isoproterenol to increase ventricular rate
No escape rhythm	1. Cardiopulmonary resuscitation 2. Place magnet over pacemaker 3. Other types of pacing if magnet does not activate the pacemaker (transcutaneous, esophageal, or transvenous) 4. Isoproterenol to increase ventricular rate

ATRIAL PACING

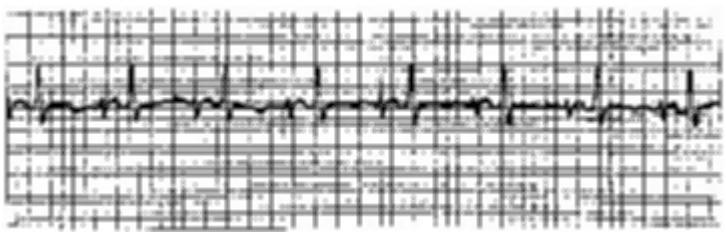

Figure. No Caption Available.

Atrial pacing as demonstrated in this figure is used when the atrial impulse can proceed through the AV node. Examples are sinus bradycardia and junctional rhythms associated with clinically significant decreases in blood pressure.

VENTRICULAR PACING

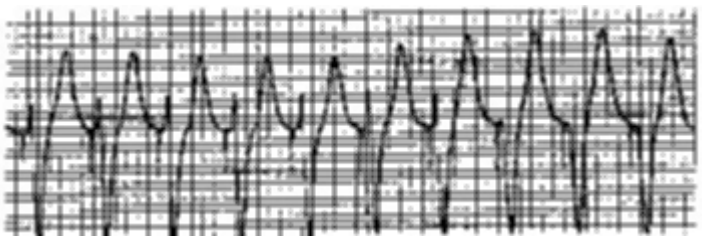

Figure. No Caption Available.

In this tracing ventricular pacing is evident by absence of atrial wave (P wave) and pacemaker spike preceding QRS complex. Ventricular pacing is employed in the presence of bradycardia secondary to AV block or atrial fibrillation.

DDD PACING

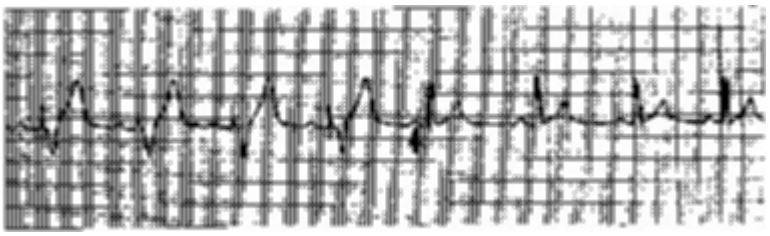

Figure. No Caption Available.

The DDD pacemaker (generator), one of the most commonly used, paces and senses both atrium and ventricle. In the first four beats, the P waves were not followed by a QRS complex within the programmed PR interval. Therefore, a ventricular pacing spike and a ventricular paced beat occurred. In the last four beats (after the arrow), atrial activity proceeded through the AV node in

the allotted amount of time; therefore, ventricular pacing was inhibited.

ATRIAL ELECTROGRAM (AEG)

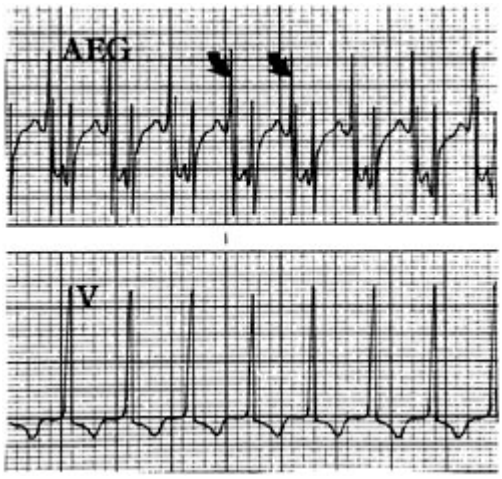

Figure. No Caption Available.

The AEG is useful in differentiating various atrial dysrhythmias. The AEG is obtained from an intracardiac or esophageal lead, if P waves are not clearly seen on the surface ECG. In this trace the V lead does not have obvious P waves; however, the AEG reveals large P waves (arrows) that precede each QRS complex. Locate the QRS on the AEG by matching the R wave on the surface ECG to the AEG. The surface and AEG must be simultaneously recorded.

Guidelines for Using the Electrocautery

1. Electromagnet interference created by an electrocautery can cause a number of problems with pacemaker or ICD function including, but not limited to, reprogramming, inhibition, noise reversion mode, electrical reset, myocardial burns, increase in threshold, rate increment changes in rate adaptive pacemakers, and inappropriate sensing and charging in ICDs.[2,3]
2. When positioning the return plate of the electrocautery,
    a. Ensure it is located so the pacemaker or ICD is not between this return plate and the active electrode.
    b. Ensure the plane described by the return plate and the active electrode of the electrocautery is perpendicular to a plane described by the pacemaker or ICD and the pacemaker's electrodes.
3. Use the smallest current required to cut or coagulate.
4. Use the electrocautery in short bursts.
5. Avoid using the electrocautery within 6 in. of the device or leads.
6. Consider using the bipolar electrocautery or the ultrasonic scalpel[4,5] to minimize interference with pacemaker or ICD function.
7. Activating the electrocautery in the area of the pacemaker or ICD, even if the active electrode is not touching the patient, will cause interference.
8. Do not use the electrocautery when an ICD is programmed to sense and deliver therapy.

9. Convert the ICD to no response either by programming or by using the magnet, depending on the manufacturer of the ICD so the device will not deliver therapy secondary to misinterpretation of signals from the electrocautery as a dysrhythmia. These maneuvers will not change the program of a pacemaker that is incorporated into an ICD.
10. If desired, convert a pacemaker that does not have an ICD to the asynchronous mode so it is not inhibited by the electrocautery.
11. A magnet will not change bradycardia-related pacing parameters in the ICD.
12. ICDs must be programmed to respond to a magnet.

ICD, implanted cardioverter defibrillator.

Additional Issues for Patients with Implanted Cardioverter Defibrillators

1. All ICDs have pacemakers incorporated into the circuitry.
2. Preoperative assessments should include those procedures that are standard for patients with heart disease.
3. Obtain a cardiology consult to help assess the patient, interrogate the ICD, program the device to no response, and program the device to respond to the magnet.
4. There is no particular anesthetic technique that is clearly right or wrong for a patient who has an ICD.
5. Apply patches for external defibrillation when the ICD is programmed to no response. Ensure these external patches are as far away as possible from the device and, if possible, not in the same plane as the device and electrodes.
6. Monitor as required for patient care. If monitoring with a pulmonary arterial catheter, discuss the issues of dislodgment of the ICD's electrodes with the patient and cardiologist. Document in the chart your discussions and the logic supporting the necessity for a pulmonary arterial catheter. Maintain sterile technique, and consider administering antibiotics just before inserting central lines.
7. Continue antidysrhythmic agents until the time of surgery. Discuss with the cardiologist the necessity of administering an additional dose of an antidysrhythmic agent if the patient experiences an intraoperative dysrhythmia.
8. Intraoperative dysrhythmias:
    a. If the patient has a dysrhythmia, rule out and treat the usual intraoperative causes to prevent a recurrence.
    b. If the dysrhythmia continues and a magnet has been used to create the no response mode, remove the magnet from the ICD and allow the ICD to charge and deliver a response.
    c. If the ICD has been programmed to the no response mode, then either quickly reprogram the ICD to deliver a response or proceed directly to external defibrillation.
    d. If external defibrillation or cardioversion is required, apply the defibrillator paddles in an anterior-posterior position if possible and deliver the shock at a level sufficient to terminate the dysrhythmia.
    e. External pacing might be required if the pacemaker/ICD is damaged with the shock.
9. Monitor the patient's ECG and be prepared to deliver an external defibrillation

when transporting the patient to and from the operating room.

10. Interrogate and reprogram the ICD when the patient has entered the postoperative care unit.

ECG, electrocardiogram; ICD, implanted cardioverter defibrillator.
