Contributing Authors

Stephen E. Abram MD
Professor
Department of Anesthesiology, Medical College of Wisconsin, Staff Anesthesiologist, Froedtert Memorial Hospital, Milwaukee, Wisconsin

J. Jeffrey Andrews MD
Professor and Vice-Chair for Education
Department of Anesthesiology, University of Alabama School of Medicine, Birmingham, Alabama

Douglas R. Bacon MD, MA

Professor of Anesthesiology and Medical History
Mayo Clinic College of Medicine, Consultant Anesthesiologist, Mayo Clinic, Rochester, Minnesota

Robert L. Barkin MBA, PharmD, FCP
Rush University Medical College, Clinical Pharmacologist, Rush Pain Center, Chicago, Illinois, Clinical Pharmacologist, The Rush North Shore Pain Center, Skokie, Illinois

Audrée A. Bendo MD
Professor and Vice Chair for Education
Department of Anesthesiology, State University of New York, Downstate Medical Center, Brooklyn, New York

Christopher M. Bernards MD
Virginia Mason Medical Center, Clinical Professor, Department of Anesthesiology, University of Washington, Staff Anesthesiologist, Seattle, Washington

Arnold J. Berry MD, MPH
Professor
Department of Anesthesiology, Emory University, Staff Anesthesiologist, Emory University Hospital, Atlanta, Georgia

Frederic A. Berry MD
Professor Emeritus of Pediatrics and Anesthesiology
Department of Anesthesiology, The University of Virginia, Charlottesville, Virginia

David R. Bevan MB
Professor and Chair
Department of Anesthesia, University of Toronto, Anesthesiologist-in-Chief, University Health Network, Toronto, Ontario, Canada

Barbara W. Brandom MD
Professor
Department of Anesthesiology, University of Pittsburgh, Attending Physician, Department of Anesthesiology, Children's Hospital of Pittsburgh, Pittsburgh, Pennsylvania

Ferne R. Braverman MD
Professor
Department of Anesthesiology, Director, Section of Obstetric Anesthesiology, Yale University School of Medicine, New Haven, Connecticut

Russell C. Brockwell MD
Associate Professor
University of Alabama School of Medicine, Chief of Anesthesiology Birmingham Veterans Affairs Medical Center, Birmingham, Alabama

Levon M. Capan MD
Professor of Anesthesiology
Department of Anesthesiology, New York University School of Medicine, Associate Director, Department of Anesthesiology, Bellevue Hospital Center, New York, New York

Barbara A. Castro MD
Associate Professor of Anesthesiology and Pediatrics
University of Virginia School of Medicine, University of Virginia Health System, Charlottesville, Virginia

Frederick W. Cheney Jr. MD
Professor and Chair
Department of Anesthesiology, University of Washington School of Medicine, Attending Anesthesiologist, University of Washington Medical Center, Seattle, Washington

Barbara A. Coda MD
Clinical Associate Professor
Department of Anesthesiology, University of Washington School of Medicine, Seattle, Washington, Staff Anesthesiologist, McKenzie Anesthesia Group, McKenzie-Willamette Hospital, Springfield, Oregon

Edmond Cohen MD
Professor of Anesthesiology
The Mount Sinai School of Medicine, Director of Thoracic Anesthesia, The Mount Sinai Medical Center, New York, New York

James E. Cottrell MD
Professor and Chairman
Department of Anesthesiology, State University of New York, Downstate Medical Center, Brooklyn, New York

Joseph P. Cravero MD
Associate Professor of Anesthesiology
Dartmouth Hitchcock Medical Center, Lebanon, New Hampshire

C. Michael Crowder MD, PhD
Associate Professor of Anesthesiology and Molecular Biology/Pharmacology
Washington University School of Medicine, Attending Anesthesiologist, Division of Neuroanesthesia, Barnes-Jewish Hospital, St. Louis, Missouri

Marie Csete MD, PhD
Associate Professor and John E. Steinhaus Professor of Anesthesiology
Emory University, Director, Liver Transplant Anesthesiology, Department of Anesthesiology, Emory University Hospital, Atlanta, Georgia

Anthony J. Cunningham MD
Professor/Clinical Vice Dean
Department of Anaesthesia, Royal College of Surgeons in Ireland, Consultant and Professor, Department of Anaesthesia, Beaumont Hospital, Dublin, Ireland

Jacek B. Cywinski MD
Department of General Anesthesiology, The Cleveland Clinic Foundation, Cleveland, Ohio

Steven Deem MD
Associate Professor of Anesthesiology and Medicine (Adjunct, Pulmonary and Critical Care)

University of Washington, Harborview Medical Center, Seattle, Washington

Stephen F. Dierdorf MD
Professor
Department of Anesthesia, Medical University of South Carolina, Charleston, South Carolina

François Donati PhD, MD, FRCPC
Professor
Department of Anesthesiology, University of Montreal, Staff Anesthesiologist, Hospital Maisonneuve-Rosemont, Montreal, Quebec, Canada

John C. Drummond MD, FRCPC
Professor of Anesthesiology
University of California, San Diego, Staff Anesthesiologist, VA Medical Center, San Diego, La Jolla, California

Thomas J. Ebert MD, PhD
Professor
Department of Anesthesiology, Medical College of Wisconsin, Staff Anesthesiologist, VA Medical Center, Milwaukee, Wisconsin

Jan Ehrenwerth MD
Professor
Department of Anesthesiology, Yale University School of Medicine, Attending Anesthesiologist, Yale–New Haven Hospital, New Haven, Connecticut

John H. Eichhorn MD
Professor
Department of Anesthesiology, University of Kentucky College of Medicine, Department of Anesthesiology, UK Chandler Medical Center, Lexington, Kentucky

James B. Eisenkraft MD
Professor of Anesthesiology
Mount Sinai School of Medicine, Attending Anesthesiologist, The Mount Sinai Hospital, New York, New York

John E. Ellis MD
Professor
Department of Anesthesia and Critical Care, Pritzker School of Medicine, The University of Chicago, Section Chief, Anesthesia for Vascular, Thoracic, and General Surgery, University of Chicago Hospitals, Chicago, Illinois

Alex S. Evers MD
Henry E. Mallinckrodt Professor and Chairman
Department of Anesthesiology, Washington University School of Medicine, Anesthesiologist-in-Chief, Barnes-Jewish Hospital, St. Louis, Missouri

Lynne R. Ferrari MD
Associate Professor of Anesthesiology
Harvard Medical School, Medical Director, Perioperative Services, Department of Anesthesia,

Perioperative and Pain Medicine, Children's Hospital, Boston, Massachusetts

Mieczyslaw Finster MD
Professor of Anesthesiology and Obstetrics and Gynecology
Columbia University College of Physicians and Surgeons, New York Presbyterian Hospital, New York, New York

Jeffrey E. Fletcher PhD
Clinical Publications Lead
Medical Communications, AstraZeneca, Wilmington, Deleware

J. Sean Funston MD
Assistant Professor
Department of Anesthesiology, University of Texas Medical Branch, Galveston, Texas

Steven I. Gayer MD, MBA
Associate Professor
Departments of Anesthesiology and Ophthalmology, University of Miami Miller School of Medicine, Director of Anesthesia Services, Bascom Palmer Eye Institute, Miami, Florida

Kathryn Glas MD
Assistant Professor
Department of Anesthesiology, Associate Director, Cardiothoracic Anesthesiology, Director, Intra-Operative Echo Service, Emory University School of Medicine, Atlanta, Georgia

Alexander W. Gotta MD
Emeritus Professor of Anesthesiology
State University of New York, Downstate Medical Center, Brooklyn, New York

John Hartung PhD
Associate Editor
Journal of Neurosurgical Anesthesiology, State University of New York, Brooklyn, New York

Tara M. Hata MD
Associate Professor
Department of Anesthesia, University of Iowa, Roy J. and Lucille A. Carver College of Medicine, University of Iowa Hospitals and Clinics, Iowa City, Iowa

Laurence M. Hausman MD
Assistant Professor
Department of Anesthesiology, Mount Sinai School of Medicine, Vice Chair, Academic Affiliations, Department of Anesthesiology, Mount Sinai Hospital, New York, New York

Thomas K. Henthorn MD
Professor and Chair
Department of Anesthesiology, University of Colorado Health Sciences Center, Denver, Colorado

Simon C. Hillier MB, ChB
Associate Professor

Department of Anesthesia, Indiana University School of Medicine, Staff Anesthesiologist, Riley Hospital for Children, Indianapolis, Indiana

Terese T. Horlocker MD
Professor
Departments of Anesthesiology and Orthopedics, Mayo Clinic College of Medicine, Rochester, Minnesota

Robert J. Hudson MD, FRCPC
Clinical Professor
Department of Anesthesiology and Pain Medicine, University of Alberta, Attending Anesthesiologist, University of Alberta Hospitals, Edmonton, Alberta, Canada

Anthony D. Ivankovitch MD
Professor and Chair
Department of Anesthesiology, Rush University Medical Center, Chicago, Illinois

Joel O. Johnson MD, PhD
Professor and Chair
Department of Anesthesiology, University of Missouri-Columbia Hospitals and Clinics, Columbia, Missouri

Raymond S. Joseph Jr. MD
Staff Anesthesiologist
Virginia Mason Medical Center, Seattle, Washington

Zeev N. Kain MD, MBA
Professor and Executive Vice-Chairman
Department of Anesthesiology, Yale University School of Medicine, Anesthesiologist-in-Chief, Yale–New Haven Children's Hospital, New Haven, Connecticut

Ira S. Kass MD
Professor
Departments of Anesthesiology, Physiology, and Pharmacology, Downstate Medical Center, Brooklyn, New York

Jonathan D. Katz MD
Clinical Professor of Anesthesiology
Yale University School of Medicine, New Haven, Connecticut

Brian S. Kaufman MD
Associate Professor
Departments of Anesthesiology, Medicine, and Neurosurgery, New York University School of Medicine, Co-Director, Critical Care, Tisch Hospital, New York, New York

Charbel A. Kenaan MD
Chief Resident in Anesthesiology
Department of Anesthesiology, Perioperative Medicine, and Pain Management, Jackson Memorial Hospital, University of Miami Miller School of Medicine, Miami, Florida

Donald A. Kroll MD, PhD
Staff Anesthesiologist
Veterans Affairs Medical Center, Biloxi, Mississippi

Carol L. Lake MD, MBA, MPH
CEO
Verefi Technologies, Inc., Elizabethtown, Pennsylvania

Preface

Transformation in the delivery of patient care, combined with changes in education, is the new paradigm for anesthesiology in the 21st century. Minimizing costs while improving efficiency and enhancing patient safety are the goals of contemporary anesthesia practice. To ensure that practitioners have incorporated the most-up-to-date information in their practice, certifying and licensing authorities have mandated continual education and testing both at the trainee and at the practicing anesthesiologist level. These changes are coupled with the need for ongoing innovation as the anesthesiologist continues to be challenged to adapt clinical management to new surgical procedures and technologies. These developments are an extension of the observation we made in the first edition of *Clinical Anesthesia*: “The major achievements of modern surgery would not have taken place without the accompanying vision of the pioneers in anesthesiology.”

Anesthesiology is recognized as the specialty that has done the most to ensure patient safety. Despite these advances, the specialty's own leadership, in addition to outside agencies, has mandated further improvement. No longer does the anesthesiologist have the luxury of admitting the patient to the hospital a day or more before the surgical procedure and of performing a leisurely workup and preoperative assessment. In the ambulatory surgery unit, for example, the patient may be available only minutes before the operation, and decisions must be made immediately as to adequacy of the preanesthetic evaluation and treatment plan. In the inpatient setting, care is perceived as being even more fragmented. For example, the health care professional performing the preoperative evaluation may not be the caregiver in the operating room. In the operating room, where costs can reach $40 to $50 per minute, “production pressure” has been noted to get “the case going.” This occurs in a setting of diminished resources, equipment, drugs, and personnel, with the simultaneous requirement to improve patient safety in the OR. Thus, the anesthesiologist must have information immediately available for the appropriate integration of care in the preincision period. In fact, the American Board of Anesthesiology, in its *Booklet of Information*, emphasizes the importance of this facet of clinical management by stating, “The ability to independently acquire and process information in a timely manner is central to assure individual responsibility for all aspects of anesthesiology care.”

Simultaneous with these clinical requirements are significant changes in the educational process for trainees and established practioners. Responsibility and accountability for one's education have increased. Certifying boards use a framework, such as Maintenance of Certification in Anesthesiology (MOCA), to ensure that the practitioner is current in aspects of patient care. This concept is based on lifelong learning, assessment of professional standing, assessment of clinical practice performance, and a written examination testing cognitive expertise. These changes require a significant shift in the manner in which textbooks present knowledge. With the advent of electronic publishing, clinicians cannot rely solely on a single textbook to supply the “answers” to a clinical conundrum or a board recertification question. As a result, *Clinical Anesthesia* remains faithful to its original goal: *To develop a textbook that supports efficient and rapid acquisition of knowledge*. However, to meet this objective, the editors have also developed a multifaceted, systematic approach to this target. *Clinical Anesthesia* serves as the foundation and reference source for the other educational tools in the Clinical Anesthesia series: *The Handbook of Clinical Anesthesia, Clinical Anesthesia for the PDA, Review of Clinical Anesthesia*, and *The Lippincott Interactive Anesthesia Library on CD-ROM* (LIAL). Each of these provides a bridge to clinical care and education.

To recognize these requirements, in this the first edition of *Clinical Anesthesia* of the 21st century, we have totally redesigned the textbook, from its cover to chapter format and inclusion

of new and relevant material. To enhance access to information, as well as align chapters with contemporary educational goals, each chapter starts with a detailed outline and Key Points. To meet the realities of the world we live in, we have added new chapters on disaster preparedness and weapons of mass destruction, genomics, obesity (bariatric surgery), and office-based anesthesia. We have encouraged contributors to develop clinically relevant themes and prioritize various clinical options considered by many the definitive strength of previous editions. In addition, each contributor emphasizes applicable areas of importance to patient safety. On occasion, redundancy between chapters may exist. We have made every effort to reduce repetition or even disagreement between chapters. Different approaches to a clinical problem also represent the realities of consultant-level anesthesia practice, however, so this diversity in approach remains in certain instances.

Finally, we wish to express our gratitude to the individual authors whose hard work, dedication, and timely submissions have expedited the production of the fifth edition. In addition, we acknowledge the contributions of colleagues and readers for their constructive comments. We also thank our secretaries, Gail Norup, Ruby Wilson and Deanna Walker, each of whom gave unselfishly of their time to facilitate the editorial process. We would also like to take this opportunity to recognize the continuing support of Lippincott Williams & Wilkins. It was more than 25 years ago that Lewis Reines, the former CEO of J.B. Lippincott, recognized the need for a major American anesthesiology textbook focused on education and clinical care. Throughout the intervening years, he has been a trusted colleague, an advisor, and, most importantly, a friend. In addition, we have been blessed with executive editors who have made singular contributions to the success of *Clinical Anesthesia*: Susan Gay, Mary Kay Smith, and Craig Percy. The enduring commitment to excellence in medical publishing continues from Lippincott Williams & Wilkins with Brian Brown, Senior Acquisitions Editor, and David Murphy, Production Manager, with the assistance of Grace Caputo, Project Director, Dovetail Content Solutions, and Chris Miller, Project Manager, TechBooks.

Chapter 1

The History of Anesthesia

Hugh M. Smith

Douglas R. Bacon

KEY POINTS

1	Anesthesiology is a young specialty historically, especially when compared to surgery or internal medicine.
2	Discoveries in anesthesiology have taken decades to build upon the observations and experiments of many people, and in some instances we are still searching. For example, the ideal volatile anesthetic has yet to be discovered.
3	Regional anesthesia is the direct outgrowth of a chance observation by an intern who would go on to become a successful ophthalmologist.
4	Pain medicine began as an outgrowth of regional anesthesia.
5	Much of our current anesthesia equipment is the direct result of anesthesiologists being unhappy with and needing better tools to properly anesthetize patients.
6	Many safety standards have been established through the work of anesthesiologists who were frustrated by the status quo.
7	Organizations of anesthesia professionals have been critical in establishing high standards in education and proficiency, which in turn has defined the specialty.
8	Respiratory critical care medicine started as the need by anesthesiologists to use positive pressure ventilation to help polio victims.
9	Surgical anesthesia, and physician specialization in its administration, has allowed for increasingly complex operations to be performed on increasingly ill patients.

Surgery without adequate pain control may seem cruel to the modern reader, yet this was the

common practice throughout most of history. While anesthesia is considered a relatively new field, surgery predates recorded human history. Human skull trephinations occurred as early as 10,000 BC, with archaeologic evidence of post-procedure bone infection and healing, proving these primitive surgeries were performed on living humans. Juice from coca leaves may have been dribbled onto the scalp wound but the recipient of these procedures was almost certainly awake while a hole was bored into his or her skull with a sharp flake of volcanic glass. This was a unique situation in anesthesia; there are no other instances in which both the operator and his patient share the effects of the same drug.

In contemporary practice, we are prone to forget the realities of pre-anesthesia surgery. Fanny Burney, a well-known literary artist from the early nineteenth century, described a mastectomy she endured after receiving a “wine cordial” as her sole anesthetic. As seven male assistants held her down, the surgery commenced: “When the dreadful steel was plunged into the breast-cutting through veins-arteries-flesh-nerves-I needed no injunction not to restrain my cries. I began a scream that lasted unintermittently during the whole time of the incision—& I almost marvel that it rings not in my Ears still! So excruciating was the agony. Oh Heaven!—I then felt the knife racking against the breast bone-scraping it! This performed while I yet remained in utterly speechless torture.”[1] Burney's description reminds us that it is difficult to overstate the impact of

anesthesia on the human condition. An epitaph on a monument to William T. G. Morton, one of the founders of anesthesia, summarizes the contribution of anesthesia: “BEFORE WHOM in all time Surgery was Agony.”[2] Although most human civilizations evolved some method for diminishing patient discomfort, *anesthesia*, in its modern and effective meaning, is a comparatively recent discovery with traceable origins in the mid-nineteenth century. How we have changed perspectives from one in which surgical pain was terrible and expected to one where patients may fairly presume they will be safe, pain free, and unaware during extensive operations is a fascinating story.

Anesthesiologists are like no other physicians: we are experts at controlling the airway and at emergency resuscitation; we are real-time cardiopulmonologists achieving hemodynamic and respiratory stability for the anesthetized patient; we are pharmacologists and physiologists, calculating appropriate doses and desired responses; we are gurus of postoperative care and patient safety; we are internists performing perianesthetic medical evaluations; we are the pain experts across all medical disciplines and apply specialized techniques in pain clinics and labor wards; we manage the severely sick or injured in critical care units; we are neurologists, selectively blocking sympathetic, sensory, or motor functions with our regional techniques; we are trained researchers exploring scientific mystery and clinical phenomenon.

Anesthesiology is an amalgam of specialized techniques, equipment, drugs, and knowledge that, like the growth rings of a tree, have built up over time. Current anesthesia practice is the summation of individual effort and fortuitous discovery of centuries. Every component of modern anesthesia was at some point a new discovery and reflects the experience, knowledge, and inventiveness of our predecessors. Historical examination enables understanding of how these individual components of anesthesia evolved. A knowledge of the history of anesthesia enhances our appreciation of current practice and intimates where our specialty might be headed.

ANESTHESIA BEFORE ETHER

1 Today, major surgery without adequate anesthesia would be unthinkable, and probably constitute grounds for malpractice litigation. And yet this paradigm, this way of seeing anesthesia as a necessary part of surgery, is a fairly recent development dating back only 160 years. Scholars have sought to explain the comparatively late arrival of anesthesia. In addition to limitations in technical knowledge, cultural attitudes toward pain are often cited as reasons humans endured centuries of surgery without effective anesthesia. For example, it is known that the Roman writer Celsius encouraged “pitilessness” as an essential characteristic of the surgeon, an attitude that prevailed for centuries. While there is some proof for this perspective, closer inspection reveals that most cultures were, in fact, sensitive to the suffering caused by surgical operations and developed methods for lessening pain. Various techniques and plant-based agents

in many parts of the world were employed to alter consciousness or as analgesics. Examination of the methods of managing pain before ether anesthesia is useful for what it illuminates about the historical roots and principal advances of our specialty.

Physical and Psychological Anesthesia

The Edwin Smith Surgical Papyrus, the oldest known written surgical document, describes 48 cases performed by an Egyptian surgeon from 3000 to 2500 BC. While this remarkable surgical treatise contains no direct mention of measures to lessen patient pain or suffering, Egyptian pictographs from the same era show a surgeon compressing a nerve in a patient's antecubital fossa while operating on the patient's hand. Another image displays a patient compressing his own brachial plexus while a procedure is performed on his palm.[3] In the sixteenth century, military surgeon Ambroise Paré became adept at nerve compression as a means of creating anesthesia.

Building upon the technique of Paré, James Moore described in 1874 the combined use of nerve compression and opium. In his book *A Method of Preventing or Diminishing Pain in Several Operations of Surgery*, Moore described a machine devised to apply continuous pressure on nerves and how, with the administration of a grain of opium, surgical pain might be lessened. Surgeon John Hunter used Moore's technique at St. Georges Hospital during the amputation of a leg below the knee following compression of the sciatic and anterior crural nerves.[4] The pain control during the surgery was judged better than without the technique.

Medical science has benefited from the natural refrigerating properties of ice and snow as well. For centuries anatomical dissections were performed only in winter because colder temperatures delayed deterioration of the cadaver, and in the Middle Ages the anesthetic effects of cold water and ice were recognized. It is unclear how frequently cold might have been used during this era but in the seventeenth century, Marco Aurelio Severino documented “refrigeration anesthesia” in some detail. By placing snow in parallel lines across the incisional plane, he was able to render a surgical site insensate within minutes. The technique never became popular, probably because of the challenge of maintaining stores of snow year-round.[5] Severino is also known to have saved numerous lives during an epidemic of diphtheria by performing tracheostomies and inserting trochars to maintain patency of the airway.[6]

Formal manipulation of the psyche to relieve surgical pain was undertaken by French physicians Charles Dupotet and Jules Cloquet in the late 1820s with hypnosis, then called *mesmerism*. Although the work of Anton Mesmer was discredited by the French Academy of Science after formal inquiry several decades earlier, proponents like Dupotet and Cloquet continued to make mesmeric experiments and pleaded to the Academie de Medicine to reconsider its utility.[7] In a well-attended demonstration in 1828, Cloquet removed the breast of a 64-year-old patient while she reportedly remained in a calm, mesmeric sleep. This demonstration made a lasting impression upon British physician John Elliotson who became a leading figure of the mesmeric movement in England in the 1830s and 1840s. Innovative and quick to adopt new advances, Elliotson performed mesmeric demonstrations and in 1843 published *Numerous Cases of Surgical Operations without Pain in the Mesmeric State*. In this work, Elliotson used the term “anaesthesia,” and again 5 years later when he gave the Harveian Oration before the Royal College of Physicians in London. This was 2 years before Oliver Wendell Holmes, who is often credited for introducing the term, but many centuries after Dioscorides first used the word “anesthesia.” Elliotson was roughly criticized by his colleagues for his unorthodox practices. Support for mesmerism faded when in 1846 renowned surgeon Robert Liston performed the first operation under ether anesthesia in England and remarked, “This Yankee dodge beats mesmerism all hollow.”[8]

Despite its inevitable demise, the mesmeric movement was an attempt to cope with surgical pain by manipulation of mental and emotional states. In modern obstetrics, the psychoprophylaxis of Lamaze classes and support provided to parturients by midwives and doulas represent forms of “psychological anesthesia” shown to reduce pharmacologic analgesia requirements and the need for regional anesthesia.

Early Analgesics and Soporifics

Dioscorides, a Greek physician from the first century AD, commented on the analgesia of mandragora, a drug prepared from the bark and leaves of the mandrake plant. He stated that the plant substance could be boiled in wine, strained, and used “in the case of persons… about to be cut or cauterized, when they wish to produce anesthesia.”[9] Mandragora was still being used to benefit patients as late as the seventeenth century. From the ninth to the thirteenth centuries, the *soporific sponge* was a dominant mode of providing pain relief during surgery. Mandrake leaves, along with black nightshade, poppies, and other herbs, were boiled together and cooked onto a sponge. The sponge was then reconstituted in hot water and placed under the patient's nose before surgery. Prior to the hypodermic syringe and routine venous access, ingestion and inhalation were the only known routes of administering medicines to gain systemic effects. Prepared as indicated by published reports of the time, the sponge generally contained morphine and scopolamine in varying amounts—drugs used in modern anesthesia.[10]

Alcohol was another element of the pre-ether armamentarium because it was thought to induce stupor and blunt the impact of pain. Although alcohol is a central nervous system depressant, in the amounts administered it produced little analgesia in the setting of true surgical pain. Fanny Burney's account, mentioned previously, demonstrates the ineffectiveness of alcohol as an anesthetic. Not only did the alcohol provide minimal pain control, it did nothing to dull her recollection of events. Laudanum was an alcohol-based solution of opium first compounded by Paracelsus in the sixteenth century. It was wildly popular in the Victorian and Romantic periods, and prescribed for a wide variety of ailments from the common cold to tuberculosis. Although appropriately used as an analgesic in some instances, it was frequently misused and abused. Laudanum was given by nursemaids to quiet wailing infants and abused by many upper-class women, poets, and artists who were unaware of its addictive potential.

Inhaled Anesthetics

The discovery of surgical anesthetics, in the modern era, remains linked to inhaled anesthetics. The compound now known as *diethyl ether* had been known for centuries; it may have been compounded first by an eighth-century Arabian philosopher Jabir ibn Hayyam, or possibly by Raymond Lully, a thirteenth-century European alchemist. But diethyl ether was certainly known in the sixteenth century, both to Valerius Cordus and Paracelsus, who prepared it by distilling sulfuric acid (oil of vitriol) with fortified wine to produce an *oleum vitrioli dulce* (sweet oil of vitriol). One of the first “missed” observations of the effects of inhaled agents, Paracelsus observed that ether caused chickens to fall asleep and awaken unharmed. He must have been aware of its analgesic qualities, because he reported that it could be recommended for use in painful illnesses.

For three centuries thereafter, this simple compound remained a therapeutic agent with only occasional use. Some of its properties were examined but without sustained interest by distinguished British scientists Robert Boyle, Isaac Newton, and Michael Faraday, none of whom made the conceptual leap to surgical anesthesia. Its only routine application came as an inexpensive recreational drug among the poor of Britain and Ireland, who sometimes drank an ounce or two of ether when taxes made gin prohibitively expensive.[11] An American variation of this practice was conducted by groups of students who held ether-soaked towels to their faces at nocturnal “ether frolics.”

Like ether, nitrous oxide was known for its ability to induce lightheadedness and was often inhaled by those seeking a thrill. It was not used as frequently as ether because it was more complex to prepare and awkward to store. It was made by heating ammonium nitrate in the presence of iron filings. The evolved gas was passed through water to eliminate toxic oxides of nitrogen before being stored. Nitrous oxide was first prepared in 1773 by Joseph Priestley, an English clergyman and scientist, who ranks among the great pioneers of chemistry. Without formal scientific training, Priestley prepared and examined several gases, including nitrous oxide, ammonia, sulfur dioxide, oxygen, carbon monoxide, and carbon dioxide.

At the end of the eighteenth century in England, there was a strong interest in the supposed wholesome effects of mineral waters and gases. Particular waters and gases were believed to prevent and treat disease, and there was great interest in the potential use of gases as remedies for scurvy, tuberculosis, and other diseases. Thomas Beddoes opened his Pneumatic Institute close to the small spa of Hotwells, in the city of Bristol, to study the effect of inhaled gases. He hired Humphry Davy in 1798 to conduct research projects for the Institute. Davy performed brilliant investigations of several gases but focused much of his attention on nitrous oxide. He measured the rate of uptake of nitrous oxide, its effect on respiration, and other central nervous system actions. His human experimental results, combined with research on the physical properties of the gas, were published in *Nitrous Oxide*, a 580-page book published in 1800.

This impressive treatise is now best remembered for a few incidental observations. Davy commented that nitrous oxide transiently relieved a severe headache, obliterated a minor headache, and briefly quenched an aggravating toothache. The most frequently quoted passage was a casual entry: “As nitrous oxide in its extensive operation appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place.”[12] This is perhaps the most famous of the “missed opportunities” to discover surgical anesthesia. Davy's lasting nitrous oxide legacy was coining the phrase “laughing gas” to describe its unique property.

Almost Discovery: Hickman, Clarke, Long, and Wells

2 As the nineteenth century wore on, societal attitudes toward pain changed, perhaps best exemplified by the romantic poets.[13] Thus, the discovery of a means to relieve pain may have become more accepted, and several more near-breakthroughs occurred that are worthy of mention. An English surgeon named Henry Hill Hickman searched intentionally for an inhaled anesthetic to relieve pain in his patients.[14] Hickman used high concentrations of carbon dioxide in his studies on mice and dogs. Carbon dioxide has some anesthetic properties, as shown by the absence of response to an incision in the animals of Hickman's study, but it was never determined if the animals were insensate because of hypoxia rather than anesthesia. Hickman's concept was magnificent; his choice of agent, regrettable.

William E. Clarke, a medical student from Rochester, New York, may have given the first ether anesthetic in January 1842. From techniques learned as a chemistry student in 1839, Clarke entertained his companions with nitrous oxide and ether. Emboldened by these experiences, in January 1842, he administered ether, from a towel, to a young woman named Hobbie. One of her teeth was then extracted without pain by a dentist

named Elijah Pope.[15] A second indirect reference to Clarke's anesthetic suggested that it was believed that her unconsciousness was due to hysteria. Clarke was advised to conduct no further anesthetic experiments.[16]

There is no doubt that 2 months later, on March 30, 1842, Crawford Williamson Long administered ether with a towel for surgical anesthesia in Jefferson, Georgia. His patient, James M. Venable, was a young man who was already familiar with ether's exhilarating effects, for he reported in a certificate that he had previously inhaled it and was fond of its use. Venable had two small tumors on his neck but refused to have them excised because he feared the pain that accompanied surgery. Knowing that Venable was familiar with ether's action, Dr. Long proposed that ether might alleviate pain and gained his patient's consent to proceed. After inhaling ether from the towel and having the procedure successfully completed, Venable reported that he was unaware of the removal of the tumors.[17] In determining the first fee for anesthesia and surgery, Long settled on a charge of $2.00.[18]

Crawford Long, although limited by a rural surgical practice, conducted the first comparative trial of an anesthetic. He wished to prove that insensibility to pain was caused by ether and was not simply a reflection of the individual's pain threshold or the result of self-hypnosis. When ether was withheld during amputation of the second of two fingers, his experimental patient, a slave boy, and a second patient, a woman from whom he removed two tumors without ether and one with,

caused Long to observe that surgery was painless with ether.[19] For Long to gain recognition as the initial discoverer of anesthesia he needed to publish his findings. Long remained silent until 1849, when ether anesthesia was already well known. He explained that he practiced in an isolated environment and had few opportunities for surgical or dental procedures.

Mid-nineteenth-century dentists practiced on the horns of a dilemma. Patients refused beneficial treatment of their teeth for fear of the pain inflicted by the procedure. From a dentist's perspective, pain was not so much life threatening as it was livelihood threatening. A few dentists searched for new ways to relieve pain and one of the first to “discover” a solution was Horace Wells of Hartford, Connecticut, whose great moment of discovery came on December 10, 1844. He observed a lecture-exhibition on nitrous oxide by an itinerant “scientist,” Gardner Quincy Colton, who encouraged members of the audience to inhale the gas. Wells observed a young man injure his leg without pain while under the influence of nitrous oxide. Sensing that nitrous oxide might provide pain relief during dental procedures, Wells contacted Colton and boldly proposed an experiment in which Wells was to be the subject. The following day, Colton gave Wells nitrous oxide before a fellow dentist, William Riggs, extracted a tooth.[20] When Wells awoke, he declared that he had not felt any pain and deemed the experiment a success. Colton taught Wells to prepare nitrous oxide, which the dentist administered with success in his practice. His apparatus probably resembled that used by Colton, a wooden tube placed in the mouth through which nitrous oxide was breathed from a small bag filled with the gas.

A few weeks later, in January 1845, Wells attempted a public demonstration in Boston at the Harvard Medical School. He had planned to anesthetize a patient for an amputation, but, when the patient refused surgery, a dental anesthetic for a medical student was substituted. Wells, perhaps influenced by a large and openly critical audience, began the extraction without an adequate level of anesthesia, and the trial was judged a failure. The exact circumstances of Wells' lack of success are not known. His patient may not have cooperated fully or the dose of anesthetic may have been inadequate. Moreover, Wells may not yet have learned that nitrous oxide lacks sufficient potency to serve predictably as an anesthetic without supplementation. In any event, the patient cried out, and Wells was jeered by his audience. No one offered Wells even conditional encouragement. No one recognized that, even though the presentation had been flawed, nitrous oxide might possess significant therapeutic potential. The disappointment disturbed Wells deeply, and while profoundly distressed, he committed suicide in 1848.

Public Demonstration of Ether Anesthesia

Another New Englander, William Thomas Green Morton, briefly shared a dental practice with Horace Wells in Hartford. Wells' daybook shows that he gave Morton a course of instruction in anesthesia, but Morton apparently moved to Boston without paying for the lessons.[21] In Boston, Morton continued his interest in anesthesia and sought instruction from chemist and physician Charles T. Jackson. After learning that ether dropped on the skin provided analgesia, he began experiments with inhaled ether, an agent that proved to be much more versatile than nitrous oxide. Bottles of liquid ether were easily transported, and the volatility of the drug permitted effective inhalation. The concentrations required for surgical anesthesia were so low that patients did not become hypoxic when breathing ether vaporized in air. It also possessed what would later be recognized as a unique property among all inhaled anesthetics: the quality of providing surgical anesthesia without causing respiratory depression. These properties, combined with a slow rate of induction, gave the patient a significant margin of safety, even in the hands of relatively unskilled anesthetists.[22]

After anesthetizing a pet dog, Morton became confident of his skills and anesthetized patients in his dental office. Encouraged by his success, Morton gained an invitation to give a public demonstration in the Bullfinch amphitheater of the Massachusetts General Hospital, the same site as Wells' failed demonstration. Many details of the October 16, 1846, demonstration are well known. Morton secured permission to provide an anesthetic to Edward Gilbert Abbott, a patient of surgeon John Collins Warren. Warren planned to excise a vascular lesion from the left side of Abbott's neck and was about to proceed when Morton arrived late. He had been delayed because he was obliged to wait for an instrument maker to complete a new inhaler (Fig. 1-1). It consisted

of a large glass bulb containing a sponge soaked with colored ether and a spout that was placed in the patient's mouth. An opening on the opposite side of the bulb allowed air to enter and be drawn over the ether-soaked sponge with each breath.[23]

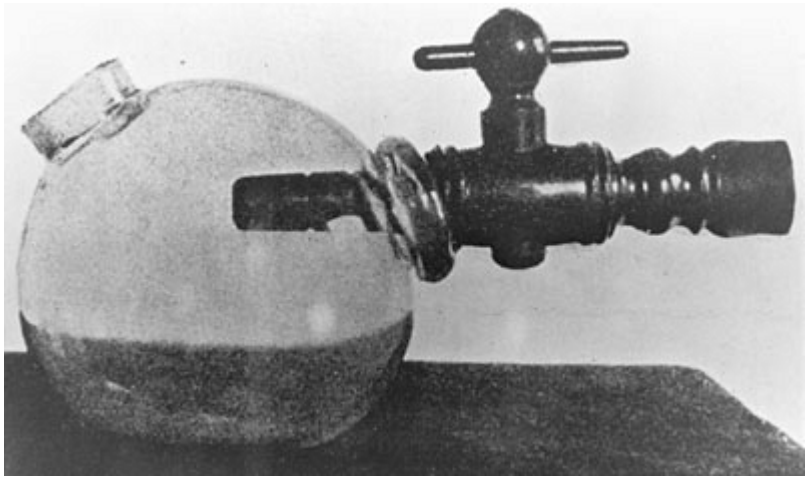

FIGURE 1-1. Morton's ether inhaler (1846).

The conversations of that morning were not accurately recorded; however, popular accounts state that the surgeon responded testily to Morton's apology for his tardy arrival by remarking, “Sir, your patient is ready.” Morton directed his

attention to his patient and first conducted a very abbreviated preoperative evaluation. He inquired, “Are you afraid?” Abbott responded that he was not and took the inhaler in his mouth. After a few minutes, Morton is said to have turned to the surgeon to respond, “Sir, your patient is ready.” Gilbert Abbott later reported that he was aware of the surgery but had experienced no pain. When the procedure ended, Warren immediately turned to his audience and uttered that famous line, “Gentlemen, this is no humbug.”[24]

What would be recognized as America's greatest contribution to nineteenth-century medicine had been realized, but Morton, wishing to capitalize on his “discovery,” refused to divulge what agent was in his inhaler. Some weeks passed before Morton admitted that the active component of the colored fluid, which he had called “Letheon,” was diethyl ether. Morton, Wells, Jackson, and their supporters soon became drawn into in a contentious, protracted, and fruitless debate over priority for the discovery. This debate has subsequently been termed “the ether controversy.” In short, Morton had applied for a patent for Letheon, and when it was granted, tried to receive royalties for the use of ether as an anesthetic. Eventually, the matter came before the U.S. Congress where the House of Representatives voted to grant Morton a large sum of money for the discovery; however, the Senate quashed the deal.

When the details of Morton's anesthetic technique became public knowledge, the information was transmitted by train, stagecoach, and coastal vessels to other North American cities, and by ship to the world. As ether was easy to prepare and administer, anesthetics were performed in Britain, France, Russia, South Africa, Australia, and other countries almost as soon as surgeons heard the welcome news of the extraordinary discovery. Even though surgery could now be performed with “pain put to sleep,” the frequency of operations did not rise rapidly, and several years would pass before anesthesia was universally recommended.

Chloroform and Obstetrics

James Young Simpson was a successful obstetrician of Edinburgh, Scotland, and among the first to use ether for the relief of labor pain. Yet he became dissatisfied with ether and sought a more

pleasant, rapid-acting anesthetic. He and his junior associates conducted a bold search by inhaling samples of several volatile chemicals collected for Simpson by British apothecaries. David Waldie suggested chloroform, which had first been prepared in 1831. Simpson and his friends inhaled it after dinner at a party in Simpson's home on the evening of November 4, 1847. They promptly fell unconscious and, when they awoke, were delighted with their success. Simpson quickly set about encouraging the use of chloroform. Within 2 weeks, he submitted his first account of its use to *The Lancet.* Although Simpson introduced chloroform with boldness, and enthusiasm, and defended its use for women in labor, he gave few anesthetics himself. His goal was simply to improve patient comfort during his operative or obstetric activities.

In the nineteenth century, the relief of obstetrical pain had significant social ramifications and made anesthesia during childbirth a controversial subject. Simpson argued against the prevailing view, which held that relieving labor pain was contrary to God's will. The pain of the parturient was perceived as both a component of punishment, and a means of atonement for the Original Sin. Less than a year after administering the first anesthesia during childbirth, Simpson addressed these concerns in a pamphlet entitled *Answers to the Religious Objections Advanced against the Employment of Anaesthetic Agents in Midwifery and Surgery and Obstetrics*. In this work, Simpson recognized the Book of Genesis as being the root of this sentiment, and noted that God promised to relieve the descendants of Adam and Eve of the curse. Additionally, Simpson asserted that labor pain was a result of scientific and anatomic causes, and not the result of religious condemnation. He stated that the upright position of humans necessitated strong pelvic muscles to support the abdominal contents. As a result, he argued, the uterus necessarily developed strong musculature to overcome the resistance of the pelvic floor and that great contractile power caused great pain. All in all, Simpson's pamphlet probably did not have much impact in terms of changing the prevailing viewpoints about controlling labor pain, but he did articulate many concepts that his contemporaries were debating at the time.[25]

Chloroform gained considerable notoriety after John Snow used it during the deliveries of Queen Victoria. The Queen's consort, Prince Albert, interviewed John Snow before he was called to Buckingham Palace to administer chloroform at the request of the Queen's obstetrician. During the monarch's labor, Snow gave analgesic doses of chloroform on a folded handkerchief. This technique was soon termed *chloroform à la reine.* Victoria abhorred the pain of childbirth and enjoyed the relief that chloroform provided. She wrote in her journal, “Dr. Snow gave that blessed chloroform and the effect was soothing, quieting, and delightful beyond measure.”[26] When the Queen, as head of the Church of England, endorsed obstetric anesthesia, religious debate over the appropriateness of anesthesia for labor pain terminated abruptly. Four years later, Snow was to give a second anesthetic to the Queen, who was again determined to have chloroform. Snow's daybook states that by the time he arrived, Prince Albert had begun the anesthetic and had given his wife “a little chloroform.”

John Snow, already a respected physician, took an interest in anesthetic practice and was soon invited to work with many leading surgeons of the day. In 1848, John Snow introduced a chloroform inhaler. He had recognized the versatility of the new agent and came to prefer it in his practice. At the same time, he initiated what was to become an extraordinary series of experiments that were remarkable in their scope and for anticipating sophisticated research performed a century later. Snow realized that successful anesthetics must not only abolish pain but also prevent movement. He anesthetized several species of animals with varying concentrations of ether and chloroform to determine the concentration required to prevent movement in response to sharp stimuli. Despite the limitations of mid-nineteenth-century technology, this work approximated the modern concept of minimum alveolar concentration (MAC).[27] Snow assessed the anesthetic action of a large number of potential anesthetics but did not find any to rival chloroform or ether. His studies led him to recognize the relationship between solubility, vapor pressure, and anesthetic potency, which was not fully appreciated until after World War II. He also fabricated an experimental closed-circuit device in which the subject (Snow himself) breathed oxygen while the exhaled carbon dioxide was absorbed by potassium hydroxide. Snow published two remarkable books, *On the Inhalation of the Vapour of Ether* (1847) and *On Chloroform and Other Anaesthetics* (1858). The latter was almost completed when he died of a

stroke at the age of 45.

THE SECOND GENERATION OF INHALED ANESTHETICS

Throughout the second half of the nineteenth century, other compounds were examined for their anesthetic potential. The pattern of fortuitous discovery that brought nitrous oxide, diethyl ether, and chloroform forward between 1844 and 1847 continued. The next inhaled anesthetics to be used routinely, ethyl chloride and ethylene, were also discovered as a result of

unexpected observations. Ethyl chloride and ethylene were first formulated in the eighteenth century. Ethyl chloride was used as a topical anesthetic and counterirritant; it was so volatile that the skin transiently “froze” after ethyl chloride was sprayed on it. Its rediscovery as an anesthetic came in 1894, when a Swedish dentist named Carlson sprayed ethyl chloride into a patient's mouth to “freeze” a dental abscess. Carlson was surprised to discover that his patient suddenly lost consciousness.

As the mechanisms to deliver drugs were refined, entirely new classes of medications were also developed, with the intention of providing safer, more pleasant pain control. Ethylene gas was the first alternative to ether and chloroform, but it had some major disadvantages. The rediscovery of ethylene in 1923 also came from a serendipitous observation. After it was learned that ethylene gas had been used to inhibit the opening of carnation buds in Chicago greenhouses, it was speculated that a gas that put flowers to sleep might also have an anesthetic action on humans. Arno Luckhardt was the first to publish a clinical study in February 1923. Within a month, Isabella Herb in Chicago and W. Easson Brown in Toronto presented two other independent studies. Ethylene was not a successful anesthetic because high concentrations were required and it was explosive. An additional significant shortcoming was a particularly unpleasant smell, which could only be partially disguised by the use of oil of orange or a cheap perfume. When cyclopropane was introduced, ethylene was abandoned.

Cyclopropane's anesthetic action was inadvertently discovered in 1929.[28] Brown and Henderson had previously shown that propylene had desirable properties as an anesthetic when freshly prepared; but after storage in a steel cylinder, it deteriorated to create a toxic material that produced nausea and cardiac irregularities in humans. Velyien Henderson, a professor of pharmacology at the University of Toronto, suggested that the toxic product be identified. After a chemist, George Lucas, identified cyclopropane among the chemicals in the tank, he prepared a sample in low concentration with oxygen and administered it to two kittens. The animals fell asleep quietly but quickly recovered unharmed. Rather than being a toxic contaminant, Lucas saw that cyclopropane was a potent anesthetic. After its effects in other animals were studied and cyclopropane proved to be stable after storage, human experimentation began.

Henderson was the first volunteer; Lucas followed. They then arranged a public demonstration in which Frederick Banting, a Nobel laureate for the discovery of insulin, was anesthetized before a group of physicians. Despite this promising beginning, further research was abruptly halted. Several anesthetic deaths in Toronto had been attributed to ethyl chloride, and concern about Canadian clinical trials of cyclopropane prevented human studies from proceeding. Rather than abandon the study, Henderson encouraged an American friend, Ralph Waters, to use cyclopropane at the University of Wisconsin. The Wisconsin group investigated the drug thoroughly and reported their clinical success in 1934.[29]

In 1930, Chauncey Leake and MeiYu Chen performed successful laboratory trials of vinethene (divinyl ether) but were thwarted in its further development by a professor of surgery in San Francisco. Ironically, Canadians, who had lost cyclopropane to Wisconsin, learned of vinethene from Leake and Chen in California and conducted the first human study in 1932 at the University of Alberta, Edmonton. International research collaboration enabled early anesthetic use of both cyclopropane and divinyl ether, advances that may not have occurred independently in either the United States or Canada.

All potent anesthetics of this period were explosive save for chloroform, whose hepatic and cardiac toxicity limited use in America. Anesthetic explosions remained a rare but devastating risk to both

anesthesiologist and patient. To reduce the danger of explosion during the incendiary days of World War II, British anaesthetists turned to trichloroethylene. This nonflammable anesthetic found limited application in America, as it decomposed to release phosgene when warmed in the presence of soda lime. By the end of World War II, however, another class of noninflammable anesthetics was prepared for laboratory trials. Ten years later, fluorinated hydrocarbons revolutionized inhalation anesthesia.

FLUORINATED ANESTHETICS

Fluorine, the lightest and most reactive halogen, forms exceptionally stable bonds. These bonds, although sometimes created with explosive force, resist separation by chemical or thermal means. For that reason, many early attempts to fluorinate hydrocarbons in a controlled manner were frustrated by the marked chemical activity of fluorine. In 1930, the first commercial application of fluorine chemistry came in the form of the refrigerant, Freon. This was followed by the first attempt to prepare a fluorinated anesthetic by Harold Booth and E. May Bixby in 1932. Although their drug, monochlorodifluoromethane, was devoid of anesthetic action, as were other drugs studied that decade, their report predicted future developments. “A survey of the properties of 166 known gases suggested that the best possibility of finding a new noncombustible anesthetic gas lay in the field of organic fluoride compounds. Fluorine substitution for other halogens lowers the boiling point, increases stability, and generally decreases toxicity.”[30]

The secret demands of the Manhattan Project for refined uranium-235 served as an impetus to better understanding of fluorine chemistry. Researchers learned that uranium might be refined through the creation of an intermediate compound, uranium hexafluoride. Earl McBee of Purdue University, who had a long-standing interest in the fluoridation of hydrocarbons, undertook part of this project. McBee also held a grant from the Mallinckrodt Chemical Works, a manufacturer of ether and cyclopropane, to prepare new fluorinated compounds, for anesthesia testing. By 1945, the Purdue team had created small amounts of 46 fluorinated ethanes, propanes, butanes, and an ether.

The anesthetic value of these chemicals would not have been appreciated, however, if Mallinckrodt had not also provided financial support for research in pharmacology at Vanderbilt University. The chair, Benjamin Robbins, was a pharmacologist, and was better able to assess the new drugs than could most other anesthesiologists of that period. Robbins tested McBee's compounds in mice, and selected the most promising for evaluation in dogs. Unfortunately, none of these compounds found a place as an anesthetic but Robbins' conclusions on the effects of fluorination, bromination, and chlorination in his landmark report of 1946 encouraged later successful studies.[31]

A team at the University of Maryland under Professor of Pharmacology John C. Krantz Jr. investigated the anesthetic properties of dozens of hydrocarbons over a period of several years, but only one, ethyl vinyl ether, entered clinical use in 1947. Because it was flammable, Krantz requested that it be fluorinated. In response, Julius Shukys prepared several fluorinated analogs. One of these, trifluoroethyl vinyl ether, or fluroxene, became the first fluorinated anesthetic. Fluroxene was marketed from 1954 until 1974. However, it was withdrawn when a delayed discovery showed a metabolite to be toxic to lower animals. Fluroxene is important for its historical interest as the first fluorinated anesthetic gas but our experience with it also underscores the need for continual surveillance of anesthetic drug actions and adverse effects.[32]

In 1951, Charles Suckling, a British chemist of Imperial Chemical Industries, was asked to create a new anesthetic. Suckling, who already had an expert understanding of

fluorination, began by asking clinicians to describe the properties of an ideal anesthetic. He learned from this inquiry that his search must consider several limiting factors, including the volatility, inflammability, stability, and potency of the compounds. After 2 years of research and testing, Charles Suckling created halothane. He first determined that halothane possessed anesthetic action by anesthetizing mealworms and houseflies before he forwarded it to pharmacologist James Raventos. Suckling also made accurate predictions as to the concentrations required for anesthesia in higher animals. After Raventos completed a favorable review, halothane

was offered to Michael Johnstone, a respected anesthetist of Manchester, England, who recognized its great advantages over other anesthetics available in 1956. After Johnstone's endorsement, halothane use spread quickly and widely within the practice of anesthesia.[33]

Halothane was followed in 1960 by methoxyflurane, an anesthetic that remained popular for a decade. By 1970, however, it was learned that dose-related nephrotoxicity following protracted methoxyflurane anesthesia was caused by inorganic fluoride. Similarly, because of persisting concern that rare cases of hepatitis following anesthesia might be a result of a metabolite of halothane, the search for newer inhaled anesthetics focused on the resistance to metabolic degradation.

Two fluorinated liquid anesthetics, enflurane and its isomer isoflurane, were results of the search for increased stability. They were synthesized by Ross Terrell in 1963 and 1965, respectively. Because enflurane was easier to create, it preceded isoflurane. Its application was restricted after it was shown to be a marked cardiovascular depressant and to have some convulsant properties. Isoflurane was nearly abandoned because of difficulties in its purification, but after Louise Speers overcame this problem, several successful trials were published in 1971. The release of isoflurane for clinical use was delayed again for more than half a decade by calls for repeated testing in lower animals, owing to an unfounded concern that the drug might be carcinogenic. As a consequence, isoflurane received more thorough testing than any other drug heretofore used in anesthesia. The era when an anesthetic could be introduced following a single fortuitous observation had given way to a cautious program of assessment and reassessment. Remarkably, no anesthetics were introduced into clinical use for another 20 years. Finally, desflurane was released in 1992, and sevoflurane was released in 1994. Xenon, a gas having many properties of the ideal anesthetic, was administered to a few patients in the early 1950s but it never gained popularity because of the extreme costs associated with its removal from air. However, interest in xenon has been renewed now that gas concentrations can be accurately measured when administered at low flows, and devices are available to scavenge and reuse the gas.

REGIONAL ANESTHESIA

3 Cocaine, an extract of the coca leaf, was the first effective local anesthetic. After Albert Niemann refined the active alkaloid and named it *cocaine*, it was used in experiments by a few investigators. It was noted that cocaine provided topical anesthesia and even produced local insensibility when injected, but Carl Koller, a Viennese surgical intern, first recognized the utility of cocaine in clinical practice.

In 1884, Carl Koller was completing his medical training at a time when many operations on the eye were performed without general anesthesia. Almost four decades after the discovery of ether, general anesthesia by mask still had limitations for ophthalmic surgery: lack of patient cooperation, interference of the anesthesia apparatus with surgical access, and the high incidence of postoperative nausea and vomiting. At that time, since fine sutures were not available and surgical incisions of the eye were not closed, postoperative vomiting threatened the extrusion of the globe's contents, putting the patient at risk for irrevocable blindness.[34]

While a medical student, Koller had worked in a Viennese laboratory in a search of a topical ophthalmic anesthetic to overcome the limitations of general anesthesia. Unfortunately, the suspensions of morphine, chloral hydrate, and other drugs that he had used had been ineffectual. In 1884, Koller's friend, Sigmund Freud, became interested in the cerebral-stimulating effects of cocaine and gave him a small sample in an envelope, which he placed in his pocket. When the envelope leaked, a few grains of cocaine stuck to Koller's finger and he absentmindedly licked his tongue. When his tongue became numb, Koller instantly realized that he had found the object of his search. In his lab, he made a suspension of cocaine crystals that he and a lab associate tested in the eyes of a frog, a rabbit, and a dog. Satisfied with the anesthetic effects seen in the animal models, Koller dropped the solution onto his own cornea. To his amazement, his eyes were insensitive to the touch of a pin.[35] As an intern, Carl Koller could not afford to attend a Congress of German Ophthalmologists in Heidelberg on September 15, 1884. However, a friend presented his article at the meeting and a revolution in ophthalmic surgery and other surgical disciplines

began. Within the next year, more than 100 articles supporting the use of cocaine appeared in European and American medical journals. In 1888, Koller immigrated to New York, where he practiced ophthalmology for the remainder of his career.

American surgeons quickly developed new applications for cocaine. Its efficacy in anesthetizing the nose, mouth, larynx, trachea, rectum, and urethra was described in October 1884. The next month, the first reports of its subcutaneous injection were published. In December 1884, two young surgeons, William Halsted and Richard Hall, described blocks of the sensory nerves of the face and arm. Halsted even performed a brachial plexus block but did so under direct vision while the patient received an inhaled anesthetic.[36] Unfortunately, self-experimentation with cocaine was hazardous, as both surgeons became addicted.[37] Addiction was an ill-understood but frequent problem in the late nineteenth century, especially when cocaine and morphine were present in many patent medicines and folk remedies.

Other regional anesthetic techniques were attempted before the end of the nineteenth century. The term “spinal anesthesia” was coined in 1885 by Leonard Corning, a neurologist who had observed Hall and Halsted. Corning wanted to assess the action of cocaine as a specific therapy for neurologic problems. After first assessing its action in a dog, producing a blockade of rapid onset that was confined to the animal's rear legs, he performed a neuraxial block using cocaine on a man “addicted to masturbation.” Corning administered one dose without effect, then after a second dose, the patient's legs “felt sleepy.” The man had impaired sensibility in his lower extremity after about 20 minutes and left Corning's office “none the worse for the experience.”[38] Although Corning did not describe escape of cerebrospinal fluid (CSF) in either case, it is likely that the dog had a spinal anesthetic and that the man had an epidural anesthetic. No therapeutic benefit was described, but Corning closed his account and his attention to the subject by suggesting that cocainization might in time be “a substitute for etherization in genito-urinary or other branches of surgery.”[39]

Two other authors, August Bier and Theodor Tuffier, described authentic spinal anesthesia, with mention of cerebrospinal fluid, injection of cocaine, and an appropriately short onset of action. In a comparative review of the original articles by Bier, Tuffier, and Corning, it was concluded that Corning's injection was extradural, and Bier merited the credit for introducing spinal anesthesia.[40]

SPINAL ANESTHESIA

Fourteen years passed before spinal anesthesia was performed for surgery. In the interval, Heinrich Quincke of Kiel, Germany, had described his technique of lumbar puncture. He offered the valuable observation that it was most safely performed at the level of the third or fourth lumbar interspace, because entry at that level was below the termination of the spinal cord. Quincke's technique was used in Kiel for the first deliberate cocainization of the spinal cord in 1899 by his surgical colleague, August Bier. Six patients received small doses of cocaine intrathecally, but, because some cried out during surgery while others vomited and experienced headaches, Bier considered it necessary to conduct further experiments before continuing this technique for surgery.

Professor Bier permitted his assistant, Dr. Hildebrandt, to perform a lumbar puncture, but, after the needle penetrated the dura, Hildebrandt could not fit the syringe to the needle and a large volume of the professor's spinal fluid escaped. They were at the point of abandoning the study when Hildebrandt volunteered to be the subject of a second attempt. Their persistence was rewarded with an astonishing success. Twenty-three minutes after the spinal injection, Bier noted: “A strong blow with an iron hammer against the tibia was not felt as pain. After 25 minutes: Strong pressure and pulling on a testicle were not painful.”[40] They celebrated their success with wine and cigars. That night, both developed violent headaches, which they attributed at first to their celebration. Bier's headache was relieved after 9 days of bedrest. Hildebrandt, as a house officer, did not have the luxury of continued rest. Bier postulated that their headaches were a result of the loss of large volumes of CSF and urged that this be avoided if possible. The high incidence of complications following lumbar puncture with wide-bore needles and the toxic

reactions attributed to cocaine explain his later loss of interest in spinal anesthesia.[41]

Surgeons in several other countries soon practiced spinal anesthesia and progress occurred by many small contributions to the technique. Theodor Tuffier published the first series of 125 spinal anesthetics from France and he later counseled that the solution should not be injected before CSF was seen. The first American report was by Rudolph Matas of New Orleans, whose first patient developed postanesthetic meningismus, a frequent complication that was overcome in part by the use of hermetically sealed sterile solutions recommended by E. W. Lee of Philadelphia and sterile gloves as advocated by Halsted. During 1899, Dudley Tait and Guidlo Caglieri of San Francisco performed experimental studies in animals and therapeutic spinals for orthopedic patients. They encouraged the use of fine needles to lessen the escape of CSF and urged that the skin and deeper tissues be infiltrated beforehand with local anesthesia.[42] This had been suggested earlier by William Halsted and the foremost advocate of infiltration anesthesia, Carl Ludwig Schleich of Berlin. An early American specialist in anesthesia, Ormond Goldan, published an anesthesia record appropriate for recording the course of “intraspinal cocainization” in 1900. In the same year, Heinrich Braun learned of a newly described extract of the adrenal gland, epinephrine, which he used to prolong the action of local anesthetics with great success. Braun developed several new nerve blocks, coined the term “conduction anesthesia,” and is remembered by European writers as the “father of conduction anesthesia.” Braun was the first person to use procaine, which, along with stovaine, was one of the first synthetic local anesthetics produced to reduce the toxicity of cocaine. Further advances in spinal anesthesia followed the introduction of these and other synthetic local anesthetics.

Before 1907, anesthesiologists were sometimes disappointed to observe that their spinal anesthetics were incomplete. Most believed that the drug spread solely by local diffusion before the property of baricity was investigated by Arthur Barker, a London surgeon.[43] Barker constructed a glass tube shaped to follow the curves of the human spine and used it to demonstrate the limited spread of colored solutions that he had injected through a T-piece in the lumbar region. Barker applied this observation to use solutions of stovaine made hyperbaric by the addition of 5% glucose, which worked in a more predictable fashion. After the injection was complete, Barker placed his patient's head on pillows to contain the anesthetic below the nipple line. Lincoln Sise acknowledged Barker's work in 1935 when he introduced the use of hyperbaric solutions of pontocaine. John Adriani advanced the concept further in 1946 when he used a hyperbaric solution to produce “saddle block,” or perineal anesthesia. Adriani's patients remained seated after injection as the drug descended to the sacral nerves.

Tait, Jonnesco, and other early masters of spinal anesthesia used a cervical approach for thyroidectomy and thoracic procedures, but this radical approach was supplanted in 1928 by the lumbar injection of hypobaric solutions of “light” nupercaine by G. P. Pitkin. Although the use of hypobaric solutions is now limited primarily to patients positioned in the jackknife position, their former use for thoracic procedures demanded skill and precise timing. The enthusiasts of hypobaric anesthesia devised formulas to attempt to predict the time in seconds needed for a warmed solution of hypobaric nupercaine to spread in patients of varying size from its site of injection in the lumbar area to the level of the fourth thoracic dermatome.

The recurring problem of inadequate duration of single-injection spinal anesthesia led a Philadelphia surgeon, William Lemmon, to devise an apparatus for continuous spinal anesthesia in 1940.[44] Lemmon began with the patient in the lateral position. The spinal tap was performed with a malleable silver needle, which was left in position. As the patient was turned supine, the needle was positioned through a hole in the mattress and table. Additional injections of local anesthetic could be performed as required. Malleable silver needles also found a less cumbersome and more common application in 1942 when Waldo Edwards and Robert Hingson encouraged the use of Lemmon's needles for continuous caudal anesthesia in obstetrics. In 1944 Edward Tuohy of the Mayo Clinic introduced two important modifications of the continuous spinal techniques. He developed the now familiar Tuohy needle[45] as a means of improving the ease of passage of lacquered silk ureteral catheters through which he injected incremental doses of local anesthetic.[46]

In 1949, Martinez Curbelo of Havana, Cuba, used Tuohy's needle and a ureteral catheter to perform the first continuous epidural anesthetic. Silk and gum elastic catheters were difficult to sterilize and sometimes caused dural infections before being superseded by disposable plastics. Yet deliberate single-injection peridural anesthesia had been practiced occasionally for decades before continuous techniques brought it greater popularity. At the beginning of the twentieth century, two French clinicians experimented independently with caudal anesthesia. The neurologist Jean Athanase Sicard applied the technique for a nonsurgical purpose, the relief of back pain. Fernand Cathelin used caudal anesthesia as a less dangerous alternative to spinal anesthesia for hernia repairs. He also demonstrated that the epidural space terminated in the neck by injecting a solution of India ink into the caudal canal of a dog. The lumbar approach was first used solely for multiple paravertebral nerve blocks before the Pagés-Dogliotti single-injection technique became accepted. As they worked separately, the technique carries the names of both men. Captain Fidel Pagés prepared an elegant demonstration of segmental single-injection peridural anesthesia in 1921, but died soon after his paper appeared in a Spanish military journal.[47] Ten years later, Achille M. Dogliotti of Turin, Italy, wrote a classic study

that made the epidural technique well known.[48] Whereas Pagés used a tactile approach to identify the epidural space, Dogliotti identified it by the loss-of-resistance technique.

Surgery on the extremities lent itself to other regional anesthesia techniques. In 1902, Harvey Cushing coined the phrase “regional anesthesia” for his technique of blocking either the brachial or sciatic plexus under direct vision during general anesthesia to reduce anesthesia requirements and provide postoperative pain relief.[49] Fifteen years before his publication, George Crile advanced a similar approach to reduce the stress and shock of surgery. Crile, a dedicated advocate of regional and infiltration techniques during general anesthesia, coined the term “anoci-association.”[50]

An intravenous regional technique with procaine was reported in 1908 by August Bier, the surgeon who had pioneered spinal anesthesia. Bier injected procaine into a vein of the upper limb between two tourniquets. Even though the technique is termed the “Bier block,” it was not used for many decades until it was reintroduced 55 years later by Mackinnon Holmes, who modified the technique by exsanguination before applying a single proximal cuff. Holmes used lidocaine, the very successful amide local anesthetic synthesized in 1943 by Lofgren and Lundquist of Sweden.

Several investigators achieved upper extremity anesthesia by percutaneous injections of the brachial plexus. In 1911, based on his intimate knowledge of the anatomy of the axillary area, Hirschel promoted a “blind” axillary injection. In the same year, Kulenkampff described a supraclavicular approach in which the operator sought out paresthesias of the plexus while keeping the needle at a point superficial to the first rib and the pleura. The risk of pneumothorax with Kulenkampff's approach led Mulley to attempt blocks more proximally by a lateral paravertebral approach, the precursor of what is now popularly known as the “Winnie block.”

Heinrich Braun wrote the earliest textbook of local anesthesia, which appeared in its first English translation in 1914. After 1922, Gaston Labat's *Regional Anesthesia* dominated the American market. Labat migrated from France to the Mayo Clinic in Minnesota, where he served briefly before taking a permanent position at the Bellevue Hospital in New York. He formed the first American Society for Regional Anesthesia.[51] After Labat's death, Emery A. Rovenstine was recruited to Bellevue to continue Labat's work, among other responsibilities. Rovenstein created the first American clinic for the treatment of chronic pain, where he and his associates refined techniques of lytic and therapeutic injections and used the American Society of Regional Anesthesia to further the knowledge of pain management across the United States.[52]

4 The development of the multidisciplinary pain clinic was one of many contributions to anesthesiology made by John J. Bonica, a renowned teacher of regional techniques. During his periods of military, civilian, and university service at the University of Washington, Bonica formulated a series of improvements in the management of patients with chronic pain. His classic text *The Management of Pain*, now in its third edition, is regarded as a classic of the literature of anesthesia.

Early Anesthesia Delivery Systems

5 The transition from ether inhalers and chloroform-soaked handkerchiefs to more sophisticated anesthesia delivery equipment occurred gradually, with incremental advances supplanting older methods. One of the earliest anesthesia apparatus designs was that of John Snow, who had realized the inadequacies of ether inhalers through which patients rebreathed via a mouthpiece. After practicing anesthesia for only 2 weeks, Snow created the first of his series of ingenious ether inhalers.[53] His best-known apparatus featured unidirectional valves within a malleable, well-fitting mask of his own design, which closely resembles the form of a modern face mask. The face piece was connected to the vaporizer by a breathing tube, which Snow deliberately designed to be wider than the human trachea so that even rapid respirations would not be impeded. A metal coil within the vaporizer ensured that the patient's inspired breath was drawn over a large surface area to promote the uptake of ether. The device also incorporated a warm water bath to maintain the volatility of the agent (Fig. 1-2). Snow did not attempt to capitalize on his creativity, in contrast to William Morton; he closed his account of its preparation with the generous observation, “There is no restriction respecting the making of it.”[54]

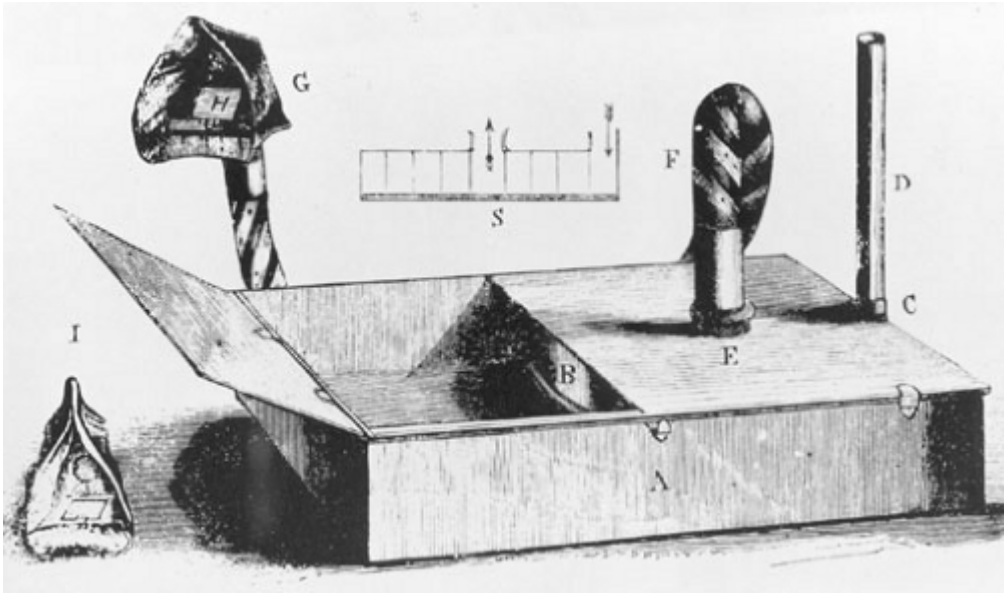

FIGURE 1-2. John Snow's ether inhaler (1847). The ether chamber *(B)* contained a spiral coil so that the air entering through the brass tube *(D)* was saturated by ether before ascending the flexible tube *(F)* to the face mask *(G)*. The ether chamber rested in a bath of warm water *(A)*.

Joseph Clover, another British physician, was the first anesthetist to administer chloroform in known concentrations through the “Clover bag.” He obtained a 4.5% concentration of chloroform in air by pumping a measured volume of air with a bellows through a warmed evaporating vessel containing a known volume of liquid chloroform.[55] Although it was realized that nitrous oxide diluted in air often gave a hypoxic mixture, and that the oxygen-nitrous oxide mixture was safer, Chicago surgeon Edmund Andrews complained about the physical limitations of delivering anesthesia to patients in their homes. The

large bag was conspicuous and awkward to carry along busy streets. He observed that, “In city practice, among the higher classes, however, this is no obstacle as the bag can always be taken in a carriage, without attracting attention.”[56] In 1872, Andrews was delighted to report the availability of liquefied nitrous oxide compressed under 750 pounds of pressure, which allowed a

supply sufficient for three patients to be carried in a single cylinder.

Critical to increasing patient safety was the development of a machine capable of delivering a calibrated amount of gas and volatile anesthetic. In the late nineteenth century, demands in dentistry instigated development of the first freestanding anesthesia machines. Three American dentist-entrepreneurs, Samuel S. White, Charles Teter, and Jay Heidbrink, developed the original series of U.S. instruments that used compressed cylinders of nitrous oxide and oxygen. Before 1900, the S. S. White Company modified Frederick Hewitt's apparatus and marketed its continuous-flow machine, which was refined by Teter in 1903. Heidbrink added reducing valves in 1912. In the same year, physicians initiated other important developments. Water-bubble flow meters, introduced by Frederick Cotton and Walter Boothby of Harvard University, allowed the proportion of gases and their flow rate to be approximated. The Cotton and Boothby apparatus was transformed into a practical portable machine by James Tayloe Gwathmey of New York. The Gwathmey machine caught the attention of a London anesthetist Henry E. G. “Cockie” Boyle, who acknowledged his debt to the American when he incorporated Gwathmey's concepts in the first of the series of “Boyle” machines that were marketed by Coxeter and British Oxygen Corporation. During the same period in Lubeck, Germany, Heinrich Draeger and his son, Bernhaard, adapted compressed-gas technology, which they had originally developed for mine rescue equipment, to manufacture ether and chloroform-oxygen machines.

In the years after World War I, several U.S. manufacturers continued to bring forward widely admired anesthesia machines. Some companies were founded by dentists, including Heidbrink and Teter. Karl Connell and Elmer Gatch were surgeons. Richard von Foregger was an engineer who was exceptionally receptive to clinicians' suggestions for additional features for his machines. Elmer McKesson became one of the country's first specialists in anesthesiology in 1910 and developed a series of gas machines. In an era of flammable anesthetics, McKesson carried nonflammable nitrous oxide anesthesia to its therapeutic limit by performing inductions with 100% nitrous oxide and thereafter adding small volumes of oxygen. If the resultant cyanosis became too profound, McKesson depressed a valve on his machine that flushed a small volume of oxygen into the circuit. Even though his techniques of primary and secondary saturation with nitrous oxide are no longer used, the oxygen flush valve is part of McKesson's legacy.

Carbon Dioxide Absorption

Carbon dioxide (CO_2) absorbance is a basic element of modern anesthetic machines. It was initially developed to allow rebreathing of gas and minimize loss of flammable gases into the room, thereby reducing the risk of explosion. In current practice, it permits decreased utilization of anesthetic and reduced cost. The first CO_2 absorber in anesthesia came in 1906 from the work of Franz Kuhn, a German surgeon. His use of canisters developed for mine rescues by Draeger was innovative, but his circuit had unfortunate limitations. The exceptionally narrow breathing tubes and a large dead space explain its very limited use, and Kuhn's device was ignored.

A few years later, the first American machine with a CO_2 absorber was independently fabricated by a pharmacologist named Dennis Jackson. In 1915, Jackson developed an early technique of CO_2 absorption that permitted the use of a closed anesthesia circuit. He used solutions of sodium and calcium hydroxide to absorb CO_2. As his laboratory was located in an area of St. Louis, Missouri, heavily laden with coal smoke, Jackson reported that the apparatus allowed him the first breaths of absolutely fresh air he had ever enjoyed in that city. The complexity of Jackson's apparatus limited its use in hospital practice, but his pioneering work in this field encouraged Ralph Waters to introduce a simpler device using soda lime granules 9 years later. Waters positioned a soda lime canister (Fig. 1-3) between a face mask and an adjacent breathing bag to which was attached the fresh gas flow. As long as the mask was held against the face, only small volumes of fresh gas flow were required and no valves were needed.[57]

FIGURE 1-3. Waters' carbon dioxide absorbance canister.

When Waters made his first “to-and-fro” device, he was attempting to develop a specialist practice in anesthesia in Sioux City, Iowa, and had achieved limited financial success. Waters believed that his device had advantages for both clinician and patient. Economy of operation was crucial when private patients and insurance companies were reluctant to pay for specialist's services, drugs, and supplies. Waters estimated that his new canister would reduce costs for gases and soda lime to less than $.50 per hour. This portable apparatus could be easily carried to private residences and hospital settings, preventing contamination of the operating environments with the malodorous and explosive vapors of ethylene. Waters even recognized that the canister supplied the added benefits of conserving body heat and humidifying inspired gases.

Waters' device featured awkward positioning of the canister close to the patient's face. Brian Sword overcame this limitation in 1930 with a freestanding machine with unidirectional valves to create a circle system and an in-line CO_2 absorber.[58] James Elam and his co-workers at the Roswell Park Cancer Institute in Buffalo, New York, further refined the CO_2 absorber, increasing the efficiency of CO_2 removal with a minimum of resistance for breathing.[59] Consequently, the circle system introduced by Sword in the 1930s, with a few refinements, became the standard anesthesia circuit in North America.

Alternative Circuits

A valveless device, the Ayre's T-piece, has found wide application in the management of intubated patients. Phillip Ayre practiced anesthesia in England when the limitations of equipment for pediatric patients produced what he described as “a protracted and sanguine battle between surgeon and anaesthetist, with the poor unfortunate baby as the battlefield.”[60] In 1937, Ayre introduced his valveless T-piece to reduce the effort of breathing in neurosurgical patients. The T-piece soon became particularly popular for cleft palate repairs, as the surgeon had free access to the mouth. Positive pressure ventilation could be achieved when the anesthetist obstructed the expiratory limb. In time, this ingenious, lightweight, nonrebreathing device evolved through more

than 100 modifications for a variety of special situations. A significant alteration was Gordon Jackson Rees' circuit, which permitted improved control of ventilation by substituting a breathing bag on the outflow limb.[61] An alternative method to reduce the amount of equipment near the patient is provided by the coaxial circuit of the Bain-Spoerel apparatus.[62] This lightweight tube-within-a-tube has served very well in many circumstances since its Canadian innovators described it in 1972.

Flow Meters

As closed and semiclosed circuits became practical, gas flow could be measured with greater accuracy. Bubble flow meters were replaced with dry bobbins or ball-bearing flow meters, which, although they did not leak fluids, could cause inaccurate measurements if they adhered to the glass column. In 1910, M. Neu had been the first to apply rotameters in anesthesia for the administration of nitrous oxide and oxygen, but his machine was not a commercial success, perhaps because of the great cost of nitrous oxide in Germany at that time. Rotameters designed for use in German industry were first employed in Britain in 1937 by Richard Salt; but as World War II approached, the English were denied access to these sophisticated flow meters. After World War II rotameters became regularly employed in British anesthesia machines, although most American equipment still featured nonrotating floats. The now universal practice of displaying gas flow in liters per minute was not a customary part of all American machines until more than a decade after World War II. Some anesthesiologists still in practice learned to calculate gas flows in the cumbersome proportions of gallons per hour.

Vaporizers

The art of a smooth induction with a potent anesthetic was a great challenge, particularly if the inspired concentration could not be determined with accuracy. This limitation was particularly true of chloroform, as an excessive rate of administration produced a lethal cardiac depression. Even the clinical introduction of halothane after 1956 might have been similarly thwarted except for a fortunate coincidence: the prior development of calibrated vaporizers. Two types of calibrated vaporizers designed for other anesthetics had become available in the half decade before halothane was marketed. The prompt acceptance of halothane was in part because of an ability to provide it in carefully titrated concentrations.

The Copper Kettle was the first temperature-compensated, accurate vaporizer. It had been developed by Lucien Morris at the University of Wisconsin in response to Ralph Waters' plan to test chloroform by giving it in controlled concentrations.[63] Morris achieved this goal by passing a metered flow of oxygen through a vaporizer chamber that contained a porex disk to separate the oxygen into minute bubbles. The gas became fully saturated with anesthetic vapor as it percolated through the liquid. The concentration of the anesthetic inspired by the patient could be calculated by knowing the vapor pressure of the liquid anesthetic, the volume of oxygen flowing through the liquid, and the total volume of gases from all sources entering the anesthesia circuit. Although experimental models of Morris' vaporizer used a water bath to maintain stability, the excellent thermal conductivity of copper was substituted in later models. When first marketed, the Copper Kettle did not feature a mechanism to indicate changes in the temperature (and vapor pressure) of the liquid. Shuh-Hsun Ngai proposed the incorporation of a thermometer, a suggestion that was later added to all vaporizers of that class.[64]

The Copper Kettle (Foregger Company) and the Vernitrol (Ohio Medical Products) were universal vaporizers—a property that remained a distinct advantage as new anesthetics were marketed. Universal vaporizers could be charged with any anesthetic liquid, and, provided that its vapor pressure and temperature were known, the inspired concentration could be calculated quickly. This feature gave an unanticipated advantage to American investigators. They were not dependent on the construction of new agent-specific vaporizers.

When halothane was first marketed in Britain, an effective temperature-compensated, agent-specific vaporizer had recently been placed in clinical use. The TECOTA (TEmperature COmpensated Trichloroethylene Air) vaporizer had been created by engineers who had been

frustrated by a giant corporation's unresponsiveness. Their vaporizer featured a bimetallic strip composed of brass and a nickel—steel alloy, two metals with different coefficients of expansion. As the anesthetic vapor cooled, the strip bent to move away from the orifice, thereby permitting more fresh gas to enter the vaporizing chamber. This maintained a constant inspired concentration despite changes in temperature and vapor pressure. After their TECOTA vaporizer was accepted into anesthetic practice, the technology was used to create the “Fluotec,” the first of a series of agent-specific “tec” vaporizers for use in the operating room.

Ventilators

Mechanical ventilators are now an integral part of the anesthesia machine. Patients are ventilated during general anesthesia by electrical or gas-powered devices that are simple to control yet sophisticated in their function. The history of mechanical positive pressure ventilation began with attempts to resuscitate victims of drowning by a bellows attached to a mask or tracheal tube. These experiments found little role in anesthetic care for many years. At the beginning of the twentieth century, however, several modalities were explored before intermittent positive pressure machines evolved.

A series of artificial environments were created in response to the frustration experienced by thoracic surgeons who found that the lung collapsed when they incised the pleura. Between 1900 and 1910, continuous positive or negative pressure devices were created to maintain inflation of the lungs of a spontaneously breathing patient once the chest was opened. Brauer (1904) and Murphy (1905) placed the patient's head and neck in a box in which positive pressure was continually maintained. Sauerbruch (1904) created a negative-pressure operating chamber encompassing both the surgical team and the patient's body and from which only the patient's head projected.[66]

In 1907, the first intermittent positive-pressure device, the Draeger “Pulmotor,” was developed to rhythmically inflate the lungs. This instrument and later American models such as the E & J Resuscitator were used almost exclusively by firefighters and mine rescue workers. A few European medical

workers had an early interest in rhythmic inflation of the lungs. In 1934 a Swedish team developed the “Spiropulsator,” which C. Crafoord later modified for use during cyclopropane anesthesia.[65] Its action was controlled by a magnetic control valve called the flasher, a type first used to provide intermittent gas flow for the lights of navigational buoys. When Trier Morch, a Danish anesthesiologist, could not obtain a Spiropulsator during World War II, he fabricated the Morch “Respirator,” which used a piston pump to rhythmically deliver a fixed volume of gas to the patient.[66]

A major stimulus to the development of ventilators came as a consequence of a devastating epidemic of poliomyelitis that struck Copenhagen, Denmark, in 1952. As scores of patients were admitted, the only effective ventilatory support that could be provided to patients with bulbar paralysis was continuous manual ventilation via a tracheostomy employing devices such as Waters' “to-and-fro” circuit. This succeeded only through the dedicated efforts of hundreds of volunteers. Medical students served in relays to ventilate paralyzed patients. The Copenhagen crisis stimulated a broad European interest in the development of portable ventilators in anticipation of another epidemic of poliomyelitis. At this time, the common practice in North American hospitals was to place polio patients with respiratory involvement in “iron lungs,” metal cylinders that encased the body below the neck. Inspiration was caused by intermittent negative pressure created by an electric motor acting on a piston-like device occupying the foot of the chamber.

Some early American ventilators were adaptations of respiratory-assist machines originally designed for the delivery of aerosolized drugs for respiratory therapy. Two types employed the Bennett or Bird “flow-sensitive” valves. The Bennett valve was designed during World War II when a team of physiologists at the University of Southern California encountered difficulties in separating inspiration from expiration in an experimental apparatus designed to provide positive pressure breathing for aviators at high altitude. An engineer, Ray Bennett, visited their

laboratory, observed their problem, and resolved it with a mechanical flow-sensitive automatic valve. A second valving mechanism was later designed by an aeronautical engineer, Forrest Bird.

The use of the Bird and Bennett valves gained an anesthetic application when the gas flow from the valve was directed into a rigid plastic jar containing a breathing bag or bellows as part of an anesthesia circuit. These “bag-in-bottle” devices mimicked the action of the clinician's hand as the gas flow compressed the bag, thereby providing positive pressure inspiration. Passive exhalation was promoted by the descent of a weight on the bag or bellows.

SAFETY STANDARDS

The introduction of safety features was coordinated by the American National Standards Institute (ANSI) Committee Z79, which was sponsored from 1956 until 1983 by the American Society of Anesthesiologists. Since 1983, representatives from industry, government, and healthcare professions have met on Committee Z79 of the American Society for Testing and Materials. They establish voluntary goals that may become accepted national standards for the safety of anesthesia equipment.

Ralph Tovell voiced the first call for standards during World War II while he was the U.S. Army Consultant in Anesthesiology for Europe. Tovell found that, as there were four different dimensions for connectors, tubes, masks, and breathing bags, supplies dispatched to field hospitals might not match their anesthesia machines. As Tovell observed, “When a sudden need for accessory equipment arose, nurses and corpsmen were likely to respond to it by bringing parts that would not fit.”[67] Although Tovell's reports did not gain an immediate response, after the war Vincent Collins and Hamilton Davis took up his concern and formed the ANSI Committee Z79. One of the committee's most active members, Leslie Rendell-Baker, wrote an account of the committee's domestic and international achievements.[68] He reported that Tovell encouraged all manufacturers to select the now uniform orifice of 22 mm for all adult and pediatric face masks and to make every tracheal tube connector 15 mm in diameter. For the first time, a Z79-designed mask-tube elbow adapter would fit every mask and tracheal tube connector.

The Z79 Committee introduced other advances. Tracheal tubes of nontoxic plastic bear a Z79 or IT (Implantation Tested) mark. The committee also mandated touch identification of oxygen flow control at Roderick Calverley's suggestion, which reduced the risk that the wrong gas would be selected before internal mechanical controls prevented the selection of an hypoxic mixture.[69] Pin indexing reduced the hazard of attaching a wrong cylinder in the place of oxygen. Diameter indexing of connectors prevented similar errors in high-pressure tubing. For many years, however, errors committed in reassembling hospital oxygen supply lines led to a series of tragedies before polarographic oxygen analyzers were added to the inspiratory limb of the anesthesia circuit.

Control of the Airway

Prior to development of techniques and equipment for safely and effectively intubating the trachea, airway management left much to be desired. Inhalers, drop techniques, and mask anesthesia functioned equally when inducing unconsciousness, but unfortunately, were equally incapable of preventing obstruction of airways. Definitive control of the airway, a skill anesthesiologists now consider paramount, developed only after many harrowing and apneic episodes spurred the development of safer airway management techniques. Preceding tracheal intubation, however, several important techniques were proposed toward the end of the nineteenth century that remain integral to anesthesiology education and practice.

Joseph Clover was the first Englishman to urge the now universal practice of thrusting the patient's jaw forward to overcome obstruction of the upper airway by the tongue. Clover also published a landmark case report in 1877 in which he performed a surgical airway. Once his patient was asleep, Clover discovered that his patient had a tumor of the mouth that obstructed the airway completely, despite his trusted jaw thrust maneuver. He averted disaster by inserting a small curved cannula of his design through the cricothyroid membrane. He continued anesthesia via the cannula until the tumor was excised. Clover, the model of the prepared anesthesiologist, remarked, “I have never used the cannula before although it has been my companion at some

thousands of anaesthetic cases."[70]

Tracheal Intubation in Anesthesia

The development of techniques and instruments for intubation ranks among the major advances in the history of anesthesiology. The first tracheal tubes were developed for the resuscitation of drowning victims, but were not used in anesthesia until 1878. The first use of elective oral intubation for an anesthetic was undertaken by Scottish surgeon William Macewan. He had practiced passing flexible metal tubes through the larynx of a cadaver before attempting the maneuver on an awake patient with an oral tumor at the Glasgow Royal Infirmary, on July 5, 1878.[71] Because topical anesthesia was not yet known,

the experience must have demanded fortitude on the part of Macewan's patient. Once the tube was correctly positioned, an assistant began a chloroform—air anesthetic via the tube. Once anesthetized, the patient soon stopped coughing. Unfortunately, Macewan abandoned the practice following a fatality in which a patient had been successfully intubated while awake but the tube became dislodged once the patient was asleep. After the tube was removed, an attempt to provide chloroform by mask anesthesia was unsuccessful and the patient died.

Although there was a sporadic interest in tracheal anesthesia in Edinburgh and other European centers after Macewan, an American surgeon named Joseph O'Dwyer is remembered for his extraordinary dedication to the advancement of tracheal intubation. In 1885, O'Dwyer designed a series of metal laryngeal tubes, which he inserted blindly between the vocal cords of children suffering a diphtheritic crisis. Three years later, O'Dwyer designed a second rigid tube with a conical tip that occluded the larynx so effectively that it could be used for artificial ventilation when applied with the bellows and T-piece tube designed by George Fell. The Fell-O'Dwyer apparatus, as it came to be known, was used during thoracic surgery by Rudolph Matas of New Orleans. Matas was so pleased with it that he predicted, "The procedure that promises the most benefit in preventing pulmonary collapse in operations on the chest is … the rhythmical maintenance of artificial respiration by a tube in the glottis directly connected with a bellows."

After O'Dwyer's death, the outstanding pioneer of tracheal intubation was Franz Kuhn, a surgeon of Kassel, Germany. From 1900 until 1912, Kuhn published several papers and a classic monograph, "*Die perorale Intubation,"* which were not well known in his lifetime but have since become widely appreciated.[72] His work might have had a more profound impact if it had been translated into English. Kuhn described techniques of oral and nasal intubation that he performed with flexible metal tubes composed of coiled tubing similar to those now used for the spout of metal gasoline cans. After applying cocaine to the airway, Kuhn introduced his tube over a curved metal stylet that he directed toward the larynx with his left index finger. While he was aware of the subglottic cuffs that had been used briefly by Victor Eisenmenger, Kuhn preferred to seal the larynx by positioning a supralaryngeal flange near the tube's tip before packing the pharynx with gauze. Kuhn even monitored the patient's breath sounds continuously through a monaural earpiece connected to an extension of the tracheal tube by a narrow tube.[68]

Intubation of the trachea by palpation was an uncertain and sometimes traumatic act. For some years, surgeons even believed that it would be anatomically impossible to visualize the vocal cords directly. This misapprehension was overcome in 1895 by Alfred Kirstein in Berlin who devised the first direct-vision laryngoscope.[73] Kirstein was motivated by a friend's report that a patient's trachea had been accidentally intubated during esophagoscopy. Kirstein promptly fabricated a hand-held instrument that at first resembled a shortened cylindrical esophagoscope. He soon substituted a semicircular blade that opened inferiorly. Kirstein could now examine the larynx while standing behind his seated patient, whose head had been placed in an attitude approximating the "sniffing position." Although Alfred Kirstein's "autoscope" was not used by anesthesiologists, it was the forerunner of all modern laryngoscopes. Endoscopy was refined by Chevalier Jackson in Philadelphia, who designed a U-shaped laryngoscope by adding a handgrip that was parallel to the blade. The Jackson blade has remained a standard instrument for endoscopists but was not favored by anesthesiologists. Two laryngoscopes that closely resembled modern L-shaped instruments were designed in 1910 and 1913 by two American surgeons, Henry

Janeway and George Dorrance, but neither instrument achieved lasting use despite their excellent designs.[74]

Anesthesiologist-Inspired Laryngoscopes

Before the introduction of muscle relaxants in the 1940s, intubation of the trachea could be challenging. This challenge was made somewhat easier, however, with the advent of laryngoscope blades specifically designed to increase visualization of the vocal cords. Robert Miller of San Antonio, Texas, and Robert Macintosh of Oxford University created their respectively named blades within an interval of 2 years. In 1941, Miller brought forward the slender, straight blade with a slight curve near the tip to ease the passage of the tube through the larynx. Although Miller's blade was a refinement, the technique of its use was identical to that of earlier models as the epiglottis was lifted to expose the larynx.[75]

The Macintosh blade, which is placed in the vallecula, rather than under the epiglottis, was invented as an incidental result of a tonsillectomy. Sir Robert Macintosh later described the circumstances of its discovery in an appreciation of the career of his technician, Mr. Richard Salt, who constructed the blade. As Sir Robert recalled, “A Boyle-Davis gag, a size larger than intended, was inserted for tonsillectomy, and when the mouth was fully opened the cords came into view. This was a surprise since conventional laryngoscopy, at that depth of anaesthesia, would have been impossible in those pre-relaxant days. Within a matter of hours, Salt had modified the blade of the Davis gag and attached a laryngoscope handle to it; and streamlined (after testing several models), the end result came into widespread use.”[76] Macintosh underestimated the popularity of the blade as more than 800,000 have been produced, and many special-purpose versions have been marketed.

The most distinguished innovator in tracheal intubation was the self-trained British anesthetist Ivan (later, Sir Ivan) Magill.[77] In 1919, while serving in the Royal Army as a general medical officer, Magill was assigned to a military hospital near London. Although he had only rudimentary training in anesthesia, Magill was obliged to accept an assignment to the anesthesia service, where he worked with another neophyte, Stanley Rowbotham.[78] Together, Magill and Rowbotham attended casualties disfigured by severe facial injuries who underwent repeated restorative operations. These procedures required that the surgeon, Harold Gillies, have unrestricted access to the face and airway. These patients presented formidable challenges, but both Magill and Rowbotham became adept at tracheal intubation and quickly understood its current limitations. Because they learned from fortuitous observations, they soon extended the scope of tracheal anesthesia.

They gained expertise with blind nasal intubation after they learned to soften semirigid insufflation tubes for passage through the nostril. Even though their original intent was to position the tips of the nasal tubes in the posterior pharynx, the slender tubes frequently ended up in the trachea. Stimulated by this chance experience, they developed techniques of deliberate nasotracheal intubation. In 1920, Magill devised an aid to manipulating the catheter tip, the “Magill angulated forceps,” which continue to be manufactured according to his original design of 75 years ago.

With the war over, Magill entered civilian practice and set out to develop a wide-bore tube that would resist kinking but be conformable to the contours of the upper airway. While in a hardware store, he found mineralized red rubber tubing that he cut, beveled, and smoothed to produce tubes that clinicians around the world would come to call “Magill tubes.” His tubes remained the universal standard for more than 40 years until rubber products were supplanted by inert plastics. Magill also rediscovered the advantage of applying cocaine to the nasal mucosa, a technique that greatly facilitated awake blind nasal intubation.

In 1926, Arthur Guedel began a series of experiments that led to the introduction of the cuffed tube. His goal was to combine the safety of tracheal intubation with the safety and economy of the closed-circuit anesthesia, recently refined by his close friend Ralph Waters.[79] Guedel transformed the basement of his Indianapolis home into a laboratory, where he subjected each step of the

preparation and application of his cuffs to a vigorous review.[80] He fashioned cuffs from the rubber of dental dams, condoms, and surgical gloves that were glued onto the outer wall of tubes. Using animal tracheas donated by the family butcher as his model, he considered whether the cuff should be positioned above, below, or at the level of the vocal cords. He recommended that the cuff be positioned just below the vocal cords to seal the airway. Waters later recommended that cuffs be constructed of two layers of soft rubber cemented together. These detachable cuffs were first manufactured by Waters' children, who sold them to the Foregger Company.

Guedel sought ways to show the safety and utility of the cuffed tube. He first filled the mouth of an anesthetized and intubated patient with water and showed that the cuff sealed the airway. Even though this exhibition was successful, he searched for a more dramatic technique to capture the attention of those unfamiliar with the advantages of intubation. He reasoned that if the cuff prevented water from entering the trachea of an intubated patient, it should also prevent an animal from drowning, even if it were submerged under water. To encourage physicians attending a medical convention to use his tracheal techniques, Guedel prepared the first of several “dunked dog” demonstrations (Fig. 1-4). An anesthetized and intubated dog, Guedel's own pet, “Airway,” was immersed in an aquarium. After the demonstration was completed, the anesthetic was discontinued before the animal was removed from the water. Airway awoke promptly, shook water over the onlookers, saluted a post, then trotted from the hall to the applause of the audience.

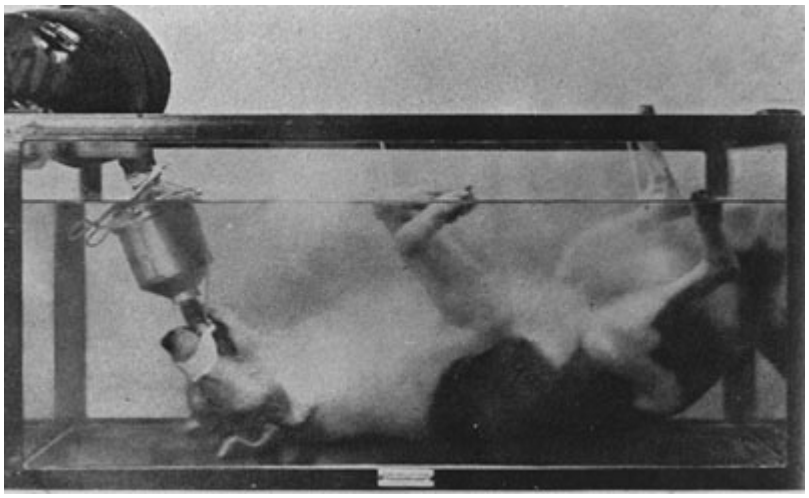

FIGURE 1-4. “The dunked dog.” Arthur Guedel demonstrated the safety of endotracheal intubation with a cuffed tube by submerging his anesthetized pet, Airway, in an aquarium while the animal breathed an ethylene-oxygen anesthetic through an underwater Waters' “to-and-fro” anesthesia circuit.

Endobronchial Tubes—The Next Step

After a patient experienced an accidental endobronchial intubation, Ralph Waters reasoned that a very long cuffed tube could be used to ventilate the dependent lung while the upper lung was being resected.[81] On learning of his friend's success with intentional one-lung anesthesia, Arthur Guedel proposed an important modification for chest surgery, the double-cuffed single-lumen tube, which was introduced by Emery Rovenstine. These tubes were easily positioned, an advantage over bronchial blockers that had to be inserted by a skilled bronchoscopist.

Following World War II, several double-cuffed single-lumen tubes were used for thoracic surgery, but after 1953, these were supplanted by double-lumen endobronchial tubes. The double-lumen tube currently most popular was designed by Frank Robertshaw of Manchester, England, and is prepared in both right- and left-sided versions. Robertshaw tubes were first manufactured from mineralized red rubber but are now made of extruded plastic, a technique refined by David

Sheridan. Sheridan was also the first person to embed centimeter markings along the side of tracheal tubes, a safety feature that reduced the risk of the tube's being incorrectly positioned.

Airway Management Devices

Conventional laryngoscopes proved inadequate for patients with “difficult airways.” A few clinicians credit harrowing intubating experiences as the incentive for invention. In 1928, a rigid bronchoscope was specifically designed for examination of the large airways. Rigid bronchoscopes were refined and used by pulmonologists. Although it was known in 1870 that a thread of glass could transmit light along its length, technological limitations were not overcome until 1964 when Shigeto Ikeda developed the first flexible fiberoptic bronchoscope. Fiberoptic-assisted tracheal intubation has become a common approach in the management of patients with difficult airways having surgery.

Roger Bullard desired a device to simultaneously examine the larynx and intubate the vocal cords. He had been frustrated by failed attempts to visualize the larynx of a patient with Pierre-Robin syndrome. In response, he developed the Bullard laryngoscope, whose fiberoptic bundles lie beside a curved blade. Similarly, the Wu-scope was designed by Tzu-Lang Wu in 1994 to combine and facilitate visualization and intubation of the trachea in patients with difficult airways.[82]

The passage of flexible fiberoptic bronchoscopes has been aided by “intubating airways” such as those designed by Berman, Ovassapian, Augustine, Williams, Luomanen, and Patil. Patients requiring continuous-oxygen administration during fiberoptic bronchoscopy may breathe through the Patil face mask, which features a separate orifice through which the scope is advanced. The Patil face mask is only one of an extensive series of aides to intubation created by the innovative “Vijay” Patil.

Dr. A. I. J. “Archie” Brain first recognized the principle of the laryngeal mask airway (LMA) in 1981 when, like many British clinicians, he provided dental anesthesia via a Goldman nasal mask. However, unlike any before him, he realized that just as the dental mask could be fitted closely about the nose, a comparable mask attached to a wide-bore tube might be positioned around the larynx. He not only conceived of this radical departure in airway management, which he first described in 1983,[83] but also spent years in single-handedly fabricating and testing scores of incremental modifications. Scores of Brain's prototypes are displayed in the Royal Berkshire Hospital, Reading, England, where they provide a detailed record of the evolution of the LMA. He fabricated his first models from Magill tubes and Goldman masks, then refined their shape by performing postmortem studies of the hypopharynx to determine the form of cuff that would be most functional. Before silicone rubber was selected, Brain had even mastered the technique of forming masks from liquid latex. Every detail of the LMA, the number and position of the aperture bars, the shape and the size of the masks, required repeated modification.

PATIENT MONITORING

In many ways, the history of late-nineteenth- and early-twentieth-century anesthesiology is the quest for the safest anesthetic. The discovery and widespread use of electrocardiography, pulse oximetry, blood gas analysis, capnography, and neuromuscular blockade monitoring have reduced patient morbidity and mortality and revolutionized anesthesia practice. While safer machines assured clinicians that appropriate gas mixtures were delivered to the patient, monitors provided an early warning of acute physiologic deterioration before patients suffered irrevocable damage.

Joseph Clover was one of the first clinicians to routinely perform basic hemodynamic monitoring. Clover developed the habit of monitoring his patients' pulse but surprisingly, this was a contentious issue at the time. Prominent Scottish surgeons scorned Clover's emphasis on the action of chloroform on the heart. Baron Lister and others preferred that senior medical students give anesthetics and urged them to “strictly carry out certain simple instructions, among which is that of never touching the pulse, in order that their attention may not be distracted from the respiration.”[84] Lister also counseled, “it appears that preliminary examination of the chest, often considered indispensable, is quite unnecessary, and more likely to induce the dreaded syncope, by

alarming the patients, than to avert it."[84] Little progress in anesthesia could come from such reactionary statements. In contrast, Clover had observed the effect of chloroform on animals and urged other anesthetists to monitor the pulse at all times and to discontinue the anesthetic temporarily if any irregularity or weakness was observed in the strength of the pulse.

Two American surgeons, George W. Crile and Harvey Cushing, developed a strong interest in measuring blood pressure during anesthesia. Both men wrote thorough and detailed examinations of blood pressure monitoring; however, Cushing's contribution is better remembered because he was the first American to apply the Riva Rocci cuff, which he saw while visiting Italy. Cushing introduced the concept in 1902 and had blood pressure measurements recorded on anesthesia records.[85] In 1894, Cushing and a fellow student at Harvard Medical School, Charles Codman, initiated a system of recording patients' pulses to assess the course of the anesthetics they administered. In 1902, Cushing continued the practice of monitoring and recording patient blood pressures and pulses. The transition from manual to automated blood pressure devices, which first appeared in 1936 and operate on an oscillometric principle, has been gradual. The development of inexpensive microprocessors has enabled routine use of automatic cuffs in clinical settings.

The first precordial stethoscope was believed to have been used by S. Griffith Davis at Johns Hopkins University.[65] He adapted a technique developed by Harvey Cushing in a laboratory in which dogs with surgically induced valvular lesions had stethoscopes attached to their chest wall so that medical students might listen to bruits characteristic of a specific malformation. Davis' technique was forgotten but was rehabilitated by Dr. Robert Smith, an energetic pioneer of pediatric anesthesiology in Boston. A Canadian contemporary, Albert Codesmith, of the Hospital for Sick Children, Toronto, became frustrated by the repeated dislodging of the chest piece under the surgical drapes and fabricated his first esophageal stethoscope from urethral catheters and Penrose drains. His brief report heralded its clinical role as a monitor of both normal and adventitious respiratory and cardiac sounds.[86] An additional benefit was that the stethoscope could protect against the risk of disconnection of a paralyzed patient from the anesthesia circuit. In the era before audible circuit disconnect alarms, the patient's survival depended upon the anesthesiologist's recognition of the sudden disappearance of breath sounds.

Electrocardiography, Pulse Oximetry, and Capnography

Clinical electrocardiography began with Willem Einthoven's application of the string galvanometer in 1903. Within two decades, Thomas Lewis had described its role in the diagnosis of disturbances of cardiac rhythm, while James Herrick and Harold Pardee first drew attention to the changes produced by myocardial ischemia. After 1928, cathode ray oscilloscopes were available, but the risk of explosion owing to the presence of flammable anesthetics forestalled the introduction of the electrocardiogram into routine anesthetic practice until after World War II. At that time, the small screen of the heavily shielded "bullet" oscilloscope displayed only 3 seconds of data, but that information was highly prized.

Pulse oximetry, the optical measurement of oxygen saturation in tissues, is one of the more recent additions to the anesthesiologist's array of routine monitors. Severinghaus states, "Pulse oximetry is arguably the most important technological advance ever made in monitoring the well-being and safety of patients during anesthesia, recovery, and critical care."[87] Although research in this area began in 1932, its first practical application came during World War II. An American physiologist, Glen Millikan, responded to a request from British colleagues in aviation research. Millikan set about preparing a series of devices to improve the supply of oxygen that was provided to pilots flying at high altitude in unpressurized aircraft. To monitor oxygen delivery and to prevent the pilot from succumbing to an unrecognized failure of his oxygen supply, Millikan created an oxygen-sensing monitor worn on the pilot's earlobe, and coined the name *oximeter* to describe its action. Before his tragic death in a climbing accident in 1947, Millikan had begun to assess anesthetic applications of oximetry.

For the next three decades, oximetry was rarely used by anesthesiologists, and then primarily in research studies such as those of Albert Faulconer and John Pender. Refinements of oximetry by a Japanese engineer, Takuo Aoyagi, led to the development of pulse oximetry. As John Severinghaus

recounted the episode, Aoyagi had attempted to eliminate the changes in a signal caused by pulsatile variations when he realized that this fluctuation could be used to measure both the pulse and oxygen saturation.[87]

Although pulse oximetry gives second-by-second data about oxygen saturation, anesthesiologists have recognized a need for breath-by-breath measurement of respiratory and anesthetic gases. After 1954, infrared absorption techniques gave immediate displays of the exhaled concentration of CO_2. Clinicians quickly learned to relate abnormal concentrations of CO_2 to threatening situations such as the inappropriate placement of a tracheal tube in the esophagus, abrupt alterations in pulmonary blood flow, and other factors. More recently, infrared analysis has been perfected to enable breath-by-breath measurement of anesthetic gases as well. This technology has largely replaced mass spectrometry, which initially had only industrial applications before Albert Faulconer of the Mayo Clinic first used it to monitor the concentration of an exhaled anesthetic in 1954.

The ability to confirm endotracheal intubation and monitor ventilation, as reflected by concentrations of CO_2 in respired gas, began in 1943. At that time, K. Luft described the principle of infrared absorption by CO_2 and he developed an apparatus for measurement.[88] Routine application of capnography in anesthesia practice was pioneered by Dr. Bob Smalhout and Dr. Zden Kalenda in the Netherlands. Breath-to-breath continuous monitoring and a waveform display of CO_2 levels help

anesthesiologists recognize abnormalities in metabolism, ventilation, and circulation.

INTRAVENOUS MEDICATIONS IN ANESTHESIA

Prior to William Harvey's description of a complete and continuous intravascular circuit in *De Motu Cordis* (1628), it was widely held that blood emanated from the heart and was propelled to the periphery where it was consumed. The idea that substances could be injected intravascularly and travel systemically probably originated with Christopher Wren. In 1657, Wren injected aqueous opium into a dog through a goose quill attached to a pig's bladder, rendering the animal “stupefied.”[89] Wren similarly injected intravenous *crocus mettalorum*, an impure preparation of antimony, and observed the animals to vomit and then die. Knowledge of a circulatory system and intravascular access spurred investigations in other areas, and Wren's contemporary, Richard Lower, performed the first blood transfusions of lamb's blood into dogs and other animals.

In the mid-nineteenth century, equipment necessary for effective intravascular injections was conceived. Vaccination lancets were used in the 1830s to puncture the skin and force morphine paste subcutaneously for analgesia.[90] The hollow needle and hypodermic syringe were developed in the following decades but were not initially designed for intravenous use. In 1845, Dublin surgeon Francis Rynd created the hollow needle for injection of morphine into nerves in the treatment of “neuralgias.” Similarly, Charles Gabriel Pravaz designed the first functional syringe in 1853 for perineural injections. Alexander Wood, however, is generally credited with perfecting the hypodermic glass syringe. In 1855, Wood published a paper on the injection of opiates into painful spots by use of hollow needle and his glass syringe.[91]

In 1872, Pierre Oré of Lyons performed what is perhaps the first successful intravenous surgical anesthetic by injecting chloral hydrate immediately prior to incision. His 1875 publication describes its use in 36 patients but several postoperative deaths lent little to recommend this method to other practitioners.[92] In 1909, Ludwig Burkhardt produced surgical anesthesia by intravenous injections of chloroform and ether in Germany. Seven years later, Elisabeth Bredenfeld of Switzerland reported the use of intravenous morphine and scopolamine. The trials failed to show an improvement over inhaled techniques. Intravenous anesthesia found little application or popularity, primarily because of a lack of suitable drugs. In the following decades, this would change.

INDUCTION AGENTS

The first barbiturate, barbital, was synthesized in 1903 by Fischer and von Mering. Phenobarbital

and all other successors of barbital had very protracted action and found little use in anesthesia. After 1929, oral pentobarbital was used as a sedative before surgery, but when it was given in anesthetic concentrations, long periods of unconsciousness followed. The first short-acting oxybarbiturate was hexobarbital (Evipal), available clinically in 1932. Hexobarbital was enthusiastically received by the anesthesia communities in Europe and North America because its abbreviated induction time was unrivaled by any other technique. A London anesthetist, Ronald Jarman, found that it had a dramatic advantage over inhalation inductions for minor procedures. Jarman instructed his patients to raise one arm while he injected hexobarbital into a vein of the opposite forearm. When the upraised arm fell, indicating the onset of hypnosis, the surgeon could begin. Patients were also amazed in that many awoke unable to believe they had been anesthetized.[93] (Soon after Evipal was introduced, Robert Macintosh administered it to Sir William Morris, the manufacturer of the Morris Garages [MG] automobiles. When Morris awoke, he learned that his surgery was completed, and was amazed by this “magic experience,” which he contrasted with his vivid recollections of the terror of undergoing a mask induction as a child in a dentist's office. Morris [later, Viscount Nuffield] insisted, over the objections of Oxford's medical establishment, on endowing a department of anesthesia for the university as a precondition of his support for a postgraduate medical center. In 1937, Sir Robert Macintosh became Oxford's first professor of anesthesiology. He led the growth of the first university department in Europe from the first fully endowed Chair of Anaesthesia and helped establish one of the most distinguished anesthesia centers in the world.)

Even though the prompt action of hexobarbital had a dramatic effect on the conduct of anesthesia, it was soon replaced by two thiobarbiturates. In 1932, Donalee Tabern and Ernest H. Volwiler of the Abbott Company synthesized thiopental (Pentothal) and thiamylal (Surital). The sulfated barbiturates proved to be more satisfactory, potent, and rapid acting than were their oxybarbiturate analogs. Thiopental was first administered to a patient at the University of Wisconsin in March 1934, but the successful introduction of thiopental into clinical practice followed a thorough investigation conducted by John Lundy and his colleagues at the Mayo Clinic in June 1934.

When first introduced, thiopental was often given in repeated increments as the primary anesthetic for protracted procedures. Its hazards were soon appreciated. At first, depression of respiration was monitored by the simple expedient of observing the motion of a wisp of cotton placed over the nose. Only a few skilled practitioners were prepared to pass a tracheal tube if the patient stopped breathing. Such practitioners realized that thiopental without supplementation did not suppress airway reflexes, and they therefore encouraged the prophylactic provision of topical anesthesia of the airway beforehand. The vasodilatory effects of thiobarbiturates were widely appreciated only when thiopental caused cardiovascular collapse in hypovolemic burned civilian and military patients in World War II. In response, fluid replacement was used more aggressively and thiopental administered with greater caution.

In 1962, ketamine was synthesized by Dr. Calvin Stevens at the Parke Davis laboratories in Ann Arbor, Michigan. One of the cyclohexylamine compounds that includes phencyclidine (PCP), ketamine was the only drug of this group that gained clinical utility. The other compounds produced undesirable postanesthetic delirium and psychomimetic reactions. In 1966, the neologism “dissociative anesthesia” was created by Guenter Corrsen and Edward Domino to describe the trance-like state of profound analgesia produced by ketamine.[94] It was released for use in 1970 and although it remains primarily an agent for anesthetic induction, its analgesic properties are increasingly studied and utilized by pain specialists.

Etomidate was first described by Paul Janssen and his colleagues in 1964, and originally given the name Hypnomidate. Its key advantages, minimal hemodynamic depression and lack of histamine release, account for its ongoing utility in clinical practice. It was released for use in 1974 and despite its drawbacks (pain on injection, myoclonus, postoperative nausea and vomiting, and inhibition of adrenal steroidogenesis), etomidate is often the drug of choice for anesthetizing hemodynamically unstable patients.

Propofol, or 2,-6 di-isopropyl phenol, was first synthesized by Imperial Chemical Industries and tested clinically in 1977. Investigators found that it produced hypnosis quickly with minimal excitation and that patients awoke promptly once the drug was discontinued. In addition to its excellent induction characteristics, propofol's antiemetic action made it an agent of choice in patient populations prone to nausea and emesis. Regrettably, Cremophor EL, the solvent with which it was formulated, produced several severe anaphylactic reactions and it was withdrawn from use. Once propofol was reformulated with egg lecithin, glycerol, and soybean oil, the drug reentered clinical practice and gained great success. Its popularity in Britain coincided with the introduction of the LMA, and it was soon noted that propofol suppressed pharyngeal reflexes to a degree that permitted the insertion of an LMA without a need for either muscle relaxants or potent inhaled anesthetics.

Opioids

Opioids (historically referred to as narcotics, although semantically incorrect—see Chapter 14) remain the analgesic workhorse in anesthesia practice. They are used routinely in the perioperative period, in the management of acute pain, and in a variety of terminal and chronic pain states. The availability of short-, medium-, and long-acting opioids, as well as the many routes of administration, gives physicians considerable flexibility in the use of these agents. The analgesic and sedating properties of opium have been known for over two millennia. Certainly the Greeks and Chinese civilizations harnessed these properties in medical and cultural practices. Opium is derived from the seeds of the poppy (Papaver somniferum), and is an amalgam of over 25 pharmacologic alkaloids. The first alkaloid isolated, morphine, was extracted by Prussian chemist Freidrich A.W. Sertürner in 1803. He named this alkaloid after the Greek god of dreams, Morpheus. Morphine became commonly used as a supplement to inhaled anesthesia and for postoperative pain control during the latter half of the nineteenth century. Codeine, another alkaloid of opium, was isolated in 1832 by Robiquet but its relatively weaker analgesic potency and nausea at higher doses limits its role in managing moderate to severe perioperative surgical pain.

Meperidine was the first synthetic opioid and was developed in 1939 by two German researchers at IG Farben, Otto Eisleb and O. Schaumann. Although many pharmacologists are remembered for the introduction of a single drug, one prolific researcher, Paul Janssen, has since 1953 brought forward more than 70 agents from among 70,000 chemicals created in his laboratory. His products have had profound effects on disciplines as disparate as parasitology and psychiatry. The pace of productive innovation in Janssen's research laboratory is astonishing. Chemical R4263 (fentanyl), synthesized in 1960, was followed only a year later by R4749 (droperidol), and then etomidate in 1964. Innovar, the fixed combination of fentanyl and droperidol, is less popular now but Janssen's phenylpeperidine derivatives, fentanyl, sufentanil and alfentanil, are staples in the anesthesia pharmacopoeia. Remifentanil, an ultra short-acting opioid introduced by Glaxo-Wellcome in 1996, is a departure from other opioids in that it has very rapid onset and equally rapid offset due to metabolism by nonspecific tissue esterases. Ketorolac, a nonsteroidal antiinflammatory drug (NSAID) approved for use in 1990, was the first parenteral NSAID indicated for postoperative pain. With a 6- to 8-mg morphine equivalent analgesic potency, Ketorolac provides significant postoperative pain control, and has particular use as a sole intravenous agent in minor procedures, or for pain attenuation when an opioid-sparing approach is essential. Ketorolac use is limited by side effects and may be inappropriate in patients with underlying renal dysfunction, bleeding problems, or compromised bone healing.

Antiemetics

Effective treatment for postoperative nausea and vomiting (PONV) evolved relatively recently and has been driven by incentives to limit hospitalization expenses and improve patient satisfaction. But PONV is an old problem for which late-nineteenth-century practitioners recognized many causes including anxiety, severe pain, sudden changes in blood pressure, ileus, ingestion of blood, and the residual effects of opioids and inhalational anesthetics. Risk of pulmonary aspiration of gastric contents and subsequent death from asphyxia or aspiration pneumonia was a feared

consequence of anesthetics, especially those preceding use of cuffed endotracheal tubes. Vomiting and aspiration during anesthesia led to the practice of maintaining an empty stomach preoperatively, a policy that continues today despite evidence that clear fluids up to 3 hours before surgery do not increase gastric volumes, change gastric pH, or increase the risk of aspiration.

A variety of treatments for nausea and vomiting were proposed by early anesthetists. James Gwathemy's 1914 publication, *Anesthesia*, commented that British surgeons customarily gave tincture of iodine in a teaspoonful of water every half hour for three or four doses. Inhalation of vinegar fumes, and rectal injection of 30 to 40 drops of tincture of opium with 60 grains of sodium bromide were also felt to quiet the vomiting center.[95] Other practitioners attempted olfactory control by placing a piece of gauze moistened with essence of orange or an aromatic oil on the upper lip of the patient.[96] A 1937 anesthesia textbook encouraged treatment of PONV with lateral positioning, “iced soda water, strong black coffee, and chloretone.”[97] Counterirritation, such as mustard leaf on the epigastrium, was also believed useful in limiting emesis.[98] As late as 1951, anesthesia texts recommended oxygen administration, whiffs of ammonia spirits, and control of blood pressure and positioning.[99] The complex central mechanisms of nausea and vomiting were largely unaffected by most of these treatments. Newer drugs capable of intervening at specific pathways were needed to have an impact on PONV. As more short-acting anesthetics were developed, the problem received sharper focus in awake postoperative patients in the recovery room. The nausea attending use of newer chemotherapy agents provided additional impetus to the development of antiemetic medications.

In 1955, a nonrandomized study using the antihistamine cyclizine showed a reduction in PONV from 27% to 21% in a group of 3,000 patients. The following year, a more rigorous study by Knapp and Beecher reported a significant benefit from prophylaxis with the neuroleptic chlorpromazine. In 1957, promethazine (Phenergan) and chlorpromazine were both found to reduce PONV when used prophylactically. Thirteen years later, a double-blind study evaluating metoclopramide was published and it became a first-line drug in the management of PONV. Droperidol, released in the early 1960s, became widely used until 2001 when concerns regarding prolongation of QT intervals prompted a warning from the Food and Drug Administration about its continued use.

The antiemetic effects of corticosteroids were first recognized by oncologists treating intracranial edema from tumors.[100] Subsequent studies have borne out the antiemetic properties of this class of drugs in treating PONV. Recognition of the serotonin 5-HT3 pathway in PONV has led to a unique class of drugs devoted only to addressing this particular problem. Ondansetron, the first representative of

this drug class, was FDA approved in 1991. Additional serotonin 5-HT3 antagonists have been approved and are available today.

Muscle Relaxants

Muscle relaxants entered anesthesia practice nearly a century after inhalational anesthetics. (See Table 1-1.) Curare, the first known neuromuscular blocking agent, was originally used in hunting and tribal warfare by native peoples of South America. The curares are alkaloids prepared from plants native to equatorial rain forests. The refinement of the harmless sap of several species of vines into toxins that were lethal only when injected was an extraordinary triumph introduced by paleopharmacologists in loincloths. Their discovery was the more remarkable because it was independently repeated on three separate continents—South America, Africa, and Asia. These jungle tribes also developed nearly identical methods of delivering the toxin by darts, which, after being dipped in curare, maintained their potency indefinitely until they were propelled through blowpipes to strike the flesh of monkeys and other animals of the treetops. Moreover, the American Indians knew of the juice of an herb that would counteract the effects of the poison if administered in time.[101]

TABLE 1-1 Events in the Development of Muscle Relaxants

Year	Event
1516	Peter Martyr d'Anghera, *De orbe novo*, published account of South American Indian arrow poisons
1596	Sir Walter Raleigh provides detailed account of arrow poison effects and antidote
1745	Charles-Marie de la Condamine returns from Ecuador and conducts curare experiments with chickens and attempted to use sugar as an antidote
1780	Abbe Felix Fontana inserts curare directly into exposed sciatic nerve of rabbit without effect, concludes that mechanism is the destruction of the irritability of voluntary muscles. Publishes *On the American Poison Ticunas* (name of South American tribe)
1811	Benjamin Collins Brodie demonstrates that animals mechanically ventilated may survive significant doses of curare
1812	William Sewell suggests use of curare in “hydrophobia” (rabies) and tetanus
1844	Claude Bernard determines that death occurs by respiratory failure, motor nerves are unable to transmit stimuli from higher centers, differential effect on muscles with peripheral and thoracic muscles being affected before respiratory muscles. Bernard concludes that the site of action is the junction between muscles and nerves, neuromuscular junction
1858	Louis Albert Sayres, New York physician, uses curare to treat tetanus in two patients
1864	Physostigmine isolated from Calabar beans by Sir T.R. Fraser, a Scottish pharmacologist
1886–1897	R. Boehm, a German chemist, demonstrated three separate classes of alkaloids in each of three types of indigenous containers: tube-curares, pot-curares, and calabash-curares
1900	Jacob Pal recognizes that physostigmine can antagonize the effects of curare
1906	Succinylcholine prepared by Reid Hunt and R. Taveau, experimented on rabbits pretreated with curare to learn of cardiac effects and so paralysis went unrecognized

1912	Arthur Lawen uses curare in surgery but report published in German and goes largely unrecognized
1938	Richard and Ruth Gill bring large quantity of curare to New York for further study by pharmaceutical company
1939	Abram E. Bennett uses curare in children with spastic disorders and to prevent trauma from metrazol therapy (precursor to ECT)
1942	Harold Griffith and Enid Johnson use curare for abdominal relaxation in surgery
1942	H. A. Halody develops Rabbit drop head Assay for standardization and large-scale production of curare and d-tubocurarine
1948	Decamethonium, a depolarizing relaxant, is synthesized
1949	Succinylcholine prepared by Daniel Bovet, the following year by J.C. Castillo and Edwin de Beer
1956	Distinction between depolarizing and nondepolarizing neuromuscular blockade is made by William D. M. Paton
1964	Pancuronium released for use in humans, synthesized by Savage and Hewett
1979	Vecuronium introduced, specifically designed to be more hepatically metabolized than pancuronium
1993	Mivacurium released for clinical use
1994	Rocuronium introduced to clinical practice

Accounts from sixteenth-century explorers of South America include reports of the poison-arrow darts used by the natives. In 1564, Sir Walter Raleigh described the effects of curare upon their targets, as well as the use of an antidote. Later, explorers brought home samples of the poison-tipped darts to Europe and Great Britain where scientific studies were undertaken. Early experiments on birds, cats, rabbits, and dogs in the 1780s verified that the poison worked by abolishing muscle function, including respiratory muscles, and that direct insertion into nerves had no effect. In 1811, Benjamin C. Brodie demonstrated that large animals such as horses and donkeys treated with curare could be kept alive if ventilated for several hours through a bellows sewn directly to the trachea.[101]

The earliest clinical use of curare in humans was to ameliorate the tortuous muscle spasms of infectious tetanus. In 1858, New York physician Louis Albert Sayres reported two cases in which he attempted to treat severe tetanus with curare at the Bellevue Hospital. Both of his patients

died. Similar efforts were undertaken to use muscle relaxants to treat epilepsy, rabies, and choreaform disorders. Treatment of Parkinson-like rigidity and the prevention of trauma from seizure therapy also preceded the use of curare in anesthesia.[102]

Interestingly, curare antagonists were developed well before muscle relaxants were ever used in surgery. In 1900, Jacob Pal, a Viennese physician, recognized that curare could be antagonized by physostigmine. This substance had been isolated from the calabar bean some 36 years earlier by Scottish pharmacologist Sir T.R. Fraser. Neostigmine methylsulphate was synthesized in 1931 and was significantly more potent in antagonizing the effects of curare.[103]

In 1938, Richard and Ruth Gill returned to New York from South America, bringing with them 11.9 kg of crude curare collected near their Ecuadorian ranch. Their motivation was a mixture of personal and altruistic goals. Some months before, while on an earlier visit to the United States, Richard Gill learned that he had multiple sclerosis. His physician, Dr. Walter Freeman, mentioned the possibility that curare might have a therapeutic role in the management of spastic disorders. When the Gills returned to the United States with their supply of crude curare, they encouraged scientists at E. R. Squibb & Co. Squibb to take an interest in its unique properties. Squibb soon offered semirefined curare to two groups of American anesthesiologists, who assessed its action but quickly abandoned their studies when it caused total respiratory paralysis in two patients and the death of laboratory animals.

The earliest effective clinical application of curare in medicine occurred in physiatry. After A. R. McIntyre refined a portion of the raw curare in 1939, Abram. E. Bennett of Omaha, Nebraska, injected it into children with spastic disorders. While no persistent benefit could be observed in these patients, he next administered it to patients about to receive metrazol, a precursor to electroconvulsive therapy. Because it eliminated seizure-induced fractures, they termed it a “shock absorber.” By 1941, other psychiatrists followed this practice and, when they found that the action of curare was protracted, occasionally used neostigmine as an antidote.

Curare was used initially in surgery by Arthur Lawen in 1912, but the published report was written in German and was ignored for decades. Lawen, a physiologist and physician from Leipzig, used curare in his laboratory before boldly producing abdominal relaxation at a light level of anesthesia in a surgical patient. Lawen's efforts were not appreciated for decades, and while his pioneering work anticipated later clinical application, safe use would have to await the introduction of regular intubation of the trachea and controlled ventilation of the lungs.[104]

Thirty years after Lawen, Harold Griffith, the chief anesthetist of the Montreal Homeopathic Hospital, learned of A. E. Bennett's successful use of curare and resolved to apply it in anesthesia. As Griffith was already a master of tracheal intubation, he was much better prepared than were most of his contemporaries to attend to potential complications. On January 23, 1942, Griffith and his resident, Enid Johnson, anesthetized and intubated the trachea of a young man before injecting curare early in the course of his appendectomy. Satisfactory abdominal relaxation was obtained and the surgery proceeded without incident. Griffith and Johnson's report of the successful use of curare in the 25 patients of their series launched a revolution in anesthetic care.[105]

Anesthesiologists who practiced before muscle relaxants recall the anxiety they felt when a premature attempt to intubate the trachea under cyclopropane caused persisting laryngospasm. Before 1942, abdominal relaxation was possible only if the patient tolerated high concentrations of an inhaled anesthetic, which might bring profound respiratory depression and protracted recovery. Curare and the drugs that followed transformed anesthesia profoundly. Because intubation of the trachea could now be taught in a deliberate manner, a neophyte could fail on a first attempt without compromising the safety of the patient. For the first time, abdominal relaxation could be attained when curare was supplemented by light planes of inhaled anesthetics or by a combination of intravenous agents providing “balanced anesthesia.” New frontiers opened. Sedated and paralyzed patients could now successfully undergo the major physiologic trespasses of cardiopulmonary bypass, deliberate hypothermia, or long-term respiratory support after surgery.

Credit for successful and safe introduction of curare and d-tubocurarine into anesthesia must in part be given to a Squibb researcher named H. A. Holaday. Crude, unstandardized preparations of curare produced uncertain clinical effects and undesirable side effects related to various impurities. Isolation of d-tubocurarine in 1935 renewed clinical interest but a method for standardizing “Intocostrin” and its purer derivative, d-tubocurarine, had yet to be devised. In the early 1940s, in part as a result of Griffith and Johnson's successful trials, Squibb embarked upon wide-scale production. Holaday developed a reliable, easily reproducible method for standardizing curare doses that became known as the Rabbit head drop assay (Fig. 1-5). The assay consisted of aqueous curare solution injected intravenously in 0.1-mL doses every 15 seconds until the endpoint, when the rabbit became unable to raise its head, was reached.[106]

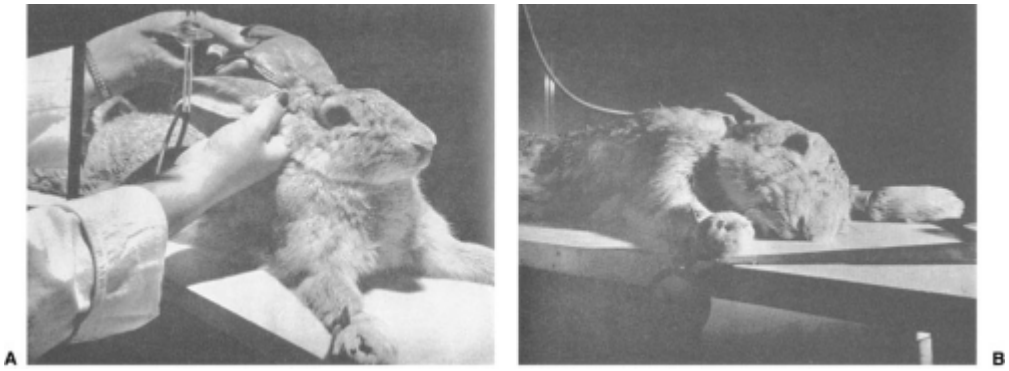

FIGURE 1-5. The rabbit head drop assay. H. A. Halloday of Squibb pharmaceutical company developed a method for standardizing doses of curare and d-tubocurarine by injecting 0.1 mL of aqueous curare solution every 15 seconds until the rabbit could no longer raise its head.

Successful clinical use of curare led to the introduction of other muscle relaxants. By 1948, gallamine and decamethonium had been synthesized. Metubine, a curare “rediscovered” in the 1970s, was used clinically in the same year. Succinylcholine was prepared by the Nobel laureate Daniel Bovet in 1949 and was in wide international use before historians noted that the drug had been synthesized and tested long beforehand.

In 1906, Reid Hunt and R. Taveaux prepared succinylcholine among a series of choline esters, which they had injected into rabbits to observe their cardiac effects. If their rabbits had not been previously paralyzed with curare, the depolarizing action of succinylcholine might have been recognized decades earlier.

The ability to monitor intraoperative neuromuscular blockade with nerve stimulators began in 1958. Working at St. Thomas' Hospital in London, T. H. Christie and H. Churchill-Davidson developed a method for monitoring peripheral neuromuscular blockade during anesthesia. It was not until 1970, however, that H. H. Ali and colleagues devised the technique of delivering four supramaximal impulses delivered at 2 Hz (0.5 seconds apart), or a “Train of Four,” as a method of quantifying the degree of residual neuromuscular blockade.[107]

Research in relaxants was rekindled in 1960, when researchers became aware of the action of maloetine, a relaxant from the Congo basin. It was remarkable in that it had a steroidal nucleus. Investigations of maloetine led to pancuronium in 1968. In the 1970s and 1980s, research shifted toward identification of specific receptor biochemistry and development of receptor-specific drugs. From these isoquinolones, four related products emerged: vecuronium, pipecuronium, rocuronium, and rapacuronium. Rapacuronium, released in the early 1990s, was withdrawn from clinical use

after several cases of intractable bronchospasm led to brain damage or death. Four clinical products based upon the steroid parent drug d-tubocurarine (atracurium, mivacurium, doxacurium, and cis-atracurium) also made it to clinical use. Recognition that atracurium and cis-atracurium undergo spontaneous degradation by Hoffmann elimination has defined a role for these muscle relaxants in patients with liver and renal insufficiency.

BLOOD, FLUIDS, AND HEMODYNAMIC CONTROL

Paleolithic cave drawings found in France depict a bear losing blood from multiple spear wounds, indicating that primitive man understood the simple relationship between blood and life.[108] Over 10,000 years later, modern anesthesiologists attempt to preserve this intimate relationship by replacing fluids and blood products when faced with intravascular volume depletion or diminished oxygen-carrying capacity from blood loss. Interestingly, knowledge of blood and volume deficits related to symptomatic hypovolemia and anemia was probably first understood and connected with the ancient art of phlebotomy, or bloodletting. Since before Hippocrates in the fifth century BC, bloodletting was practiced to restore balance to the body's four humors: blood, phlegm, black and yellow bile. From the middle ages, Barbers performing venesection advertised their services with the red (blood) and white (tourniquet) striped pole that patients squeezed and used to steady their arms during the procedure. One to four pints of blood was typically drained at a time and the procedure was stopped if the patient became faint. This amount is intriguing in that it is consistent with current understanding of acute blood loss and the volume necessary to produce symptoms secondary to anemic hypovolemic states. Recognition that phlebotomizing more than 3 to 4 pints of blood led to undesirable symptoms undoubtedly occurred by process of trial and error.[109] The obvious problem with bloodletting, erroneous therapeutic assumptions aside, was that overzealous phlebotomy could lead to hypovolemia and shock with no method available for restoring fluids to the intravascular compartment. Unrestrained venesection killed U.S. president George Washington when in 1799 he was drained of nine pints of blood in 24 hours following a throat infection.

The technique that might have saved Washington from this fate, blood transfusion, was first attempted in 1667 by physician to Louis XIV, Jean Baptiste Denis. Denis had learned of Richard Lower's transfusion of lamb's blood into a dog the previous year. Lamb's blood was most frequently used because the donating animal's essential qualities were thought to be transferred to the recipient. Despite this dangerous trans-species transfusion, Denis' first patient got better. His next two patients were not as fortunate, however, and Denis avoided further attempts. Given the poor outcomes of these early blood transfusions, and heated religious controversy regarding the implications of transferring animal-specific qualities across species, blood transfusion in humans was banned for over a hundred years in both France and England beginning in 1670.[90]

In 1900, Karl Landsteiner and Samuel Shattock independently helped lay the scientific basis of all subsequent transfusions by recognizing that blood compatibility was based upon different blood groups. Landsteiner, an Austrian physician, originally organized human blood into three groups based upon substances present on the red blood cells. The fourth type, AB group, was identified in 1902 by two students, A. Decastrello and A. Sturli. Based upon these findings, Reuben Ottenberg performed the first type-specific blood transfusion in 1907.

Transfusion of physiologic solutions occurred in 1831, independently performed by O'Shaughnessy and Lewins in Great Britain. In his letter to *The Lancet*, Lewins described transfusing large volumes of saline solutions into patients with cholera. He reported that he would inject into adults from 5 to 10 pounds of saline solution and repeat as needed.[110] Despite its publication in a prominent journal, Lewins' technique was apparently overlooked for decades and balanced physiologic solution availability would have to await the coming of analytical chemistry.

ANESTHESIA ORGANIZATION AND EDUCATION

Anesthesiology evolved slowly as a medical specialty in the United States. While ether remained the dominant anesthetic in America, the provision of anesthesia was often a service relegated to medical students, junior house officers, nurses, and nonprofessionals. The

subordinate status of anesthesia was reflected in American art. Thomas Eakins' great studies, “The Gross Clinic” of 1876 and “The Agnew Clinic” of 1889, both present the surgeon as the focus of attention, whereas the person administering the anesthetic is seen among the supporting figures. During the late nineteenth century, small communities were often served by a single physician, who assigned a nurse to “drop” ether under his direction. In larger towns, doctors practiced independently and did not welcome being placed in what they perceived to be the subordinate role of anesthetist while their competitors enhanced their surgical reputations and collected the larger fees. Many American surgeons recalled the simple techniques they had practiced as junior house officers and regarded anesthesia as a technical craft that could be left to anyone. Some hospitals preferred to pay a salary to an anesthesia nurse while gaining a profit from the fees charged for that person's services. The most compelling argument to be advanced in favor of nurse anesthesia was that of skill: a trained nurse who administered anesthetics every working day was to be preferred to a physician who gave anesthesia infrequently.

Before the beginning of the twentieth century, Mary Botsford and Isabella Herb[111] were among the first Americans to become specialists in anesthesia. Both women were highly regarded as clinicians and also were influential in the formation of specialty societies. Dr. Botsford is believed to have been the

first woman to establish a practice as a specialist in anesthesia. In 1897, she became the anesthesiologist at a children's hospital in San Francisco. Following her example, several other Californian female physicians entered the specialty. Botsford later received the first academic appointment in anesthesia in the western United States when she became clinical professor of anesthesia at the University of California, San Francisco. Dr. Botsford also served as the president of the Associated Anesthetists of the United States and Canada.[112]

One of the first physicians to actually declare himself a “specialist in anesthesia” was Sydney Ormond Goldan of New York, who published seven articles in 1900, including an early description of the use of cocaine for spinal anesthesia. After studying Goldan's early career, Raymond Fink recognized in him some of the qualities of many modern anesthesiologists: “He was brimful of enthusiasm for anesthesia, an excellent communicator and a prolific writer, a gadgeteer and the owner of several patents of anesthesia equipment.”[113] At a time when many surgeons considered that spinal anesthesia did away with their need for an anesthesiologist, Goldan was particularly bold in his written opinions. He called for equality between surgeon and anesthesiologist and was among the first to state that the anesthesiologist had a right to establish and collect his own fee. Goldan regarded the anesthesiologist as being more important than the surgeon to the welfare of the patient.

Since the training of physician anesthetists around the turn of the century lacked uniformity, many prominent surgeons preferred nurse anesthetists and directed the training of the most able candidates they could recruit. At the Mayo Clinic, there were no medical students or residents to give anesthetics in the early 1890s. The Mayo brothers turned to Edith Graham to administer anesthesia. After she married Charles Mayo, Alice Magaw became their personal anesthetist. In turn, Magaw trained Florence Henderson and many others in the art of anesthesia.[114] George W. Crile relied on the skills of Agatha Hodgins. During World War I, Agatha Hodgins, Geraldine Gerrard, Ann Penland, and Sophie Gran were among the more than 100 nurse anesthetists who attended thousands of American and Allied casualties in France. On their return to the United States, many developed schools of nurse anesthesia.[115]

ORGANIZED ANESTHESIOLOGY

Physician anesthetists sought to obtain respect among their surgical colleagues by organizing professional societies and improving the quality of training. The first American organization was founded by nine members on October 6, 1905, and called the Long Island Society of Anesthetists with annual dues of $1.00. In 1911, the annual assessment rose to $3.00 when the Long Island Society became the New York Society of Anesthetists. Although the new organization still carried a local title, it drew members from several states and had a membership of 70 physicians in

1915.[116]

One of the most noteworthy figures in the struggle to professionalize anesthesiology was Francis Hoffer McMechan. McMechan had been a practicing anesthesiologist in Cincinnati until 1911, when he suffered a severe first attack of rheumatoid arthritis, which eventually left him confined to a wheelchair and forced his retirement from the operating room in 1915. McMechan had been in practice only fifteen years, but he had written eighteen clinical articles in this short time. A prolific researcher and writer, McMechan did not permit his crippling disease to sideline his career. Instead of pursuing goals in clinical medicine, he applied his talents to establishing anesthesiology societies.[117]

McMechan supported himself and his devoted wife through editing the *Quarterly Anesthesia Supplement* from 1914 until August 1926. He became editor of the first journal devoted to anesthesia, *Current Researches in Anesthesia and Analgesia*, the precursor of *Anesthesia and Analgesia*, the oldest journal of the specialty. As well as fostering the organization of the International Anesthesia Research Society (IARS) in 1925, McMechan and his wife, Laurette, became overseas ambassadors of American anesthesia. Since Laurette was French, it was understandable that McMechan combined his own ideas about anesthesiology with concepts from abroad.[118]

In 1926, McMechan held the Congress of Anesthetists in a joint conference with the Section on Anaesthetics of the British Medical Association. Subsequently, he traveled throughout Europe, giving lectures and networking physicians in the field. Upon his final return to America, he was gravely ill and was confined to bed for 2 years. His hard work and constant travel paid dividends, however: in 1929, the IARS, which McMechan founded in 1922, had members not only from North America, but also from several European countries, Japan, India, Argentina, and Brazil.[119]

In the 1930s, McMechan expanded his mission from organizing anesthesiologists to promoting the academic aspects of the specialty. In 1931, work began on what would become the International College of Anesthetists. This body began to award fellowships in 1935. For the first time, physicians were recognized as specialists in anesthesiology. The certification qualifications were universal, and fellows were recognized as specialists in several countries. Although the criteria for certification were not strict, the College was a success in raising the standards of anesthesia practice in many nations.[120] In 1939, McMechan finally succumbed to illness, and the anesthesia world lost its tireless leader.

Other Americans promoted the growth of organized anesthesiology. Ralph Waters and John Lundy, among others, participated in evolving organized anesthesia. Waters' greatest contribution to the specialty was raising its academic standards. After completing his internship in 1913, he entered medical practice in Sioux City, Iowa, where he gradually limited his practice to anesthesia. His personal experience and extensive reading were supplemented by the only postgraduate training available, a 1-month course conducted in Ohio by E. I. McKesson. At that time, the custom of becoming a self-proclaimed specialist in medicine and surgery was not uncommon. Waters, who was frustrated by low standards and who would eventually have a great influence on establishing both anesthesia residency training and the formal examination process, recalled that before 1920, “The requirements for specialization in many Midwestern hospitals consisted of the possession of sufficient audacity to attempt a procedure and persuasive power adequate to gain the consent of the patient or his family.”[121]

In an effort to improve anesthetic care, Waters regularly corresponded with Dennis Jackson and other scientists. In 1925, he relocated to Kansas City with a goal of gaining an academic post at the University of Kansas, but the professor of surgery failed to support his proposal. The larger city did allow him to initiate his freestanding outpatient surgical facility, “The Downtown Surgical Clinic,” which featured one of the first postanesthetic recovery rooms.[122] In 1927, Erwin Schmidt, professor of surgery at the University of Wisconsin's medical school, encouraged Dean Charles Bardeen to recruit Waters.

In accepting the first American academic position in anesthesia, Waters described four objectives that have been since adopted by many other academic departments. His goals were as follows:

“(1) to provide the best possible service to patients of the institution; (2) to teach what is known of the principles of Anesthesiology to all candidates for their medical degree; (3) to help long-term graduate students not only to gain a fundamental knowledge of the subject and to master the art of administration, but also to learn as much as possible of the effective methods of teaching; (4) to accompany these efforts

with the encouragement of as much cooperative investigation as is consistent with achieving the first objectives.”[123]

Waters' personal and professional qualities impressed talented young men and women who sought residency posts in his department. He encouraged residents to initiate research interests in which they collaborated with two pharmacologists whom Waters had known before arriving in Wisconsin, Arthur Loevenhart and Chauncey Leake, as well as others with whom he became associated in Madison. Clinical concerns were also investigated. As an example, anesthesia records were coded onto punch cards to form a database that was used to analyze departmental activities. Morbidity and mortality meetings, now a requirement of all training programs, also originated in Madison. Members of the department and distinguished visitors from other centers attended them. As a consequence of their critical reviews of the conduct of anesthesia, responsibility for an operative tragedy gradually passed from the patient to the physician. In more casual times, a practitioner could complain, “The patient died because he did not take a good anesthetic.” Alternatively, the death might be attributed to a mysterious force such as “status lymphaticus,” of which Arthur Guedel, a master of sardonic humor, observed, “Certainly status lymphaticus is at times a great help to the anesthetist. When he has a fatality under anesthesia with no other cleansing explanation he is glad to recognize the condition as an entity.”[123]

In 1929, John Lundy at the Mayo Clinic organized the Anaesthetists' Travel Club, whose members were leading American or Canadian teachers of anesthesia. Each year one member was the host for a group of 20 to 40 anesthesiologists who gathered for a program of informal discussions. There were demonstrations of promising innovations for the operating room and laboratory, which were all subjected to what is remembered as a “high-spirited, energetic, critical review.”[124] The Travel Club would be critical in the upcoming battle to form the American Board of Anesthesiology.

Even during the lean years of the Depression, international guests also visited Waters' department. For Geoffrey Kaye of Australia, Torsten Gordh of Sweden, Robert Macintosh and Michael Nosworthy of England, and scores of others, Waters' department was their “mecca of anesthesia.” Ralph Waters trained 60 residents during the 22 years he was the “Chief.” From 1937 onward, the alumni, who declared themselves the “Aqualumni” in his honor, returned annually for a professional and social reunion. Thirty-four “Aqualumni” took academic positions, and, of these, 14 became chairpersons of departments of anesthesia. They maintained Waters' professional principles and encouraged teaching careers for many of their own graduates.[125] His enduring legacy was once recognized by the dean who had recruited him in 1927, Charles Bardeen, who observed, “Ralph Waters was the first person the University hired to put people to sleep, but, instead, he awakened a world-wide interest in anesthesia.”[127]

Waters and Lundy along with Paul Wood, of New York City, had an important role in establishing organized anesthesia, and the definition of the specialty. In the heart of the Great Depression, these three physicians realized that anesthesiology needed to have a process to determine who was an anesthetic specialist with American Medical Association (AMA) backing. Using the New York Society of Anesthetists, of which Paul Wood was secretary-treasurer, a new class of members, “Fellows,” was created. The “Fellows” criteria followed established AMA guidelines for specialty certification. However, the AMA wanted a national organization to sponsor a specialty board. The New York Society of Anesthetists changed its name to the American Society of Anesthetists (ASA) in 1936. Combined with the American Society of Regional Anesthesia, whose president was Emery Rovenstein, the American Board of Anesthesiology (ABA) was organized as a subordinate board to the American Board of Surgery in 1938. With McMechan's death in 1939, the AMA favored independence for the ABA, and in 1940, independence was granted.[122,127]

A few years later, the officers of the American Society of Anesthetists were challenged by Dr. M. J.

Seifert, who wrote, “An Anesthetist is a technician and an Anesthesiologist is the specific authority on anesthesia and anesthetics. I cannot understand why you do not term yourselves the American Society of Anesthesiologists.”[126] Ralph Waters was declared the first president of the newly named ASA in 1945. In that year, when World War II ended, 739 (37%) of 1,977 ASA members were in the armed forces. In the same year, the ASA's first Distinguished Service Award (DSA) was presented to Paul M. Wood for his tireless service to the specialty, one element of which can be examined today in the extensive archives preserved in the Society's Wood Library Museum at ASA headquarters, Park Ridge, Illinois.[127]

After World War II, specialties within the realm of anesthesiology began to thrive. Kathleen Belton was a superb pediatric specialist. In 1948, while working in Montreal, Belton and her colleague, Digby Leigh, wrote the classic text *Pediatric Anesthesia.* At the same time, a second pediatric anesthesiologist, Margot Deming, was the Director of Anesthesia at the Children's Hospital of Philadelphia. Pediatric anesthesia also figured in the career of Doreen Vermeulen-Cranch, who had earlier initiated thoracic anesthesia in The Netherlands and pioneered hypothermic anesthesia. Obstetric anesthesia also figured prominently in the career of Virginia Apgar. After encountering severe financial and professional frustrations during her training and while serving as Director of the Division of Anesthesia at Columbia University, Apgar turned to obstetric anesthesia in 1949. She dedicated the next decade of her multifaceted career to the care of mothers and their infants.[128]

ANESTHESIA PRACTICE TODAY AND TOMORROW

This overview of the development of anesthesiology could be extended almost indefinitely by an exploration of each subspecialty area, but an assessment of our current roles can be seen by a personal survey of the areas in which anesthesiologists serve in hospitals, clinics, and laboratories. The operating room and obstetric delivery suite remain the central interest of most specialists. Aside from being the location where the techniques described in this chapter find regular application, service in these areas brings us into regular contact with new advances in pharmacology and bioengineering.

8 After surgery, patients are transported to the postanesthesia care unit or recovery room, an area that is now considered the anesthesiologist's “ward.” Fifty years ago, patients were carried directly from the operating room to a surgical ward to be attended only by a junior nurse. That person lacked both the skills and equipment to intervene when complications occurred. After the experiences of World War II taught the value of centralized care, physicians and nurses created recovery rooms, which were soon mandated for all major hospitals. By 1960 the evolution of critical care progressed through the use of mechanical ventilators. Patients who required many days of intensive medical and nursing management were cared for in a curtained corner of the recovery room. In time, curtains drawn about one or two beds gave way to fixed partitions and the relocation of those areas to form intensive care units. The principles of resuscitative and supportive care established by anesthesiologists transformed critical care medicine.

9 The future of anesthesiology is a bright one. The safer drugs that once revolutionized the care of patients undergoing surgery are constantly being improved upon. The role of

the anesthesiologist continues to broaden, as physicians with backgrounds in the specialty have developed clinics for chronic pain control and outpatient surgery. Anesthesia practice will continue to increase in scope, both inside and outside of the operating suite, such that anesthesiologists will become even more of an integral part of the entire perioperative experience.

Chapter 2

Practice and Operating Room Management

Richard L. Lock

John H. Eichhorn

KEY POINTS

1	Anesthesiology residents, and many postgraduates also, tend to lack sufficient knowledge (with sometimes unfortunate results) about practice structures, financial matters of all types, and contracting in particular. They must educate themselves and also seek expert advice and counsel to survive (and hopefully flourish) in today's exceedingly complex medical practice milieu.
2	There are several very helpful detailed information resources on practice and OR management available from the American Society of Anesthesiologists (ASA) and other sources.
3	Securing hospital privileges is far more than a bureaucratic annoyance and must be taken seriously by anesthesiologists.
4	Anesthesiologists need to be involved, concerned, active participants and leaders in their institution and community to enhance their practice function and image.
5	Anesthesiology is the leading medical specialty in establishing and promulgating standards of practice, which have significantly positively influenced practice.
6	The immediate response to a major adverse anesthesia event is critical to the eventual result and an extremely valuable protocol is available at www.apsf.org , "Resources: Clinical Safety."
7	Managed care's influence waxes, wanes, and changes but it must always be considered by modern anesthesiologists. While cost, value, outcome, and quality issues are certainly central to all anesthesiology practices, difficulties in constructing and applying definitive measurements and rigorous statistical analysis of these parameters have prevented, so far at least, some of the potential negative influences of the core features of fully managed health care on anesthesiology practice in most circumstances.

8	Anesthesiologists must participate in operating room (OR) management in their facilities and should play a central leadership role. Operating room scheduling, staffing, utilization, and patient flow issues are complex and anesthesiologists should work hard to both thoroughly understand and positively influence them.
9	Anesthesiology personnel issues involve an elaborate balancing act and groups/departments should give these issues, as well as their constituent personnel, more attention and energy than has been traditional in the past or the anesthesia provider shortage will likely continue to worsen.
10	Attention to the many often-underemphasized details of infrastructure, organization, and administration can transform a merely endurable anesthesia practice into one that is efficient, effective, productive, collegial, and even fun.

Ongoing evolution of medical practice in the United States has accelerated to such a pace that considerations of organization, administration, and management require constant updating. Functions and details across the whole spectrum of the health care "system" or "enterprise," from the briefest and simplest primary care encounter of a single patient, through the administration and management of an anesthesiology practice group and its environment, all the way up to national policies for financing the care of the entire population, demand more attention and effort than ever before.

In the past, anesthesiologists traditionally were little involved in the management of many components of their practice beyond the strictly medical elements of applied physiology and pharmacology, pathophysiology, and therapeutics. This was, perhaps, somewhat understandable because anesthesiologists traditionally spent the vast majority of their usually very long work hours in a hospital OR. Business matters were often left to the one or two group members interested or willing to deal with an outside contractor billing agency. Often there were few if any support personnel (sometimes no office base at all other than a corner desk in the 'doctors' lounge). In many circumstances, there was little or no time to even consider or attempt management functions. Reluctant compliance with critical mandatory processes such as credentialing was secured only by the insistence of a hospital staff administrator. In that era, very little formal teaching of or training in practice management of any kind occurred in anesthesiology residency programs. Word-of-mouth handing down of what was mostly folklore was often all an anesthesiology resident had to go on after completing training and beginning practice. Interestingly in this regard, the Anesthesiology Residency Review Committee of the Accreditation Council on Graduate Medical Education now requires that the didactic curricula of anesthesiology residencies include material on practice management. Today, most residency programs offer at least a cursory introduction to issues of practice management, but these can be insufficient to prepare satisfactorily the resident being graduated for the real infrastructure, administrative, business, and management challenges of the modern practice of anesthesiology.

1 This chapter, which draws significantly from its predecessor[1] and also incorporates concepts from a related chapter[2] in the previous edition, presents a wide variety of topics that, until very recently, were not in anesthesiology textbooks. Several basic components of the administrative, organizational (including daily functioning of the OR), and financial aspects of anesthesiology practice are outlined. Included is mention of some of the issues associated with practice arrangements in the modern environment heavily influenced by various types of managed care and its permutations and combinations. Although certain of these issues are undergoing almost constant change, it is important to understand the basic vocabulary and principles in this

dynamic universe. Lack of understanding of these issues may put anesthesiologists at a disadvantage when attempting to maximize the efficiency and impact of their daily activities, to create and execute practice arrangements, and to secure fair compensation in an increasingly complex health care system with greater and greater competition for scarcer and scarcer resources.

ADMINISTRATIVE COMPONENTS OF ANESTHESIOLOGY PRACTICE

Operational and Information Resources

While it may be relatively rare, there are still situations in which a brand-new anesthesiology practice is created and there is no previously existing infrastructure, protocol, organization, habits, or tradition to draw on for guidance. Likewise, mergers and spin-offs of anesthesiology practices occur, just as in the business world. How can anesthesiologists and the administrative/support personnel they hire learn from the collective experience of the profession and thus avoid having to "reinvent the wheel" in facilitating their practice? Similarly, practicing anesthesiologists frequently recognize the need to examine and, it is hoped, improve the function of their practices through comparable efforts.

2 Overview summaries such as this chapter are intended as an introduction. Further, fortunately, the American Society of Anesthesiologists (ASA), the professional association for physician anesthesiologists in the United States, for many years has made available to its members extensive resource material regarding practice in general and specific arrangements for its execution. Citation and availability of this material can be found on the ASA website, http://www.asahq.org. Elements are updated periodically by the ASA through its physician officers, committees, task forces, administrative and support staff, and various offices. Although many of the documents generated and even the advice given in response to members' questions contain broad-brush generalities that must be interpreted in each individual practice situation, these nonetheless stand as a solid foundation on which anesthesiology practice can be formulated. In the past, many ASA members were unaware of the existence of these resources and discovered them only when referred to them during an appeal to the ASA for help resolving some significant practice or financial problem. Prospective familiarity with the principles outlined in the ASA material likely could help avoid some of the problems leading to calls for help. Selected key documents are compiled and bound into a volume that can be purchased.[3] Each spring, the ASA offers a Practice Management Conference, following which the lecture materials are published in an annual volume (see http://www.asahq.org, "Publications and Services," "Publications on Practice Management").

Background

The current atmosphere in American medicine, which creates the impression that "all of a sudden, all the rules and understandings are changing," makes it virtually mandatory that anesthesiologists be familiar with the fundamental background of their profession. The ASA "Guidelines for the Ethical Practice of Anesthesiology"[3] includes sections on the principles of medical ethics; the definition of medical direction of nonphysician personnel (including the specific statement that an anesthesiologist engaged in medical direction should not personally be administering another anesthetic); the anesthesiologist's relationship to patients and other physicians; the anesthesiologist's duties, responsibilities, and relationship to the hospital; and the anesthesiologist's relationship to nurse anesthetists and other nonphysician personnel. Further, the ASA publishes "The Organization of an Anesthesia Department"[3] and states through it that the ASA "has adopted a Statement of Policy, which contains principles that the Society urges its members to consider in structuring their own individual medical practices." This document has sections on physician responsibilities for medical care and on medical-administrative organization and responsibilities. The ASA has been particularly proactive in helping its members keep up with rapidly changing areas of both managed care and government programs with all the myriad financial implications of the evolving rules and requirements. In the past, some (probably many)

anesthesiology residents finishing training felt unprepared, in a business and organizational sense, to enter the job and practice markets. They had to learn complex difficult lessons through a self-taught crash course during negotiations for a position, sometimes to their detriment. Beyond summaries such as this chapter, reference to the considerable body of material created and presented by the ASA (which includes a thick volume specifically on the details of business arrangements[4]) is an excellent starting point to help young anesthesiologists during residency prepare for the increasing rigors of starting and managing a career in practice. Likewise, there is a great deal of information on the ASA website concerning the most recent governmental regulations, rulings, and billing codes. The ASA *Newsletter* distributed to all members now contains the monthly columns "Washington Report" and

"Practice Management," which disseminate related current developments.

Of course, the Internet is a very important source of information. In addition to the ASA, most other anesthesiology subspecialty societies and interest groups have Web locations, as do most journals. Certain anesthesiology and other journals that exist only on the Internet are now in existence, and more will likely be developed. Particularly, the website of the Anesthesia Patient Safety Foundation, http://www.apsf.org, has been cited as especially useful in promoting safe clinical practice. Electronic bulletin boards allow anesthesiology practitioners from around the world to immediately exchange ideas on diverse topics, both medical and administrative. Traditionally, the ASA has not maintained one. However, one of the original sites that remains very popular is http://www.gasnet.org and a web search ("anesthesiology + bulletin board") using a search engine such as http://www.google.com reveals a great number of sites that contain a variety of discussions about all manner of anesthesiology-related topics, including practice organization, administration, and management. Additionally, references to the entirety of the medical literature are readily accessible to any practitioner (such as by starting with http://www.nlm.nih.gov to access Medline). A modern anesthesiology practice cannot reasonably exist without readily available high-speed Internet connections.

The Credentialing Process and Clinical Privileges

3 The system of credentialing a health care professional and granting clinical privileges in a health care facility is motivated by a fundamental assumption that appropriate education, training, and experience, along with the absence of excessive numbers of bad patient outcomes, increase the chances that the individual will deliver acceptable-quality care. As a result, the systems have received considerably increased emphasis in recent years.[5] The process of credentialing health care professionals has been the focus of considerable public attention (particularly in the mass media), in part the result of very rare incidents of untrained persons (impostors) infiltrating the health care system and sometimes harming patients. The more common situation, however, involves health professionals who exaggerate past experience and credentials or fail to disclose adverse past experiences. There has been some justified publicity concerning physicians who lost their licenses sequentially in several states and simply moved on each time to start practice elsewhere (which should be much, much more difficult now).

The patient–physician relationship also has changed radically, with a concomitant increase in suspicion directed toward the medical profession. There is now a pervasive public perception that physicians are inadequately policed, particularly by their own professional organizations and hospitals. Intense public and political pressure has been brought to bear on various law-making bodies, regulatory and licensing agencies, and health care institution administrations to discover and purge both (1) fraudulent, criminal, and deviant health care providers, and (2) incompetent or simply poor-quality practitioners whose histories show sufficient poor patient outcomes to attract attention, usually through malpractice suits. Identifying and avoiding or correcting an incompetent practitioner is the goal. Verification of appropriate education, training, and experience on the part of a candidate for a position rendering anesthesia care assumes special importance in light of the legal doctrine of *vicarious liability*, which can be described as follows: if an individual, group, or institution hires an anesthesia provider or even simply approves of that person (e.g., by granting clinical privileges through a hospital medical staff), those involved in the decision may later be

held liable in the courts, along with the individual, for the individual's actions. This would be especially true if it were later discovered that the offending practitioner's past adverse outcomes had not been adequately investigated during the credentialing process.

Out of these various long-standing concerns has arisen the sometimes cumbersome process of obtaining state licenses to practice and of obtaining hospital privileges. It is somewhat analogous to passing through screening and metal detection devices at airports, which is tolerated by the individual in the interest of the safety of all, with the presumption that danger will be detected and eliminated. The stringent credentialing process is intended both to protect patients and to safeguard the integrity of the medical profession. Recently, central credentialing systems have been developed, including those affiliated with the American Medical Association, American Osteopathic Association, and, particularly, the Federation Credentials Verification Service of the Federation of State Medical Boards. These systems verify a physician's basic credentials (identity, citizenship or immigration status, medical education, postgraduate training, licensure examination history, prior licenses, board actions, etc.) once and then, thereafter, can certify the validity of these credentials to a state licensing board or medical facility. Some states do not yet accept this verification and most states seek specific supplemental information.

There are checklists of the requirements for the granting of medical staff privileges by hospitals (see the American Hospital Association Resource Center, http://www.aharc.library.net). In addition, the National Practitioner Data Bank and reporting system administered by the U.S. government now has many years' worth of information in it. This data bank is a central repository of licensing and credentials information about physicians. Many adverse situations involving a physician—particularly instances of substance abuse, malpractice litigation, or the revocation, suspension, or limitation of that physician's license to practice medicine or to hold hospital privileges—must be reported (via the state board of medical registration/licensure) to the National Practitioner Data Bank. It is a statutory requirement that all applications for hospital staff privileges be cross-checked against this national data bank. The potential medicolegal liability on the part of a facility's medical staff, and the anesthesiology group in particular, for failing to do so is significant. The Data Bank, however, is not a complete substitute for direct documentation and background checking. Often, practitioners reach negotiated solutions following quality-driven medical staff problems, thereby avoiding the mandatory reporting. In such cases, a suspect physician may be given the option to resign medical staff privileges and avoid Data Bank reporting rather than undergo full involuntary privilege revocation.

Documentation

The documentation for the credentialing process for each anesthesia practitioner must be complete. Privileges to administer anesthesia must be officially granted and delineated in writing.[3] This can be straightforward or it can be more complex to accommodate institutional needs to identify practitioners specially qualified to practice in designated anesthesia subspecialty areas such as cardiac, infant/pediatric, obstetric, intensive care, or pain management. Specific documentation of the process of granting or renewing clinical privileges is required and, unlike some other records, the documentation likely is protected as confidential peer review information. Any questions about complex sensitive issues such as this should be referred to an experienced attorney familiar with applicable federal and state law. Verification of an applicant's credentials and experience is mandatory. Because of another type of legal case, some

examples of which have been highly publicized, medical practitioners may be hesitant to give an honest evaluation (or any evaluation at all) of individuals known to them who are seeking a professional position elsewhere. Obviously, someone writing a reference for a current or former coworker should be honest. Sticking to clearly documentable facts is advisable. Stating a fact that is in the public record (such as a malpractice case lost at trial) should not justify an objection from the subject of the reference. Whether omitting such a fact is dishonest on the part of the reference writer is more of a gray area. Including positive opinions and enthusiastic recommendations, of course, is no problem. Some fear that including facts that may be perceived as negative (e.g., the lost malpractice case or personal problems such as a history of treatment

for substance abuse) and negative opinions will provoke retaliatory lawsuits (such as for libel, defamation of character, or loss of livelihood) from the subject. As a result, many reference writers in these questionable situations confine their written material to brief, simple facts such as dates employed and position held. As always, questions about complex sensitive issues such as this should be referred to an experienced attorney familiar with applicable federal and state law.

Because there should be no hesitation for a reference writer to include positive opinions, receipt of a reference that includes nothing more than dates worked and position held should be a suggestion that there may be more to the story. Receipt of such a reference about a person applying for a position should always lead to a telephone call to the writer. A telephone call is likely advisable in all cases, independent of whatever the written reference contains. Frequently, pertinent questions over the telephone can elicit more candid information. In rare instances, there may be dishonesty through omission by the reference giver even at this level. This may involve an applicant who an individual, a department or group, or an institution would like to see leave. The subject applicant may have poor-quality practice, but there may also be reluctance by the reference giver(s) to approach licensing or disciplinary authorities (because of the unpleasantness and also out of concern about retaliatory legal action). This type of "sandbagging" is fortunately infrequent. The best way to avoid it is to telephone an independent observer or source (such as a former employer or associate who no longer has a personal stake in the applicant's success or even the head nurse of an OR in which the applicant worked) when any question exists. Because the ultimate goal is optimum patient care, the subjects applying for positions generally should not object to such calls being made. Discovery of a history of unsafe practices and/or habits or of causing preventable anesthesia morbidity or mortality should elicit careful evaluation as to whether the applicant can be appropriately assigned, trained, and/or supervised to be maximally safe in the proposed new environment.

In all cases, new personnel in an anesthesia practice environment must be given a thorough orientation and checkout. Policy, procedures, and equipment may be unfamiliar to even the most thoroughly trained, experienced, and safe practitioner. This may occasionally seem tedious, but it is both sound and critically important safety policy. Being in the midst of a crisis situation caused by unfamiliarity with a new setting is not the optimal orientation session.

After the initial granting of clinical privileges to practice anesthesia, anesthesiologists must periodically renew their privileges within the institution or facility (e.g., annually or every other year). There are moral, ethical, and societal obligations on the part of the privilege-granting entity to take this process seriously. State licensing bodies often become aware of problems with health professionals very late in the evolution of the difficulties. An anesthesia provider's peers in the hospital or facility are much more likely to notice untoward developments as they first appear. However, privilege renewals are often essentially automatic and receive little of the necessary attention. Judicious checking of renewal applications and awareness of relevant peer review information is absolutely necessary. The physicians or administrators responsible for evaluating staff members and reviewing their practices and privileges may be justifiably concerned about retaliatory legal action by a staff member who is censured or denied privilege renewal. Accordingly, such evaluating groups must be thoroughly objective (totally eliminating any hint of political or financial motives) and must have documentation that the staff person in question is in fact practicing below the standard of care. Court decisions have found liability by a hospital, its medical staff group, or both when the incompetence of a staff member was known or should have been known and was not acted upon.[6] Again, questions about complex sensitive issues such as this should be referred to an experienced attorney familiar with applicable federal and state law.

A major issue in the granting of clinical privileges, especially in procedure-oriented specialties such as anesthesiology, is whether it is reasonable to continue the common practice of "blanket" privileges. This process in effect authorizes the practitioner to attempt any treatment or procedure normally considered within the purview of the applicant's medical specialty. These considerations may have profound political and economic implications within medicine, such as which type of surgeon should be doing carotid endarterectomies or lumbar discectomies. More important, however, is whether the practitioner being evaluated is qualified to do everything traditionally associated with the specialty. Specifically, should the granting of privileges to practice anesthesia

automatically approve the practitioner to handle pediatric cardiac cases, critically ill newborns (such as a day-old premature infant with a large diaphragmatic hernia), ablative pain therapy (such as an alcohol celiac plexus block under fluoroscopy), high-risk obstetric cases, and so forth? This question raises the issue of procedure-specific or limited privileges. The quality assurance (QA) and risk management considerations in this question are weighty if inexperienced or insufficiently qualified practitioners are allowed or even expected, because of peer or scheduling pressures, to undertake major challenges for which they are not prepared. The likelihood of complications and adverse outcome will be higher, and the difficulty of defending the practitioner against a malpractice claim in the event of catastrophe will be significantly increased.

There is no clear answer to the question of procedure-specific credentialing and granting of privileges. Ignoring issues regarding qualifications to undertake complex and challenging procedures has clear negative potential. On the other hand, stringent procedure-specific credentialing is impractical in smaller groups, and in larger groups encourages many small "fiefdoms," with a consequent further atrophy of the clinical skills outside of the practitioner's specific area(s). Each anesthesia department or group needs to address these issues. At the very least, the common practice of every applicant for privileges (new or renewal) checking off every line on the printed list of anesthesia procedures should be reviewed. Additionally, board certification is now essentially a standard of quality assurance of the minimum skills required for the consultant practice of anesthesiology. Subspecialty boards, such as those in pain management, critical care, and transesophageal echocardiography, further objectify the credentialing process. This is now significant because initial board certification after the year 2000 by the American Board of Anesthesiology is time limited and subject to periodic testing and recertification. Clearly, this will encourage an ongoing process of continuing medical education (CME). Many states, some institutions, even some regulatory bodies have requirements for a minimum number of hours of CME. Documentation of meeting such a standard again acts as one type of quality assurance mechanism for the individual

practitioner, while providing another objective credentialing measurement for those granting licenses or privileges.

Medical Staff Participation and Relationships

4 All medical care facilities and practice settings depend on their medical staffs, of course, for daily activities of the delivery of health care; but, very importantly, they also depend on those staffs to provide administrative structure and support. Medical staff activities are increasingly important in achieving favorable accreditation status (e.g., from the Joint Commission for the Accreditation of Healthcare Organizations [JCAHO]) and in meeting a wide variety of governmental regulations and reviews. Principal medical staff activities involve sometimes time-consuming efforts, such as duties as a staff officer or committee member. Anesthesiologists should be participants in—in fact, should play a significant role in—credentialing, peer review, tissue review, transfusion review, OR management, and medical direction of same-day surgery units, postanesthesia care units (PACUs), intensive care units (ICUs), and pain management units. Also, it is very important that anesthesiology personnel be involved in fund-raising activities, benefits, community outreach projects sponsored by the facility, and social events of the facility staff.

The role these and related activities play in anesthesia practice management may not be obvious at first glance, but this is a reflection of the unfortunate fact that, all too often, anesthesiologists have in the past chosen to have very little or no involvement in such efforts. Of course, there are exceptions in specific settings. However, it is an unmistakable reality that anesthesiologists as a group have a reputation for lack of involvement in medical staff and facility issues because of a lack of time (because of long hours in the OR) or simply a lack of interest. In fact, anesthesiology personnel are all too often perceived in a facility as the ones who slip in and out of the building essentially anonymously (often dressed very casually or even in the pajama-like comfort of scrub suits) and virtually unnoticed. This is an unfortunate state of affairs, and it has frequently come back in various painful ways to haunt those who have not been involved, or even noticed.

Anesthesiology personnel sometimes respond that the demands for anesthesiology service are so great that they simply never have the time or the opportunity to become involved in their facility and with their peers. If this is really true, it is clear that more providers of anesthesia care must be added at that facility, even if doing so slightly reduces the income of those already there.

In any case, anesthesiologists simply must make the time to be involved in medical staff affairs, both in health care facility administration and also as part of the organization, administration, and governance of the comparatively large multispecialty physician groups that provide entities with which managed care organizations (MCOs) and health care facilities can negotiate for physician services. The types and styles of these organizations vary widely and are discussed later. The point here is simple. If anesthesiologists are not involved and not perceived as interested, dedicated "team players," they will be shut out of critical negotiations and decisions. Although one obvious instance in which others will make decisions for anesthesiologists is the distribution of capitated or bundled practice fee income collected by a central "umbrella" organization, there are many such situations, and the anesthesiologists will have to comply with the resulting mandates. In the most basic terms, absence from the bargaining table and/or being seen as uninvolved in the welfare of the large group virtually ensure that anesthesiologists will not participate in key decisions or receive their "fair share of the pie."

Similarly, involvement with a facility, a medical staff, or a multispecialty group goes beyond formal organized governance and committee activity. Collegial relationships with physicians of other specialties and with administrators are central to maintenance of a recognized position and avoidance of the situation of exclusion described above. Being readily available for formal and informal consults, particularly regarding preoperative patient workup and the maximally efficient way to get surgeons' patients to the OR in a timely, expedient manner, is extremely important. No one individual can be everywhere all the time, but an anesthesiology group or department should strive to be always responsive to any request for help from physicians or administrators. It often appears that anesthesiologists fail to appreciate just how great a positive impact a relatively simple involvement (starting an intravenous line for a pediatrician, helping an internist manage an ICU ventilator, or helping a facility administrator unclog a jammed recovery room) may have. Unfortunately, anesthesiologists in a great many locations have a negative stereotype built up over years to overcome and must work hard to maintain the perception that they deserve an equal voice regarding the impact of the current changes in the health care system.

Establishing Standards of Practice and Understanding the Standard of Care

Given all the current and future changes in the anesthesiology practice environment, it is more important than ever that anesthesiologists genuinely understand what is expected of them in their clinical practice. The increasing frequency and intensity of "production pressure,"[7] with the tacit (or even explicit) directive to anesthesia personnel to "go fast" no matter what and to "do more with less," creates situations in which anesthesiologists may conclude that they must cut corners and compromise maximally safe care just to stay in business. This type of pressure has become even greater with the implementation of more and more protocols or parameters for practice, some from professional societies such as the ASA and some mandated by or developed in conjunction with purchasers of health care (government, insurance companies, or MCOs). Many of these protocols are devised to fast-track patients through the medical care system, especially when an elective procedure is involved, in as absolutely little time as possible, thus minimizing costs. Do these fast-track protocols constitute standards of care that health care providers are mandated to implement? What are the implications of doing so? Of not doing so?

To better understand answers to such questions, it is important to have a basic background in the concept of the *standard of care.* Anesthesiology personnel are fortunate in this regard because for nearly 20 years American anesthesiology has been recognized as one of the significant leaders in establishing practice standards intended to maximize the quality of patient care and help guide personnel at times of difficult decisions, including the risk–benefit and cost–benefit decisions of specific practices. Another important component of this issue is the unique legal system in the United States, in which the potential liability implications of most decisions must be considered.

Businesses, groups, and individuals have had their entire public existences destroyed by staggering legal settlements and judgments allowed by the U.S. legal system. Major attempts at reform of this system have occurred and will continue to occur. However, although a very positive restructuring of the tort liability system could alleviate some of the catecholamine-generating "sword over the head" mentality exhibited by some physicians, it will not relieve anesthesiology personnel of the responsibility to provide maximally safe care for their patients. Integration of systems and protocols to help maximize the quality of patient care, whether from formal standards or not, is an important component of managing an anesthesiology practice.

The standard of care is the conduct and skill of a prudent practitioner that can be expected by a reasonable patient. This is a very important medicolegal concept because a bad medical result due to a failure to meet the standard of care is malpractice. Extensive discussions have attempted to establish exactly the applicable standard of care. Courts have traditionally relied on medical experts knowledgeable about the point in question to give opinions as to what is the standard of care and if it has been met in an individual case. This type of standard is somewhat different from the standards promulgated by various standard-setting bodies regarding, for example, the color of gas hoses connected to an anesthesia machine or the inability to open two vaporizers on that machine simultaneously. However, ignoring the equipment standards and tolerating an unsafe situation is a violation of the standard of care. Promulgated standards, such as the various safety codes and anesthesia machine specifications, rapidly become the standard of care because patients (through their attorneys, in the case of an untoward event) expect the published standards to be observed by the prudent practitioner.

Understanding the concept of the standard of care is the key to integrating the numerous standards, guidelines, statements, practice parameters, and suggested protocols applicable to American anesthesiology practice in the unfortunately necessary constant undercurrent of concern about potential legal liability. Ultimately, the standard of care is what a jury says it is. However, it is possible to anticipate, at least in part, what knowledge and actions will be expected. There are two main sources of information as to exactly what is the expected standard of care. Traditionally, the beliefs offered by expert witnesses in medical liability lawsuits regarding what was being done in real life (de facto standards of care) were the main input juries had in deciding what was reasonable to expect from the defendant. The resulting problem is well known: except in the most egregious cases, it is usually possible for the lawyers to find experts who will support each of the two opposing sides, making the process more subjective than objective. (Because of this, there is the ASA *Guidelines for Expert Witness Qualifications and Testimony*.) Of course, there can be legitimate differences of opinion among thoughtful, insightful experts, but even in these cases the jury still must decide who is more believable, looks better, or sounds better. The second, much more objective, source for defining certain component parts of the standard of care has developed since the mid 1980s in American anesthesiology. It is the published standards of care, guidelines, practice parameters, and protocols now becoming more common. These serve as hard evidence of what can be reasonably expected of practitioners and can make it easier for a jury evaluating whether a malpractice defendant failed to meet the applicable standard of care. Several types of documents exist and have differing implications.

Leading the Way

5 Anesthesiology may be the medical specialty most involved with published standards of care. It has been suggested that the nature of anesthesia practice (having certain central critical functions relatively clearly defined and common to all situations and having an emphasis on technology) makes it the most amenable of all the fields of medicine to the use of published standards. The original intraoperative monitoring standards[8] are a classic example. The ASA first adopted its own set of basic intraoperative monitoring standards in 1986 and has modified them several times (Table 2-1).

TABLE 2-1 American Society of Anesthesiologists Standards for Basic Anesthetic

Monitoring

These Standards apply to all anesthesia care, although, in emergency circumstances, appropriate life-support measures take precedence. These standards may be exceeded at any time based on the judgment of the responsible anesthesiologist. They are intended to encourage quality patient care, but observing them cannot guarantee any specific patient outcome. They are subject to revision from time to time, as warranted by the evolution of technology and practice. They apply to all general anesthetics, regional anesthetics, and monitored anesthesia care. This set of standards addresses only the issue of basic anesthetic monitoring, which is one component of anesthesia care. In certain rare or unusual circumstances, (1) some of these methods of monitoring may be clinically impractical, and (2) appropriate use of the described monitoring methods may fail to detect untoward clinical developments. Brief interruptions of continual[a] monitoring may be unavoidable. Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record. These standards are not intended for application to the care of the obstetrical patient in labor or in the conduct of pain management.

▪STANDARD I

Qualified anesthesia personnel shall be present in the room throughout the conduct of all general anesthetics, regional anesthetics, and monitored anesthesia care.

Objective

Because of the rapid changes in patient status during anesthesia, qualified anesthesia personnel shall be continuously present to monitor the patient and provide anesthesia care. In the event there is a direct known hazard, for example, radiation, to the anesthesia personnel that might require intermittent remote observation of the patient, some provision for monitoring the patient must be made. In the event that an emergency requires the temporary absence of the person primarily responsible for the anesthetic, the best judgment of the anesthesiologist will be exercised in comparing the emergency with the anesthetized patient's condition and in the selection of the person left responsible for the anesthetic during the temporary absence.

▪STANDARD II

During all anesthetics, the patient's oxygenation, ventilation, circulation, and temperature shall be continually evaluated.

▪OXYGENATION

Objective

To ensure adequate oxygen concentration in the inspired gas and the blood during all

anesthetics.

Methods

1. Inspired gas: During every administration of general anesthesia using an anesthesia machine, the concentration of oxygen in the patient breathing system shall be measured by an oxygen analyzer with a low oxygen concentration limit alarm in use.*
2. Blood oxygenation: During all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed.* Adequate illumination and exposure of the patient are necessary to assess color.*

▪VENTILATION

Objective

To ensure adequate ventilation of the patient during all anesthetics.

Methods

1. Every patient receiving general anesthesia shall have the adequacy of ventilation continually evaluated. Qualitative clinical signs such as chest excursion, observation of the reservoir breathing bag, and auscultation of breath sounds are useful. Continual monitoring for the presence of expired carbon dioxide shall be performed unless invalidated by the nature of the patient, procedure, or equipment. Quantitative monitoring of the volume of expired gas is strongly encouraged.*
2. When an endotracheal tube or laryngeal mask is inserted, its correct positioning must be verified by clinical assessment and by identification of carbon dioxide in the expired gas. Continual end-tidal carbon dioxide analysis, in use from the time of endotracheal tube/laryngeal mask placement, until extubation/removal or initiating transfer to a postoperative care location, shall be performed using a quantitative method such as capnography, capnometry, or mass spectroscopy.*
3. When ventilation is controlled by a mechanical ventilator, there shall be in continuous use a device that is capable of detecting disconnection of components of the breathing system. The device must give an audible signal when its alarm threshold is exceeded.
4. During regional anesthesia and monitored anesthesia care, the adequacy of ventilation shall be evaluated, at least, by continual observation of qualitative clinical signs.

▪CIRCULATION

Objective

To ensure the adequacy of the patient's circulatory function during all anesthetics.

Methods

1. Every patient receiving anesthesia shall have the electrocardiogram continuously displayed from the beginning of anesthesia until preparing to leave the anesthetizing location.*
2. Every patient receiving anesthesia shall have arterial blood pressure and heart rate determined and evaluated at least every 5 minutes.*
3. Every patient receiving general anesthesia shall have, in addition to the above, circulatory function continually evaluated by at least one of the following: palpation of a pulse, auscultation of heart sounds, monitoring of a tracing of intra-arterial pressure, ultrasound peripheral pulse monitoring, or pulse plethysmography or oximetry.

▪BODY TEMPERATURE

Objective

To aid in the maintenance of appropriate body temperature during all anesthetics.

Methods

Every patient receiving anesthesia shall have temperature monitored when clinically significant changes in body temperature are intended, anticipated, or suspected.

[a]Note that *continual* is defined as "repeated regularly and frequently in steady rapid succession," whereas *continuous* means "prolonged without any interruption at any time."

Approved by House of Delegates on October 21, 1986, and last affirmed on October 15, 2003.

Reprinted with permission of the American Society of Anesthesiologists, Park Ridge, Illinois 60068-5586.

This document includes clear specifications for the presence of personnel during an anesthetic episode and for continual evaluation of oxygenation, ventilation, circulation, and temperature. The rationale for these monitoring standards is simple; it was felt that functionally mandating certain behaviors oriented toward providing the earliest, maximum possible warning of threatening developments during an anesthetic should help minimize intraoperative catastrophic patient injury. These ASA monitoring standards very quickly became part of the accepted standard of care in anesthesia practice. This means they are important to practice management because they have profound medicolegal implications: a catastrophic accident occurring while the standards are being actively ignored is very difficult to defend in the consequent malpractice suit, whereas an accident

that occurs during well-documented full compliance with the standards will automatically have a strong defense because the standard of care was being met. Several states in the United States have made compliance with these ASA standards mandatory under state regulations or even statutes. Various malpractice insurance companies offer discounts on malpractice insurance policy premiums for compliance with these standards, something quite natural to insurers because they are familiar with the idea of managing known risks to help minimize financial loss to the company. The ASA monitoring standards have been widely emulated in other medical specialties and even in fields outside of medicine. Although there are definite parallels in these other efforts (such as in obstetrics and gynecology), no other group has pursued the same degree of definition.

Many of the same management questions that led to the intraoperative monitoring standards have close parallels in the immediate preoperative and postoperative periods in the PACU. With many of the same elements of thinking, the ASA adopted Basic Standards for Preanesthesia Care (Table 2-2). This was supplemented significantly by another type of document, the ASA Practice Advisory for Preanesthesia Evaluation (http://www.asahq.org, "Publications and Services, Practice Parameters"), a 40-page meta-analysis of clinical aspects of preoperative evaluation. Also, the ASA adopted Standards for Postanesthesia Care (Table 2-3) in which there was consideration of and collaboration with the very detailed standards of practice for PACU care published by the American Society of Post Anesthesia Nurses (another good example of the sources of standards of care). This also was later supplemented by an extensive Practice Guideline.[9]

TABLE 2-2 American Society of Anesthesiologists Basic Standards for Preanesthesia Care

These Standards apply to all patients who receive anesthesia or monitored anesthesia care. Under unusual circumstances, for example, extreme emergencies, these standards may be modified. When this is the case, the circumstances shall be documented in the patient's record.

Standard I: An anesthesiologist shall be responsible for determining the medical status of the patient, developing a plan of anesthesia care, and acquainting the patient or the responsible adult with the proposed plan.

The development of an appropriate plan of anesthesia care is based upon:

1. Reviewing the medical record.
2. Interviewing and examining the patient to:
    a. Discuss the medical history, previous anesthetic experiences, and drug therapy.
    b. Assess those aspects of the physical condition that might affect decisions regarding perioperative risk and management.
3. Obtaining and/or reviewing tests and consultations necessary to the conduct of anesthesia.
4. Determining the appropriate prescription of preoperative medications as necessary to the conduct of anesthesia.

The responsible anesthesiologist shall verify that the above has been properly performed and documented in the patient's record.

Approved by House of Delegates on October 14, 1987, and affirmed on October 18, 1998.

Reprinted with permission of the American Society of Anesthesiologists, Park Ridge, Illinois 60068-5586.

TABLE 2-3 American Society of Anesthesiologists Standards for Postanesthesia Care

These Standards apply to postanesthesia care in all locations. These Standards may be exceeded based on the judgment of the responsible anesthesiologist. They are intended to encourage quality patient care, but cannot guarantee any specific patient outcome. They are subject to revision from time to time as warranted by the evolution of technology and practice. Under extenuating circumstances, the responsible anesthesiologist may waive the requirements marked with an asterisk (*); it is recommended that when this is done, it should be so stated (including the reasons) in a note in the patient's medical record.

▪STANDARD I

All patients who have received general anesthesia, regional anesthesia, or monitored anesthesia care shall receive appropriate postanesthesia management.[a]

1. A Postanesthesia Care Unit (PACU) or an area that provides equivalent postanesthesia care shall be available to receive patients after anesthesia care. All patients who receive anesthesia care shall be admitted to the PACU or its equivalent except by specific order of the anesthesiologist responsible for the patient's care.
2. The medical aspects of care in the PACU shall be governed by policies and procedures that have been reviewed and approved by the Department of Anesthesiology.
3. The design, equipment, and staffing of the PACU shall meet requirements of the facility's accrediting and licensing bodies.

▪STANDARD II

A patient transported to the PACU shall be accompanied by a member of the anesthesia care team who is knowledgeable about the patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.

▪STANDARD III

Upon arrival in the PACU, the patient shall be reevaluated and a verbal report provided to the responsible PACU nurse by the member of the anesthesia care team who accompanies the patient.

1. The patient's status on arrival in the PACU shall be documented.
2. Information concerning the preoperative condition and the surgical/anesthetic course shall be transmitted to the PACU nurse.
3. The member of the Anesthesia Care Team shall remain in the PACU until the PACU nurse accepts responsibility for the nursing care of the patient.

▪STANDARD IV

The patient's condition shall be evaluated continually in the PACU.

1. The patient shall be observed and monitored by methods appropriate to the patient's medical condition. Particular attention should be given to monitoring oxygenation, ventilation, circulation, and temperature. During recovery from all anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed in the initial phase of recovery.* This is not intended for application during the recovery of the obstetrical patient in whom regional anesthesia was used for labor and vaginal delivery.
2. An accurate written report of the PACU period shall be maintained. Use of an appropriate PACU scoring system is encouraged for each patient on admission, at appropriate intervals prior to discharge, and at the time of discharge.
3. General medical supervision and coordination of patient care in the PACU should be the responsibility of an anesthesiologist.
4. There shall be a policy to assure the availability in the facility of a physician capable of managing complications and providing cardiopulmonary resuscitation for patients in the PACU.

▪STANDARD V

A physician is responsible for the discharge of the patient from the PACU.

1. When discharge criteria are used, they must be approved by the Department of Anesthesiology and the medical staff. They may vary depending upon whether the patient is discharged to a hospital room, to the Intensive Care Unit, to a short stay unit, or home.
2. In the absence of the physician responsible for the discharge, the PACU nurse shall determine that the patient meets the discharge criteria. The name of the physician accepting responsibility for discharge shall be noted on the record.

[a]Refer to *Standards of Post Anesthesia Nursing Practice 1992*, published by American Society of Post Anesthesia Nurses (ASPAN), for issues of nursing care.
Approved by House of Delegates on October 12, 1988, and last amended on October 19, 1994.
Reprinted with permission of the American Society of Anesthesiologists, Park Ridge, Illinois 60068-5586.

A slightly different situation exists with regard to the standards for conduct of anesthesia in obstetrics. These standards were originally passed by the ASA in 1988, in the same manner as the other ASA standards, but the ASA membership eventually questioned whether they reflected a realistic and desirable standard of care. Accordingly, the obstetric anesthesia standards were downgraded in 1990 to guidelines (Table 2-4), specifically to remove the mandatory nature of the document. Because there was no agreement as to what should be prescribed as the standard of care, the medicolegal imperative of published standards has been temporarily set aside. From a management perspective, this makes the guidelines no less valuable, because the intent of optimizing care through the avoidance of complications is no less operative. However, in the event of the need to defend against a malpractice claim in this area, it is clear from this sequence of events that the exact standard of care is debatable and not yet finally established. A different ASA document, *Practice Guidelines for Obstetrical Anesthesia*, with more detail and specificity as well as an emphasis on the meta-analytic approach has been generated.[10]

TABLE 2-4 American Society of Anesthesiologists Guidelines for Regional Anesthesia In Obstetrics

These guidelines apply to the use of regional anesthesia or analgesia in which local anesthetics are administered to the parturient during labor and delivery. They are intended to encourage quality patient care but cannot guarantee any specific patient outcome. Because the availability of anesthesia resources may vary, members are responsible for interpreting and establishing the guidelines for their own institutions and practices. These guidelines are subject to revision from time to time as warranted by the evolution of technology and practice.
▪GUIDELINE I
Regional anesthesia should be initiated and maintained only in locations in which appropriate resuscitation equipment and drugs are immediately available to manage procedurally related problems.
Resuscitation equipment should include, but is not limited to: sources of oxygen and suction, equipment to maintain an airway and perform endotracheal intubation, a means to provide positive-pressure ventilation, and drugs and equipment for cardiopulmonary resuscitation.
▪GUIDELINE II
Regional anesthesia should be initiated by a physician with appropriate privileges and maintained by or under the medical direction[a] of such an individual.
Physicians should be approved through the institutional credentialing process to initiate and direct the maintenance of obstetric anesthesia and to manage procedurally related complications.
▪GUIDELINE III
Regional anesthesia should not be administered until: (1) the patient has been examined by a qualified individual[b] and (2) a physician with obstetrical privileges to perform operative vaginal or cesarean delivery, who has knowledge of the maternal and fetal status and the progress of labor and who approves the initiation of labor anesthesia, is readily available to supervise the labor and manage any obstetric complications that may arise.
Under circumstances defined by department protocol, qualified personnel may perform the initial pelvic examination. The physician responsible for the patient's obstetrical care should be informed of her status so that a decision can be made regarding present risk and further management.[b]

▪GUIDELINE IV

An intravenous infusion should be established before the initiation of regional anesthesia and maintained throughout the duration of the regional anesthetic.

▪GUIDELINE V

Regional anesthesia for labor and/or vaginal delivery requires that the parturient's vital signs and the fetal heart rate be monitored and documented by a qualified individual. Additional monitoring appropriate to the clinical condition of the parturient and the fetus should be employed when indicated. When extensive regional blockade is administered for complicated vaginal delivery, the standards for basic anesthetic monitoring[c] should be applied.

▪GUIDELINE VI

Regional anesthesia for cesarean delivery requires that the standards for basic anesthetic monitoring[c] be applied and that a physician with privileges in obstetrics be immediately available.

▪GUIDELINE VII

Qualified personnel, other than the anesthesiologist attending the mother, should be immediately available to assume responsibility for resuscitation of the newborn.[b]

The primary responsibility of the anesthesiologist is to provide care to the mother. If the anesthesiologist is also requested to provide brief assistance in the care of the newborn, the benefit to the child must be compared to the risk to the mother.

▪GUIDELINE VIII

A physician with appropriate privileges should remain readily available during the regional anesthetic to manage anesthetic complications until the patient's postanesthesia condition is satisfactory and stable.

▪GUIDELINE IX

All patients recovering from regional anesthesia should receive appropriate postanesthesia care. Following cesarean delivery and/or extensive regional blockade, the standards for postanesthesia care[d] should be applied.

1. A postanesthesia care unit (PACU) should be available to receive patients. The design, equipment, and staffing should meet requirements of the facility's

accrediting and licensing bodies.
2. When a site other than the PACU is used, equivalent postanesthesia care should be provided.

▪GUIDELINE X

There should be a policy to assure the availability in the facility of a physician to manage complications and to provide cardiopulmonary resuscitation for patients receiving postanesthesia care.

[d] Standards for Postanesthesia Care (approved by ASA House of Delegates October 12, 1988, and last amended October 19, 1994).

Approved by House of Delegates on October 12, 1988, and last amended on October 18, 2000.

Reprinted with permission of the American Society of Anesthesiologists, Park Ridge, Illinois 60068-5586.

Practice Guidelines

The newest type of related ASA document is the Practice Guideline (formerly "Practice Parameter"). This has some of the same elements as a standard of practice but is more intended to guide judgment, largely through algorithms with some element of guidelines, in addition to directing the details of specific procedures as would a formal standard. A good example of a set

of practice parameters came some years ago from the cardiologists and addressed the indications for cardiac catheterization. Beyond the details of the minimum standards for carrying out the procedure, these practice parameters set forth algorithms and guidelines for helping to determine under what circumstances and with what timing to perform it. Understandably, purchasers of health care (government, insurance companies, and MCOs) with a strong desire to limit the costs of medical care have great interest in practice parameters as potential vehicles for helping to eliminate "unnecessary" procedures and limit even the necessary ones.

The ASA has been very active in creating and publishing practice guidelines. The first published parameter (since revised) concerned the use of pulmonary artery (PA) catheters.[11] It considered the clinical effectiveness of PA catheters, public policy issues (costs and concerns of patients and

providers), and recommendations (indications and practice settings). The next month, the ASA Difficult Airway Algorithm was published (also since revised).[12] This thoughtful document synthesized a strategy summarized in a decision tree diagram for dealing acutely with airway problems. It has great clinical value, and it is reasonable to anticipate that it will be used to help many patients. However, all these documents are readily noticed by plaintiffs' lawyers, the difficult airway parameter from the ASA being an excellent example. An important and so-far undecided question is whether guidelines and practice parameters from recognized entities such as the ASA *define* the standard of care. There is no simple answer. This will be decided over time by practitioners' actions, debates in the literature, mandates from malpractice insurers, and, of course, court decisions. Some guidelines, such as the FDA preanesthetic apparatus checkout, are accepted as the standard of care. There will be debate among experts, but the practitioner must make the decision as to how to apply practice parameters such as those from the ASA. Practitioners have incorrectly assumed that they *must* do everything specified. This is clearly not true, yet there is a valid concern that these will someday be held up as defining the standard of care. Accordingly, prudent attention within the bounds of reason to the principles outlined in guidelines and parameters will put the practitioner in at least a reasonably defensible position, whereas radical deviation from them should be based on obvious exigencies of the situation at that moment or clear, defensible alternative beliefs (with documentation).

The ASA has many other task forces charged with the development of practice parameters. Several aspects of pain management, transesophageal echocardiography, policies for sedation by nonanesthesia personnel, preoperative fasting, avoidance of peripheral neuropathies, and others have been published and will likely have at least the same impact as those noted above.

On the other hand, practice protocols, such as those for the fast-track management of coronary artery bypass graft patients, that are handed down by MCOs or health insurance companies are a different matter. Even though the desired implication is that practitioners must observe (or at least strongly consider) them, they do not have the same implications in defining the standard of care as the other documents. Practitioners must avoid getting trapped. It may well not be a valid legal defense to justify action or the lack of action because of a company protocol. Difficult as it may be to reconcile with the payer, the practitioner still is subject to the classic definitions of standard of care.

The other type of standards associated with medical care are those of the JCAHO, the best-known medical care quality regulatory agency. As noted earlier, these standards were for many years concerned largely with structure (e.g., gas tanks chained down) and process (e.g., documentation complete), but in recent years they have been expanded to include reviews of the outcome of care. JCAHO standards also focus on credentialing and privileges, verification that anesthesia services are of uniform quality throughout an institution, the qualifications of the director of the service, continuing education, and basic guidelines for anesthesia care (need for preoperative and postoperative evaluations, documentation, and so forth). Full JCAHO accreditation of a health care facility is usually for 3 years. Even the best hospitals and facilities receive some citations of problems or deficiencies that are expected to be corrected, and an interim report of efforts to do so is required. If there are enough problems, accreditation can be conditional for 1 year, with a complete reinspection at that time. Preparing for JCAHO inspections starts with verification that essential group/department structure is in place; excellent examples exist.[3] The process ultimately involves a great deal of work, but because the standards usually do promote high-quality care, the majority of this work is highly constructive and of benefit to the institution and its medical staff.

Review Implications

Another type of regulatory agency is the peer review organization. Professional standards review organizations (PSROs) were established in 1972 as utilization review/QA overseers of the care of federally subsidized patients (Medicare and Medicaid). Despite their efforts to deal with quality of care, these groups were seen by all involved as primarily interested in cost containment. Various negative factors led to the PSROs' being replaced in 1984 with the peer review organization (PRO).[13] There is a PRO in each state, many being associated with a state medical association. The objectives of a PRO include 14 goals related to hospital admissions (e.g., to shift care to an

outpatient basis as much as possible) and 5 related to quality

P.35

of care (e.g., to reduce avoidable deaths and avoidable complications). The PROs comprise full-time support staff and physician reviewers paid as consultants or directors. Ideally, PRO monitoring will discover suboptimal care, and this will lead to specific recommendations for improvement in quality. There is a perception that quality of care efforts are hampered by the lack of realistic objectives and also that these PRO groups, like others before them, will largely or entirely function to limit the cost of health care services.

The practice management implications have become clear. Aside from the as-yet unrealized potential for quality improvement efforts and the occasional denial of payment for a procedure, the most likely interaction between the local PRO and anesthesiology personnel will involve a request for perioperative admission of a patient whose care is mandated to be outpatient surgery (this could also occur dealing with a managed care organization). If the anesthesiologist feels, for example, that either (1) preoperative admission for treatment to optimize cardiac, pulmonary, diabetic, or other medical status or (2) postoperative admission for monitoring of labile situations such as uncontrolled hypertension will reduce clear anesthetic risks for the patient, an application to the PRO for approval

P.36

P.37

of admission must be made and vigorously supported. All too often, however, such issues surface a day or so before the scheduled procedure in a preanesthesia screening clinic or even in a preoperative holding area outside the OR on the day of surgery. This will continue to occur until anesthesia providers educate their constituent surgeon community as to what types of associated medical conditions may disqualify a proposed patient from the outpatient (ambulatory) surgical schedule. If adequate notice is given by the surgeon, such as at the time an elective case is booked for the OR, the patient can be seen far enough in advance by an anesthesiologist to allow appropriate planning.

In the circumstance in which the first knowledge of a questionable patient comes 1 or 2 days before surgery, the anesthesiologist can try to have the procedure postponed, if possible, or can undertake the time-consuming task of multiple telephone calls to get the surgeon's agreement, get PRO approval, and make the necessary arrangements. Because neither alternative is particularly attractive, especially from administrative and reimbursement perspectives, there may be a strong temptation to "let it slide" and try to deal with the patient as an outpatient even though this may be questionable. In almost all cases, it is likely that there would be no adverse result (the "get away with it" phenomenon). However, the patient might well be exposed to an avoidable risk. Both because of the workings of probability and because of the inevitable tendency to let sicker and sicker patients slip by as lax practitioners repeatedly "get away with it" and are lulled into a false sense of security, sooner or later there will be an unfortunate outcome or some preventable major morbidity or even mortality.

The situation is worsened when the first contact with a questionable ambulatory patient is preoperatively (possibly even already in the OR) on the day of surgery. There may be intense pressure from the patient, the surgeon, or the OR administrator and staff to proceed with a case for which the anesthesia practitioner believes the patient is poorly prepared. The arguments made regarding patient inconvenience and anxiety are valid. However, they should not outweigh the best medical interests of the patient. Although this is a point in favor of screening all outpatients before the day of surgery, the anesthesiologist facing this situation on the day of operation should state clearly to all concerned the reasons for postponing the surgery, stressing the issue of avoidable risk and standards of care, and then help with alternative arrangements (including, if necessary, dealing with the PRO or MCO).

Potential liability exposure is the other side of the standard of care issue. Particularly regarding questions of postoperative admission of ambulatory patients who have been unstable in some worrisome manner, it is an extremely poor defense against a malpractice claim to state that the patient was discharged home, only later to suffer a complication because the PRO/MCO deemed that operative procedure outpatient and not inpatient surgery. As bureaucratically annoying as it

may be, it is a prudent management strategy to admit the patient if there is any legitimate question, thus minimizing the chance for complications, and later haggle with the PRO or directly with the involved third-party payer (MCO).

Policy and Procedure

Management of an anesthesiology practice involves business, organizational, and clinical issues. One important organizational point that is often overlooked is the need for a complete policy and procedure manual. Such a compilation of documents is necessary for all practices, from the largest departments covering multiple hospitals to a single-room outpatient facility with one anesthesia provider. Contemplation of this compilation of documents may evoke a collective groan from anesthesiology personnel, and maintaining this manual may be misperceived as a bureaucratic chore. Quite the contrary, such a manual can be extraordinarily valuable, as, for example, when it provides crucial information during an emergency. Some suggestions for the content of this compendium exist,[14] but, at minimum, organizational and procedural elements must be included.

The organizational elements that should be present include a chart of organization and responsibilities that is not just a call schedule but a clear explanation of who is responsible for what functions of the department and when, with attendant details such as expectations for the practitioner's presence within the institution at designated hours, telephone availability, pager availability, the maximum permissible distance from the institution, and so forth. Experience suggests it is especially important for there to be an absolutely clear specification of the availability of qualified anesthesiology personnel for emergency cesarean section, particularly in practice arrangements in which there are several people on call covering multiple locations. Sadly, these issues often are only considered after a disaster has occurred that involved miscommunication and the mistaken belief by one or more people that someone else would take care of an acute problem.

The organizational component of the policy and procedure manual should also include a clear explanation of the orientation and checkout procedure for new personnel, continuing medical education requirements and opportunities, the mechanisms for evaluating personnel and for communicating this evaluation to them, disaster plans (or reference to a separate disaster manual or protocol), QA activities of the department, and the format for statistical record keeping (number of procedures, types of anesthetics given, types of patients anesthetized, number and types of invasive monitoring procedures, number and type of responses to emergency calls, complications, or whatever the group/department decides).

The procedural component of the policy and procedure manual should give both handy practice tips and specific outlines of proposed courses of action for particular circumstances; it also should store little-used but valuable information. Reference should be made to the statements, guidelines, practice parameters, and standards appearing on the ASA website. Also included should be references to or specific protocols for the areas mentioned in the JCAHO standards: preanesthetic evaluation, immediate preinduction reevaluation, safety of the patient during the anesthetic period, release of the patient from any PACU, recording of all pertinent events during anesthesia, recording of postanesthesia visits, guidelines defining the role of anesthesia services in hospital infection control, and guidelines for safe use of general anesthetic agents. Other appropriate topics include the following:

1. Recommendations for preanesthesia apparatus checkout, such as from the U.S. Food and Drug Administration (FDA)[15] (see Chapter 21)
2. Guidelines for minimal monitoring and duration of stay of an infant, child, or adult in the PACU
3. Procedures for transporting patients to/from the OR, PACU, or ICU
4. Policy on ambulatory surgical patients—for example, screening, use of regional anesthesia, discharge home criteria

5. Policy on evaluation and processing of same-day admissions
6. Policy on recovery room admission and discharge
7. Policy on ICU admission and discharge
8. Policy on physicians responsible for writing orders in recovery room and ICU
9. Policy on informed consent and its documentation
10. Policy on the use of patients in clinical research

11. Guidelines for the support of cadaver organ donors and its termination
12. Guidelines on environmental safety, including pollution with trace gases and electrical equipment inspection, maintenance, and hazard prevention
13. Procedure for change of personnel during an anesthetic
14. Procedure for the introduction of new equipment, drugs, or clinical practices
15. Procedure for epidural and spinal narcotic administration and subsequent patient monitoring (e.g., type, minimum time, nursing units)
16. Procedure for initial treatment of cardiac or respiratory arrest
17. Policy for handling patient's refusal of blood or blood products, including the mechanism to obtain a court order to transfuse
18. Procedure for the management of malignant hyperthermia
19. Procedure for the induction and maintenance of barbiturate coma
20. Procedure for the evaluation of suspected pseudocholinesterase deficiency
21. Protocol for responding to an adverse anesthetic event
22. Policy on resuscitation of DNR patients in the OR.

Individual departments will add to the suggestions listed here as dictated by their specific needs. A thorough, carefully conceived policy and procedure manual is a valuable tool. The manual should be reviewed and updated as needed but at least annually, with a particularly thorough review preceding each JCAHO inspection. Each member of a group or department should review the manual at least annually and sign off in a log indicating familiarity with current policies and procedures.

Meetings and Case Discussion

There must be regularly scheduled departmental or group meetings. Although didactic lectures and continuing education meetings are valuable and necessary, there also must be regular opportunities for open clinical discussion about interesting cases and problem cases. Also, the JCAHO requires that there be at least monthly meetings at which risk management and QA activities are documented and reported. Whether these meetings are called case conferences, morbidity and mortality conferences, or deaths and complications, the entire department or group should gather for an interchange of ideas. More recently these gatherings have been called QA meetings. An open review of departmental statistics should be done, including all complications, even those that may appear trivial. Unusual patterns of small events may point toward a larger or systematic problem, especially if they are more frequently associated with one individual practitioner.

A problem case presented at the departmental meeting might be an overt accident, a near accident (critical incident), or an untoward outcome of unknown origin. Honest but constructive discussion, even of an anesthesiologist's technical deficiencies or lack of knowledge, should take

place in the spirit of constructive peer review. The classic question "What would you do differently next time?" is a good way to start the discussion. There may be situations in which inviting the surgeon or the internist involved in a specific case would be advantageous. The opportunity for each type of provider to hear the perspective of another discipline not only is inherently educational, but also can promote communication and cooperation in future potential problem cases.

Records of these meetings must be kept for accreditation purposes, but the enshrining of overly detailed minutes (potentially subject to discovery by a plaintiff's attorney at a later date) may inhibit true educational and corrective interchanges about untoward events. In the circumstance of discussion of a case that seems likely to provoke litigation, it is appropriate to be certain that the meeting is classified as official "peer review" and possibly even invite the hospital attorney or legal counsel from the relevant malpractice insurance carrier (to guarantee the privacy of the discussion and minutes).

Support Staff

There is a fundamental need for support staff in every anesthesia practice. Even independent practitioners rely in some measure on facilities, equipment, and services provided by the organization maintaining the anesthetizing location. In large, well-organized departments, reliance on support staff is often very great. The need for adequate staff and the inadvisability of scrimping on critical support personnel to cut costs is obvious. What is often overlooked, however, is a process analogous to that of credentialing and privileges for anesthesiologists, although at a slightly different level. The people expected to provide clinical anesthesia practice support must be qualified and must at all times understand what they are expected to do and how to do it. It is singularly unfortunate to realize only after an anesthesia catastrophe has occurred that basic details of simple work assignments, such as the changing of carbon dioxide absorbent, were routinely ignored. This indicates the need for supervision and monitoring of the support staff by the involved practitioners. Further, such support personnel are favorite targets of cost-cutting administrators who do not understand the function of anesthesia technicians or their equivalent. In the modern era, many administrators seem driven almost exclusively by the "bottom line" and cannot appreciate the connection between valuable workers such as these and the "revenue stream." Even though it is obvious to all who work in an OR that the anesthesia support personnel make it possible for there to be patients flowing through the OR, it is their responsibility to convince the facility's fiscal administrator that elimination of such positions is genuinely false economy because of the attendant loss in efficiency, particularly in turning over the room between surgeries. Further, it is also false economy to reduce the number of personnel below that are genuinely needed to retrieve, clean, sort, disassemble, sterilize, reassemble, store, and distribute the tools of daily anesthesia practice. Inadequate attention to all these steps truly creates the environment of "an accident waiting to happen." When there is threatened loss of budget funding from a health care facility for the salaries of needed anesthesia support personnel, the practitioners involved must not simply stand by and see the necessary functions thrown into a "hit-or-miss" status by a few remaining heavily overburdened workers. Vigorous defense (or initiation of and agitation for new positions if the staff is inadequate) by the anesthesia practitioners should be undertaken, always with the realization that it may be necessary in some circumstances for them to supplement the budget from the facility with some of their practice income to guarantee an adequate complement of competent workers.

Business and organizational issues in the management of an anesthesia practice are also critically dependent on the existence of a sufficient number of appropriately trained support staff. One frequently overlooked issue that contributes to the negative impression generated by some anesthesiology practices centers on being certain there is someone available to answer the telephone at all times during the hours surgeons, other physicians, and OR scheduling desks are likely to telephone. This seemingly trivial component of practice management is very important to the success of an anesthesiology practice as a business whose principal customers are the surgeons.

Certainly there is a commercial server–client relationship both with the patient and the purchaser of health care; however, the uniquely symbiotic nature of the relationship between surgeons and anesthesiologists is such that availability even for simple "just wanted to let you know" telephone calls is genuinely important. The person who answers the telephone is the representative of the practice to the world and must take that responsibility seriously. From a management standpoint, significant impact on the success of the practice as a business often hinges on such details. Further, anesthesiologists should always have permanent personal electronic pagers and reliable mobile telephones (or the radio equivalent) to facilitate communications from other members of the department or group and from support personnel. This may sound intrusive, but the unusual position of anesthesiologists in the spectrum of physicians mandates this feature of managing an anesthesiology practice. Anesthesiology personnel should have no hesitation about spending their own practice income to do so. The symbolism alone is obvious.

Anesthesia Equipment and Equipment Maintenance

Problems with anesthesia equipment have been discussed for some time.[16,17] However, compared to human error, overt equipment failure very rarely causes intraoperative critical incidents[18] or deaths resulting from anesthesia care.[19] Aside from the obvious human errors involving misuse of or unfamiliarity with the equipment, when the rare equipment failure does occur, it appears often that correct maintenance and servicing of the apparatus has not been done. These issues become the focus of anesthesia practice management efforts, which could have significant liability implications, because there can often be confusion or even disputes about precisely who is responsible for arranging maintenance of the anesthesia equipment—the facility or the practitioners who use it and collect practice income from that activity. In many cases, the facility assumes the responsibility. In situations in which that is not true, however, it is necessary for the practitioners to recognize that responsibility and seek help securing a service arrangement, because this is likely an unfamiliar obligation for clinicians.

Programs for anesthesia equipment maintenance and service have been outlined.[3,20] A distinction is made between failure as a result of progressive deterioration of equipment, which should be preventable because it is observable and should provoke appropriate remedial action, and catastrophic failure, which, realistically, often cannot be predicted. Preventive maintenance for mechanical parts is critical and involves periodic performance checks every 4 to 6 months. Also, an annual safety inspection of each anesthetizing location and the equipment itself is necessary. For equipment service, an excellent mechanism is a relatively elaborate cross-reference system (possibly kept handwritten in a notebook but ideal for maintenance on an electronic spreadsheet program) to identify both the device needing service and also the mechanism to secure the needed maintenance or repair.

Equipment handling principles are straightforward. Before purchase, it must be verified that a proposed piece of equipment meets all applicable standards, which will usually be true when dealing with recognized major manufacturers. (The recent renewed efforts of some facility administrators to save money by attempting to find "refurbished" anesthesia machines and monitoring systems should provoke thorough review by the involved practitioners of any proposed purchases of used equipment. Unlike refurbished computers, used anesthesia equipment has many moving mechanical parts that are subject to wear and eventual mechanical failure.) On arrival, electrical equipment must be checked for absence of hazard (especially leakage current) and compliance with applicable electrical standards. Complex equipment such as anesthesia machines and ventilators should be assembled and checked out by a representative from the manufacturer or manufacturer's agent. There are potential adverse medicolegal implications when relatively untrained personnel certify a particular piece of new equipment as functioning within specification, even if they do it perfectly. It is also very important to involve the manufacturer's representative in pre- and in-service training for those who will use the new equipment. On arrival, a sheet or section in the departmental master equipment log must be created with the make, model, serial number, and in-house identification for each piece of capital equipment. This not only allows immediate identification of any equipment involved in a future recall or product alert, but also serves as the permanent repository of the record of every problem, problem resolution,

maintenance, and servicing occurring until that particular equipment is scrapped. This log must be kept up to date at all times. There have been rare but frightening examples of potentially lethal problems with anesthesia machines leading to product alert notices requiring immediate identification of certain equipment and its service status.

Service

Beyond the administrative liability implications, precisely what type of support personnel should maintain and service major anesthesia equipment has been widely debated. There are significant management implications. Equipment setup and checkout have been mentioned. After that, some groups or departments rely on factory service representatives from the equipment manufacturers for all attention to equipment, others engage independent service contractors, and still other (often larger) departments have access to personnel (either engineers and/or technicians) permanently within their facility. Needs and resources differ. The single underlying principle is clear: the person(s) doing preventive maintenance and service on anesthesia equipment must be qualified. Anesthesia practitioners may wonder how they can assess these qualifications. The best way is to unhesitatingly ask pertinent questions about the education, training, and experience of those involved, including asking for references and speaking to supervisors and managers responsible for those doing the work. Whether an engineering technician who spent a week at a course at a factory can perform the most complex repairs depends on a variety of factors, which can be investigated by the practitioners ultimately using the equipment in the care of patients. Failure to be involved in this oversight function exposes the practice to increased liability in the event of an untoward outcome associated with improperly maintained or serviced equipment.

Determining when anesthesia equipment becomes obsolete and should be replaced is another question that is difficult to answer. Replacement of obsolete anesthesia machines and monitoring equipment is a key element of a risk modification program. Ten years is often cited as an estimated useful life for an anesthesia machine, but although an ASA statement repeats that idea, it also notes that the ASA promulgated a Policy for Assessing Obsolescence in 1989 that does not subscribe to any specific time interval. Anesthesia machines considerably more than 15 years old likely do not meet certain of the safety standards now in force for new machines (such as vaporizer lockout, fresh gas ratio protection, and automatic enabling of the oxygen analyzer) and, unless extensively retrofitted, do not incorporate the new technology that advanced very rapidly during the 1980s, much of it directly related to the effort to prevent untoward incidents. Further, it appears that this technology will continue to advance, particularly because of the adoption of anesthesia workstation standards by the European

Economic Union that are affecting anesthesia machine design worldwide. Note that some anesthesia equipment manufacturers, anxious to minimize their own potential liability, have refused to support (with parts and service) some of the oldest of their pieces (particularly gas machines) still in use. This disowning of equipment by its own manufacturer is a very strong message to practitioners that such equipment must be replaced as soon as possible.

Should a piece of equipment fail, it must be removed from service and a replacement substituted. Groups, departments, and facilities are obligated to have sufficient backup equipment to cover any reasonable incidence of failure. The equipment removed from service must be clearly marked with a prominent label (so it is not returned into service by a well-meaning technician or practitioner) containing the date, time, person discovering, and the details of the problem. The responsible personnel must be notified so they can remove the equipment, make an entry in the log, and initiate the repair. As indicated in the protocol for response to an adverse event, a piece of equipment involved or suspected in an anesthesia accident must be immediately sequestered and not touched by anybody—particularly not by any equipment service personnel. If a severe accident occurred, it may be necessary for the equipment in question to be inspected at a later time by a group consisting of qualified representatives of the manufacturer, the service personnel, the plaintiff's attorney, the insurance companies involved, and the practitioner's defense attorney. The equipment should thus be impounded following an adverse event and treated similarly to any object in a forensic "chain of evidence," with careful documentation of parties in contact with and

responsible for securing the equipment in question following such an event. Also, major equipment problems may, in some circumstances, reflect a pattern of failure as a result of a design or manufacturing fault. These problems should be reported to the FDA's Medical Device Problem Reporting system[21] via MedWatch on Form 3500 (at http://0-www.fda.gov.innopac.up.ac.za:80/medwatch/index.html, or telephone 800-FDA-1088). This system accepts voluntary reports from users and requires reports from manufacturers when there is knowledge of a medical device being involved in a serious incident. Whether or not filing such a report will have a positive impact in subsequent litigation is impossible to know, but it is a worthwhile practice management point that needs to be considered in the unlikely but important instance of a relevant event involving equipment failure.

Malpractice Insurance

All practitioners need liability insurance coverage specific for the specialty and role in which they are practicing. Premium rates depend on specialty, subspecialty, and whether the insured performs procedures that the insurance company's experience suggests may be more likely to result in a malpractice lawsuit. It is absolutely critical that applicants for medical liability insurance be completely honest in informing the insurer what duties and procedures they perform. Failure to do so, either from carelessness or from a foolishly misguided desire to reduce the resulting premium, may well result in retrospective denial of insurance coverage in the event of an untoward outcome from an activity the insurer did not know the insured engaged in.

Proof of adequate insurance coverage is usually required to secure or renew privileges to practice at a health care facility. The facility may specify certain minimum policy limits in an attempt to limit its own liability exposure. It is difficult to suggest specific dollar amounts for policy limits because the details of practice vary so much among situations and locations. The malpractice crisis of the 1980s eased significantly in the early 1990s for anesthesiologists, largely because of the decrease in number and severity of malpractice claims resulting from anesthesia catastrophes as anesthesia care in the United States became safer.[22,23,24] The exact analysis of this phenomenon can be debated,[25,26] but it is a simple fact that malpractice insurance risk ratings have been decreased and premiums for anesthesiologists have not been increased at the same rate as for other specialties over the past decade and, in many cases, have actually decreased. This does not mitigate the need for adequate coverage, however. In the early 2000s, coverage limits of $1 million to $3 million would seem the bare minimum advisable. This policy specification usually means that the insurer will cover up to $1 million liability per claim and up to $3 million total per year, but this terminology is not necessarily universal. Therefore, anesthesiology personnel must be absolutely certain what they are buying when they apply for malpractice insurance. In parts of the United States known for a pattern of exorbitant settlements and jury verdicts, liability coverage limits of $2 million to $5 million may be prudent and well worth the moderate additional cost. An additional feature in this regard is the potential to employ "umbrella" liability coverage above the limits of the base policy, as noted later.

Background

The fundamental mechanism of medical malpractice insurance changed significantly in the last two decades because of the need for insurance companies to have better ways to predict what their losses (amounts paid in settlements and judgments) might be. Traditionally, medical liability insurance was sold on an "occurrence" basis, meaning that if the insurance policy was in force at the time of the occurrence of an incident resulting in a claim, whenever that claim might be filed, the practitioner would be covered. Occurrence insurance was somewhat more expensive than the alternative "claims made" policies, but was seen as worth it by some (many) practitioners. These policies created some open-ended exposure for the insurer that sometimes led to unexpected large losses, even some large enough to threaten the existence of the insurance company. As a result, medical malpractice insurers have converted almost exclusively to claims-made insurance, which covers claims that are filed while the insurance is in force. Premium rates for the first year a physician is in practice are relatively low because there is less likelihood of a claim coming in (a majority of malpractice suits are filed 1 to 3 years after the event in question). The premiums

usually increase yearly for the first 5 years and then the policy is considered "mature." The issue comes when the physician later, for whatever reason, must change insurance companies (e.g., because of relocation to another state). If the physician simply discontinues the policy and a claim is filed the next year, there will be no insurance coverage. Therefore, the physician must secure "tail coverage," sometimes for a minimum number of years (e.g., 5) or sometimes indefinitely to guarantee liability insurance protection for claims filed after the physician is no longer primarily covered by the insurance policy. It may be possible in some circumstances to purchase tail coverage from a different insurer than was involved with the primary policy, but by far the most common thing done is to simply extend the existing insurance coverage for the period of the tail. This very often yields a bill for the entire tail coverage premium, which can be quite sizable, potentially staggering a physician who simply wants to move to another state where his existing insurance company is not licensed to or refuses to do business. The issue of how to pay this premium is appropriately the subject of management attention and effort within the anesthesia practice. Individual situations will vary widely, but it is reasonable for anesthesiologists organized into a fiscal entity to consider this issue at the time of the inception of the group and record their policy decisions in writing, rather than facing the potentially difficult question of how to treat one individual later. Other strategies have occasionally been employed when

insuring the tail period, including converting the previous policy to part-time status for a period of years, and purchasing "nose" coverage from the new insurer—that is, paying an initial higher yearly premium with the new insurer, who then will cover claims that may occur during the tail period. Whatever strategy is adopted, it is critical that the individual practitioner be absolutely certain through personal verification that he or she is thoroughly covered at the time of any transition. The potential stakes are much too great to leave such important issues solely to an office clerk. Further, a practitioner arriving in a new location is often filling a need or void and is urged to begin clinical work as soon as humanly possible by others who have been shouldering an increased load. It is essential that the new arrival verify with confirmation in writing (often called a "binder") that malpractice liability insurance coverage is in force before any patient contact.

Another component to the liability insurance situation is consideration of the advisability of purchasing yet another type of insurance called "umbrella coverage," which is activated at the time of the need to pay a claim that exceeds the limits of coverage on the standard malpractice liability insurance policy. Because such an enormous claim is extremely unlikely, many practitioners are tempted to forgo the comparatively modest cost of such insurance coverage in the name of economy. As before, it is easy to see that this is potentially a very false economy—if there is a huge claim. Practitioners should consult with their financial managers, but it is likely that it would be considered wise management to purchase "umbrella" liability insurance coverage.

Medical malpractice insurers are becoming increasingly active in trying to prevent incidents that will lead to insurance claims. They often sponsor risk-management seminars to teach practices and techniques to lessen the chances of liability claims and, in some cases, suggest (or even mandate) specific practices, such as strict documented compliance with the ASA Standards for Basic Anesthetic Monitoring. In return for attendance at such events and/or the signing of contracts stating that the practitioner will follow certain guidelines or standards, the insurer often gives a discount on the liability insurance premium. Clearly, it is sound practice management strategy for practitioners to participate maximally in such programs. Likewise, some insurers make coverage conditional on the consistent implementation of certain strategies such as minimal monitoring, even stipulating that the practitioner will not be covered if it is found that the guidelines were being consciously ignored at the time of an untoward event. Again, it is obviously wise from a practice management standpoint to cooperate fully with such stipulations.

Response to an Adverse Event

6 In spite of the decreased incidence of anesthesia catastrophes, even with the very best of practice, it is statistically likely that each anesthesiologist at least once in his or her professional life will be involved in a major anesthesia accident. (See Chapter 5.) Precisely because such an event is rare, very few are prepared for it. It is probable that the involved

personnel will have no relevant past experience regarding what to do. Although an obvious resource is another anesthetist who has had some exposure or experience, one of these may not be available either. Various authors have discussed what to do in that event.[27,28,29] Cooper et al. have thoughtfully presented the appropriate immediate response to an accident in a straightforward, logical, compact format[30] that should periodically be reviewed by all anesthesiology practitioners and should be included in all anesthesia policy and procedure manuals. This "adverse events protocol" is also always immediately available at http://www.apsf.org, "Resources: Clinical Safety." Unfortunately, however, the principal personnel involved in a significant untoward event may react with such surprise or shock as to temporarily lose sight of logic. At the moment of recognition that a major anesthetic complication has occurred or is occurring, help must be called. A sufficient number of people to deal with the situation must be assembled on site as quickly as possible. For example, in the unlikely but still possible event that an esophageal intubation goes unrecognized long enough to cause a cardiac arrest, the immediate need is for enough skilled personnel to conduct the resuscitative efforts, including making the correct diagnosis and replacing the tube into the trachea. Whether the anesthesiologist apparently responsible for the complication should direct the immediate remedial efforts will depend on the person and the situation. In such a circumstance, it would seem wise for a senior or supervising anesthesiologist quickly to evaluate the scenario and make a decision. This person becomes the "incident supervisor" and has responsibility for helping prevent continuation or recurrence of the incident, for investigating the incident, and for ensuring documentation while the original and helping anesthesiologists focus on caring for the patient. As noted, involved equipment must be sequestered and not touched until such time as it is certain that it was not involved in the incident.

If the accident is not fatal, continuing care of the patient is critical. Measures may be instituted to help limit damage from brain hypoxia. Consultants may be helpful and should be called without hesitation. If not already involved, the chief of anesthesiology must be notified as well as the facility administrator, risk manager, and the anesthesiologist's insurance company. These latter are critical to allow consideration of immediate efforts to limit later financial loss. (Likewise, there are often provisions in medical malpractice insurance policies that might limit or even deny insurance coverage if the company is not notified of any reportable event immediately.) If there is an involved surgeon of record, he or she probably will first notify the family, but the anesthesiologist and others (risk manager, insurance loss control officer, or even legal counsel) might appropriately be included at the outset. Full disclosure of facts as they are best known—with no confessions, opinions, speculation, or placing of blame—is currently still believed to be the best presentation. Any attempt to conceal or shade the truth will later only confound an already difficult situation. Obviously, comfort and support should be offered, including, if appropriate, the services of facility personnel such as clergy, social workers, and counselors. There is a new movement in medical risk management and insurance advocating immediate full disclosure to the victim or survivors, including "confessions" of medical judgment and performance errors with attendant sincere apologies. If indicated, early offers of reasonable compensation may be included. There have been instances when this overall strategy has prevented the filing of a malpractice lawsuit and has been applauded by all involved as an example of a shift from the "culture of blame" with punishment to a "just culture" with restitution. Laudable as this approach may sound, it would be mandatory for an individual practitioner to check with the involved liability insurance carrier, the practice group, and the facility administration before attempting it.

The primary anesthesia provider and any others involved must document relevant information. Never, ever change any existing entries in the medical record. Write an amendment note if needed with careful explanation of why amendment is necessary, particularly stressing explanations of professional judgments involved. State only facts as they are known. Make no judgments about causes or responsibility and do not "point fingers." The same guidelines hold true for the filing of the incident report in the facility, which should be done as soon as is practical. Further, all discussions with the patient or family should be carefully documented in the medical record. Recognizing that detailed memories of the events may fade in the 1 to

3 years before the practitioner may face deposition questions about exactly what happened, it is

possible that it will be recommended, immediately after the incident, that the involved clinical personnel sit down as soon as practical and write out their own personal notes, which will include opinions and impressions as well as maximally detailed accounts of the events as they unfolded. These personal notes are not part of the medical record or the facility files. These notes should be written in the physical presence of an involved attorney representing the practitioner, even if this is not yet the specific defense attorney secured by the malpractice insurance company, and then that attorney should take possession of and keep those notes as case material. This strategy is intended to make the personal notes "attorney–client work product," and thus not subject to forced "discovery" (revelation) by other parties to the case.

Follow-up after the immediate handling of the incident will involve the primary anesthesiologist but should again be directed by a senior supervisor, who may or may not be the same person as the incident supervisor. The "follow-up supervisor" verifies the adequacy and coordination of ongoing care of the patient and facilitates communication among all involved, especially with the risk manager. Lastly, it is necessary to verify that adequate postevent documentation is taking place.

Of course, it is expected that such an adverse event will be discussed in the applicable morbidity and mortality meeting. This is good and appropriate. It is necessary, however, to coordinate this activity with the involved risk manager and attorney so as to be completely certain that the contents and conclusions of the discussion are clearly considered peer review activity, and thus are shielded from discovery by the plaintiffs' attorney.

Unpleasant as this is to contemplate, it is better to have a clear plan and execute it in the event of an accident causing injury to a patient. Vigorous immediate intervention may improve the outcome for all concerned.

PRACTICE ESSENTIALS

The "Job Market" for Anesthesiologists

While it is true that in the mid 1990s, for the first time, uncertainty faced residents finishing anesthesiology training because of a perception that there were not enough jobs available, that concept faded relatively quickly. Somewhat of a manageable balance between supply and demand developed, but with a significant ongoing component of the idea that there is an overall shortage of anesthesia providers. It is likely that this fundamental paradigm will persist in the next decade.

Factors governing the issues of supply of and demand for anesthesiologists are complex and evolving. Before about 1993, with the exception of a very few of the most popular cities, finishing residents could first decide where they wanted to live and then seek an anesthesiology practice there to join or simply start one themselves. Although a maldistribution of anesthesiologists in the United States existed (and still exists, with underserved rural and inner-city areas that may have few or no physician anesthesia services), there were enough finishing residents coming into the system to populate practices across the country in a manner that created a more "normal" marketplace system in which candidates for anesthesiology jobs faced most of the same considerations as all other professionals. Another factor of historical significance (but also with potential application in the future) was the proposal in 1993 by the U.S. federal administration to restructure radically American health care delivery. Although this proposal was abandoned as too radical, it introduced an element of uncertainty that persisted long after the idea had been dismissed. This element of uncertainty led many anesthesiologists and facilities to adopt a "wait and see" attitude about hiring new anesthesiologists at that time.

Later, there was an element of "pent up demand" that opened many anesthesiologist positions later in the decade of the 1990s. Another factor is the marketplace forces that have been and continue to induce significant changes in the U.S. health care system independent of any government proposal for change. Put as simply as possible, the business community, employers who provide health care insurance for their employees, and government entities that fund programs such as Medicare and Medicaid have suggested that it may be impossible for them to continue to fund the rapidly increasing expenditures necessary to provide health care coverage. As

a result, an entire new industry, managed health care, appeared. The managed care concept is built on the idea that traditional fee-for-service health care has no incentive for health care providers, principally physicians, to limit expenditures. In fact, physicians, health care workers, and health care facilities were financially rewarded the more health care was "consumed" or rendered to patients. Accordingly, MCOs came into being, declaring to business and government that a new administrative layer was needed to control (reduce) what physicians and health care facilities spend. This management of care by outside, independent reviewers and decision makers who determine what care can and should be rendered to the patient was intended to replace the traditional fee-for-service indemnity system (bills submitted by physicians based on what they decide is necessary that are then paid after the fact by a health plan or insurance company) and thereby significantly reduce the cost for health care to employers and governments. One of the main themes of managed care plans was that there would be much less surgery. This idea led logically to questions about how many anesthesiologists really were needed in this country. Discussions occurred both outside and within organized anesthesiology about such questions,[31,32,33,34] but, predictably, no definitive answers were or are possible.

By 2001, the situation had largely reversed with the marketplace declaring a shortage of anesthesia providers and multiple attractive job offers for most residents being graduated. Senior medical students very quickly realized this and the number of highly qualified American graduates applying to anesthesiology residencies increased dramatically in the first years of the twenty-first century.[35] The situation is evolving and fluid,[36] and it is important to remember that there will always be surgery, no matter what health system changes take place. Even in the face of new potential health system reforms and also continued clinical innovation with "nonoperative procedures" replacing some traditional surgical operations, it seems likely that, again, any predictions of less need for OR anesthesia simply will not come true and there may well be, in fact, ongoing increases in demand. Moreover, anesthesiologists do more than just OR anesthesia (and likely increasingly so in the future). Accordingly, at the time of this writing, prospects for finishing anesthesiology residents are extremely bright and they must be armed with knowledge about the practice world.

Types of Practice

With the "alphabet soup" of new practice arrangements for physicians (IPA, PPO, PHO, MCO, MSO, HMO) and the rapidly evolving forces of the health care marketplace, as well as the intermittent appearance of major governmental initiatives to institute radical reform of the health care system, it is difficult to outline the details of all the possible types of opportunities for anesthesiologists. Rather, it is reasonable to provide basic background information and also suggestions of sources of further information.

At least through the first decade of the twenty-first century, residents finishing anesthesiology training will still need to choose among three fundamental possibilities: academic practice in a teaching hospital environment; a practice exclusively of patient care in the private practice marketplace; and a practice exclusively of patient care as an employee of a health care system, organization, or facility.

Teaching hospitals with anesthesiology residency programs constitute only a very small fraction of the total number of facilities requiring anesthesia services. These academic departments tend to be among the largest, but the aggregate fraction of the entire anesthesiologist population is small. It is interesting, however, that by the nature of the system, most residents finishing their training have almost exclusively been exposed only to academic anesthesiology. Accordingly, finishing residents in the past often were comparatively unprepared to evaluate and enter the anesthesiology job market. As noted, the Anesthesiology Residency Review Committee now requires teaching of job acquisition skills and practice management as part of the residency didactic curriculum.

Specialty certification by the American Board of Anesthesiology (ABA) should be the goal of all anesthesia residency graduates. Some graduating residents who know they are eventually headed

for private practice have started their attending careers as junior faculty. This allows them to obtain some clinical practice and supervisory experience and offers them the opportunity to prepare for the ABA examinations in the nurturing, protected academic environment with which they are familiar. Most residents, however, do not become junior faculty; they accept practice positions immediately. But such newly trained residents should take into account the need to become ABA-certified and build into their new practice arrangements the stipulation that there will be time and consideration given toward this goal. The hectic and unsettling time of embarking on a new career, possibly moving one's home and family, and getting acclimated to a new professional and financial environment may inhibit optimum performance on the examinations. The possibilities to avoid this disruption may be comparatively limited, but awareness of the problem can help. At the very least, it may lead to the forging of initial practice arrangements that will maximize the probability of success.

Academic Practice

For those who choose to stay in academic practice, the first question is whether to consider staying at one's training institution. On the one hand, "the devil you know is better than the devil you don't know." On the other hand, however, fear of the unknown should not inhibit investigation of all possibilities. Aside from obvious personal preferences such as area of the country, size of city, and climate, a number of specific characteristics of academic anesthesia departments can be used as screening questions.

How big is the department? Junior faculty sometimes can get lost in very big departments and be treated as little better than glorified senior residents. On the other hand, the availability of subspecialty service opportunities and significant research and educational resources can make large departments extremely attractive. In smaller academic departments, there may be fewer resources, but the likelihood of being quickly accepted as a valued, contributing member of the teaching faculty (and research team, if appropriate) may be higher. In very small departments, the number of expectations, projects, and involvements could potentially be overwhelming. Additionally, a small department may lack a dedicated research infrastructure, so it may be necessary for the faculty in this situation to collaborate with other, larger departments to accomplish meaningful academic work.

What exactly is expected of junior faculty? If teaching one resident class every other week is standard, the candidate must enthusiastically accept that assignment and the attendant preparation work and time up front. Likewise, if it is expected that junior faculty will, by definition, be actively involved in publishable research, specific plans for projects to which the candidate is amenable must be made. In such situations, clear stipulations about startup research funding and nonclinical time to carry out the projects should be obtained as much as possible. Particularly important is determining what the expectation is concerning outside funding—it can be a rude shock to realize that projects will suddenly halt after, for example, 2 years if extramural funding has not been secured.

What are the prospects for advancement? Many new junior faculty directly out of residency start with medical school appointments as instructors unless there is something else in their background that immediately qualifies them as assistant professors. It is wise to understand from the beginning what it takes in that department and medical school to facilitate academic advancement. There may be more than one academic "track;" the tenure track, for example, is usually dependent on published research whereas the clinical or teacher track relies more heavily on one's value in patient care and as a clinical educator. The criteria for promotion may be clearly spelled out by the institution—number of papers needed, involvement and recognition at various levels, grants submitted and funded, and so on—or the system may be less rigid and depend more heavily on the department chairman's and other faculty evaluations and recommendations. In either case, careful inquiry before accepting the position can avert later surprise and disappointment.

How much does it pay? Traditionally, academic anesthesiologists have not earned quite as much as those in private practice—in return for the advantage of more predictable (and maybe less

strenuous) schedules, continued intellectual stimulation, and the intangible rewards of academic success. There is now great activity and attention concerning reimbursement of anesthesiologists, and it is difficult to predict future income for any anesthesiology practice situation. However, all of the forces influencing payment for anesthesia care may significantly diminish the traditional income differential between academic and private practice. This is not a small issue. Anesthesiologists justifiably can expect to live reasonably well. Income is also a valid consideration both because anesthesiologists are frequently at least 30 years old when they finish training and are thus starting well behind their age-mates in lifetime earnings and because most physicians have substantial educational loans to repay when finishing residency. The compensation arrangements in academic practice vary widely in structure. In some cases, a faculty member is exclusively an employee of the institution, which bills and collects or negotiates group contracts for the patient care rendered by the faculty member, and then pays a negotiated amount (either an absolute dollar figure or a floating amount based on volume and/or collections—or a combination of the two) that constitutes the faculty person's entire income. Under other less common arrangements, faculty members themselves may be able to bill and collect or negotiate contracts for their clinical work. Some institutions have a (comparatively small) academic salary from the medical school for being on the faculty, but many do not; some channel variable amounts of money (from so-called Part A clinical revenue) into the academic practice in recognition of teaching and administration or simply as a subsidy for needed service. A salary from the medical school, if extant, is then supplemented significantly by the practice income. Usually, the faculty will be members of some type of group or practice plan (either for the anesthesia department alone or the entire faculty as a whole) that bills and collects or negotiates contracts and then distributes the practice income to the faculty under an arrangement that must be

examined by the candidate. In most academic institutions, practice expenses such as all overhead and malpractice insurance as well as reasonable benefits, including discretionary funds for meetings, subscriptions, books, dues, and so on, are automatically part of the compensation package, which often may not be true in private practice and must be counted in making any comparison. An important corollary issue is that of the source of the salaries of the department's primary anesthesia providers—residents and, in some cases, nurse anesthetists. Although the hospital usually pays for at least some of these, arrangements vary, and it is important to ascertain whether the faculty practice income is also expected to cover the cost of the primary providers. Overall, it is reasonable to sound out faculty, both anesthesiology and others, regarding the past and likely future commitment of the institution to the establishment and maintenance of reasonable compensation for the expected involvement.

Private Practice in the Marketplace

As noted, some residents finish their anesthesia training never having seen a private practice anesthesia setting or even talked to an anesthesiologist who has been in private practice. These candidates are ill-equipped to seek a position in the private practice marketplace. Obviously, rotations to a private practice hospital in the final year of anesthesia residency could help greatly in this regard, but not all residency programs offer such opportunities. In that case, the finishing resident who is certain about going into private practice must seek information on career development and mentors from the private sector.

Armed with as much information as possible, one fundamental initial choice is between independent individual practice and a position with a group (either a sole proprietorship, partnership, or corporation) that functions as a single financial entity. Independent practice may become increasingly less viable in many locations because of the need to be able to bid for contracts with managed care entities. However, where independent practice is possible, it usually first involves attempting to secure clinical privileges at a number of hospitals or facilities in the area in which one chooses to live. This may not always be easy, and this issue has been the subject of many (frequently unsuccessful) antitrust suits over recent years (see Antitrust Considerations). Then the anesthesiologist makes it known to the respective surgeon communities that he or she is available to render anesthesia services and waits until there is a request for his or her services. The anesthesiologist obtains the requisite financial information from the patient

and then either individually bills and collects for services rendered or employs a service to do billing and collection for a percentage fee (which will vary depending on the circumstances, especially the volume of business; for billing [without scheduling services] it would be unlikely to be more than 7% or, at the most, 8% of actual collections). How much of the needed equipment and supplies will be provided by the hospital or facility and how much by the independent anesthesiologist varies widely. If an anesthesiologist spends considerable time in one operating suite, he or she may purchase an anesthesia machine exclusively for his or her own use and move it from room to room as needed. It is likely to be impractical to move a fully equipped anesthesia machine from hospital to hospital on a day-to-day basis. Among the features of this style of practice are the collegiality and relationships of a genuine private practice based on referrals and also the ability to decide independently how much time one wants to be available to work. The downside is the potential unpredictability of the demand for service and the time needed to establish referral patterns and obtain bookings sufficient to generate a livable income.

Acknowledging that the issues presented earlier may at some times render components of these suggestions moot, it is reasonable for the graduating resident to know that when seeking a position with a private group, the applicant should search for potential practice opportunities through word of mouth, recruiting letters sent to the training program supervisor, journal advertisements, and placement services (either commercial or professional, such as that provided at the ASA annual meeting). Some of the screening questions are the same as for an academic position, but there must be even more emphasis on the exact details of clinical expectations and financial arrangements. Some residents finish residency (or fellowship training to an even greater extent) very highly skilled in complex, difficult anesthesia procedures. They can be surprised to find that in some private practice group situations, the junior-most anesthesiologist must wait some time, perhaps even years, before being eligible to do, for example, cardiac anesthesia and in the meantime will mostly be assigned more routine or less challenging anesthetics. Of course, this is not always the circumstance, but the applicant needs to investigate thoroughly to be certain that the opportunity satisfies the desire for professional challenge.

Financial arrangements in private group practices vary widely. Some groups are loose organizational alliances of independent practitioners who bill and collect separately and rotate clinical assignments and call for mutual convenience. Many groups act also as a fiscal entity, and there are many possible variations on this theme. In many circumstances in the past, new junior members started out as functional employees of the group for a probationary interval before being considered for full membership or partnership. This is not a classic employment situation because it is intended to be temporary as a prelude to full financial participation in the group. However, there have been enough instances of established groups abusing this arrangement that the ASA includes in its fundamental Statement of Policy the proviso: "Exploitation of anesthesiologists by other anesthesiologists is improper."[3] This goes on to say that after a reasonable trial period, income should reflect services rendered. Unfortunately, these statements may have little meaning or impact on groups in the marketplace. Some groups have a history of demanding excessively long trial periods during which the junior anesthesiologist's income is artificially low and then denying partnership and terminating the relationship to go on to employ a new probationer and start the cycle over again. Accordingly, new junior staff attempting to join groups should try to have such an arrangement spelled out carefully in the agreement drafted by an expert representing the anesthesiologist. Another variation of this, in an attempt to disguise the fundamentally unethical nature of the practice, is to employ anesthesiologists on a fixed salary with the false incentive of no night or weekend call. This is disingenuous, as the vast majority of income is usually generated during routine scheduled day work, for which the anesthesiologist-employee is poorly compensated. Yet another usurious scheme is for a group to employ an anesthesiologist for a period of years at a low salary and then require a further cash outlay to purchase partnership in the corporation. As the cash outlay can be quite substantial, it is frequently borrowed from the corporation, leading to a sophisticated form of indentured servitude. Sadly, when the job market conditions are poor as they were some years ago, the tendency is for there to be less likelihood of securing a prospective commitment of partnership at a specified future time. This is especially true in the more desirable areas of the United States where stories of abuse of junior "partners" have been more common. Whether this should substantially affect an

applicant's interest in or willingness to accept a position is a highly individual matter that must be evaluated by each applicant. As the market turned and the demand often exceeded the supply of new anesthesiologists, such abuses appeared less

likely. In all cases, the applicant must utilize resources[4] that allow them to enter the negotiating process armed with maximum information and reasonable expectations.

Private Practice as an Employee

There has been some trend toward anesthesiologists becoming permanent employees of any one of various fiscal entities. The key difference is that there is no intention or hope of achieving an equity position (share of ownership, usually of a partnership, thus becoming a full partner). Hospitals, outpatient surgery centers, multidisciplinary clinics, other facilities tied to a specific location where surgery is performed, physician groups that have umbrella fiscal entities specifically created to serve as the employer of physicians, and even surgeons may seek to hire anesthesiologists as permanent employees. The common thread in this system is that these fiscal entities see the anesthesiologists as additional ways of generating profits. Again, in many cases it would appear that employees are not paid a salary that is commensurate with their production of receivables. That is, the fiscal entity will pay a salary substantially below collections generated plus appropriate overhead. These arrangements are particularly favored by some large managed care organizations in certain cities that view anesthesiologists simply as expensive necessities that prevent hospitals from realizing maximum profit (although sometimes there is a promise of a lighter or more manageable schedule in these positions compared to marketplace private practice). At the height of the managed care mania of the mid to late 1990s, there were predictions that this trend would continue to grow, and that eventually most physicians in the support specialties of anesthesiology, radiology, pathology, and emergency medicine would be outright permanent employees of an organized entity of some type. While clearly this did not happen and the managed care bubble has deflated somewhat, it is impossible to speculate on the future in this regard. Many anesthesiologists believe that the future is extraordinarily bright and that anesthesiology will expand its role, predicting that anesthesiologists will increasingly assume positions of central authority in managed care and other practice entities, making decisions about the hiring and firing of physicians of other specialties.

Negotiating for a position as a permanent employee is somewhat simpler and more straightforward than it is in marketplace private practice. It parallels the usual understandings that apply to most regular employer–employee situations: job description, role expectations, working conditions, hours, pay, and benefits. The idea of anesthesiologists functionally becoming shift workers disturbs many in the profession because it contradicts the traditional professional model. On the other hand, major upheaval in the health care delivery system has sometimes led to reorganization that, until very recently, was unheard of. Again, the complex nature and multiple levels of such considerations make it a personal issue that must be carefully evaluated by each individual with full awareness and consideration of the issues outlined here.

Billing and Collecting

In practices in which anesthesiologists are directly involved with the financial management, they need to understand as much as possible about the complex world of health care reimbursement. This significant task has been made easier by the ASA, which some time ago added a significant component to its Washington, D.C., office by adding a practice management coordinator to the staff. One of the associated assignments is helping ASA members understand and work with the sometimes confusing and convoluted issues of effective billing for anesthesiologists' services. There are often updates with the latest information and codes in the monthly ASA *Newsletter*.

There continue to be proposals for significant changes in billing for anesthesiology care. However, the basics have changed only slightly in recent years. It is important to understand that many of the most contentious issues, such as the requirement for physician supervision of nurse anesthetists and the implications of that for reimbursement, apply in many circumstances mostly to Medicare and, in some states, Medicaid. Thus, the fraction of the patient population covered by

these government payers is important in any consideration. Different practice situations have different arrangements regarding the financial relationships between anesthesiologists and nurse anesthetists, and this can affect the complex situation of who bills for what. The nurses may be employees of a hospital, of the anesthesiologists who medically direct them, or of no one in that they are independent contractors billing separately (even in cases in which physician supervision—not medical direction—is required but where those physicians do not bill for that component). In 1998, Medicare mandated that an anesthesia care team of a nurse anesthetist medically directed by an anesthesiologist could bill as a team no more than 100% of the fee that would apply if the anesthesiologist did the case alone. The implications of this change are complex and variable among anesthesiology practices, particularly because there is another trend—for health care facilities that traditionally had employed nurse anesthetists to seek to shift total financial responsibility for them to the anesthesiologist practice group. Also, complex related issues played out in the early 2000 years. The federal government issued a new regulation allowing individual states to "opt out" of the requirement that nurse anesthetists be supervised by physicians and several states did so. This was opposed by the ASA. Because perioperative patient care, one component of which is administering anesthesia, is traditionally considered the practice of medicine, the implications of this change as far as the role of surgeons supervising nurse anesthetists and the malpractice liability status of nurse anesthetists practicing independently were unclear. Further, the implications of all this for billing insurers other than Medicare and Medicaid are exceedingly complex. Obviously, careful consideration of these issues and seeking out advice from knowledgeable resources (such as the ASA Washington office) is critical to fiscal stability in modern anesthesiology practice.

There has been significant consideration of the mechanism of billing for anesthesiology. There have been some suggestions that so-called schedule fees (a single predetermined fee for an anesthetic, independent of its length or complexity) will become more common. Further, there is pressure from some quarters to bundle together all the physicians' fees for one procedure into a single global professional fee that would pay the surgeon, anesthesiologist, radiologist, pathologist, and so on for one case, such as a laparoscopic cholecystectomy. However, all of this concern about billing for specific procedures could become irrelevant in systems with prospective capitated payments for large populations of patients, in which each group of involved physicians in a system would receive a fixed amount per enrolled member per month (PMPM) and agree, except in the most unusual circumstances, to provide whatever care is needed by that population for that prospective payment. These are intended to be large-scale operations involving at least tens of thousands of people ("covered lives") in each organization. There was a trend in this direction in the late 1990s, but, as with so many aspects of managed care, the actual implantation of the ideas in real life did not work out smoothly or as planned and there was a resulting retrenchment into more blended models of facility reimbursement based on DRG (diagnosis related group) codes and professional reimbursement based on a

negotiated multiple (or fraction) of the corresponding Medicare payment for that service.

Classic Methodology

Because there is still widespread application of the traditional method of billing for anesthesiology services, understanding it is very important for anesthesiologists starting practice. In this system, each anesthetic generates a value of so many "units," which represent effort and time. A conversion factor (dollars per unit) that can vary widely multiplied by the number of units generates an amount to be billed. Each anesthetic has a base value number of units (e.g., 8 for a cholecystectomy) and then the time taken for the anesthetic is divided into units, usually 15 minutes per unit. Thus, a cholecystectomy with anesthesia time of 1 hour and 50 minutes would have 8 base units and 7.33 time units for a total of 15.33 units. In some practice settings, it may be allowed to add modifiers, such as extra units for complex patients with multiple problems as reflected by an ASA physical status classification of 3 to 5 and/or E ("emergency") or for insertion of an arterial or pulmonary artery catheter. The sum is the total billing unit value. Determining the base value for an anesthetic in units depends on full and correct understanding of what operation was done. Although this sounds easy, it is the most difficult component of traditional

anesthesia billing. The process of determining the procedure done is known as coding because the procedure name listed on the anesthesia record is assigned an identifying code number from the universally used CPT-4 coding book. This code is then translated through the ASA Relative Value Guide, which assigns a base unit value to the type of procedure identified by the CPT-4 code. In the past, some anesthesiologists failed to understand the importance of correct coding to the success of the billing process. Placing this task in the hands of someone unfamiliar with the system and with surgical terminology can easily lead to incorrect coding. This can fail to capture charges and the resulting income to which the anesthesiologist is entitled or, worse, can systematically overcharge the payers, which will bring sanctions, penalties and, in certain cases, criminal prosecution. In recent years a prevailing official attitude has been that there are no simple, innocent coding errors. All upcoding (charging for more expensive services than were actually delivered) is considered to be prima facie evidence of fraud and subject to severe disciplinary and legal action. All practices should have detailed compliance programs in place to ensure correct coding for services rendered.[37] Outside expert help (such as from a health care law firm that specializes in compliance programs) is highly desirable for the process of formulating and implementing a compliance plan.

Assembly and transfer of the information necessary to generate bills must be efficient and complete. Traditionally, this involved depositing in a secure central location a paper extra copy of the anesthesia record and often a "billing sheet" with it, on which was inscribed the names of all the involved personnel and any additional information about other potentially billable services, such as invasive monitors. Any practice involved with a comprehensive electronic perioperative information management system in the facility should be using that to assemble this "front end" billing information. Short of that, some practices collect electronic information specifically generated by the anesthesia providers for that purpose. They have equipped each staff member with a hand-held organizer into which data are entered and then the device is synched with a departmental computer at the end of the day. If the OR suite has "wi-fi" (wireless electronic connection), the same function could be accomplished in real time with the providers entering the requisite information into a miniprogram on a laptop computer affixed to each anesthesia machine (or one carried by each staff member). Of course, the universal use of hand-helds or laptops could have significant other benefits to the members of the group/department. Overall, while achieving full compliance with such a protocol of billing data entry by the group's staff may take significant in-service education and training, it will only take one reduced or, better, missed paycheck to achieve full compliance by any given member. Once the information has been secured, a mechanism must be employed to generate the actual bill and communicate it to the payer (on paper, on disk, or, usually, directly computer-to-computer: "electronic claims submission"). The possible precise arrangements for doing this vary widely. Ultimately, the entity actually submitting the bill will verify that it has been paid (posting of receipts) and may or may not actually handle the incoming money. Very often, anesthesia practices or individuals who use a billing service will arrange that the payments go directly to a bank lockbox, which is a post office box (better individual than shared, even if more expensive) to which the payments come and then go directly into a bank account. This system avoids the situation of having the people who generate the bill actually handle the incoming receipts, a practice that has led to theft and fraud in a few cases. Eventual decisions about how hard to try to collect from payers who deny coverage and then from patients directly will depend on the circumstances, including local customs.

Detailed summary statistics of the work done by an anesthesiology practice group are critical for logistic management of personnel, scheduling, and financial analysis. Spreadsheet and database computer programs customized for an individual practice's characteristics will be invaluable. A summary of the types of data an anesthesia practice should track is shown in Table 2-5. Once all the data are assembled and reviewed, at least monthly analysis by a business manager or equivalent as well as officers/leaders of the practice group can spot trends very early in their development and allow appropriate correction or planning. Often the responsible members of an anesthesiology group question how effective their financial services operation is, particularly regarding net collections. This is a complex issue[38] that, again, often requires outside help. Routine internal audits can be useful but could be self-serving. No billing office or company that is honest and completely above board should ever object to a client, in this case the anesthesiology

practice group, engaging an independent outside auditor to come in and thoroughly examine both the efficiency of the operation and also "the books" concerning correctness and completeness of collections.

TABLE 2-5 Types of Data an Anesthesiology Group Should Track and Maintain Concerning Its Own Practice

Types of Data the Anesthesiology Group's Computer System Should Track

1. Transaction-based system (track each case and charge as separate record)
    - Track individual charges by CPT-4 code
    - Track individual payments by payer
2. Track all data elements on an interrelated basis
    - By place of service
    - By charge, broken down
      —by number of units (time and base)
      —by ASA modifiers
      —by number of lines
    - By CPT-4 code
    - By payer
    - By payment code (full payment, discount, write-off, or refund)
    - By diagnosis (ICD-9 code)
    - By surgeon
    - By anesthesiologist
    - By anesthesia care team provider
    - By start and stop times
    - By age
    - By gender
    - By employer
    - By ZIP code

Type of Information to Generate from These Data

1. Aggregate number of cases per year for the group
2. Total number of cases per year for each provider within the group
    - Number of cases performed by anesthesiologists
    - Number of cases performed by the anesthesia care team
3. Average number of units per case (as one measure of intensity per case)
4. Average number of units per CPT-4 code
5. Average time units per case and per CPT-4 code
    - Group should be able to calculate time units per individual surgeon
6. Average line charge per case
7. Charges per case by CPT-4 code
8. Payments per case by payer
9. Patient mix
    - Percent traditional indemnity
    - Percent managed care (broken down by each MCO for which services are provided)
    - Percent self-pay
    - Percent Medicare
    - Percent Medicaid
10. Collection rate for each population served

11. Overall collection rate
12. Costs per unit (total costs, excluding compensation ÷ total units) (costs include liability insurance, rent, collection costs, and legal and accounting fees)
13. Compensation costs per unit (total compensation ÷ total units) for MCO populations, utilization patterns by age, gender, and diagnosis

Reprinted with permission from American Society of Anesthesiologists. *Managed Care Reimbursement Mechanisms: A Guide for Anesthesiologists*. Park Ridge, IL: ASA; 1994.

Anesthesia billing and collecting are among the most complex challenges in the medical reimbursement field. Traditional anesthesia reimbursement is unique in all of medicine. The experience of many people over the years has suggested that it often is well advised to deal with an entity that is not only very experienced in anesthesia billing, but also does anesthesia billing exclusively or as a large fraction of its efforts. It is very difficult for an anesthesiologist or a family member to do billing and collecting as a side activity to a normal life. This has led to inefficient and inadequate efforts in many cases, illustrating the value of paying a reasonable fee to a professional who will devote great time and energy to this challenging endeavor.

Antitrust Considerations

Although it is true that there are many potential antitrust implications of business arrangements involving anesthesiologists—particularly with all the realignments, consolidations, mergers, and contracts associated with the advent of managed care—it is also true that the applicable statutes and regulations are poorly understood. Contrary to popular belief, the antitrust laws do not involve the rights of individuals to engage in business. Rather, the laws are concerned solely with the preservation of competition within a defined marketplace and the

rights of the consumer, independent of whether any one vendor or provider of service is involved. This misunderstanding has been the source of confusion. When an anesthesiologist has been excluded from a particular hospital's staff or anesthesia group and then sues based on an alleged antitrust violation, the anesthesiologist loses virtually automatically. This is because there is still significant competition in the relevant marketplace and competition in that market is not threatened by the exclusion of one physician from one staff.

In essence, if there are *several* hospitals offering relatively similar services to an immediate community (the market), denial of privileges to one physician by one hospital is not anticompetitive. If, on the other hand, there is only *one* hospital in a smaller market, then the same act, the same set of circumstances, could be seen very differently. In that case, there would be a limitation of competition because the hospital dominates and, in fact, may control the market for hospital services. Exclusion of one physician, then, would limit access by the consumers to alternative competing services and hence would likely be judged an antitrust violation.

The Sherman Antitrust Act is a federal law more than 100 years old. Section 1 deals with contracts, combinations, conspiracy, and restraint of trade. By definition, two or more separate economic entities must be involved in an agreement that is challenged as illegal for this section to apply. Section 2 prohibits monopolies or conspiracy to create a monopoly, and it is possible that this could apply to a single economic entity that has illegally gained domination of a market. Consideration of possible monopolistic domination of a market involves a situation in which a single entity controls at least 50% of the business in that market. The stakes are high in that the antitrust legislation provides for triple damages if a lawsuit is successful. The U.S. Department of

Justice and the Federal Trade Commission are keenly interested in the current rapid evolution in the health care industry, and thus are actively involved in evaluating situations of possible antitrust violations. There are two ways to judge violations. Under the per se rule, which is applied relatively rarely, conduct that is obviously limiting competition in a market is automatically illegal. The other type of violation is based on the rule of reason, which involves a careful analysis of the market and the state of competition. The majority of complaints against physicians are judged by this rule. The more competitors there are in a market, the less likely that any one act is anticompetitive. In a community with two hospitals, one smaller than the other, with an anesthesiology group practice exclusively at each, if the larger anesthesiology practice group buys out and absorbs the smaller, leaving only one group for the only two hospitals in the community, that may be anticompetitive, particularly if a new anesthesiologist seeks to practice solo at those hospitals.

Legal Implications

In the current era of rapidly evolving managed care arrangements, the antitrust laws are important. If physicians (individuals or groups) who normally would be competitors because they are separate economic entities meet and agree on the prices they will charge or the terms they will seek in a managed care contract, that can be anticompetitive, monopolistic, and hence possibly illegal. Note that sharing a common office and common billing service alone is not enough to constitute a true group. If, on the other hand, the same physicians join in a true economic partnership to form a new group (total integration) that is a single economic entity (and meets certain other criteria) that will set prices and negotiate contracts, that is perfectly legal. The other criteria are critical. There must be capital investment and also risk sharing (if there is a profit or loss, it is distributed among the group members)—that is, total integration into a genuine partnership. This issue is very important

in considering the drive for new organizations to put together networks of physicians that then seek contracts with major employers to provide medical care. Sometimes, hospitals or clinics attempt to form a network comprising all the members of the medical staff so that the resulting entity can bid globally for total care contracts. Any network is a joint venture of independent practitioners. If the participating physicians of one specialty in a network are separate economic entities and the network advertises one price for their services, this would seem to suggest an antitrust violation (horizontal price fixing). In the past, if a network involved fewer than 20% of one type of medical specialist in a market, that was called a "safe harbor," meaning that it was permissible for nonpartners to get together and negotiate prices. The federal government has tried to encourage formation of such networks to help reduce health care costs and, as a result, made some relevant exceptions to the application of these rules. As long as the network is nonexclusive (other nonnetwork physicians of a given specialty are free to practice in the same facilities and compete for the same patients), the network can comprise up to 30% of the physicians of one specialty in a market. Note specifically that this does not allow a local specialty society in a big city to serve as a bargaining agent on fees for its members, because it is very likely that more than 30% of the specialists in an area will be members of the society. The only real exception to this provision is in thinly populated rural areas where there may be just one physician network. In such cases (which are, so far, rare because the major managed care and network activity has occurred mainly in heavily populated urban areas), there is no limit on how many of one specialty can become network members and have the network negotiate fees, as long as the network is nonexclusive.

Clearly, these issues are very complex. Relevant legislation, regulations, and court actions all happen rapidly and often. Mergers among anesthesiology groups in a market area for the purposes of both efficiency and strength in negotiating fees have been very popular as a response to the rapidly changing marketplace. A list of questions must be answered to determine if such a merger would have anticompetitive implications. Although compendia of relevant information are available to anesthesiologists,[39,40,41] they cannot substitute for expert advice and help.

Obviously, anesthesiologists contemplating a merger or facing any one of a great number of other

situations in the modern health care arena must secure assistance from professional advisors, usually attorneys, whose job it is to be aware of the most recent developments, how they apply, and how best to forge agreements in formal contracts. Anesthesiologists hoping to find reputable advisors can start their search with word-of-mouth referrals from colleagues who have used such services. Local or state medical societies frequently know of attorneys who specialize in this area. Finally, the ASA Washington, D.C., office has compiled a state-by-state list of advisors who have worked successfully with anesthesiologists in the past.

Exclusive Service Contracts

Often, one of the larger issues faced by anesthesiologists seeking to define practice arrangements concerns the desirability of considering an exclusive contract with a health care facility to provide anesthesia services. An exclusive contract states that anesthesiologists seeking to practice at a given facility must be members of the group holding the exclusive contract and, usually, that members of the group will practice nowhere else. A hospital may want to give an exclusive contract in return for a guarantee of coverage as part of the contract. Also, the hospital may believe that such a contract can help ensure the quality of the practitioner because the contract can contain credentialing and performance criteria. It is important to understand that the hospital likely will exercise a degree of control over the anesthesiologists with such a contract in force, such as requiring them to participate as providers in any contracts the hospital makes with third-party payers and also tying hospital privileges to the existence of the contract (the so-called "clean sweep provision" that bypasses any due process of the medical staff should the hospital terminate the contract). Certain of these types of provisions constitute *economic credentialing*, which is defined as the use of economic criteria unrelated to the quality of care or professional competency of physicians in granting or renewing hospital privileges (such as the acceptance of below-market fees associated with a hospital-negotiated care contract or even requiring financial contributions in some form to the hospital). The ASA in 1993 issued a statement condemning economic credentialing.[3] The anesthesiologists involved may accept such an exclusive services contract to guarantee that they alone will get the business from the surgeons on staff at that hospital, and hence the resulting income. There may be other considerations on both sides, and these have been outlined in extensive relevant ASA publications that also include a sample contract for information purposes only.[37,40] Although many exclusive contracts with anesthesiology groups are in force, the sentiment, particularly from the ASA, is against them. As has been stated, it is critical that anesthesiologists faced with important practice management decisions such as whether to enter into an exclusive contract must seek outside advice and counsel. There are a great many nuances to these issues,[40,41,42,43] and anesthesiologists are at risk attempting to negotiate such complex matters alone, just as patients would be at risk if a contract attorney attempted to induce general anesthesia.

Denial of hospital privileges as a result of the existence of an exclusive contract with the anesthesiologists in place at the facility has been the source of many lawsuits, including the well-known Louisiana case of *Hyde v. Jefferson Parish.* In that case, the court found for the defendant anesthesiologists and the hospital, saying that there was no antitrust violation because there was no real adverse effect on competition as far as patients were concerned because there were several other hospitals within the market to which they could go, and therefore they could exercise their rights to take advantage of competition in the relevant market. Thus, existence of an exclusive contract only in the rare setting where anticompetitive effects on patients can be proved might lead to a legitimate antitrust claim by a physician denied privileges. This was proven true in the more recent *Kessel v. Monongalia County General Hospital* case in West Virginia in which an exclusive anesthesiology contract was held illegal. Therefore, again, these arrangements are by definition complex and fraught with hazard. Accordingly, outside advice and counsel are always necessary.

Hospital Subsidies

Modern economic realities have forced a significant number of anesthesiology practice groups (in both private and academic settings) to recognize that their patient care revenue, after overhead is

paid, does not provide sufficient compensation to attract and retain the number and quality of staff necessary to provide the expected clinical service (and fulfill any other group/department missions). Attempting to do the same (or more) work with fewer staff may temporarily provide increased financial compensation. Cutting benefits (discretionary personal professional expenses, retirement contributions, or even insurance coverage) may also be a component of a response to inadequate practice revenue. However, the resulting decrements in personal security, in convenience, and in quality of life as far as acute and chronic fatigue, decreased family and recreation time, and tension among colleagues fearful someone else is getting a "better deal" will quickly overcome any brief advantage of a somewhat higher income. Therefore, many practice groups in such situations are requesting their hospital

(or other health care facility where they practice) to pay them a direct cash subsidy that is used to augment practice revenue to maintain benefits and amenities while increasing the pay of staff members, hopefully to a market-competitive level that will promote recruitment and retention of group members.

Obviously, requests by a practice group for a direct subsidy must be thoroughly justified to the facility administration receiving the petition. The group's business operation should already have been examined carefully for any possible defects or means to enhance revenue generation. Explanation of the general trend of declining reimbursements for anesthesia services should be carefully documented. Facts and figures on that and also the shortage of anesthesia providers can be obtained from journal articles and ASA publications, particularly the *Newsletter*. Demand for anesthesia coverage for the surgical schedule is a key component of this proposal. Scheduling and utilization, particularly if early-morning staffing is required for many operating rooms that are routinely unused later during the traditional work day, is a major issue to be understood and presented. Any other OR inefficiencies created by hospital support staff and previous efforts to deal with them should also be highlighted. Unfavorable payer mix impact of contracts and programs initiated by the hospital also often is a major factor in situations of inadequate practice revenue. Always, the group's good will with the surgeons and the community in general should be emphasized, as well as of the indirect or "behind the scenes" services and benefits the anesthesiology group provides to the hospital.

Clearly, any request for a subsidy must be reasonable. An overly aggressive effort beyond the bounds of logic could provoke the facility to consider alternative arrangements, even up to the point of putting out a request for proposal from other anesthesiology practice groups. Therefore, thoughtful calculations are required and a careful balance must be sought, seeking enough financial support to supplement practice revenues so that members' compensation is competitive but not so much as to be excessive. Supporting statements about offers and potential earnings elsewhere must be completely honest and not exaggerated or credibility and good faith will be lost. Further, part of any agreement will be the full sharing of the group's detailed financial information with the facility administration, both at the time of the request and on an ongoing basis if the payment is more than a one-time "bail out." Plans for review and renewal should be made once a subsidy is paid.

Any subsidy will likely require a formal contract. There may be concern about malpractice liability implications for the hospital even though the practice group stays an independent entity as before. There may be "inurement" or "private benefit" concerns that could be perceived as a threat to the tax-exempt status of a nonprofit hospital. Lack of understanding of the applicable laws may lead to fears that a subsidy could be an illegal "kickback" or a violation of the Stark II self-referral prohibition. As is almost always the case, expert outside professional consultant advice, usually from an attorney who specializes exclusively in health care finance contracting, is mandatory in such circumstances. The ASA Washington, D.C., office maintains lists of consultants who have helped other anesthesiologists or groups in the past on various subjects and, also, the ASA has some basic information on subsidies to anesthesiology practice groups.[44,45]

Managed Care and New Practice Arrangements

7 As noted, managed care systems for health care delivery fundamentally exist as a mechanism

to control and then reduce health care costs by having independent reviewers and decision makers who are not the physicians rendering the care limit the health care services delivered to large groups of patients. These ideas represent a huge change for American physicians. For a time, these changes appeared inescapable, not necessarily because of government initiatives, but because of marketplace forces that result from the business community and government entities simply refusing to continue to pay ever-increasing sums for health care. However, there was a dramatic public backlash against the limitations on medical care services, so much so that several states passed laws outlining for certain circumstances what MCOs must pay for. This led to decreased expansion of managed care and to some easing of the restrictions on services in many plans. The overall impact was to slow (but not stop) the adoption of rigidly managed health care and to rekindle anew many of the concerns about how to structure and fund the health care system in this country. Some MCOs were forced to retool their operations and some went out of business entirely. However, many continued operations, albeit more quietly. The degree of penetration of managed care into market areas around the country has been highly variable. Areas such as Minneapolis, San Diego, San Francisco, eastern Massachusetts, and several other northern cities were the first to become mature managed care markets with a significant majority of the population enrolled in one or another managed care health plan. Other parts of the country with very sparsely populated areas such as sections of the Deep South and the West were not much affected because the population density was insufficient to support MCO requirements. An MCO attempts to secure health care provision contracts with employers who provide health plan coverage for their workers and with government agencies (e.g., Medicaid) responsible for the health care of large populations. Each worker or covered head of a household may have dependents covered by the plan. Each person covered in the plan is referred to as a *covered life.* An MCO probably needs contracts for at least 10,000 covered lives and preferably many more to make a legitimate entry into the marketplace. The MCO then enrolls physicians or physician groups and hospitals as providers and contracts to send its enrolled patients (the covered lives) to the health care providers under contract. The central issue is finances. The MCO seeks to enroll covered lives by offering the lowest prices possible. In turn, it seeks to contract with providers (individuals and facilities) for the lowest possible fees for medical care in return for sending large volumes of patient business to those providers.

In the initial stages of the evolution of a

managed care marketplace, the MCOs usually seek contracts with providers based on discounted fee-for-service arrangements. This preserves the basic traditional idea of production-based physician reimbursement (do more, bill more) but the price of each act of services is lower (the providers are induced to give deep discounts with the promise of significant volumes of patients) and, also, the MCO gatekeeper primary care physicians and the MCO reviewers are strongly encouraged to limit complex and costly services as much as possible. There are other features intermittently along the way, such as global fees and negotiated fee schedules (agreed-upon single prices for individual procedures, independent of length or complexity). Further, another element is introduced to encourage the providers, both gatekeepers and specialists, to reduce costs. In an application of the concept of risk-sharing (spend too much for patient care and lose income), this usually is initially manifest in the form of "withholds," the practice of the MCO holding back a fraction of the agreed-upon payment to the providers (e.g., 10 or 15%) and keeping this money until the end of the fiscal year. At that time, if there is any money left in the risk pool or withhold account after all the (partial) provider fees and MCO expenses are paid, it is distributed to the providers in proportion to their degree of participation during the year. This is a clever and powerful incentive to providers to reduce health care expenses. It is not as powerful as the stage of full risk sharing, however. As the managed care marketplace matures and MCOs grow and succeed, the existing organizations and, especially, any new ones, shift to prospective capitated payments for providers.

Prospective Payments

This eventual reimbursement arrangement constitutes an entirely new world to the providers, involving prospective capitated payments for large populations of patients, in which each group of

providers in the MCO receives a fixed amount per enrolled covered life per month (PMPM) and agrees, except in the most unusual circumstances, to provide whatever care is needed by that population for that prospective payment. The most unusual circumstances involve "carve-out" arrangements in which specific very costly and unusual conditions or procedures (such as the birth of a child with disastrous multiple congenital anomalies) are covered separately on a discounted fee-for-service basis. With full capitation, the entire financial underpinning of American medical care does a complete about-face from the traditional rewards for giving more care and doing more procedures to new rewards for giving and doing less. Some managed care contracts contain other features intended to protect the providers against unexpected overutilization by patients that would stretch the providers beyond the bounds of the original contract with the MCO. The provisions setting the boundaries are called "risk corridors," and the "stop-loss clauses" add some discounted fee-for-service payment for the excess care beyond the risk corridor (capitated contract limit). Providers who were used to getting paid more for doing more suddenly find themselves getting paid a fixed amount no matter how much or how little they do with regard to a specified population—hence the perceived incentive to do, and consequently spend, less. If the providers render too much care within the defined boundary of the contract, they essentially will be working for free, the ultimate in risk-sharing. There are clearly potential internal conflicts in such a system,[46] and how patients reacted initially to this radical change in attitude on the part of physicians demonstrated that this overall mechanism is unlikely to be readily embraced by the general public. This has forced some "return to the drawing board" thinking and it is not clear how fully managed care as it was originally constituted will evolve. What is clear is that nothing is settled and there will be ongoing debate about and experimentation in the American health care system.

Health care providers (physicians, health care workers, and facilities), in turn, allied themselves in a wide variety of organizations to create strength and desirable resources to present to the MCOs in contract negotiations. Some of these alliances were formed very quickly, almost in a panic, because of fears by providers that they might get left out of the managed care marketplace and thus deprived of major sources of income or, someday, any income at all. Management service organizations (MSOs) are joint venture network arrangements that do not involve true economic integration among the practitioners, but merely offer common services to physicians who may, as a loosely organized informal group, elect to seek MCO contracts. Preferred provider organizations (PPOs) are network arrangements of otherwise economically independent physicians who form a new corporate entity to seek managed care contracts in which there are significant financial incentives to patients to use the network providers and financial penalties for going to out-of-network providers. This has proved a relatively popular model and appears to be gaining wide acceptance. Physician–hospital organizations (PHOs) are similar entities but involve understandings between groups of physicians and a hospital so that a large package or bundle of services can be constructed as essentially one-stop points of care. Independent practice associations (IPAs) are like PPOs but are specifically oriented toward capitated contracts for covered lives with significant risk-sharing by the providers. Groups (or clinics) without walls are collections of practitioners who fully integrate economically into a single fiscal entity (true partnership) and then compete for MCO contracts on the basis of risk-sharing incentives among the partners. Fully integrated groups or health maintenance organizations (HMOs) house the group of partner provider physicians and associated support staff at a single location for the convenience of patients, a big selling point when they seek MCO contracts.

Changing Paradigm

The questions anesthesiologists face when addressing this alphabet soup of organizations are many and complex, even more complex than those faced by office-based primary care or specialty physicians, because of the interdependent relationships with health care facilities as practice locations and with surgeons. The era of solo independent practitioners may be ending in some locations where MCOs dominate. Small groups of anesthesiologists may find themselves at a competitive disadvantage unless they become part of a vertically integrated (multispecialty) or horizontally integrated (with other anesthesiologists) organization. An extensive compendium of relevant information has been prepared by the ASA.[39] Because it appears likely that many

anesthesiologists in the United States will be affected by managed care, the information in this and related publications[47] is very important. Negotiations with MCOs require expert advice, probably even more so than even the traditional exclusive contracts with hospitals noted earlier. Before any negotiation can even be considered, the MCO must provide significant amounts of information about the covered patient population. The projected health care utilization pattern of a large group of white-collar workers (and their families) from major upscale employers in an urban area will be quite different from that of a rural Medicaid population. Specific demographics and past utilization histories are absolutely mandatory for each proposed population to be covered, and this information should go directly to the advising experts for evaluation, whether the proposed negotiation is for discounted fee-for-service, a fee schedule, global bundled fees, or full capitation.

A component of the shifting thinking in the 1990s was consideration of "value-based anesthesia practice,"[2] an attempt to balance reasonably the relationship of the cost of care and ultimate patient outcomes (with a very strong emphasis on controlling costs). Elaborate modeling was employed to attempt to calculate applicable cost-benefit ratios and thus define the point on a hypothetical curve of care at which the least resource investment would yield the highest quality. A systems approach was carefully applied to attempt to define and track the component elements of both cost and outcome, which would lead to models of the larger concepts of value and quality. Understanding effectiveness and efficiency of the involved processes was essential. Quantifiable outcomes and costs were compared to national benchmarks found in the literature or from surveys. The ultimate goal was application of outcome data to the management (reduction) of costs. Medication choice and utilization by anesthesiologists was a frequently cited example of the potential beneficial application of the tenets of value-based anesthesia practice. Attempts to apply this type of analysis to overall anesthesia morbidity and mortality were complicated by the (fortunate) extreme rarity of significant adverse outcomes and the difficulty of calculating the associated actual incrementally increased costs, as well as of definitively identifying remediable causes that could be prevented through system change. Attempts to assess the relative value of different anesthetic techniques (e.g., regional vs. general) for specific surgical procedures were complicated by problems discovering the true cost of different scenarios. Analysis of the cost of

monitoring revealed the difficulty of determining the total costs saved or incurred by, for example, the insertion of a TEE in a specific patient, and, further, the belief that pulse oximetry has never been "statistically proven" to influence anesthesia outcome provoked questions about its cost and "value" in direct conflict with the fact that it is a universal standard of care. Overall, because "hard number" data readily amenable to rigorous statistical analysis for both the actual costs and the outcomes of anesthesia care have been very difficult, if not impossible, to generate, the widespread applicability of this approach in everyday anesthesia practice remains to be developed.

Significant questions were raised about the reimbursement implications for anesthesiologists of the putative managed care revolution. Again, the ASA assembled a great deal of relevant information, the understanding of which is essential to successful negotiations.[39] Table 2-5 has a list of information an anesthesia practice should have about its activities. Initial consideration of a capitated contract should involve an attempt to take all the data about the existing practice and the proposed MCO-covered population from a "capitation checklist"[39] and translate back from the proposed capitated rate to income figures that would correlate with the existing practice structure, to allow a comparison and an understanding of the relationship of the projected work in the contract to the projected income from it. It is, of course, impossible to suggest dollar values for capitated rates for anesthesiology care because details and conditions vary so widely. One ASA publication[39] used examples, purely for illustrative purposes, involving $2.50 or $4.00 PMPM, but there were unconfirmed reports at the peak of the managed care activities of capitated rates as low as $0.75 PMPM for anesthesiology. Discounted fee-for-service arrangements are easier for anesthesiologists to understand because these are directly referable to existing fee structures. Reports of groups instituting 10 to 50% discounts off the starting point of 80% of usual and customary reimbursement in various practice circumstances were circulated at national meetings of anesthesiologists. Were rigidly controlled fully mature managed care to dominate the practice community, it would be likely that the average income for anesthesiologists would decrease from

past levels. However, it likely also would be true that anesthesiologists would continue to have incomes still above average among all physicians in that market.

Health Insurance Portability and Accountability Act (HIPAA)

All health care professionals in active practice were aware of the April 2003 implementation of the Privacy Rule of the Health Insurance Portability and Accountability Act of 1996 (HIPAA), because of the required significant changes in how medical records and patient information are handled in the day-to-day delivery of health care. The impact on and requirements for anesthesiologists are summarized in a comprehensive publication from the ASA[48] that followed two educational summaries.[49,50]

Attention is focused on "protected health information" (identifiable as from a specific patient by name). Patients must be notified of their privacy rights. Usually this will be covered by the health care facility in which anesthesiologists work, but if separate private records are maintained, separate notification may be necessary. Privacy policies must be created, adopted, and promulgated to all practitioners, all of whom then must be trained in application of those policies. Often, anesthesiology groups can combine with the facilities in which they practice as an "organized health care arrangement" so that the anesthesia practitioners can be covered in part by the HIPAA compliance activities of the facility. A "privacy officer" must be appointed for the practice group. Finally, and most importantly, medical records containing protected health information must be secured so they are not readily available to those who do not need them to render care.

One of the most obvious applications for many anesthesiologists is concern about the assembled preoperative information and charts for tomorrow's cases that frequently were placed prominently in the OR holding area at the end of one work day in readiness for the next day's cases. HIPAA provisions require that all that patient information be locked away overnight. Another classic example is what many ORs refer to as "the board." Often, a large white marker board occupies a prominent wall near the front desk of an operating room suite and the rooms, cases, and personnel assignments are inscribed thereon at the beginning of the day and modified or crossed off as the day progresses. Under HIPAA, patients' names may not be used on such a board if there is any chance that anyone not directly involved in their care could see them. The same is true for similar boards in holding areas and PACUs. Many anesthesiology practices also must apply HIPAA provisions to their billing operations; the details will vary depending on the mechanisms used and a great deal will depend on which type of electronic claims submission software is being used by the billing entity actually submitting the claims.[51] Telephone calls and faxes into offices must be handled specially if containing identifiable patient information. Presentation of patient information for quality assurance or teaching purposes must be free of all identifiers unless specific individual permission has been obtained on prescribed printed forms. Requests for patient information from a wide variety of outside entities, including insurance companies and collection agencies, must be processed in HIPAA-compliant ways. HIPAA policy and actions, as well as enforcement activities, are being developed over time and as situations develop. Particularly because this system depends on patient complaints for both enforcement and policy evolution, it is likely that it will be at least several years until a well-accepted smoothly functioning system is established.

Expansion into Perioperative Medicine, Hospital Care, and Hyperbaric Medicine

As the role of the anesthesiologist changes, new opportunities should be explored. One set of ideas that has been circulating for some time led to serious suggestions that the name of the profession of anesthesiology be changed to "perioperative medicine and pain management." This suggestion illustrates that one prospective significant anesthesiology practice management strategy can be more formal organization of responsibilities for patients in the pre- and postoperative periods.

Some anesthesiologists now function at least some of the time in preoperative screening clinics because of the great fraction care of OR patients who do not spend the night before surgery in the

hospital or who do not come to a hospital at all. In such settings, these anesthesiologists frequently assume a role analogous to that of a primary care physician, planning and executing a workup of one or more significant medical or surgical problems before the patient can reasonably be expected to undergo surgery. More formalized arrangements of this type would involve the creation of designated perioperative clinics operated and staffed by anesthesiologists. Ophthalmologists and orthopedists, for example, would no longer need to try to manage their surgical patients' medical problems themselves or send their patients proposed for surgery to an internist or other primary care provider for "preop clearance" that often has little value in a complex patient facing specific anesthesia challenges that only an experienced anesthesiologist would, by definition, understand. The anesthesiologist would

assume that role at the same time the patient is undergoing preoperative evaluation for anesthesia care.

Likewise, this concept would be excellent for the postoperative period. An anesthesiologist, completely free of OR or other duties, could not only make at least twice-daily rounds on patients after surgery and provide exceedingly comprehensive pain management service, but also could follow the surgical progress and make virtually continuous reports (likely via an electronic medical record or e-mail) to the surgeon's office or alphanumeric pocket communicator. Surgeons would have a much better handle on their patients' progress while having more time to tend to other new patients in the office or the OR. The utilization review and "fast-track protocol" administrators would have a contact person who is not tied up in an OR or office continuously available. Patients would receive much more physician attention and perceive this as actually a significant improvement in their care. Equivalent outpatient or recuperative center services could easily be established. In this regard, some anesthesiologists function as hospitalists for the care of both surgical and medical patients. A fundamental aspect of the practice of anesthesiology is the management of acute problems in the hospital setting. It is logical that anesthesiologists would be among the physicians best suited to provide primary care for patients in the hospital setting. Although the comfort level of anesthesiologists varies in the fields of internal medicine and pediatrics, it is likely that this trend will continue among those anesthesiologists interested and competent in hospital care.

Finally, anesthesiologists have become increasingly involved in the practice of hyperbaric medicine and wound care. This is likely related to the familiarity of anesthesiologists with concepts of gas laws and physics, along with their constant presence in the hospital. The treatment of various medical conditions by the application of oxygen under increased pressure, usually 2 to 3 atmospheres absolute, at one time was one of the most rapidly growing hospital services. Anesthesiologists are among the leaders of this field, with unlimited opportunities for clinical care, teaching, and research. Even a brief discussion of this field is outside the scope of this chapter and interested readers are referred to the Undersea and Hyperbaric Medical Society, http://www.uhms.org.

Creative exploration of new opportunities involving these and other ideas will open new avenues for anesthesiology (or whatever the specialty is eventually called) practice.

OPERATING ROOM MANAGEMENT

8 The role of anesthesiologists in OR management has changed dramatically in the past few years. While not that long ago, most anesthesiologists avoided any responsibilities of administrative duties (contributing significantly to a potentially negative professional image, as noted earlier), more recently many anesthesia practices have pleaded for an expanded role in OR management, both to promote efficiency and also to protect their interests. With the current climate of a considerable shortage of anesthesia providers, hospitals subsidizing many anesthesiology group practices, and an increasing workload, participation in OR management is essentially mandatory. The profession needs to move beyond exclusive attention to what is and always will be the mainstay of our practice, the administration of anesthetics for surgery. The current emphasis on cost containment and efficiency will force anesthesiologists to take an active role in eliminating many dysfunctional aspects of OR practice that were previously ignored. First-

case morning start times have changed from a suggestion to a mandate. Delays of any sort are now carefully scrutinized to eliminate waste and inefficiency. While a helpful cooperative approach from the anesthesiologists may have sufficed in the past, today's anesthesiologists should take an extremely active role in OR management. Real life has demonstrated and management courses teach that strong leadership is necessary for any group to achieve their stated goals. Anesthesiologists should adopt a leading role among the other constituent personnel in the OR team. Together, anesthesiologists, surgeons, OR nurses and technicians, and, increasingly, professional administrators/managers need to determine who is best qualified to be a leader in the day-to-day management of the operating room. Clearly, different groups have different perspectives. However, anesthesiologists are in the best position to see the "big picture," both overall and on any given day. Surgeons are commonly elsewhere before and after their individual cases; nurses and administrators may lack the medical knowledge to make appropriate, timely decisions, often "on the fly." It is the anesthesiologist with the insight, overview, and unique perspective who is best qualified to provide leadership in an OR community. Anesthesiologists must step forward and aggressively seek involvement at the highest level possible in the OR at which they practice. The subsequent recognition and appreciation from the other groups (especially hospital administration) will clearly establish the anesthesiologists as concerned physicians genuinely interested in the welfare of the OR and the institution. Failure to be involved in any leadership role not only negates the desired image of anesthesiologists as concerned physicians, but also may result in a loss of autonomy in practice or a loss of support from the other groups in the OR and the institution overall.

By nature, an OR is a society unto itself with its various constituent groups, interdepartmental dynamics, and uniquely high levels of stress all defining the ebb and flow of the workplace. The essential groups: anesthesia providers, surgeons, OR staff (usually comprising nursing, scrub technicians and other support personnel), hospital administrators and/or professional managers need to develop a working relationship to survive. As diverse as the priorities of these various groups seem, it is imperative that these groups move beyond simple cooperation and construct a friendly efficient work environment that provides high-quality patient care. Because the spectrum of operating rooms varies significantly from the largest regional teaching hospital to the smallest freestanding ambulatory care center, it is difficult to provide anything but the broadest of guidelines for OR management. However, despite each facility's distinct characteristics, many of these principles can be implemented at virtually all institutions.

Organization

Traditionally (although exceptions may be increasing), in virtually every OR setting, neither the anesthesia providers nor the surgeons have been employees of the institution housing the OR. Rarely did either group/service report to a central authority. Even when one or both constituents were employees, they reported through their respective chiefs/chairmen to the chief of the medical staff, not to a hospital administration. Consequently, a natural division existed between the hospital (OR) staff and the physicians practicing there. Anesthesia providers were commonly thrust into a position of being the arbitrator between the surgeons and the OR staff, balancing what both those parties considered reasonable, desirable, and possible.

The symbiotic relationship between anesthesia providers and surgeons remains unchanged. Both groups recognize this fact and also the common goal of having the operating room function in a safe, expeditious manner. The age-old question "Who is in charge of the Operating Room?" still confronts most hospitals/institutions. Because some anesthesia groups are

subsidized by the hospital, the OR organization in such cases has changed accordingly. Many hospital administrators want to have input regarding "Who's in charge of the OR?" with an eye to increasing efficiency and throughput while reducing cost. Their wishes have an even added significance when more of their dollars are involved through the anesthesiology group subsidy. Sometimes there can be no real answer to "Who's in charge?" because of the complexity of the interpersonal relationships in the OR. Some institutions have a professional manager (often a former OR RN) whose sole job is to organize and run the OR. This individual may be vested with

enough authority to be recognized by all as the person in charge. Other institutions ostensibly have a "medical director of the OR." However, the implications to the surgeons that an anesthesiologist is in charge, or vice versa, have caused many institutions to abandon the title or retain the position but assign no authority to it. In such instances, institutions usually resolve disputes through some authority with a physician's perspective. If there is no medical director with authority to make decisions stick, central authority usually resides with the Operating Room Committee, most often populated by physicians, senior nurses, and administrators. Every operating room has this forum for major policy and fiscal decisions. As part of committee function, the standard practices of negotiation, diplomacy, and lobbying for votes are regularly carried out. The impact of such an OR committee varies widely among institutions.

Despite the constantly changing dynamics of the OR management and the frequent major frustrations, anesthesiologists should pursue a greater role in day-to-day management in every possible applicable practice setting. An anesthesiologist who is capable of facilitating the start of cases with minimal delays and solving problems "on the fly" as they arise will be in an excellent position to serve his or her department. Succeeding in this role will have a dramatic positive impact on all the OR constituents. The surgeons will be less concerned about "Who's in charge?" because their cases are getting done. The hospital administration will welcome the effort because they want something extra in return for any money they are now giving to the anesthesiology groups as a subsidy. Furthermore, the OR Committee (or whatever system for dispute resolution is in place) is still functional and has not been circumvented (and will be thankful for the absence of disputes needing resolution).

Some institutions use the term "clinical director of the OR." The person awarded this designation should be a senior-level individual with firsthand knowledge of the OR environment and function. Anesthesiologists have a better understanding of the perioperative process. They possess the medical knowledge to make appropriate decisions. Their intimate association with surgeons and their patients allows them to best allocate resources. According to a survey conducted by the American Association of Clinical Directors (AACD) in 2002, 71% of the respondents reported that an anesthesiologist was designated as the clinical director of the OR.[52]

Those in lines of authority must possess the corresponding responsibility. Who has power over who will determine a great deal about the function of an individual OR. A classic example involves pefusionists for cardiac surgery. In some circumstances, they are employed by the hospital; in others, by the cardiac surgeons; in a few, by the anesthesia group; and some are independent contractors. The organizational logistics of each of the above scenarios need to fulfill the standard functions regarding call, work shifts, policy and procedure for cardiac bypass operations, equipment purchasing, and so forth. Each institution develops its own method for dealing with these issues. Sometimes the system utilized falters and one of the constituents out of power offers to step in (or just seizes control) to rectify the deteriorated situation. Then the process begins anew, under new management. These changes are frequently viewed as healthy for the perfusionists in that previous unresolved issues can be settled (including often a pay raise). The OR that has no such cyclical changes because a very strong central authority prevents them is commonly an unappealing place to work. Problems get brushed aside or ignored until they seem to explode with vengeance onto the scene. The nature of surgery and working in an operating room creates significant stress on the people employed there. This fact remains underappreciated by the outside world but also becomes commonplace for those who work there because the stress is constant and therefore routine. Until an individual steps aside and reflects for a moment, he or she may never realize the odd nature of their workplace and changes they've been through. Because of this burnout-prone, high-stress environment, those in charge need to be understanding, sympathetic, facilitative, and often somewhat parental to all involved. The resulting collegial and supportive work environment will pay many dividends over the long run for all involved.

Other aspects that involve lines of authority also impact the daily function of the OR. Almost always, the OR staff are employees of the hospital/facility. Frequently, the hospital is perceived as being primarily concerned with containing cost and generating more revenue regardless of the situation. From a purely business perspective, paying overtime is more cost efficient than hiring

additional staff to open more operating rooms at 7 AM. This fact often works against the desires of surgeons and anesthesiologists who want more flexibility in their scheduling ability. The topic of adequate nursing and technical support personnel and function frequently dominates many OR committees. The anesthesiologist, whether clinical director or not, who has established his or her reputation as one who has the operating room's best interest in mind is in a good position to help resolve these disputes. Gone are the days when many anesthesia groups/departments have surplus funds to hire additional anesthesia technicians from their budget to help the hospital, demonstrating team spirit, promoting efficiency, and thus ensuring a healthy working relationship with administration. Sometimes, still, surgeons who feel constrained by the lack of institutional support may be able to get together and fund positions (usually dedicated scrub technicians) from their practice income. Regardless of the source of the problem, or its ultimate solution, it remains imperative that all members of the OR "family," led by the responsible anesthesiologists, practice a spirit of cooperation.

Contact and Communication

An important issue for the anesthesia providers in any OR setting is who among the group will be the contact person to interact with the OR and its related administrative functions. In situations where everyone is an independent contractor, there may be a titular chief who by design is the contact person. The anesthesiologist in this role commonly changes yearly to spread the duties among all the members. Large groups or departments that function as the sole providing entity for that hospital/facility often identify an individual as the contact person to act as the voice for the department. Furthermore, these same groups delineate someone on a daily basis to be the clinical director, or the person "running the board." Frequently, this position is best filled by one of a small dedicated fraction of the group (three people, for example) rather than rotating the responsibility among every member of the group. Experienced "board runners" have an instinctually derived better perspective on the nuances of managing the operating schedule in real time. Certain procedures may require specific training (e.g., TEE skills) that not all members of the group possess. Clearly, changes sometimes have to be made to match the ability of the anesthesia provider and the requirements of the procedure when urgent or emergent cases are posted. Another benefit of a very small number of daily clinical directors is a

relative consistency in the application of OR policies, particularly in relationship to the scheduling of cases, especially add-ons. One of the most frustrating aspects to both surgeons and OR personnel is unpredictability and inconsistency in the decisions made by the anesthesia group/department members. A patient deemed unacceptable for surgery by anesthesiologist X on Monday may be perfectly acceptable, in the same medical condition, for anesthesiologist Y on Tuesday. Disagreements are inevitable in any large group. However, day-to-day OR function may be hampered by a large number of these types of circumstances. Having one member of a very small group in charge will lead to more consistency in this process, especially if the "board runner/clinical director" has the authority to switch personnel to accommodate the situation. Without stifling individual practices, philosophies, and comfort levels, a certain amount of consistency applied to similar clinical scenarios will improve OR function immeasurably. These few dedicated directors should be able to accomplish both goals better than a large rotating group.

Another important aspect of OR organization is materials management. The availability of the required supplies for the safe administration of anesthesia needs to be maintained at all times. Usually, the institutional component of the anesthesia service staffs and maintains a location containing the specific supplies unique to the practice of anesthesia ("the workroom"). Objectives necessary for efficient materials management include the standardization of equipment, drugs, and supplies. Avoidance of duplication, volume purchasing, and inventory reduction are also worthwhile. There needs to be coordination with the OR staff as to who is responsible for acquisition of routine hospital supplies such as syringes, needles, tubing, and intravenous fluids. Decisions as to which brands of which supplies to purchase ideally should be made as a group. Often, when several companies compete against each other in an open market, lower prices are negotiable. These negotiations may occur between the anesthesia providers and the hospital administration, or by the physician components of the OR Committee. In many cases, however,

hospitals belong to large buying groups that determine what brands and models of equipment and supplies will be available, with no exceptions possible except at greatly increased cost. Sometimes, this is false economy if the provided items are inferior (cheap) or annoying and, for example, if it routinely takes opening three or four IV cannulae in the process of starting a preop IV as opposed to the higher quality and reliable single one that may cost more per cannula but is less expensive overall because so many fewer will be used. Dispassionate presentation of such logic by a respected "team-player" senior anesthesiologist to the OR Committee or director of materials management may help resolve such conundrums.

Scheduling Cases

Anesthesiologists need to participate in the OR scheduling process at their facility or institution. In some facilities the scheduling office and the associated clerical personnel work under the anesthesia group. Commonly, scheduling falls under the OR staff's responsibility. Direct control of the schedule usually resides with the OR supervisor or charge person, frequently a nurse. Whatever the arrangements, the anesthesia group must have a direct line of communication with the scheduling system. The necessary number of anesthesia providers that must be supplied often changes on a daily basis per the caseload and sometimes due to institutional policy decisions. After-hours calls must be arranged, policy changes factored in, and additions/subtractions to the surgical load (day to day, week to week, and long term as surgical practices come and go in that OR) dealt with as well. These issues are important even when all the anesthesia providers are independently contracted and are not affiliated with each other. In such situations, the titular chief of anesthesia should be the one to act as the link to the scheduling system. When the anesthesia group/department functions as a single entity, the chairman/chief, clinical director, or appointed spokesperson will be the individual who represents his or her group at meetings where scheduling decisions are made in conjunction with the OR supervisors, surgeons, and hospital administrators.

There are as many different ways to create scheduling policies as there are operating room suites. Most hospitals/facilities follow patterns established over the years. Despite all the efforts directed toward its creation, the OR schedule, both weekly time allotments and day-to-day scheduling of specific cases, remains one of the most contentious subjects for the Operating Room Committee or whatever body presides over the operating room. Recognizing the fact that it is impossible to satisfy completely even a moderate percentage of the surgeons involved, the anesthesia group should endeavor to facilitate the process as much as possible. Initially, anesthesiologists need to be sympathetic toward all the surgeons' desires/demands (stated or implied) and attempt to coordinate these requests with the institution's ability to provide rooms, equipment, and staff. Second, the anesthesia group should make every possible effort to provide enough anesthesia services and personnel to meet realistically the goals of the institution. In light of the current shortage of anesthesia providers in this country, these efforts need to be made with a great deal of open communication among all contingencies of the OR Committee as well as every member of the anesthesia group. Failure to do so will result in hard feelings, misunderstandings, and resignations among the anesthesia providers. "After all," they may claim, "the hospital across town will pay me more money for fewer hours!"

Regarding scheduling, surgeons essentially fall into one of three groups. One group wants to operate any time they can get their cases scheduled. This group wants the operating room open 24/7 and doesn't understand why they can't do their case whenever they want to. Another larger group wants "first case of the day" as often as possible so they can get to their offices. A smaller third group wants either the first time slot or an opening following that time slot, a several-hour hiatus, then to return to the OR after office hours to complete additional cases; usually starting after 5 PM. Clearly a compromise among these disparate constituencies must be reached. Obviously, none of these groups can be completely satisfied at the same institution. Anesthesiologists who approach the OR Committee regarding this dilemma with a nonconfrontational attitude will greatly facilitate agreement on a compromise. There will always be a certain amount of both overt and covert politicking by surgeons regarding scheduling.

Types of Schedules

The majority of operating rooms utilize either block scheduling (preassigned guaranteed OR time for a surgeon or surgical service to schedule cases prior to an agreed upon cutoff time, e.g., 24 or 48 hours before) or open scheduling (first come, first serve). Most large institutions have a combination of both. Block scheduling inherently contains several advantageous aspects for creating a schedule. Block scheduling allows for more predictability in the daily OR function as well as an easy review of utilization of allotted time. Historic utilization data should be reviewed with surgeons, OR staff, and the OR Committee to determine its validity. Many operating suites have found it useful to assemble rather comprehensive statistics about what occurs in each OR. Some computerized scheduling systems (see below) are part of a larger computerized perioperative information management system that automatically generates statistics. Graphic examples are 13-month "statistical control charts" or

"run charts" that show the number of cases, number of OR minutes used for those cases (and when: in block, exceeding block, evenings, nights, weekends, etc.), number of cancellations (and multiple other related parameters if desired) by service, by individual surgeon, and total for the current month and the 12 prior months, always with "control limits" (usually two standard deviations from the 13-month moving average) clearly indicated. All these data are valuable in that they generate a clear picture of what is actually going on in the OR rather than just listening to surgeons claim they are busier than ever or supervisors claim they have staff who sit around idle half the day. It is also extremely valuable in that block time allocation should be reviewed periodically and adjusted based on changes, degree of utilization, and projected needs. Inflexible block time scheduling can create a major point of contention if the assigned blocks are not regularly reevaluated. The surgeon or surgical service with the early starting block that habitually runs beyond his or her block time will create problems for the following cases. If this surgeon were made to schedule into the later block on a rotating basis, delays in his or her start caused by others may provoke improved accuracy of his or her subsequent early case postings. Adjustments in availability of block time can also be made in the setting of the "release time," the time prior to the operative date that a given block is declared not full and becomes available for open scheduling. Surgeons prefer as late a release time as possible to maintain their access to their OR block time. However, unused reserved block time wastes resources and prevents another service from scheduling. While a single "release time" rarely fits all circumstances, negotiating service-specific "release times" may lead to improved satisfaction for all. In the ideal system, enough OR time and equipment should exist to provide for each surgical service's genuine needs, while retaining the ability to add to the schedule (via open scheduling) as needed. Such an environment does not exist. Invariably, surgical demand exceeds available block and open time, leading services to request additional block time. When this time is not granted, services perversely then schedule procedures in open time before filling their block time. Surgeons who prefer open time would then be shut out of OR time. Open scheduling may reward those surgeons who run an efficient service, but it also may be a source of problems to those surgeons who have a significant portion of their service arrive unscheduled, for example, orthopedic surgeons. Some degree of flexibility will be necessary whichever system is used. The anesthesia group should adopt a neutral position in these discussions while being realistic about what can be accomplished given the number of operating rooms and the length of the normal operating day.

The handling of the urgent/emergent case posting precipitates a great deal of discussion in most OR environments. There are as many methods to handle this dilemma as there are institutions that provide emergency services. No studies allow determination of exactly what rate of OR utilization is the most cost-effective. However, many institutions subscribe to the following parameters: adjusted utilization rates averaging below 70% are not associated with full use of available block time, wasting resources, while rates above 90% are frequently associated with the need for overtime hours.[53] Different OR constituencies have different comfort zones for degrees of utilization (see Table 2-6). Most institutions cannot afford to have one or two operating rooms staffed and waiting unless there is a reliable steady supply of late open-schedule additions, that is, urgents/emergencies, during the regular work day. A previously agreed upon, clear algorithm

for the acceptance and ordering of these cases will need to be adopted. In general, critical life-threatening emergencies and elective add-ons are fairly straightforward and at the two ends of the spectrum. The critical emergency goes in the next available room whereas the elective case gets added to the end of the schedule. The so-called "urgent" patient requires the most judgment. Individual services should provide guidelines and limitations for their expected "urgent cases." These "add-on case policy" guidelines[54] should be common knowledge to everyone involved in running the operating room. Consequently, these cases, such as ectopic pregnancies, open fractures, the patient with obstructed bowels, and eye injuries, can then be triaged and inserted into the elective schedule as needed with minimal discussion from the delayed surgeon. The surgeons whose "urgent" case is presented as one that must immediately bump another service's patient, yet could wait several hours if it is their own patient that will be delayed, will have to face their own previously agreed-upon standards in a future OR Committee meeting. A simple way to express one logical policy for "urgent" cases (e.g., acute appendicitis, unruptured ectopic pregnancy, intestinal obstruction) is: (1) bump the same surgeon's elective scheduled case; (2) if none, bump a scheduled case on the same service (GYN, General A, etc.); (3) if none, bump a scheduled case from an open-schedule surgical service; and (4) if none, bump a scheduled case from a block-schedule service.[54] Some institutions require the attending surgeon of the posted urgent/emergent patient to speak personally with the surgeon of any bumped case, as opposed to letting the anesthesiologist board runner or charge nurse take the heat for delaying a scheduled case.

TABLE 2-6 OR Utilization "Comfort Zones" of the OR Personnel Constituencies

	▪FACILITY ADMINISTRATION	▪ANESTHESIOLOGY GROUP	▪OR STAFF	▪SURGEONS
Block time utilization				
>100%	++	--	---	----
85–100%	++++	++	-	---
70–84%	+++	++++	+	+/-
55–69%	+	+++	+++	++
<55%	--	-	++	++++
"+" = **favorable;** "-" = **unfavorable**

Another area of burgeoning growth that must be accounted for in the daily work schedule is the non–operating room "off-site" diagnostic test, or therapeutic intervention that requires anesthesia care. In many instances these procedures replace operations that, in the recent past, would have

been posted on the OR schedule as urgent/emergency cases. For example, cerebral aneurysm coiling and CT guided abscess drainage, among other procedures, are done in imaging suites. However, they do require anesthesia care from anesthesia personnel, albeit in a new

location. Additionally, depending on distances involved and logistics, it may even be necessary to assign two people, a primary provider and an attending, exclusively to that remote location when, had the case come to the OR, the attending may have been able to cover another or other cases also. Hospital administration or the OR Committee may try to view these cases as unrelated to OR function and, thus, purely a problem for the anesthesia group to solve. These cases must be treated with the same methodology regarding access and prioritization as all other OR procedures. To apportion hospital-based anesthesia resources reasonably, these "off-site" procedures should be subject to the same guidelines and processes as any other OR posting. Most institutions have added at least one extra anesthetizing location to their formal operating schedule to designate these "off-site" procedures (occasionally with an imaginative name such as "road show," "outfield," or "safari"). For many of these "off-site" cases, there is little or no reimbursement for anesthesia care. Most government plans and insurance carriers will probably not pay for the claustrophobic adult to receive a MAC or even a general anesthetic for an obviously needed diagnostic MRI, as much as the patient, the surgeon, and the hospital benefit from the test results. The anesthesia group, the OR Committee, and the hospital administration need to reach compromises regarding "off-site" procedures, regarding scheduling, allocation of anesthesia resources that would otherwise go to the OR, and even subsidization of the personnel costs to continue this obviously beneficial service.

Computerization

Computerized scheduling will likely benefit every operating room regardless of size. Computerization allows for a faster more efficient method of case posting than any handwritten system. Changes to the schedule can be made quickly without any loss of information. Rearranging the daily schedule is much simpler on a computer than erasing and rewriting on a ledger. Furthermore, most hospitals have adopted a computer-determined time for a given surgical procedure for that particular surgeon. Commonly, this time is the average of the last 10 of the specific procedure (e.g., total knee replacement) with the potential to add a modifier (e.g., it is a redo) that shows a material difference in the projected time length (almost always longer) for one particular patient. Suppose surgeon X has a block time of 8 hours on a given day and wants to schedule four procedures in that allotted time. The computerized scheduling program looks at surgeon X's past performances and determines a projected length for each of the procedures that are identified to the computer, usually by CPT-4 codes or possibly some other code developed locally for frequent procedures done by surgeon X. (Note that the recorded time length includes the turnover time, thus making the case time definition from the time the patient enters the OR until the time any following patient enters that OR [unless an "exception" is entered specifically for an unusual circumstance].) The use of agreed-upon codes instead of just text descriptions helps ensure accuracy because it eliminates any need for the scheduling clerk to guess what the surgeon intends to do. Bookings should not be taken without the accompanying codes. The computer then decides whether surgeon X will finish the four procedures in the allotted block time. If the computer concludes that the fourth case would finish significantly (the definition of which can be determined and entered into the program) beyond the available block time, it will not accept the fourth case into that room's schedule on that particular day. The surgeon will accept the computer's assigned times and adjust accordingly, planning only three cases, or appeal for an "exception" based on some factor not in the booking that is claimed will materially decrease the time needed for at least one of the four cases, which the surgeon must explain to the "exception czar" (anesthesiology clinical director or OR charge nurse) of the day. Note that, routinely, surgeons generally object to having actual past turnover times counted in the case length average. An alternative method has the computer simply add (to each case except the last) a projected turnover time that is agreed upon by all involved at an (often contentious) OR committee meeting. Computerizing the scheduling process significantly reduces any personal biases and smoothes out the entire operating day. The long-standing ritual of late-afternoon

disputes between the surgeons and the anesthesia group and/or OR staff whether to start the last case or not may be eliminated or at least reduced by this more realistic prospective OR scheduling method.

There are many variables to consider in any OR scheduling system. The patient population served and the nature of the institution dictate the overall structure of the OR schedule. Inner-city Level 1 Trauma Centers must accommodate emergencies on a regular basis, 24 hours a day. These centers are unlikely to create a workable schedule more than a day in advance. An ambulatory surgery center serving plastic surgery patients may see only the rare emergency bring-back bleeding patient. Their schedule may be accurate many days in advance with a high degree of expectation that the patient will arrive on time properly prepared for surgery. The anesthesia group at this ambulatory center may rarely have to make changes to the schedule, allowing them to proceed with a fairly predictable daily workload. At the inner-city trauma hospital, a great deal of flexibility and constant communication with the surgeons will be required in an attempt to get the cases done in a reasonable time frame with the inherent constraints placed on the OR staff's resources and the time available. These two extreme examples from opposite ends of the scheduling-process spectrum can provide guidelines for the majority of the institutions that fall somewhere in between. Independent of where an individual operating theater falls in this spectrum, open communication and an honest discussion among the three principle groups involved in OR scheduling is critical in maintaining a smooth functioning operating room. Avoiding the anesthesia–surgery "us versus them" mentality helps keep the schedule on track. Surgeons are frequently viewed as having totally unrealistic expectations of what the operating room is capable of accomplishing. Anesthesiologists are sometimes accused of trying to avoid work when a case is canceled for legitimate medical reasons or turnover between cases is perceived as too slow. The OR staff often feels they are being pushed too hard. These conflicting and contentious attitudes should not and need not dominate the operating room environment. When each of the three contingencies genuinely appreciates the others' points of view and everyone starts working toward a logical common goal—safe, efficient, expedient patient care—then the already stressful OR environment will be a much better place to work.

Beyond open communication, how best to work toward this mutual understanding depends on the particulars of the people involved and the environment, but some ORs report benefits from team-building exercises, leadership retreats, and even OR-wide social events. ORs with a particularly malignant history of finger-pointing and bad feelings among the personnel groups may constitute one of the few instances an outside consultant really may be valuable in that there are workplace psychologists who specialize in analyzing dysfunctional work environments and implementing changes to improve the situation for all involved.

Anesthesia Preoperative Evaluation Clinic

An anesthesia preoperative evaluation clinic (APEC) that provides a comprehensive perioperative medical evaluation usually results in a more efficient running of the operating room

schedule.[55,56] Unanticipated cancellations or delays are avoided when the anesthesia group evaluates complex patients prior to surgery. Even if the patient arrives to the OR on time the day of surgery, inadequate preoperative clearance mandating the ordering of additional tests will consume precious OR time during the delay waiting for results. Cancellations or delays adversely affect the efficiency of any operating room. Subsequent cases in that room, whether for the same or a different surgeon, may get significantly delayed or forced to be squeezed into an already busy schedule on another day. The financial impact of delays or cancellations on the institution is considerable. Revenue is lost with no offsetting absence of expenses. Worse, expenses may actually increase when overtime has to be paid, or the sterile equipment has to be repackaged after having been opened for the canceled procedure. Even worse, the inconvenienced patient and/or surgeon go to another facility.

Optimal timing for preoperative evaluation should be related to the institution's scheduling preferences, patient convenience, and the overall health of the patient. Earlier completion of the preop evaluation may not reduce the overall cancellation rate when compared to a more proximate

evaluation. However, an early evaluation and clearance may well provide a larger pool of patients available to place on the OR schedule (block or open), resulting in a more efficient use of OR time. Additionally, a protocol-driven evaluation process can anticipate possible need for time-consuming investigations (such as a cardiology evaluation for the patient with probable angina). Early recognition of a failed preoperative test allows time for another patient to be moved into the now-vacant time slot. Also, early identification of certain problems requiring special care on the day of surgery (for example, preoperative epidural or PA catheter placement) should lead to fewer unanticipated delays. Unfortunately, many issues precipitating delays are discovered on the day of surgery. Some of these preventable delays are unrelated to the patients' health status. Seemingly simple issues such as verification of a ride home, or incomplete financial information also contribute to unexpected delays. A properly functioning APEC may be able to eliminate a majority of these annoying causes of unnecessary delays.

Regardless of the institutional specifics surrounding the service provided by the APEC, further cost savings can be obtained through its proper usage by the anesthesia group. With only a basic protocol to go on, commonly a full "shotgun" battery of tests is ordered by surgeons to "cover all the bases" for every patient from a specific surgeon or surgical service in the hopes of avoiding last-minute delays on the day of surgery. The APEC frequently reduces dramatically the number of pre-op tests performed by focusing on which diagnostic tests and medical consults are really required for any specific patient. In some circumstances, the APEC may also function as an additional source of revenue for the anesthesia group when a formal preop consult on a complicated patient is ordered well in advance by the surgeon, in the same manner as would have otherwise been directed to a primary care physician for "clearance for surgery." Securing a genuinely relevant medical evaluation of the patient prior to anesthesia and surgery with its subsequent reduction of wasted OR resources and cost containment are not the only benefits of an APEC. The ability to centralize pertinent information including admission precertification/clearance, financial data, diagnostic and laboratory results, consult reports, and preoperative recommendations improves OR function by decreasing the time spent searching for all these items after changes have been made to the schedule. Patient and family education performed by the APEC frequently leads to an increase in patients' overall satisfaction of the perioperative experience. In addition, patient anxiety may be reduced secondary to the more in-depth contact possible inherent in the APEC process when compared to anesthesia practitioners meeting an ambulatory outpatient for the first time in an OR holding area immediately prior to surgery. The APEC model enables the anesthesia group to be more active and proactive in the perioperative process, improving their relations with the other OR constituents. By taking a leading role in establishing and running an APEC, the anesthesia group enhances its reputation as a cooperative, concerned entity by significantly contributing to high-quality patient care as well as the overall efficiency of the operating room function.

Anesthesiology Personnel Issues

In light of the current and future shortage of anesthesia care providers, managing and maintaining a stable supply of anesthesia practitioners promises to dominate the OR landscape for years to come. The 2002 shortfall of anesthesiologists was calculated at 100 to 3,800 and the estimate for 2005 was 500 to 3,900, the range dependent on service demand growth.[34] A survey of hospital administrators revealed that nearly 60% of them are actively recruiting anesthesiologists; over half of them have done so for more than six months.[57] The lean resident recruiting years of the mid- to late 1990's continue to impact the profession. Even though applications to anesthesiology residencies rebounded significantly, it will take many years of relatively large numbers of anesthesia residency graduates to reverse this trend. Furthermore, the supply of nonphysician anesthesia providers is also dwindling. With the aging population of nurse anesthetists and the limited number of applications to schools in that profession, as well as the very limited number of training facilities for anesthesiology assistants, the overall supply of anesthesia providers remains inadequate to meet current and, at least, short-term future demands. The need for anesthesia groups to create a flexible, attractive work environment to retain providers who might leave or retire will continue to increase.

A related issue is consideration of what is a reasonable work load for an anesthesiologist and how best to measure, if possible, the clinical productivity of an anesthesia group/department. These questions have been the subject of considerable discussion.[58,59,60,61] Subjects involve comparisons among members of the anesthesiology group, both against outside benchmarks and also against each other as well as the group as a whole against others, if possible. Beyond the simple number of FTEs, cases, and OR minutes, consideration of factors such as the nature of the facility, types of surgical practice, patient acuity, and speed of the surgeons must be incorporated to allow fair comparisons. Thoughtful filtering of resulting data should take place before dissemination of the aggregate information to all members of a group because of the understandable extreme sensitivity among stressed and fatigued anesthesiologists to a suggestion that they are not working as hard as their group/department peers.

Except in highly unusual circumstances, flexible scheduling of anesthesia providers and also fulfilling the demands placed on the group by the institution continues to be a constant balancing act. This demand assumes added significance because institutions now subsidize many anesthesia groups. Even when a majority of providers in a facility are independent contractors where it is required that a specific surgeon request their services, there are time conflicts ranging from no one at all being available to unwanted downtime. When the anesthesia group/department accepts the responsibility of providing anesthesia services for an institution, they must schedule enough providers for that OR suite on each given day. Ideally, a sufficient number of providers would be hired so that there would always be enough personnel to staff the minimum number of

rooms scheduled on any given day, as well as after-hours call duty. This situation rarely exists because it would be financially disadvantageous to have an excess number of providers with no clinical activity. Having exactly the right number of anesthesia providers in a group for the clinical load works well until one (or more) of them is out with an unplanned absence such as an extended illness or a family emergency. Many academic departments have a natural buffer with some clinicians assigned intervals of nonclinical time for research, teaching, or administrative duties. However, repeated loss of these nonclinical days because of inadequate clinical staffing in the OR leads to undermining the academic/research mission of the department. Continued loss of this time will eventually lead to resignations, thus eliminating the original buffer. Consequently, anesthesia groups/departments need to anticipate available clinical personnel and match them to the operating room demands. Ideally, this information should be accurate for several months into the future. Meeting this specification has become more difficult in the recent past. With sudden major realignments of insurance carriers, changes in managed care, and the constant bidding war for anesthesia providers, predicting both personnel availability and the corresponding operating room case load any length of time into the future may require a crystal ball. There is no easy answer to this dilemma and no clear solution presents itself, except to acknowledge that the situation exists and is likely to continue for the foreseeable future. Hospital administrators must offer reasonable assurances to the anesthesia group providing service that a given OR utilization rate is likely, as well as accurate data regarding reimbursement (payer mix and any package contracts negotiated by the hospital). This data must be provided accurately and updated frequently if a health care institution is to acquire and retain an anesthesia group staffed with the personnel to meet the expected demands.

Timing

Each operating environment has its own personnel scheduling system and expectations for the anesthesia group. Daily coordination between the anesthesia group's clinical director and the OR supervisor permits the construction of a reasonable schedule showing the number of operating rooms that day and when the schedule expects each of them to finish. Invariably, some cases take longer than anticipated, or add-ons are posted requiring the OR to run into the late afternoon or early evening. Many anesthesia providers accept this occurrence as a matter of course. Few anesthesia providers will tolerate this sequence of events as an essentially daily routine whether they are paid overtime or not. These practitioners become exhausted and resent the burdens continuously placed on them. If the OR schedule is such that add-ons frequently occur and elective cases run well into the evening, many anesthesia providers will opt to protect their

personal and family time and cut back their working hours or resign. Neither would be welcome in such a tight market. Under these circumstances, hiring additional personnel who are scheduled to arrive at a later time, for example, 11:00 AM, and then providing lunch relief and staying late (e.g., 7:30 PM or later if needed) to finish the schedule may well be a very worthwhile investment.

Another possible solution to the demands of an extended OR schedule on an anesthesia group's personnel may revolve around employing part-time anesthesia providers. Part-time opportunities could enhance a group's ability to attract additional staff. According to a *New York Times* survey, many medical practitioners (12% of male physicians and 25% of female physicians) currently work fewer than 40 hours a week.[57] In the past, a disproportionately high percentage of women chose anesthesiology as a career. In 1970, women represented 7.6% of the physician population but were 14% of anesthesiologists; much more recently, they make up 45% of the physician population and only 20% of anesthesiologists, proportionately a significant reduction.[62] Beyond the basic demographic shift among all physicians, one likely partial explanation for the decreased number of women anesthesiologists may be the lack of part-time positions, which will hamper an anesthesia groups' ability to attract and keep at least some of the female anesthesia providers.

Scheduling after-hours coverage also adds to the personnel difficulties facing the anesthesia group. The variations of call schemes are endless. The nature of the institution and the workload determine the degree of late night coverage. Major referral centers and Level 1 trauma centers require in-house primary providers. If these providers include residents and/or nurse anesthetists, then the supervising attending staff will also be in-house 24 hours a day. In other less intense settings, the primary provider will be in house with the attending taking call from home (within the boundary of a predetermined maximum arrival time, usually 30 minutes). The number of providers required to take call (in-house or back-up) is always a never-ending topic of animated discussion. Should the call team staff for a minimum, average, or potentially possible number of cases, with a call-in list as further backup? A common solution employed at many institutions is to staff the evening/night call shifts for an average workload, recognizing that on some occasions there will be idle operating rooms, and on other nights, the surgical demand will exceed the call team's numbers, resulting in a scramble. Obviously if this occurs frequently, changes are needed in the number of staff on call.

There are also medicolegal issues surrounding the call team's availability. At a small community hospital with a limited number of independent attending practitioners, the practitioners may agree to cover call on a rotating basis. The individuals not on call are usually not obligated to the OR and may well be truly unreachable. What happens then when the on-call anesthesiologist is administering an anesthetic and another true emergency case arrives in the OR suite and the remaining staff anesthesiologists are legitimately unavailable? Does that anesthesiologist leave his or her current patient under the care of an operating room nurse and go next door to tend to a more acutely (possibly critically) ill patient? Should the patient be transferred from the ER to another (hopefully nearby) hospital? These questions have no easy answers. Clearly, those practitioners on the scene have to assess in real time the relative risks and benefits and make the difficult decisions. This example is but one of the many issues facing any call scheme, whatever the size of the facility and the number of people involved, and the possible scenarios that exist in staffing an operating suite.

A related scheduling issue regarding the evening and night call assignments revolves around what to do with the call team that has worked the previous night. Should they provide anesthesia care the next day? As always, the answers to this question are as varied as there are health care facilities. If the call duty requires the practitioner(s) frequently to work much or all of the night, leaving the individual(s) stressed and fatigued, they should not be required to work the next day during normal working hours. However, if that call team normally works most of the night, but they have not had any cases to do and were able to sleep, it is not unreasonable to expect such individuals to remain in the OR in the morning and help out as long as needed. A more complicated answer involves what to do when the call assignment rarely requires a long night's work and the on-call anesthesia providers routinely have rooms assigned to them the next day, but at least one person has just finished a difficult 24-hour shift being awake working all night.

assignment with the intent of being relieved as soon as possible? Alternatively, should the practitioner go home, with the result of closing or delaying a lineup of scheduled cases, which will bring significant negative feedback to the anesthesiology group? Common sense and reason should guide everyone in such a circumstance. Anesthesia groups need to decide how to handle the possible call shift scenarios, with permutations and combinations, and clearly communicate prospectively their decisions to the OR Committee before any difficult decision has to be made one morning. As always, the medicolegal aspects of any decision such as this need to be taken into consideration. Whether or not fatigue was a factor, the practitioner who worked throughout the night before and appeared to contribute to an anesthetic catastrophe the next morning would have a very difficult defense in court. Further, the anesthesiology group may also be held liable in that their practice/policy was in place, allegedly authorizing the supposedly dangerous conduct.

Cost and Quality Issues

One of the more pervasive aspects of American medical care in today's environment is the drive to maintain and improve high-quality health care while reducing the cost of that care. Health care accounts for approximately 14% of the Gross Domestic Product, nearly triple the fraction a generation ago. Consequently, all physicians, including anesthesiologists, are urged constantly to include cost-consciousness in decisions balancing the natural desire to provide the highest possible quality of care with the overall priorities of both the health care system and the individual patient, all while facing increasingly limited resources.[63] Anesthesiologists remain a target for limiting health care expenditures. Anesthesia providers (directly and indirectly) have represented 3 to 5% of the total health care costs in the country.[64] Anesthesiologists are under more and more pressure to limit expenses. Complicated decisions are required regarding which patients are suitable for ambulatory surgery, what preoperative studies to order, what anesthetic drugs or technique is best for the patient, what monitors or equipment are reasonably required to run an OR, and the list goes on and on. Additionally, anesthesiologists must not lose sight of maintaining the quality of care in this ever-increasing cost-conscious environment in which there is intense production pressure to cut corners that is fueled by the "get away with it" mentality in which it is noted that the vast, vast majority of the time one does something inherently unsafe, nothing bad happens to the patient—setting up some subsequent patient for a potentially catastrophic adverse event when the pressured anesthesiologist does not "get away with it." With this as background, anesthesiologists legitimately can include economic considerations in their decision processes. When presented with multiple options to provide for therapeutic intervention or patient assessment, one should not automatically choose the more expensive approach (just to "cover all the bases") unless there is compelling evidence proving its value. Decisions that clearly materially increase cost should only be pursued when the benefit outweighs the risk. In anesthesia care as well as medicine in general, such decisions can be difficult regarding interventions that provide marginal benefit but contain significant cost increases.[65] To deliver high-quality anesthesia care, anesthesiologists are obliged to consider the goals of the planned intervention, the expectations of all of their customers (patients, surgeons, colleagues, hospital administrators, payers, etc.), and the costs of the anticipated care. Because cost containment initially requires accurate cost awareness, anesthesiologists need to find out in an organized manner, more than ever before, the actual costs and benefits of their anesthesia care techniques. Details will be unique to each practice setting. Because they will be excited that the anesthesiologists actually care, usually it is possible to get the cooperation of the facility administration's financial department members in researching and calculating the actual cost of anesthesia care so that thoughtful evaluations of potential reductions can be initiated.

Anesthesia drug expenses represent a small portion of the total perioperative costs. However, the great number of doses actually administered contributes substantially to aggregate total cost to the institution in actual dollars. Prudent drug selection combined with appropriate anesthetic technique can result in substantial savings. Reducing fresh gas flow from 5 L/minute to 2 L/minute wherever possible would save approximately $100 million annually in the United States.[66] While a majority of anesthesia providers usually attempt a practical approach to cost savings, they are

more frequently faced with difficult choices regarding methods of anesthesia that likely produce similar outcomes but at substantially different cost. When comparing the total costs of more expensive anesthetic drugs and techniques to lesser expensive ones, many variables need to be added to the formula. The cost of anesthetic drugs needs to include the costs of additional equipment such as special vaporizers or extra infusion pumps and the associated maintenance. There are other indirect costs that may be difficult to quantitate and are commonly overlooked. Some of these indirect costs include: increased setup time, possibly increasing room turnover time, extended PACU recovery time, and additional expensive drugs required to treat side effects. Sometimes, more expensive techniques reduce indirect costs. A propofol infusion, while more expensive than vapor, commonly results in a decreased PACU stay for a short noninvasive procedure. If fewer PACU staff are needed or patient throughput is increased, the more expensive drug can reduce overall cost. Conversely, using comparatively expensive propofol for a long procedure definitely requiring postop admission to an ICU is hardly justified. The impact of shorter-acting drugs and those with fewer side effects is context specific. During long surgical procedures, such drugs may offer limited benefits over older less expensive longer-acting alternatives.[67] Under these conditions, advocating cost containment using educational efforts may decrease drug expenditures for several categories of drugs.[68] Drugs in the same therapeutic class have widely varying costs. The acquisition expenses may vary as much as 50-fold in some pharmacological categories. It is estimated that the 10 highest expenditure drugs account for more than 80% of the anesthetic drug costs at some institutions.[69] While newer more expensive drugs may be easier to use, no data exists to support or refute the hypothesis that these drugs provide a "better" anesthetic experience when compared to carefully titrated older less expensive longer-acting drugs in the same class. Many experienced clinicians feel that patients can awaken promptly using a wide variety of general anesthetic techniques when the agents are utilized optimally.

Understanding the cost–benefit ratio for many aspects of and around anesthesia care can be difficult at best. Even when published studies provide information evaluating the outcome of a particular new therapy or intervention, determination of the specific clinical relevance remains easier said than done. Sample size, statistics, methodology, and other analytic issues often confuse the reader, making it complex and difficult to scrutinize the study results and place them in their proper perspective. What may appear a large clinically relevant difference may assume lesser importance if the sample size was too small to achieve statistical significance. Furthermore, seemingly small changes may grow to high statistical significance if the sample size is large enough. Careful attention must be devoted to any study proposing a reduction in relative risk to the patient. For example, if intervention A is associated

with a 25% actual reduction in the incidence of a complication, and intervention B is associated with a 4% actual reduction in the incidence of another complication, both could still be described as producing the same relative improvement despite different clinical application. This approach has profound importance for the analysis of cost-effectiveness. A specific anesthetic or antiemetic might need to be administered to just four patients to decrease one episode of postop nausea/vomiting (intervention A). On the other hand, one would have to use more than 100 costly new spinal needles to prevent one case of postdural puncture headache (intervention B). Calculating the minimum number required to achieve the reported effect helps the clinician determine cost-effectiveness of clinical alternatives.[2,70]

Independent of costs involved, analysis of patient outcomes relevant to the practice of anesthesia permits the anesthesiologist to establish which aspects of care deserve attention. Outcome measures are typically defined as those changes, either favorable or adverse, that occur in actual or potential health status after prior or concurrent care.[71] Health status changes include both physical and physiological parameters (such as death, cardiac arrest, length of PACU stay, postop myocardial infarction, or unexpected intensive care admission), as well as psychosocial functions (patient satisfaction, family issues, or resumption of normal life). Historically, a great deal of attention and money has been dedicated to reducing adverse clinical events. While limiting severe/catastrophic adverse effects remains a noble and worthy cause, anesthesia groups would be well served devoting a significant effort towards reducing common, non–life-threatening

adverse events related to everyday OR anesthesia.[72,73] Improved quality of care and better patient satisfaction is a legitimate yardstick upon which to measure the value of anesthesia services. Focused efforts to avoid major adverse events may dominate an anesthesia group's attention, but it must be acknowledged that other factors, such as attitude and friendliness of the staff, may be equally if not more important than some clinical outcomes.[74] A reduction of serious adverse anesthetic outcomes has a variable economic impact on total costs, depending on different assumptions regarding case mix, the added expense of improving perioperative care and/or preventing complications, the frequency of adverse complications, and the relative costs of the uncomplicated surgery.[75] Nonetheless, reducing minor but common perioperative anesthesia related incidents and complications theoretically can be economically beneficial, since these are significant predictors of PACU utilization in terms of length of PACU stay.[76]

Evaluation of outcomes and their subsequent application to cost analysis can be derived from two principal sources, data published in the literature and data collected from experience. As noted, computerized information management systems are useful tools to track outcomes and analyze the impact on the cost–benefit ledger. Using the collated data, in the same manner as for OR utilization and case load, practitioners can readily apply a statistical process to evaluate outcomes in their practice, possibly including correlation with cost.[2] This information may take on added importance in that published incidence studies may not exist for the specific outcome an anesthesia group is searching for. Cause and effect diagrams can track the parameters involved in the process and relate them to the various outcomes desired. Multiple pertinent examples could be constructed from the now extensive body of literature on the factors contributing to postop nausea and vomiting and the various possible preventions and treatments, many of which involve very expensive medications. Of course, this can be done locally within an institution. Information would be collected and stored in the database. Ideally, the database would identify and track as many variables as needed/possible to delineate sources for possible improvement and its ultimate cost analysis. Once these sources for improvement and the ensuing cost impact are known, the anesthesia group can determine whether or not to pursue changing their practice. Outcomes related to adverse effects can also be monitored. If analysis reveals a significant difference in an adverse outcome among practitioners, after all the other variables such as surgeon, patient mix, and so on, are eliminated, the outcome database can investigate the anesthetic technique utilized by that practitioner. If significant variations are identified, that practitioner would be able to learn of these variations in a non-threatening manner since computer-derived data are used as opposed to a specific case analysis, which might lead that practitioner to feel singled out for public criticism.

Another relevant application of such statistical outcome analysis is its use to improve the quality of a health care process (e.g., the perioperative experience[2]) in general. The principles of continuous quality improvement promoted by Deming[77] are being applied widely in the health care industry. Deming's approach focuses on statistical analysis of quality assessment, specifically evaluating variations in outcome parameters that are deemed meaningful to the target population (e.g. patients anesthetized). Addressing the etiologies of outcome variations rather than indicting the health care process as a whole can help resolve problematical outcome issues discovered in the analysis. If the data reveal an outcome change for the worse, prompt evaluation of the processes involved should immediately ensue with the intention of identifying the cause. Steps to eliminate or reduce the undesired outcomes can be investigated and implemented. If a beneficial change appears, the process variations then responsible for the subsequent improvement should be identified and implemented in other areas if possible. The application of the spirit of this type of beneficial continuous quality assessment and resulting improvement, with or without elaborate statistical analysis, should be an integral ongoing component of every anesthesia practice.

CONCLUSION

Practice and operating room management in anesthesiology today is more complex and more important than ever before. Attention to details that previously either did not exist or were perceived as unimportant can likely make the difference between success and failure in anesthesiology practice.

10 Outlined here are basic descriptions and understandings of many different administrative, organizational, financial, and personnel components and factors in the practice of anesthesiology. Ongoing significant changes in the health care system will provide a continuing array of challenges. Application of the principles presented here will allow anesthesiologists to extrapolate creatively from these basics to their own individual circumstances and then forge ahead in anesthesiology practice that is efficient, effective, productive, collegial, and even fun.

Chapter 3

Experimental Design and Statistics

Nathan Leon Pace

KEY POINTS

1	Statistics and mathematics are the language of scientific medicine.
2	Good research planning includes a clear biologic hypothesis, the specification of outcome variables, the choice of anticipated statistical methods, and sample size planning.
3	To avoid bias in the performance of clinical research, the crucial elements of good research design include concurrent control groups; random allocation of subjects to treatment groups; and blinding of random allocation, patients, caregivers, and outcome assessors.
4	Descriptive (mean, standard deviation, etc.) and inferential statistics (*t* test, confidence interval, etc.) are both essential methods for the presentation of research results.
5	The central limit theorem allows the use of parametric statistics for most statistical testing.
6	Systematic review and meta-analysis can synthesize and summarize the results of smaller, nonsignificant individual studies and permit more powerful inferences.

INTRODUCTION

1 Medical journals are replete with numbers. These include weights, lengths, pressures, volumes, flows, concentrations, counts, temperatures, rates, currents, energies, and forces. The analysis and interpretation of these numbers require the use of statistical techniques. The design of the experiment to acquire these numbers is also part of statistical competence. The need for these statistical techniques is mandated by the nature of our universe, which is both orderly and random at the same time. Probability and statistics have been formulated to solve concrete problems, such as betting on cards, understanding biologic inheritance, and improving food processing. Studies in anesthesia have even inspired new statistics. The development of statistical techniques is manifest in the increasing use of more sophisticated research designs and statistical

tests in anesthesia research.

If a physician is to be a practitioner of scientific medicine, he or she must read the language of science to be able to independently assess and interpret the scientific report. Without exception, the language of the medical report is increasingly statistical. Readers of the anesthesia literature, whether in a community hospital or a university environment, cannot and should not totally depend on the editors of journals to banish all errors of statistical analysis and interpretation. In addition, there are regularly questions about simple statistics in examinations required for anesthesiologists. Finally, certain statistical methods have everyday applications in clinical medicine. This chapter briefly scans some elements of experimental design and statistical analysis.

DESIGN OF RESEARCH STUDIES

The scientific investigator should view himself or herself as an experimenter and not merely as a naturalist. The naturalist goes out into the field ready to capture and report the numbers that flit into view; this is a worthy activity, typified by the *case*

report. Case reports engender interest, suspicion, doubt, wonder, and, one hopes, the desire to experiment; however, the case report is not sufficient evidence to advance scientific medicine. The experimenter attempts to constrain and control, as much as possible, the environment in which he or she collects numbers to test a hypothesis.

Sampling

Two words of great importance to statisticians are *population* and *sample.* In statistical language, each has a specialized meaning. Instead of referring only to the count of individuals in a geographic or political region, population refers to any target group of things (animate or inanimate) in which there is interest. For anesthesia researchers, a typical target population might be mothers in the first stage of labor or head-trauma victims undergoing craniotomy. A target population could also be cell cultures, isolated organ preparations, or hospital bills. A sample is a subset of the target population. Samples are taken because of the impossibility of observing the entire population; it is generally not affordable, convenient, or practical to examine more than a relatively small fraction of the population. Nevertheless, the researcher wishes to generalize from the results of the small sample group to the entire population.

Although the subjects of a population are alike in at least one way, these population members are generally quite diverse in other ways. Since the researcher can work only with a subset of the population, he or she hopes that the sample of subjects in the experiment is representative of the population's diversity. Head-injury patients can have open or closed wounds, a variety of coexisting diseases, and normal or increased intracranial pressure. These subgroups within a population are called *strata.* Often the researcher wishes to increase the sameness or homogeneity of the target population by further restricting it to just a few strata; perhaps only closed and not open head injuries will be included. Restricting the target population to eliminate too much diversity must be balanced against the desire to have the results be applicable to the broadest possible population of patients.

The best hope for a representative sample of the population would be realized if every subject in the population had the same chance of being in the experiment; this is called *random sampling.* If there are several strata of importance, random sampling from each stratum would be appropriate. Unfortunately, in most clinical anesthesia studies researchers are limited to using those patients who happen to show up at their hospitals; this is called *convenience sampling.* Convenience sampling is also subject to the nuances of the surgical schedule, the goodwill of the referring physician and attending surgeon, and the willingness of the patient to cooperate. At best, the convenience sample is representative of patients at that institution, with no assurance that these patients are similar to those elsewhere. Convenience sampling is also the rule in studying new anesthetic drugs; such studies are typically performed on healthy, young volunteers.

Performance

The researcher must define the conditions to which the sample members will be exposed. Particularly in clinical research, one must decide whether these conditions should be rigidly standardized or whether the experimental circumstances should be adjusted or individualized to the patient. In anesthetic drug research, should a fixed dose be given to all members of the sample or should the dose be adjusted to produce an effect or to achieve a specific end point? Standardizing the treatment groups by fixed doses simplifies the research work. There are risks to this standardization, however: (1) a fixed dose may produce excessive numbers of side effects in some patients; (2) a fixed dose may be therapeutically insufficient in others; and (3) a treatment standardized for an experimental protocol may be so artificial that it has no broad clinical relevance, even if demonstrated to be superior. The researcher should carefully choose and report the adjustment/individualization of experimental treatments.

Control Groups

2 Even if a researcher is studying just one experimental group, the results of the experiment are usually not interpreted solely in terms of that one group but are also contrasted and compared with other experimental groups. Examining the effects of a new drug on blood pressure during anesthetic induction is important, but what is more important is comparing those results with the effects of one or more standard drugs commonly used in the same situation. Where can the researcher obtain these comparative data? There are several possibilities: (1) each patient could receive the standard drug under identical experimental circumstances at another time; (2) another group of patients receiving the standard drug could be studied simultaneously; (3) a group of patients could have been studied previously with the standard drug under similar circumstances; and (4) literature reports of the effects of the drug under related but not necessarily identical circumstances could be used. Under the first two possibilities, the control group is contemporaneous—either a *self-control* (crossover) or *parallel control* group. The second two possibilities are examples of the use of *historical controls.*

Because historical controls already exist, they are convenient and seemingly cheap to use. Unfortunately, the history of medicine is littered with the "debris" of therapies enthusiastically accepted on the basis of comparison with past experience. A classic example is operative ligation of the internal mammary artery for the treatment of angina pectoris—a procedure now known to be of no value. Proposed as a method to improve coronary artery blood flow, the lack of benefit was demonstrated in a trial where some patients had the procedure and some had a sham procedure; both groups showed benefit.[1] There is now firm empirical evidence that studies using historical controls usually show a favorable outcome for a new therapy, whereas studies with concurrent controls, that is, parallel control group or self-control, less often reveal a benefit.[2] Nothing seems to increase the enthusiasm for a new treatment as much as the omission of a concurrent control group. If the outcome with an old treatment is not studied simultaneously with the outcome of a new treatment, one cannot know if any differences in results are a consequence of the two treatments, or of unsuspected and unknowable differences between the patients, or of other changes over time in the general medical environment. One possible exception would be in studying a disease that is uniformly fatal (100% mortality) over a very short time.

Random Allocation of Treatment Groups

Having accepted the necessity of an experiment with a control group, the question arises as to the method by which each subject should be assigned to the predetermined experimental groups. Should it depend on the whim of the investigator, the day of the week, the preference of a referring physician, the wish of the patient, the assignment of the previous subject,

he availability of a study drug, a hospital chart number, or some other arbitrary criterion? All such methods have been used and are still used, but all can ruin the purity and usefulness of the experiment. It is important to remember the purpose of sampling: by exposing a small number of subjects from the target population to the various experimental conditions, one hopes to make

conclusions about the entire population. Thus, the experimental groups should be as similar as possible to each other in reflecting the target population; if the groups are different, this introduces a bias into the experiment. Although randomly allocating subjects of a sample to one or another of the experimental groups requires additional work, this principle prevents selection bias by the researcher, minimizes (but cannot always prevent) the possibility that important differences exist among the experimental groups, and disarms the critics' complaints about research methods. Random allocation is most commonly accomplished by the use of computer-generated random numbers.

Blinding

Blinding refers to the masking from the view of patient and experimenters the experimental group to which the subject has been or will be assigned. In clinical trials, the necessity for blinding starts even before a patient is enrolled in the research study; this is called the concealment of random allocation. There is good evidence that, if the process of random allocation is accessible to view, the referring physicians, the research team members, or both are tempted to manipulate the entrance of specific patients into the study to influence their assignment to a specific treatment group[3]; they do so having formed a personal opinion about the relative merits of the treatment groups and desiring to get the "best" for someone they favor. This creates bias in the experimental groups.

Each subject should remain, if possible, ignorant of the assigned treatment group after entrance into the research protocol. The patient's expectation of improvement, a placebo effect, is a real and useful part of clinical care. But when studying a new treatment, one must ensure that the fame or infamy of the treatments does not induce a bias in outcome by changing patient expectations. A researcher's knowledge of the treatment assignment can bias his or her ability to administer the research protocol and to observe and record data faithfully; this is true for clinical, animal, and in vitro research. If the treatment group is known, those who observe data cannot trust themselves to record the data impartially and dispassionately. The appellations *single-blind* and *double-blind* to describe blinding are commonly used in research reports, but often applied inconsistently; the researcher should carefully plan and report exactly who is blinded.

Types of Research Design

Ultimately, research design consists of choosing what subjects to study, what experimental conditions and constraints to enforce, and which observations to collect at what intervals. A few key features in this research design largely determine the strength of scientific inference on the collected data. These key features allow the classification of research reports (Table 3-1). This classification reveals the variety of experimental approaches and indicates strengths and weaknesses of the same design applied to many research problems.

TABLE 3-1 Classification of Biomedical Research Reports

I. Longitudinal studies
    A. Prospective (cohort) studies
        1. Studies of deliberate intervention
            a. Concurrent controls
            b. Historical controls
        2. Observational studies
    B. Retrospective (case-control) studies
II. Cross-sectional studies

The first distinction is between *longitudinal* and *cross-sectional* studies. The former is the study of changes over time, whereas the latter describes a phenomenon at a certain point in time. For example, reporting the frequency with which certain drugs are used during anesthesia is a cross-sectional study, whereas investigating the hemodynamic effects of different drugs during anesthesia is a longitudinal one.

Longitudinal studies are next classified by the method with which the research subjects are selected. These methods for choosing research subjects can be either *prospective* or *retrospective;* these two approaches are also known as *cohort* (prospective) or *case-control* (retrospective). A prospective study assembles groups of subjects by some input characteristic that is thought to change an output characteristic; a typical input characteristic would be the opioid drug administered during anesthesia, for example, remifentanil or fentanyl. A retrospective study gathers subjects by an output characteristic; an output characteristic is the status of the subject after an event, for example, the occurrence of a myocardial infarction. A prospective (cohort) study would be one in which a group of patients undergoing neurological surgery was divided in two groups, given two different opioids (remifentanil or fentanyl), and followed for the development of a perioperative myocardial infarction. In a retrospective (case-control) study, patients who suffered a perioperative myocardial infarction would be identified from hospital records; a group of subjects of similar age, gender, and disease who did not suffer a perioperative myocardial infarction also would be chosen, and the two groups would then be compared for the relative use of the two opioids (remifentanil or fentanyl). Retrospective studies are a primary tool of epidemiology. A case-control study can often identify an association between an input and output characteristic, but the causal link or relationship between the two is more difficult to specify.

Prospective studies are further divided into those in which the investigator performs a deliberate intervention and those in which the investigator merely observes. In a study of *deliberate intervention*, the investigator would choose several anesthetic maintenance techniques and compare the incidence of postoperative nausea and vomiting. If it was performed as an *observational study*, the investigator would observe a group of patients receiving anesthetics chosen at the discretion of each patient's anesthesiologist and compare the incidence of postoperative nausea and vomiting among the anesthetics used. Obviously, in this example of an observational study, there has been an intervention; an anesthetic has been given. The crucial distinction is whether the investigator controlled the intervention. An observational study may reveal differences among treatment groups, but whether such differences are the consequence of the treatments or of other differences among the patients receiving the treatments will remain obscure.

Studies of deliberate intervention are further subdivided into those with concurrent controls and

those with historical controls. Concurrent controls are either a simultaneous parallel control group or a self-control study; historical controls

include previous studies and literature reports. A *randomized controlled trial* is thus a longitudinal, prospective study of deliberate intervention with concurrent controls.

Although most of this discussion about experimental design has focused on human experimentation, the same principles apply and should be followed in animal experimentation. The randomized, controlled clinical trial is the most potent scientific tool for evaluating medical treatment; randomization into treatment groups is relied upon to equally weight the subjects of the treatment groups for baseline attributes that might predispose or protect the subjects from the outcome of interest.

Hypothesis Formulation

3 Whether the research subjects are tissue preparations, animals, or people, the researcher is constantly faced with finding both similarities and differences among the diversities of a group of subjects. The researcher starts the work with some intuitive feel for the phenomenon to be studied. Whether stated explicitly or not, this is the *biologic hypothesis;* it is a statement of experimental expectations to be accomplished by the use of experimental tools, instruments, or methods accessible to the research team. An example would be the hope that isoflurane would produce less myocardial ischemia than fentanyl; the experimental method might be the electrocardiographic determination of ST segment changes. The biologic hypothesis of the researcher becomes a *statistical hypothesis* during research planning. The researcher measures quantities that can vary—variables such as heart rate or temperature or ST segment change. In a statistical hypothesis, statements are made about the relationship among parameters of one or more populations. A *parameter* is a number describing a variable of a population; Greek letters are used to denote parameters. The typical statistical hypothesis can be established in a somewhat rote fashion for every research project, regardless of the methods, materials, or goals. The most frequently used method of setting up the algebraic formulation of the statistical hypothesis is to create two mutually exclusive statements about some parameters of the study population (Table 3-2); estimates for the values for these parameters are acquired by sampling data. In the hypothetical example comparing isoflurane and fentanyl, φ_1 and φ_2 would represent the ST segment changes with isoflurane and with fentanyl. The *null hypothesis* is the hypothesis of no difference of ST segment changes between isoflurane and fentanyl. The *alternative hypothesis* is usually nondirectional, that is, either $\varphi_1 < \varphi_2$ or $\varphi_1 > \varphi_2$; this is known as a two-tail alternative hypothesis. This is a more conservative alternative hypothesis than assuming that the inequality can only be either less than or greater than.

TABLE 3-2 Algebraic Statement of Statistical Hypotheses

$H_0 : \varphi_1 = \varphi_2$ (null hypothesis)
$H_a : \varphi_1 \neq \varphi_2$ (alternative hypothesis)
φ_1 = Parameter estimated from sample of first population
φ_2 = Parameter estimated from sample of second population

Logic of Proof

One particular decision strategy is used almost universally to choose between the null and alternative hypothesis. The decision strategy is similar to a method of indirect proof used in mathematics called *reductio ad absurdum*. If a theorem cannot be proved directly, assume that it is not true; show that the falsity of this theorem will lead to contradictions and absurdities; thus, reject the original assumption of the falseness of the theorem. For statistics, the approach is to assume that the null hypothesis is true even though the goal of the experiment is to show that there is a difference. One examines the consequences of this assumption by examining the actual sample values obtained for the variable(s) of interest. This is done by calculating what is called a *sample test statistic*; sample test statistics are calculated from the sample numbers. Associated with a sample test statistic is a *probability.* One also chooses the *level of significance;* the level of significance is the probability level considered too low to warrant support of the null hypothesis being tested. If sample values are sufficiently unlikely to have occurred by chance (i.e., the probability of the sample test statistic is less than the chosen level of significance), the null hypothesis is rejected; otherwise, the null hypothesis is not rejected.

Because the statistics deal with probabilities, not certainties, there is a chance that the decision concerning the null hypothesis is erroneous. These errors are best displayed in table form (Table 3-3); Condition 1 and Condition 2 could be different drugs, two doses of the same drug, or different patient groups. Of the four possible outcomes, two are clearly undesirable. The error of wrongly rejecting the null hypothesis (false-positive) is called the *type I* or *alpha error.* The experimenter should choose a probability value for alpha before collecting data; the experimenter decides how cautious to be about falsely claiming a difference. The most common choice for the value of alpha is 0.05. What are the consequences of choosing an alpha of 0.05? Assuming that there is, in fact, no difference between the two conditions and that the experiment is to be repeated 20 times, then during one of these experimental replications (5% of 20) a mistaken conclusion that there is a difference would be made. The probability of a type I error depends on the chosen level of significance and the existence or nonexistence of a difference between the two experimental conditions. The smaller the chosen alpha, the smaller will be the risk of a type I error.

TABLE 3-3 Errors in Hypothesis Testing: The Two-Way Truth Table

		·REALITY (POPULATION PARAMETERS)	
		·CONDITIONS 1 AND 2 EQUIVALENT	·CONDITIONS 1 AND 2 NOT EQUIVALENT
Conclusion from Observations (Sample Statistics)	Conditions 1 and 2 equivalent[a]	Correct conclusion	False-negative type II error (beta error)
	Conditions 1 and 2 not equivalent[b]	False-positive type I error (alpha error)	Correct conclusion
[a]Do not reject null hypothesis: Condition 1 = Condition 2.			
[b]Reject null hypothesis: Condition 1 ≠ Condition 2.			

The error of failing to reject a false null hypothesis (false-negative) is called a *type II* or *beta error.* The power of a test is 1 minus beta. The probability of a type II error depends on four factors. Unfortunately, the smaller the alpha, the greater the chance of a false-negative conclusion; this fact keeps the experimenter from automatically choosing a very small alpha. Second, the more variability there is in the populations being compared, the greater the chance of a type II error. This is analogous to listening to a noisy radio broadcast; the more static there is, the harder it will be to discriminate between words. Next, increasing the number of subjects will lower the probability of a type II error. The fourth and most important factor is the magnitude of the difference between the two experimental conditions. The probability of a type II error goes from very high, when there is only a small difference, to extremely low, when the two conditions produce large differences in population parameters.

Sample Size Calculations

Discussion of hypothesis testing by statisticians has always included mention of both type I and type II errors, but researchers have typically ignored the latter error in experimental design. The practical importance of worrying about type II errors reached the consciousness of the medical research community several decades ago.[4] Some controlled clinical trials that claimed to find no advantage of new therapies compared with standard therapies lacked sufficient statistical

power to discriminate between the experimental groups and would have missed an important therapeutic improvement. There are four options for decreasing type II error (increasing statistical power): (1) raise alpha, (2) reduce population variability, (3) make the sample bigger, and (4) make the difference between the conditions greater. Under most circumstances, only the sample size can be varied. Sample size planning has become an important part of research design for controlled clinical trials. Some published research still fails the test of adequate sample size planning.

STATISTICAL TESTING

Statistics is a method for working with *sets* of numbers, a set being a group of objects. Statistics

involves the description of number sets, the comparison of number sets with theoretical models, comparison between number sets, and comparison of recently acquired number sets with those from the past. A typical scientific hypothesis asks which of two methods (treatments), *X* and *Y*, is better. A statistical hypothesis is formulated concerning the sets of numbers collected under the conditions of treatments *X* and *Y.* Statistics provides methods for deciding if the set of values associated with *X* are different from the values associated with *Y.* Statistical methods are necessary because there are sources of variation in any data set, including random biologic variation and measurement error. These errors in the data cause difficulties in avoiding bias and in being precise. Bias keeps the true value from being known and fosters incorrect decisions; precision deals with the problem of the data scatter and with quantifying the uncertainty about the value in the population from which a sample is drawn. These statistical methods are relatively independent of the particular field of study. Regardless of whether the numbers in sets *X* and *Y* are systolic pressures, body weights, or serum chlorides, the approach for comparing sets *X* and *Y* is usually the same.

Data Structure

Data collected in an experiment include the defining characteristics of the experiment and the values of events or attributes that vary over time or conditions. The former are called *explanatory variables* and the latter are called *response variables.* The researcher records his or her observations on data sheets or case record forms, which may be one to many pages in length, and assembles them together for statistical analysis. Variables such as gender, age, and doses of accompanying drugs reflect the variability of the experimental subjects. Explanatory variables, it is hoped, explain the systematic variations in the response variables. In a sense, the response variables are dependent on the explanatory variables.

Response variables are also called *dependent variables.* Response variables reflect the primary properties of experimental interest in the subjects. Research in anesthesiology is particularly likely to have repeated measurement variables, that is, a particular measurement recorded more than once for each individual. Some variables can be both explanatory and response; these are called *intermediate response variables.* Suppose an experiment is conducted comparing electrocardiographic and myocardial responses between five doses of an opioid. One might analyze how ST segments depended on the dose of opioids; here, maximum ST segment depression is a response variable. Maximum ST segment depression might also be used as an explanatory variable to address the more subtle question of the extent to which the effect of an opioid dose on postoperative myocardial infarction can be accounted for by ST segment changes. The mathematical characteristics of the possible values of a variable fit into five classifications (Table 3-4). Properly assigning a variable to the correct data type is essential for choosing the correct statistical technique. For *interval variables*, there is equal distance between successive intervals; the difference between 15 and 10 is the same as the difference between 25 and 20. *Discrete interval data* can have only integer values, for example, age in years, number of live children, or papers rejected by a journal. *Continuous interval data* are measured on a continuum and can be a decimal fraction; for example, blood pressure can be described as accurately as desired (e.g., 136, 136.1, or 136.14 mm Hg). The same statistical techniques are used for discrete and continuous data.

TABLE 3-4 Data Types

▪DATA TYPE	▪DEFINITION	▪EXAMPLES
INTERVAL		
Discrete	Data measured with an integer only scale	Parity, number of teeth

Continuous	Data measured with a constant scale interval	Blood pressure, temperature
CATEGORICAL		
Dichotomous	Binary data	Mortality, gender
Nominal	Qualitative data that cannot be ordered or ranked	Eye color, drug category
Ordinal	Data ordered, ranked, or measured without a constant scale interval	ASA physical status score, pain score

Putting observations into two or more discrete categories derives *categorical variables*; for statistical analysis, numeric values are assigned as labels to the categories. *Dichotomous data* allow only two possible values, for example, male versus female. *Ordinal data* have three or more categories that can logically be ranked or ordered; however, the ranking or ordering of the variable indicates only relative and not absolute differences between values; there is not necessarily the same difference between American Society of Anesthesiologists Physical Status score I and II as there is between III and IV. Although ordinal data are often treated as interval data in choosing a statistical technique, such analysis may be suspect; alternative techniques for ordinal data are available. *Nominal variables* are placed into categories that have no logical ordering. The eye colors blue, hazel, and brown might be assigned the numbers 1, 2, and 3, but it is nonsense to say that blue < hazel < brown.

Descriptive Statistics

4 A typical hypothetical data set could be a sample of ages (the variable) of 12 residents in an anesthesia training program (the population). Although the results of a particular experiment might be presented by repeatedly showing the entire set of numbers, there are concise ways of summarizing the information content of the data set into a few numbers. These numbers are called *sample* or *summary statistics;* summary statistics are calculated using the numbers of the sample. By convention, the symbols of summary statistics are Roman letters. The two summary statistics most frequently used for interval variables are the *central location* and the *variability*, but there are other summary statistics. Other data types have analogous summary statistics. Although the first purpose of descriptive statistics is to describe the sample of numbers obtained, there is also the desire to use the summary statistics from the sample to characterize the population from which the sample was obtained. For example, what can be said about the age of all anesthesia residents from the information in a sample? The population also has measures of central location and variability called the parameters of the population; as previously mentioned, population parameters are denoted by Greek letters. Usually, the population parameters cannot be directly calculated, because data from all population members cannot be obtained. The beauty of properly chosen summary statistics is that they are the best possible estimators of the population parameters.

5 These sampling statistics can be used in conjunction with a probability density function to provide additional descriptions of the sample and its population. Also commonly described as a probability distribution, a probability density function is an algebraic equation, $f(x)$, which gives a theoretical percentage distribution of x. Each value of x has a probability of occurrence given by

f(x). The most important probability distribution is the *normal* or *Gaussian function.* There are two parameters (population mean and population variance) in the equation of the normal function that are denoted μ and σ^2. Often called the normal equation, it can be plotted and produces the familiar bell-shaped curve. Why are the mathematical properties of this curve so important to biostatistics? First, it has been empirically noted that when a biologic variable is sampled repeatedly, the pattern of the numbers plotted as a histogram resembles the normal curve; thus, most biologic data are said to follow or to obey a normal distribution. Second, if it is reasonable to assume that a sample is from a normal population, the mathematical properties of the normal equation can be used with the sampling statistic estimators of the population parameters to describe the sample and the population. Third, a mathematical theorem (the central limit theorem) allows the use of the assumption of normality for certain purposes, even if the population is not normally distributed.

Central Location

The three most common summary statistics of central location for interval variables are the arithmetic *mean*, the *median*, and the *mode.* The mean is merely the average of the numbers in the data set. Being a summary statistic of the sample, the arithmetic mean is denoted by the Roman letter x under a bar:

$$\bar{x} = \sum_{i=1}^{n} x_i$$

If all values in the population could be obtained, then the population mean μ could be calculated similarly. Because all values of the population cannot be obtained, the sample mean is used. (Statisticians describe the sample mean as the unbiased, consistent, minimum variance, sufficient estimator of the population mean. Estimators are denoted by a hat over a roman letter, for example

$\hat{x}$

. Thus, the sample mean

$\bar{x}$

is the estimator

$\hat{x}$

of the population mean μ.)

The median is the middlemost number or the number that divides the sample into two equal parts. The median is obtained by first ranking the sample values from lowest to highest and then counting up halfway. The concept of ranking is used in nonparametric statistics. A virtue of the median is that it is hardly affected by a few extremely high or low values. The mode is the most popular number of a sample, that is, the number that occurs most frequently. A sample may have ties for the most common value and be bi- or polymodal; these modes may be widely separated or adjacent. The raw data should be inspected for this unusual appearance. The mode is always mentioned in discussions of descriptive statistics, but it is rarely used in statistical practice.

Spread or Variability

Any set of interval data has variability unless all the numbers are identical. The range of ages from lowest to highest expresses the largest difference. This spread, diversity, and variability can also be expressed in a concise manner. Variability is specified by calculating the *deviation* or *deviate* of each individual x_i from the center (mean) of all the x_i's. The *sum of the squared deviates* is always positive unless all set values are identical. This sum is

then divided by the number of individual measurements. The result is the *averaged squared deviations;* the average squared deviation is ubiquitous in statistics.

The concept of describing the spread of a set of numbers by calculating the average distance from each number to the center of the numbers applies to both a sample and a population; this average squared distance is called the *variance.* The population variance is a parameter and is represented by σ^2. As with the population mean, the population variance is not usually known and cannot be calculated. Just as the sample mean is used in place of the population mean, the sample variance

is used in place of the population variance. The sample variance is:

$$s^2 = \frac{\sum_{i=1}^{n} (x_i - \bar{x})^2}{(n-1)}$$

Statistical theory demonstrates that if the divisor in the formula for s^2 is (n - 1) rather than n, the sample variance is an unbiased estimator of the population variance. While the variance is used extensively in statistical calculations, the units of variance are squared units of the original observations. The square root of the variance has the same units as the original observations; the square roots of the sample and population variances are called the *sample* and *population standard deviations*.

It was previously mentioned that most biologic observations appear to come from populations with normal distributions. By accepting this assumption of a normal distribution, further meaning can be given to the sample summary statistics (mean and standard deviation) that have been calculated. This involves the use of the expression $\bar{x}$ ± k × s, where k = 1, 2, 3, etc. If the population from which the sample is taken is unimodal and roughly symmetric, then the bounds for 1, 2, and 3 encompasses roughly 68%, 95%, and 99% of the sample and population members.

Confidence Intervals

A confidence interval describes how likely it is that the population parameter is estimated by any particular sample statistic such as the mean. (The technical definition of confidence interval is more rigorous. A 95% confidence interval implies that if the experiment were done over and over again, then 95 of each 100 confidence intervals would be expected to contain the true value of the mean.) Confidence intervals are a range of the following form: summary statistic ± (confidence factor) × (precision factor).

The *precision factor* is derived from the sample itself, whereas the *confidence factor* is taken from a probability distribution and also depends on the specified confidence level chosen. For a sample of interval data taken from a normally distributed population for which confidence intervals are to be chosen for $\bar{x}$, the precision factor is called the *standard error of the mean* and is obtained by dividing s by the square root of the sample size:

$$SE = \frac{s}{\sqrt{n}} = \sqrt{\sum_{i=1}^{n} (x_i - \bar{x})^2 \Big/ n(n-1)}$$

The confidence factors are the same as those used for the dispersion or spread of the sample and are obtained from the normal distribution. The confidence intervals for confidence factors 1, 2, and 3 have roughly a 68%, 95%, and 99% chance of containing the population mean. Strictly speaking, when the standard deviation must be estimated from sample values, the confidence factors should be taken from the *t distribution*, another probability distribution. These coefficients will be larger than those used above. This is usually ignored if the sample size is reasonable, for example, $n > 25$. Even when the sample size is only five or greater, the use of the coefficients 1, 2, and 3 is simple and sufficiently accurate for quick mental calculations of confidence intervals on parameter estimates.

Almost all research reports include the use of SE, regardless of the probability distribution of the populations sampled. This use is a consequence of the central limit theorem—one of the most remarkable theorems in all of mathematics. The central limit theorem states that the SE can always be used, if the sample size is sufficiently large, to specify confidence intervals around the sample mean containing the population mean. These confidence intervals are calculated as described above. This is true even if the population distribution is so different from normal that s cannot be used to characterize the dispersion of the population members. Only rough guidelines can be given for the necessary sample size; for interval data, 25 and above is large enough and 4

and below is too small.

Although the SE is discussed along with other descriptive statistics, it is really an inferential statistic. Standard error and standard deviation are mentioned together because of their similarities of computation and because of the confusion of their use in research reports. This use is most often of the form "mean ± number;" some confusion results from the failure of the author to specify whether the number after the ± sign is the one or the other. More important, the choice between using *s* and using SE has become controversial; because SE is always less than *s*, it has been argued that authors seek to deceive by using SE to make the data look better than they really are. The choice is actually simple. When describing the spread, scatter, or dispersion of the sample, use the standard deviation; when describing the precision with which the population center is known, use the standard error.

Proportions

Categorical binary data, also called *enumeration data*, provide counts of subject responses. Given a sample of subjects of whom some have a certain characteristic (e.g., death, female sex), a ratio of responders to the number of subjects can be easily calculated as $p = x/n$; this ratio or rate can be expressed as a decimal fraction or as a percentage. It should be clear that this is a measure of central location of a binary data in the same way that μ was a measure of central location for continuous data. In the population from which the sample is taken, the ratio of responders to total subjects is a population parameter, denoted π; π is the measure of central location for the population. This is not related to the geometry constant pi (π = 3.14159K). As with other data types, π is usually not known but must be estimated from the sample. The sample ratio *p* is the best estimate of π. The probability of binary data is provided by the *binomial distribution function*.

Since the population is not generally known, the experimenter usually wishes to estimate π by the sample ratio *p* and to specify with what confidence π is known. If the sample is sufficiently large ($n \times p \geqslant 5$; $n \times (1 - p) \geqslant 5$), advantage is taken of the central limit theorem to derive a standard error analogous to that derived for interval data:

$$SE = \sqrt{\frac{p \times (1 - p)}{n}}$$

This sample standard error is exactly analogous to the sample standard error of the mean for interval data, except that it is

a standard error of the proportion. Just as a 95% confidence limit of the mean was calculated, so may a confidence limit on the proportion may be obtained. Larger samples and rates closer to 0.5 will make the confidence intervals more and more precise.

Inferential Statistics

There are two major areas of statistical inference: the estimation of parameters and the testing of hypotheses. The use of the SE to create confidence intervals is an example of *parameter estimation.* The testing of hypotheses or *significance testing* is the main focus of inferential statistics. Hypothesis testing allows the experimenter to use data from the sample to make inferences about the population. Statisticians have created formulas that use the values of the samples to calculate test statistics. Statisticians have also explored the properties of various theoretical probability distributions. Depending on the assumptions about how data are collected, the appropriate probability distribution is chosen as the source of critical values to accept or reject the null hypothesis. If the value of the test statistic calculated from the sample(s) is greater than the critical value, the null hypothesis is rejected. The critical value is chosen from the appropriate probability distribution after the magnitude of the type I error is specified.

There are parameters within the equation that generate any particular probability distribution; for the normal probability distribution, the parameters are μ and σ^2. For the normal distribution, each set of values for μ and σ^2 will generate a different shape for the bell-like normal curve. All probability distributions contain one or more parameters and can be plotted as curves; these parameters may be discrete (integer only) or continuous. Each value or combination of values for

these parameters will create a different curve for the probability distribution being used. Thus, each probability distribution is actually a family of probability curves. Some additional parameters of theoretical probability distributions have been given the special name *degrees of freedom* and are represented by the letters *m*, *n*, *p*, and *s*.

Associated with the formula for computing a test statistic is a rule for assigning integer values to the one or more parameters called degrees of freedom. The number of degrees of freedom and the value for each degree of freedom depend on (1) the number of subjects, (2) the number of experimental groups, (3) the specifics of the statistical hypothesis, and (4) the type of statistical test. The correct curve of the probability distribution from which to obtain a critical value for comparison with the value of the test statistic is obtained with the values of one or more degrees of freedom.

To accept or reject the null hypothesis, the following steps are performed: (1) confirm that experimental data conform to the assumptions of the intended statistical test; (2) choose a significance level (alpha); (3) calculate the test statistic; (4) determine the degree(s) of freedom; (5) find the critical value for the chosen alpha and the degree(s) of freedom from the appropriate probability distribution; (6) if the test statistic exceeds the critical value, reject the null hypothesis; (7) if the test statistic does not exceed the critical value, do not reject the null hypothesis. There are general guidelines that relate the variable type and the experimental design to the choice of statistical test (Table 3-5).

TABLE 3-5 When to Use What

▪VARIABLE TYPE	▪ONE-SAMPLE TESTS	▪TWO-SAMPLE TESTS	▪MULTIPLE-SAMPLE TESTS
Dichotomous or nominal	Binomial distribution	chi-square test, Fisher's Exact test	chi-square test
Ordinal	chi-square test	chi-square test, nonparametric tests	chi-square test, nonparametric tests
Continuous or discrete	*z* distribution or *t* distribution	Unpaired *t* test, paired *t* test, nonparametric tests	Analysis of variance, nonparametric analysis of variance

Dichotomous Data

In the experiment negating the value of mammary artery ligation, 5 of 8 patients (62.5%) having ligation showed benefit while 5 of 9 patients (55.6%) having sham surgery also had benefit.[1] Is this difference real? This experiment sampled patients from two populations—those having the real procedure and those having the sham procedure; the display of such results is usually presented as a contingency table (Table 3-6). A variety of statistical techniques allow a comparison of the success rate. These include *Fishers exact test* and (*Pearson's) chi-square test*. The chi-square test offers the advantage of being computationally simpler; it can also analyze contingency tables with more than two rows and two columns; however, certain assumptions of sample size and response rate are not achieved by this experiment. Fishers exact test fails to reject the null hypothesis for this data.

TABLE 3-6 Mammary Artery Ligation for Angina Pectoris

	·TREATMENT	
·OUTCOMES	·ACTUAL LIGATION	·SHAM LIGATION
Improved	5 (62.5%)	5 (55.6%)
Not improved	3 (37.5%)	4 (44.4%)
Fishers exact test: p >> 0.05.		
Rate Ratio = 62.5%/55.6% = 1.125, 95% Confidence Interval (0.47 to 2.7); p >> 0.05.		

The results of such experiments are often presented as rate ratios. The ratio of improvement for the experimental group (62.5%) is divided by the ratio of improvement for the control group (55.6%). A rate ratio of 1.00 (100%) fails to show a difference of benefit or harm between the two groups. In this example the rate ratio is 1.125. Thus the experimental group had a 112.5% chance of improvement compared to the control group. A confidence interval can be calculated for the rate ratio; in this example it is widely spread to either side of the 1—a confidence interval of no difference.

Interval Data

Parametric statistics are the usual choice in the analysis of interval data, both discrete and continuous. The purpose of such analysis is to test the hypothesis of a difference between population means. The population means are unknown and are estimated by the sample means. A typical example would be

the comparison of the mean heart rates of patients receiving and not receiving atropine. Parametric test statistics have been developed by using the properties of the normal probability distribution and two related probability distributions, the *t* and the *F* distributions. In using such parametric methods, the assumption is made that the sample or samples is/are drawn from population(s) with a normal distribution. The parametric test statistics that have been created for interval data all have the form of a ratio. In general terms, the numerator of this ratio is the variability of the means of the samples; the denominator of this ratio is the variability among all the members of the samples. These variabilities are similar to the variances developed for descriptive statistics. The test statistic is thus a ratio of variabilities or variances. All parametric test statistics are used in the same fashion; if the test statistic ratio becomes large, the null hypothesis of no difference is rejected. The critical values against which to compare the test statistic are taken from tables of the three relevant probability distributions. By definition, in hypothesis testing, at least one of the population means is unknown, but the population variance (s) may or may not be known. Parametric statistics can be divided into two groups according to whether or not the population variances are known. If the population variance is known, the test statistic used is called the *z* score; critical values are obtained from the normal distribution. In most biomedical applications, the population variance is rarely known and the *z* score is little used.

T TEST

An important advance in statistical inference came early in the twentieth century with the creation of *Student's t test statistic* and the *t distribution*, which allowed the testing of hypotheses when the population variance is not known. The most common use of Student's *t* test is to compare the

mean values of two populations. There are two types of *t* test. If each subject has two measurements taken, for example, one before (x_i) and one after a drug (y_i), then a one sample or *paired t test* procedure is used; each control measurement taken before drug administration is paired with a measurement in the same patient after drug administration. Of course, this is a self-control experiment. This pairing of measurements in the same patient reduces variability and increases statistical power. The difference $d_i = x_i - y_i$ of each pair of values is calculated and the average

$$\bar{d}$$

is calculated. In the formula for Student's *t* statistic, the numerator is

$$\bar{d}$$

, whereas the denominator is the standard error of

$$\bar{d}$$

(*SE*

$$\bar{d}$$

):

$$t = \frac{\bar{d}}{SE_{\bar{d}}}$$

All *t* statistics are created in this way; the numerator is the difference of two means, whereas the denominator is the standard error of the two means. If the difference between the two means is large compared with their variability, then the null hypothesis of no difference is rejected. The critical values for the *t* statistic are taken from the *t* probability distribution. The *t* distribution is symmetric and bell-shaped but more spread out than the normal distribution. The *t* distribution has a single integer parameter; for a paired *t* test, the value of this single degree of freedom is the sample size minus one. There can be some confusion about the use of the letter *t.* It refers both to the value of the test statistic calculated by the formula and to the critical value from the theoretical probability distribution. The critical *t* value is determined by looking in a *t* table after a significance level is chosen and the degree of freedom is computed.

More commonly, measurements are taken on two separate groups of subjects. For example, one group receives blood pressure treatment (x_i), whereas no treatment is given to a control group (y_i). The number of subjects in each group might or might not be identical; regardless of this, in no sense is an individual measurement in the first group matched or paired with a specific measurement in the second group. An *unpaired* or *two-sample t test* is used to compare the means of the two groups. The numerator of the *t* statistic is

$$\bar{x}$$

-

$$\bar{y}$$

. The denominator is a weighted average of the SEs of each sample. The degree of freedom for an unpaired *t* test is calculated as the sum of the subjects of the two groups minus two. As with the paired *t* test, if the *t* ratio becomes large, the null hypothesis is rejected.

Multiple Comparisons and Analysis of Variance

Experiments in anesthesia, whether they are with humans or with animals, may not be limited to one or two groups of data for each variable. It is very common to follow a variable longitudinally; heart rate, for example, might be measured five times before and during anesthetic induction. These are also called repeated measurement experiments; the experimenter will wish to compare changes between the initial heart rate measurement and those obtained during induction. The experimental design might also include several groups receiving different induction drugs, for example, comparing heart rate across groups immediately after laryngoscopy. Researchers have mistakenly handled these analysis problems with the *t* test. If heart rate is collected five times, these collection times could be labeled *A*, *B*, *C*, *D*, and *E.* Then *A* could be compared with *B*, *C*, *D*, and *E; B* could be compared with *C*, *D*, and *E;* and so forth. The total of possible pairings is ten; thus, ten paired *t* tests could be calculated for all the possible pairings of *A*, *B*, *C*, *D*, and *E.* A similar approach can be used for comparing more than two groups for unpaired data.

The use of *t* tests in this fashion is inappropriate. In testing a statistical hypothesis, the experimenter sets the level of type I error; this is usually chosen to be 0.05. When using many *t* tests, as in the example given earlier, the chosen error rate for performing all these *t* tests is

much higher than 0.05, even though the type I error is set at 0.05 for each individual comparison. In fact, the type I error rate for all *t* tests simultaneously, that is, the chance of finding at least one of the multiple *t* test

statistics significant merely by chance, is given by the formula $\alpha = 1 - 0.95^k$. If 13 *t* tests are performed (k = 13), the real error rate is 49%. Applying *t* tests over and over again to all the possible pairings of a variable will misleadingly identify statistical significance when there is, in fact, none.

The most versatile approach for handling comparisons of means between more than two groups or between several measurements in the same group is called *analysis of variance* and is frequently cited by the acronym ANOVA. Analysis of variance consists of rules for creating test statistics on means when there are more than two groups. These test statistics are called *F ratios*, after Ronald Fisher; the critical values for the *F* test statistic are taken from the *F* probability distribution that Fisher derived.

Suppose that data for three groups are obtained. What can be said about the mean values of the three target populations? The *F* test is actually asking several questions simultaneously: is group 1 different from group 2; is group 2 different from group 3; and is group 1 different from group 3? As with the *t* test, the *F* test statistic is a ratio; in general terms, the numerator expresses the variability of the mean values of the three groups, whereas the denominator expresses the average variability or difference of each sample value from the mean of all sample values. The formulas to create the test statistic are computationally elegant but are rather hard to appreciate intuitively. The *F* statistic has two degrees of freedom, denoted *m* and *n;* the value of *m* is a function of the number of experimental groups; the value for *n* is a function of the number of subjects in all experimental groups. The analysis of multigroup data is not necessarily finished after the ANOVAs are calculated. If the null hypothesis is rejected and it is accepted that there are differences among the groups tested, how can it be decided where the differences are? A variety of techniques are available to make what are called multiple comparisons after the ANOVA test is performed.

Robustness and Nonparametric Tests

Most statistical tests depend on certain assumptions about the nature of the distribution of values in the underlying populations from which experimental samples are taken. For the parametric statistics, that is, *t* tests and analysis of variance, it is assumed that the populations follow the normal distribution. However, for some data, experience or historical reasons suggest that these assumptions of a normal distribution do not hold; some examples include proportions, percentages, and response times. What should the experimenter do if he or she fears that the data are not normally distributed?

The experimenter might choose to ignore the problem of nonnormal data and inhomogeneity of variance, hoping that everything will work out. Such insouciance is actually a very practical and reasonable approach to the problem. Parametric statistics are called "robust" statistics; they stand up to much adversity. To a statistician, robustness implies that the magnitude of type I errors is not seriously affected by ill-conditioned data. Parametric statistics are sufficiently robust that the accuracy of decisions reached by means of *t* tests and analysis of variance remains very credible, even for moderately severe departures from the assumptions.

Another possibility would be to use statistics that do not require any assumptions about probability distributions of the populations. Such statistics are known as *nonparametric tests;* they can be used whenever there is very serious concern about the shape of the data. Nonparametric statistics are also the tests of choice for ordinal data. The basic concept behind nonparametric statistics is the ability to rank or order the observations; nonparametric tests are also called *order statistics.*

Most nonparametric statistics still require the use of theoretical probability distributions; the critical values that must be exceeded by the test statistic are taken from the binomial, normal, and chi-square distributions, depending on the nonparametric test being used. The *nonparametric*

sign test, *Mann-Whitney rank sum test*, and *Kruskal-Wallis one-way analysis of variance* are analogous to the paired *t* test, unpaired *t* test, and one-way analysis of variance, respectively. The currently available nonparametric tests are not used more commonly because they do not adapt well to complex statistical models and because they are less able than parametric tests to distinguish between the null and alternative hypotheses if the data are, in fact, normally distributed.

Interpretation of Results

Scientific studies do not end with the statistical test. The experimenter must submit an opinion as to the generalizability of his or her work to the rest of the world. Even if there is a statistically significant difference, the experimenter must decide if this difference is medically or physiologically important. Statistical significance does not always equate with biologic relevance. The questions an experimenter should ask about the interpretation of results are highly dependent on the specifics of the experiment. First, even small, clinically unimportant differences between groups can be detected if the sample size is sufficiently large. On the other hand, if the sample size is small, one must always worry that identified or unidentified confounding variables may explain any difference; as the sample size decreases, randomization is less successful in assuring homogenous groups. Second, if the experimental groups are given three or more doses of a drug, do the results suggest a steadily increasing or decreasing dose-response relationship? Suppose the observed effect for an intermediate dose is either much higher or much lower than that for both the highest and lowest dose; a dose-response relationship may exist, but some skepticism about the experimental methods is warranted. Third, for clinical studies comparing different drugs, devices, and operations on patient outcome, are the patients, clinical care, and studied therapies sufficiently similar to those provided at other locations to be of interest to a wide group of practitioners? This is the distinction between *efficacy*—does it work under the best (research) circumstances—and *effectiveness*—does it work under the typical circumstances of routine clinical care. Finally, in comparing alternative therapies, the confidence that a claim for a superior therapy is true depends on the study design. The strength of the evidence concerning efficacy will be least for an anecdotal case report; next in importance will be a retrospective study, then a prospective series of patients compared with historical controls, and finally a randomized, controlled clinical trial. The greatest strength for a therapeutic claim is a series of randomized, controlled clinical trials confirming the same hypothesis. There is now considerable enthusiasm for the formal synthesis and combining of results from two or more trials.

READING JOURNAL ARTICLES

Thousands of words are written each year in journal articles relevant to anesthesia. No one can read them all. How should the clinician determine which articles are useful? All that is possible is to learn to rapidly skip over most articles and concentrate on the few selected for their importance to the reader. Those few should be chosen according to their relevance and credibility. Relevance is determined by the specifics of one's anesthetic practice. Credibility is a function of the merits of the research methods, the experimental design, and the statistical

analysis; the more proficient one's statistical skills, the more rapidly one can accept or reject the credibility of a research article.

Guidelines

Six easily remembered appraisal criteria for clinical studies can be fashioned from the words WHY, HOW, WHO, WHAT, HOW MANY, and SO WHAT: (1) WHY: Is the biologic hypothesis clearly stated? (2) HOW: What is the research design? (3) WHO: Is the target population clearly defined? (4) WHAT: How was the therapy administered and the data collected? (5) HOW MANY: Are the test statistics convincing? (6) SO WHAT: Is it clinically relevant to my patients? Although the statistical knowledge of most physicians is limited, these skills of critical appraisal of the literature can be learned and can tremendously increase the efficiency and benefit of journal reading.

Resources in journal reading, print and electronic, are now widely available. For example, The Evidenced-Based Medicine Working Group—a group of mainly Canadian physicians and statisticians from McMaster University, Ontario, Canada—has been organized to de-emphasize a foundation of unsystematic clinical experience, clinical intuition, and pathophysiologic rationale as the basis for medical decision and to teach the systematic evaluation of published evidence. Now combined in a single volume, detailed topics range from "How to Use an Article about Therapy or Prevention" to "How to Use an Article about Disease Probability for Differential Diagnosis."[5] This material is also available interactively (http://www.ugi.usersguides.org/UGI/default.asp accessed 30-JUL-2004).

Statistical Resources

Accompanying the exponential growth of medical information since World War II has been the creation of a wealth of biostatistical knowledge. Textbooks with expositions of basic, intermediate, and advanced statistics abound.[6,7,8] There are new journals of biomedical statistics, including *Clinical Trials*, *Statistics in Medicine*, and *Statistical Methods in Medical Research*, whose audiences are both statisticians and biomedical researchers. Some medical journals, for example, the *British Medical Journal*, regularly publish expositions of both basic and newer advanced statistical methods. Extensive Internet resources can be linked from the home page of the long established American Statistical Association (http://0-www.amstat.org.innopac.up.ac.za:80/ accessed 30-JUL-2004) and at the StatLib (http://0-www.lib.stat.cmu.edu.innopac.up.ac.za:80/ accessed 30-JUL-2004) of Carnegie Mellon University including electronic textbooks of basic statistical methods, online statistical calculators, standard data sets, reviews of statistical software, and so on.

Example of Newer Statistics

6 Reports using a new type of research method—the systematic review—have become commonplace over the last 15 years in anesthesia journals. (As of July 2004, a literature search for "systematic review AND anesthesia" in PubMed at the National Library of Medicine returned 695 citations out of a total of 82,484 citations for systematic reviews [http://0-www.ncbi.nlm.nih.gov.innopac.up.ac.za:80/entrez accessed 15-JUL-2004].) In systematic reviews, a focused question drives the research, for example, (1) *Transient neurologic symptoms (TNS) following spinal anaesthesia with lidocaine versus other local anaesthetic*[9] or (2) *Ventilation with lower tidal volumes versus traditional tidal volumes in adults for acute lung injury and acute respiratory distress syndrome.*[10] These titles reveal some of the research design of a systematic review. There is a population of interest: (1) patients having *spinal anesthesia* and (2) *adults* [with] *acute lung injury and acute respiratory distress syndrome*. There is an intervention versus a comparison group: (1) *lidocaine versus other local anaesthetics* and (2) *ventilation with lower tidal volumes versus traditional tidal volumes*. There is an outcome for choosing success or failure: (1) occurrence of *transient neurologic symptoms (TNS)* and (2) *28-day mortality* (listed in text).

To answer the experimental question, data are obtained from randomized controlled trials already in the medical literature rather than from direct experimentation; the basic unit of analysis of this observational research is the published study. The researchers, also called the reviewers, proceed through a structured protocol, which includes in part: (1) choice of study inclusion/exclusion criteria, (2) explicitly defined literature searching, (3) abstraction of data from included studies, (4) appraisal of data quality, (5) systematic pooling of data, and (6) discussion of inferences. Binary outcomes (yes/no, alive/dead, presence/absence) within a study are usually compared by the relative risk (rate ratio) statistic. If there is sufficient clinical similarity among the included studies, a summary relative risk of the overall effect of the comparison treatments is estimated by meta-analysis; meta-analysis is a set of statistical techniques for combining results from different studies. The calculations for the statistical analyses of a meta-analysis are unfamiliar to most, but are not difficult. The results of a meta-analysis are usually present in a figure called a forest plot (see Fig 3-1).[9] The left-most column identifies the included studies and the observed data. The horizontal lines and diamond shapes are graphical representations of individual study relative risk and summary relative risk, respectively; the right-most column of the figure lists the relative risks

with 95% Confidence Intervals for the individual studies and the summary statistics. There are also descriptive and inferential statistics concerning the statistical heterogeneity of the meta-analysis and the significance of the summary statistics.

An examination of Figure 3-1 shows that many of the individual studies (8 of 12) had wide, nonsignificant confidence intervals that touch or cross the relative risk of identity (RR = 1). In this systematic review of TNS there were three subgroup comparisons: spinal lidocaine versus bupivacaine, prilocaine, and procaine; for each subgroup the relative risk of TNS was 6 to 7 times higher for lidocaine and the overall relative risk calculated from all studies was 7.13 with a 95% Confidence Interval [3.92, 12.95]. The power of summary statistics to combine evidence is clear. The reviewers concluded: "Lidocaine can cause transient neurologic symptoms (TNS) in every seventh patient who receives spinal anaesthesia. The relative risk of developing TNS is about seven times higher for lidocaine than for bupivacaine, prilocaine, and procaine. These painful symptoms disappear completely by the tenth postoperative day."[9]

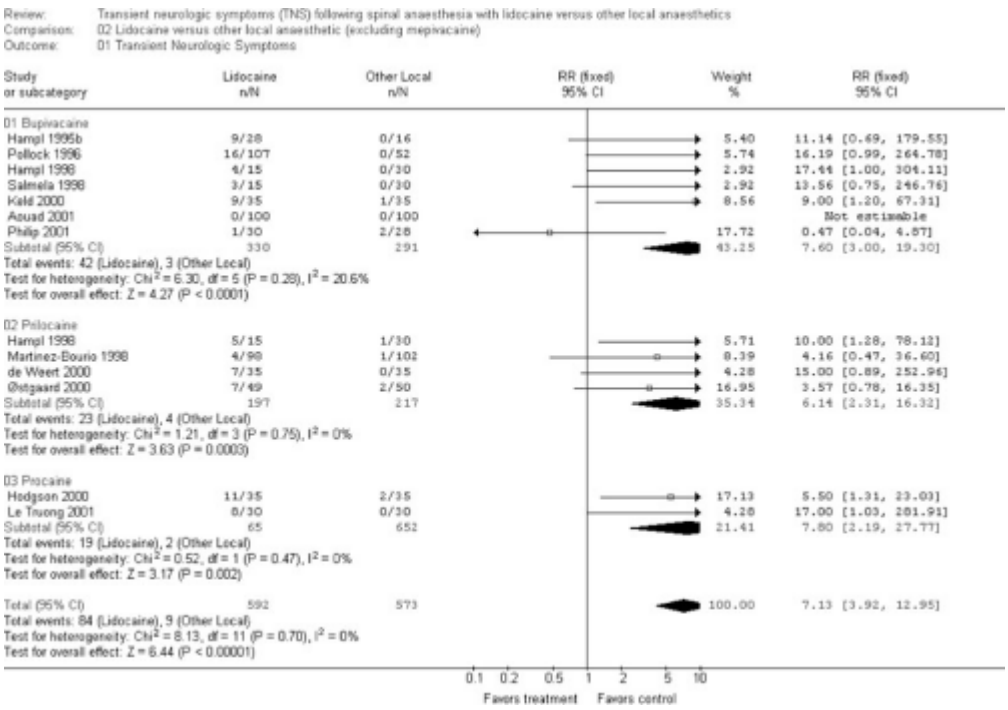

FIGURE 3-1. Forest plot modified from Graph 02/01 in Zaric D, Christiansen C, Pace NL, Punjasawadwong Y. Transient neurologic symptoms (TNS) following spinal anaesthesia with lidocaine versus other local anaesthetics (Cochrane Review). In: The Cochrane Library, Issue 3. Chichester, UK: John Wiley & Sons, Ltd., 2004. Copyright Cochrane Library, reproduced with permission.

The promotion of systematic reviews comes from several sources. Many come from the individual initiative of researchers who publish their results as stand alone reports in the journals of medicine and anesthesia. The American Society of Anesthesiologists has developed a process for the creation of practice parameters that includes among other things a variant form of systematic reviews. The most prominent proponent of systematic reviews is the Cochrane Collaboration, Oxford, UK. "The Cochrane Collaboration is an international non-profit and independent organization, dedicated to making up-to-date, accurate information about the effects of health care readily available worldwide. It produces and disseminates systematic reviews of health care interventions and promotes the search

for evidence in the form of clinical trials and other studies of interventions. The Cochrane Collaboration was founded in 1993 and named for the British epidemiologist, Archie

Cochrane" (http://www.cochrane.org, accessed July 31, 2004).

There are more than 50 collaborative review groups that provide the editorial control and supervision of systematic reviews; one of these, located in Copenhagen, prepares and maintains the accessibility of systematic reviews of the effects of health care interventions in the areas of anesthesia, perioperative medicine, intensive care medicine, and so on (http://www.cochrane-anaesthesia.suite.dk, accessed July 31, 2004). The Cochrane Collaboration has extensive documentation available electronically explaining the techniques of systematic reviews and meta-analysis. Introductory textbooks of biostatistics now include expositions on systematic reviews also.[5]

CONCLUSION

One intent of this chapter is to present the scope of support that the discipline of statistics can provide to anesthesia research. Although an intuitive understanding of certain basic principles is emphasized, these basic principles are not necessarily simple and have been developed by statisticians with great mathematical rigor. Academic anesthesia needs more workers to immerse themselves in these statistical fundamentals. Having done so, these statistically knowledgeable academic anesthesiologists will be prepared to improve their own research projects, to assist their colleagues in research, to efficiently seek consultation from the professional statistician, to strengthen the editorial review of journal articles, and to expound to the clinical reader the whys and wherefores of statistics. The clinical reader also needs to expend his or her own effort to acquire some basic statistical skills. Journals are increasingly difficult to understand without some basic statistical understanding. Some clinical problems can be best understood with a perspective based on probability. Finally, understanding principles of experimental design can prevent premature acceptances of new therapies from faulty studies.

Chapter 4

Occupational Health

Arnold J. Berry

Jonathan D. Katz

KEY POINTS

1	With the use of scavenging equipment, routine machine maintenance, and appropriate work practices, exposure to waste anesthetic gases can be reduced to levels below those recommended by National Institute for Occupational Safety and Health (NIOSH).
2	Twenty-four percent of anesthesia personnel manifest evidence of contact dermatitis in response to latex exposure and approximately 15% are sensitized and vulnerable to allergic reactions.
3	Vigilance is one of the most critical tasks performed by anesthesiologists. The vigilance task is adversely affected by several factors including poor equipment engineering and design, excessive noise in the operating room, impediments to interpersonal communication, production pressure, and fatigue.
4	Sleep deprivation and fatigue are common among anesthesiologists. Sleep deprivation can have deleterious effects on cognition, performance, mood, and health.
5	The risk of exposure to infectious pathogens can be reduced by the routine use of standard precautions, appropriate isolation precautions for infected patients, and safety devices designed to prevent needlestick injuries.
6	Hepatitis B vaccine is recommended for all anesthesia personnel because of the increased risk for occupational transmission of this bloodborne pathogen.
7	Many consider chemical dependency to be the primary occupational hazard among anesthesiologists. An incidence of 1 to 2% of controlled substance abuse has been repeatedly reported within anesthesia training programs.
8	It remains controversial whether anesthesiologists are, on average, vulnerable to premature death. However, by correcting for the fact that living anesthesiologists are, on average, younger than most other specialists, it is

apparent that anesthesiologists do not die younger.

Anesthesia personnel spend long hours, in fact, most of their waking days, in an environment filled with many potential hazards—the operating room. This setting is unique among workplaces as a result of the potential exposure to chemical vapors, ionizing radiation, and infectious agents. Additionally, anesthesia personnel are subject to heightened levels of psychological stress engendered by the high-stakes nature of the practice. Although such physical hazards as fires and explosions from flammable anesthetic agents are currently of limited concern, occupational illnesses, such as alcohol and drug abuse, are well recognized as significant within the anesthesia community. Some hazards, such as exposure to trace levels of waste anesthetic gases, have been extensively studied. Others, like suicide, have been recognized but not adequately pursued. Only within the past few decades have epidemiologic surveys been conducted to assess the health of anesthesia personnel. In general, the potential health risks to those working in the operating room may be significant, but with awareness of the problems and the use of proper precautions, they are not formidable.

PHYSICAL HAZARDS

Anesthetic Gases

Although the inhalation anesthetics diethyl ether, nitrous oxide, and chloroform were first used in the 1840s, the biologic effects of occupational exposure to anesthetic agents were not investigated until the 1960s. Reports on the effects of chronic environmental exposure to anesthetics have included epidemiologic surveys, in vitro studies, cellular research, and studies in laboratory animals and humans. Areas addressed include the potential influence of trace anesthetic concentrations on the

incidence in affected populations of the following: death, infertility, spontaneous abortion, congenital malformations, cancer, hematopoietic diseases, liver disease, neurologic disease, psychomotor, and behavioral changes.

Anesthetic Levels in the Operating Room

Early investigators established that significant levels of ether were present in the operating room when the open drop technique was used, but the first report of occupational exposure to modern anesthetics was by Linde and Bruce in 1969.[1] They sampled air at various distances from the “pop-off” valve of anesthesia machines and noted an average concentration of halothane of 10 parts per million (ppm) and of nitrous oxide of 130 ppm. (Parts per million is a volume-per-volume unit of measurement; 10,000 ppm equals 1%.) End-expired air samples taken from 24 anesthesiologists after work revealed 0 to 12 ppm of halothane. It was later demonstrated that with appropriate scavenging equipment and adequate air exchange in the operating room, levels of waste

anesthetic gases could be significantly reduced.

Waste anesthetic concentrations in modern operating rooms where routine scavenging is performed are considerably less than those found in the early studies.[2,3] This raises the questions of whether chronic exposure to these low levels of waste anesthetic gases actually constitutes a significant occupational hazard and whether results from studies performed in “unscavenged” operating rooms are applicable to current practice.

Epidemiologic Studies

Epidemiologic surveys were among the first studies to suggest the possibility of a hazard resulting from exposure to trace levels of anesthetics. Although epidemiologic studies may be useful in assessing problems of this type, they have the potential for errors associated with the collection of data and their interpretation. Valid epidemiologic studies require appropriate design strategies including the presence of an appropriate control group for the cohort being studied. When questionnaires are used to obtain personal medical information, the data may be misleading because individuals may knowingly or unknowingly give incorrect information based solely on remembered data. Cause-and-effect relationships or causality cannot be documented by epidemiologic studies unless all other possible etiologies (confounders) can be ruled out or other lines of evidence are used for substantiation. Few epidemiologic studies on the effects of occupational exposure to waste anesthetic gases fulfill these design criteria.

Reproductive Outcome. One of the largest epidemiologic studies to assess the effects of trace anesthetics on reproductive outcome was conducted by the American Society of Anesthesiologists (ASA).[4] Questionnaires were sent to 49,585 operating room personnel who had potential exposure to waste anesthetic gases (members of the ASA, the American Association of Nurse Anesthetists, the Association of Operating Room Nurses, and the Association of Operating Room Technicians). A nonexposed group of 23,911 from the American Academy of Pediatrics and the American Nurses' Association served as controls. Analyses of these data indicated that there was an increased risk of spontaneous abortion and congenital abnormalities in children of women who worked in the operating room and an increased risk of congenital abnormalities in offspring of unexposed wives of male operating room personnel. Several reviews have identified inconsistencies in the data used to compare exposed and unexposed groups and to make within-group comparisons. Expected levels of anesthetic exposure did not correlate with reproductive outcome.

The ASA subsequently commissioned a group of epidemiologists and biostatisticians to evaluate and assess conflicting data from published epidemiologic surveys.[5] After analysis of methods, they found only five studies on spontaneous abortion and congenital abnormalities in offspring of anesthesia personnel that were free of errors in study design or statistical analysis. From these studies, the relative risks (the ratio of the rate of disease among those exposed to that found in those not exposed) of spontaneous abortion for female physicians and female nurses working in the operating room were 1.4 and 1.3, respectively (a relative risk of 1.3 represents a 30% increase in risk when compared with the risk of the control population). The increased relative risk for congenital abnormalities was of borderline statistical significance for exposed physicians only. Although they found a statistically significant relative risk of spontaneous abortion and congenital abnormalities in women working in the operating room, the relative risk was small compared with other, better-documented environmental hazards. They also pointed out that duration and level of anesthetic exposure were not measured in any of the studies and that other confounding factors, such as stress, infections, and radiation exposure, were not considered.

Because personnel working in some dental operatories have exposure to nitrous oxide, the dental literature has also addressed these issues. One pertinent study used data collected via telephone interviews with 418 female dental assistants to assess the effect of nitrous oxide exposure on fertility.[6] Fecundability (the ability to conceive, which is measured by the time to pregnancy during periods of unprotected sexual intercourse) was significantly reduced in women with 5 or more hours of exposure to unscavenged nitrous oxide per week. In another study of 7,000 female dental assistants, questionnaires were used to determine rates of spontaneous abortion.[7] There was an increased rate of spontaneous abortion among women who worked for 3 or more hours per

week in offices not using scavenging devices for nitrous oxide (relative risk [RR] = 2.6, adjusted for age, smoking, and number of amalgams prepared per week). These findings must be viewed with caution because the estimates of nitrous oxide exposure were based solely on respondents' reports, and measurements of nitrous oxide concentrations in the work space were not performed. Therefore, dose–effect relationships cannot be confirmed. It is important to note that in both studies of female dental assistants, use of nitrous oxide in offices with scavenging devices was not associated with an increased risk for adverse reproductive outcomes.[6,7]

A meta-analysis of 19 epidemiologic studies, which included hospital workers, dental assistants, and veterinarians and veterinary assistants, demonstrated an increased risk of spontaneous abortion in women with occupational exposure to anesthetic gases (RR = 1.48; 95% confidence interval, 1.40 to 1.58).[8] Additional analysis demonstrated that the relative risk of 1.48 corresponded to an increased absolute risk of abortion of 6.2%. Stratification by job category indicated that the relative risk was greatest for veterinarians (RR = 2.45), followed by dental assistants (RR = 1.89) and hospital workers (RR = 1.30). When the meta-analysis was confined to five studies that controlled for several nonoccupational confounding variables, had appropriate control groups, and had sufficient response rate, the relative risk for spontaneous abortion was 1.90 (95% confidence interval, 1.72 to 2.09). The author noted that the routine use of scavenging devices has been implemented since the time that most of the studies in this analysis were performed and that there was no risk of spontaneous abortion in studies of personnel that worked in scavenged environments.

Retrospective surveys of large numbers of women who worked during pregnancy indicate that negative reproductive outcomes may be related to job-associated conditions other than exposure to trace anesthetic gases. A survey of 3,985 Swedish midwives demonstrated that night work was significantly associated with spontaneous abortions after the twelfth week of pregnancy (OR = 3.33), while exposure to nitrous oxide appeared to have no effect.[9] Using a case-control

study design, Luke et al[10] found that increased work hours, hours worked while standing, and occupational fatigue were associated with preterm birth in obstetric and neonatal nurses. These and other studies have provided data that link spontaneous abortion in women working in health care to job-related factors other than exposure to trace anesthetic gases. This casts doubt on the validity of earlier studies that did not control for occupational stresses such as fatigue, long work hours, and night shifts.

Although many of the existing epidemiologic studies have potential flaws in design, the evidence taken as a whole suggests that there is a slight increase in the relative risk of spontaneous abortion and congenital abnormalities in offspring for female physicians working in the operating room.[11] Whether these findings are attributable to anesthetic exposure or other work-related conditions cannot be definitely determined from this type of investigation. Well-designed surveys of large numbers of personnel and appropriate control groups, controlled for other factors such as work hours and night shifts, are necessary to link trace anesthetic exposures to adverse reproductive outcomes. The routine use of scavenging techniques has generally lowered environmental anesthetic levels in the operating room and may make it more difficult to prove any adverse reproductive effects using epidemiologic data. Although it is easy to measure and quantify the levels of anesthetic in the operating room air, it is harder to measure and assess the effect of other possible factors, such as stress, alterations in working schedule, and fatigue.

Neoplasms and Other Nonreproductive Diseases. One of the first surveys enumerating causes of death among anesthesiologists was reported by Bruce et al in 1968.[12] The authors compared the death rates of members of the ASA from 1947 to 1966 with those for American men and male policyholders of a large insurance company. There was a higher death rate among male anesthesiologists from malignancies of the lymphoid and reticuloendothelial tissues and from suicide, but a lower death rate from lung cancer and coronary artery disease.

In a subsequent prospective study, Bruce et al[13] compared the causes of death in ASA members during the years 1967 to 1971 with those of men insured by one company. The overall death rate for ASA members was lower than for the controls, and contrary to the previous results, there was

no increase in death rates from malignancies of lymphoid and reticuloendothelial tissues. The authors concluded that their data provided no evidence to support the speculation that lymphoid malignancies were an occupational hazard for anesthesiologists.

An ASA-sponsored study, published in 1974, found no differences in cancer rates between men exposed and those not exposed to trace concentrations of anesthetic gases.[4] For women respondents, there was a 1.3-fold to 2-fold increase in the occurrence of cancer in the exposed group, resulting predominantly from an increase in leukemia and lymphoma. The analysis of Buring et al[5] of these data confirmed an increase in relative risk of cancer in exposed women (1.4) but attributed the increase solely to cervical cancer([2,8]). They also noted that the ASA study did not assess the effect of confounding variables, such as sexual history or smoking, that may have contributed to the findings. It is doubtful that the carcinogenic effect of anesthetics would be sex related, and the conflicting results for men and women, especially in light of the low statistical significance of the data, cast doubt that anesthetics were the causative agents.

Another ASA-sponsored mortality study of anesthesiologists, covering the period from 1976 to 1995, utilized data on cause of death from the National Death Index.[14] The mortality risks of a cohort of 40,242 anesthesiologists were compared to a matched cohort of internists. There was no difference between the two groups in overall mortality risk or mortality because of cancer or heart disease, but the mean age at death for decedents was significantly lower for anesthesiologists compared to internists (66.5 years versus 69.0 years). In a subsequent study, Katz[15] used data from the American Medical Association (AMA) to conclude that there was no statistical difference in age-specific mortality among anesthesiologists, internists, and other physicians when ages of the living members of the physician groups were considered in the analyses.

Epidemiologic studies are useful tools for attempting to identify adverse effects of the operating room environment, including exposure to many substances, of which waste anesthetic gases comprise but one factor. The data from epidemiologic surveys can, at best, suggest associations but can never prove cause-and-effect relationships between an exposure to a condition or substance and a disease process. There are shortcomings in many surveys that attempt to assess the effects of waste anesthetic gases, and these have resulted in conflicting conclusions. Overall, there appears to be some evidence that the operating room environment produces a slight increase in the rate of spontaneous abortion and cancer in female anesthesiologists and nurses.[5] Mortality risks from cancer and heart disease for anesthesiologists do not differ from those for other medical specialists.

Laboratory Studies

Along with epidemiologic studies, investigators have been active in the laboratory, assessing the effects of anesthetic agents on cell, tissue, and animal models. It is thought that this work might provide the scientific evidence linking anesthetic exposure to the adverse effects that have been suggested by some epidemiologic surveys.

Cellular Effects. Nitrous oxide administered in clinically useful concentrations affects hematopoietic and neural cells by irreversibly oxidizing the cobalt atom of vitamin B_{12} from an active to inactive state. This inhibits methionine synthetase and prevents the conversion of methyltetrahydrofolate to tetrahydrofolate, which is required for DNA synthesis, assembly of the myelin sheath, and methyl substitutions in neurotransmitters. Inhibition of methionine synthetase in individuals exposed to high concentrations of nitrous oxide may result in anemia and polyneuropathy, but chronic exposure to trace levels does not appear to produce these effects.[16]

Many studies have been performed in animals to assess the carcinogenicity of anesthetics. A preliminary study suggested that isoflurane produced hepatic neoplasia when administered to mice during gestation and early life, but a subsequent, well-controlled study failed to reproduce these results.[17] Research using mice and rats found no carcinogenic effect of halothane, nitrous oxide, or enflurane.

Several investigators have used the Ames bacterial assay system for studying the mutagenicity of anesthetics. This assay is rapid, inexpensive, and has a high true-positive rate when compared

with in vivo tests. Halothane, enflurane, methoxyflurane, isoflurane, and urine from patients anesthetized with these agents was not mutagenic using this assay.[18] Urine from people working in scavenged or unscavenged operating rooms was also negative for mutagens.[19]

Other studies have used analyses of sister chromatid exchanges (SCE) or formation of micronucleated lymphocytes to assess for genotoxicity in association with anesthetic exposure. These tests may be of interest because there may be an association between these genetic changes and cancer. The majority of studies using SCE testing have been negative for enflurane, isoflurane, and sevoflurane exposure.[20] Anesthetists at an institution where waste gas scavenging was not used had an increased fraction of micronucleated lymphocytes compared to those practicing in a hospital where waste anesthetic

gases were scavenged.[21] Low-level exposure as occurs in scavenged operating rooms is not associated with increased formation of micronucleated lymphocytes. The predictive value for the association of this test to the incidence of cancer is unclear.

The data from several lines of evidence indicate that occupational exposure to the low levels of anesthetics found with effective waste gas scavenging is not associated with significant cellular effects.

Reproductive Outcome. Because of the suggestion from epidemiologic data that occupational exposure to waste anesthetic gases may have resulted in an increased rate of spontaneous abortion and congenital abnormalities, numerous studies have been performed in laboratory animals to assess reproductive outcome. Most animal experiments fail to demonstrate alterations in female or male fertility or reproduction with exposure to subanesthetic concentrations of the currently used anesthetic agents. It is important to realize that data from laboratory investigations in animals may not be directly applicable to humans.

Effects of Trace Anesthetic Levels on Psychomotor Skills

Several studies have been conducted to attempt to clarify whether low concentrations of anesthetics alter the psychomotor skills required for providing high-quality care. In one investigation, psychomotor tests were used to assess the effect of nitrous oxide (500, 50, or 25 ppm) alone or with halothane (10, 1.0, or 0.5 ppm).[22] After exposure to the highest concentrations of nitrous oxide and halothane, subjects' performance declined on four of the seven tests. Interestingly, there was a decrease in ability in six of seven tests after exposure to the same level of nitrous oxide alone. Exposure to the lowest concentrations studied, 25 ppm nitrous oxide and 0.5 ppm halothane, produced no effects as measured by this battery of tests.

Other investigators, using similar protocols, have found no effect on psychomotor test performance after exposure to trace concentrations of halothane or nitrous oxide. The reason for differences in outcome between studies is unclear, but Bruce, one of the original investigators, has attributed the psychological effects of low levels of anesthetics to unusual sensitivity in the group of paid volunteers used in the study.[23]

Recommendations of the National Institute for Occupational Safety and Health

The National Institute for Occupational Safety and Health is the federal agency responsible for ensuring that workers have a safe and healthful working environment. It meets these goals through the conduct and funding of research, through education of employers and employees about occupational illnesses, and through establishing occupational health standards. A second federal agency, the Occupational Safety and Health Administration (OSHA), is responsible for enacting job health standards, investigating work sites to detect violation of standards, and enforcing the standards by citing violators. In 1977, NIOSH published a criteria document that recommended that waste anesthetic exposure should not exceed 2 ppm (1-hour ceiling) of halogenated anesthetic agents when used alone, or 0.5 ppm of a halogenated agent and 25 ppm of nitrous oxide (time-weighted average during use).[24] In addition, it stated that operating room employees should be advised of the potential harmful effects of anesthetics. The guidelines

proposed that annual medical and occupational histories be obtained from all personnel and that any abnormal outcomes of pregnancies should be documented. The publication also included information on scavenging procedures and equipment and methods for monitoring concentrations of waste anesthetic gases in the air.

The 1977 NIOSH criteria document has not been adopted by OSHA, which currently does not have a standard for waste anesthetic gases. Some states, however, have instituted regulations calling for routine measurement of ambient nitrous oxide in operating rooms and have mandated that levels not exceed an arbitrary maximum.

In 1994, NIOSH published an alert to warn health care personnel that exposure to nitrous oxide may produce "harmful effects."[25] In this document, NIOSH recommends the following to reduce nitrous oxide exposure: (1) monitoring the air in operating rooms; (2) implementation of appropriate engineering controls, work practices, and equipment maintenance procedures; and (3) institution of a worker education program.

Since publication of the NIOSH criteria document, several volatile anesthetic agents (enflurane, isoflurane, sevoflurane, and desflurane) have been introduced into clinical practice. Although the NIOSH document addressed halogenated agents (halothane), the agents most commonly used in current practice have potencies, chemical characteristics, and rate and products of metabolism that differ significantly from older anesthetics. One must question whether the exposure thresholds cited by NIOSH in 1977 should also apply to agents that were not available at the time. It is important to note that other organizations and agencies in the United States and Europe have set occupational exposure limits for waste anesthetic gases and in most cases, these are greater than those recommended by NIOSH (Table 4-1).

TABLE 4-1 Examples of Recommended Threshold Limits[a] for Occupational Exposure to Anesthetic Agents

Country	Nitrous Oxide	Halothane	Enflurane	Isoflurane
U.S. (NIOSH)	25	2	2	2
U.S. (ACGIH)	50	50	75	N
Great Britain	100	10	50	50
Norway	100	5	2	2
Sweden	100	5	10	10

[a]Time-weighted average in parts per million.
NIOSH, National Institute of Occupational Safety and Health; **ACGIH**, American Conference of Governmental Industrial Hygienists; **N**, not determined.

In view of the conflicting scientific data and published recommendations, it is reasonable to ask what is an acceptable exposure level for waste anesthetic gases. Although it may be difficult to be certain of a threshold concentration below which

chronic exposure is "safe," it is prudent to institute measures that reduce waste anesthetic levels in the operating room environment without compromising patient safety. Methods for reducing and

monitoring waste gases in the operating room have been suggested.[3] Through the use of scavenging equipment, equipment maintenance procedures, altered anesthetic work practices, and efficient operating room ventilation systems, the environmental anesthetic concentration can be reduced to minimal levels. To ensure reduced occupational exposure, departmental programs should incorporate the ability to monitor for detection of leaks in the high- and low-pressure systems of anesthetic machines, contamination as a result of faulty anesthetic techniques such as poor mask fit or leaks around the cuffs of endotracheal tubes and laryngeal mask airways, and scavenging system malfunctions (Table 4-2). When there have been leaks of anesthetic gases, dispersion and removal of the pollutants are dependent on the adequacy of room ventilation. Standards for operating room construction from the American Institute of Architects require 15 to 21 air exchanges per hour with 3 bringing in outside air.[26] Environmental levels of anesthetics can be measured using instantaneously collected samples, continuous air monitoring, or time-weighted averages.[3] With appropriate care, environmental levels of anesthetics in the operating room can be reduced to comply with those suggested by NIOSH.

TABLE 4-2 Sources of Operating Room Contamination

▪ANESTHETIC TECHNIQUES

- failure to turn off gas flow control valves at the end of an anesthetic
- turning gas flow on before placing mask on patient
- poorly fitting masks, especially with mask induction of anesthesia
- flushing of the circuit
- filling of anesthesia vaporizers
- uncuffed or leaking tracheal tubes (e.g., pediatric) or poor-fitting laryngeal mask airways
- pediatric circuits (e.g., Jackson-Rees version of the Mapleson D system)
- sidestream sampling carbon dioxide and anesthetic gas analyzers

▪ANESTHESIA MACHINE DELIVERY SYSTEM AND SCAVENGING SYSTEM

- open/closed system
- occlusion/malfunction of hospital disposal system
- maladjustment of hospital disposal system vacuum
- leaks
  high-pressure hoses or connectors
  nitrous oxide tank mounting
  O rings
  CO_2 absorbent canisters
  low-pressure circuit

▪OTHER SOURCES

- cryo surgery units
- cardiopulmonary bypass circuits

Modified from Task Force on Trace Anesthetic Gases of the Committee on Occupational Health of Operating Room Personnel: *Waste Anesthetic Gases: Information for Management in Anesthetizing Areas and the Postanesthesia Care Unit (PACU)*. Park Ridge, Ill, American Society of Anesthesiologists, 1999, with permission from the

American Society of Anesthesiologists. A copy of the full text can be obtained from the ASA, 520 N. Northwest Highway, Park Ridge, Illinois 60068-2573.

Anesthetic Levels in the Postanesthesia Care Unit

As patients awaken from general anesthesia in the postanesthesia care unit (PACU), waste anesthetic gases are released into this environment. In a 1998 study, the time-weighted average concentrations for isoflurane, desflurane, and nitrous oxide were 1.1 ppm, 2.1 ppm, and 29 ppm, respectively, in the breathing zone of PACU nurses.[27] Half of the patients were intubated on arrival in the PACU, suggesting that they were still partially anesthetized and were exhaling a greater concentration of anesthetic gases than if they had already awakened. In contrast, other investigators reported time-weighted nitrous oxide levels less than 2.0 ppm from two PACUs.[28] The practice in these institutions was to routinely discontinue nitrous oxide at the end of surgery, approximately 5 minutes before the patient left the operating room. Also, there was adequate ventilation documented in the PACUs. NIOSH threshold limits for anesthetic gases can be obtained in the PACU by ensuring adequate room ventilation and fresh gas exchange and by discontinuing the anesthetic gases in sufficient time prior to leaving the operating room.

Chemicals

Methyl Methacrylate

Methyl methacrylate is commonly used to cement prostheses to bone or to repair bone defects. Known cardiovascular complications of methyl methacrylate in surgical patients include hypotension, bradycardia, and cardiac arrest. The effects of occupational exposure are less well documented. Reported risks from repeated occupational exposure to methyl methacrylate include allergic reactions and asthma, dermatitis, eye irritation including possible corneal ulceration, headache, and neurological signs. In one report, a health care worker suffered significant lower limb neuropathy after repeated occupational exposure to methyl methacrylate.[29]

OSHA has established an 8-hour, time-weighted average allowable exposure of 100 ppm. Concentrations as high as 280 ppm have been measured when methyl methacrylate is prepared for use in the operating room, but peak environmental concentration can be decreased by 75% when scavenging devices are properly used.

Allergic Reactions

In addition to concerns about toxic effects associated with exposure to volatile anesthetics or chemicals, anesthesiologists may develop sensitivities or allergic reactions to substances found in the health care environment.

Halothane. Repeated bouts of hepatitis in a small number of anesthesiologists have been attributed to hypersensitivity reactions rather than to a direct toxic effect of halothane. Analyses of sera from pediatric and general anesthesiologists demonstrated that exposure to halothane was

associated with an increased prevalence of autoantibodies to cytochrome P450 2E1 and hepatic endoplasmic reticulum protein (ERp58).[30] Despite the presence of these autoantibodies, only 1 of 105 pediatric anesthesiologists had symptoms of hepatic injury. These data suggest that although autoantibodies may occur in anesthesiologists exposed to volatile anesthetics, they do not appear to be the cause of anesthetic-induced hepatitis.

2 **Latex.** Latex in surgical and examination gloves has become a common source of allergic reactions among operating room personnel. In many cases, health care workers who are allergic to latex experience their first adverse reactions while they are patients undergoing surgery. The prevalence of latex

sensitivity among anesthesiologists is estimated to be 12.5 %[31] to 15.8%.[32]

Latex is a complex substance composed of polyisoprenes, lipids, phospholipids, and proteins. A number of additional substances, including preservatives, accelerators, antioxidants, vulcanizing compounds, and lubricating agents (such as cornstarch or talc), are added in the manufacture of the final product. The protein content of latex is responsible for the vast majority of generalized allergic reactions to latex-containing surgical gloves. These reactions are exacerbated by the presence of powder that enhances the potential of latex particles to aerosolize and to spread to the respiratory system of personnel and to environmental surfaces during the donning or removal of gloves.

Irritant or contact dermatitis accounts for approximately 80% of reactions resulting from wearing latex-containing gloves (Table 4-3). In the study reported by Brown et al,[31] 24% of anesthesia personnel were found to manifest evidence of contact dermatitis. True allergic reactions present as T-cell mediated contact dermatitis (Type IV) or as an IgE-mediated anaphylactic reaction.

TABLE 4-3 Types of Reactions to Latex Gloves

·REACTION	·SIGNS/SYMPTOMS	·CAUSE	·MANAGEMENT
Irritant Contact Dermatitis	Scaling, drying, cracking of skin	Direct skin irritation by gloves, powder, soaps	Identify reaction, avoid irritant, possible use of glove liner, use of alternative product
Type IV—Delayed Hypersensitivity	Itching, blistering, crusting (delayed 6–72 hours)	Chemical additives used in manufacturing (such as accelerators)	Identify offending chemical, possible use of alternative product without chemical additive, possible use of glove liner
Type I—Immediate Hypersensitivity A. Localized Contact Urticaria B. Generalized Reaction	A. Itching, hives in area of contact with latex (immediate) B. Runny nose, swollen eyes, generalized rash or hives, bronchospasm,	Proteins found in latex	Identify reaction, avoid latex-containing products, use of nonlatex or powder-free, low-protein gloves by coworkers Antihistamines,

	anaphylaxis		topical/systemic steroids Anaphylaxis protocol

A copy of the full text can be obtained from the ASA, 520 N. Northwest Highway, Park Ridge, Illinois 60068-2573.

Anesthesiologists who believe that they are allergic to latex should take immediate steps to assess this possibility.[33] A careful clinical history combined with laboratory evaluation helps to correlate the allergic symptoms with latex exposure. Once the diagnosis of allergy has been established, the affected anesthesiologist must avoid all direct contact with latex-containing products. It is also important that coworkers wear nonlatex or powderless, low latex-allergen gloves to limit the levels of ambient allergens. Because sensitization is an irreversible process, limited exposure and primary prevention of allergy is the best overall strategy.[33] Anaphylactic reactions to latex can be life threatening.

Radiation

Many modern surgical procedures rely heavily on fluoroscopic guidance techniques. As a result, anesthesiologists are at risk for being exposed to an excessive dose of radiation. The magnitude of radiation absorbed by anesthesia personnel is a function of three variables: (1) total radiation exposure intensity and time, (2) distance from the source of radiation, and (3) the use of radiation shielding. The latter two are amenable to modification by the individual. Unfortunately, the lead aprons and thyroid collars commonly worn in operating rooms leave exposed many vulnerable sites, such as the long bones of the extremities, the cranium, the skin of the face, and the eyes. Because radiation exposure is inversely proportional to the square of the distance from the source, increasing this distance is more universally protective. Radiation exposure becomes minimal at a distance greater than 36 inches from the source, a distance that is easily attainable in most anesthetizing locations.

The U.S. Regulatory Commission has established an occupational exposure limit of 5,000 mrem/year. Occupational exposure among anesthesia personnel have been reported to be considerably below this limit.[34] However, these studies were conducted before the introduction of many of the modern surgical procedures that rely heavily on fluoroscopic guidance techniques, such as major spine surgery, endovascular repair of aortic aneurysms, and invasive cardiology procedures. Pregnant workers present special concerns, and the dose to the fetus should be less than 500 mrem during the gestation period.

Oncogenesis, teratogenesis, and long-term genetic defects can occur with sufficiently high exposure to radiation. However, even low levels of radiation exposure are not inconsequential. The stochastic biologic effects of radiation are cumulative and permanent. (A *stochastic* effect is one for which the probability of the occurrence increases with an increasing dose but the severity of the resulting disease does not depend on the magnitude of the dose.) There are no published data that define the lower threshold for radiation-induced disease. Therefore, the general admonition regarding occupational radiation exposure and the basis of protection programs is as low as reasonably achievable (ALARA).

Radiation exposure should be monitored with film badges or pocket dosimeters in anesthesia personnel at risk. Monthly

documentation allows for recognition of personnel with high levels of exposure. When warranted, work practices can be evaluated and reassignment to work areas with less radiation exposure considered. Educational programs on the effects of radiation and techniques for preventing exposure are important parts of radiation safety programs.

Noise Pollution

A potential health hazard that is virtually uncontrolled in the modern hospital and specifically in the operating room is noise pollution. Noise pollution is quantified by determining both the intensity of the sound in decibels (dB) and the duration of the exposure. NIOSH has established a maximum level for safe noise exposure of 90 dB for 8 hours.[35] Each increase in noise of 5 dB halves the permissible exposure time, so that 100 dB is acceptable for just 2 hours per day. The maximum allowable exposure in an industrial setting is 115 dB.

The noise level in many operating rooms is surprisingly close to what constitutes a health hazard.[36] Ventilators, suction equipment, music, and conversation produce background noise at a level of 75 to 90 dB. Superimposed on this are sporadic and unexpected noises as dropped equipment, surgical saws and drills, and monitor alarms. Resultant noise levels frequently exceed those of a freeway and even of a rock-and-roll band.

Excessive levels of noise can have an adverse influence on the anesthesiologist's capacity to perform his or her chores. Noise can interfere with an anesthesiologist's ability to discern conversational speech and even to hear auditory alarms. Mental efficiency and short-term memory are diminished by exposure to excess noise.[36] Complex psychomotor tasks associated with anesthesiology, such as monitoring and vigilance, are particularly sensitive to the adverse influences of noise pollution.

There are also chronic ramifications of long-term exposure to excessive noise in the workplace. At the very least, noise pollution is an important factor in decreased worker productivity. At higher noise levels, workers are likely to show signs of irritability and demonstrate evidence of stress, such as elevated blood pressure. Ultimately, hearing loss may ensue.

Conversely, music can provide beneficial effects as a different kind of “background noise.” Music has proved advantageous as a supplement to sedation for awake patients during surgery. Self-selected background music can contribute to reducing autonomic responses in surgeons and improving their performance. The beneficial effects are less pronounced when the music is chosen by a third party. Unfortunately, this is often the case for the anesthesiologist.

Human Factors

The work performed by an anesthesiologist is intricate and includes a number of complex tasks. A large body of research has evolved with the goal of applying high-technology solutions to assist the anesthesiologist in managing this demanding workload. Less attention has been given to applying human factor technology to improve our workplace and ensure patient safety. Human error has been identified as a cause of patient morbidity and mortality.[37]

A number of human factor problems potentially exist in the operating room. For example, the design and positioning of equipment can be an impediment to the successful completion of all of an anesthesiologist's obligatory tasks. Anesthesia monitors are frequently placed so that attention is directed away from the patient. Indeed, nearly half of the anesthesiologist's time is spent performing tasks away from the patient–surgeon field and not directly related to patient care.[38] This was well demonstrated by observations that revealed that the insertion and monitoring of a transesophageal echocardiograph added significantly to the anesthesiologist's workload and diverted attention away from other patient-specific tasks. The ability to respond to critical incidents and to sustain complex monitoring tasks, such as maintaining vigilance (vigilance is the ability to detect changes in a stimulus during prolonged monitoring tasks when the subject has no prior knowledge of whether or when any changes might occur), are among those tasks that are most vulnerable to the distractions created by poor equipment design or placement. The critical

importance of the “vigilance” task to the practice of anesthesiology is evidenced by the fact that the seal of the American Society of Anesthesiologists bears as its only motto, “Vigilance” (Fig. 4-1), and the official motto of the Australian Society of Anaesthetists is “*Vigila et Ventila.*”

FIGURE 4-1. Official Seal of the American Society of Anesthesiologists. “VIGILANCE” has always been recognized as the most critical of the anesthesiologist's tasks.

Several aspects of the vigilance task deserve attention. By definition, this function is repetitive and monotonous. The task does not fully occupy the anesthesiologist's mental activity, but neither does it leave him or her free to perform other mental functions. Finally, the task is complex, requiring visual attention as well as manual dexterity.

Vigilance tasks are generally performed at the level of 90% accuracy.[39] In a setting where the stakes are as high as that of anesthesia, this leaves an unacceptable margin of error. In fact, human error, in part resulting from lapses in attention, accounts for a large proportion of the preventable deaths and serious injuries resulting from anesthetic mishaps in the United States annually.

In addition to poor equipment design, a number of other factors conspire to hamper the ability of the anesthesiologist to perform multiple tasks that demand cognitive skills. Any factor that requires the expenditure of excessive energy to perform a given task produces a predictable decrement in performance. Even the most trivial aspect of an operator's performance plays a significant role over the course of time. For example, if the anesthesiologist must make frequent rapid changes in observation from a dim, distant screen to a bright, nearby one, the continuous muscular activity required for pupil dilation and constriction and lens accommodation promotes fatigue and hinders performance.

Excessive energy expenditure need not be entirely physical. As more functions are monitored and more data processed during the course of a surgical procedure, increasingly larger amounts of mental work are expended. The mental work varies

directly with the difficulty encountered in extracting information from the monitors and displays competing for the anesthesiologist's attention. Engineering of the monitor displays, such as signal frequency and strength, as well as the mode of presentation of the input also significantly influence the operator's performance.

Even the alarms that have been developed with the specific goal of supplementing the task of vigilance have considerable drawbacks. In general, alarms are nonspecific (the same alarm

signaling as many as 12 different deviations from “normal”) and can be a source of frustration and confusion. They are also susceptible to artifacts and frequent false-positive alarms that can distract the observer from more clinically significant information and, therefore, it is not unusual for frequently distractive alarms to be inactivated.

Noise can have a detrimental influence on the anesthesiologist working at multiple tasks. The average noise level of 77 decibels found in operating rooms can reduce mental efficiency and short-term memory. In general, obtrusive noises, such as loud talking, excessive clanging of instruments, and “broadband” noise, are associated with decrements in performance.

Organizational issues, such as communication among team members, can have a detrimental effect on the ability of the anesthesiologist to perform well. The potential for disaster as a result of poor communication has been well illustrated in a number of airline catastrophes. The possibility for miscommunication and resultant accident is heightened in the operating room where, in contrast to the structure inherent in an airline crew, there is an absence of a well-defined hierarchical organization and there are overlaps in areas of expertise and responsibility.

“Production pressure” is an organizational concern that has the potential to create an environment in which issues of productivity supercede those of safety.[40] Production pressure has been associated with the commission of errors resulting from haste and/or deliberate deviations from known safe practices.

The application of simulation technology has proven to be very useful in the study of human performance issues in anesthesiology.[41] Much remains to be done in bringing human factor research to the anesthesiologist's work environment.

Work Hours and Night Call

Prolonged work hours that result in sleep deprivation and fatigue are a ubiquitous component of many anesthesiologists' professional lives. Ten- to 12-hour workdays are common. Additional emergency and on-call coverage frequently result in 24- to 32-hour shifts. Gravenstein reported the average anesthesiologist's work week was 56 hours.[42] Seventy-four percent of the study respondents reported that they had worked without a break for longer periods than they personally thought was safe and 64% attributed an error in anesthetic management to fatigue.

Long hours of work and night call are especially challenging for the aging anesthesiologist. Older individuals are particularly sensitive to disturbances of the sleep–wake cycle and are in general better suited to phase advances (morning work) than phase delays (nocturnal work).[43] Demands associated with night call have been identified as the most stressful aspect of practice and most frequently cited impetus toward retirement.[43]

Sleep deprivation and circadian disruption have deleterious effects on cognition, performance, mood, and health.[44] Both acute sleep loss (24 hours of on-call duty) and chronic partial sleep deprivation (less than 6 hours of sleep) result in a similar degree of neurobehavioral impairment. The nature and degree of impairment with acute sleep deprivation bears a striking similarity to that seen with alcohol intoxication.[45]

4 The deleterious effect of sleep loss and fatigue on work efficiency and accuracy is well documented in many industries.[41,46] Sleep deprivation has been implicated as a contributing factor in many well-publicized industrial accidents such as those that occurred at Chernobyl and Three Mile Island. Complex cognitive tasks that are specific to anesthesiology, such as monitoring and accurate clinical decision making, may be adversely affected by sleep deprivation. Surveys of anesthesia personnel have linked fatigue and anesthetic errors, but these contain self-reported data that may not be verifiable.[42,47] In a study of performance on an anesthesia simulator, residents in the sleep-deprived condition demonstrated progressive impairment of alertness, mood, and performance and had longer response latency to vigilance probes.[41] In spite of this, there were no significant differences in the clinical management of the simulated patients between the rested and sleep-deprived groups. Additional studies should be performed in this area to determine the role of sleep deprivation in adverse clinical events.

Subsequent to a period of sleep deprivation, performance does not return to normal levels until 24 hours of rest and recovery has occurred. An interesting phenomenon is the “end-spurt,” in which previously deteriorated performance shows improvement when the subject realizes that the task is 90% completed. The converse undoubtedly also occurs, a “let-down” with additional deterioration in performance when the procedure is unexpectedly prolonged.

An additional area of concern is the potential effect of sleep deprivation and chronic fatigue on health and psychosocial adjustment. Work schedules that disrupt circadian rhythms are associated with impaired health, emotional problems, and a decline in performance. Howard et al[48] demonstrated that residents in their routine, non–post-call state suffered from chronic sleep deprivation and had the same degree of sleepiness as measured in residents finishing 24 hours of in-house call.

The sleep-loss pattern experienced by anesthesiologists who take night call is complex and includes elements of each of the three general classes of sleep deprivation: total, partial, and selective sleep deprivation. Selective sleep deprivation resulting from frequent interruptions is most disruptive to important components of sleep including slow wave sleep (associated with “body repair”) and rapid eye movement sleep (“mind repair”). Indicators of psychosocial distress, including irritability, displaced anger, depression, and anxiety, have all been identified in house officers suffering from sleep deprivation.[49]

National attention was focused on the problems associated with sleep-deprived medical housestaff by the well-publicized Libby Zion case.[50] A large portion of this claim hinged on the allegation that fatal, avoidable mistakes were made by exhausted, unsupervised residents. A number of medical organizations and state legislatures subsequently took action to limit excessive work hours and resultant sleep deprivation among physicians, especially trainees. For example, the Accreditation Council for Graduate Medical Education (ACGME) has set universal standards that limit resident duty hours to an average of 80 hours per week and no more than 30 hours at any one time, limit the frequency of in-house call, and mandate that “off-duty” time be provided. Unfortunately, no regulations pertain to the practicing anesthesiologist or nurse anesthetist. In this area, medicine remains significantly behind other industries, most notably the transport and airline industries, in identifying and regulating work practices that permit excessively long shifts.[44]

Until changes can be made in staffing patterns, there are several strategies that can be used to prevent fatigue and the effects of sleep deprivation during long work periods.[44] Personnel should be educated on the problems associated with poor

sleep habits outside the hospital. Naps prior to the start of call as well as the use of caffeine can improve alertness during long shifts.

INFECTION HAZARDS

Anesthesia personnel are at risk for acquiring infections both from patients and from other personnel.[51] Viral infections, reflecting their prevalence in the community, are the most significant threat to health care workers. Most commonly, these are spread through the respiratory route—a mechanism that is, unfortunately, the most difficult to control effectively with environmental alterations. Other infections are propagated by hand-to-hand transmission, and hand washing is considered the single most important intervention for protection against this form of contagion.[52] Immunity against some viral pathogens can be provided through vaccination.[53] Bloodborne pathogens such as hepatitis and human immunodeficiency virus cause serious infections, but transmission can be prevented with mechanical barriers blocking portals of entry or, in the case of hepatitis B, by producing immunity by vaccination.[54] Current recommendations from the Centers for Disease Control and Prevention (CDC) for preemployment screening, infection control practices, vaccination, postexposure treatment, and work restrictions for infected personnel should be consulted for specific information related to each pathogen.[54,55,56]

Respiratory Viruses

Respiratory viruses, which are responsible for many community-acquired infections, are usually

transmitted by two routes. Small-particle aerosols produced by coughing, sneezing, or talking can propel viruses over large distances. The influenza and measles viruses are spread in this way. The second mechanism involves large droplets produced by coughing or sneezing, contaminating the donor's hands or an inanimate surface, whereupon the virus is transferred to the oral, nasal, or conjunctival mucous membranes of a susceptible person by self-inoculation. Rhinovirus and respiratory syncytial virus (RSV) are spread by this process.

Influenza Viruses

Because influenza viruses are easily transmitted, community epidemics of influenza are common, with large outbreaks occurring annually. Acutely ill patients shed virus through small-particle aerosols by coughing or sneezing for as long as 5 days after the onset of symptoms. Respiratory isolation precautions can be used for the duration of the clinical illness in an attempt to prevent spread to susceptible individuals. Because of their contact with nasopharyngeal secretions, anesthesiologists can play a role in the spread of influenza virus in hospitals.

Influenza rarely produces significant morbidity in healthy health care workers but can result in high rates of absenteeism. Hospital staff, especially those who care for patients in high-risk groups, should be immunized annually (October or November) with the inactivated (killed virus) influenza virus vaccine.[56] Antigenic variation of influenza viruses occurs over time, so that new viral strains (usually two Type A and one Type B) are selected for inclusion in each year's vaccine. During hospital outbreaks of influenza A, the antiviral agents amantadine and rimantadine are reasonably effective in preventing influenza A infection in unvaccinated hospital personnel and, if administered within 48 hours of the onset of illness, can reduce the duration and severity of illness.[57] The neuraminidase inhibitors zanamivir and oseltamivir have been shown to be effective in preventing and treating both influenza A and B.[57] Because of possible morbidity to hospitalized patients and to hospital personnel, it is recommended that during community influenza epidemics, hospitals should consider limiting elective admissions and surgery.

Respiratory Syncytial Virus

Respiratory syncytial virus is the most common cause of serious bronchiolitis and lower respiratory tract disease in infants and young children worldwide. During periods when RSV is prevalent in the community (usually late November through May in the United States), many hospitalized infants and children may carry the virus. Large numbers of virus are present in respiratory secretions of infected children, and although viable virus can be recovered for up to 6 hours on contaminated environmental surfaces, it is readily inactivated with soap and water and disinfectants. Infection of susceptible people occurs by self-inoculation when RSV in secretions is transferred to the hands, which then contact the mucous membranes of the eyes or nose.[58] Although most children have been exposed to RSV early in life, immunity is not permanent and reinfection is common.

Respiratory syncytial virus is shed for approximately 7 days after infection. Hospitalized patients with the virus should be isolated, but during seasonal outbreaks large numbers of patients may make isolation impractical.[59] Careful hand washing and the use of gowns, gloves, masks, and goggles (standard precautions) have all been shown to reduce RSV infection in hospital personnel.

Herpes Viruses

Varicella-zoster virus (VZV), herpes simplex virus Types 1 and 2, and cytomegalovirus (CMV) are members of the Herpetoviridine family. Close personal contact is required for transmission of all the herpes viruses except for VZV, which is spread by direct contact or small-particle aerosols. After primary infection with herpes viruses, the organism becomes latent and may reactivate at a later time. Most people in the United States have been infected with all of the herpes viruses by middle age. Therefore, nosocomial transmission is uncommon except in the pediatric population and in immunosuppressed patients.

Varicella-Zoster Virus. Varicella-zoster virus produces both chicken pox and herpes zoster (shingles). Although the primary infection (chicken pox) is usually uncomplicated in healthy

children, VZV infection in adults may be associated with major morbidity or death. Infection during pregnancy may result in fetal death or, rarely, in congenital defects. Health care workers with active VZV infection can transmit the virus to others.

After the primary infection, VZV remains latent in dorsal root or extramedullary cranial ganglia. Herpes zoster results from reactivation of the VZV infection and produces a painful vesicular rash in the innervated dermatome. Anesthesiologists working in pain clinics may be exposed to VZV when caring for patients who have discomfort from herpes zoster.

Varicella-zoster virus is highly contagious, especially from patients with chicken pox or disseminated zoster. The CDC estimates that the period of communicability begins 1 to 2 days before the onset of the rash and ends when all the lesions are crusted, usually 4 to 6 days after the rash appears.[60] Because VZV may be spread through airborne transmission, respiratory isolation should be used for patients with chicken pox or disseminated herpes zoster.[59] Use of gloves to avoid contact with vesicular fluid is adequate to prevent VZV spread from patients with localized herpes zoster.

Most adults in the United States have protective antibodies to VZV. Because there have been many reports of nosocomial transmission of VZV, it is recommended that all health care workers (HCW) have immunity to the virus. Anesthesia

personnel should be questioned about prior VZV infection, and those with a negative or unknown history of such infection should be serologically tested.[55] All employees with negative titers should be restricted from caring for patients with active VZV infection and should consider immunization with live, attenuated varicella vaccine.[60] Susceptible personnel with a significant exposure to people with VZV infection are candidates for varicella zoster immune globulin (VZIG), which is most effective when administered within 96 hours after exposure.[60] Personnel without VZV immunity should be reassigned to alternative locations so that they do not care for patients who have active VZV infections.

Herpes Simplex. Herpes simplex virus (HSV) infection is quite common in adults. After viral entry through the mucous membranes of the mouth, the primary infection with HSV Type 1 is usually clinically inapparent but may involve severe oral lesions, fever, and adenopathy. In healthy people, the primary infection subsides and the virus persists in a latent state within the sensory nerve ganglion innervating the site of infection. Any of several mechanisms can reactivate the virus to produce recurrent infection, which manifests in the vicinity of the primary lesion.

A second HSV, Type 2, is usually associated with genital infections and is spread by sexual contact. Newborns may become infected with HSV Type 2 during vaginal delivery.

Health care personnel may be inoculated by direct contact with body fluids carrying either herpes simplex virus Type 1 or 2.

Herpetic infection of the finger, herpetic paronychia or herpetic whitlow, is an occupational hazard for anesthesia personnel. The infection usually begins at the portal of viral entry, a site on the distal finger where the integrity of the skin has been broken, and results in vesicle formation. Within 3 weeks, the throbbing pain lessens, and the lesions begin to heal. Use of acyclovir, an antiviral drug that inhibits replication of HSV, may shorten the course of the primary cutaneous viral infection. Personnel with HSV infections of the fingers or hands should not contact patients until their lesions are healed.

Cytomegalovirus. Cytomegalovirus (CMV) infects between 50 and 85% of individuals in the United States before age 40, with most infections producing minimal symptoms. After the primary infection, the virus remains dormant, and recurrent disease only occurs with compromise of the individual's immune system. Transmission of CMV can take place through close contact with an individual excreting the virus or through contact with contaminated saliva or urine. It is unlikely that aerosols or small droplets play a role in CMV transmission.

Primary or recurrent CMV infection during pregnancy results in fetal infection in up to 2.5% of occurrences. Congenital CMV syndrome may be found in up to 10% of infected infants. Thus,

although CMV infection usually does not result in morbidity in healthy adults, it may have significant sequelae in pregnant women. CMV infection can also be deadly in immunocompromised patients, such as those undergoing bone marrow transplantation.

The two major populations with CMV infection in the hospital include infected infants and immunocompromised patients, such as those who have undergone organ transplants or those on oncology units. Routine infection control procedures (standard precautions) are sufficient to prevent CMV infection in health care workers (Tables 4-4 and 4-5).[55] Pregnant personnel should be made aware of the risks associated with CMV infection during pregnancy and of appropriate infection control precautions to be used when caring for high-risk patients. There is no evidence to indicate that it is necessary to reassign pregnant women from patient care areas in which they may have contact with CMV-positive patients.

TABLE 4-4 Prevention of Occupationally Acquired Infections[55,59,62]

▪INFECTIOUS AGENT	▪PREVENTIVE MEASURES[a]
Cytomegalovirus	Standard precautions
Hepatitis B	Vaccine; hepatitis B immune globulin, standard precautions
Hepatitis C	Standard precautions
Herpes simplex	Standard precautions; contact precautions if disseminated disease
Human immunodeficiency virus	Standard precautions; postexposure prophylactic antiretrovirals
Influenza	Vaccine; prophylactic antiretrovirals; droplet precautions
Measles	Vaccine; airborne infection isolation precautions
Rubella	Vaccine; droplet precautions
Severe acute respiratory syndrome (SARS)	Standard precautions; airborne infection isolation precautions
Tuberculosis	Airborne infection isolation precautions; isoniazid ± ethambutol for PPD conversion
Varicella-zoster	Vaccine; varicella-zoster immune globulin; airborne infection isolation and contact precautions; standard precautions if localized disease

[a]Isolation precautions outlined in Table 4-5.

TABLE 4-5 Hospital Isolation Precautions[59]

▪STANDARD PRECAUTIONS

These are to be used for the care of all patients regardless of their diagnosis or presumed infection status.

Standard precautions should be used in conjunction with other forms of isolation precautions (see below) for the care of specific patients.

1. *Hand washing*
   After touching blood, body fluids, or contaminated items even if gloves are worn.
2. *Gloves*
   Wear gloves when touching blood, body fluids, or contaminated items.
   Change gloves between tasks on the same patient when there is likely to be a high concentration of organisms.
   Remove gloves after use, before touching noncontaminated items and environmental surfaces.
3. *Mask, eye protection, face shield*
   Use during procedures likely to generate splashes of blood or body fluids that may contaminate face or mucous membranes.
4. *Gown*
   Use during procedures likely to generate splashes of blood or body fluids that may contaminate clothing or arms.
5. *Patient-care equipment*
   Handle soiled equipment in a manner that prevents skin, mucous membrane, clothing, or environmental contamination.
6. *Environmental control*
   Contaminated environmental surfaces should routinely be cleaned and/or disinfected.
7. *Linen*
   Soiled linen should be handled in a manner that prevents contamination of personnel, other patients, and environmental surfaces.
8. *Occupational health and bloodborne pathogens*
   Use care to prevent injuries when using or disposing of needles and sharp devices.

Contaminated needles should not be recapped or manipulated by using both hands. If recapping is necessary for the procedure being performed, a one-handed scoop technique or mechanical device for holding the needle sheath should be used.
Contaminated needles should not be removed from disposable syringes by hand.
Do not break or bend contaminated needles before disposal.
After use, disposable syringes and needles and other sharp devices should be placed in appropriate puncture-resistant containers located as close as practical to the area in which the items were used.
Mouthpieces, resuscitation bags, or other ventilation devices should be available for use as an alternative to mouth-to-mouth ventilation.

9. *Patient placement*
   Private rooms should be used for patients who are likely to contaminate the environment.

▪*TRANSMISSION-BASED PRECAUTIONS*

These should be used along with standard precautions for patients known or suspected to be infected or colonized with highly transmissible pathogens requiring additional precautions.

▪*AIRBORNE INFECTION ISOLATION PRECAUTIONS*

These should be used for patients known or suspected to be infected with microorganisms transmitted by airborne droplet nuclei (particles 5 μm or smaller in size) that can be dispersed over large distances by air currents.

1. *Patient placement*
   The patient should be placed in a private room with (1) documented negative air pressure relative to surrounding areas, (2) 6 to
   12 air changes per hour, (3) discharge of air outdoors or monitored high-efficiency filtration of room air before the air is circulated to other areas in the hospital.
   The door to the room should be kept closed and the patient should remain in the room.
2. *Respiratory protection*
   Respiratory protection should be worn when entering the room of a patient with known or suspected infectious pulmonary tuberculosis.
   Susceptible personnel should not enter the room of patients known or suspected to have measles or varicella if other immune caregivers are available. If susceptible persons must enter the room of a patient known or suspected to have measles or varicella, they should wear respiratory protection. Persons immune to measles or varicella need not wear respiratory protection.
3. *Patient transport*
   Patients should be transported from the isolation room only for essential purposes. When transport is necessary, a surgical mask should be placed on the patient to prevent dispersal of droplet nuclei.
4. *Patients with tuberculosis*
   Current CDC guidelines should be consulted for additional precautions.[81]

·DROPLET PRECAUTIONS

These should be used for patients known or suspected to be infected with microorganisms transmitted by large-particle droplets (particles larger than 5 μm) that can be generated during coughing, sneezing, talking, or by performing certain procedures.

1. *Patient placement*
   The patient should be placed in a private room.
2. *Respiratory protection*
   Personnel should wear a mask when working within 3 feet of the patient.
3. *Patient transport*
   Patients should be transported from the isolation room only for essential purposes.
   When transport is necessary, a surgical mask should be placed on the patient to prevent dispersal of droplets.

·CONTACT PRECAUTIONS

These should be used for patients known or suspected to be infected or colonized with epidemiologically important microorganisms transmitted by direct contact with the patient or indirect contact with environmental surfaces or patient-care items.

1. *Patient placement*
   The patient should be placed in a private room.
2. *Gloves and hand washing*
   In addition to wearing gloves as outlined under standard precautions, gloves (nonsterile) should be worn when entering the patient's room.
   Gloves should be changed after contacting infective material that may contain high concentrations of microorganisms.
   Gloves should be removed before leaving the patient's environment and hands should be washed immediately with an antimicrobial agent or a waterless antiseptic agent.
   After removal of gloves and hand washing, care should be taken so that contaminated environmental surfaces should not be touched to avoid transfer of microorganisms to other patients.
3. *Gown*
   In addition to wearing a gown as outlined under standard precautions, a gown (nonsterile) should be worn when entering the room when it is anticipated that clothing will have contact with the patient, environmental surfaces, or contaminated items or if the patient is incontinent or has diarrhea, an ileostomy, a colostomy, or wound drainage not contained by a dressing.
   The gown should be removed before leaving the patient's environment.
   Clothing should not contact potentially contaminated surfaces after removal of the gown.
4. *Patient transport*
   The patient should be transported from the room for only essential purposes.
   If it is necessary to transport the patient, precautions should be maintained to minimize the risk of transmission of microorganisms to other patients and contamination of environmental surfaces or equipment.

5. *Patient-care equipment*
   Dedicate the use of noncritical patient-care equipment (e.g., blood pressure cuffs) to a single patient to avoid transmission of microorganisms to another patient. If use of common equipment is unavoidable, then items should be adequately cleaned or disinfected before use on another patient.

Rubella

Outbreaks of rubella, or German measles, in hospital personnel have resulted in significant loss in employee working time, employee morbidity, and cost to the hospital. Although most adults in the United States are immune to rubella, up to 20% of women of childbearing age are still susceptible. Rubella infection during the first trimester of pregnancy is associated with congenital malformations or fetal death.

Rubella is transmitted by contact with nasopharyngeal droplets spread by infected individuals coughing or sneezing. Patients are most contagious while the rash is erupting but can transmit the virus from 1 week before to 5 to 7 days after the onset of the rash. Droplet precautions should be used to prevent transmission (Table 4-5).[55]

Ensuring immunity at the time of employment (evidence of prior vaccination with live rubella vaccine or serologic confirmation) should prevent nosocomial transmission of rubella to personnel. It has been shown that history is a poor indicator of immunity. A live, attenuated rubella virus vaccine, contained in measles, mumps, rubella vaccine (MMR), is available to produce immunity in susceptible personnel.[53,61] Many state or local health departments mandate rubella immunity for all HCW, and local regulations should be consulted.

Measles (Rubeola)

5 Measles virus is highly transmissible both by large droplets and by the airborne route. The virus is found in the mucus of the nose and pharynx of the infected individual and is spread by coughing and sneezing. The disease can be transmitted from

4 days prior to the onset of the rash to 4 days after its onset. Airborne precautions should be used for infected patients (Table 4-5).[55] Introduction of the measles vaccine in the United States has successfully eliminated indigenous cases of measles but importation of measles from other countries continues to occur.

Health care workers are at increased risk for acquiring measles and transmitting the virus to susceptible coworkers and patients. The CDC recommends that medical personnel have adequate immunity to measles, as documented by one of the following: evidence of two doses of live measles vaccine, a record of physician-diagnosed measles, or serologic evidence of measles immunity (Table 4-4).[55] Susceptible personnel born in or after 1957 should receive two doses of the live measles vaccine at the time of employment.[61]

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is an emerging respiratory tract infection produced by

a coronavirus, SARS-associated coronavirus (SARS-CoV). After the first cases were reported from Asia in late 2002, the disease quickly spread globally in 2003 before being controlled. SARS typically presents with a high fever, greater than 38.0°C, and is followed with symptoms of headache, generalized aches, and cough. Severe pneumonia may lead to acute respiratory distress syndrome (ARDS) and death.

SARS is spread by close person-to-person contact through virus carried in large respiratory droplets and possibly by airborne transmission. The virus can also be spread when an individual touches a contaminated object and then inoculates their mouth, nose, or eyes. Aerosolization of respiratory secretions during coughing or endotracheal suctioning has been associated with transmission of the disease to HCW, including anesthesiologists and critical care nurses. It appears that some infected individuals are “super-shedders” of the virus and present a greater risk for transmission to contacts.

One of the most important interventions to prevent the spread of SARS in the health care setting is early detection and isolation of patients who may be infected with SARS-CoV.[62] Standard and Droplet Precautions should be used when contacting patients with symptoms of a respiratory illness (Table 4-5) until it is determined that the cause of the pneumonia is not contagious. Contact and Airborne Infection Isolation (AII) should be used for patients with laboratory evidence of SARS or those strongly suspected of having SARS-CoV infection. Gloves, gown, respiratory protection (as a minimum, use a NIOSH-certified N-95 filtering respirator), and eye protection should be donned before entering a SARS patient's room or during procedures likely to generate respiratory aerosols.[62]

Viral Hepatitis

Although many viruses may produce hepatitis, the most common are Type A or infectious hepatitis, Type B (HBV) or serum hepatitis, and Type C (HCV), which is responsible for most cases of parenterally transmitted non-A, non-B hepatitis (NANBH) in the United States. Delta hepatitis, caused by an incomplete virus, occurs only in people infected with HBV. Outbreaks of an enterically transmitted NANBH (hepatitis E) have been reported from outside the United States and are usually caused by contaminated water. The greatest risks of

occupational transmission to anesthesia personnel are associated with HBV and HCV.

Hepatitis A

About 20 to 40% of viral hepatitis in adults in the United States is caused by the Type A virus. Hepatitis A is usually a self-limited illness, and no chronic carrier state exists. Spread is predominantly by the fecal–oral route, either by person-to-person contact or by ingestion of contaminated food or water. Outbreaks are usually found in institutions or other closed groups where there has been a breakdown in normal sanitary conditions. Hospital personnel do not appear to be at increased risk for hepatitis A and nosocomial transmission is rare.

Personnel exposed to patients with hepatitis A should receive immune globulin intramuscularly as soon as possible but not greater than 2 weeks after the exposure to reduce the likelihood of infection.[63] Immune globulin provides protection against hepatitis A through passive transfer of antibodies and is used for postexposure prophylaxis. Hepatitis A vaccine is not routinely recommended for HCW except for those that may be working in countries where hepatitis A is endemic.[53,63]

Hepatitis B

Hepatitis B is a significant occupational hazard for nonimmune anesthesiologists and other medical personnel who have frequent contact with blood and blood products. The prevalence (the proportion of people who have or have had the condition at the time of the survey) of hepatitis B in the general population of the United States is 3 to 5%, and the carrier rate is 0.2 to 0.9% based on serologic screening. Serosurveys including more than 2400 unvaccinated anesthesia

personnel conducted in the United States and several other countries demonstrated a mean prevalence of HBV serologic markers of 17.8% (range, 3.2–48.6%).[64] The range of seropositive findings in anesthesia personnel in various locations probably reflects the prevalence of HBV carriers in the referral population for the area. Within the United States, studies conducted before the widespread usage of hepatitis B vaccine indicated that the prevalence of hepatitis B serologic markers in anesthesia personnel ranged from 19 to 49%.

Acute HBV infection may be asymptomatic and usually resolves without significant hepatic damage. Less than 1% of acutely infected patients develop fulminant hepatitis. Approximately 10% become chronic carriers of HBV (i.e., serologic evidence demonstrated for more than 6 months). Within 2 years, half of the chronic carriers resolve their infection without significant hepatic impairment. Chronic active hepatitis, which may progress to cirrhosis and is linked to hepatocellular carcinoma, is found most commonly in individuals with chronic viral infection for more than 2 years. The implementation of routine vaccination, use of standard precautions, use of safety devices, and postexposure prophylaxis have significantly reduced the risk of occupationally acquired HBV infection and its sequelae in HCW.

The diagnosis and classification of the stage of HBV infection can be made on the basis of serologic testing. Antibody to the surface antigen (anti-HBs) appears with resolution of the acute infection and confers lasting immunity against subsequent HBV infections. Chronic HBV carriers are likely to have hepatitis B surface antigen (HBsAg) and antibody to the core antigen (anti-HBc) present in serum samples. The presence of hepatitis B e antigen (HBeAg) in serum is indicative of active viral replication in hepatocytes.

Anesthesia personnel are at risk for occupationally acquired HBV infection as a result of accidental percutaneous or mucosal contact with blood or body fluids from infected patients. Patient groups with a high prevalence of HBV include immigrants from endemic areas, users of illicit parenteral drugs, homosexual men, and patients on hemodialysis.[54] Carriers are frequently not identified during hospitalization because the clinical history and routine preoperative laboratory tests may be insufficient for diagnosis. The risk for infection after an HBV-contaminated percutaneous exposure, such as an accidental needle stick, is 37 to 62% if the source patient is HBeAg-positive and 23 to 37% if HBeAg-negative. HBV can be found in saliva, but the rate of transmission is significantly less after mucosal contact with infected oral secretions than after percutaneous exposures to blood. HBV is a hardy virus that may be infectious for at least 1 week in dried blood on environmental surfaces.

6 **Hepatitis B Vaccine.** Use of hepatitis B vaccine is the primary strategy to prevent occupational transmission of HBV to anesthesia personnel and other HCW at increased risk.[54] Administration of three doses of vaccine into the deltoid muscle results in the production of protective antibodies (anti-HBs) in more than 90% of healthy HCW. Hospitals or anesthesia departments should have policies for educating, screening, and counseling personnel about their risk of acquiring HBV infection and should make vaccination available for susceptible personnel.[54,65]

To ensure adequate postvaccination immunity, serologic testing for anti-HBs should take place within 1 to 2 months after the third dose of vaccine.[54] Protective antibodies develop in 30 to 50% of nonresponders (i.e., anti-HBs <10 mIU/mL) with a second 3-dose vaccine series. Nonresponders to vaccination, who are HBsAg-negative, remain at risk for HBV infection and should be counseled on strategies to prevent infections and the need for postexposure prophylaxis.

Vaccine-induced antibodies decline over time, with maximum titers after vaccination correlating directly with duration of antibody persistence. The CDC states that for vaccinated adults with normal immune status, routine booster doses are not necessary and periodic monitoring of antibody concentration is not recommended.[54]

When susceptible or nonvaccinated anesthesia personnel have a documented exposure to a contaminated needle or to blood from an HBsAg-positive patient, postexposure prophylaxis with HBV hyperimmune globulin (HBIG) is recommended.[54] Hepatitis B vaccine should be offered to any

unvaccinated, susceptible person who sustains a blood or body fluid exposure.

Hepatitis C

Hepatitis C virus causes most cases of parenterally transmitted NANBH and is a leading cause of chronic liver disease in the United States. Although antibody to HCV (anti-HCV) can be detected in most patients with hepatitis C, its presence does not correlate with resolution of the acute infection or progression of hepatitis, and it does not confer immunity against HCV infection.[66] Seropositivity for HCV RNA, using polymerase chain reaction, is a marker of chronic infection and continued viral presence.

Most cases of acute HCV infection are asymptomatic, but infected individuals have a high rate of progression to chronic hepatitis. Up to 60% of HCV-infected patients will have biopsy-proven chronic hepatitis, with many developing cirrhosis. HCV RNA can still be detected in more than 75% of patients after resolution of acute hepatitis C.[66] Combination therapy with interferon and ribavirin has been effective in the treatment of some cases of chronic hepatitis C. In a limited clinical trial, interferon alfa-2b was effective in preventing chronic hepatitis C in patients with acute infection.[67]

Like HBV, HCV is transmitted through blood and sexual contact, but the rate of occupational HCV infection is less than for HBV. Although HCV transmission has been documented in health care settings, the prevalence of anti-HCV in HCW in the

United States is not greater than that found in the general population. The greatest risk of occupational HCV transmission is associated with exposure to blood from an HCV-positive source, and the average rate of seroconversion after accidental percutaneous exposure is 1.8%.[54] HCV has been transmitted through blood splashes to the eye and with exposure via nonintact skin. HCV in dried blood on environmental surfaces may remain infectious for up to 16 hours, but environmental contamination does not appear to be a common route of transmission. Although HCV can be found in the saliva of infected individuals, it is not believed to represent a great risk for occupational transmission.[54]

There is no vaccine or effective postexposure prophylaxis available to prevent HCV infection, and use of immune globulin is no longer recommended after a known exposure.[54] The effectiveness of interferon has not been documented as effective prophylaxis after occupational exposure. Prevention of exposures remains as the primary strategy for protecting HCW against HCV infection. Personnel who have had a percutaneous or mucosal exposure to HCV-positive blood should have serologic testing for anti-HCV and alanine aminotransferase and counseling at the time of the exposure and at 6 months.[54]

Pathogenic Human Retroviruses

HIV Infection and AIDS

The agent that produces acquired immunodeficiency syndrome (AIDS) is the human immunodeficiency virus (HIV), one of several pathogenic human retroviruses. Current estimates suggest that 650,000 to 900,000 people in the United States are infected with HIV. According to CDC data, from 1981 through December 2002 there have been 859,000 cases of AIDS in the United States.[68]

The initial infection with HIV presents clinically as a mononucleosis-like syndrome with lymphadenopathy and rash. Although the patient then enters an asymptomatic period, monocyte-macrophage cells serve as a reservoir for the virus throughout the body, and CD4+ T cells harbor the virus in the blood. Within a few weeks after infection, an antibody may be detected by the enzyme-linked immunosorbent assay (ELISA) and is confirmed using the more specific Western blot test. After a variable length period of asymptomatic HIV infection, there is an increase in viral titer and impaired host immunity, resulting in opportunistic infections and malignancies characteristic of AIDS. As the use of highly active antiretroviral therapy became widespread in the

United States in 1996, the average length of survival after HIV infection increased.

HIV is spread by sexual contact (especially homosexual males), perinatally from infected mother to neonate, and through infected blood (transfusion or shared needles) and blood products. Although the virus can be found in saliva, tears, and urine, these body fluids have a low risk for viral transmission. Many HIV-infected patients in health care settings may not be identified as such by their initial or presenting diagnosis.

Risk of Occupational Human Immunodeficiency Virus Infection. Although there are several modes of transmission for HIV infection in the community, the most important source for occupational transmission of HIV to HCW is blood contact.[54] The rate of seroconversion in health care workers sustaining a percutaneous exposure (needle stick injury) to HIV-infected blood is estimated to be 0.3%,[69] while the rate after a mucous membrane exposure is 0.09%.[70] Transmission has occurred after blood exposure to nonintact skin, but although the rate is unknown, it is likely less than for mucous membrane exposure.

A case-control study has demonstrated that specific factors are associated with an increased rate of HIV transmission after a percutaneous injury.[71] Increased risk was associated with a deep injury, visible blood on the device producing the injury, a procedure in which the needle was placed in an artery or vein, and terminal illness (death from AIDS within 2 months) in the source patient. Therefore, the risk of occupational HIV transmission is greatest after a deep injury with a blood-filled, large-gauge, hollow-bore needle used on a patient in the terminal phase of AIDS.

The occupational risk of HIV infection is a function of the annual number of blood exposures, the rate of HIV transmission with each exposure to infected blood, and the prevalence of HIV infection in the specific patient population. Greene et al prospectively collected data on 138 contaminated percutaneous injuries to anesthesia personnel.[72] The rate of contaminated percutaneous injuries per year per full-time equivalent anesthesia worker was 0.42, and the average annual risk of HIV and HCV infection was estimated to be 0.0016 and 0.015%, respectively.

Anesthesia personnel are frequently exposed to blood and body fluids during invasive procedures such as insertion of vascular catheters, arterial punctures, and endotracheal intubation.[51,72,73] Although many exposures are mucocutaneous and can be prevented by the use of gloves and protective clothing, these barriers do not prevent percutaneous exposures such as needle stick injuries, which carry a greater risk for pathogen transmission. Because of the tasks they perform, anesthesia personnel are likely to use and be injured by large-bore, hollow needles such as IV catheter stylets and needles on syringes.[72,74] Needleless or protected needle safety devices can be used to replace standard devices to reduce the risk of needle stick injuries. Although safety devices usually are more expensive than a comparable nonsafety item, they may be more cost-effective when the cost of needle stick injury investigation and medical care for infected personnel is considered.

Percutaneous injuries have now been accepted as a significant occupational risk for health care workers.[51] The Needlestick Safety and Prevention Act of 2000 mandated that OSHA update its Bloodborne Pathogen Standard to require that exposure control plans include a process for evaluating and implementing the use of commercially available safety medical devices.[65] Employers were also required to maintain a “sharps” injury log to collect data to evaluate exposure risks and the effectiveness of safety devices. Because federal regulations require the use of safety devices, as new technologies become available, clinicians must assess these within their practice to determine which are most effective for specific tasks.

Postexposure Treatment and Prophylactic Antiretroviral Therapy. When personnel have been exposed to patients' blood or body fluids, the incident should immediately be reported to the employee health service or the designated individual within the institution. Based on the nature of the injury, the exposed worker and the source individual should be tested for serologic evidence of HIV, HBV, and HCV infection.[54] Current local laws must be consulted to determine policies for testing the source patient, and confidentiality must be maintained. When the source patient is found to be HIV-positive, the employee should be retested for HIV antibodies at 6 and 12 weeks and at 6 months after exposure, although most infected people are expected to undergo

seroconversion within the first 6 to 12 weeks. During this period, the exposed employee should follow CDC recommendations for preventing transmission of HIV to family members and patients.[54] If the source patient is found to be HIV-negative, no additional treatment is required.

The U.S. Public Health Service recommends that antiretroviral postexposure prophylaxis (PEP) be offered to HCW who have incurred a significant percutaneous exposure to HIV-infected blood.[54] The specific antiretroviral regimen is

based on the severity of exposure and the source patient. Because protocols for chemoprophylaxis are likely to change with additional research and the introduction of new antiretroviral drugs, the most current recommendations, such as those provided on the CDC website (http://0-www.cdc.gov.innopac.up.ac.za:80/niosh/topics/bbp), should be consulted prior to instituting postexposure prophylactic therapy. To be most effective, PEP should be initiated as soon as possible after exposure (less than 24 hours) and continued for 4 weeks. HCW should be counseled on the potential toxic effects of antiretrovirals so that they can make an informed decision on the risks associated with PEP. Failure of PEP has been attributed to large viral inoculum, use of a single antiviral agent, drug resistance in the virus from the source patient, and delayed initiation or short duration of PEP therapy.

Occupational Safety and Health Administration Standards, Universal Precautions, and Isolation Precautions

In the late 1980s the CDC formulated recommendations, or universal precautions, for preventing transmission of bloodborne infections (including HIV, HBV, and HCV) to HCW. The guidelines were based on the epidemiology of HBV as a worst-case model for transmission of bloodborne infections and current knowledge of the epidemiology of HIV and HCV. Because some carriers of bloodborne viruses could not be identified, universal precautions were recommended for use during all patient contact. Although exposure to blood carries the greatest risk of occupationally related transmission of HIV, HBV, and HCV, it was recognized that universal precautions should also be applied to semen, vaginal secretions, human tissues, and the following body fluids: cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic. Subsequently, the CDC synthesized the major features of universal precautions into standard precautions, a single set of precautions that should be applied to all patients (Table 4-5).[59] Standard precautions were included in a more complete set of isolation precautions, which contain guidelines (airborne precautions, droplet precautions, and contact precautions) to reduce the risk of transmission of bloodborne and other pathogens in health care settings.[59]

Standard precautions include the use of gloves when an HCW contacts mucous membranes and oral fluids, such as during endotracheal intubation and pharyngeal suctioning. The selection of specific barriers or personal protective equipment should be commensurate with the task being performed. Gloves may be all that is necessary during insertion of a peripheral intravenous catheter, whereas gloves, gown, mask, and face shield may be required during endotracheal intubation in a patient with hematemesis. Gloves should be removed after they become contaminated to prevent dissemination of blood or body fluids to equipment or other items that may be contacted by ungloved personnel. Waterless antiseptics should be available to permit anesthesia personnel to wash their hands after glove removal without leaving the operating room.

OSHA has promulgated Standards to protect employees from occupational exposure to bloodborne pathogens.[65] Employers subject to OSHA must comply with these federal regulations. The Standard requires that there must be an Exposure Control Plan specifically detailing the methods that the employer is providing to reduce employees' risk of exposure. The employer must evaluate engineering controls such as needleless devices to eliminate hazards. Work practice controls are encouraged to reduce blood exposures by altering the manner in which personnel perform tasks (e.g., an instrument rather than fingers should be used to handle needles). The employer must furnish appropriate personal protective equipment (e.g., gloves, gowns) in various sizes to permit employees to comply with universal precautions. The HBV vaccine must be offered at no charge to personnel. A mechanism for postexposure treatment and follow-up must be provided. An annual educational program should inform employees of their risk for bloodborne infection and the

resources available to prevent blood exposures. Implementation of standard precautions and OSHA regulations have been effective in decreasing the number of exposure incidents that result in HCW contact with patient blood and body fluids.

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease (CJD), caused by an infectious protein or prion, may be unsuspected in patients presenting with dementia.[75] More recently, it has been recognized that the prion strain associated with bovine spongiform encephalopathy has infected humans to produce a variant CJD. Iatrogenic transmission of CJD to patients has taken place through contaminated biologic products and surgical instruments and via blood transfusion. The risk of transmission to hospital personnel is unknown because surveillance is complicated by the long period from the time of infection until the onset of symptoms. Universal precautions should be used. Tissues with greatest risk of infectivity are brain, spinal cord, and eyes.

The prion is difficult to eradicate from equipment, and special sterilization methods are required for instruments that come into contact with high-infectivity tissues. The World Health Organization has developed infection control and sterilization guidelines for CJD (http://0-www.who.int.innopac.up.ac.za:80/emc-documents/tse/docs/whocdscsraph2003.pdf). The prion is not transmitted through respiratory routes.

Tuberculosis

The incidence of tuberculosis in the United States has declined since 1992, reversing the increase in reported cases that had begun in 1986. Although most individuals infected with tuberculosis are treated on an outpatient basis, undiagnosed patients may be hospitalized for the workup of pulmonary pathology. Hospital personnel are especially at risk for infection from unrecognized cases.[76,77] Groups with a higher prevalence of tuberculosis include (1) personal contacts of people with active tuberculosis; (2) people from countries with a high prevalence of tuberculosis; and (3) alcoholics, homeless people, and intravenous drug users.[76]

Mycobacterium tuberculosis is transmitted through viable bacilli carried on airborne particles, 1 to 5 μm in size, by coughing, speaking, or sneezing. Airborne infection isolation should be used for hospitalized patients suspected of having tuberculosis until they are confirmed as nontransmitters by sputum examination that demonstrates no bacilli.[76] Appropriate chemotherapy is the most effective means to prevent spread of tuberculous infection.[78] Elective surgery should be postponed until infected patients have had an adequate course of chemotherapy. If surgery is required, filters should be used on the anesthetic breathing circuit for patients with tuberculosis.[76,79]

Several hospital outbreaks of multidrug-resistant *M. tuberculosis* infection have been reported.[77,80] Mortality associated with these outbreaks is high. Factors responsible for nosocomial transmission include delayed diagnosis of tuberculosis so that multiple patients and personnel were exposed and delayed recognition of drug resistance resulting in inadequate initial drug therapy.

Effective prevention of spread to HCW requires early identification of infected patients and immediate initiation of airborne infection isolation (negative-pressure rooms with

air vented outside; see Table 4-5).[76,79] Patients must remain in isolation until adequate treatment is documented. If patients with tuberculosis must leave their rooms, they should wear face masks to prevent spread of organisms into the air. HCW should wear respiratory protective devices when they enter an isolation room or when performing procedures that may induce coughing, such as endotracheal intubation or tracheal suctioning.[76] The CDC recommends that respiratory protective devices worn to protect against *M. tuberculosis* should be able to filter 95% of particles 1 mm in size at flow rates of 50 liters per minute and should fit the face with a leakage rate around the seal of less than 10% documented by fit testing.[76] High-efficiency particulate air respirators (classified as N95) are NIOSH-approved devices that meet the CDC criteria for respiratory protective devices against *M. tuberculosis*.[81]

Routine periodic screening of employees for tuberculosis should be included as part of a hospital's

employee health policy with the frequency of screening dependent on the prevalence of infected patients in the hospitalized population. When a new conversion is detected by skin testing, a history of exposure should be sought to determine the source patient. Treatment or preventive therapy is based on the drug-susceptibility pattern of the *M. tuberculosis* in the source patient, if known. Personnel who have been exposed to a patient with active tuberculosis should be followed by skin testing.

Viruses in Smoke Plumes

The laser is commonly used for vaporizing carcinomatous and viral tumors. Use of lasers and electrosurgical devices is associated with several hazards, both to patients and to operating room personnel. Risks include thermal burns, eye injuries, electrical hazards, and fires and explosions. There is evidence that the smoke plumes resulting from tissue vaporization contain toxic chemicals such as benzene and formaldehyde, and in 1996, NIOSH released a Health Hazard Alert on the dangers of smoke plumes.[82]

Clinical and laboratory studies have demonstrated that when the carbon dioxide laser is used to treat verrucae (papilloma and warts), intact viral DNA could be recovered from the plume. Viable viruses can be found in plumes produced by both carbon dioxide and argon laser vaporization of a virus-loaded culture plate, but viable viruses are carried on larger particles that travel less than 100 mm from the site being vaporized.[83]

A case report describes laryngeal papillomatosis in a surgeon who had used a laser to remove anogenital condylomas from several patients.[84] Although DNA analysis of the surgeon's papillomas revealed a viral type similar to that of the condylomas, proof of transmission is lacking.

To protect operating room personnel from exposure to the viral and chemical content of the laser plume, it is recommended that a smoke evacuation system be utilized with the suction nozzle being held as close as possible to the tissue being vaporized.[85] In addition, operating room personnel working in the vicinity of the laser plume should wear gloves, goggles, and high-efficiency filter masks.[73]

EMOTIONAL CONSIDERATIONS

Stress

Stress is a well-recognized element of the operating room workplace. However, there is very little objective information specifically directed toward understanding the nature of job-related stress among anesthesiologists.[86]

Stress is a nonspecific response to any change, demand, pressure, challenge, threat, or trauma.[87] There are three distinct components of the stress response: the initiating stressors, the psychological filters that process and evaluate the stressors, and the coping mechanisms that are employed in an attempt to control the stressful situation.

Stress on the job is unavoidable and to a certain degree is desirable. A moderate, manageable level of stress is the fuel necessary for individual achievement. Hans Seyle, one of the pioneering scientists in the modern study of stress, described a beneficial effect resulting from mild, brief and controllable episodes of stress.[88] In Seyle's words, “The absence of stress is death.” On the other hand, extreme degrees of stress can be associated with disorders of the psychological homeostatic mechanism and consequently can lead to physical or mental disease. Exactly how an individual responds to a particular stressor is the product of a series of factors, including age, gender, experience, preexisting personality style, available defense and coping mechanisms, support systems, and concomitant events (such as sleep deprivation).

A number of circumstances that classically define a stressful workplace are characteristic of the practice of anesthesiology. There is a background of chronic, low-level stress punctuated by intermittent episodes of extreme stress. The demands are externally paced, usually out of the anesthesiologist's control. Habituation to the demands is difficult. Perturbations are intermittently

but continuously inserted into the system. Finally, failure to meet the demands imposed by the workplace produces grave consequences.

Certain stressors are specific to the practice of anesthesiology. Concerns about liability, long working hours and night call, production pressures, economic uncertainty, and interpersonal relations are frequently cited as sources of chronic stress for anesthesiologists. The process of inducing anesthesia (particularly with a difficult airway) can be among the most profound sources of acute stress to anesthesiologists. Physiologic changes, including heart rate and rhythm, elevations in blood pressure, and myocardial ischemia, are not uncommon. One study reported increases in the blood pressure and heart rate of anesthesiologists during all stages of the anesthetic procedure, especially during the induction.[89] There was an inverse relationship between the years of experience of the anesthesiologist and the degree of stress as manifested by heart rate change.

Interpersonal relationships impose a set of demands that can be a major source of stress to an anesthesiologist. The operating room is unique as one of the few hospital sites where two co-equal physicians simultaneously share responsibility for the care of a patient. This creates a situation in which there are overlapping realms of clinical responsibility that can upset the customary hierarchy of command. To many anesthesiologists, as well as surgeons, this shared responsibility is the source of greatest conflict and professional stress. Other workplace settings, most notably the airline industry, have made better progress in identifying and correcting sources of interpersonal friction that facilitate stress and lead to professional errors.[90]

Several personality traits, in many cases identifiable before entrance to medical school, can be predictive of the potential toward maladaptive responses to stress. Prominent among these is the obsessive-compulsive, dependent character structure. These individuals typically manifest pessimism, passivity, self-doubt, and feelings of insecurity. Commonly they respond to stress by internalizing anger and becoming hypochondriacal and depressed. Undergraduate students who demonstrate these characteristics were more likely to have their medical careers disrupted by alcoholism or drug abuse, psychiatric illness, and marital disturbances.[91] McDonald et al[92] applied some of these considerations in an attempt to identify psychological attributes that may be of value in the selection

process for anesthesiology residents. A large number of adaptive coping functions have been advocated for successful stress management.[87] Only when appropriate coping mechanisms become overwhelmed by the magnitude of the stress do the defenses tend to become inappropriate. This situation may give rise to maladaptive behavior and the personal and professional deterioration that can lead to disorders such as drug addiction, professional burnout, and suicide.

Substance Use, Abuse, and Dependence

Illicit drug use remains one of our society's major afflictions. It is estimated that 20 million Americans are drug abusers, with some 5 million addicted. *Substance abuse* is characterized by significant adverse consequences resulting from the repeated use of a substance.[93] With *chemical dependence*, the individual continues to use a substance in spite of having significant substance-related problems including symptoms of withdrawal, the need for larger amounts of the substance, unsuccessful attempts to control its use, and the need to spend increasing amounts of time seeking the substance. With time, chemical dependence leads to health, social, and economic problems.

Epidemiology

The abuse of drugs and consequent chemical dependency by physicians has attracted considerable media attention and notoriety. Recognition of the problem of substance dependence among physicians is not new. In the first edition of *The Principles and Practice of Medicine*, edited by Sir William Osler and published in 1892, it is stated: “The habit (morphia) is particularly prevalent among women and physicians who use the hypodermic syringe for the alleviation of pain, as in neuralgia or sciatica.”

It is debatable whether substance abuse is more prevalent among physicians than the general population. Hughes et al[94] found that physicians abused alcohol, minor opiates, and benzodiazepine tranquilizers more frequently than the general population. In many cases, the prescription drugs were self-prescribed and were considered by the physician to be “self-treatment.” On the other hand, physicians were less likely to use tobacco or illicit substances. A report from the National Institute on Drug Abuse concludes that HCW suffer from chemical dependency (including alcohol abuse) at a rate roughly equivalent to that of the general population (8 to 12%).[95]

In the event that a drug-related problem does exist, physicians are less likely than the population in general to seek professional assistance. Denial plays a major role in this reluctance to undergo counseling or therapy. Medical students learn early in their education to utilize denial to enable them to endure long, sleepless nights and the personal shortcomings that inevitably accompany the practice of medicine. These well-developed denial mechanisms enable the physician-addict to conclude that his or her problem is minor and that self-treatment is possible. Physicians typically enter programs for treatment only after they have reached the end stages of their illness.

It is commonly reported that chemical dependency is a specific problem for the specialty of anesthesiology and represents its primary occupational hazard.[96] One example of the increased incidence of substance abuse reported among anesthesiologists comes from the Medical Association of Georgia Disabled Doctors' Program.[97] Anesthesiologists constituted 12% of physician patients treated at the center although they represented only 3.9% of American physicians. On the other hand, other studies have failed to identify an overall excess prevalence of substance abuse among anesthesiologists with the notable exception of major opiates.[98,99]

One very troubling aspect of this problem is the increased incidence of substance abuse reported among anesthesiology residents. In the report from the Medical Association of Georgia Disabled Doctors' Program,[97] anesthesiology residents constituted 33.7% of the resident population of the treatment group, despite representing only 4.6% of the resident population.

The incidence of controlled substance abuse within anesthesiology training programs is estimated to be 1 to 2%.[100] This statistic is particularly troubling because it has persisted despite the increased emphasis placed on education and accountability of controlled substances in the recent decade. ACGME requirements mandate that anesthesiology residency programs have a written policy and an educational program regarding substance abuse, but these efforts have not successfully addressed the problem of substance abuse in training programs.

The Disease of Substance Dependence

What accounts for this unacceptably high prevalence of substance dependence among anesthesiologists? To answer this, it is important to understand substance dependence as a chronic psychosocial, biogenetic disease.[101] Addiction shares many characteristics with other common chronic illnesses: (1) it is a primary condition (not a symptom), (2) it has established etiologies, (3) it is associated with specific anatomic and physiologic changes, (4) it has a set of recognizable signs and symptoms, and (5) if left untreated, it has a predictable, progressive course.

The causative factors in this disease process involve a genetic predisposition as well as the environment. The disease results from a dynamic interplay between a susceptible host and a “favorable” environment. Vulnerability in the host is an important factor. What constitutes an instigating exposure to a drug in one person may have absolutely no effect on another. Unfortunately, there is not a predictive tool to identify the susceptible individual until he or she gets the disease.

Causative factors thought to be specific to certain anesthesiologists include job stress, an orientation toward self-medication, lack of external recognition and self-respect, the availability of addicting drugs, and a susceptible premorbid personality. Self-prescription and recreational use of drugs are commonly seen as a prelude to more extensive substance abuse and dependence. Of concern are the increasing recreational use of drugs among younger physicians and medical

students and the choice of more potent drugs with enhanced potential for addiction, such as cocaine, the synthetic opioids, propofol, and some of the newer inhalation anesthetics.

Anesthesiologists work in a climate in which large quantities of powerful psychoactive drugs are freely available. Anesthesiologists are unique because they usually prescribe as well as personally administer these drugs in contrast to most other physicians who prescribe while others administer. The experience from soldiers in the United States Army in Vietnam suggests that when there is easy access to narcotics, alcohol use declines in favor of use of opiates. As each new synthetic opioid, anesthetic induction agent, and inhalation anesthetic has become available for clinical use, it has also become a drug of choice of abusing anesthesiologists. Because availability of drugs does play a role in the onset of this disease, attention has been directed toward programs to enforce increased accountability and regulation of controlled substances.[102] However, despite widespread application of protocols to enforce greater accountability, such as satellite pharmacies for operating suites, the frequency of substance abuse has changed little, if at all, in recent years.[100]

There is an apparent association between behavior before entering medical school and subsequent development of

substance abuse.[103] Personality profiles of anesthesiologists have suggested that a disturbingly high proportion that may be associated with a predisposition toward maladaptive behavior. Talbott et al[97] have observed that many of the anesthesia residents in their treatment program specifically chose the specialty of anesthesiology because of the known availability of powerful drugs.

The consequences of untreated chemical dependence are ultimately devastating. There is a gradual and inexorable deterioration in professional, family, and social relationships. The substance abuser becomes increasingly withdrawn and isolated, first in his or her personal life, and ultimately in his or her professional existence (Table 4-6). Every attempt is made to maintain a facade of normality at work, because discovery means isolation from the source of the abused drug. When professional conduct is finally impaired such that it is apparent to the physician's colleagues, the disease is approaching its end stage.

TABLE 4-6 Signs of Substance Abuse and Dependence

▪WHAT TO LOOK FOR OUTSIDE THE HOSPITAL

1. Addiction is a disease of loneliness and isolation. Addicts quickly withdraw from family, friends, and leisure activities.
2. Addicts have unusual changes in behavior, including wide mood swings and periods of depression, anger, and irritability alternating with periods of euphoria.
3. Unexplained overspending, legal problems, gambling, extramarital affairs, and increased problems at work are commonly seen in addicts.
4. An obvious physical sign of alcoholism is the frequent smell of alcohol on the breath.
5. Domestic strife, fights, and arguments may increase in number and intensity.
6. Sexual drive may significantly decrease.
7. Children may develop behavioral problems.
8. Some addicts frequently change jobs over a period of several years in an attempt to find a “geographic cure” for their disease, or to hide it from coworkers.
9. Addicts need to be near their drug source. For a health care professional, this means long hours at the hospital, even when off duty. For alcoholics, it means calling in sick to work. Alcoholics may disappear without any explanation to bars or

hiding places to drink secretly.
10. Addicts may suddenly develop the habit of locking themselves in the bathroom or other rooms while they are using drugs.
11. Addicts frequently hide pills, syringes, or alcohol bottles around the house.
12. Persons who inject drugs may leave bloody swabs and syringes containing blood-tinged liquid in conspicuous places.
13. Addicts may display evidence of withdrawal, especially diaphoresis (sweating) and tremors.
14. Narcotic addicts often have pinpoint pupils.
15. Weight loss and pale skin are also common signs of addiction.
16. Addicts may be seen injecting drugs.
17. Tragically, some addicts are found comatose or dead before any of these signs have been recognized by others.

▪*WHAT TO LOOK FOR INSIDE THE HOSPITAL*

1. Addicts sign out ever-increasing quantities of narcotics.
2. Addicts frequently have unusual changes in behavior, such as wide mood swings and periods of depression, anger, and irritability alternating with periods of euphoria.
3. Charting becomes increasingly sloppy and unreadable.
4. Addicts often sign out narcotics in inappropriately high doses for the operation being performed.
5. They refuse lunch and coffee relief.
6. Addicts like to work alone in order to use anesthetic techniques without narcotics, falsify records, and divert drugs for personal use.
7. They volunteer for extra cases, often where large amounts of narcotics are available (e.g., cardiac cases).
8. They frequently relieve others.
9. They're often at the hospital when off duty, staying close to their drug supply to prevent withdrawal.
10. They volunteer frequently for extra call.
11. They're often difficult to find between cases, taking short naps after using.
12. Addicted anesthesia personnel may insist on personally administering narcotics in the recovery room.
13. Addicts make frequent requests for bathroom relief. This is usually where they use drugs.
14. Addicts may wear long-sleeved gowns to hide needle tracks and also to combat the subjective feeling of cold they experience when using narcotics.
15. Narcotic addicts often have pinpoint pupils.
16. An addict's patients may come into the recovery room complaining of pain out of proportion to the amount of narcotic charted on the anesthesia records.
17. Weight loss and pale skin are also common signs of addiction.
18. Addicts may be seen injecting drugs.
19. Untreated addicts are found comatose.
20. Undetected addicts are found dead.

Adapted from Farley WJ, Arnold WP: Videotape: Unmasking addiction: Chemical Dependency in Anesthesiology. Produced by Davids Productions, Parsippany, NJ, funded by Janssen Pharmaceutica, Piscataway, New Jersey, 1991.

Reprinted with permission from American Society of Anesthesiologists: Task Force on Chemical Dependence of the Committee on Occupational Health of Operating Room Personnel: Chemical Dependence in Anesthesiologists: What You Need to Know When You Need to Know It. Park Ridge, Illinois, American Society of Anesthesiologists, 1998.

In its end stage, substance dependence is often a fatal illness. Alexander et al[14] calculated a relative risk of 2.75 for drug-related deaths among anesthesiologists compared to internists. In their study of substance abuse in anesthesiologists, Ward et al[104] reported that among the 334 confirmed drug abusers, 27 died of drug overdose and in another 3, abuse was discovered at death. Gravenstein et al[105] reported 7 deaths among 44 confirmed drug abusers. Menk et al[106] found 14 drug-related deaths among the 79 drug abusers who had been reenrolled in anesthesiology residencies after treatment.

In addition to health hazards, there are significant legal and medicolegal considerations that may affect chemically dependent physicians.[96] Laws and regulations vary by state but they detail the necessary steps for handling the drug-abusing physician. In many states disciplinary action and criminal penalties can be imposed on physicians who knowingly fail to report an impaired colleague. Disciplinary action taken against an impaired physician must also be reported to the National Practitioner Data Bank to be in compliance with federal law. State medical societies often have “wellness committees,” and when chemically dependent physicians seek treatment through this venue, the legal impact may be mitigated.

Debate continues regarding the issue of compulsory random drug testing of physicians.[107] Preemployment and/or random drug screening is already well established in various industries, especially those with high public health profiles (nuclear, aviation, military). Many chairs of academic anesthesiology programs have indicated a willingness to initiate a program of random drug screening of their staff.[100] Although random drug testing is an established element of most reentry contracts for recovering anesthesiologists, serious questions remain about the legality of this approach and its effectiveness in preventing substance abuse. Because fentanyl and sufentanil are the drugs abused by many chemically dependent anesthesiologists and because routine drug screens do not detect these agents, tests that effectively identify their use are expensive and have limited availability.

When there is sufficient data to identify an anesthesiologist as having chemical dependence, an intervention should be conducted by an experienced individual. The purpose of the intervention is to demonstrate to the anesthesiologist that they have the disease and to immediately have them enter a facility for evaluation and treatment. Treatment usually begins with inpatient therapy progressing to outpatient sessions. The family is actively involved with treatment, and the individual begins association with Alcoholics Anonymous (AA) or Narcotics Anonymous (NA).

Controversy remains about the ultimate career path of the anesthesiologist in recovery from chemical dependency. Within the general population, the recidivism rate approaches 60% for patients who have been treated for drug dependency. However, physicians are highly motivated and better rehabilitation rates might be expected. Reports by Talbott et al[97] and Ward et al[104] provided early optimism that in many cases anesthesiologists could be successfully rehabilitated and safely returned to their practices. In a study that examined relapse in addicted physicians,

the rate of relapse among anesthesiologists was 40% and that of control physicians was 44%.[108] Sustained recovery for longer than 2 years occurred in 81% and 86%, respectively. Although these data suggested that the outcome for recovering anesthesiologists was similar to other physicians, a study by Menk and colleagues[106] drew a different conclusion. Among 79 opioid-dependent anesthesiology residents, there was a 66% (52 of 79) failure rate for successful rehabilitation and return to practice. Even more discouraging, there were 14 suicide or overdose deaths among the 79 returning trainees. Their conclusion was that redirection into another specialty is the safer course after rehabilitation of narcotic-dependent residents.

Because of the contradictory data, no universal recommendations can be made about reentry into the practice of anesthesia after treatment. The American Board of Anesthesiology has established a policy for candidates with a history of alcoholism or illegal use of drugs (Table 4-7). To reenter practice, the recovering physician must qualify for a valid license to practice medicine and must be recredentialed at their medical facility. This must be done in compliance with their state laws and regulations that detail the circumstances under which a recovering physician can return to practice. Federal laws, such as the Americans with Disabilities Act, impose additional considerations. Additionally, a carefully worded contract is an important first step in the reentry process to define the obligations of the physician and the department.[96,109] There should also be regular meetings with the departmental supervisor to monitor the return process. It is also generally recommended that the returning anesthesiologist not take night or weekend call or handle opioids without direct supervision for at least the first 3 months. Despite all of these precautions, the potential for relapse must be anticipated.

TABLE 4-7 Policy Statement of the American Board of Anesthesiology (ABA)

The Americans with Disabilities Act (ADA) protects individuals with a history of alcohol abuse or substance abuse who are not currently abusing alcohol or using drugs illegally. The ABA supports the intent of the ADA.

The ABA will admit qualified applicants and candidates with a history of alcohol abuse to its examination system and to examination if, in response to its inquiries, the ABA receives acceptable documentation that they do not currently pose a direct threat to the health and safety of others.

The ABA will admit qualified applicants and candidates with a history of illegal use of drugs to its examination system and to examination if, in response to its inquiries, the ABA receives acceptable documentation that they are not currently engaged in the illegal use of drugs.

After a candidate with a history of alcohol abuse or illegal use of drugs satisfies the examination requirements for certification, the ABA will determine whether it should defer awarding its certification to the candidate for a period of time to avoid certifying a candidate who poses a direct threat to the health and safety of others. If the ABA determines that deferral of the candidate's certification is appropriate because the candidate does currently pose a threat to the health and safety of others, the ABA will assess the specific circumstances of the candidate's history of alcohol abuse or illegal use of drugs to determine when the candidate should write the Board to request issuance of its certification.

Guidelines from physician treatment centers may be helpful to assist in the decisions surrounding reentry.[93] Individuals who, in most situations, can successfully return to the

practice of anesthesiology immediately after treatment (Category I) accept and understand their disease and have no evidence of accompanying psychiatric disorders. They have strong support from their family, demonstrate a balanced lifestyle, are committed to their recovery contract, and bond with AA or NA. Their anesthesiology department and hospital must be supportive of their return, and the individual must have a sponsor that supports their return to anesthesiology.

Category II includes those individuals who could possibly return to anesthesiology within a few years. They must have no or minimal denial regarding their disease and have no other psychiatric diagnoses. Their recovery skills are continually improving and they are involved, but not necessarily bonded, with AA/NA. Although their family situation may be characterized as dysfunctional, there should be tangible evidence of improvement.

Individuals who should not return to anesthesiology and would best be redirected into another medical specialty are included in Category III. These individuals may have had a history of prolonged intravenous substance use and have experienced relapses and prior treatment failures. Their disease remains active, and they have coexisting severe psychiatric diagnoses. Often, these individuals entered anesthesiology with an expectation of being able to readily obtain drugs.

Impairment

Substance abuse probably accounts for the majority of the cases of impairment among physicians. (An impaired physician is defined as one “whose performance as a professional person and as a practitioner of the healing arts is impaired because of alcoholism, drug abuse, mental illness, senility, or disabling disease.”[110]) Other factors that may lead to impairment include physical or mental illness and deterioration associated with aging. Some authorities include unwillingness or inability to keep up with current literature and techniques as a form of impairment.

Data regarding the prevalence of these disabling disorders are more difficult to obtain than are those on drug abuse. Physicians are admitted to psychiatric facilities for organic psychoses, personality disorders, schizophrenia, neuroses, and affective, disorders, particularly depression.

It is not surprising that depression should figure prominently among the personality characteristics of emotionally impaired physicians. One survey noted that approximately 30% of medical interns were clinically depressed.[111] Indeed, when exaggerated, many of the personality traits that ensure success in the physician's world, such as self-sacrifice, competitiveness, achievement orientation, denial of feelings, and intellectualization of emotions, may also serve as risk factors for depression. Several studies on alcoholic physicians have provided some insight into this link between achievement orientation and emotional disturbance. In one study, more than half of the alcoholic physicians graduated in the upper one third of their medical school class, 23% were in the upper one tenth, and only 5% were in the lower one third of their class.[112] Similarly, a report on alcohol use in medical school demonstrated better first-year grades and higher scores on Part I National Board of Medical Examiners tests among those students identified as alcohol abusers.[113] Alcohol abuse is likely a manifestation of psychological disturbance resulting from excessive degrees of stress among some students who are most determined to have flawless records.

It can be difficult to appropriately respond to the problems imposed by the impaired or unsafe anesthesiologist.[114] Fortunately, most state legislatures and medical societies have formal protocols that address the impaired physician. These programs are usually therapeutic and nonpunitive in nature and provide for a relatively nonthreatening environment for intervention for the impaired physician. The license suspension power of the State Board of Medical Examiners is exercised only in cases in which a real risk to the public welfare exists and the involved physician is unwilling to voluntarily suspend practice and accept assistance. Management protocols for dealing with the impaired physician are covered in a series of articles by Canavan.[115]

The Aging Anesthesiologist

Little research has been directed toward the challenges faced by older anesthesiologists.[43] This is

in contrast to the situation in most other industries where strict attention is paid to the competence and well-being of older workers. For example, commercial pilots are required to take regular medical examinations and conform to policies regarding hours of work.

There are no age-specific conditions placed on state medical licensure or on the practice of anesthesiology. In most cases, the decision to limit practice or retire remains at the discretion of the individual anesthesiologist based on his or her self-evaluation. Since 2000, diplomates of the American Board of Anesthesiologists have time-limited certification and must successfully complete the Maintenance of Certification in Anesthesiology program every 10 years to document continuing qualifications and to maintain certification.

As a result of a number of demographic factors, including the smaller residency class sizes observed during the mid 1990s, the mean age of the anesthesiology workforce is increasing. The greatest number (30%) of anesthesiologists are between age 45 and 54 years of age, and 56% are age 45 and older (up from 49% 10 years ago).[15]

Several physiologic changes frequently associated with aging have the potential of impacting on an individual's ability to practice anesthesiology. Potential sources of impairment including decrements in hearing, vision, short-term memory, strength, and endurance may often be compensated by other advantages conferred by older age, including the experience acquired by a lifelong practice of the specialty.

One area of particular difficulty for anesthesiologists is maintaining the stamina required for long work shifts and night call. Superimposed on a propensity to sleep disturbance, the demands of night call and associated sleep deprivation are particularly difficult for older anesthesiologists. Night call is considered one of the most stressful aspects of practice and is often cited as a reason for retirement among older anesthesiologists.

Aging among anesthesiologists raises interesting legal issues. A number of federal laws potentially impact the aging anesthesiologist's and his or her colleagues' decisions whether to continue to work and under what arrangements. These include the Age Discrimination Act, Title VII of the Civil Rights Act (“Equal Pay Act”), the Medical and Family Leave Act, the Fair Labor Standards Act, and the Employee Retirement Income Security Act (ERISA). An anesthesiologist's decision to retire must fit within the complex framework of federal and state laws and regulations. Anesthesiologists tend to retire at a younger age than do many other specialists.[116]

Mortality Among Anesthesiologists

It is debatable whether anesthesiologists are subject to premature death compared to other physicians. Early studies of anesthesiologists in the United States[13] and studies conducted in Europe[117] have demonstrated death rates among anesthesiologists less than that seen in their control groups. However, contrary results have been reported in other studies both from the United States[14] and Europe.[118] As an example, data

from Alexander et al[14] demonstrated a significant difference in the mean age at death among anesthesiologists, 66.5 ± 14.7 years, compared to their control group (internists), 69.0 ± 14.5 years. In a subsequent study, Katz[15] concluded that there was no statistical difference in age-specific mortality among anesthesiologists, internists, and other physicians when ages of the living members of the physician groups were considered in the analyses.

Suicide

Perhaps one of the most alarming of the potential occupational hazards for anesthesiologists is a frequently cited excess rate of suicide. It has been well established that among physicians in general, the rate of suicide ranks disproportionately high as a cause of death.[119] Early reports singled out anesthesiologists as being particularly vulnerable. However, this conclusion has been questioned as the result of the methodological difficulties in collecting accurate data on suicide and the frequent failure to adequately correct for confounding variables in the study populations.

Why might there be a high rate of suicide among anesthesiologists? A partial explanation lies with the high degree of stress that is an integral part of the job. The relationship between generalized stress and suicide is not direct. But, in susceptible people, feelings of inability to cope resulting from overwhelming stress can give way to despair and suicide ideation.

Extensive personality profiles collected from suicide-susceptible individuals indicate characteristics such as high anxiety, insecurity, low self-esteem, impulsiveness, and poor self-control. It is disturbing to note that in Reeve's study of personality traits of anesthesiologists,[120] some 20% manifested psychological profiles that reflected a predisposition to behavioral disintegration and attempted suicide when placed under extremes of stress. This study raises the discomforting notion that “premorbid” personality characteristics exist before entering specialty training and are not being identified in the admissions process.

One specific type of stress, that resulting from a malpractice lawsuit, may have a direct causative association with suicide among physicians in general and anesthesiologists in particular. Newspaper reports have described the emotional deterioration and ultimate suicide of experienced physicians who have become involved in a malpractice suit. One study reported that 4 of 185 anesthesiologists being sued for medical malpractice attempted or committed suicide.[121]

Substance abuse among anesthesia personnel is another potential contributor to the increased suicide rate. Individuals with chemical dependence, who are not identified and are in the end stages of the disease, may die of drug overdose, a cause of death that may be difficult to distinguish from suicide. Physicians who are impaired from chemical dependence and whose privileges to practice medicine are revoked are also at heightened risk for attempting suicide. Crawshaw et al[122] reported eight successful and two near-miss suicide attempts among 43 physicians placed on probation for drug-related disability.

Chapter 5

Professional Liability, Quality Improvement, and Anesthetic Risk

Karen L. Posner

Frederick W. Cheney Jr.

Donald A. Kroll

KEY POINTS

1	Medical malpractice refers to the legal concept of professional negligence. The patient-plaintiff must prove that the anesthesiologist owed the patient a duty, failed to fulfill this duty, that the anesthesiologist's actions caused an injury, and that the injury resulted from a breach in the standard of anesthesia care.
2	The court establishes the standard of care in a particular case by the testimony of expert witnesses. The standard of care may also be determined from published sources such as hospital policies, textbooks, and standards adopted by the American Society of Anesthesiologists.
3	Risk management programs are broadly oriented toward reducing the liability exposure of the organization. Risk management programs complement quality improvement programs in minimizing liability exposure while maximizing quality of patient care.
4	Quality improvement programs are generally guided by the requirements of the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). Quality improvement programs focus on improving the structure, process, and outcome of care.
5	Continuous quality improvement (CQI) is a systems approach to identifying and improving quality of care.
6	Anesthetic mortality has decreased recently but accidental deaths and disabling complications still occur.

In anesthesia, as in other areas of life, everything does not always go as planned. Undesirable outcomes occur regardless of the quality of care provided. The legal aspects of American medical practice have become increasingly important as the public has turned to the courts for economic

redress when their expectations of medical treatment are not met. Payers such as Medicare are increasingly depending on accreditation through bodies such as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to ensure that mechanisms are in place to deliver quality care to all patients. An anesthesia risk management program can work in conjunction with a program for quality improvement to minimize the liability risk of practice while assuring the highest quality of care for patients.

This chapter provides background for the practitioner about how the legal system handles malpractice claims and the role of risk management activity in minimizing and managing liability exposure. An introduction to the concepts of quality improvement (formerly called quality assurance) extends the discussion to the broader arena of quality of care in anesthesia practice. Finally, there is a discussion of anesthetic mortality and some anesthetic complications frequently associated with malpractice litigation.

PROFESSIONAL LIABILITY

This section addresses the basic concepts of medical liability. A more detailed discussion of the steps of the lawsuit process and appropriate actions for physicians to take when sued is available from the American Society of Anesthesiologists (ASA).[1]

Tort System

Although physicians may become involved in the criminal law system in a professional capacity, they more commonly become involved in the legal system of civil laws. Civil law is broadly divided into *contract law* and *tort law.* A tort may be loosely defined as a civil wrongdoing; negligence is one type of tort. *Malpractice* actually refers to any professional misconduct but its use in legal terms typically refers to professional negligence.

1 To be successful in a malpractice suit, the patient–plaintiff must prove four things:

1. Duty: that the anesthesiologist owed the patient a duty;
2. Breach of duty: that the anesthesiologist failed to fulfill his or her duty;

3. Causation: that a reasonably close causal relation exists between the anesthesiologist's acts and the resultant injury; and
4. Damages: that actual damage resulted because of a breach of the standard of care.

Failure to prove any one of these four elements will result in a decision for the defendant–anesthesiologist.

Duty

As a physician, the anesthesiologist establishes a duty to the patient when a doctor–patient relationship exists. When the patient is seen preoperatively, and the anesthesiologist agrees to provide anesthesia care for the patient, a duty to the patient has been established. In the most general terms, the duty the anesthesiologist owes to the patient is to adhere to the *standard of care* for the treatment of the patient. Because it is virtually impossible to delineate specific standards for all aspects of medical practice and all eventualities, the courts have created the concept of the *reasonable and prudent* physician. For all specialties, there is a national standard which has displaced the local standard.

There are certain general duties that all physicians have to their patients, and breaching these duties may also serve as the basis for a lawsuit. One of these general duties is that of obtaining informed consent for a procedure. Consent may be written, verbal, or implied. Oral consent is just as valid, albeit harder to prove years after the fact, as written consent. Implied consent for anesthesia care may be present in circumstances in which the patient is unconscious or unable, for

any reason, to give his or her consent, but where it is presumed that any reasonable and prudent patient would give consent.

Although there are exceptions to the requirement that consent be obtained, anesthesiologists should be sure to obtain consent whenever possible. Failure to do so could, in theory, expose the anesthesiologist to possible prosecution for battery.

The requirement that the consent be *informed* is somewhat more opaque. The guideline is determining whether the patient received a fair and reasonable account of the proposed procedures and the risks inherent in these procedures. The duty to disclose risks is not limitless, but it does extend to those risks that are reasonably likely in any patient under the circumstances and to those that are reasonably likely in particular patients because of their condition. For example, it would be prudent to inform the patient of possible sore throat or dental damage associated with tracheal intubation, but not about an unlikely complication such as vocal cord paralysis.

Breach of Duty

In a malpractice action, expert witnesses will review the medical records of the case and determine whether the anesthesiologist acted in a reasonable and prudent manner in the specific situation and fulfilled his or her duty to the patient. If they find that the anesthesiologist either did something that should not have been done or failed to do something that should have been done, then the duty to adhere to the standard of care has been breached. Therefore, the second requirement for a successful suit will have been met.

Causation

Judges and juries are interested in determining whether the breach of duty was the *proximate cause* of the injury. If the odds are better than even that the breach of duty led, however circuitously, to the injury, this requirement is met.

There are two common tests employed to establish causation. The first is the *but for* test, and the second is the *substantial factor* test. If the injury would not have occurred but for the action of the defendant-anesthesiologist, or if the act of the anesthesiologist was a substantial factor in the injury despite other causes, then proximate cause is established.

Although the burden of proof of causation ordinarily falls on the patient-plaintiff, it may, under special circumstances, be shifted to the physician-defendant under the doctrine of *res ipsa loquitur* (literally, “the thing speaks for itself”). Applying this doctrine requires proving that:

1. the injury is of a kind that typically would not occur in the absence of negligence,
2. the injury must be caused by something under the exclusive control of the anesthesiologist,
3. the injury must not be attributable to any contribution on the part of the patient,
4. the evidence for the explanation of events must be more accessible to the anesthesiologist than to the patient.

Because anesthesiologists render patients insensible to their surroundings and unable to protect themselves from injury, this doctrine may be invoked in anesthesia malpractice cases. All that needs to be proved is that the injury typically would not occur in the absence of negligence. At this point, the anesthesiologist is put in the position of having to prove that he or she was not negligent.

Damages

The law allows for three different types of damages. *General damages* are those such as pain and suffering that directly result from the injury. *Special damages* are those actual damages that are a

consequence of the injury, such as medical expenses, lost income, and funeral expenses. *Punitive damages* are intended to punish the physician for negligence that was reckless, wanton, fraudulent, or willful. Punitive damages are exceedingly rare in medical malpractice cases. More likely in the case of gross negligence is a loss of the license to practice anesthesia. In extreme cases, criminal charges may be brought against the physician. Determining the dollar amount of damages is the job of the jury, and the determination is usually based on some assessment of the plaintiff's condition versus the condition he or she would have been in had there been no negligence. Plaintiffs' attorneys generally charge a percentage of the damages and will, therefore, seek to maximize the award given.

Standard of Care

Because medical malpractice usually involves issues beyond the comprehension of lay jurors and judges, the court establishes the standard of care in a particular case by the testimony of *expert witnesses.* These witnesses differ from factual witnesses mainly in that they may give opinions. The trial court judge has sole discretion in determining whether a witness may be qualified as an expert. Although any licensed physician may be an expert, information will be sought regarding the witness's education and training, the nature and scope of the person's practice, memberships and affiliations, and publications. The purpose in gathering this information is not only to establish the qualifications of the witness to provide expert testimony, but also to determine the weight to be given to that testimony by the jury. In many cases the success of a suit depends primarily on the stature and believability of the expert witnesses.

In certain circumstances, the standard of care may also be determined from published societal guidelines, written policies of a hospital or department, or textbooks and monographs. Some medical specialty societies have carefully avoided applying the term “standards” to their guidelines in the hope that no binding behavior or mandatory practices have been created. In 1986 the ASA, for the first time, published *Standards for Basic Intra-Operative Monitoring* (now entitled *Standards for Basic Anesthetic Monitoring*). These standards have been

updated several times since their initial adoption and are more binding than guidelines. The essential difference between standards and guidelines is that guidelines *should* be adhered to and standards *must* be adhered to. Currently, the ASA also publishes standards on preanesthesia care and postanesthesia care, as well as guidelines for a variety of anesthesia-related activities.[2]

Causes of Suits

Since 1985, the principal cause of suits against anesthesiologists is patient injury. The ASA Committee on Professional Liability has conducted a nationwide analysis of malpractice claims against anesthesiologists.[3,4] The leading injuries in malpractice claims in the 1990s were death (22%), nerve damage (21%), and brain damage (10%). The causes of death and permanent brain damage were predominantly problems in airway management, such as inadequate ventilation, difficult intubation, premature extubation, and multifactorial and other cardiovascular events such as arrhythmia, stroke, and myocardial infarction. Nerve damage, especially to the ulnar nerve, often occurs despite apparently adequate positioning.[5,6] Spinal cord injury was the most common cause of nerve damage claims against anesthesiologists in the 1990s.[5] Chronic pain management is an increasing source of malpractice claims against anesthesiologists.[7]

Because death and brain damage are high-cost injuries, anesthesia practice is clearly a high-risk endeavor. The anesthesiologist is likely to be the target of a law suit if an untoward outcome occurs because the physician–patient relationship is usually tenuous at best. That is the patient rarely chooses the anesthesiologist, the preoperative visit is brief, and the anesthesiologist who sees the patient preoperatively may not actually anesthetize the patient. Communication between anesthesiologists and surgeons about complications is often lacking and the tendency is for the surgeon to “blame anesthesia.”

Supervision of nurse anesthetists is another endeavor that puts the anesthesiologist in a high-risk category. The more nurse anesthetists supervised by any one anesthesiologist, the greater the

exposure to the possibility of patient injury. Anesthesiologists are liable not only for the nurse anesthetists they employ but also for those they supervise who are employed by the hospital.

Because anesthesiologists are involved in the care of patients undergoing high-risk surgical procedures, they are often sued along with the surgeon in the case of an adverse outcome. This may occur even if the outcome was in no way related to the anesthetic care.

What to Do When Sued

A lawsuit begins when the patient–plaintiff's attorney files a complaint and demand for jury trial with the court. The anesthesiologist is then served with the complaint and a summons requiring an answer to the complaint. Until this happens, no lawsuit has been filed. Insurance carriers must be notified immediately after the receipt of the complaint. The anesthesiologist will need assistance in answering the complaint, and there is a time limit placed on the response.

Specific actions at this point include the following:

1. Do not discuss the case with anyone, including colleagues who may have been involved, operating room personnel, or friends.
2. Never alter any records.
3. Gather together all pertinent records, including a copy of the anesthetic record, billing statements, and correspondence concerning the case.
4. Make notes recording all events recalled about the case.
5. Cooperate fully with the attorney provided by the insurer.

The first task the anesthesiologist must perform with an attorney is to prepare an answer to the complaint. The complaint contains certain facts and allegations with which the defense may either agree or disagree. Defense attorneys rely on the frank and totally candid observations of the physician in preparing an answer to the complaint. Physicians should be willing to educate their attorneys about the medical facts of the case, although most medical malpractice attorneys will be knowledgeable and medically sophisticated.

The next phase of the malpractice suit is called *discovery.* The purpose of discovery is the gathering of facts and clarification of issues in advance of the trial. Another purpose of discovery is to assess or harass the defendant to determine how good a witness he or she will make. This occurs at several points in the discovery process, and by several mechanisms.

In all likelihood the anesthesiologist will receive a written interrogatory, which will request factual information. In consultation with the defense attorney, the interrogatory should be answered in writing, because carelessly or inadvertently misstated facts can become troublesome later.

Depositions are a second mechanism of discovery. The defendant–anesthesiologist will be deposed as a fact witness, and depositions will be obtained from other anesthesiologists who will act as expert witnesses. The defendant–anesthesiologist may be asked to suggest other anesthesiologists who would provide expert review of the medical records. A nationally recognized expert in the area in question who is not a personal friend but agrees with the defense position may be very valuable.

The plaintiff's attorney, not the defense attorney, will depose the anesthesiologist. Most often, the deposition will occur at a place and time convenient for the anesthesiologist, typically in the defense attorney's office. Despite the apparent informality of the deposition, the anesthesiologist must be constantly aware that what is said during the deposition carries as much weight as what would be said in court. It is important to be factually prepared for the deposition. A review of personal notes, the anesthetic record, and the medical record is necessary. The physician should dress conservatively and professionally because appearance and image are very important. The opposition is assessing the physician to see how he or she will appear to a jury. Answer only the

question asked, and do not volunteer information. Occasionally, physicians will be asked leading questions that are impossible to answer without qualifications. In this case, the physician may qualify his or her answer but should avoid giving lengthy opinion answers.

There will be depositions from expert witnesses, both for the plaintiff and for the defense. The anesthesiologist should work with his or her attorney to suggest questions and rebuttals. The better educated the attorney is about the medical facts, the reasons the anesthesiologist did what was done, and the alternative approaches, the better able the attorney will be to conduct these expert depositions.

If there is some merit in the case but the damages are minimal, or if proof of innocence will be difficult, there will probably be a settlement offer. There is a high cost incurred by both plaintiffs and defendants in pursuing a malpractice claim up through a jury trial. Unless there is a strong probability of a large dollar award, reputable plaintiffs' attorneys are not likely to pursue the claim. Thus, even if physicians believe that they are totally innocent of any wrongdoing, they should not be offended or angered about settling of the case: this is solely a matter of money, not medicine.

If a settlement is not reached during the discovery phase, a trial will occur. Only about 1 in 20 malpractice cases ever reaches the point of a jury trial. It usually becomes clear

during discovery whether the suit has a solid chance of being successfully prosecuted. Only those cases in which both sides feel they can win, and which are likely to have significant financial impact, will proceed to trial.

The discussion of deposition testimony also applies to testimony in court, but there are a few additional points to consider during the trial. The members of the jury will not be as sophisticated medically as the attorneys who deposed the anesthesiologist during discovery. A tendency to overuse specific medical terms should be corrected by learning to explain answers in lay terms for the benefit of the jury. Do not underestimate the intelligence of the jury, however, because talking down to them will create an unfavorable impression. If the answer to a question is not known, avoid guessing. If specific facts cannot be remembered, say so. Nobody expects total recall of events that may have occurred years before.

The defendant–physician should be present during the entire trial, even when not testifying, and should dress conservatively, neatly, and professionally. Displays of anger, remorse, relief, or hostility will hurt the physician in court. When giving testimony, the anesthesiologist must give clear answers to all questions asked. The physician should be able to give his or her testimony without using notes or documents. When it is necessary to refer to the medical record, it will be admitted into evidence. The anesthesiologist's goal is to convince the jury that he or she behaved in this case as any other competent and prudent anesthesiologist would have behaved.

It is important to keep in mind that *proof* in a malpractice case means only “more likely than not.” The patient–plaintiff must “prove” the four elements of negligence, not to absolute certainty, but only to a probability greater than 50%. On the positive side, this means that the defendant–anesthesiologist must only show that his or her actions were, more likely than not, within an acceptable standard of care.

RISK MANAGEMENT AND QUALITY IMPROVEMENT

3 Risk management and quality improvement programs work hand in hand in minimizing liability exposure while maximizing quality of patient care. Although the functions of these programs vary from one institution to another, they overlap in their focus on patient safety. They can generally be distinguished by their basic difference in orientation. A hospital risk management program is broadly oriented toward reducing the liability exposure of the organization. This includes not only professional liability (and therefore patient safety) but also contracts, employee safety, public safety, and any other liability exposure of the institution. Quality improvement programs have as their main goal the continuous maintenance and improvement of the quality of patient care. These programs may be broader in their patient safety focus than strictly risk

management.

Risk Management

Those aspects of risk management that are most directly relevant to the liability exposure of the anesthesiologist include prevention of patient injury, adherence to standards of care, documentation, and patient relations.

The key factors in the prevention of patient injury are vigilance, up-to-date knowledge, and adequate monitoring.[8] Physiologic monitoring of cardiopulmonary function, combined with monitoring of equipment function, might be expected to reduce anesthetic injury to a minimum. This was the rationale for the adoption of the ASA *Standards for Basic Anesthetic Monitoring*.[2]

The ASA website should be reviewed yearly for any changes in ASA *Standards of Practice*. It would also be reasonable to review the ASA *Guidelines and Statements* published on the ASA website. It should be noted that, although membership in the ASA is not required for the practice of anesthesiology, expert witnesses will, with virtual certainty, hold any practitioner to the ASA standards. It is also possible that, as a risk management strategy, a professional liability insurer or hospital may hold an individual anesthesiologist to standards higher than those promulgated by the ASA.

Another risk management tool is the use of checklists prior to each case, or at least daily, in an attempt to reduce equipment-related mishaps.[9,10,11] A regular schedule of equipment maintenance should be established as well as procedures to follow whenever equipment malfunction is suspected of contributing to patient injury. If equipment malfunction is suspected to have contributed to a complication, the device should be impounded and examined concurrently by the representatives of the hospital, the anesthesiologist, and the manufacturer.

Although it may seem obvious, qualified anesthesia personnel should be in continuous attendance during the conduct of all anesthetics. The only exceptions should be those that lay people (i.e., judge and jury) can understand, such as radiation hazards or an unexpected life-threatening emergency elsewhere. Even then, provisions should be made for monitoring the patient adequately. Adequate supervision of nurse anesthetists and residents is also important, as is good communication with surgeons when adverse anesthetic outcomes occur.

Informed consent should be documented with a general consent, which should include a statement to the effect that, “I understand that all anesthetics involve risks of complications, serious injury, or, rarely, death from both known and unknown causes.” In addition, there should be a note in the patient's record that the risks of anesthesia and alternatives were discussed, and that the patient accepted the proposed anesthetic plan. A brief documentation in the record that the common complications of the proposed technique were discussed is helpful. If it is necessary to change the agreed-on anesthesia plan significantly after the patient is premedicated or anesthetized, the reasons for the change should be documented in the record.

Good records can form a strong defense if they are adequate, however records can be disastrous if inadequate. The anesthesia record itself should be as accurate, complete, and as neat as possible. The use of automated anesthesia records may be helpful in the defense of malpractice cases.[12] In addition to documenting vital signs every 5 minutes, special attention should be paid to ensure that the patient's ASA classification, the monitors utilized, fluids administered, and doses and times of all administered drugs are accurately charted. Because the principal causes of hypoxic brain damage and death during anesthesia are related to ventilation and/or oxygenation, all respiratory variables that are monitored should be documented accurately. It is important to note when there is a change of anesthesia personnel during the conduct of a case. Sloppy, inaccurate anesthesia records, when enlarged and placed before a jury, can be damaging to the defense.

If a critical incident occurs during the conduct of an anesthetic, the anesthesiologist should document, in narrative form, what happened, which drugs were used, the time sequence, and who was present. This should be documented in the patient's progress notes, as catastrophic intra-anesthetic event cannot be summarized adequately in a small amount of space on the usual anesthesia record. The critical incident note should be written as soon as possible. The report

should be as consistent as possible with concurrent records, such as the anesthesia, operating room, recovery room, and cardiac arrest records. If significant

inconsistencies exist, they should be explained. Records should never be altered after the fact. If an error is made in record keeping, a line should be drawn through the error, leaving it legible, and the correction should be initialed and timed. Litigation is a lengthy process, and a court appearance to explain the incident to a jury may be years away, when memories have faded.

If anesthetic complications occur, the anesthesiologist should be honest with both the patient and family about the cause. Whenever an anesthetic complication becomes apparent postoperatively, appropriate consultation should be obtained quickly, and the departmental or institutional risk management group should be notified. If the complication is apt to lead to prolonged hospitalization or permanent injury, the liability insurance carrier should be notified. The patient should be followed closely while in the hospital, with telephone follow-up, if indicated, after discharge. Also, the anesthesiologist and surgeon should be consistent in their explanations to the patient or the patient's family as to the cause of any complication.

Jehovah's Witnesses and Other Treatment Obligations

It is important to recognize that patients have well-established rights, and that among these is the right to refuse specific treatments because of religious beliefs. In the case of Jehovah's Witnesses, the treatment refused is the administration of blood or blood products. This is a central part of their religious beliefs, which hold that the faithful will be forbidden the pleasures of the afterlife if they receive blood or blood products. Thus, for them to receive a transfusion is a mortal sin, and many Jehovah's Witnesses would actually rather die in grace than live with no possibility of salvation. Anesthesiologists recognize and respect these beliefs but are also cognizant that these convictions may conflict with the physicians' personal, religious, or ethical codes.

Minor children of Jehovah's Witness parents represent a special group for consideration. Although the U.S. Supreme Court has upheld the right of an adult to become a martyr by refusing treatments based on religious convictions, no court has extended to parents the right to martyr their children.[13] Obtaining a proper court order is of critical importance in the care of a minor child of Jehovah's Witness parents when the parents refuse to authorize a blood transfusion.

As a general rule, physicians are not obligated to treat all patients who apply for treatment in elective situations. It is well within the rights of a physician to decline to care for any patient who wishes to place burdensome constraints on the physician or to unacceptably limit the physician's ability to provide optimal care. When presented with the opportunity to provide elective care for a Jehovah's Witness, the physician may decline to provide any care or may limit, by mutual consent with the patient, his or her obligation to adhere to the patient's religious beliefs. If such an agreement is reached, it must be documented clearly in the medical record, and it is desirable to have the patient co-sign the note. Not all Jehovah's Witnesses have identical beliefs regarding blood transfusions or which methods of blood preservation or sequestration will be allowed. Some patients will not allow any blood that has left the body to be reinfused, yet others will accept autotransfusion if their blood remains in constant contact with the body (via tubing). Therefore, it is important to reach a clear understanding of which techniques for blood preservation are to be used and to document this plan in the record.

Emergency medical care imposes greater constraints on the treating physician, as there is no opportunity to decline the care of a patient with an immediately life-threatening condition. If the patient is an adult and is conscious and mentally competent, he or she has the right to refuse blood transfusion. The exceptions to patients' rights in this regard include pregnant women and adults who are the sole support of minor children. In these circumstances, the interests of the fetus in surviving may supersede the rights of the mother, as may the interests of the state in not being obligated to provide for the welfare of dependent children.[13] In either case, obtaining a court order is the best plan if time permits. If the problem concerns blood products and there is insufficient time to obtain a court order, pregnant women should be given a transfusion to save

the life of the fetus, but parents of minor children should not receive transfusions against their wishes unless the dependency of the children is obvious.

When the patient is a minor, it is important to ascertain the true wishes of the parents. Some parents know that a court order can be obtained and view this as a relief from the onerous burden of having to decide whether they are willing to let their child die. However, some parents are adamant that blood not be given, and there have been cases in which children have been ostracized by their parents and religious community for having received a court-ordered transfusion. Reaching an understanding about the consequences for the child who receives a court-ordered transfusion is therefore vital for the determination of what risks will be taken before ordering a transfusion.

The procedure for obtaining a court order may vary, depending on the specific state laws. Typically, an order may be obtained over the telephone. This call initiates the issue of a written order, which will arrive several days later. Although not a totally automatic procedure, it would be very rare for a judge to deny this order for a minor.

National Practitioner Data Bank

It is usually the obligation of the hospital risk management department to make reports and inquiries to the National Practitioner Data Bank (NPDB), a nationwide information system that theoretically would allow licensing boards and hospitals a means of detecting adverse information about physicians.[14] Simply moving into another state would no longer provide safe haven for incompetent physicians.

The NPDB requires input from five sources: (1) medical malpractice payments, (2) license actions by medical boards, (3) professional review or clinical privilege actions taken by hospitals and other health care entities (including professional societies), (4) actions taken by the Drug Enforcement Agency (DEA), and (5) Medicare/Medicaid exclusions. There has been a great deal of effort to establish a minimum reporting dollar value below which no report is necessary, but to date, any payment made on behalf of a physician in response to a written complaint or claim must be reported. Settlements made by cancellation of bills or settlements made on verbal complaints are not considered a reportable payment.

Once a report has been submitted, the physician is notified and has 60 days from the date the data bank processed the report to dispute the input. At this time, the reporting entity may correct the form or void it. Failing that, the physician has the option of putting a brief statement in the file or appealing to the U.S. Secretary of Health and Human Services, who may also either correct or void the form. Once it is entered, there is no means of purging the form. A practitioner may make a query about his or her file at any time. The existence of the NPDB reporting requirements has made physicians reluctant to allow settlement of nuisance suits because it will cause their names to be added to the data bank.

QUALITY IMPROVEMENT IN ANESTHESIA PRACTICE

4 Quality is a concept that has continued to elude precise definition in medical practice. However, it is generally accepted that attention to quality will improve patient safety and satisfaction

with anesthesia care. The field of quality assurance or quality improvement is continually evolving, as is the terminology used to describe such efforts. The term “quality assurance” has gone out of fashion, being replaced by “quality improvement” in an effort to emphasize a change in underlying philosophy. Although quality improvement programs in anesthesia are generally guided by requirements of the JCAHO, they are basically oriented toward improvement of the structure, process, and outcome of health care delivery programs. An understanding of the fundamental principles of quality improvement may clarify the relationship between the continually evolving JCAHO requirements and mandated quality improvement activities.

Structure, Process, and Outcome: The Building Blocks of Quality

Although quality of care is difficult to define, it is generally accepted that it is composed of three components: structure, process, and outcome.[15] *Structure* refers to the setting in which care was provided, for example, personnel and facilities used to provide health care services and the manner in which they are organized. This includes the qualifications and licensing of personnel, ratio of practitioners to patients, standards for the facilities and equipment used to provide care, and the organizational structure within which care is delivered. The *process* of care includes the sequence and coordination of patient care activities, that is, what was actually done. Was a preanesthetic evaluation performed and documented? Was the patient continuously attended and monitored throughout the anesthetic? *Outcome* of care refers to changes in health status of the patient following the delivery of medical care. A quality improvement program focuses on measuring and improving these basic components of care.

Continuous quality improvement (CQI) takes a systems approach to identifying and improving quality of care.[16,17] The operator is just one part of a complex system. An important underlying premise is that poor results may be a result of either random or systematic error. Random errors are inherently difficult to prevent and programs focused in this direction are misguided. System errors, however, should be controllable and strategies to minimize them should be within reach. CQI is basically the process of continually evaluating anesthesia practice to identify systematic problems (opportunities for improvement) and implementing strategies to prevent their occurrence.

A CQI program may focus on undesirable outcomes as a way to identify opportunities for improvement in the structure and process of care. The focus is not on blame but rather on identification of the causes of undesirable outcomes. Instead of asking which practitioners have the highest patient mortality rates, a CQI program may focus on the relationship between the process of care and patient mortality. What proportion of deaths was related to the patient's disease process or debilitated condition? Are these patients being appropriately evaluated for anesthesia and surgery? Were there any controllable causes, such as a lack of hands during resuscitation? The latter may lead to a modification of personnel resources (structure) or assignments (process) to be sure that adequate personnel are available at all times.

Formally, the process of CQI involves the identification of opportunities for improvement through the continual assessment of important aspects of care. Peer review and input are critical to this process. It is a process that is instituted from the bottom up, by those who are actually involved in the process to be improved, rather than from the top down by administrators. Identification of opportunities for improvement may be carried out by various means, from brainstorming sessions focusing on a systematic evaluation of care activities to the careful measurement of indicators of quality (such as morbidity and mortality). In any event, once areas are identified for improvement, their current status is measured and documented. This may involve measurement of outcomes, such as delayed recovery from anesthesia or peripheral nerve injury. The process of care leading to these problems is then analyzed. If a change is identified that should lead to improvement, it is implemented. After an appropriate time period, the status is then measured again to determine whether improvement actually resulted. Attention may then be directed to continuing to improve this process or turning to a different process to target for improvement.

An extension of the CQI method is *total quality management* (TQM). A TQM program would extend beyond patient care to apply CQI methods to all aspects of the patient care delivery system. This would include such things as billing and housekeeping, for example. With the expectation of continuing changes in the structure and financing of health care in the United States, CQI programs in anesthesia can be incorporated into TQM of the entire hospital system to maintain the quality of patient care as practice changes are implemented in response to a changing environment.

Difficulty of Outcome Measurement in Anesthesia

Improvement in quality of care is often measured by a reduction in the rate of adverse outcomes. However, adverse outcomes are relatively rare in anesthesia making measurement of improvement difficult. For example, if an institution lowers its mortality rate of surgery patients from 1 in 1,000 to 0.5 in 1,000, this difference may not be statistically significant. Many adverse outcomes in anesthesia are even more rare.

To complement outcome measurement, anesthesia CQI programs can focus on critical incidents, sentinel events, and human errors. *Critical incidents* are events that cause, or had the potential to cause, patient injury if not noticed and corrected in a timely manner. For example, a partial disconnect of the breathing circuit may be corrected before patient injury occurs, yet has the potential for causing hypoxic brain injury or death. Critical incidents are more common than adverse outcomes. Measurement of the occurrence rate of important critical incidents may serve as a proxy measure for rare outcomes in anesthesia in a CQI program designed to improve patient safety and prevent injury.

Sentinel events are single, isolated events that may indicate a systemic problem. JCAHO has a specific definition of sentinel events that will be discussed later. In general, a sentinel event may be a significant or alarming critical incident that did not result in patient injury, such as a syringe swap and administration of a potentially lethal dose of medication that was noted and treated promptly, avoiding catastrophe. Or a sentinel event may be an unexpected significant patient injury such as intraoperative death. In either case, a CQI program may investigate sentinel events in an attempt to uncover systemic problems in the delivery of care that can be corrected. For example, a syringe swap may be analyzed for confusing or unclear labeling of medications or unnecessary medications routinely stocked on the anesthesia cart, setting the scene for unintended mix-up. In the case of death, all aspects of the patient's hospital course from selection for surgery to anesthetic management may be analyzed to determine if similar deaths can be prevented by a change in the care delivery system.

Human error has garnered much attention since a government report that 98,000 Americans may die annually from medical errors in hospitals.[18] Human errors are inevitable yet potentially preventable by appropriate system safeguards.

Errors of planning involve use of a wrong plan to achieve an aim.[19] Errors of execution are the failure of a planned action to be completed as intended. [19] Modern anesthesia equipment is designed with safeguards such as alarm systems to detect errors that could lead to patient injury. Other anesthesia care processes are also amenable to human factors design principles, such as color coding of drug labels. A quality improvement program may identify human errors and institute safety systems to aid in error prevention.

JCAHO Requirements for Quality Improvement

JCAHO requirements for quality improvement activities are updated on an annual basis. In general, a hospital must adopt a method for systematically assessing and improving important functions and processes of care and their outcomes in a cyclical fashion. The general outline for this CQI cycle is the design of a process or function, measurement of performance, assessment of performance measures through statistical analysis or comparison with other data sources, and improvement of the process or function. Then the cycle repeats. JCAHO provides specific standards that must be met, with examples of appropriate measures of performance. The goal of this cycle of design, measurement, assessment, and improvement of performance of important functions and processes is to improve patient safety and quality of care.

Anesthesia care is one important function of the care of patients monitored by JCAHO. It is important that policies and procedures for administration of anesthesia be consistent in all locations within the organization.

In 2004, JCAHO adopted patient safety goals for accredited organizations. These include improved accuracy of patient identification, improved effectiveness of communication among caregivers, elimination of wrong site/wrong patient/wrong procedure surgery, improved safety of infusion pumps, and improved effectiveness of clinical alarm systems. JCAHO also requires all sentinel

events (any unexpected occurrences involving death or serious physical or psychological injury or risk thereof) to undergo Root Cause Analysis.[20] A Root Cause Analysis is typically facilitated by the hospital and includes everyone involved in the care of the affected patient in reconstructing the events to identify system process flaws that facilitated medical error. Any surgery on the wrong patient or wrong body part is included in this policy. JCAHO publishes a Sentinel Event Alert so health care organizations can learn from the experiences of others and prevent future medical errors.

Measuring Quality: Approaches to Data Collection

There are various methods in use for collection of CQI data in anesthesia. These include retrospective records review as well as self-reporting by providers of care. Checklists to report adverse events or outcomes are sometimes used. Important considerations include compliance with reporting requirements, standardization of definitions, and appropriate sampling.

Retrospective records review usually involves a random sample of anesthesia records. The actual review may be done by an anesthesia provider or by a trained medical records specialist. Explicit definitions of quality indicators would be provided, such as “hypotension = blood pressure <80% of baseline for 5 minutes or more.” Such *indicators* of possible quality problems and opportunities for improvement are restricted to data that are normally included in the anesthesia record for every patient. Records review is an especially appropriate technique for gathering data on adequacy of documentation. An asset of automated anesthesia records is that they can be programmed to screen all records for quality indicators.

For collection of data on events or outcomes that may not normally be charted, a self-reporting system may be used. This is an especially good mechanism for tracking critical incidents and sentinel events. For example, a syringe swap that was noted and corrected before drug administration is a critical incident that would not normally be included in an anesthetic record but could be reported by an anesthesia provider in a self-report system. Many self-report systems provide a checklist of events and outcomes that is completed by the provider for each anesthetic. Other systems provide general guidelines of critical incident reporting without specific check-off items.[21,22] The relevant clinical information is then obtained from the practitioner by quality improvement personnel.

Whatever system is used, it is important that it be in compliance with current JCAHO standards. Standardized definitions must be provided. In general, definitions that take into account the context of care (patient status, type of anesthetic) while maintaining explicit criteria for inclusion in the CQI system will most clearly reflect quality issues (rather than, for example, complications related purely to patient physical condition). For example, blood loss and replacement of 8 units would be considered excessive and indicative of a problem during a knee arthroscopy but would be considered minimal during a liver transplant. A strict definition of “excessive blood loss = >5 units” would identify both cases as quality issues where it would only be appropriate for the arthroscopy. Contextualization of definitions will help avoid the frustration of providers when presented with data that otherwise may be irrelevant to improving the process of anesthesia care.

Peer Review

Peer review, which refers to the review of cases by members of one's specialty, is an integral part of quality improvement programs. Peer review is commonly integrated into a quality improvement program in the context of the morbidity and mortality conference. This provides a forum for review of case management by all members of the department, integrating an educational component into the quality improvement process as differing knowledge bases and clinical experiences are shared. Peer review can provide a mechanism to analyze the structure and process of care and opportunities for improvement.

Peer review can also be incorporated into the analysis of critical incidents, sentinel events, and trends in measured outcomes of care. Peer review has the distinct advantage of credibility and an aura of fairness in a democratic system. Although personal bias in clinical care may be recognized, adherence to the “reasonable man” principle provides a basis for analysis that reflects generally

accepted principles of care. It provides a basis for analysis of trends and incidents, suggesting hypotheses for their causes and changes in the system that might improve the structure, process, and outcome of care.

However, peer review is subject to bias that may not be recognized by the participants. This is a tendency of anesthesiologists to judge care as less than appropriate if severe patient injury occurs.[23] In a study of anesthesiologists presented with identical case scenarios with differing outcomes, they were more likely to judge the care as appropriate if the injury was temporary and to judge care as less than appropriate if the injury was permanent. In conducting peer review for a CQI system, this tendency toward assessments biased by case outcome should be recognized and resisted. Careful attention to the process of care and opportunities for improvement should be made regardless of the extent of patient injury. Critical incidents resulting in no injury should be as carefully analyzed for opportunities for improvement in the structure and process of care as incidents with adverse outcomes.

Even though anesthesiologists may be biased in their assessment of case management by outcome, they exhibit only moderate levels of general agreement in their assessments.[24,25] When reviewing identical case histories, different anesthesiologists may not always agree on whether the care was appropriate. Although this disagreement may be because of differences in individually held standards and practices, it must be recognized in any analysis of case management for a CQI program. Incorporation of multiple anesthesiologists into the process of case review will compensate for this lack of agreement. Although a consensus may not be reached, decisions will not be subject to the variability of individual judgments. Incorporation of multiple peer reviewers will compensate for differences in assessments and strengthen the process by improving reliability.[25]

The Future of Quality Improvement: A Multidisciplinary Focus

JCAHO is moving toward a focus on the patient's hospital course in a multidisciplinary emphasis rather than departmental quality improvement programs. The shift in emphasis is toward an analysis of the entirety of each patient's care as the process to be improved. Each department's role is just one part of this process, and the care provided by various departments is often not the relevant unit of analysis. This shift in focus may require movement from departmental reliance on standing committees to increased use of ad hoc study groups. Comparison of outcomes of care across institutions, with adjustments for case mix, has long been the goal but has proven to be difficult to implement.

MORTALITY AND MAJOR MORBIDITY RELATED TO ANESTHESIA

Estimates of anesthesia-related morbidity and mortality are difficult to quantify. Not only are there difficulties obtaining data on complications, but different methodologies yield different estimates of anesthesia risk. Studies differ in their definitions of complications, length of follow-up, and especially in approaches to evaluation of the contribution of anesthesia care to patient outcomes. A comprehensive review of anesthesia complications is beyond the scope of this chapter. A sampling of studies of anesthesia mortality and morbidity will be presented to provide historical perspective plus a limited overview of relatively recent findings.

6 Early studies estimated the anesthesia-related mortality rate as 1 per 1,560 anesthetics.[26] More recent studies using data from the 1990s estimate the anesthesia-related death rate in the United States to be <1 per 10,000 anesthetics.[27,28] Some examples of modern estimates of anesthesia-related death from throughout the world are provided in Table 5-1. Differences in estimates may be influenced by different reporting methods, definitions, anesthesia practices, patient population, as well as actual differences in underlying complication rates.

Nevertheless, it is generally accepted that anesthesia safety has improved over the past 50+ years.

TABLE 5-1 Recent Estimates of Anesthesia-Related Death

▪REFERENCE	▪COUNTRY	▪TIME PERIOD	▪DATA SOURCES/METHODS	▪RATE OF DEATH
Newland et al.[27]	USA	1989–1999	Cardiac arrests within 24 hrs of surgery (*n* = 72,959 anesthetics) in a teaching hospital	Death related to anesthesia-attributable perioperative cardiac arrest = 0.55/10,000 anesthetics
Lagasse[28]	USA	(a) 1992–1994 (b) 1995–1999	(a) suburban teaching hospital (*n* = 115 deaths; *n* = 37,924 anesthetics) (b) urban teaching hospital (*n* = 232 deaths; *n* = 146,548 anesthetics)	Anesthesia-related death = (a) 0.79/10,000 anesthetics; (b) 0.75/10,000 anesthetics
Arbous et al.[37]	Holland	1995–1997	All deaths within 24 hrs or patients who remained unintentionally comatose 24 hrs postanesthesia (*n* = 811 in 869,483 anesthetics)—64 hospitals	Anesthesia-related death = 1.4/10,000 anesthetics
Eagle, Davis[38]	Western Australia	1990–1995	Deaths within 48 hrs or deaths in which anesthesia was considered a contributing factor (*n* = 500 deaths)	Anesthesia-related death = 1/40,000 anesthetics
Davis, ed.[39]	Australia	1994–1996	Deaths reported to the committee (*n* = 8,500,000 anesthetics)	Anesthesia-related death = 0.16/10,000 anesthetics
Irita et al.[40]	Japan	1999–2002	Deaths as a result of life-threatening events in the operating room (*n* = 3,855,384 anesthetics) in training hospitals	Death totally attributable to anesthetic management = 0.1/10,000 anesthetics
Kawashima et al.[41]	Japan	1994–1998	Questionnaires to training hospitals (*n* = 2,363,038 anesthetics)	Death totally attributable to anesthesia =

				0.21/10,000 anesthetics
Biboulet et al.[42]	France	1989–1995	ASA 1–4 patients undergoing anesthesia (*n* = 101,769 anesthetics)—cardiac arrest within 12 hrs postanesthesia (*n* = 24)	Anesthesia-related death = 0.6/10,000 anesthetics
Morray et al.[43]	USA	1994–1997	Pediatric patients from 63 hospitals (*n* = 1,089,200 anesthetics)	Anesthesia-related death = 0.36/10,000 anesthetics

Other complications related to anesthesia that have received relatively recent attention include postoperative nerve injury, awareness and recall, eye injuries and visual deficits, and dental injury. Ulnar neuropathy is one of the most common nerve injuries leading to anesthesia malpractice claims in the United States.[5] The incidence of ulnar neuropathy has been estimated between 3.7 and 50 per 10,000 patients (Table 5-2). Lower extremity neuropathy following surgery in the lithotomy position was observed in 2.7/10,000 patients (Table 5-2). [29] Awareness with recall after general anesthesia has been estimated to occur in 15 to 40 per 10,000 patients.[30,31,32]

TABLE 5-2 Rates of Selected Anesthesia Complications

▪COMPLICATION	▪REFERENCE	▪COUNTRY	▪TIME PERIOD	▪SPECIFIC COMPLICATION	▪RESULTS
Nerve injury	Warner et al.[44]	USA	1995	Ulnar neuropathy in adults following noncardiac surgery	0.5%
	Warner et al.[45]	USA	1957–1991	Persistent ulnar neuropathy following diagnostic or noncardiac procedures with anesthesia	1/2,729 patients

	Alvine et al.[46]	USA	1980–1981	Ulnar neuropathy after general anesthesia	0.26%
	Warner et al.[29]	USA	1957–1991	Lower extremity motor neuropathy following surgery in lithotomy position	1/3,608 procedures
Awareness and recall	Sandin et al.[30]	Sweden	1997–1998	Awareness and recall associated with general anesthesia	18/11,785 procedures
	Lui et al.[31]	Great Britain	1990	Awareness with recall in adults following surgery	0.2%
	Ranta et al.[32]	Finland	1994–1995	Awareness in patients >12 yrs old having general anesthesia	0.4%
Eye injuries and visual changes	Warner et al.[34]	USA	1999	New onset blurred vision lasting ⩾3 days	4.2%
	Warner et al.[35]	USA	1986–1998	New onset visual loss or visual changes lasting >30 days after noncardiac surgery	1/125,234 patients
	Roth et al.[33]	USA	1988–1992	Eye injury after	0.056%

				nonocular surgery	
Dental injury	Warner et al.[36]	USA	1987–1997	Dental injuries within 7 days of anesthesia that required intervention	1/4,537 patients

Eye injuries are a risk of anesthesia, including corneal abrasions as well as more rare complications such as blindness from ischemic optic neuropathy or central retinal artery occlusion (Table 5-2). Eye injury after nonocular surgery was observed in 5.6/10,000 patients.[33] New onset blurred vision has been observed in 4.2% of patients (Table 5-2). [34] New onset visual loss or changes lasting more than 30 days after noncardiac surgery were observed in 1/125,234 patients.[35]

Damage to teeth or dentures is perhaps the most common injury leading to anesthesia malpractice claims. Dental injury complaints are usually resolved by a hospital risk management department. Dental injuries requiring intervention were observed in 1/4537 patients.[36]

Unlike studies of anesthesia mortality, most studies of nonfatal complications do not attempt to assess the relationship between the complication and anesthesia care. Many of these complications are known risks of anesthesia. Such risks vary according to the specific surgical and anesthesia plan as well as the patient's physical characteristics. Risk management and quality improvement programs generally focus on local experience with postoperative complications in targeting emphasis areas for improvement.

Chapter 6

Cellular and Molecular Mechanisms of Anesthesia

Alex S. Evers

C. Michael Crowder

KEY POINTS

1	Despite the importance of general anesthetics, the molecular mechanisms responsible for anesthetic actions remain one of the unsolved mysteries of pharmacology.
2	The spinal cord is probably the site at which anesthetics act to inhibit purposeful responses to noxious stimulation (end point for measurements of equal potency, MAC).
3	Inhalational anesthetics can depress the excitability of thalamic neurons, potentially resulting in the loss of consciousness.
4	Synaptic function is considered a likely subcellular site of general anesthetic action. Nevertheless, the effects of anesthetics on synaptic function differ among various anesthetic agents, neurotransmitters, and neuronal preparations.
5	Ion channels (especially $GABA_A$ receptors) are a likely molecular targets of anesthetic action.
6	Direct anesthetic–protein-binding interactions may be responsible for anesthetic effects on ion channels in the central nervous system (CNS) (stereoselectivity is the strongest argument in favor of this mechanism).
7	Genetic techniques provide the most reliable and versatile methods for changing the structure of putative anesthetic targets.
8	The unitary theory of anesthesia is incorrect and there are several molecular mechanisms (anesthetics act via selective effects on specific molecular targets).

1 The introduction of general anesthetics into clinical practice 150 years ago stands as one of the seminal innovations of medicine. This single discovery facilitated the development of modern surgery and spawned the specialty of anesthesiology. Despite the importance of general

anesthetics and despite over 100 years of active research, the molecular mechanisms responsible for anesthetic action remain one of the unsolved mysteries of pharmacology.

Why have mechanisms of anesthesia been so difficult to elucidate? Anesthetics, as a class of drugs, are challenging to study for three major reasons:

1. Anesthesia, by definition, is a change in the responses of an *intact animal* to external stimuli. Making a definitive link between anesthetic effects observed in vitro and the anesthetic state observed and defined in vivo has proven difficult.

2. No structure–activity relationships are apparent among anesthetics; a wide variety of structurally unrelated compounds, ranging from steroids to elemental xenon, are capable of producing clinical anesthesia. This suggests that there are multiple molecular mechanisms that can produce clinical anesthesia.
3. Anesthetics work at very high concentrations in comparison to drugs, neurotransmitters, and hormones that act at specific receptors. This implies that if anesthetics do act by binding to specific receptor sites, they must bind with very low affinity and probably stay bound to the receptor for very short periods of time. Low-affinity binding is much more difficult to observe and characterize than high-affinity binding.

Despite these difficulties, molecular and genetic tools are now available that should allow for major insights into anesthetic mechanisms in the next decade. The aim of this chapter is to provide a conceptual framework for the reader to catalog current knowledge and integrate future developments about mechanisms of anesthesia. Five specific questions will be addressed in this chapter:

1. What is anesthesia and how do we measure it?
2. What is the anatomic site of anesthetic action in the central nervous system?
3. What are the cellular neurophysiologic mechanisms of anesthesia (e.g., effects on synaptic function versus effects on action potential generation) and what anesthetic effects on ion channels and other neuronal proteins underlie these mechanisms?
4. What are the molecular targets of anesthetics?
5. How are the molecular and cellular effects of anesthetics linked to the behavioral effects of anesthetics observed in vivo?

WHAT IS ANESTHESIA?

General anesthesia can broadly be defined as a drug-induced reversible depression of the central nervous system resulting in the loss of response to and perception of all external stimuli. Unfortunately, such a broad definition is inadequate for two reasons. First, the definition is not actually broad enough. Anesthesia is not simply a deafferented state; amnesia and unconsciousness are important aspects of the anesthetic state. Second, the definition is too broad, as all general anesthetics do not produce equal depression of all sensory modalities. For example, barbiturates are considered to be anesthetics, but they are not particularly effective analgesics. These conflicting problems with definition can be bypassed by a more practical description of the anesthetic state as a collection of "component" changes in behavior or perception. The components of the anesthetic state include unconsciousness, amnesia, analgesia, immobility, and attenuation of autonomic responses to noxious stimulation.

Regardless of which definition of anesthesia is used, essential to anesthesia are drug-induced changes in behavior or perception. As such, anesthesia can only be defined and measured in the

intact organism. Changes in behavior such as unconsciousness or amnesia can be intuitively understood in higher organisms such as mammals, but become increasingly difficult to define as one descends the phylogenetic tree. Thus, while anesthetics have effects on organisms ranging from worms[1] to man, it is difficult to map with certainty the effects of anesthetics observed in lower organisms to any of our behavioral definitions of anesthesia. This contributes to the difficulty of using simple organisms as models in which to study the molecular mechanisms of anesthesia. Similarly, any cellular or molecular effects of anesthetics observed in higher organisms can be extremely difficult to link with the constellation of behaviors that constitute the anesthetic state. The absence of a simple and concise definition of anesthesia is clearly one of the stumbling blocks to elucidating the mechanisms of anesthesia at a molecular and cellular level.

HOW IS ANESTHESIA MEASURED?

To study the pharmacology of anesthetic action, quantitative measurements of anesthetic potency are absolutely essential. To this end, Eger and colleagues have defined the concept of MAC, or minimum alveolar concentration. MAC is defined as the alveolar partial pressure of a gas at which 50% of humans do not respond to a surgical incision.[2] In animals, MAC is defined as the alveolar partial pressure of a gas at which 50% of animals do not respond to a noxious stimulus, such as tail clamp,[3] or at which they lose their righting reflex. The use of MAC as a measure of anesthetic potency has two major advantages. First, it is an extremely reproducible measurement that is remarkably constant over a wide range of species.[2] Second, the use of end-tidal gas concentration provides an index of the "free" concentration of drug required to produce anesthesia since the end-tidal gas concentration is in equilibrium with the free concentration in plasma. The MAC concept has several important limitations, particularly when trying to relate MAC values to anesthetic potency observed in vitro. First, the end point in a MAC determination is quantal: a subject is either anesthetized or unanesthetized; it cannot be partially anesthetized. Furthermore, MAC represents the average response of a whole population of subjects rather than the response of a single subject. The quantal nature of the MAC measurement makes it very difficult to compare MAC measurements to concentration-response curves obtained in vitro, where the graded response of a single preparation is measured as a function of anesthetic concentration. The second limitation of MAC measurements is that they can only be directly applied to anesthetic gases. Parenteral anesthetics (barbiturates, neurosteroids, propofol) cannot be assigned a MAC value, making it difficult to compare the potency of parenteral and volatile anesthetics. A MAC equivalent for parenteral anesthetics is the free concentration of the drug in plasma required to prevent response to a noxious stimulus in 50% of subjects; this value has been estimated for several parenteral anesthetics.[4] A third limitation of MAC is that it is highly dependent on the anesthetic end point used to define it. For example, if loss of response to a verbal command is used as an anesthetic end point, the MAC values obtained (MAC_{awake}) will be much lower than classic MAC values based on response to a noxious stimulus. Indeed, each behavioral component of the anesthetic state will likely have a different MAC value. Despite its limitations, MAC remains the most robust measurement and the standard for determining the potency of volatile anesthetics.

The foregoing discussion of MAC brings forth an important and somewhat controversial question. What drug concentration should be measured when determining anesthetic potency? When measuring potency of intravenous anesthetics, the answer to this question is relatively simple. One would like to relate the free concentration of the drug at its site of action (the biophase) to the drug's effect. It is, of course, not practical to measure the drug's concentration in the extracellular fluid of the brain, so free concentration in plasma is used as an approximation of the biophase concentration. This allows one to compare the concentration of drug required to produce anesthesia in humans to the concentrations required to produce specific effects in vitro. With the volatile anesthetics, potency is defined by MAC, which is measured in units of

partial pressure. Because the partial pressure of a dissolved gas is directly proportional to the free concentration of that gas in a liquid, alveolar partial pressures are accurate reporters of the free anesthetic concentrations in plasma and in brain tissue.

WHERE IN THE CENTRAL NERVOUS SYSTEM DO ANESTHETICS WORK?

In principle, general anesthesia could result from interruption of nervous system activity at myriad levels. Plausible targets include peripheral sensory receptors, spinal cord, brainstem, and cerebral cortex. Of these potential sites, only peripheral sensory receptors can be eliminated as an important site of anesthetic action. Animal studies have shown that fluorinated volatile anesthetics have no effect on cutaneous mechanosensors in cats[5] and can even sensitize nociceptors in monkeys.[6] Furthermore, selective perfusion studies in dogs have shown that MAC for isoflurane is unaffected by the presence or absence of isoflurane at the site of noxious stimulation, provided that the central nervous system is perfused with blood containing isoflurane.[7]

Spinal Cord

2 Clearly, anesthetic actions on the spinal cord cannot produce either amnesia or unconsciousness. However, several lines of evidence indicate that the spinal cord is probably the site at which anesthetics act to inhibit purposeful responses to noxious stimulation. This is, of course, the end point used in most measurements of anesthetic potency. Rampil and colleagues have shown that MAC values for fluorinated volatile anesthetics are unaffected in the rat by either decerebration[8] or cervical spinal cord transection.[9] Antognini and colleagues have used the strategy of isolating the cerebral circulation of goats to explore the contribution of brain and spinal cord to the determination of MAC. They found that when isoflurane is administered only to the brain, MAC is 2.9%, whereas when it is administered to the entire body, MAC is 1.2%.[10] Surprisingly, when isoflurane was preferentially administered to the body and not to the brain, isoflurane MAC was reduced to 0.8%.[11] The actions of volatile anesthetics in the spinal cord are mediated, at least in part, by direct effects on the excitability of spinal motor neurons. This conclusion has been substantiated by experiments in rats,[12] goats,[13] and humans,[14] showing that volatile anesthetics depress the amplitude of the F wave in evoked potential measurements (F-wave amplitude correlates with motor neuron excitability). These provocative results suggest not only that anesthetic actions at the spinal cord underlie the determination of MAC, but also that anesthetic actions on the brain may actually sensitize the cord to noxious stimuli. The plausibility of the spinal cord as a locus for anesthetic immobilization is also supported by several electrophysiological studies showing inhibition of excitatory synaptic transmission in the spinal cord.[15,16,17,18]

Reticular Activating System

The reticular activating system, a diffuse collection of brainstem neurons involved in arousal behavior, has long been speculated to be a site of general anesthetic action on consciousness. Evidence to support this notion came from early whole animal experiments showing that electrical stimulation of the reticular activating system could induce arousal behavior in anesthetized animals.[19] A role for the brainstem in anesthetic action is also supported by studies examining somatosensory evoked potentials. Generally, these studies show that anesthetics produce increased latency and decreased amplitude of cortical potentials, indicating that anesthetics inhibit information transfer through the brainstem.[20] In contrast, studies using brainstem auditory evoked potentials have shown variable effects ranging from depression to enhancement of information transfer through the reticular formation.[21,22,23] While there is evidence that the reticular formation of the brainstem is a locus for anesthetic effects, it cannot be the only anatomic site of anesthetic action for two reasons. First, as discussed earlier, the brainstem is not even required for anesthetics to inhibit responsiveness to noxious stimuli. Second, the reticular formation can be largely ablated without eliminating awareness.[24]

Within the reticular formation is a set of pontine noradrenergic neurons called the locus coeruleus (LC). The LC innervates a number of targets in basal forebrain and cortex including a set of GABAergic hypothalamic neurons called the ventrolateral preoptic nucleus (VLPO). The VLPO in turn innervates the tuberomammillary nucleus (TMN). The LC-VLPO-TMN pathway has been shown to be critical for non-REM sleep. Given that EEG patterns under anesthesia and non-REM sleep are

quite similar, this pathway is a particularly good candidate for a site of anesthetic action. Using stereotactic techniques, Maze and colleagues tested this hypothesis by measuring whether application of a GABAergic antagonist directly onto the TMN altered the efficacy of anesthetics.[25] Indeed, discrete application of the GABAergic antagonist gabazine onto the TMN markedly reduced the duration of sedation produced by systemically administered propofol or pentobarbital. This effect is unlikely to be a consequence of a nonspecific increase in arousal state because systemically administered gabazine did not antagonize the potency of ketamine whereas it did antagonize propofol and pentobarbital in a manner similar to application directly onto the TMN. This result strongly implicates the TMN as a site for the sedative action of GABAergic anesthetics like propofol and barbiturates.

Cerebral Cortex

3 The cerebral cortex is the major site for integration, storage, and retrieval of information. As such, it is a likely site at which anesthetics might interfere with complex functions like memory and awareness. Anesthetics clearly alter cortical electrical activity, as evidenced by the changes in surface EEG patterns recorded during anesthesia. Anesthetic effects on patterns of cortical electrical activity vary widely among anesthetics,[26] providing an initial suggestion that all anesthetics are not likely to act through identical mechanisms. More detailed in vitro electrophysiological studies examining anesthetic effects on different cortical regions support the notion that anesthetics can differentially alter neuronal function in various cortical preparations. For example, volatile anesthetics have been shown to inhibit excitatory transmission at some synapses in the olfactory cortex[27] but not at others.[28] Similarly, whereas volatile anesthetics inhibit excitatory transmission in the dentate gyrus of the hippocampus,[29] these same drugs can actually enhance excitatory transmission at other synapses in the hippocampus.[30] Anesthetics also produce a variety of effects on inhibitory transmission in the cortex. A variety of parenteral and inhalational anesthetics have been shown to enhance inhibitory transmission in olfactory cortex[28] and in the hippocampus.[31] Conversely, volatile anesthetics have also been reported to depress inhibitory transmission in hippocampus.[32] One area of the brain that has been postulated as a potential site of anesthetic action is the thalamus. The thalamus is

important in relaying sensory modalities and motor information to the cortex *via* thalamocortical pathways. A developing body of evidence indicates that inhalational anesthetics can depress the excitability of thalamic neurons, thus blocking thalamocortical communication potentially resulting in loss of consciousness.[33]

Summary

Anesthetics are able to produce effects on a variety of anatomic structures in the CNS, including spinal cord, brainstem, and cerebral cortex. Whereas certain anesthetic effects may be attributable to specific anatomic locations (e.g., purposeful response to noxious stimulation maps to the spinal cord), existing evidence provides no basis for a single anatomic site responsible for anesthesia. This difficulty in identifying a site for anesthesia might plausibly result from the various components of the anesthetic state being produced by anesthetic effects on different regions of the CNS. Nevertheless, despite the difficulty in identifying a common anatomic site for anesthesia, investigators have continued to look for other unifying principles in anesthetic action. Specifically, attention has been focused on identifying common cellular or molecular anesthetic targets that may have a wide anatomic distribution, explaining the ability of anesthetic to affect nervous system function in an anatomically diffuse manner.

HOW DO ANESTHETICS INTERFERE WITH THE ELECTROPHYSIOLOGIC FUNCTION OF THE NERVOUS SYSTEM?

In the simplest terms anesthetics inhibit or "turn off" vital central nervous system functions. They must do this by acting at specific physiologic "switches." A great deal of investigative effort has been devoted to identifying these switches. In principle, the CNS could be switched off by several means:

1. By depressing those neurons or pattern generators that subserve a pacemaker function in the CNS,
2. By reducing overall neuronal excitability; either by changing resting membrane potential or by interfering with the processes involved in generating an action potential,
3. By reducing communication between neurons—specifically, by either inhibiting excitatory synaptic transmission or enhancing inhibitory synaptic transmission.

Pattern Generators

Information concerning the effects of anesthetics on pattern-generating neuronal circuits in the CNS is limited, but clinical concentrations of anesthetics are likely to have significant effects on these circuits. The simplest evidence for this is the observation that most anesthetics exert profound effects on respiratory rate and rhythm, strongly suggesting an effect on respiratory pattern generators in the brainstem. Invertebrate studies suggest that volatile anesthetics can selectively inhibit the spontaneous (pacemaker) firing of specific neurons. As shown in Fig. 6-1, halothane (1.0 MAC) completely inhibits spontaneous action potential generation by one neuron in the right parietal ganglion of the great pond snail while producing no observable effect on the firing frequency of adjacent neurons.[34]

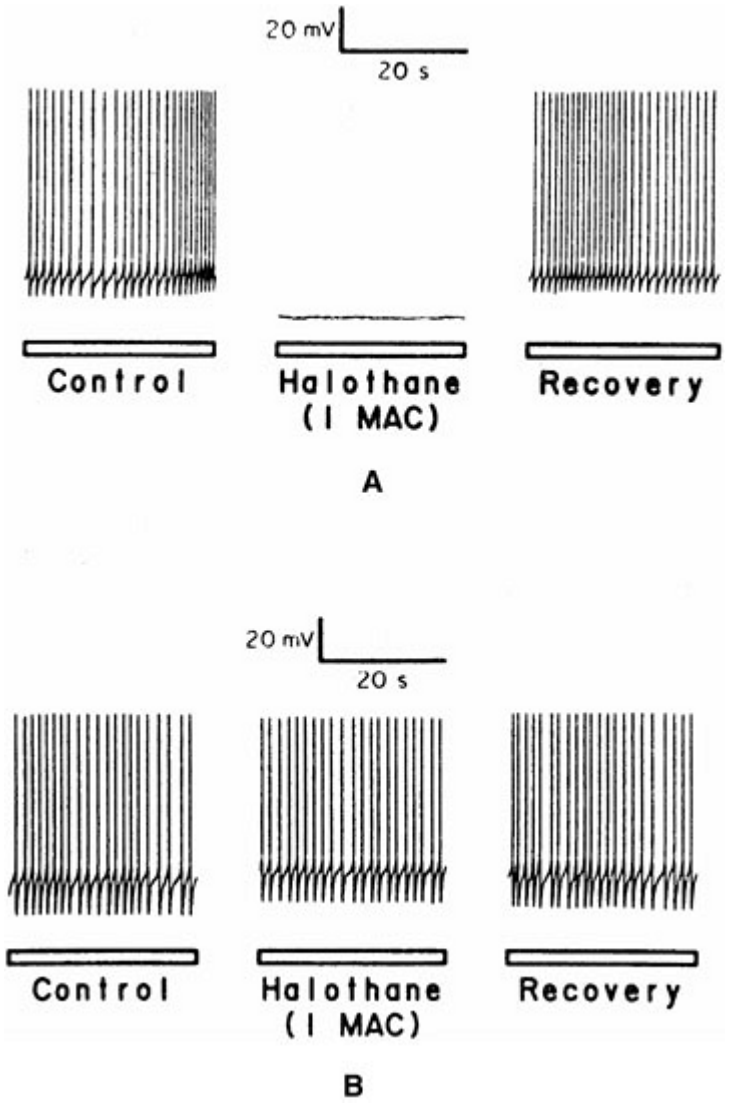

FIGURE 6-1. Selectivity of volatile anesthetic inhibition of neuronal automaticity. Halothane (1 MAC) reversibly inhibits the spontaneous firing activity of a neuron from the parietal ganglion of *Lymnaea stagnalis* **(A).** The same concentration of halothane has no effect on the

firing activity of an adjacent, and apparently identical, neuron **(B).** Note that in **(A)** halothane markedly reduces resting membrane potential in addition to inhibiting firing. (From Franks NP, Lieb WR. Mechanisms of general anesthesia. Environ Health Perspect. 1990;87:204.)

Neuronal Excitability

The ability of a neuron to generate an action potential is determined by three parameters: resting membrane potential, the threshold potential for action potential generation, and the function of voltage-gated sodium channels. Anesthetics can hyperpolarize (create a more negative resting membrane potential) both spinal motor neurons and cortical neurons,[35,36] and this ability to hyperpolarize neurons correlates with anesthetic potency. In general, the increase in resting membrane potential produced by anesthetics is small in magnitude and is unlikely to have an effect on axonal *propagation* of an action potential. Small changes in resting potential may, however, inhibit the *initiation* of an action potential either at a postsynaptic site or in a spontaneously firing neuron. Indeed, hyperpolarization is responsible for the inhibition of spontaneous action potential generation shown in Fig. 6-1. Recent evidence also indicates that isoflurane hyperpolarizes thalamic neurons, leading to an inhibition of tonic firing of action potentials.[33] There is no evidence indicating that anesthetics alter the threshold potential of a neuron for action potential generation.

However, the data is conflicting on whether the size of the action potential, once initiated, is diminished by general anesthetics. A classic paper by Larrabee and Posternak demonstrated that concentrations of ether and chloroform that completely block synaptic transmission in mammalian sympathetic ganglia have no effect on presynaptic action potential amplitude.[37] Similar results have been obtained with fluorinated volatile anesthetics in several mammalian brain preparations.[27,29] This dogma that the action potential is relatively resistant to general anesthetics has been challenged by more recent reports that volatile anesthetics at clinical concentrations produce a small but significant reduction in the size of the action potential in mammalian neurons.[38,39] In one case, the reduction in the action potential was shown to be amplified at the presynaptic terminal resulting in a large reduction in neurotransmitter release.[39] Thus, while current data still support the prevailing view that neuronal excitability is only slightly affected by general anesthetics, this small effect may nevertheless contribute significantly to the clinical actions of volatile anesthetics.

Synaptic Function

Synaptic function is widely considered to be the most likely subcellular site of general anesthetic action. Neurotransmission across both excitatory and inhibitory synapses has been found to be markedly altered by general anesthetics. General anesthetics have been shown to inhibit excitatory synaptic transmission in a variety of preparations, including sympathetic ganglia,[37] olfactory cortex,[27] hippocampus,[29] and spinal cord.[17] However, not all excitatory synapses appear to be equally sensitive to anesthetics; indeed, transmission across some hippocampal excitatory synapses has been shown to be enhanced by inhalational anesthetics.[30] In a similar fashion, general anesthetics have been shown both to enhance and depress inhibitory synaptic transmission in various preparations. In a classic paper in 1975, Nicoll and colleagues showed that barbiturates enhanced inhibitory synaptic transmission by prolonging the decay of the GABAergic inhibitory postsynaptic current.[40] Enhancement of inhibitory transmission has also been observed with many other general anesthetics, including etomidate,[41] propofol,[42] inhalational anesthetics,[28] and neurosteroids.[43] Although anesthetic enhancement of inhibitory currents has received a great deal of attention as a potential mechanism of anesthesia,[4] it is important to note that there is also a large body of experimentation showing that clinical concentrations of general anesthetics can depress inhibitory postsynaptic potentials in the hippocampus[32,44,45] and in the

spinal cord.[18] Anesthetics do appear to have preferential effects on synapses, but there is a great deal of heterogeneity in the manner in which anesthetic agents affect different synapses. This is not surprising given the large variation in synaptic structure, function (i.e., efficacy), and chemistry (neurotransmitters, modulators) extant in the nervous system.

Presynaptic Effects

General anesthetics affect synaptic transmission both pre- and postsynaptically. However, the magnitude and even the type of effect vary according to the type of synapse and the particular anesthetic. Presynaptically, neurotransmitter release from glutamatergic synapses has consistently been found to be inhibited by clinical concentrations of volatile anesthetics. For example, a study by Perouansky and colleagues conducted in mouse hippocampal slices showed that halothane inhibited excitatory postsynaptic potentials elicited by presynaptic electrical stimulation, but not those elicited by direct application of glutamate. This indicates that halothane must be acting to prevent the release of glutamate, the major excitatory neurotransmitter in the brain.[46] MacIver and colleagues extended these observations by providing evidence that the inhibition of glutamate release from hippocampal neurons is not due to effects at GABAergic synapses that could indirectly decrease transmitter release from glutamatergic neurons. Effects of intravenous anesthetics on glutamate release have also been demonstrated but the evidence is more limited and the effects potentially indirect.[47,48] The data for anesthetic effects on inhibitory neurotransmitter release is mixed. Inhibition,[49] stimulation,[50,51] and no effect[52] have been reported for volatile anesthetic and intravenous anesthetic action on GABA release. In a brain synaptosomal preparation where effects on both GABA and glutamate release could be studied simultaneously, Hemmings and coworkers found that glutamate and, to a lesser degree, GABA release were inhibited by clinical concentrations of isoflurane.[53] The mechanism underlying anesthetic effects on transmitter release have not been established. The effects of anesthetics on neurotransmitter release do not appear to be mediated by reduced neurotransmitter synthesis or storage, but rather by a direct effect on the process of neurosecretion. A variety of evidence argues that at some synapses the majority of the anesthetic effect is upstream of the transmitter release machinery, perhaps on presynaptic sodium channels (see discussion later). However, genetic data in *C. elegans* shows that the transmitter release machinery strongly influences volatile anesthetic sensitivity;[54,55] at present, it is unclear whether these findings represent species differences or different aspects of the same mechanism.

Postsynaptic Effects

Anesthetics also alter the postsynaptic response to released neurotransmitter. The effects of general anesthetics on excitatory neurotransmitter receptor function vary depending on neurotransmitter type, anesthetic agent, and preparation. Richards and Smaje examined the effects of several anesthetic agents on the response of olfactory cortical neurons to application of glutamate, the major excitatory neurotransmitter in the CNS.[56] They found that while pentobarbital, diethyl ether, methoxyflurane, and alphaxalone depressed the electrical response to glutamate, halothane was without effect. In contrast, when acetylcholine was applied to the same olfactory cortical preparation, halothane and methoxyflurane stimulated the electrical response whereas pentobarbital had no effect; only alphaxalone depressed the electrical response to acetylcholine.[57] The effects of anesthetics on neuronal responses to inhibitory neurotransmitters are more consistent. A wide variety of anesthetics, including barbiturates, etomidate, neurosteroids, propofol, and the fluorinated volatile anesthetics, have been shown to enhance the electrical response to exogenously applied GABA (for a review, see [58]). For example, Fig. 6-2 illustrates the ability of enflurane to increase both the amplitude and the duration of the current elicited by application of GABA to hippocampal neurons.[59]

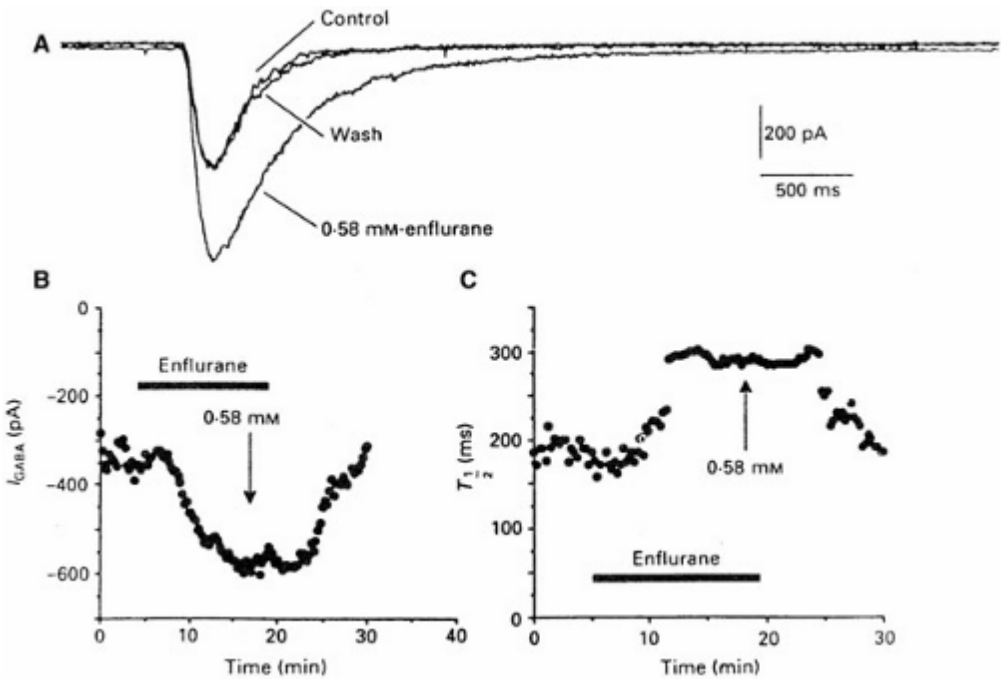

FIGURE 6-2. Enflurane potentiates the ability of GABA to activate a chloride current in cultured rat hippocampal cells. This potentiation is rapidly reversed by removal of enflurane (wash) **(Panel A).** Enflurane increases both the amplitude of the current **(Panel B)** and the time ($\tau_{1/2}$) it takes for the current to decay **(Panel C).** (Reproduced with permission from Jones MV, Brooks PA, Harrison L. Enhancement of γ-aminobutyric acid-activated Cl^- currents in cultured rat hippocampal neurones by three volatile anaesthetics. J Physiol. 1992;449:289.)

Summary

Attempts to identify a physiologic "switch" at which anesthetics act have suffered from their own success. Anesthetics produce a variety of effects on many physiologic processes that might logically contribute to the anesthetic state, including neuronal automaticity, neuronal excitability, and synaptic function. The synapse is generally thought to be the most likely relevant site of anesthetic action. Existing evidence indicates that even at this one site, anesthetics produce various effects, including presynaptic inhibition of neurotransmitter release, inhibition of excitatory neurotransmitter effect, and

enhancement of inhibitory neurotransmitter effect. Furthermore, the effects of anesthetics on synaptic function differ among various anesthetic agents, neurotransmitters, and neuronal preparations.

ANESTHETIC ACTIONS ON ION CHANNELS

5 Ion channels are one likely target of anesthetic action. The advent of patch clamp techniques in the early 1980s made it possible to directly measure the currents from single ion channel proteins. It was attractive to think that anesthetic effects on a small number of ion channels might help to explain the complex physiologic effects of anesthetics that we have already described. Accordingly, during the 1980s and 1990s a major effort was directed at describing the effects of anesthetics on the various kinds of ion channels. The following section summarizes and distills this effort. For the purposes of this discussion, ion channels are cataloged according to the stimuli to which they respond by opening or closing (i.e., their mechanism of gating).

Anesthetic Effects on Voltage-Dependent Ion Channels

A variety of ion channels can sense a change in membrane potential and respond by either opening or closing their pore. These channels include voltage-dependent sodium, potassium, and calcium channels, all of which share significant structural homologies. Voltage-dependent sodium and potassium channels are largely involved in generating and shaping action potentials. The effects of anesthetics on these channels have been extensively studied by Haydon and colleagues in the squid giant axon.[60,61] These studies show that these invertebrate sodium channels and potassium channels are remarkably insensitive to volatile anesthetics. For example, 50% inhibition of the peak sodium channel current required halothane concentrations 8 times those required to produce anesthesia. The delayed rectifier potassium channel was even less sensitive, requiring halothane concentrations more than 20 times those required to produce anesthesia. Similar results have been obtained in a mammalian cell line (GH_3 pituitary cells) where both sodium and potassium currents were inhibited by halothane only at concentrations greater than 5 times those required to produce anesthesia.[62] However, a number of studies with volatile anesthetics have challenged the notion that voltage-dependent sodium channels are insensitive to anesthetics. Rehberg and colleagues expressed rat brain IIA sodium channels in a mammalian cell line and showed that clinically relevant concentrations of a variety of inhalational anesthetics suppressed voltage-elicited sodium currents.[63] Hemmings and coworkers showed that sodium flux mediated by rat brain sodium channels was significantly inhibited by clinical concentrations of halothane.[64] Harris and colleagues documented the effects of isoflurane on a variety of sodium channel subtypes and found that several but not all subtypes are sensitive to clinical concentrations.[65] Finally as described above, in a rat brainstem neuron Wu and colleagues found that a small inhibition of sodium currents by isoflurane resulted in a large inhibition of synaptic activity.[39] Thus, sodium channel activity not only appears to be inhibited by volatile anesthetics, but this inhibition results in a significant reduction in synaptic function, at least at some mammalian synapses. Intravenous anesthetics have also been shown to inhibit sodium channels, but the concentrations for this effect are supraclinical.[66,67,68]

Voltage-dependent calcium channels (VDCC) serve to couple electrical activity to specific cellular functions. In the

nervous system, VDCCs located at presynaptic terminals respond to action potentials by opening. This allows calcium to enter the cell, activating calcium-dependent secretion of neurotransmitter into the synaptic cleft. At least six types of calcium channels (designated L, N, P, Q, R, and T) have been identified on the basis of electrophysiological properties and a larger number based on amino acid sequence similarities.[69] N-, P-, Q-, and R-type channels, as well as some of the untitled channels, are preferentially expressed in the nervous system and are thought to play a major role in synaptic transmission. L-type calcium channels, although expressed in the brain, have been best studied in their role in excitation–contraction coupling in cardiac, skeletal, and smooth muscle and are thought to be less important in synaptic transmission. The effects of anesthetics on L- and T-type currents have been well characterized,[62,70,71] and there are some reports concerning the effects of anesthetics on N- and P-type currents.[72,73,74] As a general rule, these studies have shown that volatile anesthetics inhibit VDCCs (50% reduction in current) at concentrations 2 to 5 times those required to produce anesthesia in humans, with less than a 20% inhibition of calcium current at clinical concentrations of anesthetics (Fig. 6-3). However, some studies have found VDCCs that are extremely sensitive to anesthetics. Takenoshita and Steinbach reported a T-type calcium current in dorsal root ganglion neurons that was inhibited by subanesthetic concentrations of halothane.[75] Additionally, ffrench-Mullen and colleagues have reported a VDCC of unspecified type in guinea pig hippocampus that is inhibited by pentobarbital at concentrations identical to those required to produce anesthesia.[76] Thus, VDCCs could well mediate some actions of general anesthetics, but their general insensitivity makes them unlikely to be major targets.

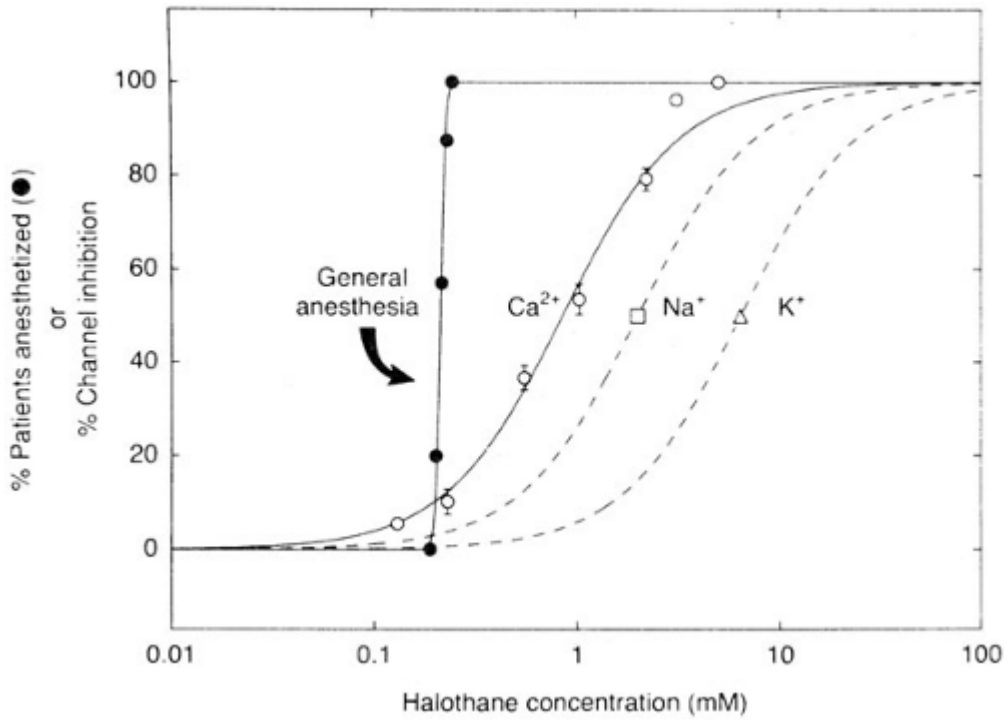

FIGURE 6-3. Halothane inhibition of voltage-dependent Ca^{2+}, Na^{+}, and K^{+} currents. The Ca^{2+} channels are L-type channels from GH_3 cells, and the Na^{+} and K^{+} channels are from the squid giant axon. The closed circles show the concentrations of halothane required to anesthetize humans. Note that the Ca^{2+} currents are inhibited about 20% by clinical concentrations of halothane whereas the Na^{+} and K^{+} currents are not inhibited at all. (Reproduced by permission from Franks NP, Lieb WR. Molecular and cellular mechanisms of anesthesia. Nature. 1994;367:607, Macmillan Magazines Ltd.)

Potassium channels are the most diverse of the ion channel types and include voltage-gated, second messenger and ligand-activated, and so-called inward rectifying channels; some channels fall into more than one category. High concentrations of both volatile anesthetics and intravenous anesthetics are required to significantly affect the function of voltage-gated K^{+} channels.[61,77,78] Similarly, classic inward rectifying K^{+} channels are relatively insensitive to sevoflurane and barbiturates.[79,80,81] However, some ligand-gated K^{+} channels are reasonably sensitive to volatile anesthetics as discussed below.

Summary

Existing evidence suggests that most VDCCs are modestly sensitive or insensitive to anesthetics, but some reports argue for significant heterogeneity in the anesthetic sensitivity of specific channel types and subtypes. In particular, some sodium channel subtypes are inhibited by volatile anesthetics and this effect may be responsible in part for a reduction in neurotransmitter release at some synapses. Additional experimental data will be required to establish whether anesthetic-sensitive VDCCs are localized to specific synapses at which anesthetics have been shown to inhibit neurotransmitter release.

Anesthetic Effects on Ligand-Gated Ion Channels

Fast excitatory and inhibitory neurotransmission is mediated by the actions of ligand-gated ion channels. Synaptically released glutamate or GABA diffuse across the synaptic cleft and bind to channel proteins that open as a consequence of neurotransmitter release. The channel proteins that bind GABA ($GABA_A$ receptors) are members of a superfamily of structurally related ligand-gated ion channel proteins that include nicotinic acetylcholine receptors, glycine receptors, and 5-

HT_3 receptors.[82] Based on the structure of the nicotinic acetylcholine receptor, each ligand-gated channel is thought to be composed of five nonidentical subunits. The glutamate receptors also comprise a family, each receptor thought to be a tetrameric protein composed of structurally related subunits.[83] The ligand-gated ion channels provide a logical target for anesthetic action because selective effects on these channels could inhibit fast excitatory synaptic transmission and/or facilitate fast inhibitory synaptic transmission. The effects of anesthetic

agents on ligand-gated ion channels are thoroughly cataloged in a review by Krasowski and Harrison.[58] The following section provides a brief summary of this large body of work.

Glutamate-Activated Ion Channels

Glutamate-activated ion channels have been classified, based on selective agonists, into three categories: AMPA receptors, kainate receptors, and NMDA receptors. Molecular biologic studies indicate that a large number of structurally distinct glutamate receptor subunits can be used to form each of the three categories of glutamate receptors.[84] This structural heterogeneity is reflected in functional heterogeneity within each category of glutamate receptor. AMPA and kainate receptors are relatively nonselective monovalent cation channels involved in fast excitatory synaptic transmission, whereas NMDA channels conduct not only Na^+ and K^+ but also Ca^{++} and are involved in long-term modulation of synaptic responses (long-term potentiation). Studies from the early 1980s in mouse and rat brain preparations showed that AMPA- and kainate-activated currents are insensitive to clinical concentrations of halothane,[85] enflurane,[86] and the neurosteroid allopregnanolone.[87] In contrast, kainate- and AMPA-activated currents were shown to be sensitive to barbiturates; in rat hippocampal neurons, 50 μM pentobarbital (pentobarbital produces anesthesia at approximately 50 μM) inhibited kainate and AMPA responses by 50%.[87] More recent studies using cloned and expressed glutamate receptor subunits show that submaximal agonist responses of GluR3 (AMPA-type) receptors are inhibited by fluorinated volatile anesthetics whereas agonist responses of GluR6 (kainate-type) receptors are enhanced.[88] In contrast both GluR3 and GluR6 receptors are inhibited by pentobarbital. The directionally opposite effects of the volatile anesthetics on different glutamate receptor subtypes may explain the earlier inconclusive effects observed in tissue, where multiple subunit types are expressed. These opposite effects have also been used as a strategy to identify critical sites on the molecules involved in anesthetic effect. By producing GluR3/GluR6 receptor chimeras (receptors made up of various combinations of sections of the GluR3 and GluR6 receptors) and screening for volatile anesthetic effect, specific areas of the protein required for volatile anesthetic potentiation of GluR6 have been identified. Subsequent site-directed mutagenesis studies have identified a specific glycine residue (Gly-819) as critical for volatile anesthetic action on GluR6-containing receptors.[89]

NMDA-activated currents also appear to be sensitive to a subset of anesthetics. Electrophysiological studies show virtually no effects of clinical concentrations of volatile anesthetics,[85,86] neurosteroids, or barbiturates[87] on NMDA-activated currents. It should be noted that there is some evidence from flux studies that volatile anesthetics may inhibit NMDA-activated channels. A study in rat brain microvesicles showed that anesthetic concentrations (0.2–0.3 mM) of halothane and enflurane inhibited NMDA-activated calcium flux by 50%.[90] In contrast, ketamine is a potent and selective inhibitor of NMDA-activated currents. Ketamine stereoselectively inhibits NMDA currents by binding to the phencyclidine site on the NMDA receptor protein.[91,92,93] The anesthetic effects of ketamine in intact animals show the same stereoselectivity as that is observed in vitro,[94] suggesting that the NMDA receptor may be the principal molecular target for the anesthetic actions of ketamine. Two other recent findings suggest that NMDA receptors may be an important target for nitrous oxide and xenon. These studies show that N_2O[95,96] and xenon[97] are potent and selective inhibitors of NMDA-activated currents. This is illustrated in Fig. 6-4, showing that N_2O inhibits NMDA-elicited, but not GABA-elicited, currents in hippocampal neurons.

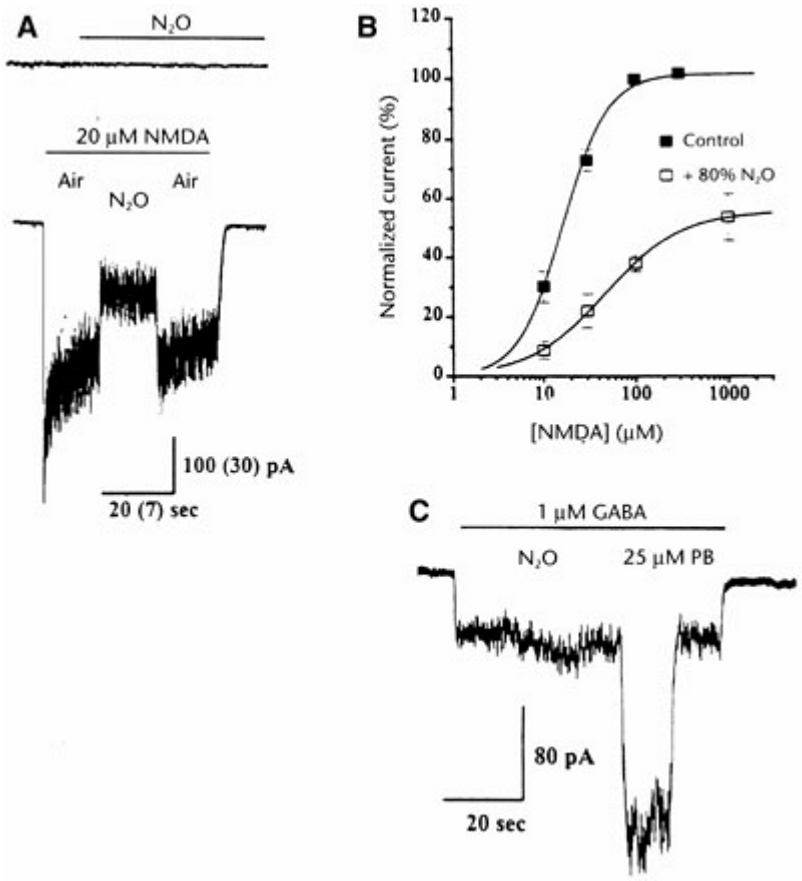

FIGURE 6-4. Nitrous oxide inhibits NMDA-elicited, but not GABA-elicited, currents in rat hippocampal neurons. **(Panel A)** 80% N_2O has no effect on holding current (upper trace), but inhibits the current elicited by NMDA. **(Panel B)** N_2O causes a rightward and downward shift of the NMDA concentration-response curve, indicating a mixed competitive/noncompetitive antagonism. **(Panel C)** 80% N_2O has little effect on GABA-elicited currents. In contrast, an equipotent anesthetic concentration of pentobarbital markedly enhances the GABA-elicited current. Nature Medicine. 1998;4:460)

GABA-Activated Ion Channels

GABA is the most important inhibitory neurotransmitter in the mammalian central nervous system. GABA-activated ion channels ($GABA_A$ receptors) mediate the postsynaptic response to synaptically released GABA by selectively allowing chloride ions to enter and thereby hyperpolarizing neurons. $GABA_A$ receptors are multisubunit proteins consisting of various combinations of α, β, γ, δ, and ε subunits, and there are many subtypes of each of these subunits. The function of $GABA_A$ receptors is modulated by a wide variety of pharmacological agents including convulsants, anticonvulsants, sedatives, anxiolytics, and anesthetics.[98] The effects of these various drugs on $GABA_A$ receptor function varies across brain regions and cell types. The following section briefly reviews the effects of anesthetics on $GABA_A$ receptor function.

Barbiturates, anesthetic steroids, benzodiazepines, propofol, etomidate, and the volatile anesthetics all modulate $GABA_A$ receptor function.[59], [98,99,100,101] These drugs produce three kinds of effects on the electrophysiological behavior of the $GABA_A$ receptor channels: potentiation, direct gating, and inhibition. *Potentiation* refers to the ability of anesthetics to increase markedly the current elicited by low concentrations of GABA, but to produce no increase in the current elicited by a maximally effective concentration of GABA.[85,102] Potentiation is illustrated in Fig. 6-5, showing the effects of halothane on currents elicited by a range of GABA concentrations in

currents generally occurs at concentrations of anesthetics within the clinical range. *Direct gating* refers to the ability of anesthetics to activate $GABA_A$ channels in the absence of GABA. Generally, direct gating of $GABA_A$ currents occurs at anesthetic concentrations higher than those used clinically, but the concentration-response curves for potentiation and for direct gating can overlap. It is not known whether direct gating of $GABA_A$ channels is either required for or contributes to the effects of anesthetics on GABA-mediated inhibitory synaptic transmission in vivo. In the case of anesthetic steroids, strong evidence indicates that potentiation, rather than direct gating of $GABA_A$ currents, is required for producing anesthesia.[103] Anesthetics can also inhibit GABA-activated currents. *Inhibition* refers to the ability of anesthetics to prevent GABA from initiating current flow through $GABA_A$ channels and has generally been observed at high concentrations of both GABA and anesthetic.[104,105] Inhibition of $GABA_A$ channels may help to explain why volatile anesthetics have, in some cases, been observed to inhibit rather than facilitate inhibitory synaptic transmission.[32]

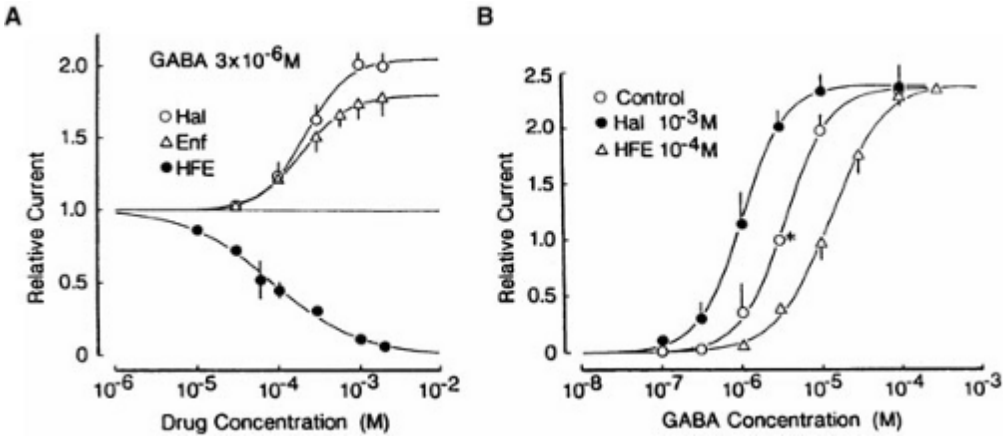

FIGURE 6-5. The effects of halothane (Hal), enflurane (Enf), and fluorothyl (HFE) on GABA-activated chloride currents in dissociated rat CNS neurons. **(Panel A)** Clinical concentrations of halothane and enflurane potentiate the ability of GABA to elicit a chloride current. The convulsant fluorothyl antagonizes the effects of GABA. **(Panel B)** GABA causes a concentration-dependent activation of a chloride current. Halothane shifts the GABA concentration-response curve to the left (increases the apparent affinity of the channel for GABA) whereas fluorothyl shifts the curve to the right (decreases the apparent affinity of the channel for GABA). (Reproduced with permission from Wakamori M, Ikemoto Y, Akaike N. Effects of two volatile anesthetics and a volatile convulsant on the excitatory and inhibitory amino acid responses in dissociated CNS neurons of the rat. J Neurophysiol. 1991;66:2014.)

Effects of anesthetics have also been observed on the function of single $GABA_A$ channels. These studies show that barbiturates,[99] propofol,[101] and volatile anesthetics[106] do not alter the conductance (rate at which ions traverse the open channel) of the channel, but that they increase the frequency with which the channel opens and/or the average length of time that the channel remains open. Collectively, the whole cell and single channel data are most consistent with the idea that clinical concentrations of anesthetics produce a change in the conformation of $GABA_A$ receptors that increases the affinity of the receptor for GABA. This is consistent with the ability of anesthetics to increase the duration of inhibitory postsynaptic potentials (IPSPs), because higher affinity binding of GABA would slow the dissociation of GABA from postsynaptic $GABA_A$ channels. It would not be expected that anesthetics would increase the peak amplitude of a GABAergic IPSP because synaptically released GABA probably reaches very high concentrations in the synapse. Higher concentrations of anesthetics can produce additional effects, either directly activating or

inhibiting $GABA_A$ channels. Consistent with these ideas, a study by Banks and Pearce showed that isoflurane and enflurane simultaneously increased the duration and decreased the amplitude of GABAergic inhibitory postsynaptic currents in hippocampal slices.[107]

Despite the similar effects of many anesthetics on $GABA_A$ receptor function, there is significant evidence that the various anesthetics do not act by binding to a single common binding site on the channel protein. First, even anesthetics that directly activate the channel probably do not bind to the GABA binding site. This is most clearly demonstrated by molecular biologic studies in which the GABA binding site is eliminated from the channel protein but pentobarbital can still activate the channel.[108] Direct radioligand binding studies have demonstrated that benzodiazepines bind to the $GABA_A$ receptor at nanomolar concentrations and that other anesthetics can modulate binding but do not bind directly to the benzodiazepine site.[98,109] A series of more complex studies examining the interactions between barbiturates, anesthetic steroids, and benzodiazepines indicates that these three classes of drugs cannot be acting at the same sites.[98] The actions of anesthetics on $GABA_A$ receptors are further complicated by the observation that steroid anesthetics can produce different effects on $GABA_A$ receptors in different brain regions.[110] This suggests the possibility that the specific subunit composition of a $GABA_A$ receptor may encode pharmacological selectivity. This is well illustrated by benzodiazepine sensitivity, which requires the presence of the γ_2 subunit subtype.[111] Similarly, sensitivity to etomidate has been shown to require the presence of a β_2 or β_3 subunit.[112] More recently, it has been shown that the presence of a δ or ε subunit in a $GABA_A$ receptor confers insensitivity to the potentiating effects of some anesthetics.[113,114]

Interestingly, $GABA_A$ receptors composed of ρ-type subunits (referred to as $GABA_C$ receptors) have been shown to be inhibited rather than potentiated by volatile anesthetics.[115] This property has been exploited, using molecular biologic techniques, by constructing chimeric receptors composed of part of the ρ receptor coupled to part of an α, β, or glycine receptor subunit. By screening these chimeras for anesthetic sensitivity, regions of the α, β, and glycine subunits responsible for anesthetic sensitivity have been identified. Based on the results of these chimeric studies, site-directed mutagenesis studies were performed to identify the specific amino acids

responsible for conferring anesthetic sensitivity. These studies revealed two critical amino acids, near the extracellular regions of transmembrane domains 2 and 3 (TM2, TM3) of the glycine and $GABA_A$ receptors that are required for volatile anesthetic potentiation of agonist effect.[116] It is not yet clear if these amino acids represent a volatile anesthetic binding site, or whether they are sites critical to transducing anesthetic-induced conformational changes in the receptor molecule. Interestingly, one of the amino acids shown to be critical to volatile anesthetic effect (TM3 site) has also been shown to be required (in the β_2/β_3 subunit) for the potentiating effects of etomidate.[117] In contrast, the TM2 and TM3 sites do not appear to be required for the actions of propofol, barbiturates, or neurosteroids.[118] Interestingly, a distinct amino acid in the TM3 region of the β_1 subunit of the $GABA_A$ receptor has been shown to selectively modulate the ability of propofol to potentiate GABA agonist effects.[118] Collectively, these molecular biologic data provide strong evidence that there are multiple unique binding sites for anesthetics on the $GABA_A$ receptor protein.

Other Ligand-Activated Ion Channels

Other members of the ligand-gated receptor superfamily include the nicotinic acetylcholine receptors (muscle and neuronal types), glycine receptors, and $5\text{-}HT_3$ receptors. A large body of work has gone into examining the effects of anesthetics on nicotinic acetylcholine receptors. The muscle type of nicotinic receptor has been shown to be inhibited by anesthetic concentrations in the clinical range[119] and to be desensitized by higher concentrations of anesthetics.[120] The muscle nicotinic receptor is an informative model to study because of its abundance and the wealth of knowledge about its structure. It is, however, not expressed in the central nervous system and hence not involved in the mechanism of anesthesia. However, a neuronal type of nicotinic receptor, which is widely expressed in the nervous system, might plausibly be involved in anesthetic mechanisms. Older studies looking at neuronal nicotinic receptors in molluscan

neurons[121] and in bovine chromaffin cells[122] indicate that these channels are inhibited by clinical concentrations of volatile anesthetics. More recent studies using cloned and expressed neuronal nicotinic receptor subunits have shown a high degree of subunit and anesthetic selectivity. Acetylcholine-elicited currents are inhibited, in receptors composed of various combinations of α_2, α_4, β_2, and β_4 subunits, by *subanesthetic* concentrations of halothane[123] or isoflurane.[124] In contrast, these receptors are relatively insensitive to propofol. Most interestingly, receptors composed of α_7 subunits are completely insensitive to both isoflurane and propofol.[124,125] Subsequent pharmacological experiments using selective inhibitors of neuronal nicotinic receptors led to the conclusion that these receptors are unlikely to have a major role in immobilization by volatile anesthetics.[126,127] However, they might play a role in the amnestic or hypnotic effects of volatile anesthetics.[128]

Glycine is an important inhibitory neurotransmitter, particularly in the spinal cord and brainstem. The glycine receptor is a member of the ligand-activated channel superfamily that, like the $GABA_A$ receptor, is a chloride-selective ion channel. A large number of studies have shown that clinical concentrations of volatile anesthetics potentiate glycine-activated currents in intact neurons[85] and in cloned glycine receptors expressed in oocytes.[129,130] The volatile anesthetics appear to produce their potentiating effect by increasing the affinity of the receptor for glycine.[130] Propofol,[101] alphaxalone, and pentobarbital also potentiate glycine-activated currents, whereas etomidate and ketamine do not.[129] Potentiation of glycine receptor function may contribute to the anesthetic action of volatile anesthetics and some parenteral anesthetics. $5\text{-}HT_3$ receptors are also members of the genetically related superfamily of ligand-gated receptor channels. Clinical concentrations of volatile anesthetics potentiate currents activated by 5-hydroxytryptamine in intact cells[131] and in cloned receptors expressed in oocytes.[132] In contrast, thiopental inhibits $5\text{-}HT_3$ receptor currents[131] and propofol is without effect on these receptor channels.[132] $5\text{-}HT_3$ receptors may play some role in the anesthetic state produced by volatile anesthetics and may also contribute to some unpleasant anesthetic side effects such as nausea and vomiting.

Summary

Several ligand-gated ion channels are modulated by clinical concentrations of anesthetics. Ketamine, N_2O, and xenon inhibit NMDA-type glutamate receptors, and this effect may play a major role in their mechanism of action. A large body of evidence shows that clinical concentrations of many anesthetics potentiate GABA-activated currents in the central nervous system. This suggests that $GABA_A$ receptors are a probable molecular target of anesthetics. Other members of the ligand-activated ion channel family, including glycine receptors, neuronal nicotinic receptors, and $5\text{-}HT_3$ receptors, are also affected by clinical concentrations of anesthetics and remain plausible anesthetic targets.

Anesthetic Effects on Second Messenger–Activated Ion Channels

Ion channels can be activated by ligands present in the cytoplasm as well as by ligands present in the extracellular space. The intracellular ligands that activate these channels are generally chemical second messengers, including cyclic nucleotides, Ca^{2+} or H^+ ions, inositol phosphates, and ATP. The structure of second messenger–activated ion channels is not as well understood as that of the voltage- or ligand-activated channels, and there is little information about anesthetic effects on these channels.

A potassium-selective channel (referred to as $I_{K(an)}$), found in snail neurons, that has many of the properties of a second messenger–activated channel is activated by clinical concentrations of volatile anesthetics.[121,133,134] $I_{K(AN)}$ shares many biophysical properties with a second messenger–activated potassium channel found in *Aplysia* neurons that is referred to as the S channel. Recent work by Yost and colleagues has shown that the S channel is also activated by clinical concentrations of volatile anesthetics.[135] The importance of volatile anesthetic activation of second messenger–activated potassium channels in invertebrates has now become apparent with the discovery of a large family of so-called "background potassium channels" in mammals. These mammalian potassium channels have a unique structure with two pore-forming domains in tandem

plus four transmembrane segments (2P/4TM; Fig. 6-6C).[136] TOK1, a member of this family, was first shown by Yost and colleagues to be activated by volatile anesthetics.[137] The laboratory of Michel Lazdunski has studied the effects of a variety of volatile anesthetics on several members of the 2P/4TM family. They found that TREK-1 channels were activated by clinical concentrations of chloroform, diethyl ether, halothane, and isoflurane (Fig. 6-6B). In contrast, closely related TRAAK channels were insensitive to all the volatile anesthetics, and TASK channels were activated by halothane and isoflurane, inhibited by diethyl ether, and unaffected by chloroform. These authors went on to show that the C-terminal regions of TASK and TREK-1 contained amino acids essential for anesthetic actions

on TASK and TREK-1 channels.[138] More recently, TREK-1 but not TASK was found to be activated by clinical concentrations of the gaseous anesthetics—xenon, nitrous oxide, and cyclopropane.[139] Thus, activation of background K^+ channels in mammalian vertebrates could be an important and general mechanism through which inhalational anesthetics regulate neuronal resting membrane potential and thereby excitability; this effect could plausibly be a significant contributor to some components of the anesthetic state.

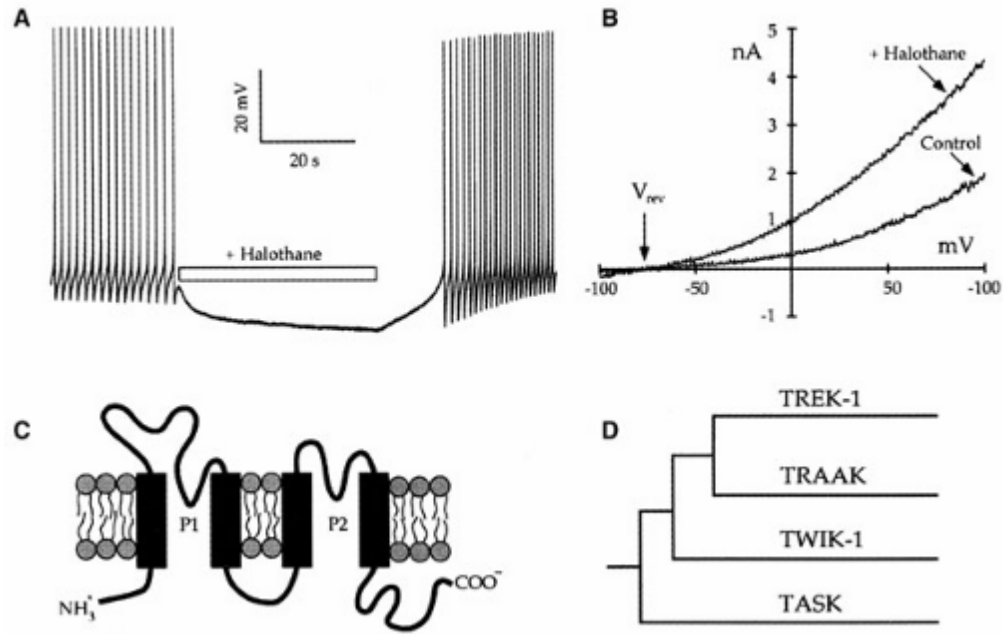

FIGURE 6-6. Volatile anesthetics activate background K^+ channels. **(Panel A)** Halothane reversibly hyperpolarizes a pacemaker neuron from *Lymnaea stagnalis* (the pond snail) by activating I_{Kan}. **(Panel B)** Halothane (300 μM) activates human recombinant TREK-1 channels expressed in COS cells. The figure shows current–voltage relationships with reversal potential (V_{rev}) of -88 mV, indicative of a K^+ channel. **(Panel C)** Predicted structure of a typical subunit of the mammalian background K^+ channels. Note the four transmembrane spanning segments *(in black)* and the two pore-forming domains (P1 and P2). Some but not all of these 2P/4TM K^+ channels are activated by volatile anesthetics. **(Panel D)** Phylogenetic tree for the 2P/4TM family. (Reproduced with permission from Franks NP, Lieb WR. Background K^+ channels: An important target for anesthetics? Nature Neurosci. 1999;2:395.)

One type of second messenger–activated channel, the calcium-dependent potassium channels, has been shown to be inhibited by clinical concentrations of anesthetics.[140] These large conductance potassium channels open in response to increases in cytoplasmic Ca^{2+} concentration and are important in modulating the shape and frequency of action potentials in the central nervous system. While a wide variety of anesthetics inhibit channel opening, this would tend to excite neurons and is thus unlikely to be important in the depressant effects of anesthetics. Anesthetic effects on these channels may contribute to the excitatory effects of low concentrations of

anesthetics and to the convulsant properties of some anesthetic agents. Several other potassium-selective ion channels are also activated by second messengers, including ATP-activated channels and channels activated by muscarinic acetylcholine receptors, but the effects of anesthetics on these channels has not been delineated.

Summary

Second messenger–activated ion channels are a plausible target for anesthetic action. Recent evidence suggests that members of the 2P/4TM family of background potassium channels may be important in producing some components of the anesthetic state.

WHAT IS THE CHEMICAL NATURE OF ANESTHETIC TARGET SITES?

The Meyer-Overton Rule

Almost 100 years ago, Meyer and Overton independently observed that the potency of gases as anesthetics was strongly correlated with their solubility in olive oil (Fig. 6-7).[141,142] This observation has significantly influenced thinking about anesthetic mechanisms in two ways. First, because a wide variety of structurally unrelated compounds obey the Meyer-Overton rule, it has been reasoned that all anesthetics are likely to act at the same molecular site. This idea is referred to as the *Unitary Theory of Anesthesia.* Second, it has been argued that since solubility in a specific solvent strongly correlates with anesthetic potency, the solvent showing the strongest correlation between anesthetic solubility and potency is likely to most closely mimic the chemical and physical properties of the anesthetic target site in the CNS. Based on this reasoning, the anesthetic target site was assumed to be hydrophobic in nature.

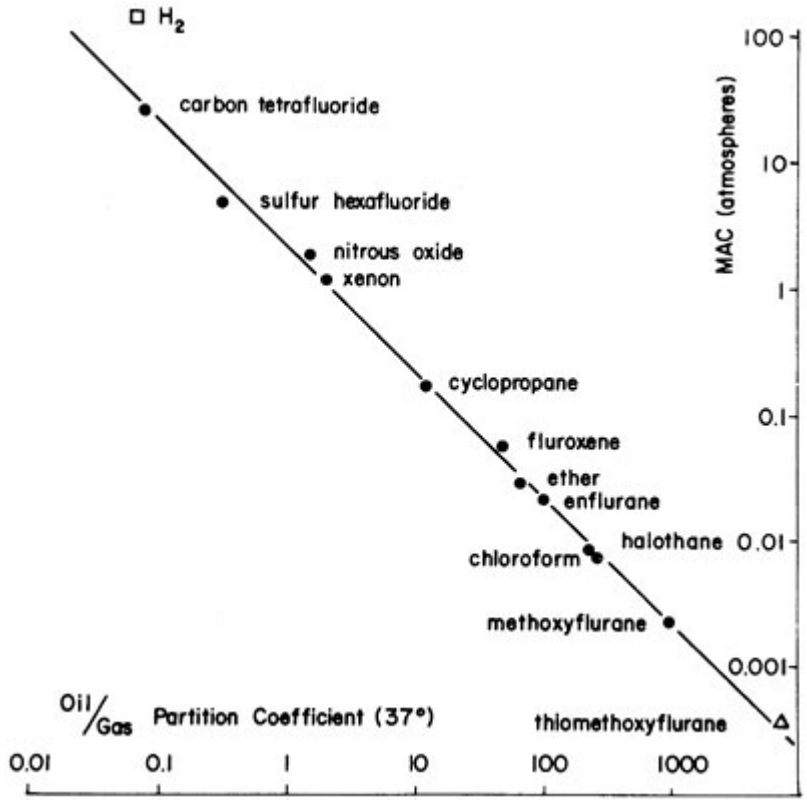

FIGURE 6-7. The Meyer-Overton rule. There is a linear relationship (on a log–log scale) between the oil/gas partition coefficient and the anesthetic potency (MAC) of a number of gases. The correlation between lipid solubility and MAC extends over a 70,000-fold difference in anesthetic potency. (Reproduced with permission from Tanfiuji Y, Eger EI, Terrell RC. Some characteristics of an exceptionally potent inhaled anesthetic: thiomethoxyflurane.

Anesth Analg. 1977;56:387.)

The Meyer-Overton correlation suffers from two limitations: (1) it only applies to gases and volatile liquids because olive oil/gas partition coefficients cannot be determined for liquid anesthetics; (2) olive oil is a poorly characterized mixture of oils. To circumvent these limitations, attempts have been made to correlate anesthetic potency with water/solvent partition

coefficients. To date, the octanol/water partition coefficient best correlates with anesthetic potency. This correlation holds for a variety of classes of anesthetics and spans a 10,000-fold range of anesthetic potencies.[143] The properties of the solvent octanol suggest that the anesthetic site is likely to be amphipathic, having both polar and nonpolar characteristics.

Exceptions to the Meyer-Overton Rule

Halogenated compounds exist that are structurally similar to the inhaled anesthetics yet are convulsants rather than anesthetics.[144] There are also convulsant barbiturates[145] and neurosteroids.[146] One convulsant compound, fluorothyl (hexafluorodiethylether), has been shown to cause seizures in 50% of mice at 0.12 vol%, but to produce anesthesia at higher concentrations (EC_{50} = 1.22 vol%).[147] The concentration of fluorothyl required to produce anesthesia is approximately predicted by the Meyer-Overton rule. In contrast, several polyhalogenated alkanes have been identified that are convulsants but that do not produce anesthesia. Based on the olive oil/gas partition coefficients of these compounds, anesthesia should have been achieved within the range of concentrations studied.[148] The end point used to determine the anesthetic effect of these compounds was movement in response to a noxious stimulus (MAC). Interestingly, some of these polyhalogenated compounds do produce amnesia in animals.[149] These compounds are thus referred to as *nonimmobilizers* rather than as nonanesthetics. Several polyhalogenated alkanes have also been identified that anesthetize mice, but only at concentrations 10 times those predicted by their oil/gas partition coefficients;[148] these compounds are referred to as *transitional* compounds. The nonimmobilizers and transitional compounds have been proposed as a "litmus test" for the relevance of anesthetic effects observed in vitro to those observed in the whole animal.

In several homologous series of anesthetics, anesthetic potency increases with increasing chain length until a certain critical chain length is reached. Beyond this critical chain length, compounds are unable to produce anesthesia, even at the highest attainable concentrations. In the series of *n*-alkanols, for example, anesthetic potency increases from methanol through dodecanol; all longer alkanols are unable to produce anesthesia.[150] This phenomenon is referred to as the *cutoff effect.* Cutoff effects have been described for several homologous series of anesthetics including *n*-alkanes, *n*-alkanols, cycloalkanemethanols,[151] and perfluoroalkanes.[152] While the anesthetic potency in each of these homologous series of anesthetics shows a cutoff, a corresponding cutoff in octanol/water or oil/gas partition coefficients has not been demonstrated. Therefore, compounds above the cutoff represent a deviation from the Meyer-Overton rule.

A final deviation from the Meyer-Overton rule is the observation that enantiomers of anesthetics differ in their potency as anesthetics. Enantiomers (mirror-image compounds) are a class of stereoisomers that have identical physical properties, including identical solubility in solvents such as octanol or olive oil. Animal studies with the enantiomers of barbiturate anesthetics,[153,154] ketamine,[94] neurosteroids,[103] etomidate,[155] and isoflurane[156] all show enantioselective differences in anesthetic potency. These differences in potency range in magnitude from a >10-fold difference between the enantiomers of etomidate or the neurosteroids to a 60% difference between the enantiomers of isoflurane. It is argued that a *major* difference in anesthetic potency between a pair of enantiomers could only be explained by a protein binding site (see Protein Theories of Anesthesia); this appears to be the case for etomidate and the neurosteroids. Enantiomeric pairs of anesthetics have also been used to study anesthetic actions on ion channels. It is argued that if an anesthetic effect on an ion channel contributes to the anesthetic state, the effect on the ion

channel should show the same enantioselectivity as is observed in whole animal anesthetic potency. Early studies showed that the (+)-isomer of isoflurane is 1.5 to 2 times more potent than the (-)-isomer in eliciting an anesthetic-activated potassium current, in potentiating $GABA_A$ currents, and in inhibiting the current mediated by a neuronal nicotinic acetylcholine receptor.[105,121] In contrast, the stereoisomers of isoflurane are equipotent in their effects on a voltage-activated potassium current and in their effects on lipid phase-transition temperature.[121] Studies with the neurosteroids[103] and etomidate[155] show that these anesthetics exert enantioselective effects on $GABA_A$ currents that parallel the enantioselective effects observed for anesthetic potency.

The exceptions to the Meyer-Overton rule do not obviate the importance of the rule. They do, however, indicate that the properties of a solvent such as octanol describe some, but not all, of the properties of an anesthetic binding site. Compounds that deviate from the Meyer-Overton rule suggest that anesthetic target site(s) are also defined by other properties including size and shape.

In defining the molecular target(s) of anesthetic molecules one must be able to account both for the Meyer-Overton rule and for the well-defined exceptions to this rule. It has sometimes been suggested that a correct molecular mechanism of anesthesia should also be able to account for pressure reversal. *Pressure reversal* is a phenomenon whereby the concentration of a given anesthetic needed to produce anesthesia is greatly increased if the anesthetic is administered to an animal under hyperbaric conditions. The idea that pressure reversal is a useful tool for elucidating mechanisms of anesthesia is based on the assumption that pressure reverses the specific physicochemical actions of the anesthetic that are responsible for

producing anesthesia; that is to say, pressure and anesthetics act on the same molecular targets. However, recent evidence suggests that pressure reverses anesthesia by producing excitation that physiologically counteracts anesthetic depression, rather than by acting as an anesthetic antagonist at the anesthetic site of action.[157] Therefore, in the following discussion of molecular targets of anesthesia, pressure reversal will not be further discussed.

Lipid vs. Protein Targets

Anesthetics might interact with several possible molecular targets to produce their effects on the *function* of ion channels and other proteins. Anesthetics might dissolve in the *lipid* bilayer, causing physicochemical changes in membrane structure that alter the ability of embedded membrane proteins to undergo conformational changes important for their function. Alternatively, anesthetics could bind directly to *proteins* (either ion channel proteins or modulatory proteins), thus either (1) interfering with binding of a ligand (e.g., a neurotransmitter, a substrate, a second messenger molecule) or (2) altering the ability of the protein to undergo conformational changes important for its function. The following section summarizes the arguments for and against lipid theories and protein theories of anesthesia.

Lipid Theories of Anesthesia

The elucidation of the Meyer-Overton rule suggested that anesthetics interact with a hydrophobic target. To investigators in the early part of the twentieth century, the most logical hydrophobic target was a lipid. In its simplest incarnation, the lipid theory of anesthesia postulates that anesthetics dissolve in the lipid bilayers of biological membranes and produce anesthesia when they reach a critical concentration in the membrane. Consistent with this hypothesis, the membrane/gas partition coefficients of anesthetic gases in pure lipid bilayers correlate strongly with anesthetic potency.[158] This simple theory can account for anesthetics that obey the Meyer-Overton rule, but cannot account for anesthetics that deviate from this rule. For example, the cutoff effect cannot be explained by this theory because compounds above the cutoff can achieve membrane concentrations equal to those of compounds below the cutoff.[159] Similarly, enantioselectivity cannot be explained by this theory. Most importantly, this simplest version of the lipid theory does not explain how the presence of the anesthetic in the membrane is translated

into an effect on the function of the embedded proteins.

Membrane Perturbation

More sophisticated versions of the lipid theory require that the anesthetic molecules dissolved in the lipid bilayer cause a change or perturbation in one or more physical properties of the membrane. According to this theory, anesthesia is a function of both the concentration of anesthetic in the membrane and the effectiveness of that anesthetic as a perturbant. This potentially could explain deviations from the Meyer-Overton rule, because nonanesthetics could achieve high concentrations in the membrane, but might not be effective perturbants. In examining this theory it is important to define explicitly the perturbation caused by an anesthetic. One can then test the relevance of a specific perturbation to the mechanism of anesthesia by measuring the perturbation caused by various compounds (anesthetics and nonanesthetics) and correlating perturbation with anesthetic potency. The specific perturbations of membrane structure that have been proposed to be causally related to the anesthetic state are briefly explored in the following section.

Membrane Expansion

Anesthetics dissolved in membranes do increase membrane volume. This occurs both because the anesthetic molecules occupy space and, in principle, because they produce changes in lipid packing and/or protein folding. The *critical volume hypothesis* is an attempt to correlate changes in membrane volume with anesthesia. This hypothesis predicts that anesthesia occurs when anesthetic dissolved in the membrane produces a critical change in membrane volume. Changes in membrane volume could compress ion channels and thus alter their function. Alternatively, increases in membrane thickness could alter neuronal excitability by changing the potential gradient across the plasma membrane.[160] Several studies have shown that anesthetics can produce changes in membrane volume.[161] However, the amount of expansion caused by clinical concentrations of anesthetics is probably very small. One study of erythrocyte membranes showed that halothane (0.27 mM = 1.0 MAC) expanded the membranes by only 0.1%.[162] Another study of erythrocyte membranes showed that both anesthetics and nonanesthetics (long-chain *n*-alkanols above the anesthetic cutoff) produced similar degrees of membrane expansion.[163] While clinical concentrations of anesthetics clearly produce membrane expansion, the small magnitude of anesthetic-induced membrane expansion, coupled with the inability of this theory to account for the cutoff effect, makes it unlikely that membrane expansion is the correct mechanism of anesthesia. A recent study by Cantor revisits this topic.[164] Based on thermodynamic modeling, he argues that anesthetics in biologic membranes preferentially distribute to the interface between lipid and aqueous phases. This distribution results in increased lateral pressure, which could alter the function of membrane-embedded ion channels. His calculations also suggest that nonimmobilizers should not show the same interfacial distribution. There is some experimental evidence showing that anesthetics, but not nonimmobilizers, do preferentially distribute to the lipid/aqueous interface in a membrane.[165] The relationship between these recent observations and anesthetic effects on protein function remains to be determined.

Membrane Disordering

Studies using nuclear magnetic resonance (NMR) spectroscopy[166] and electron spin resonance (ESR) spectroscopy[167] have shown that a variety of anesthetics can disorder the packing of phospholipids in lipid bilayers and in biological membranes. The decrease in membrane order (often referred to as an increase in membrane fluidity) can, in principle, alter the function of ion channels embedded in the lipid bilayer. The ability of anesthetics to fluidize lipid bilayers does show a modest correlation with anesthetic potency.[168] Membrane disordering can also account for the cutoff effect. Studies on synaptic membranes have shown that anesthetic alkanols (octanol, decanol, dodecanol) fluidize membranes, whereas nonanesthetic alkanols have either no effect on fluidity (tetradecanol) or a rigidifying effect (hexadecanol, octadecanol) on the membranes.[169] Unfortunately, the degree of fluidization produced by clinical concentrations of anesthetics is quite small.[168] While it is unclear how much fluidization would be required to affect ion channel

function, anesthetics produce changes in membrane fluidity that can be mimicked by changes in temperature of less than 1°C. Clearly, a 1°C increase in temperature does not cause anesthesia, or even increase anesthetic potency. It is highly unlikely that changes in the fluidity of bulk membrane lipid are responsible for general anesthesia.

Lipid Phase Transitions

Another lipid perturbation that has been proposed to account for general anesthesia is a change in lipid phase-transition behavior. In its original version this theory proposed that anesthetics promote a transition of the lipids in neuronal membranes between a solid (gel) phase and a liquid-crystalline phase. Indeed, in pure lipid systems clinical concentrations of anesthetics do decrease the temperature at which such a transition occurs.[170] A second version of this theory, the *lateral phase-separation theory*, proposed that anesthetics *prevent* phase transitions between the liquid-crystalline and the gel phase.[171] According to this theory, liquid-crystalline to gel phase transition is required for normal ion channel function; inhibition of this phase transition causes anesthesia. There is little evidence to support the phase-transition theories. Anesthetic-induced phase changes have not been observed in biologic membranes, lipid phase transitions are not known to be required for normal ion channel function, and the changes in phase-transition temperature observed in pure lipid systems are less than 1°C.

Protein Theories of Anesthesia

6 The Meyer-Overton rule could also be explained by the direct interaction of anesthetics with hydrophobic sites on proteins. Three types of hydrophobic sites on proteins might interact with anesthetics:

1. Hydrophobic amino acids comprise the core of water-soluble proteins. Anesthetics could bind in hydrophobic pockets that are fortuitously present in the protein core.
2. Hydrophobic amino acids also form the lining of binding sites for hydrophobic ligands. For example, there are hydrophobic pockets in which fatty acids tightly bind on proteins such as albumin and the low–molecular-weight fatty acid–binding proteins. Anesthetics could compete with endogenous ligands for binding to such sites on either water-soluble or membrane proteins.
3. Hydrophobic amino acids are major constituents of the α-helices, which form the membrane-spanning regions of membrane proteins; hydrophobic amino acid side chains form the protein surface that faces the membrane lipid. Anesthetic molecules could interact with the hydrophobic surface of these membrane proteins, disrupting normal lipid–protein interactions and possibly directly affecting protein conformation. This last possibility would involve the interaction of many anesthetic molecules with each membrane protein molecule and would probably be a nonselective interaction between anesthetic molecules and *all* membrane proteins.

Direct interactions of anesthetic molecules with proteins would not only satisfy the Meyer-Overton rule, but would also provide the simplest explanation for compounds that deviate from this rule. Any protein-binding site is likely to be defined by properties such as size and shape in addition to its solvent properties. Limitations in size and shape could reduce the binding affinity of compounds beyond the cutoff, thus explaining their lack of anesthetic effect. Enantioselectivity is also most easily explained by a direct binding of anesthetic molecules to defined sites on proteins; a protein-binding site of defined dimensions could readily distinguish between enantiomers on the basis of their different shape. Protein-binding sites for anesthetics could also explain the convulsant effects of some polyhalogenated alkanes. Different compounds binding (in slightly different ways) to the same binding pocket can produce different effects on protein conformation and hence on protein function. For example, there are three kinds of compounds that can bind at the benzodiazepine binding site on the $GABA_A$ channel: *agonists*, which potentiate GABA effects

and produce sedation and anxiolysis; *inverse-agonists*, which promote channel closure and produce convulsant effects; and *antagonists*, which produce no effect on their own but can competitively block the effects of agonists and inverse-agonists. By analogy, polyhalogenated alkanes could be inverse-agonists, binding at the same protein sites at which halogenated alkane anesthetics are agonists. The evidence for direct interactions between anesthetics and proteins is briefly reviewed in the following section.

Evidence for Anesthetic Binding to Proteins

One of the initial approaches to probing anesthetic interactions with proteins was to observe the effects of anesthetics on the function of a protein and to try to make inferences about binding from the functional behavior. It is entirely reasonable to assume that direct anesthetic–protein interactions are responsible for functional effects of anesthetics on purified water-soluble proteins because no lipid or membrane is present in the preparations studied. Firefly luciferase is a water-soluble, light-emitting protein, which is inhibited by a wide variety of anesthetic molecules. Numerous studies have extensively characterized anesthetic inhibition of firefly luciferase activity and have revealed the following:[172,173]

1. Anesthetics inhibit firefly luciferase activity at concentrations very similar to those required to produce clinical anesthesia.
2. The potency of anesthetics as inhibitors of firefly luciferase activity correlates strongly with their potency as anesthetics, in keeping with the Meyer-Overton rule.
3. Halothane inhibition of luciferase activity is competitive with respect to the substrate D-luciferin.
4. Inhibition of firefly luciferase activity shows a cutoff in anesthetic potency for both *n*-alkanes and *n*-alkanols.

Based on these studies it can be inferred that a wide variety of anesthetics can bind in the luciferin-binding pocket of firefly luciferase. The fact that anesthetic inhibition of luciferase activity is consistent with the Meyer-Overton rule, occurs at clinical anesthetic concentrations, and explains the cutoff effect suggests that the luciferin-binding pocket may have physical and chemical characteristics similar to those of a putative anesthetic binding site in the CNS.

More direct approaches to study anesthetic binding to proteins have included NMR spectroscopy and photoaffinity labeling. Based on early studies by Wishnia and Pinder, it was suspected that anesthetics could bind to several fatty acid–binding proteins, including *β*-lactoglobulin and bovine serum albumin (BSA).[174,175] ^{19}F-NMR spectroscopic studies confirmed[176] this, and demonstrated that isoflurane binds to approximately three saturable binding sites on BSA. Isoflurane binding is eliminated by co-incubation with oleic acid, suggesting that isoflurane binds to the fatty acid–binding sites on albumin. Other anesthetics, including halothane, methoxyflurane, sevoflurane, and octanol, compete with isoflurane for binding to BSA.[177] The studies with BSA provide direct evidence that a variety of anesthetics can compete for binding to the same site on a protein. Using this BSA model, it was subsequently shown that anesthetic binding sites could be identified and characterized using a photoaffinity labeling technique. The anesthetic halothane contains a carbon–bromine bond. This bond can be broken by ultraviolet light generating a free radical. That free radical allows the anesthetic to permanently (covalently) label the anesthetic binding site. Eckenhoff and colleagues used ^{14}C-labeled halothane to photoaffinity-label anesthetic binding

sites on BSA[178] and obtained results virtually identical to those obtained using NMR spectroscopy. Eckenhoff subsequently has identified the specific amino acids that are photoaffinity-labeled by [^{14}C] halothane.[179] NMR and photoaffinity-labeling techniques have also been applied to several other proteins. For example, saturable binding of halothane to the luciferin-binding site on firefly luciferase has been directly confirmed using NMR and photoaffinity-labeling techniques.[180] Both NMR and photoaffinity-labeling techniques are also being applied to membrane proteins. At the

current time these techniques can only be applied to purified proteins available in relatively large quantity. The muscle-type nicotinic acetylcholine receptor is one of the few membrane proteins that can be purified in large quantity. Eckenhoff has used photoaffinity labeling to show that halothane binds to this protein. The pattern of photoaffinity labeling is complex, suggesting multiple binding sites.[181] Most recently, Miller and colleagues have developed a general anesthetic that is an analog of octanol and functions as a photoaffinity label. This compound, 3-diazyrinyloctanol, also binds to specific sites on the nicotinic acetylcholine receptor.[182]

Although NMR and photoaffinity techniques can provide extensive information about anesthetic binding sites on proteins, they cannot reveal the details of the three-dimensional structure of these sites. X-ray diffraction crystallography can provide this kind of three-dimensional detail and has been used to study anesthetic interactions with a small number of proteins. To date, it has been difficult to crystallize membrane proteins; thus, these studies have been limited to water-soluble proteins. In 1965, Schoenborn and colleagues first used x-ray diffraction techniques to examine the interactions of several anesthetics with crystalline myoglobin.[183,184] These studies demonstrated that at a partial pressure of 2.5 atm (xenon MAC = 1 atm), a single molecule of xenon binds to a specific pocket in the hydrophobic core of the myoglobin molecule. The anesthetics cyclopropane and dichloromethane also bind in this pocket, but larger anesthetics do not. It should be noted that xenon occupies a small empty space in the hydrophobic core of myoglobin and that even dichloromethane is a tight fit in this space. These data provided a clear demonstration that anesthetic molecules can bind in the hydrophobic core of a water-soluble protein and that the size of the hydrophobic binding pocket can account for a cutoff in the size of anesthetic molecules that can bind in that pocket. However, myoglobin cannot bind most anesthetic molecules (because of their size) and is therefore not a good model for the actual anesthetic binding site(s) in the central nervous system.

X-ray diffraction has also been used to demonstrate that a single molecule of halothane binds in a hydrophobic pocket deep within the enzyme adenylate kinase.[185] Halothane binding was localized to the binding site for the adenine moiety of AMP (adenine monophosphate), a substrate for adenylate kinase. Consistent with this finding, halothane was found to inhibit adenylate kinase in a manner that is competitive with respect to AMP. Unfortunately, halothane binding to adenylate kinase only occurs at concentrations well beyond the clinically useful range. More recently, firefly luciferase has been crystallized in the presence and absence of the anesthetic bromoform. X-ray diffraction studies of these crystals showed that the anesthetic does bind in the luciferin-binding pocket, as had been inferred from functional studies. Interestingly, two molecules of bromoform bind in the luciferin pocket—one that is likely to compete directly with luciferin for binding and one that is not.[186] The binding data with firefly luciferase and adenylate kinase are of particular interest because they demonstrate that anesthetics can bind to endogenous ligand binding sites and that this binding strongly correlates with anesthetic inhibition of protein function. The same group has also crystallized human serum albumin in the presence of either propofol or halothane. The x-ray crystallographic data demonstrate binding of both anesthetics to preformed pockets that had been shown previously to bind fatty acids.[187] Given that both of these anesthetics bind to serum albumin at clinical concentrations, these data give the best insight yet into the structure of an anesthetic binding pocket.

A recent approach to study anesthetic interactions with proteins has been to employ site-directed mutagenesis of candidate anesthetic targets, coupled with molecular modeling to make predictions about the location and structure of anesthetic binding sites. For example, Harris, Trudell, and colleagues have used this approach to predict the location and structure of the alcohol binding site on $GABA_A$ and glycine receptors.[188] A related approach has been to develop model proteins to define the structural requirements for an anesthetic binding site. Using this approach, Johansson has shown that a four–α-helix bundle with a hydrophobic core can bind volatile anesthetics at concentrations (K_D) similar to those required to produce anesthesia.[189]

Summary

Unequivocal evidence from studies using water-soluble proteins demonstrates that anesthetics can bind to hydrophobic pockets on proteins. Functional and binding studies with firefly luciferase

demonstrate that anesthetics can bind to a protein site at clinically relevant concentrations in a manner that can account for the Meyer-Overton rule and deviations from it. Evidence that direct anesthetic–protein-binding interactions may be responsible for anesthetic effects on ion channels in the CNS remains indirect; stereoselectivity currently offers the strongest indirect argument.

Overall, current evidence strongly indicates protein rather than lipid as the molecular target for anesthetic action. While the long-standing controversy between lipid and protein theories of anesthesia may be behind us, numerous unanswered questions remain about the details of anesthetic–protein interactions including:

1. What is the stoichiometry of anesthetic binding to a protein? (i.e., Do many anesthetic molecules interact with a single protein molecule or only a few?)
2. Do anesthetics compete with endogenous ligands for binding to hydrophobic pockets on protein targets or do they bind to fortuitous cavities in the protein?
3. Do all anesthetics bind to the same pocket on a protein or are there multiple hydrophobic pockets for different anesthetics?
4. How many proteins have hydrophobic pockets in which anesthetics can bind at clinically used concentrations?

HOW ARE THE EFFECTS OF ANESTHETICS ON MOLECULAR TARGETS LINKED TO ANESTHESIA IN THE INTACT ORGANISM?

The previous sections have described how anesthetics affect the function of a number of ion channels and signaling proteins, probably via direct anesthetic–protein interactions. It is unclear which, if any, of these effects of anesthetics on protein function are necessary and/or sufficient to produce anesthesia in an

intact organism. A number of approaches have been employed to try to link anesthetic effects observed at a molecular level to anesthesia in intact animals. These approaches and their pitfalls are briefly explored in the following section.

Pharmacological Approaches

An experimental paradigm frequently used to study anesthetic mechanisms is to administer a drug thought to act specifically at a putative anesthetic target (e.g., a receptor agonist or antagonist, an ion channel activator or antagonist), then determine whether the drug has either increased or decreased the animal's sensitivity to a given anesthetic. The underlying assumption is that if a change in anesthetic sensitivity is observed, then the anesthetic is likely to act via an action on the specific target of the administered drug. This is a largely flawed strategy that has nonetheless produced a huge literature. The drugs used to modulate anesthetic sensitivity usually have their own direct effects on central nervous system excitability and thus *indirectly* affect anesthetic requirements. For example, while α_2-adrenergic agonists decrease halothane MAC,[190] they are profound CNS depressants in their own right and produce anesthesia by mechanisms distinct from those used by volatile anesthetics. Thus, the "MAC-sparing" effects of α_2-agonists provide little insight into how halothane works. A more useful pharmacological strategy would be to identify drugs that have no effect on CNS excitability but prevent the effects of given anesthetics. Currently, however, there are no such anesthetic antagonists. Development of specific antagonists for anesthetic agents would provide a major tool for linking anesthetic effects at the molecular level to anesthesia in the intact organism, and might also be of significant clinical utility.

An alternative pharmacological approach is to develop "litmus tests" for the relevance of anesthetic effects observed in vitro. One such test takes advantage of compounds that are nonanesthetic despite the predictions of the Meyer-Overton rule. It is argued that "a site affected by these nonanesthetic compounds is unlikely to be relevant to the production of anesthesia."[148] A

similar argument uses stereoselectivity as the discriminator and argues that a site that does not show the same stereoselectivity as that observed for whole animal anesthesia is unlikely to be relevant to the production of anesthesia.[191] Although these tests may be useful, they are very dependent on the assumption that anesthesia is produced via drug action at a *single* site. For example, a nonanesthetic might depress CNS excitability via its actions on an important anesthetic target site while simultaneously producing counterbalancing excitatory effects at a second site. In this case the "litmus test" would incorrectly eliminate the anesthetic site as irrelevant to whole animal anesthesia. This example is quite plausible given the convulsant effects of many of the nonanesthetic polyhalogenated hydrocarbons. Another sort of litmus test is to selectively antagonize the putative anesthetic target so that this target is no longer functional. If anesthetic effects are mediated through this target, inactivation of the target by the antagonist should result in anesthetic resistance. Using this logic, the MAC-sparing effects of $GABA_A$ and glycine receptor antagonists were used to argue that both $GABA_A$ and glycine receptors mediate some but not all of the immobilizing effects of volatile anesthetics in rodents.[192,193] This same group used the lack of effect of neuronal nicotinic antagonists on isoflurane MAC to conclude that these receptors had no role in volatile anesthetic immobilization.[127] As with many pharmacological results, the issues of specificity and efficacy of the antagonists prevent these experiments from being definitive. Nevertheless, these results are consistent with the findings that volatile anesthetics affect the function of a large number of important neuronal proteins and no one target is likely to mediate all of the effects of these drugs.

Genetic Approaches

7 An alternative approach to study the relationship between anesthetic effects observed in vitro and whole animal anesthesia is to alter the structure of putative anesthetic targets and determine how this affects whole animal anesthetic sensitivity. Genetic techniques provide the most reliable and versatile methods for changing the structure of putative anesthetic targets. Toward this end, a variety of approaches have been taken that can be methodologically categorized as selective breeding, forward genetics, and reverse genetics. Selective breeding makes use of existing genetic variance among strains that are presumably because of differences in multiple genes and attempts to breed and select for enhanced differences in the trait of interest—in this case general anesthetic sensitivity. Koblin and colleagues have successfully used this strategy to breed two strains of mice (HI and LO) that differ in their sensitivity to N_2O by almost 1.0 atm.[194] A similar strategy has been used to breed mice that have differential sensitivity to the hypnotic effects of the benzodiazepine, diazepam. The two strains of mice (DR and DS) show some modest, but consistent, differences in their sensitivity to volatile anesthetics.[195] Both sets of strains have differences in sensitivities to drugs other than general anesthetics;[196] thus, it seems likely that the genetic differences in these strains may be more general differences in brain function/excitability rather than specific differences in an anesthetic target. Nevertheless, the HI/LO and DS/DR strains demonstrated that in principle genes controlling anesthetic sensitivity, perhaps encoding anesthetic targets, could be discovered. These strains have not led as yet to the identification of the responsible genetic loci. Even under the best of circumstances, mapping genes to the point of their identification in mice is exceedingly difficult, time-consuming, and expensive. In the particular cases of mapping the anesthetic sensitivity loci in these strains, the task is made even more difficult because the phenotype being mapped requires special testing and there is overlap in anesthetic sensitivity between the strains. Further, at least for the HI/LO strains, multiple genetic loci are contributing to the differences in anesthetic sensitivity.[196] Multiple loci are much more complex to identify because typically the contribution of each to the phenotype is small and therefore easily lost in the environmental noise. Forward genetics refers to the classical approach of starting from a phenotype of interest, for example, altered anesthetic sensitivity, and moving "forward" ultimately to identify the gene of interest. Strictly speaking, selective breeding is one form of forward genetics although it rarely proceeds all the way to identification of the genes responsible for the phenotype. More commonly, forward genetics involves inducing random mutations throughout the genome of a pool of animals, then identifying the rare individual that carries a mutation producing the phenotype of interest. This approach requires screening through large numbers of animals and can be effectively accomplished only in lower organisms with a large

number of offspring and short generation times. This typically means invertebrate models such as the fruit fly or nematode.

The first true forward genetic screen for mutants with altered general anesthetic sensitivity was performed in the nematode *C. elegans* by Phil Morgan and Margaret Sedensky.[197,198] They screened for altered sensitivity to supraclinical concentrations of halothane. High halothane concentrations were used because they are required to immobilize *C. elegans*. The first mutant isolated had a three-fold reduction in its EC_{50} for halothane. Interestingly, this mutant was hypersensitive to chloroform, methoxyflurane, and thiomethoxyflurane but not

to less lipophilic anesthetics such as isoflurane and enflurane.[198] This selective hypersensitivity argues that a generalized nervous system dysfunction is unlikely to account for the halothane hypersensitivity. The mutation was genetically mapped and found to be a loss-of-function allele of the *unc-79* gene, which encodes a neuronal protein that is most similar in amino acid sequence to a large human protein encoded by a gene on chromosome 14.[199] The cellular function of either the *C. elegans* or human protein is unknown. To attempt to understand the function of *unc-79*, a search for mutations that return the halothane hypersensitivity of the *unc-79* mutants toward normal levels was undertaken. Mutations in genes encoding stomatin-like proteins, an integral membrane protein first identified in erythrocytes, were found to suppress *unc-79*.[200] Genetic evidence suggested that the *C. elegans* stomatins might control halothane sensitivity by regulating the function of a mechanically gated sodium channel.[201] Additional mutant screens identified a gene, called *gas-1*, which encodes a highly conserved mitochondrial protein functioning in the electron transport chain.[202] *gas-1* mutants were hypersensitive to all halogenated volatile anesthetics tested. The mechanistic relationship between *gas-1* and *unc-79* and its suppressors genes is unclear.

Clinical concentrations of volatile anesthetics do not immobilize *C. elegans*, but they do produce behavioral effects including loss of coordinated movement.[203] Crowder and colleagues have screened for mutants that are resistant to anesthetic-induced uncoordination and found that mutations in a set of genes encoding proteins regulating neurotransmitter release control anesthetic sensitivity. The gene with the largest effect encoded syntaxin 1A, a neuronal protein highly conserved from *C. elegans* to humans and essential for fusion of neurotransmitter vesicles with the presynaptic membrane.[54] Importantly some syntaxin mutations produced hypersensitivity to volatile anesthetics while others conferred resistance. These allelic differences in anesthetic sensitivity could not be accounted for by effects on the process of transmitter release itself;[54,55] rather, the genetic data argued that syntaxin interacts with a protein critical for volatile anesthetic action, perhaps an anesthetic target. This putative target has not yet been identified.

In *Drosophila*, clinical concentrations of volatile anesthetics disrupt negative geotaxis behavior and response to a noxious light or heat stimulus.[204,205,206] Using one or more of these anesthetics effects, Nash and colleagues performed a forward genetic screen for halothane resistance. Several *har* (*ha*lothane *r*esistance) mutants were isolated. One set of mutants, *har38* and *har85*, was found to have mutations in a gene encoding a putative cation channel with predicted structural similarities to both sodium and calcium channels.[207] Interestingly, halothane was shown to reduce glutamatergic transmission at the Drosophila larval neuromuscular junction, most likely by inhibiting glutamate release, and the *har38* and *har85* mutants were resistant to this presumed presynaptic halothane action.[208] As the identification of the syntaxin mutants suggested in *C. elegans*, this result suggests that inhibition of excitatory neurotransmitter release may be a consequential action of volatile anesthetics in disrupting behavior in *Drosophila.*

At anesthetic concentrations 1.5- to 2-fold higher than MAC, volatile anesthetics ablate response of *Drosophila* to touch.[209] Using this anesthetic end point, Gamo and colleagues have extensively screened for *Drosophila* mutants with altered sensitivity to diethyl ether. Mutated genes in two of the strains have been identified. A partial-loss-of-function mutation in the α subunit of the major neuronal sodium channel mediating action potentials (*para*) was one of the mutants. This *para* Na^+ channel mutant had about a 50% reduction in its ether EC_{50}.[210,211] A mutation in the *Drosophila* calreticulin gene was also found to produce similar hypersensitivity to ether.[212] Interestingly, this calreticulin mutant was mildly resistant to isoflurane and normally sensitive to halothane.

Calreticulin is a highly conserved protein localized to the endoplasmic reticulum of all cell types and is involved in Ca^{2+} buffering and protein folding in the ER.[213] Because of this broad role in cellular function, calreticulin's role in anesthetic sensitivity could be indirect.

As with all model organisms, a critical question to ask is how do the anesthetic mechanisms implicated in nematode and fruit fly relate to mechanisms of anesthesia in humans? Even if a similar gene exists in humans, the evolutionary divergence of the molecules and the very different nervous systems makes the relevance question impossible to answer without additional experiments. Thus, a more practical question is which of the implicated invertebrate genes deserves a potentially more arduous and expensive examination in a vertebrate species? A few criteria seem reasonable. First, is the gene involved in a process known to be affected by general anesthetics in vertebrates? Certainly, the genes in *C. elegans* and *Drosophila* encoding proteins regulating neurotransmitter release and the sodium channel fit this criterion. While mitochondrial electron transport has generally not been implicated in vertebrate anesthetic action, a case report of four children who are hypersensitive to sevoflurane by processed EEG criteria and found to carry defects in the same mitochondrial protein complex implicated in *C. elegans* is an intriguing observation that would likely not have been made without the work in *C. elegans*.[214] Second, is the gene conserved in vertebrates and does it function in the nervous system? In this regard, both the mitochondrial protein and syntaxin 1A are very highly conserved and both function in the nervous system with syntaxin 1A expressed exclusively in neurons; however, for each of these proteins one must explain the enigma of neuron-subtype-specific effects of anesthetics by a protein that functions in all neurons. A third criterion is anesthetic concentration. Do the genes regulate sensitivity to clinical concentrations of anesthetics? However, in this case, some latitude should be given for the possibility that the binding sites on the anesthetic targets are partially diverged and therefore the affinity of the target could be reduced. Certainly, experiments with $GABA_A$ receptors and model anesthetic binding proteins have shown that single amino acid changes can drastically alter anesthetic potency or affinity.[116], [215,216,217,218] Thus, anesthetic concentration criteria should not be used to exclude mechanisms as is reasonably done in more closely related species such as rodents; rather, the "correct concentration" neither rules in or out the mechanism in question but simply makes it more plausible. Finally, one should keep in mind that even if a particular anesthetic mechanism identified in invertebrates is operant in humans, it may not be the only mechanism of anesthetic action in humans and indeed it may not even be involved in anesthesia at all but rather in anesthetic side effects in other tissues such as myocardium or vascular smooth muscle. Thus, invertebrate genetics should be viewed as a means to pose novel hypotheses, some of which may be compelling enough to test in vertebrates.

Reverse genetics refers to altering the sequence of a known gene and then observing the effects of this mutation on the process of interest. In other words, reverse genetics moves from gene to phenotype as opposed to classical forward genetics that starts with a phenotype and then proceeds to identify the responsible gene(s). Reverse genetics is used typically to test a well-established hypothesis, although occasionally surprising phenotypes produce novel hypotheses. While reverse genetics is employed in both invertebrate and vertebrate models, in terms of anesthetic sensitivity, reverse genetics has been most instructive in mice.

The $GABA_A$ receptor has been extensively studied using reverse genetic techniques.[219] The genes encoding for various subunits of the $GABA_A$ receptor have been mutated so that they are either nonfunctional

(gene knockouts) or so that they have altered amino acids that might produce altered function (gene knockins). Knockouts of two α subunits of the $GABA_A$ receptor have been tested for their anesthetic sensitivity. Lack of the α1 subunit was not found to alter sensitivity of the animal to the hypnotic effects of pentobarbital.[220] Similarly, α6 subunit knockout mice were normally sensitive to halothane and enflurane.[221] Knockin mouse strains have been generated for several of the α-subunits, primarily for examining benzodiazepine action. The loss of various aspects of benzodiazepine action in these strains demonstrated that the α1 subunit mediates the sedative and amnestic actions, and is partially required for its anticonvulsant properties. Similarly, the α2 subunit was found to be essential for anxiolysis by diazepam, and α3 and α5 knockin strains were

partially resistant to its myorelaxant effects. However, none of these α-subunit knockin strains have been reported to be abnormally sensitive to any complete general anesthetics. In contrast, knockout of the β3 subunit produced mice with a markedly decreased sensitivity to the hypnotic action of both midazolam and etomidate and a mildly decreased sensitivity to halothane and enflurane in tail clamp response assays.[222] The interpretation of these data was complicated by a variety of behavioral and neurological abnormalities in these mice that suggested the possibility of an indirect effect of the mutation on anesthetic sensitivity.

In vitro electrophysiological experiments had shown that a specific β3 subunit point mutation, β3 (N265M), blocked the action of etomidate and propofol on the $GABA_A$ receptor without greatly altering receptor function in the absence of drug;[117,223] this result suggested a means to circumvent the problems produced by knocking out β3. Thus, a mouse β3(N265M) knockin strain was generated and found to be insensitive to the immobilizing effects of etomidate and propofol.[224] However, the β3(N265M) mice were not completely resistant to the loss-of-righting reflex by etomidate and propofol, indicating that other targets mediated this behavioral effect. Volatile anesthetic sensitivity was modestly reduced in the β3(N265M) mice suggesting that the β3 subunit may play some role in their action. A similar approach was taken to show that the β2 subunit is critical for the sedating but not anesthetic action of etomidate.[225,226] Finally, strains carrying a knockout mutation of the δ subunit of the $GABA_A$ receptor were found to have a shorter duration of neurosteroid-induced loss-of-righting reflex, whereas their sensitivity was normal to other intravenous and volatile anesthetics.[227] Thus, the δ subunit may play a relatively specific role in neurosteroid action.

Summary

Overall, genetic studies provide a powerful tool for determining which genes and gene products are important in producing anesthesia in an intact organism. Forward genetics has the potential to identify anesthetic mechanisms/targets that may not have been implicated by vertebrate biochemical and electrophysiological studies that are biased toward abundant ion channels. However, particularly for invertebrate genetics, the genetically identified mechanisms may not be operant in humans or may be operant in a different physiological context. Reverse genetics has strengths and weaknesses complementary to those of forward genetics. Reverse genetics rarely generates novel hypotheses or fundamental breakthroughs, but it can confirm definitively the in vivo role of a gene product. Indeed, the demonstration that the action of the general anesthetics etomidate and propofol can be blocked by a single missense mutation in a subunit of the $GABA_A$ receptor is at the same time not surprising and yet one of the most important results thus far in anesthetic mechanism research.

CONCLUSION

In this chapter evidence has been reviewed concerning the anatomic, physiologic, and molecular loci of anesthetic action. It is clear that all anesthetic actions cannot be localized to a specific anatomic site in the central nervous system; indeed, some evidence suggests that different components of the anesthetic state may be mediated by actions at disparate anatomic sites. The actions of anesthetics also cannot be localized to a specific physiologic process. While there is consensus that anesthetics ultimately affect synaptic function as opposed to intrinsic neuronal excitability, the effects of anesthetics are dependent on the agent and synapse studied and can affect presynaptic and/or postsynaptic function. At a molecular level, anesthetics show some selectivity, but still affect the function of multiple ion channels and signaling proteins. Although it is likely that these effects are mediated via direct protein–anesthetic interactions, it appears that there are numerous proteins that can

directly interact with anesthetics. All of these data suggest that the unitary theory of anesthesia is incorrect and that there are at least several molecular mechanisms of anesthesia.

In keeping with the idea that anesthesia can be produced in a variety of ways, Pancrazio and Lynch have suggested that different anesthetic targets may mediate different components of the anesthetic state.[228] As illustrated in Fig. 6-8, they suggest that the analgesic effects of opiates,

α_2-agonists, and volatile anesthetics are mediated *via* inhibition of calcium currents and/or activation of potassium currents. Sedation and amnesia, they propose, are mediated by potentiation or activation of $GABA_A$ receptors. In this model, anesthetic states can also be produced by totally independent mechanisms such as the inhibition of glutamate receptors by ketamine. Although there may be many more important anesthetic targets than those suggested by Pancrazio and Lynch, their proposal illustrates the idea that different molecular targets may mediate the various components of the anesthetic state, and that volatile anesthetics are complete anesthetics because they can interact with several of these molecular targets.

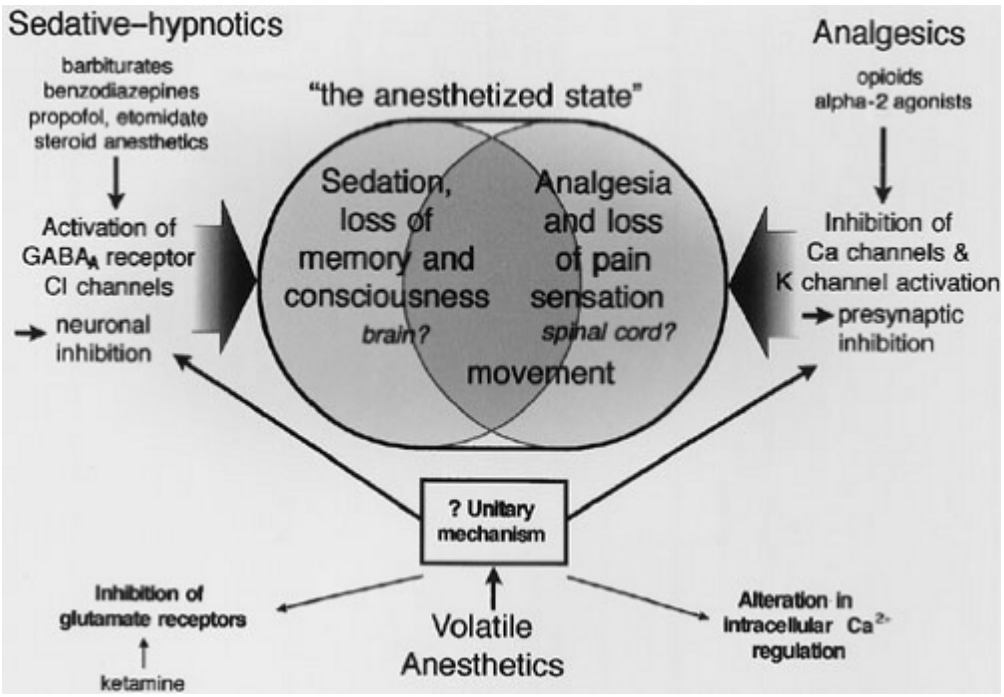

FIGURE 6-8. A multisite model for anesthesia. The model proposes that presynaptic inhibition (Ca^{2+} channel inhibition, K^+ channel activation) is responsible for analgesic effects, whereas postsynaptic $GABA_A$ receptor activation is responsible for sedation and amnesia. As indicated by the overlapping circles, the behavioral effects of Ca^{2+} channel inhibition and $GABA_A$ receptor activation are not mutually exclusive. The model suggests that some anesthetic agents predominantly affect Ca^{2+} and K^+ channels, other anesthetic agents predominantly affect $GABA_A$ receptors, and volatile anesthetics affect both. As illustrated at the bottom of the model, inhibition of glutamate receptor function is an alternative pathway by which ketamine and perhaps the volatile anesthetics produce anesthesia. (Reproduced with permission from Pancrazio JJ, Lynch C. Snails, spiders, and stereospecificity—Is there a role for calcium channels in anesthetic mechanisms? Anesthesiology. 1994;81:3.)

Although the precise molecular interactions responsible for producing anesthesia have not been fully elucidated, it has become clear that anesthetics do act via selective effects on specific molecular targets. The technologic revolutions in molecular biology, genetics, and cell physiology make it likely that the next decade will provide the answers to the century-old pharmacological puzzle of the molecular mechanism of anesthesia.

Chapter 7

Genomic Basis of Perioperative Medicine

Mihai V. Podgoreanu

Joseph P. Mathew

KEY POINTS

1	*Functional genomics* employs large-scale experimental methodologies and statistical analyses to investigate the regulation of gene expression in response to physiological, pharmacological, and pathological changes.
2	Most of genetic diversity in the population is attributable to widespread DNA sequence variations (*polymorphisms*).
3	Specific genotypes are associated with a variety of organ-specific perioperative adverse outcomes, including neurocognitive dysfunction, renal compromise, vein graft restenosis, postoperative thrombotic complications, vascular reactivity, severe sepsis, transplant rejection, and death.
4	Risk stratification based on clinical, procedural, and biological markers explains only a small part of the variability in incidence of perioperative complications. Specific genotypes may improve prediction of adverse perioperative outcomes in otherwise healthy individuals.
5	Several genes predictive of perioperative vascular response have been identified.
6	Variability in the reported incidence of both early and late neurological deficits remains poorly explained by procedural risk factors, suggesting that environmental (operative) and genetic factors may interact to determine disease onset, progression, and recovery.
7	Genetics polymorphisms are associated with acute renal injury following coronary artery bypass graft (CABG) surgery.
8	Genetic variants in the renin–angiotensin pathway and in proinflammatory cytokine genes have been associated with respiratory complications post-cardiopulmonary bypass.

9	The term "pharmacogenomics" describes how inherited variations in genes modulating drug actions are related to interindividual variability in drug response. Such variability in drug action may be *pharmacokinetic* or *pharmacodynamics.*
10	Malignant hyperthermia (MH) susceptibility results from a complex interaction between multiple genes and environment.
11	A genetic basis for increased anesthetic requirements is beginning to emerge, suggested, for instance, by the observation that desflurane requirements are increased in subjects with red hair versus dark hair.
12	In addition to the genetic control of peripheral nociceptive pathways, considerable evidence exists for genetic variability in the descending central pain modulatory pathways, potentially explaining the interindividual variability in analgesic responsiveness.
13	The large interindividual variability in the magnitude of response to injury, including activation of inflammatory and coagulation cascades, apoptosis, and fibrosis, suggests the involvement of genetic regulatory factors.
14	The standard "single gene" paradigm is insufficient to adequately describe the tissue response to severe systemic stimuli. Instead, organ injury might better be defined by patterns of altered gene and protein expression.

GENETIC BASIS OF DISEASE

1 Human biological diversity involves interindividual variability in morphology, behavior, physiology, development, susceptibility to disease, response to stressful stimuli and drug therapy (i.e., *phenotypes*). This phenotypic variation is determined, at least in part, by differences in the specific genetic makeup (i.e., *genotype*) of an individual. In 2003, the fiftieth anniversary of Watson and Crick's description of the DNA double helix structure also marked the completion of the Human Genome Project.[1] This major accomplishment provides the discipline of genomics with basic resources to study the functions and interactions of all genes in a systematic fashion, including their interaction with environmental factors, and translate the findings into clinical and societal benefits. *Functional genomics* employ large-scale experimental methodologies and statistical analyses to investigate the regulation of gene expression in response to physiological, pharmacological, and pathological changes. It also uses genetic information from clinical studies to examine the impact of genetic variability on disease characterization and outcome.[2] To integrate this new generation of genetic results into clinical practice, perioperative physicians need to understand the patterns of human genome variation, the methods of population-based genetic investigation, and the principles of gene and protein expression analysis.

Overview of Human Genetic Variation

2 Although the human DNA sequence is 99.9% identical between individuals, the variations may greatly affect a person's disease risk. In elucidating the genetic basis of disease, much of what has been investigated to date has focused on rare genetic variants (*mutations*) responsible

for monogenic disorders such as hypertrophic cardiomyopathy, long-QT syndrome, sickle cell anemia, or familial hypercholesterolemia, which are highly penetrant (carriers of the mutant gene will likely have the disease) and inherited in mendelian fashion (hence, termed mendelian diseases). However, most of the genetic diversity in the population is attributable to more widespread DNA sequence variations (*polymorphisms*), which can be either nucleotide base substitutions (*single nucleotide polymorphisms*, SNPs), short sequence repeats (*microsatellites*), or insertion/deletion of one or more nucleotides (*indels*), and may or may not be associated with a specific phenotype (Fig. 7-1). To be classified as a polymorphism, the DNA sequence alternatives (i.e., *alleles*) must exist with a frequency of at least 1% in the population. About 10 million SNPs are estimated to exist in the human genome, approximately once every 300 base pairs, located in genes as well as in the surrounding regions of the genome. Polymorphisms may directly alter the amino acid sequence and therefore potentially alter protein function, or alter regulatory DNA sequences that modulate protein expression. Sets of nearby SNPs on a chromosome are inherited in blocks, referred to as *haplotypes*. As it will be shown later, haplotype analysis is a useful way of applying genotype information in disease gene discovery.

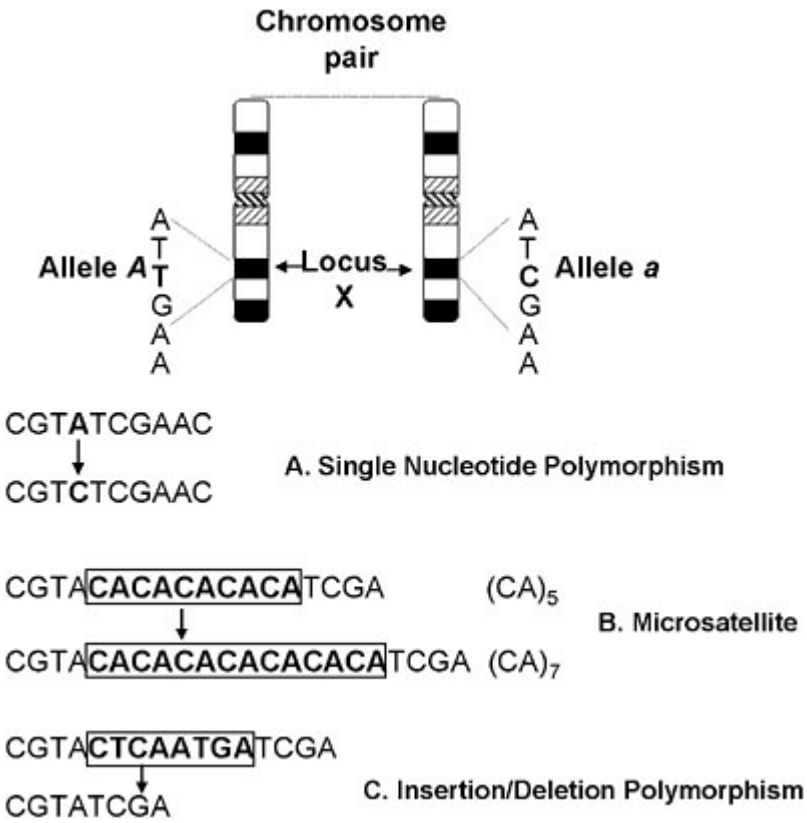

FIGURE 7-1. Categories of genetic polymorphisms. **A.** *Single nucleotide polymorphisms (SNP)* can be silent or have functional consequences ranging from changes in amino acid sequence or premature termination of protein synthesis (if they occur in the coding regions of the gene) to alterations in the expression of the gene, resulting in more or less protein (if they occur in regulatory regions of the gene such as the promoter region or the intron/exon boundaries). **B.** *Microsatellite polymorphism* with varying number of dinucleotide $(CA)_n$ repeats. **C.** *Insertion-deletion polymorphism*. NOTE: *locus*—the location of a gene/genetic marker in the genome; *alleles*—alternative forms of a gene/genetic marker; *genotype*—the observed alleles for an individual at a genetic locus; *heterozygous*—two different alleles are present at a locus; *homozygous*—two identical alleles are present at a locus. An SNP at position 1691 of a gene, with alleles G and A would be written as 1691G>A.

Many common diseases like atherosclerosis, coronary artery disease, hypertension, diabetes, cancer, asthma and our responses to injury, drugs, and nonpharmacological therapies are

genetically complex, characteristically involving an interplay of many genetic variations in molecular and biochemical pathways (i.e., *polygenic*) and genetic-environmental interactions (i.e., *multifactorial*). Therefore, complex phenotypes can be viewed as the integrated effect of many susceptibility genes and many environmental exposures (Fig. 7-2). The proportion of phenotypic variance that is the result of genetic factors is referred to as *heritability* and can be estimated by examining the increased similarity of a phenotype in related as compared to unrelated individuals. One of the major challenges and ongoing research efforts facing the postgenomic period is to connect the nearly 30,000 protein-coding genes of mammalian organisms to the genetic basis of complex polygenic diseases and the integrated function of complex biological systems. According to the "common-variants/common-disease hypothesis,"[3] it is the common functional polymorphisms that modulate individual susceptibility to common complex diseases and the manifestation, severity, and prognosis of the disease process. In the next section, we review the common strategies used to incorporate genetic analysis into clinical studies.

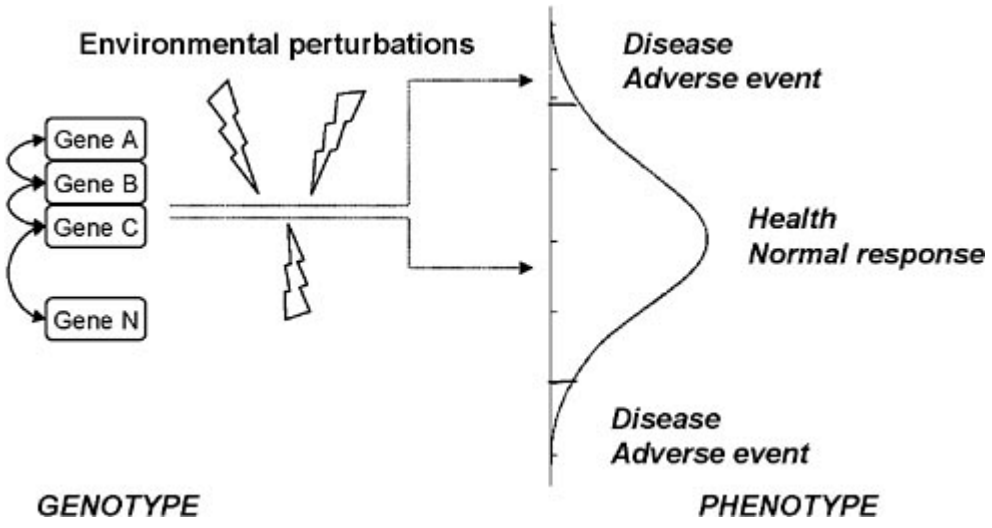

FIGURE 7-2. Common diseases (e.g., coronary artery disease, hypertension, diabetes, cancer) and individual responses to various perturbations (e.g., drug administration, hemodynamic challenge, surgical stress, trauma) are complex, involving multiple gene–gene interactions (*polygenic*) and gene–environment interactions (*multifactorial*) to produce a final clinical outcome, or *phenotype*. In these instances, rather than directly causing the disease, genetic variability may contribute to disease onset and/or progression.

Genetic Analysis of Complex Disease

Most ongoing research on complex disorders focuses on identifying genetic polymorphisms that enhance susceptibility to given conditions. Often the design of such studies is complicated by the presence of multiple risk factors, gene–environment interactions, and a lack of even rough estimates of the number of genes underlying such complex traits. Two broad strategies are being employed to identify complex trait loci. The *candidate gene* approach is motivated by what is

known about the trait biologically and can be characterized as a hypothesis-testing approach. The second strategy is a *genome scan*, in which thousands of markers uniformly distributed throughout the genome are used to locate genomic regions that may harbor genes influencing the phenotypic variability. This is a hypothesis-generating approach, allowing the detection of previously unknown trait loci.[4] Both the candidate gene and genome scan approaches can be implemented using one of two fundamental methods of identifying polymorphisms affecting common diseases: linkage analysis or association studies in human populations.

Linkage Analysis

Linkage analysis is used to identify the chromosomal location of gene variants related to a given disease. This approach has been used successfully to map hundreds of genes for rare, monogenic disorders. However, the nature of complex diseases precludes the use of extended families wherein the same disease allele acts in most affected individuals throughout a pedigree. Rather, in complex disease a multitude of genes with rare and/or common alleles create an apparently chaotic pattern of heterogeneity within and between families. The overall effect of this heterogeneity, together with the potentially weak influence of many loci, places a heavy burden on the statistical power needed to detect individual contributing genes, and may be the reason why very few genome scans so far have yielded disease loci that meet genome-wide significance criteria.[5] However, a few positive findings have emerged using this approach. Combining linkage analysis with advanced molecular genetic techniques, the chromosomal location (5q12) of a gene influencing stroke was identified,[6] and risk of myocardial infarction was mapped to a single region on chromosome 14.[7] Additionally, many determinants of complex cardiovascular and renal function have been mapped in the rat,[8] providing the first rough approximation of genomic regions linked to homeostatic control of sodium–water excretion and arterial pressure. However, within these broad regions reside hundreds of genes that may act alone or in concert to influence homeostasis. Narrowing the regions of genetic interest and identifying specific genes that participate in homeostatic control using techniques of chromosomal substitution coupled with gene expression analysis and physiological profiling is the object of intense research effort.[9]

Genetic Association Studies

As mentioned earlier, genetic effects on complex disorders are likely to involve multiple susceptibility markers of individually modest importance, thereby limiting the application of linkage analysis. Association studies examine the frequency of specific genetic polymorphisms in a population-based sample of unrelated diseased individuals and appropriately matched unaffected controls. The increased statistical power to uncover small clinical effects of multiple genes[10] and the fact that they do not require family based sample collections are the main advantages of this approach over linkage analysis. Most significant information has been gathered so far from association studies in which prior knowledge of the gene or its protein product existed. This candidate gene approach has been widely used to analyze possible associations between genetic variants and disease progression or outcome, with genes selected because of a priori hypotheses about their potential etiological role in disease, based on current understanding of the disease pathophysiology.[11] For example, genetic variants within the renin–angiotensin system,[12] nitric oxide synthase,[13] and β_2-adrenergic receptors,[14] known to modulate vascular tone, were tested and found to be associated with hypertension. Similarly, the possible effects of polymorphisms on genetic predisposition for coronary artery disease[15,16,17] or restenosis after angioplasty[18,19] have been extensively investigated, and recently, two large-scale association studies have identified gene variants that might affect susceptibility to myocardial infarction.[20,21] Accumulating evidence suggests that specific genotypes are associated with a variety of organ-specific perioperative adverse outcomes, including neurocognitive dysfunction,[22,23] renal compromise,[24,25] vein graft restenosis,[26] postoperative thrombosis,[27] vascular reactivity,[28] severe sepsis,[29] transplant rejection,[30] and death (for a review, see Ziegeler et al.[31]).

One of the main weaknesses of the association approach is that, unless the marker of interest "travels" (i.e., is in *linkage disequilibrium*) with a functional variant, or the marker allele *is* the actual functional variant, the power to detect and map complex trait loci will be reduced. Other known limitations of genetic association studies include potential false-positive findings resulting from population stratification (i.e., admixture of different ethnic or genetic backgrounds in the case and control groups)[32] and multiple comparison issues when large numbers of candidate genes are being assessed.[33] Replication of findings across different populations or related phenotypes remains the most reliable method of validating a true relationship between genetic polymorphisms and disease,[11] but poor reproducibility in subsequent studies is one of the main criticisms of the candidate gene association approach.[34] However, a recent meta-analysis suggested that lack of statistical power may be the main contributor to this inconsistent

replication and proposed more stringent statistical criteria to exclude false-positive results and the design of large collaborative association studies.[35] Ongoing efforts to develop high-resolution maps of genetic variation and haplotypes (the International HapMap Project) should facilitate the fine localization of causal genetic variants for common diseases and variable drug responses and increase the power of future association studies.

Large-Scale Gene and Protein Expression Profiling

Genomic approaches are anchored in the "central dogma" of molecular biology, the concept of transcription of messenger RNA (mRNA) from a DNA template, followed by translation of RNA into protein (Fig. 7-3). Since transcription is a key regulatory step that may eventually signal many other cascades of events, the study of RNA levels in a cell or organ (i.e., quantifying gene expression) can improve the understanding of a wide variety of biological systems. Furthermore, while the human genome contains only about 30,000 genes, functional variability at the protein level is far more diverse, resulting from extensive posttranscriptional, translational, and posttranslational modifications. It is believed that there are approximately 200,000 distinct proteins in humans, which are further modified posttranslationally by phosphorylation, glycosylation, oxidation, and disulfide structures.[36] Thus, in addition to the assessment of genetic variability at the DNA level using various genotyping techniques, analysis of large-scale variability at the RNA and protein level using microarray and proteomic approaches provides a better understanding of the overall regulatory networks involved in complex phenotypes.

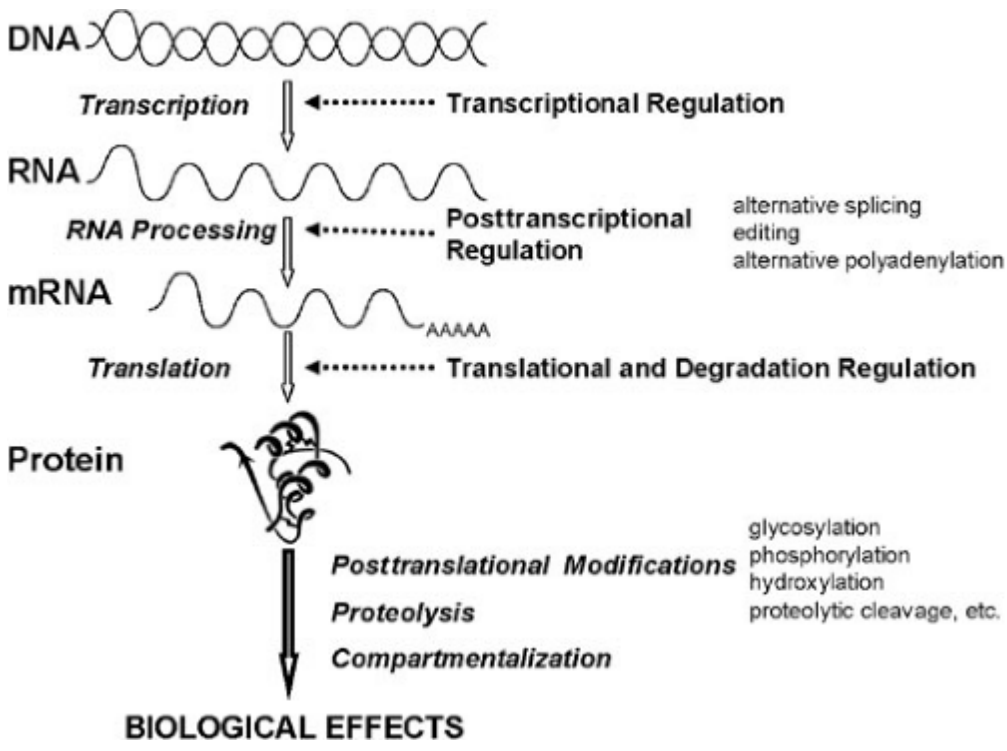

FIGURE 7-3. Central dogma of molecular biology. Protein expression involves two main processes, RNA synthesis (*transcription*) and protein synthesis (*translation*), with many intermediate regulatory steps. A single gene can give rise to multiple protein products (isoforms) via alternative splicing and RNA editing. Thus functional variability at the protein level, ultimately responsible for biological effects, is the cumulative result of genetic variability as well as extensive posttranscriptional, translational, and posttranslational modifications.

Microarray technologies have revolutionized the analysis of gene expression changes in biological events and in complex diseases, by simultaneously examining on a genome-wide scale the

expression of many thousands of transcripts in a single experiment. Some have even called microarray analysis "the essence of genomics."[37] Special algorithms used in the computational analyses of the vast amounts of data thus generated enable the identification of global patterns of gene expression and grouping genes into expression clusters. Investigating the relationship between such clusters of candidate genes provides greater insight into their potential biological relevance than simple comparisons of up- and down-regulated genes. In perioperative medicine, DNA microarrays may be applied to evaluate and catalog organ-specific responses to surgical stress and severe systemic stimuli such as cardiopulmonary bypass and endotoxemia, which can be subsequently used to identify and validate targets for therapeutic intervention.[38] Several studies have profiled myocardial gene expression in the ischemic heart, demonstrating alterations in the expression of immediate-early genes (c-*fos*, *jun*B),[39] genes coding for calcium-handling proteins (calsequestrin, phospholamban), and extracellular matrix and cytoskeletal proteins.[40] Upregulation of transcripts mechanistically involved in cytoprotection (heat shock proteins), resistance to apoptosis, and cell growth has been found in stunned myocardium.[41] Furthermore, cardiac gene expression profiling after cardiopulmonary bypass and cardioplegic arrest has identified the upregulation of inflammatory and transcription activators, apoptotic genes, and stress genes,[42] which appear to be age-related.[43] Microarray technology has also been utilized in the quest for novel cardioprotective genes, with the ultimate goal of designing strategies to activate these genes and prevent myocardial injury. Preconditioning is one of such well-studied models of cardioprotection, which can be induced by various triggers including intermittent ischemia, osmotic or redox stress, heat shock, toxins, and interestingly, inhaled anesthetics. The main functional categories of genes identified as potentially involved in cardioprotective pathways include a host of transcription factors, heat shock proteins, antioxidant genes (heme-oxygenase, glutathione peroxidase), and growth factors,[44] but different gene programs appear to be activated in ischemic versus anesthetic preconditioning, resulting in two distinct cardioprotective phenotypes.[45]

Identification of genes displaying significant changes in expression (differentially expressed) by microarray analysis can be used as an unbiased method to select candidate genes for future association studies. However, before such use, quality assurance protocols are required to validate the microarray

results. These include experiment replication, selection of cut-off values used to identify differentially expressed genes, and confirmation of findings by alternative methods (quantitative reverse transcriptase polymerase chain reaction, Northern blotting, or in situ hybridization).[5] It is important to realize that expression studies alone cannot prove function. To establish a causal relationship between the change in gene expression and the disease, every new hypothesis has to be further tested through either gain- or loss-of-function studies in biological systems (such as transgenic overexpression, dominant negative, antisense, or gene targeting strategies).[46] In spite of their limitations and only when coupled with richly annotated comparative databases, DNA microarrays have the potential to become useful tools in complex disease classification, prediction of response to treatment and prognosis, and identification of novel therapeutic targets.

The *transcriptome* (the complete collection of transcribed elements of the genome) is not fully representative of the *proteome* (the complete complement of proteins encoded by the genome), since many transcripts are not targeted for translation, as evidenced recently with the concept of gene silencing by RNA interference. Alternative splicing, a wide variety of posttranslational modifications, and protein–protein interactions responsible for biological function would remain therefore undetected by gene expression profiling. This has led to the emergence of a new field, *proteomics*, studying the sequence, modification, and function of all proteins in a biological system at a given time. Rather than focusing on "static" DNA, proteomic studies examine dynamic protein products, with the goal of identifying proteins that undergo changes in abundance, modification, or localization in response to a particular disease state, trauma, stress, or therapeutic intervention.[47] Thus, proteomics offers a more global and integrated view of biology, complementing other functional genomic approaches. Currently available methods for proteomic analysis include protein extraction, separation by two-dimensional gel electrophoresis or chromatography, followed by identification using mass spectrometry. Although rapidly improving,

these methods are currently limited by sensitivity, specificity, and throughput.[36] The development of protein arrays has the potential to become a versatile and rigorous high-throughput method for proteomic analysis and is the object of intense investigation.

Integrated genomic and proteomic data analysis may be applied in perioperative medicine to elucidate individual responses to surgical injury and provide useful prognostic information. Recently, such a combined genomic and proteomic approach was used to determine the outcome in patients undergoing thoracoabdominal aortic aneurysm repair. Expression patterns of 138 genes from peripheral blood leukocytes and the concentrations of 7 circulating plasma proteins discriminated between the patients who developed multiple organ dysfunction syndrome (MODS) and those who did not. More importantly, these patterns of genome-wide gene expression and plasma protein concentration were observed before surgical trauma and visceral ischemia-reperfusion injury, suggesting that patients who developed MODS differed in either their genetic predisposition or their preexisting inflammatory state.[48]

GENOMICS AND PERIOPERATIVE RISK PROFILING

Recognizing the significant increase in surgical burden because of accelerated aging of the population and increased reliance on surgery for treatment of disease, the National Heart, Blood and Lung Institute has recently convened a Working Group on perioperative medicine. The group concluded that perioperative complications are significant, costly, variably reported, and often imprecisely detected, and identified a critical need for accurate comprehensive perioperative outcome databases. Furthermore, presurgical risk profiling is inconsistent and deserves further attention, especially for noncardiac, nonvascular surgery and older patients.[49]

4 One of the hallmarks of perioperative medicine is the striking variability in patient responses to surgical procedures, anesthetic agents, hemodynamic challenge, and the pharmacopoeia used in the perioperative period. Although many preoperative predictors have been identified and are constantly being refined, risk stratification based on clinical, procedural, and biological markers explains only a small part of the variability in the incidence of perioperative complications. It is becoming increasingly recognized that specific genotypes may also predict adverse perioperative outcomes in otherwise healthy individuals. Such adverse outcomes will develop only in patients whose combined burden of genetic and environmental risk factors exceeds a certain threshold, which may vary with age. Identification of such genetic contributions not only to disease causation and susceptibility, but also to influencing the *response* to disease and drug therapy, and incorporation of genetic risk information in clinical decision making may lead to improved health outcomes and reduced costs. For instance, understanding the gene–environment interactions involved in atherosclerotic cardiovascular disease and neurological injury may facilitate preoperative patient optimization and resource utilization. Furthermore, understanding the role of genotypic variation in thrombosis and inflammation, the main pathophysiological mechanisms responsible for perioperative complications, may contribute to the development of target-specific therapies, thereby limiting the incidence of adverse events in high-risk patients.

Genetic Susceptibility to Adverse Perioperative Cardiovascular Outcomes

As part of the preoperative evaluation, anesthesiologists are involved in assessing the risks of perioperative complications. It is commonly accepted that patients who have underlying cardiovascular disease are at risk for adverse cardiac events after surgery, and several multifactorial risk indices have been developed and validated for patients undergoing both noncardiac surgical procedures (such as the Goldman[50] or the Lee Cardiac Risk Index[51]), as well as cardiac surgery (such as the Hannan[52] or Sergeant[53] scores). However, identifying patients at the highest risk of perioperative infarction remains difficult, and risk scores, while potentially valuable for population studies, are not an ideal tool for directing care in an individual patient.[54] Genomic approaches have been used in the search for a better assessment of the individual coronary risk profile. Numerous reports from animal models; linkage analysis; family, twin, and population association studies have definitely proven the role of genetic influences in the incidence and progression of coronary artery disease (CAD). Recent twin studies report a heritability of death

from CAD as high as 0.58. Genetic factors associated with CAD mortality are in operation throughout the entire lifespan, although they seem to be particularly important in early phases of life, as manifested by a decrease in heritability with age. Moreover, comprehensive linkage analysis[7] and association studies[20,21] have reemphasized the role of genetic variability in myocardial infarction. While these studies do not directly address the heritability of adverse perioperative myocardial events, they do suggest a strong genetic contribution

to the risk of adverse cardiovascular outcomes in general. Indeed, given similar known risk factors, many patients still manifest differences in the incidence of both early and late adverse myocardial events. Like most common diseases, perioperative cardiovascular complications involve an interplay of many genetic variations of molecular and biochemical pathways and their interactions with environmental factors (e.g., surgical procedural, pharmacological), and can therefore be classified as complex disease phenotypes. On a genetic level, functional allelic variations likely modulate, each with a small overall contribution and relative risk, individual susceptibility to develop such adverse myocardial events, and the manifestation, severity, and prognosis of the disease process. Unfortunately, although the effects of genetic predisposition for CAD or restenosis after angioplasty have been extensively investigated, only a paucity of studies exist regarding genetic risk factors directly associated with perioperative myocardial outcomes, mainly following surgical revascularization.[26,55,56] However, an increasing body of evidence has linked various genotypes to mechanistic pathways known to be involved in triggering or modulating the severity of perioperative myocardial injury, including thrombosis, inflammatory response, or vascular reactivity.

The acute phase response or stress response to surgery is characterized by an increase in fibrinogen concentration, platelet adhesiveness, and plasminogen activator inhibitor-1 (PAI-1) production. During cardiac surgery, alterations in the hemostatic system are even more complex and multifactorial, including the effects of hypothermia, hemodilution, and cardiopulmonary bypass (CPB)-induced activation of coagulation, fibrinolytic, and inflammatory pathways. Perioperative thrombotic outcomes following cardiac surgery (e.g., coronary graft thrombosis, myocardial infarction, stroke, pulmonary embolism) represent one extreme on a continuum of coagulation dysfunction, with coagulopathy at the other end of the spectrum. Pathophysiologically, the balance between bleeding, normal hemostasis, and thrombosis is markedly influenced by the rate of thrombin formation and platelet activation. Recent evidence suggests genetic variability modulates the activation of each of these mechanistic pathways,[57] suggesting significant heritability of the prothrombotic state. Several genotypes have been associated with increased risk of coronary graft thrombosis and myocardial injury following CABG. Plasminogen activator inhibitor-1 gene is an important negative regulator of fibrinolytic activity; a genetic variant in the promoter of the PAI-1 gene, consisting of an insertion (5G)/deletion (4G) polymorphism at position -675, has been consistently associated with changes in the plasma levels of PAI-1. The 4G allele was associated with increased risk of early graft thrombosis after CABG,[58] and a recent meta-analysis showed a significant effect of PAI-1 genotype on incidence of myocardial infarction.[59] Similarly, a polymorphism in the platelet glycoprotein IIIa, resulting in increased platelet aggregation (PI^{A2} polymorphism), was found to be a risk factor for thrombotic coronary graft occlusion, myocardial infarction, and death following CABG.[60] Furthermore, the PI^{A2} allele has been associated with higher postoperative concentrations of troponin I following CABG, suggesting that this platelet polymorphism contributes to perioperative myocardial injury.[61] One of the most common inherited prothrombotic risk factors is a point mutation in coagulation factor V (1691G>A) resulting in resistance to activated protein C, and referred to as factor V Leiden (FVL). FVL has been associated with various postoperative thrombotic complications following noncardiac surgery (for a review, see Donahue[27]), but interestingly, also associated with a significant reduction in postoperative blood loss and overall risk of transfusion in cardiac surgery patients.[62]

Genetic variants modulating the magnitude of postoperative inflammatory response have been identified. Polymorphisms in the promoter of the interleukin 6 (*IL6*) gene (-572G>C and -174G>C) significantly increase the inflammatory response after heart surgery with cardiopulmonary bypass (CPB)[63] and have been associated with length of hospitalization after CABG.[64] Furthermore, both apolipoprotein E genotype (the ε4 allele)[65] and several variants in the tumor necrosis factor genes

(*TNFA*-308G>A, *LTA*+250G>A) have been associated with proinflammatory effects in patients undergoing CPB.[66] Conversely, a genetic variant modulating the release of the anti-inflammatory cytokine interleukin 10 (*IL10*) in response to CPB has been reported (*IL10*-1082G>A), with high levels of IL10 being associated with postoperative cardiovascular dysfunction.[67]

5 Several genes predictive of perioperative vascular response have been identified. Significantly increased vascular responsiveness to alpha-adrenergic stimulation (phenylephrine) was found both in patients carrying the endothelial nitric oxide synthase 894G>T polymorphism[68] and in patients homozygous for *D* allele of the angiotensin converting enzyme insertion/deletion (*I/D*) polymorphism.[28,69] Also, variability in the β_2-adrenergic receptor gene has been associated with increased mean arterial blood pressure to the stress stimuli of tracheal intubation.[70]

Genetic Variability and Perioperative Event-Free Survival

Several large randomized clinical trials examining the benefits of CABG surgery and percutaneous coronary interventions relative to medical therapy and/or to one another have refined our knowledge of early and long-term survival after CABG. While these studies have helped define the subgroups of patients who benefit from surgical revascularization, they also demonstrated a substantial variability in long-term survival after CABG, altered by important demographic and environmental risk factors. Increasing evidence suggests that the angiotensin converting enzyme (ACE) gene indel polymorphism may influence post-CABG complications. In a recent study, carriers of the *D* allele had higher mortality and restenosis rates after CABG surgery compared with the *I* allele.[56] Similarly, a functionally important amino acid alteration in the β_3-integrin chain of the glycoprotein IIb/IIIa platelet receptor (the PI^{A2} polymorphism) was associated with an increased risk (odds ratio of 4.7) for major adverse cardiac events (a composite of myocardial infarction, coronary bypass graft occlusion, or death) following CABG surgery. Mechanistically, this may be related to a genetically modulated prothrombotic tendency, as PI^{A2} results in increased fibrinogen-binding and epinephrine-induced platelet aggregation,[71] and has been previously identified as a risk factor for acute coronary thrombosis.[72] We have found preliminary evidence for association between two functional polymorphisms modulating β_2-adrenergic receptor activity (Arg16Gly and Gln27Glu) and incidence of death or major adverse cardiac events following cardiac surgery.[73]

Genetic Susceptibility to Adverse Perioperative Neurologic Outcomes

6 Despite advances in surgical and anesthetic techniques, significant neurologic morbidity continues to occur following cardiac surgery, ranging in severity from coma and focal stroke (incidence up to 6%) to more subtle cognitive deficits (incidence up to 69%), with a substantial impact on the risk of perioperative death, quality of life, and resource utilization. Variability in the reported incidence of both early and late

neurological deficits remains poorly explained by procedural risk factors, suggesting that environmental (operative) and genetic factors may interact to determine disease onset, progression, and recovery.[74] Thus, cardiac surgery represents a unique clinical paradigm where, in addition to genetic predispositions, certain procedural events (such as aortic manipulation) may lead to the embolization of material to the brain. The pathophysiology of perioperative neurological injury is thought to involve complex interactions between primary pathways associated with atherosclerosis and thrombosis, and secondary response pathways like inflammation, vascular reactivity, and direct cellular injury. Many functional genetic variants have been reported in each of these mechanistic pathways involved in modulating the magnitude and the response to neurological injury, which may have implications in chronic as well as acute perioperative neurocognitive outcomes. Our group has demonstrated a significant association between the apolipoprotein E (*APOE*) E4 genotype and adverse cerebral outcomes in cardiac surgery patients.[22,74] This is consistent with other studies, suggesting a role for the *APOE* genotype in recovery from acute brain injury, such as intracranial hemorrhage,[75] closed head

injury,[76] and stroke,[77] as well as experimental models of cerebral ischemia-reperfusion injury.[78] Unlike adult cardiac surgery patients, infants carrying the *APOE* ε2 allele have recently been found at increased risk for developing adverse neurodevelopmental sequelae following cardiac surgery.[79] Mechanistically, the role of *APOE* genotypes in modulating the inflammatory response,[65] extent of aortic atheroma burden,[80] risk for coronary atherosclerosis,[81] and cerebral blood flow and autoregulation may explain the observed associations with impaired neurological outcomes.

Recent studies have suggested a role for platelet activation in the pathophysiology of adverse neurological sequelae. Genetic variants in surface platelet membrane glycoproteins, important mediators of platelet adhesion and platelet–platelet interactions, have been shown to increase the susceptibility to prothrombotic events. Among these, the PI^{A2} polymorphism in glycoprotein IIb/IIIa has been related to various adverse thrombotic outcomes, including acute coronary thrombosis[72] and atherothrombotic stroke.[82] We found the PI^{A2} allele to be associated with more severe neurocognitive decline after cardiopulmonary bypass,[23] which could represent an exacerbation of platelet-dependent thrombotic processes associated with plaque embolism.

Identifying novel predictors for risk of neurological and neurocognitive dysfunction and the molecular mechanisms underlying such risk will allow improved patient informed consent, stratification and resource allocation, development of neuroprotective agents, and therapeutic modalities tailored to the yet-to-be-discovered molecular abnormalities.

Genetic Susceptibility to Adverse Perioperative Renal Outcomes

7 Acute renal dysfunction is a common, serious complication of cardiac surgery; about 8 to 15% of patients develop moderate renal injury (>1.0 mg/dL peak creatinine rise), and up to 5% of them develop renal failure requiring dialysis.[83,84] Acute renal failure is independently associated with in-hospital mortality rates,[85] exceeding 60% in patients requiring dialysis.[84] Recent studies have demonstrated that inheritance of genetic polymorphisms in the apolipoprotein E gene (ε4 allele)[25] in the promoter region of the *IL6* gene (-174C allele[86] and -572C allele[143]) and angiotensinogen gene (842C allele)[143] are associated with acute renal injury following CABG surgery. Further identification of genotypes predictive of adverse perioperative renal outcomes may facilitate individually tailored therapy, risk stratify the patients for interventional trials targeting the gene product itself, and aid in medical decision making (e.g., selecting medical over surgical management).

Genetic Variants and Risk for Prolonged Postoperative Mechanical Ventilation

8 Prolonged mechanical ventilation (inability to extubate patient by 24 hours postoperatively) is a significant complication following cardiac surgery, occurring in 5.6% and 10.5% of patients undergoing first and repeat CABG surgery, respectively.[87] Several pulmonary and nonpulmonary causes have been identified, and scoring systems based on preoperative and procedural risk factors have been proposed and validated. Recently, genetic variants in the renin–angiotensin pathway and in proinflammatory cytokine genes have been associated with respiratory complications post–cardiopulmonary bypass. The *D* allele of a common functional insertion/deletion (*I/D*) polymorphism in the *ACE* gene, accounting for 47% of variance in circulating ACE levels,[88] has been associated with prolonged mechanical ventilation following CABG[89] and with susceptibility to and prognosis of ARDS.[90] Furthermore, a hyposecretor haplotype in the neighboring genes tumor necrosis factor alpha (*TNFA*) and lymphotoxin alpha (*LTA*) on chromosome 6 (*TNFA*-308*G*/*LTA*+250*G* haplotype)[91] and a functional polymorphism modulating postoperative interleukin 6 levels (*IL6*-174G>C)[86] have been independently associated with higher risk of prolonged mechanical ventilation post-CABG. The association was more dramatic in patients undergoing conventional CABG than in those undergoing off-pump CABG (OPCAB), suggesting that in high-risk patients identified by preoperative genetic screening OPCAB may be the optimal surgical procedure.

A next crucial step in understanding the complexity of adverse perioperative outcomes is to assess

the contribution of variations in many genes simultaneously and their interaction with traditional risk factors to the longitudinal prediction of outcomes in individual patients. The use of such outcome predictive models incorporating genetic information may help stratify mortality and morbidity in surgical patients. It may also improve prognostication, direct medical decision making both intraoperatively and during postoperative follow-up, and even suggest novel targets for therapeutic intervention in the perioperative period.

PHARMACOGENOMICS AND ANESTHESIA

Variability in response to drug therapy, both in terms of efficacy and safety, is a rule by which anesthesiologists live. In fact, much of the art of anesthesiology is the astute clinician being prepared to deal with outliers. The term "pharmacogenomics" is used to describe how inherited variations in genes modulating drug actions are related to interindividual variability in drug response. Such variability in drug action may be *pharmacokinetic* or *pharmacodynamic* (Fig. 7-4). Pharmacokinetic variability refers to variability in a drug's absorption, distribution, metabolism, and excretion that mediates its efficacy and/or toxicity. The molecules involved in these processes include drug-metabolizing enzymes (such as members of the cytochrome P450, or CYP, superfamily) and drug transport molecules that mediate drug uptake into, and efflux from, intracellular sites. Pharmacodynamic variability refers to variable drug effects despite equivalent drug delivery to molecular sites of action. This may reflect variability in the function of the molecular target of the drug, or in the pathophysiological context in which the

drug interacts with its receptor target (e.g., affinity, coupling, expression).[92] Thus, pharmacogenomics investigates complex, polygenically determined phenotypes of drug efficacy or toxicity, with the goal of identifying novel therapeutic targets and customizing drug therapy.

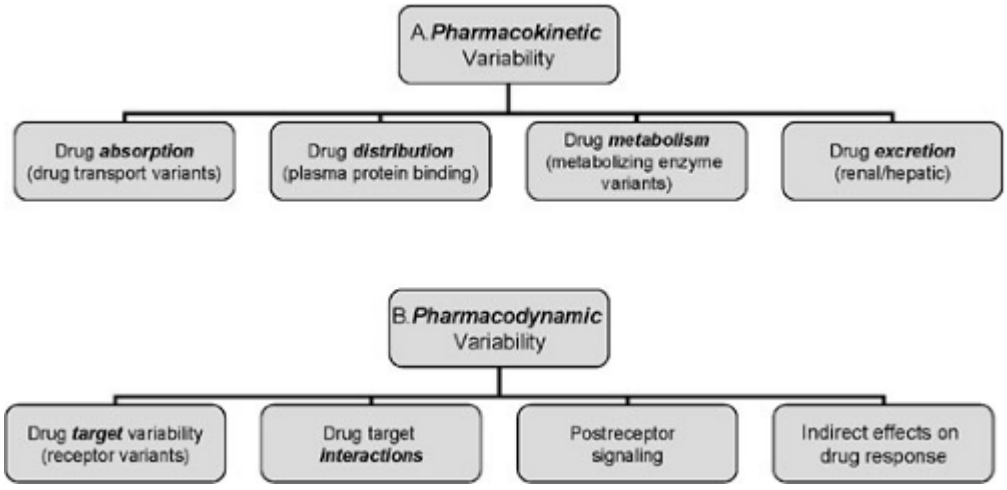

FIGURE 7-4. Pharmacogenomic determinants of individual drug response operate by pharmacokinetic and pharmacodynamic mechanisms. **A.** Genetic variants in *drug transporters* (e.g., ATP-binding cassette subfamily B member 1 or *ABCB1* gene) and *drug-metabolizing enzymes* (e.g., cytochrome P450 2D6 or *CYP2D6* gene, *CYP2C9* gene, N-acetyltransferase or *NAT2* gene, plasma cholinesterase or *BCHE* gene) are responsible for *pharmacokinetic* variability in drug response. **B.** Polymorphisms in *drug targets* (e.g., β_1 and β_2-adrenergic receptor *ADRB1*, *ADRB2* genes; angiotensin-I converting enzyme *ACE* gene), *postreceptor signaling molecules* (e.g., guanine nucleotide–binding protein β3 or *GNB3* gene), or *molecules indirectly affecting drug response* (e.g., various ion channel genes involved in drug-induced arrhythmias) are sources of *pharmacodynamic* variability.

Pseudocholinesterase Deficiency

Historically, characterization of the genetic basis for plasma pseudocholinesterase deficiency in 1956 was of fundamental importance to anesthesia and the further development and understanding of genetically determined differences in drug response.[93] Individuals with an atypical form of pseudocholinesterase resulting in a markedly reduced rate of drug metabolism are at risk for excessive neuromuscular blockade and prolonged apnea. More than 20 variants have since been identified in the butyrylcholinesterase gene (*BCHE*), the most common of which are the A-variant (209A>G) and the K-variant (1615G>A), with various and somewhat poorly defined phenotypic consequences on prolonged neuromuscular blockade. Therefore, pharmacogenetic testing is currently not recommended in the population at large, but only as an explanation for an adverse event.[94]

Genetics of Malignant Hyperthermia

10 Malignant hyperthermia (MH) is a rare autosomal dominant genetic disease of skeletal muscle calcium metabolism, triggered by administration of general anesthesia with volatile anesthetic agents or succinylcholine in susceptible individuals. The clinical MH syndrome is characterized by skeletal muscle hypermetabolism and manifested as skeletal muscle rigidity, tachycardia, tachypnea, hemodynamic instability, increased oxygen consumption and CO_2 production, lactic acidosis, and fever, progressing to malignant ventricular arrhythmias, disseminated intravascular coagulation, and myoglobinuric renal failure. MH susceptibility has been initially linked to the ryonadine receptor (*RYRI*) gene locus on chromosome 19q.[95] However, subsequent studies have shown that MH may represent a common severe phenotype that originates not only from point mutations in the *RYRI* gene (Arg614Cys), but also within its functionally and/or structurally associated proteins regulating excitation–contraction coupling (such as *a1DHPR* and *FKBP12*). It is becoming increasingly apparent that MH susceptibility results from a complex interaction between multiple genes and environment (such as environmental toxins), suggested by the heterogeneity observed in the clinical MH syndrome and the variable penetrance of the MH phenotype.[96] Current diagnostic methods (the caffeine-halothane contracture test) are invasive and potentially nonspecific. Unfortunately, because of the polygenic determinism and variable penetrance, direct DNA testing in the general population for susceptibility to MH is currently not recommended; in contrast, testing in individuals from families with affected individuals has the potential to greatly reduce mortality and morbidity.[94] Furthermore, genomic approaches may help elucidate the molecular mechanisms involved in altered RYRI-mediated calcium signaling and identify novel, more specific therapeutic targets.

Genetic Variability and Response to Anesthetic Agents

11 Anesthetic potency, defined by the minimum alveolar concentration (MAC) of an inhaled anesthetic that abolishes purposeful movement in response to a noxious stimulus, varies among individuals, with a coefficient of variation (the ratio of standard deviation to the mean) of approximately 10%.[97] This observed variability may be explained by interindividual differences in multiple genes that underlie responsiveness to anesthetics, by environmental or physiological factors (brain temperature, age), or by measurement errors. Evidence of a genetic basis for increased anesthetic requirements is beginning to emerge, suggested, for instance, by the observation that desflurane requirements are increased in subjects with red hair versus

dark hair.[98] Recent studies evaluating the genetic control of anesthetic responses, coupled with molecular modeling, neurophysiology, and pharmacologic approaches, have provided important developments in our understanding of general anesthetic mechanisms. Triggered by the seminal work of Franks and Lieb,[99,100] research shifted from the membrane lipid bilayer to protein receptors (specifically ligand- and voltage-gated ion channels) as potential anesthetic targets, ending a few decades of stagnation that were primarily a result of an almost universal acceptance of the dogma of nonspecific anesthetic action (the so-called "lipid theory"). Some of the genes responsible for phenotypic differences in anesthetic effects have been mapped in various animal models, including the fruit fly *Drosophila melanogaster*,[101] the nematode *Caenorhabditis elegans*,[102] and the mouse. Later, we summarize the three broad categories of genetic approaches that have been used in mammalian models to provide mechanistic insight into the molecular basis

of anesthetic action in humans, with an emphasis on genetically altered animal models. First, classical genetics studies identify mutations in single genes that result in individuals qualitatively different from the nonmutant (i.e., *wild type*) individuals. Numerous inbred mouse strains and several spontaneously arising mutants have been demonstrated to differ in response to anesthetics.[103] The second approach, quantitative genetics, studies the inheritance of continuously varying, quantitative traits (such as height, weight, IQ, blood pressure, response to drugs, nociceptive sensitivity). These traits are controlled by multiple genes (called *quantitative trait loci*, QTL), each contributing quantitatively to the net trait and also affected by the environment to varying degrees. Specific chromosomal regions that control sensitivity to propofol[104] and alcohol[105] have been identified using the QTL mapping technique. Because of the many potential anesthetic targets, quantitative genetics, with its ability to examine multiple genes simultaneously, holds great promise for identifying the genetic control mechanisms of anesthetic response. The classic and quantitative genetic approaches are examples of *forward genetics* in which the line of investigation progresses from an altered phenotype to the genetic basis for that observed difference (i.e., from phenotype to genotype). In contrast, *reverse genetics* explores the functional consequences of directly mutating or altering the expression of a known gene (i.e., from genotype to phenotype). Specifically, genomic manipulation of plausible candidate receptors is used to investigate their function in vitro and, through the use of genetically engineered (e.g., transgenic, knockout, and knockin) animals (Fig. 7-5), to evaluate in vivo their relationship to various anesthetic end points, such as immobility (i.e., MAC), hypnosis, amnesia, and analgesia (for reviews, see Homanics et al[106] and Sonner et al[107]).

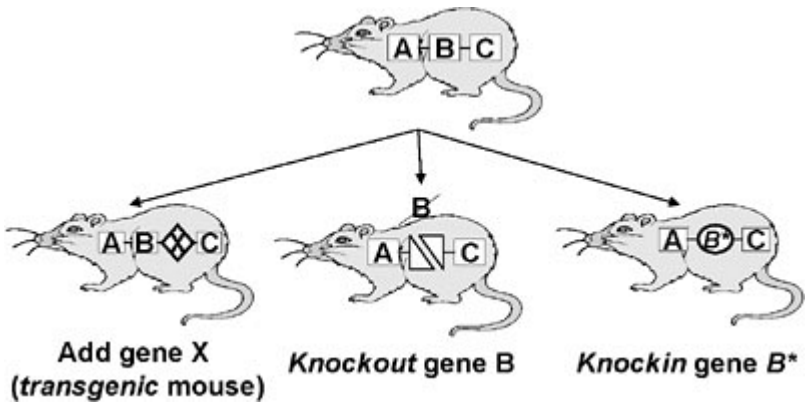

FIGURE 7-5. Genetically engineered animals used in functional genomic studies. *Transgenic* animals—gene X is introduced at random somewhere in the genome; *knockout* animals—gene B is inactivated by a direct mutation; *knockin* animals—gene *B** is introduced at a specific locus to replace gene B.

Transgenic animals overexpress or misexpress an additional gene that has been deliberately inserted into their genome. The foreign gene (i.e., *transgene*) is constructed using recombinant DNA methodology and used either to transfect embryonic stem cells growing in culture or microinjected into the pronucleus of a fertilized egg. However, the random insertion of the transgene in the genome that affects its expression pattern and the need for the transgene to have a dominant effect over the endogenous gene are major disadvantages of this technique. The process of gene targeting has enabled scientists to replace virtually any specific gene with an inactive allele (i.e., *gene knockouts*) and circumvent some of the limitations of transgenic technology. *Knockout* animals are created by inserting a vector containing the disrupted gene into mouse embryonic stem cells, with the goal of inactivating both alleles so that the gene is nonfunctional in all cells for the animal's lifetime (*global knockout*). Several thousand different

strains of knockout mice have been created and are used to investigate specific functions of particular genes and mechanisms of drug action, including the sensitivity to general anesthetic in mice lacking the β_3 subunit[108] or the α_6 subunit[109] of the $GABA_A$ receptor. These studies have identified two potential downfalls of the global knockout approach: the genome has enough redundancy to compensate for the missing pair of alleles by altering the expression of other genes (developmental compensation) and second, because the knockout affects all neurons, it is impossible to attribute a phenotype (such as MAC) to a specific neural region or circuit. To eliminate some of these confounding problems, *conditional knockouts* seek to delete a gene in a particular cell type or tissue at specific stages of development.

Knockin animals express a site-directed mutation in the targeted gene that remains under the control of endogenous regulatory elements, allowing the mutated gene to be expressed in the same amount, at the same time, and in the same tissues as the normal gene. This method has provided remarkable insight into the mechanisms of action of benzodiazepines[110] and intravenous anesthetics. In a seminal study by Jurd et al, a point mutation in the gene encoding the β_3 subunit of the $GABA_A$ receptor previously known to render the receptor insensitive to etomidate and propofol in vitro[111] was validated in vivo by creating a knockin mouse strain that proved also essentially insensitive to the immobilizing actions of etomidate and propofol.[112] A point mutation in the β_2 subunit of the $GABA_A$ receptor results in a knockin mouse with reduced sensitivity to the sedative[113] and hypothermic effects[114] of etomidate. Knockin mice harboring point mutations in the α_{2A}-adrenergic receptor have enabled the elucidation of the role of this receptor in anesthetic-sparing, analgesic, and sedative responses to dexmedetomidine.[115]

The situation is far more complex for inhaled anesthetics, which appear to mediate their effects by acting on several receptor targets. Based on combined pharmacologic and genetic in vivo studies to date, several receptors are unlikely to be direct mediators of MAC, including the $GABA_A$ (despite their compelling role in intravenous anesthetic-induced immobility), $5\text{-}HT_3$, AMPA, kainate, acetylcholine and α_2-adrenergic receptors, and potassium channels.[116] Glycine, NMDA receptors, and sodium channels remain likely candidates.[107] These conclusions, however, do not apply to other anesthetic end points, such as hypnosis, amnesia, and analgesia. Such genomic approaches have the potential to evolve into preoperative screening profiles useful in guiding therapeutic decisions, such as prevention of anesthetic awareness in

patients with a genetic predisposition to increased anesthetic requirements.

Genetic Variability and Response to Pain

Similar to the observed variability in anesthetic potency, the response to painful stimuli and analgesic manipulations varies among individuals. The sources of variability in the report and experience of pain and analgesia are multifactorial, including factors extrinsic to the organism (such as cultural factors, or circadian rhythms) and intrinsic factors (such as age, gender, hormonal status, or genetic makeup). Increasing evidence suggests that pain behavior in response to noxious stimuli and its modulation by the central nervous system in response to drug administration or environmental stimuli may be strongly influenced by genetic factors.[117]

Results from studies in twins[118] and inbred mouse strains[119] indicate a moderate heritability for chronic pain and nociceptive sensitivity, which appears to be mediated by multiple genes. Furthermore, QTL for hot-plate sensitivity and formalin test have been mapped to mouse chromosomes 4 (near the δ-opioid receptor gene), 2, and 10, respectively.[120] Various strains of knockout mice lacking target genes like neurotrophins and their receptors (e.g., nerve growth factor), peripheral mediators of nociception and hyperalgesia (e.g., substance P), opioid and nonopioid transmitters and their receptors, and intracellular signaling molecules have significantly contributed to the understanding of pain-processing mechanisms.[121]

12 In addition to the genetic control of peripheral nociceptive pathways, considerable evidence exists for genetic variability in the descending central pain modulatory pathways, potentially explaining the interindividual variability in analgesic responsiveness. One good example relevant to analgesic efficacy is cytochrome P450D6 (*CYP2D6*), a member of the superfamily of microsomal

enzymes that catalyze phase I drug metabolism and is responsible for the metabolism of a large number of therapeutic compounds. The relationship between the *CYP2D6* genotype and the enzyme metabolic rate has been extensively characterized, with at least 12 known mutations leading to a tetramodal distribution of CYP2D6 activity: ultrarapid metabolizers (5 to 7% of the population), extensive metabolizers (60%), intermediate metabolizers (25%), and poor metabolizers (10%). Currently, pharmacogenomic screening tests predict CYP2D6 phenotype with >95% reliability. The consequences of inheriting an allele that compromises CYP2D6 function include the inability to metabolize codeine (a prodrug) to morphine by O-demethylation, leading to lack of analgesia but increased side effects from the parent drug (e.g., fatigue) in poor metabolizers.[94,117]

Animal studies have mapped other polymorphic genes involved in various analgesic modalities. A QTL responsible for 28% of phenotypic variance in magnitude of systemic morphine analgesia in mice has been mapped to chromosome 10, in or near the *OPRM* (μ-opioid receptor) gene, and several putative QTL mediating nitrous oxide analgesias have been identified. The μ-opioid receptor is also subject to pharmacodynamic variability; polymorphisms in the promoter region of the *OPRM* gene modulating interleukin4-mediated gene expression have been correlated with morphine antinociception. Furthermore, an *OPRM*188A>G polymorphism associated with decreased responses to morphine-6-glucuronide was identified in humans, with implications in reduced risks of toxicity in renal failure patients.[94] A sex-specific locus on chromosome 8 has been associated with nonopioid stress-induced analgesia in females only and may be related to κ-opioid analgesia, providing a possible mechanism for sex-genetic interactions in regulating analgesic response.[117]

Genetic Variability in Response to Other Drugs Used Perioperatively

A wide variety of drugs used in the perioperative period display significant pharmacokinetic or pharmacodynamic variability that is genetically modulated, some listed in Table 7-1. Although such genetic variation in drug-metabolizing enzymes or drug targets mainly result in unusually variable drug response, genetic markers associated with rare but life-threatening side effects have also been described. Of note, the most commonly cited categories of drugs involved in adverse drug reactions include cardiovascular, antibiotic, psychiatric, and analgesic medications, and interestingly, each category has a known genetic basis for increased risk of adverse reactions.[122]

TABLE 7-1 Examples of Genetic Polymorphisms Involved in Variable Responses to Drugs Used in the Perioperative Period

▪DRUG CLASS	▪GENE NAME (GENE SYMBOL)	▪EFFECT OF POLYMORPHISM
▪PHARMACOKINETIC VARIABILITY		
β-blockers	Cytochrome P450 2D6 (*CYP2D6*)	Enhanced drug effect
Codeine, dextromethorphan	*CYP2D6*	Decreased drug effect
Ca channel blockers	Cytochrome P450 3A4 (*CYP3A4*)	Uncertain
Alfentanil	*CYP3A4*	Enhanced drug response

Angiotensin-II receptor type 1 blockers	Cytochrome P450 2C9 (*CYP2C9*)	Enhanced blood pressure response
Warfarin	*CYP2C9*	Enhanced anticoagulant effect, risk of bleeding
Phenytoin	*CYP2C9*	Enhanced drug effect
ACE inhibitors	Angiotensin-I converting enzyme (*ACE*)	Blood pressure response
Procainamide	N-acetyltransferase 2 (*NAT2*)	Enhanced drug effect
Succinylcholine	Butyrylcholinesterase (*BCHE*)	Enhanced drug effect
Digoxin	P-glycoprotein (*ABCB1, MDR1*)	Increased bioavailability
▪PHARMACODYNAMIC VARIABILITY		
β-blockers	β_1 and β_2 adrenergic receptors (*ADRB1, ADRB2*)	Blood pressure and heart rate response, airway responsiveness to β_2-agonists
QT-prolonging drugs (antiarrhythmics, cisapride, erythromycin, etc.)	Sodium and potassium ion channels (*SCN5A, KCNH2, KCNE2, KCNQ1*)	Long QT-syndrome, risk of torsade de pointes
Aspirin, glycoprotein IIb/IIIa inhibitors	Glycoprotein IIIa subunit of platelet glycoprotein IIb/IIIa (*ITGB3*)	Variability in antiplatelet effects
Phenylephrine	Endothelial nitric oxide synthase (*NOS3*)	Blood pressure response

There are more than 30 families of drug-metabolizing enzymes in humans, most with genetic polymorphisms shown to influence enzymatic activity. Of special importance to the anesthesiologists is the *CYP2D6*, one of the most intensively studied and best understood examples of pharmacogenetic variation, involved in the metabolism of several drugs including analgesics (codeine, dextromethorphan), β-blockers (Fig. 7-6), antiarrhythmics (flecainide, propafenone, quinidine), and diltiazem. Another important pharmacogenetic variation has been

described in cytochrome P450C9 (*CYP2C9*), involved in metabolizing anticoagulants (warfarin), anticonvulsants (phenytoin), antidiabetic agents (glipizide, tolbutamide), and nonsteroidal anti-inflammatory drugs (celecoxib, ibuprofen), among others. Three known *CYP2C9* variant alleles result in different enzyme activities (extensive, intermediate, and slow metabolizer phenotypes) and have clinical implications in the increased risk of life-threatening bleeding complications in slow metabolizers during standard warfarin therapy. This illustrates the concept of "high-risk pharmacokinetics," which applies to drugs with low therapeutic ratios eliminated by a single pathway (in this case CYP2C9-mediated oxidation); genetic variation in that pathway may lead to large changes in drug clearance, concentrations, and effects.[92] Dose adjustments based on the pharmacogenetic phenotype have been proposed for drugs metabolized via both CYP2D6 and CYP2C9 pathways.[94]

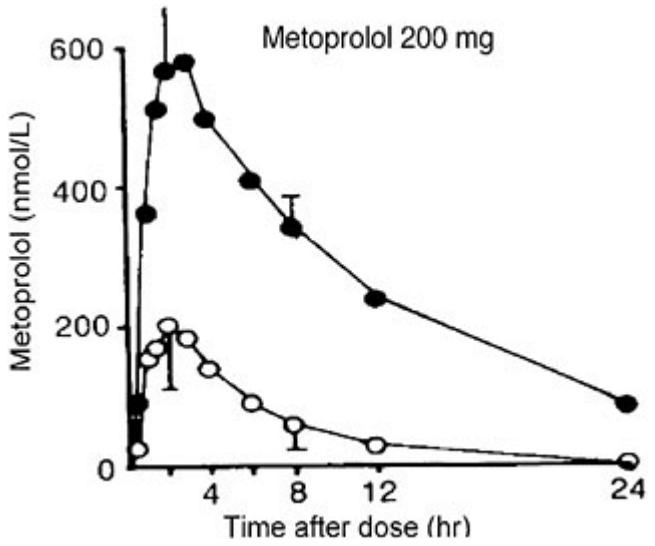

FIGURE 7-6. Genetically mediated variation in plasma metoprolol concentrations in CYP2D6 poor (•) versus extensive metabolizers (^), following a single oral dose of metoprolol tartrate (200 mg). Beta$_1$-blocking effects occur at metoprolol plasma concentrations in the 30 to 540 nmol/L range. The concentration-effect curve begins reaching a plateau between 200 and 300 nmol/L, and higher plasma levels produce little additional beta$_1$-blocking effect and diminished relative beta$_1$-selectivity with increased beta$_2$-blocking effects. (Reprinted from Bukaveckas BL, Valdes R, Linder MW: Pharmacogenetics as related to the practice of cardiothoracic and vascular anesthesia. J Cardiothorac Vasc Anesth 18:353, 2004, with permission.)

Genetic variation in drug targets (receptors) can have a profound effect on drug efficacy, and over 25 examples have already been identified. Functional polymorphisms in the β_2-adrenoreceptor (Arg16Gly, Gln27Glu) influencing the bronchodilator and vascular responses to β-agonists have been described, as well as in the β_1-adrenoreceptor (Arg389Gly), modulating the response to β-blockers.

Finally, clinically important genetic polymorphisms with indirect effects on drug response have been described. These include variants in candidate genes like sodium (*SCN5A*) and potassium ion channels (*KCNH2*, *KCNE2*, *KCNQ1*), which alter susceptibility to drug-induced long-QT syndrome and ventricular arrhythmias (torsade de pointes) associated with the use of drugs like erythromycin, terfenadine, disopyramide, sotalol, cisapride, or quinidine. Carriers of such susceptibility alleles have not manifest a QT-interval prolongation or family history of sudden death until QT-prolonging drug challenge is superimposed.[92] Predisposition to QT-interval prolongation (considered a surrogate for risk of life-threatening ventricular arrhythmias) has been responsible for more drug withdrawals from the market than any other category of adverse events in recent times, so understanding genetic predisposing factors constitutes one of the highest

priorities of current pharmacogenomic efforts.

P.143

Pharmacogenomics is emerging as an additional modifying component to anesthesia along with age, gender, comorbidities, and medication use. Specific testing and treatment guidelines allowing clinicians to appropriately modify drug utilization (e.g., adjust dose or change drug) already exist for a few compounds[94] and will likely be expanded to all relevant therapeutic compounds, together with identification of novel therapeutic targets.

GENOMICS AND CRITICAL CARE

Genetic Variability in Response to Injury

Systemic injury (including trauma and surgical stress), shock, or infection trigger physiological responses of fever, tachycardia, tachypnea, and leukocytosis that collectively define the systemic inflammatory response syndrome. This can progress to severe sepsis, septic shock, and multiple organ dysfunction syndrome, the pathophysiology of which remains poorly understood. With the genomic revolution, a new paradigm has emerged in critical care medicine: outcomes of critical illness are determined by the interplay between the *injury* and *repair* processes triggered by the initial insults.[123] Negative outcomes are thus the combined result of direct tissue injury, the side effects of resulting repair processes, and secondary injury mechanisms leading to suboptimal repair. Regulation of these repair mechanisms is currently being extensively investigated at the genomic, proteomic, and pharmacogenomic levels, aiming to model adaptive and maladaptive responses to injury, aid in development of diagnostic indices predictive of injury, monitor progress of repair, and eventually design novel therapeutic modalities that take into account the individual genetic makeup.

13 The large interindividual variability in the magnitude of response to injury, including activation of inflammatory and coagulation cascades, apoptosis,[124] and fibrosis, suggests the involvement of genetic regulatory factors. Several functional genetic polymorphisms in molecules involved in various components of the inflammatory response have been associated with differences in susceptibility to and mortality from sepsis

P.144

of different etiologies, including postoperative sepsis (for review, see Lin et al[125]). These include polymorphisms in bacterial recognition molecules like lipopolysaccharide-binding protein (*LBP*), bactericidal/permeability increing protein (*BPI*), *CD14*, toll-like receptors (*TLR4*), and pro-inflammatory cytokines like tumor necrosis alpha (*TNFA*),[126,127] lymphotoxin alpha (*LTA*),[29,128] interleukin-1 (*IL1*) and IL1 receptor antagonist (*IL1RN*),[129] and interleukin-6 (*IL6*).[130] Similarly, functional genetic variants in the PAI-1[131] and ACE[90,132] genes have been associated with poor outcomes in sepsis, reflecting the complex interaction between inflammation, coagulation, endothelial function, and vascular tone in the pathogenesis of sepsis-induced organ dysfunction.

This continuing effort to identify initial SNP-disease associations is followed by a process of selecting reliable predictive SNPs by validation in independent populations and determining which and how many markers will maximize the power to predict risk for sepsis or mortality following injury.

Functional Genomics of Injury

14 At a cellular level, injurious stimuli trigger adaptive stress responses determined by quantitative and qualitative changes in interdigitating cascades of biological pathways interacting in complex, often redundant ways. As a result, numerous clinical trials attempting to block single inflammatory mediators, such as TNFα in sepsis, have been largely unsuccessful.[133] Given these complex interconnections, the standard "single gene" paradigm is insufficient to adequately describe the tissue response to severe systemic stimuli. Instead, organ injury might better be defined by patterns of altered gene and protein expression.[134] DNA microarray technology has become a powerful high-throughput method of analyzing changes induced by various injuries on a genome-wide scale, by quantifying mRNA abundance and generating an

expression profile (the *transcriptome*) for the cell or tissue of interest. Several studies have reported the gene expression profiles in both critically ill patients and in animal models of sepsis,[135,136] acute lung injury,[137] and burn injury.[138] Furthermore, two large-scale national programs are using gene and protein expression profiles in circulating leukocytes to investigate the biological reasons behind the extreme variability in patient outcomes after similar traumatic insults (the NIH-funded Trauma Glue Grant; http://www.gluegrant.org) and to elucidate regulatory mechanisms in response to septic challenge in high-risk patients (the German National Genome Research Network).[134]

Since only less than half of the changes at mRNA level are usually translated into changes in protein expression, transcriptional profiling has to be complemented by characterizing the injury proteome for a more complete understanding of the host response to injury. Although the protein arrays are evolving rapidly, the main technology for proteomic analysis remains two-dimensional gel electrophoresis followed by mass spectrometry. Such integrated analysis of neutrophils transcriptome and proteome in response to lipopolysaccharide stimulation has identified upregulation of a variety of genes including transcriptional regulators (NF-κB), cytokines (TNFα, IL6, IL1β), and chemokines (MCP-1, MIP-3α) and confirmed the poor concordance between transcriptional and translational responses.[139]

Modeling disease entities like sepsis and multiple organ dysfunction syndrome, which are complex, nonlinear systems, requires the ability not only to measure many diverse molecular events simultaneously, but also to integrate the data using novel analytical tools based on complex systems theory and nonlinear dynamics.[140] Such analysis might help identify the key signaling nodes against which therapeutics can be directed.

FUTURE DIRECTIONS

Integration of "Omic" Information: System Biology Approaches

The Human Genome Project provides the sequence of nucleotides, localization of genes, and amino acid sequence in encoded proteins. However, less than 5% of the human genome represents DNA whose sequence ultimately encodes a protein. Although regulatory sequences and boundaries between the coding (i.e., *exons*) and noncoding (i.e., *introns*) regions of the genes are now being recognized and investigated, reaching the goals of functional genomics would require detailed knowledge of regulatory networks of gene expression as well as developmental and metabolic pathways. As mentioned earlier, microarray studies have revealed that many concurrently regulated genes share the same biochemical pathway and that cellular states can be ascribed to distinct and unique transcriptional profiles. These studies have provided a framework on which proteome analyses are based. Proteomics complements genome-based approaches by enabling the identification and characterization of differential protein expression, turnover and localization, posttranslational modifications (e.g., addition of sugar moieties or lipid attachments to a protein), and interaction with other biological molecules, thus providing new insights into the complex cellular processes involved in the response to anesthesia and surgical injury. The potential for "protein chips" to function as versatile and rigorous high-throughput methods for proteomic analyses is the object of intense investigation. Other more recent functional genomic and proteomic approaches include protein–protein, protein-DNA, or other "component–component" interaction mapping (*interactome*); systematic phenotypic analyses (*phenome*); and transcript or protein three-dimensional localization mapping (*localizome*).[141] To overcome the intrinsic limitations of all individual "omic" approaches, integration of data obtained from several distinct approaches using systems biology strategies has been proposed. This may lead to better functional annotations for the gene products and functional relationships between them and allow the formulation of relevant biological hypotheses, which can subsequently be tested using either synthetic biology or mathematical modeling of complex signaling networks.[141] Such integrative approaches to specifically study cardiovascular function (the Cardiome Project) have already been outlined. Furthermore, the scientific community needs to wrap the profiling data within the biological phenomenology, the so-called *"phenome"* in which the model under study is completely

characterized in terms of the changes at the cellular, biochemical, organ and system level (Fig. 7-7).[5]

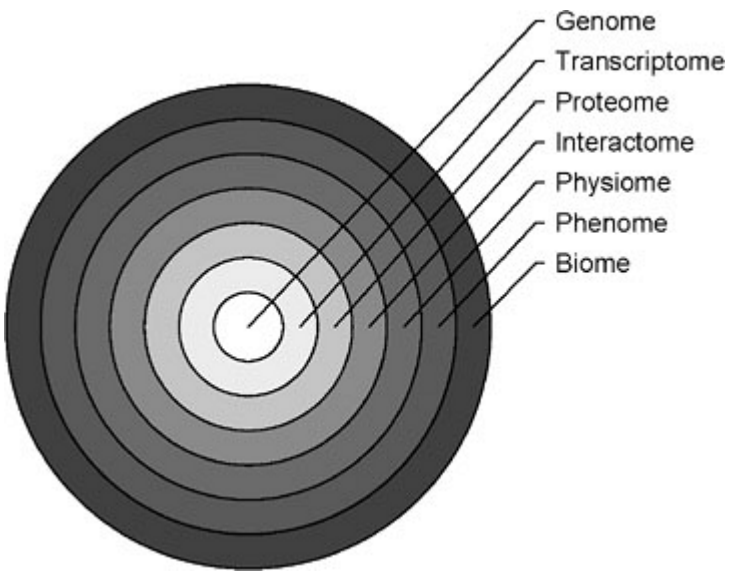

FIGURE 7-7. Integration of "omic" information. Cellular function is organized as a multilayered set of interdependent processes controlled at the level of the *genome* (DNA), *transcriptome* (messenger RNA), *proteome* (the collection of all proteins encoded within the DNA of a genome), *physiome* (regulatory networks and signaling pathways), and *phenome* (the quantitative description of the integrated functions of the living organism and its interactions both with the environment and within the phenotype itself). Relating genome variability to complex traits requires integrative systems biology approaches that will provide quantitative and mechanistic descriptions that unify signaling networks and identify critical regulatory nodes for therapeutic manipulation.

Targeted Drug Development

Genomic and proteomic approaches are rapidly becoming platforms for all aspects of drug discovery and development, from target identification and validation to individualization of drug therapy. As mentioned earlier, the human genome contains about 30,000 genes encoding for approximately 200,000 proteins, which represent potential drug targets. However, only about 120 drug targets are currently being marketed, thus making identification of novel therapeutic targets an area of intense research. Following gene identification, its therapeutic potential needs to be validated by defining the sequence function and its role in disease and demonstrating that the gene product can be manipulated with beneficial effect and no toxic effects. A developing field, *toxicogenomics*, studies the influence of toxic or potentially toxic substances on different model organisms

by evaluating the gene expression changes induced by novel drugs in a given tissue.

Sponsored by the National Institutes of Health, a nationwide collaborative effort called the Pharmacogenetics Research Network (http://0-www.nigms.nih.gov.innopac.up.ac.za:80/pharmacogenetics/) is aiming to establish a strong pharmacogenomics knowledge base (http://www.pharmgkb.org/) as well as create a shared computational and experimental infrastructure required to connect human sequence variation with drug responses and translate information into novel therapeutics.

Ethical Considerations

Although one of the aims of the Human Genome Project is to improve therapy through genome-

based prediction, there is a risk for discrimination against individuals who are genetically predisposed for a medical disorder. Such discrimination may include barriers to obtaining health, life, or long-term care insurance or obtaining employment. Thus, extensive efforts are made to protect patients participating in genetic research from prejudice, discrimination, or uses of genetic information that will adversely affect them. To address the concerns of both biomedical research and health communities, the U.S. Senate approved in 2003 the Genetic Information and Nondiscrimination Act, which provides the strong safeguards required to protect the public participating in human genome research.

Another ethical concern is the transferability of genetic tests across ethnic groups, particularly in the prediction of adverse drug responses. It is known that most polymorphisms associated with variability in drug response show significant differences in allele frequencies among populations and racial groups. Furthermore, the patterns of linkage disequilibrium are markedly different between ethnic groups, which may lead to spurious findings when markers, instead of causal variants, are used in diagnostic tests extrapolated across populations. In exploring racial disparities in health and disease outcomes, considerable debate has focused on whether race and ethnic identity are primarily social or biological constructs and the contribution of genetic variability in explaining observed differences in the rates of disease between racial groups. With the goal of personalized medicine being the prediction of risk and treatment of disease on the basis of an individual's genetic profile, some have argued that biologic consideration of race will become obsolete. However, in this discovery phase of the postgenome era, continuing to incorporate racial information in genetic studies should improve our understanding of the architecture of the human genome, and its implications for novel strategies aiming at identifying variants protecting against, or conferring susceptibility to, common diseases and modulating drug effects.[142]

CONCLUSION

The Human Genome Project has revolutionized all aspects of medicine, allowing us to assess the impact of genetic variability on disease taxonomy, characterization, and outcome and individual responses to various drugs and injuries. Mechanistically, information gleaned through genomic approaches is already unraveling long-standing mysteries behind general anesthetic action and adverse responses to drugs used perioperatively. However, a strong need remains for prospective, well-powered genetic studies in highly phenotyped surgical populations, which require the development of multidimensional perioperative databases. For the anesthesiologist, this may soon translate into prospective risk assessment incorporating genetic profiling of markers important in thrombotic, inflammatory, vascular, and neurologic responses to perioperative stress, with implications ranging from individualized additional preoperative testing and physiological optimization, to choice of perioperative monitoring strategies and critical care resource utilization. Furthermore, genetic profiling of drug-metabolizing enzymes, carrier proteins, and receptors, using currently available high-throughput molecular technologies, will enable personalized choice of drugs and dosage regimens tailored to suit a patient's pharmacogenetic profile. At that point, perioperative physicians will have far more robust information to use in designing the most appropriate and safest anesthetic plan for a given patient.

Future trends and challenges in perioperative genomics are still being defined but mainly concern interdisciplinary studies designed to combine an analytical system approach, mathematical modeling, and engineering principles with the multiple molecular and genetic factors and stimuli, and the macroscale interactions that determine the pathophysiological response to surgery.

Chapter 8

Electrical and Fire Safety

Jan Ehrenwerth

Harry A. Seifert

KEY POINTS

1	A basic principle of electricity is known as Ohm's law.
2	To have the completed circuit necessary for current flow, a closed loop must exist and a voltage source must drive the current through the impedance.
3	To receive a shock, one must contact the electrical circuit at two points, and there must be a voltage source that causes the current to flow through an individual.
4	In electrical terminology, grounding is applied to two separate concepts: the grounding of electrical power and the grounding of electrical equipment.
5	To provide an extra measure of safety from gross electrical shock (macroshock), the power supplied to most operating rooms is ungrounded.
6	The line isolation monitor (LIM) is a device that continuously monitors the integrity of an isolated power system.
7	The ground fault circuit interrupter (GFCI) is another popular device used to prevent individuals from receiving an electrical shock in a grounded power system.
8	An electrically susceptible patient (i.e., one who has a direct, external connection to the heart) they may be at risk from very small currents; this is called microshock.
9	Problems can arise if the electrosurgical return plate is improperly applied to the patient or if the cord connecting the return plate to the electrosurgical unit (ESU) is damaged or broken.

10	Fires in the operating room are just as much a danger today as they were 100 years ago when patients were anesthetized with flammable anesthetic agents.
11	The fire triad consists of a heat or ignition source, a fuel, and an oxidizer.
12	The two major ignition sources for OR fires are the ESU and the laser.
13	It is known that desiccated carbon dioxide absorbent can, in rare circumstances, react with sevoflurane to produce a fire.
14	All OR personnel should be familiar with the location and operation of the fire extinguishers.

The myriad of electrical and electronic devices in the modern operating room greatly improve patient care and safety. However, these devices also subject both the patient and operating room personnel to increased risks. To reduce the risk of electrical shock, most operating rooms have electrical systems that incorporate special safety features. It is incumbent upon the anesthesiologist to have a thorough understanding of the basic principles of electricity and an appreciation of the concepts of electrical safety applicable to the operating room environment.

PRINCIPLES OF ELECTRICITY

1 A basic principle of electricity is known as *Ohm's law*, which is represented by the equation:

$E = I \times R$

where E is electromotive force (in volts), I is current (in amperes), and R is resistance (in ohms). Ohm's law forms the basis for the physiologic equation BP = CO × SVR; that is, blood

pressure (BP) is equal to the cardiac output (CO) times the systemic vascular resistance (SVR). In this case, the blood pressure of the vascular system is analogous to voltage, the cardiac output to current, and systemic vascular resistance to the forces opposing the flow of electrons. Electrical power is measured in watts. Wattage (W) is the product of the voltage (E) and the current (I), as defined by the formula:

$W = E \times I$

The amount of electrical work done is measured in watts multiplied by a unit of time. The watt-second (a joule, J) is a common designation for electrical energy expended in doing work. The energy produced by a defibrillator is measured in watt-seconds (or joules). The kilowatt-hour is used by electrical utility companies to measure larger quantities of electrical energy.

Wattage can be thought of as a measure not only of work done but also of heat produced in any electrical circuit. Substituting Ohm's law in the formula

$W = E \times I$

$W = (I \times R) \times I$

$W = I^2 \times R$

Thus, wattage is equal to the square of the current I^2 (amperage) times the resistance R. Using these formulas, it is possible to calculate the number of amperes and the resistance of a given

device if the wattage and the voltage are known. For example, a 60-watt light bulb operating on a household 120-volt circuit would require 0.5 ampere, of current for operation. Rearranging the formula so that

$I = W/E$

we have

I = (60 watts)/(120 volts)

I = 0.5 ampere

Using this in Ohm's law

$R = E/I$

the resistance can be calculated to be 240 ohms:

R = (120 volts)/(0.5 ampere)

R = 240 ohms

It is obvious from the previous discussion that 1 volt of electromotive force (EMF) flowing through a 1-ohm resistance will generate 1 ampere of current. Similarly, 1 ampere of current induced by 1 volt of electromotive force will generate 1 watt of power.

DIRECT AND ALTERNATING CURRENTS

Any substance that permits the flow of electrons is called a *conductor.* Current is characterized by electrons flowing through a conductor. If the electron flow is always in the same direction, it is referred to as *direct current* (DC). However, if the electron flow reverses direction at a regular interval, it is termed *alternating current* (AC). Either of these types of current can be pulsed or continuous in nature.[1]

The previous discussion of Ohm's law is accurate when applied to DC circuits. However, when dealing with AC circuits, the situation is more complex because the flow of the current is opposed by a more complicated form of resistance, known as *impedance.*

IMPEDANCE

Impedance, designated by the letter Z, is defined as the sum of the forces that oppose electron movement in an AC circuit. Impedance consists of resistance (ohms) but also takes capacitance and inductance into account. In actuality, when referring to AC circuits, Ohm's law is defined as

$E = I \times Z$

An *insulator* is a substance that opposes the flow of electrons. Therefore, an insulator has a high impedance to electron flow, whereas a conductor has a low impedance to electron flow.

In AC circuits the capacitance and inductance can be important factors in determining the total impedance. Both capacitance and inductance are influenced by the frequency (cycles per second or hertz, Hz) at which the AC current reverses direction. The impedance is directly proportional to the frequency (f) times the inductance (IND):

$Z \propto (f \times \text{IND})$

and the impedance is inversely proportional to the product of the frequency (f) and the capacitance (CAP):

$Z \propto 1/(f \times \text{CAP})$

As the AC current increases in frequency, the net effect of both capacitance and inductance increases. However, because impedance and capacitance are inversely related, total impedance decreases as the product of the frequency and the capacitance increases. Thus, as frequency increases, impedance falls and more current is allowed to pass.[2]

CAPACITANCE

A *capacitor* consists of any two parallel conductors that are separated by an insulator (Fig. 8-1). A capacitor has the ability to store charge. *Capacitance* is the measure of that substance's ability to store charge. In a DC circuit the capacitor plates are charged by a voltage source (i.e., a battery) and there is only a momentary current flow. The circuit is not completed and no further current can flow unless a resistance is connected between the two plates and the capacitor is discharged.[3]

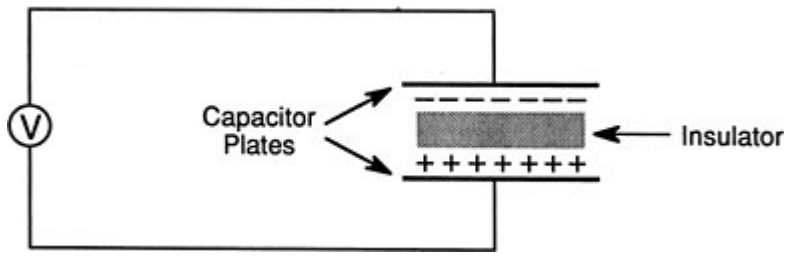

FIGURE 8-1. A capacitor consists of two parallel conductors separated by an insulator. The capacitor is capable of storing charge supplied by a voltage source.

In contrast to DC circuits, a capacitor in an AC circuit permits current flow even when the circuit is not completed by a resistance. This is because of the nature of AC circuits, in which the current flow is constantly being reversed. Because current flow results from the movement of electrons, the capacitor plates are alternately charged—first positive and then negative with every reversal of the AC current direction—resulting in an effective current flow as far as the remainder of the circuit is concerned, even though the circuit is not completed.[4]

Because the effect of capacitance on impedance varies directly with the AC frequency (Hz), the greater the AC frequency, the lower the impedance. Therefore, high-frequency currents (0.5 to 2 million Hz), such as those used by electrosurgical units (ESUs), will cause a marked decrease in impedance. For example, a 20-million–ohm impedance in a 60-Hz AC circuit will be reduced to just a few hundred ohms when the frequency is increased to 1 million Hz.[5]

Electrical devices use capacitors for various beneficial purposes. There is, however, a phenomenon known as *stray capacitance*—capacitance that was not designed into the system but is incidental to the construction of the equipment.[6] All AC-operated equipment produces stray capacitance. An ordinary power cord, for example, consisting of two insulated wires running next to each other will generate significant capacitance simply by being plugged into a 120-volt circuit, even though the piece of equipment is not turned on. Another example of stray capacitance is found in electric motors. The circuit wiring in electric motors generates stray capacitance to the metal housing of the motor.[7] The clinical importance of capacitance will be emphasized later in the chapter.

INDUCTANCE

Whenever electrons flow in a wire, a magnetic field is induced around the wire. If the wire is coiled repeatedly around an iron core, as in a transformer, the magnetic field can be very strong. *Inductance* is a property of AC circuits in which an opposing EMF can be electromagnetically generated in the circuit. The net effect of inductance is to increase impedance. Because the effect

of inductance on impedance is also dependent on AC frequency, increases in frequency will increase the total impedance. Therefore, the total impedance of a coil will be much greater than its simple resistance.[4]

ELECTRICAL SHOCK HAZARDS

Alternating and Direct Currents

Whenever an individual contacts an external source of electricity, an electrical shock is possible. An electrical current can stimulate skeletal muscle cells to contract, and thus can be used therapeutically in devices such as pacemakers or defibrillators. However, casual contact with an electrical current, whether AC or DC, can lead to injury or death. Although it takes approximately three times as much DC as AC to cause ventricular fibrillation,[3] this by no means renders DC harmless. Devices such as an automobile battery or a DC defibrillator can be sources of direct current shocks.

In the United States, utility companies supply electrical energy in the form of alternating currents of 120 volts at a frequency of 60 Hz. The 120 volts of EMF and 1 ampere of current are the effective voltage and amperage in an AC circuit. This is also referred to as RMS (root-mean-square). It takes 1.414 amperes of peak amperage in the sinusoidal curve to give an effective amperage of 1 ampere. Similarly, it takes 170 volts (120 × 1.414) at the peak of the AC curve to get an effective voltage of 120 volts. The 60 Hz refers to the number of times in 1 second that the current reverses its direction of flow.[8] Both the voltage and current waveforms form a sinusoidal pattern (Fig. 8-2).

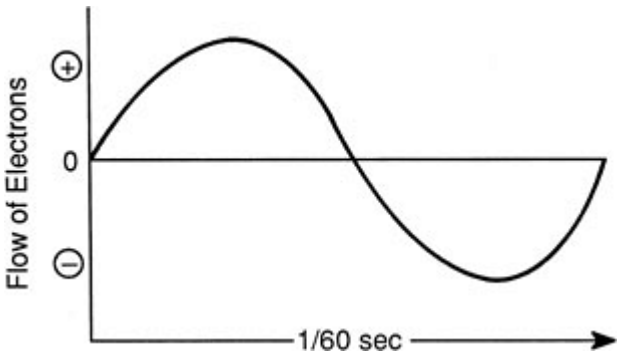

FIGURE 8-2. Sine wave flow of electrons in a 60-Hz alternating current.

2 To have the completed circuit necessary for current flow, a closed loop must exist and a voltage source must drive the current through the impedance. If current is to flow in the electrical circuit, there has to be a *voltage differential*, or a drop in the driving pressure across the impedance. According to Ohm's law, if the resistance is held constant, then the greater the current flow, the larger the voltage drop must be.[9]

The power company attempts to maintain the line voltage constant at 120 volts. Therefore, by Ohm's law the current flow is inversely proportional to the impedance. A typical power cord consists of two conductors. One, designated as *hot* carries the current to the impedance; the other is *neutral*, and it returns the current to the source. The potential difference between the two is effectively 120 volts (Fig. 8-3). The amount of current flowing through a given device is frequently referred to as the *load.* The load of the circuit is dependent on the impedance. A very high impedance circuit allows only a small current to flow and thus has a small load. A very low

impedance circuit will draw a large current and is said to be a large load. A *short circuit* occurs when there is a zero impedance load with a very high current flow.[10]

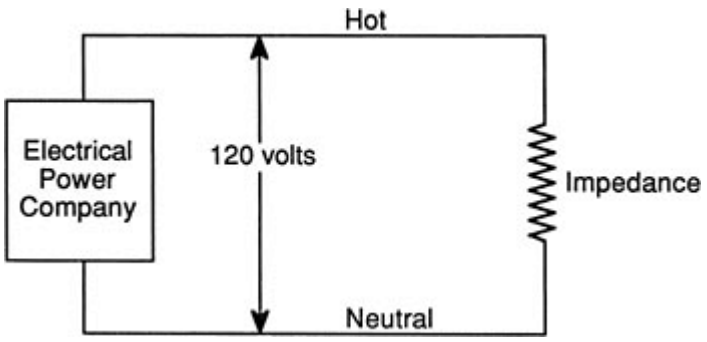

FIGURE 8-3. A typical AC circuit where there is a potential difference of 120 volts between the hot and neutral sides of the circuit. The current flows through a resistance, which in AC circuits is more accurately referred to as impedance, and then returns to the electrical power company.

Source of Shocks

3 To practice electrical safety it is important for the anesthesiologist to understand the basic principles of electricity and be aware of how electrical accidents can occur. Electrical accidents or shocks occur when a person becomes part of or completes an electrical circuit. To receive a shock, one must contact the electrical circuit at two points, and there must be a voltage source that causes the current to flow through an individual (Fig. 8-4).

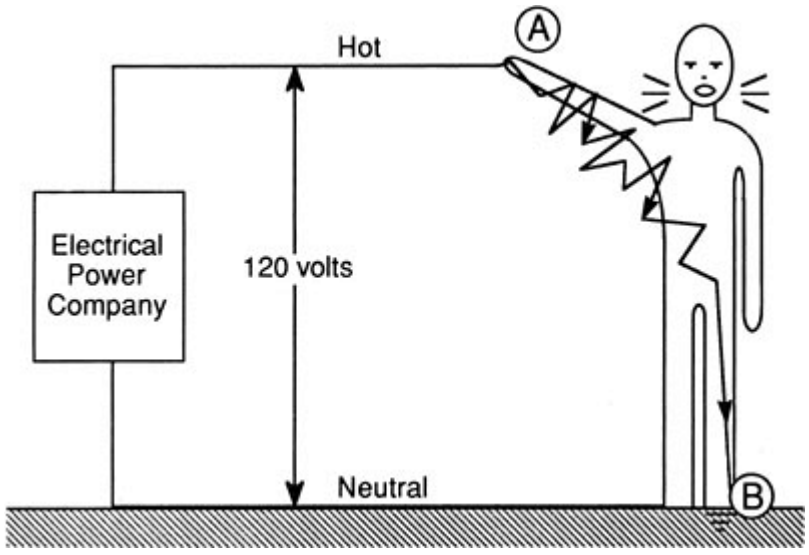

FIGURE 8-4. An individual can complete an electric circuit and receive a shock by coming in contact with the hot side of the circuit (point *A*). This is because he or she is standing on the ground (point *B*) and the contact point *A* and the ground point *B* provide the two contact points necessary for a completed circuit. The severity of the shock that the individual receives is dependent on his or her skin resistance.

When an individual contacts a source of electricity, damage occurs in one of two ways. First, the electrical current can disrupt the normal electrical function of cells. Depending on its magnitude, the current can contract muscles, alter brain function, paralyze respiration, or disrupt normal heart function, leading to ventricular fibrillation. The second mechanism involves the dissipation of electrical energy throughout the body's tissues. An electrical current passing through any resistance raises the temperature of that substance. If enough thermal energy is released, the temperature will rise sufficiently to produce a burn. Accidents involving household currents usually do not result in severe burns. However, in accidents involving very high voltages (i.e., power transmission lines), severe burns are common.

The severity of an electrical shock is determined by the amount of current (number of amperes) and the duration of the current flow. For the purposes of this discussion, electrical

shocks are divided into two categories. *Macroshock* refers to large amounts of current flowing through a person, which can cause harm or death. *Microshock* refers to very small amounts of current and applies only to the electrically susceptible patient. This is an individual who has an external conduit that is in direct contact with the heart. This can be a pacing wire or a saline-filled catheter such as a central venous or pulmonary artery catheter. In the case of the electrically susceptible patient, even minute amounts of current (microshock) may cause ventricular fibrillation.

Table 8-1 shows the effects typically produced by various currents following a 1-second contact with a 60-Hz current. When an individual contacts a 120-volt household current, the severity of the shock will depend on his or her skin resistance, the duration of the contact, and the current density. Skin resistance can vary from a few thousand to 1 million ohms. If a person with a skin resistance of 1,000 ohms contacts a 120-volt circuit, he or she would receive 120 milliamperes (mA) of current, which would probably be lethal. However, if that same person's skin resistance is 100,000 ohms, the current flow would be 1.2 mA, which would barely be perceptible.

TABLE 8-1 Effects of 60-Hz Current on an Average Human for a 1-Second Contact

▪CURRENT	▪EFFECT
	▪MACROSHOCK
1 mA (0.001 A)	Threshold of perception
5 mA (0.005 A)	Accepted as maximum harmless current intensity
10–20 mA (0.01–0.02 A)	“Let-go” current before sustained muscle contraction
50 mA (0.05 A)	Pain, possible fainting, mechanical injury; heart and respiratory functions continue
100–300 mA (0.1–0.3 A)	Ventricular fibrillation will start, but respiratory center remains intact

6,000 mA (6 A)	Sustained myocardial contraction, followed by normal heart rhythm; temporary respiratory paralysis; burns if current density is high
·MICROSHOCK	
100 µA (0.1 mA)	Ventricular fibrillation
10 µA (0.01 mA)	Recommended maximum 60-Hz leakage current
A, amperes; mA, milliamperes; µA, microamperes.	

$I = E/R$ = (120 volts)/(1,000 ohms) = 120 mA

$I = E/R$ = (120 volts)/(100,000 ohms) = 1.2 mA

The longer an individual is in contact with the electrical source, the more dire the consequences because more energy will be released and more tissue damaged. Also, there will be a greater chance of ventricular fibrillation from excitation of the heart during the vulnerable period of the electrocardiogram (ECG) cycle.

Current density is a way of expressing the amount of current that is applied per unit area of tissue. The diffusion of current in the body tends to be in all directions. The greater the current or the smaller the area to which it is applied, the higher the current density. In relation to the heart, a current of 100 mA (100,000 μA) is generally required to produce ventricular fibrillation when applied to the surface of the body. However, only 100 μA (0.1 mA) is required to produce ventricular fibrillation when that minute current is applied directly to the myocardium through an instrument having a very small contact area, such as a pacing wire electrode. In this case, the current density is 1,000-fold greater when applied directly to the heart; therefore, only 1/1,000 of the energy is required to cause ventricular fibrillation. In this case, the electrically susceptible patient can be electrocuted with currents well below 1 mA, which is the threshold of perception for humans. The frequency at which the current reverses is also an important factor in determining the amount of current an individual can safely contact. Utility companies in the United States produce electricity at a frequency of 60 Hz. They use 60 Hz because higher frequencies cause greater power loss through transmission lines and lower frequencies cause a detectable flicker from light sources.[11] The “let-go” current is defined as that current above which sustained muscular contraction occurs and at which an individual would be unable to let go of an energized wire. The let-go current for a 60-Hz AC power is 10 to 20 mA,[10,12,13] whereas at a frequency of 1 million Hz, up to 3 amperes (3,000 mA) is generally considered safe.[3] It should be noted that very high frequency currents do not excite contractile tissue; consequently, they do not cause cardiac arrhythmias.

It can be seen that Ohm's law governs the flow of electricity. For a completed circuit to exist, there must be a closed loop with a driving pressure to force a current through a resistance, just as in the cardiovascular system there must be a blood pressure to drive the cardiac output through the peripheral resistance. Figure 8-5 illustrates that a hot wire carrying a 120-volt pressure through the resistance of a 60-watt light bulb produces a current flow of 0.5 ampere. The voltage in the neutral wire is approximately 0 volts, while the current in the neutral wire remains at 0.5 ampere. This correlates with our cardiovascular analogy, where a mean blood pressure decrease of 80 mm Hg between the aortic root and the right atrium forces a cardiac output of 6

L/min^{-1} through a systemic vascular resistance of 13.3 resistance units. However, the flow (in this case, the cardiac output, or in the case of the electrical model, the current) is still the same everywhere in the circuit. That is, the cardiac output on the arterial side is the same as the cardiac output on the venous side.

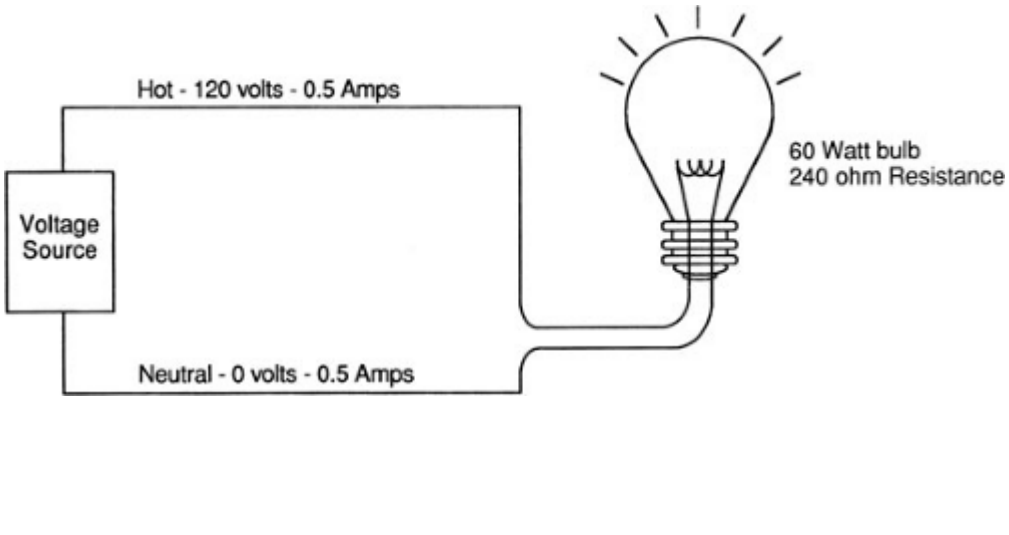

FIGURE 8-5. A 60-watt light bulb has an internal resistance of 240 ohms and draws 0.5 ampere of current. The voltage drop in the circuit is from 120 in the hot wire to 0 in the neutral wire, but the current is 0.5 ampere in both the hot and neutral wires.

Grounding

4 To fully understand electrical shock hazards and their prevention, one must have a thorough knowledge of the concepts of grounding. These concepts of grounding probably constitute the most confusing aspects of electrical safety because the same term is used to describe several different principles. In electrical terminology, grounding is applied to two separate concepts. The first is the grounding of electrical *power*, and the second is the grounding of electrical *equipment.* Thus, the concepts that (1) power can be grounded or ungrounded and that (2) power can supply electrical devices that are themselves grounded or ungrounded are not mutually exclusive. It is vital to understand this point as the basis of electrical safety (Table 8-2). Whereas electrical *power* is grounded in the home, it is usually ungrounded in the operating room. In the home, electrical *equipment* may be grounded or ungrounded, but it should always be grounded in the operating room.

TABLE 8-2 Differences between Power and Equipment Grounding in the Home and the Operating Room

	▪POWER	▪EQUIPMENT
Home	+	±
Operating room	–	+

+, grounded; –, ungrounded; ±, may or may not be grounded.

ELECTRICAL POWER: GROUNDED

Electrical utilities universally provide power that is grounded (by convention, the earth–ground potential is zero, and all voltages represent a difference between potentials). That is, one of the wires supplying the power to a home is intentionally connected to the earth. The utility companies do this as a safety measure to prevent electrical charges from building up in their wiring during electrical storms. This also prevents the very high voltages used in transmitting power by the utility from entering the home in the event of an equipment failure in their high-voltage system.[3]

The power enters the typical home via two wires. These two wires are attached to the main fuse or the circuit breaker box at the service entrance. The “hot” wire supplies power to the “hot” distribution strip. The neutral wire is connected to the neutral distribution strip and to a service entrance ground (i.e., a pipe buried in the earth) (Fig. 8-6). From the fuse box, three wires leave to supply the electrical outlets in the house. In the United States, the “hot” wire is color-coded black and carries a voltage 120 volts above ground potential. The second wire is the neutral wire color-coded white; the third wire is the ground wire, which is either color-coded green or is uninsulated (bare wire). The ground and the neutral wires are attached at the same point in the circuit breaker box and then further connected to a cold-water pipe (Figs. 8-7 and 8-8). Thus, this grounded power system is also referred to as a neutral grounded power system. The black wire is not connected to the ground, as this would create a short circuit. The black wire is attached to the “hot” (i.e., 120 volts above ground) distribution strip on which the circuit breakers or fuses are located. From here, numerous branch circuits supply electrical power to the outlets in the house. Each branch circuit is protected by a circuit breaker or fuse that limits current to a specific maximum amperage. Most electrical circuits in the house are 15- or 20-ampere circuits. These typically supply power to the electrical outlets and lights in the house. Several higher amperage circuits are also provided for devices such as an electric stove or an electric clothes dryer. These devices are powered by 240-volt circuits, which can draw from 30 to 50 amperes of current. The circuit breaker or fuse will interrupt the flow of current on the hot side of the line in the event of a short circuit or if the demand placed on that circuit is too high. For example, a 15-ampere branch circuit will be capable of supporting 1,800 watts of power.

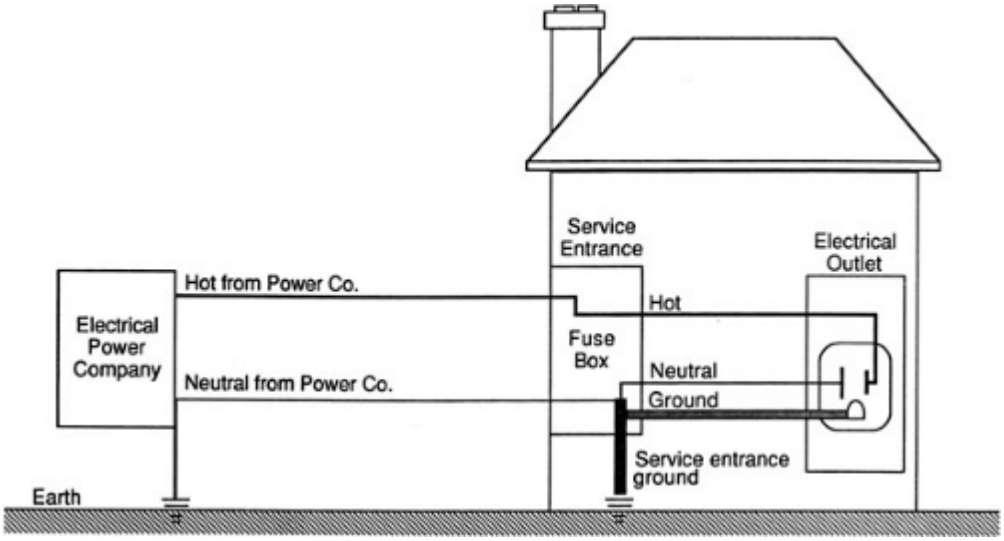

FIGURE 8-6. In a neutral grounded power system, the electric company supplies two lines to the typical home. The neutral is connected to ground by the power company and again connected to a service entrance ground when it enters the fuse box. Both the neutral and ground wires are connected together in the fuse box at the neutral bus bar, which is also attached to the service entrance ground.

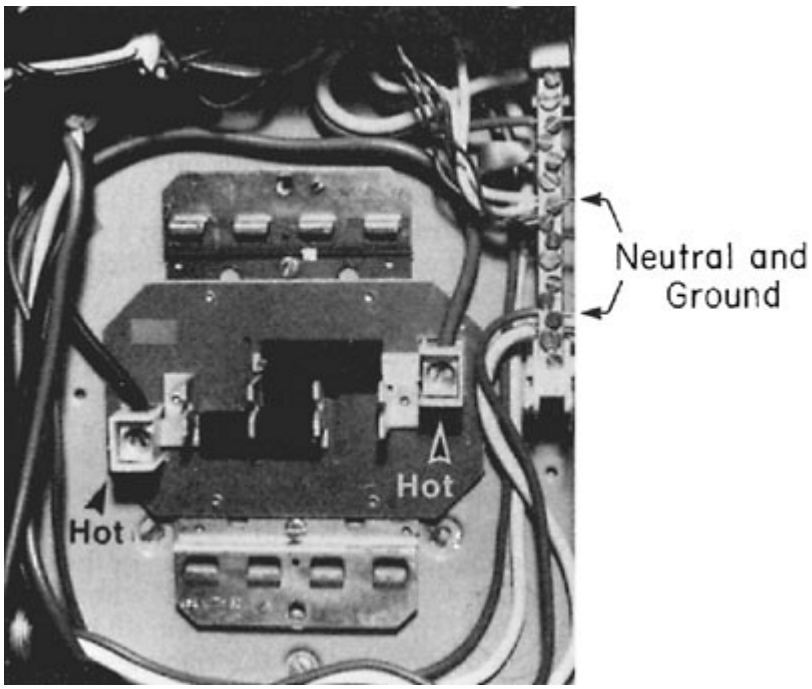

FIGURE 8-7. Inside a fuse box with the circuit breakers removed. The *arrowheads* indicate the hot wires energizing the strips where the circuit breakers are located. The *arrows* point to the neutral bus bar where the neutral and ground wires are connected.

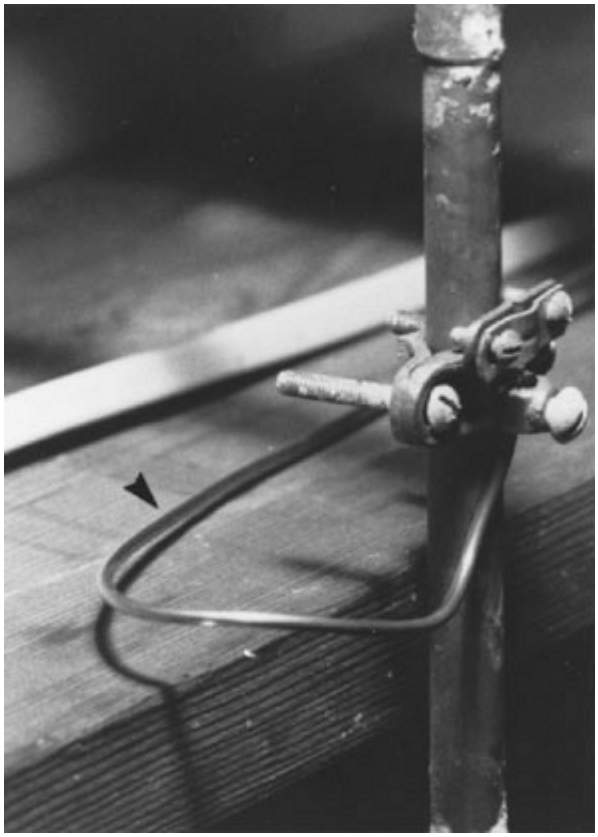

FIGURE 8-8. An older style electrical outlet consisting of just two wires (a hot and a neutral). There is no ground wire.

$W = E \times I$

W = 120 volts × 15 amperes

W = 1,800 watts

Therefore, if two 1,500-watt hair dryers were simultaneously plugged into one outlet, the load would be too great for a 15-ampere circuit, and the circuit breaker would open (trip) or the fuse would melt. This is done to prevent the supply wires in the circuit from melting and starting a fire. The amperage of the circuit breaker on the branch circuit is determined by the thickness of the wire that it supplies. If a 20-ampere breaker is used with wire rated for only 15 amperes, the wire could melt and start a fire before the circuit breaker would trip. It is important to note that a 15-ampere circuit breaker does not protect an individual from lethal shocks. The 15 amperes of current that would trip the circuit breaker far exceeds the 100 to 200 mA that will produce ventricular fibrillation.

The wires that leave the circuit breaker supply the electrical outlets and lighting for the rest of the house. In older homes the electrical cable consists of two wires, a hot and a neutral, which supply power to the electrical outlets (Fig. 8-9). In newer homes, a third wire has been added to the electrical cable (Fig. 8-10). This third wire is either green or uninsulated (bare)

and serves as a ground wire for the power receptacle (Fig. 8-11). On one end, the ground wire is attached to the electrical outlet (Fig. 8-12); on the other, it is connected to the neutral distribution strip in the circuit breaker box along with the neutral (white) wires (Fig. 8-13).

FIGURE 8-9. The *arrowhead* indicates the ground wire from the fuse box attached to a cold-water pipe.

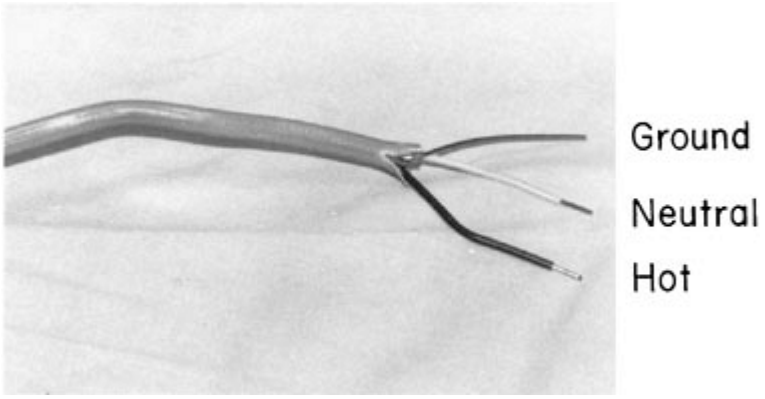

FIGURE 8-10. Modern electrical cable in which a third, or ground, wire has been added.

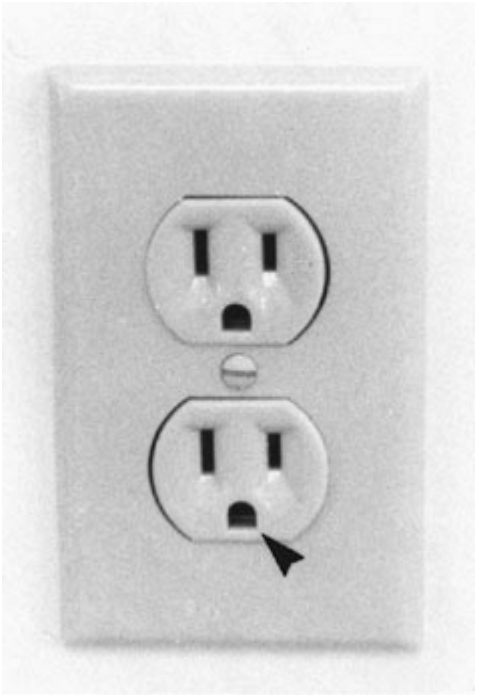

FIGURE 8-11. Modern electrical outlet in which the ground wire is present. The *arrowhead* points to the part of the receptacle where the ground wire connects.

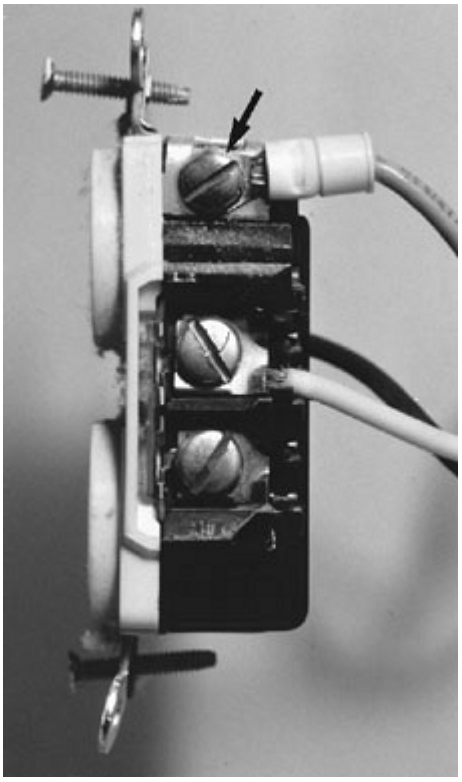

FIGURE 8-12. Detail of modern electrical power receptacle. The *arrow* points to the ground wire, which is attached to the grounding screw on the power receptacle.

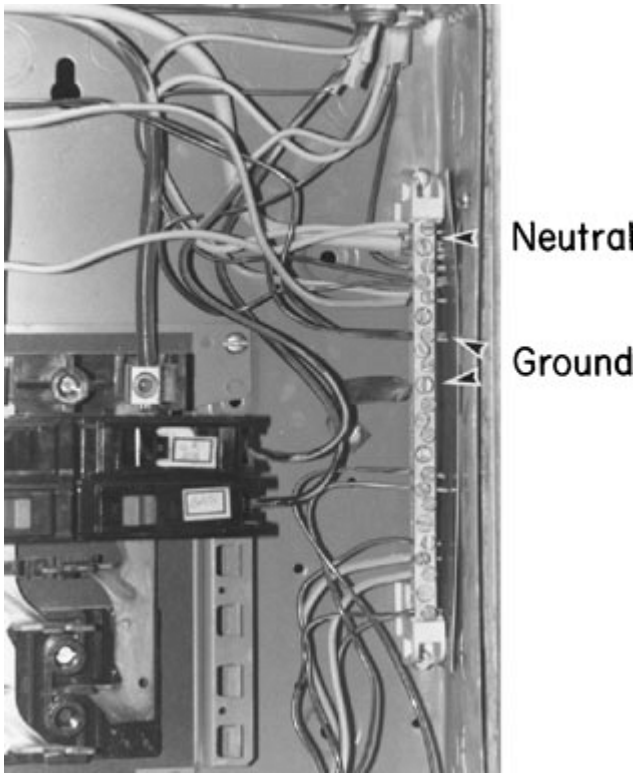

FIGURE 8-13. The ground wires from the power outlet are run to the neutral bus bar, where they are connected with the neutral wires (*arrowheads*).

It should be realized that in both the old and new situations, the power is grounded. That is, a 120-volt potential exists between the hot (black) and the neutral (white) wire and between the hot wire and ground. In this case, the ground is the earth (Fig. 8-14). In modern home construction, there is still a 120-volt potential difference between the hot (black) and the neutral (white) wire as well as a 120-volt difference between the equipment ground wire (which is the third wire), and between the hot wire and earth (Fig. 8-15).

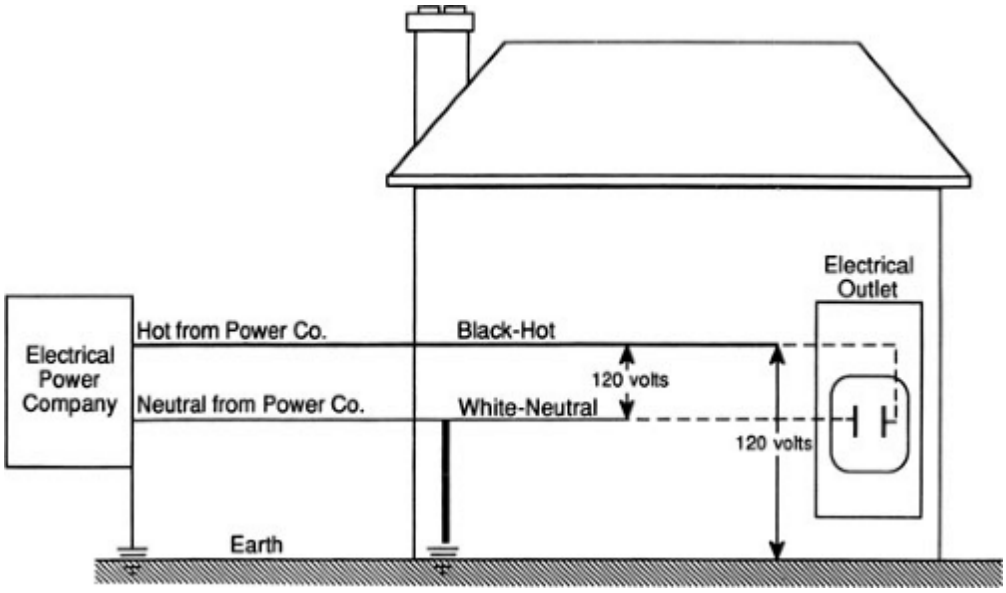

FIGURE 8-14. Diagram of a house with older style wiring that does not contain a ground wire. A 120-volt potential difference exists between the hot and the neutral wire, as well as

between the hot wire and the earth.

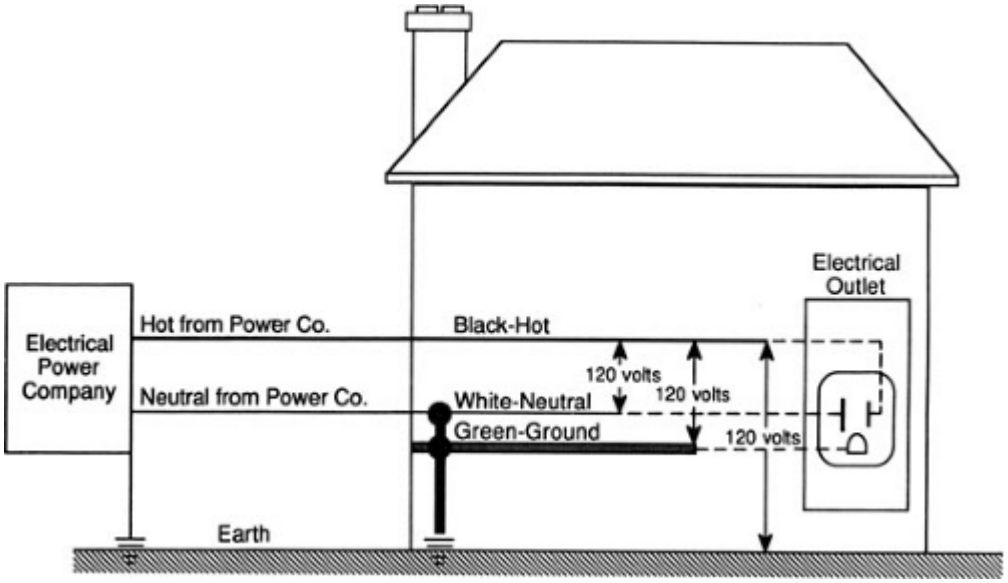

FIGURE 8-15. Diagram of a house with modern wiring in which the third, or ground, wire has been added. The 120-volt potential difference exists between the hot and neutral wires, the hot and the ground wires, and the hot wire and the earth.

A 60-watt light bulb can be used as an example to further illustrate this point. Normally, the hot and neutral wires are connected to the two wires of the light bulb socket, and throwing the switch will illuminate the bulb (Fig. 8-16). Similarly, if the hot wire is connected to one side of the bulb socket and the other wire from the light bulb is connected to the equipment ground wire, the bulb will still illuminate. If there is no equipment ground wire, the bulb will still light if the second wire is connected to any grounded metallic object such as a water pipe or a faucet. This illustrates the fact that the 120-volt potential difference exists not only between the hot and the neutral wires but also between the hot wire and any grounded object. Thus, in a grounded power system, the current will flow between the hot wire and any conductor with an earth ground.

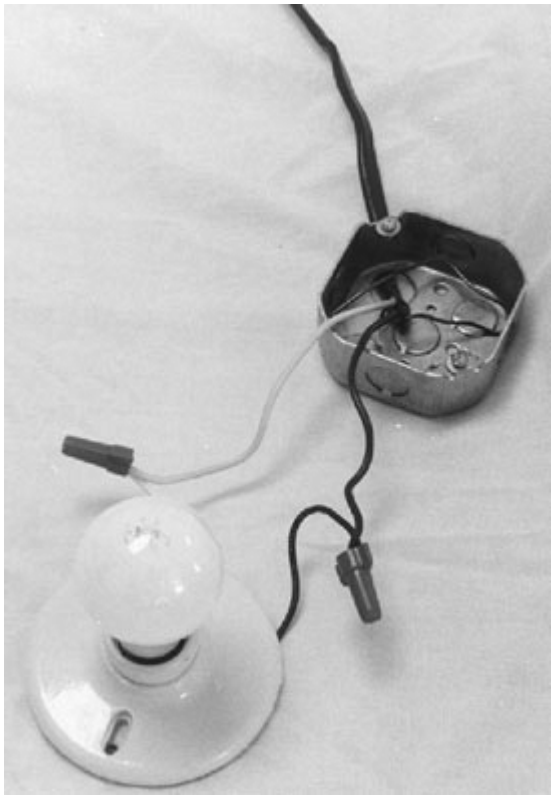

FIGURE 8-16. A simple light bulb circuit in which the hot and neutral wires are connected with the corresponding wires from the light bulb fixture.

As previously stated, current flow requires a closed loop with a source of voltage. For an individual to receive an electric shock, he or she must contact the loop at two points. Because we may be standing on ground or be in contact with an object that is referenced to ground, only one additional contact point is necessary to complete the circuit and thus receive an electrical shock. This is an unfortunate and inherently dangerous consequence of grounded power systems. Modern wiring systems have added the third wire, the equipment ground wire, as a safety measure to reduce the severity of a potential electrical shock. This is accomplished by providing an alternate, low-resistance pathway through which the current can flow to ground.

Over time the insulation covering wires may deteriorate. It is then possible for a bare, hot wire to contact the metal case or frame of an electrical device. The case would then become energized and constitute a shock hazard to someone coming in contact with it. Figure 8-17 illustrates a typical short circuit, where the individual has come in contact with the hot case of an instrument. This illustrates the type of wiring found in older homes. There is no ground wire in the electrical outlet, nor is the electrical apparatus equipped with a ground wire. Here, the individual completes the circuit and receives a severe shock. Figure 8-18 illustrates a similar example, except that now the

equipment ground wire is part of the electrical distribution system. In this example, the equipment ground wire provides a pathway of low impedance through which the current can travel; therefore, most of the current would travel through the ground wire. In this case, the person may get a shock, but it is unlikely to be fatal.

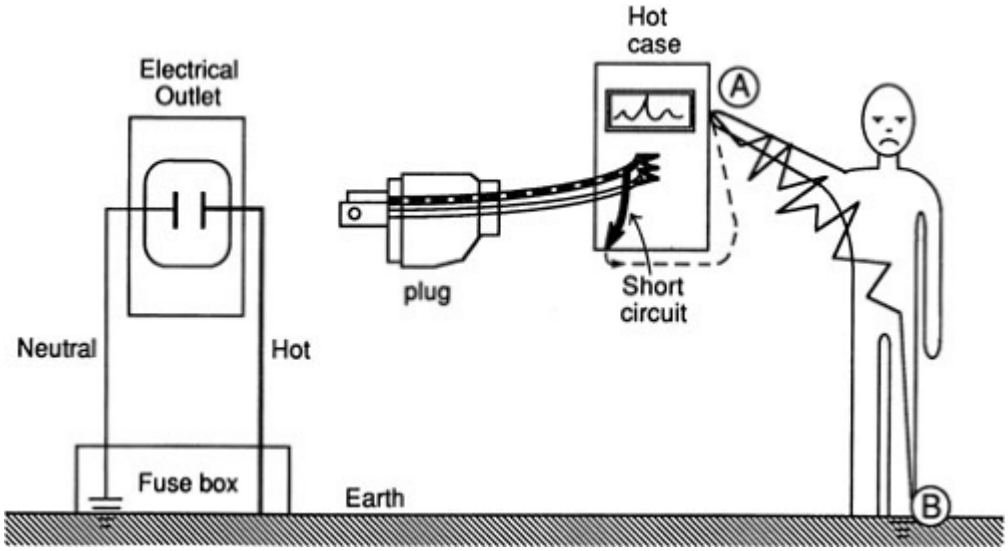

FIGURE 8-17. When a faulty piece of equipment without an equipment ground wire is plugged into an electrical outlet not containing a ground wire, the case of the instrument will become hot. An individual touching the hot case (point *A*) will receive a shock because he or she is standing on the earth (point *B*) and completes the circuit. The current (*dashed line*) will flow from the instrument through the individual touching the hot case.

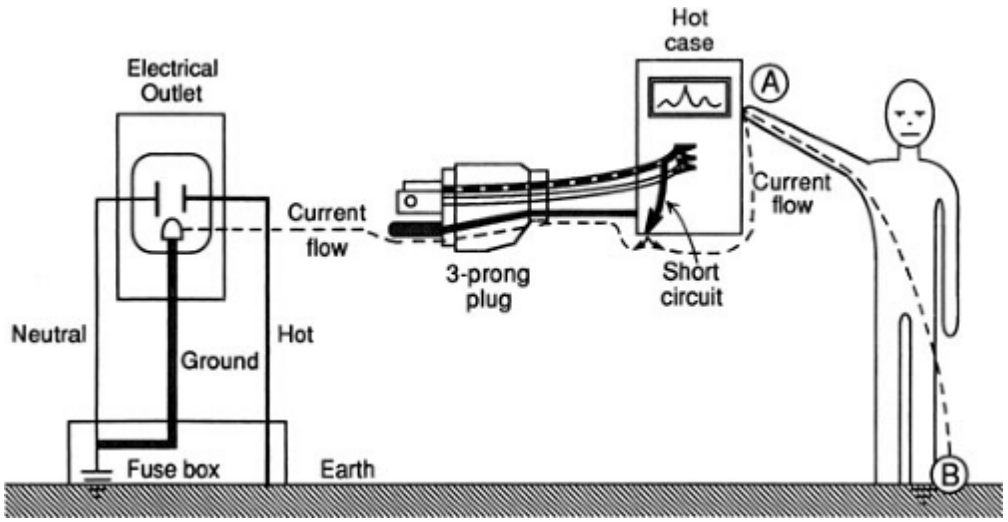

FIGURE 8-18. When a faulty piece of equipment containing an equipment ground wire is properly connected to an electrical outlet with a grounding connection, the current (*dashed line*) will preferentially flow down the low-resistance ground wire. An individual touching the case (point *A*) while standing on the ground (point *B*) will still complete the circuit; however, only a small part of the current will go through the individual.

The electrical power supplied to homes is always grounded. A 120-volt potential always exists between the hot conductor and ground or earth. The third or equipment ground wire used in modern electrical wiring systems does not normally have current flowing through it. In the event of a short circuit, an electrical device with a three-prong plug (i.e., a ground wire connected to its case) will conduct the majority of the short-circuited or “fault” current through the ground wire and away from the individual. This provides a significant safety benefit to someone accidentally contacting the defective device. If a large enough fault current exists, the ground wire also will

provide a means to complete the short circuit back to the circuit breaker or fuse, and this will either melt the fuse or trip the circuit breaker. Thus, in a grounded power system, it is possible to have either grounded or ungrounded equipment, depending on when the wiring was installed and whether the electrical device is equipped with a three-prong plug containing a ground wire. Obviously, attempts to bypass the safety system of the equipment ground should be avoided. Devices such as a “cheater plug” (Fig. 8-19) should never be used because they defeat the safety feature of the equipment ground wire.

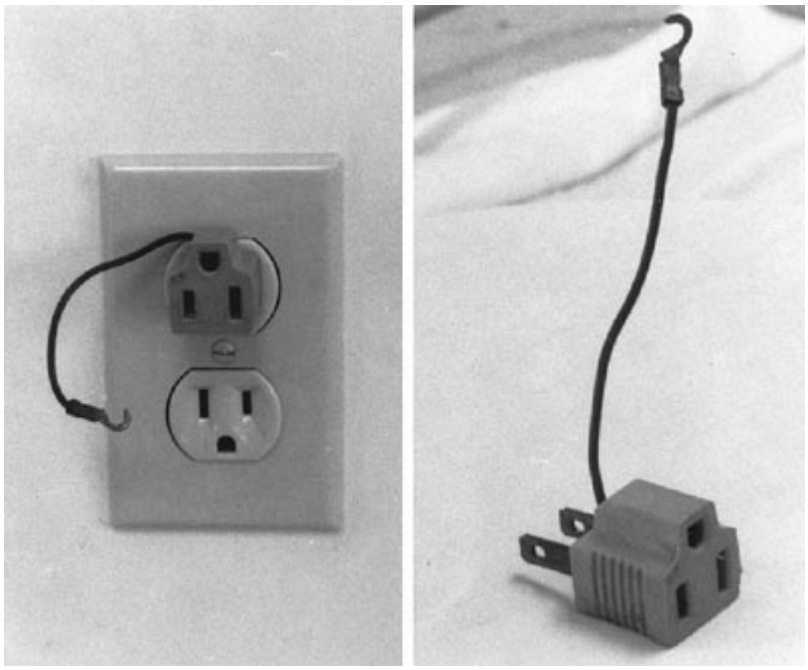

FIGURE 8-19. ***Right.*** A “cheater plug” that converts a three-prong power cord to a two-prong cord. ***Left.*** The wire attached to the cheater plug is rarely connected to the screw in the middle of the outlet. This totally defeats the purpose of the equipment ground wire.

ELECTRICAL POWER: UNGROUNDED

5 Numerous electronic devices, together with power cords and puddles of saline solutions on the floor, make the operating room an electrically hazardous environment for both patients and personnel. Bruner et al[14] found that 40% of electrical accidents in hospitals occurred in the operating room. The complexity of electrical equipment in the modern operating room demands that electrical safety be a factor of paramount importance. To provide an extra measure of safety from macroshock, the power supplied to most operating rooms is ungrounded. In this ungrounded power system, the current is isolated from ground potential. The 120-volt potential difference exists only between the two wires of the isolated power system, but no circuit exists between the ground and either of the isolated power lines.

Supplying ungrounded power to the operating room requires the use of an *isolation transformer* (Fig. 8-20). This device uses electromagnetic induction to induce a current in the ungrounded or secondary winding of the transformer from energy supplied to the primary winding. There is no direct electrical connection between the power supplied by the utility company on the primary side and the power induced by the transformer on the ungrounded or secondary side. Thus, the power supplied to the operating room is isolated from ground (Fig. 8-21). Because the 120-volt potential exists only between

the two wires of the isolated circuit, neither wire is hot or neutral with reference to ground. In this case, they are simply referred to as line 1 and line 2 (Fig. 8-22). Using the example of the light bulb, if one connects the two wires of the bulb socket to the two wires of the isolated power

system, the light will illuminate. However, if one connects one of the wires to one side of the isolated power and the other wire to ground, the light will not illuminate. If the wires of the isolated power system are connected, the short circuit will trip the circuit breaker. In comparing the two systems, the standard grounded power has a direct connection to ground, whereas the isolated system imposes a very high impedance to any current flow to ground. The added safety of this system can be seen in Figure 8-23. In this case, a person has come in contact with one side of the isolated power system (point *A*). Because standing on ground (point *B*) does not constitute a part of the isolated circuit, the individual does not complete the loop and will not receive a shock. This is because the ground is part of the primary circuit (*solid lines*), and the person is contacting only one side of the isolated secondary circuit (*cross-hatched lines*). The person does not complete either circuit (i.e., have two contact points); therefore, this situation does not pose an electric shock hazard. Of course, if the person contacts both lines of the isolated power system (an unlikely event), he or she would receive a shock.

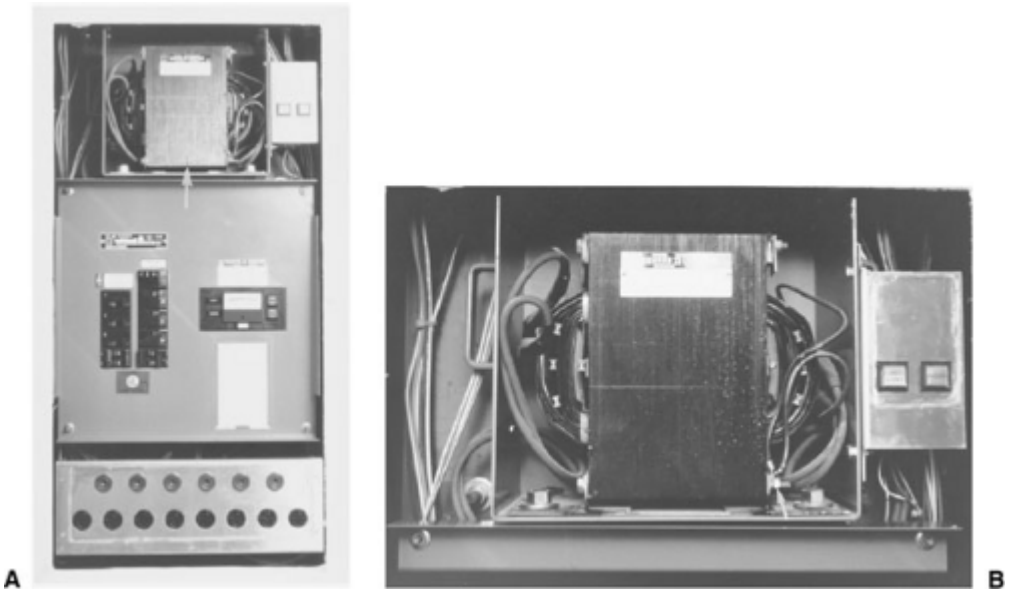

FIGURE 8-20. A. Isolated power panel showing circuit breakers, LIM, and isolation transformer (*arrow*). **B.** Detail of an isolation transformer with the attached warning lights. The arrow points to ground wire connection on the primary side of the transformer. Note that no similar connection exists on the secondary side of the transformer.

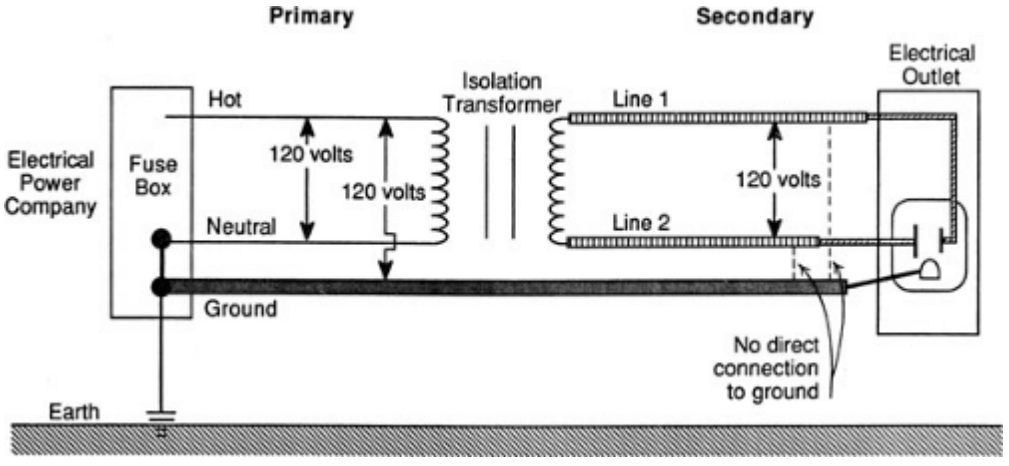

FIGURE 8-21. In the operating room, the isolation transformer converts the grounded power on the primary side to an ungrounded power system on the secondary side of the transformer. A 120-volt potential difference exists between line 1 and line 2. There is no direct connection from the power on the secondary side to ground. The equipment ground wire, however, is still present.

FIGURE 8-22. Detail of the inside of a circuit breaker box in an isolated power system. The *bottom arrow* points to ground wires meeting at the common ground terminal. *Arrows 1 and 2* indicate lines 1 and 2 from the isolated power circuit breaker. Neither line 1 nor line 2 is connected to the same terminals as the ground wires. This is in marked contrast to Figure 8-13, where the neutral and ground wires are attached at the same point.

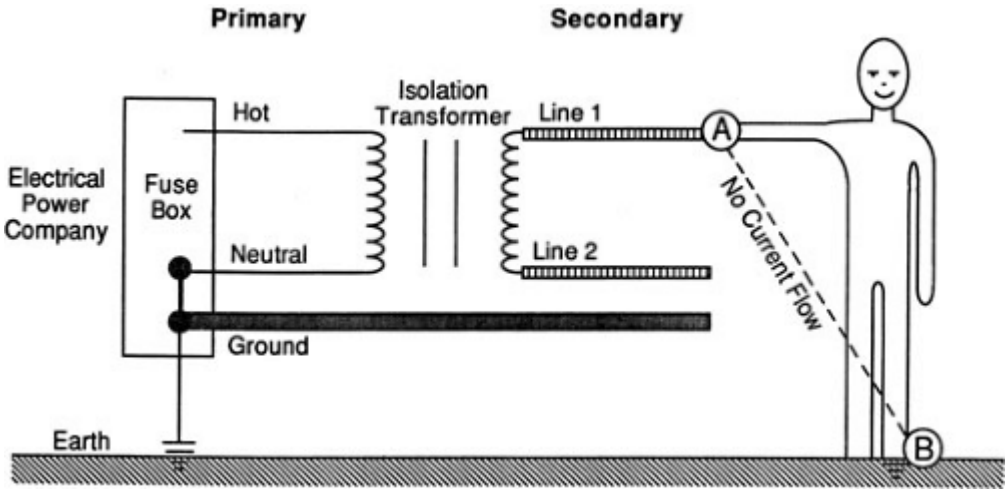

FIGURE 8-23. A safety feature of the isolated power system is illustrated. An individual contacting one side of the isolated power system (point *A*) and standing on the ground (point *B*) will not receive a shock. In this instance, the individual is not contacting the circuit at two points and thus is not completing the circuit. Point *A* (*cross-hatched lines*) is part of the isolated power system, and point *B* is part of the primary or grounded side of the circuit (*solid lines*).

If a faulty electrical appliance with an intact equipment ground wire is plugged into a standard household outlet, and the home wiring has a properly connected ground wire, then the amount of electrical current that will flow through the individual is considerably less than what will flow through the low-resistance ground wire. Here, an individual would be fairly well protected from a serious shock. However, if that ground wire were broken, the individual might receive a lethal shock. No shock would occur if the same faulty piece of equipment were plugged into the isolated power system, even if the equipment ground wire were broken. Thus, the isolated power system provides a significant amount of protection from macroshock. Another feature of the isolated power system is that the faulty piece of equipment, even though it may be partially short-circuited, will not usually trip the circuit breaker. This is an important feature because the faulty piece of equipment may be part of a life-support system for a patient. It is important to note that even though the power is isolated from ground, the case or frame of all electrical equipment is still connected to an equipment ground. The third wire (equipment ground wire) is necessary for a total electrical safety program.

Figure 8-24 illustrates a scenario involving a faulty piece of equipment connected to the isolated power system. This does not represent a hazard; it merely converts the isolated power back to a grounded power system as exists outside the

operating room. In fact, a *second* fault is necessary to create a hazard.

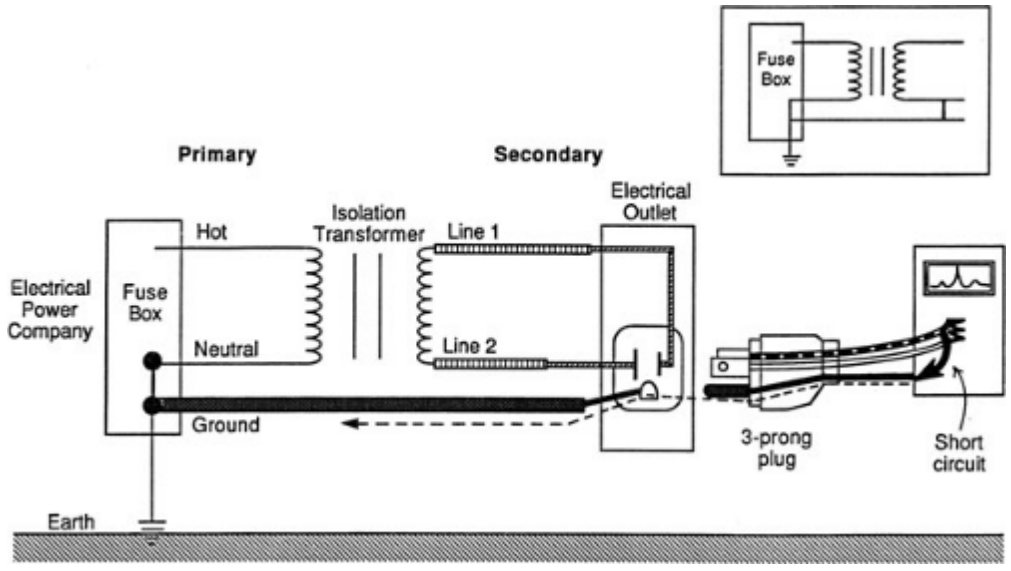

FIGURE 8-24. A faulty piece of equipment plugged into the isolated power system does not present a shock hazard. It merely converts the isolated power system into a grounded power system. The figure insert illustrates that the isolated power system is now identical to the grounded power system. The *dashed line* indicates current flow in the ground wire.

The previous discussion assumes that the isolated power system is perfectly isolated from ground.

Actually, perfect isolation is impossible to achieve. All AC-operated power systems and electrical devices manifest some degree of capacitance. As previously discussed, electrical power cords, wires, and electrical motors exhibit capacitive coupling to the ground wire and metal conduits and "leak" small amounts of current to ground (Fig. 8-25). This so-called *leakage current* partially ungrounds the isolated power system. This does not usually amount to more than a few milliamperes in an operating room. So an individual coming in contact with one side of the isolated power system would receive only a very small shock (1 to 2 mA). Although this amount of current would be perceptible, it would not be dangerous.

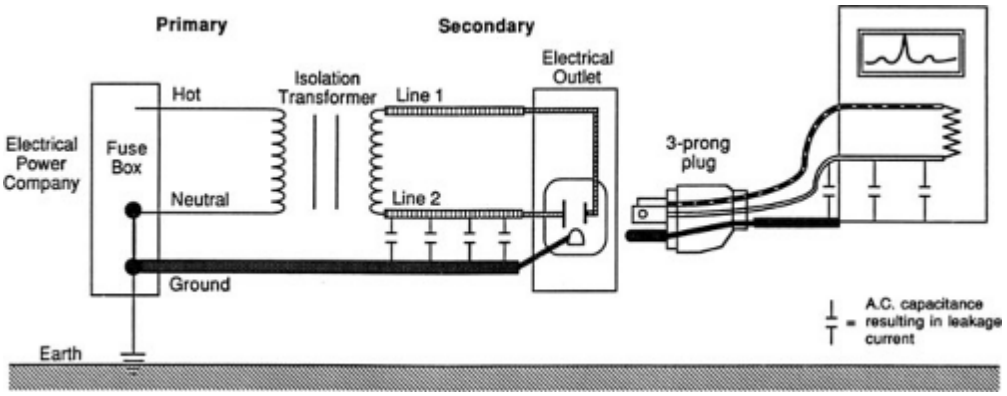

FIGURE 8-25. The capacitance that exists in AC power lines and AC-operated equipment results in small "leakage currents" that partially degrade the isolated power system.

THE LINE ISOLATION MONITOR

The *line isolation monitor* (LIM) is a device that continuously monitors the integrity of an isolated power system. If a faulty piece of equipment is connected to the isolated power system, this will, in effect, change the system back to a conventional grounded system. Also, the faulty piece of equipment will continue to function normally. Therefore, it is essential that a warning system be in place to alert the personnel that the power is no longer ungrounded. The LIM continuously monitors the isolated power to ensure that it is indeed isolated from ground, and the device has a meter that displays a continuous indication of the integrity of the system (Fig. 8-26). The LIM is actually measuring the impedance to ground of each side of the isolated power system. As previously discussed, with perfect isolation, impedance would be infinitely high and there would be no current flow in the event of a first fault situation ($Z = E / I$; if $I = 0$, then $Z = \infty$). Because all AC wiring and all AC-operated electrical devices have some capacitance, small leakage currents are present that partially degrade the isolation of the system. The meter of the LIM will indicate (in milliamperes) the total amount of leakage in the system resulting from capacitance, electrical wiring, and any devices plugged into the isolated power system.

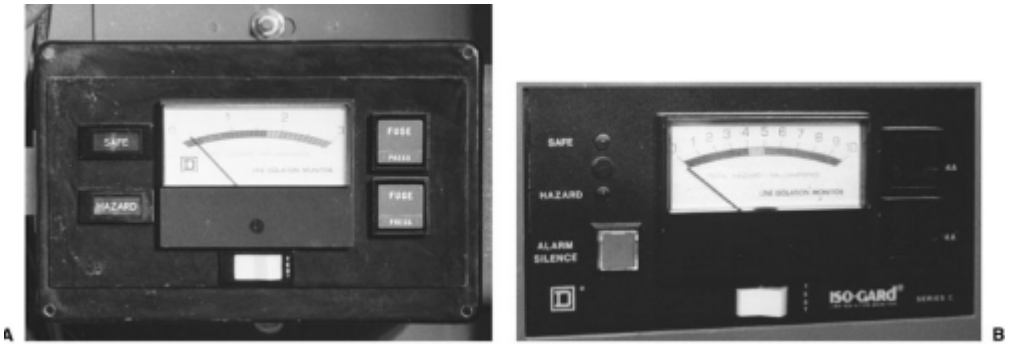

FIGURE 8-26. The meter of the line isolation monitor is calibrated in milliamperes. If the isolation of the power system is degraded such that >2 mA (5 mA in newer systems) of current could flow, the hazard light will illuminate and a warning buzzer will sound. Note the button for testing the hazard warning system. **A.** Older LIM that will trigger an alarm at 2 mA. **B.** Newer line isolation monitor that will trigger an alarm at 5 mA.

The reading on the LIM meter does not mean that current is actually flowing; rather, it indicates how much current would flow in the event of a first fault. The LIM is set to alarm at 2 or 5 mA, depending on the age and brand of the system. Once this preset limit is exceeded, visual and audible alarms are triggered to indicate that the isolation from ground has been degraded beyond a predetermined limit (Fig. 8-27). This does not necessarily mean that there is a hazardous situation, but rather that the system is no longer totally isolated from ground. It would require a second fault to create a dangerous situation.

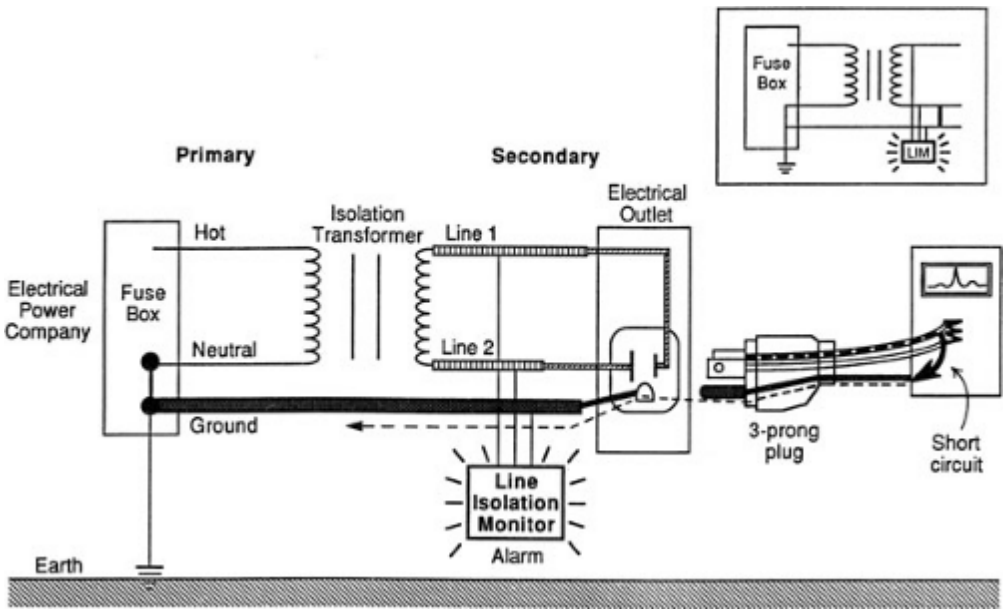

FIGURE 8-27. When a faulty piece of equipment is plugged into the isolated power system, it will markedly decrease the impedance from line 1 or line 2 to ground. This will be detected by the LIM, which will sound an alarm.

For example, if the LIM were set to alarm at 2 mA, using Ohm's law, the impedance for either side of the isolated power system would be 60,000 ohms:

$Z = E/I$

Z = (120 volts)/(0.002 ampers)

Z = 60,000 ohms

Therefore, if either side of the isolated power system had less than 60,000 ohms impedance to ground, the LIM would trigger an alarm. This might occur in two situations. In the first, a faulty piece of equipment is plugged into the isolated power system. In this case, a true fault to ground exists from one line to ground. Now the system would be converted to the equivalent of a grounded power system. This faulty piece of equipment

P.160

P.161

should be removed and serviced as soon as possible. However, this piece of equipment could still be used safely if it were essential for the care of the patient. It should be remembered, however, that continuing to use this faulty piece of equipment would create the potential for a serious electrical shock. This would occur if a second faulty piece of equipment were simultaneously connected to the isolated power system.

The second situation involves connecting many perfectly normal pieces of equipment to the isolated power system. Although each piece of equipment has only a small amount of leakage current, if the total leakage exceeds 2 mA, the LIM will trigger an alarm. Assume that in the same operating room there are 30 electrical devices, each having 100 μA of leakage current. The total leakage current (30 × 100 μA) would be 3 mA. The impedance to ground would still be 40,000 ohms (120/0.003). The LIM alarm would sound because the 2-mA set point was violated. However, the system is still safe and represents a state significantly different from that in the first situation. For this reason, the newer LIMs are set to alarm at 5 mA instead of 2 mA.

The newest LIMs are referred to as third-generation monitors. The first-generation monitor, or static LIM, was unable to detect balanced faults (i.e., a situation in which there are equal faults to ground from both line 1 and line 2). The second-generation, or dynamic, LIM did not have this problem but could interfere with physiologic monitoring. Both of these monitors would trigger an alarm at 2 mA, which led to annoying “false” alarms. The third-generation LIM corrects the problems of its predecessors and has the alarm threshold set at 5 mA.[15] Proper functioning of the LIM is dependent on having both intact equipment ground wires as well as its own connection to ground. First- and second-generation LIMs could not detect the loss of the LIM ground connection. The third-generation LIM can detect this loss of ground to the monitor. In this case the LIM alarm would sound and the red hazard light would illuminate, but the LIM meter would read zero. This condition will alert the staff that the LIM needs to be repaired. However, the LIM still cannot detect broken equipment ground wires. An example of the third-generation LIM is the *Iso-Gard* ™ made by the Square D Company (Monroe, NC).

P.162

The equipment ground wire is again an important part of the safety system. If this wire is broken, a faulty piece of equipment that is plugged into an outlet would operate normally, but the LIM would not alarm. A second fault could therefore cause a shock, without any alarm from the LIM. Also, in the event of a second fault, the equipment ground wire provides a low-resistance path to ground for most of the fault current (see Fig. 8-24). The LIM will only be able to register leakage currents from pieces of equipment that are connected to the isolated power system and have intact ground wires.

If the line isolation monitor alarm is triggered, the first thing to do is to check the gauge to determine if it is a true fault. The other possibility is that too many pieces of electrical equipment have been plugged in and the 2-mA limit has been exceeded. If the gauge is between 2 and 5 mA, it is probable that too much electrical equipment has been plugged in. If the gauge reads >5 mA, most likely there is a faulty piece of equipment present in the operating room. The next step is to

identify the faulty equipment, which is done by unplugging each piece of equipment until the alarm ceases. If the faulty piece of equipment is not of a life-support nature, it should be removed from the operating room. If it is a vital piece of life-support equipment, it can be safely used. However, it must be remembered that the protection of the isolated power system and the line isolation monitor is no longer operative. Therefore, if possible, no other electrical equipment should be connected during the remainder of the case, or until the faulty piece of equipment can be safely removed.

GROUND FAULT CIRCUIT INTERRUPTER

7 The ground fault circuit interrupter (GFCI, or occasionally abbreviated to GFI) is another popular device used to prevent individuals from receiving an electrical shock in a grounded power system. Electrical codes for most new construction require that a GFCI circuit be present in potentially hazardous (e.g., wet) areas such as bathrooms, kitchens, or outdoor electrical outlets. The GFCI may be installed as an individual power outlet (Fig. 8-28) or may be a special circuit breaker to which all the individual protected outlets are connected at a single point. The special GFCI circuit breaker is located in the main fuse/circuit breaker box and can be distinguished by its red test button (Fig. 8-29). As Figure 8-5 demonstrates, the current flowing in both the hot and neutral wires is usually equal. The GFCI monitors both sides of the circuit for the equality of current flow; if a difference is detected, the power is immediately interrupted. If an individual should contact a faulty piece of equipment such that current flowed through the individual, an imbalance between the two sides of the circuit would be created, which would be detected by the GFCI. Because the GFCI can detect very small current differences (in the range of 5 mA), the GFCI will open the circuit in a few milliseconds, thereby interrupting the current flow before a significant shock occurs. Thus, the GFCI provides a high level of protection at a very modest cost.

FIGURE 8-28. A GFCI electrical outlet with integrated test and reset buttons.

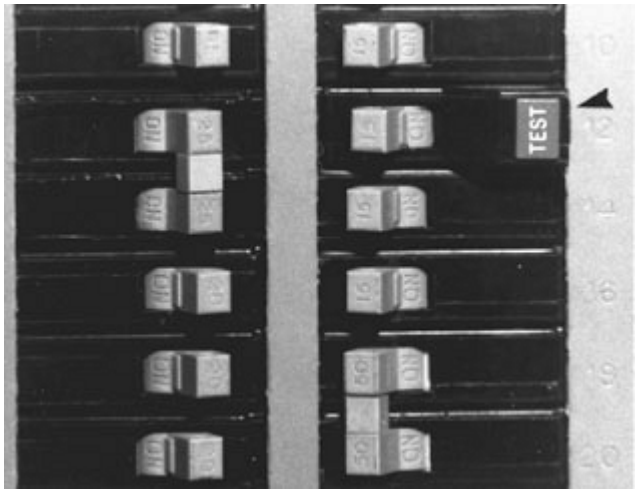

FIGURE 8-29. Special GFCI circuit breaker. The *arrowhead* points to the distinguishing red test button.

The disadvantage of using a GFCI in the operating room is that it interrupts the power without warning. A defective piece of equipment could no longer be used, which might be a problem if it were of a life-support nature, whereas if the same faulty piece of equipment were plugged into an isolated power system, the LIM would alarm, but the equipment could still be used.

MICROSHOCK

As previously discussed, macroshock involves relatively large amounts of current applied to the surface of the body. The current is conducted through all the tissues in proportion to their conductivity and area in a plane perpendicular to the current. Consequently, the "density" of the current (amperes per meter squared) that reaches the heart is considerably less than what is applied to the body surface. However, an electrically susceptible patient (i.e., one who has a direct, external connection to the heart, such as through a CVP catheter or transvenous cardiac pacing wires) may be at risk from very small currents; this is called *microshock*.[16] The catheter orifice or electrical wire with a very small surface area in contact with the heart produces a relatively large current density at the heart.[17] Stated another way, even very small amounts of current applied directly to the myocardium will cause ventricular fibrillation. Microshock is a particularly difficult problem because of the insidious nature of the hazard.

In the electrically susceptible patient, ventricular fibrillation can be produced by a current that is below the threshold of human perception. The exact amount of current necessary to cause ventricular fibrillation in this type of patient is unknown. Whalen et al[18] were able to produce fibrillation with 20 μA of current applied directly to the myocardium of dogs. Raftery

et al[19] produced fibrillation with 80 μA of current in some patients. Hull[20] used data obtained by Watson et al[21] to show that 50% of patients would fibrillate at currents of 200 μA. Because 1,000 μA (1 mA) is generally regarded as the threshold of human perception with 60-Hz AC, the electrically susceptible patient can be electrocuted with one-tenth the normally perceptible currents. This is not only of academic interest but also of practical concern because many cases of ventricular fibrillation from microshock have been reported.[22,23,24,25,26,27]

The stray capacitance that is part of any AC-powered electrical instrument may result in significant amounts of charge buildup on the case of the instrument. If an individual simultaneously touches the case of an instrument where this has occurred and the electrically susceptible patient, he or she may unknowingly cause a discharge to the patient that results in ventricular fibrillation. Once again, the equipment ground wire constitutes the major source of

protection against microshock for the electrically susceptible patient. In this case, the equipment ground wire provides a low-resistance path by which most of the leakage current is dissipated instead of stored as a charge.

Figure 8-30 illustrates a situation involving a patient with a saline-filled catheter in the heart with a resistance of ~500 ohms. The ground wire with a resistance of 1 ohm is connected to the instrument case. A leakage current of 100 μA will divide according to the relative resistances of the two paths. In this case, 99.8 μA will flow through the equipment ground wire, and only 0.2 μA will flow through the fluid-filled catheter. This extremely small current does not endanger the patient. If, however, the equipment ground wire were broken, the electrically susceptible patient would be at great risk because all 100 μA of leakage current could flow through the catheter and cause ventricular fibrillation (Fig. 8-31).

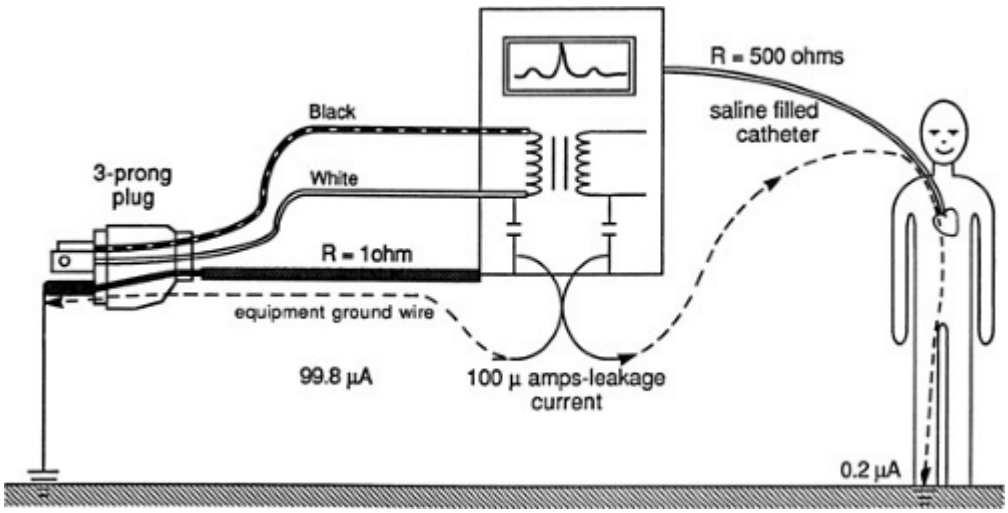

FIGURE 8-30. The electrically susceptible patient is protected from microshock by the presence of an intact equipment ground wire. The equipment ground wire provides a low-impedance path in which the majority of the leakage current (*dashed lines*) can flow.

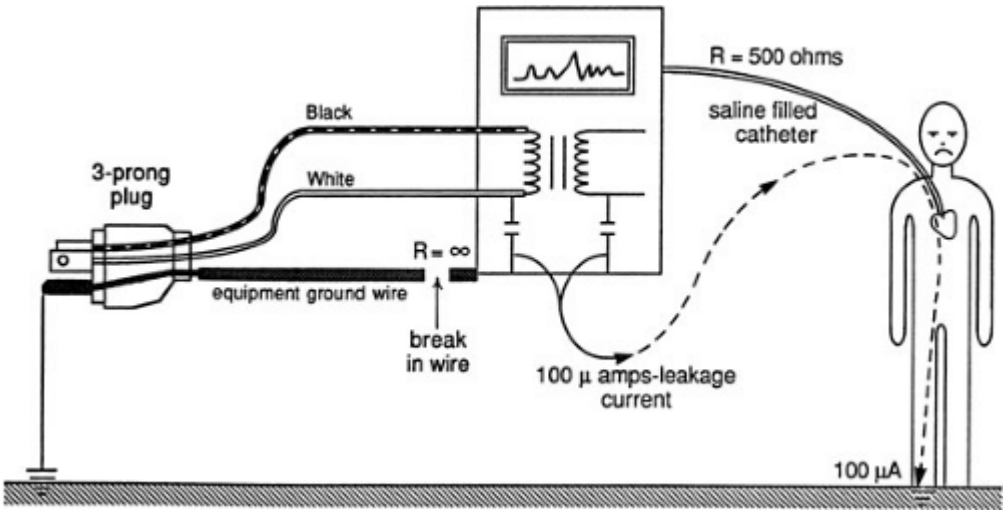

FIGURE 8-31. A broken equipment ground wire results in a significant hazard to the electrically susceptible patient. In this case, the entire leakage current can be conducted to the heart and may result in ventricular fibrillation.

Modern patient monitors incorporate another mechanism to reduce the risk of microshock for electrically susceptible patients. This mechanism involves electrically isolating all direct patient connections from the power supply of the monitor by placing a very high impedance between the patient and any device. This limits the amount of internal leakage through the patient connection to a very small value. Currently the standard is <10 µA. For instance, the output of an ECG monitor's power supply is electrically isolated from the patient by placing a very high impedance between the monitor and the patient's ECG leads.[6,28] Isolation techniques are designed to inhibit hazardous electrical pathways between the patient and the monitor while allowing the passage of the physiologic signal.

An intact equipment ground wire is probably the most important factor in preventing microshock. There are, however, other things that the anesthesiologist can do to reduce the incidence of microshock. One should never simultaneously touch an electrical device and a saline-filled central catheter or external pacing wires. Whenever one is handling a central catheter or pacing wires, it is best to insulate oneself by wearing rubber gloves. Also, one should never let any external current source, such as a nerve stimulator, come into contact with the catheter or wires. Finally, one should be alert to potential sources of energy that can be transmitted to the patient. Even stray

radiofrequency current from the electrosurgical unit (cautery) can, with the right conditions, be a source of microshock.[29]

It must be remembered that the LIM is not designed to provide protection from microshock. The microampere currents involved in microshock are far below the LIM threshold of protection. In addition, the LIM does not register the leakage of individual monitors, but rather indicates the status of the total system. The LIM reading indicates the total amount of leakage current resulting from the entire capacitance of the system. This is the amount of current that would flow to ground in the event of a first-fault situation.

The essence of electrical safety is a thorough understanding of all the principles of grounding. According to Bruner, “Grounding is neither safe nor unsafe. Its significance is dependent on what is grounded and in what context.”[9] The objective of electrical safety is to make it difficult for electrical current to pass through people. For this reason, both the patient and the anesthesiologist should be isolated from ground as much as possible. That is, their resistance to current flow should be as high as is technologically feasible. In the inherently unsafe electrical environment of an operating room, several measures can be taken to help protect against contacting hazardous current flows. First, the grounded power provided by the utility company can be converted to ungrounded power by means of an isolation transformer. The LIM will continuously monitor the status of this isolation from ground and warn that the isolation of the power (from ground) has been lost in the event that a defective piece of equipment is plugged into one of the isolated circuit outlets. In addition, the shock that an individual could receive from a faulty piece of equipment is determined by the capacitance of the system and is limited to a few milliamperes. Second, all equipment plugged into the isolated power system has an equipment ground wire that is attached to the case of the instrument. This equipment ground wire provides an alternative low-resistance pathway enabling potentially dangerous currents to flow to ground. Thus, the patient and the anesthesiologist should be as insulated from ground as possible and all electrical equipment should be grounded.

The equipment ground wire serves three functions. First, it provides a low-resistance path for fault currents to reduce the risk of macroshock. Second, it dissipates leakage currents that are potentially harmful to the electrically susceptible patient. Third, it provides information to the LIM on the status of the ungrounded power system. If the equipment ground wire is broken, a significant factor in the prevention of electrical shock is lost. Additionally, the isolated power system will appear safer than it actually is, because the LIM is unable to detect broken equipment ground wires.

Because power cord plugs and receptacles are subjected to greater abuse in the hospital than in the home, the Underwriters Laboratories (Melville, NY) has issued a strict specification for special

"hospital-grade" plugs and receptacles (Fig. 8-32). The plugs and receptacles that conform to this specification are marked by a green dot.[30] The hospital-grade plug is one that can be visually inspected or easily disassembled to ensure the integrity of the ground wire connection. Molded opaque plugs are not acceptable. Edwards reported that of 3,000 nonhospital-grade receptacles installed in a new hospital building, 1,800 (60%) were defective after 3 years.[31] When 2,000 of the nonhospital-grade receptacles were replaced with ones of hospital grade, no failures had occurred after 18 months of use.

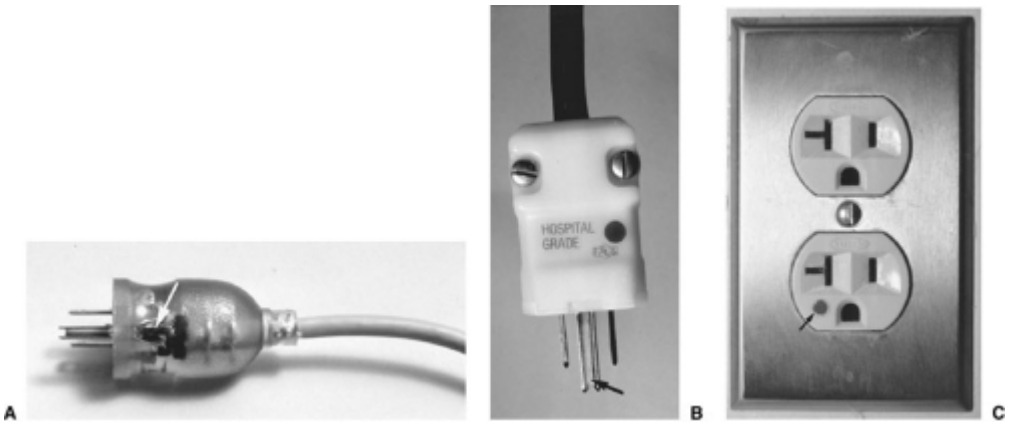

FIGURE 8-32. A. A hospital-grade plug that can be visually inspected. The *arrow* points to the equipment ground wire whose integrity can be readily verified. **B.** A hospital-grade plug that can be easily disassembled for inspection. Note that the prong for the ground wire (*arrow*) is longer than the hot or neutral prong, so that it is the first to enter the receptacle. **C.** The *arrow* points to the green dot denoting a hospital-grade power outlet.

ELECTROSURGERY

On that fateful October day in 1926 when Dr. Harvey W. Cushing first used an electrosurgical machine invented by Professor William T. Bovie to resect a brain tumor, the course of modern surgery and anesthesia was forever altered.[32] The ubiquitous use of electrosurgery attests to the success of Professor Bovie's invention. However, this technology was not adopted without a cost. The widespread use of electrocautery has, at the very least, hastened the elimination of explosive anesthetic agents from the operating room. In addition, as every anesthesiologist is aware, few things in the operating room are immune to interference from the "Bovie." The high-frequency electrical energy generated by the electrosurgery unit (ESU) interferes with everything from the ECG signal to cardiac output computers, pulse oximeters, and even implanted cardiac pacemakers.[33]

The ESU operates by generating very–high-frequency currents (radiofrequency range) of anywhere from 500,000 to 1 million Hz. Heat is generated whenever a current passes through a resistance. The amount of heat (H) produced is proportional to the square of the current and inversely proportional to the area through which the current passes ($H = I^2/A$).[34] By concentrating the energy at the tip of the "Bovie pencil," the surgeon can produce either a cut or a coagulation at any given spot. This very high frequency current behaves differently from the standard 60-Hz AC current and can pass directly across the precordium without causing ventricular fibrillation.[34] This is because high-frequency currents have a low tissue penetration and do not excite contractile cells.

The large amount of energy generated by the ESU can pose other problems to the operator and

the patient. Dr. Cushing became aware of one such problem. He wrote, “Once the operator received a shock which passed through a metal retractor to his arm and out by a wire from his headlight, which was unpleasant to say the least.”[35] The ESU cannot be safely operated unless the energy is properly routed from the ESU through the patient and back to the unit. Ideally, the current generated by the active electrode is concentrated at the ESU tip constituting a very small surface area. This energy has a high current density and is able to generate enough heat to produce a therapeutic cut or coagulation. The energy then passes through the patient to a dispersive electrode of large surface area that returns the energy safely to the ESU (Fig. 8-33).

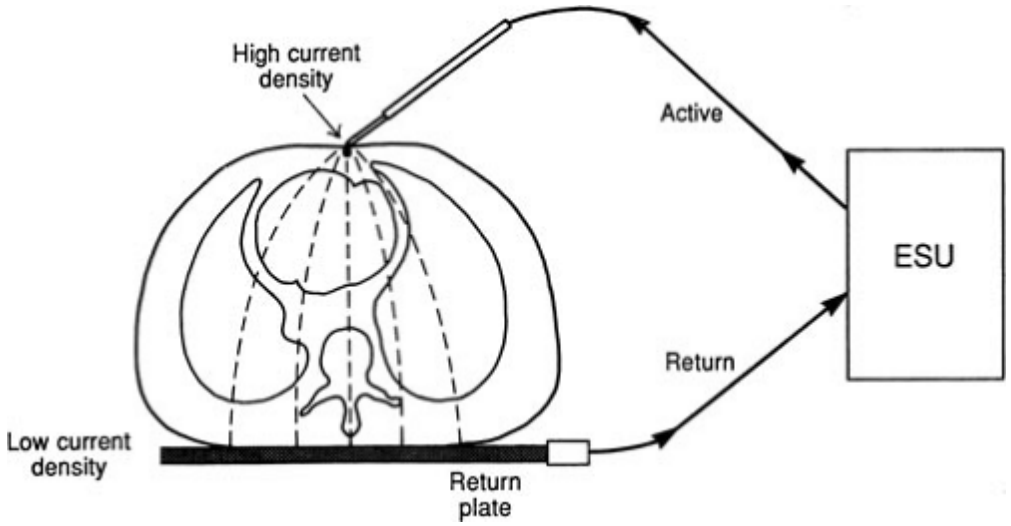

FIGURE 8-33. A properly applied ESU return plate. The current density at the return plate is low, resulting in no danger to the patient.

One unfortunate quirk in terminology concerns the return (dispersive) plate of the ESU. This plate, often incorrectly referred to as a *ground plate*, is actually a dispersive electrode of large surface area that safely returns the generated energy to the ESU via a low current density pathway. When inquiring whether the dispersive electrode has been attached to the patient, operating room personnel frequently ask, “Is the patient grounded?” Because the aim of electrical safety is to isolate the patient from ground, this expression is worse than erroneous; it can lead to confusion. Because the area of the return plate is large, the current density is low; therefore, no harmful heat is generated and no tissue destruction occurs. In a properly functioning system, the only tissue effect is at the site of the active electrode that is held by the surgeon.

9 Problems can arise if the electrosurgical return plate is improperly applied to the patient or if the cord connecting the return plate to the ESU is damaged or broken. In these instances, the high-frequency current generated by the ESU will seek an alternate return pathway. Anything attached to the patient, such as ECG leads or a temperature probe, can provide this alternate return pathway. The current density at the ECG pad will be considerably higher than normal because its surface area is much less than that of the ESU return plate. This may result in a serious burn at this alternate return site. Similarly, a burn may occur at the site of the ESU return plate if it is not properly applied to the patient or if it becomes partially dislodged during the operation (Fig. 8-34). This is not merely a theoretical possibility but is evidenced by the numerous case reports involving patients who have received ESU burns.[36,37,38,39,40,41]

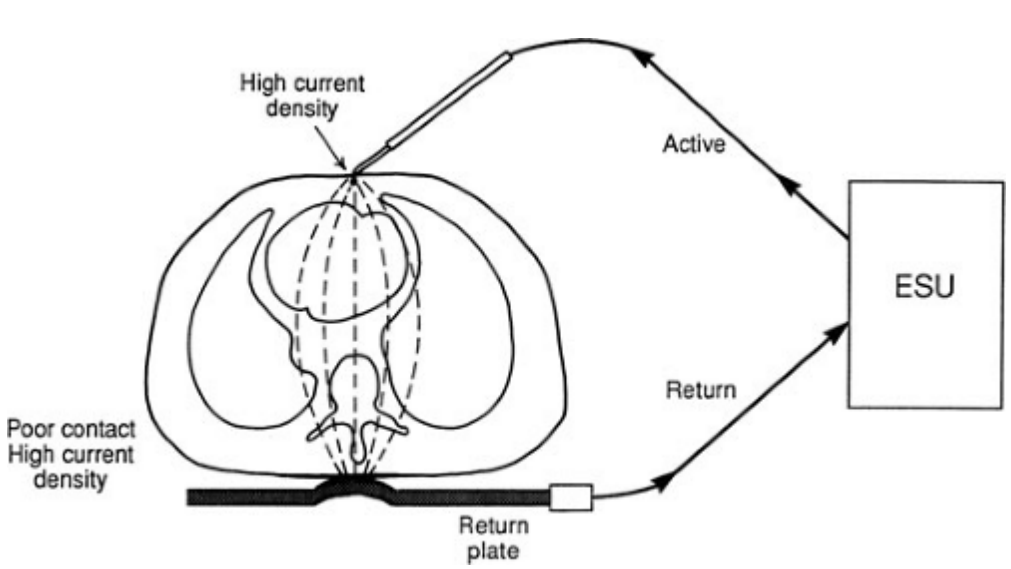

FIGURE 8-34. An improperly applied ESU return plate. Poor contact with the return plate results in a high current density and a possible burn to the patient.

The original ESUs were manufactured with the power supply connected directly to ground by the equipment ground wire. These devices made it extremely easy for ESU current to return by alternate pathways. The ESU would continue to operate normally even without the return plate connected to the patient. In most modern ESUs, the power supply is isolated from

ground to protect the patient from burns. It was hoped that by isolating the return pathway from ground, the only route for current flow would be via the return electrode. Theoretically, this would eliminate alternate return pathways and greatly reduce the incidence of burns.[5] However, Mitchell found two situations in which the current could return via alternate pathways, even with the isolated ESU circuit.[42] If the return plate were left either on top of an uninsulated ESU cabinet or in contact with the bottom of the operating room table, then the ESU could operate fairly normally and the current would return via alternate pathways. It will be recalled that the impedance is inversely proportional to the capacitance times the current frequency. The ESU operates at 500,000 to >1,000,000 Hz, which greatly enhances the effect of capacitive coupling and causes a marked reduction in impedance. Therefore, even with isolated ESUs, the decrease in impedance allows the current to return to the ESU by alternate pathways. In addition, the isolated ESU does not protect the patient from burns if the return electrode does not make proper contact with the patient. Although the isolated ESU does provide additional patient safety, it is by no means foolproof protection against the patient receiving a burn.

Preventing patient burns from the ESU is the responsibility of all professional staff in the operating room. Not only the circulating nurse, but also the surgeon and the anesthesiologist must be aware of proper techniques and be vigilant to potential problems. The most important factor is the proper application of the return plate. It is essential that the return plate have the appropriate amount of electrolyte gel and an intact return wire. Reusable return plates must be properly cleaned after each use, and disposable plates must be checked to ensure that the electrolyte has not dried out during storage. In addition, it is prudent to place the return plate as close as possible to the site of the operation. ECG pads should be placed as far from the site of the operation as is feasible. Operating room personnel must be alert to the possibility that pools of flammable “prep” solutions such as ether and acetone can ignite when the ESU is used. If the ESU must be used on a patient with a demand pacemaker, the return electrode should be located below the thorax, and preparations for treating potential dysrhythmias should be available, including a magnet to convert the pacemaker to a fixed rate, a defibrillator, and an external pacemaker. The ESU has also caused other problems in patients with pacemakers, including reprogramming and microshock.[43,44] If the surgeon requests higher than normal power settings on the ESU, this

should alert both the circulating nurse and the anesthesiologist to a potential problem. The return plate and cable must be immediately inspected to ensure that it is functioning and properly positioned. If this does not correct the problem, the return plate should be replaced. If the problem remains, the entire ESU should be taken out of service. Finally, an ESU that is dropped or damaged must be removed immediately from the operating room and thoroughly tested by a qualified biomedical engineer. Following these simple safety steps will prevent most patient burns from the ESU.

The previous discussion concerned only *unipolar* ESUs. There is a second type of ESU, in which the current passes only between the two blades of a pair of forceps. This type of device is referred to as a *bipolar* ESU. Because the active and return electrodes are the two blades of the forceps, it is not necessary to attach another dispersive electrode to the patient, unless a unipolar ESU is also being used. The bipolar ESU generates considerably less power than the unipolar and is mainly used for ophthalmic and neurologic surgery.[2]

In 1980 Mirowski et al[45] reported the first human implantation of a device to treat intractable ventricular tachyarrhythmias. This device, known as the *automatic implantable cardioverter-defibrillator* (AICD), is capable of sensing ventricular tachycardia (VT) and ventricular fibrillation (VF) and then automatically defibrillating the patient. Since 1980 thousands of patients have received AICD implants.[46,47] Because some of these patients may now present for noncardiac surgery, it is important that the anesthesiologist be aware of potential problems.[48] The use of a unipolar ESU may cause electrical interference that could be interpreted by the AICD as a ventricular tachyarrhythmia. This would trigger a defibrillation pulse to be delivered to the patient and would likely cause an actual episode of VT or VF. The patient with an AICD is also at risk for VF during electroconvulsive therapy.[48] In both cases, the AICD should be disabled by placing a magnet over the device. Although most AICDs can be disabled with a magnet, some require a special device or specific magnet to shut them off. Therefore, it is best to consult with someone experienced with the device before starting surgery. The device can be reactivated by reversing the process. Also, an external defibrillator and a noninvasive pacemaker should be in the operating room whenever a patient with an AICD is anesthetized.

Electrical safety in the operating room is a matter of combining common sense with some basic principles of electricity. Once operating room personnel understand the importance of safe electrical practice, they are able to develop a heightened awareness to potential problems. All electrical equipment must undergo routine maintenance, service, and inspection to ensure that it conforms to designated electrical safety standards. Records of these test results must be kept for future inspection because human error can easily compound electrical hazards. Starmer et al[49] cited one case concerning a newly constructed laboratory where the ground wire was not attached to a receptacle. In another study Albisser et al[50] found a 14% (198/1,424) incidence of improperly or incorrectly wired outlets. Furthermore, potentially hazardous situations should be recognized and corrected before they become a problem. For instance, electrical power cords are frequently placed on the floor where they can be crushed by various carts or the anesthesia machine. These cords could be located overhead or placed in an area of low traffic flow. Multiple-plug extension boxes should not be left on the floor where they can come in contact with electrolyte solutions. These could easily be mounted on a cart or the anesthesia machine. Pieces of equipment that have been damaged or have obvious defects in the power cord must not be used until they have been properly repaired. If everyone is aware of what constitutes a potential hazard, dangerous situations can be prevented with minimal effort.

Sparks generated by the ESU may provide the ignition source for a fire with resulting burns to the patient and operating room personnel. This is a particular risk when the ESU is used in an oxygen-enriched environment as may be present in the patient's airway or in close proximity to the patient's face. Most plastics such as tracheal tubes and components of the anesthetic breathing system that would not burn in room air will ignite in the presence of oxygen and/or nitrous oxide. Tenting of the drapes to allow dispersion of any accumulated oxygen and/or its dilution by room air or use of a circle anesthesia breathing system with minimal to no leak of gases around the anesthesia mask will decrease the risk of ignition from a spark generated by a nearby ESU.

CONDUCTIVE FLOORING

Conductive flooring was mandated for operating rooms where flammable anesthetic agents were being administered. The conductive floor was specified to have a resistance of between 25,000 and 1 million ohms. This would minimize the buildup of static charges that could cause a flammable anesthetic agent to ignite. The standards have been changed to eliminate the necessity for conductive flooring in anesthetizing areas where flammable agents are no longer used.

ENVIRONMENTAL HAZARDS

There are a number of potential electrically related hazards in the operating room that are of concern to the anesthesiologist. There is the potential for electrical shock not only to the patient but also to operating room personnel. In addition, cables and power cords to electrical equipment and monitoring devices can become hazardous. Finally, all operating room personnel should have a plan of what to do in the event of a power failure.

In today's operating room, there are literally dozens of pieces of electrical equipment. It is not uncommon to have numerous power cords lying on the floor, where they are vulnerable to damage. If the insulation on the power cable becomes damaged, it is fairly easy for the hot wire to come in contact with a piece of metal equipment. If the operating room did not have isolated power, that piece of equipment would become energized and a potential electrical shock hazard.[51] Having isolated power minimizes the risk to the patient and operating room personnel. Clearly, getting electrical power cords off the floor is desirable. This can be accomplished by having electrical outlets in the ceiling or by having ceiling-mounted articulated arms that contain electrical outlets. Also, the use of multioutlet extension boxes that sit on the floor can be hazardous. These can be contaminated with fluids, which could easily trip the circuit breaker. In one case, it apparently tripped the main circuit breaker for the entire operating room, resulting in a loss of all electrical power except for the overhead lights.[52]

Modern monitoring devices have many safety features incorporated into them. Virtually all of them have isolated the patient input from the power supply of the device. This was an important feature that was lacking from the original ECG monitors. In the early days, patients could actually become part of the electrical circuit of the monitor. There have been relatively few problems with patients and monitoring devices since the advent of isolated inputs. However, between 1985 and 1994, the Food and Drug Administration (FDA) received approximately 24 reports where infants and children had received an electrical shock including five children who died by electrocution.[53,54] These electrical accidents occurred because the electrode lead wires from either an ECG monitor or an apnea monitor were plugged directly into a 120-volt electrical outlet instead of the appropriate patient cable. In 1997, the FDA issued a new performance standard for electrode lead wires and patient cables that requires that the exposed male connector pins from the electrode lead wires must be eliminated. Therefore, the lead wires must have female connections and the connector pins must be housed in a protected patient cable (Fig. 8-35). This effectively eliminates the possibility of the patient being connected directly to an alternating current source since there are no exposed connector pins on the lead wires.

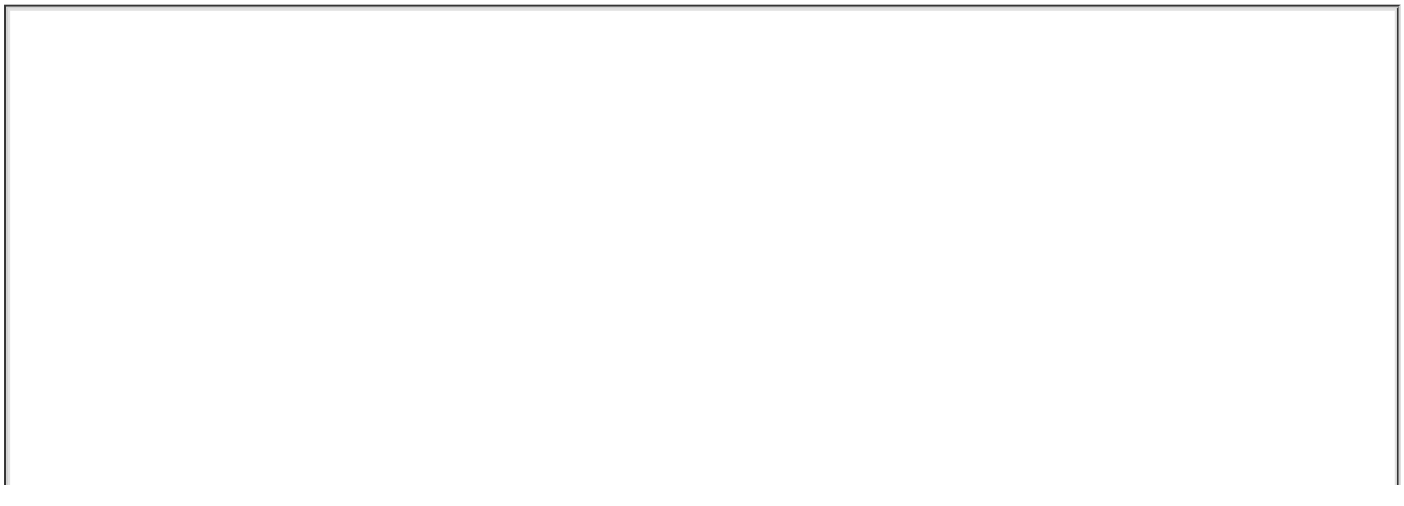

FIGURE 8-35. The current standard for patient lead wires (*left*) requires a female connector. The patient cable (*right*) has shielded connector pins that the lead wires plug into.

All health care facilities are required to have a source of emergency power. This generally consists of one or more electrical generators. These generators are configured to start up automatically and provide power to the facility within a few seconds after detecting the loss of power from the utility company. The facility is required to test these generators on a regular basis. However, not all health care facilities test them under actual load. There are numerous anecdotal reports of generators not functioning properly during an actual power failure. If the generators are not tested under actual load, it is possible that many years will pass before a real power outage puts a severe demand on the generator. If the facility has several generators and one of them fails, the increased demand on the others may be enough to cause them to fail in rapid succession.

Other situations may also cause unexpected power outages. In our facility, a construction crew was remodeling an existing operating room. They accidentally caused a short circuit in the power supply when they were working on an electrical panel. This caused the GFI in the basement to trip, thus shutting off power to a whole section of the operating room. Consequently, several operating rooms were suddenly without power at crucial junctures in surgery. The operating room personnel were waiting for the emergency generators to come on. Obviously, this was not going to happen because there was no interruption of power from the electrical utility. It took approximately 20 to 30 minutes until the source of the problem could be identified and corrected.

It is vitally important that each operating room have a contingency plan for a power failure. In most cases, the emergency generator will take over, but that is not always going to happen. There should be a supply of battery-operated light sources available in each operating room. A laryngoscope can serve as a readily available source of light that allows one to find flashlights and other pieces of equipment. The operating room's overhead lights should also be connected to some sort of battery-operated lighting system. A supply of battery-operated monitoring devices and pneumatically powered ventilators and anesthesia machines would enable life-support functions to continue. The cost of these contingencies is relatively small but the benefits can be incomparably great in an emergency.

ELECTROMAGNETIC INTERFERENCE (EMI)

Rapid advances in technology have led to an explosion in the number of wireless communication devices in the marketplace. These devices include cellular telephones, cordless telephones, walkie-talkies, and even wireless Internet access devices. All of these devices have something in common: they emit EMI. This most commonly manifests itself when traveling on airplanes. Most airlines require that these devices be turned off when the plane is taking off or landing or, in

some cases, during the entire flight. There is concern that the EMI emitted by these devices may interfere with the plane's navigation and communication equipment.

In recent years, the number of people who own these devices has increased exponentially. Indeed, in some hospitals, they form a vital link in the regular or emergency communication system. It is not uncommon for physicians, nurses, paramedics, and other personnel to have their own cellular telephones. In addition, patients and visitors may also have cellular telephones and other types of communication devices. Hospital maintenance and security personnel frequently have walkie-talkie–type radios and some hospitals have even instituted an in-house cellular telephone network that augments or replaces the paging system. There has been concern that the

EMI emitted by these devices may interfere with implanted pacemakers or various types of monitoring devices in critical care areas.

Several studies have been done to find out if cellular telephones cause problems with cardiac pacemakers. One study by Hayes et al looked at 980 patients with five different types of cellular telephones.[55] They conducted more than 5,000 tests and found that in more than 20% of the cases they could detect some interference from the cellular telephone. Patients were symptomatic in 7.2% of the cases, and clinically significant interference occurred in 6.6% of the cases. When the telephone was held in the normal position over the ear, clinically significant interference was not detected. In fact, the interference that caused clinical symptoms occurred only if the telephone was directly over the pacemaker. Other studies have demonstrated changes such as erroneous sensing and pacer inhibition.[56,57] Again, these occurred only when the telephone was close to the pacemaker. The changes were temporary, and the pacemaker reverted to normal when the cellular telephone was moved to a safe distance. Currently, the FDA guidelines are that the cellular telephones be kept at least 6 inches from the pacemaker. Therefore, the cellular telephone should not be carried in the shirt pocket, which is adjacent to the pacemaker.

Automatic implantable cardioverter-defibrillators comprise another group of devices of concern to biomedical engineers. Fetter et al conducted a study of 41 patients who had AICDs.[58] They had a 0% incidence of oversensing and concluded that the cellular telephones did not interfere with the AICDs that they tested. They did, however, recommend keeping the cellular telephone at least 6 inches from the device.

Electromagnetic interference extends well beyond that of cellular telephones. Walkie-talkies, which are frequently used by hospital maintenance and security personnel; paging systems; police radios; and even televisions all emit EMI, which could potentially interfere with medical devices of any nature. Although there are many anecdotal reports, the amount of available scientific information on this problem is scanty. Reports of interference include ventilator and infusion pumps that have been shut down or reprogrammed, interference with ECG monitors, and even an electronic wheelchair that was accidentally started because of EMI. It is a difficult problem to study because there are many different types of devices that emit EMI and a vast array of medical equipment that has the potential to interact with these devices. Even though a device may seem “safe” in the medical environment, if two or three cellular telephones or walkie-talkies are brought together in the same area at the same time, there may be unanticipated problems or interference.

Any time a cellular telephone is turned on, it is actually communicating with the cellular network, even though a call is not in progress. Therefore, the potential to interfere with devices exists. The Emergency Care Research Institute (ECRI) reported in October 1999 that walkie-talkies were far more likely to cause problems with medical devices than cellular telephones.[59] This is because they operate on a lower frequency than cellular telephones and have a higher power output. The ECRI recommends that cellular telephones be maintained at a distance of 1 meter from medical devices, while walkie-talkies be kept at a distance of 6 to 8 meters.

Some hospitals have made restrictive policies on the use of cellular telephones, particularly in critical care areas.[60] These policies are supported by little scientific documentation and are nearly impossible to enforce. The ubiquitous presence of cellular telephones carried by hospital personnel and visitors makes enforcing a ban virtually impossible. Even when people try to comply with the ban, failure is nearly inevitable because the general public is usually unaware that a cellular

telephone in the standby mode is still communicating with the tower and generating EMI.

The real solution is to “harden” devices against electromagnetic interference. This is difficult to do because of the many different frequencies on which these devices operate. Education of medical personnel is essential. When working in an operating room or critical care area, all personnel must be alert to the fact that electronic devices and pacemakers can be interfered with by EMI. Creating a restrictive policy would certainly irritate personnel and visitors, and, in some cases, may actually compromise emergency communications.[61]

CONSTRUCTION OF NEW OPERATING ROOMS

Frequently, an anesthesiologist is asked to consult with hospital administrators and architects in designing new, or remodeling older, operating rooms. In the past a strict electrical code was enforced because of the use of flammable anesthetic agents. This code included a requirement for isolated power systems and LIMs. The National Fire Protection Association (NFPA) revised its standard for health care facilities in 1984 (NFPA 99-1984). These standards do not require isolated power systems or LIMs in areas designated for use of nonflammable anesthetic agents only.[62,63] Although not mandatory, NFPA standards are usually adopted by local authorities when revising their electrical codes.

This change in the standard creates a dilemma. The NFPA 99—Standard for Health Care Facilities, 1990 Edition, mandates that “wet location patient care areas be provided with special protection against electrical shock.” Section 3-4.1.2.6 further states that “this special protection shall be provided by a power distribution system that inherently limits the possible ground fault current due to a first fault to a low value, without interrupting the power supply; or by a power distribution system in which the power supply is interrupted if the ground fault current does, in fact, exceed a value of 6 milliamperes.”

The decision of whether to install isolated power hinges on two factors. The first is whether or not the operating room is considered a wet location, and, if so, whether an interruptible power supply is tolerable. Where power interruption is tolerable, a GFCI is permitted as the protective means. However, the standard also states that “the use of an isolated power system (IPS) shall be permitted as a protective means capable of limiting ground fault current without power interruption.”

Most people who have worked in an operating room would attest to its being a wet location. The presence of blood, body fluids, and saline solutions spilled on the floor all contribute to making this a wet environment. The cystoscopy suite serves as a good example.

Once the premise that the operating room is a wet location is accepted, it must be determined whether a GFCI can provide the means of protection. The argument against using GFCIs in the operating room is illustrated by the following example. Assume that during an open heart procedure the cardiopulmonary bypass pump and the patient monitors are plugged into outlets on the same branch circuit. Also assume that during bypass, the circulating nurse now plugs in a faulty headlight. If there is a GFCI protecting the circuit, the fault will be detected and the GFCI will interrupt all power to the pump and the monitors. This undoubtedly would cause a great deal of confusion and consternation among the operating room personnel and may place the patient at risk for injury. The pump would have to be manually operated while the problem was being resolved. In addition, the GFCI could not be reset (and power restored) until the headlight was identified as the cause of the fault and unplugged from the outlet. However, if the operating room were protected with an isolated power system and LIM, the same scenario would cause the LIM to alarm, but the pump and

patient monitors would continue to operate normally. There would be no interruption of power, and the problem could be resolved without risk to the patient.

It should be realized that a GFCI is an active system. That is, a potentially hazardous current is already flowing and must be actively interrupted, whereas the isolated power system (with LIM) is designed to be safe during a first-fault situation. Thus, it is a passive system because no

mechanical action is required to activate the protection.[64]

It is likely that hospital administrators may want to eliminate isolated power systems in new operating room construction as a cost-saving measure. Others,[64,65,66] however, have advocated the retention of isolated power systems. Not to do this would be a short-sighted, foolhardy measure. This is especially true because the cost of adding isolated power is estimated to be 1% of the cost of constructing an operating room.[64] Although not perfect,[67] the isolated power system and LIM do provide both the patient and operating room personnel with a significant amount of protection in an electrically hazardous environment. The value of the isolated power system is illustrated in a report by Day in 1994.[68] He reported four instances of electrical shock to operating room personnel in a 1-year period. The operating suite had been renovated and the isolated power system removed, and it was not until the operating room personnel received a shock that a problem was discovered.

Anesthesiologists need to be aware of this cost-saving attitude and strongly encourage that new operating rooms be constructed with isolated power systems. The relatively small cost savings that the alternative would represent do not justify the elimination of such a useful safety system, and the use of GFCIs is not practical in the operating room environment.

Electrical safety should be the concern of everyone in the operating room. Accidents can be prevented only if proper installation and maintenance of the appropriate safety equipment in the operating room have occurred and the operating room personnel understand the concepts of electrical safety and are vigilant in their efforts to detect new hazards.[69]

FIRE SAFETY

10 Fires in the operating room are just as much a danger today as they were 100 years ago when patients were anesthetized with flammable anesthetic agents.[70,71] For more than 100 years, the practice of anesthesia throughout the world involved the use of flammable and explosive inhalational anesthetics such as ether and cyclopropane. It is only in the last 30 to 40 years that these agents have been phased out of use in the developed countries. Of the early inhalational anesthetics, only nitrous oxide was nonflammable, yet it is similar to oxygen in that it can readily support combustion. Since the potential consequences of a fire or explosion with ether or cyclopropane could be so devastating, everyone who worked in the operating room actively observed fire safety practices on a daily basis.[72,73]

Today, the risk of an operating room fire is probably as great or greater than the days when ether and cyclopropane were used. This is because of the routine use of potential sources of ignition (such as electrosurgical cauteries and fiberoptic light sources) in an environment rich in flammable materials (i.e., fuels). The problem is compounded by a markedly decreased awareness of the potential for an operating room fire. With the possible exception of laser surgery in or around the airway, there is rarely any special attention paid to fire safety. However, ESUs, and not lasers, are probably responsible for starting the majority of operating room fires. In fact, ESUs were implicated in the vast majority of the 146 device-associated surgical fires reported to the FDA between January 1995 and June 1998.[74]

11 For a fire to start, three elements are necessary. This is called the *Fire Triad*. The first part of the triad is a heat or ignition source, the second part is fuel, and the third part is an oxidizer.[75] A fire occurs when there is a chemical reaction of a fuel rapidly combining with an oxidizer to release energy in the form of heat and light. In the operating room there are many heat or ignition sources and these include the ESU, lasers, electrical tools such as drills, and the ends of fiberoptic light cords. The main oxidizers in the operating room are air, oxygen, and nitrous oxide. Oxygen and nitrous oxide function equally well as oxidizers, so a combination of 50% oxygen and 50% nitrous oxide would support combustion as well as 100% oxygen. Fuel for a fire can be found everywhere in the operating room. Paper drapes have largely replaced cloth drapes and these are much easier to ignite and they can burn with greater intensity.[76,77] Other sources of fuel include gauze dressings, endotracheal (ET) tubes, gel mattress pads, and even facial or body hair[78] (Table 8-3).

TABLE 8-3 Fuel Sources Commonly Found in the Operating Room

- "Prep" Agents
  - Alcohol
  - Degreasers (acetone, ether)
  - Adhesives (tincture of benzoin, Aeroplast™)
  - Chlorhexidine digluconate (Hibitane™)
  - Iodophor (Dura-Prep™)
- Drapes and Covers
  - Patient drapes (paper, plastic, cloth)
  - Equipment drapes (paper, plastic, cloth)
  - Blankets and sheets
  - Pillows, mattresses, and padding
  - Gowns
  - Masks
  - Shoe covers
  - Gloves (latex, nonlatex)
  - Clothing
  - Compression (anti-embolism) stockings
- Patient
  - Hair
  - Alimentary tract gases (methane, hydrogen)
  - Desiccated tissue
- Dressings
  - Gauze and sponges
  - Petrolatum-impregnated dressings
  - Xeroform™
  - Adhesive tape (cloth, plastic, paper)
  - Elastic bandages
  - Stockinettes
  - Sutures
  - Steri-Strips
  - Collodion
- Ointments
  - Petrolatum
  - Antibiotics (bacitracin, neomycin, polymyxin B)
  - Nitropaste (Nitro-Bid™)
  - EMLA™
  - Lip balms
- Anesthesia Equipment
  - Breathing circuit hoses
  - Masks
  - Endotracheal tubes
  - Oral and nasal airways
  - Laryngeal mask airways
  - Nasogastric tubes
  - Suction catheters and tubing
  - Scavenger hoses
  - Volatile anesthetics
  - CO_2 absorbers
  - Intravenous tubing
  - Pressure monitor tubing and plastic transducers

Other Equipment
- Charts and records
- Cardboard, wooden, and particleboard boxes and cabinets
- Packing materials [cardboard, expanded polystyrene (Styrofoam™)]
- Fiberoptic cable covers
- Wire covers and insulation
- Fiberoptic endoscope coverings
- Sphymomanometer cuffs and tubing
- Pneumatic tourniquet cuffs and tubing
- Stethoscope tubing
- Vascular shunts (Gore-tex™, Dacron™)
- Dialysis and extracorporeal circulation circuits
- Wound drains and collection systems
- Mops and brooms
- Textbooks and instruction manuals

Fire prevention is accomplished by not allowing all three of the elements to come together at the same time.[79] The problem in the operating room is that frequently each of the limbs of the fire triad is controlled by a different individual. For instance, the surgeon is frequently in charge of the ignition source, the anesthesiologist is usually administering the oxidizer, and the OR nurse frequently controls the fuel sources. It is not always evident to any one individual that all of these elements may be coming together at the same time. This is especially true in any case where there is the possibility of oxygen or an oxygen–nitrous oxide mixture being delivered around the surgical site. In these circumstances, the risk of an OR fire is markedly increased and the need for communication among the surgeon, the anesthesiologist, and the OR nurses is especially important.

There are several dangers that may result from an operating room fire. The most obvious is that the patient and operating room personnel can suffer severe burns. However, a less obvious but potentially more deadly risk can be posed by the products of combustion (called “toxicants”). When materials, especially plastics, are burned, a variety of injurious compounds can be produced. These include carbon monoxide, ammonia, hydrogen chloride, and even cyanide. Toxicants can produce injury by damaging airways and lung tissue, and can cause asphyxia. Operating room fires can often produce significant amounts of smoke and toxicants, but may not cause enough heat to activate overhead sprinkler systems. If enough smoke is produced, the operating room personnel may have to evacuate the operating room. Thus, it is essential to have a prearranged evacuation plan for both the OR personnel and the patient.

Operating room fires can be divided into two different types. The more common type of fire occurs *in* or *on* the patient. These would include endotracheal tube fires, fires during laparoscopy or bronchoscopy, or a fire in the oropharynx, which may occur during a tonsillectomy Fires occurring on the patient mainly involve head and neck surgery done under regional anesthesia or monitored anesthesia care when the patient is receiving high flows of supplemental oxygen via a face mask or nasal prongs. Since these fires occur in an oxygen-enriched environment, items such as surgical towels, drapes, or even the body hair can be readily ignited and produce a severe burn (Fig. 8-36). The other type of operating room fire is one that is remote from the patient. This would include an electrical fire in a piece of equipment or a CO_2 absorber fire.

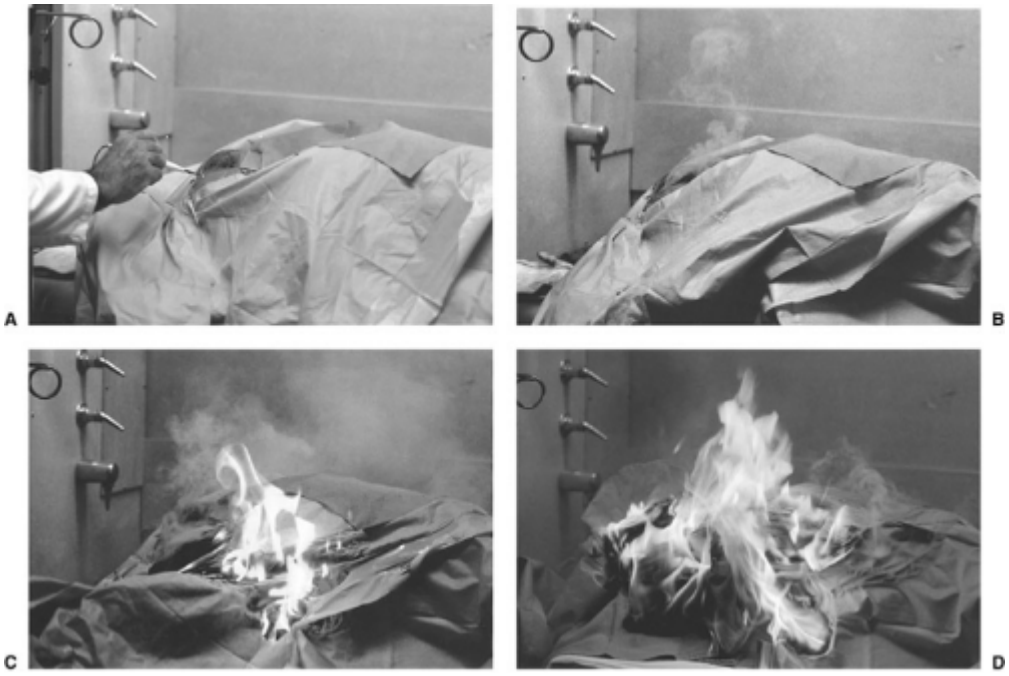

FIGURE 8-36. Simulation of fire caused by electrode during surgery. **A.** Mannequin prepared and draped for surgery. Electrosurgical unit monopolar pencil electrode applied to operative site at start of surgery. **B.** Six seconds after electrosurgical unit application. Smoke appears from under the drapes. **C.** Fourteen seconds after electrosurgical unit application. Flames burst through the drapes. **D.** Twenty-four seconds after electrosurgical unit application. Entire patient head and drapes in flames. (From Barker SJ, Polson JS. Fire in the operating room: A case report and laboratory study. Anesth Analg 93:960–965, 2001, with permission.)

12 Although major ignition sources for OR fires are the ESU and the laser, the ends of some fiberoptic light cords can also become hot enough to start a fire if they are placed on paper drapes. And although the ESU is responsible for igniting the majority of the fires,[74] it is the laser that has generated the most attention and research. Laser is the acronym that stands for *l*ight *a*mplification by *s*timulated *e*mission of *r*adiation. A laser consists of an energy source and material that the energy

excites to emit light.[80,81,82] The material that the energy excites is called the “lasing medium” and provides the name of the particular type of laser. The important property of laser light is that it is coherent, meaning that is monochromatic (or even of a single wavelength). This coherent light can be focused into very small spots that have very high power density.

There are many different types of medical lasers, and each has a specific application. The *argon laser* is used in eye and dermatologic procedures, as it is absorbed by hemoglobin and has a modest tissue penetration of between 0.05 and 2.0 mm. The potassium-titanyl-phosphate (KTP) or frequency-doubled *yttrium aluminum garnet* (YAG) lasers are also absorbed by hemoglobin and have tissue penetrations similar to that of the argon laser. The *Dilaser* has a wavelength that is easily changed and can be used in different applications, particularly in dermatologic procedures. The *neodymium-doped yttrium aluminum garnet* (Nd-YAG) laser is the most powerful of the medical lasers. Since the tissue penetration is between 2 and 6 mm, it can be used for tumor debulking, particularly in the trachea and main-stem bronchi, or in the upper airway. The energy can be transmitted through a fiberoptic cable that is placed down the suction port of a fiberoptic bronchoscope. The laser can then be used in a contact mode to treat a tumor mass. The *carbon dioxide* (CO_2) laser has very little tissue penetration and can be used where great precision is needed. It is also absorbed by water, so that minimal heat is dispersed to surrounding tissues. The CO_2 laser is used primarily for procedures in the oropharynx and in and around the vocal

cords. The *helium-neon* laser (He-Ne) produces an intense red light and thus can be used for aiming the CO_2 and the Nd-YAG lasers. It has very low power and thus will present no significant danger to OR personnel.

One of the most devastating types of OR fires occurs when an endotracheal tube is ignited *in* the patient.[83,84,85,86,87,88] If the patient is being ventilated with oxygen and/or nitrous oxide, the endotracheal tube will essentially emit a blowtorch type of flame that can result in severe injury to the trachea, lungs, and surrounding tissues. In 1987 Wolf and Simpson showed that red rubber, polyvinyl chloride, and silicone endotracheal tubes all have oxygen flammability indices (defined as "the minimum O_2 fraction in N_2 that will just support a candle-like flame for a given fuel source using a standard ignition source") of less than 26%.[89] Because these tubes will combust at such low concentrations of oxygen, they are not the best choice when using lasers or electrocautery in or around the airway.

To prevent airway fires and their potentially devastating consequences, "laser-resistant" endotracheal tubes have been developed.[90,91,92] Before the advent of these tubes, anesthesiologists often wrapped red rubber or polyvinyl chloride tubes with some sort of reflective tape. Today, this practice is discouraged because taped-wrapped tubes can be easily kinked, gaps in the tape can expose areas of the tube to the laser, and nonlaser-resistant tape might be unintentionally used. Instead, anesthesiologists are encouraged to use an endotracheal tube that is designed to be resistant to the specific laser that will be used during surgery. For instance, when using the carbon dioxide laser, the LaserFlex™ (Mallinckrodt, Pleasanton, CA) is an excellent choice. This is a flexible metal tube that has two cuffs that can be inflated with saline colored with methylene blue. The methylene blue enables the surgeon to easily recognize if he or she has accidentally penetrated one of the cuffs. The LaserFlex™ tube is highly resistant to being struck by the laser. If the Nd-YAG laser is being used, then the Lasertubus™ (Rüsch Inc., Duluth, GA) can be used. The Lasertubus™ has a soft rubber shaft that is covered by a corrugated silver foil, which is, in turn, covered in a Merocel™ sponge jacket. To provide maximum protection, the Merocel™ must be kept moist with saline. If everything is done properly, the tube will resist ignition even with several strikes from the laser.

As previously stated the ESU is a frequent ignition source for an OR fire.[93,94] A typical example of how an ESU could cause ignition would be during a tonsillectomy in a child where the anesthesiologist was using an uncuffed, flammable endotracheal tube. In this case, the oxygen or oxygen–nitrous oxide mixture could leak around the endotracheal tube and pool at the operative site, providing an oxygen-enriched environment. When the surgeon uses the ESU (or laser) to cauterize the tonsil bed, the combination of high concentration of oxidizer (oxygen or oxygen–nitrous oxide mixture), fuel (endotracheal tube), and ignition source (the ESU) could easily start a fire.[95,96]

The best way to prevent this type of fire is to take steps to prevent the three legs of the fire triad from coming together. For example, mixing the oxygen with air to keep the inspired oxygen concentration as low as possible, thus reducing the available oxidizer. Another possibility would be to place wet pledgets around the endotracheal tube, which would prevent the escape of oxygen or oxygen–nitrous oxide mixture from the trachea into the operative field. This reduces the available oxidizer and would keep the endotracheal tube and tissues from becoming desiccated, thus reducing their suitability as fuel sources. However, the pledgets must be kept moist, or they will dry out and become an additional source of fuel for a fire.

A related situation that requires a different solution can arise when a critically ill patient requires a tracheostomy.[97,98] These patients may require very high concentrations of inspired oxygen to maintain tissue oxygenation, so that any decrease in F_iO_2 or interruption of ventilation would not be tolerated. In this circumstance, the best option for preventing a fire would be to avoid the use of electrocautery (ignition source) when opening the trachea.

The Nd-YAG laser can be used to treat tumors of the lower trachea and main-stem bronchi. Most commonly, the surgeon will use a fiberoptic bronchoscope (FOB) and pass the laser fiber through the suction port of the bronchoscope. The FOB can be used in conjunction with a rigid metal

bronchoscope or passed through an 8.5 or 9.0 mm polyvinyl chloride (PVC) endotracheal tube. A special laser resistant tube would not be used in this circumstance, because the FOB and laser fiber pass through the endotracheal tube and focus on tissue distal to the tube. Fire safety precautions available in this setting include titrating the concentration of inspired oxygen to as low as the patient can tolerate while maintaining a saturation of between 90 and 95% (ideally keeping the inspired oxygen below 30%), keeping the tip of the endotracheal tube and FOB away from the site of surgery and out of the “line of fire” of the laser, and removing charred and desiccated tissue from the surgical field. The use of a rigid metal bronchoscope instead of an endotracheal tube will eliminate the possibility of setting the tube on fire but does not eliminate the possibility of setting the fiberoptic bronchoscope on fire. This would also necessitate the use of a jet venturi system to ventilate the patient, which would, in turn, deliver oxygen at a concentration between 40 and 60%.

There are a number of basic safety precautions that should be taken whenever a laser is used in surgery. Since laser light can be reflected off any metal surface, it is important that all OR personnel wear protective goggles that are specific to the type of laser being used. The anesthesiologist needs to be aware that the laser goggles may make it difficult to read certain monitor displays. In addition, it is important that the patient's eyes be covered with wet gauze or eye packs. Operating room personnel should also wear high-filtration masks since the laser “plume” may contain vaporized virus particles or chemical toxins. Finally, all doors to the OR should have warning signs that a laser is in use, and all windows should be covered with black window shades.

Laparoscopic surgery in the abdomen is another potential risk for a fire in the patient. In 1993, Newman et al showed that nitrous oxide administered to the patient as part of their anesthetic can, over 30 minutes, diffuse into the abdominal cavity and attain a level that could support combustion.[99] In fact, when sampling the abdominal gas contents after 30 minutes, the mean nitrous oxide concentration was 36%; however, in certain patients it reached a concentration of 47%. Both methane and hydrogen are flammable gases that are frequently present in bowel gas in significant concentrations. Methane concentration in bowel gas can be up to 56% and hydrogen has been reported as high as 69%. With the maximum abdominal concentration of 47% nitrous oxide mixed with carbon dioxide, it would require the maximum of 56% of methane to be flammable. Therefore, this represents a relatively small hazard. In contrast, a concentration of 69% hydrogen is flammable if the nitrous oxide concentration is greater than 29%. Therefore, a fire is possible if the surgeon, while using the ESU, enters the bowel with a high concentration of hydrogen, and the intra-abdominal nitrous oxide content is greater than 29%.

Today, it is routine to use carbon dioxide to inflate the abdomen during laparoscopic surgery. Carbon dioxide is an excellent choice as it does not support combustion. However, a serious fire risk could occur if a mixture of carbon dioxide and oxygen was accidentally substituted for the carbon dioxide cylinder. Greilich reported such a case in 1995 in which the abdomen was inflated using a tank containing 14% carbon dioxide and 86% oxygen.[100] A flash fire occurred when the surgeon used the ESU. This was possible because all tanks with a CO_2 concentration greater than 7% have the same pin index as a tank with 100% CO_2.

In recent years, fires *on* the patient seem to have become the most frequent type of OR fire. These cases occur most often during surgery in and around the head and neck where the patient is receiving monitored anesthesia care (MAC) and supplemental oxygen is being administered by either a face mask or nasal cannula.[101,102,103,104,105] In these cases, the oxygen can collect under the drapes if not properly vented, and when the surgeon uses the ESU or the laser, a fire can easily start. There are many things that can act as fuel such as the surgical towels, paper drapes, disinfecting “prep” solutions, sponges, plastic tubing from the oxygen face mask, and even the body hair. These fires start very quickly and in only a few seconds can turn into an intense blaze. Even if the fire is quickly extinguished, the patient will usually sustain a significant burn.

The most important principle that the anesthesiologist has to keep in mind is to titrate the inspired oxygen concentration to a level that is low, yet safe for the patient. Oxygen should be

treated just as any other drug and should be administered to provide optimum benefits and minimal side effects. If the anesthesia machine has the ability to deliver air, then the nasal cannula or face mask can be attached to the anesthesia circuit by using a small #3 or #4 15-mm ET tube adapter. This is attached to the right angle elbow of the circuit. If the anesthesia machine is equipped with an auxiliary oxygen flowmeter that has a removable nipple adaptor, then a humidifier can be installed in place of the nipple adaptor. The humidifier has a Venturi mechanism through which room air is entrained and thus the oxygen concentration that is delivered to the face mask can be varied from 28 to 100%. Finally, if this machine has a common gas outlet that is easily accessible, then a nasal cannula or face mask can be attached at this point using the same small 3- or 4-mm endotracheal tube adaptor. If it is not possible to dilute the oxygen with air, then it is important that the drapes be arranged in such a manner that there is no oxygen buildup beneath them. Tenting the drapes and having the surgeon use an adhesive sticky drape that seals the operative site from the oxygen flow are steps that will help reduce the risk of a fire.

It is potentially possible to discontinue the use of oxygen before the surgeon plans to use the ESU or laser. This would have to be done several minutes beforehand to allow any oxygen that has built up to dissipate. If the surgeon is planning to use the ESU or laser during the entire case, then this may not be practical.

In recent years, newer surgical prep solutions have been introduced into the OR. These typically come prepackaged in a “paint stick” applicator with a sponge on the end. DuraPrep™ is one of these prep solutions. It consists of Iodophor™ mixed with isopropyl alcohol. The concentration of alcohol in this solution is 74%, which is highly flammable and can easily be the fuel for an OR fire. In 2001, Barker and Polson reported just such a case.[101] In a laboratory re-creation of the case, he found that if the DuraPrep™ had been allowed to dry completely (4 to 5 minutes), then the fire did not occur. The other problem with these types of prep solutions is that small pools of the solution can accumulate if the person doing the prep is not careful. The alcohol in these small puddles will continue to evaporate for a period of time and the alcohol vapors are also extremely flammable.

It is important to bear in mind that halogenation of hydrocarbon anesthetics confers relative, but not absolute, resistance to combustion. Even the newer, “nonflammable” volatile anesthetics can, under certain circumstances, present fire hazards. For example, sevoflurane is nonflammable in air, but can serve as a fuel at concentrations as low as 11% in oxygen and 10% in nitrous oxide.[106] In addition, sevoflurane and desiccated CO_2 absorbent (either soda lime or Baralyme®) can undergo exothermic chemical reactions that have been implicated in several fires that involved the anesthesia breathing circuit.[107,108,109,110] At least some of these fires have injured patients. To prevent future fires, the manufacturer of sevoflurane has recommended that anesthesiologists employ several measures, including avoiding the use of desiccated CO_2 absorbent and monitoring the temperature of the absorber and the inspired concentration of sevoflurane. If an elevated temperature or an inspired sevoflurane concentration that differed unexpectedly from the vaporizer setting is detected, it is recommended that the patient be disconnected from the anesthesia circuit and monitored for signs of thermal or chemical injury and that the CO_2 absorbent be removed from the circuit and/or replaced.

Another way to prevent this type of fire is to use a CO_2 absorbent that does not contain a strong alkali, as do soda lime and Baralyme®. Amsorb® is a CO_2 absorbent that contains calcium hydroxide and calcium chloride, but no strong alkali.[111] In experimental studies, Amsorb® is unreactive with currently used volatile anesthetics and does not produce carbon monoxide or Compound A with desiccated absorbent. Therefore, it would not interact with sevoflurane and undergo an exothermic chemical reaction.

13 It is known that desiccated carbon dioxide absorbent can in rare circumstances react with sevoflurane to produce a fire. This seems to be a unique property of sevoflurane and would be highly unlikely with isoflurane or desflurane. Laster et al published an experimental report that compared the thermal effects of the three agents in desiccated Baralyme®.[112] They found that with both isoflurane and desflurane the temperature

transiently increased to about 100°C, then spontaneously decreased. However, with sevoflurane the temperature continued to increase to more than 200°C (and in one case to over 300°C). Two of the five sevoflurane experiments resulted in fires, illustrating the importance of the sevoflurane–desiccated Baralyme^{R} combination as a potential source of fire in the operating room.

If a fire does occur, it is important to extinguish it as soon as possible. The first step is to interrupt the fire triad by removing one component. This is best accomplished by removing the oxidizer from the fire. Therefore, if an endotracheal tube is on fire, disconnecting the anesthetic circuit from the tube, or disconnecting the inspiratory limb of the circuit, will usually result in the fire immediately going out. It is not recommended to remove a burning endotracheal tube because this may cause even greater harm to the patient. Once the fire is extinguished, the endotracheal tube can be safely removed, the airway inspected via bronchoscopy, and the patient's trachea reintubated.

If the fire is on the patient, extinguishing it with a basin of saline may be the most rapid and effective method to put it out. Use of a sheet or towel may also extinguish the fire. If the drapes are burning, particularly if they are paper drapes, they must be removed and placed on the floor. Paper drapes are impervious to water, thus throwing water or saline on them will do little to extinguish the fire. Once the burning drapes are removed from the patient, the fire can then be extinguished with a fire extinguisher. In most operating room fires, the sprinkler system is not activated. This is because sprinklers are usually not located directly over the OR table and OR fires seldom get hot enough to activate the sprinklers.

14 All operating room personnel should be familiar with the location and operation of fire extinguishers in the area. These extinguishers are divided into three classes, termed A, B, and C. Class A extinguishers are used on paper, cloth, and plastic materials. Class B extinguishers are used for fires when liquids or grease are involved, and Class C extinguishers are used for energized electrical equipment. A single fire extinguisher may be useful for any one, two, or all three types of fires. Probably the best fire extinguisher for the operating room is the carbon dioxide extinguisher. This can be used on Class B and Class C fires and some Class A fires. Other extinguishers are water mist, or new environmentally friendly fluorocarbon extinguishers that replaced the Halon fire extinguisher. Finally, many operating rooms are equipped with a fire hose, which is pressurized water that is delivered at a rate of 50 gallons/minute. Such equipment is best left to the fire department to use, unless there is a need to rescue someone from a fire. To effectively use a fire extinguisher, the acronym PASS can be used. This stands for Pull the pin to activate the fire extinguisher, Aim at the base of the fire, Squeeze the trigger, and Sweep the extinguisher back and forth across the base of the fire. When responding to a fire the acronym RACE is useful. This stands for Rescue, Alarm, Confine, Extinguish. Clearly, having a plan that everyone is familiar with will greatly facilitate extinguishing the fire and minimize the harm to the patient and equipment. Fire drills are an important part of the plan and can help personnel become familiar with the exits, evacuation routes, and location of fire extinguishers and how to shut off gas and electrical supplies. If all of the OR personnel communicate with each other, the risk of a fire will be greatly reduced. It is important to never assume that others know what you are doing. Verbally confirm that the heat source has been placed in standby and not on the drapes. Lasers and ESUs should have their own holders and the surgeon needs to be sure which control activates the laser and which control activates the ESU. It is important that all prep solutions with alcohol be dry before surgery begins. During head and neck surgery, the anesthesiologist should inform the surgeon that there is an open source of oxygen being administered to the patient. Only through heightened awareness, continuing education, and communication can the legs of the fire triad be kept apart and the risk of an OR fire minimized.

KEY POINTS

1	The Henderson–Hasselbalch equation describes the relationship between pH, $PaCO_2$, and serum bicarbonate. The Henderson equation defines the previous relationship but substitutes hydrogen concentration for pH.
2	The pathophysiology of metabolic alkalosis is divided into generating and maintenance factors. A particularly important maintenance factor is renal hypoperfusion, often a result of hypovolemia.
3	Metabolic acidosis occurs as a consequence of the use of bicarbonate to buffer endogenous organic acids or as a consequence of external bicarbonate loss. The former causes an increase in the anion gap (Na^+ - [Cl^- + [HCO_3^-]]).
4	When substituting mechanical ventilation for spontaneous ventilation in a patient with severe metabolic acidosis, it is important to maintain an appropriate level of ventilatory compensation, pending effective treatment of the primary cause for the metabolic acidosis.
5	Sodium bicarbonate, never proved to alter outcome in patients with lactic acidosis, should be reserved for those patients with severe acidemia.
6	The addition of iatrogenic respiratory alkalosis to metabolic alkalosis can produce severe alkalemia.
7	Tight control of blood glucose in critically ill patients has been associated with substantial improvements in mortality.
8	In patients undergoing moderate surgical procedures, generous administration of fluids is associated with fewer minor complications, such as nausea, vomiting, and drowsiness.

9	In patients undergoing colon surgery, careful perioperative fluid restriction has been associated with lower mortality and better wound healing.
10	Homeostatic mechanisms are usually adequate for the maintenance of electrolyte balance. However, critical illnesses and their treatment strategies can cause significant perturbations in electrolyte status, possibly leading to worsened patient outcome.
11	Calcium, phosphorus, and magnesium are all essential for maintenance and function of the cardiovascular system. In addition, they also provide the milieu that ensures neuromuscular transmission. Disorders affecting any one of these electrolytes may lead to significant dysfunction and possibly result in cardiopulmonary arrest.
12	Disorders of the concentration of sodium, the principal extracellular cation, are dependent on the total body water concentration and can lead to neurologic dysfunction. Disorders of potassium, the principal intracellular cation, are influenced primarily by insults that result in increased total body losses of potassium or changes in distribution.

As a consequence of underlying diseases and of therapeutic manipulations, surgical patients may develop potentially harmful disorders of acid-base equilibrium, intravascular and extravascular volume, and serum electrolytes. Precise perioperative management of acid-base status, fluids, and electrolytes may limit perioperative morbidity and mortality.

ACID-BASE INTERPRETATION AND TREATMENT

To facilitate management of perioperative acid-base disturbances, this chapter reviews the pathogenesis, major complications, physiologic compensatory mechanisms, and treatment

of the four simple acid-base disorders: metabolic alkalosis, metabolic acidosis, respiratory alkalosis, and respiratory acidosis.

Overview of Acid-Base Equilibrium

1 The conventional approach to describing acid-base equilibrium is the Henderson–Hasselbalch equation:

$$\mathrm{pH} = 6.1 + \log \frac{[\mathrm{HCO_3^-}]}{0.03 \times \mathrm{PaCO_2}} \qquad (9\text{-}1)$$

where 6.1 = the pK_a of carbonic acid and 0.03 is the solubility coefficient in blood of carbon dioxide (CO_2). Conventional acid-base terminology defines acid-base disturbances as metabolic (i.e., those in which the bicarbonate concentration [HCO^-_3] is primarily increased or decreased) and respiratory (i.e., those in which $PaCO_2$ is primarily increased or decreased). pH, the term used to define the acidity or alkalinity of solutions or blood, is the negative logarithm of the hydrogen ion concentration ([H^+]). The simpler Henderson equation (the origins of which precede the Henderson–Hasselbalch equation)[1] clearly expresses the relationship between the three major variables measured or calculated in blood gas samples:

$$[H^+] = \frac{24 \times PaCO_2}{[HCO_3^-]} \qquad (9\text{-}2)$$

To convert pH to $[H^+]$, assume that $[H^+]$ is 40 mmol/L at a pH of 7.4; that an increase in pH of 0.10 pH units reduces $[H^+]$ to 0.8 × the starting $[H^+]$ concentration; that a decrease in pH of 0.10 pH units increases the $[H^+]$ by a factor of 1.25; and that small changes (i.e., <0.05 pH units) produce approximately a 1.0 mmol/L increase in $[H^+]$ for each 0.01 decrease in pH or a decrease in $[H^+]$ of one mmol/L per 0.01 increase in pH. These rules-of-thumb only approximate the logarithmic relationship between pH and $[H^+]$. The more the pH deviates from 7.4, the less accurate the rules become.

The alternative Stewart approach to acid-base interpretation distinguishes between the independent variables and dependent variables that define pH.[1,2] The independent variables are $PaCO_2$, the strong (i.e., highly dissociated) ion difference (SID), and the concentration of proteins, which usually are not strong ions. The strong ions include sodium (Na^+), potassium (K^+), chloride (Cl^-), and lactate. The SID, calculated as ($Na^+ + K^+ - Cl^-$), under normal circumstances is approximately 42 mEq/L. In general, the Stewart approach provides more insight into the mechanisms underlying acid-base disturbances, in contrast to the Henderson–Hasselbalch approach, which is more descriptive. However, the clinical interpretation or treatment of common acid-base disturbances is rarely handicapped by the simpler constructs of the conventional Henderson–Hasselbalch or Henderson equations.

Metabolic Alkalosis

2 Metabolic alkalosis, usually characterized by an alkalemic pH (>7.45) and hyperbicarbonatemia (>27.0 mEq/L), is the commonest acid-base abnormality in critically ill patients and is associated with increased cost, morbidity, and mortality.[3] Factors that generate metabolic alkalosis include nasogastric suction and diuretic administration (Table 9-1).[4] Maintenance of metabolic alkalosis is dependent on a continued stimulus, such as renal hypoperfusion, hypokalemia, hypochloremia, or hypovolemia, for distal tubular reabsorption of $[HCO^-_3]$.

TABLE 9-1 Generation and Maintenance of Metabolic Alkalosis

·GENERATION	·EXAMPLE	·MAINTENANCE
I. Loss of acid from extracellular space		
A. Loss of gastric fluid	Vomiting; nasogastric drainage	↓ effective arterial volume (EAV)
B. Loss of acid into urine; continued Na^+ delivery to the distal tubule in presence of hyperaldosteronism	1. Primary aldosteronism 2. Diuretic administration	1. K^+ depletion + aldosterone excess 2. ↓ EAV + K^+ depletion
II. Excessive HCO_3^- loads		
A. Absolute	$NaHCO_3$ administration	↓EAV

1. HCO_3^-	Lactate, acetate, citrate administration	↓EAV
2. Metabolic conversion of salts of organic acid anions to HCO_3^-	Alkali administration to patients with renal failure	Renal failure
B. Relative		
1. Alkaline loads in renal failure		
III. Posthypercapnic state	Abrupt correction of chronic hypercapnia	↓EAV

Metabolic alkalosis exerts multiple physiologic effects. Metabolic alkalosis is associated with hypokalemia, ionized hypocalcemia, secondary ventricular arrhythmias, increased digoxin toxicity, and compensatory hypoventilation (hypercarbia), although $PaCO_2$ rarely exceeds 55 mmHg (Table 9-2).[4] Alkalemia also increases bronchial tone and, through a combination of increased bronchial tone and decreased ventilatory effort, may promote atelectasis. Alkalemia may reduce tissue oxygen availability by shifting the oxyhemoglobin dissociation curve to the left and by decreasing cardiac output. During anesthetic management, inadvertent addition of iatrogenic respiratory alkalosis to preexisting metabolic alkalosis may produce cardiovascular depression, dysrhythmias, and the other complications of severe alkalemia (Table 9-3).

TABLE 9-2 Rules of Thumb for Respiratory Compensation in Response to Metabolic Alkalosis and Metabolic Acidosis

Metabolic alkalosis
1. $PaCO_2$ increases approximately 0.5 to 0.6 mmHg for each 1.0 mEq/L increase in $[HCO^-_3]$ 2. The last two digits of the pH should equal the $[HCO^-_3]$ + 15
Metabolic acidosis
1. $PaCO_2 = [HCO^-_3] \times 1.5 + 8$ 2. $PaCO_2$ decreases 1.2 mmHg for every 1.0 mEq/L in $[HCO^-_3]$ to a minimum of 10 to 15 mmHg 3. The last two digits of the pH equal $[HCO^-_3]$ + 15

TABLE 9-3 Metabolic Alkalosis Plus Hyperventilation

	·NORMAL	·CHRONIC DIURETIC ADMINISTRATION	·INTRAOPERATIVE HYPERVENTILATION
·BLOOD GASES			
pH	7.40	7.47	7.62
$PaCO_2$ (mmHg)	40	45	30
$[HCO_3^-]$ (mEq/L)	24	32	29
·ELECTROLYTES			
"CO_2" (mEq/L)	25	33	30
Note: Respiratory alkalosis, produced by an inappropriately high minute ventilation, has been added to the previously compensated metabolic alkalosis induced by chronic diuretic administration. "CO_2", Total CO_2.			

In patients in whom arterial blood gases have not yet been obtained, serum electrolytes and a history of major risk factors, such as vomiting, nasogastric suction, or chronic diuretic use, can suggest metabolic alkalosis. Total "CO_2" (usually abbreviated on electrolyte reports as CO_2) should be about 1.0 mEq/L greater than $[HCO_3^-]$ calculated on simultaneously obtained arterial blood gases. If either calculated $[HCO_3^-]$ on the arterial blood gases or "CO_2" on the serum electrolytes exceeds normal (24 and 25 mEq/L, respectively) by

>4.0 mEq/L, either the patient has a primary metabolic alkalosis or has conserved bicarbonate in response to chronic hypercarbia. Recognition of hyperbicarbonatemia on the preoperative serum electrolytes justifies arterial blood gas analysis and should alert the anesthesiologist to the likelihood of factors that generate or maintain metabolic alkalosis.

Treatment of metabolic alkalosis consists of etiologic and nonetiologic therapy. Etiologic therapy consists of measures such as expansion of intravascular volume or the administration of potassium. To restore intravascular volume, administration of 0.9% saline tends to increase serum $[Cl^-]$ and decrease serum $[HCO_3^-]$.[5] Although hypoproteinemia can cause a mild metabolic alkalosis,[6] such changes usually require no specific treatment. Nonetiologic therapy includes administration of acetazolamide (a carbonic anhydrase inhibitor that causes renal bicarbonate wasting) or $[H^+]$ as ammonium chloride, arginine hydrochloride, or 0.1 N hydrochloric acid (100 mmol/L), or acid dialysis. Of the preceding, 0.1 N hydrochloric acid most rapidly corrects life-threatening metabolic alkalosis but must be infused into a central vein; peripheral infusion will cause severe tissue damage.

Metabolic Acidosis

3 Metabolic acidosis, usually characterized by an acidemic pH (<7.35) and hypobicarbonatemia (<21 mEq/L), can be innocuous or reflect a life-threatening emergency.[7] Metabolic acidosis occurs as a consequence of buffering by bicarbonate of endogenous or exogenous acid loads or as a consequence of abnormal external loss of

bicarbonate. Approximately 70 mmol of acid metabolites are produced, buffered, and excreted daily; these include about 25 mmol of sulfuric acid from amino acid metabolism, 40 mmol of organic acids, and phosphoric and other acids.[8] Extracellular volume (ECV) in a 70-kg adult contains 336 mmol of bicarbonate buffer (24 mEq/L × 14 l of ECV). Glomerular filtration of plasma volume necessitates reabsorption of 4,500 mmol of bicarbonate daily, of which 85% is reabsorbed in the proximal tubule and 10% in the thick ascending limb, and the remainder is titrated by proton secretion in the collecting duct.[8]

Calculation of the anion gap (Na^+ - [Cl^-] + [HCO_3^-]) distinguished between two types of metabolic acidosis (Table 9-4).[9] The anion gap is normal (<13 mEq/L) in situations, such as diarrhea, biliary drainage, and renal tubular acidosis, in which bicarbonate is lost externally. The anion gap also is normal or reduced in hyperchloremic acidosis associated with perioperative infusion of substantial quantities of 0.9% saline.[5,10,11] Metabolic acidosis associated with a high anion gap (>13 mEq/L) occurs because of production of excess lactic acid or ketoacids, increased retention of waste products (such as sulfate and phosphate) that are inadequately excreted in uremic states, and ingestion of toxic quantities of substances such as aspirin, ethylene glycol, and methanol. In those circumstances, bicarbonate ions are consumed in buffering hydrogen ions, while the associated anion replaces bicarbonate in serum. Because three-quarters of the normal anion gap consists of albumin, the calculated anion gap should be corrected for hypoalbuminemia by adding to the calculated anion gap the difference between measured serum albumin and a normal albumin concentration of 4.0 g/dL multiplied by 2.0 to 2.5.[12,13]

TABLE 9-4 Differential Diagnosis of Metabolic Acidosis

▪ELEVATED ANION GAP	▪NORMAL ANION GAP
Three diseases	
1. Uremia 2. Ketoacidosis 3. Lactic acidosis Toxins 1. Methanol 2. Ethylene glycol 3. Salicylates 4. Paraldehyde	1. Renal tubular acidosis 2. Diarrhea 3. Carbonic anhydrase inhibition 4. Ureteral diversions 5. Early renal failure 6. Hydronephrosis 7. HCl administration 8. Saline administration
Correction of the anion gap for hypoalbuminemia is essential for effective perioperative use.	

4 Sufficient reductions in pH may reduce myocardial contractility, increase pulmonary vascular resistance, decrease systemic vascular resistance, and impair the response of the cardiovascular system to endogenous or exogenous catecholamines. It is particularly important to note that failure of a patient to appropriately hyperventilate in response to metabolic acidosis is physiologically equivalent to respiratory acidosis and suggests impending deterioration. If a patient with metabolic acidosis requires mechanical ventilation, every attempt should be made to maintain an appropriate level of ventilatory compensation until the primary process can be corrected (see Table 9-2). Table 9-5 illustrates failure to maintain

compensatory hyperventilation.

TABLE 9-5 Failure to Maintain Appropriate Ventilatory Compensation for Metabolic Acidosis

		·SPONTANEOUS VENTILATION		·MECHANICAL VENTILATION
Arteria 1	pH	7.29		7.13
blood gases	$PaCO_2$ (mmHg)	29	→→→→→→→→	49
	$[HCO_3^-]$ (mEq/L)	14		16
In the presence of metabolic acidosis, an otherwise innocuous increase in $PaCO_2$ may create a life-threatening decrease in pH.				

The anesthetic implications of metabolic acidosis are proportional to the severity of the underlying process. Although a patient with hyperchloremic metabolic acidosis may be relatively healthy, those with lactic acidosis, ketoacidosis, uremia, or toxic ingestions will be chronically or acutely ill.

Preoperative assessment should emphasize volume status and renal function. If shock is the etiology, direct arterial pressure monitoring and preload may require assessment via echocardiography or pulmonary arterial catheterization. Intraoperatively, one should be concerned about the possibility of exaggerated hypotensive responses to drugs and positive pressure ventilation. Preoperative compensatory hyperventilation should be maintained during anesthesia and monitored using capnography and arterial blood gases. In planning intravenous fluid therapy, consider that balanced salt solutions tend to increase $[HCO_3^-]$ and pH and 0.9% saline tends to decrease $[HCO_3^-]$ and pH.[5,10]

The treatment of metabolic acidosis consists of the treatment of the primary pathophysiologic process (i.e., hypoperfusion, hypoxia, and if pH is severely decreased, administration of $NaHCO_3^-$). Hyperventilation, though an important compensatory response to metabolic acidosis, is not definitive therapy for metabolic acidosis. The initial dose of $NaHCO_3$ can be calculated as:

$$\text{NaHCO}_3(\text{mEq/L}) = \frac{\text{Wt (kg)} \times 0.3 \times (24\ \text{mEq/L} - \text{Actual HCO}_3^-)}{2} \quad (9\text{-}3)$$

where 0.3 = the assumed distribution space for bicarbonate and 24 mEq/L is the normal value for $[HCO_3^-]$ on arterial blood gas determination. The calculation markedly underestimates dosage in severe metabolic acidosis. In infants and children, an appropriate initial dose is 1.0 to 2.0 mEq/kg of body weight.

5 One continuing controversy is the use of $NaHCO_3$ to treat acidemia induced by lactic acidosis. In critically ill patients with lactic acidosis, there were no important differences between the physiologic effects (other than changes in pH) of 0.9 M $NaHCO_3$ and 0.9 M sodium chloride.[14] Importantly, $NaHCO_3$ did not improve the cardiovascular response to catecholamines and actually reduced plasma ionized calcium.[14] Although many clinicians continue to administer

$NaHCO_3$ to patients with persistent lactic acidosis and ongoing deterioration, neither $NaHCO_3$ nor dichloroacetate[15] has improved outcome. The buffer THAM (tris-hydroxymethyl aminomethane) is effective at reducing $[H^+]$ and does not generate CO_2 as a byproduct of buffering[16]; however, there is no generally accepted indication for THAM.

Respiratory Alkalosis

6 Respiratory alkalosis, usually characterized by an alkalemic pH (>7.45) and always characterized by hypocarbia ($PaCO_2 \leqslant 35$ mmHg), describes an increase in minute ventilation that is greater than that required to excrete metabolic CO_2 production. Because respiratory alkalosis may be a sign of pain, anxiety, hypoxemia, central nervous system (CNS) disease, or systemic sepsis, the development of spontaneous respiratory alkalosis in a previously normocarbic patient requires prompt evaluation. The hyperventilation syndrome, a diagnosis of exclusion, is most often encountered in the emergency department.[17]

Respiratory alkalosis, like metabolic alkalosis, may produce hypokalemia, hypocalcemia, cardiac dysrhythmias, bronchoconstriction, and hypotension, and may potentiate the toxicity of digoxin. In addition, both brain pH and cerebral blood flow are tightly regulated and respond rapidly to changes in systemic pH.[18] Doubling minute ventilation reduces $PaCO_2$ to 20 mmHg and halves cerebral blood flow; conversely, halving minute ventilation doubles $PaCO_2$ and doubles cerebral blood flow. Acute hyperventilation may be useful in neurosurgical procedures to reduce brain bulk and to control intracranial pressure (ICP) during emergent surgery for noncranial injuries associated with acute closed head trauma. In those situations, intraoperative monitoring of arterial blood gases, correlated with capnography, will document adequate reduction of $PaCO_2$. Acute profound hypocapnia (<20 mmHg) may produce EEG evidence of cerebral ischemia. If $PaCO_2$ is maintained at abnormally high or low levels for 8 to 24 hours, cerebral blood flow will return toward previous levels, associated with a return of cerebrospinal fluid $[HCO_3^-]$ toward normal.[19]

Treatment of respiratory alkalosis per se is often not required. In most patients, the most important steps are recognition and treatment of the underlying etiology.[17] For instance, correction of hypoxemia or hypoperfusion-induced lactic acidosis should result in resolution of the associated increases in respiratory drive. Preoperative recognition of chronic hyperventilation necessitates intraoperative maintenance of a similar $PaCO_2$.

Respiratory Acidosis

Respiratory acidosis, usually characterized by a low pH (<7.35) and always characterized by hypercarbia ($PaCO_2 \geqslant 45$ mmHg), occurs because of a decrease in minute alveolar ventilation ($\dot{V}_A$), an increase in production of carbon dioxide ($\dot{V}_{CO2}$), or both, from the equation:

$$PaCO_2 = K\frac{\dot{V}_{CO2}}{\dot{V}_A} \qquad (9\text{-}4)$$

where K = constant (rebreathing of exhaled, carbon dioxide-containing gas may also increase $PaCO_2$). Respiratory acidosis may be either acute, without compensation by renal $[HCO_3^-]$ retention, or chronic, with $[HCO_3^-]$ retention offsetting the decrease in pH (Table 9-6). A reduction in $\dot{V}_A$ may be because of an overall decrease in minute ventilation ($\dot{V}_E$) or to an increase in the amount of wasted ventilation ($\dot{V}_D$), according to the equation:

$$\dot{V}_A = \dot{V}_E - \dot{V}_D \qquad (9\text{-}5)$$

TABLE 9-6 Rules of Thumb for [HCO_3^-] and pH Changes in Response to Acute and Chronic Changes in $PaCO_2$

Decreased $PaCO_2$
1. pH increases 0.10 for every 10 mmHg decrease in $PaCO_2$. 2. [HCO_3^-] decreases 2 mEq/L for every 10 mmHg decrease in $PaCO_2$. 3. pH will nearly normalize if hypocarbia is sustained. 4. [HCO_3^-] will decrease 5 to 6 mEq/L for each chronic 10 mmHg ↓ in $PaCO_2$.[a]
Increased $PaCO_2$
1. pH will decrease 0.05 for every acute $PaCO_2$ increase of 10 mmHg. 2. [HCO_3^-] will increase 1.0 mEq/L for every $PaCO_2$ increase of 10 mmHg. 3. pH will return toward normal if hypercarbia is sustained. 4. [HCO_3^-] will increase 4 to 5 mEq/L for each chronic 10 mmHg increase in $PaCO_2$.
[a]Hospitalized patients rarely develop chronic compensation for hypocarbia because of stimuli that enhance distal tubular reabsorption of sodium.

Decreases in $\dot{V}_E$ may occur because of central ventilatory depression by drugs or central nervous system injury, because of increased work of breathing, or because of airway obstruction or neuromuscular dysfunction. Increases in $\dot{V}_D$ occur with chronic obstructive pulmonary disease, pulmonary embolism, and most acute forms of respiratory failure. $\dot{V}_{CO2}$ may be increased by sepsis, high-glucose parenteral feeding, or fever.

Patients with chronic hypercarbia because of intrinsic pulmonary disease require careful preoperative evaluation. The ventilatory restriction imposed by upper abdominal or thoracic surgery may compound ventilatory insufficiency. Administration of opioids and sedatives, even in small doses, may cause hazardous ventilatory depression. Preoperative evaluation should consider direct arterial pressure monitoring and frequent intraoperative blood gas determinations, as well as postoperative pain management. Intraoperatively, a patient with chronic hypercapnia should be ventilated to maintain a normal pH. An abrupt increase in minute ventilation may result in profound alkalemia (analogous to the addition of hyperventilation to metabolic alkalosis described in Table 9-3). Postoperatively, prophylactic ventilatory support may be required for selected patients with severe lung disease and chronic hypercarbia. Epidural opioid administration represents one potential alternative that may provide adequate postoperative analgesia without undue depression of ventilatory drive.

The treatment of respiratory acidosis depends on whether the process is acute or chronic. Acute respiratory acidosis may require mechanical ventilation unless a simple etiologic factor (i.e., narcotic overdosage or residual muscular blockade) can be treated quickly. Bicarbonate administration rarely is indicated unless severe metabolic acidosis is also present or unless mechanical ventilation is ineffective in reducing acute hypercarbia. In contrast, chronic respiratory acidosis is rarely managed with ventilation. Rather, efforts are made to improve pulmonary function to permit more effective elimination of carbon dioxide. In patients requiring

mechanical ventilation for acute respiratory failure, ventilation with a lung-protective strategy may result in hypercapnia, which in turn has been managed with alkalinization.

PRACTICAL APPROACH TO ACID-BASE INTERPRETATION

Rapid interpretation of a patient's acid-base status involves the integration of three sets of data: arterial blood gases, electrolytes, and history. A systematic, sequential approach facilitates interpretation (Table 9-7). Acid-base assessment usually can be completed before initiating therapy; however, the first step in interpretation may disclose disturbances (e.g., respiratory acidosis or metabolic acidosis with pH <7.1) that require immediate attention.

TABLE 9-7 Sequential Approach to Acid-Base Interpretation

1. Is the pH life threatening, requiring immediate intervention?
2. Is the pH acidemic or alkalemic?
3. Could the entire arterial blood gas picture represent only an acute increase or decrease in $PaCO_2$?
4. If the answer to question #3 is "No," is there evidence of a chronic respiratory disturbance or of an acute metabolic disturbance?
5. Are appropriate compensatory changes present?
6. Is an anion gap present?
7. Do the clinical data fit the acid-base picture?

The next step is to determine whether a patient is acidemic (pH <7.35) or alkalemic (pH >7.45). The pH status will usually indicate the predominant primary process, that is, acidosis produces acidemia; alkalosis produces alkalemia. (Note that the suffix "-osis" indicates a primary process that, if unopposed, will produce the corresponding pH change. The suffix "-emia" refers to the pH. A compensatory process is not considered an "-osis.") Of course, a patient may have mixed "-oses," that is, more than one primary process.

The next step is to determine whether the entire arterial blood gas picture is consistent with a simple acute respiratory alkalosis or acidosis (see Table 9-6). For example, a patient with acute hypocapnia ($PaCO_2$ 30 mmHg) would have a pH increase of 0.10 units to a pH of 7.50 and a calculated $[HCO_3^-]$ of 22.

If changes in $PaCO_2$, pH, and $[HCO_3^-]$ are not consistent with a simple acute respiratory disturbance, chronic respiratory acidosis (⩾24 hours) or metabolic acidosis or alkalosis should be considered. In chronic respiratory acidosis, pH

becomes nearly normal as bicarbonate is retained by the kidneys (see Table 9-6), usually at a ratio of 4 to 5 mEq/L per 10 mmHg chronic increase in $PaCO_2$.[20] For example, chronic hypoventilation at a $PaCO_2$ of 60 mmHg would be associated with an increase in $[HCO_3^-]$ of 8 to 10 mEq/L ($[HCO_3^-]$ of 32 to 34 mEq/L) and a pH of 7.35 to 7.38. If neither an acute nor chronic respiratory change could have resulted in the arterial blood gas measurements, then a metabolic disturbance must also be present.

Respiratory compensation for metabolic disturbances occurs more rapidly than renal compensation for respiratory disturbances (see Table 9-2). Several general rules describe compensation. First, overcompensation is rare. Second, inadequate or excessive compensation suggests an additional primary disturbance. Third, hypobicarbonatemia associated with an increased anion gap is never compensatory.

The next question, whether an anion gap is present, should be assessed even if the arterial blood gases appear straightforward. The simultaneous occurrence of metabolic alkalosis and metabolic acidosis (as a consequence of pathophysiology producing a high anion gap) may result in an unremarkable pH and [HCO_3^-]; the combined abnormality may only be appreciated by examining the anion gap.[21] As noted previously, correct assessment of the anion gap requires correction for hypoalbuminemia.[12,13] Metabolic acidoses associated with increased anion gaps require specific treatments, thus necessitating a correct diagnosis. This is particularly important in managing hyperchloremic metabolic acidosis after administration of large volumes of 0.9% saline perioperatively or even in critically ill hospitalized patients.[22] In these circumstances, no anion gap would be expected and no specific treatment of metabolic acidosis would be required. [5,23]

The final question is whether the clinical data are consistent with the arterial blood gas data. Failure to consider clinical status also may lead to serious errors in gas acid-base interpretation.

Examples

The foregoing has summarized an approach that simplifies interpretation. The following two hypothetical cases will be approached using the algorithm and rules discussed earlier.

Example #1

A 65-year-old female has undergone 12 hours of an expected 16-hour radical neck dissection and flap construction. Estimated blood loss is 1,000 mL. She has received three units of packed red blood cells and nine liters of 0.9% saline. Her blood pressure and heart rate have remained stable while anesthetized with 0.5% to 1.0% isoflurane in 70:30 nitrous oxide and oxygen. Urinary output is adequate. Arterial blood gas levels are shown in Table 9-8.

TABLE 9-8 Hypobicarbonatemia and Hyperchloremic Acidosis during Prolonged Surgery

Arterial blood gases	pH	7.38
	$PaCO_2$	32 mmHg
	[HCO^-_3]	17 mEq/L
Electrolytes	Na^+	140 mEq/L
	Cl^-	116 mEq/L
	CO_2	18 mEq/L
	Anion Gap	6 mEq/L
Serum albumin		2.0 g/dL

The step-by-step interpretation is as follows:

1. The pH is not life threatening.
2. The pH is <7.40 but is not frankly acidemic.
3. The arterial blood gases cannot be adequately explained by acute hypocarbia. The predicted pH would be 7.48 and the predicted [HCO^-_3] would be 22 mEq/L (see Table 9-6).
4. A metabolic acidosis appears to be present.
5. The question of compensation is not pertinent during general anesthesia with controlled mechanical ventilation, given that $PaCO_2$ is not determined by the patient's ventilatory control. However, spontaneous hypocapnia of this magnitude would represent slight overcompensation (see Table 9-2) and should prompt a search for a reason for primary respiratory alkalosis.
6. During prolonged anesthesia and surgery, one might assume the presence of lactic acidosis and provide additional fluid therapy or otherwise attempt to improve perfusion. However, serum electrolytes reveal an anion gap that is slightly less than normal (see Table 9-8), indicating that the metabolic acidosis is probably the result of dilution of the extracellular volume with a high-chloride fluid.[5] Correction of the anion gap for the serum albumin of 2.0 g/dl only increases the anion gap to 10 to 11 mEq/L, again consistent with a hyperchloremic metabolic acidosis.[10] A random urine sample could help confirm this etiology (Table 9-9).[8] Hyperchloremic acidosis secondary to infusion of high-chloride fluid requires no treatment. The arterial blood gases and serum electrolytes are compatible with the clinical picture.

TABLE 9-9 Evaluation of Hyperchloremic Acidosis

	·URINARY SOLUTES			
	NH_4^+	Cl^-	A^-	Na^+
GI tract HCO_3^- loss	↑	↓	↔	↓
	(a)	(b)		(c)
Generated/ingested organic	↑	↔	↑	↑
acids	(a)		(d)	(e)
HCI intake or equivalent[a]	↑	↑	↔	↑
	(a)	(f)		(e)
Inadequate renal HCO_3^-	↓	↔	↔	↔
	(g)			

Renal HCO_3^- loss	↓	↔	↔	↔
	(g)			

[a]NH_4Cl, chloride salts of amino acids or dilutional acidosis; ↔ designates normal: (a) NH_4^+ >1 mmol/kg daily; (b) FE_{Cl} <1 mmol/kg daily. FE = fractional excretion of a solute. Urinary unmeasured anion concentration (sum of urinary K^+, NH_4^+, and Na^+ less Cl^-) estimates sum of urinary sulphate and organic anion concentrations.
From Gluck SL: Acid-base. Lancet 352:474, 1998.

Example #2

A 35-year-old male, 3 days after appendectomy, develops nausea with recurrent emesis persisting for 48 hours. An arterial blood gas reveals the results shown in the middle column of Table 9-10.

TABLE 9-10 Metabolic Alkalosis Secondary to Nausea and Vomiting with Subsequent Lactic Acidosis Secondary to Hypovolemia

		▪NORMAL	▪METABOLIC ALKALOSIS	▪METABOLIC ACIDOSIS
Blood gases	pH	7.40	7.50	7.40
	$PaCO_2$ (mmHg)	40	46	40
	$[HCO^-_3]$ (mEq/L)	24	35	24
Serum electrolytes	Na^+ (mEq/L)	140	140	140
	Cl^- (mEq/L)	105	94	94
	CO_2 (mEq/L)	25	36	25
	Anion gap (mEq/L)	10	10	21

1. The pH of 7.50 requires no immediate intervention.

2. The pH is alkalemic, suggesting a primary alkalosis.

3. An acute $PaCO_2$ of 46 mmHg would yield a pH of approximately 7.37; therefore, this is not simply an acute ventilatory disturbance.
4. The patient has a primary metabolic alkalosis as suggested by the $[HCO_3^-]$ of 35 mEq/L.
5. The limits of respiratory compensation for metabolic alkalosis are wide and difficult to predict for individual patients. The rules of thumb, summarized in Table 9-2, suggest that $[HCO_3^-]$ + 15 should equal the last two digits of the pH and that the $PaCO_2$ should increase 5 to 6 mmHg for every 10 mEq/L change in serum $[HCO_3^-]$, that is, pH = 7.50 and $PaCO_2$ = 46 mmHg.
6. The anion gap is 12 mEq/L.
7. The diagnosis of a primary metabolic alkalosis with compensatory hypoventilation is consistent with the history of recurrent vomiting. Consider how the arterial blood gases would change if vomiting were sufficiently severe to produce hypovolemic shock and lactic acidosis (third column, Table 9-10).

This sequence illustrates the important concept that the final pH, $PaCO_2$, and $[HCO_3^-]$ represent the result of all of the vectors operating on acid-base status. Complex, or "triple disturbances," can only be interpreted using a thorough, stepwise approach.

FLUID MANAGEMENT

Physiology

Body Fluid Compartments

Accurate replacement of fluid deficits necessitates an understanding of the distribution spaces of water, sodium, and colloid. Intracellular volume (ICV), which constitutes 40% of total body weight, and extracellular volume (ECV), which constitutes 20% of body weight, comprise total body water (TBW), which therefore constitutes 60% of total body weight. Plasma volume (PV) equals about one-fifth of ECV, the remainder of which is interstitial fluid volume (IFV). Red cell volume, approximately 2 liters, is part of ICV.

The distribution volume of sodium-free water is TBW. The distribution volume of infused sodium is ECV, which contains equal sodium concentrations ($[Na^+]$) in the PV and IF. Plasma $[Na^+]$ is approximately 140 mEq/L. The predominant intracellular cation, potassium, has an intracellular concentration ($[K^+]$) approximating 150 mEq/L. Albumin, the most important oncotically active constituent of ECV, is unequally distributed in PV (~4 g/dL) and IFV (~1 g/dL). The IFV concentration of albumin varies greatly among tissues; however, ECV is the distribution volume for colloid solutions.

Distribution of Infused Fluids

Conventionally, clinical prediction of plasma volume expansion (PVE) after fluid infusion assumes that body fluid spaces are static. Kinetic analysis of PVE replaces the static assumption with a dynamic description. As an example of the static approach, assume that a 70-kg patient has suffered an acute blood loss of 2,000 mL, approximately 40% of the predicted 5-liter blood volume. The formula describing the effects of replacement with 5% dextrose in water (D5W), lactated Ringer's solution, or 5% or 25% human serum albumin is as follows:

$$\text{Expected PV increment} = \text{volume infused} \times \frac{\text{normal PV}}{\text{distribution volume}} \quad (9\text{-}6)$$

Rearranging the equation yields the following:

$$\text{Volume infused} = \text{expected PV increment} \times \text{distribution volume/normal PV} \quad (9\text{-}7)$$

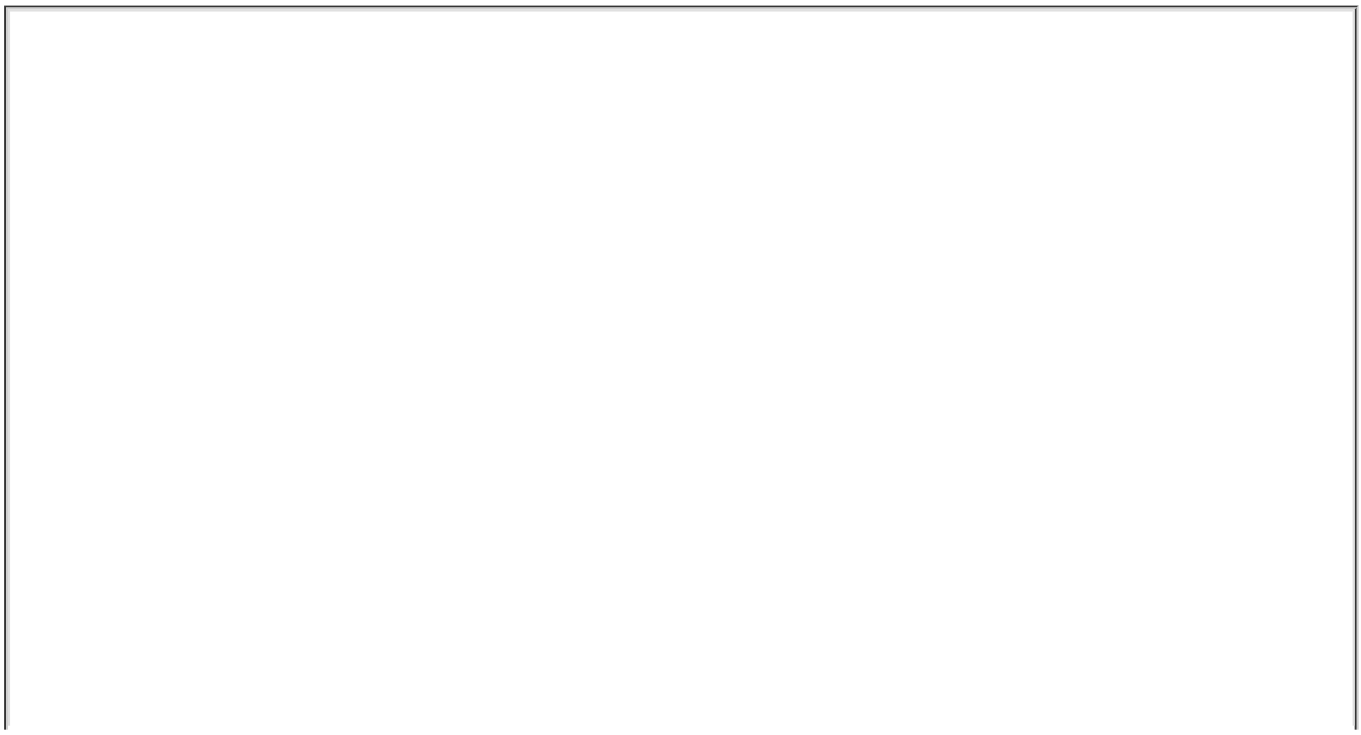
To restore blood volume using D5W requires 28 liters:

$$28 \text{ liters} = 2 \text{ liters} \times 42 \text{ liters}/3 \text{ liters} \quad (9\text{-}8)$$

where 2 liters is the desired PV increment, 42 liters = TBW in a 70-kg person, and 3 liters is the normal estimated PV.

To restore blood volume using lactated Ringer's solution requires 9.1 liters:

$$9.1 \text{ liters} = 2 \text{ liters} \times 14 \text{ liters}/3 \text{ liters} \quad (9\text{-}9)$$



where 14 liters = ECV in a 70-kg person.

If 5% albumin, which exerts colloid osmotic pressure similar to plasma, were infused, the infused volume initially would remain in the PV, perhaps attracting additional interstitial fluid intravascularly. Twenty-five percent human serum albumin, a concentrated colloid, expands PV by approximately 400 mL for each 100 mL infused.

However, in kinetic terms, these analyses are simplistic. Infused fluid does not simply equilibrate throughout an assumed distribution volume, but is added to a highly regulated system that attempts to maintain intravascular, interstitial, and intracellular volume. Kinetic models of intravenous fluid therapy allow clinicians to predict more accurately the time course of volume changes produced by infusions of fluids of various compositions. Kinetic analysis permits estimation of peak volume expansion and rates of clearance of infused fluid and complements analysis of "pharmacodynamic" effects, such as changes in cardiac output or cardiac filling pressures.

Figure 9-1 illustrates the conceptual kinetic model proposed by Svensén and Hahn.[24] A practical physiologic tracer for

kinetic analysis should permit frequent measurements to define clearance curves more completely. Svensén and Hahn[24] evaluated three endogenous tracers—blood water concentration, serum albumin concentration, and hemoglobin concentration [Hb]—in volunteers who received infusions of acetated Ringer's solution, 6% dextran 70, or 7.5% saline. Although much less tedious than blood water calculations, [Hb] provided similar estimates of volumes of distribution and elimination rate constants. After infusing the test fluids, Svensén and Hahn fitted the results to one-volume and two-volume-of-fluid-space (VOFS) models. The two-compartment VOFS model is most likely to be superior to the one-compartment model when urinary excretion in response to infusion is small.[25]

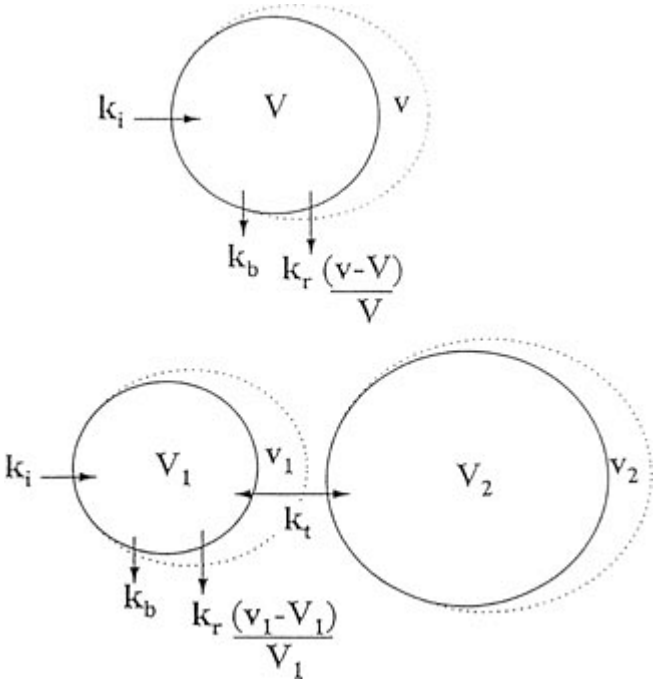


FIGURE 9-1. Schematic drawing of the kinetic model used to calculate the size of the body fluid spaces expanded by intravenous infusions of fluid in humans. Data are fitted to a one-volume or two-volume-of-fluid-space (VOFS) model. The assumptions underlying the one-compartment VOFS model (**top**) are as follows: (1) during fluid infusion, fluid enters an expandable space of volume *v* at a constant rate k_i; (2) the expandable fluid space has a target volume *V*, which the body strives to maintain; (3) volume *v* changes by fluid being eliminated from the fluid space at a basal rate, k_b (perspiration and basal diuresis), and at a controlled rate. The controlled rate is proportional by a constant k_r to the relative deviation of *v* from the target volume *V*. The assumptions behind the two-compartment VOFS model (**bottom**) are similar: (1) during fluid infusion, fluid enters an expandable space of volume v_1 at a constant rate k_i; (2) there is a secondary expandable fluid space of volume v_2 exchanging fluid with the primary fluid space; (3) volume v_1 changes through exchange with the secondary fluid space and as a result of fluid being eliminated from the primary fluid space at a basal rate, k_b (perspiration and basal diuresis), and at a controlled rate; (4) the primary and secondary fluid spaces have target volumes V_1 and V_2, which the system strives to maintain by acting on the controlled elimination mechanism k_r, which is proportional to the relative deviation from the target volume of the primary fluid space, and by acting on the fluid exchange mechanism; (5) the net rate of fluid exchange between the two spaces is proportional to the difference in relative deviations from the target volumes by a constant k_t. (From Svensén C, Hahn RG: Volume kinetics of Ringer solution, dextran 70, and hypertonic saline in male volunteers. Anesthesiology 87: 204, 1997.)

Figure 9-2 shows the mean plasma volume dilution curves obtained with the infusion of Ringer's solution or dextran 70. All dextran infusions were consistent with a one-VOFS model, suggesting that the colloid infusion remained in the PV. Hypertonic crystalloid, like isotonic crystalloid, was associated in individual instances with a mixture of one- and two-VOFS models

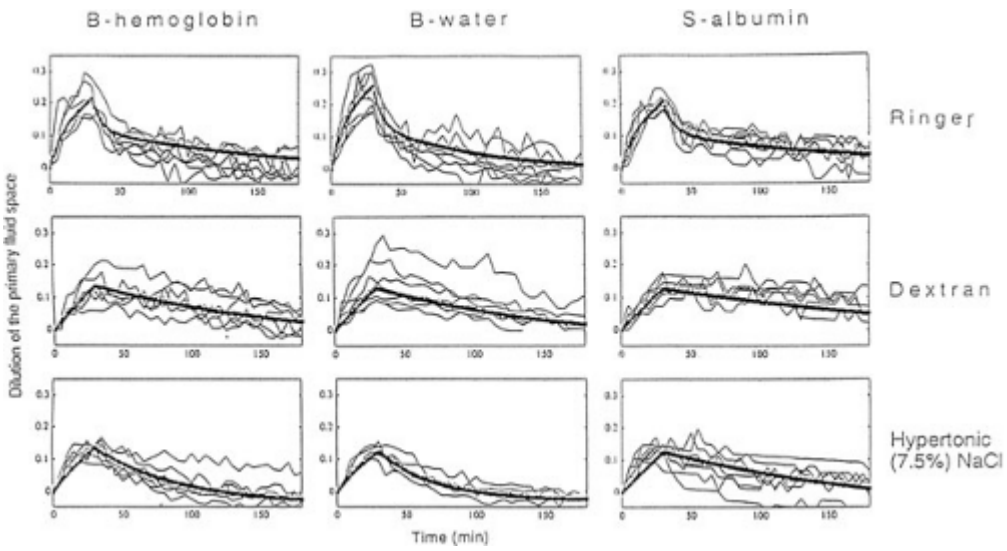

FIGURE 9-2. Kinetic curves obtained after infusion in adult male volunteers of 25 mL/kg of acetated Ringer' s solution (Ringer) or 5 mL/kg of dextran 70 over 30 minutes. Dilution of plasma volume is calculated from changes in hemoglobin concentration (B-hemoglobin), blood water (B-water) concentration, and serum albumin (S-albumin) concentration. (From Svensén C, Hahn RG: Volume kinetics of Ringer solution, dextran 70, and hypertonic saline in male volunteers. Anesthesiology 87: 204, 1997.)

Using this approach, the effects of common physiologic and pharmacologic influences can be examined in experimental animals or humans. For example, in chronically instrumented sheep, isoflurane anesthesia was associated with similar kinetics of PV expansion after fluid infusion, but reduced urinary output in anesthetized in comparison to conscious sheep, demonstrated that expansion of extravascular volume was actually greater during anesthesia[26]; subsequent experiments demonstrated that this effect was attributable to isoflurane and not to mechanical ventilation during anesthesia.[27] Isoflurane is associated with extravascular fluid accumulation, although these observations must be confirmed in anesthetized humans and other anesthetics must be examined.

Regulation of Extracellular Fluid Volume

Total body water content is regulated by the intake and output of water. Water intake includes ingested liquids plus an average of 750 mL ingested in solid food and 350 mL that is generated metabolically. Insensible losses are normally 1 L/day and GI losses are 100 to 150 mL/day. Thirst, the primary mechanism of controlling water intake, is triggered by an increase in body fluid tonicity or by a decrease in extracellular volume.

Reabsorption of filtered water and sodium is enhanced by changes mediated by the hormonal factors antidiuretic hormone (ADH), atrial natriuretic peptide (ANP), and aldosterone. Renal water handling has three important components: (1) delivery of tubular fluid to the diluting segments of the nephron; (2) separation of solute and water in the diluting segment; and (3) variable reabsorption of water in the collecting ducts. In the descending loop of Henle, water is reabsorbed while solute is retained to achieve a final osmolality of tubular fluid of approximately 1,200 mOsm/kg (Fig. 9-3). This concentrated fluid is then diluted by the active reabsorption of electrolytes in the ascending limb of the loop of Henle and in the distal tubule, both of which are relatively impermeable to water. As fluid exits the distal tubule and enters the collecting duct, osmolality is approximately 50 mOsm/kg. Within the collecting duct, water reabsorption is modulated by ADH (also called vasopressin). Vasopressin binds to V_2 receptors along the basolateral membrane of the collecting duct cells, then stimulates the synthesis and

insertion of the aquaporin-2 water channel into the luminal membrane of collecting duct cells.[28]

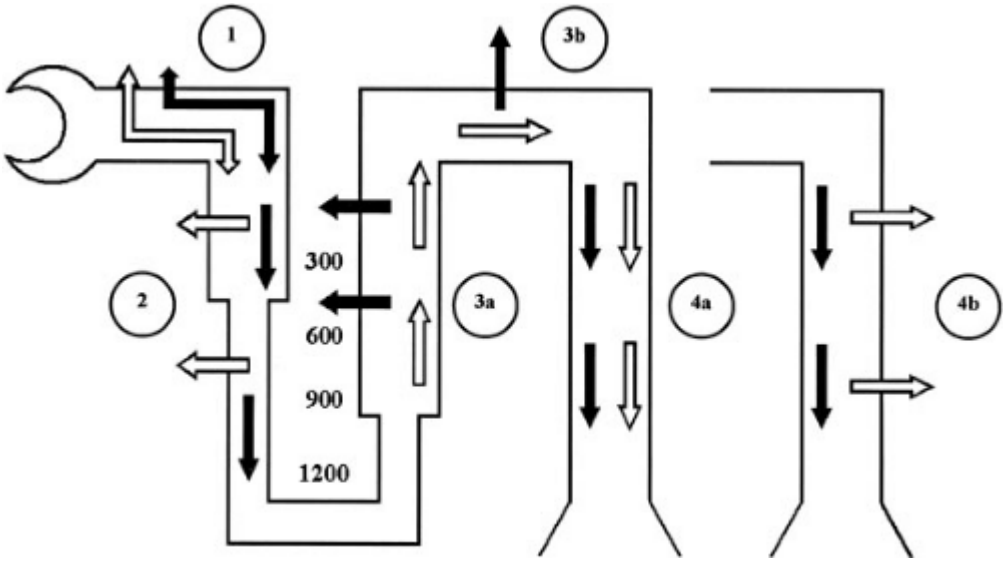

FIGURE 9-3. Renal filtration, reabsorption, and excretion of water. *Open arrows* represent water and *solid arrows* represent electrolytes. Water and electrolytes are filtered by the glomerulus. In the proximal tubule (*1*), water and electrolytes are absorbed isotonically. In the descending loop of Henle (*2*), water is absorbed to achieve osmotic equilibrium with the interstitium while electrolytes are retained. The numbers (300, 600, 900, and 1,200) between the descending and ascending limbs represent the osmolality of the interstitium in mOsm/kg. The delivery of solute and fluid to the distal nephron is a function of proximal tubular reabsorption; as proximal tubular reabsorption increases, delivery of solute to the medullary (*3a*) and cortical (*3b*) diluting sites decreases. In the diluting sites, electrolyte-free water is generated through selective reabsorption of electrolytes while water is retained in the tubular lumen, generating a dilute tubular fluid. In the absence of vasopressin, the collecting duct (*4a*) remains relatively impermeable to water and a dilute urine is excreted. When vasopressin acts on the collecting ducts (*4b*), water is reabsorbed from these vasopressin-responsive nephron segments, allowing the excretion of a concentrated urine. (From Fried LF, Palevsky PM: Hyponatremia and hypernatremia. Med Clin North Am 81(3):585, 1997.)

Plasma hypotonicity suppresses ADH release, resulting in excretion of dilute urine. Hypertonicity stimulates ADH secretion, which increases the permeability of the collecting duct to water and enhances water reabsorption. In response to changing plasma [Na^+], changing secretion of ADH can vary urinary osmolality from 50 to 1,200 mOsm/kg and urinary volume from 0.4 to 20 L/day (Fig. 9-4). Other factors that stimulate ADH secretion, though none as powerfully as plasma tonicity, include hypotension, hypovolemia, and nonosmotic stimuli such as nausea, pain, and medications, including opiates.

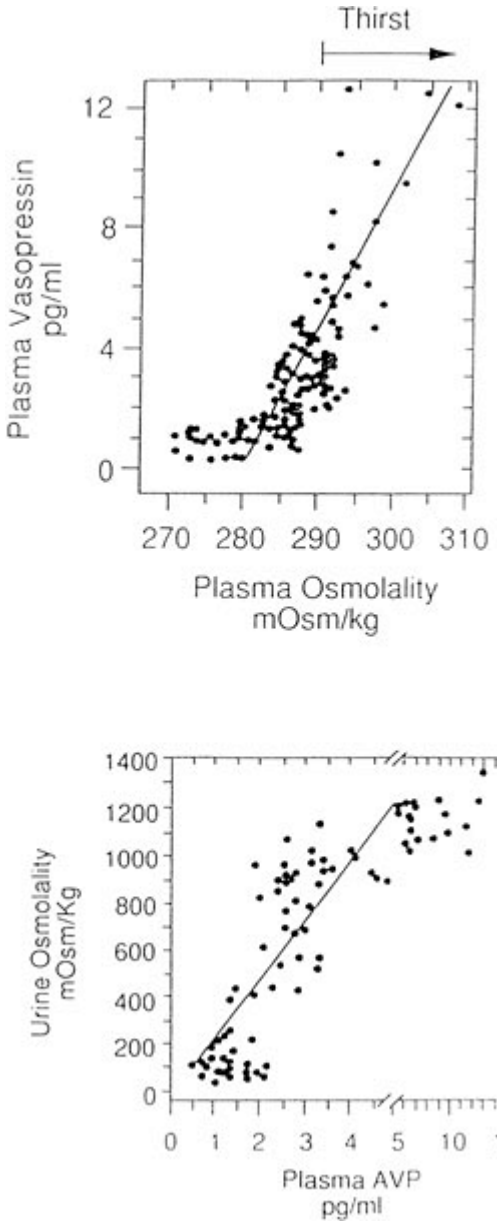

FIGURE 9-4. Top: Relationship between plasma osmolality and plasma vasopressin (AVP; also referred to as ADH). **Bottom:** Relationship between plasma AVP and urinary osmolality. (From Fried LF, Palevsky PM: Hyponatremia and hypernatremia. Med Clin North Am 81(3):585, 1997.)

Two powerful hormonal systems regulate total body sodium. The natriuretic peptides, ANP, brain natriuretic peptide, BNP, and C-type natriuretic peptide, defend against sodium overload[29] and the renin-angiotensin-aldosterone axis defends against sodium depletion and hypovolemia. ANP, released from the cardiac atria in response to increased atrial stretch, exerts vasodilatory effects and increases the renal excretion of sodium and water. ANP secretion is decreased during hypovolemia. Even in patients with chronic (nonoliguric) renal insufficiency, infusion of ANP in low, nonhypotensive doses increased sodium excretion and augmented urinary losses of retained solutes.[30]

Aldosterone is the final common pathway in a complex response to decreased effective arterial volume, whether decreased effective arterial volume is true or relative (edematous states or hypoalbuminemia). In this pathway, decreased

stretch in the baroreceptors of the aortic arch and carotid body and stretch receptors in the great veins, pulmonary vasculature, and atria result in increased sympathetic tone. Increased

sympathetic tone, in combination with decreased renal perfusion, leads to renin release and formation of angiotensin I from angiotensinogen. Angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II, which stimulates the adrenal cortex to synthesize and release aldosterone.[31,32] Acting primarily in the distal tubules, high concentrations of aldosterone cause sodium reabsorption and may reduce urinary excretion of sodium nearly to zero. Intrarenal physical factors are also important in regulating sodium balance. Sodium loading decreases colloid osmotic pressure, thereby increasing the glomerular filtration rate (GFR), decreasing net sodium

reabsorption and increasing distal sodium delivery, which, in turn, suppresses renin secretion.

Fluid Replacement Therapy

Maintenance Requirements for Water, Sodium, and Potassium

Two simple formulas are used interchangeably to estimate maintenance water requirements (Table 9-11). In healthy adults, sufficient water is required to balance gastrointestinal losses of 100 to 200 mL/day, insensible losses of 500 to 1,000 mL/day (half of which is respiratory and half is cutaneous), and urinary losses of 1,000 mL/day. Urinary losses exceeding 1,000 mL/day may represent an appropriate physiologic response to ECV expansion or an inability to conserve salt or water.

TABLE 9-11 Maintenance Water Requirements

▪WEIGHT (kg)	▪mL/kg/hr	▪mL/kg/d
1–10	4	100
11–20	2	50
21–n	1	20

Daily requirements for sodium and potassium are approximately 75 mEq/L and 40 mEq/L, respectively, although wider ranges of sodium intake than potassium intake are physiologically tolerated because renal sodium conservation and excretion are more efficient than potassium conservation and excretion. Therefore, healthy, 70-kg adults require 2,500 mL/day of water containing a $[Na^+]$ of 30 mEq/L and a $[K^+]$ of 15 to 20 mEq/L. Intraoperatively, fluids containing sodium-free water (i.e., $[Na^+]$ <130 mEq/L) are rarely used in adults, because of the necessity for replacing isotonic losses and the risk of postoperative hyponatremia.

Dextrose

Traditionally, glucose-containing intravenous fluids have been given in an effort to prevent hypoglycemia and limit protein catabolism. However, because of the hyperglycemic response associated with surgical stress, only infants and patients receiving insulin or drugs that interfere with glucose synthesis are at risk for hypoglycemia. Iatrogenic hyperglycemia can limit the effectiveness of fluid resuscitation by inducing an osmotic diuresis and, in animals, may aggravate ischemic neurologic injury.[33] Although associated with worse outcome after subarachnoid hemorrhage[34] and traumatic brain injury[35] in humans, hyperglycemia may also

constitute a hormonally mediated response to more severe injury. In critically ill patients, evidence strongly suggests that tight control of plasma glucose (maintenance of plasma glucose between 80 and 110 mg/dL) is associated with reduced mortality and morbidity.[36,37,38,39] Evidence also suggests that glucose control improves outcome in surgical patients.[40]

Surgical Fluid Requirements

Water and Electrolyte Composition of Fluid Losses. Surgical patients require replacement of PV and ECV losses secondary to wound or burn edema, ascites, and gastrointestinal secretions. Wound and burn edema and ascitic fluid are protein rich and contain electrolytes in concentrations similar to plasma. Although gastrointestinal secretions vary greatly in composition, the composition of replacement fluid need not be closely matched if ECV is adequate and renal and cardiovascular functions are normal. Substantial loss of gastrointestinal fluids requires more accurate replacement of electrolytes (i.e., potassium, magnesium, phosphate). Chronic gastric losses may produce hypochloremic metabolic alkalosis that can be corrected with 0.9% saline; chronic diarrhea may produce hyperchloremic metabolic acidosis that may be prevented or corrected by infusion of fluid containing bicarbonate or bicarbonate substrate (e.g., lactate). If cardiovascular or renal function is impaired, more precise replacement may require frequent assessment of serum electrolytes.

Fluid Shifts During Surgery. Replacement of intraoperative fluid losses must include consideration of fluid that accumulates extravascularly in surgically manipulated tissue. Therefore, guidelines have been developed for replacement of fluid losses during surgical procedures. The simplest formula provides, in addition to maintenance fluids and replacement of estimated blood loss, 4 mL/kg/h for procedures involving minimal trauma, 6 mL/kg/h for those involving moderate trauma, and 8 mL/kg/h for those involving extreme trauma.

8 However, formulas for intraoperative fluid replacement will no doubt undergo considerable debate and reformulation over the next few years. Clinical trials suggest that perioperative fluid management may strongly influence both minor and major morbidity and that the influence may be specific to the type of surgery and to the types of fluid used. Yogendran et al[41] randomized 200 ASA I–III, ambulatory surgical patients to receive either 20 mL/kg or 2 mL/kg of Plasmalyte as a bolus over 30 minutes before surgery; patients receiving the higher dose had less postoperative thirst, drowsiness, dizziness, and nausea. Holte et al[42] randomized 48 ASA I–II patients undergoing laparoscopic cholecystectomy to receive either 15 mL/kg or 40 mL/kg of lactated Ringer's solution intraoperatively; the higher dose of fluid was associated with improved postoperative pulmonary function and exercise capacity, reduced neurohumoral stress response, and improvements in nausea, general sense of well-being, thirst, dizziness, drowsiness, fatigue, and balance function. In marked contrast, Brandstrup et al[43] randomized 172 elective colon surgery patients to either restrictive perioperative fluid management or standard perioperative fluid management with the primary goal of maintaining preoperative body weight in the fluid-restricted group. By design, the fluid-restricted group received less perioperative fluid and acutely gained <1 kg in contrast to >3 kg in the standard therapy group.

9 More importantly, total postoperative complications were significantly fewer in the fluid-restricted group (Table 9-12). Cardiopulmonary and tissue-healing complications were also significantly reduced in association with fluid restriction.

Mobilization of Expanded Interstitial Fluid

An important corollary of perioperative IFV expansion is the mobilization and return of accumulated fluid to the ECV and the PV, colloquially termed "deresuscitation." In most patients, mobilization occurs on approximately the third postoperative day. If the cardiovascular system and kidneys cannot effectively transport and excrete mobilized fluid, such as in the patient with borderline cardiac function, hypervolemia and pulmonary edema may occur.

Colloids, Crystalloids, and Hypertonic Solutions

Physiology and Pharmacology

Osmotically active particles attract water across semipermeable membranes until equilibrium is attained. The *osmolarity* of a solution refers to the number of osmotically active particles per *liter* of solvent; *osmolality*, a measurement of the number of osmotically active particles per *kilogram*, can be estimated as follows:

$$\text{Osmolality} = ([Na^+] \times 2) + (\text{Glucose}/18) + (\text{BUN}/2.3) \quad (9\text{-}10)$$

where osmolality is expressed in mOsm/kg, $[Na^+]$ is expressed in mEq/L, serum glucose is expressed in mg/dL, and BUN is blood urea nitrogen expressed in mg/dL. Sugars, alcohols, and

radiographic dyes increase measured osmolality, generating an increased "osmolal gap" between the measured and calculated values.

A hyperosmolar state occurs whenever the concentration of osmotically active particles is high. Both uremia (increased BUN) and hypernatremia (increased serum sodium) increase serum osmolality. However, because urea distributes throughout TBW, an increase in BUN does not cause *hypertonicity.* Sodium, largely restricted to the ECV, causes hypertonicity, that is, osmotically mediated redistribution of water from ICV to ECV. The term "tonicity" is also used colloquially to compare the osmotic pressure of a parenteral solution to that of plasma.

Although only a small proportion of the osmotically active particles in blood consist of plasma proteins, those particles are essential in determining the equilibrium of fluid between the interstitial and plasma compartments of ECV. The reflection coefficient (σ) describes the permeability of capillary membranes to individual solutes, with 0 representing free permeability and 1.0 representing complete impermeability. The reflection coefficient for albumin ranges from 0.6 to 0.9 in various capillary beds. Because capillary protein concentrations exceed interstitial concentrations, the osmotic pressure exerted by plasma proteins (termed *colloid osmotic pressure* or *oncotic*

pressure) is higher than interstitial oncotic pressure and tends to preserve PV. The filtration rate of fluid from the capillaries into the interstitial space is the net result of a combination of forces, including the gradient from intravascular to interstitial colloid osmotic pressures and the hydrostatic gradient between intravascular and interstitial pressures. The net fluid filtration at any point within a systemic or pulmonary capillary is represented by Starling's law of capillary filtration, as expressed in the equation:

$$Q = \underline{kA}[(P_c - P_i) + \sigma(\pi_i - \pi_c)] \qquad (9\text{-}11)$$

where Q = fluid filtration, $\underline{k}$ = capillary filtration coefficient (conductivity of water), $\underline{A}$ = the area of the capillary membrane, P_c = capillary hydrostatic pressure, P_i = interstitial hydrostatic pressure, σ = reflection coefficient for albumin, π_i = interstitial colloid osmotic pressure, and π_c = capillary colloid osmotic pressure.

The IFV is determined by the relative rates of capillary filtration and lymphatic drainage. P_c, the most powerful factor promoting fluid filtration, is determined by capillary flow, arterial resistance, venous resistance, and venous pressure. If capillary filtration increases, the rates of water and sodium filtration usually exceed protein filtration, resulting in preservation of π_c, dilution of π_i, and preservation of the oncotic pressure gradient, the most powerful factor opposing fluid filtration. When coupled with increased lymphatic drainage, preservation of the oncotic pressure gradient limits the accumulation of IF. If P_c increases at a time when lymphatic drainage is maximal, then IFV accumulates, forming edema.

Clinical Implications of Choices Between Alternative Fluids

If membrane permeability is intact, colloids such as albumin or hydroxyethyl starch preferentially expand PV rather than IFV. Concentrated colloid-containing solutions (e.g., 25% albumin) exert sufficient oncotic pressure to translocate substantial volumes of IFV into the PV. Plasma volume expansion unaccompanied by IFV expansion offers apparent advantages: lower fluid requirements, less peripheral and pulmonary edema accumulation, and reduced concern about the cardiopulmonary consequences of later fluid mobilization.

However, exhaustive research has failed to establish the superiority of either colloid-containing or crystalloid-containing fluids (Table 9-13). Systematic reviews of available comparisons of colloid versus crystalloid[44] and albumin versus crystalloid[45] suggest unchanged mortality associated with colloid use, although crystalloid may be superior in multiply traumatized patients.[46] Despite the lack of compelling evidence suggesting that perioperative use of colloid influences mortality, Moretti et al[47] reported that patients who were randomized to receive 6% hetastarch had less postoperative nausea and vomiting than those who received lactated Ringer's solution without colloid. In addition, colloid administration appears to have been an

essential component of perioperative management strategies that demonstrated improved morbidity after colon surgery[43] and after major surgery in conjunction with goal-directed fluid challenges.[48,49]

TABLE 9-13 Claimed Advantages and Disadvantages of Colloid vs. Crystalloid Intravenous Fluids

·SOLUTION	·ADVANTAGES	·DISADVANTAGES
Colloid	Smaller infused volume	Greater cost
	Prolonged increase in plasma volume Greater peripheral edema Less cerebral edema	Coagulopathy (dextran > HES) Pulmonary edema (capillary leak states)
		Decreased GFR Osmotic diuresis (low molecular weight dextran)
Crystalloid	Lower cost	Transient hemodynamic improvement
	Greater urinary flow	Peripheral edema (protein dilution)
	Replaces interstitial fluid	Pulmonary edema (protein dilution plus high PAOP)

HES, hydroxyethyl starch; GFR, glomerular filtration rate; PAOP, pulmonary arterial occlusion pressure.

Although hydroxyethyl starch, the most commonly used synthetic colloid, is less expensive than albumin, large doses (exceeding 20 mL/kg/d) produce laboratory evidence of coagulopathy.[50] Recently, a new hydroxyethyl starch formulation has been introduced that contains a different mix of molecular sizes and is dissolved in a base consisting of a balanced salt solution rather than 0.9% saline. Proposed advantages of the new formulation include less risk of inducing coagulopathy and of hyperchloremic metabolic acidosis.[51] However, lower molecular weight hetastarch formulations appear to influence coagulation less.[50] Further refinement is likely to occur in the distinctions among various clinically available colloids.[52]

Implications of Crystalloid and Colloid Infusions on Intracranial Pressure

Because the cerebral capillary membrane, the blood-brain barrier, is highly impermeable to sodium, abrupt changes in serum osmolality produced by changes in serum sodium produce reciprocal changes in brain water. In anesthetized rabbits, reducing plasma osmolality from 295 mOsm/kg to 282 mOsm/kg (which decreases plasma osmotic pressure by ~250 mmHg) increased cortical water content and ICP; in contrast, reducing colloid osmotic pressure from 20 to 7 mmHg produced no significant change in either variable.[53] Similar independence of brain

water and ICP from colloid osmotic pressure has been demonstrated with prolonged hypoalbuminemia[54] and in animals after forebrain ischemia[55] and focal cryogenic injury.[56] In contrast, after fluid percussion brain injury, increasing colloid oncotic pressure with hetastarch reduced brain water in comparison to infusion of 0.9% saline (Fig. 9-5).[57]

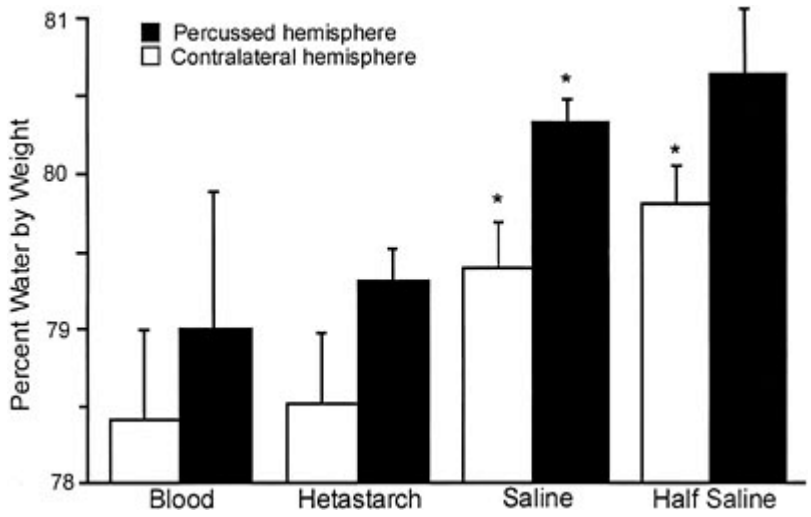

FIGURE 9-5. The percentage of water content (mean ± SD; wet-dry method) of the percussed (*right*) hemisphere and in the contralateral (*left*) hemisphere in animals that underwent isovolemic exchange with whole blood, hetastarch, normal saline, or half-normal saline. Within each group, the water content of the percussed hemisphere was greater than the water content of the contralateral hemisphere. **P* <0.05 versus the corresponding hemisphere in the whole blood and hetastarch groups. (From Drummond JC, Patel PM, Cole DJ *et al*: The effect of the reduction of colloid oncotic pressure, with and without reduction of osmolality, on post-traumatic cerebral edema. Anesthesiology 88:993, 1998.)

Clinical Implications of Hypertonic Fluid Administration

An ideal alternative to conventional crystalloid and colloid fluids would be inexpensive, would produce minimal peripheral or pulmonary edema, would generate sustained hemodynamic effects, and would be effective even if administered in small volumes. Hypertonic, hypernatremic solutions appear to fulfill some of these criteria (Table 9-14).

TABLE 9-14 Hypertonic Resuscitation fluids: Advantages and Disadvantages

·SOLUTION	·ADVANTAGES	·DISADVANTAGES
Hypertonic crystalloid	Inexpensive	Hypertonicity
	Promotes urinary flow	Subdural hemorrhage
	Small initial volume	Transient effect

	Improved myocardial contractility?	
	Arteriolar dilation	
	Reduced peripheral edema	
	Lower intracranial pressure	
Hypertonic crystalloid plus colloid (in comparison to hypertonic crystalloid alone)	Sustained hemodynamic response Reduced subsequent volume requirements	Added expense Coagulopathy (dextran > HES) Osmotic diuresis Impaired crossmatch (dextran) Hypertonicity

HES, hydroxyethyl starch.
From Prough DS, Johnston WE: Fluid resuscitation in septic shock: No solution yet. Anesth Analg 69:699, 1989.

Current enthusiasm for hypertonic resuscitation was stimulated by the work of Velasco et al[58] who successfully used small volumes (6.0 mL/kg) of 7.5% hypertonic saline as the sole resuscitative measure in dogs after severe hemorrhage. Hypertonic solutions exert favorable effects on cerebral hemodynamics, in part because of the reciprocal relationship between plasma osmolality and brain water.[53] ICP increased during resuscitation from hemorrhagic shock with lactated Ringer's solution but remained unchanged if 7.5% saline was infused in a sufficient volume to comparably improve systemic hemodynamics.[59] However, improvements in ICP gradually are lost. Delayed increases in ICP were reported after hypertonic resuscitation from hypovolemic shock accompanied by an intracranial mass lesion.[60] In addition, systemic hemodynamic improvement produced by hypertonic resuscitation is short lived.[59] Strategies to prolong the therapeutic effects beyond 30 to 60 minutes include continued infusion of hypertonic saline, subsequent infusion of blood or conventional fluids, or addition of colloid to hypertonic resuscitation.

Despite concerns about central nervous system dysfunction because of hypertonicity and hypernatremia associated with hypertonic saline, acute increases in serum sodium from 155 to 160 mEq/L produced no apparent harm in humans resuscitated with hypertonic saline.[61] Central pontine myelinolysis, which follows rapid correction of severe, chronic hyponatremia, has not been observed in clinical trials of hypertonic resuscitation. Despite theoretical considerations favoring the use of hypertonic saline in resuscitation of patients with traumatic brain injury, a randomized trial failed to demonstrate an improvement in outcome.[62]

Will clinicians routinely use hypertonic or combination hypertonic/hyperoncotic fluids for resuscitation in the future? Pending further preclinical work, the theoretical advantages of such fluids appear most attractive in the acute resuscitation of hypovolemic patients who have decreased intracranial compliance.[63]

Assessment of Hypovolemia and Tissue Hypoperfusion

For most surgical patients, conventional clinical assessment of the adequacy of intravascular volume is appropriate. For high-risk patients, goal-directed hemodynamic management may be superior.

Conventional Clinical Assessment. Clinical quantification of blood volume and ECV begins with recognition of deficit-generating settings, such as bowel obstruction, preoperative bowel preparation, chronic diuretic use, sepsis, burns, and trauma. Physical signs that suggest hypovolemia include oliguria, supine hypotension, and a positive tilt test. Oliguria

implies hypovolemia, although hypovolemic patients may be nonoliguric and normovolemic patients may be oliguric because of renal failure or stress-induced endocrine responses.[64] Supine hypotension implies a blood volume deficit exceeding 30%, although arterial blood pressure within the normal range could represent relative hypotension in an elderly or chronically hypertensive patient.

In the tilt test, a positive response is defined as an increase in heart rate $\geqslant$20 beats/min and a decrease in systolic blood pressure $\geqslant$20 mmHg when the subject assumes the upright position. However, young, healthy subjects can withstand acute loss of 20% of blood volume while exhibiting only postural tachycardia and variable postural hypotension. In contrast, orthostasis may occur in 20 to 30% of elderly patients despite normal blood volume.[65] In volunteers, withdrawal of 500 mL of blood[66] was associated with a greater increase in heart rate on standing than before blood withdrawal but no significant difference in the response of blood pressure or cardiac index.

Laboratory evidence that suggests hypovolemia or ECV depletion includes azotemia, low urinary sodium, metabolic alkalosis (if hypovolemia is mild), and metabolic acidosis (if hypovolemia is severe). Hematocrit is virtually unchanged by acute hemorrhage until fluids are administered or until fluid shifts from the interstitial to the intravascular space. BUN, normally 8.0 to 20 mg/dL, is increased by hypovolemia, high protein intake, gastrointestinal bleeding, or accelerated catabolism and decreased by severe hepatic dysfunction. Serum creatinine (SCr), a product of muscle catabolism, may be misleadingly low in elderly adults, females, and debilitated or malnourished patients. In contrast, in muscular or acutely catabolic patients, SCr may exceed the normal range (0.5 to 1.5 mg/dL) because of more rapid muscle breakdown. A ratio of BUN:SCr exceeding the normal range (10 to 20) suggests dehydration. In prerenal oliguria, enhanced sodium reabsorption should reduce urinary [Na^+] to $\leqslant$20 mEq/L and enhanced water reabsorption should increase urinary concentration (i.e., urinary osmolality >400; urine/plasma creatinine ratio >40:1). However, the sensitivity and specificity of measurements of urinary variables may be misleading. Although hypovolemia does not generate metabolic alkalosis, ECV depletion is a potent stimulus for the maintenance of metabolic alkalosis. Severe hypovolemia may result in systemic hypoperfusion and lactic acidosis.

Intraoperative Clinical Assessment. Visual estimation, the simplest technique for quantifying intraoperative blood loss, assesses the amount of blood absorbed by gauze squares and laparotomy pads and adds an estimate of blood accumulation on the floor and surgical drapes and in suction containers. Both surgeons and anesthesiologists tend to underestimate losses.

Assessment of the adequacy of intraoperative fluid resuscitation integrates multiple clinical variables, including heart rate, blood pressure, urinary output, arterial oxygenation, and pH. Tachycardia is an insensitive, nonspecific indicator of hypovolemia. In patients receiving potent inhalational agents, maintenance of a satisfactory blood pressure implies adequate intravascular volume. Preservation of blood pressure, accompanied by a CVP of 6 to 12 mmHg, more strongly suggests adequate replacement. During profound hypovolemia, indirect measurements of blood pressure may significantly underestimate true blood pressure. In

patients undergoing extensive procedures, direct arterial pressure measurements are more accurate than indirect techniques and provide convenient access for obtaining arterial blood samples. An additional advantage of direct arterial pressure monitoring may be recognition of increased systolic blood pressure variation accompanying positive pressure ventilation in the presence of hypovolemia.[67,68]

Urinary output usually declines precipitously during moderate to severe hypovolemia. Therefore, in the absence of glycosuria or diuretic administration, a urinary output of 0.5 to 1.0 mL/kg/h during anesthesia suggests adequate renal perfusion. Arterial pH may decrease only when tissue hypoperfusion becomes severe. Cardiac output can be normal despite severely reduced regional blood flow. Mixed venous hemoglobin desaturation, a specific indicator of poor systemic perfusion, reflects average perfusion in multiple organs and cannot supplant regional monitors such as urinary output.

Oxygen Delivery as a Goal of Management. No intraoperative monitor is sufficiently sensitive or specific to detect hypoperfusion in all patients. One key variable that has been associated with improved outcome in high-risk surgical patients and critically ill patients is a systemic oxygen delivery (Do_2)$\geqslant$600 mL $O_2/m^2/min$ (equivalent to a CI of 3.0 $L/m^2/min$, a [Hgb] of 14 g/dL, and 98% oxyhemoglobin saturation). Boyd et al randomized 107 patients to conventional treatment or fluid plus dopexamine to maintain oxygen delivery $\geqslant$600 mL $O_2/m^2/min$ and demonstrated a decrease in mortality and in the number of complications in the patients managed at the higher level of oxygen delivery.[69] Based on these results, the authors calculated that the cost of obtaining a survivor was 31% lower in the protocol group.[70] Wilson et al randomized 138 patients undergoing major elective surgery into three groups.[71] One group received routine perioperative care; one received fluid and dopexamine preoperatively, intraoperatively, and postoperatively to maintain oxygen delivery $\geqslant$600 mL $O_2/m^2/min$; and the third received fluid plus epinephrine preoperatively, intraoperatively, and postoperatively to achieve the same end points. In the two groups in which oxygen delivery was supported, only 3 of 92 died, compared to 8 of 46 control patients. However, the complication rate was significantly lower in the dopexamine group than in the epinephrine group. In contrast, Hayes et al, who randomized 109 patients to conventional treatment or oxygen delivery $\geqslant$600 mL $O_2/m/min$ using a combination of volume and dobutamine, demonstrated an increase in mortality in the treatment group maintained at the higher levels and speculated that aggressive elevations in Do_2 actually may have been harmful.[72]

At present, available data are consistent with several inferences. First, there is no apparent benefit for patients other than surgical patients[73] and patients undergoing initial resuscitation from septic shock in the emergency room.[74] In surgical patients, early initiation of goal-directed resuscitation is associated with better outcome than delayed initiation.[75] Second, outcome may be strongly influenced by the choice of inotropic agents. Third, increased fluid given as part of goal-oriented resuscitation has been associated with an increased incidence of abdominal compartment syndrome in trauma patients.[76]

Several studies have reported improved outcome based on adjustment of perioperative fluids through the use of an esophageal Doppler monitor that estimates descending aortic blood flow and quantifies the duration of systole.[77] Using the esophageal Doppler to guide administration of colloid boluses, Venn et al[48] and Gan et al[49] have reported shortened length of hospital stay after hip surgery and major surgery, respectively. Horowitz and Kumar[78] have speculated that the infusion of colloid and not the monitor-driven algorithm were responsible for the improved results.

10 ELECTROLYTES

Sodium

Physiologic Role

11 Na^+, the principal extracellular cation and solute, is essential for generation of action

potentials in neurologic and cardiac tissue. Disorders (pathological increases or decreases) of *total body sodium* are associated with corresponding increases or

decreases of ECV and PV. Disorders of sodium *concentration*, that is, hyponatremia and hypernatremia, usually result from relative excesses or deficits, respectively, of water. Regulation of total body sodium and [Na^+] is accomplished primarily by the endocrine and renal systems (Table 9-15). Secretion of aldosterone and ANP control *total body sodium*. ADH, which is secreted in response to increased osmolality or decreased blood pressure, primarily regulates [Na^+].

TABLE 9-15 Regulation of Electrolytes

▪ELECTROLYTE	▪REGULATED BY
Sodium	Aldosterone
	ANP
	[Na^+] altered by ADH
Potassium	Aldosterone
	Epinephrine
	Insulin
	Intrinsic renal mechanisms
Calcium	PTH
	Vitamin D
Phosphorus	Primarily renal mechanisms
	Minor: PTH
Magnesium	Primarily renal mechanisms
	Minor: PTH, vitamin D

ANP, atrial natriuretic peptide; [Na^+], sodium concentration; ADH, antidiuretic hormone; PTH, parathyroid hormone.

Hyponatremia

Hyponatremia, defined as [Na^+] <130 mEq/L, is the most common electrolyte disturbance in hospitalized patients. In the majority of hyponatremic, hospitalized patients, total body sodium is normal or increased. The most common clinical associations with hyponatremia include the postoperative state, acute intracranial disease, malignant disease, medications, and acute pulmonary disease. Hyponatremia is associated with substantially increased mortality,[79] both as a direct effect of hyponatremia and because hyponatremia is associated with severe systemic disease.

The signs and symptoms of hyponatremia depend on both the rate and severity of the decrease in plasma [Na^+]. Symptoms that can accompany severe hyponatremia ([Na^+] <120 mEq/L) include loss of appetite, nausea, vomiting, cramps, weakness, altered level of consciousness, coma, and seizures.

Acute CNS manifestations relate to brain overhydration. Because the blood-brain barrier is poorly permeable to sodium but freely permeable to water, a rapid decrease in plasma [Na^+] promptly increases both extracellular and intracellular brain water. Because the brain rapidly compensates for changes in osmolality, acute hyponatremia produces more severe symptoms than chronic hyponatremia. The symptoms of chronic hyponatremia probably relate to depletion of brain electrolytes. Once brain volume has compensated for hyponatremia, rapid increases in [Na^+] may lead to abrupt brain dehydration.

Hyponatremia is classified as pseudohyponatremia or true hyponatremia. Pseudohyponatremia was an artifact associated with the use of flame photometry, now an obsolete technique, to measure plasma [Na^+] in severely hyperproteinemic or hyperlipidemic patients. The current analytic method, direct potentiometry, directly measures [Na^+] and is uninfluenced by nonaqueous components such as proteins and lipids.

In true hyponatremia, serum osmolality may be normal, high, or low (Fig. 9-6). Hyponatremia with a normal or high serum osmolality results from the presence of a nonsodium solute, such as glucose or mannitol, which holds water within the extracellular space and results in dilutional hyponatremia. The presence of a nonsodium solute (or of factitious hyponatremia) may be inferred if measured osmolality exceeds calculated osmolality by >10 mOsm/kg. For example, plasma [Na^+] decreases approximately 2.4 mEq/L for each 100-mg/dL rise in glucose concentration, with perhaps even greater decreases as glucose concentration >400 mg/dL.[80] In anesthesia practice,

a common cause of hyponatremia associated with a normal osmolality is the absorption of large volumes of sodium-free irrigating solutions (containing mannitol, glycerine, or sorbitol as the solute) during transurethral resection of the prostate.[81] Neurologic symptoms are minimal if mannitol is employed because the agent does not cross the blood-brain barrier and is excreted with water in the urine. In contrast, as glycine or sorbitol is metabolized, hypoosmolality will gradually develop and cerebral edema may appear as a late complication, that is, hypoosmolality is more important in generating symptoms than hyponatremia per se.[81] True hyponatremia with a normal or elevated serum osmolality also may accompany renal insufficiency. BUN, included in the calculation of total osmolality, distributes throughout both ECV and ICV. Calculation of *effective* osmolality (2[Na^+] + glucose/18) excludes the contribution of urea to tonicity and demonstrates true hypotonicity.

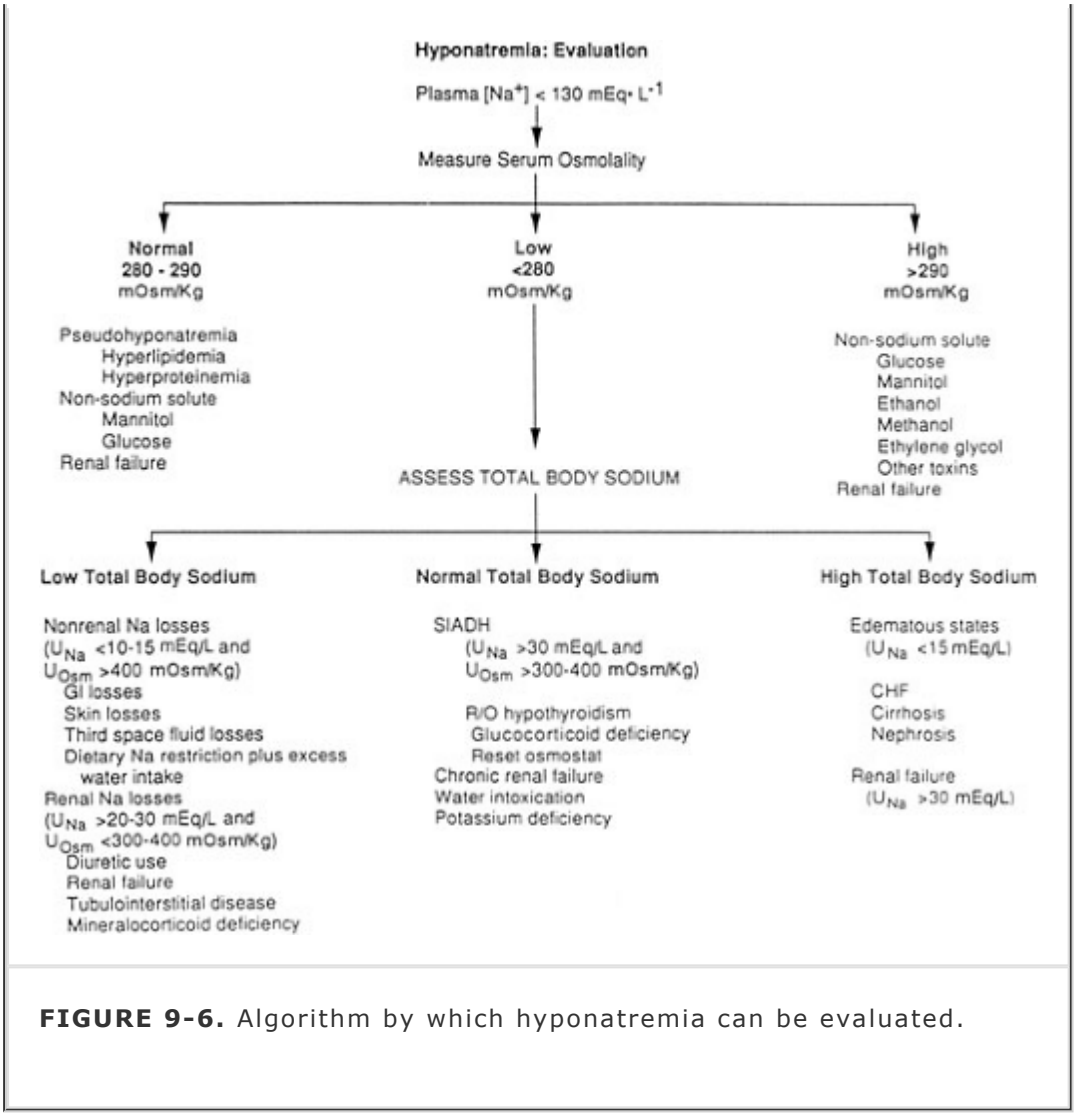

FIGURE 9-6. Algorithm by which hyponatremia can be evaluated.

True hyponatremia with low serum osmolality may be associated with a high, low, or normal total body sodium and PV. Therefore, hyponatremia with hypoosmolality (see Fig. 9-6) is evaluated by assessing total body sodium content, BUN, SCr, urinary osmolality, and urinary [Na^+]. Hyponatremia with increased total body sodium is characteristic of edematous states, that is, congestive heart failure, cirrhosis, nephrosis, and renal failure. Aquaporin 2, the vasopressin-regulated water channel, is upregulated in experimental congestive heart failure[82] and cirrhosis[83] and decreased by chronic vasopressin stimulation.[84] In patients with renal insufficiency, reduced urinary diluting capacity can lead to hyponatremia if excess free water is given.

The underlying mechanism of hypovolemic hyponatremia is secretion of ADH in response to volume contraction in association with ongoing oral or intravenous intake of hypotonic fluid.[85] Angiotensin II also decreases renal free water clearance. Thiazide diuretics, unlike loop diuretics, promote hypovolemic hyponatremia by interfering with urinary dilution in the distal tubule.[85] Hypovolemic hyponatremia associated with a urinary [Na^+] $\geqslant$20 mmol/L suggests mineralocorticoid deficiency, especially if serum [K^+], BUN, and SCr are increased.[85]

The cerebral salt-wasting syndrome is an often severe, symptomatic salt-losing diathesis that appears to be mediated by brain natriuretic peptide[86] and is independent of *the syndrome of inappropriate antidiuretic hormone (SIADH) secretion*; patients at risk include those with cerebral lesions as a result of trauma, subarachnoid hemorrhage, tumors, and infection.[87,88,89]

Euvolemic hyponatremia most commonly is associated with nonosmotic vasopressin secretion, for example, glucocorticoid deficiency, hypothyroidism, thiazide-induced hyponatremia, SIADH, and the reset osmostat syndrome. Total body sodium and ECV are relatively normal and edema is rarely evident. SIADH may be idiopathic but also is associated with diseases of the central nervous system and with pulmonary disease (Table 9-16). Euvolemic hyponatremia is usually

associated with exogenous ADH administration, pharmacologic potentiation of ADH action, drugs that mimic the action of ADH in the renal tubules or excessive ectopic ADH secretion. Tissues from some small-cell lung cancers, duodenal cancers, and pancreatic cancers increase ADH production in response to osmotic stimulation.[90]

From Fried LF, Palevsky PM: Hyponatremia and hypernatremia. Med Clin North Am 81 (3):585, 1997.

12 At least 4% of postoperative patients develop plasma [Na^+] <130 mEq/L.[91] Although neurologic manifestations usually do not accompany postoperative hyponatremia, signs of hypervolemia are occasionally present.[91] Much less frequently, postoperative hyponatremia is accompanied by mental status changes seizures and transtentorial herniaton,[92] attributable in part to intravenous administration of hypotonic fluids, secretion of ADH, and other factors, including drugs and altered renal function, that influence perioperative water balance.[93] Menstruating women may be particularly vulnerable to brain damage secondary to postoperative hyponatremia.[94] Smaller patients change plasma [Na^+] more in response to similar volumes of hypotonic fluids. In an editorial accompanying a report[95] of apparent postoperative SIADH in a 30-kg, 10-year-old girl, Arieff [96] suggested that children receive no sodium-free water perioperatively. Postoperative hyponatremia can develop even with infusion of isotonic fluids if ADH is persistently increased. Twenty-four hours after surgery, mean plasma [Na^+] in 22 women (mean age 42 years) undergoing uncomplicated gynecologic surgery had decreased from 140± 1 mEq/L to 136±0.5 mEq/L.[97] Although the patients retained sodium perioperatively, they retained proportionately more water (an average of 1.1 L of electrolyte-free water). Careful postoperative attention to fluid and electrolyte balance may minimize the occurrence of symptomatic hyponatremia.

If both [Na^+] and measured osmolality are below the normal range, hyponatremia is further evaluated by first assessing volume status using physical findings and laboratory data. In hypovolemic patients or edematous patients, the ratio of BUN to SCr should be >20:1. Urinary [Na^+] is generally <15 mEq/L in edematous states and volume depletion is >20 mEq/L in hyponatremia secondary to renal salt wasting or renal failure with water retention.

The criteria for the diagnosis of SIADH include hypotonic hyponatremia; urinary osmolality >100 to 150 mOsm/kg; absence of extracellular volume depletion; normal thyroid and adrenal function; and normal cardiac, hepatic, and renal function. Urinary [Na^+] should be >30 mEq/L unless fluids have been restricted. Arieff [96] has argued that the diagnosis of SIADH may be inaccurately applied to functionally hypovolemic postoperative patients in whom, by definition, ADH secretion would be "appropriate."

Treatment of hyponatremia associated with a normal or high serum osmolality requires reduction of the elevated concentrations of the responsible solute. Uremic patients are treated by free water restriction or dialysis. Treatment of edematous (hypervolemic) patients necessitates restriction of both sodium and water (Fig. 9-7). Therapy is directed toward improving cardiac output and renal perfusion and using diuretics

to inhibit sodium reabsorption. In hypovolemic, hyponatremic patients, blood volume must be restored, usually by infusion of 0.9% saline, and excessive sodium losses must be curtailed. Correction of hypovolemia usually results in removal of the stimulus for ADH release, accompanied by a rapid water diuresis.

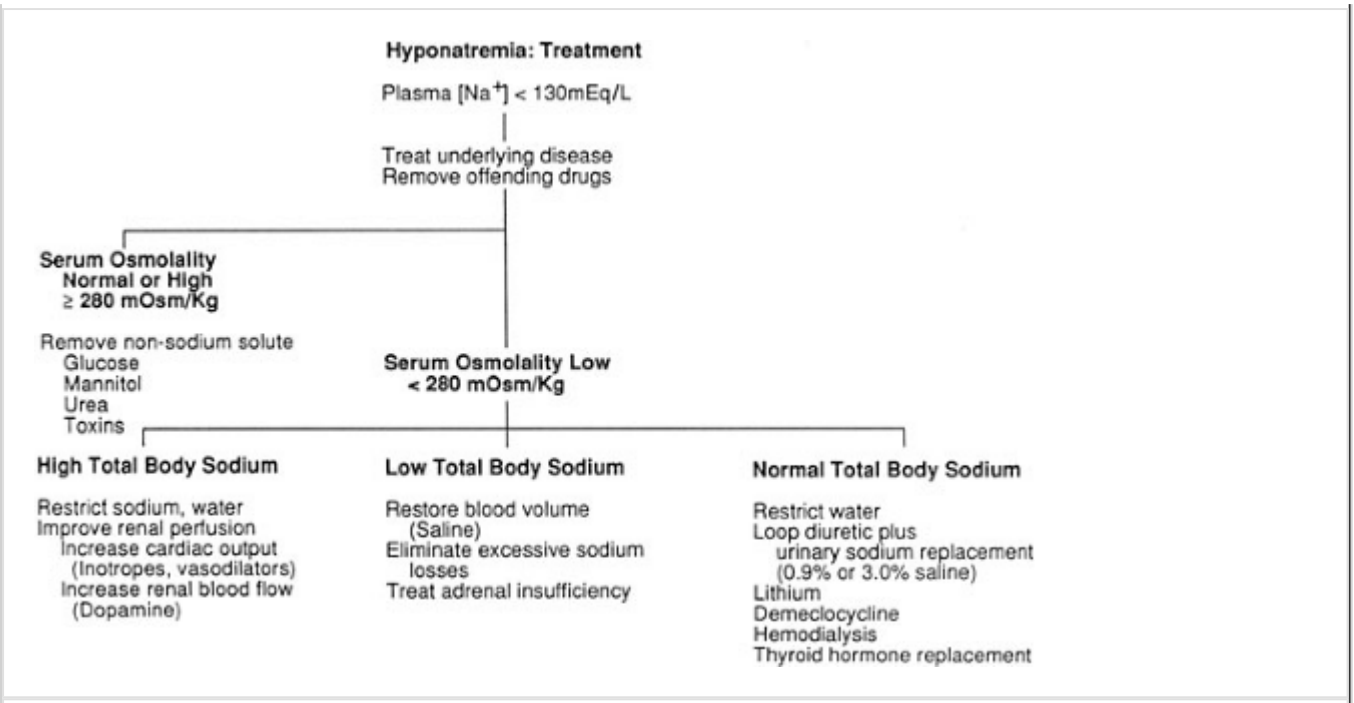

FIGURE 9-7. Hyponatremia is treated according to the etiology of the disturbance, the level of serum osmolality, and a clinical estimation of total body sodium.

The cornerstone of SIADH management is free water restriction and elimination of precipitating causes. Water restriction, sufficient to decrease TBW by 0.5 to 1.0 L/d, decreases ECV even if excessive ADH secretion continues. The resultant reduction in GFR enhances proximal tubular reabsorption of salt and water, thereby decreasing free water generation, and stimulates aldosterone secretion. As long as free water losses (i.e., renal, skin, gastrointestinal) exceed free water intake, serum [Na^+] will increase. During treatment of hyponatremia, increases in plasma [Na^+] are determined both by the composition of the infused fluid and by the rate of renal free water excretion.[98] Free water excretion can be increased by administering furosemide.

Neurologic symptoms or profound hyponatremia ([Na^+] <115 to 120 mEq/L) requires more aggressive therapy. Hypertonic (3%) saline is most clearly indicated in patients who have seizures or patients who acutely develop symptoms of water intoxication secondary to intravenous fluid administration. In such cases, 3% saline may be administered at a rate of 1 to 2 mL/kg/h, to increase plasma [Na^+] by 1 to 2 mEq/L/h; however, this treatment should not continue for more than a few hours. Three percent saline may only transiently increase plasma [Na^+] because ECV expansion results in increased urinary sodium excretion. Intravenous furosemide, combined with quantitative replacement of urinary sodium losses with 0.9% or 3.0% saline, can rapidly increase plasma [Na^+], in part by increasing free water clearance.

The rate of treatment of hyponatremia continues to generate controversy, extending from "too fast, too soon" to "too slow, too late." Although delayed correction may result in neurologic injury, inappropriately rapid correction may result in abrupt brain dehydration (Fig. 9-8) or permanent neurologic sequelae (i.e., osmotic demyelination syndrome),[99] cerebral hemorrhage, or congestive heart failure. The symptoms of the osmotic demyelination syndrome vary from mild (transient behavioral disturbances or seizures) to severe (including pseudobulbar palsy and quadriparesis).[100]

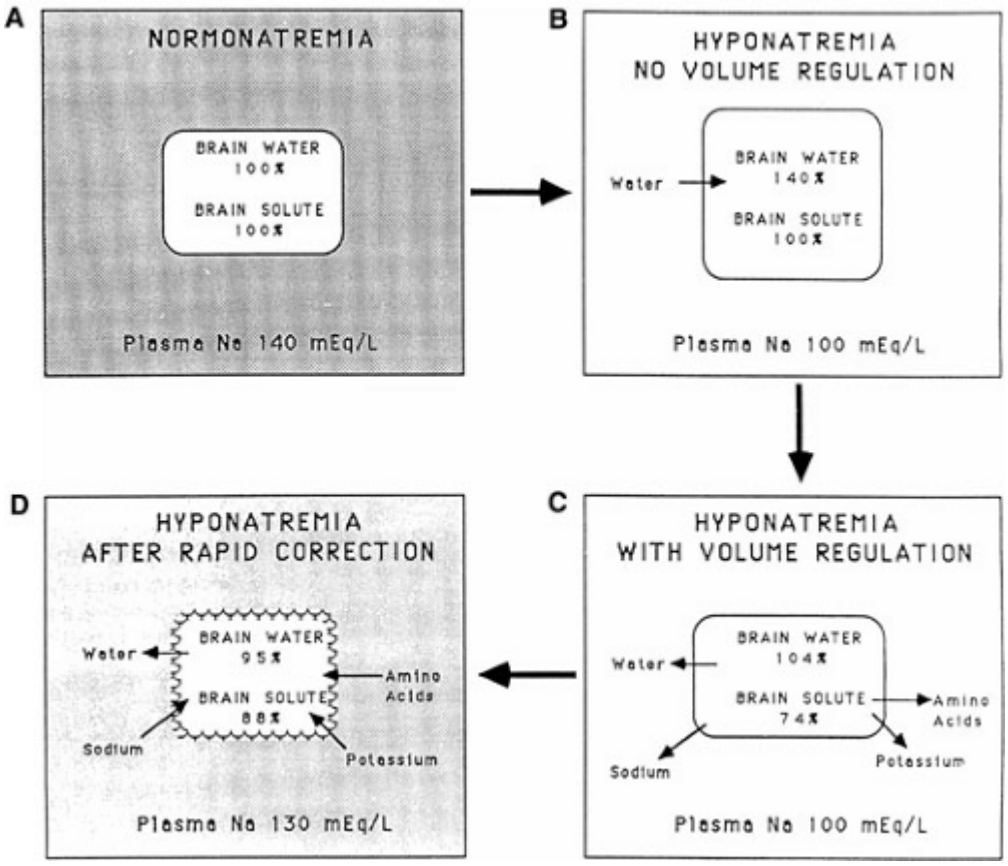

FIGURE 9-8. Brain water and solute in concentrations in hyponatremia. If normal plasma sodium (Na) **(A).** suddenly decreased, the increase in brain water theoretically would be proportional to the decrease in plasma Na **(B).** However, because of adaptive loss of cerebral intracellular solute, cerebral edema is minimized in chronic hyponatremia **(C).** Once adaptation has occurred, a rapid return of plasma Na concentration toward a normal level results in brain dehydration **(D).** (From Sterns RH: Vignettes in clinical pathophysiology. Neurological deterioration following treatment for hyponatremia. Am J Kidney Dis 13:434, 1989.)

The principal determinants of neurologic injury appear to be the magnitude and chronicity of hyponatremia and the rate of correction. The osmotic demyelination syndrome is more likely when hyponatremia has persisted >48 hours.[101] Most patients in whom the osmotic demyelination syndrome is fatal have undergone correction of plasma $[Na^+]$ of more than 20 mEq/L/day. Other risk factors for the development of the osmotic demyelination syndrome include alcoholism, poor nutritional status, liver disease, burns, and hypokalemia.

The clinician faces formidable difficulties in predicting the rate at which plasma $[Na^+]$ will increase because increases in plasma $[Na^+]$ are determined both by the composition of the infused fluid and by the rate of renal free water excretion.[98] The expected change in plasma $[Na^+]$ resulting from 1 liter of selected infusate can be estimated using the following equation:[102]

$$\Delta[Na^+]_s = \frac{[Na^+]_{inf} - [Na^+]_s}{TBW + 1} \qquad (9\text{-}12)$$

where $\Delta[Na^+]_s$ = the change in the patient's serum $[Na^+]$, $[Na^+]_{inf}$ = $[Na^+]$ of the infusate, $[Na^+]_s$ = the patient's serum $[Na^+]$, TBW = the patient's estimated total body water in liters, and 1 = a factor added to take into account the volume of infusate.

Treatment should be interrupted or slowed when symptoms improve. Frequent determinations

of [Na^+] are important to prevent correction at a rate >10 mEq/L/24hr.[101] Initially, plasma [Na^+] may be increased by 1 to 2 mEq/L/hr; however, plasma [Na^+] should not be increased more than 10 mEq/L in 24 hours or 25 mEq/L in 48 hours.[100] Another proposed sequence for treating symptomatic hyponatremia is to increase [Na^+] promptly by about 10 mmol, then to proceed more slowly. The rationale is that cerebral water is increased by approximately 10% in chronic hyponatremia.[85] Hypernatremia should be avoided. Once the plasma [Na^+] exceeds 120 to 125 mEq/L, water restriction alone is usually sufficient to normalize [Na^+]. As acute hyponatremia is corrected, CNS signs and symptoms usually improve within 24 hours, although 96 hours may be necessary for maximal recovery.

For patients who require long-term pharmacologic therapy of hyponatremia, demeclocycline is now the drug of choice.[85] Although better tolerated than lithium, demeclocycline may induce nephrotoxicity, a particular concern in patients with hepatic dysfunction. Hemodialysis is occasionally necessary in severely hyponatremic patients who cannot be adequately managed with drugs or hypertonic saline. Once hyponatremia has

improved, careful fluid restriction is necessary to avoid recurrence of hyponatremia. In the future, vasopressin receptor antagonists may be used to treat hyponatremia.[103]

Hypernatremia

Hypernatremia ([Na^+] >150 mEq/L) indicates an absolute or relative water deficit. Normally, slight increases in tonicity or [Na^+] stimulate thirst and ADH secretion. Therefore, severe, persistent hypernatremia occurs only in patients who cannot respond to thirst by voluntary ingestion of fluid, that is, obtunded patients, anesthetized patients, and infants.

Hypernatremia produces neurologic symptoms (including stupor, coma, and seizures), hypovolemia, renal insufficiency (occasionally progressing to renal failure), and decreased urinary concentrating ability.[104,105] Because hypernatremia frequently results from diabetes insipidus (DI) or osmotically induced losses of sodium and water, many patients are hypovolemic or bear the stigmata of renal disease. Postoperative neurosurgical patients who have undergone pituitary surgery are at particular risk of developing transient or prolonged DI. Polyuria may be present for only a few days within the first week of surgery, may be permanent, or may demonstrate a triphasic sequence: early DI, return of urinary concentrating ability, then recurrent DI.

The clinical consequences of hypernatremia are most serious at the extremes of age and when hypernatremia develops abruptly. Geriatric patients are at increased risk of hypernatremia because of decreased renal concentrating ability and thirst.[106] Brain shrinkage secondary to rapidly developing hypernatremia may damage delicate cerebral vessels, leading to subdural hematoma, subcortical parenchymal hemorrhage, subarachnoid hemorrhage, and venous thrombosis. Polyuria may cause bladder distention, hydronephrosis, and permanent renal damage. At the cellular level, restoration of cell volume occurs remarkably quickly after tonicity is altered (Fig. 9-9).[107] Although the mortality of hypernatremia is 40 to 55%, it is unclear whether hypernatremia is the cause or a marker of severe associated disease.

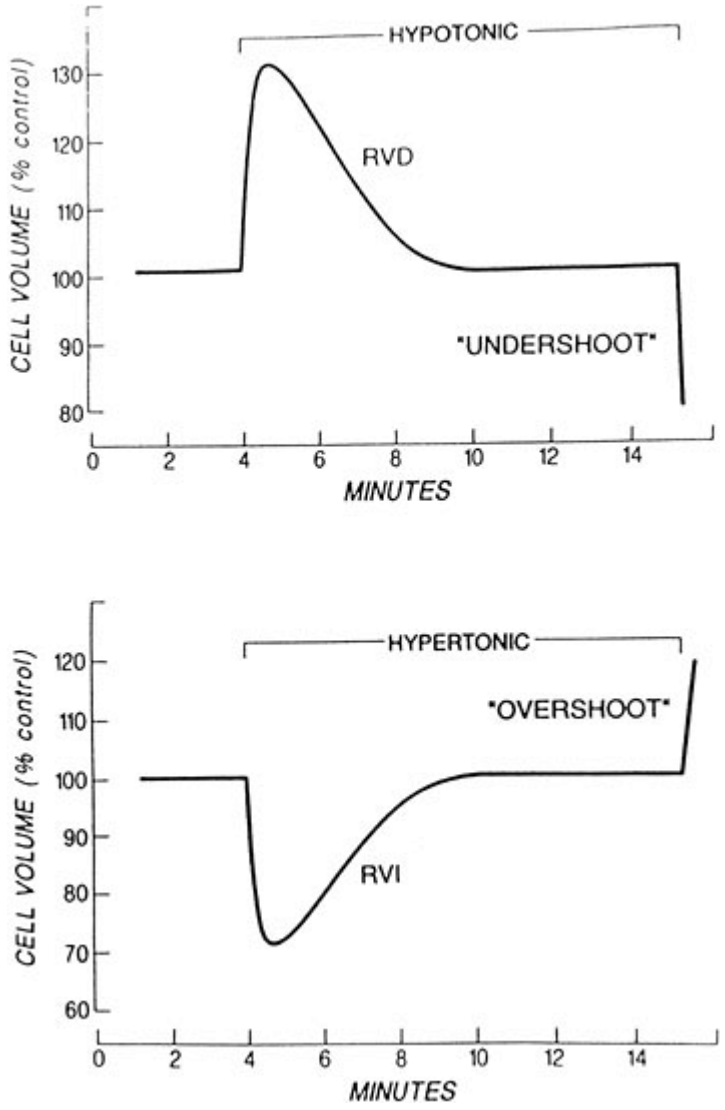

FIGURE 9-9. Activation of mechanisms regulating cell volume in response to acute osmotic stress. Regulatory volume decrease and regulatory volume increase refer to compensatory losses and gains of solutes. Although the course of these regulatory volume decreases and increases varies with the type of cell and experimental conditions, typically the responses occur over a period of minutes. Returning volume-regulated cells to normotonic conditions causes shrinkage or swelling. (From McManus ML, Churchwill KB, Strange K: Regulation of cell volume in health and disease. N Engl J Med 333:1260, 1995.)

Surprisingly, if plasma [Na^+] is initially normal, moderate acute increases in plasma [Na^+] do not appear to precipitate central pontine myelinolysis. However, larger accidental increases in plasma [Na^+] have produced severe consequences in children. In experimental animals, acute severe hypernatremia (acute increase from 146 to 170 mEq/L) caused neuronal damage at 24 hours, suggestive of early central pontine myelinolysis.[108]

By definition, hypernatremia indicates an absolute or relative water deficit and is always associated with hypertonicity. Hypernatremia can be generated by hypotonic fluid loss, as in burns, GI losses, diuretic therapy, osmotic diuresis, renal disease, mineralocorticoid excess or deficiency, and iatrogenic causes, or can be generated by isolated water loss, as in central or nephrogenic DI (Fig. 9-10). The acquired form of nephrogenic DI is more common and usually less severe than the congenital form. As chronic renal failure advances, most patients have defective concentrating ability, resulting in resistance to ADH associated with hypotonic urine. Because hypovolemia accompanies most pathologic water loss, signs of hypoperfusion also may

be present. In many patients, before the development of hypernatremia, an increased volume of hypotonic urine suggests an abnormality in water balance. Although uncommon as a cause of hypernatremia, isolated sodium gain occasionally occurs in patients who receive large quantities of sodium, such as treatment of metabolic acidosis with 8.4% sodium bicarbonate, in which $[Na^+]$ is approximately 1,000 mEq/L, or perioperative or prehospital treatment with hypertonic saline resuscitation solutions.

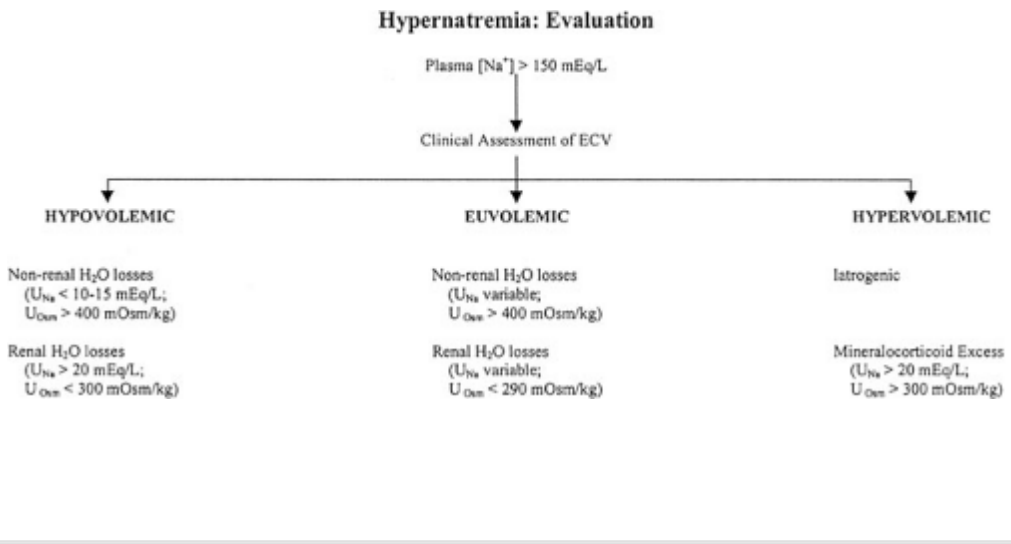

FIGURE 9-10. Severe hypernatremia is evaluated by first separating patients into hypovolemic, euvolemic, and hypervolemic groups based on assessment of extracellular volume (ECV). Next, potential etiologic factors are diagnostically assessed. $[Na^+]$, serum sodium concentration; U_{Na}, urinary sodium concentration; U_{OSm}, urinary osmolality.

Hypernatremic patients can be separated into three groups, based on clinical assessment of ECV (see Fig. 9-10). Note that plasma $[Na^+]$ does not reflect total body sodium, which must be estimated separately based on signs of the adequacy of ECV. In polyuric, hypernatremic patients, the next differential diagnostic decision is between solute diuresis and DI. Measurement of urinary sodium and osmolality can help to differentiate the

various causes. A urinary osmolality <150 mOsm/kg in the setting of hypertonicity and polyuria is diagnostic of DI.

Treatment of hypernatremia produced by water loss consists of repletion of water as well as associated deficits in total body sodium and other electrolytes (Table 9-17). Common errors in treating hypernatremia include excessively rapid correction as well as failing to appreciate the magnitude of the water deficit and failing to account for ongoing maintenance requirements and continued fluid losses in planning therapy.

TABLE 9-17 Hypernatremia: Acute Treatment

Sodium depletion (hypovolemia)
Hypovolemia correction (0.9% saline)
Hypernatremia correction (hypotonic fluids)
Sodium overload (hypervolemia)
Enhance sodium removal (loop diuretics, dialysis)
Replace water deficit (hypotonic fluids)
Normal total body sodium (euvolemia)

Replace water deficit (hypotonic fluids)
Control diabetes insipidus
  Central diabetes insipidus:
    DDAVP, 10–20 μg intranasally; 2–4 μg sc
    Aqueous vasopressin, 5 U q 2–4 hours im or sc
Nephrogenic diabetes insipidus:
    Restrict sodium, water intake
    Thiazide diuretics

The first step in treating hypernatremia is to estimate the TBW deficit, which can be accomplished by inserting the measured plasma [Na^+] into the equation:

$$\text{TBW deficit} = 0.6 \times \text{body weight (kg)} \times [([Na^+] - 140)/140] \qquad (9\text{-}13)$$

where 140 is the middle of the normal range for [Na^+].

Hypernatremia must be corrected slowly because of the risk of neurologic sequelae such as seizures or cerebral edema (Fig. 9-11).[109] At the cellular level, restoration of cell volume occurs remarkably quickly after tonicity is altered; as a consequence, acute treatment of hypertonicity may result in overshooting the original, normotonic cell volume.[107,109] The water deficit should be replaced over 24 to 48 hours, and the plasma [Na^+] should not be reduced by more than 1 to 2 mEq/L/h. Reversible underlying causes should be treated. Hypovolemia should be corrected promptly with 0.9% saline. Although the [Na^+] of 0.9% saline is 154 mEq/L, the solution is effective in treating volume deficits and will reduce [Na^+] that exceeds 154 mEq/L. Once hypovolemia is corrected, water can be replaced orally or with intravenous hypotonic fluids, depending on the ability of the patient to tolerate oral hydration. In the occasional sodium-overloaded patient, sodium excretion can be accelerated using loop diuretics or dialysis.

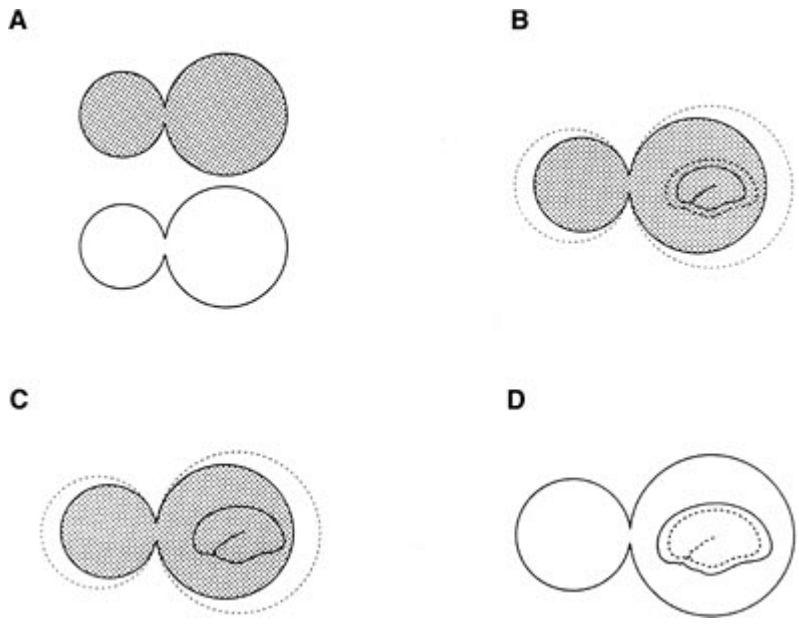

FIGURE 9-11. A. The concentration of sodium is reflected in the intensity of the

stippling: the upper figure, representing extracellular volume (smaller circle) and intracellular volume (larger circle), is more heavily stippled, that is, serum sodium is higher. **B.** In response to an acute increase in serum sodium resulting from water loss, both intracellular and extracellular volume substantially decrease. The brain (schematically illustrated) shrinks in proportion to the reduction in intracellular volume in other tissues. **C.** However, owing to the production of idiogenic osmoles, the brain rapidly restores its intracellular volume, despite the persistent reduction in intracellular volume in other tissues and in extracellular volume. **D.** With excessively rapid correction of hypernatremia (the reduction in serum sodium is reflected in the decrease in the intensity of stippling), the brain expands to greater than its original size. The resulting increase in cerebral edema and intracranial pressure can cause severe neurologic damage. (Modified from Feig PU: Hypernatremia and hypertonic syndromes. Med Clin North Am 65:271, 1981.)

The management of hypernatremia secondary to DI varies according to whether the etiology is central or nephrogenic (see Table 9-17). The two most suitable agents for correcting central DI (an ADH deficiency syndrome) are desmopressin (DDAVP) and aqueous vasopressin. DDAVP, given subcutaneously in a dose of 1 to 4 µg or intranasally in a dose of 5 to 20 µg every 12 to 24 hours, is effective in the vast majority of patients. DDAVP is less likely than vasopressin to produce vasoconstriction and abdominal cramping.[110] Incomplete ADH deficits (partial DI) often are effectively managed with pharmacologic agents that stimulate ADH release or enhance the renal

response to ADH. Chlorpropamide, which potentiates the renal effects of vasopressin, and carbamazepine, which enhances vasopressin secretion, have been used to treat partial central DI, but are associated with clinically important side effects. In nephrogenic DI, salt and water restriction or thiazide diuretics induce contraction of ECV, thereby enhancing fluid reabsorption in the proximal tubules. If less filtrate passes through into the collecting ducts, less water will be excreted.

Potassium

Physiologic Role

Potassium plays an important role in cell membrane physiology, especially in maintaining resting membrane potentials and in generating action potentials in the central nervous system and heart. Potassium is actively transported into cells by a Na/K ATPase pump, which maintains an intracellular [K^+] that is at least 30-fold greater than extracellular [K^+]. Intracellular potassium concentration ([K^+]) is normally 150 mEq/L, while the extracellular concentration is only 3.5 to 5.0 mEq/L. Serum [K^+] measures about 0.5 mEq/L higher than plasma [K^+] because of cell lysis during clotting. Total body potassium in a 70-kg adult is approximately 4,256 mEq, of which 4,200 mEq is intracellular; of the 56 mEq in the ECV, only 12 mEq is located in the PV. The ratio of intracellular to extracellular potassium contributes to the resting potential difference across cell membranes and therefore to the integrity of cardiac and neuromuscular transmission. The primary mechanism that maintains potassium inside cells is the negative voltage created by the transport of three sodium ions out of the cell for every two potassium ions transported in (Fig. 9-12).[111] Both insulin and β-adrenergic agonists promote potassium entry into cells.[111,112] In contrast, α-adrenergic agonists impair cellular potassium uptake.[113] Metabolic acidosis tends to shift potassium out of cells, while metabolic alkalosis favors movement into cells.

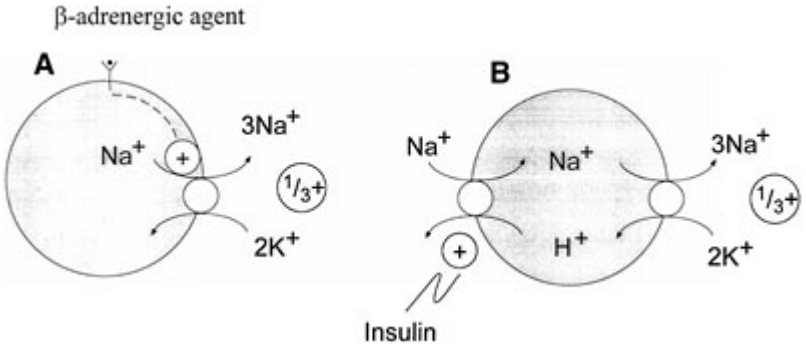

FIGURE 9-12. Hormones shifting potassium into cells. Major hormones involved are: **(A)** insulin and **(B)** β-2 adrenergic agents. (From Halperin ML, Kamel KS: Potassium. Lancet 352:135, 1998.)

Usual potassium intake is between 50 and 150 mEq/day. Freely filtered at the glomerulus, most potassium excretion is urinary, with some fecal elimination. Most filtered potassium is reabsorbed; usually, excretion is approximately equal to daily intake. As long as GFR is >8 mL/kg, dietary potassium intake, unless greater than normal, can be excreted. Assuming a plasma [K^+] of 4.0 mEq/L and a normal GFR of 180 L/day, 720 mEq of potassium is filtered daily, of which 85 to 90% is reabsorbed in the proximal convoluted tubule and loop of Henle. The remaining 10 to 15% reaches the distal convoluted tubule, which is the major site at which potassium excretion is regulated. Excretion of potassium ions is a function of open potassium channels and the electrical driving force in the cortical collecting duct.[111]

The two most important regulators of potassium excretion are the plasma [K^+] and aldosterone, although there is some evidence to suggest involvement of the central nervous system and of an enteric reflex mediated by potassium-rich meals.[114] Potassium secretion into the distal convoluted tubules and cortical collecting ducts is increased by hyperkalemia, aldosterone, alkalemia, increased delivery of Na^+ to the distal tubule and collecting duct, high urinary flow rates, and the presence in luminal fluid of nonreabsorbable anions such as carbenicillin,

phosphates, and sulfates. As sodium reabsorption increases, the electrical driving force opposing reabsorption of potassium is increased. Aldosterone increases sodium reabsorption by inducing a more open configuration of the epithelial sodium channel[115]; potassium-sparing diuretics (amiloride and triamterene) and trimethroprim block the epithelial sodium channel, thereby increasing potassium reabsorption.[116] Magnesium depletion contributes to renal potassium wasting.

Hypokalemia

Uncommon among healthy persons, hypokalemia ([K^+] <3.0 mEq/L) is a frequent complication of treatment with diuretic drugs and occasionally complicates other diseases and treatment regimens (Table 9-18).[113] As a general rule, a chronic decrement of 1.0 mEq/L in the plasma [K^+] corresponds to a total body deficit of approximately 200 to 300 mEq. In uncomplicated hypokalemia, the potassium deficit exceeds 300 mEq if plasma [K^+] is <3.0 mEq/L and 700 mEq if plasma [K^+] is <2.0 mEq/L. Plasma [K^+] poorly reflects total body potassium; hypokalemia may occur with normal, low, or high total body potassium.

	Intrinsic renal transport defects
	Barter's syndrome
	Gitelman's syndrome

Modified from Weiner ID, Wingo CS: Hypokalemia consequences, causes, and correction. J Am Soc Nephrol 8:1179, 1997.

Hypokalemia causes muscle weakness and, when severe, may even cause paralysis. With chronic potassium loss, the ratio of intracellular to extracellular [K^+] remains relatively stable; in contrast, acute redistribution of potassium from the extracellular to the intracellular space substantially changes resting membrane potentials.

Cardiac rhythm disturbances are among the most dangerous complications of potassium deficiency. Acute hypokalemia causes hyperpolarization of the cardiac cell and may lead to ventricular escape activity, re-entrant phenomena, ectopic tachycardias, and delayed conduction. In patients taking digoxin, hypokalemia increases toxicity by increasing myocardial digoxin binding and pharmacologic effectiveness. Hypokalemia contributes to systemic hypertension, especially when combined with a high-sodium diet.[117] In diabetic patients, hypokalemia impairs insulin secretion and end-organ sensitivity to insulin. Although no clear threshold has been defined for a level of hypokalemia below which safe conduct of anesthesia is compromised, [K^+] <3.5 mEq/L has been associated with an increased incidence of perioperative dysrhythmias, especially atrial fibrillation/flutter, in cardiac surgical patients.[118]

Potassium depletion also induces defects in renal concentrating ability, resulting in polyuria and a reduction in GFR. Potassium replacement improves GFR, although the concentrating deficit may not improve for several months after treatment. If hypokalemia is sufficiently prolonged, chronic renal interstitial damage may occur. In experimental animals, hypokalemia was associated with intrarenal vasoconstriction and a pattern of renal injury similar to that produced by ischemia.[119]

Hypokalemia may result from chronic depletion of total body potassium or from acute redistribution of potassium from the ECV to the ICV. Redistribution of potassium into cells occurs when the activity of the sodium–potassium ATPase pump is acutely increased by extracellular hyperkalemia or increased intracellular concentrations of sodium, as well as by insulin, carbohydrate loading (which stimulates release of endogenous insulin), β_2-adrenergic agonists, and aldosterone.[111] Both metabolic and respiratory alkalosis lead to decreases in plasma $[K^+]$.[111,117]

Causes of chronic hypokalemia include those etiologies associated with renal potassium conservation (extrarenal potassium losses; low urinary $[K^+]$) and those with renal potassium wasting (Fig. 9-13).[111,117] A low urinary $[K^+]$ suggests inadequate dietary intake or extrarenal depletion (in the absence of recent diuretic use). Diuretic-induced urinary potassium losses are frequently associated with hypokalemia, secondary to increased aldosterone secretion, alkalemia, and increased renal tubular flow. Aldosterone does not cause renal potassium wasting unless sodium ions are present; that is, aldosterone primarily controls sodium reabsorption, not potassium excretion. Renal tubular damage because of nephrotoxins such as aminoglycosides or amphotericin B may also cause renal potassium wasting.

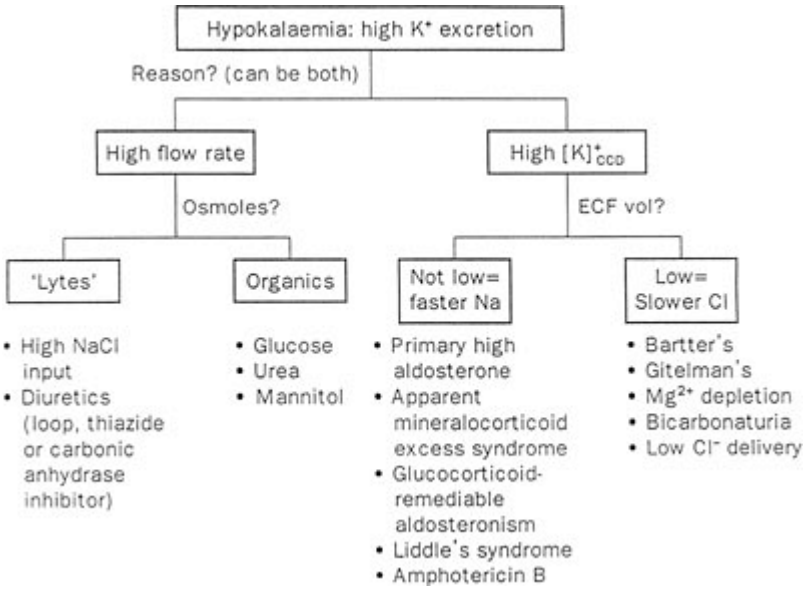

FIGURE 9-13. Approach to managing hypokalemia. Causes for excessive excretion of potassium (>15 mmol/day) despite hypokalemia are too high a flow rate in the cortical collecting duct ([CCD], left limb) and/or too high a concentration of potassium [K+] in lumen of the CCD (right limb). Both flow rate and CCD [K+] should be evaluated. Final considerations are shown by bullets. A relatively slower Cl^- reabsorption in CCD is suggested by high plasma renin activity and NaCl wasting despite low extracellular fluid volume; the converse applies for relatively faster Na^+ reabsorption. (From Halperin ML, Kamel KS: Potassium. Lancet 352:135, 1998.)

Initial evaluation of hypokalemia includes a medical history (e.g., diarrhea, vomiting, diuretic or laxative use), physical examination (e.g., hypertension, cushingoid features, edema),

measurement of serum electrolytes (e.g., magnesium), arterial pH assessment, and evaluation of the electrocardiogram (ECG). A majority of trauma patients develop hypokalemia that returns to normal within 24 hours without specific therapy.[113] Measurement of 24-hour urinary excretion of sodium and potassium may distinguish extrarenal from renal causes. Magnesium deficiency, associated with aminoglycoside and cisplatin therapy, can generate hypokalemia that is resistant to replacement therapy. Plasma renin and aldosterone levels may be helpful in the differential diagnosis. Characteristic electrocardiographic changes associated with

hypokalemia include flat or inverted T waves, prominent U waves, and ST segment depression.

The treatment of hypokalemia consists of potassium repletion, correction of alkalemia, and removal of offending drugs (Table 9-19). Hypokalemia secondary only to acute redistribution may not require treatment. There is no urgent need for potassium replacement therapy in mild to moderate hypokalemia (3 to 3.5 mEq/L), especially if it is a chronic state and the patient has no symptoms. If total body potassium is decreased, oral potassium supplementation is preferable to intravenous replacement. Potassium is usually replaced as chloride salt because coexisting chloride deficiency may limit the ability of the kidney to conserve potassium.

TABLE 9-19 Hypokalemia: Treatment

Correct precipitating factors
Increased pH
Decreased [Mg^{2+}]
Drugs
Mild hypokalemia ([K^+] >2.0 mEq/L)
Intravenous KCl infusion ⩽10 mEq/h
Severe hypokalemia ([K^+] ⩽2.0 mEq/L, paralysis, or electrocardiographic [ECG] changes)
Intravenous KCl infusion ⩽40 mEq/h
Continuous ECG monitoring
If life threatening, 5–6 mEq bolus

Potassium repletion must be performed cautiously (i.e., usually at a rate ⩽10 to 20 mEq/h) because the magnitude of potassium deficits is unpredictable. The plasma [K^+] and the ECG must be monitored during rapid repletion (10 to 20 mEq/h) to avoid hyperkalemic complications.[113,120] The plasma [K^+] and ECG should be monitored to detect inadvertent hyperkalemia. Particular care should be taken in patients who have concurrent acidemia, type IV renal tubular acidosis, or diabetes mellitus, or in those patients receiving nonsteroidal anti-inflammatory agents, ACE inhibitors, or β-blockers, all of which delay movement of extracellular potassium into cells.

However, in patients with life-threatening dysrhythmias secondary to hypokalemia, serum [K^+] must be rapidly increased. Assuming that PV in a 70-kg adult is 3.0 L, administration of 6.0 mEq/L of potassium in 1.0 minute will increase serum [K^+] by no more than 2.0 mEq/L because redistribution into interstitial fluid will decrease the quantity remaining in the plasma volume.[111]

Hypokalemia associated with hyperaldosteronemia (e.g., primary aldosteronism, Cushing syndrome) usually responds favorably to reduced sodium intake and increased potassium intake. Hypomagnesemia, if present, aggravates the effects of hypokalemia, impairs potassium conservation, and should be treated. Potassium supplements or potassium-sparing diuretics should be given cautiously to patients who have diabetes mellitus or renal insufficiency, which limit compensation for acute hyperkalemia. In patients, such as those who have diabetic ketoacidosis, who are both hypokalemic and acidemic, potassium administration should precede correction of acidosis to avoid a precipitous decrease in plasma [K^+] as pH increases.

In patients with normal serum potassium accompanied by symptoms of potassium depletion (e.g., muscle fatigue), history of potassium loss or insufficient intake, or in patients in whom potassium depletion may be of special threat, for example, patients on diuretics, digitalis, or β-2 adrenergic agonists, muscle biopsy with measurement of muscle potassium concentration may be a useful procedure to detect and quantify potassium depletion.

Hyperkalemia

The most lethal manifestations of hyperkalemia ([K^+] >5.0 mEq/L) involve the cardiac conducting system and include dysrhythmias, conduction abnormalities, and cardiac arrest. In anesthesia practice, the classic example of hyperkalemic cardiac toxicity is associated with the administration of succinylcholine to paraplegic, quadriplegic, or severely burned [121] patients. If plasma [K^+] is <6.0 mEq/L, cardiac effects are negligible. As the concentration increases further, the electrocardiogram shows tall, peaked T waves, especially in the precordial leads. With further increases, the PR interval becomes prolonged, followed by a decrease in the amplitude of the P wave. Finally, the QRS complex widens into a pattern resembling a sine wave, as a prelude to cardiac standstill (Fig. 9-14).[122] Hyperkalemic cardiotoxicity is enhanced by hyponatremia, hypocalcemia, or acidosis. Because progression to fatal cardiotoxicity is unpredictable and often swift, the presence of hyperkalemic ECG changes mandates immediate therapy. The life-threatening cardiac effects usually require more urgent treatment than other manifestations of hyperkalemia. However, ascending muscle weakness appears when plasma [K^+] approaches 7.0 mEq/L, and may progress to flaccid paralysis, inability to phonate, and respiratory arrest.

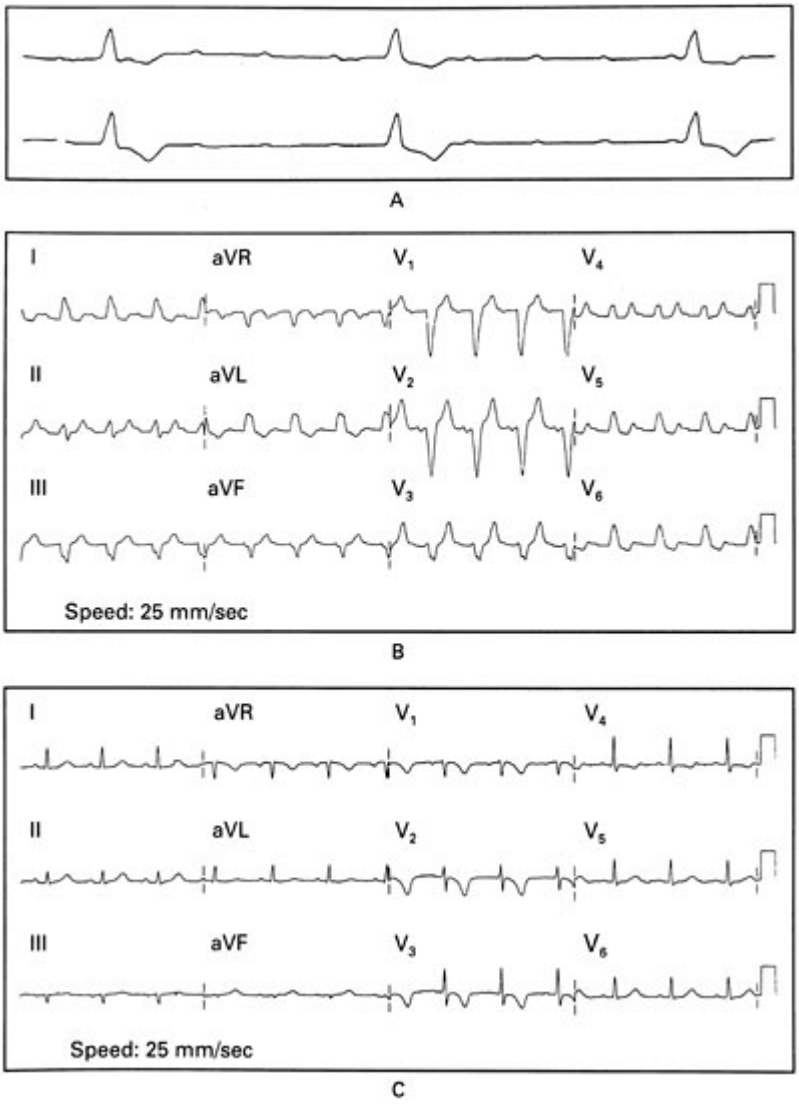

FIGURE 9-14. Electrocardiographic changes as a result of hyperkalemia occurring in a 42-year-old woman undergoing placement of an arteriovenous fistula for permanent hemodialysis access to treat end-stage renal disease. **A.** During dissection of the brachial artery under local anesthesia, her cardiac rhythm converted from normal sinus rhythm to complete heart block with ventricular escape (approximately 25 beats per minute). Two ampules of calcium gluconate (9.2 mEq) were administered intravenously. **B.** An

electrocardiogram revealed sinus tachycardia with profound prolongation of the QRS interval (left bundle-branch morphology), first-degree atrioventricular block, and "peaked" T waves. The serum potassium concentration was 8.6 mmol/L. **C.** After reduction of the serum potassium concentration, the electrocardiogram showed sinus rhythm with normalization of the PR and QRS intervals. Anteroseptal ST wave and T wave changes were noted on subsequent electrocardiograms. A cardiac exercise imaging study did not show ischemia. (From Kuvin JT: Electrocardiographic changes of hyperkalemia. N Engl J Med 338:662, 1998.)

The most important diagnostic issues are medical history, emphasizing recent drug therapy, and assessment of renal function. Although the ECG may provide the first suggestion of hyperkalemia in some patients, and despite the well-described effects of hyperkalemia on cardiac conduction and rhythm, the ECG is an insensitive and nonspecific method of detecting hyperkalemia.[123] If hyponatremia is also present, adrenal function should be evaluated.

Hyperkalemia may occur with normal, high, or low total body potassium stores. A deficiency of aldosterone, a major regulator of potassium excretion, leads to hyperkalemia in adrenal insufficiency and hyporeninemic hypoaldosteronism, a state associated with diabetes mellitus, renal insufficiency, and advanced age. Because the kidneys excrete potassium, severe renal insufficiency commonly causes hyperkalemia. Patients with chronic renal insufficiency can maintain normal plasma [K^+] despite markedly decreased GFR because urinary potassium excretion depends on tubular secretion rather than glomerular filtration if GFR exceeds 8 mL/min.

Drugs are now the most common cause of hyperkalemia, especially in elderly patients.[124] Drugs that may limit potassium excretion include nonsteroidal anti-inflammatory drugs, ACE inhibitors, cyclosporin, and potassium-sparing diuretics such as triamterene. Drug-induced hyperkalemia most commonly occurs in patients with other predisposing factors, such as diabetes mellitus, renal insufficiency, advanced age, or hyporeninemic hypoaldosteronism. ACE inhibitors are particularly likely to produce hyperkalemia in patients who have congestive heart failure.[125]

In patients who have normal total body potassium, hyperkalemia may accompany a sudden shift of potassium from the ICV to the ECV because of acidemia, increased catabolism, or

rhabdomyolysis. Metabolic acidosis and respiratory acidosis tend to cause an increase in plasma [K^+]. However, organic acidoses (i.e., lactic acidosis, ketoacidosis) have little effect on [K^+], whereas mineral acids cause significant cellular shifts. In response to increased hydrogen ion activity because of addition of acids, potassium will increase if the anion remains in the extracellular volume.[111] Neither lactate nor ketoacids remain in the extracellular fluid. Therefore, hyperkalemia in these circumstances reflects tissue injury or lack of insulin.[111] Pseudohyperkalemia, which occurs when potassium is released from cells in blood collection tubes, can be diagnosed by comparing serum and plasma K^+ levels from the same blood sample. Hyperkalemia usually accompanies malignant hyperthermia.

The treatment of hyperkalemia is aimed at eliminating the cause, reversing membrane hyperexcitability, and removing potassium from the body (Fig. 9-15).[111,125] Emergent management of severe hyperkalemia is listed in detail in Table 9-20.[125] Mineralocorticoid deficiency can be treated with 9-α-fludrocortisone (0.025 to 0.10 mg/day). Hyperkalemia secondary to digitalis intoxication may be resistant to therapy because attempts to shift potassium from the ECV to the ICV are often ineffective. In this situation, use of digoxin-specific antibodies has been successful.

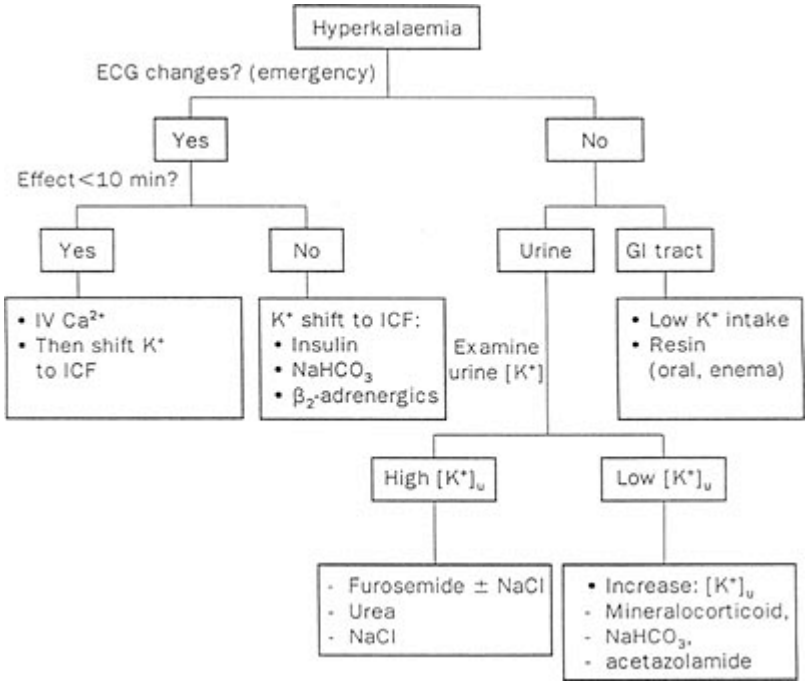

FIGURE 9-15. Treatment of patient with hyperkalemia. If an emergency is present (usually cardiac), intravenous Ca^{2+} must be given. This treatment should be given promptly. Efforts are also taken to shift potassium into cells with insulin with or without $NaHCO_3$. Longer term strategies are to limit intake of potassium, prevent its absorption in the gastrointestinal tract, and promote its excretion; the latter includes measuring urine $[K^+]$ and flow rate to decide leverage for therapy. (From Halperin ML, Kamel KS: Potassium. Lancet 352:135, 1998.)

TABLE 9-20 Severe Hyperkalemia:[a] Treatment

Reverse membrane effects
Calcium (10 mL of 10% calcium chloride IV over 10 min)
Transfer extracellular $[K^+]$ into cells
Glucose and insulin (D10W + 5–10 U regular insulin per 25–50 g glucose)
Sodium bicarbonate (50 to 100 mEq over 5–10 min)
β-2 agonists
Remove potassium from body
Diuretics, proximal or loop
Potassium-exchange resins (sodium polystyrene sulfonate)
Hemodialysis
Monitor ECG and serum $[K^+]$ level

[a]Potassium concentration ($[K^+]$) >7.0 mEq/L or electrocardiographic (ECG) changes.

Membrane hyperexcitability can be antagonized by translocating potassium from the ECV to the ICV, removing excess potassium, or (transiently) by infusing calcium chloride to depress the membrane threshold potential. Pending definitive treatment, rapid infusion of calcium chloride (one gram of $CaCl_2$ over 3 minutes, or two to three ampules of 10% calcium gluconate over 5 minutes) may stabilize cardiac rhythm (see Fig. 9-14). Calcium should be given cautiously if

bicarbonate (50 to 100 mEq over 5 to 10 minutes in a 70-kg adult) transiently promotes movement of potassium from the ECV to the ICV. Bicarbonate can be administered even if pH exceeds 7.40; however, it should not be administered to patients with congestive cardiac failure or hypernatremia. Insulin, in a dose-dependent fashion, causes cellular uptake of potassium by increasing the activity of the sodium/potassium ATPase pump. However, when used alone, bicarbonate is relatively ineffective and is no longer favored.[125] Insulin increases cellular uptake of potassium best when high insulin levels are achieved by intravenous injection of 5 to 10 U of regular insulin, accompanied by 50 mL of 50% glucose.[125] β-2 adrenergic drugs such as salbutamol and albuterol also increase potassium uptake by skeletal muscle and reduce plasma [K^+], an action that may explain hypokalemia with severe, acute illness. β-2 agonists have been used to treat hyperkalemia.[126] Salbutamol, a selective β-2 agonist, decreases serum potassium acutely when given by inhalation or intravenously. In 15 pediatric patients with baseline serum [K^+] of 6.6 mEq/L, a single infusion of salbutamol (5 μg/kg over 15 minutes) reduced serum [K^+] to 5.7 mEq/L after 30 minutes and 4.9 mEq/L after 120 minutes.[127] When using β-2 adrenergic agents to reduce serum [K^+], the potential for generating cardiac dysrhythmias should be recognized.[128]

Potassium may be removed from the body by the renal or gastrointestinal routes. Furosemide promotes kaliuresis in a dose-dependent fashion. Sodium polystyrene sulfonate resin (Kayexalate), which exchanges sodium for potassium, can be given orally (30 g) or as a retention enema (50 g in 200 mL of 20% sorbitol). However, sodium overload and hypervolemia are potential risks. Rarely, when temporizing measures are insufficient, emergency hemodialysis may remove 25 to 50 mEq/h. Peritoneal dialysis is less efficient.

Calcium

Physiologic Role

Calcium is a divalent cation found primarily in the extracellular fluid. The free calcium concentration [Ca^{2+}] in ECV is approximately 1 mM, whereas the free [Ca^{2+}] in the ICV approximates 100 mM, a gradient of 10,000 to 1. Circulating calcium consists of a protein-bound fraction (40%), a chelated fraction (10%), and an ionized fraction (50%), which is the physiologically active and homeostatically regulated component.[129] Acute acidemia increases and acute alkalemia decreases ionized calcium. Because mathematical formulae that "correct" total calcium measurements for albumin concentration are inaccurate in critically ill patients,[130] ionized calcium should be directly measured.

In general, calcium is essential for all movement that occurs in mammalian systems. Essential for normal excitation-contraction coupling, calcium is also necessary for proper function of muscle tissue, ciliary movement, mitosis, neurotransmitter release, enzyme secretion, and hormonal secretion. Cyclic AMP (cAMP) and phosphoinositides, which are major second messengers regulating cellular metabolism, function primarily through the regulation of calcium movement. Activation of numerous intracellular enzyme systems requires calcium. Calcium is important both for generation of the cardiac pacemaker activity and for generation of the cardiac action potential, and therefore is the primary ion responsible for the plateau phase of the action potential. Calcium also plays vital functions in membrane and bone structure.

Serum [Ca^{2+}] is regulated by multiple factors (Fig. 9-16),[131] including a calcium receptor[132,133] and several hormones. Parathyroid hormone (PTH) and calcitriol, the most important neurohumoral mediators of serum [Ca^{2+}][134] (see Table 9-15), mobilize calcium from bone, increase renal tubular reabsorption of calcium, and enhance intestinal absorption of calcium. Vitamin D, after ingestion or cutaneous manufacture under the stimulus of ultraviolet light, is 25-hydroxylated to calcidiol in the liver and then is 1-hydroxylated to calcitriol, the active metabolite, in the kidney. Even in the absence of dietary calcium intake, PTH and vitamin D can maintain a normal circulating [Ca^{2+}] by mobilizing calcium from bone.

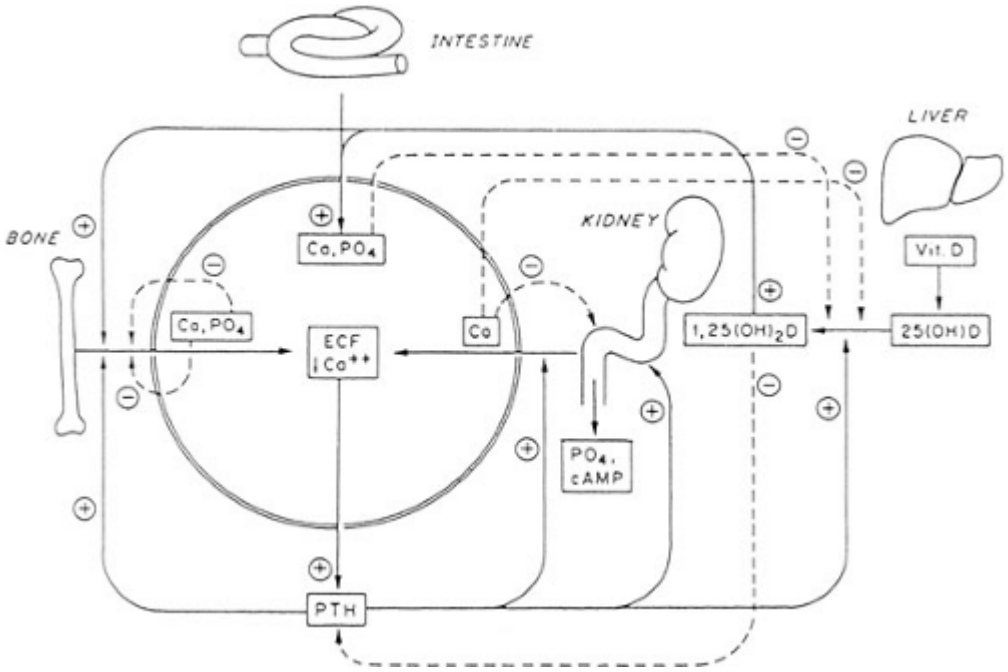

FIGURE 9-16. Schematic representation of the regulatory system maintaining Ca^{2+}_o homeostasis. The *solid arrows* and *lines* delineate effects of parathyroid hormone and 1,25 $(OH)_2D_3$ on their target tissues; *dashed arrows* and *lines* show examples of how extracellular Ca^{2+} or phosphate ions act directly on tissues regulating mineral ion metabolism. Ca, calcium; PO_4, phosphate; ECF, extracellular fluid; PTH, parathyroid hormone; 1,25 $(OH)_2D_3$, 1,25 dihydroxyvitamin D; 25(OH)D, 25-hydroxyvitamin D; negative signs indicate inhibitory actions and plus signs indicate stimulatory effects. Hypocalcemia

Hypocalcemia (ionized $[Ca^{2+}]$ <4.0 mg/dL or <1.0 mmol/L) occurs as a result of failure of PTH or calcitriol action or because of calcium chelation or precipitation, not because of calcium deficiency alone. PTH deficiency can result from surgical damage or removal of the parathyroid glands or from suppression of the parathyroid glands by severe hypo- or hypermagnesemia. Burns, sepsis, and pancreatitis may suppress parathyroid function and interfere with vitamin D action.

Vitamin D deficiency may result from lack of dietary vitamin D or vitamin D malabsorption in patients who lack sunlight exposure. Hyperphosphatemia-induced hypocalcemia may occur as a consequence of overzealous phosphate therapy, from cell lysis secondary to chemotherapy, or as a result of cellular destruction from rhabdomyolysis. Precipitation of $CaHPO_4$ complexes occurs with hyperphosphatemia. However, ionized $[Ca^{2+}]$ only decreases approximately 0.019 mM for each 1.0 mM increase in phosphate concentration. In massive transfusion, citrate may produce hypocalcemia by chelating calcium; however, decreases are usually transient and produce no cardiovascular effects. A healthy, normothermic adult who has intact hepatic and renal function can metabolize the citrate present in 20 units of blood per hour without becoming hypocalcemic.[135] However, when citrate clearance is decreased (e.g., by hepatic or renal disease or hypothermia) and when blood transfusion rates are rapid (e.g., >0.5 to 2 mL/kg/min), hypocalcemia and cardiovascular compromise may occur. Alkalemia resulting from hyperventilation or sodium bicarbonate injection can acutely decrease $[Ca^{2+}]$.

The hallmark of hypocalcemia is increased neuronal membrane irritability and tetany (Table 9-

21). Early symptoms include sensations of numbness and tingling involving fingers, toes, and the circumoral region. In frank tetany, tonic contraction of respiratory muscles may lead to laryngospasm, bronchospasm, or respiratory arrest. Smooth muscle spasm can result in abdominal cramping and urinary frequency. Mental status alterations include irritability, depression, psychosis, and dementia. Hypocalcemia may impair cardiovascular function and has been associated with heart failure, hypotension, dysrhythmias, insensitivity to digitalis, and impaired β-adrenergic action.

Reduced *ionized* serum calcium occurs in as many as 88% of critically ill patients, 66% of less severely ill ICU patients, and 26% of hospitalized non-ICU patients.[136] Patients at particular risk include patients after multiple trauma and cardiopulmonary bypass. In most such patients, ionized hypocalcemia is clinically mild ($[Ca^{2+}]$ 0.8 mmol/L to 1.0 mmol/L).

Initial diagnostic evaluation should concentrate on history and physical examination, laboratory evaluation of renal function, and measurement of serum phosphate concentration. Latent hypocalcemia can be diagnosed by tapping on the facial nerve to elicit Chvostek's sign or by inflating a sphygmomanometer to 20 mmHg above systolic pressure, which produces radial and ulnar nerve ischemia and causes carpal spasm known as Trousseau's sign. The differential diagnosis of hypocalcemia can be approached by addressing four issues: age of the patient, serum phosphate concentration, general clinical status, and duration of hypocalcemia.[137] High phosphate concentrations suggest renal failure or hypoparathyroidism. In renal insufficiency, reduced phosphorus excretion results in hyperphosphatemia, which down-regulates the 1α-hydroxylase responsible for the renal conversion of calcidiol to calcitriol. This, in combination with decreased production of calcitriol secondary to reduced renal mass, causes reduced intestinal absorption of calcium and hypocalcemia.[134] Low or normal phosphate concentrations

imply vitamin D or magnesium deficiency. An otherwise healthy patient with chronic hypocalcemia probably is hypoparathyroid. Chronically ill adults with hypocalcemia often have disorders such as malabsorption, osteomalacia, or osteoblastic metastases. Clinical diagnosis of hypocalcemia in the patient receiving multiple transfusions, because of citrate excess, is often difficult. The only manifestation may be hypotension as a result of poor cardiac function, which is difficult to differentiate from hypotension as a result of hypovolemia.

The definitive treatment of hypocalcemia necessitates identification and treatment of the underlying cause (Table 9-22). Symptomatic hypocalcemia usually occurs when serum ionized [Ca^{2+}] is <0.7 mM. The clinician should carefully consider whether mild, asymptomatic ionized hypocalcemia requires therapy, particularly in ischemic and septic states in which experimental evidence suggests that calcium may increase cellular damage.

TABLE 9-22 Hypocalcemia: Acute Treatment

Administer calcium
IV: 10 mL 10% calcium gluconate[a] over 10 min, followed by elemental calcium 0.3–2.0 mg/kg/h
Oral: 500–100 mg elemental calcium q 6 hours
Administer vitamin D
Ergocalciferol, 1,200 μg/day ($T_{1/2}$ = 30 days)
Dihydrotachysterol, 200–400 μg/day ($T_{1/2}$ = 7 days)
1,25-dihydroxycholecalciferol, 0.25–1.0 μg/day ($T_{1/2}$ = 1 day)
Monitor electrocardiogram

[a]Calcium gluconate contains 93 mg elemental calcium per 10-mL vial. $T_{1/2}$, half-life.

Unnecessary offending drugs should be discontinued. Hypocalcemia resulting from hypomagnesemia or hyperphosphatemia is treated by repletion of magnesium or removal of phosphate. Treatment of a patient who has tetany and hyperphosphatemia requires coordination of therapy to avoid the consequences of metastatic soft tissue calcification.[138] Potassium and other electrolytes should be measured and abnormalities should be corrected. Hyperkalemia and hypomagnesemia potentiate hypocalcemia-induced cardiac and neuromuscular irritability. In contrast, hypokalemia protects against hypocalcemic tetany; therefore, correction of hypokalemia without correction of hypocalcemia may provoke tetany.

Mild, ionized hypocalcemia should not be overtreated. For instance, in most patients after cardiac surgery, administration of calcium only increases blood pressure[139] and actually attenuates the β-adrenergic effects of epinephrine.[139] In normocalcemic dogs, calcium chloride primarily acts as a peripheral vasoconstrictor, with transient reduction of myocardial contractility; in hypocalcemic dogs, calcium infusion significantly improves contractile performance and blood pressure (Table 9-23).[140] Therefore, calcium infusions should be of

limited value in surgical patients unless there is demonstrable evidence of hypocalcemia.[140] Calcium salts appear to confer no benefit to patients already receiving inotropic or vasoactive agents.

TABLE 9-23 Serum Ionized [Ca^{2+}] Concentration and Hemodynamic Variables One Minute after Calcium Administration (5 mg/kg Intravenous Bolus) in Normocalcemic and Hypocalcemic (Produced by CPD Administration) Dogs

	·NORMOCALCEMIC		·HYPOCALCEMIC

From Mathru M, Rooney MW, Goldberg SA *et al*: Separation of myocardial versus peripheral effects of calcium administration in normocalcemic and hypocalcemic states using pressure-volume (conductance) relationships. Anesth Analg 77:250, 1993.

The cornerstone of therapy for confirmed, symptomatic, ionized hypocalcemia ([Ca^{2+}] <0.7 mM) is calcium administration. In patients who have severe hypocalcemia or hypocalcemic symptoms, calcium should be administered intravenously. In emergency situations, in an averaged-sized adult, the "rule of 10s" advises infusion of 10 mL of 10% calcium gluconate (93 mg elemental calcium) over 10 minutes, followed by a continuous infusion of elemental calcium, 0.3 to 2 mg/kg/h (i.e., 3 to 16 mL/h of 10% calcium gluconate for a 70-kg adult). Calcium salts should be diluted in 50 to 100 mL D5W (to limit venous irritation and thrombosis), should not be mixed with bicarbonate (to prevent precipitation), and must be

given cautiously to digitalized patients because calcium increases the toxicity of digoxin. Continuous ECG monitoring during initial therapy will detect cardiotoxicity (e.g., heart block, ventricular fibrillation). During calcium replacement, the clinician should monitor serum calcium, magnesium, phosphate, potassium, and creatinine. Once the ionized [Ca^{2+}] is stable in the range of 4 to 5 mg/dL (1.0 to 1.25 mM), oral calcium supplements can substitute for parenteral therapy. Urinary calcium should be monitored in an attempt to avoid hypercalciuria (>5 mg/kg per 24 hours) and urinary tract stone formation.

When supplementation fails to maintain serum calcium within the normal range, or if hypercalciuria develops, vitamin D may be added. Although the principal effect of vitamin D is to increase enteric calcium absorption, osseous calcium resorption is also enhanced. When rapid changes in dosage are anticipated or an immediate effect is required (e.g., postoperative hypoparathyroidism), shorter acting calciferols such as dihydrotachysterol may be preferable. Because the effect of vitamin D is not regulated, the dosages of calcium and vitamin D should be adjusted to raise the serum calcium into the low normal range.

Adverse reactions to calcium and vitamin D include hypercalcemia and hypercalciuria. If hypercalcemia develops, calcium and vitamin D should be discontinued and appropriate therapy given. The toxic effects of vitamin D metabolites persist in proportion to their biologic half-lives (ergocalciferol, 20 to 60 days; dihydrotachysterol, 5 to 15 days; calcitriol, 2 to 10 days). Glucocorticoids antagonize the toxic effects of vitamin D metabolites.

Hypercalcemia

Although ionized [Ca^{2+}] most accurately demonstrates hypercalcemia (ionized [Ca^{2+}] >1.5 mmol/L or total serum calcium >10.5 mg/dL), hypercalcemia customarily is defined in terms of total serum calcium. In hypoalbuminemic patients, total serum calcium can be estimated by assuming an increase of 0.8 mg/dL for every 1 g/dL of albumin concentration below 4.0 g/dL. Patients in whom total serum calcium is less than 11.5 mg/dL are usually asymptomatic. Patients with moderate hypercalcemia (total serum calcium 11.5 to 13 mg/dL) may show symptoms of lethargy, anorexia, nausea, and polyuria. Severe hypercalcemia (total serum calcium >13 mg/dL) is associated with more severe neuromyopathic symptoms, including muscle weakness, depression, impaired memory, emotional lability, lethargy, stupor, and coma. The cardiovascular effects of hypercalcemia include hypertension, dysrhythmias, heart block, cardiac arrest, and digitalis sensitivity. Skeletal disease may occur secondary to direct osteolysis or humoral bone resorption.

Hypercalcemia impairs urinary concentrating ability and renal excretory capacity for calcium by irreversibly precipitating calcium salts within the renal parenchyma and by reducing renal blood flow and GFR. In response to hypovolemia, renal tubular reabsorption of sodium enhances renal calcium reabsorption. Effective treatment of severe hypercalcemia is necessary to prevent progressive dehydration and renal failure leading to further increases in total serum calcium, because volume depletion exacerbates hypercalcemia.[141] Hypercalcemia occurs when calcium enters the extracellular volume more rapidly than the kidneys can excrete the excess. Clinically, hypercalcemia most commonly results from an excess of bone resorption over bone formation, usually secondary to malignant disease, hyperparathyroidism, hypocalciuric hypercalcemia, thyrotoxicosis, immobilization, and granulomatous diseases. Granulomatous diseases produce hypercalciuria and hypercalcemia because of conversion by granulomatous tissue of calcidiol to calcitriol.[134]

Malignancy may produce hypercalcemia either through bone destruction or secretion by malignant tissue of hormones that promote hypercalcemia.[142] Although weakness, weight

loss, and anemia associated with primary hyperparathyroidism may suggest malignancy, these may result simply from the primary disease process. Hypercalcemia associated with granulomatous diseases (e.g., sarcoidosis) results from the production of calcitriol by granulomatous tissue. To compensate for increased gut absorption or bone resorption of calcium, renal excretion can readily increase from 100 to more than 400 mg/day. Factors that

promote hypercalcemia may be offset by coexisting disorders, such as pancreatitis, sepsis, or hyperphosphatemia, that cause hypocalcemia.

Although definitive treatment of hypercalcemia requires correction of underlying causes, temporizing therapy may be necessary to avoid complications and to relieve symptoms. Total serum calcium exceeding 14 mg/dL represents a medical emergency. General supportive treatment includes hydration, correction of associated electrolyte abnormalities, removal of offending drugs, dietary calcium restriction, and increased physical activity. Because anorexia and antagonism by calcium of ADH action invariably lead to sodium and water depletion, infusion of 0.9% saline will dilute serum calcium, promote renal excretion, and can reduce total serum calcium by 1.5 to 3 mg/dL. Urinary output should be maintained at 200 to 300 mL/h. As GFR increases, sodium ions increase calcium excretion by competing with calcium ions for reabsorption in the proximal renal tubules and loop of Henle.

Furosemide further enhances calcium excretion by increasing tubular sodium. Patients who have renal impairment may require higher doses of furosemide. During saline infusion and forced diuresis, careful monitoring of cardiopulmonary status and electrolytes, especially magnesium and potassium, is required. Intensive diuresis and saline administration can achieve net calcium excretion rates of 2,000 to 4,000 mg per 24 hours, a rate eight times greater than saline alone, but still somewhat less than the rate of removal achieved by hemodialysis (i.e., 6,000 mg every 8 hours). Patients treated with phosphates should be well hydrated.

Bone resorption, the primary cause of hypercalcemia, can be minimized by increasing physical activity and initiating drug therapy.[131,143] Bisphosphonates, currently the first-line therapy for acute hypercalcemia, inhibit osteoclast function and viability. Bisphosphonates are the principal drugs for the management of hypercalcemia mediated by osteoclastic bone resorption.[144] Pamidronate, unlike earlier biphosphonates, does not appear to worsen renal insufficiency. More recently released biphosphonates include alendronate, risendronate, and zolecronic acid. Risendronate has been associated with less gastrointestinal morbidity than alendronate.[145,146] Zoledronic acid has the most rapid onset of action among the biphosphonates and prolongs the duration before relapse of hypercalcemia; however, zoledronic acid has been associated with compromised renal function.[143]

Other osteoclast-inhibiting agents used to treat hypercalcemia include mithramycin and calcitonin.[147] Mithramycin, a cytotoxic agent, lowers serum calcium primarily by inhibiting bone resorption, probably because of toxicity to osteoclasts. The hypocalcemic effect, usually seen within 12 to 24 hours following a single intravenous dose of 25 µg/kg, peaks at 48 to 72 hours, and persists for 5 to 7 days. Major toxic effects of mithramycin, more likely to occur in patients with renal insufficiency, include thrombocytopenia, nephrotoxicity, and hepatotoxicity. Calcitonin lowers serum calcium within 24 to 48 hours and is more effective when combined with glucocorticoids.[143] Usually calcitonin reduces total serum calcium by only 1 to 2 mg/dL. Although calcitonin is relatively nontoxic, more than 25% of patients may not respond. Thus, calcitonin is unsuitable as a first-line drug during life-threatening hypercalcemia.

Hydrocortisone is effective in treating hypercalcemic patients with lymphatic malignancies, vitamin D or A intoxication, and diseases associated with production by tumor or granulomas of $1,25(OH)_2D$ or osteoclast-activating factor. Glucocorticoids rarely improve hypercalcemia secondary to malignancy or hyperparathyroidism. In the near future, calcium receptor agonists may become the treatments of choice for suppressing primary and secondary hyperparathyroidism. Currently undergoing initial clinical trials, these agents also reduce inorganic phosphate concentration (Pi) and the calcium × phosphate produce.[148]

Phosphates lower serum calcium by causing deposition of calcium in bone and soft tissue. Because the risk of extraskeletal calcification of organs such as the kidneys and myocardium is less if phosphates are given orally, the intravenous route should be reserved for patients with life-threatening hypercalcemia or patients in whom other measures have failed.

Phosphate

Physiologic Role

Phosphorus, in the form of inorganic phosphate (Pi), is distributed in similar concentrations throughout intracellular and extracellular fluid. Of total body phosphorus, 90% exists in bone, 10% is intracellular, and the remainder, <1%, is found in the extracellular fluid. Phosphate circulates as the free ion (55%), complexed ion (33%), and in a protein-bound form (12%). Blood levels vary widely: the normal total Pi ranges from 2.7 to 4.5 mg/dL in adults.

Control of Pi is achieved by altered renal excretion and redistribution within the body compartments. Absorption occurs in the duodenum and jejunum and is largely unregulated. Phosphate reabsorption in the kidney is primarily regulated by PTH, dietary intake, and insulin-like growth factor.[149] Phosphate is freely filtered at the glomerulus and its concentration in the glomerular ultrafiltrate is similar to plasma. The filtered phosphate is then reabsorbed in the proximal tubule where it is cotransported with sodium.[149] Proximal tubular reabsorption of phosphorus occurs by passive cotransport with sodium.[150] Cotransport is regulated by phosphorus intake and PTH.[151] Phosphate excretion is increased by volume expansion and decreased by respiratory alkalosis.

Phosphates provide the primary energy bond in ATP and creatine phosphate. Therefore, severe phosphate depletion results in cellular energy depletion. Phosphorus is an essential element of second-messenger systems, including cAMP and phosphoinositides, and a major component of nucleic acids, phospholipids, and cell membranes. As part of 2,3-diphosphoglycerate, phosphate promotes release of oxygen from the hemoglobin molecule. Phosphorus also functions in protein phosphorylation and acts as a urinary buffer.

Hypophosphatemia

Hypophosphatemia is characterized by low levels of phosphate-containing cellular components, including ATP, 2,3-diphosphoglycerate, and membrane phospholipids. Serious life-threatening organ dysfunction may occur when the serum Pi falls below 1 mg/dL. Neurologic manifestations of hypophosphatemia include paresthesias, myopathy, encephalopathy, delirium, seizures, and coma.[152] Hematologic abnormalities include dysfunction of erythrocytes, platelets, and leukocytes. Because hypophosphatemia limits the chemotactic, phagocytic, and bactericidal activity of granulocytes, associated immune dysfunction may contribute to the susceptibility of hypophosphatemic patients to sepsis.[153] Muscle weakness and malaise are common. Respiratory muscle failure and myocardial dysfunction are potential problems of

particular concern to anesthesiologists. Rhabdomyolysis is a complication of severe hypophosphatemia.[154]

Common in postoperative and traumatized patients, hypophosphatemia (Pi <2.5 mg/dL) is caused by three primary abnormalities in Pi homeostasis: an intracellular shift of Pi, an increase in renal Pi loss, and a decrease in gastrointestinal Pi absorption. Carbohydrate-induced hypophosphatemia (*refeeding syndrome*),[155] mediated by insulin-induced cellular Pi uptake, is the type most commonly encountered in hospitalized patients. Hypophosphatemia may also occur as catabolic patients become anabolic, and during medical management of diabetic ketoacidosis. Acute alkalemia, which may reduce serum Pi to 1 to 2 mg/dL, increases intracellular consumption of Pi by increasing the rate of glycolysis. Hyperventilation significantly reduces Pi and, importantly, the effect is progressive after cessation of hyperventilation.[156] Acute correction of respiratory acidemia may also result in severe hypophosphatemia. Respiratory alkalosis probably explains the hypophosphatemia associated with gram-negative bacteremia and salicylate poisoning. Excessive renal loss of Pi explains the hypophosphatemia associated with hyperparathyroidism, hypomagnesemia, hypothermia, diuretic therapy, and renal tubular defects in Pi absorption. Excess gastrointestinal loss of Pi is most commonly secondary to the use of Pi-binding antacids or to malabsorption syndromes.

Measurement of urinary Pi aids in differentiation of hypophosphatemia as a result of renal losses from that because of excessive gastrointestinal losses or redistribution of Pi into cells.

Extrarenal causes of hypophosphatemia cause avid renal tubular Pi reabsorption, reducing urinary excretion to <100 mg/day.

Patients who have severe (<1 mg/dL) or symptomatic hypophosphatemia require intravenous phosphate administration (Table 9-24).[152,156] In chronically hypophosphatemic patients, 0.2 to 0.68 mmol/kg (5 to 16 mg/kg elemental phosphorus) should be infused over 12 hours. For moderately hypophosphatemic adult patients suffering from critical illness, the use of 15 mmol boluses (465 mg) mixed with 100 mL of 0.9% sodium chloride and given over a 2-hour period safely repletes phosphate.[157] The dosage is then adjusted as indicated by the serum Pi level, because the cumulative deficit cannot be predicted accurately. Oral therapy can be substituted for parenteral Pi once the serum Pi level exceeds 2.0 mg/dL. Continued therapy with Pi supplements is required for 5 to 10 days to replenish body stores.

TABLE 9-24 Hypophosphatemia: acute treatment

Parenteral phosphate, 0.2 mM–0.68 mM/kg (5–16 mg/kg) over 12 hours
Potassium phosphate (93 mg/mL of phosphate)
Sodium phosphate (93 mg/mL of phosphate)

Phosphate should be administered cautiously to hypocalcemic patients because of the risk of precipitating more severe hypocalcemia. In hypercalcemic patients, Pi may cause soft-tissue calcification. Phosphorus must be given cautiously to patients with renal insufficiency because of impaired excretory ability. During treatment, close monitoring of serum Pi, calcium, magnesium, and potassium is essential to avoid complications.

Hyperphosphatemia

The clinical features of hyperphosphatemia (Pi >5.0 mg/dL) relate primarily to the development of hypocalcemia and ectopic calcification. Hyperphosphatemia is caused by three basic mechanisms: inadequate renal excretion, increased movement of Pi out of cells, and increased Pi or vitamin D intake. Rapid cell lysis from chemotherapy, rhabdomyolysis, and sepsis can cause hyperphosphatemia, especially when renal function is impaired. Renal failure is the most common cause of hyperphosphatemia.[151] Renal excretion of Pi remains adequate until the GFR falls below 20 to 25 mL/min.

Measurements of BUN, creatinine, GFR, and urinary Pi are helpful in the differential diagnosis of hyperphosphatemia. Normal renal function accompanied by high Pi excretion (>1,500 mg/day) indicates an oversupply of Pi. An elevated BUN, elevated creatinine, and low GFR suggest impaired renal excretion of Pi. Normal renal function and Pi excretion less than 1,500 mg/day suggest increased Pi reabsorption (i.e., hypoparathyroidism).

Hyperphosphatemia is corrected by eliminating the cause of the Pi elevation and correcting the associated hypocalcemia. Calcium supplementation of hypocalcemic patients should be delayed until serum phosphate has fallen below 2.0 mmol/L (6.0 mg/dL).[134] The serum concentration of Pi is reduced by restricting intake, increasing urinary excretion with saline and acetazolamide (500 mg every 6 hours), and increasing gastrointestinal losses by enteric administration of

aluminum hydroxide (30 to 45 mL every 6 hours). Aluminum hydroxide absorbs Pi secreted into the bowel lumen and increases Pi loss even if none is ingested. Hemodialysis and peritoneal dialysis are effective in removing Pi in patients who have renal failure.

Magnesium

Physiologic Role

Magnesium is an important, multifunctional, divalent cation located primarily in the intracellular space (intracellular magnesium ~2,400 mg; extracellular magnesium ~280 mg). Approximately 50% of magnesium is located in bone, 25% is found in muscle, and less than 1% of total body magnesium circulates in the serum. Of the normal circulating total magnesium concentration (1.5 to 1.9 mEq/L or 0.75 to 0.95 mmol/L or 1.5 to 1.9 mg/dL),[151] there are three components: protein bound (30%), chelated (15%), and ionized (55%), of which only ionized magnesium is active.

Magnesium is necessary for enzymatic reactions involving DNA and protein synthesis, energy metabolism, glucose utilization, and fatty acid synthesis and breakdown.[158,159] As a primary regulator or cofactor in many enzyme systems, magnesium is important for the regulation of the sodium-potassium pump, Ca-ATPase enzymes, adenyl cyclase, proton pumps, and slow calcium channels. Magnesium has been called an endogenous calcium antagonist, because regulation of slow calcium channels contributes to maintenance of normal vascular tone, prevention of vasospasm, and perhaps to prevention of calcium overload in many tissues. Because magnesium partially regulates PTH secretion and is important for the maintenance of end-organ sensitivity to both PTH and vitamin D, abnormalities in ionized magnesium concentration ($[Mg^{2+}]$) may result in abnormal calcium metabolism. Magnesium functions in potassium metabolism primarily through regulating sodium–potassium ATPase, an enzyme that controls potassium entry into cells, especially in potassium-depleted states, and controls reabsorption of potassium by the renal tubules. In addition, magnesium functions as a regulator of membrane excitability and serves as a structural component in both cell membranes and the skeleton.

Because magnesium stabilizes axonal membranes, hypomagnesemia decreases the threshold of axonal stimulation and

increases nerve conduction velocity. Magnesium also influences the release of neurotransmitters at the neuromuscular junction by competitively inhibiting the entry of calcium into the presynaptic nerve terminals. The concentration of calcium required to trigger calcium release and the rate at which calcium is released from the sarcoplasmic reticulum are inversely related to the ambient magnesium concentration. Thus, the net effect of hypomagnesemia is muscle that contracts more in response to stimuli and is tetany prone.

Magnesium is widely available in foods and is absorbed through the GI tract, although dietary consumption appears to have decreased over several decades.[159] The distal tubule is the major site of magnesium regulation. Plasma $[Mg^{2+}]$ regulates magnesium reabsorption through the Ca^{2+}/Mg^{2+}–sensing receptor, located on the capillary side of cells in the thick ascending limb.[160] While both magnesium and Pi are primarily regulated by intrinsic renal mechanisms,[158] PTH exerts a greater effect on renal loss of Pi.

Magnesium has been used to help manage an impressive array of clinical problems in patients who are not hypomagnesemic.[161] Therapeutic hypermagnesemia is used to treat patients with premature labor, preeclampsia, and eclampsia. Because magnesium blocks the release of catecholamines from adrenergic nerve terminals and the adrenal glands, magnesium has been used to reduce the effects of catecholamine excess in patients with tetanus and pheochromocytoma. Magnesium administration may influence dysrhythmias by direct effects on myocardial membranes, by altering cellular potassium and sodium concentrations, by inhibiting cellular calcium entry, by improving myocardial oxygen supply and demand, by prolonging the effective refractory period, by depressing conduction, by antagonizing catecholamine action on

the conducting system, and by preventing vasospasm. Administration of magnesium reduces the incidence of dysrhythmias after myocardial infarction and in patients with congestive heart failure.[162] In humans with ischemic myocardium, magnesium prevented ischemic increases in action potential duration and membrane repolarization.[163] After acute myocardial infarction, intravenous magnesium administration decreased short-term mortality.[164] In addition, magnesium may be useful as treatment for a torsades de pointes ventricular dysrhythmia, even in normomagnesemic patients.[165]

Hypomagnesemia

The clinical features of hypomagnesemia ([Mg^{2+}] <1.8 mg/dL), like those of hypocalcemia, are characterized by increased neuronal irritability and tetany (Table 9-25).[166] Symptoms are rare when the serum [Mg^{2+}] is 1.5 to 1.7 mg/dL; in most symptomatic patients serum [Mg^{2+}] is <1.2 mg/dL. Patients frequently complain of weakness, lethargy, muscle spasms, paresthesias, and depression. When severe, hypomagnesemia may induce seizures, confusion, and coma. Cardiovascular abnormalities include coronary artery spasm, cardiac failure, dysrhythmias, and hypotension. Severe hypomagnesemia may reduce the response of adenylate cyclase to stimulation of the PTH receptor.[167] Hypomagnesemia can aggravate digoxin toxicity and congestive heart failure.

TABLE 9-25 Manifestations of Altered Serum Magnesium Concentrations

▪MAGNESIUM LEVEL			
▪mg/dL	▪mEq/L	▪mmol/L	▪MANIFESTATION
<1.2	<1	<0.5	Tetany Seizures Arrhythmias

From Topf JM, Murray PT: Hypomagnesemia and hypermagnesemia. Rev Endocr Metab Disord 4:195, 2003.

Rarely resulting from inadequate dietary intake, hypomagnesemia most commonly is caused by inadequate gastrointestinal absorption, excessive magnesium losses, or failure of renal magnesium conservation. Excessive magnesium loss is associated with prolonged nasogastric suctioning, gastrointestinal or biliary fistulas, and intestinal drains. Inability of the renal tubules to conserve magnesium complicates a variety of systemic and renal diseases, although advanced renal disease with a decreased GFR may lead to magnesium retention. Polyuria, whether secondary to ECV expansion or to pharmacologic or pathologic diuresis, may result in excessive urinary magnesium excretion. Various drugs, including aminoglycosides,

cis-platinum, cardiac glycosides, and diuretics, enhance urinary magnesium excretion. Intracellular shifts of magnesium as a result of thyroid hormone or insulin administration may also decrease serum [Mg^{2+}].

Because the sodium-potassium pump is magnesium dependent, hypomagnesemia increases myocardial sensitivity to digitalis preparations and may cause hypokalemia as a result of renal potassium wasting. Attempts to correct potassium deficits with potassium replacement therapy alone may not be successful without simultaneous magnesium therapy. Magnesium is important in the regulation of potassium channels. The interrelationships of magnesium and potassium in cardiac tissue have probably the greatest clinical relevance in terms of arrhythmias, digoxin toxicity, and myocardial infarction. Both severe hypomagnesemia and hypermagnesemia suppress PTH secretion and can cause hypocalcemia. Severe hypomagnesemia may also impair end-organ response to PTH.

Hypomagnesemia is associated with hypokalemia, hyponatremia, hypophosphatemia, and hypocalcemia. The reported prevalence of hypomagnesemia in hospitalized and critically ill patients varies from 11 to 61%, with the variability attributable to differences in measurement technique.[168] Development of a specific electrode to measure ionized [Mg^{2+}] has demonstrated an association between hypomagnesemia, use of diuretics, and development of sepsis.[168] Patients who develop hypomagnesemia while in intensive care have an increased mortality.[168] Of alcoholic patients admitted to the hospital, 30% are hypomagnesemic.[169] Serum [Mg^{2+}] may not reflect intracellular magnesium content. Peripheral lymphocyte magnesium concentration correlates well with skeletal and cardiac magnesium content.

Measurement of 24-hour urinary magnesium excretion is useful in separating renal from nonrenal causes of hypomagnesemia. Normal kidneys can reduce magnesium excretion to less than 1 to 2 mEq/day in response to magnesium depletion. Hypomagnesemia accompanied by high urinary excretion of magnesium (>3 to 4 mEq/day) suggests a renal etiology. In the magnesium-loading test, urinary Mg^{2+} excretion is measured for 24 hours after an intravenous magnesium load.[170]

Magnesium deficiency is treated by the administration of magnesium supplements (Table 9-26). One gram of magnesium sulfate provides approximately 4 mmol (8 mEq, or 98 mg) of elemental

magnesium. Mild deficiencies can be treated with diet alone. Replacement must be added to daily magnesium requirements (0.3 to 0.4 mEq/kg/day). Symptomatic or severe hypomagnesemia ([Mg^{2+}] <1.0 mg/dL) should be treated with parenteral magnesium: 1 to 2 g (8 to 16 mEq) of magnesium sulfate as an intravenous bolus over the first hour, followed by a continuous infusion of 2 to 4 mEq/h. Therapy should be guided subsequently by the serum magnesium level. The rate of infusion should not exceed 1 mEq/min, even in emergency situations, and the patient should receive continuous cardiac monitoring to detect cardiotoxicity. Because magnesium antagonizes calcium, blood pressure and cardiac function should be monitored, although blood pressure and cardiac output usually change little during magnesium infusion. Treatment of hypomagnesemia during cardiopulmonary bypass decreased the incidence of postoperative ventricular tachycardia from 30 to 7% and increased the frequency of continuous sinus rhythm from 5 to 34%.[171]

TABLE 9-26 Hypomagnesemia: Acute Treatment

Intravenous Mg[a]: 8–16 mEq (1–2 g $MgSO_4$) bolus over 1 hour, followed by 2–4 mEq/h (250–500 mg/h $MgSO_4$) as continuous infusion Intramuscular Mg[a]: 10 mEq q 4–6 hours
[a]$MgSO_4$: 1 g = 8 mEq Mg; $MgCl_2$: 1 g = 10 mEq Mg.

During repletion, patellar reflexes should be monitored frequently and magnesium withheld if they become suppressed. Patients who have renal insufficiency have a diminished ability to excrete magnesium and require careful monitoring during therapy. Repletion of systemic magnesium stores usually requires 5 to 7 days of therapy, after which daily maintenance doses of magnesium should be provided. Magnesium can be given orally, usually in a dose of 60 to 90 mEq/day of magnesium oxide. Hypocalcemic, hypomagnesemic patients should receive magnesium as the chloride salt, because the sulfate ion can chelate calcium and further reduce the serum [Ca^{2+}].

Hypermagnesemia

Most cases of hypermagnesemia ([Mg^{2+}] >2.5 mg/dL) are iatrogenic, resulting from the administration of magnesium in antacids, enemas, or parenteral nutrition, especially to patients with impaired renal function. Other rarer causes of mild hypermagnesemia are hypothyroidism, Addison's disease, lithium intoxication, and familial hypocalciuric hypercalcemia. Hypermagnesemia is rarely detected in routine electrolyte determinations.[166,172,173] Hypermagnesemia antagonizes the release and effect of acetylcholine at the neuromuscular junction. The result is depressed skeletal muscle function and neuromuscular blockade. Magnesium potentiates the action of nondepolarizing muscle relaxants and decreases potassium release in response to succinylcholine. The clinical features of progressive hypermagnesemia are listed in Table 9-25.[166]

The neuromuscular and cardiac toxicity of hypermagnesemia can be acutely, but transiently, antagonized by giving intravenous calcium (5 to 10 mEq) to delay toxicity while more definitive therapy is instituted.[166] All magnesium-containing preparations must be stopped. Urinary excretion of magnesium can be increased by expanding ECV and inducing diuresis with a

combination of saline and furosemide. In emergency situations and in patients with renal failure, magnesium may be removed by dialysis.

Chapter 10

Hemotherapy and Hemostasis

John C. Drummond

Charise T. Petrovitch

KEY POINTS

1	In terms of the transfusion-transmitted infectious diseases, the American blood supply has never been safer than it is today.
2	The three leading causes of transfusion-related death in the United States are ABO incompatibility, transfusion-related acute lung injury (TRALI), and sepsis caused by bacterial infections.
3	In the setting of massive transfusion, assuming maintenance of isovolemia, critical dilution of clotting factors and platelets will occur after an average replacement of 140% and 230% of blood volume, respectively.
4	Coagulation factor and platelet replacement should be determined by laboratory assessment and/or observation of clinical coagulopathy and *not* EBL-driven formulas.
5	The red blood cell (RBC) transfusion “trigger” for most patients will lie between hemoglobin values of 7 and 10 g/dL.
6	Platelet administration thresholds relevant to anesthesiologists will lie usually between 50,000 and 100,000/uL.
7	Normal coagulation can be achieved with clotting factor levels of 20 to 30% of normal. Those levels can usually be achieved by administration of 10 to 15 mL/kg of fresh frozen plasma (FFP).
8	A patient who has received 10 to 12 units of group O RBCs should not be switched back to his or her own ABO group unless testing has been performed to confirm that significant titers of Anti-A or Anti-B antibodies are not present.
9	The classical, dual-cascade (intrinsic and extrinsic pathway) model of coagulation is an inadequate representation of coagulation, as it occurs in vivo.

10	In vivo, coagulation is initiated principally by contact of factor VII with extravascular tissue factor leading first to platelet activation followed by the generation of large amounts of thrombin by activated clotting factors acting on the phospholipid surface provided by activated platelets.
11	Von Willebrand's disease is the most common hereditary bleeding disorder and some form of the disease, which may be subclinical prior to surgery, is present in approximately 1% of the population.
12	Factors II, VII, IX, and X and Proteins C and S are dependent on vitamin K for their synthesis. Vitamin K deficiency occurs frequently in hospitalized patients because of dietary insufficiency, gut sterilization, and malabsorption. A high index of suspicion should be maintained.
13	As many as 5% of patients who receive heparin therapy for 5 days will develop heparin-induced thrombocytopenia/thrombosis. The clinical manifestations are more often the result of thrombosis and thromboembolism than thrombocytopenia.

The knowledge that the human immunodeficiency virus (HIV) is transmissible by blood generated public fear of transfusion and led to dramatic changes in the approach to the patient requiring blood products. While the transfusion-related risk of acquiring HIV is now vanishingly small, there remain numerous other hazards associated with blood products. The administration of blood products should be undertaken only with a complete understanding of those hazards and of the potential benefits. Accordingly, this chapter begins with a review of the risks associated with the administration of blood products, followed by a discussion of the factors that determine the necessity for the administration of the three most commonly used components, packed red blood cells (RBCs), fresh frozen plasma (FFP), and platelets, and then a discussion of conservation techniques for minimizing the necessity for transfusion.

The remainder of the chapter presents a description of the preparation of blood products, a discussion of the physiology of hemostasis, a description of tests of the hemostatic mechanism, and finally a review of common bleeding disorders, including discussion of the effects of pharmacologic agents on hemostasis.

THE RISKS OF BLOOD PRODUCT ADMINISTRATION

The risks can be subdivided into those of infectious and noninfectious etiologies. An excellent review has been provided by Kleinman et al.[1] Transfusion-transmissible infections, in particular viral infections, have had the highest profile and will therefore be addressed first. However, in reality, the morbidity and mortality associated with nonviral hazards is far greater.

Infectious Risks Associated with Blood Product Administration

The potentially transmittable diseases/agents are numerous and include several viruses: hepatitis A, B, C, D, and E; the human T-cell lymphotropic viruses (HTLV-1, HTLV-2); the human immunodeficiency viruses 1 and 2; cytomegalovirus; West Nile virus (WNV); the Epstein-Barr virus; parvovirus B19; the GBV-C virus (also called hepatitis G); transfusion-transmitted virus (TTV); the SEN virus; prions (Creutzfeldt-Jakob and variant Creutzfeldt-Jakob); Lyme disease; contaminating bacteria; parasites (malaria, Chagas disease, ehrlichiosis, babesiosis); and

syphilis.[1] Several of these will not be considered further. While GBV-C, TTV, and SENV are transmitted by transfusion, they do not appear to cause clinical disease; the rate of transmission of Parvovirus B19 is very low and clinical disease is extremely infrequent;[1] there have been no reported instances of transfusion-transmitted Lyme disease and only one instance of ehrlichiosis.[2]

1 Estimates of the frequency of infectious agents in the North American blood supply are presented in Table 10-1. The rate of viral infectivity has decreased dramatically in the last two decades. It is in particular the advent of universal (in the United States) nucleic acid testing (NAT) for HIV and the hepatitis C virus (HCV) that has reduced the frequency of transmission of those agents to very low levels, that is, about one in two million. Hepatitis B virus (HBV) remains the greatest risk, currently about 1/350,000 donor exposures.[3] All of these estimates are derived from the observed rates of seropositivity among donors and the statistical likelihood of administration of blood from donors whose infection is in the “window period” between contracting the virus and detectability by the available assays. Using NAT testing, the window periods for HIV and HCV are 13 and 12 days, respectively.[1] For HBV, using HbsAg testing, the window period is 59 days. A NAT test for HBV is available[4] and will probably be implemented by or before 2008.

TABLE 10-1 Estimates of the rate (per donor exposure) of transfusion-transmitted infectious disease

• Hepatitis B[3] (HBV)	1/350,000
• Hepatitis C[3] (HCV)	1/2,000,000
• Human immunodeficiency virus[3] (HIV)	1/2,000,000
• Human T-cell lymphotrophic virus[5] (HTLV)	1/2,900,000
• Bacterial sepsis/endotoxin reaction[5]	
RBC	1/30,000
Platelets	1/2,000

Hepatitis C Virus

The significance of HCV is that, despite its commonly mild initial presentation, in 85% of patients it progresses to a chronic state with significant associated morbidity and mortality. Twenty percent of chronic carriers develop cirrhosis and 1 to 5% develop hepatocellular carcinoma.[6,7]

Hepatitis B Virus

It is estimated that only 35% of HBV-exposed patients will develop acute disease,[8] although approximately 1% will develop fulminant acute hepatitis. In approximately 85% of patients, the disease resolves spontaneously, 9% develop chronic persistent hepatitis, 3% develop chronic active hepatitis, 1% develop cirrhosis with or without chronic active hepatitis, and 1% develop hepatocellular carcinoma.[9] The current estimate of risk in the United States is 1 HBV infection per 350,000 donor exposures.

Hepatitis A Virus

Transmission of hepatitus A virus (HAV) by transfusion has been very rare. Blood banks screen for HAV by history only and there is no carrier state for this virus. The infectious period is limited to 1 to 2 weeks. The diagnosis depends on hepatitis antibody seroconversion.

Human Immunodeficiency Virus

The most feared complication of a blood transfusion is the transmission of HIV, the causative agent of the acquired immunodeficiency syndrome (AIDS). It is a retrovirus, so called because its propagation requires translation of RNA to DNA. Current screening tests are directed at both HIV 1 and HIV 2, though the latter has been an extremely infrequent cause of human disease. The incidence of transfusion-related HIV infection has fallen dramatically and progressively with the implementation of a series of serologic screening tests of donors, including, very recently, NAT testing. The current estimate of risk in the United States is 1 HIV infection per 1.5 to 2 million donor exposures. For reference, that risk was approximately 1:100 in the early 1980s and 1:400,000 in 1997.[10]

Human T-Cell Lymphotropic Virus

HTLV-1 and HTLV-2 belong to the same retrovirus family as HIV. The incidence of clinical disease resulting from

transmitted virus appears to be very low. They are associated with T-cell leukemia and lymphoma rather than the generalized immunodeficiency of AIDS. In the United States, all donor units are screened for the presence of antibody to HTLV-I and HTLV-2.

Cytomegalovirus

Transfusion-associated CMV infections are usually benign and self-limited. However, CMV may cause serious, even fatal, infections in the immunocompromised. Patients at risk include premature neonates, solid organ and bone marrow transplant recipients, and those patients with severely depressed immune function. CMV pneumonia is an important infectious cause of death in allogenic bone marrow transplant recipients.[11] Leukoreduction reduces, but does not prevent, CMV transmission.[12] Restriction of immunocompromised patients to blood from CMV seronegative donors is required in many centers.

Parasitic Diseases

Transfusion-transmitted malaria is relatively common in regions where the disease is endemic but has been rare in the United States.[1] Because the parasite resides within the red cell, the hazard is associated almost exclusively with RBC transfusion. Chagas disease is caused by a protozoan (Trypanosoma cruzi) that is endemic to South and Central America (including Mexico). Significant clinical disease has been rare in North America and has occurred almost exclusively in immunocompromised transfusion recipients.

Bacterial Contamination of Blood Components

Bacterial contamination occurs at a much higher frequency (Table 10-1) than any of the other infections discussed in this section and is associated with substantial mortality.[13] Fatalities are estimated to occur at the rate of between 1: 1-6,000,000 transfused units[5], with the rate being substantially greater with platelet than RBC administration because the former are stored at room temperature and because platelet administration commonly involves pools of 6 to 10 units. A psoralen-based photochemical process that inactivates the DNA and RNA of bacteria (as well as viruses and protozoa) has recently shown efficacy without causing material impairment of platelet function and may serve to address this problem of bacterial contamination of platelets.[14] The source of the bacteria can be donor blood, donor skin flora, or contaminants introduced during collection, processing, and storage. Numerous Gram-positive and -negative organisms can occur in

platelets. Goodnough et al identified the organisms in order of frequency as Staphylococcus aureus, Klebsiella pneumoniae, Serratia marcescens, and Staphylococcus epidermidis.[8] Only a limited number of bacteria, including Yersinia enterocolitica and certain Serratia and Pseudomonas species can grow at RBC storage temperatures.[1]

The patient who receives contaminated blood transfusion will rapidly experience some combination of fever, chills, tachycardia, emesis, and shock and may develop disseminated intravascular coagulation (DIC) and acute renal failure. The reactions are variable in severity and an index of suspicion should be maintained in order to distinguish these reactions from other major and minor transfusion reactions. The transfusion should be stopped immediately and blood cultures obtained.

West Nile Virus

WNV is a mosquito-borne flavivirus (as is dengue fever) that became epidemic, principally in Midwestern states, including Nebraska, Colorado, and Kansas, in 2002. Although the majority of infected individuals are either asymptomatic or develop only a mild illness, encephalitis/meningitis can occur and the death rate among confirmed cases is 5–10%.[3,15] Transmission by blood transfusion and organ transplantation has been confirmed. Fortunately, the window period between infection and clinical symptoms is short, at around 3 days, and the period of infectivity also appears to be relatively brief. Individual donor NAT testing for WNV is being performed in areas of high incidence.[3]

Prion-Related Diseases

Prions are the causative agents of Creutzfeldt-Jakob disease (CJD) and variant Creutzfeldt-Jakob disease (vCJD). The latter is the human disease caused by the agent responsible for bovine spongiform encephalitis (BSE). All three are fatal, degenerative neurologic diseases caused by an abnormally folded variant of a protein that is constitutively present. Between the beginning of the BSE epidemic in England in 1984 and February 2004, 156 cases of vCJD had been reported, with all but 10 occurring in the United Kingdom.[16] The risk of transfusion-related vCJD is undefined. CJD has never been known to have been transmitted by transfusion and there has been only a single reported case of apparently transfusion related vCJD.[17] However, the incubation period of vCJD may be as long as 6 years so the true transmission rate may be, as yet, underrecognized. Nonetheless, it is to be hoped that changes in animal husbandry practices combined with exclusion of donors who have sojourned in high-risk areas will minimize whatever risk exists.

Noninfectious Risks Associated with Blood Product Administration

The noninfectious risks associated with blood product administration, the majority of which are immunologically mediated, and their approximate incidences are presented in Table 10-2.

TABLE 10-2 The Noninfectious Adverse Reactions Associated with Blood Product Administration and Their Approximate Incidences[1,5,10]

·ADVERSE REACTION	·INCIDENCE
Acute hemolytic transfusion reactions	1/25,000–50,000
Delayed hemolytic transfusion reactions	1/2,500
Minor allergic reactions	1/200–250

Anaphylactic/-toid reactions	1/25,000–50,000
Febrile reactions	1/200
Transfusion-related acute lung injury (TRALI)	1/5,000
Graft-versus-Host Disease	Rare
Immunomodulation	(?) 1/1

Immunologically Mediated Transfusion Reactions

Reactions to transfused blood products can occur as a result of the presence of antibodies that are either constitutive (e.g., Anti-A, Anti-B) or that have been formed as a result of prior exposure to donor RBCs, white blood cells, platelets, and/or proteins, or as a consequence of the effects of transfused white cells.

Reactions to RBC Antigens

Acute Hemolytic Transfusion Reactions. The most feared of the immune reactions is the immediate acute hemolytic

transfusion reaction (AHTR) against foreign RBCs. Hemolysis of the donor RBCs often leads to acute renal failure, disseminated intravascular coagulation, and death. There are more than 300 different antigens on human red cells, but many are weak immunogens that usually do not elicit a clinically detectable antibody response. The antibodies that fix complement and commonly produce immediate intravascular hemolysis include anti-A, anti-B, anti-Kell, anti-Kidd, anti-Lewis, and anti-Duffy.[18]

The incidence of AHTRs is estimated to be on the order of 1 per 12,000 units transfused.[1] ABO incompatibility is among the three leading causes of transfusion-related deaths in the United States with a frequency in recent years slightly less than TRALI and narrowly greater than bacterial contamination (L. Holness, MD, personal communication, November 2004). In one jurisdiction (Canada), clerical/care provider errors were responsible for the majority of the incompatible blood transfusions that resulted in patient death.[1] It is an uncomfortable irony that, at the time of this writing, one of the principal hazards to the patient resides not in the blood supply per se, but rather in the process that delivers it to the patient.

When incompatible blood is administered, antibodies and complement in recipient plasma attack the corresponding antigens on donor RBCs. Hemolysis ensues. The hemolytic reaction may take place in the intravascular space and/or it may occur extravascularly within the endoplasmic reticulum. The antigen–antibody complexes activate Hageman factor (factor XII), which in turn acts on the kinin system to produce bradykinin. The release of bradykinin increases capillary permeability and dilates arterioles, both of which contribute to hypotension. Activation of the complement system results in the release histamine and serotonin from mast cells, resulting in bronchospasm. Thirty to fifty percent of patients develop DIC.[18]

Hemolysis releases hemoglobin into the blood. Initially it is bound to haptoglobin and albumin until the binding sites are saturated, then it circulates unbound in the blood until it is excreted by the kidneys. Renal damage occurs for several reasons. Blood flow to the kidneys is reduced in the presence of systemic hypotension and renal vasoconstriction. Free hemoglobin in the form of acid

hematin or red cell stroma may precipitate in the renal tubules causing mechanical obstruction.[18] Antigen–antibody complexes may be deposited in the glomeruli. If the patient develops DIC, fibrin thrombi will also be deposited in the renal vasculature, further compromising perfusion.

The signs and symptoms of a hemolytic transfusion reaction include fever, chills, nausea, vomiting, diarrhea, and rigors. The patient is hypotensive and tachycardic (bradykinin effects) and may appear flushed and dyspneic (histamine). Chest and back pains result from diffuse intravascular occlusion by agglutinated red cells. The patient is often restless and has a headache and a sense of impending doom. Hemoglobinuria will occur as well as diffuse bleeding with the development of DIC. With renal failure, oliguria develops. During general anesthesia, many of the signs are masked. Hypotension and hemoglobinuria and diffuse bleeding be may the only clues that a hemolytic transfusion reaction has occurred. However, hypotension and bleeding are nonspecific and fairly common in the operating room environment and the diagnosis may not be suspected until hemoglobinuria is observed. A reasonable index of suspicion should be maintained during administration of RBCs to anesthetized patients in order to avoid critical delay in diagnosis.

If a reaction is suspected, the transfusion should be stopped and the identity of the patient and the labeling of the blood rechecked. Management has three main objectives—maintenance of systemic blood pressure, preservation of renal function, and the prevention of DIC. Systemic blood pressure should be supported by administration of volume, pressors, and inotropes as required. Urine output should be promoted by administration of fluids and the use of diuretics, either mannitol or furosemide, or both. Sodium bicarbonate can be administered to alkalinize the urine. There currently is no specific therapy to prevent the development of DIC. However, preventing hypotension and supporting cardiac output to prevent stasis and hypoperfusion, both of which contribute to the evolution of DIC, are important.

Laboratory tests should include (1) a repeat crossmatch and (2) a direct antiglobulin (Coombs) test. The direct antiglobulin test is the definitive test for an acute hemolytic transfusion reaction. It examines recipient RBCs for the presence of surface immunoglobulins and complement. Patient serum is also examined for the presence of antibodies that react with the donor cells. Serum haptoglobin level, plasma, and urine hemoglobin and bilirubin assays are usually performed. However, these are evidence only of hemolysis, not specifically of an immune reaction.[18] Laboratory tests to establish baseline coagulation status including platelet count, PT, aPTT, TT, fibrinogen level, and fibrin degradation products should be performed.

Examination of the patient's plasma after brief centrifugation for the pinkish discoloration caused by free hemoglobin is a simple, rapid screening test when a hemolytic transfusion reaction is suspected.[18] Hemolysis can be a result of other causes, including overheating prior to transfusion or inadvertent use of a hypotonic solution as a diluent. However, hemolysis should be assumed to indicate a hemolytic transfusion reaction until proven otherwise.

Delayed Hemolytic Transfusion Reactions. Numerous instances have been reported in which transfused red cells are rapidly eliminated from the circulation at a short interval (days) after an apparently “compatible” crossmatch. Many of these events are delayed hemolytic transfusion reactions (DHTRs).[19] These reactions occur when the donor RBCs bear an antigen to which the recipient has previously been exposed by either transfusion or pregnancy. Over time, the recipient antibodies fall to levels too low to be detected by compatibility testing. When re-exposure occurs, the recipient undergoes an anamnestic response and produces more antibody that eventually lyses the foreign RBCs. Typically the antibody-coated RBC is sequestered extravascularly and lysis occurs in the spleen and reticuloendothelial system. Because the red cell destruction occurs extravascularly, symptoms are less severe and the reaction is less likely to be fatal. Unlike AHTRs, which usually involve antibodies in the ABO system, DHTRs commonly involve antibodies against Rhesus (Rh), Kell, Duffy, and Kidd antigens. The frequency of delayed hemolytic reactions is reported to be 1 per 800 to 2,500 transfusions.[18,20]

Evidence of hemolysis is usually detected by the first or second week following transfusion. The reaction may be undetected or may be identified because of the combination of a low-grade fever, increased bilirubin with or without mild jaundice, and/or an unexplained reduction in hemoglobin concentration. The diagnosis is confirmed by a positive direct antiglobulin test (Coombs test).

Serum haptoglobin is also decreased. The reaction is self-limiting and the clinical manifestations resolve as the transfused cells are removed from the circulation.[18]

Reactions to Donor Proteins

Minor Allergic Reactions. Allergic reactions to proteins in donor plasma cause urticarial reactions in 0.5% of all transfusions.[1,5,10] The reaction is almost always associated with the transfusion of fresh frozen plasma, but because there is a small volume of donor plasma present in other blood products

(RBCs, platelets), allergic reactions can occur with transfusion of these components as well. The patient may have itching, swelling, and a rash as a result of the release of histamine. These mild symptoms can be treated with diphenhydramine. Patients who experience severe urticarial reactions may benefit from the use of saline washed cells.[18]

Anaphylactic Reactions. Infrequently a more severe form of allergic reaction involving anaphylaxis will occur in which the patient experiences dyspnea, bronchospasm, hypotension, laryngeal edema, chest pain, and shock. Anaphylaxis precipitated by a transfusion is a rare, but potentially fatal, event. It occurs when patients with hereditary IgA deficiency who have been sensitized by previous transfusions or pregnancy are exposed to blood with “foreign” IgA protein. Treatment consists of discontinuation of the transfusion and epinephrine and methylprednisolone. Washed red cells, frozen deglycerolized red cells, or red cells from IgA-deficient donors should subsequently be used for these patients.[18]

White Cell–Related Transfusion Reactions

Febrile Reactions. Patients who receive multiple transfusions of RBCs or platelets often develop antibodies to the HLA antigens on the passenger leukocytes in these products. During subsequent RBC transfusions, febrile reactions may occur as a result of antibody attack on donor leukocytes. The febrile response occurs in about 1% of all red blood cell transfusions. Typically, the patient experiences a temperature increase of more than 1 degree centigrade within 4 hours of a blood transfusion and defervesces within 48 hours.[18] Patients may experience fever only but they may also develop chills, respiratory distress, anxiety,[21] headache, myalgias, nausea, and a nonproductive cough. Febrile reactions can be treated with acetaminophen. A leukocyte-mediated febrile transfusion reaction should be distinguished from a hemolytic transfusion reaction (direct Coombs test). Leukoreduction (see later) reduces or prevents these reactions.

Transfusion-Related Acute Lung Injury. Transfusion-related acute lung injury (TRALI) is a noncardiogenic form of pulmonary edema associated with blood product administration. It has been associated with administration of all blood components but occurs most frequently with RBCs (whole blood or packed cells), FFP, and platelets. The incidence is frequently estimated to be 1:5,000 units transfused. However, it is likely that TRALI is both underrecognized and underreported. TRALI, with a mortality of 5 to 8%, was the most common cause of transfusion-related death reported to the FDA for the years 2001 to 2003, although but it was only narrowly ahead of ABO incompatibility and bacterial contamination (L. Holness, MD, personal communication, November 2004).

Detailed reviews of TRALI are available.[22,23] In most instances, TRALI occurs when agents present in the plasma phase of donor blood activate leukocytes in the host.[24] Those agents are probably most often antileukocyte antibodies in donor blood formed as a result of previous transfusion or pregnancy. In some instances, the opposite reaction, aggregation of donor leukocytes and recipient antibodies, may be the cause when the recipient has been alloimmunized against WBC antigens. Because antigranulocyte antibodies can be demonstrated in most but not all instances of TRALI, it is suspected that biologically active lipids can also be the initiator of the pulmonary insult. Those lipids are thought to be derived from the breakdown over time of the membranes of the cellular elements in stored blood products. It also appears that TRALI requires the presence of some preexisting and predisposing inflammatory condition in the recipient, for example, sepsis, trauma, surgery.

The clinical appearance is very similar to the adult respiratory distress syndrome (ARDS), though the mortality rate is substantially less than that associated with the latter. Beginning within 6 hours after transfusion, and often more rapidly, the patient develops dyspnea, chills, fever, and noncardiogenic pulmonary edema. Chest x-ray reveals bilateral infiltrates. Severe pulmonary insufficiency can develop. Treatment is largely supportive. The transfusion should be stopped if the reaction is recognized in time. The patient should be given supplemental oxygen and ventilatory support as necessary, ideally using the same low tidal volume lung protective strategies that are employed in ARDS.[25] The pulmonary edema is noncardiogenic. Accordingly, diuretics are not warranted. Glucocorticoids have been administered but there are no data to support that practice.

Patients who have experienced this reaction previously may benefit from the use of washed PRBCs. Multiparous female donors have been identified as frequent sources of antileukocyte antibodies and it has been proposed that these “femmes fatales”[26] be excluded from the donor pool.[27]

Graft-versus-Host Disease (GVHD). Packed RBCs and platelet concentrates both contain a significant number of viable donor lymphocytes. When transfused (“transplanted”) into immunocompromised patients, the donor lymphocytes may become engrafted, proliferate, and establish an immune response against the recipient. In essence, the engrafted lymphocytes reject the host.[28]

Patients at risk for GVHD include organ transplant recipients, neonates who have undergone a blood-exchange transfusion,[18] and patients immunocompromised by many other disease processes. GVHD typically progresses rapidly to pancytopenia and the fatality rate is very high. Transfusion-associated GVHD has also been reported in apparently immunocompetent patients when a genetic relationship exists between the donor and the recipient. In these circumstances, the recipient may share HLA antigen haplotypes with the donor lymphocytes. The patients, although immunologically competent, fail to reject the transfused cells because they do not recognize them as foreign. The transfused donor lymphocytes, however, recognize the host as foreign and a GVHD reaction takes place.[29] Because of this phenomenon, the American Association of Blood Banks has recommended that directed donations from first-degree relatives be irradiated to inactivate donor lymphocytes.

2 GVHD has been reported only after the transfusion of cellular blood components. It has not occurred following transfusion of FFP, cryoprecipitate, or frozen red cells.[29] Ideally, cellular blood products intended for immunocompromised patients and directed donor units from relatives should always be irradiated.[21] Leukoreduction may reduce the incidence of GVHD, but it does not prevent it.[1] Irradiation remains the only effective means for preventing GVHD.[30]

Immunomodulation. Alteration of immune function has been associated with allogenic transfusion. The initial observations were of decreased rates of transplant rejection[31] and decreased rates of spontaneous abortion in patients who had received homologous transfusions. Alteration in immune surveillance was inferred. Numerous adverse effects of transfusion, presumed to reflect this attenuation of immunocompetence, have been reported, including increased mortality, accelerated recurrence of malignancy, increased risk of infection, and more rapid progression of HIV/AIDS.[32] The studies addressing cancer, infection, and mortality have been very thoroughly reviewed by Vamvakas et al. Those authors questioned the validity of the conclusions on the basis of the failure, in most reports, to control for compounding variables.[33] The issue, in short, is: patients with more severe illness are more likely to require transfusion and are at increased risk of complications independent of the transfusion. Subsequent reports of an adverse effect of allogenic blood, with allowance made for confounding variables, have appeared.[34]

Transfused white cells are thought to be the mediators of the immunity attenuating effects, although the precise mechanisms have not been defined. These observations have led to the development and application of techniques for leukocyte depletion of donor blood products.

Leukoreduction. Many countries including Canada, France, Portugal, and the United Kingdom and

certain states and regions within the United States have already adopted the practice of leukoreduction of 100% of their blood supplies, and the entire United States is moving toward that objective. There are several well-confirmed benefits of leukoreduction including reduction in the development of alloimmunization and platelet refractoriness,[35] reduction in the incidence of febrile nonhemolytic transfusion reactions,[36] and reduction in (but not prevention of[12]) the transmission of CMV. However, selective leukoreduction could readily be applied for the patients to whom these benefits are relevant. The advocacy of universal leukoreduction is based on the premise that it might serve to accomplish the various benefits listed as “Reported but unconfirmed” in Table 10-3.

TABLE 10-3 Benefits of Leukoreduction

- **CONFIRMED BENEFITS**
  - Decreased alloimmunization/platelet refractoriness in multiply transfused leukemics[35]
  - Prevention of febrile reactions to RBC transfusions[36]
  - Reduction of CMV transmission[12]
- **REPORTED BUT UNCONFIRMED BENEFITS[37]**
  - Decreased postoperative infections
  - Decreased postoperative mortality[38]
  - Shortened hospitalization
  - Prevention of transfusion-related HIV acceleration[39]
  - Prevention of transfusion-related increase in tumor recurrence
  - Reduced incidence/severity of GVHD

While many of the putative benefits are unconfirmed, additional reports of benefits attributable to leukoreduction are being added to the literature.[38,40] Although skepticism persists, the common view is that, in spite of the associated costs, because the hazards of leukoreduction are minimal, the possible benefits justify proceeding with universal leukoreduction.[41,42]

Universal leukoreduction, when fully implemented, will employ prestorage depletion to prevent the release of mediators from WBCs during storage. This is especially relevant to platelets, which are stored at room temperature. In the interim, clinicians using bedside filtering should appreciate that the available filters are less efficient at higher temperatures and filtering should therefore ideally be performed before blood warms to room temperature. Clinicians should also be attentive to the possibility of severe, apparently bradykinin-mediated, hypotension in patients who receive bedside filtered blood. The reaction appears to occur more frequently, though not exclusively, in patients receiving angiotensin converting enzyme inhibitors (which reduce breakdown of bradykinin).[43]

Other Noninfectious Risks Associated with Transfusion

Massive Transfusion

The rapid transfusion of large volumes of stored blood can have several consequences. Some of these are functions of properties of the blood itself, of the agents used to preserve and anticoagulate it, and of the biochemical reactions that occur during storage. There are other complications that are not unique to blood transfusions, but which may occur with the rapid transfusion of any large volume of fluid.

Hypothermia. The administration of one unit of PRBCs at 4 degrees centigrade will reduce the core temperature of a 70-kg patient approximately 0.25 degrees C. Hypothermia slows coagulation (as it does all enzymatically mediated reactions) and causes sequestration of platelets. At 29°C (at which temperature the risk of cardiac dysrhythmias is critical), PT and aPTT will increase approximately 50% over normothermic values and platelet count will decrease by approximately

40%.[44] Dysrhythmias may be seen at higher core temperatures if unwarmed blood is administered rapidly, in particular through central access catheters. While there is a general conviction that "cold patients bleed," there have been no quantitative correlations of temperature and bleeding in the clinical setting. Temperatures of 33°C are commonly used in elective neurosurgery without clinically apparent coagulopathy. However, Ferrara et al[45] reviewed the clinical course of 45 patients who received massive transfusion following trauma. The duration of hypotension was similar in patients who survived and those who did not. However, the degree of acidosis and hypothermia was more extreme in the nonsurvivors and the nonsurvivors developed coagulopathies despite adequate blood, plasma, and platelet replacement. In studies of this nature, it is difficult to separate the effects of the common clinical concomitants of hypothermia, for example, acidosis, shock, massive transfusion, massive tissue injury, from those of hypothermia per se. Furthermore, the significance of hypothermia may lie in the interaction with other variables. In spite of the ambiguity, hypothermia should be carefully avoided and aggressively corrected in the patient receiving massive transfusion. Accordingly, transfusions administered rapidly or in substantial volume should be warmed, to prevent hypothermia. With decreasing body temperature, cardiac output declines, tissue perfusion is impaired (as a consequence of both vasoconstriction and a left shifting of the O2-Hb dissociation curve), and metabolic acidosis may develop. Shivering on emergence can increase oxygen consumption by 400%. Hypothermia has been associated with increased postoperative morbidity and mortality including increased rates of postoperative infection.[46,47]

3 **Volume Overload.** Circulatory volume overload occurs when blood or fluid is transfused too rapidly for compensatory fluid redistribution to take place.

4 **Dilutional Coagulopathy.** Administration of large volumes of fluid deficient in platelets and clotting factors will predictably lead to the development of a coagulopathy as a consequence of dilution. There has been considerable discussion of whether, in the face of massive transfusion of blood products, patients will first manifest deficiencies of platelets or clotting factors. The initial conclusion was that thrombocytopenia would develop first. In retrospect, that clinical conclusion may have been the consequence of a wider use of whole blood than prevails today. In spite of the lability of factors V and VIII, sufficient concentrations of these factors probably remain in banked whole blood to maintain coagulation function even in the face of very large transfusions. The same is probably *not* true when patients receive only the small residual plasma volume present with packed RBCs. Investigations of patients receiving large volume isovolemic transfusions suggest that clinically significant dilution of fibrinogen; factors II, V, and VIII; and platelets will occur after volume exchanges of approximately 140%, 200 to 230%, and 230% (i.e., 1.4, 2, and 2.3 blood volumes), respectively.[48] Resuscitation from hypovolemia will result in reaching these thresholds at smaller percentage volume exchanges. However, calculations of this nature should not be used as a guide to blood product administration but merely as a means of

anticipating clinically relevant occurrences. The decision to administer fresh frozen plasma or platelets will depend on clinical and laboratory evidence of coagulopathy.

Decreases in 2,3-Diphosphoglycerate (2,3-DPG). Storage of red blood cells is associated with a progressive decrease in intracellular ATP and 2,3-DPG with a resultant left shifting of the O2-Hb dissociation curve. Accordingly, transfusion of the 2,3-DPG–depleted blood while increasing the patient's hemoglobin value will result in less efficient oxygen delivery than would occur with native hemoglobin at the same hematocrit. After transfusion, 2,3-DPG levels return toward normal over 12 to 24 hours.[49]

Acid-Base Changes. When CPD solution is added to a unit of freshly drawn blood, pH decreases to approximately 7.0 to 7.1. Further reduction of pH will occur during storage as a consequence of ongoing metabolism of glucose to lactate. At the end of 21 days, the pH may be as low as 6.9, but much of this is the result of the production of CO2 that is rapidly eliminated following the transfusion. Whether rapid infusion of this acidic bank blood leads to metabolic acidosis is debated. In the past, some clinicians have administered sodium bicarbonate empirically to patients on a fixed schedule (e.g., sodium bicarbonate 44.6 mEq after each 5 units of bank blood infused). Others contend that the citrate from the CPD solution is metabolized by the patient to

endogenous bicarbonate and that acid-base disturbance is therefore self-correcting. Clinically, in the injured patient who is hypotensive and poorly perfused and has inadequate tissue oxygenation, it will be difficult to differentiate what portion of the metabolic acidosis is because of rapid transfusion and what portion is because of the production of lactic acid.[46] The appropriate course is to base bicarbonate therapy on blood gas analysis.

Hyperkalemia. During storage, potassium moves out of the RBCs, in part to maintain electrochemical neutrality as hydrogen ions generated during storage redistribute. The potassium concentration in plasma may reach levels variously reported to be between 17 and 24 mEq/L at 21 to 35 days or 19 to 35 mEq/L in blood stored for 21 days. Hazard exists if large volumes of stored blood are administered rapidly. Rates in excess of 90 to 120 mL/min have been associated with hyperkalemia. Furthermore, while there are only 20 to 60 mL of plasma in a unit of packed RBCs, contemporary infusion devices allow blood to be transfused at rates of 500 to 1,000 mL/min. At these infusion rates, critical hyperkalemia can occur and intraoperative arrests have been documented.[50] ECG changes associated with hyperkalemia include peaked T waves, a prolonged PR interval, and a widened QRS complex. If ECG changes are observed, the transfusion should be stopped and intravenous calcium should be administered. Bicarbonate, dextrose, and insulin may also be appropriate according to the severity of the episode.

Citrate Intoxication. Commonly used additive solutions contain citrate, which anticoagulates by chelation of ionized calcium. When large volumes of stored blood (> one blood volume) are administered rapidly, the citrate can cause a temporary reduction in ionized calcium levels. Citrate is normally metabolized efficiently by the liver and decreased ionized calcium levels should not occur unless the rate of transfusion exceeds 1 mL/kg per minute or about 1 unit of blood per 5 minutes in an average-sized adult. Note that the now common Additive Solution (AS) preservative blood has a much smaller citrate content than citrate-phosphate-dextrose-adenine (CPDA) blood. However, most of the citrate administered during massive transfusion is in the FFP rather than the PRBCs. Impaired liver function or perfusion will lower the rate threshold for developing citrate intoxication. Note that critical cardiac consequences occur before hypocalcemia has significant implications for coagulation. Signs of citrate intoxication (hypocalcemia) include: hypotension, narrow pulse pressure, and elevated intraventricular end-diastolic pressure and central venous pressure, prolonged Q-T interval, widened QRS complexes, and flattened T waves.

Microaggregate Delivery. Stored blood contains microaggregates. Platelet aggregates form during the second to fifth day of storage and after approximately 10 days, larger aggregates composed of fibrin, degenerated white cells, and platelets appear. Macroaggregates of RBCs also develop. Standard fluid administration sets contain 170 micron filters, which will remove these larger “clots.” Micropore filters, typically with a 40-micron pore size, have been advocated but both their efficiency at removing the microaggregates and the significance to patient well-being is uncertain. Microaggregates have been implicated in the pathogenesis of pulmonary insufficiency and the development of ARDS, which often follows large volume transfusions (defined as >10 to 12 units in 24 hrs).[21,51] However, the available data do not confirm this suspicion and suggest that pulmonary injury and the occurrence of ARDS are more often related to the type of injury and the magnitude or severity of the injury than to the volume of blood transfused. Hypotension and sepsis may play a much greater role in the development of ARDS than microaggregates and some of what has been attributed to microaggregates may in fact be TRALI. A practical consideration nonetheless frequently prompts clinicians to introduce a micropore filter between the blood unit and the administration set. Unfiltered blood may clog the 170-micron filter of the standard set and it is less time-consuming to change the 40-micron filter periodically, for example, after every fourth RBC unit, than to exchange the entire administration set.

RBCs are frequently diluted with crystalloid solutions to increase the rate at which the blood can be transfused. Normal saline is commonly recommended in preference to lactated Ringer's solution (LR). In fact, the amount of citrate present in stored blood is more than sufficient to bind the small amounts of calcium in the 100 to 300 cc of LR typically used for dilution.[52] There is no evidence that any clinically significant sequelae have resulted from the use of LR as an RBC diluent.[51]

BLOOD PRODUCTS AND TRANSFUSION THRESHOLDS

Red Blood Cells

The question level of what hemoglobin/hematocrit level justifies the risks associated with the administration of blood has been widely discussed (Table 10-4). The once all but inviolable “10 to 30” rule has been abandoned. Experience with several patient subpopulations (renal failure, military casualties, Jehovah's Witnesses) and systematic study has revealed that considerable greater degrees of anemia can be well tolerated

and that, in many situations, morbidity and mortality rates did not increase until hemoglobin levels fell below 7 g/dL.[53,54] The contemporary transfusion trigger for general medical-surgical patients is now 21%/7.0 g/dL (Hgb/Hct). However, there is evidence that the threshold for patients with cardiac disease should be higher.[53] That evidence includes a well-conducted study supporting a threshold of 30%/10 g/dL (Hgb/Hct) in patients who have suffered a recent acute myocardial infarction[55] and an observational study suggesting better outcomes in patients with several cardiac diagnoses (cardiac and vascular surgery, ischemic heart disease, dysrhythmias) above a threshold of 9.5 g/dL.[56] *The Practice Guidelines for Blood Component Therapy* developed by the American Society of Anesthesiologists (ASA) state that “red blood cell transfusion is rarely indicated when the hemoglobin concentration is greater than 10 g/dL and is almost always indicated when it is less than 6 g/dL. The indications for autologous transfusion my be more liberal than for allogeneic (homologous) transfusion.”[57]

TABLE 10-4 Hazards Associated with Massive Transfusion

Hypothermia
Volume overload
Dilutional coagulopathy
Reduced O_2 carrying capacity (decreased 2,3-DPG)
Metabolic acidosis
Hyperkalemia
Citrate intoxication
Microaggregate delivery

5 The clinician's responsibility is to anticipate, on a patient-by-patient basis, the minimum hemoglobin level (probably in the range of 7 to 10 g/dL) that will avoid organ damage as a result of oxygen deprivation. Determining this individual transfusion trigger requires reference to the many elements of patient condition that determine demand for the delivery of oxygen and the physiologic reserve (Table 10-5). Ultimately the decision to transfuse red blood cells should be made based on the clinical judgment that the oxygen-carrying capacity of the blood must be increased to prevent oxygen consumption from outstripping oxygen delivery.

TABLE 10-5 Conditions That May Decrease Tolerance for Anemia and Influence the RBC Transfusion Threshold

Increased oxygen demand

- Hyperthermia
- Hyperthyroidism
- Sepsis
- Pregnancy

Limited ability to increase cardiac output

- Coronary artery disease
- Myocardial dysfunction (infarction, cardiomyopathy)
- Beta adrenergic blockade
- Inability to redistribute CO
- Low SVR states
- —Sepsis
- —Postcardiopulmonary bypass
- —Occlusive vascular disease (cerebral, coronary)

Left shift of the O_2–Hb curve

- Alkalosis
- Hypothermia

Abnormal hemoglobins

- Presence of recently transfused Hb (decreased 2,3-DPG)
- HbS (sickle cell disease)
- Acute anemia (limited 2,3-DPG compensation)

Impaired oxygenation

- Pulmonary disease
- High altitude

Ongoing or imminent blood loss

- Traumatic/surgical bleeding
- Placenta previa or accreta, abruption, uterine atony
- Clinical coagulopathy

Compensatory Mechanisms during Anemia

When anemia develops, but blood volume is maintained (isovolemic hemodilution), four compensatory mechanisms serve to maintain oxygen delivery: (1) an increase in cardiac output, (2) a redistribution of blood flow to organs with greater oxygen requirements, (3) increases in the extraction ratios of some vascular beds, and (4) alteration of oxygen–hemoglobin binding to allow the hemoglobin to deliver oxygen at lower oxygen tensions.

1. Increased cardiac output.

   With isovolemic hemodilution, cardiac output increases primarily because of an increase in stroke volume brought about by reductions in systemic vascular resistance (SVR). There are two principal determinants of SVR: vascular tone and the viscosity of blood.[58] As hematocrit decreases, reduction of blood viscosity decreases SVR. This decrease in SVR increases stroke volume and consequently cardiac output and blood flow to the tissues. Over a wide range of hematocrits, isovolemic hemodilution is self-correcting. Linear decreases in the oxygen carrying capacity of the blood are matched by improvements in oxygen transport. Because oxygen transport is optimal at hematocrits of 30%, oxygen delivery may remain constant between the hematocrits of 45 and 30%.[58] Further reductions in hematocrit are accompanied by increases in cardiac output, which reach 180% of control as the hematocrit approaches 20%. The exact hemoglobin value at which cardiac output rises varies among individuals and is influenced by age and whether the anemia is acute or develops slowly.[59]

2. Redistribution of cardiac output.

With isovolemic hemodilution, blood flow to the tissues increases but this increased blood flow is not distributed equally to all tissue beds. Organs with higher extraction ratios (brain and heart) receive disproportionately more of the increase in blood flow than organs with low extraction ratios (muscle, skin, viscera).

The redistribution of blood flow to the coronary circulation is the principal means by which the healthy heart compensates for anemia.[58] Coronary blood flow may increase by 400 to 600%. Because the heart under basal conditions already has a high extraction ratio (between 50 and 70% vs. 30% in most tissues) and the primary compensation for anemia involves cardiac work (increasing CO), the heart must rely on redistributing blood flow to increase oxygen supply.[60] These factors make the heart the organ at greatest risk under conditions of isovolemic hemodilution. When the heart can no longer increase either cardiac output or coronary blood flow, the limits of isovolemic hemodilution are reached. Further decreases in oxygen delivery will result in myocardial injury.

3. Increased oxygen extraction.

   Increasing oxygen extraction ratio (ER) is thought to play an important adaptive role when the normovolemic hematocrit drops below 25%. Increased oxygen extraction in multiple tissue beds leads to an increase in the whole body ER and consequently to a decrease in mixed venous oxygen saturation. One investigation demonstrated that as hematocrit decreases to 15%, whole body oxygen ER increases from 38 to 60%, and the SvO2 decreases from 70 to 50% or less.[46] Some organs (brain and heart) already have high extraction ratios under basal conditions and have a limited capacity to increase oxygen delivery by this mechanism. The heart, under basal conditions, extracts between 55 and 70% of the oxygen delivered.[61,62] In contrast, in kidney and skin, the ER is 7 to 10%. In clinical practice, we cannot measure the extraction ratios of the various organs. Because the heart has the highest ER, it is the organ at greatest risk under conditions of normovolemic anemia.[46]

4. Changes in oxygen–hemoglobin affinity.

   The affinity of hemoglobin for oxygen is described by the sigmoid shaped oxygen–hemoglobin dissociation curve. This curve relates the partial pressure of oxygen in the blood to the percentage saturation of the hemoglobin molecule with oxygen. The partial pressure of oxygen at which the hemoglobin molecule is 50% saturated with oxygen and 50% unsaturated is termed the P50. P50 for normal adult hemoglobin at 37 degrees C and a pH of 7.4 is 27 mmHg. Changes in acid-base status or temperature can shift the oxyhemoglobin dissociation curve to the left or right, lowering or raising the P50 value respectively. When the curve is shifted to the left as with hypothermia or alkalosis, the P50 is lowered. With a lower P50, the hemoglobin molecule is more “stingy” and requires lower oxygen partial pressures to release oxygen to the tissues, that is, the hemoglobin molecule does not release 50% of its oxygen until an ambient PO_2 less than 27 mmHg is reached. This may impair tissue oxygenation. By contrast, right shifting of the oxygen-hemoglobin dissociation curve, as occurs with increases in temperature or acidosis, results in an increase of P50, decreased hemoglobin affinity for the oxygen molecule, and release of oxygen to tissues at higher partial pressures of oxygen.

   When anemia develops slowly, the affinity of hemoglobin for oxygen may be decreased, that is, the curve is right shifted, as a result of the accumulation in red blood cells of 2,3-phosphoglycerate (2,3-DPG). Synthesis of supranormal levels of 2,3-DPG begins at a Hb of 9 g/dL. At Hb levels of 6.5 the curve is shifted more prominently. Stored red blood cells become depleted of 2,3-DPG. Temperature reduction and storage-related pH decreases also reduce the P50 of stored blood. These changes, however, are reversed in vivo but the resynthesis of 2,3-DPG by red blood cells may require from 12 to 36 hours.[60]

Isovolemic Anemia versus Acute Blood Loss

Although the same compensatory mechanisms are operative in acute and chronic anemias, they have different degrees of importance and occur at different levels of hemoglobin. With acute blood loss, hypovolemia induces stimulation of the adrenergic nervous system, leading to vasoconstriction and tachycardia. Increased cardiac output does not contribute. In chronically anemic patients, cardiac output increases as the hemoglobin decreases to approximately 7–8 g/dL.[59] In these patients, the accumulation of 2,3-DPG in the red blood cells, thereby increasing the P50 of Hb, is the important first mechanism for compensation.[63]

Platelets

While published guidelines for platelet administration are available, there is once again a substantial requirement for clinician judgment. The indications for platelet administration presented in Table 10-6 are an amalgam of recommendations presented by the ASA in 1996 and the British Committee for Standards in Haematology in 2003.[57,64]

TABLE 10-6 Indications for the Administration of Platelets

Nonbleeding patients without other abnormalities of hemostasis[65]	<10,000/uL
Lumbar puncture, epidural anesthesia, central line placement, endoscopy with biopsy, liver biopsy, or laparotomy in patients without other abnormalities of hemostasis	<50,000/uL
Intended procedures in which closed cavity bleeding might be especially hazardous, for example, neurosurgery	<100,000/uL
To maintain platelets during ongoing bleeding and transfusion not less than	50,000/uL
To maintain platelets during DIC with ongoing bleeding not less than	50,000/uL
Microvascular bleeding attributed to platelet dysfunction, for example, uremia,[a] postcardiopulmonary bypass, or in association with massive transfusion	Clinician judgment

[a]After a trial of DDAVP if permitted by the clinical situation.[66]

6 Table 10-6 makes it apparent that the platelet administration thresholds that will most often be relevant to anesthesiologists will lie between 50,000 and 100,000/uL. The threshold within that range at which platelets are administered should be based on the likelihood of the intended procedure to cause bleeding, the hazard of bleeding should it occur. For example, intracranial neurosurgery > peripheral orthopaedics and the presence or possibility of additional causes of coagulation disturbance, for example, recent administration of antiplatelet agents, cardiopulmonary bypass, DIC, dilution as a result of large volume administration. Bleeding manifestations can vary substantially from patient to patient in the face of similar platelet counts. This occurs because some platelets are more effective than others. When thrombocytopenia results from peripheral destruction of platelets, the bone marrow continues to produce normal, young, large platelets that are hemostatically very effective. A patient with these platelets may have more effective primary hemostasis than a patient with the same platelet count but whose

platelets were produced by a less active, less healthy bone marrow.

One platelet unit will typically increase platelet count by 5 to 10,000/uL. However, the increase must be verified by platelet count, especially in patients who may have been alloimmunized by frequent platelet administration.

Fresh Frozen Plasma

7 In spite of the fact that over 2,000,000 units of FFP are administered annually in the United States there is remarkably little systematically derived evidence of efficacy.[67] Nonetheless, the use of FFP to restore coagulation factor levels is inevitably valid in many clinical circumstances. The indications for fresh frozen plasma administration presented in Table 10-7 are an amalgam of recommendations presented by the ASA in 1996 and the British Committee for Standards in Haematology in 2004.[57,68]

TABLE 10-7 Indications for the Administration of Fresh Frozen Plasma

Correction of single coagulation factor deficiencies for which specific concentrates are not available (principally Factor V)
Correction of multiple coagulation factor deficiencies, for example, DIC, with evidence of microvascular bleeding and PT and/or aPTT >1.5 times normal
Urgent reversal of warfarin therapy[a]
Correction of microvascular bleeding during massive transfusion (>1 blood volume) when PT/aPTT cannot be obtained in a timely manner
[a]Prothrombin complex concentrate (II, VII, IX, X) is an alternative that has been reported to be more effective than FFP.[69]

Cryoprecipitate

Cryoprecipitate contains factor VIII, the von Willebrand factor (vWF), fibrinogen, fibronectin, and factor XIII. Virally inactivated Factor VIII coagulation factor concentrates, some of which contain clinically effective concentrations of vWF (Antihemophilic Factor, e.g., Humate P®, Alphanate®) are now available. As a result, hemophilia A and von Willebrand's disease (vWD) are usually treated (in consultation with a hematologist) with those concentrates rather than cryoprecipitate.

The remaining indications for cryoprecipitate are presented in Table 10-8.[5]

TABLE 10-8 Indications for the Administration of Cryoprecipitate

Prophylaxis before surgery or treatment of bleeding in patients with congenital dysfibrinogenemias
Microvascular bleeding when there is a disproportionate decrease in fibrinogen, e.g., DIC and very massive transfusion,[a] with fibrinogen <80–100 mg/dL (or assay result not available)
Prophylaxis before surgery or treatment of bleeding in hemophilia A or vWD if concentrates are unavailable or ineffective
Bleeding because of uremia that is unresponsive to DDAVP

[a]FFP is the first-line component for the factor depletion associated with massive transfusion.

BLOOD CONSERVATION STRATEGIES

Because of the many hazards of blood product administration, numerous techniques and alternatives have been explored (Table 10-9).

TABLE 10-9 Blood Conservation Techniques

- Preoperative autologous donation
- Acute normovolemic hemodilution
- Intraoperative blood salvage
- Postoperative blood salvage
- Pharmacologic agents
  - Erythropoietin
  - Blood substitutes (hemoglobin and nonhemoglobin based)
  - DDAVP (Section VII)
  - Antifibrinolytics (Section VII)

Autologous Donation

Preoperative donation and perioperative salvage of autologous blood have been used extensively as part of programs to reduce homologous blood administration. Autologous blood may be collected days to weeks prior to surgery (predonation); it may be donated immediately prior to surgery (isovolemic hemodilution); or it may be salvaged from the surgical field or wound drains and reinfused (blood salvage). Deciding whether any of these options is appropriate for individual patients presents another challenge in transfusion medicine.

Preoperative Autologous Donation

Preoperative autologous donation (PAD) of blood has been applied principally in patients undergoing major orthopaedic procedures (total hip and knee replacement, scoliosis procedures) and prostatic and cardiac surgery.[70,71] However, the systematic experience has frequently failed to confirm a reduction in allogenic blood exposure[72,73,74] and utilization is declining.[75] Effectiveness has probably been limited because the patients' erythropoietic response is often not vigorous, in which case the process may simply result in an anemia at the time of surgery. PAD has other

disadvantages. The PAD procedure is more expensive than the collection of homologous blood. In addition, if autologous blood is unused, most institutions discard it and do not permit “crossover” to other patients. Practices with respect to infectious agent testing also vary. Some institutions will store and permit return to the donor of HIV-, hepatitis-, or CMV-infected blood while others discard it. Note also that the transfusion of autologous blood does not eliminate the chance of either human error during blood collection, processing, and reinfusion or the risk of bacterial contamination. Some institutions perform a crossmatch prior to return of blood to the donor and others do not. This underscores the caveat that no transfusion is without risk.

The medical condition of the patient must be considered prior to recommending PAD.[71] Severe aortic stenosis, significant coronary disease or myocardial dysfunction, and low initial hematocrit and blood volume (body weight less than 110 pounds) are relative contraindications to PAD.[76] If the patient's hemoglobin level, cardiac status, and general condition permit, blood can be donated at weekly intervals prior to surgery. Four units is typically the maximum donation because of the shelf life of the first unit collected.

Patients making PAD should receive supplemental iron, for example, 2 mg/kg/day for 3 weeks. In addition, PAD can be supplemented with administration of recombinant erythropoietin (Epo).

Erythropoietin

The effectiveness of Epo in hastening recovery of hematocrit in conjunction with PAD and in improving hematocrit in patients not submitted to PAD has been demonstrated.[77,78,79,80] However, the practice has not become widespread in part because of the expense of the agent (not less than 500 to 1,600 USD/patient depending on the regimen used) and in part because of the necessity for frequent (e.g., weekly times 3 weeks and 2 additional injections in the final week) parenteral (subcutaneous or iv) administration of Epo. Selective administration of Epo to anemic patients has resulted in more obvious reduction in allogenic blood administration[81,82] than has administration to “all comers.”[83,84] Epo, a recombinant product, is usually accepted by Jehovah's Witnesses and its efficacy in that population has been demonstrated.[85] The recent demonstration of the reduction of transfusion requirements in critically ill patients by Epo[86] may increase awareness and encourage its systematic

use in anemic elective surgical patients. An alternative erythropoietic agent, darbopoietin alpha, has recently been developed. Its longer half-life results in a more sustained erythropoietic effect than occurs with Epo.[87]

Acute Normovolemic Hemodilution

Acute normovolemic hemodilution (ANH) entails withdrawal of the patient's blood early in the intraoperative period with concurrent administration crystalloids or colloids to maintain normovolemia. The rationale is that during the ensuing surgery, the patient will lose blood of low hematocrit and the withdrawn blood will be available for reinfusion at the end of the operation. The end point for the initial withdrawal is a hematocrit of 27 to 33%, depending on the patient's cardiovascular and respiratory reserve. Selection for this technique should rely on careful evaluation of the patient for coronary or cerebral vascular disease. This procedure evolved in the anticipation that it would reduce total red cell loss and homologous blood administration. However, both mathematical modeling and empiric experience have revealed only a modest benefit with respect to reducing the necessity for homologous RBCs.[80,88,89,90,91] By way of example, Goodnough[92] calculated that, in a 100-kg patient from whom three units of blood is withdrawn and replaced by asanguinous fluid, if the subsequent blood loss is 2,800 mL, 215 mL of RBCs (about one unit) will be saved. For patients of limited body size, low starting hematocrit, or blood loss less than 70% of one blood volume,[93] avoidance of allogenic blood or patient benefit might be difficult to achieve. A recent meta-analysis, while confirming that reduction of allogenic blood on the order of one unit per patient was common among the reported investigations, on the basis of the modest savings and the scientific merit of the investigations, concluded that “the literature supports only modest benefits from preoperative ANH. Widespread adoption of ANH cannot be encouraged.”[94] Nonetheless, there are reports of favorable experiences in liver resection,

prostatectomy, total hip arthroplasty, and abdominal aortic surgery.[80,95,96,97] It is possible that in the future the efficacy of ANH will be enhanced by administration of preoperative erythropoietics and/or by the use of either hemoglobin-based oxygen-carrying compounds or perflourocarbon emulsions to permit withdrawal of larger volumes of blood.

ANH has also been employed for the purpose of making fresh autologous blood at the end of procedures in which either a dilutional or cardiopulmonary bypass-related coagulopathy may occur. The efficacy in this context has not been confirmed by systematic study. Blood collected and reinfused for this purpose should not be passed through a 40-micron filter to avoid platelet elimination.

Perioperative Blood Salvage

Perioperative blood salvage refers to the recovery of shed blood from the surgical field or wound drains and readministration to the patient. In most instances, the process involves “washing” of the salvaged material with return of only the RBC component of blood. In some instances, usually those involving wound drainage, blood is returned filtered but otherwise unprocessed.

Intraoperative Blood Salvage

Intraoperative blood salvage (IBS) is employed with many surgical procedures that have the potential to require homologous transfusion. Contemporary “cell saver” devices anticoagulate the salvaged blood as it leaves the surgical field, separate the RBCs from other liquid and cellular elements by centrifugation, and then wash the salvaged RBCs extensively with saline. The RBCs are typically returned to the patient suspended in saline in aliquots of 125 or 225 mL with a hematocrit of 45 to 65%[98]. Higher hematocrits can be achieved at the expense of the additional time required for slower filling of the centrifuge chamber.

IBS has been used commonly during cardiovascular surgical procedures, aortic reconstruction, spinal instrumentation, joint arthroplasty, liver transplantation, resection of arteriovenous malformations,[99] and occasionally in the management of trauma patients.[100] There have been numerous demonstrations that IBS can reduce the use of homologous RBCs.[101,102] The presence of infection, malignant cells, urine, bowel contents, and amniotic fluid in the operative field have been viewed as contraindications. However, though malignant cells are known to be retained with RBCs after the washing process, IBS has been applied in the management of hepatic and urologic malignancies without evidence of metastasis.[103,104] At least one IBS washing device has also been shown to remove the critical procoagulant factors present in amniotic fluid[105] and IBS has been employed successfully in Cesarean section.[106] However, the safety of IBS use in that context is unconfirmed and should not be routine.[107]

The potential complications of IBS are largely a function of the reinfusion of materials that might remain after the washing process. These include fat, microaggregates such as platelets and leukocytes, air, red cell stroma, free hemoglobin, heparin, bacteria, and debris from the surgical field. Most of these are in fact removed quite efficiently by contemporary cell salvage equipment. Bacteria are the exception and contamination of cell saver return with skin organisms is relatively common.[101] Leukocyte reduction filters have been shown to remove most bacteria[108] and may be relevant to the use of IBS in trauma. Massive air embolism has occurred as a result of user error. Direct return from the cell saver apparatus has now been largely abandoned in favor of return via an intermediary bag under the control of the anesthesiologist. Care should still be taken in the event that pressure infuser devices are applied to these bags.

A dilutional coagulopathy in association with large volume IBS is to be expected because essentially all clotting factors and most platelets are removed by the washing process. Management is the same as for a dilutional coagulopathy occurring with administration of homologous or PAD blood. A DIC-like coagulopathy, the “salvaged blood syndrome,”[109] has also been associated with IBS. However, it seems likely that this syndrome was the result of inadequate preparation of blood by older cell salvage devices. Unwashed, salvaged blood has been shown to contain numerous constituents that influence the coagulation process: thromboplastic material, interleukins, complement, fibrin degradation products, and factors released from

activated leukocytes and platelets.[99] The majority of these, however, are quite efficiently removed by contemporary processing devices and their presence is used as an argument against the return of unprocessed blood (see later).[110]

An additional coagulopathy risk arises with the use of thrombin and microfibrillar collagen or cellulose products in the surgical field.[111] These agents are not reliably removed by the washing process and suction of blood to the IBS device should be discontinued during the use of these agents and resumed after the field has been irrigated.

The clinician should appreciate that the recovery of shed RBCs by the IBS process is on the order of 50%. Allogenic blood will therefore frequently be necessary in spite of the IBS and blood and fluid replacement calculations should take this into account.[112,113]

Postoperative Blood Salvage

Postoperative recovery of blood from mediastinal chest tubes and wound drains after hip and knee replacement with immediate reinfusion of “unwashed” blood has been employed quite commonly. The many substances present in the unprocessed blood (previous section) suggest that coagulation dysfunction might result and many are skeptical regarding the wisdom of this practice.[98,110] However, there have been only occasional reports of apparent adverse consequences.[114] This may reflect the fact that the recovered and reinfused volumes are usually small.

Hemoglobin-Based Oxygen Carrying Solutions

It seems possible that hemoglobin-based oxygen carrying solutions (HBOCs) will become available in the near future. Hemopure® (Biopure, Inc) has been approved for clinical use in South Africa. However, although numerous polymerized hemoglobin products have been studied only one, PolyHeme®, Northfield Laboratories, is currently in phase III trial in the United States. The many products studied use bovine, outdated human, or recombinant hemoglobin that has been entirely separated from red cell membranes (stroma) and polymerized to increase half-life. The initial difficulties with renal failure caused by stroma and excessive free hemoglobin have been overcome. However, there are several residual difficulties with which clinicians will probably have to contend including methemoglobinemia, interference with some calorimetrically based laboratory assays (including creatinine, total bilirubin and LDH), some degree of vasoconstriction caused by nitric oxide binding by free Hb, and a relatively short half-life. Polymerization increases half-life to 18 to 36 hours but that period is sufficiently short that O_2-carrying capacity will usually become inadequate before native reticulocytosis can compensate.[115,116] Perflourocarbon emulsions[116] appear to be further from potential clinical application than HBOCs and will not be discussed here.

The Jehovah's Witness

In general, Jehovah's Witnesses will accept neither administration of homologous blood products nor the readministration of autologous products that have left the circulation. However, their faith allows significant personal discretion and the wishes of each patient must be clarified. Few will permit the administration of the common whole blood components and the majority will decline PAD. However, many will accept procedures that maintain extracorporeal blood in continuity with the circulation. The acceptability of cardiopulmonary bypass, acute normovolemic hemodilution, and perioperative cell salvage must be clarified with each patient individually. Most will permit administration of Epo.

COLLECTION AND PREPARATION OF BLOOD PRODUCTS FOR TRANSFUSION

Red Blood Cells

In the preparation of red blood cells for transfusion, whole blood is first collected in bags

containing citrate-phosphate-dextrose-adenine (CPDA) or CPD solution. The citrate chelates the calcium present in blood and prevents coagulation. PRBCs are prepared by centrifugation. The two common preparations ultimately delivered to the clinician have either CPDA or so-called Additive Solution as the preservative. CPDA blood has a hematocrit of about 70 to 75%, contains 50 to 70 mL of residual plasma in a total volume of 250 to 275 mL, and has a shelf life of 35 days. With the Additive Solution preparation, the original preservative and most of the plasma (10 to 15 mL residual) is removed and replaced with 100 mL of Additive Solution. This results in a lower hematocrit, 60%, in a total volume of 250 to 350 mL; less citrate per unit, 75 to 80% fewer microaggregates; and a longer shelf life, 42 days. Additive Solution RBCs are thought to regenerate 2,3-DPG more rapidly. The pH and K+ content of the two preparations are similar. The smaller plasma volume in Additive Solution blood results in smaller amounts of coagulation factors in PRBCs but also a potentially lesser risk of allergic reactions and TRALI.

Sequential centrifugation at various spin speeds and durations is used to separate whole blood into components; including packed RBCs, platelet concentrates, cryoprecipitate, leukocyte-poor RBCs, and cell-free plasma. For preparation of platelet concentrates, centrifugation is first performed at room temperature. This separates the platelet-rich plasma fraction from the red blood cells. To separate all other blood components, centrifugation is carried out between 1 degree and 6 degrees C.

There are alternative RBC preparations that eliminate the various “passengers.” Saline-washed RBCs may be used for patients who experience reactions to foreign proteins. White cells can be removed by washing, irradiation, or leukofiltration. The administration of one unit of packed RBCs will increase the Hb and Hct of a 70-kg adult by approximately 1 g/dL and 3%, respectively.

RBCs can be frozen and stored indefinitely. However, preservatives to prevent freeze-thaw associated damage must be added and subsequently removed before administration, which must occur within 24 hours of thawing. The process is expensive and therefore not widely used.

Compatibility Testing

Compatibility testing involves three separate procedures involving both donor and recipient blood: ABO, Rh blood type identification, antibody screening of donor plasma, and the donor/recipient crossmatch.

ABO, Rhesus Typing

The first step is to determine the ABO blood group type and the Rh status of both donor and recipient blood. This is a critical step because most of the fatal hemolytic transfusion reactions result from the transfusion of ABO-incompatible blood. Blood types are defined according to the antigens present on the surface of the RBCs. Patients with type A blood have type A antigens on the surface of their red cells. Type B blood has B antigens. When both antigens are present the patient is said to have type AB blood and when both are lacking, the patient is said to have type O blood. The serum constitutively contains antibodies to the AB antigens that are lacking on the RBC. Patients with type A blood have antibodies against the B antigen and vice versa. Patients with no antigens on their cells, type O blood, will have both anti-A and anti-B antibodies in the plasma. The approximate frequencies of ABO blood types in the U.S. are presented in Table 10-10.

TABLE 10-10 Major RBC Surface Antigen Incidence (%) in the U.S. Population[117]

·GROUP	·WHITES	·BLACKS
O	45	49

A	40	27
B	11	20
AB	4	4
Rh (D)	85	92

Patients with the Rhesus (D) antigen are said to be Rh-positive and those who lack the D antigen are termed Rh-negative. Approximately 85% of the population is Rh-positive. In contrast to the A and B blood groups, anti-D antibodies are not constitutively present in the serum of an Rh-negative patient. However, 60 to 70% of Rh-negative patients exposed to donor Rh-positive RBCs will develop anti-D antibodies. There is a latency before these antibodies are synthesized. As a consequence, the reaction between the Rh-positive donor cells and

the anti-D evolves slowly and may not be clinically apparent on first exposure. This process, whereby a foreign antigen stimulates the synthesis of the corresponding antibody, is termed “alloimmunization.” Subsequent exposure of these Rh-negative individuals to Rh-positive cells may result in an acute hemolytic reaction.

In determining what donor blood group types may be compatible for transfusion to a particular recipient, it is useful to focus on which antibodies will be present in the recipient plasma. It is the reaction of these antibodies with donor RBC antigens that can activate complement and lead to intravascular hemolysis of the red cell. Type O+ recipients [type O, Rh(D)-positive] will have both anti-A and anti-B antibodies, but not the anti-D antibody in their plasma. These patients must not receive either type A, type B, or type AB blood. They must receive type O blood but it may be Rh-positive or Rh-negative. In contrast, patients with blood type AB- (Type AB, Rh-negative), will lack both the A and B antibodies in their plasma and may or may not have the anti-D antibody in their plasma. They can receive A-, B-, AB-, or O- blood. Individuals with the greatest number of antigens on their RBCs have the fewest constitutive antibodies in their plasma and can receive all blood types (Types A+, A-, B+, B-, AB+, AB-, O+, and O-), and are referred to as universal recipients. Individuals with the fewest antigens on their cells (type O-negative) have the greatest number of antibodies in their plasma. Type O-negative RBCs can be administered to all ABO, Rh types and these individuals are referred to as universal donors.

The Antibody Screen

The antibody screen, an indirect Coombs test, is performed to identify recipient antibodies against RBC antigens. Commercially supplied RBCs, selected for the panel of antigens they possess, are mixed with both donor and recipient serum to screen for the presence of unexpected antibodies. Only about 4 in 1,000 blood donations demonstrate unexpected antibodies. The likelihood that the antibody screen will miss a potentially dangerous antibody has been estimated to be no more than 1 in 10,000. If the recipient plasma screen is positive, the antibody must be identified and appropriate antigen negative donor units selected. The antibody screening of recipient plasma should be repeated if the patient has been transfused since the last antibody screening test.

The Crossmatch

Donor RBCs are mixed with recipient serum. This test requires about 45 minutes and is carried out

in three phases: (1) the immediate phase, (2) incubation phase, and (3) antiglobulin phase.

The immediate phase serves primarily to ensure that there have been no errors in ABO-Rh typing. The test entails examination of a mixture of donor RBCs and patient serum for macroscopic agglutination. This immediate phase crossmatch requires only 1 to 5 minutes and detects ABO incompatibilities and those caused by antibodies in the MN, P, and Lewis systems.

The second phase, the incubation phase, requires 30 to 45 minutes and detects antibodies primarily in the Rh system.

The third phase, the antiglobulin phase, also called the antiglobulin crossmatch or the indirect antiglobulin test, entails the addition of antiglobulin sera at the end of the incubation phase. This phase is performed only on blood yielding a positive antibody screen and requires 60 to 90 minutes. The test identifies the presence of antibodies attached to antigens on the surface of the donor red blood cells. This phase is an attempt to identify the most incomplete antibodies (i.e., those that do not cause agglutination) from all blood group systems, including Rh, Kell, Kidd, and Duffy systems.

In patients who have been transfused previously or who may have been exposed to foreign red blood cell antigens during pregnancy, only 1 in 100 will have an antibody other than the anti-A, anti-B, and/or anti-Rh antibodies and many of these are not reactive at physiologic temperatures. Determining the ABO blood group type and Rh status alone yields the probability that the transfusion will be compatible in 99.8% of instances. The addition of the 30- to 45-minute antibody screen improves the likelihood of a compatible transfusion to 99.94%; the addition of a complete crossmatch increases this to 99.95%.[63] In patients who have not previously been transfused or pregnant, the odds that an incompatible transfusion will occur when uncrossmatched blood is administered is only 1 in 1,000. For those who have previously been exposed to foreign red blood cell antigens, the likelihood that they will have developed an antibody is about 1 in 100. Nonetheless, all blood banks perform the crossmatch. However, these data reveal that the administration, in emergency situations, of uncrossmatched blood to patients with no history of pregnancy or transfusion should entail relatively low risk.

Type and Screen Orders

When blood is ordered preoperatively for surgical cases in which it is unlikely that the blood will actually be transfused, the orders should be for “type and screen” only. The ABO, Rh status of the patient is determined and the antibody screen (see earlier) is performed to determine the presence of antibodies other than ABO in the potential recipient's plasma. If the antibody screen is negative, type specific uncrossmatched blood will result in a hemolytic reaction in less than 1/50,000 units[5]. If the screen is positive, the blood bank proceeds to identify a pool of potentially compatible units.

Emergency Transfusions

8 The exsanguinating patient may require RBCs before complete compatibility testing can be performed. If testing is to be abbreviated, there is a preferred order for selecting partially tested blood. The first choice is to transfuse type-specific, partially crossmatched blood. In urgent situations in which a patient needs blood before compatibility testing can be completed, the use of uncrossmatched blood is indicated. If the patient's ABO and Rh type is unknown or has not been tested on a current sample, group O RBCs should be administered until there is time to complete ABO and Rh testing. Rh-negative blood is preferable if the patient's Rh type is unknown or if the patient is a woman of child-bearing age. If Rh-negative blood is not available for a critically ill, bleeding Rh-negative patient, Rh-positive blood should not be withheld. If the blood bank has time to test a current sample, then ABO and Rh type-specific uncrossmatched RBCs can be administered. In either case, the blood bank will begin compatibility tests as soon as possible

if a current pretransfusion sample is available. If a non group O patient receives a large volume of group O red cells, the combined amount of anti-A and/or anti-B present in the small amounts in the residual plasma each PRBC unit may react with the patient's own A, B, or AB red cells and

cause some hemolysis. For this reason, non group O patients who have received group O red cells approximating one patient blood volume (10 to 12 units) during the period of acute blood loss should not be switched back to their own ABO group[118] unless testing has been performed to confirm that significant titers of anti-A or anti-B antibodies are not present. The decision as to whether or not to switch to type-specific blood should be made, in conjunction with the blood bank, on the basis of that result and administration of type O blood should continue in the interim.

Platelets

Platelets are separated from plasma by centrifugation. They are commonly supplied as single-donor units with the platelets suspended in a small quantity of residual plasma. One unit of platelets will increase the platelet count of a 70-kg recipient by 5 to 10,000/mm^3. A common practice is to administer one unit/10 kg of body weight. Accordingly, platelet transfusion will often entail exposure to multiple donors. Donor exposure can be minimized by the use of single-donor platelet pheresis packs that contain the platelet equivalent of approximately six single units in a volume of 200 to 400 mL. These are obtained by serial blood withdrawals from a single donor followed by centrifugation and return of the RBCs to the donor.

Platelet viability is optimal at 22°C but storage is limited to 4 to 5 days. The short shelf time means that platelets are usually administered before the results of the newly introduced nucleic acid antigen (NAT) testing for viral agents are available.

Platelets bear both ABO and human leukocyte antigens (HLA). ABO compatibility is ideal because incompatibility shortens the life span of the platelet. However, it is not required. ABO/HLA-matched platelets are indicated for patients who become refractory to random donor platelets. Platelets do not carry the Rh antigen. However, administration of platelets from an Rh-positive donor to an Rh-negative female of child-bearing age should be avoided in order to prevent sensitization as a result of passenger RBCs in the platelet preparation. If it occurs, Rh-immune globulin should be administered.

Platelets should be administered through a filter. The standard 170-micron filter is sufficient and there is no advantage or necessity to use the 40-micron filters typically used for RBC administration.[5]

Fresh Frozen Plasma

Plasma is separated from the RBC component of whole blood by centrifugation. One unit has a volume of 200 to 250 mL. It will contain the preservative added at the time of collection, usually CPD-adenine. To preserve the two labile clotting factors (V and VIII), it is frozen promptly and thawed only immediately prior to administration. FFP must be ABO compatible. Rh-positive plasma can be given to an Rh-negative recipient but ideally this should be avoided in young females because of the possibility of alloimmunization to the Rh antigen on passenger RBCs in the FFP.

Solvent Detergent Plasma

One of the principal hazards of FFP administration has been virus transmission. Three procedures, pasteurization, photochemical treatment, and solvent detergent (SD) treatment, have been used to inactivate viruses. The SD technique is highly effective in inactivating all of the lipid encapsulated viruses, for example, HIV, HCV, HBV, and HTLV. The disadvantage of the SD technique is that the process involves pooling of large numbers of single FFP units (>1,000) and is not effective against nonlipid enveloped viruses (HAV, parvovirus) or the agent of Creutzfeldt-Jakob disease. The concern with SD plasma is that the pooling process might result in wide dissemination of an infectious agent. The incidence of parvovirus viremia among donors is estimated to be between 0.03 and 0.6%.[119] Parvovirus infection has been reported as a consequence of transfusion. While the disease is usually self-limited, significant morbidity, for example, red cell aplasia, meningitis, especially in immunocompromised patents, can occur.[119] The future of SD plasma is not clear to the authors of this review.

Cryoprecipitate

Cryoprecipitate is the precipitate that remains when FFP is thawed slowly at 4°C. It is a concentrated source of factor VIII, factor XIII, vWF, and fibrinogen. One unit of cryoprecipitate (the yield from one unit of FFP) contains sufficient fibrinogen to increase fibrinogen level 5 to 7 mg/dL.[120] Accordingly, it is usually provided in bags that contain 10 or 20 units. ABO compatibility is not essential because of the limited antibody content of the associated plasma vehicle (10 to 20 mL). Viruses can be transmitted with cryoprecipitate. It is stored at -20°C and thawed immediately prior to use.

Factor VIII and IX

Recombinant and virally inactivated FVII concentrates are available.

Antithrombin III

Virus-treated antithrombin III (ATIII) concentrates are available. They have been employed in the treatment of congenital and acquired ATIII deficiencies.[121] The latter include DIC and fulminant hepatic failure.

THE HEMOSTATIC MECHANISM

Normal “hemostasis” involves a series of physiologic checks and balances that assure that blood remains in an invariably liquid state as it circulates throughout the body but, once the vascular network is violated, transforms rapidly to a solid state. That transformation to a solid state, that is, coagulation, must inevitably be complemented by processes for eliminating clot that is no longer needed for hemostasis. The latter is accomplished by fibrinolysis

The Nomenclature of Coagulation

Understanding the coagulation process has been made more difficult by the complexity of the nomenclature. An early attempt was made to standardize it by assigning Roman numerals to each of the 12 known clotting factors. Unfortunately, the factors were numbered in the order in which they were discovered and not in the sequence in which they interact. To complicate matters, the first 4 of the original 12 factors are usually referred to by their common names, fibrinogen,

prothrombin, tissue thromboplastin (tissue factor), and calcium, and not by their Roman numerals. Factor VI no longer exists; it proved to be activated factor V. The more recently discovered clotting factors, for example, prekallikrein and high–molecular-weight kininogen, have not been assigned Roman numerals. They too are identified by common names, and to further complicate matters, some have more than one name (Table 10-11).

TABLE 10-11 Factor Nomenclature and Half-Lives

·FACTOR	·SYNONYMS	·IN VIVO HALF-LIFE (HOURS)
I	Fibrinogen	100–150
II	Prothrombin	50–80
III	Tissue thromboplastin, tissue factor (TF)	

IV	Calcium ion	
V	Proaccelerin, labile factor	24
VII	Serum prothrombin conversion accelerator (SPCA), stable factor	6
VIII	Antihemophilic factor (AHF)	12
vWF	von Willebrand factor	24
IX	Christmas factor	24
X	Stuart-Power factor, Stuart factor, autoprothrombin	25–60
XI	Plasma thromboplastin antecedent (PTA)	40–80
XII	Hageman factor	50–70
XIII	Fibrin stabilizing factor (FSF)	150
Prekallikrein	Fletcher factor	35
HMW kininogen	Fitzgerald, Flaujeac, or Williams factor; contact-activation cofactor	150

The Coagulation Mechanism

9 The classical, dual-cascade (intrinsic and extrinsic pathway) model of coagulation (Figs. 10-1 and 10-2) is now recognized to be an inadequate representation of in vivo coagulation. It failed to explain several clinical phenomena. First, persons lacking factor XII, prekallikrein, or high–molecular-weight kininogen do not bleed abnormally, suggesting that contact activation is not critical for normal hemostasis. Second, patients with only trace quantities of factor XI withstand major trauma without unusual bleeding and those completely lacking factor XI have only a mild hemorrhagic disorder. Factor XI therefore appears to have a more minor role in coagulation than ascribed to it by classical theory. Next, deficiencies of factor VIII (an extrinsic pathway factor) and factor IX (an intrinsic pathway factor) lead to Hemophilia A and B, respectively. The classical

description of two pathways of coagulation leaves it unclear clear why either type of hemophiliac could not simply clot via the unaffected pathway. Most importantly it is now appreciated that while the classical theories may provide a reasonable model of in vitro coagulation tests, that is, the aPTT and PT, they fail to incorporate the central role of cell-based phospholipid surfaces in the in vivo coagulation process. The three stages of that process, which has been thoroughly defined and

described by Hoffman, are summarized in the next sections and in Figure 10-3.[122]

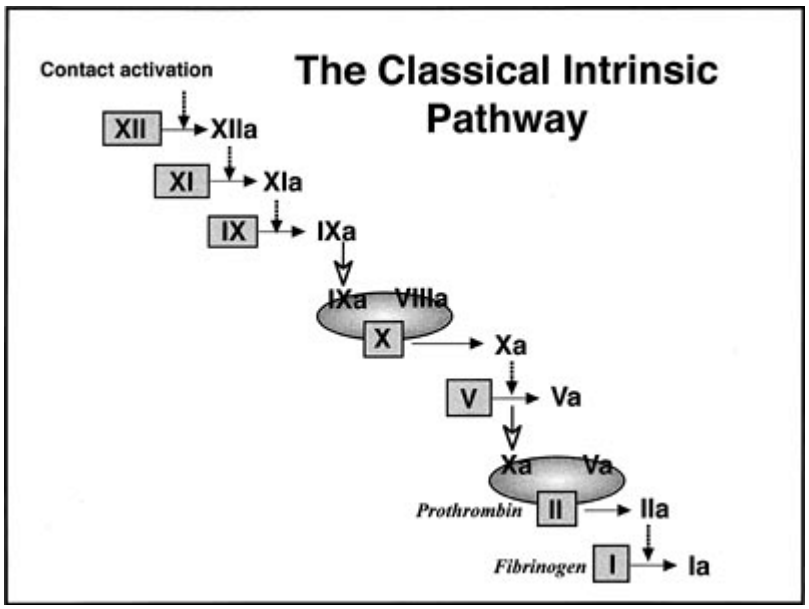

FIGURE 10-1. The classical intrinsic pathway of coagulation. A cascade initiated by contact with a foreign surface leads to the formation of the fibrin (Ia) necessary for the generation of a fibrin clot. The *dotted arrows* indicate the occurrence of an enzymatically mediated conversion of an inactive factor to its active form. The *open-headed arrows* indicate the translocation of an activated factor to participate in a subsequent reaction. The *shaded spheroids* represent the phospholipid surfaces (usually provided by activated platelets).

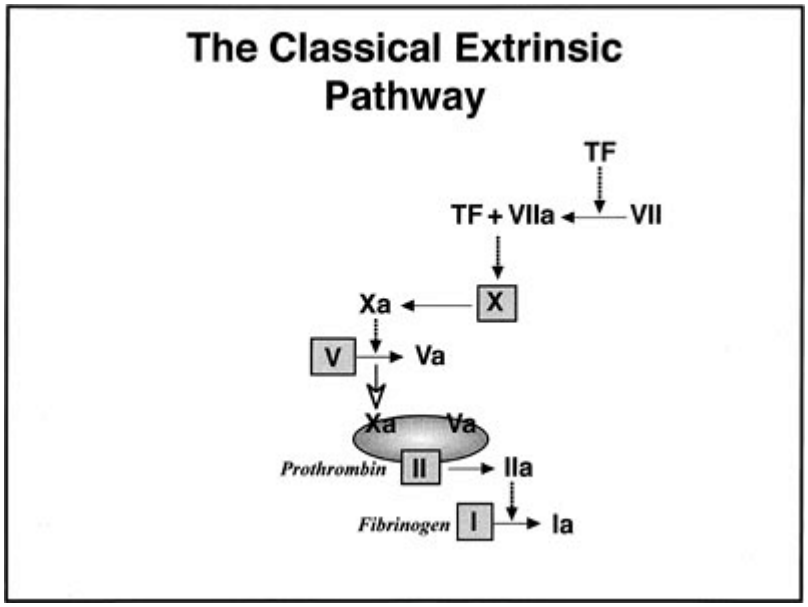

FIGURE 10-2. The classical extrinsic pathway of coagulation. This pathway is depicted as it was originally thought to occur, that is, largely extravascularly and independent of the classical intrinsic pathway (compare Fig. 10-1). The *dotted arrows* indicate the occurrence of an enzymatically mediated conversion of an inactive factor to its active form. The *open-headed arrows* indicate the translocation of an activated factor to a phospholipid surface to participate in a reaction complex. The *shaded spheroid* represents the phospholipid surface (usually provided by activated platelets).

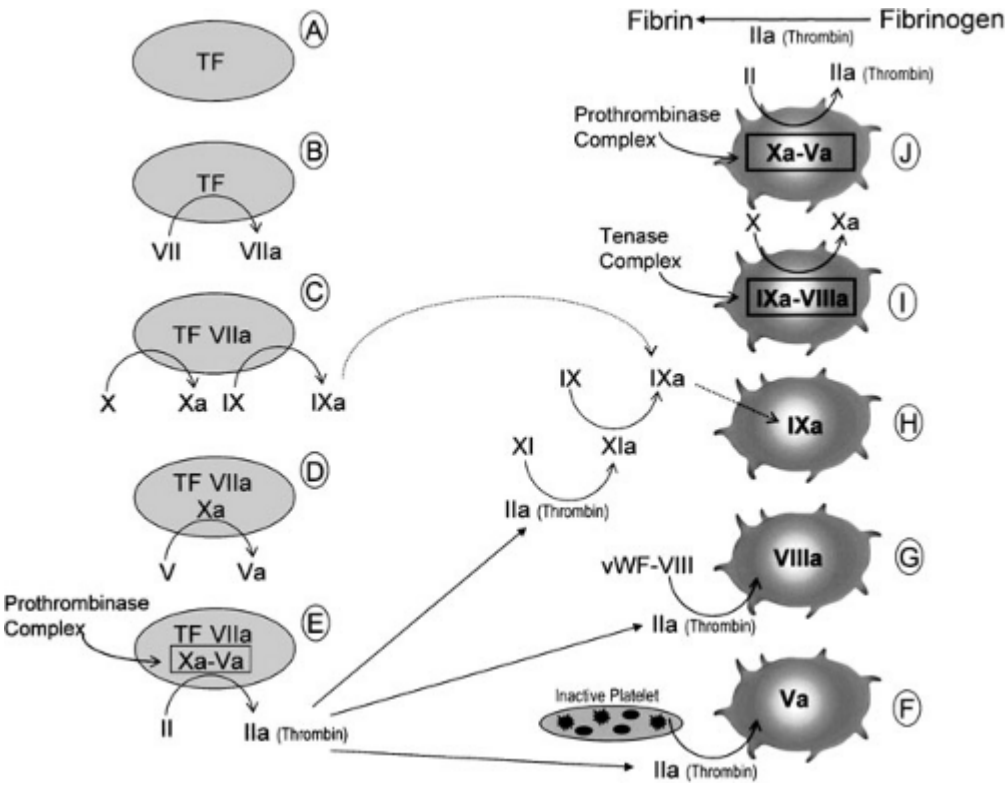

FIGURE 10-3. The coagulation mechanism. See text. TF, membrane-bound tissue factor on a extravascular cell surface; vWF-VIII:C, circulating factor VIII bound to its carrier protein, the von Willebrand factor.

Activation

Activation of the coagulation process begins when a breach in the vascular endothelium exposes blood to the membrane-bound protein, tissue factor (TF) (Fig. 10-3A). TF activates circulating FVII to yield a complex of TF and activated (a) FVII (FVIIa) (Fig. 10-3B). The TF-VIIa complex in turn activates factors IX and X (Fig. 10-3C). Xa then activates FV (Fig. 10-3D), resulting in the formation of the “prothrombinase complex,” composed of Xa and Va, on the phospholipid surface provided by membrane bound TF. The prothrombinase complex catalyzes the conversion of prothrombin (FII) to thrombin (FIIa) (Fig. 10-3E). It is this initial formation of thrombin in small amounts that advances the coagulation process to the more efficient “amplification” phase that follows. (For those in need of a mnemonic, it is the “nickel-dime,” Va-Xa prothrombinase complex that is responsible for the initial, modest thrombin generation.)

Amplification

While it was the phospholipid surface provided by membrane-bound TF that initiated the coagulation process, it is now the phospholipid surface provided by platelets that serves to perpetuate it. The breach in the vascular tree that began the activation process also exposed platelets to collagen to which they become bound by vWF via the GPIb receptor on the platelet surface (Fig 10-4). The thrombin just generated by the TF-bound prothrombinase complex supports the amplification of the coagulation process in four ways. First, it further activates the adjacent platelets (Fig. 10-3F). That activation results in platelet surface changes, most notably the appearance of the GPIIIb/IIa receptor, and in the release of the contents of platelet granules (Fig. 10-5). Among those contents are ADP, a powerful platelet activator and proaggregant that rapidly recruits other platelets to the growing platelet mass, and Factor V. Thrombin's second effect is to promote the activation FV to FVa (Fig. 10-3F). Third, thrombin releases circulating FVIII from its carrier molecule (vWF) and activates it (Fig. 10-3G); and fourth, thrombin activates FXI (Fig. 10-3H). FXIa in turn activates FIX (Fig. 10-3H), further adding to the pool of IXa that first formed during the activation phase above (Fig. 10-3C). The net result of this amplification stage is the availability of activated platelets and activated factors V, VIII, and IX.

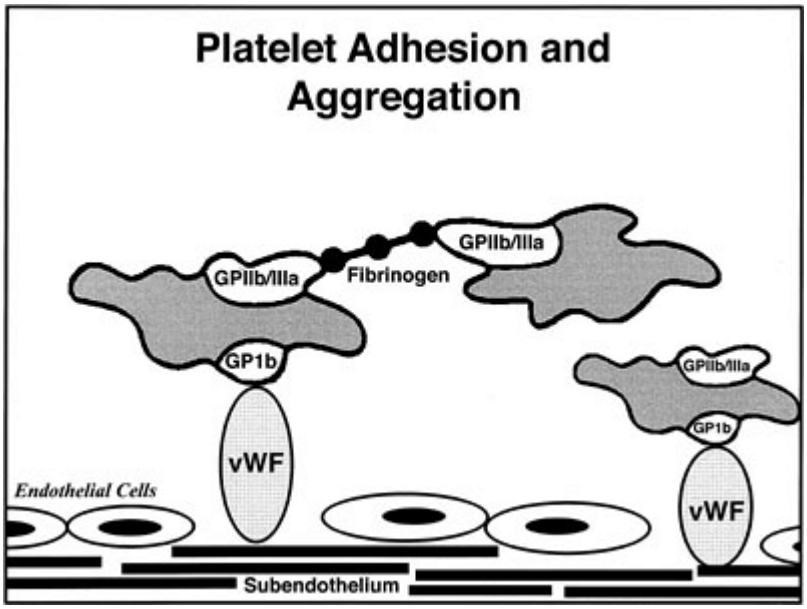

FIGURE 10-4. Platelet release reaction. Platelets undergo a release reaction coincident with shape change or in response to physiologic agonists including epinephrine, ADP, and thrombin. The numerous substances released from the alpha and dense granules of platelets

contribute to platelet aggregation (fibrinogen), to the activation and adhesion of additional platelets (ADP, epinephrine, thrombin, vWF) and to clot formation (vWF, fibrinogen, thrombin, calcium, Factors V and XI, fibronectin).

Propagation

10 The platelet then provides the phospholipid surface on which two coagulation factor complexes form and act to produce the explosive generation of thrombin. First, VIIIa and IXa form the "tenase complex," which activates FX (Fig. 10-3I). The resultant Xa forms additional prothrombinase complex (Xa–Va) and large amounts of thrombin are elaborated (Fig. 10-3J). (For mnemonic purposes it is "eight-nine and nickel-dime" that together are responsible for the thrombin burst.) Thrombin (IIa) catalyzes the formation of fibrin from

fibrinogen and fibrin acts to crosslink the platelets to reinforce the friable platelet plug (see Fig. 10-4). Thrombin also activates thrombin activatable fibrinolysis inhibitor (TAFI) and FXIII (neither shown), both of which serve to stabilize the fibrin clot. Fibrin monomers initially aggregate relatively loosely to form a clot composed of fibrin S (soluble), which is held together only by hydrogen bonds. FXIII (fibrin stabilizing factor) mediates the formation of covalent peptide bonds between the fibrin monomers to yield a stable (insoluble) fibrin clot.

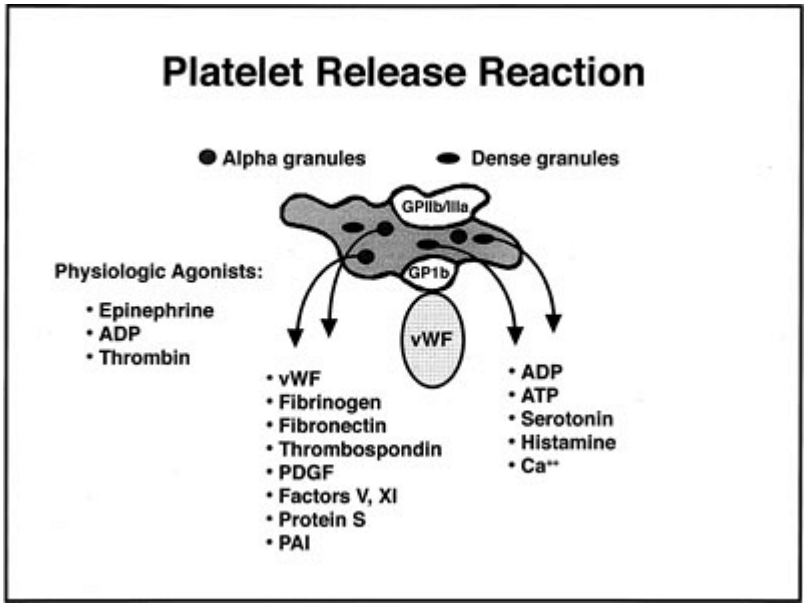

FIGURE 10-5. Platelet adhesion and aggregation. When the endothelium is denuded, von Willebrand factor (vWF) binds to collagen in the subendothelial layer. Platelets patrolling the blood vessel lining adhere via their glycoprotein (GP) 1b receptors to vWF. The binding of vWF to the GP1b receptors initiates platelet activation. Platelets change their shape from discoid to spheroid and extrude multiple pseudopods. Platelets aggregate to one another by crosslinking via fibrinogen (or vWF, not shown) between glycoprotein IIb/IIIa receptors expressed on the platelet surface during the process of platelet activation.

Additional Principles of Coagulation

A few additional facts will aid in achieving a broader understanding of coagulation:

1. Most clotting factors circulate in an inactive form.

   Most of the clotting factors circulate as inactive proenzymes. During the process of coagulation, a portion of the molecule is cleaved off, resulting in active enzymes (designated by the addition of a lower case “a” after the Roman numeral, e.g., Xa), most of which are serine proteases.

2. Most clotting factors are synthesized by the liver.

   Accordingly, their normal structure and function are dependent on normal hepatic activity. One possible exception is factor VIII, which probably also has some extrahepatic synthesis.

3. Factor VIII is actually a large, two-molecule complex (vWF and coagulant factor VIII).

   Factor VIII circulates as a very large complex of two distinct protein components. The high–molecular-weight portion (VIIIR:Ag) encompasses both the factor VIII antigen (used to identify “factor VIII” in the laboratory assay) and the vWF. The vWF portion serves as a carrier protein for the second and smaller component of this macromolecular complex, VIIIC, which contains the factor VIII coagulant activity. The vWF has a second function in addition to its role as carrier protein. During the process of primary hemostasis when the endothelial lining has been denuded, vWF mediates adhesion of platelets to collagen. Absence of the smaller portion of the factor VIII complex (VIII:C) results in hemophilia A. Absence of vWF causes two hemostatic abnormalities: (1) a defect in primary hemostasis because of a failure of platelet adhesion to the sites of vascular injury and (2) clinical hemophilia A because of an absence of circulating factor VIII:C. Restoration of vWF levels restores normal hemostasis. Synthesis of the vWF occurs in endothelial cells and megakaryocytes. The site of synthesis of the coagulant portion of factor VIII is unknown but may be located in the hepatic sinusoidal endothelial cells.

4. Four clotting factors are vitamin K dependent.

   Four of the clotting factors, II, VII, IX, and X, require vitamin K for completion of their synthesis in the liver. Each undergoes a final enzymatic addition of a carboxyl group that requires the presence of vitamin K. The carboxyl group enables these factors to bind (with calcium as a cofactor) to phospholipid surfaces. Without vitamin K, factors II, VII, IX, and X are produced in normal amounts but are nonfunctional.

   The anticoagulant action of vitamin K antagonists is the result to their ability to inhibit this final carboxylation step. The warfarin-like drugs compete with vitamin K for binding sites on the hepatocyte. With sufficient warfarin administration, vitamin K is displaced and the vitamin K–dependent factors are not carboxylated. Of the four vitamin K–dependent factors, factor VII has the shortest half-life. It is the first clotting factor to disappear from the circulation when a patient is placed on warfarin or begins to develop vitamin K deficiency.

5. Factors V and VIII have short storage half-lives.

   Factors V and VIII are also referred to as the “labile factors” because their coagulant activity is not durable in stored blood. While packed RBCs contains residual plasma with clotting factors, massive transfusion with stored blood will nonetheless lead to a dilutional coagulopathy because of diminished activity of factors V and VII.

Fibrinolysis

The process of fibrinolysis leads to the dissolution of fibrin clots. Fibrinolysis serves to remodel fibrin clots and “recanalize” vessels that have been occluded by thrombosis.

The Formation of Plasmin

Fibrinolysis involves primarily the production of plasmin, an active fibrinolytic enzyme. Plasmin is

formed by the conversion of plasminogen to plasmin (Fig. 10-6). Plasmin does not circulate freely because it is rapidly degraded by circulating antiplasmins. Instead, plasminogen, the precursor to plasmin, circulates and when it comes into contact with fibrin binds to it. In fact, when a fibrin clot is forming, plasminogen is incorporated into the growing fibrin clot together with tissue plasminogen activator (t-PA). Once bound to the fibrin surface, plasminogen is converted to plasmin by t-PA. The bound plasmin is protected from attack by circulating antiplasmins because the binding site by which the plasmin binds to the fibrin is the same site to which the antiplasmins bind.[123] When plasmin is released into the bloodstream (with its binding site exposed), it is immediately neutralized by alpha-2 antiplasmin. Thus, like the coagulation cascade, the fibrinolytic system relies on surface-mediated reactions both for the production of plasmin and for the localization of fibrinolysis to the site of vascular injury.

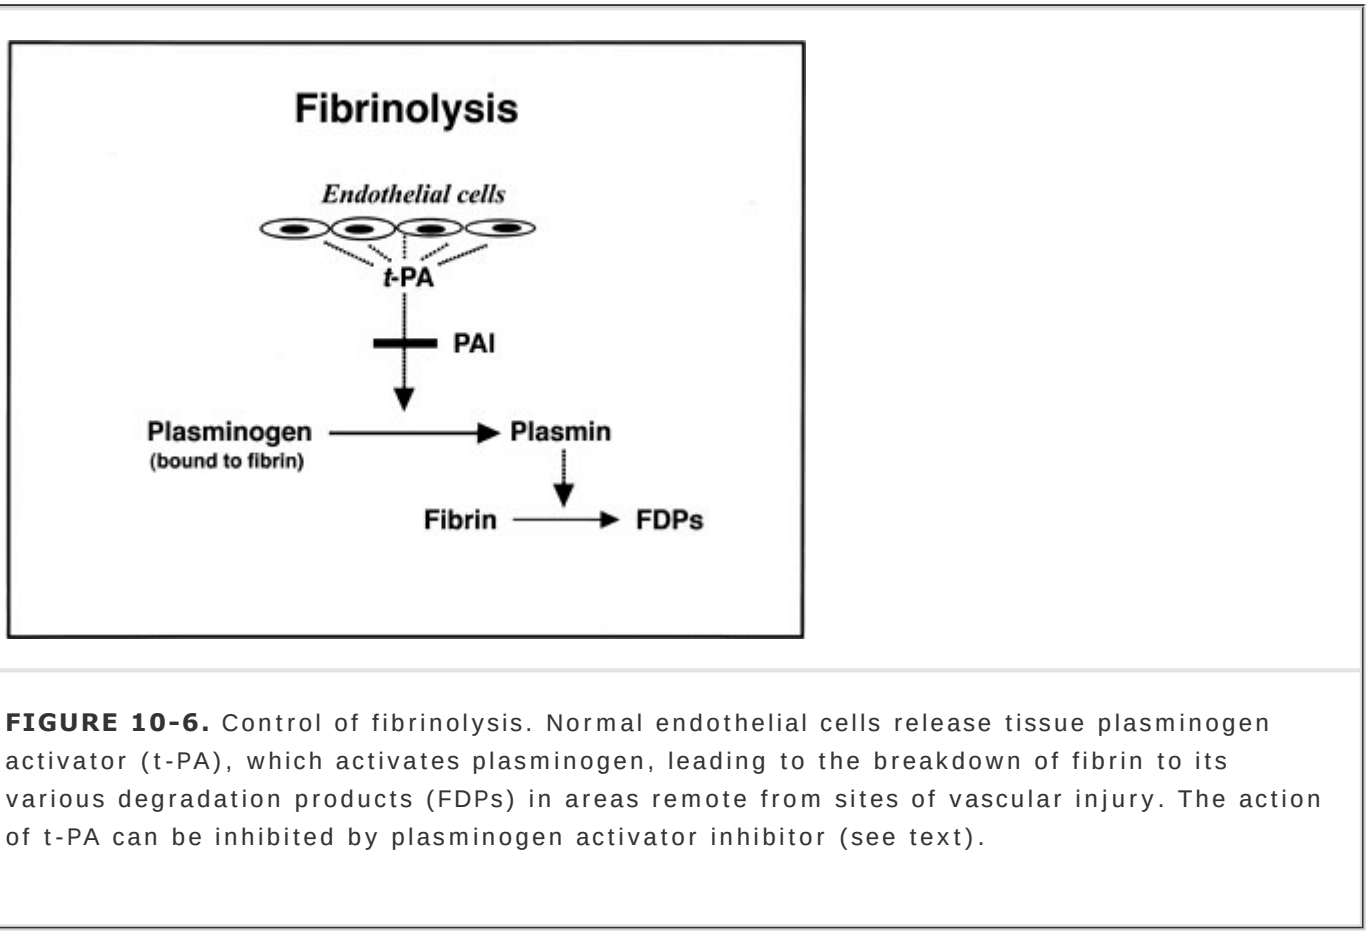

FIGURE 10-6. Control of fibrinolysis. Normal endothelial cells release tissue plasminogen activator (t-PA), which activates plasminogen, leading to the breakdown of fibrin to its various degradation products (FDPs) in areas remote from sites of vascular injury. The action of t-PA can be inhibited by plasminogen activator inhibitor (see text).

Tissue Plasminogen Activator

Tissue plasminogen activator, which converts plasminogen to plasmin, is produced by vascular endothelial cells. This site of synthesis is important to the maintenance of the “nonthrombogenic” endothelial surface. If a clot begins to form on the normal endothelial surface, several mechanisms, including the elaboration of t-PA from endothelial cells, will rapidly inhibit clot formation or lead to its dissolution. t-PA release from endothelial cells can be stimulated by several factors. If sufficient thrombin has been synthesized, thrombin will form a complex with thrombomodulin and activate protein C. Activated protein C (APC) then stimulates the release of t-PA from endothelial cells. t-PA is also released from the endothelium in response to venous occlusion, physical activity, stress, or vasoactive drugs (such as epinephrine, vasopressin, and DDAVP).[124] t-PA, once released from endothelial cells, selectively binds to fibrin, much like plasminogen, which also selectively binds to fibrin. Bound to fibrin, the t-PA converts plasminogen to plasmin.

t-PA does not activate circulating plasminogen. This has important implications. Because t-PA activates only plasminogen bound to fibrin, the process of fibrinolysis by plasmin is localized to the fibrin clot. Therefore, under normal circumstances, widespread, uncontrolled fibrinolysis is prevented. The vascular endothelium and platelets also synthesize an inhibitor of t-PA,

plasminogen activator inhibitor (PAI-1), which reduces the amount of plasmin formed and serves to slow the fibrinolytic process (Fig. 10-6). Some patients with thrombotic disorders have been found to have increased levels of this inhibitor.[124] A similar inhibitor is found in placental tissue. It may be that the progressive "hypercoagulable state" associated with pregnancy is related to increased levels of this t-PA inhibitor.[124]

Plasminogen Activators

There are plasminogen activators in addition to t-PA. Urokinase is present in the urine but unlike t-PA, it has no affinity for fibrin and is not present in circulating blood.[123] Physiologic activators of the fibrinolytic system include vigorous exercise, anoxia, and stress, in addition to factor XIIa and thrombin. Exogenous plasminogen activators include streptokinase, urokinase, and recombinant t-PA. These fibrinolytic agents all differ with respect to their action, clot specificity, systemic fibrinolytic effect, antigenic effect, and efficacy. Proteins derived from streptococci and staphylococci have also been found to be activators of the fibrinolytic system. The therapeutic fibrinolytic agents, streptokinase and urokinase, differ from t-PA in that they will activate circulating plasminogen. These lead to more widespread fibrinolysis. Fibrinolytic therapy has been used in the treatment of unstable angina, acute peripheral arterial occlusions, deep vein thrombosis, and pulmonary embolism, and in occluded indwelling catheters and arteriovenous shunts.

Fibrin Degradation Products

The primary action of plasmin is to degrade fibrin clots. The degradation products produced are called fibrin degradation products (FDPs) or fibrin split products (FSPs). Their structure varies according to whether plasmin cleaves fibrinogen, fibrin that is crosslinked, or fibrin that is not crosslinked.[125] Under normal circumstances, FDPs are removed from the blood by the liver, kidney, and reticuloendothelial system. They normally have half-lives of about 9 hours. However, if the FDPs are produced at a rate that exceeds their normal clearance, they will accumulate. This happens when the fibrinolytic system is excessively active. In high concentrations, FDPs impair platelet function, inhibit thrombin, and prevent the crosslinking of fibrin strands.[126] The defective polymerization of the fibrin monomers results in a clot that is more readily degraded by plasmin.[124] In such high concentrations, FDPs lead to bleeding because FDPs are "inhibitors" of both platelets and coagulation.

Excess Circulating Plasmin

Under normal circumstances, once plasmin has degraded fibrin clot and escapes from the fibrin surface, it is rapidly inactivated by antiplasmins. Deficiency of alpha-2 antiplasmin

leads to a bleeding tendency because, with reduced levels of antiplasmin in the circulation, plasmin can circulate. In addition, in pathologic conditions in which the fibrinolytic system produces large quantities of plasmin (primary fibrinolysis), the antiplasmin capacity may be exceeded and plasmin may circulate. This can also happen when fibrinolysis is stimulated in response to disseminated intravascular coagulation (secondary fibrinolysis). Excess plasmin can lead to a coagulopathy. This is because plasmin primarily degrades fibrin; but because it is a serine protease, it can also degrade other coagulation factors, for example, fibrinogen, factor V, factor VIII, factor XIII, and also vWF.[124] Plasmin can also digest the platelet receptor, GPIb. Accordingly, circulating plasmin inhibits platelet function and disrupts coagulation.

Summary of the Control of Fibrinolysis

Under normal conditions, plasmin is generated only at the site of clot formation, is protected from degradation while attached to fibrin, and is destroyed rapidly once released into the circulation.

Control of Coagulation—The Checks and Balances

Coagulation must be precisely regulated to prevent rampant, uncontrolled clotting, such as that

which occurs with DIC. Several mechanisms regulate and control coagulation.

Endothelial Inhibition

The first line of defense is the vascular endothelium. The intact endothelial has properties that serve to limit both platelet aggregation and coagulation and to induce fibrinolysis should a clot begin to form on normal endothelium. They are summarized in Table 10-12.

TABLE 10-12 Endothelial Control of Platelet Aggregation, Coagulation, and Fibrinolysis

Endothelial control of platelet aggregation
Synthesis of prostacyclin
Synthesis of ADPases and nitric oxide
Endothelial inhibition of coagulation
Synthesis of thrombomodulin
Synthesis of heparan sulfate
Endothelial control of fibrinolysis
Synthesis of t-PA

The Thromboxane–Prostacyclin Balance. Primary hemostasis is, in part, controlled by the balance between the actions of two prostaglandins, thromboxane A_2 and prostacyclin. Thromboxane A_2 (TxA_2) is synthesized at the site of vascular damage by activated platelets. TxA_2 has two hemostatic effects: (1) it is a potent vasoconstrictor that causes blood vessels to constrict locally and shunt blood flow away from the site of injury, and (2) it stimulates additional ADP release from platelets and thereby causes recruitment of additional platelets.[127]

Remote from the site of vascular damage, normal endothelial cells synthesize prostacyclin (PGI2). PGI2, which is also synthesized from arachidonic acid, has actions opposite those of TxA_2. PGI2 inhibits platelet activation, secretion, and aggregation and is a potent vasodilator. It therefore serves to prevent platelet aggregation and clot formation on the endothelial surface beyond the site of injury.

Nitric Oxide and ADPase. The effects of prostacyclin are potentiated by nitric oxide (formerly called endothelium-dependent relaxing factor, EDRF), which is constitutively synthesized by normal endothelium and which also has vasodilatory and platelet antiaggregant effects.[128] As an additional means of preventing clot formation on the surface of normal endothelium, ADPases are expressed on the outer membrane of endothelial cells and serve to degrade “surplus” ADP that might otherwise initiate platelet aggregation on normal surfaces.

Inhibition of Coagulation

Many factors serve to limit and localize clot formation. First, the clotting factors themselves circulate in an inactive form. Once they do become activated, normal blood flow dilutes their concentration and washes them away from sites of injury, limiting clot formation. Activated clotting factors are preferentially removed from the circulation by the liver and the reticuloendothelial system. And finally, the fact that some interactions of the coagulation pathway require the presence of a phospholipid surface localizes clot formation to these phospholipid surfaces. Several specific coagulation inhibiting systems exist. Three of them are depicted in Figure 10-7 and described later.

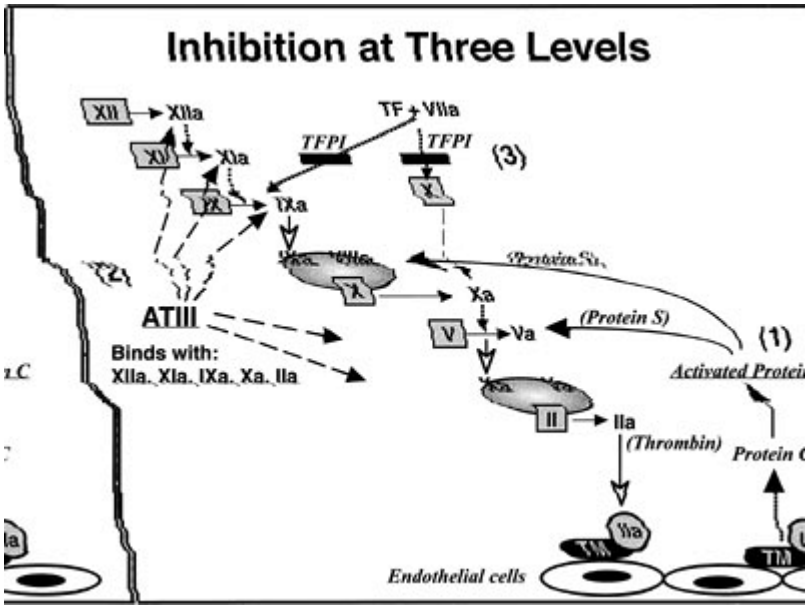

FIGURE 10-7. Inhibition of coagulation at three levels. Three important mechanisms that serve to prevent unrestrained coagulation are depicted. (1) A complex of thrombomodulin (TM) and thrombin (IIa) activates protein C, which, with protein S as a cofactor, inhibits activated factors V and VIII. (2) Antithrombin III (AT III) binds, and thereby inhibits, several activated clotting factors (XIIa, XIa, IXa, Xa, IIa). (3) Tissue factor pathway inhibitor (TFPI) inhibits both of the pathways that lead to the activation of Factor X (see text).

Thrombin, Thrombomodulin, and Protein C and Protein S. Thrombin, in a negative feedback manner, can decrease its own synthesis by inhibition of factors V and VIII. That inhibition is accomplished via protein C, a vitamin K–dependent anticoagulant protein. Protein C circulates in plasma as an inactive precursor until it is activated by thrombin. Thrombomodulin is a protein located on the vascular endothelial cell surface. The binding of thrombin to thrombomodulin alters the thrombin molecule such that it can no longer directly activate clotting factors V and VIII or catalyze the conversion of fibrinogen to fibrin (Fig. 10-3). Instead, the thrombin–thrombomodulin complex rapidly converts protein C to active protein C (APC). APC, with protein S as a cofactor, cleaves and inactivates factors Va and VIIIa. Like protein C, protein S is vitamin K dependent. The location of thrombomodulin on the endothelial surface is strategic. Where the endothelium is intact, the thrombomodulin-thrombin-protein C interaction will inhibit coagulation and

maintain the “nonthrombogenic” property of the endothelial lining. Where the endothelium has been stripped away or damaged, this anticoagulant mechanism will be absent and clotting can continue unopposed.

Thrombin and Antithrombin III. ATIII is a circulating serine protease inhibitor that binds to thrombin and thereby inactivates it. ATIII can bind and inactivate each of the activated clotting factors of the classical “intrinsic” coagulation cascade—factors XIIa, XIa, IXa, and Xa[129] (see Fig. 10-7). By virtue of its broad inhibitory action, ATIII plays a central role in the regulation of hemostasis in vivo. The ATIII molecule has two critical binding sites, one of which reacts with thrombin (and the other activated clotting factors), and a second to which heparin can bind. In the absence of heparin, ATIII has a relatively low affinity for thrombin. However, when heparin is bound to ATIII, the efficiency of binding of ATIII to thrombin and the other factors increases dramatically. Congenital ATIII deficiency (levels 40 to 50% of normal) can lead to dangerous thrombotic events. Acquired deficiencies of ATIII may occur in a number of conditions, including liver disease, prolonged heparin administration, nephrotic syndrome, DIC, sepsis, preeclampsia, fatty liver of pregnancy, and following surgery.[130] Plasma ATIII levels are sometimes depressed by oral contraceptive use. ATIII concentrates have been used in ATIII deficiency states, including

heparin resistance.[131,132]

Tissue Factor Pathway Inhibitor (TFPI). Superficially, the description of the cell-based coagulation mechanism still leaves in place one of the inadequacies of the classical cascade theories of coagulation, that is, if activated factor Xa can be formed via the direct action of the VIIa/TF complex, why is it that hemophiliacs bleed? Why do they appear to be dependent on both factors VIII and IX to produce activated factor X (Xa)? The answer lies in the existence of a feedback inhibitor of the extrinsic pathway known as tissue factor pathway inhibitor (TFPI) (see Fig. 10-7). TFPI, which is generated in a factor Xa-dependent fashion, is a potent inhibitor of the formation of factor Xa by both VIIa/TF-initiated sequences.[133] In the presence of TFPI, further activation of factor X becomes entirely dependent on the reaction sequences of the classical intrinsic pathway. The TF pathway can initiate the first flurry of thrombin generation—enough to activate platelets and stimulate cofactors V and VIII. Thereafter, continued thrombin production appears to require the action of factors VIIIa and IXa.[122]

Heparan Sulfate. There is a fourth native anticoagulant mechanism. The endothelial surface is coated with a mucopolysaccharide referred to as the glycocalyx. One of the constituents of this glycocalyx is a naturally occurring heparin-like component, heparan sulfate. Much like heparin, heparan has the ability to accelerate the binding of ATIII to thrombin and the other activated clotting factors of the classical intrinsic pathway. This heparan sulfate is well positioned because it is at this blood-endothelial interface that activated factors of the coagulation cascade are being generated. The presence of heparan sulfate on the endothelial surface further helps to promote the “antithrombotic” property of the normal endothelial lining.

The Complexities of the Hemostatic Mechanism

The preceding sections reveal that many mechanisms interact to maintain the liquid state of the blood under normal circumstances and to transform blood into a solid clot when injury occurs. These mechanisms include numerous feedback processes. The complexity is revealed by the existence of “double agents,” which act at some times as procoagulants and at other times as anticoagulants. Chief among them is thrombin. Thrombin is primarily a procoagulant. Under normal circumstances, it promotes primary hemostasis by activating platelets and promotes coagulation by direct activation of factors V, VIII, and XIII. Thrombin, in the final step of the coagulation cascade, cleaves fibrinogen to fibrin. However, it also has anticoagulant effects. As described in the coagulation section earlier, when thrombin is first synthesized, it stimulates production of TFPI, which slows coagulation via the tissue factor pathway and makes continued coagulation dependent on the reaction complex formed by factors VIII and IXa. Thrombin also inhibits coagulation through its interaction with thrombomodulin and protein C. Activated protein C stimulates the release of t-PA from endothelial cells and by this mechanism it has a fibrinolytic effect. Recall, however, that the thrombin generated as part of the thrombin burst at the end of the propagation phase of coagulation also causes the release of the fibrinolysis inhibitor TAFI. Accordingly, thrombin acts at different loci as a procoagulant, an anticoagulant, a profibrinolytic, and an antifibrinolytic.

The Hemostatic Mechanism: Summary

Under normal circumstances, the hemostatic mechanism is quiescent with many of the potential participants circulating in an inactive form. Only when the endothelial lining is breached is the hemostatic mechanism set in motion. With collagen and tissue factor exposed, the intertwined processes of platelet-mediated primary hemostasis and factor-mediated coagulation begin and rapidly the vascular injury is sealed by a platelet mass into which are incorporated fibrinogen, thrombin, plasminogen, and t-PA. The completion of the coagulation process converts fibrinogen into fibrin and the platelet plug is transformed into a fibrin clot. Simultaneously, several properties of adjacent intact endothelium (elaboration of ADPases, prostacyclin, thrombomodulin, heparans, and t-PA) serve to prevent extension of the clot beyond the site of injury. Within the clot, plasmin, generated from the trapped plasminogen and t-PA, begins the process of fibrinolysis. Over time, the entire fibrin clot dissolves, new endothelial cells line the vessel, and

flow is restored.

LABORATORY EVALUATION OF THE HEMOSTATIC MECHANISM

Laboratory Evaluation of Primary Hemostasis

Platelet Count

A platelet count should be the first test ordered in the evaluation of primary hemostasis. The platelet count is quick, accurate, and reproducible. However, it reveals only platelet numbers and gives no information regarding their function. Normal platelet counts range between 50,000 and 440,000/mm^3. Counts below 150,000/mm^3 are defined as thrombocytopenia. Spontaneous bleeding is unlikely in patients with platelet counts >10 to 20,000/mm^3.[65] With counts from 40 to 70,000/mm^3, bleeding induced by surgery may be severe.

Bleeding Time

The Ivy bleeding time is the most widely accepted clinical test of platelet function. Both poor platelet function and thrombocytopenia can prolong the bleeding time. A blood pressure cuff is placed around the upper arm and inflated to 40 mmHg. A cut is made on the volar surface of the forearm and the wound blotted at 30-second intervals until bleeding stops. The

Simplate Bleeding Time (BT) device, which utilizes a spring-loaded lancet, standardizes the size and depth of the cut. The normal range for the Ivy BT is 2 to 9 minutes. Variations in venous pressure, blotting technique, and patient cooperation result in a lack of precision and reproducibility that make this test somewhat less reliable than other coagulation tests. The BT is purported to evaluate the time necessary for a platelet plug to form following vascular injury. This requires a normal number of circulating platelets, platelets with normal function (which can adhere and aggregate) and an appropriate platelet interaction with the blood vessel wall. A prolongation of the BT may be a result of (1) thrombocytopenia, (2) platelet dysfunction (adhesion, aggregation), and (3) vascular abnormalities such as scurvy or the Ehlers-Danlos syndrome. BTs are prolonged in patients with many conditions that cause platelet dysfunction, for example, use of aspirin or uremia. However, prolonged BTs have been observed with numerous disorders that are not associated with platelet dysfunction, for example, vitamin K deficiency of the newborn, amyloidosis, congenital heart disease, the presence of factor VIII inhibitors.[134] Whether or not the BT test represents a specific measure of in vivo platelet function is debated. The test is unpleasant for the patient and leaves a small scar. In spite of the correlation of BT with conditions known to influence platelet function, and in spite of BT quite reliably becoming progressively prolonged as platelet count falls below 80,000/uL, there are no convincing data to confirm that bleeding time is a reliable predictor of the bleeding that will occur in association with surgical procedures.

Platelet Function Analyser

The PFA-100 is a point-of-care device. The test is based on variation in the resistance to passage of platelets through a standard aperture in the presence of platelet activators, for example, collagen and ADP. Its predictive value has not been well confirmed and it is not yet used widely.[135]

Platelet Aggregometry

The ability of platelets to aggregate can be assessed quantitatively by observing the response to stimulation with ADP, epinephrine, collagen, or ristocetin. The platelet aggregometer measures platelet aggregation spectrophotometrically. Clot retraction is another function of platelets that can be assessed grossly. When maintained at 37°C, a clot should begin to retract within 2 to 4 hours. This test is difficult to quantify and only qualitative results (retraction vs. no retraction) are usually reported.

Laboratory Evaluation of Coagulation

Evolution of the Prothrombin Time (PT) and the Partial Thromboplastin Time (PTT)

When blood is placed in a glass test tube, clot formation occurs in response to contact with the foreign surface. No exogenous reagents are required because all of the factors necessary for contact to initiate coagulation are “intrinsic” to blood. The time to formation of a clot via this pathway can be prolonged by deficiencies of any factors in the classical intrinsic pathway. However, the observation that, even in hemophiliacs, the addition of thromboplastin (now more commonly called tissue factor) to the test tube could shorten the time to clot formation suggested the presence of an alternative pathway of fibrin formation. That pathway required the addition of something “extrinsic to blood” and did not require the presence of factors VIII or IX. In 1936, when Quick introduced the PT to clinical medicine, sufficient “thromboplastin” was used to yield a clotting time of approximately 12 seconds. Under these circumstances, even patients lacking factors VIII or IX showed normal clotting times.[136] However, when “dilute” thromboplastin (or a “partial” thromboplastin) was used in lieu of the “12-second reagent,” hemophiliacs showed much longer clotting times than did healthy controls. The two different pathways could be tested individually simply by varying the amount and type of thromboplastin added to blood. With “complete thromboplastin,” coagulation could proceed via reactions that were independent of factors VIIIa and IXa. With a lesser thromboplastin stimulus, coagulation would proceed via a sequence of reactions that required the presence of factors VIIIa and IXa.

Basic Elements of the PT and PTT

The PT and the PTT differ primarily by the type of thromboplastin that is used. Calcium must also be added because of the chelating agent in the blood specimen container. The time to fibrin strand formation is then measured.

Prothrombin Time

The PT evaluates the coagulation sequence initiated by TF and leading to the formation of fibrin without the participation of factors VIII or IX, that is, the classical extrinsic pathway (see Fig. 10-2). The PT measures the time to fibrin strand formation via a short sequence of reactions involving only TF, and factors VII, X, V, II (prothrombin), and I (fibrinogen). Tissue factor forms a complex with VIIa and together this complex activates factor X. From that point, coagulation proceeds via the common pathway of coagulation. The test does not evaluate the coagulation process that is initiated by the classical intrinsic pathway or that sequence of reactions initiated by tissue factor that generate Xa via the reaction complex formed by factors IXa and VIIIa.

The normal PT is 10 to 12 seconds. The PT will be prolonged if deficiencies, abnormalities, or inhibitors of factors VII, X, V, II, or I are present. The PT test has limitations. First, it is not very sensitive to deficiencies of any of these factors. In fact, the coagulant activity of these factors must drop to 30% of normal before the PT is prolonged. The PT is most sensitive to a decrease in factor VII and least sensitive to changes in prothrombin (factor II). When prothrombin levels are only 10% of normal, the increase in the PT may be only 2 seconds. Also, PT will not be prolonged until the fibrinogen level is below 100 mg/dL. A prolonged PT does not define the exact hemostatic defect. However, if the aPTT (see later) is normal, then a prolonged PT is most likely to represent a deficiency or abnormality of factor VII. Because factor VII has the shortest half-life of the clotting factors synthesized in the liver, factor VII is the clotting factor that first becomes deficient with liver disease, vitamin K deficiency, or warfarin therapy. Prolongation of the PT may also occur because of deficiencies of multiple factors. However, when multiple factor deficiencies coexist, the PTT or activated PTT (see later) will usually be prolonged as well.

International Normalized Ratio. Another difficulty with the PT test is that many different thromboplastin reagents are used. This results in wide variation in normal values, which makes comparison of PT results between laboratories difficult. The International Normalized Ratio was introduced to circumvent this difficulty.[137] Each thromboplastin is compared with an internationally

accepted standard thromboplastin and assigned an International Sensitivity Index (ISI). If the test thromboplastin is equivalent to the international standard, it will have an ISI index of 1. Once the ISI number has been determined, PT test times obtained with that reagent are normalized and reported as an International Normalized Ratio.[138]

Partial Thromboplastin Time

The PTT assesses the function of the classical intrinsic and final common pathways (see Fig. 10-1). It entails the addition of a “partial thromboplastin” (usually a phospholipid extracted from rabbit brain or human placenta) and calcium to citrated plasma. The PTT reflects the time to fibrin strand formation via the classical “intrinsic pathway” of coagulation. The PTT will reveal deficiencies, abnormalities, or inhibitors to one or more coagulation factors—high–molecular-weight kininogen (HMWK), prekallikrein, XII, XI, IX, VIII, X, V, II, and I. The normal values for PTT vary widely. However, the PTT has been made more reproducible and the range of normal values narrower by the addition of contact activator in addition to the partial thromboplastin; hence the name “activated” partial thromboplastin time (aPTT).[139] Surface activation in the laboratory parallels the contact-activation phase involving factors XII and XI, prekallikrein, and high–molecular-weight kininogen that are thought to initiate the intrinsic pathway in vivo. Diatomaceous earth, kaolin, celite, and ellagic acid are used as surface activators. The aPTT is much faster than the PTT, which may be as long as 120 seconds, because it eliminates the lengthy “natural” contact-activation phase. Normal aPTT values are between 25 and 35 seconds.[140] The aPTT is prolonged when there is a deficiency, abnormality, or inhibitor of factors XII, XI, IX, VIII, X, V, II, and I (i.e., all factors except VII and XIII). The aPTT is most sensitive to deficiencies of factors VIII and IX, but, as is the case with the PT, levels of these factors must be reduced to approximately 30% of normal values before the test is prolonged. Heparin prolongs the aPTT but with high levels will also prolong PT. As with the PT, the level of fibrinogen must also be reduced to 100 mg/dL before the aPTT is prolonged. FXII deficiency, which is a relatively common cause of aPTT prolongation, does not cause a clinical coagulopathy. aPTT results (like those of the PT) vary from laboratory to laboratory because of nonstandardization of the phospholipids and activators.

Activated Clotting Time

The activated clotting time (ACT) is similar to the aPTT in that it tests the ability of blood to clot in a test tube and is dependent on factors that are all “intrinsic” to blood (the classical intrinsic pathway of coagulation). Fresh whole blood is added to a test tube that contains a particulate surface activator of factors XII and XI. The time to clot formation is measured. Partial thromboplastin or a platelet phospholipid substitute is not added. Coagulation is therefore dependent on adequate amounts of platelet phospholipid being present in the blood sample. The automated ACT is widely used to monitor heparin therapy in the operating room. Normal values are in the range of 90 to 120 seconds.[139] The ACT is far less sensitive than the aPTT to factor deficiencies in the classical intrinsic coagulation pathway. In fact, the ACT may not be prolonged until the coagulant activity of some of the factors is reduced to 1% of normal.

Thrombin Time

Thrombin time (TT), also called the “thrombin clotting time,” is a measure of the ability of thrombin to convert fibrinogen to fibrin. This test, which is performed by adding exogenous thrombin to citrated plasma, bypasses all the preceding reactions. The thrombin time may be prolonged because of conditions that effect either the substrate, fibrinogen, or the action of the enzyme thrombin. The TT is prolonged when there is an inadequate amount of fibrinogen (<100 mg/dL) or when the fibrinogen molecules that are present are abnormal (dysfibrinogenemia), for example, advanced liver disease. Thrombin's enzymatic function can be inhibited by inhibitors such as heparin (complexed to ATIII), FDPs, or by inhibitors that may be seen in patients with plasma cell myeloma and other immunoproliferative conditions.[141] The normal TT is <30 seconds.

Reptilase Time

When the thrombin time is prolonged, the reptilase time can be used to differentiate between the effects of heparin and FDPs. Reptilase, which is derived from a snake venom, converts fibrinogen to fibrin. The action of reptilase is unaffected by heparin but is inhibited by FDPs. A prolonged TT and a normal reptilase time suggest the presence of heparin. Prolongation of both TT and reptilase time will occur in the presence of FDPs, or when fibrinogen level is low. The normal reptilase time is 14 to 21 seconds.

Ecarin Clotting Time

Direct thrombin inhibitors (DTI) (hirudin, argatroban, bivalirudin, lepirudin) are frequently used in patients with heparin-induced thrombocytopenia. At low DTI concentrations, TT and ACT provide reasonable correlations with DTI concentrations, but with the concentrations required for cardiopulmonary bypass the correlation becomes poor and the risk of overdose with these agents, for which there are no antagonists, becomes significant. The ecarin clotting time (ECT) provides a better correlation and can be used for monitoring in this context.[142] The test employs the venom of the Saw-Scaled (a.k.a. Sawtooth) Viper (Echis carinatus). A metalloprotease in the venom converts normal prothrombin to a form that is inhibited by the DTIs in a dose-dependent manner.

Fibrinogen Level

Normal values are between 160 and 350 mg/dL. Below 100 mg/dL, fibrinogen may be inadequate to produce a clot. Fibrinogen is rapidly depleted during DIC. A marked increase in fibrinogen may occur in response to stress including surgery and trauma. Levels in excess of 700 mg/dL may occur. Because of this increase, in spite of rapid fibrinogen consumption during a hypercoagulable state such as DIC, the fibrinogen level may still appear to be “normal.”

Laboratory Evaluation of Fibrinolysis

Fibrin Degradation Products and D-Dimer

The fibrin degradation products (FDP) test identifies the breakdown products of fibrin (crosslinked or uncrosslinked) and fibrinogen itself. The D-dimer assay is specific for breakdown products of crosslinked fibrin. FDPs will be increased in any state of accelerated fibrinolysis, including advanced liver disease, fibrinolysis associated with cardiopulmonary bypass, administration of exogenous thrombolytics, for example, streptokinase, and DIC. D-dimer is specific to conditions in which extensive lysis of the crosslinked fibrin of mature thrombus is occurring, in particular DIC but also DVT and PE.

The Thromboelastogram

Thromboelastography provides a measure of the mechanical properties of evolving clot as a function of time. A principal advantage of this test is that the processes it measures require the integrated action of all the elements of the hemostatic process: platelet aggregation, coagulation, and fibrinolysis. The thromboelastogram (TEG®) is obtained by placing a specimen of blood in a rotating cuvette into which a “piston” is lowered. As clot formation begins, the piston rotates as function of the adherence of the evolving fibrin clot to the piston. The piston

is connected to a recorder and the rotation of the piston results in a to and fro excursion of the stylus, the amplitude of which is proportional to the speed of piston rotation.

Figure 10-8 depicts a normal thromboelastogram. Several parameters are derived from the TEG®. The most commonly used ones and their interpretation are as follows.[144]

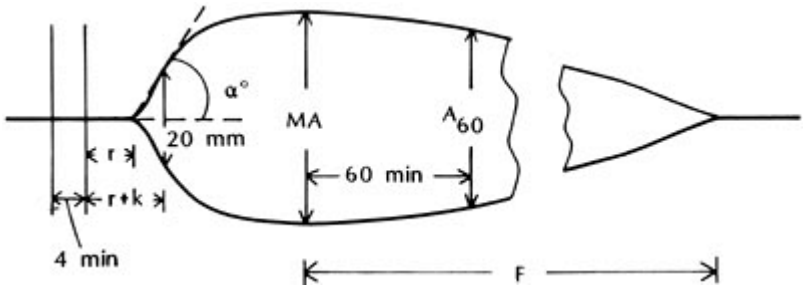

FIGURE 10-8. The normal thromboelastogram and the variables commonly derived from it. See text for explanation. (From Kang et al, Epsilon-aminocaproic acid for treatment of fibrinolysis during liver transplantation. Anesthesiology 66:766, 1987, with permission.)

R, the reaction time, is the interval until initial clot formation. It requires thrombin formation, and prolongation is usually indicative of an intrinsic pathway factor deficiency.

K, the clot formation time, is the interval required after R for the thromboelastogram to achieve a width of 20 mm. Prolongation occurs with deficiencies of thrombin formation or generation of fibrin from fibrinogen.

The alpha angle, like K, is a measure of the speed of clot formation. A decrease of the alpha angle has similar significance to a prolongation of K.

MA, the maximum amplitude, is a measure of the strength of the fully formed clot. It reflects primarily platelet number and function, although it also requires proper fibrin formation to achieve normal values. MA typically occurs between 30 and 60 minutes.

The (MA + x)/ MA, the ratio of the amplitude at a specific time interval (x) after MA divided by MA, is used as a measure of the rate of fibrinolysis. The (MA +60)/MA ratio has been used most widely.[145] A ratio of less than 0.85 is evidence of abnormal fibrinolysis.[146] In clinical practice, particularly in liver transplantation, a nonquantitative appreciation of the typical tear drop shape (Fig. 10-9) is used more often to support a diagnosis of increased fibrinolysis than are specific numerical values. F, the interval from MA to return to a zero amplitude, is a measure of the rate of fibrinolysis. F is sufficiently long in normal subjects that often the test is usually terminated before this time elapses.

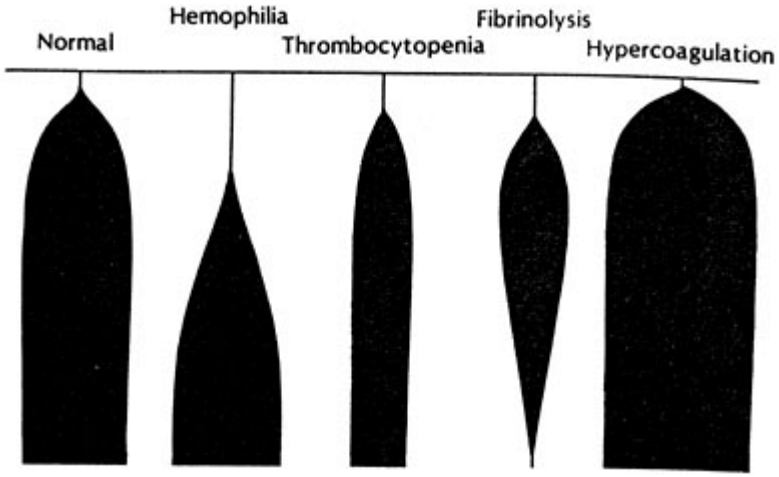

FIGURE 10-9. Thromboelastogram patterns seen in normal subjects and in subjects with four abnormalities of hemostasis. (From Kang YG: Monitoring and treatment of coagulation. Winter KM, Kang YG: Hepatic Transplantation: Anesthetic and Periperative management, p. 151. New York, Praeqer, 1986, with permission.)

The thromboelastogram has been employed in cardiac surgery, major trauma, and hepatic transplantation. It is in the latter that it is used most frequently. Commonly, in that context, an increased R prompts the administration of FFP, a decreased MA leads to platelet administration, and the tear drop configuration of fibrinolysis to the administration of antifibrinolytics. The use of the thromboelastogram in liver transplantation has been shown to decrease both the amount of RBCs and FFP transfused as compared with transfusion guided by routine coagulation tests.[148]

Interpretation of Tests of the Hemostatic Mechanism

An effective approach to the interpretation of coagulation tests is to appreciate in advance the constellation of test results (the coagulation "profile") that is likely to occur with each of the common bleeding disorders (Table 10-13). The most commonly ordered coagulation tests are the platelet count, PT, aPTT, and occasionally BT. When a greater disruption of the hemostatic mechanism is suspected, further tests including fibrinogen, TT, and assays for fibrin degradation products and the D-dimer may be ordered.

TABLE 10-13 Interpretation of Coagulation Tests

·PLATELET COUNT	·BLEEDING TIME	·aPTT	·PT	·TT	·FIBRINOGEN	·FDPs	·POSSIBLE CAUSE	·EX
↓	N or ↓	N	N	N	N	N	↓ Production sequestration ↑ Consumption Immune destruction	Radia chem Splen Exten tissue dama HIT
N	↑	N	N	N	N	N	Platelet	Drugs

							dysfunction	NSAID Clopid IIb/II inhibi uremi vWD
N	↑	↑	N	N	N	N	Severe vWF deficiency	vWD
N	N	↑	N	N	N	N	Factor deficiency Factor inhibition Antiphospholipid antibody	Hemo or B Low-c hepar LMWH Poor collec techn Lupus antico
N	N	N	↑	N	N	N	Factor VII deficiency	Early diseas Early K defi Early Coum thera
N	N	↑	↑	↑	N	N	Multiple factor deficiencies	Late K defi Late Coum thera Hepar thera
↓	↑	↑	↑	↑	↓	N	Dilution of factors and platelets	Massi transf
↓	↑	↑	↑	↑	↓	↑	Hypercoagulable state ± ↓ production of factors	DIC[c] Advar liver

↑, increased; ↓, decreased; N, normal; aPTT, “activated” partial thromboplastin time; PT, prothrombin

TT, thrombin time; FDPs, fibrin degradation products; HIT, heparin-induced thrombocytopenia; vWF, v Willebrand factor; vWD, von Willebrand's disease; LMWH, low–molecular-weight heparin; NSAIDs, nonsteroidal anti-inflammatory drugs; DIC, disseminated intravascular coagulation.

[a]aPTT prolongation is more likely to occur with LMWHs with lower Xa/IIa effect ratios, for example, tin than with greater ratios, for example, enoxaparin.

[b]Bleeding time may also be prolonged in association with a marked aPTT increase.

[c]DIC may be distinguished by the presence of D-dimers.

Because the coagulation defects that appear most often are revealed as abnormal values of PT and/or aPTT, Figure 10-10 provides an algorithm for the evaluation of those abnormalities.

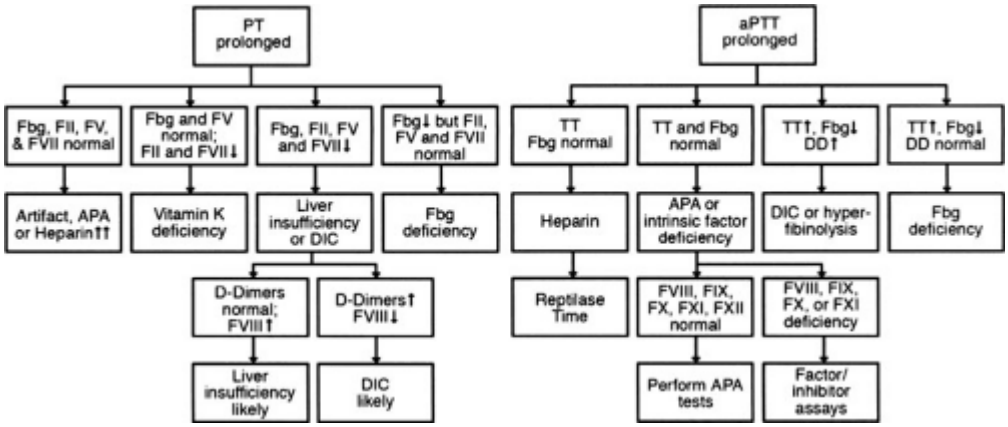

FIGURE 10-10. An approach to the evaluation of prolonged PT and/or aPTT. APA, antiphospholipid antibody (e.g., lupus anticoagulant, anticardiolipin and anti-B2-GPI antibodies); DD, D-dimers; DIC, disseminated intravascular coagulation. (Reproduced [with modification] from Bombeli T, Spahn DR: Updates in perioperative coagulation: Physiology and management of thromboembolism and haemorrhage. Br J Anaesth 93:275, 2004, with permission.)

Common Coagulation Profiles

Platelet Count Decreased (Normal aPTT and PT). Differential diagnosis: causes (see later) of decreased platelet production, excess consumption, platelet destruction, or sequestration in the spleen (see bleeding disorders, thrombocytopenia).

Prolonged BT (Normal Platelet Count, aPTT, PT). Differential diagnosis: antiplatelet drug ingestion (NSAIDs, ASA, clopidogrel, etc.), uremia, vWD (although the factor VIII:C levels may be decreased with vWD [type 1], only 25 to 30% of VIII:C coagulant activity is necessary to produce a normal aPTT).

Prolonged aPTT (Normal Platelet Count and PT). Differential diagnosis: heparin, the lupus anticoagulant or other antiphospholipid antibodies, for example, anticardiolipin and anti-B2-GPI

antibodies, deficiency of factor XII, HMWK, or prekallikrein, Hemophilia A or B, vWD, acquired factor inhibitors, poor collection technique.

Disorders that produce this combination affect factors of the intrinsic pathway (prekallikrein, HMWK, factors XII, XI, IX, VIII) and/or the common pathway (X, V, II, and I). With heparin therapy, initially only the aPTT is prolonged. At higher doses both the aPTT and PT are prolonged. The lupus “anticoagulant” and other antiphospholipid antibodies are common causes of a prolonged aPTT. That prolongation is the result of the binding of the phospholipid used to initiate coagulation in vitro. The patients do not have a bleeding diathesis. In fact, they have a prothrombotic tendency. This laboratory abnormality is not corrected when the patient's plasma is mixed with normal plasma because of the presence of inhibitors. Deficiencies of factor XII, HMWK, or prekallikrein, in particular FXII, are also common causes of aPTT prolongation. However, they are not usually associated with a significant clinical hemostatic defect. Collection technique can prolong the aPTT either by heparin contamination or because factors V and VIII, the labile factors, may be consumed if the blood becomes partially clotted prior to delivery to the laboratory.[149] The aPTT is very sensitive to factor VIII deficiency.

When a PTT is prolonged in isolation, is it less likely to be because of a bleeding disorder that involves multiple factor deficiencies (such as liver disease, vitamin K deficiency, the administration of warfarin, or the coagulopathy associated with massive transfusion or DIC). Heparin therapy or congenital disorders of hemostasis are more probable.

Prolonged PT (Normal Platelet Count and aPTT). Differential diagnosis: vitamin K deficiency, warfarin administration, early liver dysfunction, FVII deficiency, acquired coagulation factor inhibitors.

Because of the vitamin K–dependent factors, factor VII has the shortest half-life, depletion of the vitamin K–dependent factors will first prolong the PT and later the aPTT as well. Similarly, the development of liver disease will lead to deficiencies of factor VII first and initially prolong only the PT. With further deterioration of liver function, both the PT and the aPTT

will be prolonged. Liver disease can also lead to thrombocytopenia and platelet dysfunction. Acquired coagulation factor inhibitors are rare but can occur in patients with lymphoma or collagen vascular disease.

Prolonged PT and aPTT (Normal Platelet Count). Differential diagnosis: vitamin K deficiency, warfarin, heparin.

Although liver disease can produce multiple factor deficiencies and this pattern, the platelet count is usually decreased. FDPs will also be elevated (see later).

Prolonged PT, aPTT, and TT (Normal Platelet Count). Differential diagnosis: heparin, DTIs or FDPs, hypofibrinogenemia, dysfibrinogenemia.

Simultaneous prolongation of the TT makes the diagnosis of simple vitamin K deficiency or warfarin therapy unlikely. TT is sensitive to minute levels of heparin. Addition of protamine or reptilase time will identify heparin. FDPs may be elevated with fibrinolytic therapy, DIC, or liver disease. DIC and liver disease usually result in thrombocytopenia as well. A normal platelet count makes heparin or extensive fibrinolysis more likely.

Prolonged PT, aPTT, TT (Decreased Platelet Count). Differential diagnosis: DIC, dilution by massive transfusion, liver disease, heparin therapy.

FDPs and D-dimer are elevated in DIC and allow differentiation from dilutional effects and excess heparin. Heparin causes thrombocytopenia only when prolonged exposure results in HIT. FDPs, but not D-dimer, are elevated in severe liver disease.

The interpretation of coagulation tests may be made more difficult by the fact that patients who develop a bleeding diathesis in the perioperative period may have more than one bleeding disorder (e.g., DIC and coagulopathy as a result of massive transfusion) and may also have a surgical

cause for bleeding.

DISORDERS OF HEMOSTASIS: DIAGNOSIS AND TREATMENT

The hemostatic mechanism involves an intricate balance that serves to limit blood loss in the event of vascular injury while maintaining the liquid character of blood at other times. Under normal circumstances, an equilibrium between clotting and bleeding is maintained with the help of multiple activators, inhibitors, cofactors, and feedback loops, both positive and negative. Under pathologic circumstances, that equilibrium may be lost, leading to either hemorrhagic or thrombotic complications. Accordingly, disorders of hemostasis can be broadly classified into those that lead to abnormal bleeding and those that lead to abnormal clotting. The disorders may be further categorized according to whether they involve platelets, clotting factors, and/or the presence or absence of inhibitors (such as FDPs). Finally, disorders may be hereditary or acquired. These organizational frameworks will be helpful in reaching a diagnosis on the basis of the results of coagulation tests. The treatment that follows from diagnosis may require administration of hemostatic agents (platelets and/or clotting factors) or the use of pharmacologic agents. The latter may be chosen for effects on platelets (desmopressin, antiplatelet drugs), on clotting factors (vitamin K, warfarin, heparin), or on naturally occurring inhibitors (antifibrinolytic agents, protamine, fibrinolytics).

The preoperative history is invaluable in the identification of disorders of hemostasis. Abnormalities of primary hemostasis, usually caused by reduced platelet number or function, will be revealed by evidence of “superficial” (skin and mucosal) bleeding including easy bruising, petechiae, prolonged bleeding from minor skin lacerations, recurrent epistaxis, and menorrhagia. Coagulation abnormalities are associated with “deep” bleeding events including hemarthroses or hematomas after blunt trauma.

Hereditary Disorders of Hemostasis

Von Willebrand's Disease

Von Willebrand's disease is the most common hereditary bleeding disorder. Some form of the disease is present in approximately 1% of the general population, though it is overtly symptomatic in only about 10% of those afflicted.[151] vWD is the result of abnormal synthesis of the von Willebrand factor (vWF). The vWF, a protein synthesized by endothelial cells, megakaryoctyes, and platelets, is important for both primary hemostasis, that is, the binding of platelets to sites of vascular injury, and coagulation, the latter through its role as a carrier protein/stabilizer for FVIII. The vWF has several distinct binding domains responsible for its several hemostatic functions. Those domains include sites that are specific for collagen (for adherence to the subendothelium), the platelet GPIb receptor (for platelet adhesion to collagen), the platelet GPIIb/IIIa receptor (for platelet aggregation), and factor VIII:C (for its carrier protein function). There are at least 50 genetic variations of vWD, which accounts for its phenotypic heterogeneity. There are three principal subtypes. Type 1, which comprises 70 to 80% of vWD, is a quantitative defect. vWF is present but is secreted in reduced amount. Patients with Type 1 vWD present with a pattern of bleeding that is characteristic of abnormalities of primary hemostasis. Type 2 vWD, which comprises 20 to 30% of patients with vWD, includes a host of qualitative defects of vWF. Some mutations affect the platelet interactions of vWF and others the factor VIII interaction. Type 2 is subdivided into four subtypes. 2B is characterized by a variant of the vWF that causes abnormal aggregation of platelets and thrombocytopenia. The abnormal vWF has a high affinity for the platelet GPIb receptor. The bleeding diathesis is probably the result of formation and clearance of vWF-platelet complexes and the resultant thrombocytopenia. In the subtype 2N (Normandy) vWD, the vWF has a markedly reduced affinity for factor VIII. These patients demonstrate normal platelet function, but bleed because of decreased factor VIII coagulant activity. These patients are readily misdiagnosed as having mild hemophilia A. Type 3, which is very rare, entails a complete absence of vWF, resulting in a severe abnormality of both primary hemostasis and coagulation.

The Role of vWF in Hemostasis. vWF is essential for platelet plug formation. It mediates platelet adhesion to the subendothelial surface of blood vessels. After binding to the

subendothelium, the vWF undergoes a conformational change that allows platelets to adhere via their glycoprotein GPIb receptors (Fig. 10-4). This binding can only occur after the conformational change and in solution, platelets will not spontaneously bind to vWF. The antibiotic ristocetin can induce the platelet GPIb-vWF interaction and, accordingly, is the basis for one laboratory test of platelet function. vWF also participates in platelet to platelet aggregation. Platelet aggregation occurs by binding of vWF molecules to the GPIIb/IIIa receptors on the surface of several platelets. The vWF also acts as a carrier protein for the coagulant activity of factor VIII, referred to as VIII:C, with which it circulates in a complexed form that prolongs VIII:C's circulation time.

Diagnosis and Treatment of vWD. History will commonly reveal abnormal bleeding from mucosal surfaces. Sixty percent of the patients will report epistaxis, 50% report menorrhagia, and 35% will acknowledge gingival bleeding, easy bruising, and hematomas.[152] vWD should be considered in patients who give a history of unexplained postoperative bleeding,

particularly following tonsillectomy or dental extraction. Although this is a hereditary disease, a clear family history is not always evident because disease severity varies substantially.

Specialized laboratory tests, ideally directed by a hematologist, may be required to confirm the diagnosis and type of vWD. One or more vWF markers including vWF factor antigen (vWF:Ag), vWF ristocetin cofactor activity (vWF:RCo), or vWF collagen binding activity (vWF:CB) will be diminished or absent. Because vWD is a carrier protein/stabilizer of FVIII, FVIII half-life is diminished and FVIII levels are characteristically also decreased.[151] What is important for the anesthesiologist to appreciate is that the results of the most commonly ordered coagulation tests, the platelet count, the aPTT, and the PT, may be normal in the patient with vWD. While the half-life of VIII:C is diminished in vWD there is usually sufficient VIII:C to yield a normal aPTT in basal conditions.

The two established treatments for vWD are DDAVP and factor concentrates.[153] DDAVP (1-deamino-8-D-arginine vasopressin), which promotes release of vWF, is effective first-line therapy for the large majority (approximately 80%) of patients with vWD, including those with type 1 and type 2A disease. However the recognition of subtype 2B (see earlier) is important because DDAVP will cause thrombocytopenia in these patients.[154] DDAVP, given intravenously in a dose of 0.3 ug/kg, increases factor VIII:C and vWF two- to fivefold in most patients. Its effect is maximal after 30 minutes and elevated levels persist for 6 to 8 hours[152] (see Pharmacologic Therapy: Desmopressin section). For the 20% of patients who do not respond adequately to DDAVP, factor concentrates, for example, Haemate-P, will be appropriate. Their efficacy is well confirmed.[155,156] Antifibrinolytic agents, epsilon-aminocaproic acid, and tranexamic acid are sometimes used in combination with DDAVP to manage these patients during the perioperative period.[154] They may be given intravenously or orally. They have also been administered topically, as mouthwashes, in patients with vWD undergoing dental extractions. Oral contraceptives (estrogens) have been used to treat patients with vWD and menorrhagia or who are undergoing elective surgery.[154] The mechanism of action of the estrogens is not well understood, although a connection with vWF synthesis is suspected. Antiplatelet drugs should be avoided in patients with vWD.

The Hemophilias

Hemophilia A results from mutations that lead to either deficient or functionally defective factor VIII:C. Hemophilia B (Christmas disease) and hemophilia C are caused by deficiency or abnormality of factors IX and XI, respectively.[157] The relative frequencies of the three hemophilias are factor VIII:C, 85%; factor IX, 14%; and factor XI, 1%. Rare inherited deficiencies of factors II, VII, V, and XI also occur.[157] Both hemophilia A and B are sex-linked recessive disorders, which therefore occur almost exclusively in males. Hemophilia C is an autosomal recessive disorder that occurs almost exclusively in Ashkenazi Jews.[157] About 50% of operations in hemophiliacs are orthopaedic procedures required for treatment of the arthritic consequences of hemarthroses.

Hemophilia A. Factor VIII is a very large macromolecule with two components, the coagulant factor VIII (VIII:C) and the von Willebrand factor. The VIII:C molecule circulates bound to and protected by vWF. In hemophilia A, patients have normal levels of vWF, but have reduced or

defective factor VIII:C. Hemophilia A occurs in approximately 1 in 10,000 males.

Hemophiliacs experience deep tissue bleeding, hemarthroses, and hematuria most commonly. Clinically, hemophilia A can be classified as mild, moderate, and severe. Patients with mild disease have factor levels of 5 to 30% of normal and usually bleed abnormally only following trauma. Patients with moderate disease have factor levels of 1 to 5% and occasionally bleed spontaneously as well as following trauma. The great majority of hemophiliacs have the severe form of the disease. Factor VIII:C levels are less than 1% of normal and they frequently experience spontaneous bleeding episodes. The severity of clinical symptoms usually correlates with the level of clotting factor activity. Like the patient with vWD, hemophiliacs should avoid aspirin and other platelet inhibiting agents.

Diagnosis and treatment of hemophilia A. Patients with hemophilia A will commonly report a history that reveals the X-linked recessive pattern of disease inheritance. Diagnosis of hemophilia A is made on the basis of a prolonged aPTT and specific factor assays demonstrating a deficiency of factor VIII coagulant activity with normal levels of vWF, factor IX, and factor XI. The patient will have a normal PT and BT. Hemophilia A is treated with plasma-derived concentrates that have been treated by viral attenuation procedures or, now more commonly, with recombinant factor VIII.[157]

If a hemophiliac presents for elective surgery, the patient's hematologist should be consulted. The required factor replacement will be dependent on (1) the patient's plasma volume and (2) the desired procoagulant activity. The patient's plasma volume can be assumed to be equal to 40 mL of plasma per kilogram of body weight. A 60-kg person would have a plasma volume of 2,400 mL. One unit of procoagulant activity per milliliter of plasma is defined as a plasma procoagulant level of 100%. A procoagulant level of 25% is a common target for achieving control of a bleeding episode. This would mean that a total of 600 units (25% × 2,400 mL) of factor VIII:C would be required. For elective surgery, the level of factor VIII:C activity is usually raised to 50 to 100% of normal. Many hemophiliacs develop inhibitors to factor VIII:C. The presence of the inhibitor increases the amount of factor VIII:C that must be administered to manage a given hemostatic challenge. Recombinant activated FVIIa (see later) may be required for the patient with inhibitors.

DDAVP will also increase plasma factor VIII:C and vWF concentrations and may be effective in mild hemophilia A. DDAVP is thought to cause the release of factor VIII:C from liver endothelial cells. There is a large variation in patient response to DDAVP and it is most effective in patients with factor VIII:C levels greater than 5%.[66,158] It is given iv in a dose of 0.3 ug/kg in 50 mL of saline over 15 to 30 minutes. It causes a prompt increase in factor VIII:C. However, tachyphylaxis does develop, which limits its usefulness.

The antifibrinolytics epsilon aminocaproic acid and tranexamic acid have been used to treat hemophiliac patients prior to dental procedures. The agents are contraindicated in bleeding episodes involving joints or the urinary tract because the clots that do form may not be lysed for a long period of time.

Hemophilia B. Factor IX deficiency is also an X-linked recessive disorder, occurring in ca. 1/25,000 males,[157] that produces a bleeding diathesis that is clinically indistinguishable from hemophilia A. A recombinant FIX factor concentrate is now available. Typically, minor hemorrhage is managed by achieving FIX levels of 20 to 30% of normal. Levels of 50 to 100% are sought for more severe hemorrhage and in anticipation of surgery. Factor IX complex concentrates, also known as prothrombin complex concentrates (II, VII, IX, X), have been used in the face of resistance to FIX concentrates. However, they convey an infectious hazard and may entail a risk of thrombosis and DIC because of the presence of activated factors.

Protein C and Protein S Deficiency

Hereditary deficiencies of protein C and protein S are associated with thromboembolic events originating on the venous

side of the circulation, for example, DVT, PE, and stroke as a consequence of paradoxical

embolization. The complete absence of protein C is associated with death in infancy. Patients who experience thromboembolic events and have decreased levels of protein C or protein S should remain on anticoagulant therapy indefinitely.

Acquired Disorders of Hemostasis

For mnemonic purposes, it is helpful to classify bleeding disorders according to which of the three hemostatic processes are involved: primary hemostasis (platelet disorders), coagulation (clotting factor disorders), fibrinolysis (production of inhibitors such as FDPs), or some combination of the three. Similarly, it is useful to use the results of coagulation tests to determine whether the clinical problem involves primary hemostasis (decreased platelet count, increased bleeding time, etc.), coagulation (prolonged PT and aPTT, decreased factor levels, etc.), fibrinolysis (increased FDPs, increased D-dimer), or some combination of the three. Ultimately, therapeutic decisions (e.g., administration of platelets, FFP, or an antifibrinolytic agent) will similarly be oriented to treatment of one or more of these processes.

Acquired Disorders of Platelets

The clinical conditions that cause an isolated disorder of primary hemostasis typically involve abnormalities of either platelet number or function.

Thrombocytopenia. Platelets are derived from megakaryocytes in the bone marrow in response to thrombopoietin, which is synthesized by the liver. The causes of thrombocytopenia may be categorized as follows: (1) inadequate production by the bone marrow, (2) increased peripheral consumption or destruction (nonimmune mediated), (3) increased peripheral destruction (immune mediated), (4) dilution of circulating platelets, and (5) sequestration (Fig. 10-11).

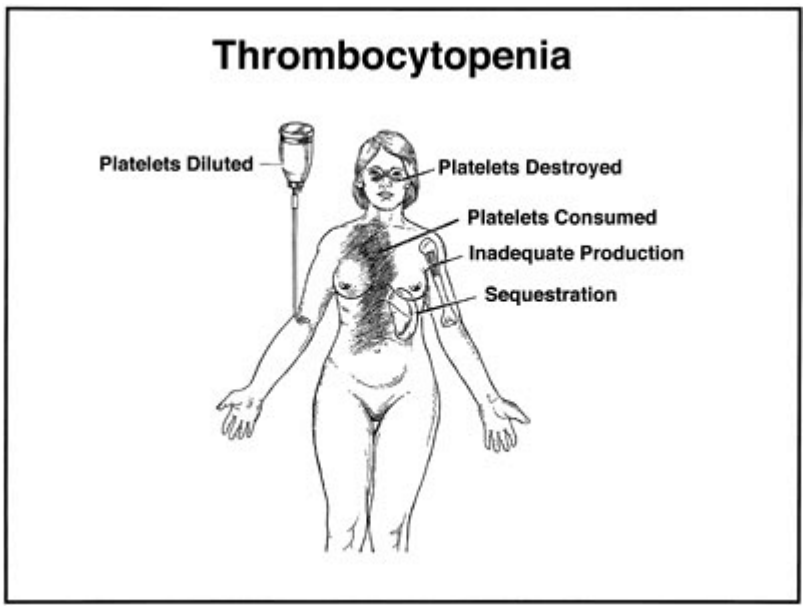

FIGURE 10-11. Thrombocytopenia. The figure depicts the five processes that can lead to thrombocytopenia. They include platelet destruction, as occurs immunologically in lupus erythematosus; platelet consumption, as occurs with burns or other massive tissue injury conditions; inadequate production, as can occur with marrow infiltration, chemotherapy, or radiation; sequestration, as can occur in the presence of splenomegaly; and dilution, occurring during massive transfusion.

1. Bone marrow production of platelets can be impaired in many ways. Physical and chemical agents (radiation and chemotherapy), various drugs (thiazide diuretics, sulfonamides,

diphenylhydantoin, alcohol), infectious agents (hepatitis B, TB, overwhelming sepsis), and chronic disease states (uremia, liver disease) can all cause bone marrow suppression. Infiltration of the bone marrow by cancer cells or replacement by fibrosis will also result in inadequate platelet production.

2. Accelerated nonimmunologically mediated consumption can occur in many conditions that cause extensive activation of coagulation with or without the occurrence of DIC. After extensive tissue damage such as occurs with burns or massive crush injuries, which denude vascular endothelium, the normal process of hemostasis activates platelets, leading to their consumption and to thrombocytopenia. In a similar fashion, the interaction of platelets with nonendothelialized structures such as large vascular grafts can also lead to a transient thrombocytopenia. Platelets are consumed in patients with an extensive vasculitis such as occurs with toxemia of pregnancy. The many conditions that cause DIC (see later) will also cause platelets to be consumed or destroyed faster than they can be produced.
3. Immunologically mediated consumption can be caused by various drugs (heparin, quinidine, cephalosporins) and autoimmune disorders (systemic lupus erythematosis, rheumatoid arthritis, thrombotic thrombocytopenic purpura). Alloimmunization resulting from previous blood transfusions or pregnancy can cause refractoriness to platelet transfusions.
4. Dilution of platelets will occur in the context of massive transfusion (see later and Collection and Preparation of Blood Products for Transfusion section).
5. Under normal conditions, approximately one-third of platelets are sequestered in the spleen. When the spleen enlarges, an increasing number are sequestered and thrombocytopenia may result. This may occur with the splenomegaly associated with myelodysplastic syndromes and cirrhosis of the liver, though in the latter condition decreased production also contributes to thrombocytopenia.

Disorders of Platelet Function

Uremia. Platelet dysfunction is common in uremic patients.

The accumulation of guanidino succinic acid and hydroxy phenolic acid is thought to contribute to this dysfunction through interference with the platelet's ability to expose the PF3 phospholipid surface. These compounds are dialysable and, accordingly, dialysis frequently improves the hemostatic defect associated with uremia. An additional abnormality involving the interaction of vWF with platelet receptors is also suspected. DDAVP (desmopressin), which among other effects induces immediate release of vWF from endothelial cells, rapidly improves platelet adhesiveness.[159] However, the mechanism of this effect is not understood. It is not simply a matter of restoring vWF levels because circulating vWF is typically present in normal levels in uremia. Administration of erythropoietin and conjugated estrogens have also been observed to cause gradual improvement of the hemostatic defect associated with uremia. The mechanisms of these effects are similarly not known. Cryoprecipitate will also improve the platelet dysfunction of uremia but, given the efficacy of DDAVP, the associated risks are not justified. When life-threatening bleeding occurs in the uremic patient, platelet concentrates should be administered.

Antiplatelet agents. Numerous medications are administered expressly for the purpose of platelet inhibition in order to reduce the risk of myocardial infarction, stroke, and other thromboembolic complications. They induce platelet dysfunction by several mechanisms, which include inhibition of cyclooxygenase, inhibition of phosphodiesterase, ADP

receptor antagonism, and blockade of the glycoprotein IIb/IIIa receptor.

Cyclooxygenase inhibitors. Aspirin is the prototype. Aspirin produces irreversible inhibition of platelet cyclo-oxygenase (cox), which prevents synthesis of thromboxane A_2, a potent platelet proaggregant and vasoconstrictor. In moderate doses, there is selective sparing of the synthesis of prostacyclin (antiaggregant, vasodilator), which results in “tilting” the balance substantially in favor of platelet inhibition. Indomethacin, phenylbutazone, and all the nonsteroidal anti-

inflammatory agents similarly inhibit cyclooxygenase. However, their inhibition is promptly reversible with clearance of the drug. The recently introduced cox-2 inhibitors selectively inhibit the cox-2 isoform, the isoform responsible for generating the mediators of pain and inflammation, while sparing the cox-1 isoform, inhibition of which causes both gastric damage, decreased renal blood flow, and inhibition of platelet thromboxane A_2. Accordingly, platelet function should not be impaired. However, there has been concern that cox-2 inhibitors, which should reduce prostacyclin generation by vascular endothelial cells, may thereby actually tilt the natural balance toward platelet aggregation.[160] That concern has been reinforced by the report in 2004 of an increased rate of myocardial ischemic events in patients taking cox-2 inhibitors, and the withdrawal of certain cox-2 inhibitors from the market.

Phosphodiesterase inhibitors. Cyclic AMP is an inhibitor of platelet aggregation and levels are increased by inhibition of phosphodiesterase. Dipyridamole, which is used for stroke prophylaxis alone or more commonly in combination with aspirin, and cilostazol appear to act primarily by this mechanism. Caffeine, aminophylline, and theophylline will also similarly produce mild, reversible platelet inhibition.

ADP receptor antagonists. Ticlopidine and clopidogrel, which are administered for stroke prophylaxis, block the ADP receptor, activation of which leads to expression of the IIb/IIIa receptor. They noncompetitively and irreversibly inhibit ADP-induced platelet aggregation. Ticlopidine has been withdrawn from the market because of the occurrence of neutropenia and thrombotic thrombocytopenic purpura.

Glycoprotein IIb/IIIa receptor antagonists. These agents block platelet aggregation by blocking the GPIIb/IIIa receptor. The IIb/IIIa site, by which fibrinogen crosslinks platelets, is the final common pathway for platelet aggregation. The IIb/IIIa antagonists have been used principally for the management of acute coronary syndromes. They include abciximab, a monoclonal antibody, tirofiban, and eptifibatide. These agents all require iv administration. Their effect is reversible. The half-lives are approximately 2.5 hours for tirofiban and eptifibatide and 12 hours for abciximab.[161] However, abciximab has a relatively high affinity for the IIb/IIIa receptor and platelet dysfunction may be longer (ca. 48 hours) than implied by half-life. All of these agents have also been associated with thrombocytopenia, the incidence of which has been greater for abciximab (2.5%) than tirofiban and eptifibatide (0.5%).[162] Note that these agents cause prolongation of the ACT.[161]

Herbal Medication and Vitamins. Several herbal medications, including ginkgo biloba, ginseng, garlic, and ginger, may cause inhibition of platelet function. Because the actual risks are not well defined, they should be discontinued before surgery, and in particular, before cardiac, neurologic, and cosmetic surgical procedures. Vitamin E is also a platelet inhibitor and should similarly be discontinued.[163]

Other Conditions. Myeloproliferative and myelodysplastic syndromes can produce intrinsic defects in platelets. In these disorders, the platelets may be abnormal in both morphology and function. Platelet dysfunction occurs in conjunction with conditions that also cause other hemostatic abnormalities (liver disease, fibrinolytic states including DIC, storage defects) and is discussed in the following section.

Acquired Disorders of Clotting Factors (Including Anticoagulant Therapy)

Vitamin K Deficiency

Hepatic synthesis of clotting factors II, VII, IX, and X, as well as protein C and protein S requires the presence of vitamin K. Vitamin K is necessary for the enzymatic carboxylation of the vitamin K–dependent clotting factors. The carboxyl group enables these factors to bind via a calcium bridge to phospholipid surfaces during the coagulation process. When vitamin K deficiency occurs, these factors are depleted in an order determined by their individual half-lives. Factor VII has the shortest half-life and is the first to be depleted, then factors IX and X, and finally factor II.

12 "Vitamin K" actually refers to a group of vitamins.[164] Vitamin K_1 (phylloquinone) is found in leafy green vegetables. The greatest quantities occur in Brussels sprouts. Vitamin K_2 (menaquinone) is synthesized by the normal intestinal flora. It is uncommon for patients to develop vitamin K deficiency solely because of dietary deficiency but it may occur in patients who are receiving parenteral nutrition without vitamin K supplementation and who are being treated concurrently with broad-spectrum antibiotics that destroy the gut flora. Because the body has no appreciable stores of vitamin K, deficiencies can develop in roughly 1 week. Newborns, who have a sterile gut at birth, have been noted to develop vitamin K deficiency.

Vitamin K is a fat-soluble vitamin and therefore requires bile salts for absorption from the jejunum. Patients with biliary obstruction, pancreatic insufficiency, malabsorption syndromes, GI obstruction, or rapid GI transit can develop vitamin K deficiency as a result of inadequate absorption.

Diagnosis and Treatment of Vitamin K Deficiency. Vitamin K deficiency will cause prolongation of the PT. This occurs because factor VII is depleted first. With more prolonged deficiency, the aPTT will also be increased because of declining levels of factors IX and X. Platelet count will be normal. Vitamin K may be administered orally, intramuscularly, or intravenously. Urgent treatment of vitamin K deficiency is best accomplished by the intramuscular or intravenous administration of vitamin K (Aquamephyton), usually in doses 1 to 5 mg. Vitamin K should be administered slowly to avoid the occurrence of hypotension. Improvement of the coagulation disturbance will begin to be apparent within 6 to 8 hours.

Warfarin Therapy

Warfarin produces its anticoagulant effect by competition with vitamin K for the carboxylation binding sites. Administration of warfarin leads to the depletion of factors II, VII, IX, X, protein C, and protein S. As with vitamin K deficiency, FVII is the first factor to be depleted. Subsequently, FIX and FX are depleted, and then FII. Accordingly, initially only the PT will be prolonged. With higher doses, the aPTT will be affected as well.

Warfarin is administered for the prevention of deep venous thrombosis and pulmonary embolism and to patients with atrial fibrillation, some prosthetic heart valves, and ventricular mural thrombi in the setting of acute myocardial. Patients with protein S or protein C deficiency may also be treated with long-term anticoagulation with warfarin. Warfarin therapy is adjusted according to the international internalized ratio (INR) (see tests of the hemostatic mechanism). The primary untoward effect of warfarin therapy is bleeding. Rapid reversal (12 to

24 hours) of warfarin effect[69] can be accomplished by administration of vitamin K, 5 mg iv. Smaller doses, 0.5 to 3 mg, should be used in less-urgent situations when the objective is to lower rather than normalize INR. INR should be rechecked at 6-hour intervals. Vitamin K administration may have to be repeated at 12-hour intervals. In situations of greater urgency, FFP has been administered. However, as noted in Disorders of Hemostasis: Diagnosis and Treatment section, prothrombin complex concentrate, which contains FII, VII, IX, X, is an alternative that has been reported to be more effective than FFP[165,166] because FFP administration frequently fails to achieve adequate concentrations of FIX[165] and because some patients cannot tolerate the requisite volume, that is, ca. 15 mL/kg. If FFP or concentrates are administered for rapid reversal and sustained reversal is desired, vitamin K should be administered simultaneously because of FVII's short (6 hours) half-life. Recombinant FVIIa (see later) has also been used to achieve rapid normalization of INR.[167]

Heparin Therapy

Heparin is used widely for anticoagulation in vascular surgery and in procedures requiring cardiopulmonary bypass (CPB). It inhibits coagulation principally through its interaction with one of the body's natural anticoagulant proteins, antithrombin III (ATIII). Heparin binds to ATIII and in so doing causes a conformational change that greatly increases ATIII's inhibitory activity. In spite of its name, anti-"thrombin" III, ATIII also inhibits several activated factors including, in

addition to IIa (thrombin), Xa, IXa, Xia, and XIIa. It is most active against thrombin and Xa. Heparin also increases the activity of a second native antithrombin, heparin cofactor II. Heparin cofactor II inhibits thrombin and not the other activated factors. Its contribution to the clinical effects of heparin is not clear. Resistance to heparin can occur in patients who are deficient in ATIII on either a hereditary or an acquired basis. The latter may occur in patients on sustained heparin therapy or in the presence of depletion by a consumptive coagulopathy. Heparin responsiveness can be restored by administration of ATIII (ATIII concentrates[131,132] or FFP).

Low–Molecular-Weight Heparin (LMWH). Low–molecular-weight fractions of heparin have been employed principally for deep vein thrombosis prophylaxis and treatment and are supplanting subcutaneous unfractionated heparin and coumadin for these indications.[168] There are several available agents: including certoparin, dalteparin, danaparoid, enoxaparin, reviparin, and tinzaparin. These agents do not appear to differ in their efficacy[150] and enoxaparin is used most widely in the United States. LMWHs, which also act via ATIII, have greater activity against factor Xa than thrombin (IIa). However, the ratio of that activity varies among the agents, for example, enoxaparin 3.8:1; tinzaparin 1.9:1.[169] Accordingly, the effect of these agents on standard coagulation tests will vary (minimal for enoxaparin[170]) as will the effect of protamine neutralization, which is very incomplete for enoxaparin. Monitoring is usually not required or performed. If it is deemed necessary, the anti-Xa level is the appropriate test. The LMWHs cause less platelet inhibition and are associated with a lesser incidence of heparin induced thrombocytopenia.[171] There has been considerable discussion of optimal dose regimens. European practitioners have often started prophylaxis 12 to 24 hours preoperatively. However, there is little evidence that that practice is superior to postprocedure initiation.[150] While twice-daily dosing with enoxaparin has been common in North America, once-daily regimens are usually sufficient. Because of the relatively long half-life of enoxaparin, twice-daily dosing poses a problem with respect to removal of epidural catheters because there is no anticoagulant nadir (see Chapter 40).

13 **Heparin-Induced Thrombocytopenia/Thrombosis.[172]** As many as 5% of patients who receive heparin therapy for 5 days will develop thrombocytopenia as a result of antibodies (usually IgG) directed against platelet factor 4-heparin complexes on the platelet surface. Onset requires several days in the heparin-naïve patient but can occur much more quickly (10 to 12 hours) in those who have been exposed within the preceding 100 days.[173] Occurrence appears to be dose related and is more common with bovine than porcine heparin. Heparin-induced thrombocytopenia/thrombosis (HITT) is relatively uncommon with LMWH and requires longer periods of exposure.[174] While HITT is most often identified because of thrombocytopenia, not all patients become markedly thrombocytopenic. Thrombotic and thromboembolic events, including DVT, PE, limb or acral ischemia, MI, stroke, not infrequently reveal the occurrence of HITT.[172] Diagnosis is complicated by the fact that not all patients who develop antiplatelet antibodies have clinical HITT. A hematologist should be consulted. Treatment entails withdrawal of heparin after instituting an alternate anticoagulant, for example, a DTI (hirudin, argatroban, lepirudin, bivalirudin) or a heparinoid, for example, danaparoid (but not a LMWH). Warfarin is contraindicated because the combination of protein C and S inhibition by warfarin in the face of ongoing platelet clumping may aggravate thrombosis. Platelets similarly should not be administered unless thrombocytopenia is extreme.

Heparin in Cardiopulmonary Bypass. A comprehensive discussion of the use and monitoring of heparin therapy in CPB is beyond the scope of this chapter. Extensive reviews are available.[175,176] In brief, the common practice is to maintain ACT >480 to 500 seconds for the duration of bypass. There is substantial variation in the heparin–ACT dose-response relationship, probably because of variability in heparin binding to many native surfaces including platelets, WBCs, endothelium, and plasma proteins including the vWF and ATIII.[175,176] While there is controversy, it appears that there is greater hazard in allowing ACT to be on the “low side” than in maintaining more complete heparinization.[177] Evidence of platelet activation is less apparent when longer ACTs are maintained. Whether this is a function of direct inhibition of platelets, which are subject to contact activation by the CPB circuit, binding of vWF, or the result of reduced formation of thrombin and inhibition of platelets by its breakdown products (FDPs) is not apparent to the authors of this review. Protamine is administered for reversal of heparin effect. Many clinicians employ an “mL-

for-mL" technique. However, a more careful titration of protamine against ACT is ideal to avoid excessive administration of protamine, which has inherent anticoagulant effects including platelet inhibition, stimulation of t-PA release from endothelium, and inhibition of fibrinogen cleavage by thrombin.[178]

Various alternatives have been considered for the patient with HIT who requires CPB. Plasmaphereis prior to surgery with subsequent use of heparin has been employed.[179] The nonheparin alternatives for anticoagulation include specific inhibitors of thrombin (see later) and the defibrinogenating agent Ancrod (from the venom of the Malaysian pit viper). The contact activation of platelets is not inhibited and it may be appropriate to administer platelet inhibitors simultaneously. Experience is limited and well-defined protocols are not established.

Direct Thrombin Inhibitors

The agents most commonly used CPB when there are contraindications to heparin are the DTIs. This group includes hirudin, argatroban, lepirudin, and bivalirudin. Hirudin is a recombinant product and the others are synthetic. There are disadvantages to their use in CPB. The first is that there is no antidote. Termination of effect is largely dependent on renal

elimination. The exception is bivalirudin, which is in part cleared by proteolysis by thrombin. In the patient with renal failure or in urgent situations, elimination can be accomplished by dialysis or hemofiltration.[180]

Ximelagatran is a direct thrombin inhibitor that can be taken orally. It has no relevance to CPB but has undergone phase three trial in the prevention of recurrent venous thromboembolism with favorable results.[181] It has a relatively short half-life (ca. 4 hours) and is largely eliminated by the kidneys. Because of predictable bioavailability, coagulation monitoring is usually not employed. Like other DTIs, it will prolong TT, aPTT, PT, and ACT, but not in a well dose-related manner. As with the other DTIs, if monitoring is required, the ecarin clotting time (see earlier) is probably the preferred method.[181]

Inhibitors of Xa

These agents (fondaparinux, idraparinux) act via antithrombin to inhibit FXa. The prototype is fondaparinux. It is an increasingly popular alternative for DVT prophylaxis,[168] in part because its very predictable uptake (after once-daily subcutaneous administration) and kinetics make monitoring and dosage adjustment unnecessary.[181,182] However, these agents have long half-lives (fondaparinux, 17 hours; idraparinux, 80 hours[181]) and there is no antidote. Excretion is via the kidneys. Therapeutic doses do not cause changes in PT, aPTT, or ACT.[181]

Acquired Combined Disorders of Platelets and Clotting Factors with Increased Fibrinolysis

Liver Disease. Chronic liver disease is associated with abnormalities of all three phases of hemostasis: primary hemostasis, coagulation, and fibrinolysis.[183] Table 10-14 provides an overview of these abnormalities.

TABLE 10-14 The Etiology of Hemostatic Abnormalities in Liver Disease

Thrombocytopenia
Decreased production
Hypersplenism
Increased consumption (DIC)
Impaired platelet function
Decreased FDP clearance

Decreased factor synthesis
  Decreased hepatocyte function
  Vitamin K deficiency (diet, malabsorption)
Increased factor consumption
  Decreased clearance of activated factors
  Decreased synthesis of inhibitors (protein C, protein S)
Increased fibrinolysis
  Decreased synthesis of alpha-2 antiplasmin
  Decreased clearance of t-PA
  Decreased synthesis of PAI-1

Impaired primary hemostasis. Impaired primary hemostasis occurs as a result of both thrombocytopenia and impaired platelet function. The former is largely the result of decreased production, which in turn is probably the result of decreased thrombopoietin secretion by the liver. Hypersplenism may also contribute but its role has been overemphasized. Platelet dysfunction can occur when liver disease is sufficiently advanced that clearance of FDPs is impaired or when DIC complicates the coagulation disturbance. The FDPs coat the surface of platelets and impair aggregation. Ethanol can also directly contribute to platelet dysfunction by inhibition of the synthesis of ADP, ATP, and thromboxane A_2. Accordingly, when faced with a patient with liver disease who is bleeding, a normal platelet count cannot be assurance of intact primary hemostasis. DDAVP may be helpful, but transfusion of platelet concentrates may be necessary.

Disturbances of coagulation. With liver disease, factor production decreases and consumption increases. The liver synthesizes all of the clotting factors (with the probable exception of factor VIII). As with vitamin K deficiency, hepatic disease first leads to a deficiency of factor VII since it has the shortest half-life. Thereafter, deficiencies will develop in factors II, IX, and X. Dietary deficiency of vitamin K, as may occur in alcoholics, and with diminished secretion of bile salts leading to malabsorption, will exaggerate these deficiencies. If impaired coagulation is the result of vitamin K deficiency and not hepatic damage, then parenteral vitamin K may be helpful in restoring factor levels of II, VII, IX, and X. Further deterioration of hepatic function will affect the remaining factors, I, V, XI, and XII. Impaired liver function can also cause a thrombotic tendency, which leads to increased consumption of clotting factors. This occurs for two reasons. First, synthesis of the natural anticoagulants, antithrombin III, protein C, and protein S, may be diminished thereby altering the balance of pro- and anticoagulant forces, and second, clearance of activated clotting factors from the circulation may be impaired thereby allowing persistent activation of the coagulation cascade.

Increased fibrinolysis. Increased fibrinolysis occurs as a result of decreased clearance of t-PA from the circulation by the impaired liver and decreased hepatic synthesis of alpha-2 antiplasmin.[184] For uncertain reasons, the production of the natural inhibitor of the plasmin system, PAI-1, is diminished.[185] The combination of accelerated coagulation and increased fibrinolysis in patients with advanced liver disease can lead to a persistent, low-grade DIC. The release into the circulation of the breakdown products of necrotic hepatocytes may contribute to the development of DIC.[164]

Diagnosis and treatment of coagulation abnormalities associated with liver disease. The initial laboratory evaluation should include platelet count, PT, aPTT, fibrinogen level, and D-dimer. In the event of thrombocytopenia and clinical bleeding or pending surgery, platelet transfusions are appropriate. If the PT is prolonged (>1.5 times control), vitamin K should be administered speculatively. In the absence of a response to vitamin K (which requires a minimum of 8 hours), factor deficiencies should be treated with FFP with attention to the possibility of volume overload. Cryoprecipitate is appropriate in the event of hypofibrinogenemia (fibrinogen <100 to 125 g/dL).

However, cryoprecipitate does not contain the vitamin K–dependent factors. While antifibrinolytics have been applied in the context of liver transplantation, they should not otherwise be used for bleeding associated with liver disease because of the catastrophic consequences of administering these agents in the face of an unrecognized DIC.[186]

Diagnosis of DIC (see later) is often difficult because the laboratory tests used to identify DIC are already abnormal in patients with liver dysfunction. Thrombocytopenia, prolonged PT and aPTT, decreased fibrinogen level, and circulating FDPs will commonly occur in the absence of DIC. Elevated D-dimer is somewhat more specific for the occurrence of DIC.

Disseminated Intravascular Coagulation. Detailed reviews of DIC are available.[187,188] DIC is characterized by excessive deposition of fibrin throughout the vascular tree, with simultaneous depression of the normal coagulation inhibitory mechanisms and impaired fibrin degradation. It is triggered by the appearance of procoagulant material (tissue factor or equivalent) in the circulation in amounts sufficient to overwhelm the mechanisms that normally restrain and localize clot

formation. That appearance may be the result of either extensive endothelial injury, which exposes tissue factor of fibroblastic origin, or the release of TF into the circulation as occurs with amniotic fluid embolus, extensive soft tissue damage, severe head injury, or any cause of a systemic inflammatory response. Table 10-15 lists the numerous clinical conditions that have been associated with DIC. For reasons not entirely clear, the native pathways that inhibit coagulation, antithrombin III and the protein C pathway are simultaneously inhibited. The accelerated process of clot formation causes both tissue ischemia and, ultimately, critical depletion of platelets and factors. Simultaneously, the fibrinolytic system is activated and plasmin is generated to lyse the extensive fibrin clots. Fibrin degradation products appear in the circulation. FDPs stimulate release of plasminogen activator inhibitor, type 1 (PAI-1), from the endothelium and thrombolysis becomes impaired. The FDPs also inhibit platelet aggregation and prevent the normal crosslinking of fibrin monomers. Depleted of platelets and clotting factors and inhibited by FDPs, the coagulation system fails and the patient bleeds. Simultaneously, the microvascular occlusion by fibrin causes tissue ischemia, contributing to multiorgan failure.

TABLE 10-15 Clinical Conditions Associated with Disseminated Intravascular Coagulopathy

Sepsis (Gram + or -)
Viremias
Obstetric conditions
Amniotic fluid embolus
Fetal death in utero
Abruptio placentae
Preeclampsia
Extensive tissue damage
Burns
Trauma
Liver failure
Extensive cerebral injury
Head injury
Stroke
Extensive vascular endothelial damage
Vasculitis
Preeclampsia
Hemolytic transfusion reactions
Metastatic malignancies

Leukemia Snake venoms

Table 10-15 reveals that several clinical entities that are encountered frequently in anesthetic and critical care practice are associated with the development of DIC. Sepsis is the most common cause. Endotoxins or lipopolysaccharide break down products from Gram-negative and -positive bacteria, respectively, incite an inflammatory response that includes the generation of cytokines (tumor necrosis factor alpha, various interleukins). These cytokines in turn stimulate the release or expression of TF by endothelial cells, macrophages, and monocytes, and the DIC sequence is initiated.

Several obstetric conditions can cause DIC. Amniotic fluid embolism, placental abruption, and fetal death in utero result in the direct release of TF-equivalent material into the circulation. Preeclampsia is characterized by a systemic vasculitis. The associated endothelial damage causes an initially low-grade DIC that accelerates as vasculitis-related damage leads to release of TF from ischemic tissues, in particular placenta.

Large burns, extensive traumatic soft tissue injuries, severe brain injury, and hemolytic transfusion reactions can also liberate TF-equivalent material into the circulation and incite DIC. Certain malignancies, most notably promyelocytic leukemia and adenocarcinomas, are associated with DIC. However, with malignancy–associated DIC, thrombotic manifestations are more likely to appear first, whereas with the others mentioned earlier, the hemorrhagic diathesis is often the first clinical manifestation.

A few general conditions such as acidosis, shock, and hypoxia are associated with DIC. Shock promotes coagulation because one of the control mechanisms (rapid blood flow) is compromised. Clearance of activated clotting factors is reduced when blood flow is decreased. Acidosis and hypoxia may contribute to both tissue and endothelial damage.

The clinical manifestations of DIC are a consequence of both thrombosis and bleeding. Bleeding is a more common clinical presentation in patients with acute, fulminant DIC. Petechiae, ecchymoses, epistaxis, gingival/mucosal bleeding, hematuria, and bleeding from wounds and puncture sites may be evident. With the chronic forms of DIC, thrombotic manifestations are more likely. Organs with the greatest blood flow, for example, kidney and brain, typically sustain the greatest damage. Pulmonary function may deteriorate as a consequence microthrombus accumulation.

Diagnosis of DIC. There is no absolutely consistent constellation of laboratory findings among routine tests.[187] Increased PT, aPTT, thrombocytopenia, a decreased fibrinogen level, and the presence of FDPs and D-dimer may all be noted. The peripheral smear may reveal schistocytes (fragmented RBCs reflecting the microangiopathy that occurs as a consequence of widespread fibrin deposition). Thrombocytopenia (<100,00/uL) is not always evident early in the process, but true DIC without sequential reduction in platelet count is very unlikely. PT and aPTT may remain normal in spite of decreasing factor levels because of the presence of high levels of activated factors including thrombin and Xa. Fibrinogen level may not be decreased, that is, <100 mg/dL,

initially. Fibrinogen is an “acute phase reactant,” which increases in response to stress and the early consumption of fibrinogen may simply reduce its levels to “normal.” FDPs are a sensitive measure of fibrinolytic activity although they not specific for DIC. D-dimer (which is a breakdown product of the crosslinked fibrin in a mature clot) is somewhat more specific for DIC, but not entirely so, and should be measured when that diagnosis is suspected.

Various other laboratory assays have been employed to support a diagnosis of DIC,[187] but should probably not be considered part of the anesthesiologist's routine. They include levels of prothrombin fragments F1+F2 (a marker of prothrombin conversion to thrombin-increased), thrombin-ATIII (TAT) complexes (increased), ATIII (decreased), alpha-2 antiplasmin (decreased by binding to excess plasmin), protein C (decreased), plasminogen (decreased), and factor VIII (decreased in DIC but normal with hepatic failure without DIC).

Treatment of DIC. Treatment should focus on management of the underlying condition. Septicemia will require antibiotic therapy. The obstetric conditions are frequently self-limited, although evacuation of the uterus or hysterectomy may be warranted. Hypovolemia, acidosis, and hypoxemia should be corrected to prevent their contribution to the DIC process. When bleeding is or may become life threatening, the consumptive coagulopathy must be treated. Platelets will be required for thrombocytopenia, for example, $<50{,}000/mm^3$. FFP will replace the clotting factor deficiencies. Fibrinogen level should be raised to >100 mg/dL. When hypofibrinogenemia is severe (<50 mg/dL) cryoprecipitate may be required. Six units of cryoprecipitate will increase fibrinogen level by approximately 50 mg/dL in a 70-kg patient.[189]

Heparin has been advocated. However, the contemporary practice is to restrict its use to only those situations where thrombosis is clinically problematic, principally DIC associated with malignancies. There is no proven benefit in situations

in which bleeding is the predominant manifestation. Antifibrinolytics have been considered. However, their use in the face of widespread thrombosis is potentially disastrous and they should not be used. Antithrombin III concentrates have been administered. The hope is that its administration will serve to slow the runaway coagulation process. However, a beneficial effect on outcome from DIC has not been confirmed (see data review by Levi[188]) and its use should be viewed as experimental. An insufficiency in the protein C endogenous coagulation inhibition system is thought to contribute to the prothrombotic state in DIC. Activated protein C has been shown to decrease mortality and organ failure in patients with sepsis and that improvement is also evident among patients with sepsis with overt DIC.[190] Its use should be considered in any sustained episode of DIC.[190]

Cardiopulmonary Bypass and Coagulation. The management of anticoagulation and post-CPB bleeding are addressed in the chapter on Cardiac Anesthesia.

Pharmacologic Therapy

Recombinant Factor VIIa (rFVIIa, NovoSeven®, Novo Nordisk, Bagsvaerd, Denmark)

Recombinant FVIIa was developed for, and its only current “on-label” use is, the treatment of patients with hemophilia A or B and inhibitors to exogenous FVIII or FIX preparations. However, it is fast becoming the hemostatic agent of last (and sometimes earlier) resort in many clinical situations. Its use has been reported in trauma, hepatic failure, and in cardiac, prostatic, hepatic, spinal, neurologic, and hepatic transplantation surgery. It has been used to reverse the anticoagulant effect of warfarin and selective Xa inhibitors. It has been administered to patients with thrombocytopenia and both congenital (Bernard Soulier syndrome, Glanzmann's thrombasthenia) and acquired (uremia, aspirin, ADP and IIb/IIIa antagonists) platelet abnormalities.[167]

The mechanism of action is uncertain. It is clearly more than an augmentation of the native functions of FVII. Were that the case, it would not be effective in hemophilia. However, FVIIa, whose preferred ligand is TF, also undergoes low affinity binding to activated platelets. In the

concentrations achieved with typical rVIIa dosing, the serum levels are several hundred times those achieved physiologically and are probably sufficient to activate Xa on the platelet surface and to achieve the “thrombin burst” necessary to support the propagation phase of coagulation (Fig. 10-3).[122] Because rVIIa is an active procoagulant only when it is in contact with TF or activated platelets, unwanted coagulation has been very infrequent. However, it should be viewed as relatively contraindicated in clinical states in which TF may be circulating freely, that is, in most of the conditions associated with DIC.

The appropriate dosing of this expensive agent (1,020 USD for 1.2 mg at UCSD) is not well defined. The dose used most often in hemophilia has been 90 ug/kg. However, doses as low as 20 ug/kg have been effective in some reports.[191] The current, somewhat arbitrary, algorithm in place at the University of California, San Diego, provides for the administration of 60 ug/kg for profuse bleeding unresponsive to conventional therapy specifies. That dose is rounded to the nearest 1,200 ug in recognition that the agent is supplied in vials of 1.2 mg. The half-life is ca. 2.5 hours and repeat dosing at 2-hour intervals may be required.

Desmopressin

Desmopressin (DDAVP, 1-deamino-8-D-arginine vasopressin) is a synthetic analogue off the natural hormone vasopressin. The actions of vasopressin are thought to mediated by two general classes of receptors: V1 receptors, which mediate smooth muscle contraction in the peripheral vasculature, and V2 receptors, which regulate water resorption in the collecting ducts of the nephron. Desmopressin has no activity at the V1 receptors and accordingly has virtually no vasoconstrictor effect. It does, however, act at V2 receptors. In fact, desmopressin is a more potent antidiuretic than vasopressin and has a more prolonged activity. Desmopressin was used primarily for clinical conditions such as diabetes insipidus until its hemostatic effects were recognized. The hemostatic effects of desmopressin are thought to be mediated by “low-affinity, extra-renal V2-like” receptors.[159] Desmopressin causes release of coagulation factor VIII:C, vWF, and tissue plasminogen activator. Desmopressin is thought to release VIII:C from the sinusoidal liver endothelial cells and the vWF from endothelial cells. In mild hemophilia A, desmopressin can increase the circulating factor VIII:C concentration two- to sixfold. Desmopressin also increases platelet adhesiveness and shortens the bleeding time, though the mechanism of these effects is not fully understood. It appears to entail more than a simple increase in the plasma vWF level.

Indications. Desmopressin has proven effective treatment for certain types of vWD and mild hemophilia (see earlier). Desmopressin has been shown to reduce the bleeding time in a variety of conditions associated with platelet dysfunction. It produces rapid and temporary correction of prolonged bleeding times in uremic patients following intravenous or intranasal administration. In cirrhotics, desmopressin increases the concentrations of larger vWF multimers and shortens prolonged bleeding times. Desmopressin also decreases the prolonged bleeding times caused by many drugs including aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), dextran, clopidogrel, and heparin.[159]

The prophylactic use of desmopressin in cardiac surgical patients has been controversial. Because platelet dysfunction and thrombocytopenia are common, numerous studies have been performed. Those that have revealed decreased blood loss or blood product administration have involved principally patients who were predisposed to blood loss, for example, redo procedures[192,193,194,195] and patients receiving aspirin.[196]

Dosage Recommendations. Desmopressin is commonly administered intravenously in a dose of 0.3 mg/kg. The effect of desmopressin is almost immediate. Peak levels of factor VIII:C and vWF are achieved within 30 to 60 minutes and the effect lasts for several hours.[159] Desmopressin administration may be repeated after 8 to 12 hours. When used in cardiac surgery, the drug should be administered after termination of cardiopulmonary bypass. Water balance should be monitored. However, while congestive cardiac failure and hyponatremia and seizures in children have been reported, clinically significant water retention is relatively uncommon. Desmopressin may be administered as a nasal spray and is available for home use for both mild hemophiliacs and patients with vWD (type 1). Intravenous administration causes a more rapid rise in VIII:C

levels and is therefore preferable for acute hemostatic challenges.

Antifibrinolytics

Antifibrinolytic agents have been used frequently in situations in which exaggerated fibrinolysis is suspected of contributing to intraoperative bleeding. The situations in which favorable effects on blood loss and replacement have been reported include cardiopulmonary bypass procedures, hepatic transplantation, scoliosis surgery, total joint replacement, and prostate surgery.[197,198,199,200,201] The use of antifibrinolytic mouthwashes in the context of dental procedures in patients with hemophilia has

been mentioned elsewhere in this chapter. There are three commonly available antifibrinolytics. They are the lysine analogues, epsilon-aminocaproic acid and tranexamic acid, and the serine protease inhibitor aprotinin.

Epsilon-Aminocaproic Acid (EACA) and Tranexamic Acid (TXA). EACA and TXA bind to and produce a structural change in both plasminogen and plasmin. That structural change prevents the conversion of plasminogen to plasmin and also prevents plasmin from degrading fibrinogen and fibrin. The dual action of these agents results in two effects on the hemostatic mechanism. First, decreased synthesis of plasmin from plasminogen results in reduced fibrinolysis. The second effect of these drugs, the inactivation of plasmin, decreases the formation of degradation products of fibrinogen and fibrin. These FDPs have anticoagulant effects, including the inhibition of platelet aggregation and the inhibition of the crosslinking of fibrin strands, which are thereby avoided.

Aprotinin. Aprotinin produces its antifibrinolytic effect by a different mechanism. It is an inhibitor of numerous serine protease enzymes including plasmin and kallikrein. The latter participates in the process of contact activation of Factor XII. As a consequence of its inhibition of plasmin, aprotinin, like EACA and TXA, prevents degradation of fibrinogen and fibrin. As is the case with EACA and TXA, the reduction in FDPs should improve both platelet and coagulation function. However, aprotinin is believed to have additional beneficial effects on the inflammatory response to CPB, in general, and on platelets, in particular.[202,203] The mechanism of these effects is not known with certainty. However, thrombin is a serine protease that can activate platelets via a “protease activated receptor” (PAR) on the platelet surface.[202] Better preservation of the GP1b receptor (which is necessary for initial platelet adhesion to vascular defects) has been reported during CPB in patients who received aprotinin.[204] Aprotinin also appears to reduce neutrophil activation and transmigration across capillary endothelium, perhaps via an effect on an endothelial PAR[205] and may therefore also blunt the neutrophil mediated component of the response to endothelial injury.

Use of antifibrinolytics in cardiac surgery. Meta-analyses of the many studies of these agents performed in the context of CPB confirm that, overall, blood loss and the administration of allogeneic blood is diminished by the use of all three agents.[197,206,207] Concern has been expressed that antifibrinolysis might lead to an increased rate of graft occlusion, myocardial infarction, and renal failure. However, the meta-analyses have not borne out those concerns.[197,206,207] There does not appear to be a clear consensus as to which of the three agents is most appropriate in the context of CPB. Various authors have argued that EACA and TXA are preferable to aprotinin because they are less expensive and have apparently similar efficacy.[208,209] However, the most recent of those meta-analyses reported a trend toward a reduced incidence of atrial fibrillation and a reduced incidence of stroke in patients receiving aprotinin[207] and this result may well create a stronger bias in favor of aprotinin.

The patterns of use of antifibrinolytic agents in cardiac surgery vary substantially among institutions. Few appear to use these agents routinely for all CPB procedures. Some reserve their use for situations more likely to be associated with post-CPB bleeding, for example, redo procedures, circulatory arrest procedures. Still others appear to reserve antifibrinolytics for refractory bleeding postcardiopulmonary bypass. The latter seems less logical because much of the activation of the hemostatic mechanism occurs during CPB.

There is a small but finite rate of allergic responses to aprotinin. Accordingly, a test dose has

been recommended for patients who have had prior exposure to aprotinin. The potential for developing sensitivity has been used as a rationale for avoiding administration of aprotinin in circumstances where it is not clearly indicated, for example, first time coronary artery bypass graft (CABG), so that it may be used safely in the event of a redo procedure. The risk of an anaphylactic/toid response appears to decline very substantially with reexposure intervals greater than six months.[210]

Use of antifibrinolytics in liver transplantation. Accelerated fibrinolysis occurs commonly in patients undergoing hepatic transplantation. This is probably, in part, the consequence of decreased clearance of activated clotting factors by the diseased liver. More importantly, hepatic clearance ceases entirely during the anhepatic phase. In addition, with reperfusion of the donor liver, there is an “explosive” release of t-PA into the systemic circulation.[211] Aprotinin, EACA, and TXA have all been used and reported to reduce blood loss in hepatic transplantation.[143,200,211,212,213] Some advocate prophylactic administration for all patients,[200] while others administer these agents only in response to the demonstration, typically by thromboelastography, of hyperfibrinolysis.[143,214]

Use of antifibrinolytics in orthopaedic and other surgery. There have been numerous reports of reduction of transfusion requirement in scoliosis and joint replacement surgery[198,199,201] However, meta-analysis has not confirmed the efficacy in noncardiac surgery and the available data do not permit a determination of the relative efficacy of EACA, TXA, and aprotinin.[197]

CONCLUSIONS

The approach to the bleeding patient requires a knowledge of the basic hemostatic mechanism and common bleeding disorders, an ability to interpret coagulation tests, and an appreciation of the risks involved with blood component therapy. The hemostatic balance is delicate and complex and it is the responsibility of the anesthesiologist to anticipate, prevent, and treat disturbances of that balance. Preoperative evaluation must identify those patients whose inherited or acquired medical conditions or whose current medications may influence these processes. With respect to medications, there are a rapidly increasing number of agents that are administered specifically for the purpose of altering the hemostatic balance, for example, clopidogrel, t-PA, low–molecular-weight heparin. As the patient proceeds through surgery and the postoperative period, the anesthesiologist must determine whether bleeding is surgical in nature or the result of a preexisting or evolving hemostatic defect that will require the transfusion of hemostatic blood components—platelets, fresh frozen plasma, or cryoprecipitate—or the administration of pharmacologic agents.

Chapter 11

Basic Principles of Clinical Pharmacology

Robert J. Hudson

Thomas K. Henthorn

KEY POINTS

1	Most drugs must pass through cell membranes to reach their sites of action. Consequently, drugs tend to be relatively lipophilic, rather than hydrophilic.
2	Most drugs are either organic bases or organic acids. A greater extent of ionization at physiologic pH will limit the rapidity of drug uptake and distribution.
3	The liver is the most important organ for metabolism of drugs. Hepatic drug clearance depends on three factors: the intrinsic ability of the liver to metabolize a drug, hepatic blood flow, and the extent of binding of the drug to blood components.
4	The kidneys eliminate hydrophilic drugs and relatively hydrophilic metabolites of lipophilic drugs. Renal elimination of lipophilic compounds is negligible.
5	The cytochrome P450 (CYP) superfamily is the most important group of enzymes involved in drug metabolism. It and other drug-metabolizing enzymes exhibit genetic polymorphism.
6	In pharmacokinetic models, the volume of distribution quantifies the extent of drug distribution. The greater the affinity of tissues for the drug, relative to blood, the greater the volume of distribution.
7	Generally, more lipophilic drugs are more highly bound to plasma proteins and have greater volumes of distribution.
8	In pharmacokinetic models, the elimination clearance quantifies the ability of drug-eliminating organs to irreversibly remove drugs from the body. High values for elimination clearance indicate efficient drug elimination.
	All else being equal, an increase in the volume of distribution of a drug will

9	increase its elimination half-life; an increase in elimination clearance will decrease elimination half-life.
10	Pharmacologic effects can be analyzed by both dose-response curves and concentration-response relationships. A disadvantage of dose-response curves is the inability to distinguish between pharmacokinetic and pharmacodynamic variability.
11	Many drugs bind to specific receptors. Receptors are dynamic entities that adapt to their environment by changing in response to exposure their agonists or antagonists.
12	During continuous infusions of drugs that partition rapidly and extensively into body tissues, the rate of rise to the eventual steady-state plasma drug concentration is determined primarily by the half-lives of the early distribution phases, P.248 not the elimination half-life. Thus, drug concentrations rapidly approach the steady-state concentration during the first minutes, and then rise much more slowly after the first hour, of the infusion.
13	Target-controlled infusions are achieved with computer-controlled infusion pumps in Europe and Asia (not yet FDA-approved in the United States), and permit clinicians to make use of the drug concentration–effect relationship, optimally accounting for pharmacokinetics, and predicting the offset of drug effect.

Over four decades ago, Dr. E. M. Papper[1] emphasized the importance of understanding the pharmacology of anesthetics:

> Clinical anaesthetists have administered millions of anaesthetics during more than a century with little precise information of the uptake, distribution, and elimination of inhalational and non-volatile anaesthetic agents. Considering how serious is the handicap of not knowing those fundamental and important facts about the drugs they have used so often, the record of success and safety in clinical anaesthesia is an extraordinary accomplishment indeed. It can in some measure be attributed to the accumulated experience and successful teaching of a highly developed sense of intuition from generation to generation of anaesthetists. It can also be attributed in part to the ability to learn by error after observing patients come uncomfortably close to injury and even to death.
>
> In the last few years, however, sufficient fundamental information has become available to explain these clinical successes. The empirical process of giving an anaesthetic can be better understood because of the specific data provided by the studies reported in this symposium and by the work of others which has preceded them.

Knowledge of the principles of pharmacology and specific properties of individual drugs is even more important today. New anesthetics, opioids, and neuromuscular blockers have recently

become available. We do not have the benefit of decades of experience with new drugs, so we must depend on carefully conducted investigations for the information needed to use them optimally. As Dr. Papper wrote:

> If the anaesthetist studies the pharmacology of these agents and understands their pharmacokinetic properties, he can with reasonable certainty predict which of these newer anaesthetic agents will hold promise for clinical utility … the clinician can spare his patients much danger and his own work many hardships if he is aware of the physicochemical and pharmacological [properties] of new agents.

Our patients are also changing. Many have comorbidities that were once considered contraindications to anesthesia and surgery. Therefore, we must consider the impact of chronic diseases and associated pharmacotherapy on the responses to drugs administered during the perioperative period. Comprehensive knowledge of clinical pharmacology is a prerequisite to the practice of anesthesiology.

The first sections of this chapter discuss the biologic and pharmacologic factors that influence drug absorption, distribution, and elimination. Quantitative analysis of these processes is discussed in the section on pharmacokinetics. The next section presents the fundamentals of pharmacodynamics—those factors that determine the relationship between drug concentration and pharmacologic effects. Mechanisms of drug interactions are then reviewed. The final section discusses clinical application of pharmacokinetics and pharmacodynamics, and systems for delivery of intravenous drugs. Although specific properties of drugs are used to illustrate basic pharmacologic principles, detailed information regarding the pharmacology of drugs used in anesthesiology is presented in succeeding chapters.

TRANSFER OF DRUGS ACROSS MEMBRANES

1 Drug absorption, distribution, metabolism, and excretion of drugs all require transfer of drugs across cell membranes. Most drugs must also traverse cell membranes to reach their sites of action. Biologic membranes consist of a lipid bilayer with a nonpolar core and polar elements on their surfaces. Proteins are embedded in the lipid bilayer and are oriented similarly, with ionic, polar groups on the membrane surfaces and hydrophobic groups in the membrane interior. The nonpolar core hinders the passage of water-soluble molecules, so that only lipid-soluble molecules easily traverse cell membranes.

Transport Processes

Drugs can cross cell membranes either by passive processes or by active transport. *Passive diffusion* occurs when a concentration gradient exists across a membrane. The rate of passive transfer is directly proportional to the concentration gradient and the lipid solubility of the drug. Passage of water-soluble drugs is restricted to small aqueous channels through the membrane. These channels are so small that only molecules less than 200 D pass through them readily. Capillary endothelial cells, except those in the central nervous system (CNS), permit transfer of much larger molecules, such as albumin (molecular weight ~67,000 D). Because of these unique features, diffusion of drugs across capillary membranes outside the CNS is limited by blood flow, not by lipid solubility.[2]

Some drugs are transferred through cell membranes of hepatocytes, renal tubular cells, and others by *active transport.* This is an energy-requiring process that is both specific and saturable. Active transport can move compounds against concentration gradients. *Facilitated diffusion* shares some characteristics with active transport. It is also carrier mediated, specific, and saturable, but does not require energy and cannot overcome a concentration gradient.[2]

Effects of Molecular Properties

2 Most drugs are too large to pass through aqueous membrane channels and must traverse the

lipid component of membranes. Almost all drugs are either weak acids or weak bases, and are present in both ionized and nonionized forms at physiologic pH. The nonionized form is more lipid soluble and able easily to traverse cell membranes. The nonionized fraction of weak acids, such as salicylates and barbiturates, is greater at low pH values, so acidic drugs become more lipid soluble as pH decreases. The nonionized fraction of weak bases like opioids and local anesthetics increases as the pH becomes more alkaline. The pK_a is the pH at which exactly 50% of a weak acid or base is present in each of the ionized and nonionized forms. The closer the pK_a is to the ambient pH, the greater the change in the degree of ionization for a given change in pH. If there is a pH gradient across a membrane, drug will be trapped on the side that has the higher ionized fraction, because only the

nonionized drug is diffusible. This phenomenon is known as *ion trapping.* The total drug concentration is greater on the side of the membrane with the higher ionized fraction. However, at equilibrium, the concentration of nonionized drug will be the same. In most situations, the range of pH values is too small to cause major changes in the degree of ionization. However, there are major pH changes in the upper gastrointestinal (GI) tract, which can affect drug absorption.

DRUG ABSORPTION

Except after intravenous (iv) injections, drugs must be absorbed into the circulation before they can be delivered to their sites of action. Therefore, absorption is an important determinant of both the intensity and duration of drug action. Incomplete absorption limits the amount of drug reaching the site of action, reducing the peak pharmacologic effect. Rapid absorption is a prerequisite for rapid onset of action. In contrast, slow absorption permits a sustained duration of action because of the "depot" of drug at the absorptive site. The speed of absorption depends on the solubility and concentration of drug. All drugs must dissolve in water to reach the circulation. Consequently, drugs in aqueous solutions are absorbed faster than those in solid formulations, suspensions, or organic solvents, such as propylene glycol. A high concentration of drug facilitates absorption. Increased blood flow to the site of injection increases the rate of absorption. Decreased blood flow secondary to hypotension, vasoconstrictors, or other factors slows drug absorption. Vasoconstrictors added to local anesthetics delay absorption after subcutaneous injection. This prolongs the duration of action at the site of injection and lessens the chance of systemic toxicity.

Route of Administration

In general medical practice, drugs are most commonly administered orally. The advantages of oral administration are convenience, economy, and safety. Disadvantages include the requirement for a cooperative patient, incomplete absorption, and metabolism of the drug in the GI tract and liver before it reaches the systemic circulation.[2] In anesthesia, drugs are most frequently administered via iv and inhalational routes. Both permit rapid and reasonably predictable attainment of the desired blood concentration.

Oral Administration

Absorption from the GI tract is highly variable because of the multiple factors involved. Tablets and capsules must disintegrate before the drug can dissolve in the GI lumen. The drug must then cross the GI epithelium and pass into the portal circulation. The most important site of absorption of all drugs is the small intestine, because of its large surface area and the anatomic characteristics of its mucosa. The nonionized fraction of weak acids such as barbiturates is higher at low pH values, which favors absorption from the stomach. However, the effect of pH on ionization of acidic drugs in the stomach is offset by the small surface area and thickness of the gastric mucosa and the rapidity of gastric emptying. Basic drugs are highly ionized at low pH, so they cannot cross the gastric mucosa. The more alkaline pH of the small intestine increases the nonionized fraction of basic drugs such as opioids, facilitating their absorption.

Once drugs enter the portal circulation, they must traverse the liver before reaching the systemic circulation. Some drugs are extensively metabolized during this initial pass through the liver, so

that only a small fraction of the drug reaches the systemic circulation. This is called the *first-pass effect.* Depending on the magnitude of the first-pass effect, the oral dose must be proportionately larger than the iv dose to achieve the same pharmacologic response. Metabolism of some drugs by the GI mucosa also contributes to the first-pass effect.[3]

Sublingual Administration

Drug absorbed from the oral mucosa passes directly into the systemic circulation, eliminating the first-pass effect. Because of the small surface area for absorption, this route is efficacious only for nonionized, highly lipid-soluble drugs, such as nitroglycerin.

Transcutaneous Administration

Only lipid-soluble drugs can penetrate intact skin sufficiently to produce systemic effects. Drug "patches" applied to the skin are now widely used. These systems consist of an adhesive containing a reservoir of drug that is slowly released after the patch is applied, producing a stable pharmacologic effect. Drugs currently administered in this fashion include scopolamine (for motion sickness) and nitroglycerin. Opioid patches are used for treatment of chronic pain. Transcutaneous absorption of drugs from patches is passive, so the onset time is delayed. This disadvantage can be overcome by using an electric current to "drive" ionized drugs into the skin, a process is called *iontophoresis.* Transcutaneous iontophoretic administration of fentanyl has been described.[4]

Intramuscular and Subcutaneous Injection

Absorption of drugs from subcutaneous tissue is relatively slow, permitting a sustained effect. The rate of absorption can be altered by changes in the drug formulation. Examples of such manipulations are the various preparations of insulin and the addition of vasoconstrictors to local anesthetic solutions. Uptake of drugs after intramuscular injection is more rapid than after subcutaneous administration because of greater blood flow. Drugs in aqueous solution are very readily absorbed. The effect of drugs in nonaqueous solutions, such as diazepam in propylene glycol, is less predictable because of erratic absorption.[5]

Intrathecal, Epidural, and Perineural Injection

Intrathecal injection of local anesthetics or other drugs close to their sites of action in the spinal cord permits the use of very low doses, eliminating the risk of adverse systemic drug effects. This is not an advantage of epidural anesthesia or major perineural regional anesthesia because of the greater total dose required. The major disadvantage of these routes of injection is the expertise they require.

Inhalational Administration

Uptake of inhalational anesthetics from the pulmonary alveoli to the blood is exceedingly rapid because of their low molecular weight and high lipid solubility, and the large total alveolar surface area, and because alveolar blood flow is almost equal to cardiac output.

Intravenous Injection

Intravenous injection eliminates the need for absorption, so that therapeutic blood concentrations are rapidly attained. This is especially advantageous when rapid onset of action is desired. It also simplifies titration of the dose to individual patients' responses. Unfortunately, rapid onset also has its hazards; should an adverse drug reaction or overdose occur, the effects are immediate and potentially severe.

Bioavailability

Bioavailability is defined as the fraction of the total dose that reaches the systemic circulation. Bioavailability is reduced by factors such as incomplete absorption from the site of injection or GI

tract, the first-pass effect, or pulmonary uptake of drugs.

Even after iv injection, the bioavailability of drugs formulated in lipid suspensions may be less than 100%. These suspensions contain small lipid droplets. Some, but not all, of the drug diffuses from the lipid droplets into the plasma. These droplets are taken up by the liver and metabolized. Presumably, some drug is also metabolized before it is released back into the circulation. The bioavailability of the lecithin suspension of diazepam is 30% less than that of diazepam in propylene glycol, even with direct iv injection.[6]

DRUG DISTRIBUTION

After absorption or injection into the systemic circulation, drugs are distributed throughout the body. Highly perfused organs, such as the brain, heart, lungs, liver, and kidneys, receive most of the drug soon after injection. Delivery to muscle, skin, fat, and other less well perfused tissues is slower, and equilibration of distribution into these tissues may take several hours or even days.

Capillary membranes are freely permeable in most tissues, so drugs pass quickly into the extracellular space. Subsequent distribution varies according to the physicochemical properties of the drug. Distribution of highly polar, water-soluble drugs such as the neuromuscular blockers is essentially limited to extracellular fluid. Lipid-soluble drugs like propofol easily cross cell membranes and are therefore distributed much more extensively.

Distribution of drugs into the CNS is unique. Brain capillaries do not have the large aqueous channels typical of capillaries in other tissues. Consequently, diffusion of water-soluble drugs into the brain is severely restricted—hence the term *blood-brain barrier*. In contrast, distribution of highly lipid-soluble drugs into the CNS is limited only by cerebral blood flow. For more polar compounds, the rate of entry into the brain is proportional to the lipid solubility of the nonionized drug.

Drugs accumulate in tissues because of binding to tissue components, pH gradients, or uptake of lipophilic drugs into fat. These tissue stores can act as reservoirs that prolong the duration of drug action, either in the same tissue, or by delivery to the site of action elsewhere after reabsorption into the circulation.

Binding of drugs to plasma proteins and erythrocytes influences distribution to other tissues. Only free, unbound drug can cross capillary membranes. The extent of tissue uptake of drugs depends on the affinity of drug binding to blood constituents, relative to the overall affinity of binding to tissue components.

Redistribution

The rapid entry and equally rapid egress of lipophilic drugs from richly perfused organs such as the brain and heart is referred to as *redistribution.* This phenomenon is illustrated by the events that follow an injection of thiopental. The brain concentration of thiopental peaks within 1 minute because of high blood flow to the brain and the high lipid solubility of thiopental. As the drug is taken up by other, less well perfused tissues, the plasma level rapidly decreases. This creates a concentration gradient from cerebral tissue to the blood, so that thiopental quickly diffuses back into the blood, where it is redistributed to other tissues that are still taking up the drug. Ultimately, adipose tissue contains much of the drug remaining in the body because of the high lipid solubility of thiopental. However, recovery from a single dose of thiopental depends predominantly on redistribution of thiopental from the brain to muscle, because of the larger mass and greater perfusion of muscle compared to adipose tissue.[7,8]

A single moderate dose of thiopental (<5 to 6 mg/kg) has a very short duration of action because of redistribution. If repeated injections are given, the concentration of thiopental builds up in the peripheral tissues, and termination of drug action becomes increasingly dependent on the much slower process of drug elimination. Termination of the pharmacologic effects of other lipophilic drugs, such as fentanyl and its derivatives, and propofol, is also governed by these factors.

Placental Transfer

Most drugs cross the placenta by simple diffusion, so propofol and other lipid-soluble drugs with low molecular weights are most readily transferred. Highly polar, water-soluble compounds such as the neuromuscular blocking drugs do not cross the placenta to a significant extent. Fetal pH is slightly lower than maternal pH. This pH gradient causes the ionized fraction of weak bases, such as opioids and local anesthetics, to be higher in the fetus. Therefore, the fetal total drug level may be higher than predicted from the maternal total drug level because of ion trapping.[9] Different total drug concentrations can also result from differences between mother and fetus in the extent of drug binding to plasma proteins. However, regardless of the effects of pH and protein binding, the concentration of free, nonionized drug is the same on both sides of the placenta once equilibrium is reached. For most drugs, this is the most important form, because it has the most pharmacologic activity.

DRUG ELIMINATION

Elimination is an inclusive term referring to all the processes that remove drugs from the body. Elimination occurs either by excretion of unchanged drug or by metabolism (biotransformation) and subsequent excretion of metabolites. The liver and kidneys are the most important organs for drug elimination. The liver eliminates drugs primarily by metabolism to less active compounds and, to a lesser extent, by hepatobiliary excretion of drugs or their metabolites. The primary role of the kidneys is the excretion of water-soluble, polar compounds. Drugs having these properties, such as some nondepolarizing neuromuscular blockers, undergo renal excretion intact.[10] The kidneys also excrete water-soluble metabolites of drugs that initially undergo biotransformation. Pulmonary excretion is the major route for elimination of anesthetic gases and vapors.

The term "drug clearance," or "elimination clearance," describes the ability to remove drug from the blood. Drug clearance is the theoretical volume of blood from which drug is completely and irreversibly removed in a given time interval. It is analogous to creatinine clearance, which quantitatively describes the ability of the kidneys to eliminate creatinine. Like creatinine clearance, drug clearance has units of flow, milliliters per minute (mL/min). Many drugs are cleared by more than one route, and multiple elimination pathways are additive. Consequently, total drug clearance is equal to the sum of the clearances of all of the elimination pathways.

Total drug clearance can be calculated with pharmacokinetic models of blood concentration versus time data. However, clearance by individual organs and the biologic factors influencing drug elimination cannot be estimated from blood concentration data alone. Additional data, such as the

hepatic arteriovenous drug concentration difference or the rate of urinary excretion of the drug, are needed to determine the contribution of a specific organ to total drug clearance.

Hepatic Drug Clearance

3 Drug clearance by the liver is dependent on three factors: (1) hepatic blood flow, (2) the intrinsic ability of the liver to irreversibly eliminate the drug from the blood, and (3) the extent of drug binding to plasma proteins or other blood constituents. The interrelationships between these factors have been described with the *venous equilibration model* of hepatic drug clearance.[11,12] According to this model, the unbound concentration of drug in hepatic venous blood is in equilibrium with the unbound concentration in hepatocytes. This unbound drug within the liver is available for elimination by biotransformation or biliary excretion.

The venous equilibration model is based on two assumptions: that hepatic drug clearance is limited by delivery of drug to the liver, and that elimination is a first-order process.[11] By definition, *first order* means that a constant fraction of the drug is eliminated per unit time. The fraction of the drug removed from the blood passing through the liver is the hepatic extraction ratio, *E:*

$$E = \frac{C_a - C_v}{C_a} \qquad (11\text{-}1)$$

where C_a is the mixed hepatic arterial–portal venous drug concentration and C_v is the mixed hepatic venous drug concentration. The total hepatic drug clearance, Cl_H, is:

$$Cl_H = Q \cdot E \qquad (11\text{-}2)$$

where Q is hepatic blood flow. Therefore, hepatic clearance is a function of hepatic blood flow and the ability of the liver to extract drug from the blood. The ability to extract drug depends on the activity of drug-metabolizing enzymes and the capacity for hepatobiliary excretion.

The concept of *intrinsic clearance* was developed to account for the effects of blood flow and drug binding in the blood on elimination.[11] Intrinsic clearance represents the ability of the liver to remove drug from the blood in the absence of any limitations imposed by blood flow or drug binding. The relationship of total hepatic drug clearance to the extraction ratio and intrinsic clearance, Cl_I, is:

$$Cl_H = Q \cdot E = Q\left(\frac{Cl_1}{Q + Cl_1}\right) \qquad (11\text{-}3)$$

The right-hand side of Equation 11-3 indicates that if intrinsic clearance is very high (many times larger than hepatic blood flow), total hepatic clearance approaches hepatic blood flow. On the other hand, if intrinsic clearance is very small, hepatic clearance will be similar to intrinsic clearance. These relationships are shown in Figure 11-1.

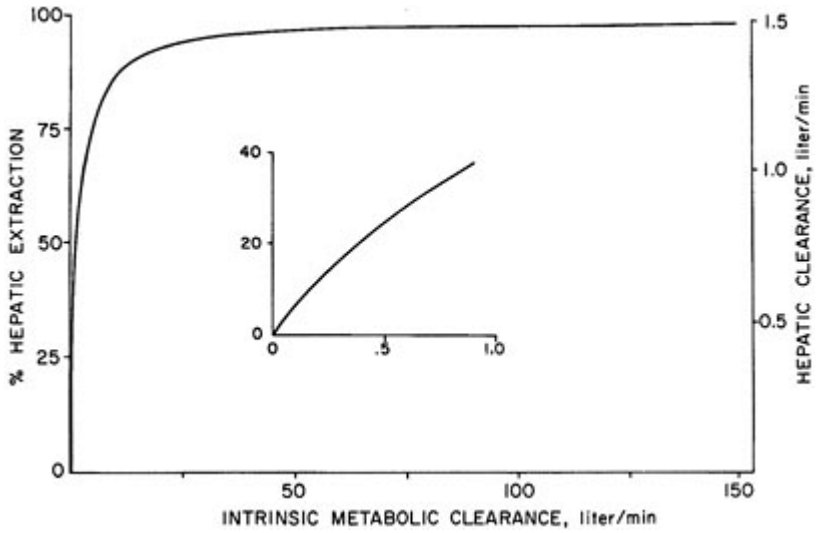

FIGURE 11-1. The relationship between hepatic extraction ratio, intrinsic clearance, and hepatic clearance at the normal hepatic blood flow of 1.5 L/min. For drugs with high intrinsic clearance (>25 L/min), increasing intrinsic clearance has little effect on hepatic extraction and total hepatic clearance. The inset demonstrates the relationship at low values of intrinsic clearance on an expanded scale. (Reprinted with permission from Wilkinson GR, Shand DG: A physiologic approach to hepatic drug clearance. Clin Pharmacol Ther 18:377, 1975.)

Thus, hepatic drug clearance and extraction are determined by two independent variables, intrinsic clearance and hepatic blood flow. Changes in either will change hepatic clearance. However, the extent of the change depends on the initial intrinsic clearance. If the inherent ability of the liver to eliminate a drug (intrinsic clearance) is doubled, then the extraction ratio also increases, but not necessarily to the same extent. The extraction ratio and intrinsic clearance do not have a simple, linear relationship:

$$E = \frac{Cl_1}{Q + Cl_1} \qquad (11\text{-}4)$$

If the initial intrinsic clearance is small relative to hepatic blood flow, then the extraction ratio is also small, and Equation 11-4 indicates that doubling intrinsic clearance will produce an almost proportional increment in the extraction ratio, and, consequently, clearance. However, if intrinsic clearance is much greater than hepatic blood flow, a twofold change in intrinsic clearance has a negligible effect on the extraction ratio and drug clearance. In nonmathematical terms, high intrinsic clearance indicates efficient hepatic elimination. It is hard to enhance an already efficient process, whereas it is relatively easy to improve on inefficient drug clearance because of low intrinsic clearance.

The effect of changes in hepatic blood flow also depends on the magnitude of intrinsic clearance. If extraction and intrinsic clearance are high, a decrease in hepatic blood flow causes a small increase in the extraction ratio (Fig. 11-2) that is insufficient to offset the effects of reduced hepatic flow (Eq. 11-4). Consequently, changes in hepatic blood flow produce virtually proportional changes in clearance of drugs with high extraction ratios (Fig. 11-3). For drugs having a low intrinsic clearance, a decrease in hepatic blood flow is associated with a larger, almost proportional increase in the extraction ratio (see Fig. 11-2). This largely offsets the effects of changes in blood flow, so that clearance of drugs with low extraction ratios is essentially independent of hepatic blood flow (see Fig. 11-3).

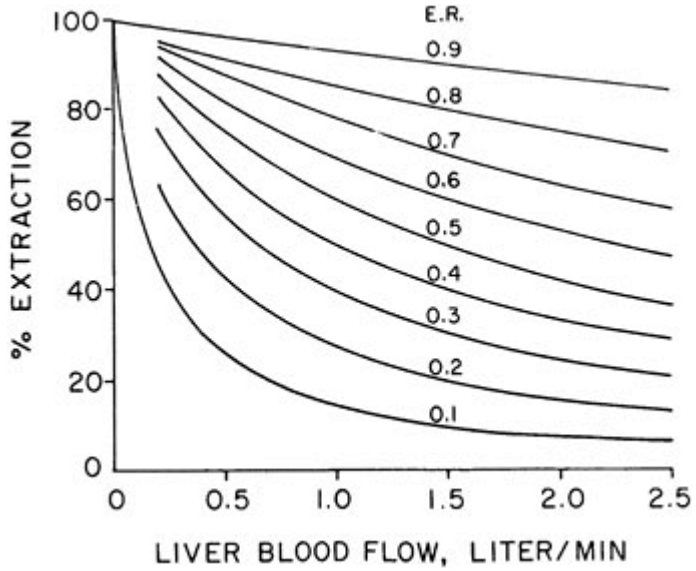

FIGURE 11-2. The effect of changes in hepatic blood flow on extraction of drugs with different extraction ratios. The extraction ratios at the normal hepatic blood flow of 1.5 L/min are above the corresponding curves. (Reprinted with permission from Wood AJJ: Drug disposition and pharmacokinetics. FIGURE 11-3. The effect of changes in hepatic blood flow on hepatic clearance of drugs with different extraction ratios. The extraction ratios for each curve at 1.5 L/min flow are indicated. The *arrows* indicate the normal physiologic range of hepatic blood flow. (Reprinted with permission from Wood AJJ: Drug disposition and pharmacokinetics. In Wood M, Wood AJJ [eds]: Drugs and Anesthesia—Pharmacology for Anesthesiologists, p 27. Baltimore, Williams & Wilkins, 1990. After Wilkinson GR, Shand DG: A physiologic approach to hepatic drug clearance. Clin Pharmacol Ther 18:377, 1975.)

Hepatic clearance of drugs with extraction ratios ⩽30% is independent of changes in liver blood flow, but very sensitive to the liver's ability to metabolize the drug, which can vary as a result of pathologic conditions, inhibition or induction of drug-metabolizing enzymes, or interindividual differences. In contrast, variations of hepatic clearance of drugs with high extraction ratios (>70%) are determined primarily by liver blood flow. Drugs with intermediate extraction ratios, between 30 and 70%, share characteristics with both the other groups. Drugs can be classified as having either high, intermediate, or low extraction ratios (Table 11-1).

TABLE 11-1 Classification of Drugs Encountered in Anesthesiology According to Hepatic Extraction Ratios

·LOW	·INTERMEDIATE	·HIGH
diazepam	alfentanil	alprenolol
lorazepam	methohexital	bupivacaine
methadone	midazolam	diltiazem
phenytoin	vecuronium	fentanyl
rocuronium		ketamine
theophylline		lidocaine
thiopental		meperidine
		metoprolol
		morphine

		naloxone nifedipine propofol propranolol sufentanil verapamil
Drugs eliminated primarily by other organs are not included in this table.		

Binding of drugs to plasma proteins and other blood components may also affect drug clearance. Whether or not drug binding influences drug clearance depends on the extraction ratio and the extent of binding. Three classes of hepatic clearance can be defined by integrating the effects of drug binding in the blood and the extraction ratio.[13] Clearance of drugs with high extraction ratios is *flow limited* because it depends only on

hepatic perfusion and is not affected by changes in drug binding or intrinsic clearance. The combination of a low extraction ratio and a high free fraction results in *capacity-limited, binding-insensitive* clearance, which is affected by changes in intrinsic clearance but is not significantly influenced by binding or hepatic perfusion. Drugs with low extraction ratios and low free fractions have *capacity-limited, binding-sensitive* clearance, which is not greatly affected by changes in hepatic blood flow but depends on both intrinsic clearance and the free drug concentration. Elimination of drugs with intermediate extraction ratios and binding is influenced by all three biologic factors—hepatic blood flow, intrinsic clearance, and the free drug concentration in the blood. The relative importance of these three factors cannot be predicted unless the extraction ratio and the unbound fraction in the blood are known.

Physiologic, Pathologic, and Pharmacologic Alterations in Hepatic Drug Clearance

At rest, approximately 30% of cardiac output perfuses the liver. The hepatic artery provides roughly 25% of total hepatic flow, with the remainder supplied via the portal vein. Many physiologic and pathologic conditions alter hepatic blood flow, but there is little information regarding the effect of these changes in blood flow on hepatic drug clearance. The splanchnic circulation responds to a variety of stimuli, and splanchnic flow is often sacrificed to meet the demands of other tissues.

Moving from the supine to the upright position decreases cardiac output, which produces a reflex increase in systemic vascular resistance. The splanchnic circulation participates in this generalized vasoconstriction, which decreases hepatic blood flow by 30 to 40%.[12] Clearance of aldosterone, which has a high hepatic extraction ratio, is decreased in the upright position.[12] Postural changes probably also influence clearance of drugs with high hepatic extraction ratios, but this has not been systematically investigated.

Exercise, heat stress, and hypovolemia all decrease splanchnic blood flow in proportion to the associated increase in heart rate, which suggests that these responses are mediated by the sympathetic nervous system.[12] As expected, these conditions decrease clearance of indocyanine green, which has a high hepatic extraction ratio. In contrast, the clearance of antipyrine, a drug with a low extraction ratio, is not affected by these conditions.[14]

Decreases in cardiac output cause reflex splanchnic vasoconstriction, which reduces hepatic blood flow in proportion to the reduction in cardiac output.[15] Lidocaine clearance is reduced in patients

with congestive cardiac failure.[16] Consequently, if usual doses of lidocaine are given to patients with heart failure, the risk of lidocaine toxicity is increased. Marked

reduction in hepatic blood flow causes hepatocellular dysfunction; therefore, severe congestive heart failure decreases drug clearance by reducing both intrinsic clearance and hepatic blood flow.[17] Cardiovascular collapse severely compromises both liver blood flow and hepatocellular function.[12] In experimental hemorrhagic shock, clearance of lidocaine was decreased by 40%, whereas hepatic blood flow declined by 30%.[18] The reduction in clearance is too large to be caused solely by decreased hepatic perfusion, implying a concomitant reduction in intrinsic clearance secondary to hepatic ischemia.

Liver disease can decrease drug clearance because of hepatocellular dysfunction, altered hepatic blood flow, or both.[12] Cirrhosis reduces clearance of drugs with high extraction ratios, including lidocaine,[16] meperidine,[19,20] and propranolol.[21] This is secondary to decreased hepatic perfusion, which can be the result of reduced total liver blood flow, intrahepatic shunting, or extrahepatic shunting of portal venous blood.[12] Portosystemic shunting increases the bioavailability of orally administered drugs with high extraction ratios.[12] Cirrhosis also decreases clearance of drugs with low extraction ratios, such as diazepam,[22,23] because of impaired hepatocellular function, which decreases intrinsic clearance. Acute viral hepatitis reduces the clearance of drugs with both high (meperidine,[24] lidocaine[25]) and low (diazepam[22]) hepatic extraction ratios. These observations indicate that both acute and chronic liver diseases affect liver function and blood flow in a parallel fashion. Consequently, in chronic therapy, doses of any drug cleared by the liver should be reduced in patients with hepatic disease.

Drugs that alter splanchnic hemodynamics affect clearance of highly extracted drugs. Propranolol decreases hepatic blood flow, thus decreasing its own clearance[12] and the clearance of concomitantly administered lidocaine.[26] The volatile anesthetics all decrease hepatic blood flow, although isoflurane does so to a lesser extent than halothane or enflurane.[27,28] Intra-abdominal surgery causes a further decrease in hepatic perfusion.[27] Hypotension produced by spinal anesthesia reduces splanchnic blood flow.[29] In contrast to the volatile anesthetics, nitrous oxide, opioids, and barbiturates have little effect on hepatic blood flow.[12] Although they are potentially of great clinical importance, the effects of these hemodynamic alterations have not been thoroughly investigated. It is logical to assume that the clearance of drugs with high hepatic extraction ratios will be reduced during anesthesia and surgery.

Renal Drug Clearance

4 Although the kidneys do metabolize drugs, their major function in drug elimination is to excrete water-soluble drugs, and metabolites produced elsewhere (primarily the liver), into the urine. Renal clearance of drugs is determined by the net effects of three processes: glomerular filtration, tubular secretion, and tubular reabsorption.[30,31]

Glomerular filtration cannot eliminate drugs efficiently. The glomerular filtration rate (GFR) is approximately 20% of renal plasma flow.[32] Consequently, even if none of the drug is bound to plasma proteins, only about 20% can be removed by glomerular filtration. Drug binding to plasma proteins and erythrocytes reduces the amount filtered, because only unbound drug can pass through the glomerular membrane into the renal tubule. If a drug is neither secreted nor reabsorbed by the renal tubules, then renal drug clearance will be equal to glomerular clearance. Drugs and metabolites excreted in this fashion have low renal extraction ratios, and their renal clearance depends on the degree of binding to blood constituents. Therefore, protein binding is a major determinant of both hepatic and renal clearance of drugs with low extraction ratios.

Proximal renal tubular cells have two discrete mechanisms for secreting acidic and basic organic compounds.[30] These processes are carrier mediated, so they are saturable. Drugs with similar physicochemical characteristics compete for available carrier molecules and interfere with each other's secretion. If a drug is very avidly secreted by tubular cells and not subsequently reabsorbed, it will have a high renal extraction ratio. Renal clearance of such drugs is largely determined by the magnitude of renal blood flow.[30] This is analogous to the importance of liver

blood flow in the clearance of drugs with high hepatic extraction ratios.

Clearance of drugs filtered by the glomeruli or secreted by the proximal renal tubule may be decreased by subsequent reabsorption from the renal tubule. If this is extensive, the drug will have a very low renal extraction ratio and negligible renal clearance. Tubular reabsorption occurs by active, carrier-mediated transport that is similar to active secretion. Drugs can also be reabsorbed by passive diffusion across the tubular epithelium. The progressive reabsorption of water from the renal tubule facilitates passive reabsorption of drugs by creating a tubule-to-plasma concentration gradient for the drug. Consequently, oliguria can decrease renal drug clearance.[31] Passive reabsorption is determined by the lipid solubility and degree of ionization of a drug. Highly lipophilic drugs like propofol are almost completely reabsorbed and have virtually no renal clearance. For less lipophilic drugs, the degree of ionization is a major determinant of the extent of passive reabsorption because only the nonionized drug readily diffuses across the renal tubular epithelium. Urine pH can range from 4.5 to 8.0, which can cause large changes in the ionized fraction of weak acids and bases, particularly if the pK_a is close to or within this range. Urine pH can be manipulated to increase renal drug clearance after overdoses.

Physiologic, Pharmacologic, and Pathologic Alterations in Renal Drug Clearance

In adults, renal blood flow is approximately 1,200 mL/min, so renal plasma flow is approximately 700 mL/min. About one-fifth of the plasma is filtered by the glomerulus, resulting in an average GFR of 125 mL/min. Renal blood flow and GFR are autoregulated, so they remain fairly constant as long as mean arterial pressure is between 70 and 160 mmHg.[32] Consequently, renal drug clearance is more constant than hepatic clearance, because renal blood flow usually varies less than hepatic blood flow.

The capacity for excreting endogenous and exogenous compounds depends on the number of functionally intact nephrons. Decreased glomerular filtration is accompanied by a parallel loss of renal tubular function. Therefore, clearance of endogenous creatinine, which is essentially equivalent to the GFR, can be used to estimate overall renal function. It follows that renal drug clearance is proportional to creatinine clearance, even for drugs eliminated primarily by tubular secretion. This principle has been used to develop nomograms for reducing drug doses according to the creatinine clearance in the presence of renal dysfunction.[33] Many drugs, including lidocaine,[34] pancuronium,[35] and meperidine,[36] have pharmacologically active metabolites that are excreted by the kidneys. Therefore, both parent drugs and their metabolites can contribute to drug toxicity in patients with renal failure.

Renal function decreases progressively with age. By age 80 years, creatinine clearance is reduced by about 50%.[37] Despite the age-related decrease in glomerular filtration rate, serum creatinine is not elevated in healthy elderly patients because muscle mass, the primary source of creatinine, also decreases with age. Therefore, even if serum creatinine is normal, renal clearance of drugs is reduced in elderly patients.

The kidneys eliminate many drugs encountered in anesthetic practice (Table 11-2). In renal failure, doses of these drugs must be reduced to avoid adverse effects. In addition to renal

disease, other pathologic processes can impair kidney function. Low cardiac output states reduce renal blood flow, glomerular filtration, and, consequently, renal drug clearance.[30] Advanced hepatic cirrhosis also interferes with renal function,[30] and this combination, the *hepatorenal syndrome*, reduces elimination of almost all drugs.

TABLE 11-2 Drugs with Significant Renal Excretion Encountered in Anesthesiology

Aminoglycosides	Pancuronium

Atenolol	Penicillins
Cephalosporins	Pipecuronium
Digoxin	Procainamide
Doxacurium	Pyridostigmine
Edrophonium	Rocuronium
Nadolol	Quinolones
Neostigmine	

DRUG METABOLISM

Unless tolerance develops, termination of drug action depends on removal of the drug from its sites of action. (Tolerance is defined as decreasing pharmacologic effect with sustained exposure to a drug. It results in higher doses [or concentrations] being required to maintain a given effect. The mechanisms responsible for tolerance are diverse. They include adaptive or reflex responses to drug effects that alter the observed effects and alterations in the number or sensitivity of receptors.) Most operations are completed within a relatively short period (duration of anesthesia <2 to 3 hours). In such cases, drug redistribution is the primary mechanism responsible for reducing drug concentrations in the blood. This, in turn, establishes the concentration gradient required for removal of drugs from their sites of action. Drug metabolism is more important in terminating effects of drugs that are not extensively redistributed, or when larger, or repeated, doses are administered. This could occur after prolonged anesthesia (>4 to 5 hours). Consideration of drug metabolism is also important in the therapeutics of critical care and pain therapy.

Drugs must usually cross biologic membranes to reach their sites of action, so most are relatively lipid soluble. This property makes their excretion difficult, because lipophilic compounds are readily reabsorbed from the gut and the distal renal tubule. Metabolism, or *biotransformation* of drugs to more polar, water-soluble compounds, facilitates the ultimate excretion of metabolites in the bile and urine. Biotransformation is a protective mechanism for preventing the accumulation and resultant toxicity of various lipophilic compounds acquired from the environment.

Metabolites are usually less active pharmacologically than the parent drug. However, this is not always true. Many benzodiazepines have metabolites that have similar pharmacologic effects.[5] The analgesic effects of codeine are a result of its biotransformation to morphine. Metabolites can also be toxic. The major metabolite of meperidine is normeperidine, which can cause seizures.[36] If metabolites are pharmacologically active or toxic, further biotransformation or excretion is required for termination of their effects.

Metabolism of drugs and other exogenous compounds, known collectively as *xenobiotics*, occurs primarily in the liver. Other organs, including the kidneys, lungs, gut, and skin, also metabolize drugs, but extrahepatic biotransformation is quantitatively unimportant in most instances.

Biotransformation Reactions

Biotransformation reactions have classically been divided into two groups. *Phase I* reactions alter the molecular structure of xenobiotics by modifying an existing functional group of the drug, by adding a new functional chemical group to the compound, or by splitting the original molecule into two fragments. These changes in molecular structure result from oxidation, reduction, or hydrolysis of the parent compound. *Phase II* reactions consist of the coupling, or conjugation, of a variety of endogenous compounds to polar chemical groups. The polar chemical group at which

conjugation occurs is frequently the result of a previous Phase I reaction, hence the "Phase I–Phase II" nomenclature. However, not all drugs are eliminated by this sequential pathway of biotransformation. Oxidation of thiopental produces its major metabolite, thiopental carboxylic acid,[38] which undergoes renal excretion without undergoing a Phase II biotransformation. Morphine is directly conjugated to form morphine glucuronide without first undergoing a Phase I reaction.

Phase I Reactions

Phase I reactions may hydrolyze, oxidize, or reduce the parent compound. *Hydrolysis* is the insertion of a molecule of water into another molecule, which forms an unstable intermediate compound that subsequently splits apart. Thus, hydrolysis cleaves the original substance into two separate molecules. Hydrolytic reactions are the primary way amides, such as lidocaine and other amide local anesthetics, and esters, such as succinylcholine, are metabolized.

Many drugs are biotransformed by oxidative reactions. *Oxidations* are defined as reactions that remove electrons from a molecule. The common element of most, if not all, oxidations is an enzymatically mediated reaction that inserts a hydroxyl group (OH) into the drug molecule.[39] In some instances, this produces a chemically stable, more polar hydroxylated metabolite. However, hydroxylation usually creates unstable compounds that spontaneously split into separate molecules. Many different biotransformations are effected by this basic mechanism. Dealkylation (removal of a carbon-containing group), deamination (removal of nitrogen-containing groups), oxidation of nitrogen-containing groups, desulfuration, dehalogenation, and dehydrogenation all follow an initial hydroxylation.[39] Hydrolysis and hydroxylation are comparable processes. Both have an initial, enzymatically mediated step that produces an unstable compound that rapidly dissociates into separate molecules.

Some drugs are metabolized by *reductive reactions*, that is, reactions that add electrons to a molecule. In contrast to oxidations, where electrons are transferred from NADPH to an oxygen atom, the electrons are transferred to the drug molecule. Oxidation of xenobiotics requires oxygen, but reductive biotransformation is inhibited by oxygen, so it is facilitated when the intracellular oxygen tension is low.[40]

The Cytochromes P450. The cytochromes P450 (CYP) are enzymes that catalyze most biotransformations. These hemoproteins, when reduced by carbon monoxide, have an absorption spectrum with a peak at the 450-nm wavelength, hence their name. CYP are incorporated into the smooth endoplasmic reticulum of hepatocytes. The endoplasmic reticulum is an intracellular network of tubules similar in ultrastructure to cellular membranes. Other tissues, including the lungs, kidneys, and skin, also contain CYP, but in much smaller amounts.[41] Upper intestinal enterocytes contain high concentrations of CYP, which contributes to the first-pass effect by metabolizing drugs absorbed from the GI tract before they reach the systemic circulation.[3,41,42] CYP are capable of metabolizing hundreds of compounds, including endogenous substances such

as steroids and amines, as well as drugs and other exogenous compounds acquired from the environment.[42] CYP isoenzymes oxidize their substrates primarily by the insertion of an atom of oxygen in the form of a hydroxyl group, while another oxygen atom is reduced to water.

5 CYP is a superfamily of related enzymes.[43] More than 2,000 CYP isoenzymes have been identified in plants, animals, and microbiologic species.[44] In humans, 57 CYP members, grouped into 42 subfamilies and 18 families according to amino acid sequences, have been identified.[45] CYP families share ⩾40% sequence identity and are denoted by an Arabic numeral (i.e., CYP2, CYP3). Subfamilies share ⩾55% identity and are designated sequentially using a letter (CYP3A, CYP3B, etc.). Individual members of a family are assigned a second numeral (such as CYP3A4, CYP3A5).[45]

Several constitutive CYPs are involved in the production of various endogenous compounds, such as cholesterol, steroid hormones, prostaglandins, and eicosanoids.[45] In addition to the constitutive forms, production of various CYPs can be induced by a wide variety of xenobiotics.[46] CYP drug-metabolizing activity increases after exposure to various exogenous chemicals, including many

drugs.[44,47] The number and type of CYPs present at any time depends on exposure to different xenobiotics. The CYP system is able to protect the organism from the deleterious effects of accumulation of exogenous compounds because of its two fundamental characteristics—broad substrate specificity and the capability to adapt to exposure to different substances by induction of different CYP isoenzymes.

Biotransformations can be inhibited if different substrates compete for the drug-binding site on the same CYP member. The effect of two competing substrates on each other's metabolism depends on their relative affinities for the enzyme. Biotransformation of the compound with the lower affinity is inhibited to a greater degree. This is the mechanism by which the H_2 receptor antagonist cimetidine inhibits the metabolism of many drugs, including meperidine, propranolol, and diazepam.[48,49,50] The newer H_2 antagonist ranitidine has a different structure and causes fewer clinically significant drug interactions.[51] Other drugs, notably calcium channel blockers and antidepressants, also inhibit oxidative drug metabolism in humans.[52,53] Information regarding both induction and inhibition of different CYP isoenzymes by specific compounds has become available.[53] This information allows clinicians to predict which combinations of drugs are more likely to lead to clinically significant interactions because of altered drug metabolism by the cytochrome P450 system.

CYP isoenzymes from families 1, 2, and 3 effect 70 to 80% of all Phase I metabolism of all clinically used drugs.[54] CYP3A4 is the single most important enzyme, accounting for 40 to 45% of all CYP-mediated drug metabolism.[54] The CYP2 family accounts for a similar percentage of CYP-mediated biotransformation.[54] Tables 11-3 and 11-4 group drugs encountered in anesthetic practice according to the CYP isoenzymes responsible for their biotransformation.[41,55] Some drugs are metabolized by more than one CYP isoenzyme.

TABLE 11-3 Substrates of CYP3A4 Encountered in Anesthesiology

Acetaminophen
Alfentanil
Alprazolam
Bupivacaine
Cisapride
Codeine
Cortisol

	omeprazole
	propranolol

	warfarin
Compiled from references 41 and 55.	

Induction and inhibition of hepatic drug-metabolizing enzyme systems change the intrinsic hepatic clearance of drugs. This is most important for drugs with low hepatic extraction ratios, because intrinsic clearance is the primary determinant of their hepatic clearance. Altered drug-metabolizing enzyme activity has little effect on drugs with high hepatic extraction ratios because their clearance depends primarily on hepatic blood flow.

Phase II Reactions

Phase II reactions are also known as *conjugation* or *synthetic reactions.* Many drugs do not have a polar chemical group suitable for conjugation, so conjugation occurs only after a Phase I reaction. Other drugs, such as morphine, already have a polar group that serves as a "handle" for conjugation, and they undergo these reactions directly. Various endogenous compounds can be attached to parent drugs or their Phase I metabolites to form different conjugation products.[56] These endogenous substrates include glucuronic acid, acetate, and amino acids. Mercapturic acid conjugates result from the binding of exogenous compounds to glutathione. Other conjugation reactions produce sulfated or methylated derivatives of drugs or their metabolites. Like the cytochrome P450 system, the enzymes that catalyze Phase II reactions are inducible.[47] Phase II reactions produce conjugates that are polar, water-soluble compounds. This facilitates the ultimate excretion of the drug via the kidneys or hepatobiliary secretion. Like CYP, there are different families and superfamilies of the enzymes that catalyze Phase II biotransformations.[56]

Factors Affecting Biotransformation

Drug metabolism varies substantially between individuals because of variability in the genes controlling the numerous enzymes responsible for biotransformation. For most drugs, individual subjects' rates of metabolism have a unimodal

distribution. However, distinct subpopulations with different rates of elimination of some drugs have been identified. The resulting multimodal distribution of individual rates of metabolism is known as *polymorphism.* For example, different genotypes result in either normal, low, or (rarely) absent plasma pseudocholinesterase activity, accounting for the well-known differences in individuals' responses to succinylcholine, which is hydrolyzed by this enzyme. Many drug-metabolizing enzymes exhibit genetic polymorphism, including CYP and various transferases that catalyze phase II reactions.[54,56,57,58,59]

Drug metabolism also varies with age. The fetus and neonate have less capacity for most biotransformations, especially those catalyzed by the CYP superfamily.[60] Neonates also have less capacity for most phase II biotransformation, with the exception of sulfate conjugation.[60] Impaired conjugation of bilirubin causes "physiologic jaundice." Biotransformation capacities rapidly in the postpartum period, reaching adult capacity by 1 year of age.[60]

Metabolism of some drugs may also be decreased in geriatric patients, although it is difficult to separate the effects of age per se from the effects of organ dysfunction, which is more prevalent in the elderly. Some, but not all, investigations suggest decreased CYP activity in the elderly.[61] Conjugation capacity has little or no age-related changes.[61]

Men have greater capacity for most Phase II reactions, and for Phase I reactions catalyzed by CYP2E1.[62,63] There do not appear to be any sex-related differences in CYP2C9 or CYP2C19 activity.[62,63] CYP3A isoenzymes metabolize the largest number of medications. Whether there are any clinically relevant differences between men and women in CYP3A activity is controversial.[62,63]

Exposure to various foreign compounds can alter drugmetabolizing enzyme activity. Barbiturates, phenytoin, macrolide antibiotics, imidazole antifungal agents, and corticosteroids can cause drug interactions secondary to induction of hepatic drug-metabolizing enzymes.[47] Chronic ethanol consumption induces enzyme activity, but acute intoxication inhibits the biotransformation of some drugs.[64] Smoking increases the metabolism of many drugs secondary to enzyme induction by polycyclic hydrocarbons in tobacco smoke.[65]

Liver disease profoundly affects drug disposition. It is difficult to distinguish the impact of altered biotransformation per se from other effects of liver disease: altered binding of drugs to plasma proteins and decreased liver blood flow. Nonetheless, hepatic disease decreases clearance of drugs with low hepatic extraction ratios,[13,66] which implies impaired biotransformation. Decreased in vitro activity in cirrhotic livers of some, but not all, CYP isoforms has been reported, although this also depends on the severity of the hepatic impairment.[67] Congestive heart failure decreases metabolism of lidocaine and theophylline.[17] Renal failure decreases CYP activity not only in the kidneys, but also in the intestines and liver.[68] This is primarily because of downregulation of CYP gene expression.[68] Hepatic Phase II biotransformation is also reduced by renal failure. Presumably, substances that decrease biotransformation enzyme activity and downregulate gene expression accumulate in patients with renal failure.[68]

Effects of Anesthesia and Surgery on Biotransformation

Drug disposition is altered in the perioperative period. Although many other factors are probably also involved, biotransformation reactions are affected by anesthesia and surgery. In dogs anesthetized with halothane, the intrinsic hepatic clearance of propranolol is decreased, which implies that hepatic drug-metabolizing ability is impaired.[69] Halothane inhibits demethylation of aminopyrine in a dose-dependent fashion. Isoflurane has less effect, and enflurane does not affect aminopyrine biotransformation.[70]

Many investigators have studied the effects of anesthesia and surgery on antipyrine clearance. Antipyrine, an antipyretic that is no longer used therapeutically, does not bind to plasma proteins, has a low hepatic extraction ratio, and is not cleared by the kidneys. Therefore, clearance of antipyrine is solely dependent on the activity of hepatic drug-metabolizing enzymes. This permits the use of antipyrine clearance as an indicator of hepatic drug-metabolizing activity.[71] Clearance of antipyrine is generally increased after surgery conducted with a wide variety of general anesthetic techniques,[72,73] although there are exceptions to this rule. General anesthesia with enflurane does not appear to increase antipyrine clearance.[74] After operations lasting more than 4 hours, antipyrine clearance is decreased.[75] Presumably, major surgical trauma interferes with drug metabolism, although the precise mechanisms are not known. Antipyrine clearance is also increased after spinal anesthesia.[73] Therefore, general anesthesia is not a prerequisite for increased rates of biotransformation in the postoperative period, and other perioperative factors also affect drug metabolism. For example, the caloric source of iv nutritional regimens influences antipyrine clearance. It is decreased when the only caloric source is 5% dextrose, and increased when amino acids are substituted for dextrose.[76]

Factors other than altered rates of biotransformation, such as decreased hepatic blood flow during surgery,[27,28] can affect drug elimination in the perioperative period. In many patients the magnitude of these changes is too small to cause any clinically evident problems. However, in some patients clinically significant changes in drug elimination could occur. Decreased drug clearance can result in higher concentrations of drugs and increase the risk of adverse effects,

especially after prolonged surgery. Clinicians must be aware of the potential for excessive pharmacologic effects and must tailor doses accordingly.

BINDING OF DRUGS TO PLASMA PROTEINS

Drugs are present in the blood in two fractions. Some are simply dissolved in plasma water; the rest is bound to various components of whole blood, such as plasma proteins and red blood cells. Ideally, drug concentrations should be measured in whole blood because drugs are transported in blood, not plasma, and drugs equilibrate between erythrocytes and plasma very quickly.[77] Unfortunately, measurement of total drug levels and drug binding in whole blood is technically more difficult than in plasma or serum, so few investigators have directly measured whole blood binding. As a compromise, the blood:plasma concentration ratio can be used to estimate whole blood binding.

Drugs bind to plasma proteins in a reversible fashion that obeys the law of mass action. The rate constants of the association and dissociation reactions are k_1 and k_2, respectively. These reactions are very rapid, having half-lives of a few milliseconds. Binding of drugs to blood constituents other than proteins, such as erythrocytes, proceeds in an analogous fashion. The equilibrium dissociation constant, k_d, quantifies the affinity of drug-protein binding:

$$K_a = \frac{k_2}{k_1} = \frac{[\text{unbound drug}] \times [\text{protein}]}{[\text{drug-protein complex}]} \qquad (11\text{-}5)$$

The dissociation constant has units of moles per liter (mol/L), and is the drug concentration at which 50% of the binding sites are occupied. The degree of binding is dependent on the affinity of the protein for the drug, the protein concentration, and the concentration of drug available for binding.

The extent of plasma drug binding can be expressed as the *percentage of drug bound*, which is the percentage of the total drug present that is bound to plasma proteins. Alternatively,

the *free fraction*, which is the percentage of drug not bound to plasma proteins, can be used. For example, approximately 83% of fentanyl is bound to plasma proteins—thus, the free fraction is about 17%.[78,79]

Protein binding is affected by many factors, including temperature and pH.[77] At high drug concentrations, binding sites become saturated and the free fraction increases. There are also qualitative differences between species in plasma proteins that affect drug binding, and binding to purified human albumin may not correlate with binding in plasma.[77] Consequently, to provide clinically useful information, in vitro measurement of drug binding must be conducted at physiologic temperature and pH, with human plasma, and at concentrations within the usual therapeutic range.

Drug–protein binding has important pharmacologic implications, because only unbound drug can cross cell membranes to reach its sites of action. Also, free drug is more readily available for elimination. This has led to the frequently held misconception that drug bound to plasma proteins and other blood constituents is pharmacologically inert. This is not the case. As soon as unbound drug leaves circulation, the law of mass action dictates that some drug will dissociate from binding sites, which tends to restore the free drug concentration. This occurs almost instantaneously, so that the bound fraction of drug serves as a dynamic reservoir that buffers acute changes in the free drug concentration.

As discussed earlier, clearance of some drugs depends on the degree of protein binding. The extent of distribution of drugs throughout the body also depends on the degree of binding. At equilibrium, the portion of the total drug in the body that is in extravascular sites is determined by the relative affinity of blood binding versus binding to all other tissues. A drug that is highly bound to plasma proteins or erythrocytes cannot be extensively distributed unless it has even greater affinity for extravascular binding sites.

Binding Proteins

Two plasma proteins are primarily responsible for drug binding: albumin and α_1-acid glycoprotein (AAG). Drugs also bind to other plasma proteins, such as globulins or lipoproteins, and to erythrocytes. Drugs can bind to more than one protein. For example, fentanyl and sufentanil bind to albumin, AAG, globulins, and also to red blood cells.[79]

Albumin is the most important drug-binding protein. In addition to a wide range of drugs, including barbiturates, benzodiazepines, and penicillins, albumin binds endogenous compounds such as bilirubin. Many drugs bind to more than one site on the albumin molecule, and most drugs have one or two high-affinity, primary binding sites and a variable number of secondary, low-affinity sites. Studies with radioactively labeled drugs indicate that albumin has at least three discrete, high-affinity drug-binding sites. Diazepam, digitoxin, and warfarin each bind to a different site. The sites at which other drugs bind to albumin and the affinity of the drug–albumin bond can be determined by using these three markers.[80] This permits prediction of the likelihood of drug interactions as a result of one drug displacing another. Drugs that compete for the same binding site are more likely to displace one another than drugs that bind at different sites, and the drug with the lower affinity for the binding site will be more easily displaced.

Factors Affecting Drug Binding

The physicochemical properties of drugs influence binding to plasma proteins. Albumin is the major binding protein for organic acids, such as penicillins and barbiturates. Basic drugs also bind to albumin, but to a lesser extent. The primary binding protein for many basic drugs is AAG (Table 11-5). Basic drugs also bind to lipoproteins and globulins. AAG is an acute phase reactant, and its concentration increases in many acute and chronic illnesses.

TABLE 11-5 Drugs Binding to α_1-Acid Glycoprotein

Alfentanil	Methadone
Alprenolol	Propranolol
Bupivacaine	Quinidine
Disopyramide	Ropivacaine
Fentanyl	Sufentanil
Lidocaine	Verapamil
Meperidine	

In general, the greater the lipid solubility of a drug, the greater the binding to plasma proteins (Table 11-6).[79,81,82,83,84,85,86,87,88,89,90,91,92,93,94,95,96,97,98,99] Water-soluble drugs, such as neuromuscular blocking agents, are bound to a substantially lesser extent than lipid-soluble drugs, like propofol. This is also true for drugs that belong to the same class. The degree of binding of opioids parallels their lipid solubility: morphine is the least bound, fentanyl and its derivatives are highly bound, and meperidine is intermediate.

Similarly, bupivacaine is bound to a greater extent than lidocaine.

TABLE 11-6 Plasma Protein Binding of Some Drugs Used in Anesthesiology

·CLASS/DRUG	·PERCENTBOUND	·REFERENCE
Opioids		
Alfentanil	92	79
Fentanyl	84	79
Meperidine	53–63	81
Methadone	60–90	82
Morphine	20–35	82,83,84
Sufentanil	92	79
Intravenous Anesthetics		
Methohexital	73	85
Propofol	98	86
Thiopental	85	87
Neuromuscular Blockers		
Pancuronium	11–29	88,89
Rocuronium	46	90
Vecuronium	30	88
Local Anesthetics[a]		
Bupivacaine	95	91
Lidocaine	70	91
Ropivacaine	94	92

Benzodiazepines		
Diazepam	97–99	93
Lorazepam	88–92	94
Midazolam	96	95
Cardiovascular Drugs		
Digoxin	20–30	96
Diltiazem	77–80	97
Esmolol	55	98
Nifedipine	96–98	97
Propranolol	89	99
Verapamil	84–91	97

[a]At nontoxic concentrations. At toxic plasma concentrations, binding of local anesthetic decreases, leading to a marked increase in the free drug concentration.

Many physiologic and pathologic states cause quantitative and qualitative changes in the primary drug-binding plasma proteins, albumin and AAG. Drug binding may also be affected by acid-base disturbances that alter the degree of ionization of drugs and proteins, and by accumulation of endogenous compounds that compete for drug-binding sites.

Maternal and Neonatal Drug Binding

Binding of drugs in pregnancy and in the fetus or neonate has received much attention because of its impact on placental drug transfer. Pregnant women have reduced levels of albumin, and the binding of many organic acids, such as phenytoin, is decreased at term.[100] Although thiopental is also an organic acid, unlike phenytoin, the free fraction of thiopental is not increased in patients undergoing cesarean section,[101] so that usual doses of thiopental do not result in excessive free drug levels. This is fortunate, because high free drug levels would increase the risk of side effects and enhance placental transfer of the drug. The free fraction of diazepam, which binds primarily to albumin, is increased at term.[102] AAG levels are not changed during pregnancy.[102] However, the free fractions of lidocaine and propranolol are, nonetheless, increased at term.[102]

Neonates have decreased levels of albumin and AAG,[100,101,102,103] and neonatal albumin has less affinity for some drugs.[100,103] Consequently, the free fraction of many drugs, especially those that bind to AAG, is higher in the neonate than in the mother.[103] Although binding of many drugs is decreased in neonates, this does not affect the unbound concentration of drugs transferred across

the placenta. Under near steady-state conditions, maternal and fetal free drug concentrations are the same, although the total fetal level is lower. Because the free drug is the more pharmacologically active species, the decrease in maternal plasma protein drug binding is of greater consequence as far as placental transfer of drugs is concerned. Decreased drug binding must be considered in neonatal therapeutics.[60]

Age and Sex

The plasma concentrations of the primary drug-binding proteins change with increasing age: albumin decreases slightly, whereas AAG tends to increase.[104,105,106] The free fractions of lidocaine, meperidine, and propranolol, all of which bind to AAG, are not changed in the elderly.[81,106,107] Similarly, binding of drugs to albumin is minimally altered. The binding of midazolam does not change,[95] and diazepam binding may decrease slightly.[22,104,108] The typical magnitude of age-associated decreases in drug binding is illustrated by thiopental. The average free fraction of thiopental of 18% in young adults only increases to 22% in geriatric patients.[109] Clinically significant changes in drug binding in elderly patients are more often caused by pathologic processes than by age per se. Age-related changes in drug–protein binding are usually not clinically significant.[110]

Studies comparing drug binding in men and women have not found any clinically significant differences between the sexes. This is not surprising, because the concentrations of albumin and AAG in men and women do not differ significantly.[105]

Hepatic Disease

The plasma albumin concentration is often decreased in patients with liver disease. Drug binding may also be affected by qualitative changes in the albumin molecule that decrease affinity for drugs, and by accumulation of endogenous substances, such as bilirubin, that compete for drug-binding sites.[13] Although hepatic diseases vary widely in pathophysiology and severity, it is possible to make some generalizations regarding their impact on drug binding. The free fractions of drugs that bind primarily to albumin are increased. This is true for organic bases such as diazepam[22,111] and morphine,[83] and for the organic acids phenytoin[83] and thiopental.[112,113] The free fractions of basic drugs, such as meperidine[24] and lidocaine,[25] are not increased in patients with acute viral hepatitis, which suggests that drug binding to AAG is minimally affected by liver disease.

Renal Disease

Albumin levels tend to decrease in all types of renal disease. However, even when albumin levels are normal, binding of phenytoin[83] and thiopental[87] is decreased. The free fraction of phenytoin is correlated with both the albumin concentration and the severity of renal dysfunction.[83] This indicates that renal failure reduces the affinity of albumin for organic acids. Dialysis does not restore the affinity of albumin for thiopental or phenytoin.[83,87] The plasma–protein binding of many other organic acids is also decreased in renal failure.[114]

The effect of renal disease on the binding of basic drugs depends on whether the drug binds primarily to albumin or to AAG, and on the type of renal disease. The free fraction of diazepam, which binds primarily to albumin, is increased in the nephrotic syndrome, renal failure, and after renal transplantation.[115] Similarly, binding of morphine is decreased in uremia.[83] Binding of other basic drugs varies according to the changes in AAG in different types of renal disease. Lidocaine binding increases in renal failure and after renal transplantation, conditions associated with increased AAG levels.[115] Likewise, propranolol binding is increased in patients with renal disease and elevated concentrations of AAG.[99] Lidocaine binding is not altered in nephrotic patients who have normal levels of AAG.[115]

Other Diseases, Surgery, and Trauma

Patients with inflammatory diseases, such as rheumatoid arthritis and Crohn's disease, have

increased levels of AAG and, consequently, decreased free fractions of drugs that bind to this protein.[99,116] Malignant disease is also associated with elevated levels of AAG, and increased binding of lidocaine, propranolol, and other basic drugs has been demonstrated in patients with cancer.[117] In contrast, albumin tends to decrease in patients with malignancies, which can decrease binding of acidic drugs.[116] After acute myocardial infarction, AAG levels double and remain elevated for about 3 weeks.[118] Consequently, the binding of lidocaine and propranolol is increased.[118,119]

The catabolic state that follows surgery and trauma decreases plasma albumin levels.[120] In contrast, the concentration of AAG increases after trauma[121] and surgery[122] and remains elevated for several weeks. These changes result in alterations in drug binding. The free fraction of phenytoin increases after surgery, probably secondary to decreased levels of albumin, although the contemporaneous increase in free fatty acids may result in competition for binding sites.[120] Higher AAG levels increase binding of basic drugs, such as lidocaine and propranolol, after trauma[121] and surgery.[123,124]

PHARMACOKINETIC PRINCIPLES

The concentration of a drug at its site or sites of action is a fundamental determinant of its pharmacologic effects. Because drugs are transported to and from their sites of action in the blood, the concentration at the active site is in turn a function of the concentration in the blood. The change in drug concentration over time in the blood, at the site of action, and in other tissues is a result of complex interactions of multiple biologic factors with the physicochemical characteristics of the drug. Together, these factors determine the rate, extent, and pattern

of drug absorption, distribution, metabolism, and excretion. The term "pharmacokinetics," derived from the Greek words *pharmakon* (medicine) and *kinesis* (movement), refers to the quantitative analysis of the relationship between the dose of a drug and the ensuing changes in drug concentration in the blood and other tissues.

Early pharmacokinetic studies of intravenous and inhalational anesthetics used physiologic or perfusion models. In these models, body tissues are classified according to similarities in perfusion and affinity for drugs.[125] Highly perfused tissues, including the brain, heart, lungs, liver, and kidneys, make up the vessel-rich group. Muscle and skin comprise the lean tissue group, and fat is considered as a separate group. The vessel-poor group, which has minimal effect on drug distribution and elimination, is composed of bone and cartilage. Physiologic pharmacokinetic models made major contributions to understanding the factors influencing recovery from thiopental. These models established that awakening after a single dose was primarily the result of redistribution of thiopental from the brain to muscle and skin.[7,8] Distribution to other tissues and metabolism played minor roles. This fundamental concept, *redistribution*, also applies to all lipophilic drugs. Physiologic models have also contributed greatly to our understanding of the uptake and distribution of inhalational anesthetics.[126]

Physiologic pharmacokinetic models provide much insight into factors affecting drug action. They can predict the effects of physiologic changes, such as altered regional blood flows or reduced cardiac output, on drug distribution and elimination. The disadvantage of perfusion-based models is their complexity. Verification of these models requires measurement of drug concentrations in many different tissues, which is rarely practical.[125] Because of these disadvantages, simpler pharmacokinetic models have been developed. In these models the body is envisaged as composed of one or more *compartments.* Drug concentrations in the blood are used to define the relationship between dose and the time course of changes of the drug concentration.[127] It is critically important to understand that the different "compartments" of a compartmental pharmacokinetic model cannot be equated with the tissue groups that make up physiologic pharmacokinetic models. Compartments are theoretical entities that are used to derive pharmacokinetic parameters, such as clearance, volume of distribution, and half-lives. These parameters quantify drug distribution and elimination.

Although the simplicity of compartmental models, compared to physiologic pharmacokinetic

models, has its advantages, it also has some disadvantages. For example, cardiac output is not a parameter of compartmental models, and compartmental models therefore cannot be used to predict directly the effect of cardiac failure on drug disposition. However, compartmental pharmacokinetic models can still quantify the effects of reduced cardiac output on the disposition of a drug if a group of patients with cardiac failure is compared to a group of otherwise healthy subjects.

The discipline of pharmacokinetics is, to the despair of many, mathematically based. In the succeeding sections, formulas are used to illustrate the concepts needed to understand and interpret pharmacokinetic studies. Readers are encouraged to concentrate on the concepts, not the formulas.

Pharmacokinetic Concepts

Rate Constants and Half-Lives

The disposition of most drugs follows *first-order* kinetics. A first-order kinetic process is one in which a constant fraction of the drug is removed during a finite period of time. This fraction is equivalent to the rate constant of the process. Rate constants are usually denoted by the letter *k* and have units of "inverse time," such as min^{-1} or h^{-1}. If 10% of the drug is eliminated per minute, then the rate constant is 0.1 min^{-1}. Because a constant fraction is removed per unit of time in first-order kinetics, the absolute amount of drug removed is proportional to the concentration of the drug. It follows that, in first-order kinetics, the rate of change of the concentration at any given time is proportional to the concentration present at that time. When the concentration is high, it will fall faster than when it is low. First-order kinetics apply not only to elimination, but also to absorption and distribution.[127]

Rather than using rate constants, the rapidity of pharmacokinetic processes is often described with half-lives—the time required for the concentration to change by a factor of 2. Half-lives are calculated directly from the corresponding rate constants with this simple equation:

$$t_{1/2} = \frac{(\ln 2)}{k} = \frac{0.693}{k} \qquad (11\text{-}6)$$

Thus, a rate constant of 0.1 min^{-1} translates into a half-life of 6.93 minutes. The half-life of any first-order kinetic process, including drug absorption, distribution, and elimination, can be calculated. First-order processes asymptotically approach completion, because a constant fraction of the drug, not an absolute amount, is removed per unit of time. However, after five half-lives, the process will be almost 97% complete (Table 11-7). For practical purposes, this is close enough to 100% and can be considered as such.

TABLE 11-7 Half-Lives and Percent of Drug Removed

·NUMBER OF HALF-LIVES	·PERCENT OF DRUG REMAINING	·PERCENT OF DRUG REMOVED
0	100	0
1	50	50
2	25	75
3	12.5	87.5

4	6.25	93.75
5	3.125	96.875

Volumes of Distribution

6 The volume of distribution quantifies the extent of drug distribution. The physiologic factor that governs the extent of drug distribution is the overall capacity of tissues versus the capacity of blood for that drug. Overall tissue capacity for uptake of a drug is in turn a function of the total mass of the tissues into which a drug distributes and their average affinity for the drug. In compartmental pharmacokinetic models, drugs are envisaged as distributing into one or more "boxes," or compartments. These compartments cannot be equated directly with specific tissues. Rather, they are hypothetical entities that permit analysis of drug distribution and elimination and description of the drug concentration versus time profile.

The volume of distribution is an "apparent" volume because it represents the size of these hypothetical boxes, or compartments, that is necessary to explain the concentration of drug in a reference compartment, usually called the *central* or *plasma compartment.* The volume of distribution, *Vd*, relates the total amount of drug present to the concentration observed in the central compartment:

$$Vd = \frac{\text{total amount of drug present}}{\text{concentration}} \qquad (11\text{-}7)$$

This formula is logical. If a drug is extensively distributed, then the concentration will be lower relative to the amount of drug present, which equates to a larger volume of distribution. For example, if a total of 10 mg of drug is present and the concentration is 2 mg/L, then the apparent volume of distribution is 5 L. On the other hand, if the concentration was 4 mg/L, then the volume of distribution would be 2.5 L.

7 Simply stated, the apparent volume of distribution is a numeric index of the extent of drug distribution that does not have any relationship to the actual volume of any tissue or group of tissues. It may be as small as plasma volume, or, if overall tissue uptake is extensive, the apparent volume of distribution may greatly exceed the actual total volume of the body (Fig. 11-4). In general, lipophilic drugs have larger volumes of distribution than hydrophilic drugs (see Fig. 11-4). Because the volume of distribution is a mathematical approximation, it cannot be directly correlated with the anatomic and physiologic factors that influence drug distribution. Determination of the volume of distribution from a compartmental model does not provide any information regarding the tissues into which the drug actually distributes or the concentrations in those tissues. Despite these limitations, the volume of distribution provides useful information. For example, an increase in the volume of distribution means that a larger loading dose will be required to "fill up the box" and achieve the same concentration. Various pathologic conditions can alter the volume of distribution, necessitating therapeutic adjustments.

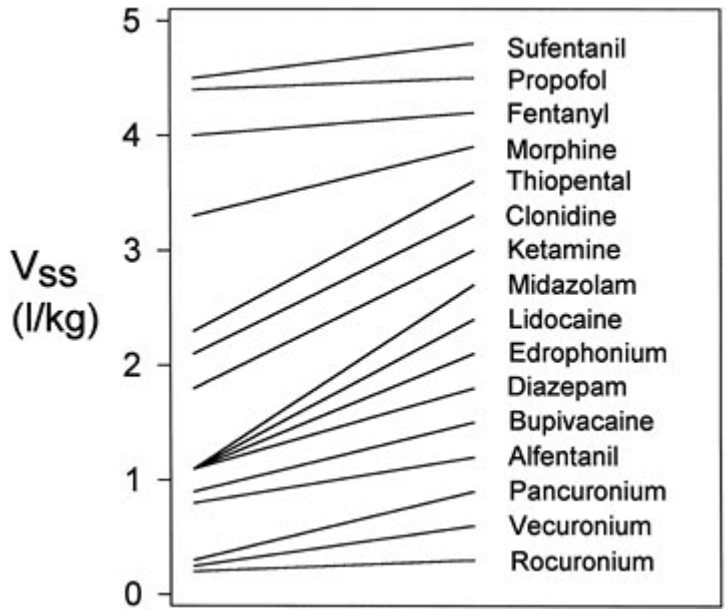

FIGURE 11-4. The volume of distribution of some drugs used in anesthesiology.

Total Drug Clearance

8 In compartmental pharmacokinetic models, the ability of the system as a whole to irreversibly eliminate a drug is quantified by the *total drug clearance* or *elimination clearance.* Elimination clearance is the portion of the volume of distribution from which drug is completely and irreversibly removed during a given time interval. It is analogous to creatinine clearance, and, like creatinine clearance, drug clearance has units of flow. Drug clearance is often corrected for weight or body surface area, in which case the units are mL/min/kg or mL/min/m^2, respectively.

Elimination clearance, *Cl*, can be calculated from the declining blood levels observed after an iv injection, as follows:

$$Cl = \frac{\text{dose}}{\text{area under the concentration versus time curve}} \qquad (11\text{-}8)$$

Again, this formula is intuitively logical. If a drug is rapidly removed from the plasma, its concentration will fall more quickly than the concentration of a drug that is less readily eliminated. This results in a smaller area under the concentration versus time curve, which equates to greater clearance.

A significant limitation of calculating elimination clearance from compartmental pharmacokinetic models is that the relative contribution of different organs to drug elimination cannot be determined. Nonetheless, estimation of drug clearance with these models has made important contributions to clinical pharmacology. In particular, these models have provided a great deal of clinically useful information regarding altered drug elimination in various pathologic conditions.

Compartmental Pharmacokinetic Models

One-Compartment Model

Although for most drugs the one-compartment model is an oversimplification, it does serve to illustrate the basic relationships among clearance, volume of distribution, and the elimination half-life. In this model, the body is envisaged as a single homogeneous compartment. Drug distribution after injection is assumed to be instantaneous, so there are no concentration gradients within the

compartment. The concentration can decrease only by elimination of drug from the system. The plasma concentration versus time curve for a hypothetical drug with one-compartment kinetics is shown in Figure 11-5. With the concentration plotted on a logarithmic scale, the concentration versus time curve becomes a straight line. The slope of the logarithm of concentration versus time is equal to the first-order elimination rate constant.

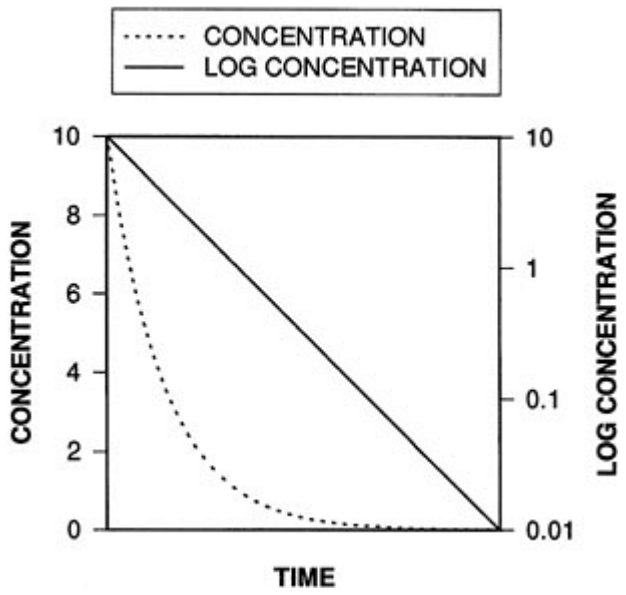

FIGURE 11-5. The plasma concentration, plotted on both linear (—, *left vertical axis*) and logarithmic (---, *right vertical axis*) scales, versus time for a hypothetical drug exhibiting one-compartment, first-order pharmacokinetics.

Immediately after injection, before any drug can be eliminated, the amount of drug present is equal to the dose. Therefore, by modifying Equation 11-7, the volume of distribution can be calculated:

$$Vd = \frac{\text{dose}}{\text{initial concentration}} \qquad (11\text{-}9)$$

In the one-compartment model, drug clearance, *Cl*, is equal to the product of the elimination rate constant, k_e, and the volume of distribution:

$$Cl = k_e \cdot Vd \qquad (11\text{-}10)$$

Combining Equations 11-6 and 11-10 yields:

$$Cl = \frac{0.693 \cdot Vd}{t_{1/2}}; \text{thus}: \frac{0.693 \cdot Vd}{Cl} \qquad (11\text{-}11)$$

9 Therefore, the greater the clearance, the shorter the elimination half-life, which is easy to understand. Less obvious is the impact of the volume of distribution on the elimination half-life. It is easiest to understand if the physiologic correlate of a large volume of distribution is considered. A large volume of distribution reflects extensive tissue uptake of a drug, so that only a small fraction of the total amount of drug is in the blood and accessible to the organs of elimination. Consequently, the greater the volume of distribution, the longer the elimination half-life. For drugs that exhibit multicompartment pharmacokinetics, the relationship among clearance, volume of distribution, and the elimination half-life is not a simple linear one such as Equation 11-11. However, the same principles apply. All else being equal, the greater the clearance, the shorter the elimination half-life; the larger the volume of distribution, the longer the elimination half-life. Thus, the elimination half-life depends on two other variables, clearance and volume of distribution, that characterize, respectively, the extent of drug distribution and efficiency of drug

elimination.

Two-Compartment Model

For many drugs, a graph of the logarithm of the plasma concentration versus time after an iv injection is similar to the schematic graph shown in Figure 11-6. There are two discrete phases in the decline of the plasma concentration. The first phase after injection is characterized by a very rapid decrease in concentration. The rapid decrease in concentration during this "distribution phase" is largely caused by passage of drug from the plasma into tissues. The distribution phase is followed by a slower decline of the concentration owing to drug elimination. Elimination also begins immediately after injection, but its contribution to the drop in plasma concentration is initially much smaller than the fall in concentration because of drug distribution.

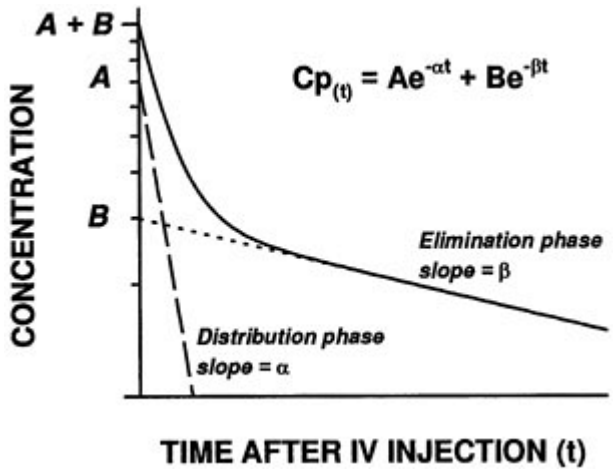

FIGURE 11-6. A schematic graph of the plasma concentration, on a logarithmic scale, versus time for a drug with a distribution phase preceding the elimination phase (two-compartment or biexponential kinetics). See text for explanation.

To account for this biphasic behavior, one must consider the body to be made up of two compartments, a central (or plasma) compartment and a peripheral compartment (Fig. 11-7). This two-compartment model assumes that it is the central compartment into which the drug is injected and from which the blood samples for measurement of concentration are obtained, and that drug is eliminated only from the central compartment. Drug distribution within the central compartment is considered to be instantaneous. In reality, this last assumption cannot be true. However, drug uptake into some of the highly perfused tissues is so rapid that it cannot be detected as a discrete phase on the plasma concentration versus time curve.

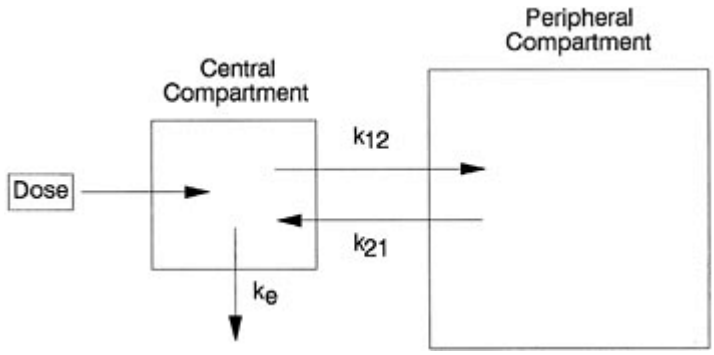

FIGURE 11-7. A two-compartment pharmacokinetic model. See text for explanation.

The distribution and elimination phases can be characterized by graphic analysis of the plasma concentration versus time curve, as shown in Figure 11-6. The elimination phase line is extrapolated back to time zero (the time of injection). At any time, the difference between the total concentration and the concentration on the extrapolated elimination phase line is equal to a corresponding point, at that time, on the distribution phase line. In Figure 11-6, the zero time intercepts of the distribution and elimination lines are points *A* and *B*, respectively. The *hybrid rate constants*, α and β, are equal to the slopes of the two lines, and are used to calculate the distribution and elimination half-lives; α and β are called hybrid rate constants because they depend on both distribution and elimination processes.

At any time after an iv injection, the plasma concentration of drugs with two-compartment kinetics is equal to the sum of two exponential terms:

$$Cp_{(t)} = Ae^{-\alpha t} + Be^{-\beta t}, \qquad (11\text{-}12)$$

where t = time, $Cp_{(t)}$ = plasma concentration at time t, A = y-axis intercept of the distribution phase line, α = hybrid rate constant of the distribution phase, B = y-axis intercept of the elimination phase line, and β = hybrid rate constant of the elimination phase. The first term characterizes the distribution phase and the second term characterizes the elimination phase. Immediately after injection, the first term represents a much larger fraction of the total plasma concentration than the second term. After several distribution half-lives, the value of the first term approaches zero, and the plasma concentration is essentially equal to the value of the second term (see Fig. 11-6).

In multicompartment models, the drug is initially distributed only within the central compartment. Therefore, the initial apparent volume of distribution is the volume of the central compartment. Immediately after injection, the amount of drug present is the dose, and the concentration is the extrapolated concentration at time t = 0, which is equal to the sum of the intercepts of the distribution and elimination lines. The volume of the central compartment, $V1$, is calculated by modifying Equation 11-7:

$$V1 = \frac{\text{dose}}{\text{initial plasma concentration}} = \frac{\text{dose}}{A + B} \qquad (11\text{-}13)$$

The volume of the central compartment is important in clinical anesthesiology because it is the pharmacokinetic parameter that determines the peak plasma concentration after an iv bolus injection. Hypovolemia, for example, reduces the volume of the central compartment. If doses are not correspondingly

reduced, the higher plasma concentrations will increase the incidence of adverse pharmacologic effects.

Immediately after iv injection, all of the drug is in the central compartment. Simultaneously, three processes begin. Drug moves from the central to the peripheral compartment, which also has a volume, $V2$. This intercompartmental transfer is a first-order process, and its magnitude is quantified by the rate constant k_{12}. As soon as drug appears in the peripheral compartment, some passes back to the central compartment, a process characterized by the rate constant k_{21}. The transfer of drug between the central and peripheral compartments is quantified by the *distributional* or *intercompartmental clearance:*

$$\begin{aligned} \textit{Intercompartmental clearance} &= V1 \cdot k_{12} \\ &= V2 \cdot k_{21} \end{aligned} \qquad (11\text{-}14)$$

$= V_2 \cdot k_{21}$

The third process that begins immediately after administration of the drug is irreversible removal

of drug from the system via the central compartment. As in the one-compartment model, the elimination rate constant is k_e, and *elimination clearance* is:

$$\textit{Elimination clearance} = V1 \cdot k_e \qquad (11\text{-}15)$$

The rapidity of the decrease in the central compartment concentration after iv injection depends on the magnitude of the compartmental volumes, the intercompartmental clearance, and the elimination clearance.

At equilibrium, the drug is distributed among the central and the peripheral compartment, and by definition, the concentrations in the compartments are equal. Therefore, the ultimate volume of distribution, termed the volume of distribution at steady-state (V_{ss}), is the sum of $V1$ and $V2$. Extensive tissue uptake of a drug is reflected by a large volume of the peripheral compartment, which, in turn, results in a large V_{ss}. Consequently, V_{ss} can greatly exceed the actual volume of the body.

As in the single-compartment model, in multicompartment models the elimination clearance is equal to the dose divided by the area under the concentration versus time curve. This area, as well as the compartmental volumes and intercompartmental clearances, can be calculated from the intercepts and hybrid rate constants, without having to reach steady-state conditions.[128]

Three-Compartment Model

After iv injection of some drugs, the initial, rapid distribution phase is followed by a second, slower distribution phase before the elimination phase becomes evident. Therefore, the plasma concentration is the sum of three exponential terms:

$$Cp_{(t)} = Ae^{-\alpha t} + Be^{-\beta t} + G^{-\gamma t}, \qquad (11\text{-}16)$$

where t = time, $Cp_{(t)}$ = plasma concentration at time t, A = intercept of the rapid distribution phase line, α = hybrid rate constant of the rapid distribution phase, B = intercept of the slower distribution phase line, α = hybrid rate constant of the slower distribution phase, G = intercept of the elimination phase line, and β = hybrid rate constant of the elimination phase. This triphasic behavior is explained by a three-compartment pharmacokinetic model (Fig. 11-8). As in the two-compartment model, the drug is injected into and eliminated from the central compartment. Drug is reversibly transferred between the central compartment and two peripheral compartments, which accounts for two distribution phases. Drug transfer between the central compartment and the more rapidly equilibrating, or "shallow," peripheral compartment is characterized by the first-order rate constants k_{12} and k_{21}. Transfer in and out of the more slowly equilibrating, "deep" compartment is characterized by the rate constants k_{13} and k_{31}. In this model, there are three compartmental volumes: *V1, V2*, and *V3*, whose sum equals V_{ss}; and three clearances: the rapid intercompartmental clearance, the slow intercompartmental clearance, and elimination clearance.

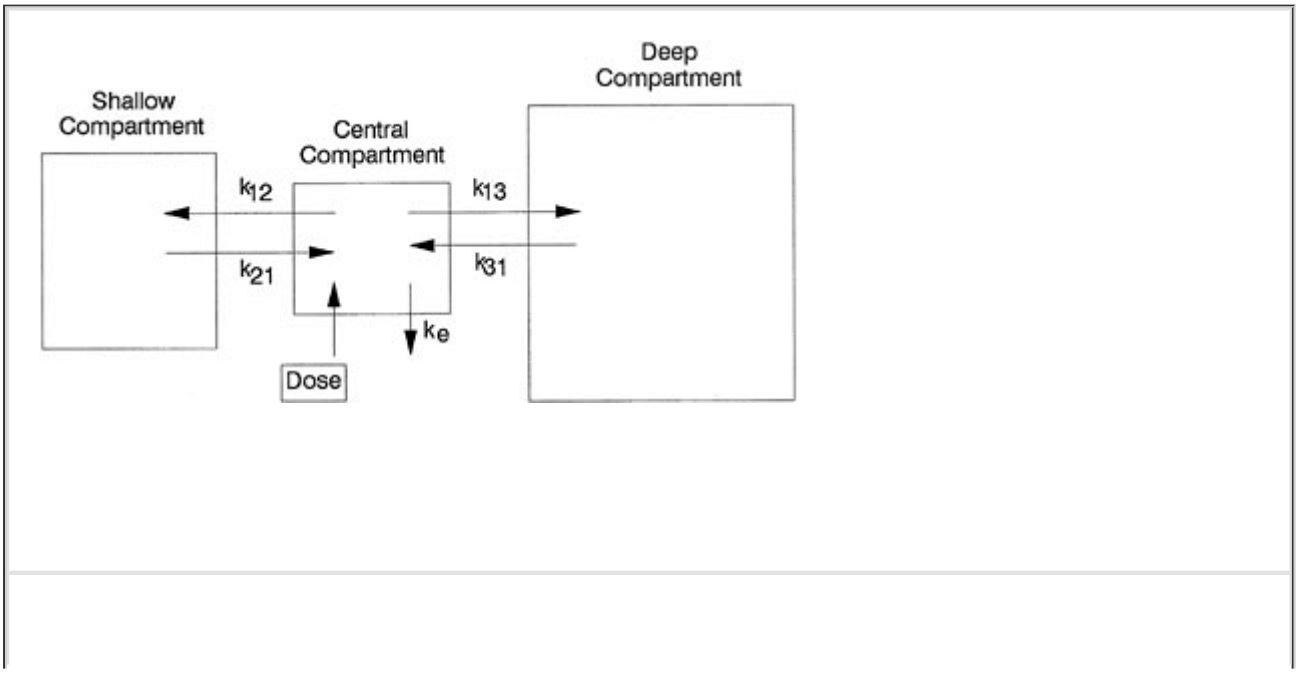

FIGURE 11-8. A three-compartment pharmacokinetic model. See text for explanation.

The pharmacokinetic parameters of interest to clinicians, such as clearance, volumes of distribution, and distribution and elimination half-lives, are determined by calculations analogous to those used in the two-compartment model. Accurate estimates of these parameters depend on accurate characterization of the measured plasma concentration versus time data. A frequently encountered problem is that the duration of sampling is not long enough to define accurately the elimination phase.[129] Similar problems arise if the assay cannot detect low concentrations of the drug. Whether a drug exhibits two- or three-compartment kinetics is of no clinical consequence. In fact, some drugs have two-compartment kinetics in some patients and three-compartment kinetics in others.[108,130] In selecting a pharmacokinetic model, the most important factor is that it accurately characterize the measured concentrations. In general, the model with the smallest number of compartments or exponents that accurately reflects the data is used.

Almost all earlier pharmacokinetic studies used *two-stage modeling*. With this technique, pharmacokinetic parameters were estimated independently for each subject and then averaged to provide estimates of the typical parameters for the population. One problem with this approach is that if outliers are present, averaging parameters could result in a model that does not accurately predict typical drug concentrations. Currently, most pharmacokinetic models are developed using *population pharmacokinetic modeling*, which has been made feasible because of advances in modeling software and increased computing power. With these techniques, the pharmacokinetic parameters are estimated using all the concentration versus time data from the entire group of subjects in a single stage, using sophisticated nonlinear regression methods. This modeling technique provides single estimates of the typical parameter values for the population.

Effects of Hepatic or Renal Disease on Pharmacokinetic Parameters

As discussed earlier, hepatic and renal disease not only affect the ability to eliminate drugs, but also change the binding of drugs to plasma proteins. Consequently, the effects of altered protein binding and the effects of impaired organ function must be considered to understand fully the impact of hepatic or renal disease on pharmacokinetic variables.

The extent of drug distribution depends on the relative affinity of blood versus tissues for the drug. Therefore, if the free fraction in plasma increases, the volume of distribution must also increase. The magnitude of the change depends on the

initial free fraction and volume of distribution. An increase in the free fraction will produce the greatest increase in the volume of distribution for drugs that are highly bound to plasma proteins and have small volumes of distribution. In contrast, changes in plasma protein binding of drugs with large volumes of distribution have minimal effects on the volume of distribution, because so little of the total amount of drug is in the plasma.[131]

In theory, a parallel change in tissue binding would cancel the effect of changes in plasma binding. However, this appears to be uncommon. Increased volumes of distribution of diazepam[22] and propranolol[132] associated with increased free fractions have been observed in patients with hepatic disease. Decreased binding of thiopental in patients with renal failure also increases the volume of distribution.[87]

The effect of altered protein binding on total drug clearance also depends on the initial magnitude of the clearance. Increases in the free fraction of drugs with low hepatic extraction ratios and drugs eliminated primarily by glomerular filtration cause a proportional increase in clearance. In contrast, altered protein binding has little effect on drugs with high hepatic or renal clearance. The effect of an increased free fraction on elimination depends on the net effect on clearance and the volume of distribution.[131] The elimination half-life will increase if increased volume of

distribution is the paramount change, or decrease if increased clearance predominates.

Diverse pathophysiologic changes preclude precise prediction of the pharmacokinetics of a given drug in individual patients with hepatic or renal disease. However, some generalizations can be made. Binding of drugs to albumin is decreased, so that doses of drugs given as an iv bolus, such as thiopental, should be reduced. In patients with hepatic disease, the elimination half-life of drugs metabolized or excreted by the liver is often increased because of decreased clearance, and, possibly, increased volume of distribution. Repeated doses of such drugs as benzodiazepines, opioids, and barbiturates may accumulate, leading to excessive and prolonged pharmacologic effects. Recovery from small doses of drugs such as thiopental and fentanyl is largely the result of redistribution, so recovery from conservative doses will be minimally affected. In patients with renal failure, similar concerns apply to the administration of drugs excreted by the kidneys. It is almost always better to underestimate a patient's dose requirement, observe the response, and give additional drug if necessary.

Nonlinear Pharmacokinetics

The physiologic and compartmental models thus far discussed are based on the assumption that drug distribution and elimination are first-order processes. Therefore, their parameters, such as clearance and elimination half-life, are independent of the dose or concentration of the drug. However, the rate of elimination of a few drugs is dose dependent, or *nonlinear.*

Elimination of drugs involves interactions with either enzymes catalyzing biotransformation reactions or carrier proteins for transmembrane transport. If sufficient drug is present, the capacity of the drug-eliminating systems can be exceeded. When this occurs, it is no longer possible to excrete a constant fraction of the drug present to the eliminating system, and a constant amount of drug is excreted per unit time. Phenytoin is a well-known example of a drug that exhibits nonlinear elimination at therapeutic concentrations. In theory, all drugs are cleared in a nonlinear fashion. In practice, the capacity to eliminate most drugs is so great that this is usually not evident, even with toxic concentrations.

PHARMACODYNAMIC PRINCIPLES

In its broadest sense, pharmacodynamics is the study of the effects of drugs on the body. Classically, pharmacologic effects have been quantified by dose-response studies. Advances in drug assay techniques and data analysis now allow definition of the relationship between the drug concentration and the associated pharmacologic effect in vivo. As a result, the term "pharmacodynamics" has acquired a more specific definition: the quantitative analysis of the relationship between the drug concentration in the blood, or at the site of action, and the resultant effects of the drug on physiologic processes.[133]

Dose-Response Curves

10 Dose-response studies determine the relationship between increasing doses of a drug and the ensuing changes in pharmacologic effects. Schematic dose-response curves are shown in Figure 11-9, with the dose plotted on both linear and logarithmic scales. There is a curvilinear relationship between dose and the intensity of response. Low doses produce little pharmacologic effect. Once effects become evident, a small increase in dose produces a relatively large change in effect. At near-maximal response, large increases in dose produce little change in effect. Usually the dose is plotted on a logarithmic scale (see Fig. 11-9, right panel), which demonstrates the linear relationship between the logarithm of the dose and the intensity of the response between 20 and 80% of the maximum effect.

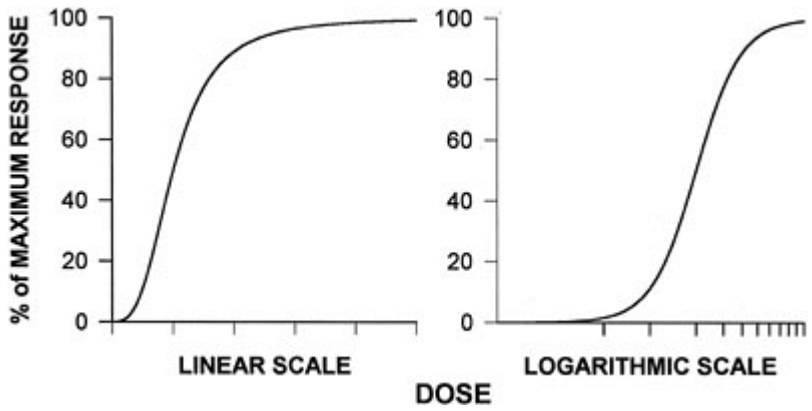

FIGURE 11-9. Left panel: A schematic curve of the effect of a drug plotted against dose. **Right panel:** The same curve, replotted with dose on a logarithmic scale. This yields the familiar sigmoid dose-response curve, which is linear between 20 and 80% of the maximal effect.

Dose-response curves provide information regarding four aspects of the relationship of dose and pharmacologic effect. The *potency* of the drug—the dose required to produce a given effect—is determined. Potency is usually expressed as the dose required to produce a given effect in 50% of subjects, the *ED50.* The *slope* of the curve between 20 and 80% of the maximal effect indicates the rate of increase in effect as the dose is increased. The maximum effect is referred to as the *efficacy* of the drug. Finally, if curves from multiple subjects are generated, the *variability* in potency, efficacy, and the slope of the dose-response curve can be estimated.

The dose needed to produce a given pharmacologic effect varies considerably, even in "normal" patients. The patient most resistant to the drug usually requires a dose two- to threefold greater than the patient with the lowest dose requirements. This variability is caused by differences between individuals in the relationship between drug concentration and pharmacologic effect, superimposed on differences in pharmacokinetics.

Dose-response studies have the disadvantage of not being able to determine whether variations in pharmacologic response are caused by differences in pharmacokinetics, pharmacodynamics, or both.

Concentration-Response Relationships

Ideally, the concentration of drug at its site of action should be used to define the concentration-response relationship. Unfortunately, these data are rarely available, so the relationship between the concentration of drug in the blood and pharmacologic effect is studied instead. This relationship is easiest to understand if the changes in pharmacologic effect that occur during and after an iv infusion of a hypothetical drug are considered. If a drug is infused at a constant rate, the plasma concentration initially increases rapidly and asymptotically approaches a steady-state level after approximately five elimination half-lives have elapsed (Fig. 11-10). The effect of the drug initially increases very slowly, then more rapidly, and eventually also reaches a steady state. When the infusion is discontinued, indicated by point *C* in Figure 11-10, the plasma concentration immediately decreases because of drug distribution and elimination. However, the effect stays the same for a short period, and then also begins to decrease—there is always a time lag between changes in plasma concentration and changes in pharmacologic response. Figure 11-10 also demonstrates that the same plasma concentration is associated with different responses if the concentration is changing. At points *A* and *B* in Figure 11-10, the plasma concentrations are the

same, but the effects at each time differ. When the concentration is increasing, there is a concentration gradient from blood to the site of action. When the infusion is discontinued, the concentration gradient is reversed. Therefore, at the same plasma concentration, the concentration at the site of action is higher after, compared to during, the infusion. This is associated with a correspondingly greater effect.

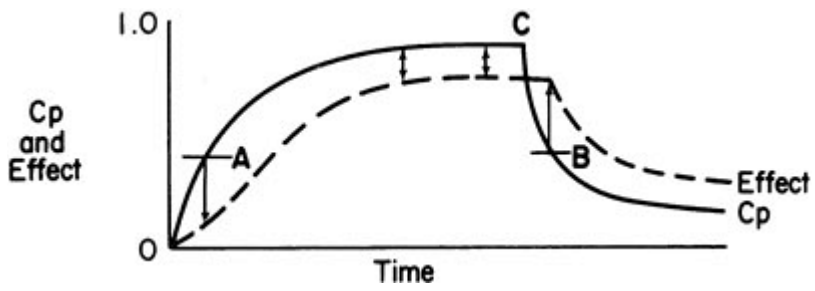

FIGURE 11-10. The changes in plasma drug concentration and pharmacologic effect during and after an intravenous infusion. See text for explanation. (Reprinted with permission from Stanski DR, Sheiner LB: Pharmacokinetics and pharmacodynamics of muscle relaxants. Anesthesiology 51:103, 1979.)

In theory, there must be some degree of temporal disequilibrium between plasma concentration and drug effect for all drugs with extravascular sites of action. However, for some drugs, the time lag may be so short that it cannot be demonstrated. The magnitude of this temporal disequilibrium depends on several factors:

1. perfusion of the organ on which the drug acts
2. the tissue:blood partition coefficient of the drug
3. the rate of diffusion or transport of the drug from the blood to the cellular site of action
4. the rate and affinity of drug–receptor binding
5. the time required for processes initiated by the drug-receptor interaction to produce changes in cellular function

The consequence of this time lag between changes in concentration and changes in effects is that the plasma concentration will have an unvarying relationship with pharmacologic effect only under steady-state conditions. At steady state, the plasma concentration is in equilibrium with the concentrations throughout the body, and is thus directly proportional to the steady-state concentration at the site of action. Plotting the logarithm of the steady-state plasma concentration versus response generates a curve identical in appearance to the dose-response curve shown in the right panel of Figure 11-9. The $Cp_{ss}50$, the steady-state plasma concentration producing 50% of the maximal response, is determined from the concentration-response curve. Like the ED50, the $Cp_{ss}50$ is a measure of sensitivity to a drug, but the $Cp_{ss}50$ has the advantage of being unaffected by pharmacokinetic variability. Because it takes five elimination half-lives to approach steady-state conditions, it is not practical to determine the $Cp_{ss}50$ directly. For drugs with long elimination half-lives, the pseudoequilibrium during the elimination phase can be used to

approximate steady-state conditions, because the concentrations in plasma and at the site of action are changing very slowly.

The onset and duration of pharmacologic effects depend not only on pharmacokinetic factors but also on the pharmacodynamic factors governing the degree of temporal disequilibrium between changes in concentration and changes in effect. The magnitude of the pharmacologic effect is a function of the amount of drug present at the site of action, so increasing the dose increases the peak effect. Larger doses have a more rapid onset of action because pharmacologically active concentrations at the site of action occur sooner. Increasing the dose also increases the duration of action because pharmacologically effective concentrations are maintained for a longer time.

Integrated pharmacokinetic–pharmacodynamic models fully characterize the relationships between time, dose, plasma concentration, and pharmacologic effect.[133] This is accomplished by adding an "effect compartment" to a standard compartmental pharmacokinetic model. The effect compartment is also called the *biophase.* Transfer of drug between central compartment and the effect compartment, or biophase, is assumed to be a first-order process, and the pharmacologic effect is assumed to be directly related to the concentration in the biophase. By quantifying the time lag between changes in plasma concentration and changes in pharmacologic effect, these models can also define the $Cp_{ss}50$, even without steady-state conditions. These models have contributed greatly to our understanding of factors influencing the response to intravenous anesthetics,[134,135] opioids,[136,137] and nondepolarizing muscle relaxants[138,139] in humans.

Dose-response and concentration-response relationships can be altered by many factors, such as drug interactions or pathologic conditions. They are also affected by the development of tolerance, which increases the ED50 and $Cp_{ss}50$. When tolerance develops rapidly, it is referred to as *tachyphylaxis*, or *acute tolerance.*

Drug–Receptor Interactions

The biochemical and physiologic effects of drugs, neurotransmitters, and hormones result from the binding of these compounds to receptors, which initiates changes in cellular function. In addition to the well-known muscarinic and nicotinic cholinergic receptors, and α- and β-adrenoceptors, there are specific receptors for histamine, serotonin, dopamine, eicosanoids, peptide hormones, steroid hormones, endorphins and exogenous opiates, benzodiazepines, and calcium channel blockers, to name a few. Subtypes of many of these receptors have been characterized. Most receptors are protein molecules

situated in the cell membrane, although some are located within the cell.

Binding of drugs to receptors, like the binding of drugs to plasma proteins, is usually reversible, and follows the law of mass action:

$$[drug] + [receptor] \equiv [drug\text{–}receptor\ complex] \quad (11\text{-}17)$$

The higher the concentration of free drug or unoccupied receptor, the greater the tendency to form the drug-receptor complex. Plotting the percentage of receptors occupied by a drug against the logarithm of the concentration of the drug yields a sigmoid curve, as shown in Figure 11-11.

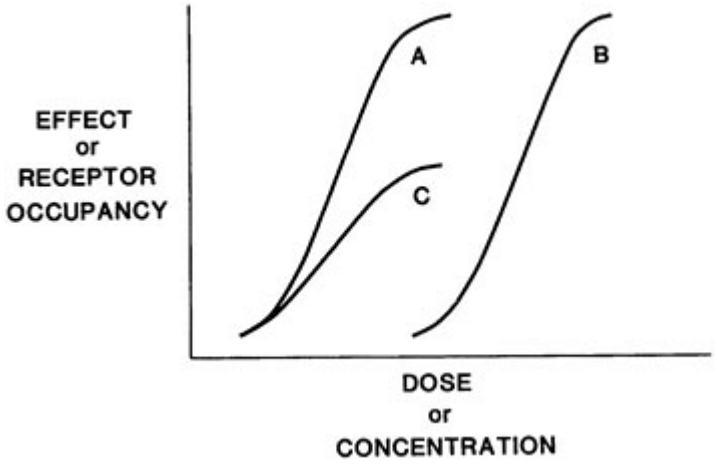

FIGURE 11-11. Schematic dose-response curves representing various conditions. Either dose or concentration is plotted on the *x*-axis, and either effect or the number of receptors occupied on the *y*-axis. Curve *A* is a typical dose-response curve. Curve *B* is a parallel rightward shift of the curve and represents a drug that is less potent than the drug depicted by curve *A*, but is a full agonist and thus capable of producing the same maximal effect. Curve *B* would also result if the drug used to generate curve *A* was studied in the presence of a competitive antagonist. Curve *C* is shifted to the right, with a reduction in slope and the maximal effect. This is the curve observed with partial agonists and also when a full agonist (curve *A*) is studied in the presence of a noncompetitive antagonist.

It is often assumed that the percentage of the maximal effect observed at any given drug concentration is equal to the percentage of receptors occupied by the drug. However, this is not always the case. At the neuromuscular junction, only 20 to 25% of the postjunctional nicotinic cholinoceptors need to bind acetylcholine to produce contraction of all the fibers in the muscle.[140] Thus, 75 to 80% of the receptors can be considered "spare receptors." The presence of spare receptors has two important consequences. Equation 11-17 indicates that the higher the concentration of unoccupied receptors, the greater the tendency to form the drug–receptor complex. Therefore, spare receptors permit near-maximal effects at very low concentrations of drugs or neurotransmitters.[141] The other corollary of the existence of spare receptors is that most of the receptors must be occupied by an antagonist before transmission is affected. This accounts for the "margin of safety" of neuromuscular transmission.[140]

The binding of drugs to receptors and the resulting changes in cellular function are the last two steps in the complex series of events between administration of the drug and production of its pharmacologic effects. There are two primary mechanisms by which the binding of an agonist to a receptor changes cellular function: receptor-linked membrane ion channels called *ionophores*, and guanine nucleotide binding proteins, referred to as *G-proteins.* The nicotinic cholinoceptor in the neuromuscular postsynaptic membrane is one example of a receptor-ionophore complex. Binding of acetylcholine opens the cation ionophore, leading to an influx of Na^+ ions, propagation of an action potential, and, ultimately, muscle contraction.[142] The β-amino butyric acid (GABA) receptor–chloride ionophore complex is another example of this type of effector mechanism. Binding of either endogenous neurotransmitters (GABA) or exogenous agonists (benzodiazepines and iv anesthetics) increases Cl^- conductance, which hyperpolarizes the neuron and decreases its excitability.[143] α-Adrenoceptors are the prototypical receptors that alter cellular function via G-proteins. G-proteins change the intracellular concentrations of various so-called *second messengers*, such as Ca^{2+} and cyclic AMP.[144]

Receptors are not static entities. Rather, they are dynamic cellular components that adapt to their environment. For example, administration of α-adrenergic agonists leads to desensitization of α-

adrenoceptors.[145] This occurs by several mechanisms: reduced ability to combine with G-proteins; *sequestration*, which is the removal of receptors from the cell membrane so they are no longer accessible to agonists; and by *downregulation*, a decrease in the total number of receptors. Administration of adrenoceptor antagonists increases the number of receptors.[145]

Agonists, Partial Agonists, and Antagonists

Drugs that bind to receptors and produce an effect are called *agonists.* Drugs may be capable of producing the same maximal effect, although they may differ in potency. Agonists that differ in potency but bind to the same receptors will have parallel concentration-response curves (curves *A* and *B* in Fig. 11-11). Differences in potency of agonists reflect differences in affinity for the receptor. *Partial agonists* are drugs that are not capable of producing the maximal effect, even at very high concentrations (curve *C* in Fig. 11-11).

Compounds that bind to receptors without producing any changes in cellular function are referred to as *antagonists.* Binding of agonists to receptors is inhibited by antagonists. Competitive antagonists bind reversibly to receptors, and their blocking effect can be overcome by high concentrations of an agonist. Therefore, *competitive antagonists* produce a parallel shift in the dose-response curve, but the maximum effect is not altered (see Fig. 11-11, curves *A* and *B*). *Noncompetitive antagonists* bind irreversibly to receptors. This has the same effect as reducing the number of receptors and shifts the dose-response curve downward and to the right, decreasing both the slope and the maximum effect (curves *A* and *C* in Fig. 11-11). The effect of noncompetitive antagonists is reversed only by synthesis of new receptor molecules.

Agonists produce a structural change in the receptor molecule that initiates changes in cellular function. Partial agonists may produce a qualitatively different change in the receptor, whereas antagonists bind without producing a change in the receptor that results in altered cellular function. The underlying mechanisms by which different compounds that bind to the same receptor act as agonists, partial agonists, or antagonists are not fully understood.

DRUG INTERACTIONS

Taking into account premedication, perioperative antibiotics, iv agents used for induction or maintenance, inhalational anesthetics, opioids, muscle relaxants, the drugs used to restore neuromuscular transmission, and postoperative analgesics, 10 or more drugs may be given for a relatively "routine" anesthetic. Consequently, thorough understanding of the mechanisms of drug interactions and knowledge of specific interactions with drugs used in anesthesia are essential to the safe practice of anesthesiology. Indeed, anesthesiologists often deliberately take advantage of drug interactions. For example,

when cholinesterase inhibitors are given to reverse the effects of neuromuscular blockers on nicotinic cholinoceptors, atropine or glycopyrrolate is administered concomitantly to avoid such undesirable side effects as bradycardia and bronchospasm, which would result from increased acetylcholine binding to muscarinic cholinoceptors.

Drug interactions because of physicochemical properties can occur in vitro. Mixing acidic drugs, such as thiopental, and basic drugs, such as opioids or muscle relaxants, results in the formation of insoluble salts that precipitate.[146] Another type of in vitro reaction is absorption of drugs by plastics. Examples include the uptake of nitroglycerin by polyvinyl chloride infusion sets[147] and the absorption of fentanyl by the apparatus used for cardiopulmonary bypass.[148]

Drugs can alter each other's absorption, distribution, and elimination. Absorption from the GI tract is altered by drugs like ranitidine, which alters gastric pH,[51] and metoclopramide, which speeds gastric emptying.[149] Vasoconstrictors are added to local anesthetic solutions to prolong their duration of action at the site of injection and to decrease the risk of systemic toxicity from rapid absorption.

Drugs that compete for binding sites on plasma proteins have complex interactions.[77] Displacement of a drug from plasma proteins affects its distribution. The increase in the free drug

concentration increases tissue uptake of the drug, increasing the volume of distribution. The extent of the effect on drug distribution depends on the fraction of the total drug in the body that is bound to plasma proteins. The change in distribution will be greatest when drugs with relatively large bound fractions and small volumes of distribution are displaced. Displacement of one drug by another may produce toxic-free-drug concentrations. When a steady state is reestablished, the effect of decreased binding on total and free drug concentrations depends on the rate of clearance of the drug. For drugs with low extraction ratios, clearance varies with the degree of binding, and clearance increases proportionately to the increase in free fraction. Therefore, when a steady state is reestablished, the total drug concentration will be lower, but the free drug level will be the same as the level before displacement. Clearance of drugs with high extraction ratios is not restricted to the free fraction and is not affected by changes in binding. Consequently, when a new steady state is reached, the total drug concentration is unchanged, and the higher free drug level will persist. Adverse interactions are thus most likely to occur if the displaced drug has high (nonrestrictive) clearance, a small volume of distribution, and relatively high binding to plasma proteins.

Drugs that inhibit or induce the enzymes that catalyze biotransformation reactions can affect clearance of other concomitantly administered drugs. Clearance can also be affected by drug-induced changes in hepatic blood flow. Drugs that are cleared by the kidneys and have similar physicochemical characteristics compete for the transport mechanisms involved in renal tubular secretion.

Pharmacodynamic interactions fall into two broad classifications. Drugs can interact, either directly or indirectly, at the same receptors. Opioid antagonists directly displace opioids from opiate receptors. Cholinesterase inhibitors indirectly antagonize the effects of neuromuscular blockers by increasing the amount of acetylcholine, which displaces the blocking drug from nicotinic receptors. Pharmacodynamic interactions can also occur if two drugs affect a physiologic system at different sites. Benzodiazepines and opioids, each acting on their own specific receptors, appear to interact synergistically.[150,151] Although receptors and mechanisms are not as well defined as for the benzodiazepine–opioid interaction, this is presumably how volatile anesthetics increase sensitivity to neuromuscular blocking drugs[138] and also how premedication increases sensitivity to inhalational anesthetics.[152]

CLINICAL APPLICATION OF PHARMACOKINETICS AND PHARMACODYNAMICS TO ADMINISTRATION OF INTRAVENOUS AGENTS

While no new inhaled anesthetics have been synthesized since the 1960s, intravenous drugs that act on the central nervous system continue to be developed. Anesthesiologists have become accustomed to the exquisite control of anesthetic blood (and effect site) concentrations afforded by modern volatile anesthetic agents and their vaporizers, coupled to end-tidal anesthetic gas monitoring. To achieve similar degrees of control of intravenously administered anesthetic drug concentrations in blood and in the central nervous system, new technologies aimed at improving intravenous infusion devices, as well as new software to manage the daunting pharmacokinetic principles involved, are needed. This section examines the current state of infusion devices and the pharmacokinetic and pharmacodynamic principles specifically required for precise delivery of anesthetic agents.

Infusion Pumps

Originally designed over 30 years ago to control intravenous nutrition, infusion pumps have been developed for the large intensive care unit (ICU) and hospital-based market for an ever-widening variety of drugs. Anesthesia-specific pumps remain a relative rarity because the overall market is smaller. Anesthesia is the only arena in which a highly trained individual continuously monitors both the infusion pump and the patient. Optimally, the control interface for infusion pumps would be analogous to the switches, knobs, and dials found on anesthesia machines, allowing for rapid adjustments with a minimum number of steps to actuate the new infusion rate.[153] However, most pumps currently available in hospitals are designed for safe management by personnel with

varying skill levels and protection from those with no skill level, that is, patients, family members, and so on. These systems often feature time-consuming, menu-driven, double-checked programming; detection of minute air bubbles; and alarms when the pump is left on "pause" or "standby" mode, none of which are necessarily required or desired by anesthesiologists.[153]

Since the therapeutic indices and the need to accurately predict emergence are largely similar for inhaled and intravenous agents, similar precision in the drug delivery systems is required. Table 11-8 lists the theoretical attributes of an ideal anesthesia-specific infusion pump. While elimination of the aforementioned "safety" features is desirable, in many ways such pumps should be more sophisticated than generic infusion pumps. Specifically, they should display information relevant to the conduct of an anesthetic, including assurance that the correct drug is being delivered precisely as programmed. The latter is a particular problem with most currently used pumps, resulting in underdosing and patient awareness, as well as other misadventures.[154,155,156,157] Other improvements from standard hospital pumps should include a different set of alarm conditions, the ability to variably set air detection limits, and a mechanism for rapidly effecting changes in pump programming. A pump with these specifications would obviously require the continuous presence of a highly trained individual. However, drugs being delivered via an anesthesia-specific

pump that would continue to be infused outside of the OR, for example, anesthetic agents and vasoactive drugs, would then need to be switched to another infusion device upon arrival at another care setting.

TABLE 11-8 Desirable Features for Intravenous Infusion Devices

Low acquisition and operating costs
Accuracy over a wide range of flow rates to allow use with multiple drug formulations in adult and pediatric patients
Small size and battery backup for transporting patients
Controls that allow rapid changes in drug delivery
Pause function without alarm
Programmability:
  Drug identification
  Ability to enter patient weight and drug concentration, allowing user to set dose in mass units rather than volumes (i.e., mg/h or µg/kg/min instead of mL/h)
  Preset bolus dose in mass units or volume, with reversion to continuous infusion rate after completion of bolus
  Computer interface for data acquisition and control
  Target-controlled infusion capability
Displays:
  All programmed parameters
  Current infusion rate and cumulative dose
  Visible in low ambient light
Safety features:
  Drug identification (analogous to vaporizer)
  Audio and visual alarms for empty drug reservoir, air inline, occlusion, impending battery depletion, nonspecific malfunction
  Variable air detection limits
  Sensing and control circuits to detect discrepancies between programmed and actual flow rates
  Microprocessor-based integration of drug identification, patient weight, and set dose

to alert user of potential overdoses

Pharmacokinetic and Pharmacodynamic Principles of Drug Infusions

While pharmacokinetic and pharmacodynamic principles and data have contributed greatly to our understanding of drug action in anesthesia, their primary utility and ultimate purpose are to determine optimal dosing with as much mathematical precision and clinical accuracy as possible. In most pharmacotherapeutic scenarios outside of anesthesia care, the time scales for onset of drug effect, its maintenance, and its offset are measured in days, weeks, or even years. In such cases, global pharmacokinetic variables such as total volume of distribution (V_{SS}), elimination clearance (Cl_e), and half-life ($t_{1/2}$) are sufficient and utilitarian parameters for calculating dose regimens.[158] However, in the OR and ICU, the temporal tolerances for onset and offset of desired drug effects are measured in minutes. Consequently, these global variables are insufficient to describe the details of kinetic behavior of drugs in the minutes following intravenous administration. This is particularly true of lipid-soluble hypnotics and opioids that rapidly and extensively distribute throughout the various tissues of the body, because distribution processes dominate pharmacokinetic behavior during the time frame of most anesthetics. Additionally, the therapeutic indices of many intravenous anesthetic drugs are small and two-tailed (i.e., an underdose, resulting in awareness, is a "toxic" effect). Optimal dosing in these situations requires use of all the variables of a multicompartmental pharmacokinetic model to account for drug distribution in blood and other tissues.

It is not easy to intuit the pharmacokinetic behavior of a multicompartmental system by simple examination of the kinetic variables.[159] Computer simulation is required to meaningfully interpret dosing or to accurately devise new dosing regimens. In addition, there are several pharmacokinetic concepts that are uniquely applicable to intravenous administration of drugs with multicompartmental kinetics and must be taken into account when administering intravenous infusions.

Rise to Steady-State Concentration

The drug concentration versus time profile for the rise to steady state is the mirror image of its elimination profile. In a one-compartment model with a decline in concentration versus time that is mono-exponential following a single dose, the rise of drug concentration to the steady-state concentration (C_{SS}) is likewise mono-exponential during a continuous infusion. That is, in one elimination half-life an infusion is halfway to its eventual steady-state concentration, in another half-life it reaches half of what remains between halfway and steady state (i.e., 75% of the eventual steady state is reached in two elimination half-lives), and so on for each half-life increment. The equation describing this behavior is:

$$Cp_{(t)} = C_{SS}\left[1 - e^{-kt}\right] \qquad (11\text{-}18)$$

where $Cp_{(t)}$ = the concentration at time *t*, *k* is the rate constant related to the elimination half-

life, and *t* is the time from the start of the infusion. This relationship can also be described by:

$$Cp_{(n)} = C_{SS}\left[1 - (1/2)^n\right] \qquad (11\text{-}19)$$

in which *Cp(n)* is the concentration at *n* half-lives. Equation 11-19 indicates that during a constant infusion, the concentration reaches 90% of C_{SS} after 3.3 half-lives, which is usually deemed close enough for clinical purposes.

However, for a drug such as propofol, which partitions extensively to pharmacologically inert body tissues (e.g., muscle, gut), a mono-exponential equation, or single-compartment model, is insufficient to describe the time course of propofol concentrations in the first minutes and hours after beginning drug administration. Instead, a multicompartmental or multiexponential model must be used.[158] With such a model, the picture changes drastically for the plasma drug concentration rise toward steady state. The rate of rise toward steady state is determined by the distribution rate constants to the degree that their respective exponential terms contribute to the total area under the concentration versus time curve. Thus, for the three-compartment model describing the pharmacokinetics of propofol, Equation 11-18 becomes:

$$Cp_{(t)} = C_{SS}\left[\frac{A}{A+B+G}\left(1 - e^{-\alpha t}\right) + \frac{B}{A+B+G}\left(1 - e^{-\beta t}\right) + \frac{G}{A+B+G}\left(1 - e^{-\gamma t}\right)\right] \qquad (11\text{-}20)$$

in which *t* = time; $Cp_{(t)}$ = plasma concentration at time; *A* = coefficient of the rapid distribution phase and *α* = hybrid rate constant of the rapid distribution phase; *B* = coefficient of the slower distribution phase and *β* = hybrid rate constant of the slower distribution; and *G* = coefficient of elimination phase and γ = hybrid rate constant of the elimination phase. *A* + *B* + *G* is the sum of the coefficients of all the exponential terms. For most lipophilic anesthetics and opioids, *A* is

typically one order of magnitude greater than *B*, and *B* is in turn an order of magnitude greater than *G.* Therefore, distribution-phase kinetics for intravenous anesthetics have a much greater influence on the time to reach C_{SS} than do elimination-phase kinetics.

For example, with propofol having an elimination half-life of approximately 6 hours,[160] the simple one-compartment rule in Equation 11-19 tells us that it would take 6 hours from the start of a constant rate infusion to reach even 50% of the eventual steady-state propofol plasma concentration and 12 hours to reach 75%. In contrast, with a full three-compartment propofol kinetic model,[160] Equation 11-20 accurately predicts that 50% of steady state is reached in less than 30 minutes and 75% will be reached in less than 4 hours. This example emphasizes the necessity of using multicompartment models to describe the clinical pharmacokinetics of intravenous anesthetics.

Concentration-Effect Relationship

The fundamental goal driving the advances in pharmacokinetics and pharmacodynamics during the past three decades has been to better understand and predict drug concentration–effect relationships. For inhaled anesthetics, end-tidal concentration measurements allow a very close approximation of this goal in the clinical setting. For drugs that are not inhaled, clinicians must operate at the level of the dose-effect relationship, that is, clinicians observe the effect resulting from an administered because it is not possible to know the drug concentration at the time of the observed effect. Dose-effect relationships are inherently more difficult to interpret and control because of the multiple pharmacokinetic factors affecting the relationship between the dose of drug administered and the concentration at the effect site. For this reason anesthesiologists have not generally been able to take full advantage of the advances in our understanding of the clinical pharmacology of intravenous anesthetics.

Isoconcentration Nomogram

The rise toward steady state described by a multicompartmental system can be both visualized and put to clinical use by a concept introduced by Shafer in 1994 called an isoconcentration nomogram (Fig. 11-12).[161] This graphical tool allows users to employ concentration-effect, rather than dose-effect, relationships when determining optimal dosing of intravenous anesthetic agents. The nomogram is constructed by calculating the plasma drug concentration versus time curve for a constant-rate infusion from a set of pharmacokinetic variables for a particular drug. From this single simulation, one can readily visualize (and estimate) the rise toward steady-state plasma drug concentration described by the drug's pharmacokinetic model. By simulating a range of potential infusion rates a series of curves of identical shape are then plotted on a single graph with drug concentrations at any time that are directly proportional to the infusion rate.

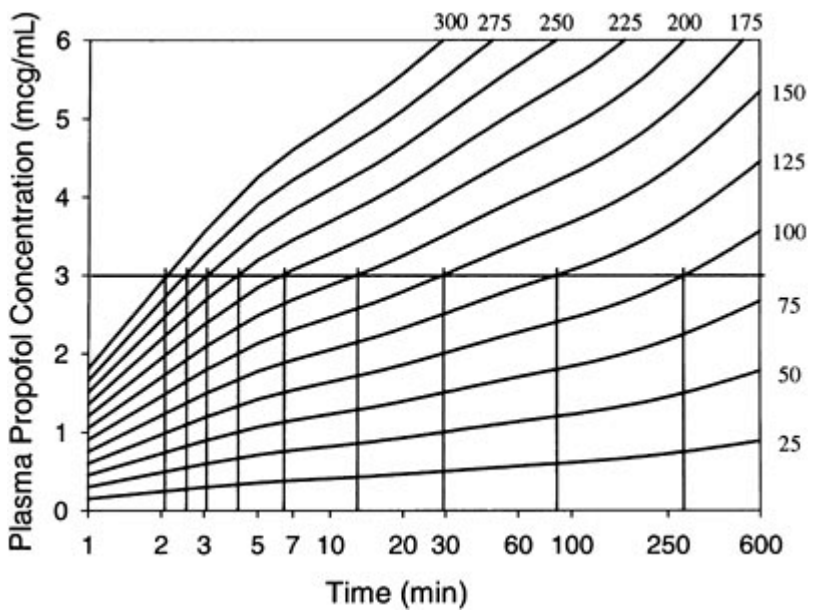

FIGURE 11-12. Isoconcentration nomogram for determining propofol infusion rates designed to maintain a desired plasma propofol concentration. This nomogram is based on the pharmacokinetics of Schnider et al[160] and plotted on a log–log scale to better delineate the early time points. Curved lines represent the plasma propofol concentration versus time plots, resulting from the various continuous infusion rates indicated along the right and upper borders (units in μg/kg/min). A horizontal line is placed at the desired target plasma propofol concentration (3 μg/mL in this case) and vertical lines are placed at each intersection of a curved concentration-time plot. The vertical lines indicate the times that the infusion rate should be set to the one represented by the next intersected curve as one moves from left to right along the horizontal line drawn at 3 μg/mL. In this example the infusion rate would be reduced from 300 μg/kg/min to 275 μg/kg/min at 2.5 minutes, to 250 μg/kg/min at 3 minutes, to 225 μg/kg/min at 4.5 minutes, and so on until it is turned to 100 μg/kg/min at 260 minutes.

By placing a horizontal line at the desired plasma drug concentration (*y*-axis) the times (*x*-axis) at which the horizontal intersects the line for a particular infusion rate will represent the times at which the infusion rate should be set to the rate on the intercepting line.[162] In the example shown (see Fig. 11-12) with 25 μg/kg/min increments, the predicted plasma propofol concentrations remain within 10% of the target from 2 minutes onward with a bias of underestimation. If never allowing the estimated concentration to fall below the target is desired, then the time to decrease to the next lower infusion should be at the midpoint of the subsequent interval. Extending the infusions to the subsequent midpoint times will introduce a maximum overestimation bias of approximately 17% with the illustrated infusion increments (Fig. 11-13). Biases would be

increased or decreased by constructing nomograms with larger or smaller infusion increments, respectively.

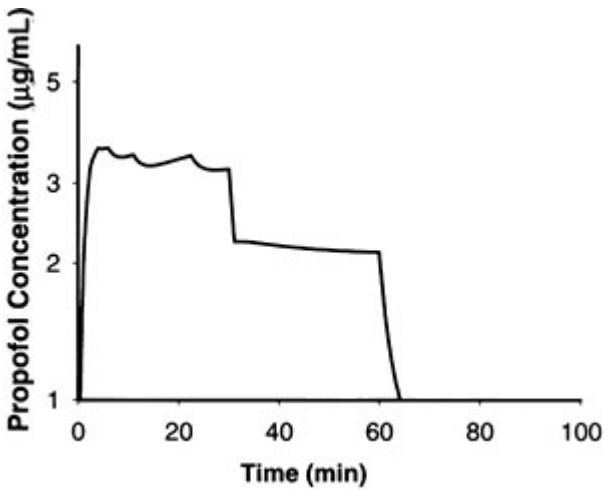

FIGURE 11-13. Simulated plasma propofol concentration history resulting from the information in the isoconcentration nomogram in Figure 11-12 and extending the times to switch the infusion to the next lower increment to the midpoint of the subsequent time segment (i.e., the switch from 250 to 225 µg/kg/min was at 5 minutes, rather than at 4.5 minutes). Note that for the first 30 minutes, this sequence predicts plasma propofol concentrations that are always slightly above 3 µg/mL (see text). At 30 minutes the target is adjusted to 2 µg/mL and so the infusion is stopped for 1 minute and 10 seconds to allow for the concentration to fall by one-third (see text) before resuming an infusion at 75 µg/kg/min. The infusion is stopped at 60 minutes in this case.

The nomogram can also be used to increase or reduce the targeted plasma propofol concentration. To target a new plasma drug concentration, a new horizontal line can be drawn at the desired concentration. The infusion rate that is closest to the current time intersect is the one that should be used initially, followed by the decremental rates dictated by the subsequent intercept times. For best results when increasing the target concentration, a bolus equal to the product of V1 (the central compartment volume) and the incremental change in concentration should be administered. Likewise, when decreasing the concentration the best strategy is to turn off the infusion for the duration predicted by the applicable context-sensitive decrement time and resume the infusion rate predicted for the current time plus the context-sensitive decrement time. For instance, if after 30 minutes one wishes to decrease the target plasma propofol concentration from 3 µg/mL to 2 µg/mL (a 33% decrement at a time context of 30 minutes), one would shut off the infusion for 1 minute and 10 seconds to let the concentration fall by 33% and then restart at 75 µg/kg/min. The estimated plasma propofol concentrations from this nomogram-guided dosing scheme is shown in Figure 11-13.

Target-Controlled Infusions

A more comprehensive means of bridging the gap between dose-effect and concentration-effect came with the introduction of the concept of target-controlled infusions (TCI), which was first described by Schwilden et al[163,164] in early 1980s. Other software systems were developed in North America by groups at Stanford University[165] and Duke University.[166] By the late 1990s a commercially available TCI system for propofol (Diprifusor®) was introduced. This greatly increased both anesthesiologists' interest in this mode of delivery and their understanding of the concentration-effect relationships for hypnotics and opioids.

12 To accomplish target-controlled infusions, the mathematical calculations of the pharmacokinetic events that convert a dose into a plasma or effect site concentration are interfaced between the anesthesia provider and the infusion pump by means of a computer. With TCI, the clinician prescribes a desired concentration (the target) and the computer-controlled pump calculates and produces the drug infusion rates required to reach and maintain the desired concentration. The success of this approach is influenced by the extent to which the drug pharmacokinetic and pharmacodynamic parameters programmed into the computer match those of the particular patient at hand. While this same limitation applies to the more rudimentary (non-TCI) dosing done routinely in every clinical setting, we must examine the special ramifications of pharmacokinetic–pharmacodynamic model misspecification with TCI in any discussion of its future importance in the clinical setting.

The mathematical principles governing TCI are actually quite simple. For a computer-control pump to produce and maintain a plasma drug concentration it must first administer a dose equal to the product of the central compartment V1 and the target concentration. Then for each moment after that, the amount of drug to be administered into the central compartment to maintain the target concentration is equal to drug eliminated from the central compartment *plus* drug distributed from the central compartment to peripheral compartments *minus* drug returning to the central compartment from peripheral compartments. The software keeps track of the estimated drug in each compartment over time and applies the rate constants for intercompartmental drug transfer from the pharmacokinetic model to these amounts to determine drug movement at any given time. It then matches the estimated concentrations to the target concentration at any time to determine the amount of drug that should be infused. The software can also predict future concentrations, usually with the assumption that the infusion will be stopped so that emergence from anesthesia or the dissipation of drug effect will occur optimally according to the context-sensitive recovery time, or half-life.[167,168]

Because there is a delay or hysteresis between the attainment of a drug concentration in the plasma and the production of a drug effect, it is advantageous to have the mathematics of this delay incorporated into TCI. By adding the kinetics of the effect site it is possible to target effect site concentrations as would be in keeping with the principle of working as closely to the relevant concentration-effect relationship as possible. A dose scheme that targets concentrations in a compartment remote from the central compartment (i.e., the effect site) has no closed form solution for calculating the infusion rate(s) needed. Instead, the solution is solved numerically and involves some additional concepts that must be considered, namely the time to peak effect, T_{MAX}, and the volume of distribution at peak effect, V_{DPE}. These are discussed later. In principle, targeting the effect site necessitates producing an overshoot in plasma drug concentrations during induction and for subsequent target increases. This is similar in concept to overpressurizing inhaled anesthetic concentrations to achieve a targeted end-tidal concentration. However, unlike the inspiratory limb of an anesthesia circuit, the plasma compartment seems to be closely linked to cardiovascular effects, and large overshoots in plasma drug concentration may produce unwanted side effects.

The performance of TCI is influenced by the variance between pharmacokinetic parameters determined from group or population studies and the individual patient. Median absolute performance errors for fentanyl,[165] alfentanil,[169] sufentanil,[170] midazolam,[171,172] and propofol[172,173] are in the range of ±30% when literature values for pharmacokinetic parameters are used to drive the TCI device and fall to approximately ±7% when the average kinetics of the test subjects themselves are used.[169] Divergence (the percentage change of the absolute performance error) is generally quite low (approximately 1%) when target concentrations remain relatively stable, but increase to nearly 20% when the frequency of concentration steps is as frequent as every 12 minutes.[173] These data suggest that while a considerable error may exist (±30%) between the targeted drug concentration and the one actually achieved in a patient, the concentration attained will not vary much over time. Thus, incremental adjustments in the target should result in incremental and stable new concentrations in the patient as long as the incremental adjustments are not too frequent.

In Europe and Asia, devices for delivering propofol by TCI are commercially available from at least

three companies (Graseby, Alaris, and Fresenius) with similar performance parameters.[174] In the United States, there are still no FDA-approved devices. For investigational purposes, STANPUMP (developed by Steve Shafer at Stanford University) can be interfaced via an RS232 port to an infusion pump. STANPUMP currently provides pharmacokinetic parameters for 19 different drugs, but has the ability to accept any kinetic model for any drug provided by the user. (Information regarding STANPUMP is available at http://0-www.anesthesia.stanford.edu.innopac.up.ac.za:80/pkpd/. Accessed August 27, 2004.) RUGLOOP© is TCI software (developed by Michel Struys of Ghent University), which is similar to STANPUMP but operates in Windows® rather than DOS® and is capable of controlling multiple drug infusions simultaneously. (Information regarding RUGLOOP is available at http://www.anesthesia-uzgent.be/rugloop.htm. Accessed August 27, 2004.)

While the pharmacologic principle of relating a concentration rather than a dose is scientifically sound, few studies have actually attempted to determine whether TCI improves clinical performance or outcome. Only a few limited studies

have actually compared manual infusion control versus TCI. Some have shown better control and a more predictable emergence with TCI,[175,176] whereas others have simply shown no advantage.[177,178]

TCI principles continue to be developed beyond the scope of intravenous anesthesia techniques. TCI has been used to provide postoperative analgesia with alfentanil.[179,180] In this system a desired target plasma alfentanil concentration was set in the range of 40 to 100 ng/mL. A demand by the patient automatically increased the target level by 5 ng/mL. Lack of a demand caused the system to gradually reduce the targeted level. The quality of analgesia was judged to be superior to standard morphine PCA.

Similarly, TCI has been used to provide patient-controlled sedation with propofol.[181] The TCI was set to 1 μg/mL and a demand by the patient increased the level by 0.2 μg/mL. As with the TCI analgesia system, the lack of a demand caused the system to gradually reduce the targeted plasma propofol concentration. The timing and increment of the decrease were adjusted by the clinician. Over 90% of patients were satisfied with this method of sedation.

TIME TO MAXIMUM EFFECT COMPARTMENT CONCENTRATION (T_{MAX})

Earlier in this chapter, the delay between attaining a plasma concentration and an effect site concentration was described. This delay, or hysteresis, is presumed to be a result of transfer of drug between the plasma compartment, V1, and an effect compartment, V_e. By simultaneously modeling the plasma drug concentration versus time data (pharmacokinetics) and the measured drug effect (pharmacodynamics), an estimate of the drug transfer rate constant, k_{e0}, between plasma and the putative effect site can be estimated.[138] However, estimates of k_{e0}, like all rate constants, are model specific.[182] That is, k_{e0} cannot be transported from one set of kinetic parameters determined in one specific pharmacokinetic–pharmacodynamic study to any another set of pharmacokinetic parameters. Likewise, it is not valid to compare estimates of k_{e0} among studies of the same drug or across different drugs and, therefore, one should not be surprised that reported values for k_{e0} for the same drug vary markedly among studies. The model-independent parameter that characterizes the delay between the plasma and effect site is the time to maximal effect, or T_{MAX}.[182] Accordingly, if the T_{MAX} and the pharmacokinetics for a drug are known from independent studies, a k_{e0} can be estimated by numeric techniques for the independent kinetic set that would produce the known effect site T_{MAX}.

The concept of a transportable, model-independent parameter that characterizes the kinetics of the effect site is important for robust effect site–targeted, computer-controlled infusions. This is because there many more pharmacokinetic studies characterizing a wider variety of patient types and groups in the literature than there are complete pharmacokinetic–pharmacodynamic studies. By making the generally valid assumption that intraindividual differences are small in a drug's rate of effect site equilibration, it is possible with a known T_{MAX} to estimate effect site kinetics for a

drug across a wide variety of patient groups where only the pharmacokinetics are known. This cannot be done in a valid manner using k_{E0} or $t^1/_{2KE0}$ alone.[182]

V_{DPE}

While the plasma concentration can be brought rapidly to the targeted drug concentration by administering a bolus dose to the central compartment (C · V1) and then held there by a computer-controlled infusion (Fig. 11-14), the time for the effect site to reach the target concentration will be much longer than T_{MAX} (4 minutes for propofol effect site concentration to reach 95% of that targeted). It is possible to calculate a bolus dose that will attain the estimated effect site concentration at T_{MAX} without overshoot in the effect site. However, plasma drug concentration will overshoot (Fig. 11-15). This is done by combining the concept of describing drug distribution as an expanding volume of distribution that starts at V1 and approaches V_β (the apparent volume of distribution during the elimination phase) over time with the concept of T_{MAX}.[183,184]

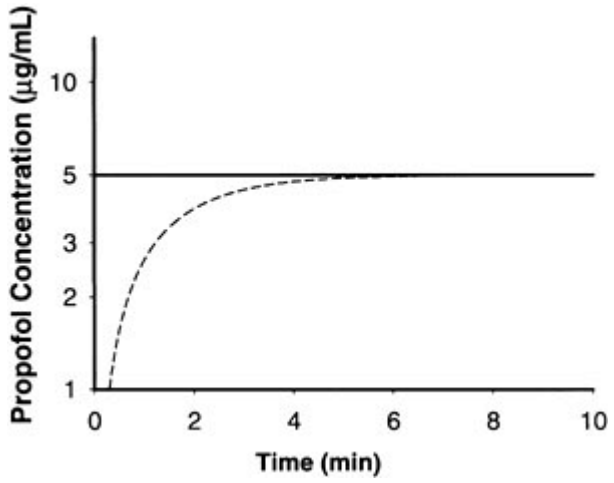

FIGURE 11-14. This is a simulation of a target-controlled infusion (TCI) in which the plasma concentration is targeted at 5 µg/mL. The *solid line* represents the predicted plasma propofol concentration of 5 µg/mL, which in theory is attained at time t = 0 and is then maintained by a variable rate infusion. The *dashed line* is the predicted effect site concentration under the conditions of a constant pseudo–steady-state plasma concentration. Note that 95% of the target concentration is reached in the effect site at approximately 4 minutes.

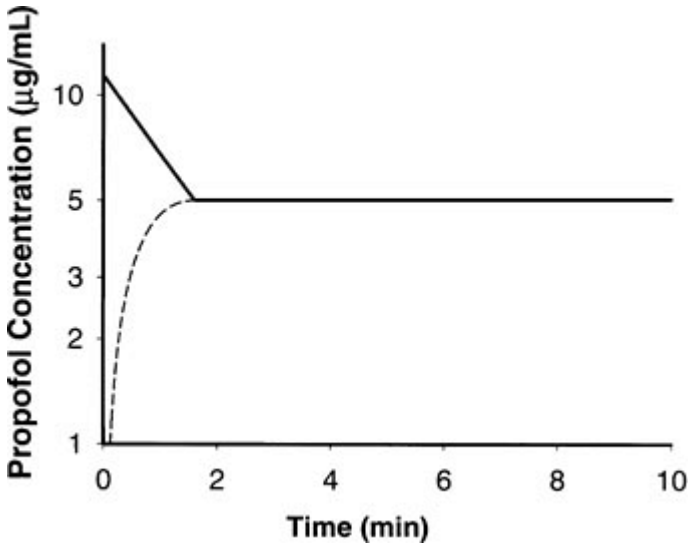

FIGURE 11-15. This is a simulation of a target controlled infusion (TCI) in which the effect site concentration is targeted at 5 µg/mL. The *solid line* represents the predicted plasma propofol concentration that results from a bolus dose, given at time t = 0, that is predicted to purposely overshoot the plasma propofol concentration target until time t = T_{MAX} (1.6 minutes). At T_{MAX} pseudo-equilibration between the effect site and the plasma occurs and both concentrations are then predicted to be the same until the target is changed. Note that the effect site attains the target in less than half the time with effect site targeting compared to the plasma concentration targeting seen in Figure 11-14.

Volume of distribution over time is calculated by dividing the total amount of drug remaining in the body by the plasma

drug concentration at each time t. The time-dependent volume at the time of peak effect (or T_{MAX}) is V_{DPE}. The product of the targeted effect site concentration and V_{DPE} plus the amount lost to elimination in the time to T_{MAX} becomes the proper bolus dose that will attain the target concentration at the effect site as rapidly as possible without overshoot. In practical terms this bolus is given at time t = 0, after which the infusion stops until time t = T_{MAX}. It then resumes infusing drug in its normal "stop loss" manner.

Some software programs for controlling target-controlled infusions include this concept in their algorithms. In the case of the propofol kinetics used to construct the isoconcentration nomogram in Figure 11-13, the pharmacokinetic–pharmacodynamic parameter set of Schnider et al[160] predicts a T_{MAX} of 1.6 minutes, a V_{DPE} of 16.62 L, and an elimination loss of 23.8% of the dose over 1.6 minutes in a 70-kg man. Thus the proper propofol bolus for a targeted effect site propofol concentration of 5 µg/mL is 109 mg. The computer-controlled infusion pump will deliver this dose as rapidly as possible and then begin a targeted infusion for 5 µg/mL at t = 1.6 minutes (see Fig. 11-15).

Frontend Pharmacokinetics

The term "frontend pharmacokinetics" refers to the intravascular mixing, pulmonary uptake, and recirculation events that occur in the first few minutes during and after intravenous drug administration.[185] These kinetic events and the drug concentration versus time profile that results are important because the peak effect of rapidly acting drugs occurs during this temporal window.[186,187] Although it has been suggested that frontend pharmacokinetics be utilized to guide drug dosing,[188] current TCI does not incorporate frontend kinetics into the models from which drug infusion rates are calculated. Not doing so may introduce further error.[189]

TCI relies on pharmacokinetic models that are based on the simplifying assumption of instantaneous and complete mixing within V1. However, the determination of V1 is routinely overestimated in most pharmacokinetic studies. Overestimation of V1, when used to calculate TCI infusion rates, results in plasma drug concentrations that overshoot the desired target concentration, especially in the first few minutes after beginning TCI. Furthermore, correct description of drug distribution to tissues is dependent on an accurate V1 estimate, so inaccuracies caused by not taking frontend pharmacokinetics into account may be persistent and result in undershoot as well as overshoot. Simulation indicates that pharmacokinetic parameters derived from studies in which the drug is administered by a short (approximately 2 minutes) infusion better estimate V1 and tissue-distribution kinetics than those from a rapid intravenous bolus infusion.[189] When the latter drug administration method is used, full characterization of the frontend recirculatory pharmacokinetics is required to obtain valid estimates of V for use in TCI.[189]

Closed-Loop Infusions

When a valid, and nearly continuous, measure of drug effect is available, drug delivery can be automatically titrated by feedback control. Such systems have been used experimentally for

control of blood pressure,[190] oxygen delivery,[191] blood glucose,[192] neuromuscular blockade,[193] and depth of anesthesia.[193,194,195,196,197,198,199] A target value for the desired effect measure (the output of the system) is selected and the rate of drug delivery (the input into the system) is dependent on whether the effect measure is above, below, or at the target value. Thus the output feeds back and controls the input. Standard controllers (referred to as *proportional-integral-derivative* [or PID] *controllers*) adjust drug delivery based on both the integral, or magnitude, of the deviation from target and the rate of deviation, or the derivative.

Under a range of responses, standard PID controllers work quite well. However, they have been shown to develop unstable characteristics in situations where the output may vary rapidly and widely. Schwilden et al[200] have proposed a controller in which the output (measured response) controls not only the input (drug infusion rate), but also the pharmacokinetic model driving the infusion rate. This is a so-called *model-driven* or *adaptive* closed-loop system. Such a system has performed well in clinical trials,[201] and in a simulation of extreme conditions it was demonstrated to outperform a standard PID controller.[196]

Closed-loop systems for anesthesia are the most difficult to design and implement because the precise definition of "anesthesia" remains elusive, as does a robust monitor for "anesthetic depth." Because modification of consciousness must accompany anesthesia, processed EEG parameters that correlate with level of consciousness, such as the Bispectral Index (BIS),[201,202] electroencephalographic entropy,[203] and auditory evoked potentials,[198] make it possible to undertake closed-loop control of anesthesia. There is keen interest in further developing these tools to make them more reliable because, advances in pharmacokinetic modeling, including the effect compartment, the implementation of such models into drug delivery systems, and the creation of adaptive controllers based on these models, has made routine closed-loop delivery of anesthesia imaginable.[204] So far it has been difficult to bring a true closed-loop system to market in medical applications, because of the regulatory agency hurdles. From a regulatory point of view, an open-loop TCI system is much easier to attain and offers many of the benefits of actual closed-loop systems. Unless there is a regulatory or a design "breakthrough," closed-loop systems for anesthesia will likely remain in the theoretical and experimental realms.

Chapter 12

Autonomic Nervous System: Physiology and Pharmacology

Noel W. Lawson

Joel O. Johnson

KEY POINTS

1	The autonomic nervous system (ANS) participates in nearly all of the physiologic processes of the human body and an understanding of its function is essential for anesthesiologists.
2	The function of the ANS is intimately tied to neurohumeral mechanisms covered elsewhere in the text.
3	Perioperative β-blockade has been proven to be beneficial in certain patients with compromised cardiovascular function.
4	Knowledge of the effects of prescribed oral medication on the ANS is essential in the perioperative management of the surgical patient.
5	Angiotensin-converting enzyme (ACE) inhibitors may precipitate hypotension in the perioperative patient.

AUTONOMIC PHARMACOLOGY

Anesthesiology is the practice of autonomic medicine. Drugs that produce anesthesia also produce potent autonomic side effects. The greater part of our training and practice is spent acquiring skills in averting or utilizing the autonomic nervous system (ANS) side effects of anesthetic drugs under a variety of pathophysiologic conditions. The success of any anesthetic depends on how well homeostasis is maintained. The numbers that we faithfully record during the course of anesthesia reflect ANS function and not necessarily the presence of surgical anesthesia.

AUTONOMIC NERVOUS SYSTEM PURPOSE

1 The ANS includes that part of the central and peripheral nervous system concerned with involuntary regulation of cardiac muscle, smooth muscle, glandular, and visceral functions. ANS activity refers to visceral reflexes that function essentially below the conscious level. The term autonomic remains the best description of this ubiquitous system, as opposed to automatic. ANS implies self-controlling, whereas automatic implies nonreflexic or intrinsic responses;

responsive to changes in somatic motor and sensory activities of the body. The physiologic evidence of visceral reflexes as a result of somatic events is abundantly clear. Psychosomatic disease is an expression of this connection. The ANS is therefore not as distinct an entity as the term suggests. Neither somatic nor ANS activity occurs in isolation.[1] The ANS organizes visceral support for somatic behavior and adjusts body states in anticipation of emotional behavior or responses to the stress of disease (i.e., fight or flight).

Traditionally, the ANS has been viewed as strictly a peripheral, efferent (motor) system. This concept is no longer tenable. Afferent fibers from visceral structures are the first link in the reflex arcs of the ANS, whether relaying visceral pain or changes in vessel stretch. Most ANS efferent fibers are accompanied by sensory fibers that are now commonly recognized as components of the ANS. However, the afferent components of the ANS cannot be as distinctively divided as can the efferent nerves. ANS visceral sensory nerves are anatomically indistinguishable from somatic sensory nerves. The clinical importance of visceral afferent fibers is more closely associated with chronic pain management.

FUNCTIONAL ANATOMY

2 The ANS falls into two divisions by anatomy, physiology, and pharmacology. Langley divided this nervous system into two parts in 1921. He retained the term "sympathetic" (SNS) introduced by Willis in 1665 for the first part and introduced the term parasympathetic (parasympathetic nervous system, PNS) for the second. The term "autonomic nervous system" was adopted as a comprehensive name for both. Ordinarily, activation of the SNS produces expenditure of body energy, whereas the PNS produces conservation or accumulation of energy resources. Table 12-1 lists the complementary effects of SNS (adrenergic) and PNS (cholinergic) activity of organ systems.

TABLE 12-1 Homeostatic Balance Between Adrenergic and Cholinergic Effects

·ORGAN SYSTEM	·RESPONSE ·ADRENERGIC	·CHOLINERGIC
HEART		
Sinoatrial node	Tachycardia	Bradycardia
Atrioventricular node	Increased conduction	Decreased conduction
His-purkinje	Increased automaticity and conduction velocity	Minimal
Myocardium	Increased contractility, conduction velocity, automaticity	Minimal decrease in contractility
Coronary vessels	Constriction (α_1) and dilation (β_1)	Dilation and constriction?[a]

BLOOD VESSELS		
Skin and mucosa	Constriction	Dilation
Skeletal muscle	Constriction (α_1) > dilation (β_2)	Dilation
Pulmonary	Constriction	?Dilation
BRONCHIAL SMOOTH MUSCLE	Relaxation	Contraction
GASTROINTESTINAL TRACT		
Gallbladder and ducts	Relaxation	Contraction
Gut motility	Decreased	Increased
Secretions	Decreased	Increased
Sphincters	Constriction	Relaxation
BLADDER		
Detrusor	Relaxes	Contracts
Trigone	Contracts	Relaxes
GLANDS		
Nasal	Vasoconstriction and reduced secretion	Stimulation of secretions
Lacrimal Parotid Submandibular Gastric Pancreatic		
SWEAT GLANDS	Diaphoresis (cholinergic)	None
APOCRINE GLANDS	Thick, odiferous secretion	None

EYE		
Pupil	Mydriasis	Miosis
Ciliary muscle	Relaxation for far vision	Contraction for near vision
[a]See the Interaction of Autonomic Nervous System Receptors section.		

Central Autonomic Organization

Pure central ANS or somatic centers are not known. An extensive overlap of function occurs. Integration of ANS activity occurs at all levels of the cerebrospinal axis. Efferent ANS

activity can be initiated locally and by centers located in the spinal cord, brainstem, and hypothalamus. The cerebral cortex is the highest level of ANS integration. Fainting at the sight of blood is an example of this higher level of somatic and ANS integration. ANS function has also been successfully modulated through conscious, intentional efforts demonstrating that somatic responses are always accompanied by visceral responses and vice versa.

The principal site of ANS organization is the hypothalamus. SNS functions are controlled by nuclei in the posterolateral hypothalamus. Stimulation of these nuclei results in a massive discharge of the sympathoadrenal system (Table 12-2). PNS functions are governed by nuclei in the midline and some anterior nuclei of the hypothalamus. The anterior hypothalamus is involved with regulation of temperature. The supraoptic hypothalamic nuclei regulate water metabolism and are anatomically and functionally associated with the posterior lobe of the pituitary (see Interaction of Autonomic Nervous System Receptors section). This hypothalamic–neurohypophyseal connection represents a central ANS mechanism that affects the kidney by means of antidiuretic hormone. Long-term blood pressure control, reactions to physical and emotional stress, sleep, and sexual reflexes are regulated through the hypothalamus.

The medulla oblongata and pons are the vital centers of acute ANS organization. Together, they integrate momentary hemodynamic adjustments and maintain the sequence and automaticity of ventilation. Integration of afferent and efferent ANS impulses at this central nervous system (CNS) level is responsible for the tonic activity exhibited by the ANS. Control of peripheral vascular resistance and blood pressure is an example of this tonic activity. Tonicity holds visceral organs in a state of intermediate activity that can either be diminished or be augmented by altering the rate of nerve firing. The nucleus tractus solitarius, located within the medulla, is the primary area for relay of afferent chemoreceptor and baroreceptor information from the glossopharyngeal and vagus nerves. Increased afferent impulses from these two nerves inhibit peripheral SNS vascular tone, producing vasodilation, and increase vagal tone, producing bradycardia. High spinal cord transection eliminates the medulla and results in hypotension. Studies of patients with high spinal cord lesions show that a number of reflex changes are mediated at the spinal or segmental level. ANS hyperreflexia is an example of spinal cord mediation of ANS reflexes without integration of function from higher inhibitory centers.[1]

Peripheral Autonomic Nervous System Organization

The peripheral ANS is the efferent (motor) component of the ANS and consists of two complementary parts: the SNS and the PNS. Most organs receive fibers from both divisions (Fig. 12-1). In general, activities of the two systems produce opposite but complementary effects (see Table 12-1). Actions of the two subdivisions are supplementary in some tissues such as the salivary glands. A few tissues, such as sweat glands and spleen, are innervated by only SNS fibers. Although the anatomy of the somatic and ANS sensory pathways is identical, the motor pathways are characteristically different. The efferent somatic motor system, like somatic afferents, is composed of a single (unipolar) neuron with its cell body in the ventral gray matter of the spinal cord. Its myelinated axon extends directly to the voluntary striated muscle unit. In contrast, the efferent (motor) ANS is a two-neuron (bipolar) chain from the CNS to the effector organ (Fig. 12-2). The first neuron of both the SNS and PNS originates within the CNS but does not make direct contact with the effector organ. Instead, it relays the impulse to a second station known as an ANS ganglion, which contains the cell body of the second ANS (postganglionic) neuron. Its axon contacts the effector organ. Thus, the motor pathways of both divisions of the ANS are schematically a serial, two-neuron chain consisting of a preganglionic neuron and a postganglionic effector neuron (Fig. 12-3).

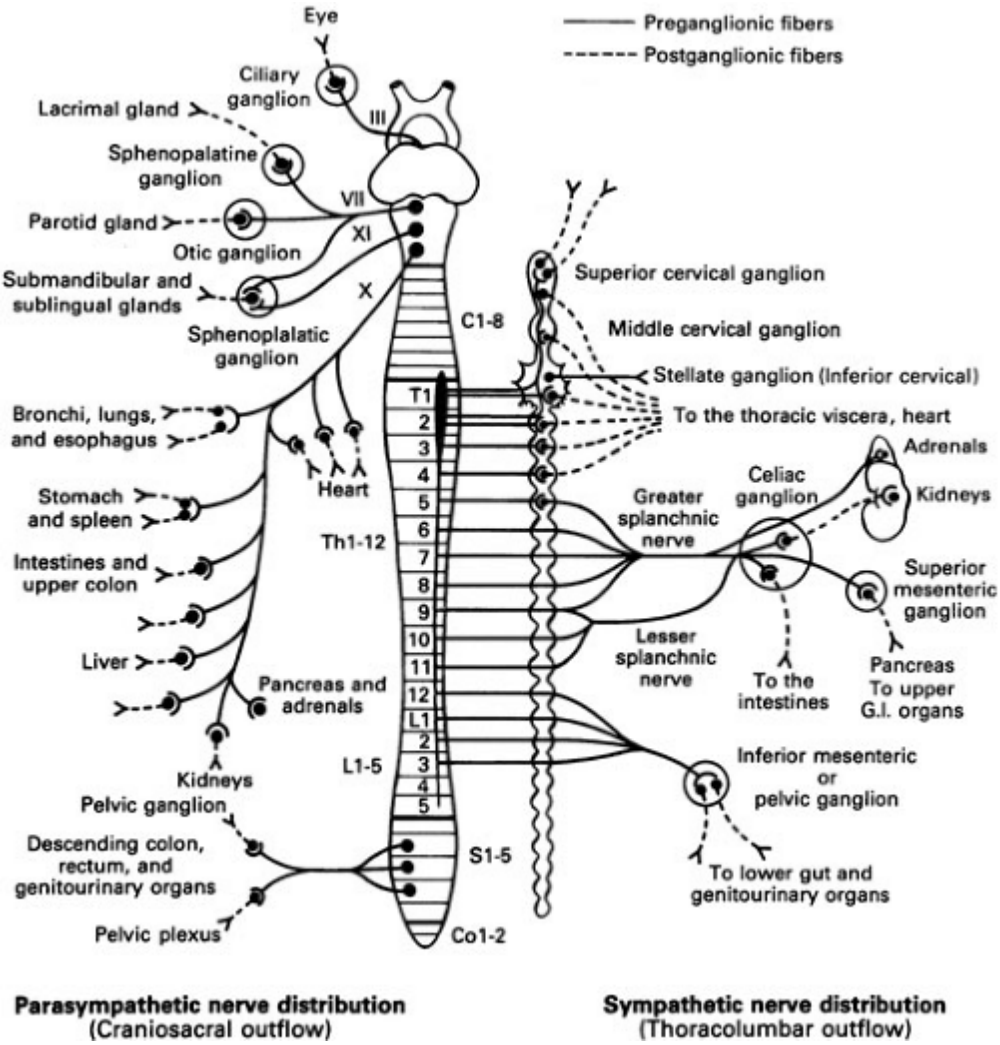

FIGURE 12-1. Schematic distribution of the craniosacral (parasympathetic) and thoracolumbar (sympathetic) nervous systems. Parasympathetic preganglionic fibers pass directly to the organ that is innervated. Their postganglionic cell bodies are situated near or within the innervated viscera. This limited distribution of parasympathetic postganglionic fibers is consistent with the discrete and limited effect of parasympathetic function. The postganglionic sympathetic neurons originate in either the paired sympathetic ganglia or one of the unpaired collateral plexuses. One preganglionic fiber influences many postganglionic neurons. Activation of the SNS produces a more diffuse physiologic response rather than discrete effects.

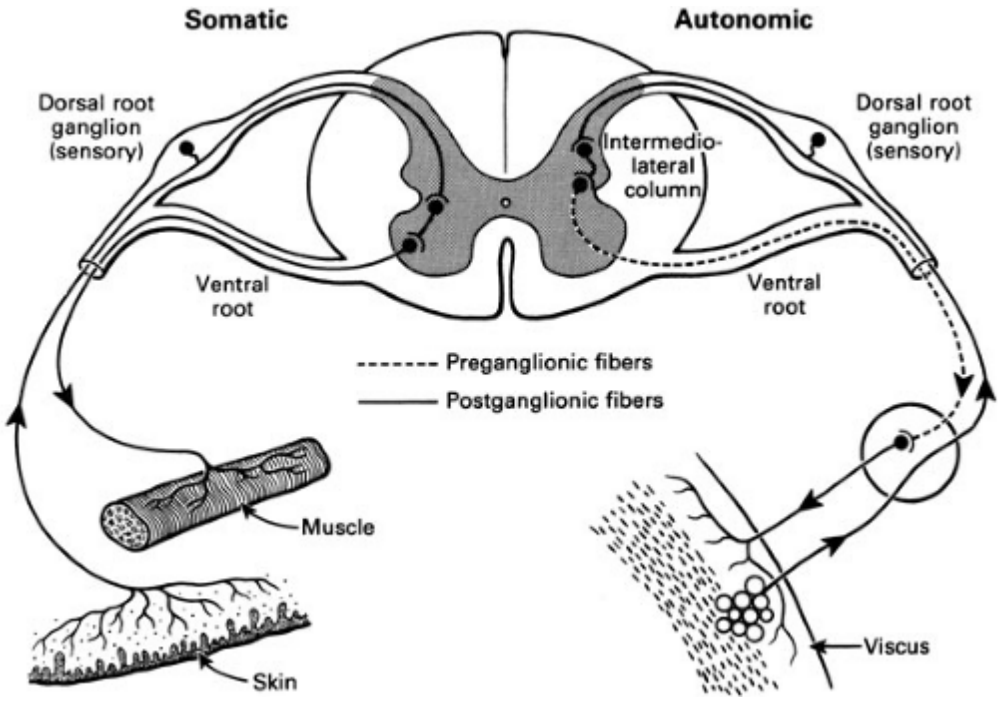

FIGURE 12-2. Comparison of somatic and autonomic reflex arcs. Somatic arcs are unipolar and autonomic arcs are bipolar.

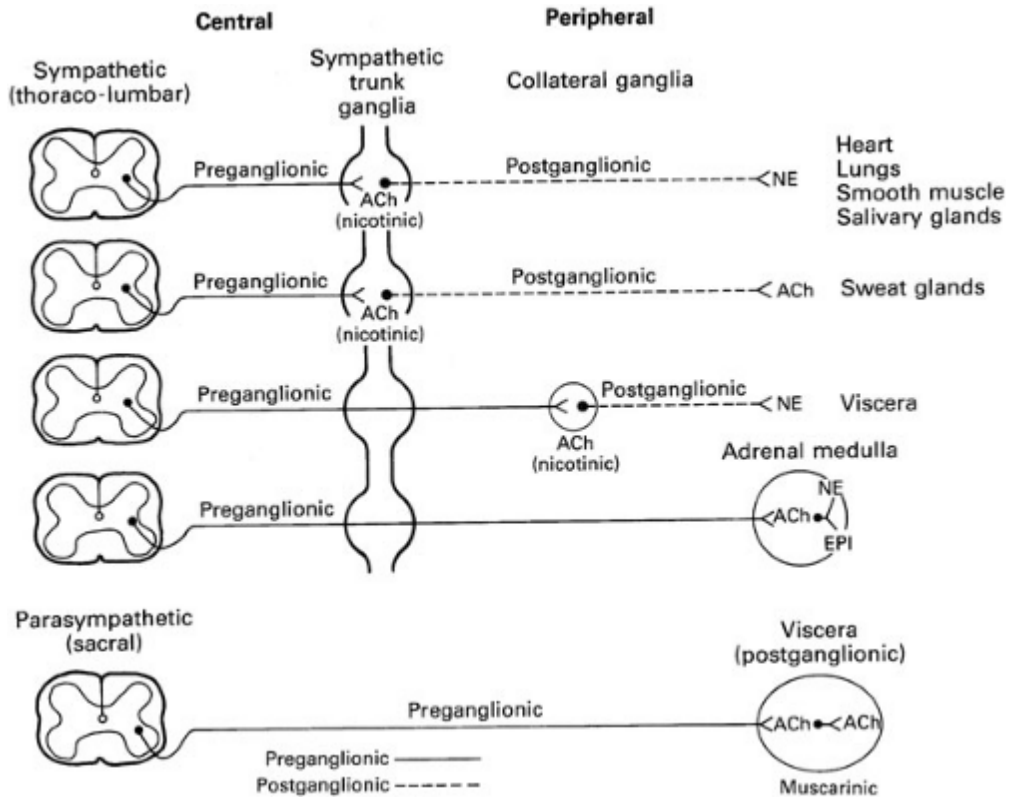

FIGURE 12-3. Schematic diagram of the efferent ANS. Afferent impulses are integrated centrally and sent reflexly to the adrenergic and cholinergic receptors. Sympathetic fibers ending in the adrenal medulla are preganglionic, and acetylcholine (ACh) is the neurotransmitter. Stimulation of the chromaffin cells, acting as postganglionic neurons, releases epinephrine (EPI) and norepinephrine (NE).

Preganglionic fibers of both subdivisions are myelinated with diameters of less than 3 mm.[1] Impulses are conducted at a speed of 3 to 15 m/s The postganglionic fibers are unmyelinated and conduct impulses at slower speeds of less than 2 m/s. They are similar to unmyelinated visceral and somatic afferent C fibers (Table 12-3). Compared with the myelinated somatic nerves, the ANS conducts impulses at speeds that preclude its participation in the immediate phase of a somatic response.

DESCRIPTION OF NERVE FIBERS	GROUP		DIAMETER (μm)	CONDUCTION VELOCITY (m/s)
Myelinated somatic	A	Alpha α	20	120
		Beta β		
		Gamma γ		5–40 (pain fibers)
		Delta δ	3–4	5–40 (pain fibers)
		Epsilon ε	2	5
Myelinated visceral (preganglionic autonomic)	B		<3	3–15
Unmyelinated somatic	C		<2	0.5–2 (pain fibers)

TABLE 12-3 Classification of Nerve Fibers

Sympathetic Nervous System or Thoracolumbar Division

The efferent SNS is referred to as the thoracolumbar nervous system. The origin of its preganglionic fibers provides the anatomic basis for this designation. Figure 12-1 demonstrates the distribution of the SNS and its innervation of visceral organs.

The preganglionic fibers of the SNS (thoracolumbar division) originate in the intermediolateral gray column of the 12 thoracic (T1-12) and the first three lumbar segments (L1-3) of the spinal cord. The myelinated axons of these nerve cells leave the spinal cord with the motor fibers to form the white (myelinated) communicating rami (Fig. 12-4). The rami enter one of the paired 22 sympathetic ganglia at their respective segmental levels. On entering the paravertebral ganglia of the lateral sympathetic chain, the preganglionic fiber may follow

one of three courses: (1) synapse with postganglionic fibers in ganglia at the level of exit, (2) course upward or downward in the trunk of the SNS chain to synapse in ganglia at other levels, or (3) track for variable distances through the sympathetic chain and exit without synapsing to terminate in an outlying, unpaired, SNS collateral ganglion (see Fig. 12-4). The adrenal gland is an exception to the rule. Preganglionic fibers pass directly into the adrenal medulla without synapsing in a ganglion (see Fig. 12-3). The cells of the medulla are derived from neuronal tissue and are analogous to postganglionic neurons.

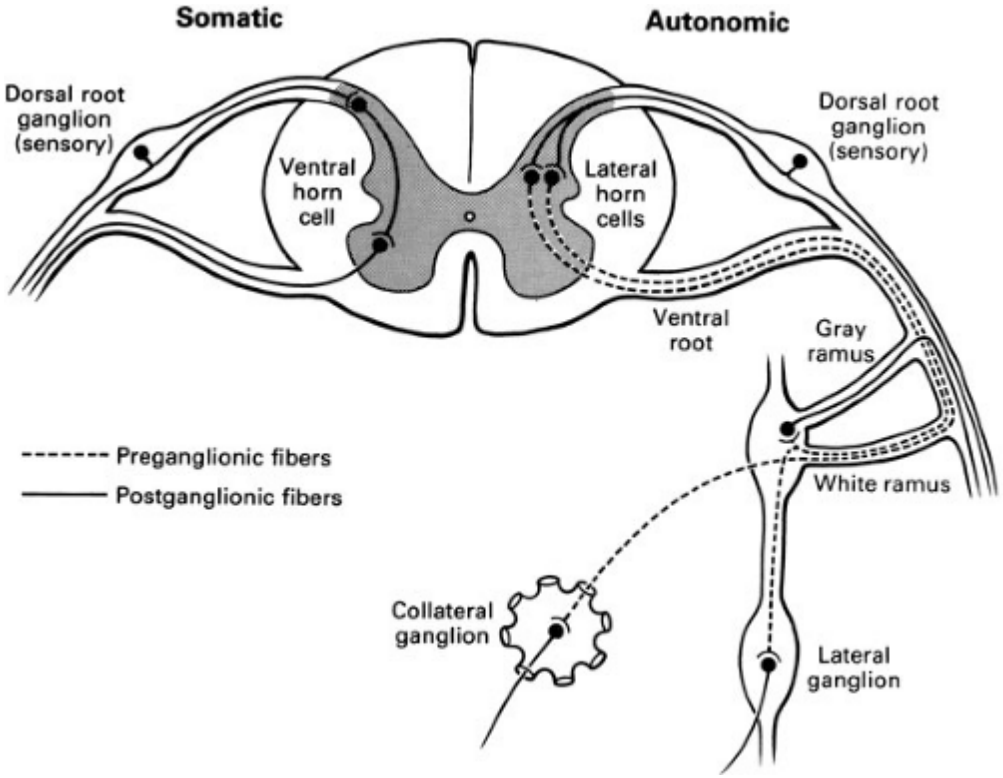

FIGURE 12-4. The spinal reflex arc of the somatic nerves is shown on the left. The different arrangements of neurons in the sympathetic system are shown on the right. Preganglionic fibers coming out through white rami may make synaptic connections following one of three courses: (1) synapse in ganglia at the level of exit, (2) course up or down the sympathetic chain to synapse at another level, or (3) exit the chain without synapsing to an outlying collateral ganglion.

The sympathetic postganglionic neuronal cell bodies are located in ganglia of the paired lateral SNS chain or unpaired collateral ganglia in more peripheral plexuses. Collateral ganglia, such as the celiac and inferior mesenteric ganglia (plexus), are formed by the convergence of preganglionic fibers with many postganglionic neuronal bodies. SNS ganglia are almost always located closer to the spinal cord than to the organs they innervate. The sympathetic postganglionic neuron can therefore originate in either the paired lateral paravertebral SNS ganglia or one of the unpaired collateral plexus. The unmyelinated postganglionic fibers then proceed from the ganglia to terminate within the organs they innervate.

Many of the postganglionic fibers pass from the lateral SNS chain back into the spinal nerves, forming the gray (unmyelinated) communicating rami at all levels of the spinal cord (see Fig. 12-4). They are distributed distally to sweat glands, pilomotor muscle, and blood vessels of the skin and muscle. These nerves are unmyelinated C type fibers (see Table 12-3) and are carried within the somatic nerves. Approximately 8% of the fibers in the average somatic nerve are sympathetic.[1]

The first four or five thoracic spinal segments generate preganglionic fibers that ascend in the neck to form three special paired ganglia. These are the superior cervical, middle cervical, and cervicothoracic ganglia. The last is known as the stellate ganglion and is actually formed by the fusion of the inferior cervical and first thoracic SNS ganglia. These ganglia provide sympathetic innervation of the head, neck, upper extremities, heart, and lungs. Afferent pain fibers also travel with these nerves, accounting for chest, neck, or upper extremity pain with myocardial ischemia.

Activation of the SNS produces a diffused physiologic response (mass reflex) rather than discrete

effects. Function follows design. SNS postganglionic neurons outnumber the preganglionic neurons in an average ratio of 20:1 to 30:1.[2] One preganglionic fiber influences a larger number of postganglionic neurons, which are dispersed to many organs. In addition, the SNS response is augmented by the hormonal release of epinephrine (EPI) from the adrenal medulla.

Parasympathetic Nervous System or Craniosacral Division

The PNS, like the SNS, has both preganglionic and postganglionic neurons. This division is sometimes called the craniosacral outflow because the preganglionic cell bodies originate in the brainstem and sacral segments of the spinal cord. PNS preganglionic fibers are found in cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus). The sacral outflow originates in the intermediolateral gray horns of the second, third, and fourth sacral nerves. Figure 12-1 shows the distribution of the PNS division and its innervation of visceral organs.

The vagus (cranial nerve X) nerve has the most extensive distribution of all the PNS, accounting for more than 75% of PNS activity. The paired vagus nerves supply PNS innervation to the heart, lungs, esophagus, stomach, small intestine, proximal half of the colon, liver, gallbladder, pancreas, and upper portions of the ureters. The sacral fibers form the pelvic visceral nerves, or nervi erigentes. These nerves supply the remainder of the viscera that are not innervated by the vagus. They supply the descending colon, rectum, uterus, bladder, and lower portions of the ureters and are primarily concerned with emptying. Various sexual reactions are also governed by the sacral PNS. The PNS is responsible for penile erection, but SNS stimulation governs ejaculation.

In contrast to the SNS division, PNS preganglionic fibers pass directly to the organ that is innervated. The postganglionic cell bodies are situated near or within the innervated viscera and generally are not visible. The proximity of PNS ganglia to or within the viscera provides a limited distribution of postganglionic fibers. The ratio of postganglionic to preganglionic fibers in many organs appears to be 1:1 to 3:1, compared with the 20:1 found in the SNS system. Auerbach's plexus in the distal colon is the exception, with a ratio of 8,000:1. The fact that PNS preganglionic fibers synapse with only a few postganglionic neurons is consistent with the discrete and limited effect of PNS function. For example, vagal bradycardia can occur without a concomitant change in intestinal motility or salivation. Mass reflex action is not a characteristic of the PNS. The effects of organ response to PNS stimulation are outlined in Table 12-1.

Autonomic Innervation

Heart

The heart is well supplied by the SNS and PNS. These nerves affect cardiac pumping in three ways: (1) by changing the rate (chronotropism), (2) by changing the strength of contraction (inotropism), and (3) by modulating coronary blood flow. The PNS cardiac vagal fibers approach the stellate ganglia and then join the efferent cardiac SNS fibers; therefore, the vagus nerve to the heart and lungs is a mixed nerve containing both PNS and SNS efferent fibers. The PNS fibers are distributed mainly to the sinoatrial and atrioventricular (AV) nodes and to a lesser extent to the atria. There is little or no distribution to the ventricles. Therefore, the main effect of vagal cardiac stimulation to the heart is chronotropic. Vagal stimulation decreases the rate of sinoatrial node discharge and decreases excitability of the AV junctional fibers, slowing impulse conduction to the ventricles. A strong vagal discharge can completely arrest sinoatrial node firing and block impulse conduction to the ventricles.[3]

The physiologic importance of the PNS on myocardial contractility is not as well understood as that of the SNS. Cholinergic blockade can double the heart rate (HR) without altering contractility of the left ventricle. Vagal stimulation of the heart can reduce left ventricular maximum rate of tension development (dP/dT) and decrease contractile force by as much as 10 to

20%. However, PNS stimulation is relatively unimportant in this regard compared with its

predominant effect on HR.

The SNS has the same supraventricular distribution as the PNS, but with stronger representation to the ventricles. SNS efferents to the myocardium funnel through the paired stellate ganglia. The right stellate ganglion distributes primarily to the anterior epicardial surface and the interventricular septum. Right stellate stimulation decreases systolic duration and increases HR. The left stellate ganglion supplies the posterior and lateral surfaces of both ventricles. Left stellate stimulation increases mean arterial pressure and left ventricular contractility without causing a substantial change in HR. Normal SNS tone maintains contractility approximately 20% above that in the absence of any SNS stimulation.[4] Therefore, the dominant effect of the ANS on myocardial contractility is mediated primarily through the SNS. Intrinsic mechanisms of the myocardium, however, can maintain circulation quite well without the ANS, as evidenced by the success of cardiac transplants (see Denervated Heart).[5]

Early investigations, performed in anesthetized, open-chest animals, demonstrated that cardiac ANS nerves exert only slight effects on the coronary vascular bed; however, more recent studies on chronically instrumented, intact, conscious animals show considerable evidence for a strong SNS regulation of the small coronary resistance and larger conductance vessels.[6] (See Adrenergic Receptors section.)

Different segments of the coronary arterial tree react differently to various stimuli and drugs. Large conductance vessels, the primary location for atheromatous plaques, are found on the epicardial surface, whereas the small, precapillary resistance vessels are found within the myocardium. Normally, the large conductance vessels contribute little to overall coronary vascular resistance. Fluctuations in resistance reflect changes in lumen size of the small, precapillary vessels. Blood flow through the resistance vessels is regulated primarily by the local metabolic requirements of the myocardium. The larger conductance vessels, however, can constrict markedly with neurogenic stimulation. Neurogenic influence also assumes a greater role in the resistance vessels when they become hypoxic and lose autoregulation. There is a strong interaction between SNS and PNS nerves in organs with dual, antagonistic innervation.

Peripheral Circulation

The SNS nerves are by far the most important regulators of the peripheral circulation. The PNS nerves play only a minor role in this regard. The PNS dilates vessels, but only in limited areas such as the genitals. SNS stimulation produces both vasodilation and vasoconstriction, with vasoconstrictor effects predominating. The effect is determined by the type of receptors on which the SNS fiber terminates (see Receptors). SNS constrictor receptors are distributed to all segments of the circulation. This distribution is greater in some tissues than in others. Blood vessels in the skin, kidneys, spleen, and mesentery have an extensive SNS distribution, whereas those in the heart, brain, and muscle have less SNS innervation. SNS stimulation of the coronary arteries may produce vasoconstriction or vasodilation, depending on the predominant receptor activity at the time of stimulation (see Table 12-1). Vagal stimulation may also produce coronary vasoconstriction (see *β*-Adrenergic Receptors section). However, local autoregulatory factors usually have the predominant influence on coronary vascular tone.

Basal vasomotor tone is maintained by impulses from the lateral portion of the vasomotor center in the medulla oblongata that continually transmits impulses through the SNS, maintaining partial arteriolar and venular constriction. Circulating EPI from the adrenal medulla has additive effects. This basal ANS tone maintains arteriolar constriction at an intermediate diameter.[7] The arteriole, therefore, has the potential for either further constriction or dilation. If the basal tone were not present, the SNS could only effect vasoconstriction and not vasodilation.[1] The SNS tone in the venules produces little resistance to flow compared with the arterioles and the arteries. The importance of SNS stimulation of veins is to reduce or increase their capacity. By functioning as a reservoir for approximately 80% of the total blood volume, small changes in venous capacitance produce large changes in venous return and, thus, cardiac preload.

Lungs

The lungs are innervated by both the SNS and PNS. Postganglionic SNS fibers from the upper thoracic ganglia (stellate) pass to the lungs to innervate the smooth muscles of the bronchi and pulmonary blood vessels. PNS innervation of these structures is from the vagus nerve.

SNS stimulation produces bronchodilation and pulmonary vasoconstriction.[8] Little else has been proven conclusively about the vasomotor control of the pulmonary vessels other than that they adjust to accommodate the output of the right ventricle. The effect of stimulation of the pulmonary SNS nerves on pulmonary vascular resistance is not great but may be important in maintaining hemodynamic stability during stress and exercise by balancing right and left ventricular output. Stimulation of the vagus nerve produces almost no vasodilation of the pulmonary circulation. The phenomenon of hypoxic pulmonary vasoconstriction appears to be an important force in regulation of pulmonary blood flow. Hypoxic pulmonary vasoconstriction is a local phenomenon capable of providing a faster adjustment to needs.

Both the SNS and the vagus nerve provide active bronchomotor control. SNS stimulation causes bronchodilation, whereas vagal stimulation produces constriction. PNS stimulation may also increase secretions of the bronchial glands. Vagal receptor endings in the alveolar ducts also play an important role in the reflex regulation of the ventilation cycle.[9] The lung has important nonventilatory activity as well. It serves as a metabolic organ that removes local mediators such as norepinephrine (NE) from the circulation and converts others, such as angiotensin 1, to active compounds.[10] (See Interaction with Other Regulatory Systems section.)

AUTONOMIC NERVOUS SYSTEM: NEUROTRANSMISSION

Transmission of excitation across the terminal junctional sites (synaptic clefts) of the peripheral ANS occurs through the mediation of liberated chemicals (Fig. 12-5). Transmitters interact with a receptor on the end organ to evoke a biologic response. The ANS can be pharmacologically subdivided by the neurotransmitter secreted at the effector cell. Pharmacologic parlance designates the SNS and PNS as adrenergic and cholinergic, respectively. The terminals of the PNS postganglionic fibers release acetylcholine (ACh). With the exception of sweat glands, NE is considered the principal neurotransmitter released at the terminals of the sympathetic postganglionic fibers (see Fig. 12-3). Co-transmission of ATP, neuropeptide Y (NPY), and NE has been demonstrated at vascular sympathetic nerve terminals in a number of different tissues including muscle, intestine, kidney, and skin (see SNS Neurotransmission section). The preganglionic neurons of both systems secrete ACh.

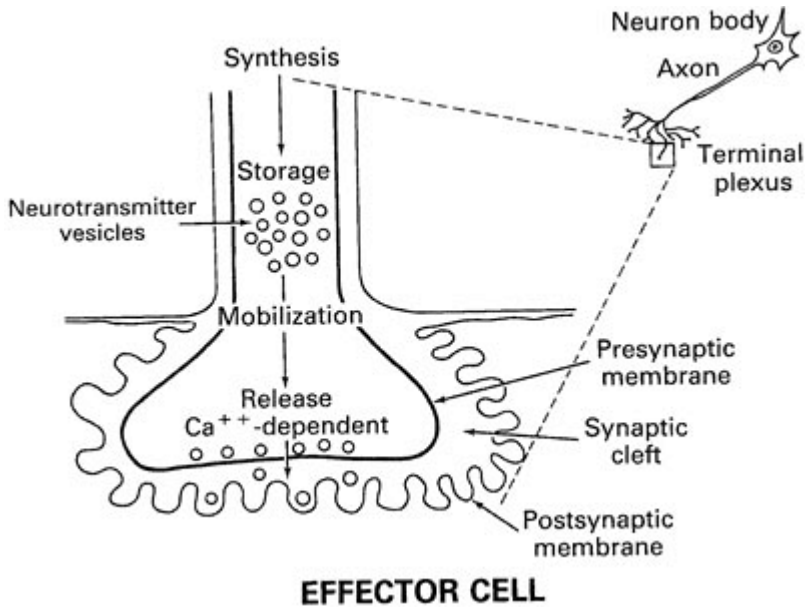

FIGURE 12-5. The anatomy and physiology of the terminal postganglionic fibers of sympathetic and parasympathetic fibers are similar.

The terminations of the postganglionic fibers of both ANS subdivisions are anatomically and physiologically similar. The terminations are characterized by multiple branchings called terminal effector plexuses, or reticulae. These filaments surround the elements of the effector unit "like a mesh stocking."[11] Thus, one SNS postganglionic neuron, for example, can

innervate ~25,000 effector cells (e.g., vascular smooth muscle). The terminal filaments end in presynaptic enlargements called varicosities. Each varicosity contains vesicles, ~500 μ in diameter, in which the neurotransmitters are stored (see Fig. 12-5). The varicosities are also heavily populated with mitochondria, which relates to the increased energy (adenosine triphosphate, ATP) requirements of ACh and NE synthesis. The rate of synthesis depends on the level of ANS activity and is regulated by local feedback. The distance between the varicosity and the effector cell (synaptic or junctional cleft) varies from 100 μ in ganglia and arterioles to as much as 20,000 μ in large arteries. This distance determines the amount of transmitter required to stimulate and the time it takes to diffuse to the effector cell. The time for diffusion is directly proportional to the width of the synaptic gap. Depolarization releases the vesicular contents into the synaptic cleft by exocytosis.

Parasympathetic Nervous System Neurotransmission

Synthesis

ACh is considered the primary neurotransmitter of the PNS. ACh is formed in the presynaptic terminal by acetylation of choline with acetyl coenzyme A. This step is catalyzed by choline acetyl transferase (Fig. 12-6). ACh is then stored in a concentrated form in presynaptic vesicles. A continual release of small amounts of ACh, called quanta, occurs during the resting state. Each quantum results in small changes in the electrical potential of the synaptic end plate without producing depolarization. These are known as miniature end-plate potentials. Arrival of an action potential causes a synchronous release of hundreds of quanta, resulting in depolarization of the end plate. Release of ACh from the vesicles is dependent on influx of calcium (Ca^{2+}) from the interstitial space. Drugs that alter Ca^{2+} binding or influx may decrease ACh release and affect end-organ function. ACh is not reused like NE; therefore, it must be synthesized constantly.

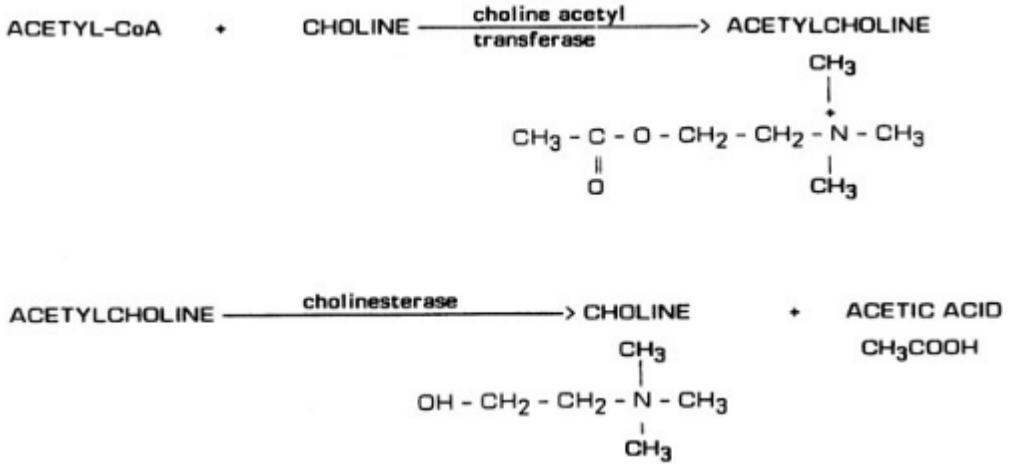

FIGURE 12-6. Synthesis and metabolism of acetylcholine.

Metabolism

The ability of a receptor to modulate function of an effector organ is dependent on rapid recovery to its baseline state after stimulation. For this to occur, the neurotransmitter must be quickly removed from the vicinity of the receptor. ACh removal occurs by rapid hydrolysis by acetylcholinesterase (see Fig. 12-6). This enzyme is found in neurons, at the neuromuscular junction, and in various other tissues of the body. A similar enzyme, pseudocholinesterase or plasma cholinesterase, is also found throughout the body but only to a limited extent in nervous tissue. It does not appear to be physiologically important in termination of the action of ACh. Both acetylcholinesterase and pseudocholinesterase hydrolyze ACh, as well as other esters (such as the ester-type local anesthetics), but they may be distinguished by specific biochemical tests.[3]

Sympathetic Nervous System Neurotransmission

Traditionally, the catecholamines EPI and NE were considered the exclusive mediators of peripheral SNS activity. Evidence accumulated over the past two decades, though, suggests roles for ATP as an additional sympathetic neurotransmitter. NE is released from localized presynaptic vesicles of nearly all postganglionic sympathetic nerves. Vascular SNS nerve terminals, though, also release ATP. Thus, ATP and NE are co-neurotransmitters. They are released directly into the site where they act. Their postjunctional effects appear to be synergistic in tissues studied to date.

The SNS fibers ending in the adrenal medulla are preganglionic, and ACh is the neurotransmitter (see Fig. 12-3). It interacts with the chromaffin cells in the medulla, causing release of EPI and NE. The chromaffin cells take the place of the postganglionic neurons. Stimulation of the sympathetic nerves to the adrenal medulla, however, causes the release of large

quantities of a mixture of EPI and NE into the circulation to become neurotransmitter hormones. The greater portion of this hormonal surge is normally EPI. EPI and NE, when released into the circulation, are classified as hormones in that they are synthesized, stored, and released from the adrenal medulla to act at distant sites.

Hormonal EPI and NE have almost the same effects on effector cells as those caused by local direct sympathetic stimulation; however, the hormonal effects, although brief, last about 10 times as long as those caused by direct stimulation.[12] EPI has a greater metabolic effect than NE. It can increase the metabolic rate of the body as much as 100%.[1] It also increases glycogenolysis in the liver and muscle with glucose release into the blood. These functions are all necessary to prepare the body for fight or flight. Some of the overall vascular tone results from the basal resting secretion of the adrenal medulla in addition to the tone that is maintained directly through stimulation from central vasomotor centers in the medulla.

Catecholamines: The First Messenger

The endogenous catecholamines in humans are dopamine (DA), NE, and EPI. Dopamine is a neurotransmitter in the CNS. It is primarily involved in coordinating motor activity in the brain. It is the precursor of NE. NE is synthesized and stored in nerve endings of postganglionic SNS neurons. It is also synthesized in the adrenal medulla and is the chemical precursor of EPI. Stored EPI is located chiefly in chromaffin cells of the adrenal medulla. Eighty to 85% of the catecholamine content of the adrenal medulla is EPI and 15 to 20% is NE. The brain contains both noradrenergic and dopaminergic receptors, but circulating catecholamines do not cross the blood-brain barrier. The catecholamines present in the brain are synthesized there. Endogenous catecholamines are unique in that several intermediates in the synthesis function as neurotransmitters.

A catecholamine is any compound of a catechol nucleus (a benzene ring with two adjacent hydroxyl groups) and an amine-containing side chain.[13] The chemical configuration of six of the more common catecholamines in clinical use is demonstrated in Figure 12-7. A true catecholamine must possess this basic structure. Catecholamines are often referred to as adrenergic drugs

because their effector actions are mediated through receptors specific for the SNS. Synthetic catecholamines can activate these same receptors because of their structural similarity. For example, clonidine is an *a*-2 receptor agonist that does not possess a catechol nucleus and even has two ring systems that are aplanar to each other (Fig. 12-8). However, clonidine enjoys a remarkable spatial similarity to NE that allows it to activate the receptor.[14] Drugs that produce sympathetic-like effects but lack the basic catecholamine structure are defined as sympathomimetics. All clinically useful catecholamines are sympathomimetics, but not all sympathomimetics are catecholamines (Table 12-4).

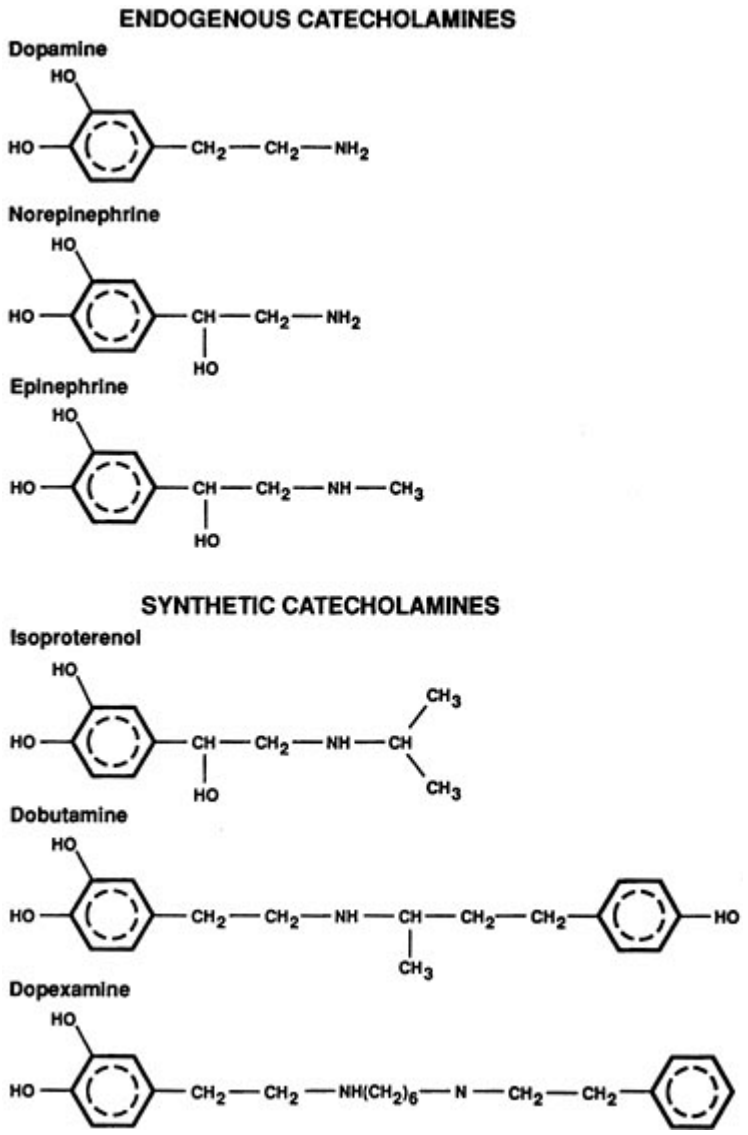

FIGURE 12-7. The chemical configurations of three endogenous catecholamines are compared with those of three synthetic catecholamines. Sympathomimetic drugs differ in their hemodynamic effects largely because of differences in substitution of the amine group on the catechol nucleus.

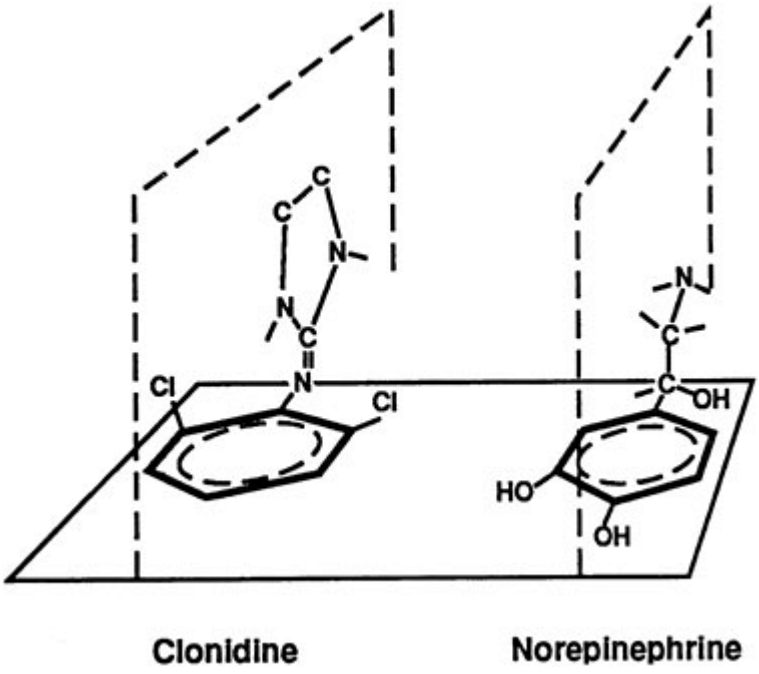

FIGURE 12-8. The spatial similarity of clonidine and NE allows it to activate presynaptic *a*-2 receptors inhibiting NE release.

TABLE 12-4 Sympathomimetic Drugs

·DRUG	·TRADE NAME
·ADRENERGIC AMINES	
Catecholamines	
Epinephrine	Adrenalin
Norepinephrine	Levophed
Dopamine[a]	Inotropin
Dobutamine	Dobutrex
Dopexamine	
Isoproterenol	Isuprel
Noncatecholamines	

Metaraminol[a],[b]	Aramine
Mephentermine[b]	Wyamine
Ephedrine[b]	Ephedrine
Methoxamine	Vasoxyl
Phenylephrine	Neo-Synephrine
Clonidine	
NONADRENERGICS	
Xanthines	Aminophylline
Glucagon	Glucagon
Digitalis	Lanoxin
Calcium salts	
Naloxone	Narcan
Amrinone	Inocor
[a]Direct-acting catecholamine with some indirect action.	
[b] Primarily indirect-acting with some direct action. Adrenergic amines produce sympathomimetic effects via adrenergic receptors.	
Nonadrenergics produce sympathomimetic effects exclusive of the adrenergic receptor.	

The effects of endogenous or synthetic catecholamines on adrenergic receptors can be direct or indirect (see Table 12-4). Indirect-acting catecholamines (i.e., ephedrine) have little intrinsic effect on adrenergic receptors but produce their effects by stimulating release of the stored neurotransmitter from SNS nerve terminals. Some synthetic and endogenous catecholamines stimulate adrenergic receptor sites directly, whereas others have a mixed mode of action. The actions of direct-acting catecholamines are independent of endogenous NE stores; however, the indirect-acting catecholamines are totally dependent on adequate neuronal stores of endogenous NE.

Synthesis

The main site of NE synthesis is in or near the postganglionic nerve endings. Some synthesis does occur in vesicles near the cell body that pass to the nerve endings.[15] Phenylalanine or tyrosine is taken up into the axoplasm of the nerve terminal and synthesized into either NE or EPI. Figure 12-9 demonstrates this synthesis cascade. Tyrosine hydroxylase catalyzes the conversion of tyrosine to dihydroxyphenylalanine. This is the rate-limiting step at which NE synthesis is controlled through feedback inhibition.[16] Dihydroxyphenylalanine and the subsequent compounds in this cascade are catecholamines.

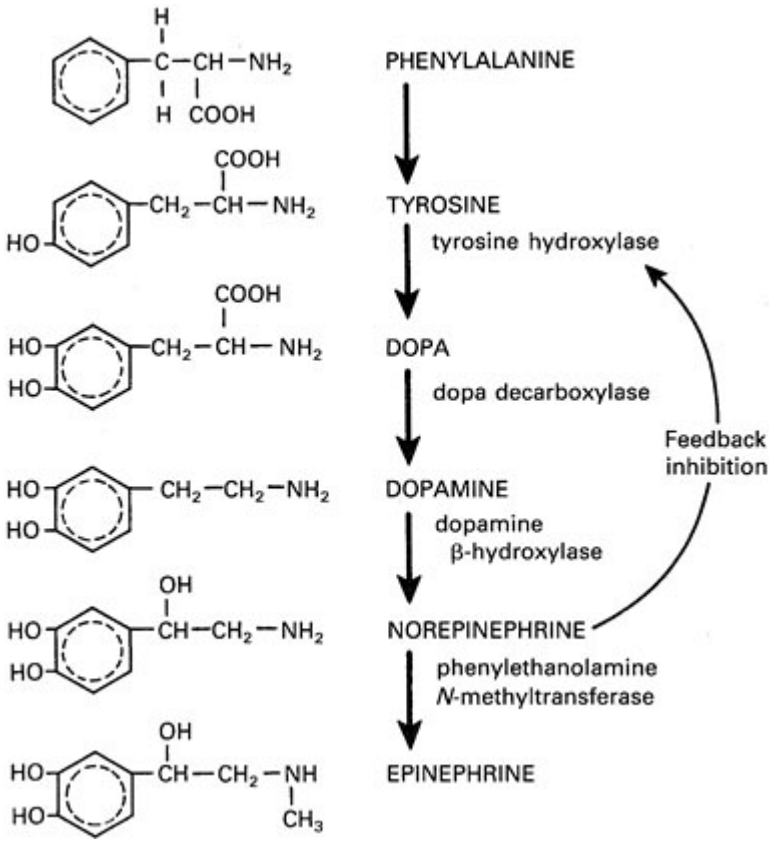

FIGURE 12-9. Schematic of the synthesis of catecholamines. The conversion of tyrosine to DOPA by tyrosine hydroxylase is inhibited by increased NE synthesis. Epinephrine is shown in these steps but is primarily synthesized in the adrenal medulla.

Dopamine synthesis occurs in the cytoplasm of the neuron. Dopamine then enters the storage vesicles. Synthesis stops at this point where dopamine is the neurotransmitter. The vesicles of peripheral postganglionic neurons contain the enzyme dopamine-b-hydroxylase, which converts dopamine to NE. The adrenal medulla additionally contains phenylethanolamine-N-methyltransferase, which converts NE to EPI. This reaction takes place outside the medullary vesicles, and the newly formed EPI then enters the vesicle for storage (Fig. 12-10). All the endogenous catecholamines are stored in presynaptic vesicles and released on arrival of an action potential. Excitation-secretion coupling in sympathetic neurons is Ca2+-dependent.

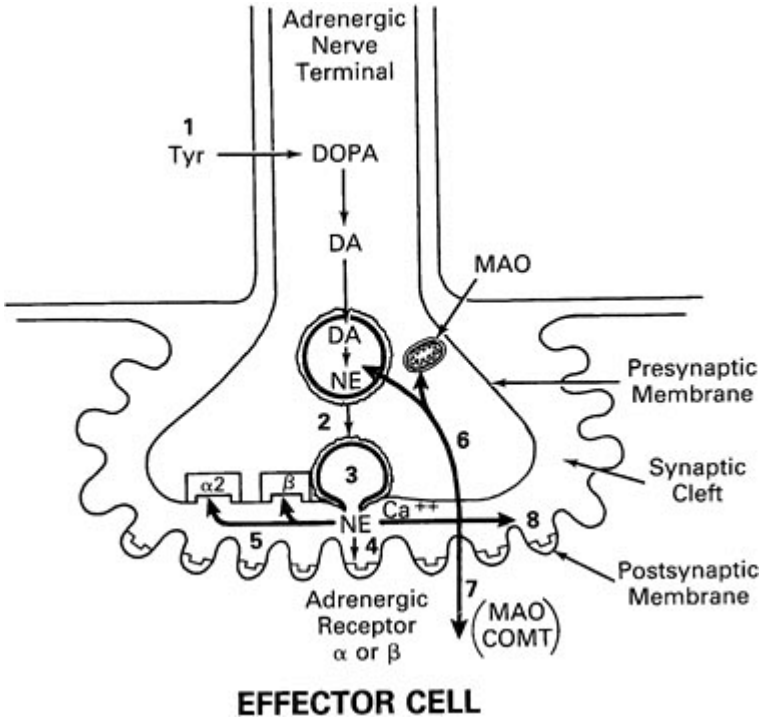

FIGURE 12-10. Schematic of the synthesis and disposition of NE in adrenergic neurotransmission. (1) Synthesis and storage in neuronal vesicles; (2) action potential permits calcium entry with (3) exocytosis of NE into synaptic gap. (4) Released NE reacts with receptor on effector cell. NE (5) may react with presynaptic *α*-2 receptor to inhibit further NE release or with presynaptic *β* receptor to enhance reuptake of NE (6) (uptake 1). Extraneuronal uptake (uptake 2) absorbs NE into effector cell (7) with overflow occurring systemically (8). MAO, monoamine oxidase; COMT, catechol-*O*-methyltransferase; Tyr, tyrosine; DOPA, dihydroxyphenylalanine; NE, norepinephrine.

Regulation

Increased SNS nervous activity, as in congestive heart failure (CHF) or chronic stress, stimulates the synthesis of catecholamines.[17] Glucocorticoids from the adrenal cortex stimulate an increase in phenylethanolamine-N-methyltransferase that methylates NE to EPI.

The release of NE is dependent on depolarization of the nerve and an increase in calcium ion permeability.[17] This release is inhibited by colchicine and prostaglandin E2, suggesting a contractile mechanism. Blockade of prostaglandin synthesis enhances NE release. NE inhibits its own release by stimulating presynaptic (prejunctional) *α*-2 receptors. Phenoxybenzamine

and phentolamine, *α*-receptor antagonists, increase the release of NE by blocking inhibitory presynaptic *α*-2 receptors (Fig. 12-11). Other receptors may also be important in NE regulation. (See Other Receptors section.)

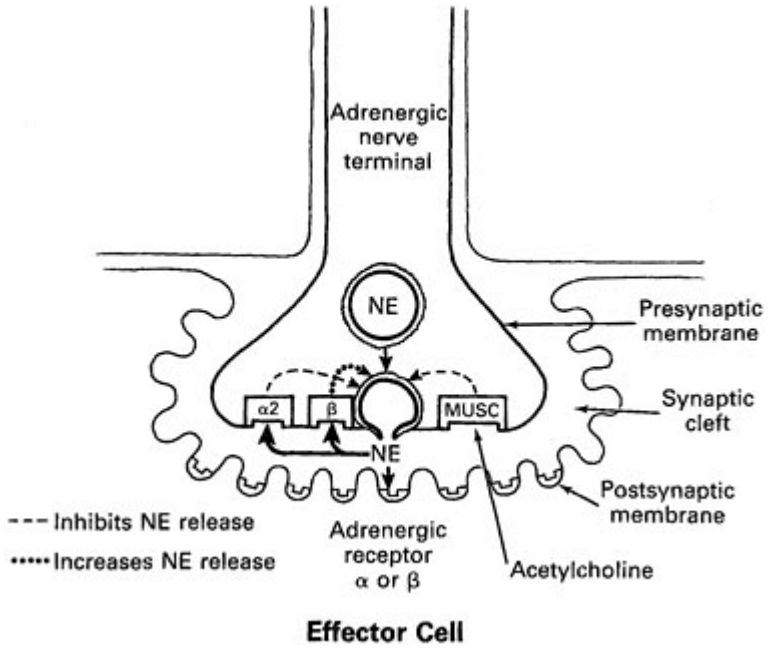

FIGURE 12-11. This schematic demonstrates just a few of the presynaptic adrenergic receptors thought to exist. Agonist and antagonist drugs are clinically available for these receptors (see Table 12-5). The *α*-2 receptors serve as a negative feedback mechanism whereby NE stimulation inhibits its own release. Presynaptic *β* stimulation increases NE uptake, augmenting its availability. Presynaptic muscarinic (MUSC) receptors respond to ACh diffusing from nearby cholinergic terminals. They inhibit NE release and can be blocked by atropine.

Inactivation

The catecholamines are removed from the synaptic cleft by three mechanisms (see Fig. 12-10). These are reuptake into the presynaptic terminals, extraneuronal uptake, and diffusion. Termination of NE at the effector site is almost entirely by reuptake of NE into the terminals of the presynaptic neuron (uptake 1) for reuse. Uptake 1 is an active, energy-requiring, temperature-dependent process.

The reuptake of NE in the presynaptic terminals is also a stereospecific process. Structurally similar compounds (guanethidine, metaraminol) may enter the vesicles and displace the neurotransmitter. Tricyclic antidepressants and cocaine inhibit the reuptake of NE, resulting in high synaptic NE concentrations and accentuated receptor response. In addition, evidence suggests that NE reuptake is mediated by a presynaptic *β*-adrenergic mechanism because *β*-blockade causes marked elevations of EPI and NE[18] (see Figs. 12-10 and 12-11), whereas a blockade does not. Extraneuronal uptake (uptake 2) is a minor pathway for inactivating NE. NE is taken up by effector cells and other extraneuronal tissues. The NE that is taken up by the extraneuronal tissue is metabolized by monoamine oxidase and by catechol-O-methyltransferase to form vanillylmandelic acid (Fig. 12-12). The minute amount of catecholamine that escapes uptake 1 and uptake 2 diffuses into the circulation (uptake 3), where it is similarly metabolized in the liver and kidney. The importance of uptake 1 and uptake 2 is diminished when sympathomimetics are given exogenously. EPI is inactivated by the same enzymes. Whereas uptake 1 is the predominant pathway for inactivation of the endogenous catecholamines, uptake 3 is the predominant pathway for catecholamines given exogenously and is clinically important. This accounts for the longer duration of action by exogenous catecholamines than that noted at the local synapse. The former is slow (liver metabolism) and the latter is fast (uptake 1).

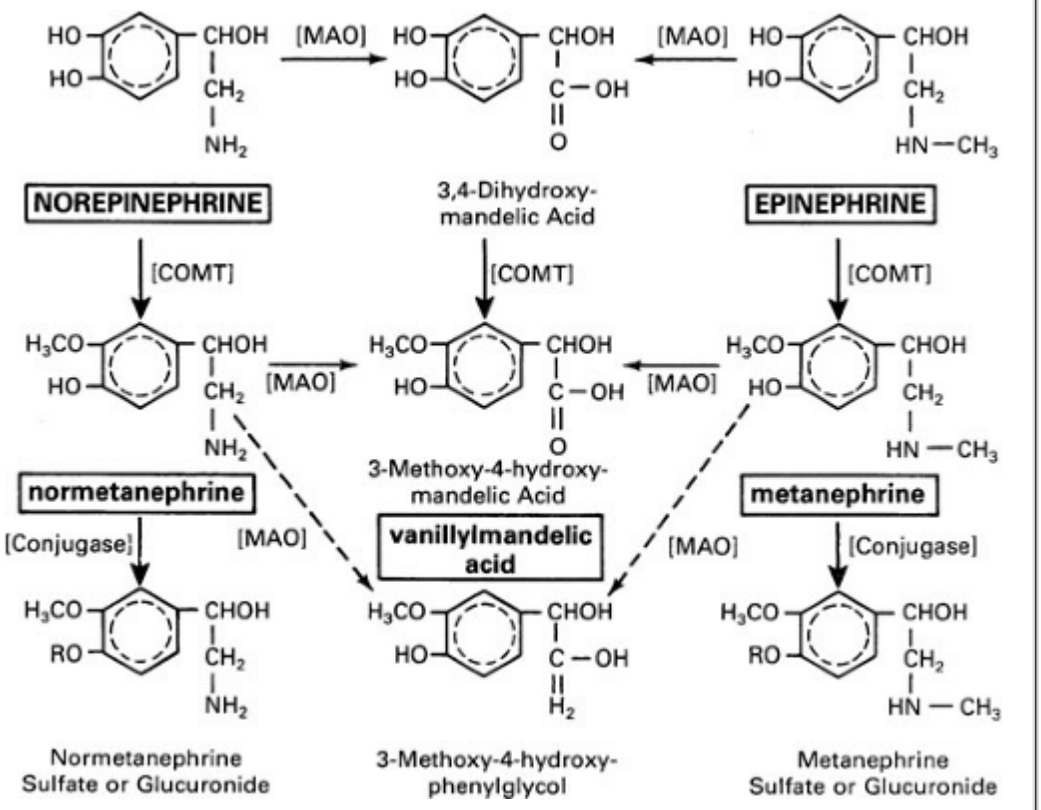

FIGURE 12-12. Catabolism of NE and EPI.

The final metabolic product of the catecholamines is vanillylmandelic acid. Vanillylmandelic acid constitutes the major metabolite (80 to 90%) of NE found in the urine. Less than 5% of released NE appears unchanged in the urine. The metabolic products excreted in the urine provide a gross estimate of SNS activity and can facilitate the clinical diagnosis of pheochromocytoma.

RECEPTORS

An agonist is a substance that interacts with a receptor to evoke a biologic response. ACh, NE, EPI, DA, and ATP are the major agonists of the ANS. An antagonist is a substance that interferes

with the evocation of a response at a receptor site by an agonist. Receptors are therefore regarded as target sites that when activated by an agonist will lead to a response by the effector cell. Receptors are protein macromolecules and are located in the plasma membrane. Several thousand receptors have been demonstrated in a single cell. The enormity of this network is realized when it is considered that ~25,000 single cells can be innervated by a single neuron.[19]

Cholinergic Receptors

ACh is the neurotransmitter at three distinct classes of receptors. These receptors can be differentiated by their anatomic location and their affinity to bind various agonists and antagonists.[20] ACh mediates the "first messenger" function of transmitting impulses in the PNS, the ganglia of the SNS, and the neuroeffector junction of striated, voluntary muscle (see Fig. 12-3). The receptors are referred to as cholinoceptive or cholinergic receptors. The PNS is referred to as the cholinergic system.

Cholinergic receptors are further subdivided into muscarinic and nicotinic receptors because muscarine and nicotine stimulate them selectively.[3] However, both muscarinic and nicotinic receptors respond to ACh (see Cholinergic Drugs section). Muscarine activates cholinergic receptors at the postganglionic PNS junctions of cardiac and smooth muscle throughout the body. Muscarinic stimulation is characterized by bradycardia, decreased inotropism, bronchoconstriction,

miosis, salivation, gastrointestinal (GI) hypermotility, and increased gastric acid secretion (see Table 12-1). Muscarinic receptors can be blocked by atropine without effect on nicotinic receptors (see Cholinergic Drugs section).

Muscarinic receptors are known to exist in sites other than PNS postganglionic junctions. They are found on the presynaptic membrane of sympathetic nerve terminals in the myocardium, coronary vessels, and peripheral vasculature (see Fig. 12-11). These are referred to as adrenergic muscarinic receptors because of their location; however, they are stimulated by ACh. Stimulation of these receptors inhibits release of NE in a manner similar to *α*-2 receptor stimulation.[6] Muscarinic blockade removes inhibition of NE release, augmenting SNS activity. Atropine, the prototypical muscarinic blocker, may produce sympathomimetic activity in this manner as well as vagal blockade. Neuromuscular blocking drugs that cause tachycardia are thought to have a similar mechanism of action.

ACh acting on presynaptic adrenergic muscarinic receptors is a potent inhibitor of NE release.[18] The prejunctional muscarinic receptor may play an important physiologic role because several autonomically innervated tissues (e.g., the heart) possess ANS plexuses in which the SNS and PNS nerve terminals are closely associated.[3] In these plexuses, ACh, released from the nearby PNS nerve terminals (vagus nerve), can inhibit NE release by activation of presynaptic adrenergic muscarinic receptors (see Fig. 12-11).

Nicotinic receptors are found at the synaptic junctions of both SNS and PNS ganglia. Because both junctions are cholinergic, ACh or ACh-like substances such as nicotine will excite postganglionic fibers of both systems (see Fig. 12-3). Low doses of nicotine produce stimulation of ANS ganglia, whereas high doses produce blockade. This dualism is referred to as the nicotinic effect (see Ganglionic Drugs section). Nicotinic stimulation of the SNS ganglia produces hypertension and tachycardia by causing the release of EPI and NE from the adrenal medulla. Adrenal hormone release is mediated by ACh in the chromaffin cells, which are analogous to postganglionic neurons (see Fig. 12-3). A further increase in nicotine concentration produces hypotension and neuromuscular weakness as it becomes a ganglionic blocker. The cholinergic neuroeffector junction of skeletal muscle also contains nicotinic receptors, although they are not identical to the nicotinic receptors in ANS ganglia.

Adrenergic Receptors

Von Euler differentiated the physiologic effects of EPI and NE in 1946.[14] The adrenergic receptors were termed adrenergic or noradrenergic, depending on their responsiveness to EPI or NE. The dissimilarities of these two drugs led Ahlquist in 1948 to propose two types of opposing adrenergic receptors, termed alpha (*α*) and beta (*β*). This postulation implied that selective antagonism of these receptors was possible. The receptors can be classified according to the order of potency by which they are affected by SNS agonists and antagonists. Receptors that respond with an order of potency of NE ⩾ EPI > isoproterenol are called *α* receptors. Those responding with an order of potency of isoproterenol > EPI ⩾ NE are called *β* receptors (Table 12-5). The development of new agonists and antagonists with relatively selective activity allowed subdivision of the *β* receptors into β_1 and β_2. *α* receptors were subsequently divided into α_1 and α_2. The concept of relative selective activity arises from differential potencies among tissue groups to the same drug, such that two dose-response curves are obtained (Fig. 12-13). The sympathomimetic adrenergic drugs in current use differ from one another in their effects largely because of differences in substitution on the amine group, which influences the relative *α* or *β* effect (see Fig. 12-7).[13]

[a]Listed in decreasing order of potency.

[b]Nonselective.

[c]β_1-adrenergic responses are greater.

Pluses indicate strength of potency.

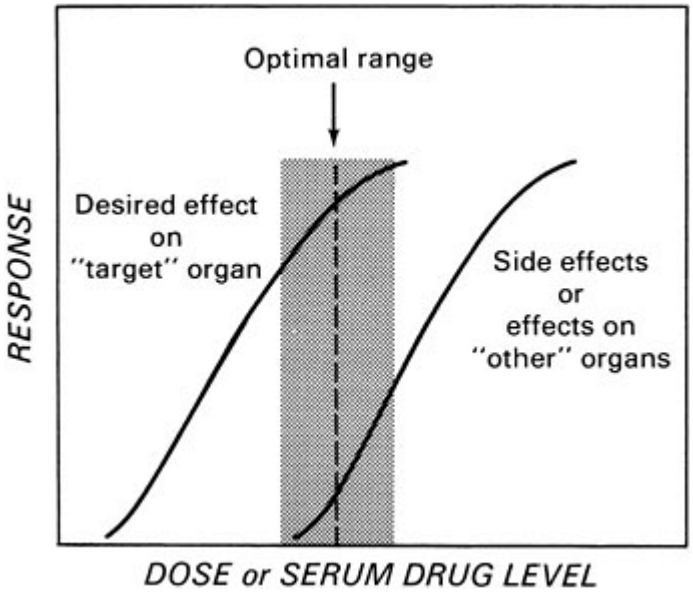

FIGURE 12-13. Relative dose-response relationship on target and other organs. Relative selectivity is illustrated by showing the relationship between two dose-response curves. The curve on the left represents the desired response of bronchodilation using a relatively selective β-2 agonist. The unwanted effects on other organs that occur at higher doses are represented by the curve on the right. For example, an increased HR (β-1 effect) may occur with higher doses of a relatively select β-2 agonist. The optimal range is that concentration of drug that will give the maximal desired response with minimal effects on other organs. The size of the optimal range is dependent on the therapeutic index, or the distance between the two curves. These are usually established in vitro where drug concentration can be precisely controlled. For many cardiovascular drugs, the optimal range is small, and wide fluctuations in serum level of the drug are common; therefore, secondary or side effects are often seen during drug therapy.

Another major peripheral adrenergic receptor specific for dopamine is termed the dopaminergic (DA) receptor. Further studies have revealed not only subsets of the α and β receptors but also the DA receptor. These DA receptors have been identified in the CNS and in renal, mesenteric, and coronary vessels. The physiologic importance of these receptors is a matter of controversy because there are no identifiable *peripheral* DA neurons. Dopamine measured in the circulation is assumed to result from spillover from the brain.

The function of dopamine in the CNS has long been known, but the peripheral DA receptor has been elucidated only within the past 25 years. The presence of the peripheral DA receptor was obscured because dopamine does not affect the DA receptor exclusively. It also stimulates α and β receptors in a dose-related manner.[21] However, DA receptors function independently of α or β blockade and are modified by DA antagonists such as haloperidol, droperidol, and phenothiazines. Thus, there is a necessity for the addition of the DA receptor and its subsets (DA1 and DA2).

The anatomic location and amino acid structure of receptor binding sites have been made possible through radioligand studies. The distribution of adrenoreceptors in organs and tissues is not uniform and their function differs not only by their location but also in their numbers and/or distribution.[22] Adrenoceptors are found in two loci in the sympathetic neuroeffector junction. They are found in both the presynaptic (prejunctional) and postsynaptic (postjunctional) sites as well as extrasynaptic sites (Fig. 12-14). Table 12-6 is a review of the function and synaptic location of some of the clinically important sites.

TABLE 12-6 Adrenergic Receptors

·RECEPTOR	·SYNAPTIC SITE	·ANATOMIC SITE	·ACTION	·LV FUNCTION AND STROKE VOLUME
α_1	Postsynaptic	Peripheral vascular smooth muscle	Constriction	Decreased
		Renal vascular smooth muscle	Constriction	
		Coronary arteries, epicardial	Constriction

	Postsynaptic	Renal and mesenteric vasculature	? Vasoconstriction	

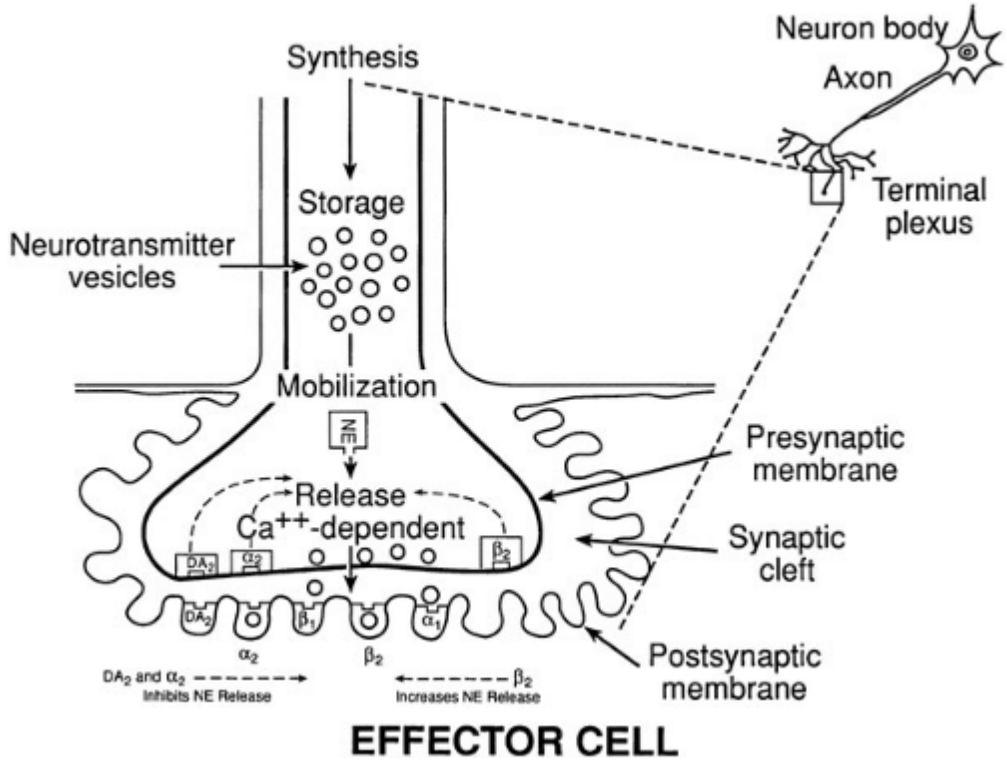

FIGURE 12-14. Loci of several known adrenergic receptors. The presynaptic *α*-2 and DA receptors serve as a negative feedback mechanism, whereby stimulation of NE inhibits its own release. Presynaptic *β*-2 stimulation increases NE uptake, augmenting its availability.

Postsynaptic *α*-2 and *β*-2 receptors are extrasynaptic and are considered noninnervated hormonal receptors.

Prejunctional receptors are considered innervated in that they are in the immediate vicinity of the neurotransmitter released by a sympathetic action potential. Postjunctional receptors are considered to be innervated or noninnervated depending on their proximity to the synaptic cleft.[23] Receptors located directly on postjunctional membranes are considered to be innervated. However, most postsynaptic *α*-2 and *β*-2 receptors are extrasynaptic and considered noninnervated even though they are located in the vicinity of the postsynaptic membrane. These receptors are influenced more by hormonal catecholamines (EPI) than by neurotransmitter (NE).

Extrasynaptic receptors also seem to be less influenced by factors causing the "up or down" regulation of receptor numbers and sensitivity. This may explain the clinical observation of why EPI may work where other agonists, which work on synaptic receptors, may be ineffective. The agonist–receptor interaction of noninnervated receptors is of slower onset and longer duration as well.

α-Adrenergic Receptors

Two classes of clinically important *α* receptors have been demonstrated, *α*-1 and *α*-2. This classification is based on their response to the *α* antagonists yohimbine and prazosin. Prazosin is a more potent antagonist of *α*-1 receptors, whereas *α*-2 receptors are more sensitive to yohimbine. The *α*-1- adrenergic receptors are found in the smooth muscle cells of the peripheral

vasculature of the coronary arteries, skin, uterus, intestinal mucosa, and splanchnic beds (see Table 12-5). The *α*-1 receptors serve as postsynaptic activators of vascular and intestinal smooth muscle as well as of endocrine glands. Their activation results in either decreased or increased tone, depending on the effector organ. The response in resistance and capacitance vessels is constriction, whereas in the intestinal tract it is relaxation. There is now a large body of evidence documenting the presence of postjunctional *α*-1 adrenoreceptors in the mammalian heart. *α*-1 adrenoreceptors have been shown to have a positive inotropic effect on cardiac tissues from most mammals studied, including humans.[24] Experimental work strongly supports the concept that enhanced myocardial *α*-1 responsiveness plays a primary role in the genesis of malignant arrhythmias induced by catecholamines during myocardial ischemia and reperfusion. Drugs possessing potent *α*-1 antagonist activity such as prazosin and phentolamine provide significant antiarrhythmic activity. The clinical mechanism and significance of these findings are not yet clear.[25] However, there is no doubt that *α*-1 adrenergic antagonists prevent catecholamine-induced ventricular arrhythmias.[26] In contrast, studies of the effects of *β*-antagonists in experimental and clinical myocardial infarction have provided conflicting results.

The discovery of presynaptic *α*-adrenoreceptors and their role in the modulation of NE transmission provided the stimulus for the subclassification of *α* receptors into *α*-1 and *α*-2 subtypes.[27] Presynaptic *α*-1 receptors have not been identified and appear confined to the postsynaptic membrane. *α*-2 receptors are found on both presynaptic and postsynaptic membranes of the adrenergic neuroeffector junction. Table 12-6 reviews these sites. Postsynaptic membranes contain a near equal mix of *α*-1 and *α*-2 receptors.

The *α*-2 adrenoreceptors may be subdivided even further into as many as four possible subtypes. Many actions have been attributed to the postsynaptic *α*-2 receptor, including arterial and venous vasoconstriction, platelet aggregation, inhibition of insulin release, inhibition of bowel motility, stimulation of growth hormone release, and inhibition of antidiuretic hormone release.

α-2 receptors can be found in cholinergic pathways as well as in adrenergic pathways. They can significantly modulate parasympathetic activity as well. Current research implies that *α*-2 stimulation in parasympathetic pathways plays a role in the modulation of the baroreceptor reflex

(increased sensitivity),

P.289

vagal mediation of heart rate (bradycardia), bronchoconstriction, and salivation (dry mouth). However, cholinergic receptors can also be found in adrenergic pathways; thus, muscarinic and nicotinic receptors have been found in presynaptic and postsynaptic locations, where they in turn modulate sympathetic activity (see Fig. 12-11). Maze speculates that although the functional role of the postsynaptic *α*-2 receptor in the CNS has not been well characterized, it is probable that the features that are so desirable to the anesthesiologist, such as sedation, anxiolysis, analgesia, and hypnosis, are mediated through this site.

Stimulation of presynaptic *α*-2 receptors mediates inhibition of NE release into the synaptic cleft, serving as a negative feedback mechanism.[28] The central effects are primarily related to a reduction in sympathetic outflow with a concomitantly enhanced parasympathetic outflow (e.g., enhanced baroreceptor activity). This results in a decreased systemic vascular resistance, decreased cardiac output (CO), decreased inotropic state in the myocardium, and decreased HR. The peripheral presynaptic *α*-2 effects are similar, and NE release is inhibited in postganglionic neurons. However, stimulation of postsynaptic *α*-2 receptors, like the *α*-1 postsynaptic receptor, affects vasoconstriction.

P.290

NE acts on both *α*-1 and *α*-2 receptors. Thus, NE not only activates smooth muscle vasoconstriction (postsynaptic *α*-1 and *α*-2 receptors) but also stimulates presynaptic *α*-2 receptors and inhibits its own release. Selective stimulation of the presynaptic *α*-2 receptor could produce a beneficial reduction of peripheral vascular resistance. Unfortunately, most known presynaptic *α*-2 agonists also stimulate the postsynaptic *α*-2 receptors, causing vasoconstriction. Blockade of *α*-2 presynaptic receptors, however, ablates normal inhibition of NE, causing vasoconstriction. Vasodilation occurs with the blockade of postsynaptic *α*-1 and *α*-2 receptors.

***α* Receptors in the Cardiovascular System.** The presence of postsynaptic *α*-1 and *α*-2 receptors in the mammalian myocardium and coronary arteries as well as the peripheral vasculature are known.[25]

Coronary Arteries. The presence of postsynaptic *α*-1 and *α*-2 receptors in the coronary arteries of humans has not been established with certainty, but other mammalian models have demonstrated their presence. Sympathetic nerves cause coronary vasoconstriction, which is mediated more by postsynaptic *α*-2 than *α*-1 receptors. The larger epicardial arteries possess mainly *α*-1 receptors, whereas *α*-2 receptors and some *α*-1 receptors are present in the small coronary artery resistance vessels.[29] Epicardial vessels contribute only 5% to the total resistance of the coronary circulation; therefore, *α*-1 agonists such as phenylephrine have little influence on coronary resistance.[30]

Myocardial ischemia has been shown to increase *α*-2 receptor density in the coronary arteries. Ischemia has also been shown to cause a reflex increase in sympathetic activity mediated by *α* mechanisms. This cascade may further increase coronary constriction. Postsynaptic *α*-1 receptors do not rely on extracellular Ca2+ to constrict the vessel, whereas the *α*-2–constrictor response is highly dependent on extracellular influx and exquisitely sensitive to calcium channel inhibitors.[31]

Myocardium. The role of *β* receptors in mediating catecholamine-induced inotropism and arrhythmogenesis is known. Studies have shown the presence of postsynaptic myocardial *α*-1 receptors, which also exert a major, facilatory, positive inotropic effect on the myocardium of several species of mammals including humans. Their contribution to malignant reperfusion arrhythmogenesis has also been recognized.

Phenylephrine, an *α*-1 agonist, can increase myocardial contractility two- to threefold compared with a six- to sevenfold increase produced by isoproterenol, a pure *β* agonist.[32] Myocardial postsynaptic *α*-1 receptors mediate perhaps as much as 30 to 50% of the basal inotropic tone of the normal heart. The inotropic response of the normal myocardium is more sensitive to *β* agonists.

Postsynaptic myocardial *α*-1 receptors play a more prominent inotropic role in the failing heart by

serving as reserve to the normally predominant *β*-1 receptors. Although the response to both *α*-1 and *β*-1 agonists is reduced in the failing myocardium, the interaction between the two receptors is more apparent. Chronic heart failure is known to produce a reduced density (down-regulation) of myocardial *β*-1 receptors as a result of high levels of circulating catecholamines. However, there is no evidence of down-regulation of either *α*-1 or *β*-2 receptors with failure.[33]

The increase in density of myocardial *α*-1 adrenoreceptors shows a relative increase with failure and myocardial ischemia.[33] Thus, enhanced myocardial *α*-1 receptor numbers, and sensitivity, may contribute to positive inotropism seen during ischemia as well as to the malignant arrhythmias that occur with reperfusion. Intracellular mobilization of cytosolic Ca2+ by the activated *α*-1 myocardial receptors during ischemia appears to contribute to these arrhythmias.[33] The *α*-1 receptor also increases the sensitivity of the contractile elements to Ca2+. Drugs possessing potent *α*-1 antagonism such as prazosin and phentolamine have been shown to possess significant antiarrhythmic activity, although of limited usefulness because of hypotension. Enhanced *α*-1 activity with myocardial ischemia may explain why the antiarrhythmic benefits of *β* antagonists in patients with acute myocardial infarction are far from certain. The contribution of *β* receptors to positive inotropism and arrhythmogenesis during ischemia and reperfusion may be overshadowed by the *α* receptors during acute failure and ischemia.

Peripheral Vessels. Activation of the presynaptic *α*-2 vascular receptors produces vasodilation, whereas the postsynaptic *α*-1 and *α*-2 vascular receptors subserve vasoconstriction. Presynaptic vascular *α*-2 receptors inhibit NE release. This represents a negative feedback mechanism by which NE inhibits its own release via the prejunctional receptor. Presynaptic *α*-2 agonists, such as clonidine, inhibit NE release at the neurosympathetic junction producing vasodilatation. The effects of selective presynaptic *α*-2 receptor agonists to ameliorate coronary vasoconstriction in humans are unclear. Excitation of the inhibitory presynaptic *α*-2 receptors by endogenous or synthetic catecholamines also inhibits NE release. However, most sympathomimetics are nonselective *α* agonists that will excite equally presynaptic *α*-2 vasodilators and vasoconstrictive postsynaptic *α*-1 and *α*-2 receptors.

Postsynaptic *α*-1 and *α*-2 receptors coexist in both the arterial and venous sides of the circulation with the relative distribution of *α*-2 receptors being greater on the venous side.[34] This may explain why pure *α*-1 agonists, such as methoxamine, produce little venoconstriction, whereas many nonselective agonists such as phenylephrine produce significant venoconstriction. NE is the most potent venoconstrictor of all the catecholamines. Clinically, venoconstriction would have the effect of preloading by shifting venous capacitance centrally, whereas stimulation of *arterial* postsynaptic *α*-1 and *α*-2 receptors would effect afterloading by increasing arterial resistance.

***α* Receptors in the Central Nervous System.** All subtypes of the *α*, *β*, and DA receptors have been found in various regions of the brain and spinal cord. The functional role of the cerebral *α* and *β* receptors suggests a close association with blood pressure and HR control. Cerebral and spinal cord presynaptic *α*-2 receptors are also involved in inhibition of presynaptic NE release. Although the brain contains adrenergic and dopaminergic receptors, circulating catecholamines do not cross the blood-brain barrier. The catecholamines in the brain are synthesized there. Many actions have been attributed to the cerebral postsynaptic *α*-2 receptor. This includes inhibition of insulin release, inhibition of bowel motility, stimulation of growth hormone release, and inhibition of antidiuretic hormone release. Central neuraxis injection of *α*-2 agonists, such as clonidine, act to produce analgesia, sedation, and cardiovascular depression. The increased duration of epidural or intrathecal anesthesia by the addition of nonselective *α* agonists to the local anesthetic may also produce additional analgesia through this mechanism.

***α* Receptors in the Kidney.** The kidney has an extensive and exclusive adrenergic innervation of the afferent and efferent glomerular arterioles, proximal and distal renal tubules, ascending loop of Henle, and juxtaglomerular apparatus. The greatest density of innervation is in the thick ascending loop of Henle, followed by the distal convoluted tubules and proximal tube. Both *α*-1 and *α*-2 subtypes are found in the kidney with the *α*-2 receptor dominating. The *α*-1 receptor is predominant in the renal vasculature and elicits vasoconstriction, which modulates renal blood flow. Tubular *α*-1 receptors enhance sodium and water resorption, leading to antinatriuresis,

whereas tubular *α*-2 receptors promote sodium and water excretion.

β-Adrenergic Receptors

The *β*-adrenergic receptors, like the *α* receptor, have been divided into subtypes. They are designated as the *β*-1 and *β*-2 subtypes. The *β*-1 receptors predominate in the myocardium, the sinoatrial node, and the ventricular conduction system. The *β*-1 receptors also mediate the effects of the catecholamines on the myocardium. These receptors are equally sensitive to EPI and NE, which distinguishes them from the *β*-2 receptors. Effects of *β*-1 stimulation are outlined in Table 12-5. Table 12-6 outlines their effects specifically on the cardiovascular system.

The *β*-2 receptors are located in the smooth muscles of the blood vessels in the skin, muscle, and mesentery, and in bronchial smooth muscle. Stimulation produces vasodilation and bronchial relaxation. The *β*-2 receptors are more sensitive to EPI than NE. The *β*-1 receptors are suggested to be innervated receptors responding to neuronally released NE, whereas *β*-2 receptors are "normal" receptors responding primarily to circulating EPI.[35]

β receptors are found in both presynaptic and postsynaptic membranes of the adrenergic neuroeffector junction (see Table 12-6). *β*-1 receptors are distributed to postsynaptic sites and have not been identified on the presynaptic membrane. Presynaptic *β* receptors are mostly of the *β*-2 subtype. The effects of activation of the presynaptic *β*-2 receptor are diametrically opposed to those of the presynaptic *α*-2 receptor. The presynaptic *β*-2 receptor accelerates endogenous NE release, whereas blockade of this receptor will inhibit NE release. Antagonism of the presynaptic *β*-2 receptors produces a physiological result similar to activation of the presynaptic *α*-2 receptor.

The postsynaptic *β*-1 receptors are located on the synaptic membrane and are innervated receptors responding primarily to neuronal NE. The postsynaptic *β*-2 receptors, like the postsynaptic *α*-2 receptor, are considered noninnervated, extrasynaptic, normal receptors responding primarily to circulating EPI.

β Receptors in the Cardiovascular System

3 ***Myocardium.*** *Myocardial β* receptors were originally classified as *β*-1 receptors. Those in the vascular and bronchial smooth muscle were called the *β*-2 subtype. However, studies have confirmed the coexistence of *β*-1 and *β*-2 receptors in the myocardium.[35] Both *β*-1 and *β*-2 receptors are functionally coupled to adenyl cyclase, suggesting a similar involvement in the regulation of inotropism and chronotropism.

Postsynaptic *β*-1 receptors are distributed predominantly to the myocardium, the sinoatrial node, and the ventricular conduction system. The *β*-2 receptors have the same distribution but are presynaptic. Activation of the presynaptic *β*-2 receptor accelerates the release of NE into the synaptic cleft. The *β*-2 receptor approximates 20 to 30% of the *β* receptors in the ventricular myocardium and up to 40% of the *β* receptors in the atrium.

The increased catecholamine levels associated with heart failure lead to a proportionally greater down-regulation of the *β*-1 receptor density with a relative sparing of the *β*-2 subtype and an increase in the *α*-1 subtype. The *β*-2 receptors increasingly mediate the inotropic response to catecholamines during heart failure and are facilitated by the *α*-1 receptor.

The effect of NE on inotropism in the normal heart is mediated entirely through the postsynaptic *β*-1 receptor, whereas the inotropic effects of EPI are mediated through both the *β*-1 and *β*-2 myocardial receptors. The *β*-2 receptors may also mediate the chronotropic responses to EPI because selective *β*-1 antagonists are less effective in suppressing induced tachycardia than the nonselective *β*-1 antagonist propranolol.

Peripheral Vessels. The postsynaptic vascular *β* receptors are virtually all of the *β*-2 subtype. The *β*-2 receptors are located in the smooth muscle of the blood vessels of the skin, muscle, mesentery, and bronchi. Stimulation of the postsynaptic *β*-2 receptor produces vasodilation and bronchial relaxation. Modest vasoconstriction occurs when subjected to blockade because the

actions of the vascular postsynaptic *β*-2 receptors no longer oppose the actions of the *α*-1 and *α*-2 postsynaptic receptors.

***β* Receptor in the Kidney.** The kidney contains both *β*-1 and *β*-1 receptors, with the *β*-1 being predominant. Renin release from the juxtaglomerular apparatus is enhanced by *β* stimulation. *β*-blockers inhibit this response. The *β*-1 receptor evokes renin release in humans. Renal *β*-2 receptors also appear to regulate renal blood flow at the vascular level. They have been identified pharmacologically and mediate a vasodilatory response.

Dopaminergic Receptors

Dopamine, synthesized in 1910, was recognized in 1959 not only as a vasopressor and the precursor of NE and EPI, but also as an important central and peripheral neurotransmitter. Dopamine receptors (DA) have been localized in the CNS, on blood vessels, and on postganglionic sympathetic nerves (see Table 12-6). Two clinically important types of DA receptors have been recognized. These are the DA1 and DA2 receptors. The DA1 receptors are postsynaptic, whereas the DA2 receptors are both presynaptic and postsynaptic. The presynaptic DA2 receptors, like the presynaptic *α*-2 receptor, inhibit NE release and can produce vasodilatation.[36] The postsynaptic DA2 receptor may subserve vasoconstriction similar to that of the postsynaptic *α*-2 receptor.[37] This effect is opposite to that of the postsynaptic DA1 renal vascular receptor. Unpublished data suggest that dopamine may be the intrinsic regulator of renal function.[38] The zona glomerulose of the adrenal cortex also contains DA2 receptors, which inhibit release of aldosterone.

Myocardium. Defining specific dopaminergic receptors has been difficult because dopamine also exerts effects on the *α* and *β* receptors.[39] DA receptors have not been described in the myocardium. Effects of dopamine are those related to activation of *β*-1 receptors, which promote positive inotropism and chronotropism. *β*-2 activation would produce *some* systemic vasodilatation.

Peripheral Vessels. The greatest numbers of DA1-postsynaptic receptors are found on vascular smooth muscle cells of the kidney and mesentery, but are also found in the other systemic arteries including coronary, cerebral, and cutaneous arteries. The vascular receptors are, like the *β*-2 receptors, linked to adenyl cyclase and mediate smooth muscle relaxation. Activation of these receptors produces vasodilatation, increasing blood flow to these organs. Concurrent activation of vascular presynaptic DA2 receptors also inhibits NE release at presynaptic *α*-2 receptors, which may also contribute to peripheral vasodilatation. Higher doses of dopamine can mediate vasoconstriction via the postsynaptic *α*-1 and *α*-2 receptors. The constrictive effect is relatively weak in the cardiovascular system where the action of dopamine on adrenergic receptors is 1/35 and 1/50 as potent as that of EPI and NE, respectively.[40]

Central Nervous System. DA receptors have been identified in the hypothalamus where they are involved in prolactin release. They are also found in the basal ganglia where they coordinate motor function.[39] Degeneration of dopaminergic neurons of the substantia nigra is the source of Parkinson's disease. Another central action of dopamine is to stimulate the chemoreceptor trigger zone of the medulla, producing nausea and vomiting. Dopamine antagonists such as haloperidol and droperidol are clinically effective in countering this action.

Kidney and Mesentery. Apart from their effect on the vessels of the kidney and mesentery, DA receptors on the smooth muscle of the esophagus, stomach, and small intestine enhance secretion production and reduce intestinal motility.[40]

Metoclopramide, a dopamine antagonist, is useful for aspiration prophylaxis by promoting gastric emptying.

The distribution of DA receptors in the renal vasculature is well known, but DA receptors have other functions within the kidney. DA1 receptors are located on renal tubules, which inhibit sodium resorption with subsequent natriuresis and diuresis. The natriuresis may be the result of a combined renal vasodilatation, improved CO, and tubular action of the DA1 receptors. Juxtaglomerular cells also contain DA1 receptors, which increase renin release when activated.

This action modulates the diuresis produced by DA1 activation of the tubules.

Dopamine has unique autonomic effects by activating specific peripheral dopaminergic receptors, which promote natriuresis and reduce afterload via dilatation of the renal and mesenteric arterial beds. Peripheral dopaminergic activity serves as a natural antihypertensive mechanism.[41] Its actions are overshadowed by the opposite effect of its main biologic partner, NE.[42] Plasma NE levels are known to increase with aging, likely the result of reduced clearance. Peripheral dopaminergic activity is known to diminish. Subtle changes in the DA–NE balance with aging may account for the diminished ability of the aged kidney to excrete a salt load. This may also contribute to the uniform finding of increasing systolic blood pressure in societies with high salt consumption.

Other Receptors

Adenosine Receptors

Adenosine produces inhibition of NE release. The effect of adenosine is blocked by caffeine and other methylxanthines. The physiologic and pharmacologic roles of adenosine-mediated inhibition of NE release are not clearly defined. The physiologic function of these receptors may be the reduction of sympathetic tone under hypoxic conditions when adenosine production is enhanced. As a consequence of reduced NE release, cardiac work would be decreased and oxygen demand reduced. Adenosine has been effectively used to produce controlled hypotension.[42]

Serotonin

Serotonin (5-hydroxytryptamine) depresses the response of isolated blood vessels to SNS stimulation and decreases release of labeled NE in these preparations. This inhibitory action of serotonin is antagonized by raising the external calcium ion concentration. Thus, serotonin may inhibit neuronal NE release by a mechanism that limits the availability of calcium ions at the nerve terminal.

Prostaglandin E2, Histamine, and Several Opioids

Prostaglandin E2, histamine, and several opioids have been reported to act on prejunctional receptor sites to inhibit NE release in certain sympathetically innervated tissue. However, these inhibitory receptors are unlikely to play a physiologic role in limiting NE release because inhibitors of cyclo-oxygenase, histamine antagonists, and naloxone produce no increase in NE release.

Histamine acts in a manner similar to the neurotransmitters of the SNS. It has membrane receptors specific for histamine, with the individual response being determined by the type of cell being stimulated. Two receptors for histamine have been determined. These have been designated H1 and H2, for which it has been possible to develop specific agonists and antagonists. Stimulation of the H1 receptors produces bronchoconstriction and intestinal contraction. The major role of the H2 receptors is related to acid production by the parietal cells of the stomach; however, histamine is present in relatively high concentrations in the myocardium and cardiac conducting tissue, where it exerts positive inotropic and chronotropic effects while depressing dromotropism. The positive inotropic and chronotropic effects of histamine are H2 receptor effects that are not blocked by β antagonism. These effects are blocked by H2 antagonists, such as cimetidine, which accounts for the occasional report of cardiovascular collapse following the use of cimetidine.[43] The negative dromotropic effect and that of coronary spasm caused by histamine are H1 receptor effects.

Adrenergic Receptor Numbers or Sensitivity

Receptors, once thought to be static entities, are now thought to be dynamically regulated by a variety of conditions and in a constant state of flux. Receptors are synthesized in the sarcoplasmic reticulum (SR) of the parent cell, where they may remain extrasynaptic or externalize to the synaptic membranes where they may cluster. Membrane receptors may be removed or internalized

to intracellular sites for either dehydration or recycling.

The number and sensitivity of adrenergic receptors can be influenced by normal, genetic, and developmental factors. Changes in the number of receptors alter the response to catecholamines. Alteration in the number, or density, of receptors is referred to as either up-regulation or down-regulation. As a rule, the number of receptors is inversely proportional to the ambient concentration of the catecholamines. Extended exposure of receptors to their agonists markedly reduces, but does not ablate, the biologic response to catecholamines.[44] For example, increased adrenergic activity occurs in response to reduced perfusion as a result of acute or chronic myocardial dysfunction. Plasma catecholamines are increased. As a result, myocardial postsynaptic β-1 receptors "downregulate." This is thought to explain the diminished inotropic and chronotropic response to β-1 agonists and exercise in patients with chronic heart failure. However, calcium-induced inotropism is not impaired because β-2 receptor (extrasynaptic) numbers remain relatively intact.[45] The β-2 receptors may account for up to 40% of the inotropism of the failing heart compared with 20% in the normal heart.[46] Tachyphylaxis to infused catecholamines is also thought to be the result of acute down-regulation of receptor numbers. There appears to be a reduction in numbers or sensitivity of β receptors in hypertensive patients who also have elevated plasma catecholamines. Down-regulation is the presumptive explanation for the lack of correlation between plasma catecholamine levels and the blood pressure elevation in patients with pheochromocytoma. Chronic use of β agonists such as terbutaline, isoproterenol, or EPI for the treatment of asthma can result in tachyphylaxis because of down-regulation. Even short-term use (1 to 6 hours) of β agonists may cause down-regulation of receptor numbers.

Down-regulation is reversible on termination of the agonist. Chronic treatment of animals with nonselective β-blockade causes a 100% increase in the number of β receptors.[47] This accounts for the propranolol withdrawal syndrome in which the acute discontinuation of the β antagonist leaves the α receptors unopposed plus an increased number of β receptors. Clonidine withdrawal can be explained by the same mechanism.[48] Acute discontinuation of the α-2- inhibitory agonist would permit a resumption of stimulation of adrenoreceptors that up-regulated during the time NE release was inhibited.

Up- or down-regulation of receptor numbers may not alter sensitivity of the receptor. Likewise, sensitivity may be increased or decreased in the presence of normal numbers of receptors. The pharmacologic factors affecting up- or down-regulation of the α and β receptors are similar.

AUTONOMIC NERVOUS SYSTEM REFLEXES AND INTERACTIONS

The ANS reflex has been compared to the computer circuit. This control system, as in all reflex systems, has (1) sensors, (2) afferent pathways, (3) CNS integration, and (4) efferent pathways to the receptors and efferent organs. Fine adjustments are made at the local level according to positive and negative feedback mechanisms. The baroreceptor is an example. The variable to be controlled (blood pressure) is sensed (carotid sinus), integrated (medullary vasomotor center), and adjusted through specific effector–receptor sites. Drugs or disease can interrupt this circuit at any point. β-blockers may attenuate the effector response, whereas an α agonist such as clonidine may alter both the effector and the integrator functions of blood pressure control (see Antihypertensives section).[48]

Baroreceptors

Several reflexes in the cardiovascular system help control arterial blood pressure, CO, and HR. Cardiovascular ANS reflexes are an anachronism. The business of circulation is to provide blood flow. Yet the most important controlled variable to which the sensors are attuned is blood pressure, a product of flow and resistance.

Etienne Marey noted in 1859 that the pulse rate is inversely proportional to the blood pressure, and this is known as Marey's law. Subsequently, Hering, Koch, and others demonstrated that the alterations in HR evoked by changes in blood pressure stretch are dependent on baroreceptors located in the aortic arch and the carotid sinuses. These pressure sensors react to alterations in

stretch caused by blood pressure. Compliance of the stretch receptors and their sensitivity may be altered by carotid sinus atherosclerosis. Thus, carotid artery disease may be one source of hypertension rather than the result.

Impulses from the carotid sinus and aortic arch reach the medullary vasomotor center by the glossopharyngeal and vagus nerves, respectively. Increased sensory traffic from the baroreceptors, caused by increased blood pressure, inhibits SNS effector traffic. The relative increase in vagal tone produces vasodilation, slowing of the HR, and a lowering of blood pressure. Real increases in vagal tone occur when blood pressure exceeds normal limits.[49]

The arterial baroreceptor reflex can best be demonstrated by the Valsalva maneuver (Fig. 12-15). The Valsalva maneuver raises the intrathoracic pressure by forced expiration against a closed glottis. The arterial blood pressure rises momentarily as the intrathoracic blood is forced into the heart (preload). Sustained intrathoracic pressure diminishes venous return, reduces the CO, and drops the blood pressure. Reflex vasoconstriction and tachycardia ensue. Blood pressure returns to normal with release of the forced expiration, but then briefly "overshoots" because of the vasoconstriction and increased venous return. A slowing of the HR accompanies the overshoot in pressure, according to Marey's law.

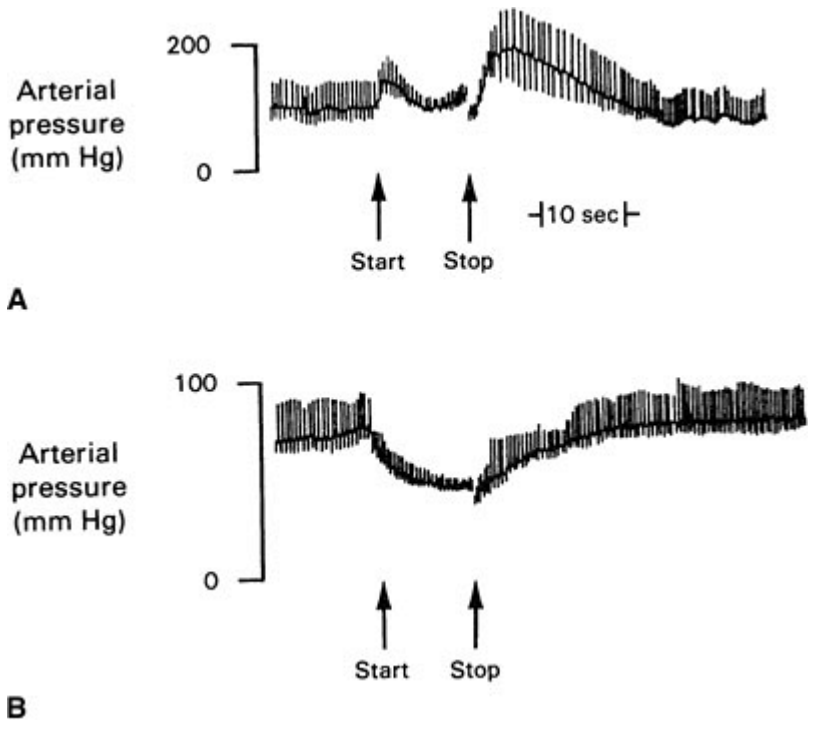

FIGURE 12-15. A. The normal blood pressure response to the Valsalva maneuver is demonstrated. Pulse rate moves in a reciprocal direction according to Marey's law of the heart. **B.** An abnormal Valsalva response is shown in a patient with C5 quadriplegia.

The cardiovascular responses to the Valsalva maneuver require an intact ANS circuit from peripheral sensor to peripheral adrenergic receptors. The Valsalva maneuver has been used to identify patients at risk for anesthesia because of ANS instability (see Fig. 12-15). This was once a major concern in patients receiving drugs that depleted catecholamines, such as reserpine. Dysfunction of the SNS is implicated if exaggerated and prolonged hypotension develops during the forced expiration phase (50% from resting mean arterial pressure).[4] In addition, the overshoot at the end of the Valsalva maneuver is absent. Dysfunction of the PNS can be assumed if the HR does not respond appropriately to the blood pressure changes. The Valsalva maneuver may still be a valid clinical preoperative test for detecting the autonomic dysautonomia that accompanies diabetes.

Venous baroreceptors may be more dominant in the moment-to-moment regulation of CO. Baroreceptors in the right atrium and great veins produce an increase in HR when stretched by increased right atrial pressure.[50] Reduced venous pressure decreases HR. Unlike the arterial baroreceptors, venous sensors are not thought to alter vascular tone; however, venoconstriction is postulated to occur when atrial pressures decline. Stretch of the venous receptors produces changes in HR opposite to those produced when the arterial pressure sensors are stimulated. The arterial and venous pressure receptors are separately monitoring two of the four major determinants of CO: afterload and preload, respectively. Venous baroreceptors sample preload by stretch of the atrium. Arterial baroreceptors survey resistance, or afterload, as reflected in the mean arterial pressure. Afterload and preload produce opposite effects on CO; thus, one should not be surprised that the venous and arterial baroreceptors produce effects opposite those of a similar stretch stimulus, pressure.

Bainbridge described the venous baroreceptor reflex and demonstrated that it can be abolished by vagal resection. Numerous investigators have confirmed the acceleration of the HR in response to volume. However, the magnitude and direction of the HR response are dependent on the prevailing HR at the time of stimulation. The denervated, transplanted mammalian heart also accelerates in response to volume loading. HR, like CO, can apparently be adjusted to the quantity of blood entering the heart.[51]

The Bainbridge reflex relates to the characteristic but paradoxical slowing of the heart seen with spinal anesthesia. Blockade of the SNS levels of T1-4 ablates the efferent limb of the cardiac accelerator nerves. This source of cardiac deceleration is obvious, as the vagus nerve is unopposed. However, bradycardia during spinal anesthesia is more related to the development of arterial hypotension than to the height of the block. The primary defect in the development of spinal hypotension is a decrease in venous return. Theoretically, the arterial

hypotension should reflexly produce a tachycardia through the arterial baroreceptors. Instead, bradycardia is more common. Greene suggests that in the unmedicated person, the venous baroreceptors are dominant over the arterial. A reduced venous pressure, therefore, slows HR.[52] In contrast, humorally mediated tachycardia is the usual response to hypotension or acidosis from other causes.

Denervated Heart

Reflex modulation of the adrenergic agonists is best seen in the denervated transplant heart, which retains the recipient's innervated sinoatrial node and the donor's denervated sinoatrial node.[53] Table 12-7 is a summary of drug effects on the transplanted heart. NE simultaneously activates *α* and *β* receptors of the intact heart and vessels. NE infusion in the transplanted heart produces a slowing of the recipient's atrial rate through vagal feedback as the blood pressure rises. In the unmodulated donor heart, atrial rate increases. Methoxamine-induced hypertension and nitrite-induced hypotension fail to induce deceleration and acceleration of the donor atrial rate. The baroreceptors are therefore not operant in the transplanted heart. Isoproterenol, a pure *β* agonist, increases the discharge rate of both the recipient and donor node by direct action, with the donor rate near doubling that of the recipient node. Atropine accelerates the recipient's atrial rate, whereas no effect is seen on the donor rate, which now controls HR. Hypersensitivity to *β* cardiac stimulation in denervated dog hearts has been demonstrated. Patients who have undergone chemical sympathectomy with bretylium or guanethidine are known to be hyperreactive to the usual doses of catecholamines.

β-blockade produces comparable slowing of the sinoatrial node of both recipient and donor. The exercise capability of the denervated heart is conspicuously reduced by *β*-blockade, presumably because of its reliance on circulating catecholamines. Propranolol has also been demonstrated to reduce the *β* response to chronotropic effects of NE and isoproterenol in the transplanted heart. The CO of the transplanted heart varies appropriately with changes in preload and afterload.

Interaction of Autonomic Nervous System Receptors

Strong interactions have been noted between SNS and PNS nerves in organs that receive dual, antagonistic innervation. Release of NE at the presynaptic terminal is modified by the PNS. For example, vagal inhibition of left ventricular contractility is accentuated as the level of SNS activity is raised. This interaction is termed "accentuated antagonism" and is mediated by a combination of presynaptic and postsynaptic mechanisms. The coronary arteries present an example of this phenomenon and deserve special attention. The concept of accentuated antagonism has yet to be clearly defined because it is unusual for high SNS and PNS activity to coexist, except during anesthesia. The importance of accentuated antagonism in the intact, conscious human has yet to be demonstrated; however, it may explain the clinical observation that angina and myocardial infarction owing to coronary spasm in humans are not often related to cardiac work, as is angina caused by sclerotic coronary disease. Attacks of angina usually occur at rest, often waking the patient from sleep. This diurnal variation also corresponds to the greatest activity of the PNS system. The mechanism by which coronary arterial spasm occurs remains unknown, but this continues to be an exciting area of investigation.

The myocardium and coronary vessels are abundantly supplied with adrenergic and cholinergic fibers. Strong activity of both *α* and *β* receptors has been demonstrated in the coronary vascular bed. Selective stimulation of both the *α*-1 and postsynaptic *α*-2 receptors increases coronary vascular resistance, whereas selective α blockade eliminates this effect. Therefore, both *β*-1 and *α*-1 adrenoreceptors are present on coronary arteries and accessible to NE from sympathetic nerves.[54]

The close anatomic proximity of the postganglionic vagal and SNS nerve endings in coronary arteries provides the morphologic basis for strong interaction. SNS and PNS nerve

terminals are found in such close proximity that transmitters from one can easily reach the other and affect transmitter release. In addition, the presynaptic adrenergic terminals of the myocardium and coronary vessels, like all blood vessels examined, contain muscarinic receptors.[18] Recent observations confirm that muscarinic agents and vagal stimulation, acting on the presynaptic, SNS muscarinic receptor, inhibit the release of NE in a manner similar to that of the presynaptic *α*-2 and DA2 receptors (see Fig. 12-11). Conversely, blockade of the muscarinic receptors with atropine markedly augments the positive inotropic responses to catecholamines.[3] Suppression of NE release explains, in part, vagal-induced attenuation of the inotropic response to strong SNS stimulation (accentuated antagonism) and only a weak negative inotropic effect of vagal stimulation when there is low background SNS activity. This may also explain why vagal activity reduces the vulnerability of the myocardium to fibrillation during infusions of NE.

ACh may cause coronary spasm during periods of high SNS tone.[6] Inhibition of NE release by presynaptic adrenergic muscarinic receptors of the smooth muscle of coronary vessels would lessen the coronary relaxation normally produced by NE on the *β*-1 receptor (see Fig. 12-11). In anesthetized dogs, the rate of NE outflow into the coronary sinus blood, evoked by cardiac SNS stimulation, is markedly diminished by simultaneous vagal efferent stimulation.[55] This action is known to be prevented by atropine, which also causes coronary vasodilation. Methacholine, a muscarinic parasympathomimetic agent, has been reported to cause coronary vasoconstriction.[56] However, it simultaneously reduces ventricular irritability by reducing NE release in myocardial fibers.[3]

Interaction with Other Regulatory Systems

The ANS is integrally related to several endocrine systems that ultimately summate to control

blood pressure and regulate homeostasis. These include the renin–angiotensin system, antidiuretic hormone, glucocorticoids, and insulin.

Antidiuretic hormone or vasopressin is formed in the hypothalamus and released from nerve endings in the posterior pituitary gland. It causes vasoconstriction and increased resorption of water in the distal collecting ducts of the kidney. It therefore affects not only central blood volume but also plasma osmolality. The primary regulator of antidiuretic hormone release is plasma osmolality; however, several other stimuli may outweigh this control in stressful situations. Release is also triggered by decreased central blood volume via low-pressure atrial receptors and hypotension via the carotid baroreceptors. Stress, pain, hypoxia, anesthesia, and surgery also stimulate release of antidiuretic hormone. Infusion of catecholamines may alter its release, but these effects appear to be mediated by the carotid baroreceptors. ANS drugs that induce hypotension or decrease cardiac filling may induce release of antidiuretic hormone and thus affect plasma osmolality.

Both *α* and *β* receptors have been found in the endocrine pancreas and modulate insulin release (see Table 12-5). *β* stimulation increases insulin release, whereas *α* stimulation decreases it. The overall importance of this interaction is not entirely clear, but decreased tolerance to glucose and potassium has been noted in subjects taking *β*-blocking drugs.[57]

The renin–angiotensin system is a complex endocrine system that modulates both blood pressure and water-electrolyte homeostasis (Fig. 12-16). Renin is a proteolytic enzyme contained within the cells of the juxtaglomerular apparatus of the renal cortex. When released, it acts on plasma angiotensinogen to form angiotensin I. Angiotensin I is then converted to angiotensin II by converting enzyme in the lung. Angiotensin II is a powerful direct arterial vasoconstrictor. It also acts on the adrenal cortex to release aldosterone and on the adrenal medulla to release EPI. In addition to its direct effects on vascular smooth muscle, angiotensin II augments NE release via presynaptic receptors, thus enhancing peripheral SNS tone. A group of drugs called angiotensin-converting enzyme (ACE) inhibitors act by interfering with the formation or function of angiotensin II. These drugs have been found useful in the treatment of essential and renovascular hypertension and of congestive heart failure. Captopril, enalapril, and lisinopril inhibit the action of converting enzyme, thus preventing the conversion of angiotensin I to angiotensin II.[58] They have supplanted diuretics and *β*-blockers as first-line agents in the treatment of hypertension.

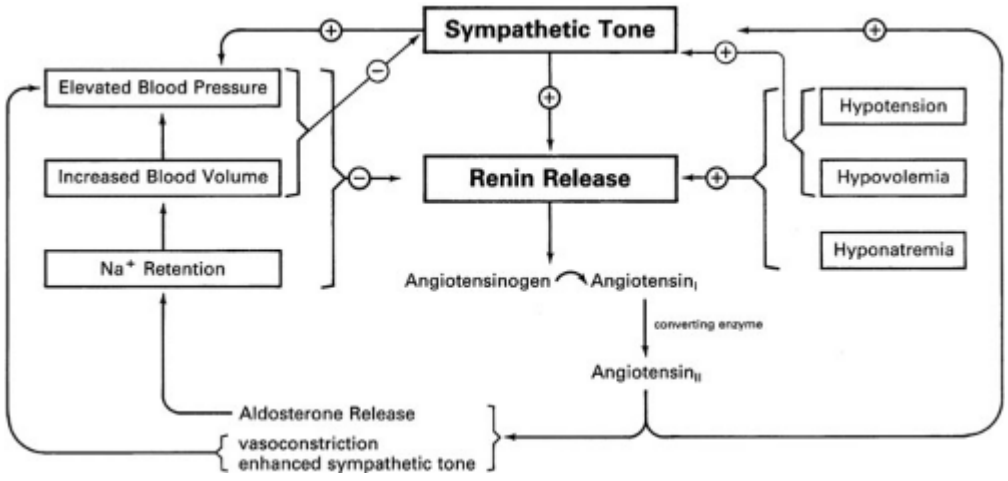

FIGURE 12-16. The interactions of the renin–angiotensin and SNS in regulating homeostasis are shown schematically along with the physiologic variables that modulate their function. Arrows with a plus sign (+) represent stimulation, and those with a minus sign (-) represent inhibition.

Renin is released in response to hyponatremia, decreased renal perfusion pressure, and ANS

stimulation via β receptors on juxtaglomerular cells. Changes in sympathetic tone may thus alter renin release and affect homeostasis in a variety

of ways. The ANS is also intimately related to adrenocortical function. As outlined earlier, glucocorticoid release modulates phenylethanolamine-N-methyltransferase formation and thus synthesis of EPI. Glucocorticoids are also important in regulating the response of peripheral tissues to changes in SNS tone. Thus, the ANS is intimately related to other homeostatic mechanisms.

CLINICAL AUTONOMIC NERVOUS SYSTEM PHARMACOLOGY

4 The clinical application of ANS pharmacology is based on knowledge of ANS anatomy, physiology, and molecular pharmacology. Drugs that modify ANS activity can be classified by their site of action, mechanism of action, or pathology for which they are most commonly used. Antihypertensive drugs are an example of the third category. This classification is a matter of degree because considerable functional overlap occurs. An example of classification by site relates to the ganglionic agonists or blocking agents. ANS drugs can be further categorized as those that act at the prejunctional membrane and those acting postjunctionally. They can then be more specifically classified by the predominant receptor or receptors on which they act.

Mode of Action

ANS drugs may be broadly classified by mode of action according to their mimetic or lytic actions. This may also be termed agonist or antagonist. A sympathomimetic, such as ephedrine, mimics SNS sympathetic activity by stimulation of adrenergic receptor sites both directly and indirectly. Sympatholytic drugs cause dissolution of SNS activity at these same receptor sites. β receptor blockers are examples of sympatholytic drugs. The terms "parasympathomimetic" and "parasympatholytic" are self-explanatory and may be further divided by their site of action on the muscarinic or nicotinic receptors.

Several modes of ANS drug action become evident when one follows the cascade of neurotransmission. The mode is related to site. Drugs that act on prejunctional membranes may therefore (1) interfere with transmitter synthesis (α-methyl paratyrosine), (2) interfere with transmitter storage (reserpine), (3) interfere with transmitter release (clonidine), (4) stimulate transmitter release (ephedrine), or (5) interfere with reuptake of transmitter (cocaine). Drugs may also modify metabolism of the neurotransmitter in the synaptic cleft (anticholinesterase). Drugs acting at postjunctional sites may directly stimulate postjunctional receptors and interfere with transmitter agonist at the postjunctional receptor.

The ultimate response of an effector organ to an agonist or antagonist depends on (1) the drug, (2) its plasma concentration, (3) the number of receptors in the effector organ, (4) binding by the receptor, (5) the concurrent activities of other drugs and hormones, (6) the cellular metabolic status, and (7) reflex adjustments by the organism. This is the source of conflicting results for drugs used in differing clinical circumstances.

Ganglionic Drugs

SNS and PNS ganglia are pharmacologically similar in that transmission through these ANS ganglia is affected by ACh (see Fig. 12-3). Most ganglionic agonists and antagonists are not selective and affect SNS and PNS ganglia equally. This nonselective property creates many undesirable and unpredictable side effects, which have limited the clinical usefulness of this category of drugs.

Agonists

There are essentially no clinically useful ganglionic agonists. Nicotine is the prototypical ganglionic agonist. In low doses, it stimulates ANS ganglia and the neuromuscular junction of striated muscle. High doses produce ganglionic and neuromuscular blockade. Low-dose stimulation and high-dose blockade are referred to as nicotinic effects in describing any drug with similar effects.

Most ganglionic agonists and antagonists produce their effects through their nicotinic effects. The protean side effects of nicotinic stimulation render it useful only as an investigative tool.

Despite its lack of clinical usefulness, nicotine is widely used in the form of tobacco. The novice tobacco user can often describe the overlap of SNS and PNS side effects of nicotinic stimulation, which appear as nausea and vomiting, tachycardia, bradycardia, diarrhea, and sometimes fainting as a result of high-dose ganglionic blockade.[3]

Antagonists

Drugs that interfere with neurotransmission at ANS ganglia are known as ganglionic blocking agents. Nicotine, in high doses, is the prototypical ganglionic blocking agent also; however, early stimulatory nicotinic activity can be blocked at the ganglia and muscle end plates with other ganglionic blockers and muscle relaxants, respectively, without blocking muscarinic effects. Ganglionic blockers produce their nicotinic effects by competing, mimicking, or interfering with ACh metabolism. Hexamethonium, trimethaphan, and pentolinium produce a selective nondepolarizing blockade of neurotransmission at ANS ganglia without producing nicotinic neuromuscular blockade. They compete with ACh in the ganglia without stimulating the receptors. The introduction of drugs that produce vasodilation directly or by action on the SNS vasomotor center has made the ganglionic blockers obsolete. d-Tubocurare (dTC) produces a competitive nondepolarizing block of both motor end plates and ANS ganglia. The action of motor paralysis predominates, but the concomitant ganglionic blockade at higher doses explains part of the hypotensive effect often seen with the use of dTC for muscle relaxation. Histamine release is the major hypotensive factor that is common to dTC and other ganglionic blockers. Anticholinesterase drugs may produce nicotinic type ganglionic blockade by competition with ACh as well as by persistent depolarization via accumulated ACh.

Trimethaphan is the only ganglionic blocker available in the United States. Trimethaphan produces blockade by competition with ACh for receptors, thus stabilizing the postsynaptic membrane. However, side effects and rapid onset tachyphylaxis have markedly reduced its use in anesthesia.[59] The patient's pupils become fixed and dilated during administration, which obscures eye signs, an important consideration for neurosurgery. In this regard, it is distinctly inferior to nitroprusside. The major advantage of trimethaphan is its short duration of action, which is the result of pseudocholinesterase hydrolysis.

Cholinergic Drugs

Cholinergic drugs may be classified by the following outline, which follows physiologic response and site of action.

I. Cholinergic drugs: agonists[3]
    A. Nicotinic

        1. ANS ganglionic transmission
        2. Neuromuscular transmission
    B. Muscarinic
        1. Direct acting
        2. Indirect acting

II. Cholinolytic agents: antagonists
    A. Nicotinic
        1. ANS ganglionic transmission

2. Neuromuscular transmission

B. Muscarinic

Muscarinic Agonists

The cholinomimetic muscarinic drugs act at sites in the body where ACh is the neurotransmitter of the nerve impulse. These drugs may be divided into three groups, the first two of which are direct muscarinic agonists.[60] The third group acts indirectly. These groups are choline esters (ACh, methacholine, carbamylcholine, bethanechol), alkaloids (pilocarpine, muscarine, arecoline), and anticholinesterases (physostigmine, neostigmine, pyridostigmine, edrophonium, echothiophate).

Direct Cholinomimetics. ACh has virtually no therapeutic applications because of its diffuse action and rapid hydrolysis by cholinesterase (see Fig. 12-6). One may encounter the use of topical ACh (1%) drops during cataract extraction when a rapid miosis is desired. Systemic effects are not usually seen because of the rapidity of ACh hydrolysis.

Other choline esters have been synthesized, mostly derivatives of ACh, which possess more selective muscarinic activity than ACh. They differ from ACh in being more resistant to inactivation by cholinesterase and thus having a more prolonged and useful action. They also differ from ACh in their relative muscarinic and nicotinic activities. The best studied of these drugs are methacholine, bethanechol, and carbamylcholine.[3] The chemical structures of ACh and these choline esters are shown in Figure 12-17. Their pharmacologic actions are compared with those of ACh in Table 12-8. These are not important drugs in anesthesiology but anesthesiologists may encounter patients who are receiving them. They may be useful in the postoperative period to alleviate cardiac tachydysrhythmias, urinary retention, and ileus.

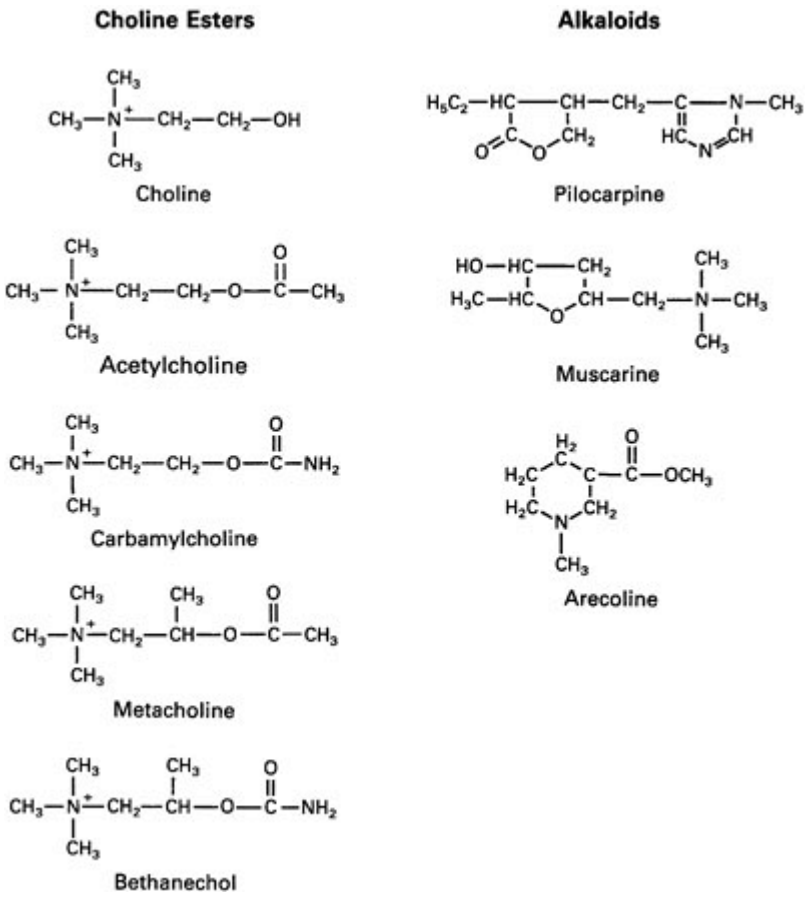

FIGURE 12-17. Chemical structures of direct-acting cholinomimetic esters and alkaloids.

ACh is a quaternary ammonium compound that interacts with postsynaptic receptors, causing conformational membrane changes. This results in increased permeability to small ions and, thus, depolarization. All the receptors translate the reversible binding of ACh into openings of discrete channels in excitable membranes, allowing Na+ and K+ ions to flow along their electrochemical gradients. Structure–activity relationships point to the presence of two important binding sites on the receptor, an esteractic site that binds the ester end of the molecule and an ionic site that binds the quaternary amine portion (see Fig. 12-6). Subtle changes in the structure of the compound can markedly alter the responses among different tissue groups. The degree of muscarinic activity falls if the acetyl group is replaced, but this confers a resistance to enzymatic hydrolysis. Carbamylcholine is synthesized by replacing the acetyl group with carbamyl (see Fig.

12-17). It possesses both muscarinic and nicotinic actions but is virtually resistant to esterase hydrolysis (see Table 12-8). Bethanechol is also resistant to hydrolysis but possesses mainly muscarinic activity. β-methyl substitution produces methacholine, which is less resistant to hydrolysis but is primarily a muscarinic agonist.

Methacholine slows the heart and dilates peripheral blood vessels. It is used to terminate supraventricular tachydysrhythmias, especially paroxysmal tachycardia, when other measures have failed. It also increases intestinal tone. Methacholine should not be given to patients with asthma. Hypertensive patients may also develop marked hypotension. Side effects are those of PNS stimulation such as nausea, vomiting, and flushed sweating. Overdose is treated with atropine.

Bethanechol is relatively selective for the gastrointestinal and urinary tracts. In usual doses it does not slow the heart or lower the blood pressure, as does methacholine. Bethanecol is of value in treating postoperative abdominal distention (nonobstructive paralytic ileus), gastric atony following bilateral vagotomy, congenital megacolon, nonobstructive urinary retention, and some cases of neurogenic bladder. It is not a parenteral drug. Precautions are as for methacholine.

Direct-acting cholinomimetic alkaloids include muscarine, pilocarpine, and arecoline. They act at the same sites as ACh, and their effects are similar to those of ACh as described in Table 12-8. There are no uses for these drugs in anesthesiology. Pilocarpine is the only drug of this group used therapeutically in the United States. Its sole use is for the treatment of glaucoma, for which it is the standard. It is used as a topical miotic drug in ophthalmologic practice to reduce intraocular pressure in glaucoma.

Common side effects of cholinomimetic alkaloids are those of intense PNS stimulation, which include gastrointestinal cramping, hypotension, diaphoresis, salivation, diarrhea, and bladder pain.[3] Muscarinic agonists are particularly dangerous in patients with myasthenia gravis (who are receiving anticholinesterases), bulbar palsy, cardiac disease, asthma, peptic ulcer, progressive muscular atrophy, or mechanical intestinal obstruction or urinary retention.[61]

Indirect Cholinomimetics. The indirect-acting cholinomimetic drugs are of greater importance to the anesthesiologist than are the direct-acting drugs. These drugs produce cholinomimetic effects indirectly as a result of inhibition or inactivation of the enzyme acetylcholinesterase, which normally destroys ACh by hydrolysis. They are referred to as cholinesterase inhibitors or anticholinesterases. Table 12-9 lists therapeutic cholinesterase inhibitors and their major indications. Most of these drugs inhibit both acetylcholinesterase and pseudocholinesterase. Inhibition of acetylcholinesterase

permits the accumulation of ACh transmitter in the synapse, resulting in intense PNS activity similar to that of the direct cholinomimetic agents. The action of ACh is therefore potentiated and prolonged. Their effects can be predicted from a knowledge of ANS pharmacology previously presented. Some of the acetylcholinesterase drugs (i.e., edrophonium) may also stimulate cholinergic receptors by direct action. The accumulation of ACh by the anticholinesterases potentially can produce all of the following: (1) stimulation of muscarinic receptors at ANS effect organs, (2) stimulation followed by depression of all ANS ganglia and skeletal muscle (nicotinic), and (3) stimulation with later depression of cholinergic receptor sites in the CNS. All of these effects may be seen with lethal doses of anticholinesterase drugs, but therapeutic doses only produce the first two.

TABLE 12-9 Cholinesterase Inhibitors

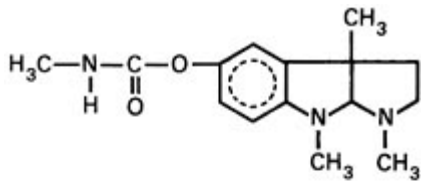
·DRUG	·TRADE NAME	·ROUTE	·DURATION	·INDICATIONS

Reversible				
Physostigmine	Eserine	Topical	6–12 hr	Glaucoma
Pyridostigmine	Mestinon	Oral, iv, im	4 hr	Myasthenia gravis
	Regonol			Reversal of neuromuscular blockade
Neostigmine	Prostigmin	Oral, iv	4–6 hr	Myasthenia gravis
				Reversal of neuromuscular blockade
Edrophonium	Tensilon	iv	1–2 hr	Reversal of neuromuscular blockade
	Enlon			Diagnosis of myasthenia gravis
Demecarium	Humorsol	Topical	3–5 days	Glaucoma
Ambenonium	Mytelase	Oral	4 hr	Myasthenia gravis
Nonreversible				
Echothiophate	Phospholine	Topical	3–14 days	Glaucoma
Isofluorophate		Topical	3–7 days	Glaucoma research
Malathion		Topical		Insecticide—relatively safe for mammals because of rapid hepatic metabolism
Parathion		Topical		Insecticide—highly toxic to higher animals; frequent accidental poisoning
Sarin (GB)	Nerve gas	Topical and gas		

Tabun	Nerve gas	Topical and gas	No indications for the use of nerve gas
Soman	Nerve gas	Topical and gas	
Note: Atropine should always be given prior to or with iv cholinesterase inhibitors and when only nicotinic effects are desired; muscarinic effects are dangerous when excessive.			

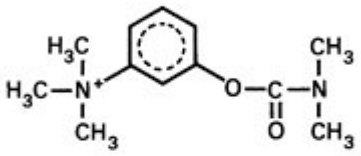
Actions of therapeutic significance of the anticholinesterase drugs to the anesthesiologist concern the eye, the intestine, and the neuromuscular junction. The effects of anticholinesterases are useful in the treatment of myasthenia gravis, glaucoma, and atony of the gastrointestinal and urinary tracts. Anticholinesterase drugs are used routinely in anesthesia to reverse nondepolarizing neuromuscular block.

The most prominent pharmacologic effects of the anticholinesterase drugs are muscarinic. Their most useful actions are their nicotinic effects.[3] Muscarinic activity is evoked by lower concentrations of ACh than are necessary to produce the desired nicotinic effect. For example, the anticholinesterase neostigmine reverses neuromuscular blockade by increasing ACh concentration at the muscle end plate, a nicotinic receptor. Nicotinic reversal of neuromuscular blockade can usually be produced safely only when the patient has been protected by atropine or other muscarinic blockers. This prevents the untoward muscarinic effects of bradycardia, hypotension, bronchospasm, or intestinal spasm. Conversely, neuromuscular paralysis may be produced or increased if excessive anticholinesterase is used. Excess accumulation of ACh at the motor end plates produces a depolarizing block similar to that produced by succinylcholine or nicotine.



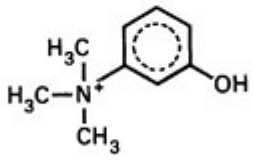
Reversal of neuromuscular blockade in patients who have had bowel anastomosis was at one time a major controversy. Some thought that the muscarinic effects of anticholinesterase drugs (hypermotility) increased the risk of anastomotic leakage[62] whereas others found no association between their use and subsequent breakdown.[63] National experience has favored the latter opinion.

Clinically, anticholinesterase drugs may be divided into two types: the reversible and nonreversible cholinesterase inhibitors.[60] Reversible cholinesterase inhibitors delay the hydrolysis of ACh from 1 to 8 hours. Nonreversible drugs are so named because their inhibitory effects may last from days to weeks. The differences in duration of various anticholinesterases apparently depend on whether they inhibit the anionic or esteratic site of acetylcholinesterase. Therefore, the anticholinesterase drugs have also been pharmacologically

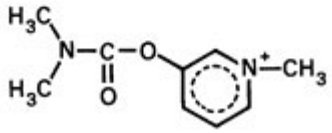


subdivided. Drugs that inhibit the anionic site are called competitive inhibitors. Their action is a result of competition between the anticholinesterase and ACh for the anionic site. These drugs tend to be short acting. Edrophonium is an example of this type. Drugs that inhibit the esteratic site are called acid-transferring inhibitors. These drugs include the longer- acting neostigmine, pyridostigmine, and physostigmine. Thus, the differences in the mechanism of inhibition produced by prosthetic inhibitors (edrophonium) and acid-transferring inhibitors (neostigmine) account for the longer duration of action associated with the latter agents.

Most of the reversible cholinesterase inhibitors are quaternary ammonium compounds and do not cross the blood-brain barrier. Physostigmine is a tertiary amine that readily passes into the CNS (Fig. 12-18). It produces central muscarinic stimulation and, thus, is not used to reverse neuromuscular blockade but can be used to treat atropine poisoning. Conversely, atropine is used



to treat physostigmine poisoning. Physostigmine has also been found to be a specific antidote in the treatment of postoperative delirium (see Central Anticholinergic Syndrome section).[3]



Physostigmine

Neostigmine

Edrophonium

Pyridostigmine

FIGURE 12-18. Structural formulas of clinically useful reversible anticholinesterase drugs. Physostigmine is a tertiary amine and crosses the blood-brain barrier. It is useful in treating the central anticholinergic syndrome.

The irreversible cholinesterase inhibitors are mostly organo-phosphate compounds. In addition, the organophosphate compounds are highly lipid soluble; they readily pass into the CNS and are rapidly absorbed through the skin. They are used as the active ingredient in potent insecticides and chemical warfare agents known as nerve gases. Table 12-9 lists some of these agents. The only therapeutic drug of this group is echothiophate, which is available in the form of topical drops for the treatment of glaucoma. Its primary advantage is its prolonged duration of action. Topical absorption is variable but considerable. Echothiophate can remain effective for 2 or 3 weeks following cessation of therapy.[64] A history of use of echothiophate is important in avoiding prolonged action of succinylcholine, which requires pseudocholinesterase for its hydrolysis.

Organophosphate poisoning manifests all the signs and symptoms of excess ACh.[65] The antidote cartridges dispensed to troops to counter the effects of anticholinesterase nerve gases contain only atropine, which would effectively counter

the muscarinic effects of the gas; however, atropine does little to counter the high-dose nicotinic muscle paralysis or the central ventilation depression that contributes to death from nerve gases. Treatment requires high doses of atropine, 35 to 70 mg/kg IV every 3 to 10 minutes until muscarinic symptoms abate. Lower doses at less frequent intervals may be required for several

days. Central ventilatory depression and nicotinic paralysis or weakness require respiratory support and specific therapy of the cholinesterase lesion. Pralidoxime has been reported to reactivate cholinesterase activity by hydrolysis of the phosphate enzyme complex. It is particularly effective with parathion poisoning and is the only cholinesterase reactivator available in the United States.[60]

Muscarinic Antagonists

Muscarinic antagonist refers to a specific drug action for which the term "anticholinergic" is widely used. Any drug that interferes with the action of ACh as a transmitter can be considered an anticholinergic agent. The term anticholinergic refers to a broader classification that would include the nicotinic antagonists.

Atropinic Drugs. Atropine, scopolamine, and glycopyrrolate are the most commonly used muscarinic antagonists used in anesthesia (Fig. 12-19).

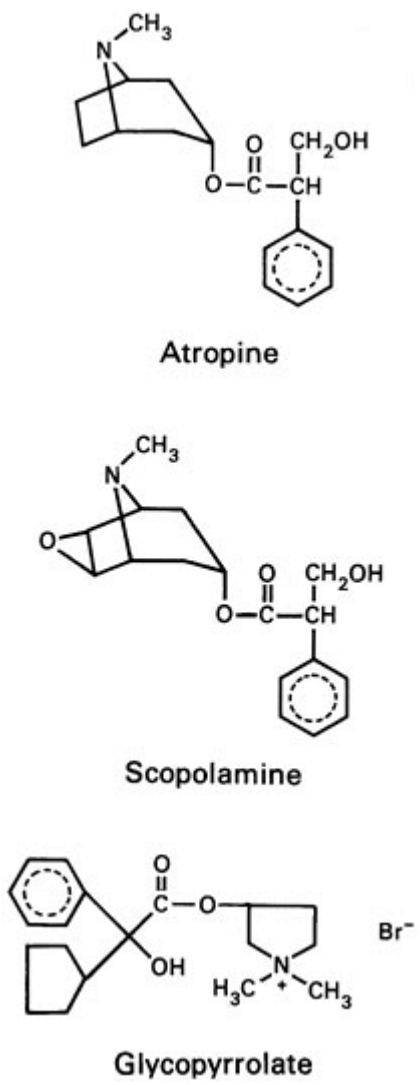


FIGURE 12-19. Structural formulas of the clinically useful antimuscarinic drugs.

The actions of these drugs include inhibition of salivary, bronchial, pancreatic, and gastrointestinal secretions to antagonize the muscarinic side effects of anticholinesterases during reversal of muscle relaxants. Atropine is useful in increasing CO with sinus bradycardia as a result of vagal stimulation if hypoxia is ruled out. It has many uses outside of anesthesia for the treatment of renal colic, gastrointestinal spasm, gastric secretion, and asthma. Historically, atropine was introduced to anesthesia practice to prevent excessive secretions during ether anesthesia and to

prevent vagal bradycardia during the administration of chloroform.[66] Atropine and scopolamine also possess antiemetic action. Atropine, however, reduces the opening pressure of the lower esophageal sphincter, which theoretically increases the risk of passive regurgitation. Atropinic drugs also produce dilation of the pupil (mydriasis) and paralysis of accommodation (cycloplegia).

Antimuscarinic agents do not inhibit transmission equally, and there are marked variations in sensitivity at different muscarinic sites owing to differences in penetration and affinities of the various receptors. Differences in relative potency between the different antimuscarinics are outlined in Table 12-10. Glycopyrrolate produces less tachycardia than atropine and is a more potent antisialogogue.

TABLE 12-10 Comparison of Antimuscarinic Drugs

	·DURATION						
	·IV	·IM	·CNS	·GI TONE	·GASTRIC ACID	·AIRWAY SECRETIONS[a]	·HEART RATE
Atropine	15–30 min	2–4 hr	++	--	–	–	+++[c]
Scopolamine	30–60 min	4–6 hr	+++[b]	–	–	----	–0[c]
Glycopyrrolate	2–4 hr	6–8 hr	0	---	---	---	+0

[a]Secretions may be reduced by inspissation.

[b]CNS effect often manifest as sedation before stimulation.

[c]May decelerate initially.

The antimuscarinic effects of the atropinic drugs are the result of competitive inhibition of ACh at the receptors of organs innervated by cholinergic postganglionic nerves. The antagonism can be overcome by sufficient concentrations of cholinomimetic drugs or anticholinesterases that increase ACh levels at the receptor site. This explains most of the therapeutic actions of atropinic drugs; however, they are neither purely antimuscarinic nor purely antagonist.[3]

The belladonna alkaloids (atropine and scopolamine) also block ACh transmission to sweat glands, which, although they are cholinergic, are innervated by the SNS. Antimuscarinic agents produce antinicotinic actions at higher doses and result in important actions on CNS transmission that are pharmacologically similar to the postganglionic cholinergic function.

Atropine and scopolamine are tertiary amines (see Fig. 12-19) and easily penetrate the blood-brain barrier and placenta. Glycopyrrolate is a quaternary amine that, like the reversible anticholinesterase drugs, does not easily penetrate these barriers. Glycopyrrolate, a synthetic

antimuscarinic, has gained popularity because it avoids the central effects of the other two drugs. Atropine and scopolamine have notable CNS effects that are dissimilar. Scopolamine differs from atropine mainly in its central depressant effects, which produce sedation, amnesia, and euphoria. Such properties are widely used for premedication for cardiac patients in combination with morphine and a major tranquilizer. Atropine, as a premedicant, has slight effects on the CNS, including mild stimulation. Higher doses such as those given for reversal of muscle relaxants (1 to 2 mg) may produce restlessness, disorientation, hallucinations, and delirium (see Central Anticholinergic Syndrome section). Excessive stimulation may be followed by depression and paralysis of respiration. Occasionally, scopolamine in low doses may cause restlessness and delirium. This syndrome is more frequently seen in the elderly and patients experiencing pain, for example, in obstetric patients.

Atropine and scopolamine are noted to produce a paradoxical bradycardia when given in low doses. Scopolamine (0.1 to 0.2 mg) usually causes more slowing than atropine but also produces less cardiac acceleration at higher doses. The usual intramuscular premedicant doses of scopolamine causes either a decrease or no change in HR. The paradoxical bradycardia was once thought to be caused by an early central inhibition of the medullary cardioinhibitory center. However, this phenomenon occurs in animals that have had total vagotomy. Atropine may also produce sympathomimetic effects by blocking presynaptic muscarinic receptors found on adrenergic nerve terminals.[6] ACh stimulation of these receptors inhibits NE release, and blockade by atropine releases this inhibition (see Cholinergic Receptors Section).

Atropinic drugs are widely used in ophthalmology as mydriatics and cycloplegics. Atropine is contraindicated in patients with narrow-angle glaucoma. Pupillary dilation thickens the peripheral part of the iris, which narrows the iridocorneal angle. Drainage of aqueous humor is impaired, and intraocular pressure increases. Doses of atropine used for premedication have little effect in this regard, whereas equal doses of scopolamine cause mydriasis. Prudence would dictate avoidance of either agent in patients with narrow-angle glaucoma. The need for antimuscarinic premedication is questionable in this situation.

Atropine is best avoided where tachycardia would be harmful, as may occur in thyrotoxicosis, pheochromocytoma, or obstructive coronary artery disease. Atropine should be avoided in hyperpyrexial patients because it inhibits sweating.

Central Anticholinergic Syndrome. The belladonna alkaloids have long been known to produce undesirable side effects ranging from stupor (scopolamine) to delirium (atropine). This syndrome has otherwise been called postoperative delirium and atropine toxicity. The central anticholinergic syndrome appears to involve the muscarinic receptor.[3] Biochemical studies have demonstrated abundant muscarinic ACh receptors in the brain that can be affected by any drug possessing antimuscarinic activity and capable of crossing the blood-brain barrier. Hundreds of drugs exist that meet these criteria with which this syndrome has been associated. Table 12-11 lists some of those drugs.[3]

TABLE 12-11 Antimuscarinic Compounds Associated with Central Anticholinergic Syndrome

Belladonna Alkaloids
Atropine sulfate
Scopolamine hydrobromide
Synthetic and Natural Tertiary Amine Compounds
Dicyclomine (Bentyl)—antispasmodic with local anesthetic activity
Thiphenamil (Trocinate)—antispasmodic with local anesthetic activity
Procaine
Cocaine
Cyclopentolate (Cyclogyl) mydriatic

Quaternary Derivatives of Belladonna Alkaloids
Methscopolamine bromide (Pamine)—antispasmodic
Homatropine methylbromide—sedative, antispasmodic
Homatropine hydrobromide—ophthalmic solution—mydriatic
Synthetic Quaternary Compounds
Methantheline bromide (Banthine)
Propantheline bromide (Pro-Banthine)
Antihistamines
Chlorpheniramine (Ornade)
Diphenhydramine (Benadryl)
Plants
Deadly nightshade (atropine)
Bittersweet
Potato leaves and sprouts
Jimson or loco weed
Coca plant (cocaine)
Over-the-Counter
Asthma-Dor—atropine-like
Compoz—scopolamine sedation
Sleep Eze—scopolamine sedation
Sominex—scopolamine sedation
Antiparkinson Drugs
Benztropine (Cogentin)
Trihexphenidyl (Artane)
Biperiden (Akineton)
Ethopropazine (Parsidol)
Procyclidine (Kemadrin)
Antipsychotic Drugs
Chlorpromazine (Thorazine)
Thioriazine (Mellaril)
Haloperidol (Haldol)
Droperidol (Inapsine)
Promethazine (Phenegran)
Tricyclic Antidepressants
Amitriptyline (Elavil)
Imipramine (Tofranil)
Desipramine (Norpramine, Pertofrane)
Synthetic Opioids
Meperidine
Methadone

Note: Trade names are given in parentheses.

High doses of atropinic alkaloids rapidly produce dryness of the mouth, blurred vision with photophobia (mydriasis), hot and dry skin (flushed), and fever. Mental symptoms range from sedation, stupor, and coma to anxiety, restlessness, disorientation, hallucinations, and delirium. Convulsions and ventilatory arrest may occur if lethal poisoning has occurred. Although an alarming reaction may occur, fatalities are rare. Intoxication is usually short lived and followed by amnesia. These reactions can be controlled by the intravenous (iv) injection of physostigmine. Physostigmine is an anticholinesterase that, by virtue of being a tertiary amine, readily passes into the CNS to counter antimuscarinic activity. It should be given slowly in 1-mg doses, not exceeding 3 mg, to avoid producing peripheral cholinergic activity. Neostigmine, pyridostigmine,

and edrophonium are not effective because they cannot pass into the CNS. Likewise, atropine is an effective antidote for physostigmine overdose. The duration of physostigmine action may be shorter than that of the offending antimuscarinic agent and require repeated injection if symptoms recur. Physostigmine appears safe when used within dose recommendations and when indications are established. Central disorientation alone does not establish a diagnosis. Peripheral signs of antimuscarinic activity should be present in addition to a central anticholinergic syndrome.

Physostigmine has been reported to reverse the CNS effects of many of the drugs listed in Table 12-11, including antihistamines, tricyclic antidepressants, and tranquilizers. Reversal of the sedative effects of opioids and benzodiazepines has also been reported.[67] However, anticholinesterase agents potentiate cholinergic synaptic transmission and increase neuronal activity, even if no receptor antagonist is present. Thus, arousal may not be a function independent of its cholinesterase activity, and claims that physostigmine is a nonspecific CNS stimulant may not be warranted and could, in fact, be dangerous.[3]

Hemodynamics

Until recently, sympathomimetics were the most common means of treating the hypotension associated with shock. A vasopressor is a drug that is used to elevate arterial blood pressure above the existing level because the pressure is too low. However, elevation of arterial blood pressure alone has repeatedly been demonstrated to be an insufficient goal in the treatment of shock.[68] The goal, instead, is to reestablish blood flow to vital organs. Although blood pressure has been the historical gold standard for estimating perfusion, there is no correlation between blood pressure and flow (Fig. 12-20).[69] In physiologic as well as constructed systems, flow tends to be least when pressure is highest. Flow used in this context refers to CO.

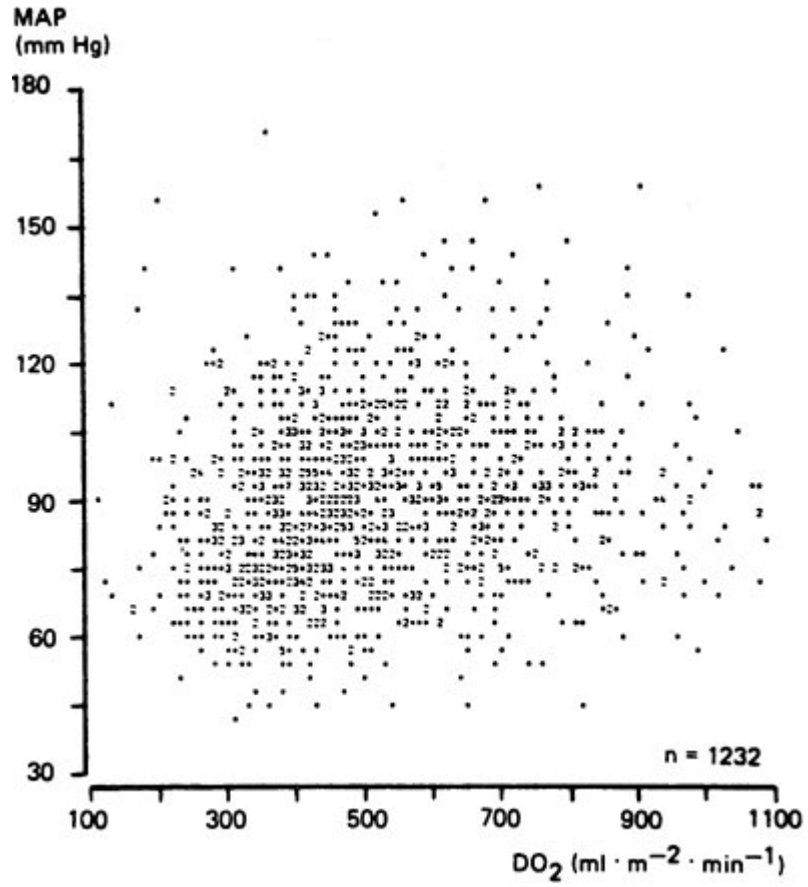

FIGURE 12-20. Correlation between mean arterial pressure (MAP) and O_2 delivery (DO_2) during the perioperative period in patients undergoing aorta bifemoral bypass grafting. (Reprinted with permission from Reinhart K: Principles and Practice of Svo_2 Monitoring, p 121. London, Intensive Care World, King and Worth, Publishers, vol 5, no 4, Dec 1988.)

Oxygen transport is the product of the arterial oxygen content (DO_2) and CO:

$DO_2 = Cao_2 \times CO$

Therefore, there is a close correlation between oxygen transport and CO. Unfortunately, oxygen transport is not identical to cellular oxygen supply, which can be inadequate despite normal or elevated oxygen transport. Cellular oxygen supply can be inadequate because of maldistribution of blood flow to vital organs or from the inability of the cell to use oxygen.[69] Improving cellular oxygen utilization remains enigmatic, but the catecholamines can be of some assistance in the redistribution of flow.

The physiologic equation that expresses how flow (CO) is generated states that CO is the product of the HR and stroke volume (SV):

$CO = HR \times SV$

However, SV is determined by three factors: (1) the contractile or inotropic state of the myocardium, (2) preload, or end-diastolic myocardial fiber length, and (3) afterload, or

resistance to ejection. The physiologic determinants of CO can therefore be expressed as:

$CO = HR \times (inotropism:preload:afterload)$

Synchrony of AV contraction is an additional determinant when dysrhythmias develop. This equation is illustrated in Figure 12-21 to emphasize that the biologic mechanisms that produce and regulate flow are interdependent. Terms such as "inotropism," "preload," and "afterload"

cannot be defined independently or isolated in the clinical setting. We can now measure, calculate, and manipulate each of the links in the chain of events that determine flow. Note that blood pressure is not among the determinants of flow. It is the product and not the cause. Most catecholamines affect one or more of these factors via the receptors and may cause changes in blood pressure by altering flow, vascular tone, or both. A measured blood pressure does not distinguish changes in flow, resistance, inotropism, or HR; therefore, blood pressure and oxygen transport do not correlate.

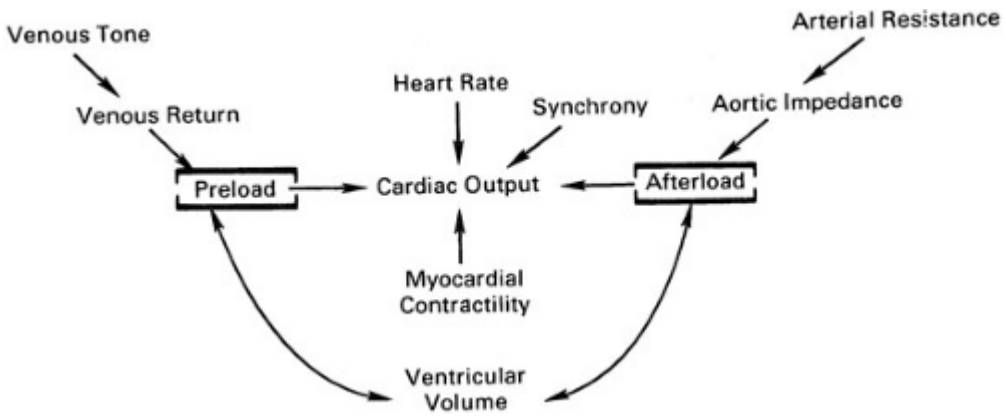

FIGURE 12-21. The four principal factors determining CO are demonstrated. Synchrony of AV contraction is an additional factor becoming important with the development of cardiac dysrhythmias. (Reprinted with permission from Lawson NW, Wallfisch HK: Cardiovascular pharmacology: A new look at the "pressors". In Stoelting RK, Barash PG, Gallagher TJ (eds): Advances in Anesthesia, p 195, Chicago, Year Book Publishers, 1986.)

Heart Rate

HR becomes an important support of CO when SV is decreased. A change in either HR or SV invariably causes an alteration of the other by reflex activity. Tachycardias can reduce SV by not allowing sufficient diastolic ventricular filling time. Coronary blood flow to the ventricles and especially the subendocardium occurs primarily during diastole. The subepicardial muscle is perfused during systole as well as diastole. However, subendocardial blood flow is totally dependent on diastolic perfusion time, diastolic pressure, and microcirculatory tone.[70]

Diastolic perfusion time becomes even more critical with ventricular hypertrophy. Increases in HR will not only shorten the percent diastolic perfusion time for the endocardium but also increase oxygen demand.[71] Increased HR, alone, has been shown to increase the severity of ischemia and the incidence of reperfusion arrhythmias. Animal studies have shown that myocardial blood flow and contractile function decrease with increased inotropic activity and tachycardia. This does not occur when increased inotropism is not accompanied by tachycardia.

Diastolic perfusion time has a curvilinear relationship with HR, increasing rapidly as rates fall below 75 beats/min (Fig. 12-22). Once HR goes above 90 beats/min in the adult, there is little further decrease in percent diastole. There is an exponential increase in percent diastole below rates of 70 beats/min.[70] Wide swings in percent diastolic time are of little consequence in the patient with normal coronary function but can be critical in those with obstructive coronary artery disease.

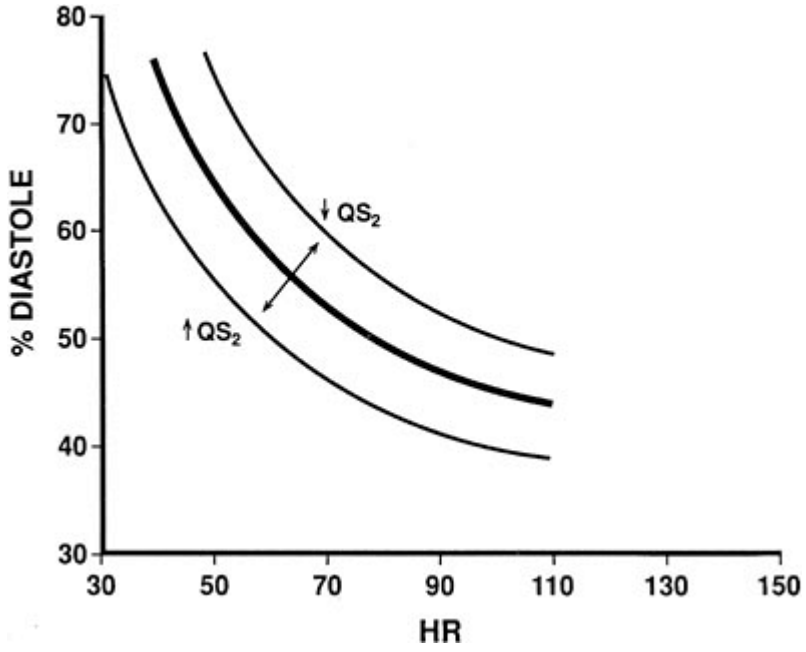

FIGURE 12-22. Small changes in HR produce large changes in percent diastole especially at low HRs because of the curvilinear relationship between rate and diastolic time. Shortening of electromechanical systole (QS_2) produces an upward shift of the curve. Shortening of QS_2 or a decrease in HR, or both, will increase percent diastolic perfusion time. Cardioactive drugs may affect diastolic perfusion time through either or both mechanisms.[70]

Two factors actually determine the duration of systole: HR and electromechanical systole (QS2). HR and QS2 have an inverse relationship (Fig. 12-23).[70] Percent diastolic perfusion time is calculated as the cardiac cycle (R-R) minus QS2. A decrease in HR and/or shortening in QS2 will result in prolongation of the total diastolic period and vice versa. HR is the more

important factor because small changes in the HR can produce significant changes in percent diastole as a result of the curvilinear relationship between HR and diastolic perfusion time. Changes in HR alone produce movement along that curve, whereas changes in QS2 result in shifts of the curve. Dopamine and dobutamine (DBT) affect diastolic perfusion time by altering HR and QS2. DBT has been shown to increase percent diastole without significantly altering HR. The increase in diastolic perfusion time is because of a shortening of QS2. Isoproterenol reduces percent diastole because it reduces QS2 proportional to the increase in HR. β-blockers, particularly atenolol, will significantly decrease HR and increase percent diastole because it has little effect on QS2 in the usually clinical dose range. The beneficial effects of β-blockers on myocardial oxygen delivery and consumption can be related to a reduced HR alone, although higher doses may reduce inotropism as well. Diastolic perfusion pressure may also increase with β-blockade because of an unopposed relative increase in vascular tone.

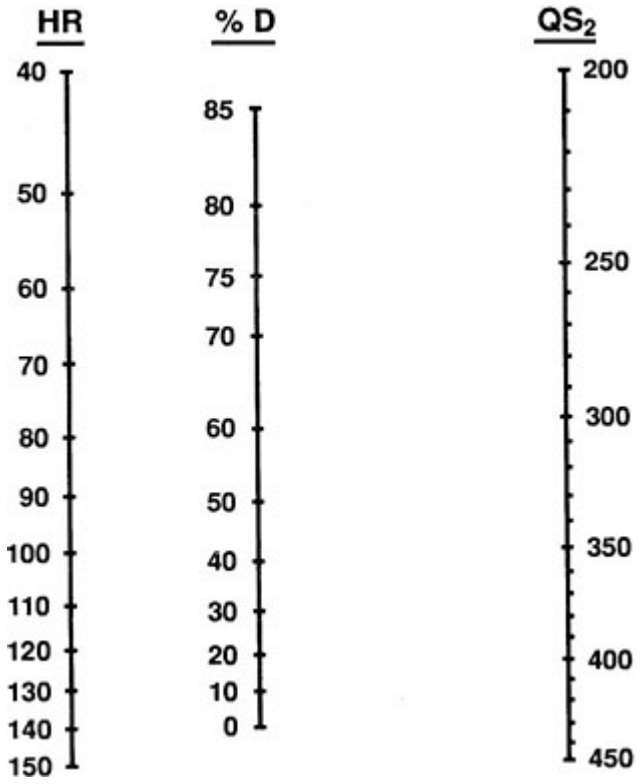

FIGURE 12-23. Nomogram for the relationship between electromechanical systole (QS_2), heart rate (HR), and percent diastole. The percent diastole can be obtained from QS_2 and HR.[70] (Reprinted from Boudoulas H, Rittgers SE, Lewis RP, Leier CV, Weissler AM: Changes in diastolic time with various pharmacologic agents. Circulation 60:164, 1979.)

Preload

Preload is clinically synonymous with the volume of venous return to the heart, which establishes CO by the purported Frank-Starling mechanism. Preload has repeatedly been demonstrated to be of paramount importance in supporting cardiovascular function in the normal heart. It can be increased by adding volume to the circulation or by acute venous constriction. The catecholamines can be selected for their effect on preload by either increasing (α-1, α-2) or decreasing (β-2, DA1, DA2) venous tone.[72] Positive or negative preloading can be a major unrecognized benefit of some sympathomimetic agents. Although venoconstriction produces little increase in total vascular resistance (afterload), minimal venoconstriction is capable of producing large shifts of blood volume into the central circulation because the capacitance vessels contain 60 to 80% of the total blood volume, an effect that has largely been ignored. The central distributive effect of a catecholamine may be as important as its inotropic action in increasing the CO in the hypovolemic patient. Likewise, a central distribution of capacitance blood may be undesirable if the heart is failing, even though that agent may possess inotropic properties.

Afterload

Afterload is a measure of impedance to ventricular ejection and is the dominant factor in determining CO when inotropism is impaired. In the absence of outlet obstruction, the clinical correlate of afterload to the left ventricle is the systemic vascular resistance reflected by the mean arterial pressure. Afterload is the only factor of the four major determinants of CO that, if increased, will reduce flow. Ohm's law states that blood flow through any organ is directly related to the blood pressure gradient across that organ but is inversely proportional to the resistance (afterload).

Inotropism

Inotropism is defined as the force and velocity of ventricular contraction when preload and afterload are held constant. Vasoactive drugs can be described as having either a positive or negative inotropic effect. Inotropic agents, such as DA and DBT, represent therapeutic agents that altogether increase myocardial contractility. As yet, there are no clinically feasible means to directly measure inotropism at the bedside. We can define failure of inotropism better than we can define what it is. The myocardium permits CO to be regulated at any level below its inotropic state.

Several direct indicators of cardiac inotropism appear useful in lieu of direct force velocity measurements. Pump function can be estimated clinically by work-pressure curves using the Frank-Starling mechanism. When inotropism is normal, CO is more dependent on extracardiac factors such as preload and afterload (see Fig. 12-21).

Lusitropism

Lusitropism is a factor determining CO that is not depicted in Figure 12-21. Lusitropism describes abnormalities of myocardial relaxation, or diastole, as opposed to problems of inotropism. Some vasodilators such as nitroglycerin and some sympathomimetic "inodilators" are thought to improve cardiac function by promoting diastolic relaxation and thus ventricular filling (preloading) and coronary perfusion. Lusitropic dysfunction may play a larger role in chronic heart failure than earlier appreciated because lusitropic dysfunction is now known to play a large role in many myocardial disease processes and may, in fact, precede inotropic dysfunction. Decreased lusitropism is characteristic of the aging myocardium.

Figure 12-21 deliberately emphasizes preload and afterload as balancing forces in producing CO. They are antagonistic and assume differing degrees of dominance depending on whether the myocardium is healthy or failing. Preload is the dominant regulator of CO in the normal cardiovascular system. Afterload dominates flow regulation when the myocardium is failing. Figure 12-24 compares the contrasting effects of preload and afterload on the CO of both the healthy and failing myocardium. Acute increases (in afterload) in the healthy patient are tolerated, up to a fourfold increase. In contrast, even small increases in afterload produce large reductions in CO when the myocardium is depressed by disease or anesthesia. The use of vasodilators for afterload reduction in the patient with a failing myocardium is based on this concept.

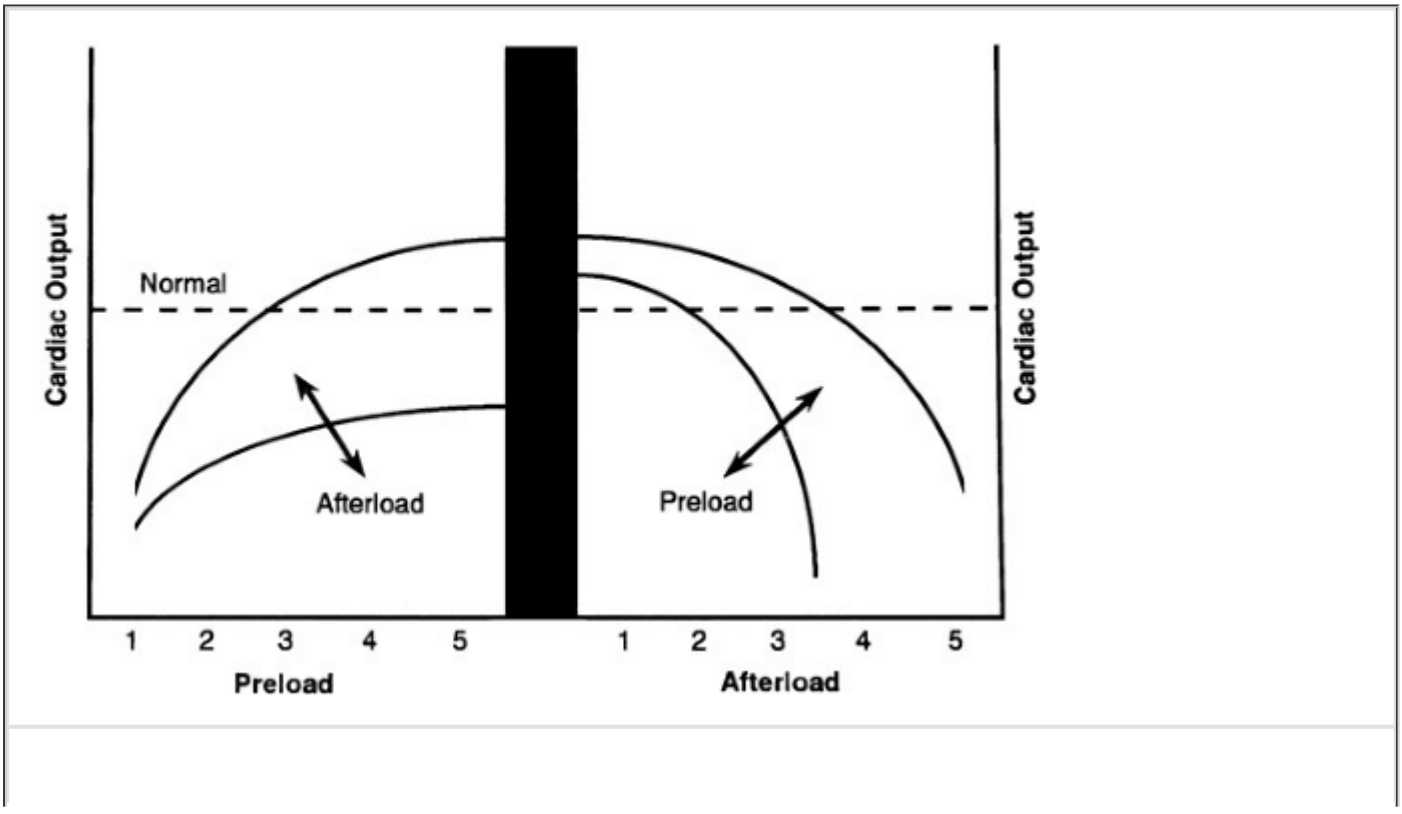

FIGURE 12-24. The contrasting effects of preload and afterload on CO. Increasing preload increases output in the normal myocardium, but to a lesser degree in the failing myocardium. Increased afterload is usually tolerated by the normal myocardium, but even small increases produce large reductions in output in the failing myocardium.

The weak links in the chain of cardiovascular events that produce blood flow and oxygen transport can now be selectively detected and manipulated rather than just the mindless increase in blood pressure. The term "vasopressor," once synonymous with vasoconstriction, has now become a generic term for several species of vasoactive drugs that, by whatever means, increase CO that may or may not increase blood pressure. Their uses in anesthesia include (1) maintenance or organ perfusion, (2) treatment of allergic reactions, (3) prolongation of the action of local anesthetics, and (4) for cardiopulmonary resuscitation.

Low-Output Syndrome

Patients with the low CO syndrome have abnormalities of either the heart, blood volume, or blood flow distribution. Those remaining in this state for more than 1 hour usually have dysfunction of all three components. Modern hemodynamic monitoring has pinpointed hypovolemia, relative or absolute, as the most common cause of the low-output syndrome, regardless of the etiology. Initial treatment with adrenergic amines in this setting is likely to delay volume repletion and potentiate the shock state. The proper hemodynamic management of septic shock, the most commonly seen distributive abnormality, remains controversial, but volume repletion is the primary consideration. Likewise, the initial treatment of cardiac dysfunction is optimum volume replacement because hypovolemia is a frequent accompaniment of impaired myocardial performance. Ventricular performance may be improved solely on the basis of increased preload.

The treatment of cardiogenic shock is an example of the low-flow state that requires multiple autonomic interventions common to other forms of the low-output syndrome. An acute reduction of left ventricular contractility (inotropism) produces a cascade of events that worsen in cyclic fashion (Fig. 12-25). One could draw this cascade beginning with any one of the five determinants of CO. Loss of contractility produces a reduction in CO, increased left ventricular end-diastolic pressure, and a host of compensatory reflexes. These compensatory mechanisms include increased sympathetic activity that augments contractility and rate. Chronic dysfunction produces a third compensatory mechanism, hypertrophy.

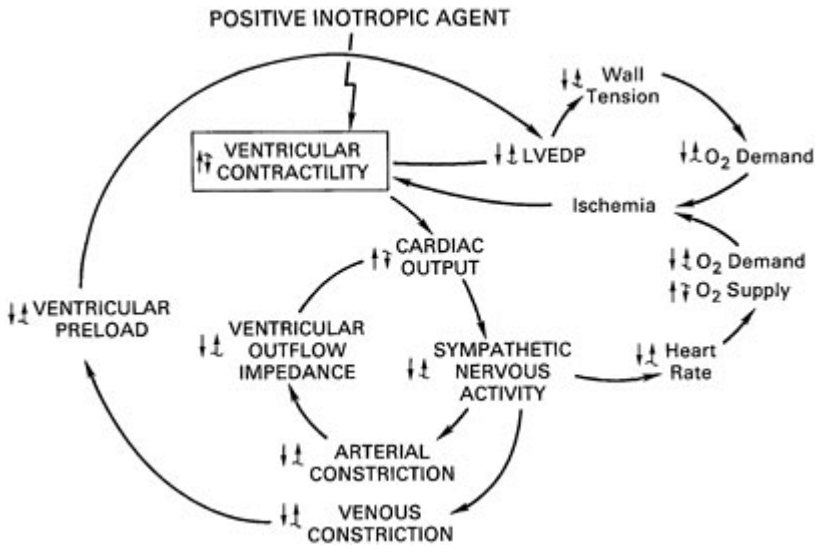

FIGURE 12-25. Reversal of heart failure by intervention (↑) with the ideal positive inotropic

agent depicted. (Reprinted with permission from Evans DB, Weishaar RE, Kaplan HR: Strategy for the discovery and development of a positive inotropic agent. Pharmacol Ther 16:303, 1982.)

The attributes of the ideal inotropic drug are listed in Table 12-12. The inotropic agent needed for the patient illustrated in Figure 12-25 would be rapid acting and short lived and would not increase HR, preload (unless hypovolemic), afterload, or infarct size. Because the ideal inotropic drug is not available, the peripheral side effects of any inotropic agent become critical to selection because all are multireceptor agonists.

TABLE 12-12 Characteristics of the Ideal Positive Inotropic Agent

Enhances contractile state by increasing velocity and force of myocardial fiber shortening
Lacks tolerance
Does not produce vasoconstriction
No cardiac dysrhythmias
Does not affect heart rate
Controllability—immediate onset and termination of action
Elevates perfusion pressure by raising cardiac output rather than systemic vascular resistance
Redistributes blood flow to vital organs
Direct-acting—not dependent on release of endogenous amines
Compatible with other vasoactive drugs
Effective orally or parenterally

Myocardial failure exists when the heart cannot pump enough blood to meet metabolic needs. The clinical manifestations of heart failure result from peripheral circulatory derangements that are the result of the heart's forward output lagging behind the input. Venous pressure increases and produces congestion. There are marked pathophysiologic differences between chronic heart failure and acute failure from infarction. Patients with chronic heart failure have retention of sodium and water and are typically hypervolemic, whereas patients with acute heart failure are either normovolemic or, commonly, hypovolemic. Cardiomegaly is a common compensatory feature of chronic heart failure (late) but is absent with acute heart failure. Circulating catecholamines and myocardial catecholamine content are decreased in chronic failure but markedly elevated in the acute infarct. Thus, the response to inotropic drugs in chronic heart failure is influenced not only by the lack of myocardial catecholamine stores but also by down-regulation of β receptors. The CO in chronic failure is borderline to decreased, whereas it is usually normal or elevated with acute failure as a result of compensatory mechanisms.

Acute failure is the most common complication of infarction, occurring in 40 to 50% of patients, which reflects a 20 to 25% involvement of the myocardium. In contrast to the patient with chronic heart failure, this dysfunction is usually transient, lasting between 48 to 72 hours. Drugs with a predominant inotropic action are used alone or in combination to acutely improve cardiac contractility. Therefore, one has to be concerned that myocardial damage is not extended during this transient period by inappropriate inotropic or chronotropic support. This is not as major a concern in the patient with hypertrophy, in whom increased inotropism may actually reduce oxygen consumption by reducing ventricular mass.

Table 12-13 presents one approach to the management of cardiogenic shock listed in order of relative importance. The use of sympathomimetic support is placed in proper perspective. It

emphasizes the essential role that invasive hemodynamic monitoring and volume management play in confirming a diagnosis of cardiogenic failure. Although volume

expansion and reduction of afterload may improve CO, other pharmacologic interventions may still be necessary to optimize CO and its distribution. Invasive monitoring is a prerequisite for the rational use of the vasoactive drugs to (1) establish that a sympathomimetic is necessary, (2) select drugs for the hemodynamic condition, (3) follow resultant hemodynamic changes because many of the beneficial effects of the catecholamines are hidden to the clinical eye, and (4) avoid complications of pressor therapy that are visible to all.

TABLE 12-13 Management of Low Output Syndrome Caused by Myocardial Dysfunction

1. Assure adequate ventilation and oxygenation
2. Relieve pain and symptoms of recurrent ischemia
3. Institute hemodynamic monitoring (pulmonary artery, pulmonary capillary wedge, and arterial pressures; urine output; cardiac output)
4. Optimize left ventricular filling pressure
5. Correct metabolic abnormalities
6. Control dysrhythmias (#2 priority if life threatening)
7. Pharmacologic support
    a. Vasodilators
    b. Inotropic drugs
    c. Diuretics—chronic heart failure
8. Rule out "correctable" causes of shock (septal or left ventricle rupture, mitral regurgitation, acute aneurysm)
9. Mechanical support of circulation
10. Surgical correction if possible

Note: Hemodynamic monitoring is essential in confirming a diagnosis, optimizing filling pressures and cardiac output, selecting pharmacologic support, and avoiding complications. Adjustment of left ventricular filling pressure may require additional volume or a relative volume reduction with vasodilators. The diagnostic criteria for cardiogenic shock are not met until step 4 is accomplished.

Adrenergic Drugs—Selection

The selection of vasoactive drugs requires a knowledge of both the hemodynamic disturbance and pharmacology of the available drugs. The catecholamines and sympathomimetic drugs continue to be the pharmacologic mainstay of cardiovascular support for the low-flow state. Sustained interest in the catecholamines is related to their predictable pharmacodynamics and favorable pharmacokinetic profiles. Their effects are linearly related to plasma levels, which are directly related to the rate of infusion. There are few clinical surprises within any given dose range and the pharmacokinetics of catecholamines allow rapid titration to the effect. The half-life of most is short, ranging from 2 to 3 minutes. Undesirable side-effects dissipate within minutes of lowering or stopping the infusion. Sympathomimetics, as a group, produce a wide range of hemodynamic effects and can be used in combination to achieve a yet wider spectrum of effects. As a result, one need become familiar with only a few agents to manage most clinical situations.

Table 12-14 is a summary of the hemodynamic effects of some of the currently popular and once popular sympathomimetic drugs. Many of the hemodynamic effects are dose related. The dose ranges are listed and a standard infusion rate cited. Standard rates of infusion are simply guidelines, and the actual dose administered should be determined by patient response.

The goal for managing the low-output or high-output shock syndrome is to establish and maintain adequate tissue perfusion. Aggressive fluid therapy will suffice in most instances. Sympathomimetics are not a substitute for volume. However, once intravascular volume is optimized, a vasoactive drug may be required to sustain CO. The term "inodilator" has entered our lexicon during the early 1990s to supplant the more archaic term vasopressor. This neologism reflects a change in philosophy in managing low-flow states, particularly those characterized by heart failure. The new synthetic sympathomimetics have been chemically engineered to obtain inotropism and vasodilation rather than for pressor effects. The potential for benefit or harm can best be understood in terms of receptor characteristics. For example, activation of the inotropic β-1 and β-2 receptors results in positive inotropism and chronotropism. Selective stimulation of the vascular β-2 receptors causes vasodilatation. Left ventricular outflow may improve as a function of decreased afterload reduction and inotropism. However, chronotropism may not be a desirable feature in a patient with mitral stenosis or coronary artery disease.

Catecholamine Receptor–Effector Coupling

The net physiologic effect of a sympathomimetic is usually defined as the algebraic sum of its relative actions on the α, β, and DA receptors.[73] Most adrenergic drugs activate or block these receptors to varying degrees. Each catecholamine has a distinctive effect, qualitatively and

quantitatively, on the myocardium and peripheral vasculature. Table 12-15 demonstrates the relative potency of the adrenergic amines on the various myocardial and vascular receptors. This relative potency is also dose related, adding yet another variable. The use of pluses (+) or zeros (0) is the classical method by which the relative sensitivities of catecholamine-receptor coupling are demonstrated. The use of the (+) is also symbolic of the apparent summation effect of the catecholamines on the receptors. The summation effect further implies a finite number of adrenergic receptor sites to which adrenergic agonists can compete.

Isoproterenol	0	0	+++++	+++++	0	0

[a]The clinical significance of the effects of agonism and antagonism is not yet known.

For many years, the emphasis on catecholamines was focused almost entirely on their actions on the myocardium and on arteriolar resistance vessels. Changes in venous resistance contribute little to total vascular resistance and blood pressure. However, small changes in venous capacitance result in large changes in venous return because 60 to 70% of the circulating blood volume is the venous circulation.[50] The effect of the sympathomimetic amines on the venous circulation appears to be distributive in that acute venular constriction increases the central blood volume (preload), whereas dilatation decreases venous return by the promotion of peripheral pooling.[74] The distributive effect of a catecholamine may be as important as its inotropic action and more important than its arteriolar effect.[10] Further definition should elucidate some of the complex and confusing data in the literature generated when clinical observations are limited solely to adrenergic effects on the myocardium and arteriolar vasculature.

Intravenous and intra-arterial infusions of EPI in humans have been shown to cause marked constriction of the veins. Arteriolar vasoconstriction may or may not precede venoconstriction; however, SV does not increase until the onset of venoconstriction. The initial increase in CO seen with the infusion of EPI is more an effect of increased preload than an arteriolar or direct cardiac effect. NE produces a similar effect, but the onset of venoconstriction is slower.

A differential ability of the amines to constrict veins has been noted in animals.[75] The data are expressed as the average percentage contribution of venous resistance to total change

in vascular resistance (Table 12-16). Methoxamine and NE are considered equipotent *α*-1 arteriolar vasoconstrictors; however, these effects differ dramatically from their effects on venoconstriction. The lack of venoconstrictor response to methoxamine has been demonstrated in humans.

TABLE 12-16 Average Percentages of Contributions of Increments in Venous Resistance to Increments in Total Resistance (ΔVR/ΔTR × 100)

After Zimmerman BG, Abboud FN, Eckstein JW: Comparison of the effects of sympathomimetic amines upon venous and total vascular resistance in the foreleg of the dog. J Pharmacol Exp Ther 139:290, 1963, with permission.

A similar study in humans found similar results.[76] Table 12-17 demonstrates relative potencies of several catecholamines on resistance versus capacitance vessels. These data represent only the relative potencies of the amines within either resistance or capacitance vessels and are not a comparison of potency ratios between the two. Nevertheless, the data point out the marked differences between the agents. NE is the most potent amine with respect to arteriolar and venous constriction. Metaraminol is 1.5 times more potent than phenylephrine in constricting resistance vessels; however, phenylephrine is 1.5 times more effective in constricting capacitance vessels than metaraminol. NE proved to be 12 times more potent than metaraminol in constricting resistance vessels and 24 times more effective in constricting capacitance vessels.

After Schmid PG, Eckstein JW, Abboud FM: Comparison of the effects of several sympathomimetic amines on resistance and capacitance vessels in the forearm of man. Circulation 34:III–209, 1966, with permission.

Brown et al[77] reported the responses of resistance and capacitance vessels to catecholamines in humans on cardiopulmonary bypass. This is a unique method of examining hemodynamic drug response because flow rate (CO) is fixed, excluding the myocardial effects of the drugs. Changes in resistance or capacitance are reflected as either changes in pressure or changes in reservoir volume, respectively. The *a* agonist phenylephrine produced a marked decrease in venous capacitance (venoconstriction). Arteriolar resistance increased also, but to a lesser degree, confirming the study by Schmid et al.[76] Dopamine produces significant venoconstriction at doses that have no direct arteriolar or cardiac effect, confirming studies of dopamine in animals (Fig. 12-26).[77]

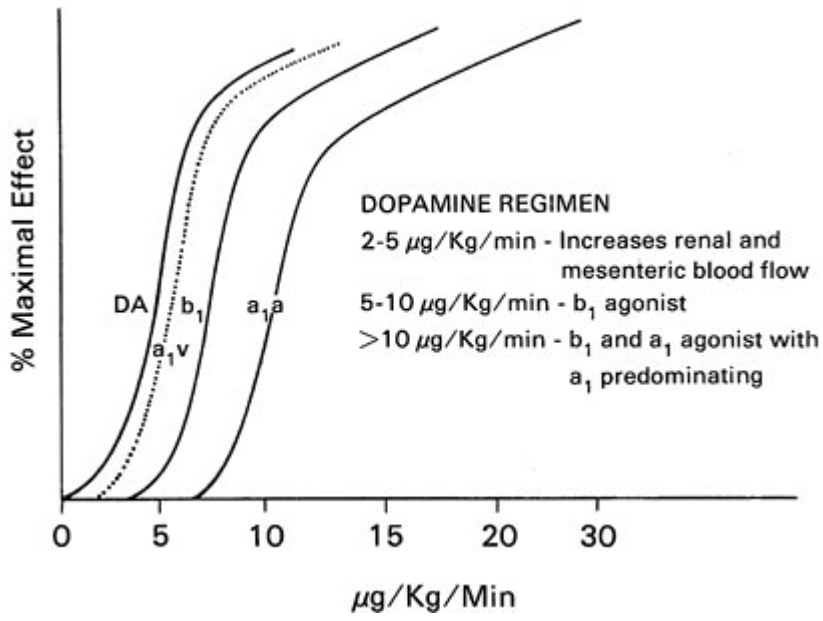

FIGURE 12-26. The spectrum of dose-related adrenergic activity of dopamine is demonstrated. Progressive rates of infusion produce dopaminergic (DA), *β*, then *a* activity. Infusion rates of greater than 15 *μ*g/kg/min produce a predominant *a* effect, like that of NE. Early *a*-1 venoconstriction may be an important redistributive feature of infused dopamine.

Table 12-18 is a summary of the available data on the relative potencies of the amines on the *a* receptors of the resistance and capacitance vessels. Scant data permit inaccuracies, but the table is derived from sources that demonstrate remarkable consistency. It is offered as a clinical guide to drug selection. The peripheral receptors of both resistance and capacitance vessels subserve vasoconstriction, but with divergent effects on afterload and preload; therefore, the *a*-1 receptors

have been subdivided into *α*-1 arterial (*α*-1a) and *α*-1 venous (*α*-1v). Note that methoxamine and phenylephrine, both pure *α* drugs, are equipotent arterial vasoconstrictors. Phenylephrine, however, is a potent venous constrictor, but methoxamine has virtually no effect on the capacitance vessels. Dopamine has potent venoconstrictor (*α*-1v) effect at doses at which few *α*-1a or *β*-1 effects are noted.

TABLE 12-18 Comparison of Relative α_1 Catecholamine Responses on Peripheral Resistance and Capacitance Vessels[a]

Adverse Effects

The major adverse effects of the sympathomimetic amines are related to excessive *α* or *β* activity. The potential for harm can be understood in terms of receptor characteristics. Excessive *β*-1 activity may increase contractility but increase HR and myocardial oxygen consumption beyond supply. Severe dysrhythmias are a frequent companion of excess *β*-1 activity as a result of increased conduction velocity, automaticity, and ischemia. The *β*-2 activity has the potential to increase CO by

reducing resistance (afterload) while reducing blood pressure. An excessive decrease in diastolic pressure, however, reduces obstructive coronary perfusion and may further aggravate myocardial ischemia. The *β*-1 and *β*-2 effects of adrenergic agonists are more useful clinically than *α*-1 effects and can be used for longer periods of time. Unfortunately, it is difficult to separate the inotropic, dromotropic, and chronotropic effects in the clinical setting. The characteristics of the ideal positive inotropic agent are listed in Table 12-12 for comparison with each drug as it is discussed.

Drugs with prominent *α*-1 agonist effects may produce an increase in blood pressure but reduce total flow because of increases in arteriolar resistance (afterload). A more prominent *α*-1 venous constriction may improve CO by increasing preload or precipitate failure if preload exceeds the contractile limits of the myocardium (see Fig. 12-24).

In general, the *α* effects of the sympathomimetics are of benefit only when used for specific indications and for the briefest possible time. Other measures are usually more effective in improving flow and are indicated before a pressor should be used. The only time an adrenergic amine should be used as a pressor or in a pressor dose range without consideration of flow is when arterial perfusion pressure must be increased immediately to prevent imminent death or morbidity.[78] Cardiopulmonary resuscitation is the primary example where a pressor effect is necessary to create diastolic coronary perfusion during closed- or open-heart massage. Any drug with strong *α* agonist properties seems equally effective in this regard. EPI, with its added *β* properties, has been the first-line agent for this situation. Vasopressin has been added to this first line. Drugs that vasodilate, such as isoproterenol, have little use in this setting even if they possess inotropic properties. Another situation in which a vasoconstrictor may be justified as a temporary measure is acute hypotension when cerebral, coronary, or extracorporeal bypass perfusion pressure is the prime consideration.

The prolonged use of adrenergic agonists with strong *α* properties commonly results in tachyphylaxis. This phenomenon is probably caused by increasing plasma volume loss through ischemic capillaries and down-regulation of the adrenergic receptors. Precapillary sphincters are under local myogenic control and relax when hypoxic and acidotic, despite strong α stimulation. Postcapillary sphincters are more functional in an hypoxic and acidotic milieu but are under stronger central neurogenic control. Continued postcapillary tone in the face of precapillary relaxation increases hydrostatic pressure with a net loss of intravascular volume. These events are just a few of the explanations for the once mysterious so-called levophed shock, in which patients were unable to be weaned from NE infusions.[79]

Adrenergie Agonists—*α β*, DA

Methoxamine and Phenylephrine. Methoxamine is the prototype pure *α* vasoconstrictor. Phenylephrine produces similar actions, but there are important clinical differences. Methoxamine possesses only *α*-1 properties and produces almost no venoconstriction. Its only pharmacologic effects are to increase arterial resistance, increase afterload, and reduce flow, even though blood pressure is elevated. Few clinical uses for methoxamine remain. It has been useful for treating paroxysmal atrial tachycardias. A single iv dose of methoxamine can break a paroxysmal atrial tachycardia reflexly through baroreceptor stretch, obviating the need for use of digitalis or countershock. Carotid massage produces similar results by a similar mechanism.

Phenylephrine, also considered a pure *α* drug, increases venous constriction and arterial

constriction in a dose-related manner. Constriction of capacitances vessels precede arteriolar constriction. Venous constriction may be its most redeeming feature when compared with the purely arteriolar effect of methoxamine. One cannot discount the possibility of an inotropic effect now that *α*-1 receptors are known to exist in the myocardium that improve inotropism. Acutely, venoconstriction favors venous return (preload), even though arterial resistance (afterload) also increases. The net effect may result in an increase in pressure and CO. Phenylephrine, like methoxamine, does not change CO in normal individuals but can cause a decreased output in patients with ischemic heart disease.[80] Phenylephrine has continued to be favored in operating rooms to briefly increase blood pressure during cardiopulmonary bypass as well as during intracranial and peripheral vascular procedures. It does not produce dysrhythmias. Phenylephrine is also useful in reversing right-to-left shunt in tetralogy of Fallot when patients are having "spells" during anesthesia.[81] The arterial vasoconstrictors may reduce the size of an ischemic injury when used in conjunction with intra-aortic balloon pumping or nitroglycerin.[82]

Norepinephrine. NE is the naturally occurring mediator of the SNS and the immediate precursor of EPI. It produces direct-acting hemodynamic effects on the *α* and *β* receptors in a dose-related manner when given by infusion. NE produces increased CO and blood pressure when given in low doses (see Table 12-14). Higher doses reduce flow because *α* arteriolar constriction supersedes the *β* effects. Reflex baroreceptor bradycardias may occur via active *β* stimulation.

Increased plasma levels of the endogenous catecholamines NE and EPI are the sympathetic milieu (stress) in which exogenous sympathomimetics are ordinarily given. NE is the catecholamine standard against which other catecholamines are compared. Intravenous NE has received an unseemly reputation over the years that is not merited. Studies indicate that NE was being used in doses that are orders of magnitude greater than that necessary to obtain its best response in producing CO rather than producing a blood pressure. They do not correlate (see Fig 12-20). Complications such as renal failure and tissue necrosis are routine and can be expected when NE is used. If NE is used simply to titrate to blood pressure rather than measured flow, the amount of NE infused is 5 to 10 times more than necessary to obtain the best oxygen delivery and oxygen consumption.[3] Although NE is less commonly used in the critically ill patient than other catecholamines, a resurgence of interest in this agent is noted. It has remained clinically useful because its effects are predictable, prompt, and potent.

Objections to the use of NE for the treatment of cardiogenic shock are based on two considerations: (1) vasoconstriction increases the pressure work of the left ventricle, with an adverse effect on the oxygen economy of the ischemic pump and (2) these drugs cause further vasoconstriction and organ ischemia in a syndrome in which intense constriction may already have occurred.[16] The use of NE requires the use of invasive monitoring; otherwise, complications are to be expected. It is not usually necessary to elevate the systolic blood pressure above 90 to 100 mm Hg. At this level of infusion, the CO will normally be increased as a *β* effect without excessive peripheral vasoconstriction. NE is also a potent venoconstrictor, which will alter interpretation of venous filling pressures as a guide to adequate volume repletion.

Other undesirable effects associated with NE include renal arteriolar constriction and oliguria. In addition, prolonged therapy may produce a reduction in plasma volume as a result of fluid transudation. Indeed, in some instances, cardiogenic shock requiring continuous NE infusions has been reversed by fluid infusions.[16]

Norepinephrine should only be administered in a centrally placed iv to avoid tissue necrosis from extravasation. It can be used for its intropic effect at low doses and titrated to effect while monitoring cardiac output. Monitoring of blood pressure alone or titrating to a predetermined effect is often detrimental to cardiac output. Blood pressure increases are usually a result of increases in SVR and can diminish forward flow and contribute to cardiac failure. Even moderate doses of norepinephrine may have a detrimental effect on end-organ perfusion, which has given the drug an ill-gotten reputation when used to titrate to pressure rather than flow. However, in those clinical conditions characterized by a low perfusion pressure and high flow (vasodilatation) and maldistribution of flow (sepsis), norepinephrine has been shown to improve renal

and splanchnic blood flow by increasing pressure provided the patient has been volume resuscitated.

Epinephrine. EPI is the prototypical endogenous catecholamine. It is synthesized, stored, and released from the adrenal medulla and is the key hormonal element in the fight-or-flight response. It is the most widely used catecholamine in medicine. It is used to treat asthma, anaphylaxis, cardiac arrest, and bleeding and to prolong Regional Anesthesia. The cardiovascular effects of EPI, when given systemically, result from its direct stimulation of both *α* and *β* receptors. This is dose dependent and is outlined in Table 12-14.

The effect of EPI on the peripheral vasculature is mixed. It has predominantly *α*-stimulating effects in some beds (skin, mucosa, and kidney) and *β*-stimulating actions in others (skeletal muscle). These effects are also dose dependent. At therapeutic doses, *β*-adrenergic effects predominate in the peripheral vessels, and total resistance may be reduced. Constriction, however, is maintained in the renal and cutaneous areas because of its dominant *α* effect in these areas. An increase in CO with EPI may be a result of a redistribution of blood to low resistance vessels in the muscle, but with further reduction in flow to vital organs. Cardiac dysrhythmias are a prominent hazard, and the strong chronotropic effects of EPI have limited its use in the treatment of cardiogenic shock.

Epinephrine is commonly used in the perioperative period in anesthesia. It is often used to produce a bloodless field in dentistry, otolaryngology, and skin grafting either topically or in local and field blocks. Anesthesiologists often use it to prolong regional anesthesia. The addition of epinephrine to arthroscopic infusions to attain a bloodless field is another area of increased epinephrine usage with the development of these techniques. These infusions are usually safe in maintaining a dry operative field because the solutions are very dilute at around 1:3,000,000. However, the large volumes infused, the unpredictable absorption of the epinephrine, especially in denuded cancellous bone, offers the opportunity of exposure of the patient to an excessive amount of epinephrine over a short period of time despite the dilution.[83] The unexpected complications are those of epinephrine overdose, that is, acute heart failure, pulmonary edema, or cardiac arrhythmias and arrest in the otherwise young and healthy patient. Impending problems during the infusion of intra-articular fluids will be noted by an increasing blood pressure exceeding that attributable to surgical pain or hypertension that is poorly responsive to deepening of anesthesia. Absent a pulsatile flow or vasoconstriction oximetry may become dysfunctional. The patient will appear pale and cyanotic. Unless alert, one may unintentionally treat an unexpected acute heart failure or cardiac arrest with the very agent that caused the problem. The outcome is universally poor. Vasodilators and *β*-blockers may save the day instead.

Intravenous and locally infiltrated adrenergic agents should be used cautiously during inhalation anesthesia, especially with halothane. The following schedule has been found to be relatively safe during inhalation anesthesia.[84] (1) EPI concentrations no greater than 1:100,000–1:200,000 (1:200,000 = 5 μg/mL). (2) Adult dose should be no greater than 10 mL of 1:100,000 or 20 mL of 1:200,000 within 10 minutes. (3) Total should not exceed 30 mL of 1:100,000 (60 mL of 1:200,000) within 1 hour.

The dose of submuscosally injected EPI necessary to produce ventricular cardiac dysrhythmia in 50% of patients anesthetized with a 1.25 MAC of a volatile anesthetic was 10.9, 10.9, and 6.7 μg/kg during administration of halothane, enflurane, and isoflurane, respectively.[85] No data are currently available for sevoflurane or desflurane. The incidence of cardiac dysrhythmia is eliminated when this dose is halved in patients anesthetized with halothane or isoflurane. In contrast with adults, children seem to tolerate higher doses of subcutaneous EPI without developing cardiac dysrhythmia.[86]

Ephedrine. Ephedrine is the most commonly used noncatecholamine sympathomimetic agent. It is used extensively for treating hypotension following spinal or epidural anesthesia. Ephedrine stimulates both *α* and *β* receptors by direct and indirect actions. It is predominantly an indirect-acting pressor, producing its effects by causing NE release.[16] Tachyphylaxis develops rapidly and is probably related to the depletion of NE stores with repeated injection. The cardiovascular effects of ephedrine (see Table 12-14) are nearly identical to those of EPI but less potent. Its

effects are sustained about 10 times longer than those of EPI.

Ephedrine remains the pressor of choice in obstetrics because uterine blood flow improves linearly with blood pressure.[52] This effect is probably not related to its arteriolar vasoconstriction but rather to its venoconstrictive action. Ephedrine is a weak, indirect-acting sympathomimetic agent that produces venoconstriction to a greater degree than arteriolar constriction (see Table 12-18), at the doses ordinarily used.[87] This may be its most important and unappreciated effect. It causes a redistribution of blood centrally, improves venous return (preload), increases CO, and restores uterine perfusion. The mild *β* action restores HR simultaneously with improved venous return. An increased blood pressure is noted as a result rather than a cause of these events. Mild *α*-1 arteriolar constriction does occur, but the net effect of improving venous return and HR is increased CO (Fig. 12-27). Uterine blood flow is spared. This response, however, depends on the patient's state of hydration.

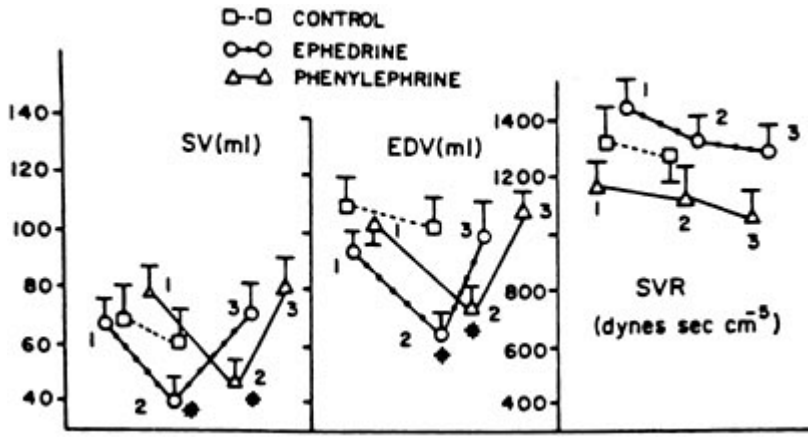

FIGURE 12-27. Stroke volume (SV), end-diastolic volume (EDV), and systemic vascular resistance (SVR) (1) before regional block, (2) during hypotension, and (3) after therapy with ephedrine or phenylephrine. The increase in stroke volume was related entirely to an increased venous return secondary to venoconstriction in these awake, healthy patients. The afterload effects of phenylephrine at higher doses predominate in patients with heart disease or myocardial depression and reduce CO. (Reprinted with permission from Ramanthan S, Grant G: Vasopressor therapy for hypotension due to epidural anesthesia for cesarean section. Acta Anaesthesiol Scand 32:4, 1988.)

Neosynephrine is an attractive alternate vasopressor for obstetrics for similar reasons. It produces strong *α*-1 venoconstriction and volume redistribution at infusion rates at which *α*-1a or *β* effects are minimal (see Table 12-15). Alternatively, the primary disadvantage of the venoconstriction of low doses of dopamine is its lack of immediate availability as an iv push drug. It requires more careful titration than ephedrine. The prophylactic administration of "pressors" before spinal blockade in obstetrics can produce misleading clinical estimates of volume status because of its effects on venous return and arterial pressure.[88]

Isoproterenol. Isoproterenol is a potent balanced *β*-1 and *β*-2 receptor agonist with no vasoconstrictor effects. It increases HR and contractility while decreasing systemic vascular resistance. Although it can increase CO, it is not useful in shock because it redistributes blood to nonessential areas by its preferential effect on the cutaneous and muscular vessels.[89] As a result, it produces variable and unpredictable results on CO and blood pressure. Isoproterenol is a potent dysrhythmogenic drug and extends myocardial ischemic areas. Deleterious effects on an evolving cardiac ischemic process include cardiac dysrhythmias, tachycardia, and reduced diastolic

coronary perfusion pressure and time. Increased myocardial oxygen demand makes it an unattractive drug for patients in cardiogenic shock.

Isoproterenol is helpful in managing cardiac failure associated with bradycardia, asthma, and cor pulmonale. It is also a useful chemical pacemaker in third-degree heart block until an artificial pacemaker can be inserted or the cause can be removed. Isoproterenol might be useful in treating both idiopathic and secondary pulmonary hypertension.[15,16] It has also been reported as useful in improving the forward flow in patients with regurgitant aortic valvular disease, but it should not be used if there is an accompanying stenosis.[82]

Dobutamine. Dobutamine is a synthetic catecholamine modified from the classic inodilator isoproterenol. Isoproterenol was, in turn, synthesized from dopamine. Variations and similarities in structure can be seen in Figure 12-7.

DBT has clear advantages over isoproterenol and dopamine in many clinical situations. It acts directly on β-1 receptors but exerts much weaker β-2 stimulation than isoproterenol. It does not cause NE release or stimulate DA receptors. DBT, unlike isoproterenol or DPX, possesses weak α-1 agonism, which can be unmasked by β-blockade as a prompt and dramatic increase in blood pressure.[90] Ordinarily, changes in arterial blood pressure do not occur because the mild α-1 activity is countered by the β-2 activity. DBT produces strong inotropism but with weak chronotropic or vascular effects. Increases in CO are primarily through increased inotropism and secondarily by reduced afterload.

DBT increases automaticity of the SA node and increases conduction through the AV nodes and ventricles. DBT produces less increase in HR per unit gain in CO than dopamine, but it is not devoid of chronotropic activity. Troublesome tachycardias can occur in sensitive individuals and caution should be exercised in patients with established atrial fibrillation or recurrent tachycardias. Early studies found DBT preferable to dopamine, EPI, or isoproterenol because of its reduced chronotropic effects.[91] DBT increases HR more than EPI for a given increase in CO.[92]
