the procedure (i.e., hemorrhage), which required aggressive management.

Anticoagulation management can complicate regional anesthesia in endoAAAR patients. One disadvantage of using epidural or continuous spinal catheter techniques is the need to wait until heparin effect has dissipated before removing the catheter. In most patients, postoperative pain is not a significant issue after successful endoAAAR, particularly if the groin incisions have been infiltrated with local anesthetic. Therefore, maintaining an epidural or subarachnoid catheter after surgery is not generally necessary to provide analgesia, unless more extensive adjuvant procedures such as iliac artery repair have been performed. Obviously, the normal cautions that apply to regional anesthesia in patients receiving preoperative anticoagulation therapy apply to those undergoing endoAAAR.

Endovascular repair likely represents an advance in care but not a panacea. Clinicians caring for these patients must be prepared for complications. Regional and local anesthesia with sedation may be a key part of the management of these patients if the caveats discussed previously are kept in mind.

Protecting the Spinal Cord and Visceral Organs

Thoracic aortic occlusion reduces distal blood flow tremendously. Various strategies have been used to protect the spinal cord from ischemia, including maintenance of proximal hypertension during cross-clamping, local, or systemic hypothermia, CSF drainage, and various drugs (including magnesium, steroids, papaverine, naloxone, and barbiturates) to protect the brain and spinal cord during resection of abdominal or thoracoabdominal aneurysms, or coarctation repairs. Spinal cord sensory-evoked, motor-evoked potentials and CSF lactate concentrations may prove useful in predicting patients at risk for spinal cord ischemia and in gauging spinal cord protection, but there is limited experience in the use of the techniques. Spinal cord metabolism can be reduced by moderate hypothermia and high-dose barbiturates. Local hypothermia achieved by infusion of cold saline into the epidural space, when combined with CSF drainage, has been reported to significantly reduce paraplegia rate. Alternatively, femoral-femoral bypass and deep hypothermic cardiac arrest may be used in patients at high risk of paraplegia. Reperfusion injury may be addressed by the use of mannitol, steroids, calcium channel blockers, and avoidance of hyperglycemia. The multitude of proposed pharmacologic and surgical maneuvers to reduce spinal

cord ischemia and neurologic deficits after thoracic aortic occlusion highlights the serious nature of this complication and the lack of consensus on its prevention. Table 32-7 summarizes some of these approaches. We still believe short cross-clamp times are the common element of successful regimens.

TABLE 32-7 Methods of spinal cord protection during descending thoracic aortic surgery[170]

- Limitation of cross-clamp duration
- Distal circulatory support
- Reattachment of critical intercostal arteries
- CSF drainage
- Hypothermia
  - Moderate systemic (32–34°C)
  - Epidural cooling
  - Circulatory arrest
- Maintenance of proximal blood pressure
  - Pharmacotherapy
    - Systemic:
      - Corticosteroids, barbiturates, naloxone, calcium channel antagonists, O_2 free radical scavengers, NMDA antagonists, mannitol, magnesium, vasodilators (adenosine papaverine, prostacyclin), perfluorocarbons, colchicine
  - Intrathecal:
    - Papaverine, magnesium, tetracaine, perfluorocarbons
- Avoidance of postoperative hypotension
- Sequential aortic clamping
- Enhanced monitoring for spinal cord ischemia
  - Somatosensory-evoked potentials
  - Motor-evoked potentials
  - Hydrogen-saturated saline
  - Avoidance of hyperglycemia

CSF, cerebrospinal fluid; NMDA, N-methyl-D-aspartate.

Some surgeons place a Gott shunt, a heparinized tube that can decompress the heart and also provide distal perfusion. The Gott shunt can be placed proximally into the ascending aorta (the most common site), aortic arch, descending aorta, or left ventricle and inserted distally into the descending aorta (most commonly), femoral artery, or abdominal aorta. Even with a Gott shunt or partial bypass, there is an obligatory time of visceral ischemia when the visceral blood supply arises from a point between the proximal and distal clamps. Placement of a shunt may result in atheroembolism, which can produce rather than prevent ischemic injury and death. Other surgeons may place a temporary ex vivo right axillofemoral bypass graft before positioning for thoracotomy. After the thoracic aortic surgery is completed, the axillofemoral graft is removed. The placement of a shunt or distal perfusion attenuates the hemodynamic response to aortic unclamping, reduces acidosis, and could conceivably ameliorate the hormonal and metabolic changes that accompany aortic occlusion.

Other groups have chosen to use partial bypass, either from the left atrium or ascending aorta to the iliac or femoral artery to provide distal perfusion and decompress the heart. A heat exchanger may be used to induce hypothermia, which may be neuroprotective. Segmental sequential surgical repair may minimize the duration of ischemia to any given vascular bed. Intercostal artery reattachment in hopes of preserving blood flow to the anterior spinal cord may also be beneficial.

After reperfusion, the heat exchanger can be used to warm the patient. Other potential advantages of left atrial–left femoral artery shunt with centrifugal pump support are better operative field exposure, afterload reduction, maintenance of stable distal aortic perfusion, and reduced (but not eliminated) head and neck edema.

A markedly reduced incidence of neurologic deficits has been reported when distal aortic perfusion is combined with drainage of CSF.[118] CSF drainage is used in the hope of improving the pressure gradient, allowing spinal cord blood flow as aortic occlusion lowers distal arterial pressures and increases the CVP. The new endovascular techniques represent an alternative therapy when anatomy permits; lower paraplegia rates have been reported compared with open surgery.[103]

Monitoring and Anesthetic Choices for Aortic Reconstruction

We routinely place arterial catheters in patients undergoing aortic reconstruction. In patients undergoing thoracic aortic clamping with distal perfusion, we may also measure distal arterial pressure and CSF pressure. We may place a pulmonary artery catheter (PAC) in patients undergoing suprarenal aortic cross-clamp, but rarely in patients when the clamp will be infrarenal. However, we may place PACs in patients with a

history of CHF or poor left ventricular function on preoperative or intraoperative echocardiography, diabetes with end-organ damage, cor pulmonale, or renal insufficiency. We recognize, however, that more recent large randomized trials and observational studies have not been able to demonstrate any improvements in outcome with pulmonary artery catheters.[119] Therefore, although we occasionally use them in major vascular surgery in patients with associated end-organ dysfunction, we do not believe that pulmonary artery catheterization is required for vascular surgery.

For patients undergoing thoracic or thoracoabdominal aortic resection, we may place a large double-lumen introducer in an internal jugular or subclavian vein. This large catheter provides two very large-bore routes for volume resuscitation and allows passage of a PAC if desired. For a patient undergoing an infrarenal procedure, we are generally satisfied with a simple 9F introducer in the right internal jugular vein (with a triple-lumen central venous catheter or a PAC) and a large-bore peripheral intravenous catheter.

If we elect to drain CSF, we place specialized silastic lumbar drainage catheters into the intrathecal space at L3–L4 or L4–L5. These catheters have a one-way pressure valve that allow drainage only when the CSF pressure exceeds 5 to 10 mm Hg. Some clinicians have placed them the night before surgery in case a "bloody tap" results so clotting may be assured. We generally wait until after the likelihood of paraplegia has declined and until after coagulopathy (which is common after thoracoabdominal repair) has resolved to remove CSF drains, usually on the second or third postoperative day.

Virtually all anesthetic techniques and drugs have been used for aortic reconstructive surgery. We believe our ability to maintain hemodynamic equilibrium and attend to detail is more crucial to outcome than is the choice of drugs.

Halogenated agents produce vasodilation that has advantages and disadvantages. It provides an additional means of controlling afterload and preload but can lead to an increased need for intravascular volume. Volatile drugs also permit careful, deliberate induction, manipulation of hemodynamic variables, and adjustment of dose. They can also be used to treat stress-induced increases in left ventricular filling pressures.[120] They provide a moderate degree of muscle relaxation, decreasing the need for muscle relaxants and increasing the ease of reversing paralysis. Volatile anesthetics also facilitate tracheal extubation at the end of surgery. Thus, the stressful stimuli and hypertension associated with continued intubation of the trachea after surgery are avoided. Also, this approach permits early assessment of neurologic function and the presence of angina (although the vast majority of episodes of postoperative myocardial ischemia are "silent"). Perhaps the most important reason to routinely include volatile agents into general anesthetics is the increasing awareness that volatile anesthetics improve preconditioning mechanisms and reduce the size of MI should it occur.[121] These effects have been documented in

animal models and on-pump CABG models, although we await specific information in vascular surgery patients.

All commonly used opioids produce similar cardiovascular effects unless they are administered rapidly in large doses. Induction of anesthesia with opioids, which can be accomplished quickly, decreases the cardiac index by a small amount. In sufficient doses, opioids produce analgesia and hypnosis, with only slight decreases in cardiac contractility and blood pressure. Higher doses predictably decrease peripheral vascular resistance, especially when administered after benzodiazepines. With continual infusion of opioids or other drugs, anesthesia can be maintained throughout the surgical procedure. Surgical stimulation after opioid induction significantly increases the heart rate, arterial blood pressure, and systemic vascular resistance. Nitroglycerin, nitroprusside, or a volatile anesthetic (our usual choice) can be added to the opioid for manipulation of the circulation during cross-clamping and unclamping.

Nitrous oxide can be used with opioids or with the inhalational drugs. However, it increases afterload and myocardial work, while depressing myocardial inotropic performance and output. In one study of patients undergoing abdominal aortic surgery, nitrous oxide increased the need for nitroglycerin to treat elevated PCWP and myocardial ischemia, although clinical outcome was not affected. Nitrous oxide may decrease renal and splanchnic blood flows, and may have long-lasting toxic effects by causing nutritional, neurologic, and immunologic deficits. Nitrous oxide acutely increases homocyteine concentrations, and this can be associated with increased perioperative myocardial ischemia in vascular surgery; pretreatment with B vitamins can mitigate this response.[122] Nitrous oxide can also contribute to bowel distention.

Our work suggests that large doses (15 to 20 mcg/kg) of the synthetic narcotic sufentanil improve patient outcome after aortic reconstruction. High-dose sufentanil anesthesia alone was associated with less major (cardiac and renal) morbidity than isoflurane anesthesia (Table 32-8). Sufentanil may have a protective effect because of its superior blockade of the

adrenergic stress response. Further study is needed to determine whether all opioids are protective. A disadvantage of the opioids is that most linger into the postoperative period. However, in more than 50% of the patients who received a high-dose, opioid-nitrous oxide anesthetic technique (sufentanil 15 to 20 μg/kg) for suprarenal aortic reconstruction, tracheal extubation was accomplished in the operating room. High-dose opioid anesthetics also produce excellent postoperative analgesia. Our current practice relies on smaller doses of sufentanil (2 to 5 mcg/kg), combined with 0.5 to 1.0 MAC volatile agent if an epidural is not used.

TABLE 32-8 Morbidity after aortic reconstruction with one of two different anesthetic agents

·MORBIDITY	·ISOFLURANE-BASED ANESTHETIC(n = 50)	·SUFENTANIL-BASED ANESTHETIC(n = 46)

Combined general epidural and general spinal anesthetics have been used successfully for aortic reconstruction. A detailed description of the advantages and disadvantages of regional anesthetics can be found below in lower-extremity revascularization. For patients requiring thoracotomy, the analgesia provided by thoracic epidural infusion of narcotics and/or local anesthetics may be particularly helpful in improving spirometric function. Thoracic epidural local anesthetics can also dilate coronary arteries and help prevent stress-induced elevations in PCWP. Some clinicians are reluctant to use epidural anesthesia for supraceliac aortic reconstruction because of concerns about concurrent heparinization and the associated incidence of paraplegia. In such patients, the use of peridural narcotics without local anesthetics can preserve sensory and motor function and can allow early assessment of neurologic integrity. Because urinary catheters are typically left in place for at least 36 hours after aortic reconstruction surgery, urinary retention is not a major issue. We often use intrathecal or epidural narcotics after supraceliac aortic occlusion. Animal studies have shown that intrathecal naloxone improves neurologic function after thoracic aortic occlusion, but results in humans have been inconclusive. Another disadvantage of epidural local anesthetics is that although patients must receive increased amounts of intravenous fluids, they are still likely to become hypotensive after reperfusion.[123] Therefore, we are prepared for the possibility of fluid overload toward the end of the procedure. Alternatively, infusions of dopamine or dobutamine may be used to maintain systemic vascular resistance and contractility in the presence of the sympathectomy induced by the use of local anesthetics for regional block.

We believe prophylaxis of stress and pain by any mechanism (epidural anesthetics, opiate infusion, or α_2-agonists) may result in lower morbidity in those least able to tolerate the myocardial and cardiovascular demands of stress.

Management of Elective Aortic Surgery

We believe prehydration reduces variations in blood pressure on induction of anesthesia. After the patient's preoperative condition has been optimized, the range of hemodynamic variables for that

patient is determined. The anesthetic management is then planned to keep the patient within 20% of this range, as long as the PCWP does not exceed 15 mm Hg, the heart rate does not exceed 80 to 90 beats/min, and signs of organ ischemia are absent. In the preoperative holding area or in the operating room, the monitors and catheters that are needed for induction of anesthesia are placed, usually a radial artery catheter in the nondominant hand, a manual blood pressure cuff, pulse oximeter, ECG (leads II and V_5), ST segment trend monitor, precordial stethoscope, a 16-gauge intravenous line, and, occasionally, a central venous or pulmonary artery catheter. We generally induce anesthesia with small incremental doses of propofol and judicious amounts of opiates, lidocaine, or esmolol to blunt responses to intubation; we are aware that the combination of propofol and beta-blockers or ACE inhibitors can cause hypotension in elderly or hypovolemic patients. The remainder of the pre–cross-clamping phase is devoted to meticulous attention to the details of maintaining temperature homeostasis (unless hypothermia is desired for its potential spinal cord protection): maintaining volume homeostasis as judged by heart rate, blood pressure, pulmonary capillary pressure, or CVP; maintaining left ventricular end-diastolic volume as assessed by echocardiography; ensuring absence of organ ischemia; monitoring (but usually not treating) urine output; and keeping systemic and pulmonary blood pressures and heart rate in the patient's usual range. Every increase in blood pressure or heart rate is either anticipated or treated as soon as it occurs with 25 to 50 μg of sufentanil.

For the half-hour immediately before cross-clamping and aortic occlusion, the patient is kept slightly hypovolemic by examining the ventricular volume by means of echocardiography or by keeping PCWP at 5 to 15 mm Hg. At the time of occlusion we are prepared to give a vasodilating drug through an intravenous catheter placed specifically for that purpose to avoid hypotension from an accidental bolus of vasodilator. Alternatively, we may increase the concentration of volatile anesthetic, or inject local anesthetics into the epidural catheter. Both of these approaches require careful attention to avoid hypotension. A novel approach to reduce blood pressure in the face of aortic occlusion has been described using placement of 15 cm positive end-expiratory pressure immediately before cross-clamp, with removal just before unclamping.[124] This approach facilitates volume loading and reduces hypotension after unclamping. Our approach is different when we are concerned about spinal cord perfusion in patients whose aorta will be occluded at the thoracic level without distal perfusion. In these instances, we will accept some proximal hypertension while the aorta is occluded in the hope of obtaining higher distal perfusion pressures and preventing distal ischemia. This choice may come at the expense of myocardial well-being. In fact, 92% of the patients we studied had ischemia, as evidenced by abnormal motion and thickening of the left ventricle (see Table 32-6). More distal levels of temporary occlusion are less stressful hemodynamically.

7 Administration of exogenous vasoconstrictors is avoided, if possible. Phenylephrine doubles the incidence of wall motion abnormalities observed by echocardiography compared with the incidence in patients whose blood pressure is maintained simply by light anesthesia and endogenous vasoconstrictors.[34] Rather than relying on vasoconstrictors, we ensure adequate volume at the time of cross-clamp removal by replacing blood lost during occlusion with crystalloid or colloid, warmed cell-saver blood, or banked blood to keep the hematocrit slightly above 30% because it will decrease to 30% in the postocclusion period. We believe that this is the minimal acceptable value for patients in this risk group.[48] Guided by filling pressures or echocardiographic estimates of volume, we are careful not to dilate the left ventricle to an abnormal size.

We routinely use autotransfusion devices and prefer to have a technician to operate them. We continue to do this even though autotransfusion devices may not reduce transfusion of allogenic blood but only delay it.[125] After the sixth unit of blood has been given and if more blood loss is anticipated, or after 8 units of blood have been administered, 10 units of platelets are requested for the patient (and occasionally 2 units of fresh frozen plasma). Because a large part of the vascular tree is excluded from circulation during temporary aortic occlusion, blood loss can be considerable during supraceliac cross-clamping without the onset of hypotension or tachycardia. Evisceration of bowel, often necessary for optimal exposure of the thoracoabdominal aorta, further depletes intravascular volume. Blood loss into the pleural or retroperitoneal cavity may not be readily detected.

Immediately before and during removal of the cross-clamp, we stop infusing vasodilators. We allow blood pressure, PCWP, and filling volumes to go as high as possible without the

occurrence of myocardial ischemia. The surgeon then opens the aorta gradually to ensure that severe hypotension does not develop and that there is not too much bleeding from the suture line. Pathophysiologic events on removal of the aortic cross-clamp are associated with inadequate preload. We therefore infuse crystalloid, colloid, or blood just before reperfusion. Guided by filling pressures or echocardiographic estimates of volume, or both, we are careful not to dilate the left ventricle.

Volume replacement and maintenance are mainstays of therapy before, during, and immediately after removal of the aortic cross-clamp. At this point in the procedure, pulmonary artery pressures or CVP may increase because reperfusion of ischemic tissues is associated with the release of lactic acid and other unknown mediators that can cause pulmonary vasoconstriction. Mannitol prophylaxis may prevent part of this response, and we frequently give mannitol 0.5 to 1.0 g/kg immediately before release of the clamp.

During closure, we again ensure adequate organ perfusion, as well as hemodynamic and temperature homeostasis, and we reverse the effects of muscle relaxants. Reversal is easier when patients are warm. Hypothermia after aortic reconstruction is associated with other complications, including coagulopathy, low cardiac output states, and significantly higher incidences of organ dysfunction and death. We routinely use forced-air warming on the upper portion of the body in these patients, although their lateral position and extensive exposure during thoracic procedures make maintaining normothermia difficult.

During emergence from anesthesia, we use infusions of nitroglycerin and esmolol or another β-adrenergic blocking agent to prevent hemodynamic variations outside the patient's normal range. If ventilation is adequate and fluid replacements have been modest and we do not suspect airway edema, the trachea is extubated; otherwise, controlled ventilation is maintained until spontaneous ventilation is judged adequate. If we elect to use a predominantly inhalational anesthetic technique, we often place a thoracic epidural catheter and administer epidural local anesthetics and opioids for postoperative analgesia. When the sufentanil-based technique described previously is used, rarely is much additional pain therapy needed for 24 hours. We continue to provide prophylactic beta-blockade into the postoperative period, as tolerated. In unstable patients, esmolol may be infused; in more stable patients, we will often prescribe metoprolol 5 to 10 mg intravenously q6h, as long as heart rate >55 beats/minute and blood pressure >110 mm Hg.

Anesthesia for Emergency Aortic Surgery

The most common cause of emergency aortic reconstruction is a leaking or ruptured aortic aneurysm. Ruptured aneurysms can be atherosclerotic, mycotic, syphilitic, or inflammatory, or may occur in patients with the marfanoid syndrome. Ruptured aneurysms carry associated mortality roughly 10 times greater than elective repair. Therefore, efforts should be made to increase the number of elective operations performed for aortic aneurysms before they rupture, as urgent/emergent surgery is associated with increased mortality even in the absence of frank rupture.

Symptoms of ruptured AAAs include pain, faintness or frank collapse, and vomiting. Pain in the back, abdomen, or both is almost always present. Therefore, many surgeons believe pain in combination with a known AAA or pulsatile abdominal mass indicates dissection or rupture and the immediate need for surgical exploration until proved otherwise. Ruptures most commonly occur into the retroperitoneum. This site permits tamponade of the hemorrhage; however, retroperitoneal hemorrhage and subsequent hematoma can displace the left renal vein, inferior vena cava, and intestine, possibly leading to damage to these structures during the surgical approach. Venous hemorrhage is often much more difficult to control than arterial hemorrhage.

Approximately 25% of aneurysms rupture into the peritoneal cavity, a site associated with a great degree of exsanguination. Other sites of rupture include adjacent structures after formation of fistulae with the inferior vena cava, iliac veins, or renal veins. Aortoenteric fistulae can occur. The

mortality from these fistulae is high, often exceeding 50%. The importance of controlling bleeding gives credence to the inescapable sense of urgency that accompanies such events.

Management of hemodynamically unstable patients is challenging. Shock frequently accompanies rupture. However, the absence of hypotension does not rule out the possibility of rupture, and shock may occur suddenly. Rapid diagnosis with immediate laparotomy and control of the proximal aorta are of the highest priority. If systolic blood pressure is <90 mm Hg, some clinicians advocate the administration of oxygen by face mask, with tracheal intubation performed only after proximal control of the aorta has been achieved. We prefer an awake intubation, with very slow induction of anesthesia after the airway is secured. However, in uncooperative patients we may perform a rapid-sequence tracheal intubation after small doses of etomidate (0.1 mg/kg) and a steroid. Almost simultaneously, laparotomy is begun so the surgeon can clamp the aorta.

We attempt to replace volume to normalize systemic blood pressure. However, when rupture is suspected, rapid control of the proximal portion of the aorta is probably more important than optimizing the patient's preoperative condition. Alternatively, a balloon may be passed from the femoral artery under fluoroscopic control to occlude the aorta above the site of rupture. The patient is resuscitated quickly (before induction of anesthesia, if possible) with crystalloid, colloid, packed red blood cells, and even type-specific non–cross-matched blood if necessary, administered via large-bore peripheral or central venous catheters by roller pumps or pressured bags. If type-specific blood is not available, O-negative washed red blood cells may be given. We emphasize the importance of large-bore peripheral catheters placed in the most easily accessible vein, often 14-gauge catheters in each antecubital fossa. We recommend the use, when possible, of fluid warmers that deliver rapid volumes of normothermic fluids.

Once the aorta is controlled with a cross-clamp, and blood pressure and perfusion are restored, additional venous access and a radial, brachial, or axillary arterial line are secured. Attention may then be turned to placing a CVP or pulmonary artery catheter once blood pressure is adequate. Even more quickly, an echocardiographic probe can be inserted for rapid assessment of left ventricular volume and contractility. At this point, volume administration is guided by means of PCWP or by TEE. High-normal filling pressures are desirable for attenuation of hypotension after removal of the aortic clamp. Some patients with hemorrhagic shock will require infusions of dopamine, epinephrine, or norepinephrine to sustain an adequate blood pressure even after restoration of normal blood volume. Vasopressin may be particularly effective in restoring blood pressure when hemorrhagic shock is resistant to catecholamines. These patients are often profoundly acidotic; if we administer sodium bicarbonate, we increase ventilation to help eliminate the extra carbon dioxide produced. We do not hesitate to paralyze and administer propofol, midazolam, and/or opioids to these patients if they are hemodynamically stable because they usually require postoperative mechanical ventilation of the lungs and sedation to minimize cardiovascular stress. Acute respiratory distress syndrome develops frequently in patients who survive surgery for a ruptured aneurysm.

Due to hypothermia from massive fluid resuscitation and the aortic occlusion above the hepatic artery, replacement blood may not pass through the liver in amounts adequate to allow

for metabolism of citrate. Therefore, if hypotension due to poor myocardial contractility (which may be easily assessed with TEE) or coagulopathy develops, administration of calcium may be therapeutic. It has been suggested that the aggressive fluid resuscitation of trauma patients in the emergency room before transport to the operating room may result in increased mortality, perhaps by causing hypothermia or dilutional coagulopathy, or by raising blood pressure and increasing bleeding. At present, however, we cannot recommend allowing patients to remain hypotensive but believe attention should be paid to maintaining temperature, adequate hematocrit, and coagulation, in addition to simply normalizing intravascular volume.

We routinely use autotransfusion in patients with actual or suspected rupture of an aortic aneurysm, even though some have questioned its effectiveness in reducing transfusion requirements.[125]

8 The complications that occur during aortic occlusion can usually be linked to the heart,

central nervous system, or kidneys. Organ dysfunction can be minimized by maintaining intraoperative values for hemodynamic variables within the normal preoperative range, ensuring cardiac dilation does not occur at any point, and minimizing episodes of tachycardia. Attention to the details of preoperative drug therapy, preoperative hydration, and temperature homeostasis may also promote an improved outcome. Further, vigilance must continue into the postoperative period if morbidity and mortality are to be minimized. As opposed to elective aortic reconstruction, in which preserving myocardial function is the primary goal, in emergency resection the crucial factor for patient survival is first rapid control of blood loss and reversal of hypotension, and then preservation of myocardial function.

LOWER-EXTREMITY REVASCULARIZATION

The number of patients undergoing lower-extremity revascularization has increased as surgeons attempt to improve functional status in elderly patients. Many patients undergo revision or repeat operations. They often have complex medical histories and diseases of multiple organ systems that present additional challenges beyond those of routine anesthetic management. Despite this fact, patients are now frequently admitted to the hospital on the day of surgery. For others, surgery is emergent or urgent. In all these situations, the primary goal of anesthetic management is to prevent the development of perioperative complications. These patients are at particularly high risk for perioperative cardiac complications, including myocardial ischemia and infarction, low cardiac output (forward failure), and pulmonary edema (backward failure). Krupski et al.[15] showed that the incidence of cardiac morbidity after infrainguinal procedures may exceed that associated with abdominal aortic procedures because patients scheduled for distal procedures often have more preoperative cardiac risk factors than patients scheduled for aortic procedures. Yet, patients undergoing lower-extremity revascularization may receive less attentive care than patients undergoing "major" procedures.

Increasingly, endovascular repair may involve angioplasty and or stenting of smaller vessels, including femoral arteries. However, restenosis after stenting may necessitate repeated percutaneous or surgical revascularization procedures. Increasingly, these procedures may be performed by cardiologists, and they may be performed without an anesthesiologist present. The use of drug-eluting stents that deliver drugs such as paclitaxel to the site of vascular injury may reduce the incidence of neointimal hyperplasia and restenosis. Their use in the coronary circulation reduces restenosis and may or may not reduce morbid events.[126]

In addition to maintaining adequate cardiac function, another goal of our anesthetic and perioperative care is to ensure adequate perfusion and to prevent hypercoagulable responses to surgery to maintain graft patency in the immediate postoperative period. Pulmonary, renal, neurologic, and hepatic dysfunction may occur following vascular surgery; proper intraoperative and postoperative management may also help prevent these adverse outcomes. Anesthetic techniques that reduce the stress response may improve outcome. We believe ideal anesthetic management of these patients may decrease morbidity and mortality, as well as hasten recovery and hospital discharge.

Because some patients may undergo multiple procedures, anesthesiologists may become cynical about the effectiveness of lower-extremity revascularization; however, long-term patency and limb salvage rates are good, demanding that anesthesiologists do all they can to optimize outcome in these procedures. The typical cost of a limb salvage procedure approaches $20,000, which may be less than the cost of amputation when rehabilitation and the loss of independence are considered.

There are three clinical indications for elective surgery for chronic peripheral occlusive disease: (1) claudication, (2) ischemic rest pain or ulceration, and (3) gangrene. Patients with claudication have symptoms on walking that are relieved by rest. Such patients are not at significant risk for imminent limb loss. Patients with rest pain, ulceration, or gangrene are at variable risk for imminent limb loss and may have severe progressive ischemia. Thus, reconstruction for such patients is semiurgent or urgent. When a patient presents with a gangrenous (black) or pregangrenous (blue) toe, several causes other than progression of chronic arteriosclerotic occlusive disease must be considered. Emboli may originate from the heart, a proximal aneurysm,

or any proximal atherosclerotic lesion. Intra-arterially administered lytic agents, particularly urokinase, may have been administered, precluding regional anesthesia. Local infection is particularly common in diabetic patients.

Vascular reconstruction procedures are generally categorized as either inflow or outflow procedures. Inflow reconstruction involves bypass of the obstruction in the aortoiliac segment, whereas outflow procedures are those performed distal to the inguinal ligament for bypass of femoral-popliteal or distal obstructions. The most common inflow reconstruction procedure for obstructions in the aortoiliac segment is aortofemoral bypass. The usual vascular reconstruction below the inguinal ligament is a bypass graft that originates in the common femoral artery and extends to the popliteal or tibial artery. Such a bypass may be performed with a reversed saphenous vein, the saphenous vein in situ, or a prosthetic graft.

The complexity of femoral-popliteal and femorotibial bypass varies widely. The site for distal anastomosis and the quality of the outflow vessels are assessed by preoperative contrast or magnetic resonance angiography. Prosthetic bypasses can be performed more quickly and require less dissection than the saphenous vein bypass because it is not necessary to make multiple incisions for vein harvest. Prosthetic bypasses, however, have significantly lower patency rates than saphenous vein bypasses when they extend below the knee. The best short-term and long-term results are achieved with the saphenous vein, but this technique requires longer operative time and greater technical expertise than are needed for prosthetic grafts. The duration and complexity of the operation are usually determined by the quality of the saphenous vein, as well as the quality and size of the distal outflow vessels. In the past, the choice of a vascular prosthesis for a femoral-popliteal, above-knee, arterial bypass graft reflected the surgeon's preference. However, a Veterans Affairs randomized trial of different bypass graft materials for patients with femoral-popliteal, above-knee bypass grafts found that after 5 years, above-knee saphenous vein bypass grafts had a significantly better patency rate (73%) than

cryopreserved human umbilical vein bypass grafts (53%), which had a significantly better patency rate than PTFE bypass grafts (39%).[127] Limb salvage was worse with prosthetic conduits, whereas bypass graft thromboses and amputations within the first 30 days were highest in the umbilical vein group. Therefore, although the anesthesiologist may rightly perceive that saphenous vein harvest and preparation prolong the surgery and anesthetic, this is done for the patient's benefit.

In a reversed saphenous vein bypass, the vein is dissected, all branches are ligated and divided, and the vein is excised. The direction of the saphenous vein is reversed to permit blood flow in the direction of the valves, and the vein is tunneled from the femoral artery to the distal vessel. The use of the vein in situ offers significant advantages over the reversed-vein bypass; because the vein is not removed from its bed, it is subjected to little trauma; twisting or kinking is unlikely. These advantages have improved patency rates. The use of intraluminal angioscopy is reported to result in better vein preparation, smaller incisions, improved patency, and shorter hospital stay. The quality of the repair is determined from the pulse quality, Doppler ultrasound studies, or completion angiography.

The surgeons' concerns for patients with peripheral vascular insufficiency include not only those problems involving the cardiovascular system, but also specific problems related to the operative repair. Tunneling of the graft between the incisions may be more stimulating than other parts of the procedure and may cause hypertension under general anesthesia. The patient is usually given heparin during the procedure. In most cases, the heparin effect is not antagonized because bleeding problems are rare and graft reocclusion is a concern. Graft patency is evaluated carefully in the recovery room. Most surgeons believe the patient's feet should be kept warm and that the patient should be well hydrated so peripheral vasoconstriction, which may limit outflow from the new graft, is prevented. If graft thrombosis develops early in the postoperative period, the patient is promptly returned to the operating room for graft thrombectomy, as well as for evaluation and correction of the cause of the thrombosis. It can be anticipated that, during graft thrombectomy, significant blood loss will occur with flushing of the graft.

Anesthetic Management of Elective Lower-Extremity Revascularization

There is perhaps no other disease entity about which the anesthesiologist can be misled so easily than vascular disease of the lower extremity. One is apt to hear, "Oh, it's just a local procedure," or "Just put a spinal in and let's get on with it; you don't have to read the chart." However, the morbidity and mortality following distal operations approach those following infra-aortic reconstruction and are mainly of cardiac origin.[15] Thus, although we often use epidural or spinal anesthetics and opioids for pain relief, we pay close attention to body temperature, oxygen delivery, and hemodynamic homeostasis during peripheral vascular procedures and during aortic procedures that involve much greater hemodynamic fluctuations. The devices and the concerns previously described apply, with special attention to the postoperative period. It is during the postoperative period that most cardiac problems arise, and pain relief and correction of hemodynamic and fluid disequilibria are most likely to be needed. Care must be taken not to allow overhydration to occur intraoperatively in support of blood pressure, and then to cause CHF as the epidural sympathectomy wears off. Dye loads given for "completion angiography" also contribute to fluid shifts; thus, monitoring of cardiac preload is important for a successful outcome.

We often monitor hemodynamic variables invasively in patients undergoing lower-extremity revascularization. We place a radial arterial line in many patients, because the associated morbidity is low. An arterial line provides real-time information on blood pressure that can guide pharmacologic therapy for the rapid hemodynamic fluctuations that accompany induction of, and emergence from, anesthesia. Arterial cannulation also facilitates blood drawing in the crucial first 24 hours after surgery, especially in diabetics. If percutaneous radial artery catheterization is impossible, we rely instead on noninvasive blood pressure measurement.

We may place CVP catheters for various reasons. Blood loss may be insidious and unrecognized during prolonged, revision, infrapopliteal, or in situ procedures. Rapid blood loss or hemodynamic changes are not usually encountered with distal reconstruction, but the procedures tend to be lengthy, making intraoperative urinary drainage advisable. Our experience is that blood loss may be underestimated, and we may measure the CVP and obtain a hematocrit every 2 hours in patients undergoing below-knee procedures. Because the major morbidity and mortality with this procedure are related to the cardiovascular system, with rates above 8% and 2%, respectively, the noninvasive nature and the absence of hemodynamic alterations should not lull the anesthesiologist into a casual attitude.

Cardiac preload is reduced by epidural and spinal anesthesia due to the venodilation caused by their sympatholytic properties. Later, as the spinal or epidural anesthetic recedes, the patient's blood volume is distributed back to the central circulation. This "autotransfusion" can lead to elevated filling pressures, which may precipitate CHF if not recognized and treated appropriately. In our experience, CVP monitoring is helpful in diagnosing and treating postoperative hypovolemia. The early diagnosis and treatment of even subtle hypovolemia may be important in preventing postoperative renal dysfunction and early graft thrombosis. In some patients, the placement of a triple-lumen catheter allows for concurrent volume loading, multiple drug infusions, and CVP monitoring. Central venous catheters are also useful in the patient who will have vein harvested from the upper extremities. The risks associated with central catheter placement can be minimized by attention to strict aseptic technique during placement by an experienced or closely supervised practitioner. The risks associated with an indwelling catheter can be minimized by inserting a single-lumen or double-lumen catheter where feasible and removing the catheter as soon as it is no longer needed.

We do not believe the information obtained from a PAC justifies the additional risks (including heart block, dysrhythmia, pulmonary artery rupture, and pulmonary infarction) associated with routine use of this monitor in this patient population. Berlauk et al.[128] found that patients who were monitored during lower-extremity revascularization with PACs had a lower incidence of early graft occlusion than did patients with CVP monitoring. This study has been criticized because patients in the PAC group received nitroglycerin and volume loading (which have been previously shown to reduce morbidity from vascular surgery), whereas those in the CVP group did not. Also,

the investigators and practitioners were not blinded to the randomization groups, so the potential for introduction of bias during diagnosis and treatment was very high. We believe the prophylactic use of nitrates and volume loading in this study may have contributed more to the observed improved outcome than did the use of PACs. Therefore, we rarely use PACs. We may use PACs in patients with severe left ventricular dysfunction, renal failure, diabetes mellitus with autonomic neuropathy, and severe cor pulmonale and pulmonary hypertension. Further discussions about invasive monitoring can be found earlier in the chapter.

9 The choice of anesthetic for lower-extremity revascularization is individualized for each patient. Table 32-9 summarizes

the advantages and disadvantages of regional versus general anesthesia for this procedure.[129] The patient may have a preference for one technique over another based on previous experiences. Technical factors may contribute to the decision: obesity, previous laminectomy, or severe kyphoscoliosis may make it difficult to establish neuraxial blockade. Septicemia, local infection, anticoagulation, and certain neurologic diseases provide varying degrees of relative and absolute contraindications to regional anesthetic techniques. Regional anesthesia may be poorly tolerated by patients who are orthopneic, uncomfortable lying still for many hours, or demented and uncooperative. Indeed, failed regional anesthesia (11% of spinals and 16% of epidurals) is associated with 9% mortality, compared with 2% for successful regional or general anesthesia for femoral bypass.[117] Sedation allows patients to better tolerate a regional anesthetic for a long procedure, but we administer sedation judiciously because these patients are often frail or at risk for pulmonary aspiration. The combination of a high level of regional blockade and sedation may rarely produce cardiovascular collapse. The patient with rest pain who has received narcotic premedication may become very sedated or even apneic when the pain is suddenly relieved by a regional anesthetic. The argument that regional anesthesia allows the patient to be a monitor for myocardial ischemia by being able to complain of angina may be specious because the vast majority of episodes of perioperative myocardial ischemia are painless. Regional anesthesia may offer several advantages, however, including avoidance of hyperdynamic responses to tracheal intubation and extubation, reduced incidences of postoperative respiratory and infectious complications, and reduced postoperative hypercoagulability and graft thrombosis[130] (see Table 32-9). Other studies refute any effects of regional anesthesia on thrombotic outcomes and suggest only higher costs for postoperative surveillance. In some cases, the combination of regional and general anesthesia may provide patients with the benefits of each technique. To reduce the incidence of pruritus and respiratory depression from epidural narcotic analgesia, some anesthesiologists routinely infuse naloxone or place partial opiate agonists into the epidural space.

TABLE 32-9 Regional Anesthesia versus General Anesthesia

▪ANESTHETIC TECHNIQUE	▪ADVANTAGES	▪DISADVANTAGES
Regional	Effective blockade of stress response Patient as monitor (dyspnea, angina) Improved graft blood flow Possible prevention of postoperative hypercoagulability Postoperative analgesia Possible prevention or improvement of chronic pain syndromes (RSD)	Time-consuming May be technically difficult May be inadequate for the surgery Patient discomfort during long cases Sympathectomy requires volume loading Respiratory depression (from sedation or high level of blockade)

	Possible improved cardiopulmonary morbidity	Rare neurologic sequelae Precludes thrombolytic therapy
General	Controlled airway Hemodynamics easily controlled Reliable Patient comfort ensured for long cases	Hyperdynamic state after surgery Large fluctuations in cathecholamine levels Postoperative hypercoagulability not inhibited Greater perturbation of respiratory mechanics

From Tzeng GF: Hemostatic interventions and regional anesthesia for vascular surgery. Prob Anesth 11:207, 1999.

The operative procedure may also dictate the choice of anesthetic. Prolonged in situ and/or repeat procedures may not be amenable to a single-shot spinal technique; catheter spinal or continuous epidural techniques may be useful in these situations. The use of microcatheters for continuous spinal anesthesia was abandoned after reports of cauda equina syndrome, but the use of continuous spinal anesthesia through a larger catheter (e.g., those intended for use in the epidural space) does not appear to be a problem because it permits better dispersal and dilution of local anesthetic in the CSF. The incidence of postdural puncture headache is low in elderly patients. At times, we have combined spinal and epidural anesthesia for lengthy procedures. If the procedure takes longer than the 4 to 6 hours of surgical anesthesia provided by long-acting local anesthetics (often supplemented with 0.1 to 0.15 mg of preservative-free morphine), then the epidural catheter can be used to supplement surgical anesthesia and provide postoperative analgesia. Alternatively, an LMA may be placed for the duration of the procedure.

The formation of an epidural hematoma or abscess is a dreaded complication of any neuroaxial anesthetic technique. We try to ensure every health care provider who participates in the care of patients who have had epidural or spinal anesthesia is vigilant for the signs of an epidural hematoma and is aware of the need for its emergent operative evacuation. Severe back pain or pressure is the earliest symptom of epidural hematoma formation. The pain often develops a radicular component, and the patient may develop focal neurologic findings that correlate with injury to the spinal cord or nerve root. Both CT and MRI are acceptable imaging modalities for the diagnosis of a lumbar epidural hematoma. Time is of the essence, for if the spinal cord compression persists for longer than 6 to 12 hours, catastrophic paralysis may result. One must realize that if the patient is recovering from a general or a regional anesthetic, the spinal cord may have been compressed long before the patient started to complain. If a hematoma is diagnosed by CT, MRI, or myelography, the patient must have an emergent laminectomy and decompression if the risk of paralysis is to be minimized.[129]

Coagulopathy therefore represents a relative contraindication to regional anesthesia. The degree of coagulopathy at which it becomes unsafe to perform regional anesthesia is unknown, is highly controversial, and must be part of the risk–benefit calculation in each patient. Table 33-12 summarizes some suggestions for management of regional anesthetics and anticoagulation therapy; they have been reviewed earlier in the chapter.[12]

General anesthesia for lower-extremity revascularization has the advantage of obviating patient discomfort and lack of cooperation (see Table 32-9). It allows for adequate oxygenation and ventilation, and facilitates hemodynamic manipulation. Its use is virtually mandated in patients

plexus blocks are performed coincidentally). General anesthesia has been associated with a higher incidence of postoperative respiratory complications in some studies. However, although reduction in cardiac complications is often a stated reason for avoiding general anesthesia, more recent series have been unable to show such an effect in patients undergoing lower-extremity revascularization. Regional anesthetics may or may not reduce postoperative thrombotic complications. We do not believe the evidence favoring regional anesthesia is so overwhelming that we would withhold a general anesthetic from most patients to whom we have offered a regional anesthetic. Peripheral nerve blocks ("3-in-1," femoral sciatic block) may also be useful during and after lower-extremity revascularization.[131]

Specific types of general anesthetic may be preferred for patients undergoing vascular surgery. High-dose narcotic anesthetics may be associated with less renal insufficiency and CHF after aortic reconstruction than are volatile anesthetics.[132] This effect may be attributed to the superior ability of narcotics to blunt the adrenergic response to surgery. Despite these findings, we usually provide general anesthesia with doses of narcotics, which, although generous, still permit extubation in the operating room. Patients who receive general anesthesia can have a carefully controlled emergence and extubation, whether in the operating room or later in the ICU. We prefer to perform tracheal extubation at the end of surgery in the operating room, with the same intense monitoring of hemodynamics used during induction of anesthesia. We believe it is important to appreciate the complex physiology of the anesthetic emergence. This period is punctuated by large increases in catecholamine levels (see Fig. 32-3) and a high incidence of myocardial ischemia.[130] Emergence is a period of careful titration: opiates are infused to control pain and blunt sympathetic discharge, while still allowing the patient to ventilate effectively. Therefore, while still intubated and breathing spontaneously, patients receive incremental doses of narcotics titrated to adequate respiration (respiratory rate 8 to 16 min^{-1}; end-tidal PCO_2 <50 mm Hg). However, the anesthesiologist does not have the luxury of administering large amounts of opiates to blunt this response during the anesthetic emergence if he or she wants to extubate the patient in the operating room. Therefore, additional intravenous drugs are often required to control hemodynamics during emergence. Our usual practice is to titrate intravenous labetalol, metoprolol, dexmedetomidine infusion, or esmolol for extubation to keep heart rate below 80 beats · min^{-1} in the vast majority of patients who can tolerate β-adrenergic receptor blockade.

Anesthesia for Emergency Surgery for Peripheral Vascular Insufficiency

Emergency surgery for peripheral vascular insufficiency is required when acute arterial occlusion results in severe ischemia and threatens the viability of a limb. Immediate operation and restoration of blood flow are needed if limb loss is to be avoided. Depending on the etiology of the occlusion, the patient may or may not be at very high risk. Although this problem may appear to be localized to an extremity, the occluding material may originate in the heart or in major arteries. Therefore, peripheral vascular occlusion may be the result of a more serious cardiovascular problem. In fact, some patients with acute peripheral vascular occlusion are the sickest patients we have ever anesthetized.

With acute arterial occlusion, the involved extremity suddenly becomes cold and pulseless. Patients usually complain of coldness, pain, numbness, and paresthesias, and they may lose motion and sensation. Abnormal sensation in the toes, feet, and legs in response to light touch and pinprick, as well as abnormal proprioception and loss of motor function in the feet and toes, are hallmarks of acute ischemia and nonviability. If the ischemia is not reversed in a matter of hours, irreversible loss of viability is likely to result.

Acute arterial occlusion may develop in patients with preexisting peripheral occlusive or aneurysmal disease caused by thrombosis of a stenotic or ulcerated atherosclerotic artery. Acute arterial occlusion can also occur in patients with normal peripheral arteries that contain emboli. Such embolism is usually of cardiac origin in patients with cardiac dysrhythmias, recent MIs, or

ventricular aneurysms.

The cause is important in planning operative treatment. If the cause is an arterial embolus, Fogarty embolectomy through a groin incision with or without angioscopy under local anesthesia may suffice. However, if the cause is thrombosis of severely diseased atherosclerotic arteries, bypass reconstruction will be required. Although preoperative angiography may be of help in the differential diagnosis, often the cause is not uncovered until the vessel is opened. Thus, the anesthesiologist must be prepared for either a simple procedure or a complex, extended procedure. An incision in the groin is usually made for exposure of the femoral artery. Attempts to pass Fogarty catheters proximally and distally are made in the effort to establish flow and extract the thrombus. If flow is not restored in this manner, more complex reconstructive procedures such as aortofemoral, axillofemoral, or femoral-popliteal bypass may be required. Femoral venous drainage (into the autotransfusion suction if available) on restoration of flow to the femoral artery can aid in management by washing the initial venous effluent from an acutely ischemic extremity. Drainage may entail significant blood loss, but subsequent washing in a cell salvage device before reinfusion may prevent hyperkalemia. Significant fluid losses can also be anticipated when the artery is flushed during thrombectomy and fluid is sequestered in edematous revascularized tissue. Serum potassium levels can change quickly because cell death and release of intracellular potassium into the circulation can be anticipated. Myoglobin may also be released into the circulation, and the development of a compartment syndrome is a possibility. Skill and intensive care as meticulous as that given patients with visceral ischemia may also benefit patients with peripheral vascular insufficiency. Free radical scavengers such as mannitol and N-acetyl cysteine may be given to mitigate reperfusion responses; sodium bicarbonate may or may not be given at the time of reperfusion.

Anticoagulants are commonly administered to patients suspected of having peripheral vascular occlusion. If a patient has received anticoagulants, the appropriateness of using a major conduction block (subarachnoid or epidural block with or without catheter placement) is controversial. We believe regional anesthesia should be avoided when patients have received thrombolytic therapy.[12]

CONCLUSION

Patients undergoing vascular reconstruction are generally persons who are elderly. Vascular disease is a generalized process; thus, patients having surgery for a specific vascular disorder are likely to have atherosclerotic disease elsewhere in the vascular system. Most of the patients have CAD. The skills of the anesthesiologist can therefore greatly influence outcome in vascular surgery. The considerations for preoperative patient evaluation are the same as for patients with cardiac disease undergoing other noncardiac procedures. Many have a history of smoking and COPD; renal insufficiency, and lipid abnormalities are frequently present. The major morbidity in each operation relates to myocardial well-being; therefore, the heart should be the major focus of the anesthesiologist's attention.

Attempts to segregate patients who have significant CAD by use of preoperative testing are controversial. The benefits of coronary revascularization are likely to persist long after vascular surgery in patients with triple-vessel CAD.

In cerebrovascular surgery, the goals in anesthesia management (i.e., ensuring adequate myocardial and brain perfusion and a rapidly arousable patient) may be facilitated with the use of neurophysiologic monitoring as a guide to afterload reduction. In aortic reconstruction, ensuring intact myocardial function is probably the best way of making certain that spinal cord, visceral, and renal perfusion will be adequate.

In the case of peripheral occlusive disease, the absence of hemodynamic changes should not lull the anesthesiologist into loss of vigilance with regard to myocardial well-being. In addition, vigilance in ensuring routine prehydration and use of a warming device are probably more important to outcome than is occasional brilliance. We prefer the diligent, compulsive practitioner to the occasionally brilliant one. Nowhere is such diligence needed more than in the postoperative

period, when most morbidity related to the heart occurs. Perhaps it is most important to remember that the best patient results are achieved when intraoperative vigilance is extended to the preoperative and postoperative periods as well. Technologic changes in endovascular surgery will reduce the stress of revascularization, but the patient population presenting for repair may evidence even greater comorbidity as selection criteria for surgical candidates become more permissive.

Chapter 33

Anesthesia and the Eye

Kathryn E. McGoldrick

Steven I. Gayer

KEY POINTS

1	Although apprehension is predictable in potentially blind patients awaiting surgery, this problem is often exacerbated in the elderly whose coping mechanisms may be diminished by depression or dementia.
2	Inhalation anesthetics cause dose-related reductions in IOP. The exact mechanisms are unknown, but postulated etiologies include depression of a control center in the diencephalon, reduction of aqueous humor production, enhancement of aqueous outflow, or relaxation of the extraocular muscles.
3	The oculocardiac reflex is triggered by pressure on the globe and by traction on the extraocular muscles, as well as on the conjunctiva or on the orbital structures. This reflex, the afferent limb of which is trigeminal and the efferent limb vagal, may also be elicited by performance of a retrobulbar block, by ocular trauma, and by direct pressure on tissue remaining in the orbital apex after enucleation.
4	Ophthalmic drugs may significantly alter the patient's reaction to anesthesia. Similarily, anesthetic drugs and maneuvers may dramatically influence intraocular dynamics.
5	Several anesthetic options are available for many types of ocular procedures, including general anesthesia, retrobulbar block, peribulbar anesthesia, sub-Tenon's (episcleral) block, topical analgesia, and intracameral injection.
6	The complications of ophthalmic anesthesia can be both vision and life threatening.
7	With intraocular procedures, profound akinesia and meticulous control of intraocular pressure (IOP) are requisite. However, with extraocular surgery, the significance of IOP fades, whereas concern about elicitation of the oculocardiac reflex assumes prominence.

Anesthesia for ophthalmic surgery presents many unique challenges (Table 33-1). In addition to possessing technical expertise, the anesthesiologist must have detailed knowledge of ocular anatomy, physiology, and pharmacology. It is essential to appreciate that ophthalmic drugs may significantly alter the reaction to anesthesia and that, concomitantly, anesthetic drugs and maneuvers may dramatically influence intraocular dynamics. Patients undergoing ophthalmic surgery may represent extremes of age and coexisting medical diseases (e.g., diabetes mellitus, coronary artery disease, essential hypertension, chronic lung disease), but they are likely to be in the elderly age group. Indeed, the elderly constitute the most rapidly growing subset of the U.S. population, with the 2002 Census reporting 4.2 million Americans age 85 years or older, an increase of 30% since 1990. Moreover, the elderly are a uniquely vulnerable group with reduced functional reserve and a myriad of age-related diseases. The economic implication of these age-related diseases is staggering. For example, age-related

macular degeneration is the leading cause of blindness in individuals older than 65 years of age in the United States, affecting more than 1.75 million people. Because of the rapid aging of our population, this number will increase to almost 3 million by 2020.[1] More recent prevalence studies suggest that the number of persons with Alzheimer's disease in the United States is 4.5 million. Given that the percentage of individuals with Alzheimer's disease increases by a factor of two with approximately every 5 years of age, 1% of 60 year olds and about 30% of 85 year olds have the disease. Without advances in therapy, the number of symptomatic cases in the United States is predicted to increase to 13.2 million by 2050.[2] Current annual expenditures on care for patients with Alzheimer's disease exceed $84 billion,[3] a statistic that underscores the urgency of seeking more effective therapeutic and prophylactic interventions. Moreover, although apprehension is predictable in blind or potentially blind patients awaiting surgery, this problem is often exacerbated in the elderly whose coping mechanisms may be diminished by depression or dementia.

TABLE 33-1 Requirements of Ophthalmic Surgery

Safety
Akinesia
Profound analgesia
Minimal bleeding
Avoidance or obtundation of oculocardiac reflex
Control of intraocular pressure
Awareness of drug interactions
Smooth emergence

It is mandatory to be knowledgeable about the numerous surgical procedures unique to the specialty of ophthalmology. Whereas the list of ocular surgical interventions is lengthy, these procedures may, in general, be classified as extraocular or intraocular. This distinction is critical because anesthetic considerations are different for these two major surgical categories. For example, with intraocular procedures, profound akinesia (relaxation of recti muscles) and meticulous control of intraocular pressure (IOP) are requisite. However, with extraocular surgery, the significance of IOP fades, whereas concern about elicitation of the oculocardiac reflex assumes prominence.

OCULAR ANATOMY

The anesthesiologist should be knowledgeable about ocular anatomy to enhance his or her

understanding of surgical procedures and to aid the surgeon in the performance of regional blocks when needed[4] (Fig. 33-1). Salient subdivisions of ocular anatomy include the orbit, the eye itself, the extraocular muscles, the eyelids, and the lacrimal system.

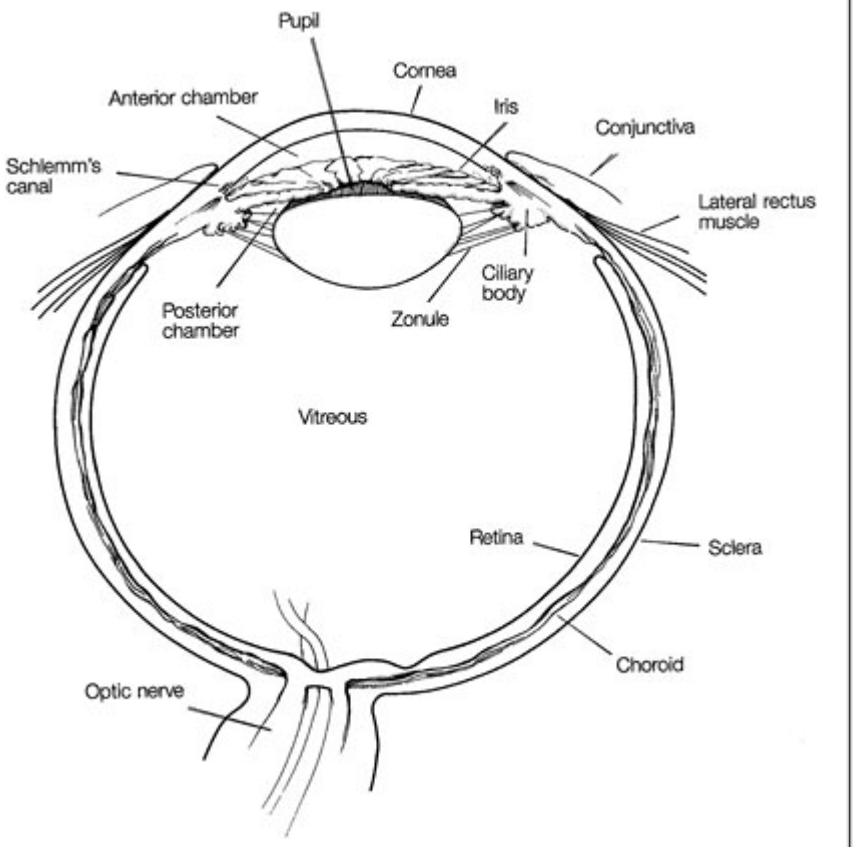

FIGURE 33-1. Diagram of ocular anatomy.

The orbit is a bony box, or pyramidal cavity, housing the eyeball and its associated structures in the skull. The walls of the orbit are composed of the following bones: frontal, zygomatic, greater wing of the sphenoid, maxilla, palatine, lacrimal, and ethmoid. A familiarity with the surface relationships of the orbital rim is mandatory for the skilled performance of regional blocks.

The optic foramen, located at the orbital apex, transmits the optic nerve and the ophthalmic artery, as well as the sympathetic nerves from the carotid plexus. The superior orbital fissure transmits the superior and inferior branches of the oculomotor nerve; the lacrimal, frontal, and nasociliary branches of the trigeminal nerve; and the trochlear and abducens nerves and the superior and inferior ophthalmic veins. The inferior orbital or sphenomaxillary fissure contains the infraorbital and zygomatic nerves and communication between the inferior ophthalmic vein and the pterygoid plexus. The infraorbital foramen, located about 4 mm below the orbital rim in the maxilla, transmits the infraorbital nerve, artery, and vein. The lacrimal fossa contains the lacrimal gland in the superior temporal orbit. The supraorbital notch, located at the junction of the medial one-third and temporal two-thirds of the superior orbital rim, transmits the supraorbital nerve, artery, and vein. The supraorbital notch, the infraorbital foramen, and the lacrimal fossa are clinically palpable and function as major landmarks for administration of regional anesthesia.

The eye itself is actually one large sphere with part of a smaller sphere incorporated in the anterior surface, constituting a structure with two different radii of curvature. The coat of the eye is composed of three layers: sclera, uveal tract, and retina. The fibrous outer layer, or sclera, is protective, providing sufficient rigidity to maintain the shape of the eye. The anterior portion of the sclera, the cornea, is transparent, permitting light to pass into the internal ocular structures. The double-spherical shape of the eye exists because the corneal arc of curvature is steeper than the scleral arc of curvature. The focusing of rays of light to form a retinal image commences at

the cornea.

The uveal tract, or middle layer of the globe, is vascular and in direct apposition to the sclera. A potential space, known as the suprachoroidal space, separates the sclera from the uveal tract. This potential space, however, may become filled with blood during an expulsive or suprachoroidal hemorrhage, often associated with surgical disaster. The iris, ciliary body, and choroid compose the uveal tract. The iris includes the pupil, which, by contractions of three sets of muscles, controls the amount of light entering the eye. The iris dilator is sympathetically innervated; the iris sphincter and the ciliary muscle have parasympathetic innervation. Posterior to the iris lays the ciliary body, which produces aqueous humor (see Formation and Drainage of Aqueous Humor section). The ciliary muscles, situated in the ciliary body, adjust the shape of the lens to accommodate focusing at various distances. Large vessels and a

network of small vessels and capillaries known as the choriocapillaris constitute the choroid, which supplies nutrition to the outer part of the retina.

The retina is a neurosensory membrane composed of 10 layers that convert light impulses into neural impulses. These neural impulses are then carried through the optic nerve to the brain. Located in the center of the globe is the vitreous cavity, filled with a gelatinous substance known as vitreous humor. This material is adherent to the most anterior 3 mm of the retina, as well as to large blood vessels and the optic nerve. The vitreous humor may pull on the retina, causing retinal tears and retinal detachment.

The crystalline lens, located posterior to the pupil, refracts rays of light passing through the cornea and pupil to focus images on the retina. The ciliary muscle, whose contractile state causes tautness or relaxation of the lens zonules, regulates the thickness of the lens.

In addition, six extraocular muscles move the eye within the orbit to various positions. The bilobed lacrimal gland provides most of the tear film, which serves to maintain a moist anterior surface on the globe. The lacrimal drainage system—composed of the puncta, canaliculi, lacrimal sac, and lacrimal duct—drains into the nose below the inferior turbinate. Blockage of this system occurs frequently, necessitating procedures ranging from lacrimal duct probing to dacryocystorhinostomy, which involves anastomosis of the lacrimal sac to the nasal mucosa.

Covering the surface of the globe and lining the eyelids is a mucous membrane called the *conjunctiva.* Because drugs are absorbed across the membrane, it is a popular site for administration of ophthalmic drugs.

The eyelids consist of four layers: (1) the conjunctiva, (2) the cartilaginous tarsal plate, (3) a muscle layer composed mainly of the orbicularis and the levator palpebrae, and (4) the skin. The eyelids protect the eye from foreign objects; through blinking, the tear film produced by the lacrimal gland is spread across the surface of the eye, keeping the cornea moist.

Blood supply to the eye and orbit is by means of branches of both the internal and external carotid arteries. Venous drainage of the orbit is accomplished through the multiple anastomoses of the superior and inferior ophthalmic veins. Venous drainage of the eye is achieved mainly through the central retinal vein. All these veins empty directly into the cavernous sinus.

The sensory and motor innervations of the eye and its adnexa are very complex, with multiple cranial nerves supplying branches to various ocular structures. A branch of the oculomotor nerve supplies a motor root to the ciliary ganglion, which in turn supplies the sphincter of the pupil and the ciliary muscle. The trochlear nerve supplies the superior oblique muscle. The abducens nerve supplies the lateral rectus muscle. The trigeminal nerve constitutes the most complex ocular and adnexal innervation. In addition, the zygomatic branch of the facial nerve eventually divides into an upper branch, supplying the frontalis and the upper lid orbicularis, whereas the lower branch supplies the orbicularis of the lower lid.

OCULAR PHYSIOLOGY

Despite its relatively diminutive size, the eye is a complex organ, concerned with many intricate

physiologic processes. The formation and drainage of aqueous humor and their influence on IOP in both normal and glaucomatous eyes are among the most important functions, especially from the anesthesiologist's perspective. An appreciation of the effects of various anesthetic manipulations on IOP requires an understanding of the fundamental principles of ocular physiology.

Formation and Drainage of Aqueous Humor

Two-thirds of the aqueous humor is formed in the posterior chamber by the ciliary body in an active secretory process involving both the carbonic anhydrase and the cytochrome oxidase systems (Fig. 33-2). The remaining third is formed by passive filtration of aqueous humor from the vessels on the anterior surface of the iris.

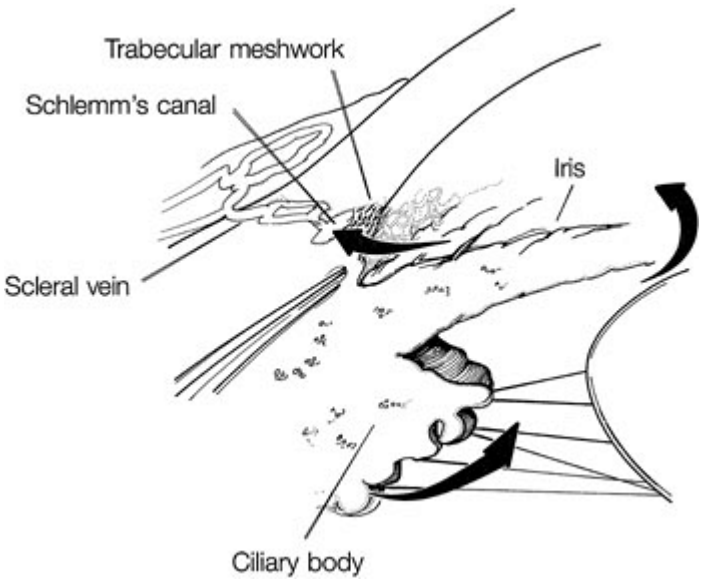

FIGURE 33-2. Ocular anatomy concerned with control of intraocular pressure.

At the ciliary epithelium, sodium is actively transported into the aqueous humor in the posterior chamber. Bicarbonate and chloride ions passively follow the sodium ions. This active mechanism results in the osmotic pressure of the aqueous being many times greater than that of plasma. It is this disparity in osmotic pressure that leads to an average rate of aqueous humor production of 2 µL/min.

Aqueous humor flows from the posterior chamber through the pupillary aperture and into the anterior chamber, where it mixes with the aqueous formed by the iris. During its journey into the anterior chamber, the aqueous humor bathes the avascular lens and, once in the anterior chamber, it also bathes the corneal endothelium. Then, the aqueous humor flows into the peripheral segment of the anterior chamber and exits the eye through the trabecular network, Schlemm's canal, and episcleral venous system. A network of connecting venous channels eventually leads to the superior vena cava and the right atrium. Thus, obstruction of venous return at any point from the eye to the right side of the heart impedes aqueous drainage, elevating IOP accordingly.

Maintenance of Intraocular Pressure

IOP normally varies between 10 and 21.7 mm Hg and is considered abnormal above 22 mm Hg. This level varies 1 to 2 mm Hg with each cardiac contraction. Also, a diurnal variation of 2 to 5 mm Hg is observed, with a higher value noted on awakening. This higher awakening pressure has been ascribed to vascular congestion, pressure on the globe from closed lids, and mydriasis—all of which occur during sleep. If IOP is too high, it may produce opacities by interfering with normal

corneal metabolism.

During anesthesia, a rise in IOP can produce permanent visual loss. If the IOP is already elevated, a further increase can trigger acute glaucoma. If penetration of the globe occurs when the IOP is excessively high, rupture of a blood vessel with

subsequent hemorrhage may transpire. IOP becomes atmospheric once the eye cavity has been entered, and any sudden rise in pressure may lead to prolapse of the iris and lens, and loss of vitreous. Thus, proper control of IOP is critical.

Three main factors influence IOP: (1) external pressure on the eye by the contraction of the orbicularis oculi muscle and the tone of the extraocular muscles, venous congestion of orbital veins (as may occur with vomiting and coughing), and conditions such as orbital tumor; (2) scleral rigidity; and (3) changes in intraocular contents that are semisolid (lens, vitreous, or intraocular tumor) or fluid (blood and aqueous humor). Although these factors are significant in affecting IOP, the major control of intraocular tension is exerted by the fluid content, especially the aqueous humor.

Sclerosis of the sclera, not uncommonly seen in the elderly, may be associated with decreased scleral compliance and increased IOP. Other degenerative changes of the eye linked with aging can also influence IOP, the most significant being a hardening and enlargement of the crystalline lens. When these degenerative changes occur, they may lead to anterior displacement of the lens–iris diaphragm. A resultant shallowness of the anterior chamber angle may then occur, reducing access of the trabecular meshwork to aqueous. This process is usually gradual, but, if rapid lens engorgement occurs, angle-closure glaucoma may transpire.

Changes in the nature of the vitreous that affect the amount of unbound water also influence IOP. Myopia, trauma, and aging produce liquefaction of vitreous gel and a subsequent increase in unbound water, which may lower IOP by facilitating fluid removal. However, under different circumstances, the opposite may occur, that is, the hydration of more normal vitreous may be associated with elevation of IOP. Hence, it is often prudent to produce a slightly dehydrated state in the surgical patient with glaucoma.

Intraocular blood volume, determined primarily by vessel dilation or contraction in the spongy layers of the choroid, contributes significantly to IOP. Although changes in arterial or venous pressure may secondarily affect IOP, excursions in arterial pressure have much less importance than do venous fluctuations. In chronic arterial hypertension, ocular pressure returns to normal levels after a period of adaptation brought about by compression of vessels in the choroid as a result of increased IOP. Thus, a feedback mechanism reduces the total volume of blood, keeping IOP relatively constant in patients with systemic hypertension.

However, if venous return from the eye is disturbed at any point from Schlemm's canal to the right atrium, IOP increases substantially. This is caused both by increased intraocular blood volume and distention of orbital vessels, as well as by interference with aqueous drainage. Straining, vomiting, or coughing greatly increase venous pressure and raise IOP as much as 40 mm Hg or greater. The deleterious implications of these activities cannot be overemphasized. Laryngoscopy and tracheal intubation may also elevate IOP, even without any visible reaction to intubation, but especially when the patient coughs. Topical anesthetization of the larynx may attenuate the hypertensive response to laryngoscopy but does not reliably prevent associated increases in IOP.[5] Ordinarily the pressure elevation from such increases in blood volume or venous pressure dissipates rapidly. However, if the coughing or straining occurs during ocular surgery when the eye is open, as in penetrating keratoplasty, the result may be a disastrous expulsive hemorrhage, at worst, or a disconcerting loss of vitreous, at best.

Despite the significant role of venous pressure, scleral rigidity, and vitreous composition, maintenance of IOP is determined primarily by the rate of aqueous formation and the rate of aqueous outflow. The most important influence on formation of aqueous humor is the difference in osmotic pressure between aqueous and plasma. This fact is illustrated by the equation:

$$\mathrm{IOP} = K[(\mathrm{OPaq} - \mathrm{OPpl}) + \mathrm{CP}] \qquad (33\text{-}1)$$

where *K* is coefficient of outflow, OPaq is osmotic pressure of aqueous humor, OPpl is osmotic pressure of plasma, and CP is capillary pressure. Hypertonic solutions such as mannitol are used to lower IOP because a small change in the solute concentration of plasma can markedly influence the formation of aqueous humor and hence IOP.

Fluctuations in aqueous outflow may also produce a dramatic alteration in IOP. The most significant factor controlling aqueous humor outflow is the diameter of Fontana's spaces, as illustrated by the equation:

$$A = \frac{r^4(\text{Piop} - \text{Pv})}{8\eta L} \qquad (33\text{-}2)$$

where *A* is volume of aqueous outflow per unit of time, *r* is radius of Fontana's spaces, Piop is IOP, Pv is venous pressure, η is viscosity, and *L* is length of Fontana's spaces. When the pupil dilates, Fontana's spaces narrow, resistance to outflow is increased, and IOP rises. Because mydriasis is undesirable in both closed-angle and open-angle glaucoma, miotics such as pilocarpine are applied conjunctivally in patients with glaucoma.

Glaucoma

Glaucoma is a condition characterized by elevated IOP, resulting in impairment of capillary blood flow to the optic nerve with eventual loss of optic nerve tissue and function. Two different anatomic types of glaucoma exist: open-angle or chronic simple glaucoma, and closed-angle or acute glaucoma. (Other variations of these processes occur but are not especially germane to anesthetic management.)

With open-angle glaucoma, the elevated IOP exists with an anatomically open anterior chamber angle. It is believed that sclerosis of trabecular tissue results in impaired aqueous filtration and drainage. Treatment consists of medication to produce miosis and trabecular stretching. Commonly used eyedrops are epinephrine, timolol, dipivefrin, and betaxolol. Closed-angle glaucoma is characterized by the peripheral iris moving into direct contact with the posterior corneal surface, mechanically obstructing aqueous outflow. People who have a narrow angle between the iris and posterior cornea are predisposed to this condition. In these patients, mydriasis can produce such increased thickening of the peripheral iris that corneal touch occurs and the angle is closed. Another mechanism producing acute, closed-angle glaucoma is swelling of the crystalline lens. In this case, pupillary block occurs, with the edematous lens blocking the flow of aqueous from the posterior to the anterior chamber. This situation can also develop if the lens is traumatically dislocated anteriorly, thus physically blocking the anterior chamber.

It was previously believed by some clinicians that patients with glaucoma should not be given atropine. However, this claim is untenable. Atropine in the dose range used clinically has no effect on IOP in either open-angle or closed-angle glaucoma. When 0.4 mg of atropine is given parenterally to a 70-kg person, approximately 0.0001 mg is absorbed by the eye.[6] Garde et al.[7] reported, however, that scopolamine has a greater mydriatic effect than atropine and recommended not using scopolamine in patients with known or suspected closed-angle glaucoma.

Equation 33-2, describing the volume of aqueous outflow per unit of time, clearly demonstrates that outflow is exquisitely sensitive to fluctuations in venous pressure. Because a rise in

venous pressure produces an increased volume of ocular blood and decreased aqueous outflow, it is obvious that considerable elevation of IOP occurs with any maneuver that increases venous pressure. Hence, in addition to preoperative instillation of miotics, other anesthetic goals for the patient with glaucoma include perioperative avoidance of venous congestion and overhydration. Furthermore, hypotensive episodes are to be avoided because these patients are allegedly vulnerable to retinal vascular thrombosis.

Primary congenital glaucoma is classified according to age of onset, with the infantile type presenting any time after birth until 3 years of age. The juvenile type presents between the ages of 37 months and 30 years. Moreover, childhood glaucoma may also occur in conjunction with

various eye diseases or developmental anomalies such as aniridia, mesodermal dysgenesis syndrome, and retinopathy of prematurity.

Successful management of infantile glaucoma is crucially dependent on early diagnosis. Presenting symptoms include epiphora, photophobia, blepharospasm, and irritability. Ocular enlargement, termed *buphthalmos*, or "ox eye," and corneal haziness secondary to edema are common. Buphthalmos is rare, however, if glaucoma develops after 3 years of age because by then the eye is much less elastic.

Because infantile glaucoma is frequently associated with obstructed aqueous outflow, management of it often requires surgical creation, by goniotomy or trabeculotomy, of a route for aqueous humor to flow into Schlemm's canal. However, advanced disease may be unresponsive to even multiple goniotomies, and the more radical trabeculectomy or some other variety of filtering procedure may be necessary.

The juvenile form of glaucoma, in which the cornea and eye size are normal, is commonly associated with a family history of open-angle glaucoma and is treated similarly to primary open-angle glaucoma.

In cases of pediatric secondary glaucoma, goniotomy and filtering may be unsuccessful, whereas cyclocryotherapy may affect a reduction in IOP, pain, and corneal edema. The ciliary body is destroyed with a cryoprobe cooled to -70°C, thus dramatically decreasing aqueous formation.

It is essential to appreciate that the high IOP frequently encountered in infantile glaucoma can be reduced by more than 15 mm Hg when surgical anesthesia is achieved. One study, however, demonstrated minimal effect of halothane on IOP when the concentration ranged narrowly between 0.5% and 1.0%.[8] Some clinicians maintain that ketamine is a useful drug to use for examination under anesthesia when infantile glaucoma is part of the differential diagnosis because ketamine does not appear to reduce IOP, giving a spuriously low reading. Moreover, even normal infants sporadically have pressures in the mid-20s. Hence, diagnosis is not based exclusively on the numerical pressure recorded under anesthesia. Other factors such as corneal edema and increased corneal diameter, tears in Descemet's membrane, and cupping of the optic nerve are considered in making the diagnosis. If these aberrations are noted, surgical intervention may be mandatory, even in the setting of a reputedly normal IOP.

EFFECTS OF ANESTHESIA AND ADJUVANT DRUGS ON INTRAOCULAR PRESSURE

Central Nervous System Depressants

Inhalation anesthetics purportedly cause dose-related decreases in IOP. The exact mechanisms are unknown, but postulated etiologies include depression of a central nervous system (CNS) control center in the diencephalon, reduction of aqueous humor production, enhancement of aqueous outflow, or relaxation of the extraocular muscles.[6] Moreover, virtually all CNS depressants, including barbiturates, neuroleptics, opioids, tranquilizers,[6] and hypnotics, such as etomidate and propofol, lower IOP in both normal and glaucomatous eyes. Etomidate, despite its proclivity to produce pain on intravenous injection and skeletal muscle movement, is associated with a significant reduction in IOP.[9] However, etomidate-induced myoclonus may be hazardous in the setting of a ruptured globe.

Controversy, however, surrounds the issue of ketamine's effect on IOP. Administered intravenously or intramuscularly, ketamine initially was believed to increase IOP significantly, as measured by indentation tonometry.[10] Corssen and Hoy[11] also reported a slight but statistically significant increase in IOP that appeared unrelated to changes in blood pressure or depth of anesthesia. However, nystagmus made proper positioning of the tonometer difficult and may have resulted in less-than-accurate measurements.

Conflicting results arose from a study in which 2 mg/kg of ketamine given intravenously to adults failed to have a significant effect on IOP.[12] Furthermore, a pediatric study reported no increase in IOP after an intramuscular ketamine dose of 8 mg/kg. Indeed, values obtained were similar to

those reported with halothane and isoflurane.[13,14]

Some of the confusion may arise from differences in premedication practices and from the use of different instruments to measure IOP. More recent studies have used applanation tonometry rather than indentation tonometry. However, even if future studies should confirm that ketamine has minimal or no effect on IOP, ketamine's proclivity to cause nystagmus and blepharospasm makes it a less-than-optimal agent for many types of ophthalmic surgery.

Ventilation and Temperature

Hyperventilation decreases IOP, whereas asphyxia, administration of carbon dioxide, and hypoventilation have been shown to elevate IOP.[15]

Hypothermia lowers IOP. On initial consideration, hypothermia might be expected to raise IOP because of the associated increase in viscosity of aqueous humor. However, hypothermia is linked with decreased formation of aqueous humor and with vasoconstriction; hence, the net result is a reduction in IOP.

Adjuvant Drugs

Ganglionic Blockers, Hypertonic Solutions, and Acetazolamide

Ganglionic blockers such as tetraethylammonium and pentamethonium cause a dramatic decrease in IOP. Trimethaphan also significantly lowers IOP in normal subjects, despite mydriasis.

Intravenous administration of hypertonic solutions such as dextran, urea, mannitol, and sorbitol elevates plasma osmotic pressure, thereby decreasing aqueous humor formation and reducing IOP. As effective as urea is in reducing IOP, intravenous mannitol has the advantage of fewer side effects. Mannitol's onset, peak (30 to 45 minutes), and duration of action (5 to 6 hours) are similar to those of urea. Moreover, both drugs may produce acute intravascular volume overload. Sudden expansion of plasma volume secondary to efflux of intracellular water into the vascular compartment places a heavy workload on the kidneys and heart, often resulting in hypertension and dilution

of plasma sodium. Furthermore, mannitol-associated diuresis, if protracted, may trigger hypotension in volume-depleted patients.

Intravenous administration of acetazolamide inactivates carbonic anhydrase and interferes with the sodium pump. The resultant decrease in aqueous humor formation lowers IOP. However, the action of acetazolamide is not limited to the eye, and systemic effects include loss of sodium, potassium, and water secondary to the drug's renal tubular effects. Such electrolyte imbalances may then be linked to cardiac dysrhythmias during general anesthesia.

An advantage of acetazolamide is its relative ease of administration. Whereas large volumes of hypertonic solutions must be infused to reduce IOP, acetazolamide is easily given as a typical adult dose of 500 mg dissolved in 10 mL of sterile water. Acetazolamide may also be given orally, and topical carbonic anhydrase inhibitors are commercially available.

Neuromuscular Blocking Drugs

Neuromuscular blocking drugs have both direct and indirect actions on IOP. Hence, a paralyzing dose of *d*-tubocurarine directly lowers IOP by relaxing the extraocular muscles. The same is true of equipotent doses of the other nondepolarizing drugs, including pancuronium[16] (Fig. 33-3). However, if paralysis of the respiratory muscles is accompanied by alveolar hypoventilation, the latter secondary effect may supervene to increase IOP.

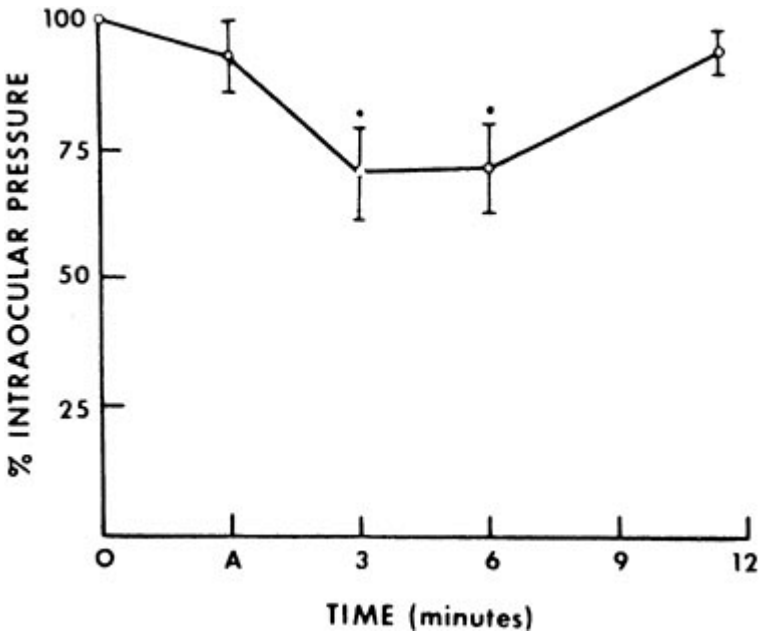

FIGURE 33-3. Mean intraocular pressure after administration of thiopental, 3 to 4 mg/kg, and pancuronium, 0.08 mg/kg at 0. A, loss of lid reflex; *P < .05. (Reprinted with permission from Litwiller RW, DeFazio CA, Rushia EF: Pancuronium and intraocular pressure. Anesthesiology 42:750, 1975.)

In contrast to nondepolarizing drugs, the depolarizing drug succinylcholine elevates IOP. Lincoff et al.[17] reported extrusion of vitreous after succinylcholine administration to a patient with a surgically open eye. An average peak IOP increase of about 8 mm Hg is produced within 1 to 4 minutes of an intravenous dose. Within 7 minutes, return to baseline usually transpires.[18] The ocular hypertensive effect of succinylcholine has been attributed to several mechanisms, including tonic contraction of extraocular muscles,[6] choroidal vascular dilation, and relaxation of orbital smooth muscle. One study speculates that the succinylcholine-induced increase in IOP is multifactorial but primarily the result of the cycloplegic action of succinylcholine, producing a deepening of the anterior chamber and increased outflow resistance.[19] Because they studied eyes with the extraocular muscles detached and still observed an elevation in IOP, these investigators proposed that changes in extraocular muscle tone do not contribute significantly to the increase in IOP observed after succinylcholine administration.

A variety of methods have been advocated to prevent succinylcholine-induced elevations in IOP. However, although some attenuation of the increase results, none of these techniques consistently and completely block the ocular hypertensive response. Prior administration of such drugs as acetazolamide, propranolol, and nondepolarizing neuromuscular blocking drugs has been suggested. The efficacy of pretreatment with nondepolarizing drugs is controversial.

In 1968, using indentation tonometry, Miller et al.[20] reported that pretreatment with small amounts of gallamine or *d*-tubocurarine prevented succinylcholine-associated increases in IOP. However, in 1978, using the more sensitive applanation tonometer, Meyers et al.[21] were unable to consistently circumvent the ocular hypertensive response after similar pretreatment therapy (Table 33-2). In addition, Verma[22] claimed that a "self-taming" dose of succinylcholine was protective, but in a controlled study using applanation tonometry, Meyers et al.[23] challenged this claim. Although intravenous pretreatment with lidocaine, 1 to 2 mg/kg, may blunt the hemodynamic response to laryngoscopy,[5,24] such therapy does not reliably prevent the ocular hypertensive response associated with succinylcholine and intubation.[25] However, Grover and associates[26] claimed that pretreatment with lidocaine, 1.5 mg/kg intravenously, 1 minute before induction with thiopental and succinylcholine offered protection from IOP increases

due to succinylcholine and may therefore be of value in rapid-sequence induction for open eye injuries.

TABLE 33-2 Effects of Succinylcholine on Intraocular Pressure: Double-Blind *d*-Tubocurarine or Gallamine Pretreatment

·Pretreatment[a]	·MEAN AGE (yr)	·INTRAOCULAR PRESSURE(mm Hg, MEAN ± SE) BASELINE	·3 MIN AFTER PRETREATMENT	·1 MIN AFTER SUCCINYLCHOLINE[b]
d-Tubocurarine	13.4	13.0 ± 1.0	12.3 ± 1.2	24.0 ± 1.3
Gallamine	8.7	10.9 ± 1.1	10.6 ± 1.0	23.4 ± 2.3

[a] *d*-Tubocurarine, 0.09 mg · kg^{-1}, or gallamine, 0.3 mg/kg.

Certainly, no one would disagree that succinylcholine—if unaccompanied by pretreatment with a nondepolarizing neuromuscular blocking drug—is contraindicated in patients with penetrating ocular wounds and should not be given for the first time after the eye has been opened. Nonetheless, it is no longer valid to recommend that succinylcholine be used only with extreme reluctance in ocular surgery. Clearly, any succinylcholine-induced increment in IOP is usually dissipated before surgery is started. Of concern, however, is Jampolsky's[27] warning that succinylcholine be avoided in patients undergoing repeat strabismus surgery because the forced duction test (FDT) does not return to baseline for approximately 30 minutes after administration of the drug. More recent and quantitatively sophisticated studies by France et al.[28] supported this caveat, although the latter investigators suggest waiting only 20 minutes after administration of succinylcholine before performing the FDT.

OCULOCARDIAC REFLEX

3 Bernard Aschner and Guiseppe Dagnini first described the oculocardiac reflex in 1908. This reflex is triggered by pressure on the globe and by traction on the extraocular muscles, as well as on the conjunctiva or the orbital structures. Moreover, the reflex may also be elicited by performance of a retrobulbar block,[29] by ocular trauma, and by direct pressure on tissue remaining in the orbital apex after enucleation. The afferent limb is trigeminal, and the efferent limb is vagal. Although the most common manifestation of the oculocardiac reflex is sinus bradycardia, a wide spectrum of cardiac dysrhythmias may occur, including junctional rhythm, ectopic atrial rhythm, atrioventricular blockade, ventricular bigeminy, multifocal premature ventricular contractions, wandering pacemaker, idioventricular rhythm, asystole, and ventricular tachycardia.[30] This reflex may appear during either local or general anesthesia; however, hypercarbia and hypoxemia are believed to augment the incidence and severity of the problem, as

may inappropriate anesthetic depth.

Reports on the alleged incidence of the oculocardiac reflex are remarkable in their striking variability. Berler's study[29] reported an incidence of 50%, but other sources quote rates ranging from 16 to 82%. Commonly, those articles disclosing a higher incidence included children in the study population, and children tend to have more vagal tone.

A variety of maneuvers to abolish or obtund the oculocardiac reflex have been promulgated. None of these methods has been consistently effective, safe, and reliable. Inclusion of intramuscular anticholinergic drugs such as atropine or glycopyrrolate in the usual premedication regimen for oculocardiac reflex prophylaxis is ineffective.[31]

Atropine given intravenously within 30 minutes of surgery is believed to reduce incidence of the reflex. However, reports differ concerning dosage and timing. Moreover, some anesthesiologists claim that prior intravenous administration of atropine may yield more serious and refractory cardiac dysrhythmias than the reflex itself. Clearly, atropine may be considered a potential myocardial irritant. A variety of cardiac dysrhythmias[32] and several conduction abnormalities,[33] including ventricular fibrillation, ventricular tachycardia, and left bundle-branch block, have been attributed to intravenous atropine.

Although administration of retrobulbar anesthesia may provide some cardiac antidysrhythmic value by blocking the afferent limb of the reflex arc, such a regional technique is not devoid of potential complications, which include, but are not limited to, optic nerve damage, retrobulbar hemorrhage, and stimulation of the oculocardiac reflex arc by the retrobulbar block itself.

It is generally believed that, in adults, the aforementioned prophylactic measures, fraught with inherent hazards, are usually not indicated. If a cardiac dysrhythmia appears, initially the surgeon should be asked to cease operative manipulation. Next, the patient's anesthetic depth and ventilatory status are evaluated. Commonly, heart rate and rhythm return to baseline within 20 seconds after institution of these measures. Moreover, Moonie et al.[34] noted that, with repeated manipulation, bradycardia is less likely to recur, probably secondary to fatigue of the reflex arc at the level of the cardioinhibitory center. However, if the initial cardiac dysrhythmia is especially serious or if the reflex tenaciously recurs, atropine should be administered intravenously, but only after the surgeon stops ocular manipulation.

During pediatric strabismus surgery, however, some anesthesiologists administer intravenous atropine, 0.02 mg/kg, before commencing surgery.[35] Alternatively, glycopyrrolate, 0.01 mg/kg administered intravenously, may be associated with less tachycardia than atropine in this setting.

ANESTHETIC RAMIFICATIONS OF OPHTHALMIC DRUGS

4 There is considerable potential for drug interactions during administration of anesthesia for ocular surgery. Topical ophthalmic drugs may produce undesirable systemic effects or may have deleterious anesthetic implications. Systemic absorption of topical ophthalmic drugs may occur from either the conjunctiva or the nasal mucosa after drainage through the nasolacrimal duct. In addition, from spillover, some percutaneous absorption through the immature epidermis of the premature infant may transpire.[36] Occluding the nasolacrimal duct by pressing on the inner canthus of the eye for a few minutes after each instillation greatly decreases systemic absorption. Some of the potentially worrisome topical ocular drugs include acetylcholine, anticholinesterases, cocaine, cyclopentolate, epinephrine, phenylephrine, and timolol. In addition, intraocular sulfur hexafluoride and other intraocular gases have important anesthetic ramifications. Furthermore, certain ophthalmic drugs given systemically may produce untoward sequelae germane to anesthetic management. Drugs in this category include glycerol, mannitol, and acetazolamide.

Acetylcholine

Acetylcholine is sometimes used intraocularly after lens extraction to produce miosis. The local use of this drug may occasionally result in such systemic effects as bradycardia, increased salivation, and bronchial secretions, as well as bronchospasm. The side effects, including hypotension and bradycardia, that may develop in patients given acetylcholine after cataract

extraction may be rapidly reversed with intravenous atropine. Furthermore, vagotonic anesthetic agents such as halothane can accentuate the effects of acetylcholine.

Anticholinesterase Agents

Echothiophate is a long-acting anticholinesterase miotic that lowers IOP by decreasing resistance to the outflow of aqueous humor. Useful in the treatment of glaucoma, echothiophate is absorbed into the systemic circulation after instillation in the conjunctival sac. Any of the long-acting anticholinesterases may prolong the action of succinylcholine because, after 1 month or more of therapy, plasma pseudocholinesterase activity may be less than 5% of normal. It is said, moreover,

that normal enzyme activity does not return until 4 to 6 weeks after discontinuation of the drug.[37] Hence, the anesthesiologist should anticipate prolonged apnea if these patients are given a usual dose of succinylcholine. In addition, a delay in metabolism of ester local anesthetics should be expected.

Cocaine

Cocaine, introduced to ophthalmology in 1884 by Koller, has limited topical ocular use because it can cause corneal pits and erosion. However, as the only local anesthetic that inherently produces vasoconstriction and shrinkage of mucous membranes, cocaine is commonly used in nasal packs during dacryocystorhinostomy. The drug is so well absorbed from mucosal surfaces that plasma concentrations comparable to those after direct intravenous injection are achieved. Because cocaine interferes with catecholamine uptake, it has a sympathetic nervous system potentiating effect.

Historically, epinephrine had often been mixed with cocaine in hopes of augmenting the degree of vasoconstriction produced. This practice is both superfluous and deleterious because cocaine is a potent vasoconstrictor in its own right, and the combination of epinephrine with cocaine may trigger dangerous cardiac dysrhythmias. It has been shown that cocaine used alone, without topical epinephrine, to shrink the nasal mucosa in conjunction with halothane or enflurane does not sensitize the heart to endogenous epinephrine during halothane or enflurane anesthesia. However, animal studies have shown that after pretreatment with exogenous epinephrine, cocaine facilitates the development of epinephrine-induced cardiac dysrhythmias during halothane anesthesia.[38]

The usual maximal dose of cocaine used in clinical practice is 200 mg for a 70-kg adult, or 3 mg/kg. However, 1.5 mg/kg is preferable because this lower dose has been shown not to exert any clinically significant sympathomimetic effect in combination with halothane.[39] Although 1 g is considered to be the usual lethal dose for an adult, considerable variation occurs. Furthermore, systemic reactions may appear with as little as 20 mg.

Meyers[40] described two cases of cocaine toxicity during dacryocystorhinostomy, underscoring that cocaine is contraindicated in hypertensive patients or in patients receiving drugs such as tricyclic antidepressants or monoamine oxidase inhibitors. In addition, sympathomimetics such as epinephrine or phenylephrine should not be given with cocaine.

Obviously, before administering cocaine or another potent vasoconstrictor for dacryocystorhinostomy, the physician should carefully search out possible contraindications. To avoid toxic levels, doses of dilute solutions should be meticulously calculated and carefully administered. If serious cardiovascular effects occur, labetalol should be used to counteract them.[41] In the past, propranolol was widely used to control cocaine-induced hypertension,[42] but a lethal hypertensive exacerbation has been ascribed to unopposed α-adrenergic stimulation.[43] Labetalol offers the advantage of combined α-blockade and β-blockade.

Cyclopentolate

Despite the popularity of cyclopentolate as a mydriatic, it is not without side effects, which

include CNS toxicity. Manifestations include dysarthria, disorientation, and frank psychotic reactions. Purportedly, CNS dysfunction is more likely to follow use of the 2% solution as opposed to the 1% solution. Furthermore, cases of convulsions in children after ocular instillation of cyclopentolate have been reported. Hence, for pediatric use, 0.5 to 1.0% solutions are recommended. At higher concentrations, cyclopentolate also causes cycloplegia.

Epinephrine

Although topical epinephrine has proved useful in some patients with open-angle glaucoma, the 2% solution has been associated with such systemic effects as nervousness, hypertension, angina pectoris, tachycardia, and other dysrhythmias.[44]

Some anesthesiologists have maintained that it is unwise to use topical or intraocular epinephrine in patients being anesthetized with a halogenated hydrocarbon. However, the iris, with its rich supply of adrenergic receptors, is able to capture with extreme rapidity the epinephrine given into the eye. Apparently, there is not much systemic absorption from the globe.

Phenylephrine

Pupillary dilation and capillary decongestion are reliably produced by topical phenylephrine. Although systemic effects secondary to topical application of prudent doses are rare,[45] severe hypertension, headache, tachycardia, and tremulousness have been reported.

In patients with coronary artery disease, severe myocardial ischemia, cardiac dysrhythmias, and even myocardial infarction may develop after topical 10% eyedrops. Those with cerebral aneurysms may be susceptible to cerebral hemorrhage after phenylephrine in this concentration. In general, a safe systemic level follows absorption from either the conjunctiva or the nasal mucosa after drainage by the tear ducts. However, phenylephrine should not be given in the eye after surgery has begun and venous channels are patent.

Children are especially vulnerable to overdose and may respond in a dramatic and adverse fashion to phenylephrine drops. Hence, the use of only 2.5%, rather than 10%, phenylephrine is recommended in infants and the elderly, and the frequency of application should be strictly limited in these patient populations.

Timolol and Betaxolol

Timolol, a nonselective β-adrenergic blocking drug, historically has been a popular antiglaucoma drug. Because significant conjunctival absorption may occur, timolol should be administered with caution to patients with known obstructive airway disease, congestive heart failure, or greater than first-degree heart block. Life-threatening asthmatic crises have been reported after the administration of timolol drops to some patients with chronic, stable asthma.[46] The development of severe sinus bradycardia in a patient with cardiac conduction defects (left anterior hemiblock, first-degree atrioventricular block, and incomplete right bundle branch block) has been reported after timolol.[47] Moreover, timolol has been implicated in the exacerbation of myasthenia gravis[48] and in the production of postoperative apnea in neonates and young infants.[49]

In contrast to timolol, a newer antiglaucoma drug, betaxolol, a β_1-blocker, is said to be more oculospecific and have minimal systemic effects. However, patients receiving an oral beta-blocker and betaxolol should be observed for potential additive effect on known systemic effects of β-blockade. Caution should be exercised in patients receiving catecholamine-depleting drugs. Although betaxolol has produced only minimal effects in patients with obstructive airways disease, caution should be exercised in the treatment of patients with excessive restriction of pulmonary function. Moreover, betaxolol is contraindicated in patients with sinus bradycardia, congestive

heart failure, greater than first-degree heart block, cardiogenic shock, and overt myocardial failure.

Intraocular Sulfur Hexafluoride

For a patient with a retinal detachment, intraocular sulfur hexafluoride or other gases such as certain perfluorocarbons may be injected into the vitreous to facilitate reattachment mechanically. These recommendations do not apply to open-eye procedures, during which volume and pressure changes are readily compensated for by fluid and gas leak.

Stinson and Donlon[50] suggested terminating nitrous oxide 15 minutes before gas injection to prevent significant changes in the size of the intravitreous gas bubble. The patient is then given virtually 100% oxygen, or a combination of oxygen and air (admixed with a small percentage of volatile agent), for the balance of the operation without adversely affecting intravitreous gas dynamics. Furthermore, if a patient requires reoperation and general anesthesia after intravitreous gas injection, nitrous oxide should be avoided for 5 days subsequent to air injection and for 10 days after sulfur hexafluoride injection[51] (Table 33-3).

TABLE 33-3 Differential Solubilities of Gases

	·BLOOD: GAS PARTITION COEFFICIENTS
Sulfur hexafluoride	0.004
Nitrogen	0.015
Nitrous oxide	0.468

Perfluoropropane and octafluorocyclobutane may also be used in vitreoretinal surgery to support the retina. Like sulfur hexafluoride, these gases are relatively insoluble and require discontinuance of nitrous oxide at least 15 minutes before injection. If the patient requires reoperation, it must be remembered that perfluoropropane lingers in the eye for longer than 30 days.[52] A Medic-Alert bracelet might be helpful in these circumstances.

Systemic Ophthalmic Drugs

In addition to topical and intraocular therapies, various ophthalmic drugs given systemically may result in complications of concern to the anesthesiologist. These systemic drugs include glycerol, mannitol, and acetazolamide. For example, oral glycerol may be associated with nausea, vomiting, and risk of aspiration. Hyperglycemia or glycosuria, disorientation, and seizure activity may also occur after oral glycerol.

The recommended intravenous dose of mannitol is 1.5-2 g/kg given over a 30- to 60-minute interval. However, serious systemic problems may result from rapid infusion of large doses of mannitol. These complications include renal failure, congestive heart failure, pulmonary congestion, electrolyte imbalance, hypotension or hypertension, myocardial ischemia, and, rarely, allergic reactions. Clearly, the patient's renal and cardiovascular status must be thoroughly evaluated before mannitol therapy.

Acetazolamide, a carbonic anhydrase inhibitor with renal tubular effects, should be considered contraindicated in patients with marked hepatic or renal dysfunction or in those with low sodium levels or abnormal potassium values. As is well known, severe electrolyte imbalances can trigger serious cardiac dysrhythmias during general anesthesia. Furthermore, people with chronic lung

disease may be vulnerable to the development of severe acidosis with long-term acetazolamide therapy. Topically active carbonic anhydrase inhibitors have been developed, are now commercially available, and appear to be relatively free of clinically important systemic effects.

PREOPERATIVE EVALUATION

Establishing Rapport and Assessing Medical Condition

Preoperative preparation and evaluation of the patient begin with the establishment of rapport and communication among the anesthesiologist, the surgeon, and the patient. Most patients realize that surgery and anesthesia entail inherent risks, and they appreciate a candid explanation of potential complications, balanced with information concerning probability or frequency of permanent adverse sequelae. Such an approach also fulfills the medicolegal responsibilities of the physician to obtain informed consent.

A thorough history of the patient and physical examination are the foundation of safe patient care. A complete list of medications that the patient is currently taking, both systemic and topical, must be obtained so potential drug interactions can be anticipated and essential medication will be administered during the hospital stay. Naturally, a history of any allergies to medicines, foods, or tape should be documented. Clearly, knowledge of any personal or family history of adverse reactions to anesthesia is mandatory. The requisite laboratory data vary, depending on the medical history and physical status of the patient, as well as the nature of the surgical procedure. Indeed, the American Society of Anesthesiologists (ASA) task force on preoperative evaluation concluded that routine preoperative tests are commonly not useful in assessing and managing patients' perioperative experience. In a more recent multicenter study of cataract patients, for example, Schein[53] demonstrated that "routine" testing does not improve patient safety or outcome. Some physicians and laypersons misinterpreted the results and conclusions of this investigation, believing that patients having cataract surgery need no preoperative evaluation. It is vital to note that all patients in this trial received regular medical care and were evaluated by a physician preoperatively. Patients whose medical status indicated a need for preoperative lab tests were excluded from the study. Clearly, testing should be based on the results of the history and physical examination. Because "routine" testing for the more than 1.5 million cataract operations in the United States is estimated to cost $150 million annually, the favorable economic impact of this "targeted" approach is obvious.

Many elderly adult candidates for ophthalmic surgery are on antiplatelet or anticoagulant therapy because of a history of coronary or vascular pathology. Such patients are at higher risk for perioperative hemorrhagic events, including retrobulbar hemorrhage, circumorbital hematoma, intravitreous bleeding, and hyphema. Traditionally, antiplatelet and anticoagulant medications were withheld for an appropriate length of time before eye surgery. However, this strategy may increase the risk of such adverse events as myocardial ischemia or infarction, cerebrovascular accident, and deep venous thrombosis. Several studies exploring this controversial issue suggest that cataract surgery can be safely performed under regional anesthesia without discontinuing anticoagulants,[54,55] especially if the prothrombin time is approximately 1.5 times control.[56] A more recent multicenter study of almost 20,000 cataract patients older than 50 years of age attempted to establish the

risks and benfits of continuing aspirin or Coumadin therapy.[57] Despite the large population studied, the rate of complications was so low that absolute differences in risk were minimal. Patients who continued therapy did not have more ocular hemorrhage; those who discontinued treatment did not have a greater incidence of medical events. Nonetheless, it is critical to appreciate that these investigations focused specifically on cataract operations. Retinal surgery may be another matter.

Patients presenting for ocular surgery are often at the extremes of age—ranging from premature babies with retinopathy of prematurity to nonagenarians. Hence, special age-related considerations such as altered pharmacokinetics and pharmacodynamics apply. In addition, elderly patients frequently have multiple comorbitities that include thyroid dysfunction, cardiopulmonary,

and renal diseases. Hypertension is encountered in the majority of geriatric patients. Those with poorly controlled blood pressure should not receive dilating eye drops, such as phenylephrine, without consulting an anesthesiologist. Systemic absorption of high concentrations (e.g., >2.5% phenylephrine) or improperly instilled mydriatics can precipitate a hypertensive crisis with potentially devastating consequences.

The anesthesiologist must be aware of the anesthetic implications of congenital and metabolic diseases with ocular manifestations. Diabetics often present with ocular complications, and the anesthesiologist must be knowledgeable about the systemic disturbances of physiology that affect these patients. Indeed, the list of congenital and metabolic diseases associated with ocular pathologic effects that have significant anesthetic implications is lengthy. A partial summary includes syndromes such as Crouzon's, Apert's, Goldenhar's (oculoauriculovertebral dysplasia), Sturge-Weber, Marfan's, Lowe's (oculocerebrorenal syndrome), Down (trisomy 21), Wagner-Stickler, and Riley-Day (familial dysautonomia). Other diseases in this category are homocystinuria, malignant hyperthermia, myotonia dystrophica, and sickle cell disease.[58]

Anesthesia Options

The requirements of ophthalmic surgery include safety, akinesia, profound analgesia, minimal bleeding, avoidance or obtundation of the oculocardiac reflex, prevention of intraocular hypertension, awareness of drug interactions, and a smooth emergence devoid of vomiting, coughing, or retching (see Table 33-1). Moreover, the exigencies of ophthalmic anesthesia mandate that the anesthesiologist be positioned remote from the patient's airway, sometimes creating certain logistic problems.

5 A number of anesthetic options exist, including general anesthesia, retrobulbar block, peribulbar anesthesia, sub-Tenon's (episcleral) block, topical anesthesia, and intracameral injection. General anesthesia is administered for the vast majority of children. Some adolescent and most adult patients can be cared for with regional or topical anesthesia and monitored anesthesia care (MAC), with or without sedation. The choice of anesthesia technique should be individualized based on the patient's needs and preferences, the nature and duration of the procedure, and the preferences and skills of the anesthesiologist and the surgeon.

Traditionally, the most commonly selected regional anesthetic technique for cataract surgery had been the retrobulbar block. Since the mid-1990s, peribulbar injection has surpassed retrobulbar block in popularity because of a relatively superior safety profile. Recently, however, topical analgesia has become more commonly used for cataract surgery in the United States (59% versus 41% for block techniques),[59] and sub-Tenon's blocks have surged in popularity in the United Kingdom and New Zealand.[60] Anesthesia for adult patients undergoing retina surgery is still accomplished primarily with peribulbar or retrobulbar block,[61] although some surgeons prefer general anesthesia for certain patients. More recently, anesthesiologists have had increasing interest in administering ocular anesthesia, and workshops in ophthalmic regional anesthesia are often conducted at major regional and national meetings. Many ophthalmologists and administrators encourage anesthesiologists to administer the blocks to facilitate operating room efficiency.

When a regional anesthetic of the orbit is administered, either by the anesthesiologist or the ophthalmologist, it is the responsibility of the anesthesiologist to monitor the patient's vital signs, electrocardiogram (ECG), and oxygen saturation. Sedation may be administered before performance of the block and/or initiation of surgery. The anesthesiologist must be vigilant for the oculocardiac reflex, signs of brainstem anesthesia, and the need for airway support or other interventions.

Anesthesia Techniques

More than 40 years ago, it was common for ophthalmic procedures to involve large ocular incisions. General endotracheal anesthesia, with deep and sustained neuromuscular paralysis and placement of sandbags to surround the patient's head, were typical strategies to ensure perioperative immobility. In more recent years, general anesthesia typically has been reserved for

children and adults who are unabe to communicate, cooperate, or remain suitably stationary. Although endotracheal anesthesia is necessary for patients at risk of aspiration, the laryngeal mask airway (LMA) has been increasingly accepted as a means to secure the airway in patients with no risk factors for aspiration who are having eye surgery with general anesthesia.[62] The LMA is not only safe and effective in this setting, but it also offers the advantage of less increase in IOP on insertion and removal than is encountered with an endotracheal tube.[63] Similarly, less bucking and coughing on emergence and during the recovery phase has been noted.[64] Vigilance must be maintained, however, to detect initial misplacement or intraoperative displacement of the LMA. In addition, intraoperative laryngospasm in infants and neonates is not uncommon with an LMA.

Retrobulbar and Peribulbar Blocks. Needle-based ophthalmic regional anesthesia was first described by Knapp in 1884.[65] Then, in the early twentieth century, Atkinson introduced the retrobulbar block.[66] Retrobulbar block is a practical means to achieve analgesia and profound akinesia of the globe. The peribulbar block is a more recently introduced needle-based technique that varies from the retrobulbar block in terms of the depth and angulation of needle placement within the orbit. Traditionally, the four rectus muscles, along with connective tissue septae, were believed to create a defined compartment known as the orbital cone. This so-called cone extends from the rectus muscle origins around the optic foramen at the apex of the orbit to the attachment of the muscles to the globe anteriorly. Retrobulbar blocks are accomplished by directing a needle toward the orbital apex with sufficient depth and angulation such that the cone is penetrated (Figs. 33-4 and 33-5). Local anesthetic is then instilled in the cone, behind the eye. Cadaveric dissections, however, have shown the fallacy of the classic concept of the cone. There is no complete intermuscular septum encircling the rectus muscles, linking them together to form an impermeable compartment behind the globe akin to the brachial plexus sheath in the axilla.[67] Ripart and colleagues[68] clearly demonstrated that extraconal injections of dye into cadaveric specimens diffused into the intraconal space, and solutions placed within the cone distributed to the extraconal space. Thus, the peribulbar block is executed by directing

a needle to less depth and with minimal angulation, parallel to the globe, toward the greater wing of the sphenoid bone (Figs. 33-6 and 33-7). Local anesthetic instilled in this extraconal space will eventually penetrate toward the optic nerve and other structures, establishing conduction anesthesia. The peribulbar block is theoretically safer because the needle tip is kept at a greater distance from vital intraorbital structures and brain.

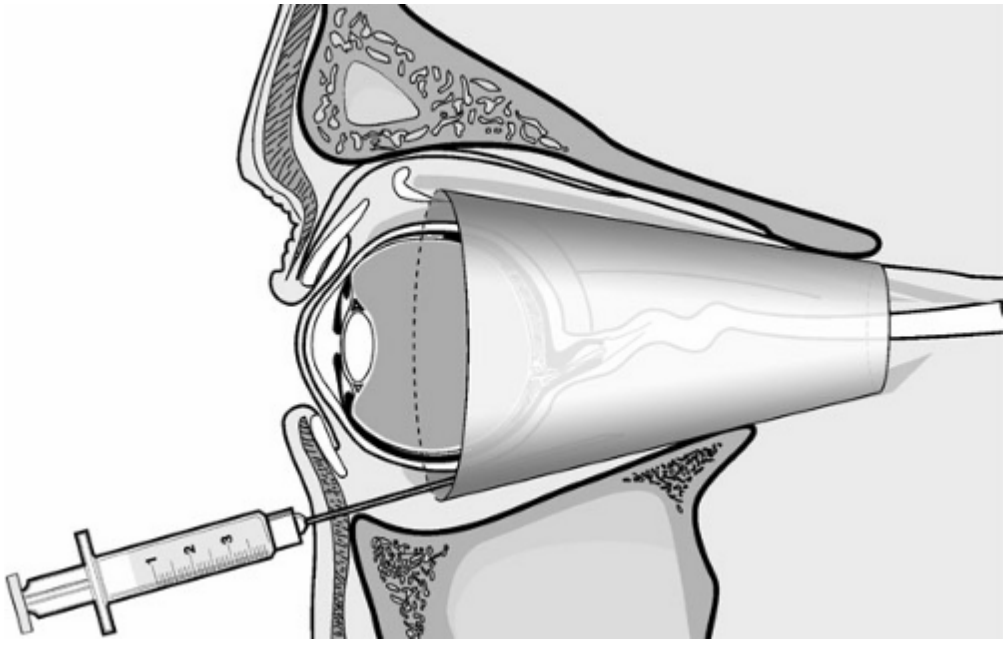

FIGURE 33-4. Retrobulbar (intraconal) block and schematic representation of the intraorbital

muscle cone.

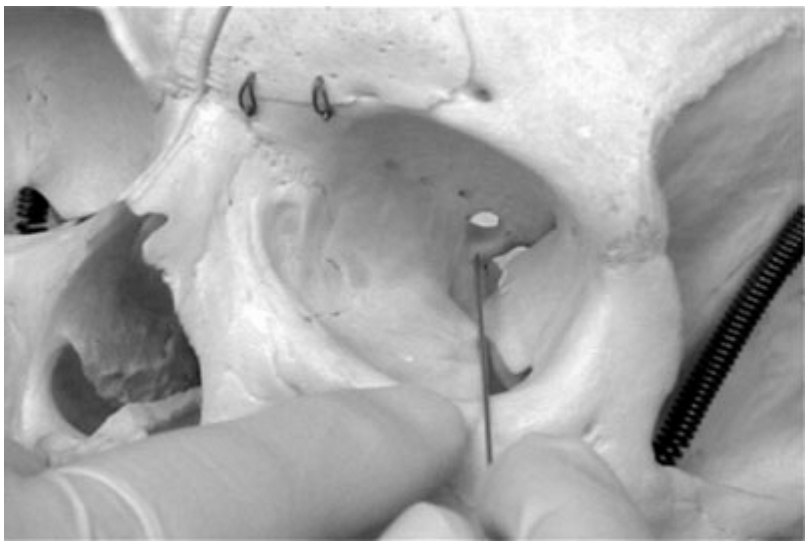

FIGURE 33-5. Needle placement for retrobulbar block.

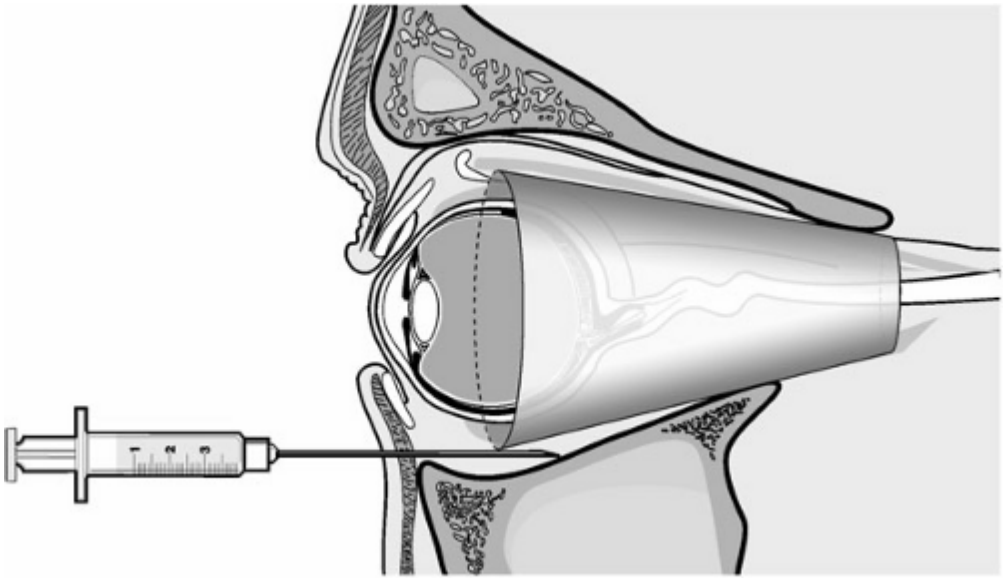

FIGURE 33-6. Peribulbar (extraconal) block and schematic representation of the intraorbital muscle cone.

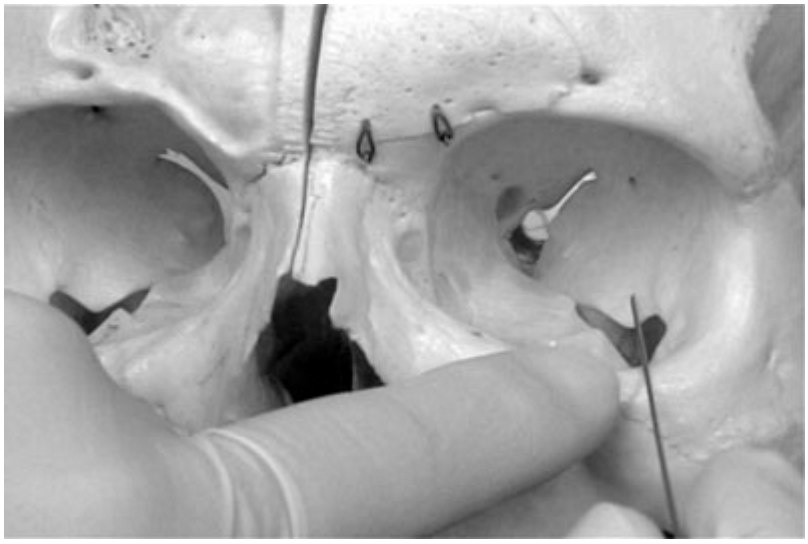

FIGURE 33-7. Needle placement for peribulbar block.

A retrobulbar or so-called intraconal block positions local anesthetics deep within the orbit proximate to the nerves and muscle origins. Thus, it requires low volume, has rapid onset, and yields intense depth of anesthesia. The peribulbar, or extraconal block, placed further from the optic and other orbital nerves, requires larger volumes of local anesthetic and has longer latency of onset. The needle entry point for both blocks is at the same inferotemporal location. The junction of the lateral third and medial two-thirds of the inferior orbital rim in line with the lateral limbal margin has been the conventional access point. However, locating the needle entry point more laterally may serve to decrease the likelihood of injecting local anesthetics into the delicate inferior rectus muscle. This is important because intramuscular injection of anesthetics has been postulated as a potential cause of postoperative strabismus.[69] Medial approaches at the caruncle have also been popularized more recently.[70] Supplementation of anesthesia with an injection above the globe may not be prudent because the preponderance of vessels lie in the superior orbit. In addition, the belly of the superior oblique muscle and the trochlear muscle can be encountered superonasally. Katsev and colleagues[71] demonstrated that the tips of commonly used 1.5–in. (38-mm) needles can reach critical structures in the densely packed apex of the orbit in almost 20% of retrobulbar blocks. Consequently, 1.25-in. (31-mm) needles are appropriate. Controversy exists over the advantages of sharp versus dull needles. Dull needles may require more force to penetrate the globe. However, sharp needles are less painful to insert and may cause less damage in the face of inadvertent globe puncture.[72] In the past, patients were asked to gaze superonasally while a block was conducted. Unsold and colleagues[73] found, however, that this maneuver caused the optic nerve to stretch directly in the path of the incoming needle during retrobulbar injection, exposing it to risk of needle trauma. Patients should be instructed to maintain gaze in the neutral position, leaving the optic nerve lax within the orbit in the course of needle insertion.[74]

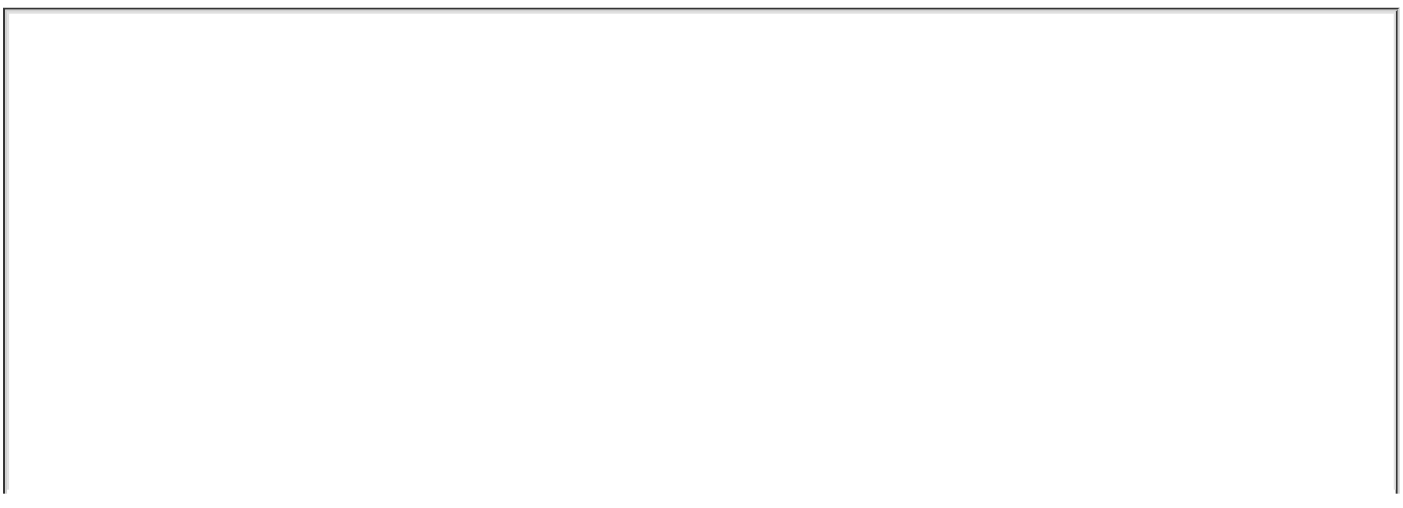
6 Akinesia of the eyelids is obtained by blocking the branches of the facial nerve supplying the orbicularis muscle. Lid akinesia is often a direct consequence of the larger volume of local anesthetic used for peribulbar blocks. Retrobulbar blocks, in contrast, often leave the orbicularis oculi fully functional. Thus, a facial nerve block is performed in conjunction with retrobulbar block to prevent squeezing of the eyelid that could result in extrusion of intraocular contents during corneal transplantation, for example. Since first used for ophthalmic surgery by Van Lint in 1914, numerous methods of facial nerve blockade have been described. These techniques block the facial nerve after its exit point from the skull in the stylomastoid foramen. Moving distally to proximally to the foramen, the techniques include the Van Lint, Atkinson, O'Brien, and Nadbath-Rehman methods. Although each has advantages and disadvantages, the Nadbath-Rehman approach can potentially produce the most serious systemic consequences. With this approach, a 27-gauge, 12-

mm needle is inserted between the mastoid process and the posterior border of the mandibular ramus. Due to the proximity of the jugular foramen (10 mm medial to the stylomastoid foramen) to the injection site, ipsilateral paralysis of cranial

nerves IX, X, and XI can occur, producing hoarseness, dysphagia, pooling of secretions, agitation, respiratory distress, or laryngospasm. Moreover, because the Nadbath-Rehman block produces complete hemifacial akinesia that interferes with oral intake, this approach is not recommended for outpatients.

Complications associated with needle-based ophthalmic anesthetics may be local or systemic, and may result in blindness or even death (Table 33-4). Bleeding may be superficial or deep, arterial or venous. Superficial hemorrhage may produce an unsightly circumorbital hematoma. Retrobulbar hemorrhage, when arterially based, may produce precipitous bleeding and a palpable, dramatic increase in IOP, as well as globe proptosis and entrapment of the upper lid. With the globe's vascular supply in jeopardy, the patient's long-term ultimate visual acuity may be quickly compromised. Consultation with an ophthalmologist should be immediately sought, and fundoscopic examination, tonometric measurement of IOP, ultrasound to assess presence/location of blood, and even a lateral canthotomy may be warranted. Continuous ECG monitoring is indicated because the oculocardiac reflex may appear as blood extravasates from the muscle cone. The decision to proceed with surgery in the presence of a mild or moderate hemorrhage is dependent on numerous factors, including the degree of bleeding, the nature of the planned ophthalmologic surgery, and the patient's condition.

TABLE 33-4 Complications of Needle-Based Ophthalmic Anesthesia



Stimulation of oculocardiac reflex arc
Superficial hemorrhage → circumorbital hematoma
Retrobulbar hemorrhage ± retinal perfusion compromise → loss of vision
Globe penetration ± intraocular injection → retinal detachment, loss of vision
Trauma to optic nerve or orbital cranial nerves → loss of vision
Optic nerve sheath injection → orbital epidural anesthesia
Extraocular muscle injury, leading to postoperative strabismus, diplopia
Intra-arterial injection, producing immediate convulsions
Central retinal artery occlusion
Inadvertent brainstem anesthesia → contralateral amaurosis, neurocardiopulmonary compromise

Penetration of the sclera is a distinct possibility with needle-based anesthesia techniques. Mechanical trauma, with potential retinal detachment, and chemical injury by local anesthetics to delicate retina tissue can occur. Blindness or very poor vision may be the result. Globe puncture is defined as a single entry into the eye, whereas perforation is caused by two full-thickness wounds — an entry and a subsequent exit. The globe's posterior pole is the most commonly penetrated area. Risk factors for posterior pole needle injury include presence of an elongated globe, recessed orb, and/or atypical-shaped eye. The AP distance of an eye may be long because of myopia or presence of globe-enveloping intraorbital hardware such as a scleral buckle. Some patients have an abnormal outpouching of the eye termed staphyloma. Most staphyloma are located at the posterior of the globe, surrounding the juncture of the eye with the optic nerve. By definition, a retrobulbar anesthetic is conducted by purposefully angling the needle steeply and deeply within the orbit behind the globe. If the globe is longer than one assumes, then it is at greater risk of penetration or puncture by the retrobulbar needle. In one more recent study, ultrasound detection determined that often the tip of the needle, placed in retrobulbar fashion, is much closer to the posterior pole of the globe than presupposed by physicians.[75] Peribulbar anesthesia entails shallower placement of the needle without directing the

needle inward toward the orbital apex; thus, it is associated with a lower incidence of globe-needle injury. Be aware, however, that it is still possible to engage the needle with sclera laterally.

The risk of penetrating the sclera with a needle is also inversely proportional to the anesthesiologist's education and experience. This is affirmed by several reports of globe injuries rendered by inadequately educated or trained personnel in the early 1990s.[76] In a survey of 284 directors of anesthesiology and ophthalmology programs, no formal training or education in ophthalmic regional anesthesia techniques was provided to anesthesia residents in the vast majority of academic programs.[77] This survey concluded that anesthesiologists who perform needle-based ophthalmic blocks should have knowledge of orbital anatomy and the ocular risk factors that were noted previously. Thus, appropriate preanesthesia history-taking includes direct interrogation concerning myopia or previous scleral buckle surgery, as both imply increased globe length. Physical exam of surface anatomy should note the position of the globe within the orbit and whether enophthalmos is present. A recessed eye is at greater risk of needle-tip misadventure. The most important laboratory exam is the preoperative ultrasound. For patients undergoing cataract surgery, an ultrasound is *always* performed to calculate the appropriate intraocular lens to insert intraoperatively. This ultrasound reveals the length and shape of the eye. An axial length greater than 26 mm confers greater risk of perforation. In the event that the ultrasound report is not found in the patient's chart, the anesthesiologist should inquire about the results before embarking on a needle-based block.

Brainstem anesthesia and inadvertent intravascular injection of local anesthetics are two additional potentially devastating consequences of needle-based ocular anesthesia. In the course of accidental intravascular arterial injection, local anesthetics flow from the needle via a branch of the ophthalmic artery in retrograde fashion to the internal carotid artery and then to the circle of Willis. Rapid redistribution of local anesthetic to the brain results in immediate onset of convulsions, and cardiopulmonary instability may also occur. Although the incidence of brainstem anesthesia is rare, it is even less common with peribulbar versus retrobulbar blocks. Brainstem anesthesia is a consequence of the direct spread of local anesthetic agents to the brain along the meningeal sheath surrounding the optic nerve. In contradistinction to intra-arterial injection, symptoms are not always immediate. There is a continuum of sequelae dependent on the concentration and volume of drug that gains access centrally, as well as the specific areas where the anesthetics spread (Fig. 33-8). One case report described the insidious onset of unconsciousness and apnea over 7 minutes, without concomitant seizures or cardiovascular collapse.[78] Nicoll et al.[79] reported 16 cases of apparently central spread of anesthetics in a series of 6,000 retrobulbar blocks. Eight patients developed respiratory arrest. Other protean CNS signs may include violent shivering; contralateral amaurosis; eventual loss of consciousness; apnea; and hemiplegia, paraplegia, quadriplegia, or hyperreflexia. Blockade of cranial nerves VIII to XII results in deafness, vertigo, vagolysis, dysphagia, aphasia, and loss of neck muscle power. It is axiomatic that personnel skilled in airway maintenance and ventilatory and circulatory support should be immediately available whenever retrobulbar or other needle-based anesthetic blocks are administered.

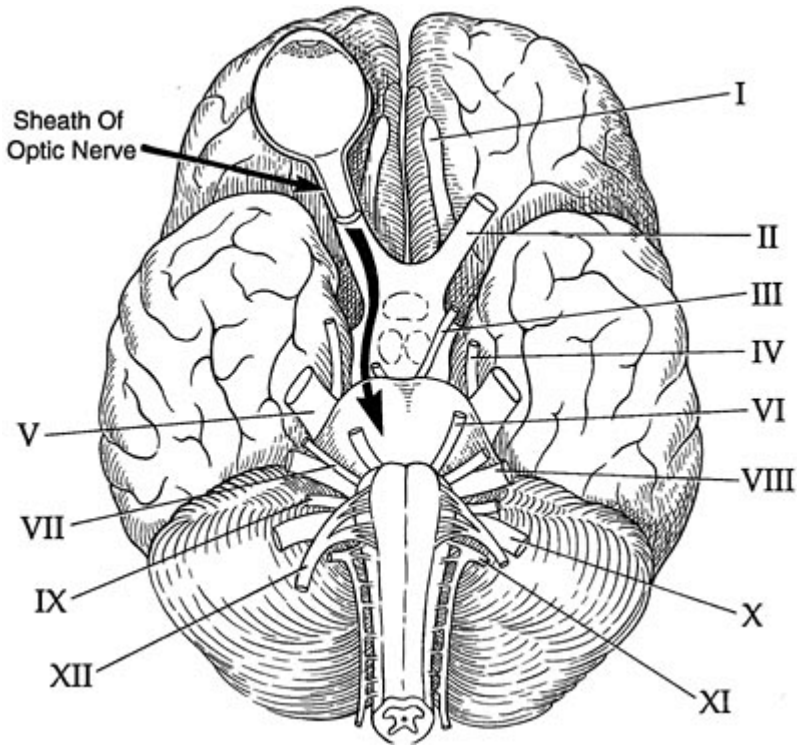


FIGURE 33-8. Base of the brain and the path that local anesthetic agents might follow if inadvertently injected into the subarachnoid space. This route includes the cranial nerves, pons, and midbrain. (Reprinted with permission from Javitt JC, Addiego R, Friedberg HL *et al*: Brain stem anesthesia after retrobulbar block. Ophthalmology 94:718, 1987.)

Cannula-Based Techniques. Cannula-based ophthalmic regional anesthesia was first described by Swan in 1956.[80] The sub-Tenon's block was rediscovered and popularized in the 1990s as another practical means to achieve analgesia and akinesia of the globe, while offering potential advantages in certain circumstances over needle-based blocks. Magnetic resonance imaging (MRI) studies have shown that local anesthetics, instilled beneath Tenon's capsule, spread into the posterior orbit.[81] The block is accomplished by inserting a blunt cannula through a small incision in the conjunctiva and Tenon's capsule, also known as the episcleral membrane, with subsequent infusion of local anesthetics (Fig. 33-9). Onset of analgesia is rapid. The ultimate extent of globe akinesia is proportional to the volume of local anesthetic injected. One large prospective study by Guise[82] of 6,000 such blocks found this technique to be highly effective. Advantages, particularly for very myopic patients who have elongated axial lengths, include decreased risk of posterior pole perforation because needles are not placed into the posterior orbit.

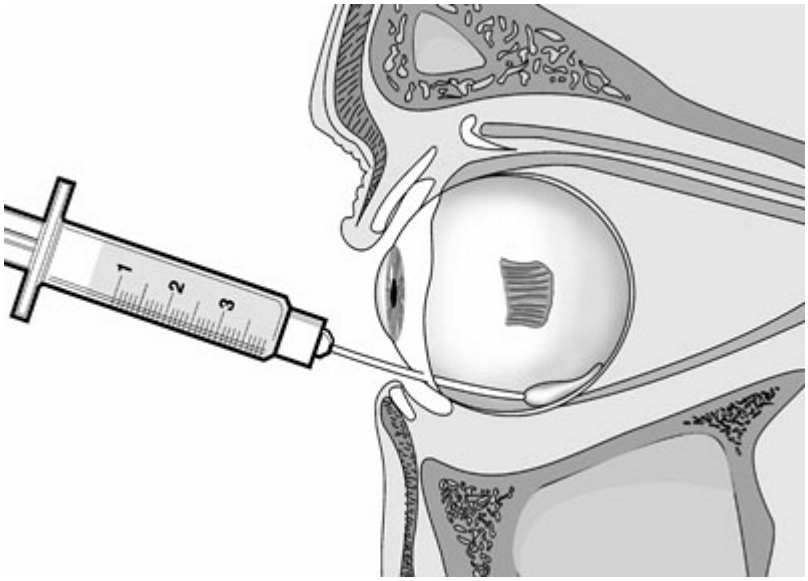

FIGURE 33-9. Sub-Tenon's (episcleral) block with blunt cannula.

After application of topical anesthetic, the episcleral space can be accessed from all quadrants with blunt-tipped scissors; however, the incision is most commonly made in the inferonasal

quadrant. The cannula is guided through the opening with the aid of a toothless forceps. It is common for local anesthetics to leak retrograde out of the incision site. Conjunctival bleeding (especially if diathermy is not used), chemosis, and ballooning up of the conjunctiva and Tenon's capsule are common. Fortunately, these are cosmetic issues that rarely affect outcome. Guise[82] estimated the incidence of minor hemorrhage to be less than 10% and had to abandon only one case because of a large subconjunctival hemorrhage that was not sight threatening. Thus, the sub-Tenon's block may be a prudent ocular anesthesia technique for the anticoagulated patient at risk for retrobulbar hemorrhage.

Major complications of sub-Tenon's ocular anesthesia include globe perforation,[83] major orbital hemorrhage, rectus muscle trauma, postoperative strabismus, orbital cellulitis, and brainstem anesthesia.[84] A greater proportion of complications seem to be associated with longer (18 to 25 mm), more rigid, metallic cannulae. Shorter (12 mm), more flexible, plastic cannulae may be preferable. However, they are associated with a higher incidence of conjunctival hemorrhage and chemosis. Variations of sub-Tenon's blocks include a more recently introduced ultrashort cannula (6 mm) and needle-based episcleral block techniques.[85]

Topical Analgesia. Ophthalmologists have also been returning to a technique that was popularized during the early 1900s—the use of topical anesthetic agents, particularly when the surgical incision is being made through clear cornea. Indeed, surface analgesia was the technique of choice for cataract surgery until the evolution of effective needle-based methods of regional anesthesia and improved safety of general anesthesia in the 1930s. Multiple advances in cataract surgery that have enabled faster operations, with greater control and less trauma, have allowed ophthalmologists to reexamine the use of topical anesthesia for this procedure. Phacoemulsification, with its small incisions, is clearly the procedure of choice in using topical anesthesia; however, planned extracapsular procedures can also be performed under topical anesthesia, thereby circumventing potential complications of peribulbar or retrobulbar block. Certainly, fully anticoagulated patients are excellent candidates for topical analgesia, as are monocular patients who are spared the trauma of prolonged local anesthetic-induced postoperative amaurosis. Potential disadvantages of topical anesthesia include eye movement during surgery, patient anxiety, and, rarely, allergic reactions. Patient selection is critical and should be restricted to individuals who are alert and able to follow instructions, and who can control their eye

movements. Patients who are demented or photophobic, or who cannot communicate, are inappropriate candidates, as are those with an inflamed eye. Similarly, patients with small pupils who may require significant iris manipulation or those who need large scleral incisions may be contraindicated for topical anesthesia.

Topical analgesia can be achieved with local anesthetic drops or gels. Anesthetic gels produce greater levels of drug in the anterior chamber than equal doses of drops and may afford superior surface analgesia.[86] Intracameral injection of 0.1 to 0.2 mL of 1% preservative-free lidocaine into the anterior chamber supplements the analgesia effects but may be deleterious to cornal endothelium.[87] Concerns about increased potential for postoperative endophthalmitis with gel-based topical analgesia exist because gels might theoretically form a barrier to bactericidal agents. Therefore, if administered, gels should be applied after antiseptic solutions, taking care to apply anesthetic drops before the use of caustic bactericidal preps.

Choice of Local Anesthetics, Block Adjuvants, and Adjuncts. Anesthetics for ocular surgery are selected based on onset and duration needed. Fast-onset, brief duration local anesthetics are optimal for procedures such as cataract surgery or pterygium excision. Longer-acting agents are indicated for lengthier operations such as vitreoretinal surgery. A tradition of mixing different local anesthetics to produce a block with shorter latency of onset, yet longer duration of effect, has been a paradigm of ophthalmic anesthesia. Vasoconstrictors may improve the quality of the block by delaying washout of drug from the orbit. There is concern, however, that epinephrine, the most common vasoconstrictor additive, may compromise retinal perfusion.[88]

Sodium bicarbonate, morphine sulfate, clonidine, and even vecuronium have been used as local anesthetic adjuvants in ophthalmic surgery. Without question, however, hyaluronidase has been the most popular ancillary agent used to modify ocular local anesthetic actions since it was introduced by Atkinson in 1949. It acts by hydrolyzing hyaluronic acid, a natural substance that binds cells together, keeping them cohesive. Thus, hyaluronidase increases tissue permeability, serves to promote dispersion of local anesthetics through tissues within the orbit, reduces the increase in orbital pressure associated with the volume of injected anesthetics, and enhances the quality of orbital blockade. Furthermore, hyaluronidase may reduce the risk of local anesthetic-induced extraocular muscle injury because clustered increases of postoperative diplopia were reported after national shortages of the drug in 1998 and 2000.[89] However, this is a controversial claim because it is possible, if not likely, that many who were administering orbital blocks may have modified their technique in response to the shortage, placing needles deeper, using more injections, or depositing larger volumes of local anesthetics.

Intravenous osmotic agents, such as mannitol and glycerin, as well as carbonic anhydrase inhibitors can be given to reduce vitreous volume and decrease IOP after it is artificially increased by local anesthetics. Digital pressure to soften the globe was described almost 50 years ago.[90] Mechanical means developed shortly thereafter and a number of devices are available. Essentially, they are all variations on a ball, balloon, or bag theme. The Super Pinky ball, the Honan IOP Reducer, and the Buys Mercury Reducer (soon to be eliminated because of pollutant concerns expressed by the U.S. Environmental Protection Agency) are examples. Immediately after administration of regional orbital anesthesia, the compression device may be positioned on the eye for 5 to 20 minutes. Reduction of IOP to below baseline levels is not uncommon. However, excessive pressure on the globe by these devices may impede blood flow, causing ischemic optic neuropathy or central retinal artery occlusion, possibly leading to blindness.[91] The Honan device addresses this potentially catastrophic complication with a pneumatic bellows that maintains even compression of the globe coupled to a manometric gauge that indicates a numeric value of applied pressure. A safety valve limits the amount of inflation of the bellows. With the increasing popularity of smaller incisions, lower-profile prosthetic lenses, and topical analgesia for cataract surgery, there is less need for IOP-reducing devices.

General Principles of Monitored Anesthesia Care. Many advocate the intravenous administration of an appropriate agent immediately before performance of ocular regional anesthesia to provide comfort and amnesia. What should be avoided at all costs, however, is the combination of local anesthesia with heavy sedation in the form of high doses of opioids,

benzodiazepines, and hypnotics. This polypharmacology is highly unsatisfactory because of the pharmacologic vagaries in the geriatric population and the attendant risks of respiratory depression, airway obstruction, hypotension, CNS aberrations, and prolonged recovery time. This undesirable technique has all the disadvantages of a general anesthetic in the absence of a tracheal tube or LMA without the advantage of controllability that general anesthesia offers. After the block has been performed, the patient should be relaxed but awake to avoid head movement associated with snoring or sudden abrupt movement on awakening. Clearly, patients under conscious sedation must be capable of responding rationally to commands and must be

able to maintain airway patency. Undersedation should likewise be avoided because tachycardia and hypertension may have deleterious effects, especially in patients with coronary artery disease. Moreover, patients with orthopedic deformities or arthritis must be meticulously positioned and given comfortable padding on the operating table. Adequate ventilation about the face is essential for all patients to avoid carbon dioxide accumulation, and each must be comfortably warm. (The hazards of shivering in patients with cardiac disease and, for that matter, in any patient having delicate eye surgery are well known.) Continuous ECG monitoring is vital, lest performance of the retrobulbar block, pressure on the orbit, or tugging on the extraocular muscles stimulates the oculocardiac reflex arc and produces dangerous cardiac dysrhythmias. Likewise, pulse oximetry is essential.

Studies have confirmed that most cataract operations performed in the United States are conducted with the patient under some form of local anesthesia (either retrobulbar, peribulbar, or parabulbar injection, or topical analgesia), with monitoring equipment used in 97% of cases and an anesthesiologist present in 78% of cases.[92] Indeed, many anesthesiologists have long wondered whether CMS will decide not to reimburse for monitored anesthesia care for "routine" cataract cases.

An important study by Rosenfeld and colleagues[93] is the first to assess the need for monitored anesthesia care in cataract surgery. These investigators prospectively studied the incidence and the nature of interventions required by anesthesia personnel in 1,006 consecutive cataract operations (both phacoemulsification and extracapsular techniques were included) performed under peribulbar block. They also analyzed the risk factors for intervention, including patient demographic data, medical history, and preoperative laboratory tests, for reliability in predicting those patients at greatest risk for intervention. They found that 37% of patients required some type of intervention and that, in general, the majority of those interventions could not have been predicted before surgery. The interventions ranged from minor forms, such as verbal reassurance and hand holding, to administering such intravenous medications as supplemental sedation or antihypertensive, pressor, or antiarrhythmic agents, or to providing respiratory assistance. Although hypertension, lung disease, renal disease, and a diagnosis of cancer were related to interventions, these four conditions combined accounted for only a small portion of the needed interventions. Moreover, although many of the interventions were relatively minor, several were more serious, and 30% of the interventions were considered (by the involved anesthesia personnel) to be critical to the success of the operation. The investigators concluded that monitored anesthesia care by qualified anesthesia personnel is reasonable and justified and contributes to the quality of patient care when cataract surgery is performed with local anesthesia. Although there were few, if any, injection-related problems, one wonders if the conclusion regarding need for anesthesia involvement would be different if the majority of cases had received topical analgesia. Given that analgesia is less profound with a topical approach, it seems likely that anesthesia care is equally appropriate to provide comfort, support, and indicated drugs for these patients. For both ethical and technical reasons, the ophthalmologist's attention must not be distracted from the microsurgical field.

ANESTHETIC MANAGEMENT IN SPECIFIC SITUATIONS

General Concepts and Objectives

Most patients undergoing eye surgery are either younger than 10 years of age or older than 55

years of age. In children, operations on the ocular adnexa, including lid surgery, repair of lacrimal apparatus, and adjustment of extraocular muscles, are common. However, surgery on the anterior segment, such as cataract removal, glaucoma procedures, and trauma repair, is definitely not limited to the adult population. Nor are posterior segment operations such as scleral buckling and vitrectomy the exclusive domain of geriatrics.

Most ocular procedures demand profound analgesia but minimal skeletal muscle relaxation. The airway must be protected from obstruction, and the anesthesiologist must distance himself or herself—along with anesthetic apparatus—from the surgical field. Depending on whether the patient is a child or an adult and various other factors previously discussed, a decision is reached regarding selection of local or general anesthesia. Additional preparation must include, of course, identification of underlying diseases, such as asthma, diabetes mellitus, or nephropathy. The patient should also be prepared emotionally for the recovery period, when he or she may awaken with one or both eyes closed by bandages. This is important not only to spare him or her fear and anxiety but to prevent much of the thrashing about that fright might produce, to the detriment of the eye.

Preoperative sedation is chosen carefully and is usually administered intravenously immediately before surgery because the vast majority of ophthalmic procedures are performed on an ambulatory basis. Except for strabismus correction, retinal detachment surgery, and cryosurgery, ophthalmic procedures are usually associated with little pain. Thus, the routine use of opioid premedication, replete with emetic potential, is ill advised. Rather, premedication should be prescribed with a view toward amnesia, sedation, and antiemesis.

Analgesia and akinesis are then secured through either local or general anesthesia, with careful attention paid to proper control of IOP and to the possible appearance of the oculocardiac reflex. The anesthesiologist strives to provide a smooth intraoperative course and to prevent coughing, retching, and vomiting, lest harmful increases in IOP transpire that could hinder successful surgery. If general anesthesia is elected, extubation of the trachea should be accomplished before there is a tendency to cough. The administration of intravenous lidocaine, 1.5 to 2 mg/kg, before extubation of the trachea is helpful in attenuating coughing. Likewise, prophylactic intravenous droperidol—the "black box" warning issued by the U.S. Food and Drug Administration (FDA) not withstanding—is valuable in reducing the incidence and severity of nausea and vomiting. If droperidol is ineffective as a prophylactic agent, then the more expensive ondansetron or dolasetron may be administered as a "rescue" antiemetic. If the patient is deemed to be at extremely high risk for postoperative nausea and vomiting, prophylactic multimodal antiemetic therapy may be selected in conjunction with total intravenous anesthesia with propofol.

"Open-Eye, Full-Stomach" Encounters

The anesthesiologist involved in caring for a patient with a penetrating eye injury and a full stomach confronts special challenges. He or she must weigh the risk of aspiration against the risk of blindness in the injured eye that could result from elevated IOP and extrusion of ocular contents.

As in all cases of trauma, attention should be given to the exclusion of other injuries, such as skull and orbital fractures, intracranial trauma associated with subdural hematoma formation, and the possibility of thoracic or abdominal bleeding.

Although regional anesthesia is often a valuable alternative for the management of trauma patients who have recently eaten, this option had traditionally been considered contraindicated in patients with penetrating eye injuries because of the

potential to extrude intraocular contents via pressure generated by local anesthetics. Nonetheless, some anecdotal case reports of successful use of ophthalmic blocks in this setting have been published. Recognizing that there are several distinct permutations of eye injuries, Gayer and colleagues developed techniques to safely block patients with *select* open-globe injuries.[94] In a 4-year period, 220 disrupted eyes were repaired via regional anesthesia at Bascom Palmer Eye Institute. A significant number of injuries were caused by intraocular foreign bodies and

dehiscence of cataract or corneal transplant incisions. Blocked eyes tended to have more anterior, smaller wounds than those repaired via general anesthesia. There was no outcome difference—that is, change of visual acuity from initial evaluation until final examination—between the eyes repaired via regional versus general anesthesia. Moreover, combined topical anesthesia and sedation for *selected* patients with open-globe injuries has also been reported.[95]

Nonetheless, it is not always possible to determine the extent of disruption preoperatively, and general anesthesia is typically considered prudent in this setting. Preoperative prophylaxis against aspiration may involve administering H_2 receptor antagonists to elevate gastric fluid pH and to reduce gastric acid production. Metoclopramide may be given to induce peristalsis and enhance gastric emptying.

Frequently, a barbiturate, nondepolarizing neuromuscular blocking drug technique is described as the method of choice for the emergency repair of an open eye injury; the nondepolarizing drug pancuronium in a dose of 0.15 mg/kg has been shown to lower IOP. However, this method has its disadvantages, including risk of aspiration and death during the relatively lengthy period—ranging from 75 to 150 seconds—that the airway is unprotected. Performance of the Sellick maneuver during this interval affords some protection. Furthermore, a premature attempt at intubation of the trachea produces coughing, straining, and a dramatic rise in IOP, emphasizing the need to confirm the onset of drug effect with a peripheral nerve stimulator while appreciating, nonetheless, that muscle groups vary in their response to muscle relaxants. Moreover, the cardiovascular side effects of tachycardia and hypertension may prove worrisome in patients with coronary artery disease. Also, the long duration of action of intubating doses of pancuronium may mandate postoperative mechanical ventilation of the lungs. Intermediate-acting nondepolarizing drugs such as vecuronium have briefer durations of action, and less dramatic, if any, circulatory effects, but nevertheless have an onset of action similar to that of pancuronium.

Several studies have explored the use of extremely large doses of nondepolarizing muscle relaxants to accelerate the onset of adequate relaxation for endotracheal intubation. Using vecuronium doses of 0.2 and 0.4 mg/kg, Casson and Jones[96] found mean onset times of 95 and 87 seconds, respectively. Ginsberg et al.[97] found comparable albeit slightly longer onset times.

Succinylcholine offers the distinct advantages of swift onset, superb intubating conditions, and brief duration of action. If administered after careful pretreatment with a nondepolarizing drug and an induction dose of thiopental (4 to 6 mg/kg), succinylcholine produces only small increases in IOP.[98] Although the advisability of this technique has been debated vociferously, there are no published reports of loss of intraocular contents from a pretreatment barbiturate–succinylcholine sequence when used in this setting.[99] Moreover, in 1993, McGoldrick[100] pointed out that Lincoff's 1957 watershed article states: "Various communications have been received from ophthalmologists who have used succinylcholine in surgery. This includes several reports of cases in which succinylcholine was given *to forestall impending vitreous prolapse* only to have a prompt expulsion of vitreous occur" (our italics).[17] Under such desperate circumstances, it is extremely difficult to attribute the expulsion of vitreous directly to succinylcholine.[100]

What about the so-called priming principle?[101] This concept involves using approximately one-tenth of an intubating dose of nondepolarizing drug, followed 4 minutes later by an intubating dose. Then, after waiting an additional 90 seconds, intubation of the trachea may be performed. However, studies in this area demonstrate wide variability and disconcerting scatter of data. Future investigations should use a randomized, double-blind design because studies of intubating conditions are notoriously difficult to interpret. Moreover, priming is not devoid of risk; a case of pulmonary aspiration after a priming dose of vecuronium has been reported.[102]

Rocuronium, with its purportedly rapid onset, may prove to be a useful drug in these circumstances provided adequate doses (1.2 mg/kg intravenously) are administered. However, additional data are needed before rocuronium can be enthusiastically recommended in this challenging situation. Moreover, rocuronium has an intermediate duration of action that could be disadvantageous, compared with succinylcholine, in a patient with an unrecognized difficult airway. It was hoped that rapacuronium (Org 9487), with its swift onset, would emerge as a viable alternative to succinylcholine. However, rapacuronium is no longer available in the United States

because of its role in triggering intractable bronchospasm in some patients. A new ultrashort-acting nondepolarizing alternative (GW280430A) to succinylcholine is currently undergoing clinical investigation in human volunteers.

Perhaps the wisest approach to the management of open-eye, full-stomach situations is summarized by Baumgarten and Reynolds,[103] who wrote in 1985:

> It may be possible to devise a combination of intravenous anesthetics and nondepolarizing relaxants that totally prevents coughing after rapid intubation. Until this combination is devised and confirmed in a large, controlled double-blind series, clinicians should not apply the priming principle to the open eye-full stomach patient. Use of a blockade monitor to predict intubating conditions may be unreliable, since muscle groups vary in their response to nondepolarizing relaxants. At this time, succinylcholine with precurarization probably remains the most tenable compromise in the open eye-full stomach challenge.

Strabismus Surgery

Approximately 3% of the population has malalignment of the visual axes, which may be accompanied by diplopia, amblyopia, and loss of stereopsis (Table 33-5). Indeed, strabismus surgery is the most common pediatric ocular operation performed in the United States, and it entails a variety of techniques to weaken an extraocular muscle by moving its insertion on the globe (recession) or to strengthen an extraocular muscle by eliminating a short strip of the tendon or muscle (resection).

TABLE 33-5 Concerns with Various Ocular Procedures

▪PROCEDURE	▪CONCERNS
Strabismus repair	Forced duction testing
	Oculocardiac reflex
	Oculogastric reflex
	Malignant hyperthermia
Intraocular surgery	Proper control of IOP
	Akinesia
	Drug interactions
	Associated systemic disease
Retinal detachment surgery	Oculocardiac reflex

	Proper control of IOP
	Nitrous oxide interaction with air, sulfur hexafluoride, or perfluorocarbons

IOP, intraocular pressure.

Infantile strabismus occurs within the first 6 months of life and is often observed in the neonatal period. Although most patients with strabismus are healthy, normal children, the incidence of strabismus is increased in those with CNS dysfunction such as cerebral palsy and meningomyelocele with hydrocephalus. Moreover, strabismus may be acquired secondary to oculomotor nerve trauma or sensory abnormalities such as cataracts or refractive aberrations.

In addition to the well-known propensity of strabismus surgery to trigger the oculocardiac reflex (previously discussed), there is also an increased incidence of malignant hyperthermia in patients with conditions such as strabismus or ptosis. This observation is consistent with the impression that people susceptible to malignant hyperthermia often have localized areas of skeletal muscle weakness or other musculoskeletal abnormalities. Other aspects of strabismus surgery of interest

to anesthesiologists include succinylcholine-induced interference with the FDT and an increased incidence of postoperative nausea and vomiting.

In formulating a surgical treatment plan for incomitant strabismus, ophthalmologists often find the FDT to be exquisitely helpful in differentiating between a paretic muscle and a restrictive force preventing ocular motion. To perform the FDT, the surgeon grasps the sclera of the anesthetized eye with a forceps near the corneal limbus and moves the eye into each field of gaze, concomitantly assessing tissue and elastic properties. This simple test provides valuable clues to the presence and site of mechanical restrictions of the extraocular muscles and is most valuable in patients who have previously undergone strabismus surgery, in those who may have paralysis of one of the extraocular muscles, and in those who have sustained orbital trauma.

France et al.[28] quantitated the magnitude and duration of change of the FDT after succinylcholine administration. They demonstrated that quantitation of the force necessary to rotate the globe remained significantly elevated over control for 15 minutes, even though the rise in IOP and the skeletal muscle paralysis lasted less than 5 minutes. Because succinylcholine interferes with FDT, its use is contraindicated less than 20 minutes before testing. Hence, France et al. suggested performing the FDT on the anesthetized patient either while mask inhalation anesthesia is being administered, before intubation of the trachea; after intubation, facilitated by nondepolarizing neuromuscular blocking drugs; or after intubation under moderately deep inhalation anesthesia, unaided by succinylcholine.

Eye movement under general anesthesia is well documented, and in nonaligned eyes this tendency is augmented such that divergent squints diverge more and convergent squints converge less. A more recent report discloses that surgeons at a regional eye teaching hospital in the United Kingdom who specialize in strabismus surgery are increasingly requesting that, if the FDT is being used, nondepolarizing neuromuscular blockade be incorporated into the anesthetic management so muscle tone is minimal or absent during testing.[104]

Once intubation of the trachea has been accomplished, anesthesia is commonly maintained with

halothane; desflurane; sevoflurane; or isoflurane, nitrous oxide, and oxygen. The patient is carefully monitored with a precordial stethoscope, ECG, blood pressure device, pulse oximeter, end-tidal carbon dioxide measurement, and temperature probe. If bradycardia occurs, the surgeon is asked to discontinue ocular manipulation, and the patient's ventilatory status and anesthetic depth are quickly assessed. If additional intravenous atropine is indicated, it is not given while the oculocardiac reflex is active in case even more dangerous cardiac dysrhythmias are triggered.

The laryngeal mask airway is gaining popularity for strabismus surgery in the United States, provided the patient is not at risk for aspiration. The laryngeal mask can be inserted without the use of muscle relaxants, causes less hemodynamic perturbation, and is associated with less straining and coughing on removal.

Vomiting after eye muscle surgery is common, giving credibility to the existence of the oculogastric reflex. The administration of droperidol, 0.075 mg/kg at induction of anesthesia before manipulation of the eye, has been shown to reduce the incidence of vomiting after strabismus surgery to a clinically acceptable level of approximately 10% without prolonging recovery time.[105] Moreover, a lower dose of droperidol, 0.02 mg/kg intravenously, administered immediately after anesthetic induction in patients with strabismus may decrease both the incidence and severity of nausea and vomiting.[106]

Prophylactic intravenous administration of ondansetron also appears to be efficacious. More studies are needed to document the efficacy of some of the other serotonin receptor antagonists, such as dolasetron, granisetron, tropisetron, and ramosetron in this setting. Combination therapy consisting of one or two antiemetics, each with a different mechanism of action, plus a glucocorticoid such as dexamethasone is also gaining popularity.[107] Moreover, a total intravenous technique with proprofol has also been associated with a low incidence of emesis after strabismus surgery.[108] In addition, avoiding narcotics may be helpful. One study demonstrates that the nonopioid analgesic ketorolac, in a dose of 0.75 mg/kg intravenously, provides analgesia comparable with that of morphine in pediatric patients with strabismus, but with a much lower incidence of nausea and vomiting in the first 24 hours.[109]

Intraocular Surgery

Advances in both anesthesia and in technology now permit a level of controlled intraocular manipulation not possible one-quarter century ago (see Table 33-5).

Proper control of IOP is crucial for such intraocular procedures as glaucoma drainage surgery, open sky vitrectomy, penetrating keratoplasty (corneal transplantation), and traditional intracapsular cataract extraction. Before scleral incision (when IOP becomes equal to atmospheric pressure), a low-normal IOP is essential because abrupt decompression of a hypertensive eye could result in iris or lens prolapse, vitreous loss, or expulsive choroidal hemorrhage. Available data have not demonstrated a major difference in the rate of complications such as vitreous loss and iris prolapse between local anesthesia and general anesthesia.

Many anesthetic techniques may be safely used for elective intraocular surgery. If general anesthesia is selected, virtually any of the inhalation drugs may be given after intravenous induction of anesthesia with a barbiturate or propofol, neuromuscular blocking drug, and topical laryngeal lidocaine. Because complete akinesia is essential for delicate intraocular surgery, nondepolarizing drugs are administered, followed by neuromuscular function monitoring to ensure a 90 to 95% twitch suppression level during surgery. Because proper control of IOP is critical, controlled ventilation of the lungs is used, along with end-tidal carbon dioxide monitoring to ensure avoidance of hypercarbia.

Maximal pupillary dilation is important for many types of intraocular surgery and can be induced by continuous infusion of epinephrine 1:200,000 in a balanced salt solution, delivered through a small-gauge needle placed in the anterior chamber. Almost simultaneous with its administration, the drug is

removed by aspirating it from the anterior chamber. The iris usually dilates immediately on

contact with the epinephrine infusion, and drug uptake is presumably limited by the associated intense vasoconstriction of the iris and ciliary body. However, epinephrine may also be potentially absorbed by drainage through Schlemm's canal into the venous system or by spillover of the infusion into the conjunctival vessels or drainage to the nasal mucosa.

At the completion of surgery, any residual neuromuscular blockade is reversed. On resumption of spontaneous ventilation, the patient's trachea is extubated (often in the lateral position) with the patient still deeply anesthetized and after intravenous administration of lidocaine to prevent coughing. Atropine and neostigmine may be safely used to reverse neuromuscular blockade, even in patients with glaucoma because this combination of drugs, in conventional doses, has minimal effects on pupil size and IOP.

Retinal Detachment Surgery

Surgery to repair retinal detachments involves procedures affecting intraocular volume, frequently using a synthetic silicone band or sponge to produce a localized or encircling scleral indentation (see Table 33-5). Furthermore, internal tamponade of the retinal break may be accomplished by injecting an expandable gas such as sulfur hexafluoride into the vitreous. Because of blood gas partition coefficient differences, the administration of nitrous oxide may enhance the internal tamponade effect of sulfur hexafluoride intraoperatively, only to be followed by a dramatic drop in IOP and volume on discontinuation of nitrous oxide. The injected sulfur hexafluoride bubble, in the presence of concomitant administration of nitrous oxide, can cause a rapid and dramatic rise in IOP, reaching a peak within 20 minutes[50,51] (see Intraocular Sulfur Hexafluoride section). Because the resultant rise in IOP may compromise retinal circulation, Stinson and Donlon[50] recommended cessation of nitrous oxide administration 15 minutes before gas injection to prevent significant changes in the volume of the intravitreous gas bubble. Furthermore, Wolf et al.[51] stated that if a patient requires anesthesia after intravitreous gas injection, nitrous oxide should be omitted for 5 days after an air injection and for 10 days after sulfur hexafluoride injection. Perfluoropropane, moreover, remains in the eye longer than 30 days.

Alternatively, silicone oil, a vitreous substitute, may be injected to achieve internal tamponade of a retinal break.

Retinal detachment operations are basically extraocular but may briefly become intraocular if the surgeon elects to perforate and drain subretinal fluid. Furthermore, rotation of the globe with traction on the extraocular muscles may elicit the oculocardiac reflex so the anesthesiologist must be vigilant about potential cardiac dysrhythmias. In addition, because it is desirable to have a soft eye while the sclera is being buckled, intravenous administration of acetazolamide or mannitol is common during retinal surgery to lower IOP.

These patients are usually managed in the same manner as those having intraocular surgery, except that maintenance of intraoperative skeletal muscle paralysis is not as critical as during intraocular surgery. Hence, inhalational anesthetics need not be accompanied during surgery by nondepolarizing neuromuscular blocking drugs.

POSTOPERATIVE OCULAR COMPLICATIONS

The incidence of eye injuries associated with nonocular surgery is low. In a study by Roth and colleagues[110] of 60,965 patients undergoing nonocular surgery from 1988 to 1992, the incidence of eye injury was 0.056% (34 patients). Twenty-one of these 34 patients sustained corneal abrasion, although other injuries included conjunctivitis, blurry vision, red eye, chemical injury, direct ocular trauma, and blindness. Independent risk factors for greater relative risk of ocular injury were protracted surgical procedures, lateral intraoperative positioning, head or neck surgery, general anesthesia, and (for some unknown reason) surgery on a Monday. A specific mechanism of injury could be identified in only 21% of cases. In the ASA Closed Claims Study published in 1992 (which analyzed only cases involving litigation), eye injuries represented merely 3% of all claims, but the serious nature of some of the injuries were reflected in large financial awards.[111] Similar to the findings of Roth et al., in the Closed Claims Study the specific mechanism of injury could be ascertained in only a minority of cases. A more recent Closed Claims

Study published in 2004 examining injuries associated with regional anesthesia reported that the proportion of regional anesthesia claims linked to eye blocks increased from 2% in the 1980s to 7% in the 1990s.[112] These injuries were typically permanent and related to the block technique. More than half of the claims resulted in blindness. Almost all these claims involved retrobulbar or peribulbar block performed by anesthesiologists. Topical anesthesia for cataract removal is becoming more common and may result in a reduced prevalence of these complications.

Although infrequent and often transient, eye injuries can result occasionally in blindness or more limited, but nonetheless permanent, visual impairment. Postoperative complications after nonocular surgery include corneal abrasion and minor visual disturbances, chemical injuries, thermal or photic injury, and serious visual disturbances, including blindness. Serious injury may result from such diverse conditions as acute corneal epithelial edema, glycine toxicity and other visual disturbances associated with transurethral resection of the prostate, retinal ischemia, ischemic optic neuropathy, cortical blindness, and acute glaucoma. It appears that certain types of surgery, including complex spinal surgery in the prone position; operations involving extracorporeal circulation; and neck, nasal, or sinus surgery may increase the risk of serious postoperative visual complications.

Corneal Abrasion

Although the most common ocular complication of general anesthesia is corneal abrasion,[113] the incidence varies widely, depending on the perioperative circumstances. In a prospective study, Cucchiara et al.[114] found a 0.17% incidence of corneal abrasion in 4,652 neurosurgical patients whose eyes were protected, whereas Batra and Bali[113] one decade earlier reported a 44% incidence of corneal abrasion when eyes were left unprotected and partly open. A variety of mechanisms can result in corneal abrasion, including damage caused by the anesthetic mask, surgical drapes, and spillage of solutions. During intubation of the trachea, moreover, the end of plastic watch bands or hospital ID cards clipped to the laryngoscopist's vest pocket can injure the cornea. Ocular injury may also occur due to loss of pain sensation, obtundation of protective corneal reflexes, and decreased tear production during anesthesia. Therefore, it may be prudent to tape the eyelids closed immediately after induction, and during mask ventilation and laryngoscopy. In addition to taping the eyelids closed, applying protective goggles, and instilling petroleum-based ointments into the conjunctival sac may provide protection. Disadvantages of ointments include occasional allergic reactions; flammability, which may make their use undesirable during surgery around the face and contraindicated during laser surgery; and blurred vision in the early postoperative period. The blurring and foreign-body

sensation associated with ointments may actually increase the incidence of postoperative corneal abrasions if they trigger excessive rubbing of the eyes while the patient is still emerging from anesthesia. Moreover, halothane absorption into paraffin-based ointments can damage the cornea, and even water-based (methylcellulose) ointments may be irritating and cause scleral erythema. It would seem prudent, therefore, to close the eyelids with tape during general anesthesia for procedures away from the head and neck. For certain procedures on the face, ocular occluders or tarsorrhaphy may be indicated. Special attention should also be devoted to frequent checking of the eyes during procedures on a prone patient.

Patients with corneal abrasion usually complain of a foreign-body sensation, pain, tearing, and photophobia. The pain is typically exacerbated by blinking and ocular movement. It is wise to have an ophthalmologic consultation immediately. Treatment typically consists of the prophylactic application of antibiotic ointment and patching the injured eye shut. Although permanent sequelae are possible, healing usually occurs within 24 hours.

Chemical Injury

Spillage of solutions during skin preparation may result in chemical damage to the eye. The FDA reported serious corneal damage from eye contact with Hibiclens, a 4% chlorhexidine gluconate solution formulated with a detergent. Again, with meticulous attention to detail, this misadventure is preventable. Treatment consists of liberal bathing of the eye with balanced salt solution to

remove the offending agent. After surgery, it may be desirable to have an ophthalmologist examine the eye to document any residual injury or lack thereof.

Photic Injury

Direct or reflected light beams may permanently damage the eye. The potential for serious injury to the cornea or retina from certain laser beams requires that the patient's eyes be protected with moist gauze pads and metal shields, and that operating room personnel wear protective glasses. These goggles must be appropriately tinted for the specific wavelength they are intended to block. Clear goggles may be worn when working with the carbon dioxide laser, whereas for work with the argon, Nd-YAG, or Nd-YAG-KTP laser, the goggles must be tinted orange, green, and orange-red, respectively.

Mild Visual Symptoms

After anesthesia, transient, mild visual disturbances such as photophobia or diplopia are common. Blurred vision in the early postoperative period may reflect residual effects of petroleum-based ophthalmic ointments or ocular effects of anticholinergic drugs administered in the perioperative period (see Corneal Abrasion section).

In contrast, the complaint of postoperative visual loss is rare and is cause for alarm. Several of the following conditions may be associated with visual loss after anesthesia and surgery, and should be included in the differential diagnosis: hemorrhagic retinopathy, retinal ischemia, retinal artery occlusion, ischemic optic neuropathy, cortical blindness, and acute glaucoma.

Hemorrhagic Retinopathy

Retinal hemorrhages that occur in otherwise healthy people secondary to hemodynamic changes associated with turbulent emergence from anesthesia or protracted vomiting are termed Valsalva retinopathy. Fortunately, these venous hemorrhages are usually self-limiting and resolve completely in a few days to a few months.

Because no visual changes occur unless the macula is involved, most cases are asymptomatic. However, if bleeding into the optic nerve occurs, resulting in optic atrophy, or if the hemorrhage is massive, permanent visual impairment may ensue. In some instances of massive hemorrhage, vitrectomy may offer some improvement.

Retinal venous hemorrhage has also been described after injections of local anesthetics, steroids, or saline into the lumbar epidural space, and these cases have been summarized by Purdy and Ajimal.[115] The patients all received large injections ($\geqslant$40 mL) into the epidural space, and they subsequently developed blurry vision or headaches. On funduscopic examination, retinal hemorrhage was consistently observed. Eight of the nine patients described had complete recovery. It is believed that the hemorrhage is produced by rapid epidural injection, which causes a sudden increase in intracranial pressure. This increase in cerebrospinal fluid pressure causes an increase of retinal venous pressure, which may cause retinal hemorrhages. It is possible that obesity, hypertension, coagulopathies, preexisting elevated cerebrospinal fluid pressure (as seen in pseudotumor cerebri), and such retinal vascular diseases as diabetic retinopathy may be risk factors. Caution is recommended when injecting drugs or fluid into the epidural space; a slow injection rate and using the minimal volume necessary to accomplish the desired objective are strongly recommended.

Retinal ischemia

Retinal bleeding may also originate from the arterial circulation. This bleeding may be associated with extraocular trauma. Funduscopic examination shows cotton-wool exudates, and this condition is known as Purtscher's retinopathy. Purtscher's retinopathy should be ruled out when a trauma patient complains of postanesthetic visual loss. This condition is associated with a poor prognosis, and most patients sustain permanent visual impairment.

Retinal ischemia or infarction may also result from direct ocular trauma secondary to external pressure exerted by an ill-fitting anesthetic mask, especially in a hypotensive setting, and from embolism during cardiac surgery, or from the intraocular injection of a large volume of sulfur hexafluoride in the presence of high concentrations of nitrous oxide. It may also result from increased ocular venous pressure associated with impaired venous drainage or elevated IOP.

The importance of carefully positioning patients and scrupulously monitoring external pressure on the eye cannot be overemphasized, especially when the patient is in the prone or jackknife positions. When the head is dependently positioned, venous pressure may be elevated. If external pressure is applied to the globe from improper head support, perfusion pressure to the eye is likely to be reduced. An episode of systemic hypotension in this setting could further decrease perfusion pressure and thereby decrease intraocular blood flow, resulting in possible retinal ischemia.

It is imperative that for procedures in the prone position, a padded or foam headrest be used. The patient's eyes must be in the opening of this headrest and they must be checked at frequent intervals for pressure. If the patient's head is too large to fit properly into the headrest, then a pin head-holder should be used. During some spine procedures, a steep head-down position may be used to decrease venous bleeding and enhance surgical exposure. This position, in combination with deliberate hypotension and infusion of large quantities of crystalloid, may increase the risk of compromising the ocular circulation.

It seems prudent to avoid combining these three risk factors to any significant degree.

Central retinal arterial occlusion and branch retinal arterial occlusion are important, and frequently preventable, causes of postoperative visual loss. Cases have occurred following spinal, nasal, sinus, or neck surgery, as well as after coronary artery bypass graft (CABG) surgery. In addition to external pressure on the eye, causes can include emboli from carotid plaques or other sources, as well as vasospasm or thrombosis after radical neck surgery complicated by hemorrhage and hypotension, and after intranasal injection of α-adrenergic agonists. Several cases have followed intra-arterial injections of corticosteroids or local anesthetics in branches of the external carotid artery, with possible retrograde embolization to the ocular blood supply.[116] Mabry[117] suggested that, to produce retrograde flow into the branches of the ophthalmic artery, the needle must be positioned intra-arterially, and the perfusion pressure must be overcome during the injection. Therefore, when injecting in the nasal and sinus areas, topical vasoconstrictors should be applied to decrease the size of the vascular bed, and a small (25-gauge) needle on a low-volume syringe should be used to minimize injection pressure. Moreover, because some cases have followed injections of corticosteroids combined with other drugs, it is believed that this practice may predispose to formation of drug crystals and should therefore be discouraged.

In cases of central retinal arterial occlusion, funduscopic examination discloses a pale, edematous retina and a cherry-red spot. Platelet-fibrin, cholesterol, calcific, or crystalloid emboli may be found in narrowed retinal arterioles. Computed tomography (CT) and MRI studies are negative.

Prevention is much more successful than treatment. It may be possible to apply ocular massage (contraindicated if glaucoma is a possibility) to dislodge an embolus to more peripheral sites, and intravenous acetazolamide and 5% carbon dioxide inhalation have been used to increase retinal blood flow. The prognosis, however, is typically poor, and approximately 50% of patients with central retinal arterial occlusion eventually have optic atrophy.

ischemic Optic Neuropathy

Ischemic optic neuropathy (ION) in the nonsurgical setting is the most common cause of *sudden* visual loss in patients older than 50 years of age, and it may be either arteritic or nonarteritic. Our discussion is limited to postoperative ION and contrasts the similarities and differences between anterior ischemic optic neuropathy (AION) and posterior ischemic optic neuropathy (PION). Due to a perceived increase in the incidence of postoperative visual loss since the mid-1990s, the Committee on Professional Liability of the ASA established the Postoperative Visual

Loss Database on July 1, 1999, to better identify associated risk factors so these tragic complications might be prevented in the future.[118] Because the incidence of postoperative vision loss after spine surgery in the prone position may be as high as 1%, it would seem prudent to discuss this potential complication preoperatively with the patient during the informed consent process.

Anterior ischemic Optic Neuropathy

Although the multifactorial pathophysiology of AION has not been completely established, it is believed to involve temporary hypoperfusion or nonperfusion of the vessels supplying the anterior portion of the optic nerve, although intra-axonal edema and disturbed autoregulation to the optic nerve head may also play a role.[116] Coexisting systemic disease, especially involving the cardiovascular system and (to a lesser extent) the endocrine system, is common in patients in whom AION develops. Male gender also strongly predominates. Other risk factors for postoperative AION include CABG and other thoracovascular operations, as well as spinal surgery. Although massive bleeding, anemia, and hypotension are commonly described intraoperative risk factors, a retrospective survey of surgeons who perform spinal fusion surgery disclosed that hypotension and anemia were equally prevalent in patients in whom ION developed and in those in whom it did not.[119] Other possible risk factors are increased IOP or orbital venous pressure. Although emboli may also play a role, AION is not usually caused by emboli because emboli preferentially lodge in the central retinal artery rather than in the short posterior ciliary arteries that supply the anterior optic nerve.

Increased IOP caused by extrinsic compression of the eye decreases retinal blood flow that can produce both retinal and optic nerve injury. Moreover, increased IOP can result from large infusions of crystalloid when the head is steeply dependent, as during many spinal operations.[120] Increased orbital venous pressure results in a decreased perfusion pressure gradient to the optic nerve head. Interestingly, one patient who had ION despite perioperative normotension had marked facial edema after surgery of protracted duration.[120] Similarly, a study in cardiac surgery patients revealed that increases in IOP correlated with the degree of hemodilution and the use of crystalloid priming solution.[121] Patients with AION were more likely to have significant weight gain within 24 hours of open heart surgery, again suggesting the role of elevated ocular venous pressure in impeding blood flow to the optic nerve.

According to Roth and Gillesberg,[116] a complex interaction of factors such as ocular venous pressure, hemodilution, hypotension, release of endogenous vasoconstrictors, and individual risk factors such as atherosclerosis and aberrant optic nerve circulation may be implicated in the development of AION. Therefore, specific recommendations for preventative strategies are elusive. Clearly, however, external pressure on the eyes must be meticulously avoided. It also seems prudent to minimize time in the prone position when the head is notably dependent. In patients with preexisting cardiovascular disease, significant hypertension, or glaucoma, it seems advisable to maintain systemic blood pressure as close to baseline as possible.[116] Recommendations about specific hematocrit levels are difficult to make at this time and should be individualized based on a constellation of circumstances, but it seems prudent to have a different "transfusion threshold" in high-risk patients.

Patients with AION typically have painless visual loss that may not be noted until the first postoperative day (or possibly later), an afferent pupillary defect, altitudinal field defects, and optic disc edema or pallor. MRI or CT initially show enlargement of the optic nerve. However, optic atrophy is detected by MRI later.

The prognosis for AION varies but is often grim. Although there is no recognized treatment for AION, Williams et al.[122] reviewed the various therapies that may be instituted. These include intravenous acetazolamide, furosemide, mannitol, and steroids. Maintaining the head-up position could be helpful if increased ocular venous pressure is operative. Surgical optic nerve sheath fenestration or decompression is not only ineffective, but may actually be harmful.[123]

Posterior ischemic Optic Neuropathy

The posterior optic nerve has a less luxuriant blood supply than the anterior optic nerve. In contrast to AION, relatively few cases have been reported after CABG, and PION appears to be less related to coexisting cardiovascular disease. As with AION, male patients outnumber female patients four to one. Many cases have been associated with surgery involving the

neck, nose, sinuses, or spine. In approximately one-third of cases reported, facial edema has been noted.[116] Approximately 11% of cases were associated with cardiopulmonary bypass procedures.

PION is produced by reduced oxygen delivery to the retrolaminar part of the optic nerve. Most likely, compression of the pial vessels (supplied by small collaterals from the ophthalmic artery) or embolic phenomena produce ischemia. However, severe systemic hypotension, anemia, or venous stasis may also be contributory.[116]

A hypoxic insult in this region results in a slower development of ischemic damage so a symptom-free period often precedes the loss of vision. In some patients, the onset of symptoms may be delayed several days. Typical findings include an afferent pupillary defect or nonreactive pupil. Disc edema is not a feature of PION because of its retroorbital position. CT scan in the early postoperative period may reveal enlargement of the intraorbital portion of the optic nerve. Bilateral blindness is more common with PION than AION, possibly indicating involvement of the optic chiasm. Concomitant disease of the eye or ocular blood supply may be related to PION.[116] Some cases may show partial improvement spontaneously, but often no improvement is noted. Steroids may be considered for treatment. Preventative strategies are as outlined for AION.

Cortical Blindness

Brain injury rostral to the optic nerve may cause cortical blindness. The impairment is produced by damage to the visual path beyond the lateral geniculate nucleus or the visual cortex in the occipital lobe. Similar to AION, cortical blindness is a significant concern in patients undergoing CABG, and systemic disease is often present. Emboli and sustained, profound hypotension are common causes. Other events implicated in the pathophysiology include cardiac arrest, hypoxemia, intracranial hypertension, exsanguinating hemorrhage, vascular occlusion, thrombosis, and vasospasm.

Differential diagnostic features include a normal optic disc on fundoscopy and normal pupillary responses. There is, however, loss of optokinetic nystagmus with normal eye motility. CT and MRI are helpful in delineating the extent of brain infarction associated with cortical blindness. Occipital lesions are frequently bilateral and CT findings typically indicate posterior cerebral artery thrombosis, basilar artery occlusion, posterior cerebral artery branch occlusion, or watershed infarction. Lesions after CABG often include the parietooccipital area.

Whereas most cases of ION do not improve significantly or completely, visual recovery from cortical blindness in previously healthy patients may be considerable but prolonged. Preventive strategies include maintenance of adequate systemic perfusion pressure and, in cardiac surgery, minimizing manipulation of the aorta, meticulous removal of air and particulate matter during valvular procedures, and use of an arterial line filter in selected patients during bypass.

Visual Symptoms After Transurethral Resection of the Prostate

Visual disturbances associated with transurethral resection of the prostate (TURP) are transient and often the result of the TURP syndrome, wherein excessive absorption of irrigating fluid can produce cardiac failure, hyponatremia, serious dysrhythmias, seizures, and coma. Visual disturbances can extend the gamut from subtle changes, such as seeing halos or a bluish hue, to complete absence of light perception.

Liberal bladder irrigation is required during TURP to remove clots and other detritus to enhance visibility for the surgeon. Factors postulated to influence the volume of irrigant absorbed include the extent of opening of the prostatic venous sinuses, the hydrostatic pressure of the irrigation fluid, the venous pressure at the irrigant–blood interface, and, arguably, the duration of the

resection.

Glycine 1.5%, although slightly hypoosmolar, does not cause clinically significant hemolysis and is one of the most commonly used irrigating solutions. Glycine toxicity is probably the most important mechanism resulting in TURP-associated visual dysfunction, although the disturbance may be multifactorial. An inhibitory neurotransmitter in the CNS, glycine freely crosses the blood–brain barrier and depresses the spontaneous and evoked activity of retinal neurons. In addition, glycine is metabolized to serine and ammonia, both of which have been linked to CNS disturbances after TURP. Serine is known to have inhibitory effects on the retina similar to those produced by glycine.

Hyponatremia can occur independently of glycine toxicity and produce hypoosmolality-induced CNS dysfunction. The degree of brain dysfunction is determined by the rapidity and the severity of the reduction in sodium concentration. Symptoms include hallucinations, psychosis, focal neurologic signs, seizures, and coma. It has been suggested that TURP-associated hypoosmolality produces occipital cortical edema, but this has not been definitively established.

Preventive strategy should focus on taking all possible measures to avoid excessive absorption of irrigating solution. Moreover, a high index of suspicion is necessary because significant amounts of irrigant may be absorbed even if the surgeon does not see any open venous sinuses. Thus, it is difficult, if not impossible, to estimate the degree of fluid absorption without confirmatory laboratory data.

Acute Glaucoma

Although topical application of such mydriatic drugs as atropine and scopolamine is contraindicated in patients with known, chronic glaucoma, the systemic use of anticholinergics in usual premedicating doses is safe for glaucomatous eyes. The use of an atropine–neostigmine combination for reversal of neuromuscular blockade is also safe in patients with glaucoma. Topical ophthalmic medications that are being administered to control glaucoma should be continued through the perioperative period.

Acute angle-closure glaucoma typically occurs spontaneously but has been reported, albeit rarely, after both spinal and general anesthesia. Acute angle-closure glaucoma caused by pupillary block is a serious, multifactorial disease. Risk factors include genetic predisposition, shallow anterior chamber depth, increased lens thickness, small corneal diameter, female gender, and advanced age. One study[124] explored possible precipitating events in at-risk patients and found no evidence that the type of anesthetic agent, the duration of surgery, the volume of parenteral fluids, or the intraoperative blood pressure were related to the development of acute angle-closure glaucoma.

Despite its seriousness, acute angle-closure glaucoma may be difficult to recognize. However, physicians should be knowledgeable about this potential complication because diagnostic delay may detrimentally affect visual outcome and cause permanent optic nerve damage. Fazio et al.[125] recommended that the preoperative evaluation include a thorough ocular history and a penlight examination to detect a shallow anterior chamber. Those patients considered at risk should then undergo a preoperative ophthalmic evaluation and perioperative miotic therapy. After surgery, these patients should be scrupulously watched for red eye or a fixed dilated pupil, as well as for

complaints of pain and blurred vision. Acute glaucoma is a true emergency, and ophthalmologic consultation should be secured immediately to acutely decrease IOP with systemic and topical therapy. The intense periorbital pain typically described by these patients is an important aid in differential diagnosis.

Postcataract Ptosis

Ptosis after cataract surgery is not uncommon, and multiple factors have been implicated in its etiology.[126,127] These include the presence of a preexisting ptosis, injection of anesthetic solution into the upper lid when performing facial nerve block, retrobulbar injection, injection of peribulbar anesthesia through the upper eyelid at the 12 o'clock position, ocular compression or massage,

the eyelid speculum, placement of a superior rectus bridle suture with traction on the superior rectus–levator complex, creation of a large conjunctival flap, prolonged or tight patching in the postoperative period, and postoperative eyelid edema. Feibel and colleagues[126] believed that the development of postcataract ptosis is multifactorial and that no single aspect of cataract surgery is the sole contributor. More recently, Taylor et al. used MRI immediately after diagnosis of diplopia in four patients who received peribulbar block.[127] They found peribulbar edema consistent with direct local anesthetic-induced myotoxicity after presumed inadvertent intramuscular injection. Although local anesthetics are clearly myotoxic, the local anesthetic injection cannot be isolated as the primary factor because postsurgical ptosis is also seen in patients undergoing surgery with general anesthesia.

Chapter 34

Anesthesia for Otolaryngologic Surgery

Lynne R. Ferrari

Alexander W. Gotta

KEY POINTS

1	The restricted spaces in the airway require an understanding and cooperative relationship between surgeon and anesthesiologist, and the use of specially adapted equipment suitable to these cramped areas.
2	Despite only mild to moderate tonsillar enlargement on physical examination, children with obstructive sleep apnea have upper airway obstruction while awake and apnea during sleep. The clinician should not underestimate the severity of the problem based on tonsillar size alone.
3	Posttonsillar hemorrhage may result in unappreciated large volumes of swallowed blood originating from the tonsillar fossa. These patients must be considered to have a full stomach, and anesthetic precautions addressing this situation must be taken.
4	The middle ear and sinuses are air-filled, nondistensible cavities. During procedures in which the eardrum is replaced or perforation is patched, N_2O should be discontinued or, if this is not possible, limited to a maximum of 50% during the application of the tympanic membrane graft to avoid pressure-related displacement.
5	In a LeFort Iii fracture, the fracture line may pass through the cribriform plate of the ethmoid bone, creating a fistula between the nasopharynx and the subarachnoid space within the skull. Clinical and radiographic studies are mandated to determine the integrity of the cribriform plate.
6	Upper airway tumors may be friable and lead to significant hemorrhage during intubation. Prior radiation therapy may lead to fibrosis and ankylosis in the temporomandibular joint, rendering orotracheal intubation difficult.
7	Prior to extubation after temporomandibular arthroscopy, the oral cavity and neck must be examined carefully to rule out the presence of extracapsular extravasation of irrigation fluid. Extravasation can lead to airway closure.

8 After extensive facial trauma or resection of tumors of the upper airway, it is prudent to keep the patient intubated until edema has subsided. Extraoral facial edema should lead the physician to suspect intraoral edema and possible airway compromise.

1 The anesthetic management of a patient undergoing surgery of the head, neck, ear, nose, and throat challenges the anesthesiologist to devise an anesthetic plan that will accommodate the needs of the surgeon, anesthesiologist, and patient. Among the problems that must be solved are the following:

1. Diagnosing alterations in a patient's airway created by infection, tumor, trauma, or congenital defect
2. Establishing and maintaining the airway in a patient whose anatomy has been distorted
3. Creating a shared operative field that enables the anesthesiologist to ventilate the patient's lungs and monitor the patient safely, and allows the surgeon to perform his or her tasks
4. Selecting appropriate anesthetic drugs compatible with the surgical procedure
5. Defining the appropriate moment for extubating the trachea of the postoperative patient

EVALUATING THE AIRWAY

In the healthy human, air flows through the upper respiratory passages; into the trachea, bronchi, and bronchioles; and into alveoli. This occurs seemingly without either thought or effort, and the actual work of respiration in the unobstructed airway is minimal. However, airway obstruction due to tumor, infection,

or trauma may significantly alter the clinical presentation and make gas exchange a laborious, energy-consuming process. This may leave the patient exhausted, incapable of maintaining adequate gas exchange, and finally succumbing to respiratory failure. Clinically, evident upper airway obstruction is a late sign, significant obstruction and anatomic distortion may be present in a patient with minimal evidence of disease. It is a most unwelcome experience for the anesthesiologist to discover a large, unexpected, obstructed upper airway at the time of attempted tracheal intubation.

In the presence of tumor, other mass lesions, or infection in the airway, it may be useful to obtain radiologic evaluation of the airway with plain films of the tracheal and laryngeal air columns or computed tomography (Ct) and magnetic resonance imaging studies of the airway. Significant anatomic distortion is usually evident and may help the anesthesiologist determine the most appropriate technique for securing the airway.

ANESTHESIA FOR PEDIATRIC EAR, NOSE, AND THROAT SURGERY

Particularly challenging to the anesthesiologist is the safe management of the pediatric patient undergoing surgery of the ear, nose, and throat (Ent). The restricted spaces in the airway of the child require an understanding and cooperative relationship between surgeon and anesthesiologist, and the use of specially adapted equipment suitable to these cramped areas.

Tonsillectomy and Adenoidectomy

Untreated adenoidal hyperplasia may lead to nasopharyngeal obstruction, causing failure to thrive, speech disorders, obligate mouth breathing, sleep disturbances, orofacial abnormalities with a narrowing of the upper airway, and dental abnormalities. Surgical removal of the adenoids is usually accompanied by tonsillectomy; however, purulent adenitis, despite adequate medical therapy, and recurrent otitis media with effusion secondary to adenoidal hyperplasia are improved with adenoidectomy alone.

Tonsillectomy is one of the more commonly performed pediatric surgical procedures today.[1] Chronic or recurrent acute tonsillitis, peritonsillar abscess, tonsillar hyperplasia, and obstructive sleep apnea syndrome are the major indications for surgery.[2,3,4] In addition, patients with cardiac valvular disease are at risk for endocarditis from recurrent streptococcal bacteremia secondary to infected tonsils. Tonsillar hyperplasia may lead to chronic airway obstruction resulting in sleep apnea, Co_2 retention, cor pulmonale, failure to thrive, swallowing disorders, and speech abnormalities. These risks are eliminated with removal of the tonsils.

Obstruction of the oropharyngeal airway by hypertrophied tonsils leading to apnea during sleep is an important clinical syndrome referred to as *obstructive sleep apnea syndrome.* Despite only mild to moderate tonsillar enlargement on physical examination, these patients have upper airway obstruction while awake and apnea during sleep. The goals of treatment are to relieve airway obstruction and increase the cross-sectional area of the pharynx, which is successful in two-thirds of cases.[5] Some patients require the use of nasal constant positive airway pressure during sleep, whereas others may require a tracheostomy to bypass the chronic upper airway obstruction that is present. The two most frequent levels of obstruction during sleep are at the soft palate and the base of the tongue.[6] Most children will have tremendous improvement in their symptoms after tonsillectomy.

2 In children with long-standing hypoxemia and hypercarbia, increased airway resistance can lead to cor pulmonale (Fig. 34-1). Patients have electrocardiographic evidence of right ventricular hypertrophy, with one-third of them having chest radiographs consistent with cardiomegaly. Each apneic episode causes progressively increasing pulmonary artery pressure with significant systemic and pulmonary artery hypertension leading to ventricular dysfunction and cardiac dysrhythmias.[7] Often, these patients have dysfunction in the medulla or hypothalamic areas of the central nervous system causing persistently elevated Co_2, despite relief of airway obstruction. This group of patients has a hyperreactive pulmonary vascular bed, and the increased pulmonary vascular resistance and myocardial depression in response to hypoxia, hypercarbia, and acidosis are far greater than what is expected for that degree of physiologic alteration in the normal population. Cardiac enlargement is frequently reversible with digitalization and surgical removal of the tonsils and adenoids.

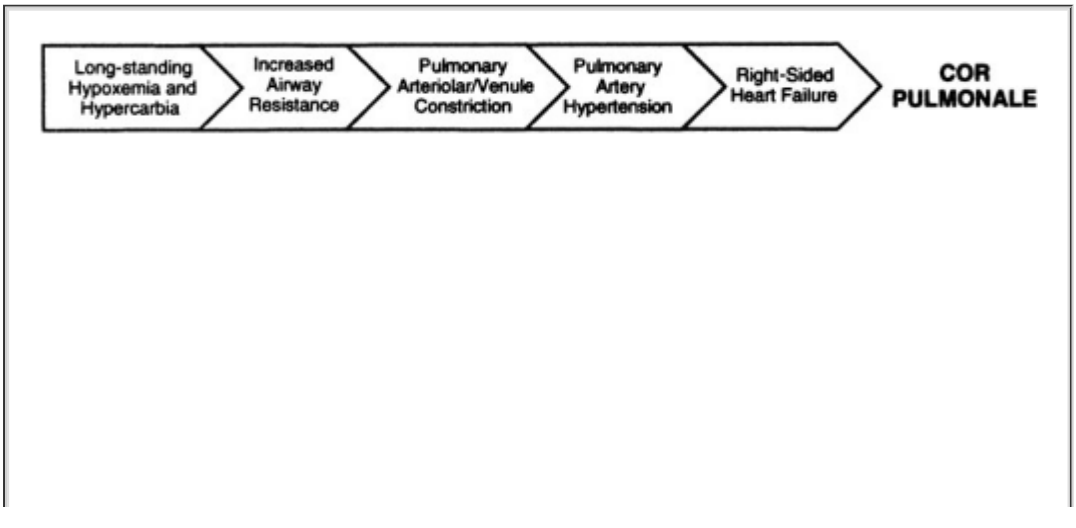

FIGURE 34-1. Events leading to cor pulmonale.

Preoperative Evaluation

A thorough history is the basis for the preoperative evaluation. Because patients requiring tonsillectomy and adenoidectomy have frequent infections, the parent should be questioned for current use of antibiotics, antihistamines, or other medicines. A history of sleep apnea should be sought. The physical examination should begin with observation of the patient. The presence of audible respirations, mouth breathing, nasal quality of the speech, and chest retractions should be noted. Mouth breathing may be the result of chronic nasopharyngeal obstruction. An elongated face, retrognathic mandible, and a high-arched palate may be present.[8] The oropharynx should be inspected for evaluation of tonsillar size to determine the ease of mask ventilation and tracheal intubation (Fig. 34-2). The presence of wheezing or rales on auscultation of the chest may be a result of lower respiratory manifestation of pharyngitis or tonsillitis. The presence of inspiratory stridor or prolonged expiration may indicate partial airway obstruction from hypertrophied tonsils or adenoids.

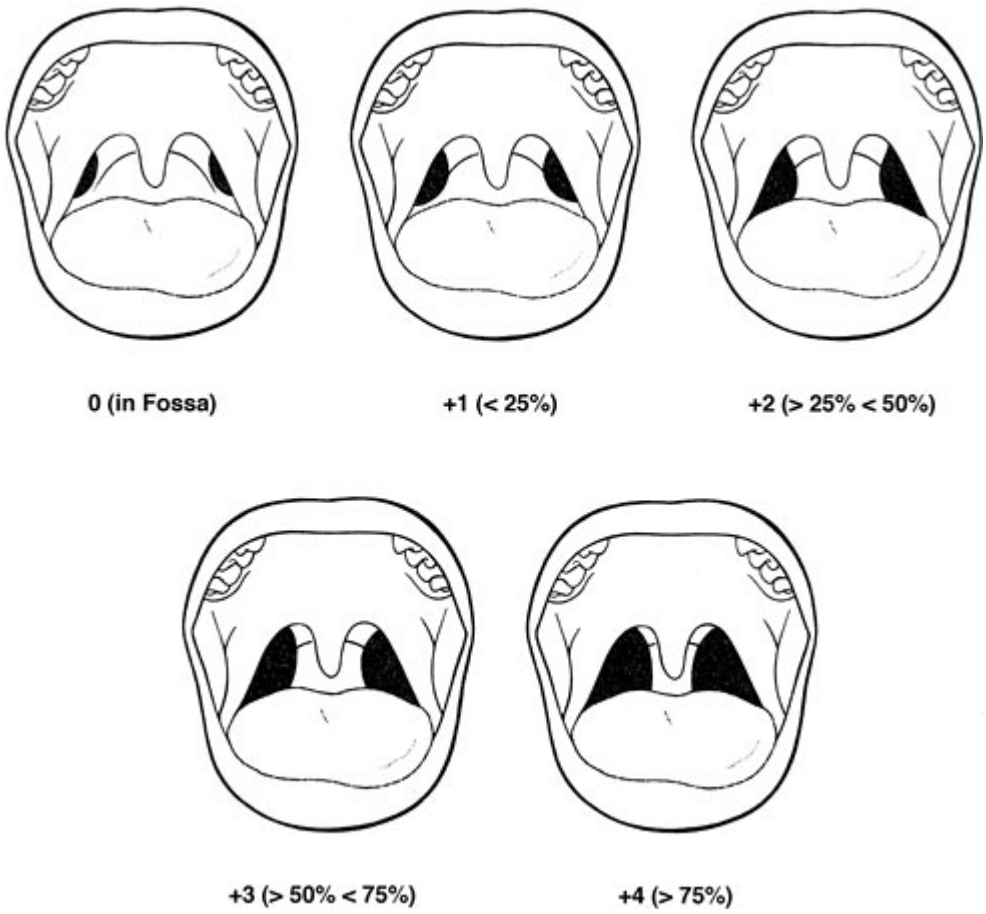

FIGURE 34-2. Classification of tonsil size, including percentage of oropharyngeal area occupied by hypertrophied tonsils.

Measurement of hematocrit and coagulation PARAmeters is suggested. Many nonprescription cold medications and antihistamines contain aspirin, which may affect platelet function, and this should be taken into consideration. Chest radiographs and electrocardiograms (Ecgs) are not required unless specific history of abnormalities in these areas is elicited, such as recent pneumonia, bronchitis, upper respiratory infection (Uri), or history consistent with cor pulmonale. In those

children with a history of cardiac abnormalities, an echocardiogram may be indicated.

Anesthetic Management

The goals of the anesthesia for tonsillectomy and adenoidectomy are to render the child unconscious in the most atraumatic manner possible, provide the surgeon with optimal operating conditions, establish intravenous access to provide a route for

volume expansion and medications should they be necessary, and to provide rapid emergence so the patient is awake and able to protect the recently instrumented airway. Premedication may be used as determined by the anesthesiologist during the preanesthetic visit. Sedative premedication should be avoided in children with obstructive sleep apnea, intermittent obstruction, or very large tonsils. An antisialagogue is often included to minimize secretions in the operative field.

Anesthesia is usually induced with a volatile drug, oxygen, and nitrous oxide (N_2O) by mask. Parental presence in the operating room (Or) during mask induction is often helpful in the anxious unpremedicated child. Tracheal intubation is best accomplished under deep inhalation anesthesia or aided by a short-acting nondepolarizing muscle relaxant. The possibility exists for blood in the pharynx to enter the trachea during the surgical procedure. For this reason, the supraglottic area may be packed with petroleum gauze, or a cuffed endotracheal tube may be used provided an appropriate leak around the endotracheal tube is obtained. Monitoring consists of precordial stethoscope, Ecg, automated blood pressure, pulse oximetry, and end-tidal Co_2.

Emergence from anesthesia should be rapid, and the child should be alert before transfer to the recovery area. The child should be awake and able to clear blood or secretions in the oropharynx as efficiently as possible before removal of the endotracheal tube. Maintenance of airway and pharyngeal reflexes is of utmost importance in the prevention of aspiration, laryngospasm, and airway obstruction. There is no difference in the incidence of airway complications on emergence between patients who are extubated awake or deep.[9]

The use of the laryngeal mask airway (Lma) for adenotonsillectomy was described in 1990; however, it was not until the widespread availability of a streamlined flexible model that it was widely used.[10,11] The wide, rigid tube of the original model did not fit under the mouth gag and was easily compressed or dislodged during full mouth opening. The newer, flexible model has a soft, reinforced shaft that easily fits under the mouth gag without becoming dislodged or compressed. Adequate surgical access can be achieved, and the lower airway is protected from exposure to blood during the procedure.[12,13]

Insertion is possible after either the intravenous administration of 3.5 mg/kg propofol or when sufficient depth of anesthesia is achieved using a volatile agent administered by mask. The same depth of anesthesia should be obtained during insertion of the Lma as would be required for performing laryngoscopy and endotracheal intubation. Positive-pressure ventilation should be avoided when the Lma is used during tonsillectomy, although gentle assisted ventilation is both safe and effective if peak inspiratory pressure is kept below 20 cm H_2O.[14]

Tonsillar enlargement can make Lma insertion difficult, so care in placement is essential.[15] Maneuvers to overcome this difficulty include increased head extension, lateral insertion of the mask, anterior displacement of the tongue, pressure on the tip of the Lma using the index finger as it negotiates the pharyngeal curve, or use of the laryngoscope if all else fails. Dislodgment of the device does not occur during extreme head extension, assuming good position and ventilation were obtained before changes in head position.[16]

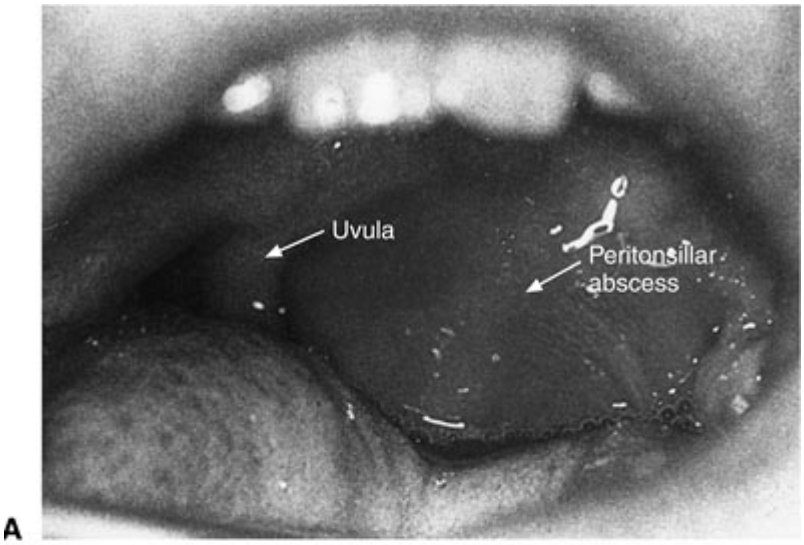
Advantages of the Lma over traditional endotracheal intubation are a decrease in the incidence of postoperative stridor and laryngospasm and an increase in immediate postoperative oxygen saturation. If the child is breathing spontaneously at a regular rate and depth, the Lma may be removed before emergence from anesthesia. The oropharynx should be gently suctioned with a soft, flexible catheter, the Lma deflated and removed, an oral airway inserted, and the respirations assisted with 100% oxygen delivered by mask. It is often distressing for young children to awaken with the Lma still in place, and although the device is an appropriate

substitute for oral airway in the adult population, the same is not so in children. If the practitioner wants to remove the Lma when the child has emerged from anesthesia, it should be deflated and removed as soon as possible after the return to consciousness.

Complications

The incidence of emesis after tonsillectomy ranges from 30 to 65%.[17] Whether this is due to irritant blood in the stomach or interference with the gag reflex by inflammation and edema

at the surgical site remains unclear. Central nervous system stimulation from the gastrointestinal tract, as may be seen with gastric distention from the introduction of swallowed or insufflated air, may trigger the emetic center. Decompressing the stomach with an orogastric tube may be helpful in preventing this response. Treatment with ondansetron 0.10 to 0.15 mg/kg either with or without dexamethasone has been shown to be very effective in reducing posttonsillectomy nausea and vomiting.[18] Postoperative administration of meperidine increases the probability of emesis, and other analgesic agents should be administered. Dehydration secondary to poor oral intake as a result of nausea, vomiting, or pain can occur after tonsillectomy in 1% of cases. Vigorous intravenous hydration during surgery can offset the physiologic effects of later decreases in fluid intake.



3 The most serious complication of tonsillectomy is postoperative hemorrhage, which occurs at a frequency of 0.1 to 8.1%. Approximately 75% of postoperative tonsillar hemorrhage occurs within 6 hours of surgery. Most of the remaining 25% occurs within the first 24 hours of surgery, although bleeding may be noted until the sixth postoperative day.[19] Sixty-seven percent of postoperative bleeding originates from the tonsillar fossa, 27% in the nasopharynx, and 7% in both. Initial attempts to control bleeding may be made using pharyngeal packs and cautery. If this fails, patients must return to the Or for exploration and surgical hemostasis.

Unappreciated large volumes of blood originating from the tonsillar bed may be swallowed. These patients must be considered to have a full stomach, and anesthetic precautions addressing this situation must be taken. A rapid sequence induction accompanied by cricoid pressure and a styletted endotracheal tube is often recommended. Because the amount of blood swallowed can be considerable, blood pressure must be checked in both the erect and supine positions to look for orthostatic changes resulting from decreases in vascular volume. Intravenous access and hydration must be established before the induction of anesthesia. A variety of laryngoscope blades and endotracheal tubes, as well as functioning suction apPARAtus, should be prepared in duplicate because blood in the airway may impair visualization of the vocal cords and cause plugging of the endotracheal tube.

Pain after adenoidectomy is usually minimal but is severe after tonsillectomy. This contributes to poor fluid intake and overall discomfort of patients. An increase in postoperative pain medication requirements has been noted in patients having laser or electrocautery as part of the operative tonsillectomy compared with those who have had sharp surgical dissection and ligation of blood vessels to achieve hemostasis.[20] Intraoperative administration of corticosteroids may decrease edema formation and subsequent patient discomfort. Although infiltration of the peritonsillar space with local anesthetic and epinephrine has been shown to be effective in reducing intraoperative blood loss, it does not decrease postoperative pain.[21]

Peritonsillar abscess, or quinsy tonsil, is a condition that may require immediate surgical intervention to relieve potential or existing airway obstruction. An acutely infected tonsil may undergo abscess formation, producing a large mass in the lateral pharynx that can interfere with swallowing and breathing (Figs. 34-3 to 34-5). Fever, pain, and trismus are frequent symptoms. Treatment consists of surgical drainage of the abscess, either with or without tonsillectomy, and intravenous antibiotic therapy. Although the airway seems compromised, the peritonsillar abscess is usually in a fixed location in the lateral pharynx and does not interfere with ventilation of the patient by mask after induction of general anesthesia. Visualization of the vocal cords should not be impaired because the pathologic process is supraglottic and well above the laryngeal inlet. Laryngoscopy must be carefully performed, avoiding manipulation of the larynx and surrounding

structures. Intubation should be gentle because the tonsillar area is tense and friable and inadvertent rupture of the abscess can occur, leading to spillage of purulent material into the trachea.

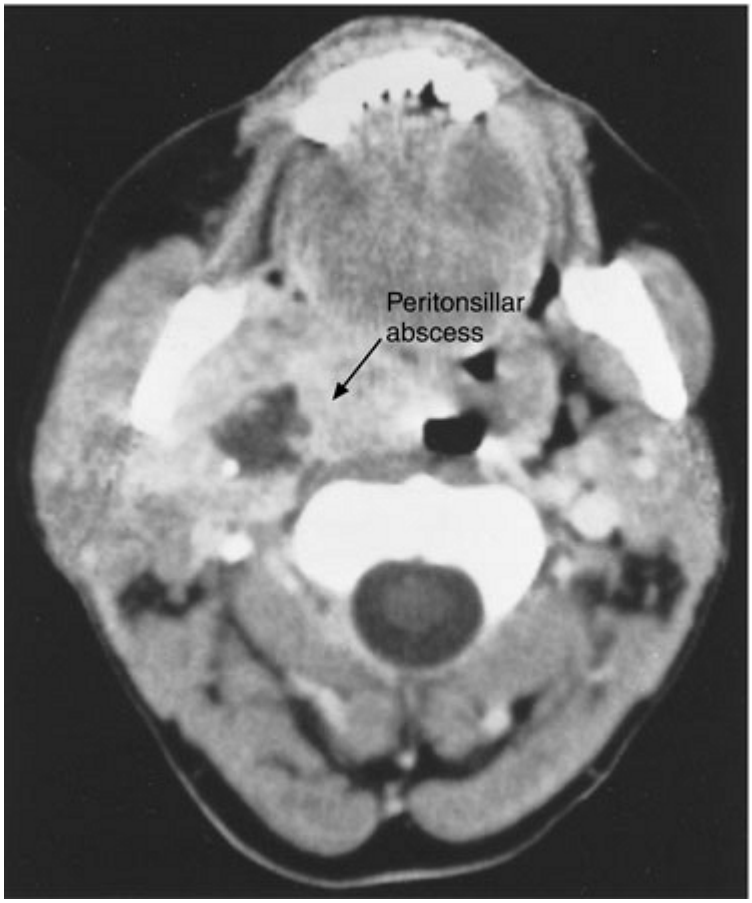

FIGURE 34-5. Computed tomography scan of a patient with a peritonsillar abscess.

Acute postoperative pulmonary edema is an infrequent but potentially life-threatening complication encountered when airway obstruction is suddenly relieved. One proposed mechanism is that during inspiration before adenotonsillectomy, the negative intrapleural pressure that is generated causes an increase in venous return, enhancing pulmonary blood volume. In the healthy child without airway obstruction, pleural pressure ranges from –2.5 cm to –10.0 cm H_2O during inspiration. Intrapleural pressure generated in the child with airway obstruction can be as much as –30 cm H_2O, which when transmitted to the interstitial peribronchial and perivascular spaces causes disruption of the capillary walls of the pulmonary microvasculature. Concurrent with a negative transpulmonary gradient is an increase in venous return to the right side of the heart, thus increasing preload, which in the setting of “leaky capillaries” facilitates transudation of fluid into the alveolar space. To counterbalance this, positive intrapleural and alveolar pressure is generated during exhalation, which decreases pulmonary venous return and blood volume. This is similar to an expiratory “grunt” mechanism in which the transpleural pressures generated are similar to those present during a Valsalva maneuver.

The rapid relief of airway obstruction results in decreased airway pressure, an increase in venous return, an increase in pulmonary hydrostatic pressure, hyperemia, and finally

pulmonary edema. The all-important counterbalance of the expiratory “grunt” in limiting pulmonary venous return is lost when the obstruction is relieved. Contributing factors are the increased volume load on both ventricles, as well as the inability of the pulmonary lymphatic system to remove acutely large amounts of fluid. The anesthesiologist may attempt to prevent this situation during induction of anesthesia by applying moderate amounts of continuous positive pressure to the airway, thus allowing time for circulatory adaptation to take place. This physiologic sequence is similar to that seen in patients with severe acute airway obstruction

secondary to epiglottitis or laryngospasm.

Negative-pressure pulmonary edema is signaled by the appearance of frothy pink fluid in the endotracheal tube of an intubated patient or the presence of a decreased oxygen saturation, wheezing, dyspnea, and increased respiratory rate in the immediate postoperative period in a previously extubated patient. Mild cases may present with minimal symptoms. The differential diagnosis of negative-pressure pulmonary edema includes aspiration of gastric contents, adult respiratory distress syndrome, congestive heart failure, volume overload, and anaphylaxis. A chest radiograph illustrating diffuse, usually bilateral interstitial pulmonary infiltrates combined with an appropriate clinical history will confirm the diagnosis.[22]

Treatment is usually supportive, with maintenance of a patent airway, oxygen administration, and diuretic therapy in some cases. Endotracheal intubation and mechanical ventilation with positive end-expiratory pressure may be necessary in severe cases. Resolution is usually rapid and may occur within hours of surgery. Most cases resolve without treatment within 24 hours. There is currently no reliable method for predicting which children will experience this clinical syndrome after their airway obstruction has been resolved.[23]

Adenoidectomy patients may be safely discharged on the same day after recovering from anesthesia. Tonsillectomy has been a procedure that warranted postoperative admission of the patient to the hospital for observation, administration of analgesics, and hydration. Many centers are discharging tonsillectomy patients on the day of surgery without adverse outcomes, and this trend will likely continue.[19,20,24,25] It is recommended that patients be observed for early hemorrhage for a minimum of 6 hours and be free from significant nausea, vomiting, and pain prior to discharge. Ability to take fluid by mouth is not a requirement for discharge home. However, intravenous hydration must be adequate to prevent dehydration. Excessive somnolence and severe vomiting are indications for hospital admission. There is a set of patients in whom early discharge is not advised, and those patients should be admitted to the hospital after tonsillectomy. The characteristics of such patients are LISTed in Table 34-1.[26]

TABLE 34-1 Tonsillectomy and Adenoidectomy Inpatient Guidelines: Recommendation of the American Academy Of Otolaryngology–Head and Neck Surgery Pediatric Otolaryngology Committee

Admit patients to the hospital after adenotonsillectomy if they meet any of the following criteria:

- Age ⩽3 yr
- Abnormal coagulation values with or without an identified bleeding disorder in the patient or family
- Evidence of obstructive sleep disorder or apnea due to tonsillar or adenoidal hypertrophy
- Systemic disorders that put the patient at increased preoperative cardiopulmonary, metabolic, or general medical risk
- Child with craniofacial or other airway abnormalities, including, but not limited to, syndromic disorders such as Treacher Collins syndrome, Crouzon's syndrome, Goldenhar syndrome, Pierre Robin anomalad, C.H.A.R.G.E. association, achondroplasia, and, most prominently, Down syndrome, as well as isolated airway abnormalities such as choanal atresia and laryngotracheal stenosis
- When the procedure is being done for acute peritonsillar abscess
- When extended travel time, weather conditions, and home social conditions are not consistent with close observation, cooperation, and ability to return to the hospital quickly at the discretion of the attending physician

Ear Surgery

The ear and its associated structures are target organs for many pathologic conditions. General anesthesia for surgery of the ear has its own set of unique considerations that must be addressed.

Myringotomy and Tube Insertion

Chronic serous otitis in children can lead to hearing loss, and drainage of accumulated fluid in the middle ear is effective treatment for this condition. Myringotomy, which creates an

opening in the tympanic membrane for fluid drainage, may be performed alone. During healing, the drainage path may become occluded. Therefore, tube placement is usually included. The insertion of a small plastic tube in the tympanic membrane serves as a vent for the ostium and allows for continued drainage of the middle ear until the tubes are naturally extruded in 6 months to 1 year or surgically removed at an appropriate time (Fig. 34-6).

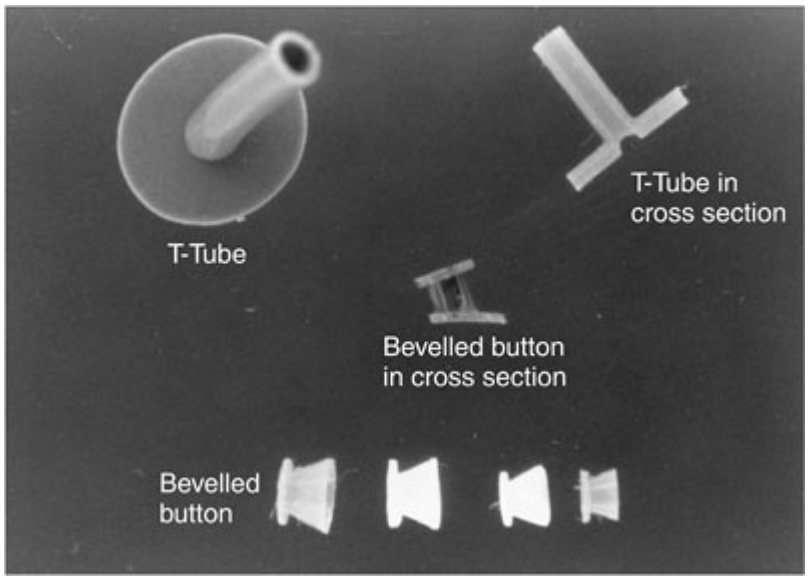

FIGURE 34-6. Two types of myringotomy tubes, both are 2.5 mm in internal diameter. Both the ventilating T-tube and the beveled-button ventilating tube (large and small) are shown in full and cross-sectional views. (Courtesy of Michael Cunningham, Md, Boston, Ma.)

Myringotomy and tube insertion is a relatively short procedure, and anesthesia may be effectively accomplished with a potent inhalation drug, oxygen, and N_2O administered by mask. Premedication is not recommended because most sedative drugs used for premedication will far outlast the duration of the surgical procedure. Patients with chronic otitis frequently have accompanying recurrent Uris. It is often the eradication of middle ear fluid that resolves the concomitant Uri. Because tracheal intubation is not required for routine patients, the criteria for cancellation of surgery and anesthesia may be different for this procedure. No significant difference in perioperative morbidity between asymptomatic patients and those fulfilling Uri criteria has been demonstrated.[27,28] It is recommended that patients with Uri symptoms receive supplemental postoperative oxygen.[29]

Middle Ear and Mastoid

Tympanoplasty and mastoidectomy are two of the most common procedures performed on the middle ear and accessory structures. To gain access to the surgical site, the head is positioned on a head rest, which may be lower than the operative table, and extreme degrees of lateral rotation may be required. Extreme tension on the heads of the sternocleidomastoid muscles must be

avoided. The laxity of the ligaments of the cervical spine and the immaturity of odontoid process in children make them especially prone to C1–C2 subluxation.

Ear surgery often involves surgical identification and preservation of the facial nerve, which requires isolation of the nerve by the surgeon and verification of its function by means of electrical stimulation (Fig. 34-7). This is accomplished by brainstem auditory-evoked potential and electrocochleogram monitoring, which requires that muscle relaxation be avoided and a volatile drug is the primary anesthetic.[30] If an opioid-relaxant technique is chosen, however, at least 30% of the muscle response, as determined by a twitch monitor, should be preserved. This suggests that it is not mandatory to avoid skeletal muscle relaxants in the anesthetic management of patients undergoing surgical procedures when monitoring of facial nerve function is necessary.

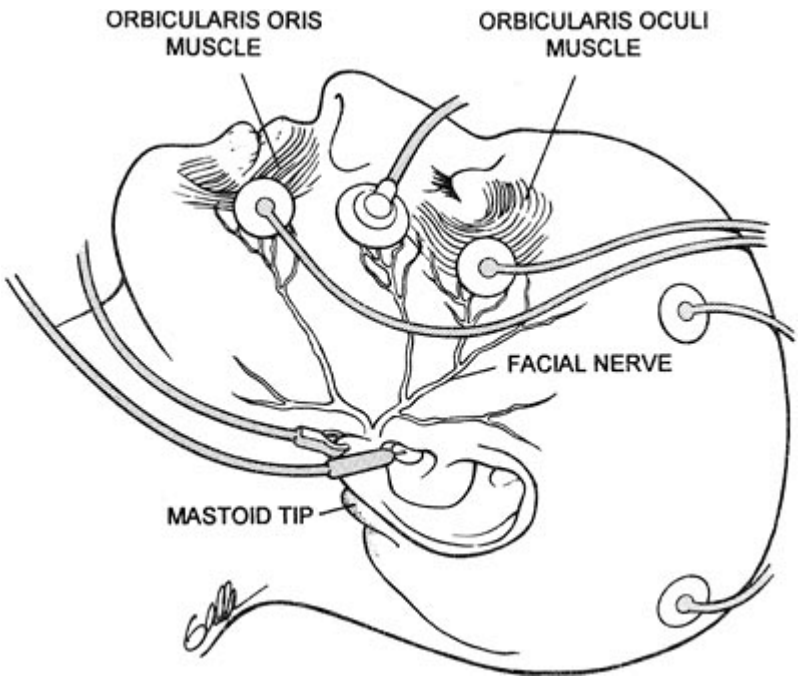

FIGURE 34-7. Illustration of facial nerve and monitoring electrodes. (Courtesy of Steve Ronner, PhD, Boston, Ma.)

Bleeding must be kept to a minimum during surgery of the small structures of the middle ear. Relative hypotension, keeping the mean arterial pressure 25% below baseline, is effective. Concentrated epinephrine solution, often 1:1,000, can be injected in the area of the tympanic vessels to produce

vasoconstriction. Close attention should be paid to the volume of injected epinephrine to avoid dysrhythmias and wide swings in blood pressure.

4 The middle ear and sinuses are air-filled, nondistensible cavities. An increase in the volume of gas in these structures results in an increase in pressure. N_2O diffuses along a concentration gradient into the air-filled middle ear spaces more rapidly than nitrogen moves out. Passive venting occurs at 20 to 30 cm H_2O pressure, and it has been shown that use of N_2O results in pressures that exceed the ability of the eustachian tube to vent the middle ear within 5 minutes, leading to pressure buildup.[31] During procedures in which the eardrum is replaced or perforation is patched, N_2O should be discontinued or, if this is not possible, limited to a maximum of 50% during the application of the tympanic membrane graft to avoid pressure-related displacement.

After N_2O is discontinued, it is quickly reabsorbed, creating a void in the middle ear with resulting negative pressure. This negative pressure may result in serous otitis, disarticulation of the

ossicles in the middle ear (especially the stapes) and hearing impairment, which may last up to 6 weeks after surgery. The use of N_2O is related to a high incidence of postoperative nausea and vomiting, which is a direct result of negative middle ear pressure during recovery. The vestibular system is stimulated by traction placed on the round window by the negative pressure that is created. Although all patients have the potential for nausea and vomiting after surgery, children younger than 8 years of age seem to be most affected. If the use of N_2O cannot be avoided, vigorous use of antiemetics is warranted.

Airway Surgery

Stridor

Noisy breathing due to obstructed airflow is known as *stridor*. Inspiratory stridor results from upper airway obstruction; expiratory stridor results from lower airway obstruction; and biphasic stridor is present with midtracheal lesions. The evaluation of a patient with stridor begins with a thorough history. The age of onset suggests a cause because laryngotracheomalacia and vocal cord PARAlysis are usually present at or shortly after birth, whereas cysts or mass lesions develop later in life (Table 34-2). Information indicating positions that make the stridor better or worse should be obtained, and placing a patient in a position that allows gravity to aid in reducing obstruction can be of benefit during anesthetic induction.

TABLE 34-2 Causes of Stridor

▪SUPRAGLOTTIC AIRWAY	▪LARYNX	▪SUBGLOTTIC AIRWAY
Laryngomalacia	Laryngocele	Tracheomalacia
Vocal cord PARAlysis	Infection (tonsillitis, peritonsillar abscess)	Vascular ring
Subglottic stenosis	Foreign body	Foreign body
Hemangiomas	Choanal atresia	Infection (croup, epiglottitis)
Cysts	Cyst	
	Mass	
	Large tonsils	
	Large adenoids	
	Craniofacial abnormalities	

Physical examination reveals the general condition of a patient and the degree of the airway

compromise. Laboratory examination may include assessment of hemoglobin, a chest radiograph, and barium swallow, which can aid in identifying lesions that may be compressing the trachea. Ct scan and tomograms may be indicated in isolated instances but are not routinely ordered. Specific note of the signs and symptoms LISTed in Table 34-3 should be made.

TABLE 34-3 Clinical Evaluation of Patients With Stridor

Respiratory rate
Heart rate
Wheezing
Cyanosis
Chest retractions
Nasal flaring
Level of consciousness

Laryngomalacia is the most common cause of stridor in infants. It is most often due to a long epiglottis that prolapses posteriorly and prominent arytenoid cartilages with redundant aryepiglottic folds that obstruct the glottic opening during inspiration.[32] The definitive diagnosis is obtained by direct laryngoscopy and rigid or flexible bronchoscopy. Preliminary examination is usually carried out in the surgeon's office. A small, flexible fiberoptic bronchoscope is inserted through the nares into the oropharynx, and the movement of the vocal cords is observed. Alternatively, it may be accomplished in the Or before anesthetic induction in an awake patient or in a lightly anesthetized patient during spontaneous respiration. Patients must be spontaneously breathing so the vocal cords move freely. After deepening anesthesia, a rigid bronchoscope is inserted through the vocal cords and the subglottic area is inspected; the lower trachea and bronchi are evaluated with a rigid or flexible fiberoptic bronchoscope.

Bronchoscopy

Small infants may be brought into the Or unpremedicated. Older children and adults may experience respiratory depression and worsening of airway obstruction if heavy premedication is administered, so light sedation is suggested. The airway must be protected from aspiration of gastric contents during prolonged airway manipulation; therefore, premedication with the full regimen of acid aspiration prophylaxis may be indicated.

The goals of anesthesia are analgesia, an unconscious patient, and a “quiet” surgical field.[33] Coughing, bucking, or straining during instrumentation with the rigid bronchoscope may cause difficulty for the surgeon and result in damage to the patient's airway. At the conclusion of the procedure,

patients should be returned to consciousness quickly, with airway reflexes intact. For most patients, a pulse oximeter, blood pressure cuff, Ecg, and precordial stethoscope are applied before induction of anesthesia. Inhalation induction by mask is accompanied by oxygen and a volatile agent administered in increasing concentrations in children and intravenous drugs in adults. Patients should be placed in the position that produces the least adverse effect on airway symptoms (often the sitting position). An intravenously administered antisialagogue may help decrease secretions that can obscure the view through the bronchoscope.

The size of a bronchoscope refers to the internal diameter. Because the external diameter may be

significantly greater than in an endotracheal tube of similar size (Table 34-4), care must be taken to select a bronchoscope of proper external diameter to avoid damage to the laryngeal structures.

TABLE 34-4 Comparison of External Diameter of Standard Endotracheal Tubes Versus Rigid Bronchoscope

▪ENDOTRACHEAL TUBE		▪RIGID BRONCHOSCOPE
▪Internal Diameter(mm)	▪External Diameter(mm)	▪External Diameter(mm)
2.5	3.5	4.2
3.0	4.3	5.0
3.5	4.9	5.7
4.0	5.5	6.7
5.0	6.8	7.8
6.0	8.2	8.2

Adapted with permission from Mallinckrodt Medical, Inc., St. Louis, Mo.

A rigid bronchoscope can be used for ventilation of the lungs during examination of the airway. It is inserted through the vocal cords, and ventilation is accomplished through a side port, which can be attached to the anesthesia circuit. During ventilation with the viewing telescope in place, high resistance may be encountered as a result of partial occlusion of the lumen. High fresh gas flow rates, large tidal volumes, and high inspired volatile anesthetic concentrations are often necessary to compensate for leaks around the ventilating bronchoscope and the high resistance encountered when the viewing telescope is in place. Manual ventilation at higher-than-normal rates is most effective in achieving adequate ventilation. Adequate time for exhalation must be provided for passive recoil of the chest.

An alternative method of ventilation is the jet ventilation technique, which involves intermittent bursts of oxygen delivered under pressure through a 16-gauge catheter attached to a rigid bronchoscope.[34] Intermittent flow is accomplished by depressing the lever of an on–off valve. The use of jet ventilation techniques is associated with the additional risks of pneumothorax or pneumomediastinum due to rupture of alveolar blebs or a bronchus.[35]

Because ventilation may be intermittent and at times suboptimal, it is recommended that oxygen be used as the carrier gas during bronchoscopic examination. Intravenous drugs that cause excessive respiratory depression should be avoided. It is wise to ask the surgeon if movement of the vocal cords will be observed at the conclusion of the procedure or if tracheal or bronchial dynamics will be evaluated during the procedure so the anesthetic may be planned accordingly (i.e., spontaneous respirations preserved during light levels of anesthesia versus no respiratory efforts and the use of short-acting muscle relaxants).

Maintenance of anesthesia is usually accomplished with a volatile anesthetic. Intravenous anesthetics combined with muscle relaxation best maintain a constant level of anesthesia because

the delivery of volatile anesthetics through the bronchoscope may be interrupted, and anesthetic depth can vary. At the conclusion of rigid bronchoscopy, an endotracheal tube is usually placed in the trachea to control the airway during recovery of anesthesia. This tube is particularly important if muscle relaxants have been used because passive regurgitation of gastric contents may be more likely to occur in PARAlyzed patients. An additional advantage of placing an endotracheal tube is that if the surgeon should want to examine the distal airways, a small, flexible fiberoptic bronchoscope can be passed through the endotracheal tube.

Pediatric Airway Emergencies

Upper airway emergencies may be life threatening and demand immediate treatment. Rapid respiratory failure can occur in patients with croup, epiglottitis, or foreign body aspiration, and few clinical situations are more challenging to the anesthesiologist.

Epiglottitis

Acute epiglottitis is one of the most feared infectious diseases in children and adults, and is the result of *Haemophilus influenzae* type B. It can progress with extreme rapidity from sore throat to airway obstruction to respiratory failure and ultimately to death if proper diagnosis and intervention are not rapidly implemented. Patients are usually between 2 and 7 years of age, although epiglottitis has been reported in younger children and adults. Vaccination against *H. influenzae* type B polysaccharide is now recommended before 2 years of age to provide immunity before the greatest period of vulnerability in pediatric patients.

Characteristic signs and symptoms of acute epiglottitis include sudden onset of fever; dysphagia; drooling; thick, muffled voice; and preference for the sitting position with the head extended and leaning forward. Retractions, labored breathing, and cyanosis may be observed in cases where respiratory obstruction is present. However, in the early stages, the patient may be pale and toxic without respiratory distress. *Supraglottitis* may be a more appropriate designation because it is the tissues of the supraglottic structures—from the vallecula to the arytenoids—that are involved in the infectious process. At no time (in the emergency room or radiography suite) should direct visualization of the epiglottis be attempted in the unanesthetized patient. The differential resulting from negative

pressure inside and atmospheric pressure outside the extrathoracic airway results in slight narrowing during normal inspiration. The pressure differential on inspiration is exaggerated in the patient with airway obstruction. This dynamic collapse of the airway may become life threatening in the struggling, agitated patient, and every attempt should be made to keep him or her calm. Blood drawing, intravenous catheter insertion, and excessive manipulation of the patient, as well as sedation, should be avoided before securing the airway to avoid the possibility of total obstruction.

If the clinical situation allows, oxygen should be administered by mask, and lateral radiographs of the soft tissues in the neck may be obtained. Thickening of the aryepiglottic folds and swelling of the epiglottis may be noted. Radiologic examination should only be carried out if skilled personnel and adequate equipment accompany the patient at all times. The patient with severe airway compromise should proceed from the emergency department directly to the operating suite, accompanied by both the anesthesiologist and surgeon. Parental presence in this situation may calm an anxious and frightened child.

In all cases of epiglottitis, an artificial airway is established by means of tracheal intubation. In some centers where personnel experienced in the management of the compromised airway are not available, tracheostomy is a less favored alternative. In the Or, the child is kept in the sitting position while monitors are placed. A pulse oximeter and precordial stethoscope are essential. If it is believed to be helpful, one parent may accompany the child and remain in the Or during the induction of general anesthesia. The Or must be prepared with equipment and personnel for laryngoscopy, rigid bronchoscopy, and tracheostomy. Anesthetic induction is accomplished by inhalation of oxygen and increasing concentrations of halothane or sevoflurane. After loss of

consciousness occurs, intravenous access should be secured and the child lowered into the supine position. Laryngoscopy followed by oral tracheal intubation is then accomplished without the use of muscle relaxants. The endotracheal tube chosen should be at least one size (0.5 mm) smaller than would normally be chosen, and a stylette is often useful. Once the surgeon has examined the larynx, noting the appearance of the epiglottis, aryepiglottic folds, and surrounding tissues, the endotracheal tube may be changed to a nasotracheal tube and secured. Tissue and blood cultures are taken, and antibiotic therapy is initiated. The child is then transferred to the intensive care unit for continued observation and radiographic confirmation of tube placement. Sedation is appropriate at this time. Tracheal extubation is usually attempted 48 to 72 hours later in the Or, when a significant leak around the nasotracheal tube is present and visual inspection of the larynx by flexible fiberoptic bronchoscopy confirms reduction in swelling of the epiglottis and surrounding tissues.

Laryngotracheobronchitis

Laryngotracheobronchitis (Ltb), or croup, occurs in children from 6 months to 6 years of age, but is primarily seen in children younger than 3 years of age. It is usually viral in etiology, and its onset is more insidious than that of epiglottitis. The child presents with low-grade fever, inspiratory stridor, and a “barking” cough. Radiologic examination confirms the diagnosis, and subglottic narrowing of the airway column secondary to circumferential soft-tissue edema produces the “steeple” sign characteristic of Ltb. Approximately 6% of patients with Ltb require admission to the hospital. Treatment includes cool, humidified mist and oxygen therapy, usually administered in a tent for mild to moderate cases. More severe cases of Ltb are accompanied by tachypnea, tachycardia, and cyanosis. Racemic epinephrine administered by nebulizer is beneficial. The use of steroids has been surrounded by a great deal of controversy, but current opinion is that a short course of steroids may be beneficial. In rare circumstances, thick secretions are present in the airway, and the child requires intubation to allow pulmonary toilet and suctioning to be carried out. Management in the intensive care unit and extubation are carried out in the same fashion as for epiglottitis.

Foreign Body Aspiration

A major cause of morbidity and mortality in children and adults is aspiration of a foreign body. Any history of coughing, choking, or cyanosis while eating (peanuts, popcorn, jelly beans, hot dogs) should suggest the possibility of foreign body aspiration. Any patient who presents to the emergency room with refractory wheezing should be suspected of this diagnosis. Physical findings include decreased breath sounds, tachypnea, stridor, wheezing, and fever. These signs indicate an obstructive–inflammatory process in the airway. Some foreign bodies are identifiable on radiologic examination; however, 90% are radiolucent, and air trapping, infiltrate, and atelectasis are all that are noted. The most common site of foreign body aspiration is the main-stem bronchus, the right being more frequent than the left. Food particles comprise the majority of aspirated ITEMs; however, beads, pins, and small toys are not unusual. Each type of aspirated ITEM has potential complications associated with it. Vegetable ITEMs expand with moisture encountered in the respiratory tract and can fragment into multiple pieces, thus creating a situation where the original foreign body is in one bronchus and, with coughing, a fragment is dislodged and transported to the other bronchus. Oil-containing objects, such as peanuts, cause a chemical inflammation and sharp objects cause bleeding in addition to the obstruction.

All aspirated foreign bodies in the airway should be removed in the Or and considered to be emergency situations. No sedation should be administered to patients before removal of the foreign body. If the patient has recently eaten, full stomach precautions must be taken and anesthesia should be induced intravenously (topical Emla cream may be applied to the skin before intravenous catheter insertion in small children) by rapid sequence, and gentle cricoid pressure maintained during intubation of the trachea. If the child has not recently eaten, anesthesia may be induced by inhalation of sevoflurane in oxygen by mask. Inhalation induction can be prolonged secondary to obstruction of the airway, and N_2O should be avoided to reduce air trapping distal to the obstruction. After evacuation of the stomach by orogastric tube, the airway may be given over

to the surgeon, who replaces the endotracheal tube with a rigid bronchoscope and removes the aspirated object.

Spontaneous ventilation should be preserved until the location and nature of the foreign body have been determined. Ventilation via the bronchoscope requires careful attention. Hypoxia and hypercarbia may occur because of inadequate ventilation caused by an excessively large leak around the bronchoscope or, more commonly, inability to provide adequate gas exchange through a narrow-lumen bronchoscope fitted with an internal telescope. These conditions are remedied by frequent removal of the telescope and withdrawal of the bronchoscope to the midtrachea, allowing effective ventilation. Bronchospasm may occur during examination of the respiratory tract and should be treated with increasing depths of anesthesia, nebulized albuterol, or intravenous bronchodilators. Although rare, pneumothorax should be suspected if acute deterioration occurs during the procedure.

Once the foreign body has been removed, examination of the entire tracheobronchial tree is carried out to detect any additional objects or fragments. Often, vigorous irrigation and suctioning distal to the obstruction are required to remove secretions and prevent the possibility of postobstructive pneumonia. Steroids are administered if inflammation of the airway mucosa is observed. Close postoperative observation of the

patient is required so that early intervention may be instituted in the event of respiratory compromise secondary to airway edema or infection.

ANESTHESIA FOR PEDIATRIC AND ADULT SURGERY

Certain surgical procedures are commonly performed in both adults and children, including nasal surgery and laser surgery of the airway. Surgery for maxillofacial trauma and upper airway tumors or infection, as well as temporomandibular joint (Tmj) arthroscopy, are conducted more commonly in adults.

Laser Surgery of the Airway

One of the greatest advances in airway surgery has been the use of the laser (*l*ight *a*mplification by *s*timulated *e*mission of *r*adiation). For use in the airway, the laser provides precision in targeting lesions, minimal bleeding and edema, preservation of surrounding structures, and rapid healing. The laser consists of a tube with reflective mirrors at either end and an amplifying medium between them to generate electron activity, resulting in the production of light.[36] The Co_2 laser is the most widely used in medical practice, having particular application in the treatment of laryngeal or vocal cord papillomas, laryngeal webs, resection of redundant subglottic tissue, and coagulation of hemangiomas. The laser is an especially useful modality for the surgeon because the invisible beam of light affords an unobstructed view of the lesion during resection. The energy emitted by a Co_2 laser is absorbed by water contained in blood and tissues. Human tissue is approximately 80% water, and laser energy absorbed by tissue water rapidly increases the temperature, denaturing protein and vaporizing the target tissue. The thermal energy of the laser beam cauterizes capillaries as it vaporizes tissues; thus, bleeding and postoperative edema are minimized.

The properties that give the laser a high degree of specificity also supply the route by which a misdirected laser beam may cause injury to a patient or to unprotected Or personnel.[37] The eyes are especially vulnerable, and all Or personnel should wear laser-specific eye goggles with side protectors to prevent injury. Due to the limited penetration (0.01 mm) of the Co_2 laser, it may cause injury only to the cornea. Other lasers such as the neodymium–yttrium-aluminum-garnet (Nd-Yag) have deeper penetration, and may cause retinal injury and scarring. The eyes of a patient undergoing laser treatment must be protected by taping them shut, followed by the application of wet gauze pads and a metal shield. Any stray laser beam is absorbed by the wet gauze, preventing penetration of the eyes. Laser radiation increases the temperature of absorbent material, and flammable objects such as surgical drapes must be kept away from the path of the laser beam. To avoid cutaneous burns from deflected beams, wet towels should be applied to

exposed skin of the face and neck when the laser is being used in the airway. Laser smoke plumes may cause damage to the lungs, with interstitial pneumonia has been reported with long-term exposure. In addition, it has been postulated that during laser application cancer cells and virus particles, including human immunodeficiency virus, are vaporized, and the resultant smoke plume, if inhaled, may be a vehicle for spread. The use of specially designed surgical masks for filtering laser smoke is recommended.

Most anesthetic techniques are suitable for laser surgery provided that patients are immobile and the laser beam can be directed at a target that is entirely still and in full view. Both N_2O and oxygen support combustion. The primary gas for anesthetic maintenance should consist of blended air and oxygen or helium and oxygen. A pulse oximeter should be used at all times.

Anesthesia during laser surgery may be administered with or without an endotracheal tube. The choice of endotracheal tube used during laser surgery can affect the safety of the technique. All standard polyvinyl chloride (Pvc) endotracheal tubes are flammable, and can ignite and vaporize when in contact with the laser beam. Red rubber endotracheal tubes wrapped with reflective metallic tape do not vaporize, but instead deflect the laser beam. The unwrapped cuff below the vocal cords is still vulnerable to laser injury. Cuffed endotracheal tubes should be inflated with sterile saline to which methylene blue has been added so a cuff rupture from a misdirected laser spark is readily detected by the blue dye and extinguished by the saline.[38] Endotracheal tubes have been manufactured specifically for use during laser surgery. Some have a double cuff to ensure protection of the airway in the event of a cuff rupture, whereas others have a special matte finish that is effective in deflecting the laser beam throughout the entire length. Nonreflective flexible metal endotracheal tubes are also specifically manufactured for use during laser surgery. The outer diameter of each size of metal laser tube is considerably greater than the Pvc counterpart, especially in the small sizes used for pediatric anesthesia (Figs. 34-8 and 34-9, Table 34-5).

TABLE 34-5 Comparison of Standard Plastic Versus Metal Endotracheal Tubes

	▪EXTERNAL DIAMETER (mm)	
▪INTERNAL DIAMETER(mm)	▪PLASTIC	▪METAL
3.0 (uncuffed)	4.3	5.2
3.5 (uncuffed)	4.9	5.7
4.0 (uncuffed)	5.5	6.1
4.5 (cuffed)	6.2	7.0
5.0 (cuffed)	6.8	7.5
5.5 (cuffed)	7.5	7.9
6.0 (cuffed)	8.2	8.5

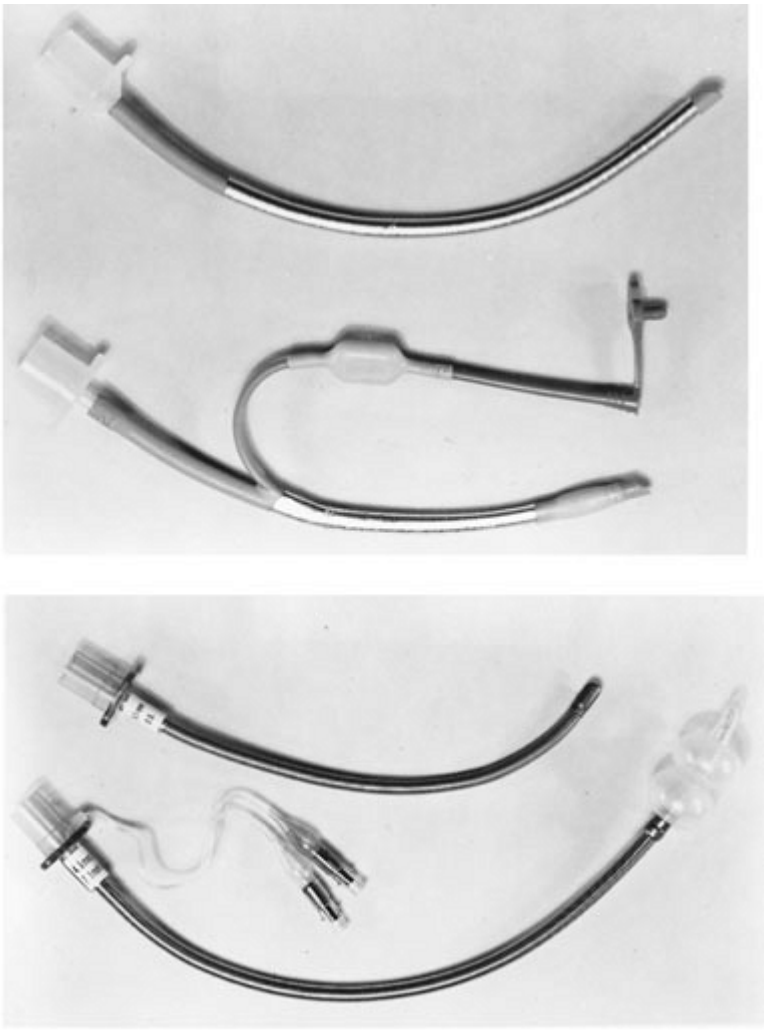

FIGURE 34-8. A. Cuffed and uncuffed rubber endotracheal tubes wrapped with reflective metallic tape. **B.** Cuffed and uncuffed flexible metal endotracheal tubes for use during laser surgery of the airway. (Reprinted with permission from Ferrari Lr: Anesthesia for otorhinolaryngology procedures. In Cote C, Ryan J, Todres D, Goudsouzian N [eds]: A Practice of Anesthesia for Infants and Children, 2nd ed, Chapter 18, Philadelphia, Wb Saunders, 1993.)

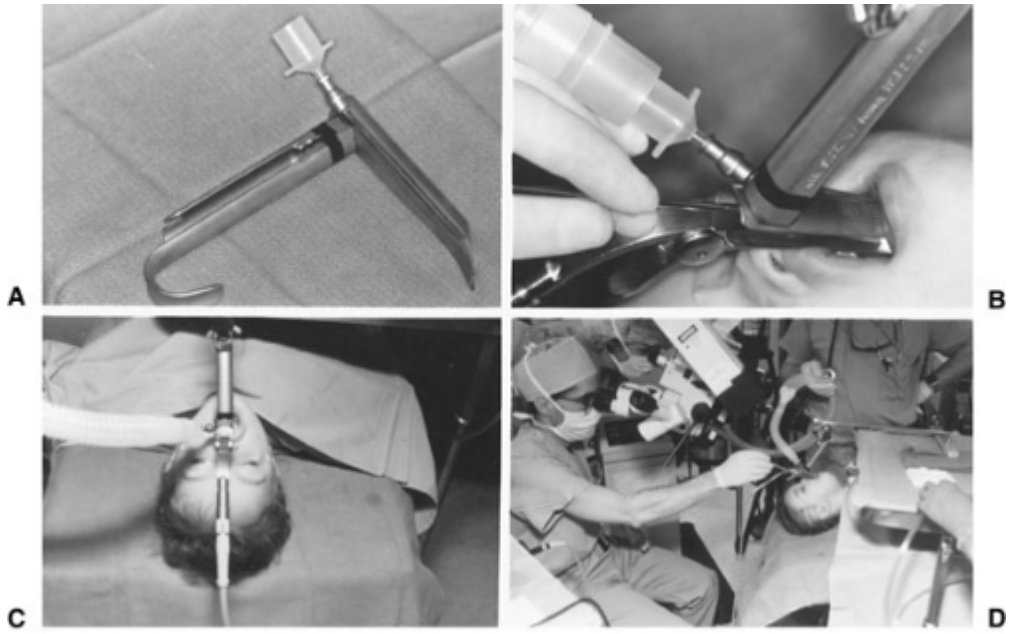

FIGURE 34-9. A. The surgical laryngoscope fitted with an endotracheal tube connector. **B.** The surgical laryngoscope positioned in the patient's pharynx and connected to the anesthesia circuit. **C.** Surgical view of the anesthetized, spontaneously breathing patient. **D.** Laser-aided resection of vocal cord lesion.

An apneic technique is preferred by some surgeons, especially when working on the airway of small infants and children. The advantage of this technique is an unobstructal

surgical field to the absence of an endotracheal tube, which may obscure the surgical field. In this circumstance, a child is anesthetized and rendered immobile by use of a muscle relaxant or deep inhalation of a volatile anesthetic. The patient's trachea is not intubated, and the airway is given over to the surgeon, who uses the laser for brief periods. Between laser applications, the patient's lungs are ventilated by mask. Because apnea is a component of this technique, it is prudent to ventilate the lungs with oxygen. Although this technique has been widely used with safety, there is a greater potential for debris and resected material to enter the trachea.

The use of a jet ventilator is a modification of the apneic technique that does not require tracheal intubation but does provide for oxygenation during laser surgery uses a jet ventilator. The operating laryngoscope is fitted with a catheter through which oxygen is delivered under pressure through a variable reducing value (see Fig. 34-9). Additional room air is entrained, and the patient's lungs are ventilated with this combination of gases. This technique produces a quiet surgical field because large chest excursions of the diaphragm are eliminated and ventilation is uninterrupted. In morbidly obese patients and those with severe small airway disease, effective ventilation is not accomplished with this technique, and an alternate technique should be used.

The final technique that may be used without the aid of an endotracheal tube is spontaneous ventilation with the “oxiscope.” In this technique, a surgical laryngoscope fitted with an oxygen insufflation port is inserted into the larynx. The volatile anesthetic gas is mixed with oxygen and administered through the side port. Anesthesia is maintained without muscle relaxant in the spontaneously breathing patient in this manner. Propofol may be infused to decrease the concentration of inhaled volatile anesthetic, and the vocal cords may be sprayed with 4% lidocaine to decrease reactivity. This technique is advantageous in that longer periods of uninterrupted laser application may be provided. Disadvantages include the absence of complete control of the airway, limited protection from laryngospasm, limited protection from debris entering the airway, presence of vocal cords motion and difficult scavenging.

Nasal Surgery

Nasal surgery may be successfully accomplished under either general anesthesia or conscious sedation. Whichever method is selected, profound vasoconstriction is required. Cocaine packs, local anesthetics, and epinephrine infiltration are often used simultaneously. All three of these agents can cause cardiac irritability, and both epinephrine and cocaine are known to produce varying degrees of hypertension. The simultaneous use of these medications causes cumulative and often dangerous side effects. Young, healthy patients may be able to tolerate these effects. The older patient, or one who has known cardiovascular compromise, may benefit from slow, sequential administration of these medications guided by heart rate, cardiac rhythm, and blood pressure. The potent inhalation anesthetics do have varying degrees of dysrhythmogenic potential and should be used with caution in the face of pharmacologically induced alterations in cardiac rhythm.

A moderate degree of controlled hypotension combined with head elevation decreases bleeding in the surgical site, but some blood may passively enter the stomach. The placement of an oropharyngeal pack or suctioning of the stomach at the conclusion of surgery may attenuate postoperative retching and vomiting.

Maxillofacial Trauma

Traumatic disruption of the bony, cartilaginous, and soft-tissue components of the face and upper airway challenge the

anesthesiologist to recognize the nature and extent of the injury and consequent anatomic alteration, create a plan for securing the airway safely, implement the plan without doing further damage, maintain the airway during the administration of an anesthetic, and determine when and how to extubate the patient's trachea. Also necessary is the creation of a comfortable environment for both surgeon and anesthesiologist in a limited work space.

Anatomy

It is conventional to divide the facial skeleton into thirds. The lower third consists of the mandible, with its subdivisions of midline symphysis, body, angle, ramus, condyle, and coronoid process. The middle third contains the zygomatic arch of the temporal bone, blending into the zygomaticomaxillary complex, the maxillae, nasal bones, and orbits. The superior third consists of the frontal bone. Actually, there are two skeletons, facial and cranial, each one in contiguity with the other. Great forces are generated within the facial skeleton during the normal physiologic process of mastication. To prevent injury of one skeleton against the other, there is a series of bony buttresses built into the relationship between the two skeletons. Horizontal posterior displacement of the facial skeleton is limited by the zygomatic process of the temporal bone, oblique posterior displacement by the pterygoid process of the sphenoid bone, and vertical posterior displacement by the greater wing of the sphenoid bone. Upward displacement is held in check by the zygomatic process of the frontal bone, the nasal part of the frontal bone, and the roof of the mandibular fossa.

In addition to the buttresses, there are two arches lending stability to the craniofacial skeleton. An arch extends from the mandibular condyle to the coronoid process, and another arch is created by the zygomatic arch of the temporal bone extending into the zygomaticomaxillary complex.

This combination of bony buttresses and arches creates a normal vector of force dispersion and distribution. Thus, a blow to the mandible may be of sufficient magnitude to fracture the mandible at the point of impact or elsewhere, but does not extend the fracture line into the base of the skull. However, a blow to the midface, especially from in front and above, does not follow a normal vector of force dispersion and redistribution and tends to create an abnormal shearing force, which may tear the facial skeleton from the cranial skeleton and extend the fracture into the base of the skull. In any patient with severe midfacial trauma, a fracture of the base of the

skull must be considered.

The mandible is a tubular bone and, as such, derives its strength from the cortices and is least vulnerable to fracture where the cortex is thickest (i.e., at the anteroinferior margin).[39] Moving posteriorly, the cortex thins and a greater incidence of fractures is found at the angle of the mandible, the ramus, and the condyle.[40,41,42] Another common point of fracture is in the body of the mandible at the level of the first or second molar. These are laboratory observations, but clinical experience indicates that this distribution occurs after high-velocity, high-impact trauma, such as in an automobile accident. After personal trauma, such as inflicted by a fist, a blunt weapon, or a fall, there is a greater tendency for a fracture of the symphysis, PARAsymphysis, and body to occur. This may not only result from lesser versus greater energy impact and redistribution, but also from the person's tendency to turn the head away from an impending blow and thus take the force of impact on the side of the face and the body of the mandible rather than on the symphysis.[43]

The mandible has a unique, horseshoe shape that causes forces to gather at points of vulnerability, often distant from the point of impact.[41] If this phenomenon is unrecognized, it can create serious problems in diagnosis. It may be known, for example, that the patient was struck on the symphysis, but it must also be recognized that he or she may have a fracture of the condyle, perhaps with involvement of the Tmj and limitation of jaw mobility.

LeFort Classification of Fractures

In 1901, Rene LeFort of Lille, France, published the results of a series of rather bizarre experiments.[44] He attempted to determine if there is a reliable means of detecting facial fractures by examining facial soft-tissue injuries and by using the nature and extent of these injuries as indicators of bony disruption. This relationship does not exist. Extensive soft-tissue injury does not necessarily indicate bony trauma, and conversely, serious fractures may exist with relatively little soft-tissue disruption. In the course of his studies, LeFort determined the common lines of midface fracture, which are thus eponymous and called LeFort I, LeFort Ii, and LeFort Iii fractures.

The LeFort I fracture is a horizontal fracture of the maxilla, passing above the floor of the nose but involving the lower third of the septum, mobilizing the palate, maxillary alveolar process, and the lower third of the pterygoid plates and parts of the palatine bones. The fracture segment may be displaced posteriorly or laterally or rotated about a vertical axis.

The LeFort Ii fracture is pyramidal, beginning at the junction of the thick upper part of the nasal bone, with the thinner portion forming the upper margin of the anterior nasal aperture. The fracture crosses the medial wall of the orbit, including the lacrimal bone beneath the zygomaticomaxillary suture; crosses the lateral wall of the antrum; and passes posteriorly through the pterygoid plates. The fracture segment may be displaced posteriorly or rotated about an axis.

5 In a LeFort Iii fracture, the line of fracture PARAllels the base of the skull, sePARAting the midfacial skeleton from the base of the cranium. The line of fracture passes through the base of the nose and the ethmoid bone in its depth, and through the orbital plates. The cribriform plate of the ethmoid may or may not be fractured. The fracture line crosses the lesser wing of the sphenoid, then downward to the pterygomaxillary fissure and sphenopalatine fossa. From the base of the inferior orbital fissure, the fracture extends laterally and upward to the frontozygomatic suture and downward and backward to the root of the pterygoid plates. A LeFort Iii fracture results from massive force applied to the midface. The zygomata are displaced and rotational force applied to the zygomatic arches. The arches are usually fractured as a result.

With this fracture, the midface is mobilized and often distracted posteriorly. The normal convexity of the face may be replaced by a concavity, giving rise to the characteristic “dish face deformity” of a LeFort Iii fracture. Even if this facial concavity is not clinically evident, the presence of a LeFort Iii fracture should be suspected if the incisive edges of the maxillary and mandibular teeth are apposed, instead of the normal position in which the maxillary incisors shingle over the mandibular incisors. This apposition serves as a subtle clue to minimal posterior displacement of the midface.

Tumors

Neoplastic growths can occur anywhere within the upper airway and may achieve significant size with little evidence of airway obstruction. These tumors are often friable and bleed readily. Attempted tracheal intubation can induce significant hemorrhage and edema and cause severe compromise of the airway. Prior radiation therapy may cause extensive fibrosis, increased intraoperative bleeding, and ankylosis of the Tmj, making tracheal intubation under direct vision difficult or impossible. Consultation with a surgeon as to the nature and

extent of the tumor, and its potential to bleed, together with review of appropriate radiographs and prior therapy, are important in determining techniques for airway management. Tumors of the head and neck are usually associated with abuse of both cigarettes and alcohol, with consequent abnormalities of both pulmonary and hepatic function.

Upper Airway Infection

Infectious processes in the upper airway may be of sufficient size to mimic neoplasms and present the same problems of airway distortion, compression, and compromise. The same precautions must be taken in dealing with airway abscesses as with tumors. An added problem is the ability of an abscess to leak spontaneously, dribbling pus into the lungs, contaminating and infecting them, and producing scattered areas of pneumonitis; or to rupture during tracheal intubation, flooding the lungs with purulent material.

Ludwig's Angina

Ludwig's angina is an overwhelming generalized septic cellulitis of the submandibular region.[45,46] It generally occurs after dental extraction, especially of the second or third mandibular molars, whose roots lie below the attachment of the mylohyoid muscle. The infection is bilateral and involves three fascial spaces: submandibular, submental, and sublingual. Ludwig's angina is characterized by brawny induration of the upper neck, usually without obvious fluctuation, and the patient has a typical open-mouthed appearance. Involvement of the sublingual space pushes the tongue upward and backward, and it usually protrudes from the open mouth. Soft-tissue swelling in the suprahyoid region, coupled with upward and posterior displacement of the tongue, as well as the frequent presence of laryngeal edema, can close the airway and asphyxiate the patient.

Early signs and symptoms include chills, fever, drooling of saliva, inability to open the mouth, and difficulty in speaking. The cause is often hemolytic streptococci, but may be a mixture of aerobic and anaerobic organisms, including gas-forming bacteria.[47] Although fluctuation is rarely appreciated, abscesses may be present but their presence hidden by the thick, indurated tissue of the neck. The infectious process may spread into the thorax, causing empyema, pericarditis, pericardial effusion, and pulmonary infiltrates. Patients with Ludwig's angina often require incision and drainage of whatever purulent material is present, coupled with airway decompression. Airway management may be extremely difficult. Although inhalation anesthesia and intubation have been advocated,[48] preliminary tracheostomy using local anesthesia in the awake patient is the safest course. The patient with Ludwig's angina is commonly septic, extremely ill, and often poorly hydrated.

Temporomandibular Joint Arthroscopy

Open surgery of the human Tmj was first described in 1887, in a discussion of operative repair of displaced interarticular cartilage of the joint.[49] Although open surgery of the joint is still sometimes considered necessary, the development of small-gauge arthroscopes and lasers has made arthroscopic surgery of the Tmj an increasingly popular technique, frequently performed on an ambulatory basis.[50] Common indications for arthroscopic correction of Tmj lesions include the following[50]: (1) internal joint derangement with closed lock, (2) internal joint derangement with painful clicking, (3) osteoarthritis, (4) hypermobility, (5) fibrous ankylosis, and (6) arthralgia. Other less common indicators include chondromalacia and synovitis.

Tmj disease is usually caused by spasm of the muscles of mastication secondary to chronic tensing of these muscles as an involuntary mental tension–relieving mechanism. The patient population is unique in that 86% of patients with chronic Tmj dysfunction have significant psychopathology, with major depression in 74% and somatoform disorder in 50%.[51] A total of 40% of the patients are preoccupied with facial pain, yet have no physical findings accounting for the pain. Many of these patients habitually use mood-altering or tension-abating drugs such as benzodiazepines, phenothiazines, or lithium.

Nasotracheal intubation is usually preferred, allowing the surgeon the option of intraoral manipulation during surgery. Complications of Tmj arthroscopy are rare but include partial or total hearing loss, infection, hemorrhage requiring open arthrotomy, and temporary or permanent deficits of the fifth and eighth cranial nerves and temporary seventh nerve paresis.[51,52]

Of particular importance to the anesthesiologist is partial or even complete closure of the airway due to extracapsular extravasation of the fluid used to irrigate the joint during arthroscopy.[53] Significant amounts of fluid can leak into the soft tissues of the neck and compromise the airway. After Tmj arthroscopy, the patient's trachea should not be extubated until the oral cavity, especially on the affected side, and neck have been examined carefully and no evidence of unusual swelling that might indicate extravasated fluid is found.

Patient Evaluation

The patient who has sustained facial trauma or whose airway is clearly distorted by tumor or infection may present with an obvious pathologic process that can distract the physician from completing a total evaluation of the patient. In the patient with facial trauma, other injuries may not be as apparent but may represent a greater threat to the patient's well-being. In patients with maxillofacial injury due to low-velocity, low-impact blows (as from a fist), 4% had major (life-threatening) other injuries, and 10% had minor (non–life-threatening) injuries. With high-velocity, high-impact (motor vehicle) accidents, 32% had major and 31% minor other injuries.[54] Of great importance, cervical spine fractures occurred in 1.2% of high-velocity injuries. Other studies have reported a 5.5% incidence of cervical spine injury in patients with facial skeletal trauma.[55] Any level of the cervical spine may be involved, but injuries at C2 (31%) and C6–C7 (50%) predominate. Cranial fractures and intracranial injury are also not uncommon.

SECURING THE AIRWAY

In most instances of anesthesia for head and neck surgery, tracheal intubation is effected without significant problems. Grave difficulties can arise in patients with tumor or infection or other facial trauma. If any of these processes has so altered the airway that attempted tracheal intubation risks airway compromise and an inability to ventilate the lungs, then awake tracheal intubation or preliminary tracheostomy is mandated. History, physical examination, appropriate radiographs, and surgical consultation are the foundation of airway evaluation and choice of intubating technique. The technique of an “awake look” before a decision to anesthetize and PARAlyze a patient is particularly hazardous and misleading. Muscle tone and labored respiration in the awake patient help identify the rima glottis or some seemingly familiar anatomic structure but disappear once anesthesia and PARAlysis have been induced, and

it may be impossible to identify the entrance to the airway and intubate the trachea.

For the anesthesiologist to be able to intubate the trachea of a patient under direct vision, the patient must be able, at a minimum, to open the mouth and extend the tongue beyond the incisors. After maxillofacial trauma, there may be serious limitation in mobility owing to one or more factors, including pain, trismus, edema, and mechanical dysfunction of the Tmj. Pain yields to an anesthetic and muscle relaxant, presenting no problem.

Trismus is spasm of the masseter muscles, binding the jaw closed, secondary to trauma or infection. Trismus, too, succumbs to an anesthetic and muscle relaxant, but with an important caveat. If the trismus has been present for 2 weeks or if the jaw has been closed for some other reason for 2 weeks, the masseters acquire a degree of fibrosis that limits their response to an

anesthetic and relaxant. A jaw closed for 2 weeks for whatever cause merits consideration for awake tracheal intubation. Edema varies in severity and consequences from mild to extreme and may occasionally cause serious limitation in jaw mobility.

Mechanical dysfunction in the jaw arises from several causes. A fracture of the condyle in its articulation in the Tmj may create a situation in which the jaw is locked closed and is unresponsive to an anesthetic and muscle relaxant. A fracture of the zygomatic arch of the temporal bone will always causes some decrease in jaw mobility. This bone is well protected, enveloped in the tough temporal fascia. Nonetheless, a severe blow to the side of the head may fracture the bone, pushing bony segments down onto the coronoid process of the mandible. There is a biphasic motion in the mandible, rotation about an axis passing through the condyles, and anterior-posterior motion (translation). This anterior motion is limited by the bony impingement on the coronoid process, and Tmj function is thus restricted by the limitation in translation. Usually, the decrease in function is not severe enough to make tracheal intubation impossible, but it may be, making the decision as to whether to anesthetize and PARAlyze the patient or perform awake tracheal intubation difficult. The anesthesiologist in doubt is cautioned to err on the side of conservatism.

Patients with Tmj dysfunction undergoing arthroscopic surgery may present with either closed or open lock and be unsuitable for intubation of the trachea after induction of anesthesia. Patients with large cervical abscesses may require awake intubation or tracheostomy. If the abscess has caused anatomic distortion or respiratory difficulty, awake intubation or tracheostomy is usually mandatory. Early tracheostomy in Ludwig's angina is preferred, and no patient should ever be observed to the point of airway compromise.[56] In any instance in which awake intubation is elected in the infected patient, provision must be available for immediate tracheostomy.

Awake Intubation

Passing an endotracheal tube through the mouth or nose and into the larynx and trachea of an awake patient is a formidable procedure that the patient resists fiercely, stimulated by the protestations of highly sensitive airway reflexes. To overcome these reflexes, the airway must be anesthetized using a combination of topical local anesthetic and superior laryngeal nerve block.

The *superior laryngeal nerve* is a branch of the vagus arising from the nodose ganglion and coursing with the main trunk of the vagus until it reaches the level of the larynx, where it springs forward and terminates in two branches, internal and external. The external branch of the superior laryngeal nerve penetrates and innervates the cricothyroid muscle, a tensor of the vocal cords. The internal branch penetrates the thyrohyoid membrane, ramifies, and provides sensory innervation from the base of the tongue to the vocal cords.[57] Once it has penetrated the thyrohyoid membrane, it lies in a closed space, bounded medially by the laryngeal mucosa, laterally by the thyrohyoid membrane, superiorly by the inferior border of the hyoid bone, and inferiorly by the superior surface of the thyroid cartilage. The anatomic landmarks for superior laryngeal nerve block are as follows:

1. The hyoid bone, a freely movable bone in the upper part of the neck, articulating with no other bone
2. The thyroid cartilage, the largest component of the larynx, usually easily identified
3. The thyrohyoid membrane binding the two together

With the patient lying supine, a 22-gauge needle attached to a syringe containing 2 mL of 2% lidocaine is aimed directly at the hyoid, traveling PARAllel to the operating table. When the needle strikes the hyoid, the operator can appreciate the characteristic gritty feeling of a needle on bone, similar to striking the rib while doing an intercostal block. The needle is then walked caudad until it just slips off the bone, penetrating the thyrohyoid membrane. After negative aspiration, lidocaine may be injected and the block repeated on the other side.[58]

Contraindications to a superior laryngeal nerve block are relative, not absolute, and include the following:

1. A full stomach, because of the possibility of vomiting and aspiration into an airway whose protective reflexes have been partially obtunded
2. Tumor at the site of block
3. Infection at the site of block

Tumor and infection are considered to be relative contraindications because of the possibility of dissemination of either tumor or infection secondary to the manipulation associated with the block. Risks must be weighed against benefit, and very often benefit wins. Protection against aspiration can be increased by the presence of knowledgeable help, an operating table that can swing quickly into the Trendelenburg position, and efficient suction apPARAtus.

Local anesthetic may be instilled into the nose for nasotracheal intubation and into the mouth and oropharynx for either nasal or oral intubation. A vasoconstrictor, such as 0.5% phenylephrine hydrochloride or 0.05% oxymetazoline, should also be instilled in the nose to shrink the nasal mucosa, decrease the risk of trauma, and create a larger passage for tracheal intubation. Topical anesthetic may be applied to the trachea below the level of the vocal cords by introducing a 22-gauge needle attached to a syringe containing 4 mL of 2% lidocaine and injecting the drug rapidly into the trachea at the end of the maximal expiration. The injection of the drug excites a vigorous cough reflex, spraying the local anesthetic along the tracheal side walls and inferior surface of the vocal cords. As a supplement to direct tracheal instillation of local anesthetic and bilateral superior laryngeal nerve block, local anesthetic (e.g., 2% lidocaine) may be nebulized in a handheld nebulizer and inhaled by the patient. This is a tedious process, demanding long, slow breaths and inhalation of the nebulized anesthetic over the course of at least 20 minutes. The endotracheal tube may then be passed into the anesthetized airway using a guided, fiberoptic technique or blindly. Complications of superior laryngeal nerve block include intravascular injection of local anesthetic. The carotid sheath lies just posterior to the site of block and, if the needle is angled posteriorly, the sheath may be entered and the anesthetic injected directly into the carotid artery or internal jugular vein.

The role of the Lma in head and neck surgery awaits clarification. The Lma may be useful in temporarily securing a compromised airway. In any situation, however, where the airway is jeopardized by blood or pus, or the anatomy distorted

by trauma, the airway must be secured with a cuffed endotracheal or tracheostomy tube. The intubating Lma may facilitate awake intubation.[59] The flexible Lma is unsafe in head and neck surgery in the presence of foreign material such as blood, bone fragments, or pus.[60]

A modification of the Lma is the Lma-ProSeal, which has a double cuff and a double-lumen design that sePARAtes the airway and the alimentary tract, thus providing a safe escape channel for regurgitated fluids. Incorporated in its design is an independent drain tube that opens at the upper esophageal sphincter, permitting drainage of gastric fluids and allowing blind insertion of an orogastric tube. However, only a properly placed endotracheal tube offers complete airway protection.

The Lma-Fastrach is a modification of the intubating Lma, designed specifically for the anatomically difficult airway, especially the patient who cannot open his or her mouth fully. When used with the Lma-Fastrach, endotracheal tube intubation can be effected without moving the patient. This tube is a straight, silicone, wire-reinforced, cuffed tube, not exceeding 8 mm internal diameter, and capable of being passed entirely through an Lma-Fastrach. The use of this device may make possible an otherwise very difficult intubation.

LeFort III Fractures

A LeFort Iii fracture may involve the cribriform plate of the ethmoid bone, thus violating the sePARAtion of nasopharynx and base of the skull and allowing entrance into the intracranial subarachnoid space. Nasotracheal intubation risks the introduction of foreign material from the nasopharynx into the subarachnoid space and the consequent development of meningitis. More important, it risks the introduction of the endotracheal tube into the substance of the brain, with direct mechanical damage. Even positive-pressure bag and mask ventilation is contraindicated because the increase in volume and pressure within the nasopharynx can force foreign material[61] or air into the skull.[62]

The problems of securing the airway in a patient with a LeFort Iii fracture are ordinarily obviated by doing a preliminary tracheostomy using local anesthetic in an awake patient. This has the added advantage of sePARAting surgeon and anesthesiologist and allowing each an adequate working space. Nasotracheal intubation can be performed in a patient with a LeFort Iii fracture provided three criteria are met: (1) absence of clinical signs of basal skull fracture, (2) absence of radiographic evidence of basal skull fracture, and (3) a compelling reason for doing so. Occasionally (rarely), these three criteria are fulfilled.

Anesthetic Management of the Traumatized Upper Airway

After tracheal intubation has been achieved or tracheostomy performed, general or intravenous anesthetics may be used. The use of ketamine as a sole anesthetic in an attempt to obviate the necessity of performing a difficult tracheal intubation is perilous and should be avoided. Ketamine is a potent respiratory depressant[63] in bolus doses, increases intracranial pressure[64] (Icp), and causes focal alterations in the cerebral metabolic rate.[65] Because there is a significant incidence of intracranial trauma associated with maxillofacial trauma, the brain must be protected and alterations in Icp avoided. Opioids have little effect on Icp and are useful in anesthetic management. However, the dose may be difficult to determine because of the high incidence of drug abuse associated with trauma. Inhalation anesthetics are safe and effective, and Icp can be moderated by altering the $PaCO_2$. The halogenated ethers are particularly useful, but the halogenated alkane halothane should be avoided because of the high incidence of cardiac arrhythmias associated with its use.[66]

Extubation

When tracheostomy has been incorporated into the anesthetic-surgical plan, it is maintained at the termination of the procedure, and the only decision facing the anesthesiologist is whether to allow spontaneous respiration or to create suitable conditions for continued mechanical ventilation by maintaining the patient anesthetized and PARAlyzed. This decision is contingent on such factors as the nature and duration of surgery, the patient's prior physical condition, and concurrent respiratory disease, a frequent concomitant of head and neck tumors.

8 After trauma, infection, or extensive oral resection for tumor, the endotracheal tube must not be removed until there is clearly subsidence of any edema that might compromise the unprotected airway. Particular attention must be given to the submandibular area, where extensive edema pushes the tongue upward and posteriorly and risks the airway. An edematous tongue protruding past the incisors is an ominous warning of dangerous edema. If substantial edema is present, a waiting period of 24 to 36 hours is usually indicated. Serious infection may require a longer period of time to resolve. An oral endotracheal tube may be removed over a tube changer. When removing a nasotracheal tube, a useful technique is to place a fiberoptic bronchoscope through the tube and into the airway and to remove the tube over the bronchoscope so it can be replaced immediately if necessary.

Chapter 35

The Renal System and Anesthesia For Urologic Surgery

Jerome F. O'Hara Jr.

Jacek B. Cywinski

Terri G. Monk

KEY POINTS

1	Renal filtration and reabsorption are susceptible to alterations by surgical illness and anesthesia. Autoregulation of renal blood flow (RBF) is effective over a wide range of mean arterial pressure (50 to 150 mm Hg). Autoregulation of urine flow does not occur, but a linear relationship between mean arterial pressure above 50 mm Hg and urine output is observed.
2	Renal medullary blood flow is low (receives 2% of total RBF) but essential to the kidneys' ability to concentrate urine. During periods of reduced RBF, the metabolically active medullary thick ascending limb (mTAL) may be especially vulnerable to ischemic injury.
3	Patient response to surgical stress uses intrinsic mechanisms for sodium and water conservation. Renal cortical vasoconstriction, shift in RBF to salt-and-water-conserving juxtamedullary nephrons, decrease in glomerular filtration rate (GFR), retention of salt and water result.
4	The patient's stress response may induce a decrease in RBF and GFR, causing afferent arteriolar constriction. If an extreme situation is not reversed, ischemic damage to the kidney may result in acute renal failure (ARF).
5	Anesthetic-induced reductions in RBF have been described for many agents, but are usually clinically insignificant and reversible. Likewise, anesthetic agents have not been shown to interfere with renal neurohumoral responses to physiologic stress.
6	Overall, there are no conclusive comparative studies demonstrating superior renal protection or improved renal outcome with general versus regional anesthesia.

7	Isolated ARF carries a mortality of up to 10% in surgical patients, with acute tubular necrosis (ATN) being the etiology for ARF in most of these patients.
8	Surgical patients with nondialysis chronic renal failure (CRF) are at higher risk to develop end-stage renal disease (ESRD). The single most reliable predictor of postoperative renal dysfunction is preoperative renal dysfunction.
9	Maintaining adequate intravascular volume and hemodynamic stability with aggressive management of kidney hypoperfusion is a basic tenet of anesthetic care to prevent ARF.
10	Irrigation fluid absorption during the transurethral resection of the prostate (TURP) procedure is directly related to the number and size of venous sinuses opened, duration of the resection, hydrostatic pressure of the irrigating fluid, and venous pressure at the irrigant–blood interface. Studies comparing general with spinal anesthesia reveal no difference in mortality and morbidity.

The kidney plays a central role in implementing and controlling a variety of homeostatic functions, including excreting metabolic waste products in the form of urine, while keeping extracellular fluid volume and composition constant. Renal dysfunction can occur perioperatively as a direct result of surgical or medical disease, prolonged reduction in renal oxygen delivery, nephrotoxin insult, or, frequently, a combination of the three. The first part of this chapter reviews renal physiology and pathophysiologic states as they relate to anesthetic practice, and then addresses strategies for recognizing and managing patients at risk for renal failure. The second part describes current urological procedures and their attendant anesthetic management issues.

RENAL ANATOMY AND PHYSIOLOGY

Anatomy and Innervation of the Genitourinary System

The kidneys and ureters are located in the retroperitoneal space, with their center at the L2 vertebral body. Renal pain sensation is conveyed back to spinal cord segments T10–L1 by sympathetic fibers. Sympathetic innervation is supplied by preganglionic fibers from T8–L1. The vagus nerve provides parasympathetic innervation to the kidney, and the S2–S4 spinal segments supply the ureters (Fig. 35-1).

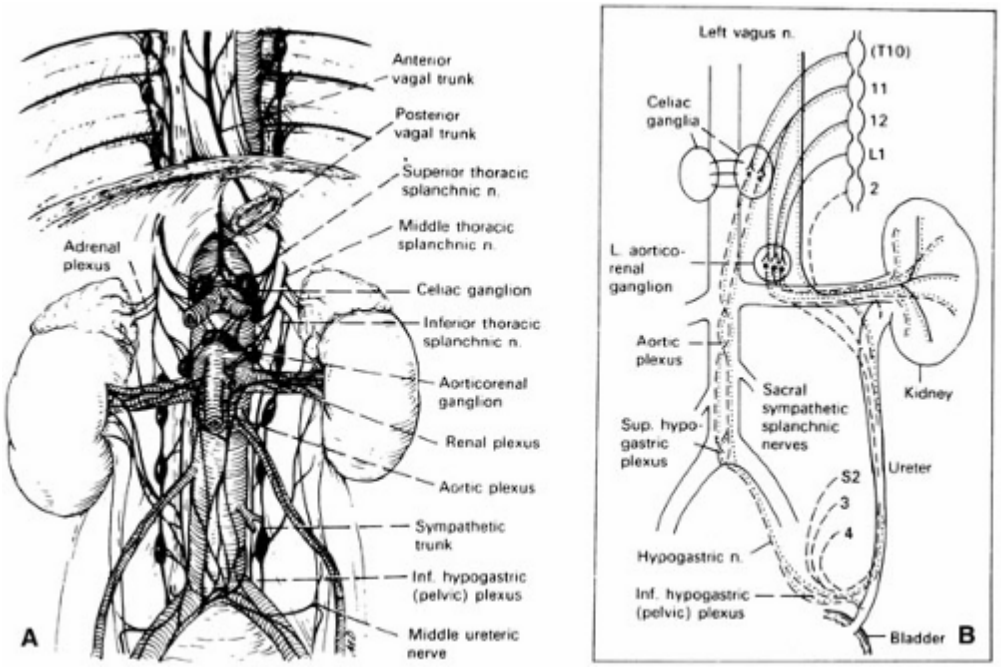

FIGURE 35-1. A. Anatomy and innervation of the kidney and ureters. **B.** Schematic illustration of the autonomic and sensory nerve pathways supplying the kidney and ureters. (Reprinted with permission from Ansell JS, Gee WF: Diseases of the kidney and ureter. In Bonica JJ [ed]: The Management of Pain, p 1233. Philadelphia, Lea & Febiger, 1990.)

The bladder is located in the retropubic space and receives its innervation from sympathetic nerves originating from T11–L2, which conduct pain, touch, and temperature sensations, whereas bladder stretch sensation is transmitted via parasympathetic fibers from segments S2–S4. Parasympathetics also provide the bladder with most of its motor innervation (Fig. 35-2).

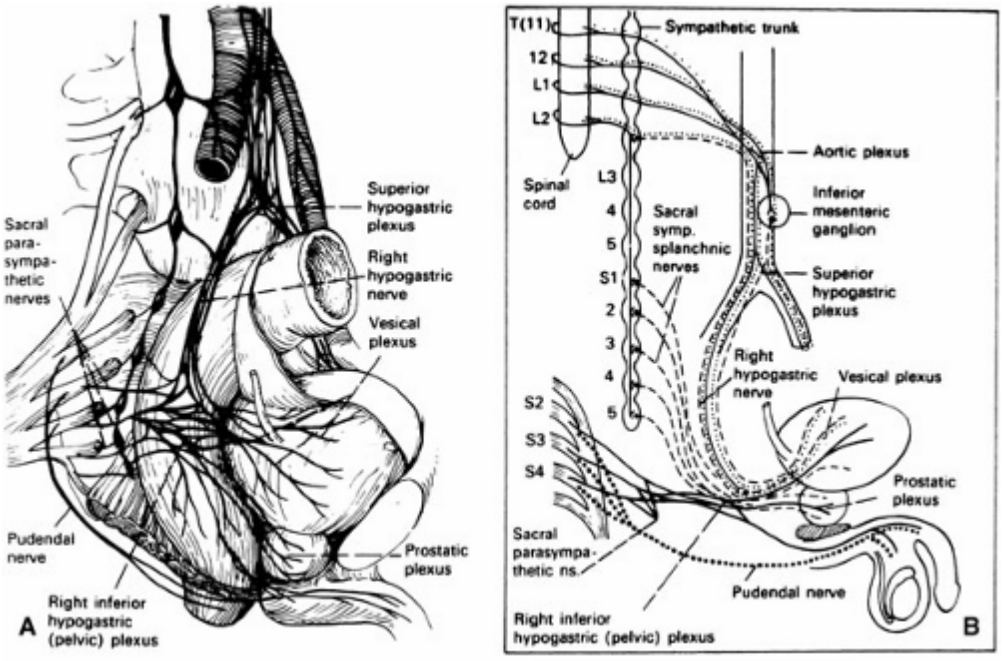

FIGURE 35-2. A. Anatomy and innervation of the urinary bladder and prostate. **B.** Schematic illustration of the innervation of the bladder, penis, and scrotum. Solid lines, preganglionic fibers; dashed lines, postganglionic fibers; dotted lines, sensory fibers. (Reprinted with

permission from Gee WF, Ansell JS: Pelvic and peritoneal pain of urologic origin. In Bonica JJ [ed]: The Management of Pain, p 1369. Philadelphia, Lea & Febiger, 1990.)

The prostate, penile urethra, and penis also receive sympathetic and parasympathetic fibers from the T11–L2 and S2–S4 segments, respectively. The pudendal nerve provides pain sensation to the penis via the dorsal nerve of the penis. Sensory innervation of the scrotum is via cutaneous nerves, which project to lumbosacral segments, whereas testicular sensation is conducted to lower thoracic and upper lumbar segments (see Fig. 35-2).

Anatomy of the Nephron

The *nephron* is the microscopic functional unit of the kidney and is elegantly designed to carry out its excretory and regulatory roles (Fig. 35-3). The *glomerulus* is a capillary network that serves as the basic filtering unit of the nephron and is situated in the outer cortex of the kidney. Blood to be filtered enters the glomerular tuft through the afferent arteriole and eventually exits the glomerulus through the efferent arteriole. The initial segment of the renal tubular system, called *Bowman's capsule*, envelops the glomerulus. The glomerular filtrate passes from Bowman's capsule into the proximal tubule and then into the descending loop of Henle, which dips deep into the medullary portion of the kidney. The ascending limb of the loop ascends back to the cortex. In the cortex, the distal tubule comes into contact with the afferent and efferent arterioles to form the juxtaglomerular apparatus. The distal tubule then proceeds through the cortex to join with other tubules to form cortical collecting ducts. These collecting ducts again plunge into the medulla, coalesce, and eventually empty urine into the renal pelvis, which is drained by the ureters. Blood supply to the entire tubular system comes from the glomerular efferent arteriole, which branches into an extensive capillary network. Some of these peritubular capillaries, the *vasa recta*, descend deep into the medulla to parallel the loops of Henle. The vasa recta then return in a cortical direction with the loops, join other peritubular capillaries, and empty into the cortical veins.

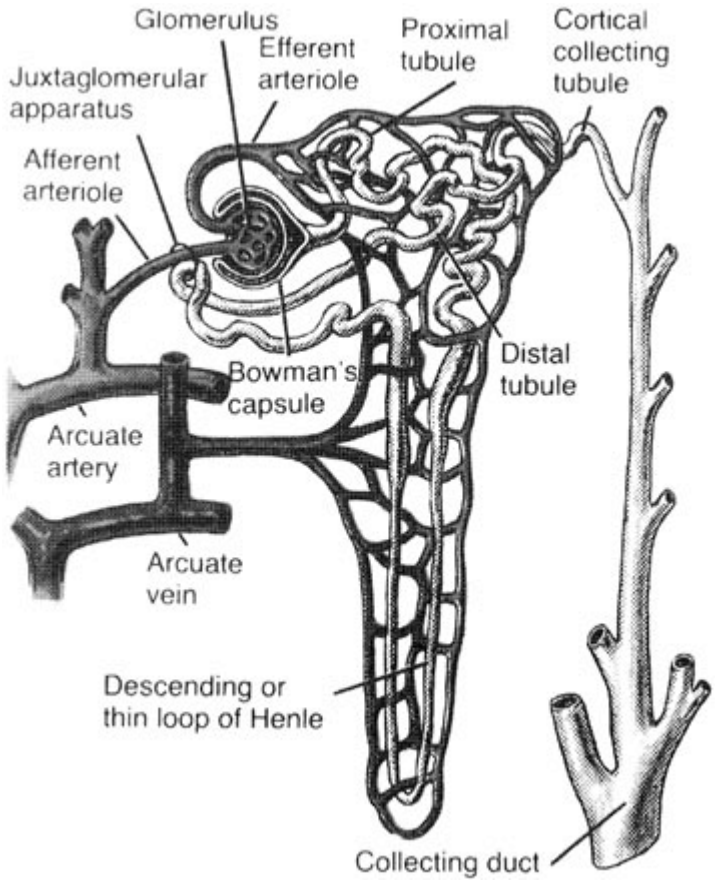

FIGURE 35-3. Anatomy of the nephron. (Reprinted with permission from Guyton AC: Formation of urine by the kidney: Renal blood flow, glomerular filtration, and their control. In Guyton AC [ed]: Textbook of Medical Physiology, 8th ed, p 287. Philadelphia, WB Saunders, 1991.)

Renal Physiology

The kidney fulfills its dual roles of waste excretion and body fluid management by filtering large amounts of fluid and solutes from the blood, reabsorbing needed components of this filtrate, and secreting waste products into the tubular fluid.[1] Filtration and reabsorption are susceptible to alterations by surgical illness and anesthesia and are the focus of this discussion.

Glomerular Filtration

Urine production begins with filtration of water and solutes from blood flowing through the afferent arteriole. The glomerular membrane serves as the filter, whereas Bowman's capsule acts as the initial receptacle for the filtrate. The kidneys receive ~20% of the systemic cardiac output and are able to filter 10% of this volume to produce 180 L/day of glomerular filtrate. More than 99% of the filtered fluid is reabsorbed and returned to the circulation, resulting in 1 to 2 L of urine output per day in healthy adults.

The *glomerular filtration rate* (GFR) is a measure of glomerular function expressed as milliliters of filtrate produced per minute. GFR can be thought of as the product of the tendency of the glomerular membrane to allow filtration to occur

(i.e., glomerular permeability and surface area) and the pressure inside the glomerular capillary that forces fluid through the filter.

The *ultrafiltration constant* (Kf) is directly related to glomerular capillary permeability and glomerular surface area. Glomerular capillary permeability is relatively constant, but the glomerular surface area can be reduced by intense sympathetic or angiotensin II stimulation, which in turn decreases GFR.

Changes in glomerular filtration pressure exercise the greatest influence on GFR in the normal and pathologic states. The two major determinants of filtration pressure are glomerular capillary pressure (P_{GC}) and glomerular oncotic pressure (π_{GC}). P_{GC} is directly related to renal artery pressure, but is heavily influenced by arteriolar tone at points upstream (afferent) and downstream (efferent) from the glomerulus. An increase in afferent arteriolar tone, as occurs with intense sympathetic or angiotensin II stimulation, causes filtration pressure and GFR to fall. Milder degrees of sympathetic or angiotensin activity cause a selective increase in efferent arteriolar tone, which tends to increase filtration pressure and GFR. The π_{GC} is directly dependent on plasma oncotic pressure. Afferent arteriolar dilatation enhances GFR by increasing glomerular flow, which in turn elevates glomerular capillary pressure. Efferent arteriolar constriction intense enough to slow glomerular blood flow produces opposing effects on the GFR.

Autoregulation of Renal Blood Flow and Glomerular Filtration Rate

From the preceding discussion, it is apparent that renal blood flow (RBF) and perfusion pressure determine GFR, in large part. To maintain relatively constant rates of RBF and glomerular filtration over a wide range of physiologic demands, the kidney must exercise some control over its own performance. Renal autoregulation of blood flow and filtration is accomplished by local feedback signals that modulate glomerular arteriolar tone.

1. Autoregulation of RBF is effective over a wide range of arterial pressure (Fig. 35-4). Two separate mechanisms for regulating blood flow to the glomerulus have been proposed, and

both involve modulation of afferent arteriolar tone. A myogenic reflex has been postulated in which an increase in arterial pressure causes the afferent arteriolar wall to stretch and then through the reflex to constrict, whereas a decrease in arterial pressure causes arteriolar dilatation. The other proposed mechanism of RBF autoregulation is a phenomenon called *tubuloglomerular feedback*, which is also responsible for autoregulation of GFR.

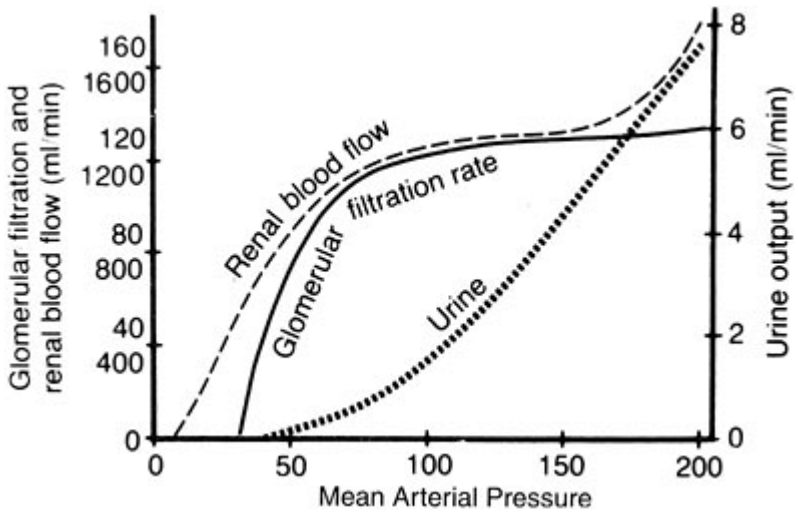

FIGURE 35-4. Autoregulation of glomerular filtration rate and renal blood flow over a wide range of arterial pressures. Note that urine output is not subject to autoregulation. (Reprinted with permission from Guyton AC: Formation of urine by the kidney: Renal blood flow, glomerular filtration, and their control. In Guyton AC [ed]: Textbook of Medical Physiology, 8th ed, p 293. Philadelphia, WB Saunders, 1991.)

Tubuloglomerular feedback control of RBF and GFR works by using the composition of distal tubular fluid to influence glomerular function through the *juxtaglomerular apparatus*. When RBF falls, the concomitant decrease in GFR results in

less chloride ion delivery to the juxtaglomerular apparatus, which then signals the afferent arteriole to dilate. Glomerular flow and pressure then increase, and GFR returns to previous levels. Chloride ion also acts as the feedback signal for control of efferent arteriolar tone. When GFR falls, declining chloride ion delivery to the juxtaglomerular apparatus triggers release of *renin*, which causes formation of *angiotensin II*. In response to angiotensin, efferent arteriolar constriction increases glomerular pressure, which increases glomerular filtration. Simultaneous afferent arteriolar dilatation and efferent arteriolar constriction allow glomerular flow and filtration to increase.

Note from Fig. 35-4 that autoregulation of urine flow does not occur and that there is a linear relationship between mean arterial pressure above 50 mm Hg and urine output.

Tubular Reabsorption of Sodium and Water

The renal tubular system is responsible for selectively reabsorbing the vast quantities of fluid and solutes filtered by the glomeruli. Waste materials are thereby separated from essential solutes and excreted in the minimum volume of water possible.

The active, energy-dependent reabsorption of sodium begins almost immediately as filtrate enters the proximal tubule. Here, an adenosine triphosphatase pump drives the sodium into tubular cells while chloride ions passively follow. Glucose, amino acid, and other organic compound reabsorption is strongly coupled to sodium in the proximal tubule. Normally, the proximal tubule reabsorbs ~65% of the filtered sodium, but no active sodium transport occurs in the loop of Henle until the medullary thick ascending limb (mTAL) is reached. Cells of the mTAL are metabolically

active in their role of reabsorbing sodium and chloride, and have a high oxygen consumption compared with the thin portions of the descending and ascending limbs. Sodium pumps in the distal tubule and collecting duct are unique in that they are under control of the adrenal hormone aldosterone.

Reabsorption of water is a passive, osmotically driven process tied to sodium and other solute reabsorption. Water reabsorption also depends on peritubular capillary pressure; high capillary pressure opposes water reabsorption in the proximal tubule and tends to increase urine output. The proximal tubule reabsorbs ~65% of filtered water in an isosmotic fashion with sodium and chloride. The descending limb of the loop of Henle allows water to follow osmotic gradients into the renal interstitium. However, the thin ascending limb and mTAL are relatively impermeable to water and play a key role in producing concentrated urine. Only approximately 15% of filtered water is reabsorbed by the loop of Henle, and the remaining 20% of the filtrate volume flows into the distal tubule. There, and in the collecting duct, water reabsorption is controlled entirely by antidiuretic hormone (ADH) secreted by the pituitary gland.

Conservation of water and excretion of excess solute by the kidneys would become untenable without the ability to produce concentrated urine. This is accomplished by establishing a hyperosmotic medullary interstitium and regulating water permeability of the distal tubule and collecting duct with ADH.

2 The medullary interstitium would eventually lose its hyperosmolarity by washout of solutes were it not for the unique role of the vasa recta. The vasa recta prevents medullary solute washout by providing for a countercurrent exchange of ions, which continually "recycles" solutes between its descending and ascending arms. Medullary blood flow is low (it receives 2% of total RBF) but essential to renal concentrating ability. During periods of reduced RBF, the metabolically active mTAL may be especially vulnerable to ischemic injury.[2]

All that is now necessary to produce concentrated urine is to alter the water permeability of the distal tubule and collecting duct in response to bodily needs. ADH increases the water permeability of these structures and allows for passive diffusion of water (under considerable osmotic pressure) back into the circulation. The posterior pituitary releases ADH in response to an increase in either extracellular sodium concentration or extracellular osmolality. In addition, ADH release can be triggered by a perceived reduction in intravascular fluid volume. The arterial baroreceptors are activated when hypovolemia leads to a decrease in blood pressure, whereas atrial receptors are stimulated by a decline in atrial filling pressure. Both of these circulatory reflex systems stimulate release of ADH from the pituitary and cause retention of water by the kidney in an effort to return the intravascular volume toward normal. ADH also causes renal cortical vasoconstriction when it is released in large amounts, such as during the physiologic stress response to trauma, surgery, or other critical illness. This induces a shift of RBF to the hypoxia-prone renal medulla.

Neurohumoral regulation of sodium reabsorption by the kidney is another important component of the physiologic response to stress. The hormonal messengers involved in sodium management also have potent vasoactive effects on both the renal and systemic vasculature.

Renin-Angiotensin-Aldosterone System. Renin-angiotensin activity plays an important role in regulating RBF and GFR. Renin release by the renal afferent arteriole may be triggered by hypotension, increased tubular fluid chloride ion concentration, or sympathetic stimulation. Renin enhances angiotensin II production, which induces renal efferent arteriolar vasoconstriction. Angiotensin II also promotes ADH release from the posterior pituitary, sodium reabsorption by the proximal tubule, and aldosterone release by the adrenal medulla. Aldosterone, in turn, stimulates the distal tubule and collecting duct to actively reabsorb sodium (and water), resulting in intravascular volume expansion. Sympathetic nervous system stimulation may also directly cause release of aldosterone. Thus, response of the body to surgical stress uses existing mechanisms for sodium and water conservation. This results in renal cortical vasoconstriction, a shift in RBF to salt-and-water–conserving juxtamedullary nephrons, a decrease in GFR, and salt and water retention. Clinically, this tendency toward oliguria and edema formation may persist for several days into the postoperative period because of ongoing stress (pain, sepsis, hypovolemia).

Renal Vasodilator Mechanisms. Opposing the salt and water retention and vasoconstriction observed in stress states and mediated by the sympathetic nervous system, ADH, and

the renin-angiotensin-aldosterone system are the actions of *atrial natriuretic peptide* (ANP), *nitric oxide*, and the renal *prostaglandin* system. ANP is released by the cardiac atria in response to increased stretch under conditions of relative hypervolemia. Both salt and water excretion increase as ANP blocks reabsorption of sodium in the distal tubule and collecting duct. ANP also increases GFR, causes systemic vasodilatation, inhibits release of renin, opposes production and action of angiotensin II, and decreases aldosterone secretion.[3,4,5] Nitric oxide produced by the kidney opposes the renal vasoconstrictor effects of angiotensin II and the adrenergic nervous system, increases sodium and water excretion, and participates in the tubuloglomerular feedback system.[6]

Prostaglandins are produced by the kidney as part of a complex system that modulates RBF and opposes the actions of ADH, norepinephrine, and the renin-angiotensin-aldosterone system.[7] Stress states, renal ischemia, and hypotension stimulate the production of renal prostaglandins through the enzymes phospholipase A_2 and cyclooxygenase. Prostaglandins produced by cyclooxygenase activity cause dilatation of renal arterioles (antiangiotensin II), whereas their distal tubular effects result in an increase in sodium and water excretion (anti-ADH and aldosterone). The renal prostaglandin system is important in maintaining RBF and sodium and water excretion during times of high physiologic stress and poor renal perfusion.[7] This defensive role for the prostaglandins has been confirmed by experiments demonstrating that cyclooxygenase inhibition has damaging effects in the ischemic kidney, but not in the unstressed state.[8] Conversely, stimulation of prostaglandin synthesis or administration of exogenous prostaglandin E_2 protects the kidney from hypoxic injury.[9]

RENAL DYSFUNCTION AND ANESTHESIA

Altered renal function can be represented as a clinical continuum that ranges from normal compensatory changes during stress to frank renal failure. Clinically, there is considerable overlap between compensated and decompensated renal dysfunctional states.

3 The kidney under stress reacts in a predictable manner to help restore intravascular volume and maintain blood pressure. The sympathetic nervous system reacts to trauma, shock, or pain by releasing norepinephrine, which acts much like angiotensin II on the renal arterioles. Norepinephrine also activates the renin-angiotensin-aldosterone system and causes ADH release. The net result of modest activity of the stress response system is characterized by a shift of blood flow from the renal cortex to the medulla, avid sodium and water reabsorption, and decreased urine output. A more intense stress response may induce a decrease in RBF and GFR by causing afferent arteriolar constriction. If this extreme situation is not reversed, ischemic damage to the kidney may result, and acute renal failure (ARF) may become clinically manifest.

4 More often, some other insult contributes to renal failure in the "stressed" patient with coexisting renal vasoconstriction.[10]

5 With the exception of methoxyflurane and possibly enflurane, anesthetic agents do not directly cause renal dysfunction or interfere with normal compensatory mechanisms activated by the stress response. Nephrotoxicity of methoxyflurane appears to be due to its metabolism, which results in release of fluoride ions believed to be responsible for the renal injury.[11] It has been suggested that renal, not hepatic, metabolism of methoxyflurane may be responsible for generating fluoride ions locally that contribute to nephrotoxicity.[12] Enflurane nephrotoxicity may occur,[13] but it seems to be of minor clinical importance, even in patients with preexisting renal dysfunction.[14] Controversy over sevoflurane-induced nephrotoxicity appears to be waning and is discussed in Chapter 15. Anesthetic-induced reductions in RBF have been described for many agents, but are clinically insignificant and reversible.[15,16] Likewise, anesthetic agents have not been shown to interfere with renal neurohumoral responses to physiologic stress.

6 Although direct anesthetic effects on the kidney are usually not harmful, indirect effects may combine with hypovolemia, shock, nephrotoxin exposure, or other renal vasoconstrictive

states to produce renal dysfunction. If the chosen anesthetic technique causes a protracted reduction in cardiac output or sustained hypotension that coincides with a period of intense renal vasoconstriction, renal dysfunction or failure could result. This is true for either general or regional anesthesia. There are no comparative studies demonstrating superior renal protection or improved renal outcome with general versus regional anesthesia.

Acute Renal Failure

7 ARF is a sudden decrease in renal function resulting in inability of the kidneys to excrete nitrogenous and other wastes. This is manifested by accumulation of creatinine and urea in the blood (uremia) and is often accompanied by reduced urine production, although nonoliguric forms of postoperative ARF are common.[17] Isolated ARF carries a mortality of <10%.[18] In surgical patients, acute tubular necrosis (ATN) is the most common etiology of ARF. ARF frequently occurs in the setting of critical surgical illness with multiple organ failure (MOF) (it is rarely an isolated event), mortality is alarmingly high (up to 90%), and the mortality rate may be higher for surgical patients than for medical patients with renal failure.[19]

A contributing factor to poor outcome is the fact that extracorporeal renal support appears to have had little success in altering the course of ARF in critically ill surgical patients.[20,21] Even studies that advocate use of extracorporeal technology report mortality of between 50% and 70%.[22,23,24,25]

Active renal failure can be classified as arising from *prerenal* factors causing renal hypoperfusion, numerous *intrinsic* renal etiologies, or *postrenal* causes (obstructive uropathy). There are many pathophysiologic similarities between the various causes of renal failure that ultimately lead to a common syndrome referred to as *organic ARF* (Fig. 35-5).

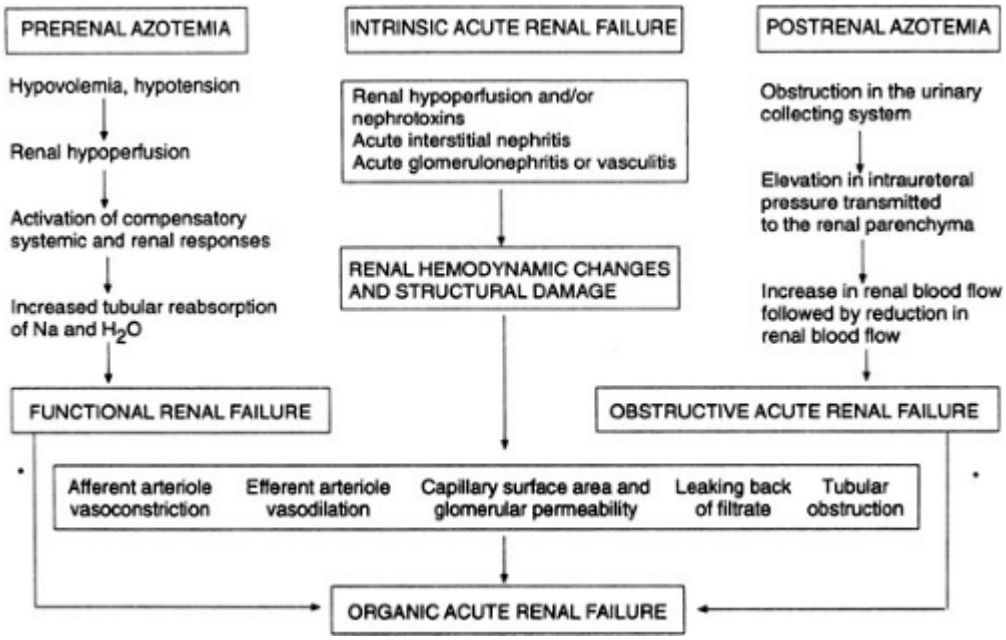

FIGURE 35-5. Mechanisms of acute renal failure. *, Depending on severity and duration of injury. (Reprinted with permission from Pellanda MV, Fabris A, Ronco C: Etiology and pathophysiology of acute renal failure. In Pinsky MR, Dhainaut JFA [eds]: Pathophysiologic Foundations of Critical Care, p 575. Baltimore, Williams & Wilkins, 1993.)

Prerenal Azotemia and Acute Tubular Necrosis

Prerenal azotemia is the increase in blood urea nitrogen (BUN) associated with renal hypoperfusion or ischemia that has not caused renal parenchymal damage. As such, it forms a

continuum with ATN. The metabolically active cells of the mTAL of Henle are especially vulnerable to hypoxic damage because of their relatively high oxygen consumption-to-delivery ratio.[2] Necrosis of tubular cells releases debris into the tubules, causing flow obstruction, increased tubular pressure, and back leak of tubular fluid (see Fig. 35-5). Often, prerenal failure is precipitated in patients with preexisting renal vasoconstriction (e.g., volume depletion, heart failure, sepsis) by nephrotoxin exposure or reduction in cardiac output.[26]

Intrinsic Acute Renal Failure

The term "intrinsic" not only implies a primary renal etiology of ARF, but also includes ischemia, toxins, and renal parenchymal diseases. ATN remains the most common ischemic lesion and represents an extension of prerenal azotemia, whereas cortical necrosis may follow a massive renovascular insult such as prolonged suprarenal aortic clamping or renal artery

embolism. Nephrotoxins often act in concert with hypoperfusion or underlying renal vasoconstrictive states to damage renal tubules or microvasculature. Several common nephrotoxins, some of which are difficult to avoid in a hospitalized patient population, are listed in Table 35-1. Renal parenchymal diseases may affect either the glomerulus or interstitium, and are frequently immune mediated or part of a more systemic disorder that targets the kidney.

TABLE 35-1 Nephrotoxins Commonly Found in the Hospital Setting

·EXOGENOUS	·ENDOGENOUS
Antibiotics	Calcium (hypercalcemia)
Aminoglycosides, cephalosporins, amphotericin B, sulfonamide, tetracyclines, vancomycin Anesthetic agents	Uric acid (hyperuricemia and hyperuricosuria) Myoglobin (rhabdomyolysis)
Methoxyflurane, enflurane	Hemoglobin (hemolysis)
Nonsteroidal anti-inflammatory drugs	Bilirubin (obstructive jaundice)
Aspirin, ibuprofen, naproxen, indomethacin, ketorolac	Oxalate crystals Paraproteins
Chemotherapeutic–immunosuppressive agents	
Cisplatinum, cyclosporin A, methotrexate, mitomycin, nitrosoureas, tacrolimus	
Contrast media	

Postrenal Azotemia: Obstructive Uropathy

Downstream obstruction of the urinary collecting system is the least common pathway to organic ARF, accounting for <5% of cases.[26] The obstructing lesion may occur at any level of the collecting system, from the renal pelvis to the distal urethra. Intraluminal pressure then rises and

is eventually transmitted back to the glomerulus, thereby reducing its filtration pressure.

Intraoperative Oliguria: Prerenal Azotemia or Acute Tubular Necrosis

Several real-time RBF monitors are being developed for intraoperative and critical care use (see Perioperative Assessment of Renal Function section). However, urine flow rate has traditionally been used as a measure of renal "well-being," a job for which it is ill suited.[27] Nevertheless, oliguria (urine flow rate of <0.5 mL/kg/hr) may be a useful sign of renal hypoperfusion when other objective signs of reduced systemic blood flow are present and the overall clinical scenario is appropriate. The presumption should be that intraoperative oliguria is a normal response to the stress of surgery and ongoing blood and fluid losses. If a fluid bolus improves the urine flow rate, or the heart rate and blood pressure indicate hypovolemia, further fluid administration is indicated. Isolated hypovolemia can usually be corrected relatively quickly as long as ongoing loss of blood and intravascular fluid are also replaced. If oliguria persists and signs of heart failure or volume overload appear, the patient's hemodynamic profile can be further assessed with a pulmonary artery catheter or transesophageal echocardiography to optimize cardiac output and systemic oxygen delivery and to improve renal perfusion.

When sepsis is responsible for poor urine output, hypotension is a common finding and is usually secondary to systemic vasodilation, hypovolemia, and depressed myocardial contractility. Hypovolemia should be corrected with vigorous fluid resuscitation, while combinations of inotropic–vasopressor agents, such as dopamine, norepinephrine, phenylephrine, or dobutamine, are given to increase cardiac output, systemic vascular resistance, and renal perfusion pressure.[28,29,30]

Chronic Renal Failure

Patients with nondialysis chronic renal failure (CRF) are at increased risk of developing *end-stage renal disease* (ESRD). ESRD is the term used to describe a clinical syndrome characterized by multiple organ dysfunction that would prove fatal without dialysis. These patients have GFRs <25% of normal. Lesser degrees of renal dysfunction are categorized as renal insufficiency (25 to 40% of normal GFR) or decreased renal reserve (60 to 75% of normal GFR). Patients with decreased renal reserve are asymptomatic and frequently do not have

abnormally elevated blood levels of creatinine or urea (Fig. 35-6). Renal insufficiency results in clearly abnormal creatinine and BUN values, but nocturia (due to decreased concentrating ability) may be the only symptom.

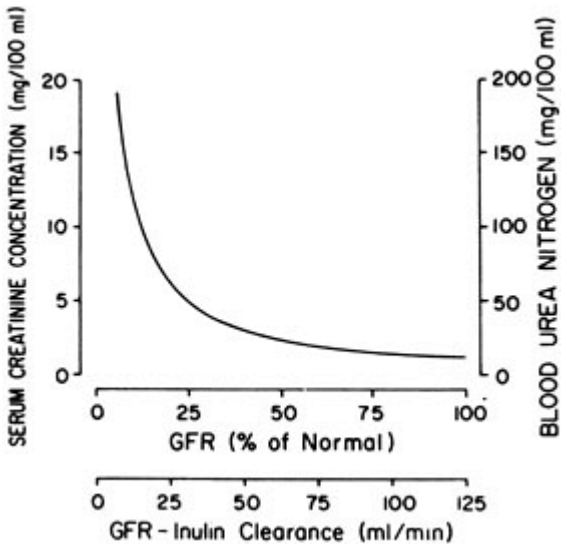

FIGURE 35-6. Relationship of serum creatinine concentration and blood urea nitrogen levels

to glomerular filtration rate (GFR). (Reprinted with permission from Valtin H: Renal Dysfunction: Mechanisms Involved in Fluid and Solute Imbalance, p 206, Boston, Little, Brown, 1979.)

The *uremic syndrome* represents the most extreme form of CRF, which occurs as the surviving nephron population and GFR decrease below 10% of normal. It results in inability of the kidney to perform its two major duties: regulating the volume and composition of extracellular fluid and excreting waste products. The loss of homeostasis, accumulation of cellular toxins, and inability of the kidney to maintain water balance causes multiple organ system dysfunction in the uremic syndrome[31] (Table 35-2). Water balance in ESRD becomes difficult to manage because the number of functioning nephrons is too small either to concentrate or to fully dilute the urine. This results in the inability to conserve water and to excrete excess water. Patients with uremic syndrome usually require frequent or continuous dialysis.

TABLE 35-2 The Uremic Syndrome

Delayed gastric emptying, anorexia, nausea, vomiting, hiccups, upper gastrointestinal tract inflammation/hemorrhage
▪NEUROMUSCULAR
Encephalopathy, seizures, tremors, myoclonus
Sensory and motor polyneuropathy
Autonomic dysfunction, decreased baroreceptor responsiveness, dialysis-associated hypotension
▪ENDOCRINE-METABOLISM
Renal osteodystrophy
↓ Glucose intolerance

Hypertriglyceridemia, ↑ atherosclerosis

Life-threatening hyperkalemia may occur in CRF because of slower-than-normal potassium clearance. Situations predisposing patients with renal failure to hyperkalemia are presented in Table 35-3. Derangements in calcium, magnesium, and phosphorus metabolism are also commonly seen in CRF (see Table 35-2).

TABLE 35-3 Factors Contributing to Hyperkalemia in Chronic Renal Failure

▪POTASSIUM INTAKE
Increased dietary intake
Exogenous IV supplementation
Potassium salts of drugs
Sodium substitutes
Blood transfusion
Gastrointestinal hemorrhage
▪POTASSIUM RELEASE FROM INTRACELLULAR STORES
Increased catabolism, sepsis
Metabolic acidosis
β-Adrenergic blocking agents

Digitalis intoxication (Na-K-ATPase inhibition)
Insulin deficiency
Succinylcholine
▪POTASSIUM EXCRETION
Acute decrease in GFR
Constipation
Potassium-sparing diuretics
Angiotensin-converting enzyme inhibitors (decreased aldosterone secretion)
Heparin (decreased aldosterone effect)

Na-K-ATPase, Na-K-adenosine triphosphatase; GFR, glomerular filtration rate; IV, intravenous.

Metabolic acidosis occurs in two forms in ESRD: a hyperchloremic, normal–anion-gap acidosis and a high-gap acidosis due to inability to excrete titratable acids. Both render patients susceptible to an endogenous acid load as may occur in shock states, hypovolemia, or an increase in catabolism.

Cardiovascular complications of the uremic syndrome are primarily due to volume overload, high renin–angiotensin activity, autonomic nervous system hyperactivity, acidosis, and electrolyte disturbances. Hypertension due to extracellular fluid volume expansion, autonomic factors, and hyperreninemia is an almost universal finding in ESRD. Together with volume overload, acidemia, anemia, and high-flow arteriovenous fistulae created for dialysis access, hypertension contributes to development of myocardial dysfunction and heart failure. Pericarditis may occur secondary to uremia or dialysis, with pericardial tamponade developing in 20% of the latter group.[32] Pulmonary problems associated with CRF are limited to changes in lung water and control of ventilation. Pulmonary edema and restrictive pulmonary dysfunction are commonly seen in patients with renal failure and are responsive to dialysis. Hypervolemia, heart failure, reduced serum oncotic pressure, and increased pulmonary capillary permeability are factors in the development of pulmonary edema. Chronic metabolic acidosis may be responsible, in part, for the hyperventilation seen in patients with ESRD, but increased lung water and poor pulmonary compliance also stimulate ventilation.

The anemia of CRF is due to reduced levels of erythropoietin, red cell damage, ongoing gastrointestinal blood loss, and iron or vitamin deficiencies. Recombinant human erythropoietin has improved the management of anemia in ESRD.[33] Platelet dysfunction may aggravate blood loss, but it is responsive to dialysis, cryoprecipitate, and desmopressin acetate (or DDAVP). Acquired defects in both cellular and humoral immunity probably account for the high prevalence of serious infections (60%) and high mortality due to sepsis in CRF (30%).

Issues related to the gastrointestinal, neuromuscular, and endocrine-metabolism organ systems are listed in Table 35-2.

Anesthetic Agents in Renal Failure

Significant renal impairment may affect the disposition, metabolism, and excretion of commonly used anesthetic agents. Inhalational anesthetics are, of course, an exception to the rule that drugs with central nervous system activity (which generally are lipid soluble) must be converted to more hydrophilic compounds by the liver before being excreted by the kidney. Water-soluble metabolites of agents that are not inhaled may accumulate in renal failure and contribute to prolongation of clinical effects if they possess even a small percentage of the pharmacologic activity of the parent drug. Drugs that are eliminated unchanged by the kidneys (e.g., certain nondepolarizing muscle relaxants, the cholinesterase inhibitors, many antibiotics, digoxin) may have a prolonged elimination half-life when given to patients with renal failure. Many drugs used in the practice of anesthesia are highly protein bound and may demonstrate exaggerated clinical effects when protein binding is reduced by uremia. Renal failure may also increase the volume of distribution of certain agents, thereby prolonging their elimination half-life. There is a paucity of data concerning the effects of renal failure on anesthetic drug metabolism,[34,35] and suspected pharmacodynamic changes in patients with renal failure have proved difficult to document for most drugs.[36]

Induction Agents and Sedatives

Thiopental serves as an example of how reduced protein binding in CRF may affect clinical use of an anesthetic agent. Burch and Stanski[37] showed that the free fraction of a thiopental induction dose is nearly doubled in patients with renal failure. This accounts for the exaggerated clinical effects of thiopental in these patients and explains the need for a decreased induction dose in uremic patients compared with normal patients.

Ketamine is less extensively protein bound than thiopental, and renal failure appears to have minimal influence on its free fraction. Redistribution and hepatic metabolism are largely responsible for termination of the anesthetic effects, with <3% of the drug excreted unchanged in the urine. Norketamine, the major metabolite, has one-third the pharmacologic activity of the parent drug and is further metabolized before it is excreted by the kidney.[38] Poor renal function is not known to alter the pharmacokinetics or clinical profile of ketamine.[39]

Etomidate, although only 75% protein bound in normal patients, has a larger free fraction in ESRD.[40] The decrease in protein binding does not seem to alter the clinical effects of an etomidate anesthetic induction in patients with renal failure.

Propofol undergoes extensive, rapid hepatic biotransformation to inactive metabolites that are renally excreted. Its pharmacokinetics appear to be unchanged in patients with renal failure,[41,42] and there are no reports of prolongation of its effects in ESRD.

The benzodiazepines, as a group, are extensively protein bound. CRF increases the free fraction of benzodiazepines in plasma, which may potentiate their clinical effect. Certain benzodiazepine metabolites are pharmacologically active and have the potential to accumulate with repeated administration of the parent drug to anephric patients. For example, 60 to 80% of midazolam is excreted as its (active) α-hydroxy metabolite,[43] which accumulates during long-term infusions in patients with renal failure.[44] ARF appears to slow the plasma clearance of midazolam,[44] whereas repeated diazepam or lorazepam administration in CRF may carry a risk of active metabolite-induced sedation.[35] Alprazolam is one of the few drugs related to anesthesia practice that has undergone pharmacodynamic studies in patients with CRF. Schmith et al.[45] found that when decreased protein binding and increased free fraction of alprazolam are taken into account, patients with CRF are actually more sensitive to its sedative effects than normal persons.

Dexmedetomidine is a relatively new sedative agent primarily metabolized in the liver. Volunteers with renal impairment receiving dexmedetomidine experienced a longer-lasting sedative effect

than subjects with normal kidney function. The most likely explanation is that less protein binding of dexmedetomidine occurs in subjects with renal dysfunction.[46]

Opioids

Single-dose studies of morphine pharmacokinetics in renal failure demonstrate no alteration in its disposition. However, chronic administration results in accumulation of its 6-glucuronide metabolite, which has potent analgesic and sedative effects.[47] There is also a decrease in protein binding of morphine in ESRD, which mandates a reduction in its initial dose. Meperidine is remarkable for its neurotoxic, renally excreted metabolite (normeperidine) and is not recommended for use in patients with poor renal function. Hydromorphone is metabolized to hydromorphone-3-glucuronide, which is excreted by the kidneys. This active metabolite accumulates in patients with renal failure and may cause cognitive dysfunction and myoclonus.[48] Oxycodone elimination was found to be prolonged in a single-dose study of patients with CRF.[49] Repeated dosing of oxycodone should result in prolonged opioid effects. Codeine also has the potential for causing prolonged narcosis in patients with renal failure and cannot be recommended for long-term use.[47]

Fentanyl appears to be an excellent opioid for use in ESRD because of its lack of active metabolites, unchanged free fraction, and short redistribution phase.[35] Small to moderate doses, titrated to effect, are well tolerated by uremic patients. However, a dose of 25 µg/kg given to patients undergoing renal transplantation resulted in prolonged opioid effect that correlated with preoperative BUN.[50] Alfentanil has been shown to

have reduced protein binding but no change in its elimination half-life or clearance in ESRD, and is extensively metabolized to inactive compounds.[51] Therefore, caution should be exercised in administering a loading dose, but the total dose and infusion dose should be similar to those for patients with normal renal function. The free fraction of sufentanil is unchanged in ESRD; however, its pharmacokinetics are variable, and it has been reported to cause prolonged narcosis.[52]

Remifentanil is rapidly metabolized by blood and tissue esterases to a weakly active (about 4,600 times less potent as µ-opioid agonist), renally excreted metabolite, and remifentanil acid. Renal failure has no effect on clearance of remifentanil, but elimination of the principal metabolite, remifentanil acid, is markedly reduced. However, the clinical implications of this metabolite are limited.[53]

Muscle Relaxants

Muscle relaxants are the most likely group of drugs used in anesthetic practice to produce prolonged effects in ESRD because of their reliance on renal excretion (Table 35-4). (See also Chapter 16.) Only succinylcholine, atracurium, *cis*-atracurium, and mivacurium appear to have minimal renal excretion of the unchanged parent compound. Most nondepolarizing muscle relaxants must be either hepatically excreted or metabolized to inactive forms to terminate their activity in the absence of renal function. Some muscle relaxants have renally excreted, active metabolites that may contribute to their prolonged duration of action in patients with ESRD. Although the following discussion focuses on the pharmacology of individual muscle relaxants, coexisting acidosis and electrolyte disturbances, as well as drug therapy (e.g., aminoglycosides, diuretics, immunosuppressants, magnesium-containing antacids), may alter the pharmacodynamics of muscle relaxants in patients with renal failure.[54]

TABLE 35-4 Nondepolarizing Muscle Relaxants in Renal Failure[54,56,57,63,65,69,70,236,237,238]

▪DRUG	▪% RENAL EXCRETION	▪HALF-LIFE (hr) NORMAL/ESRD	▪RENALLY EXCRETED	▪USE IN ESRD

			ACTIVE METABOLITE	
d-Tubocurarine	60	1.4–2.2	-	Avoid
Metocurine	45–60	6/11.4	-	Avoid
Pancuronium	30	2.3/4–8	+	Avoid
Gallamine	>85	2.5/6–20	-	Avoid
Pipecuronium	37	1.8–2.3/4.4	+	Avoid
Doxacurium	30	1.7/3.7	-	Avoid
Vecuronium	30	0.9/1.4	+	Normal single, smaller repeat doses; avoid prolonged CI
Rocuronium	30	1.2–1.6/1.6–1.7	-	Normal single, repeat doses, increased variability
Atracurium/*cis*-atracurium	<5	0.3/0.4	-	Normal single, repeat, CI doses
Mivacurium	<7	2 min/2 min	-	Duration 1.5 × normal, lower CI dose
Rapacuronium	<12	0.5/0.5	++	Normal single dose, much smaller repeat dose, avoid CI

CI, continuous infusion; ESRD, end-stage renal disease.

Succinylcholine has a long history of use in CRF that has been somewhat confused by conflicting reports of plasma cholinesterase activity in renal failure.[55,56] Its use can be justified as part of a rapid-sequence intubation technique because its duration of action in ESRD is not significantly prolonged. Use of a continuous infusion of succinylcholine, however, is more problematic because the major metabolite, succinylmonocholine, is weakly active and excreted by the kidney. Concern about the increase in serum potassium levels after succinylcholine administration (0.5 mEq/L in normal subjects) implies that the serum potassium should be normalized to the extent possible in patients with renal failure, but clinical experience has shown that the acute small increase in potassium following administration of succinylcholine is well tolerated in patients with persistently elevated potassium levels. Use of the long-acting muscle relaxants, doxacurium and pipecuronium, might also be questioned in patients with known renal insufficiency. In a single-dose study of doxacurium, Cook et al.[57] demonstrated an increased elimination half-life, reduced plasma clearance, and prolonged duration of effect in patients with renal failure. These data support the observations of Cashman et al.[58] that renal failure nearly doubles the clinical duration of doxacurium. Similar findings have been reported for the pharmacokinetics of pipecuronium.

Intermediate-acting muscle relaxants (atracurium, *cis*-atracurium, vecuronium, and rocuronium) have a distinct advantage in ESRD because of their shorter duration. The risk of a clinically significant, prolonged block is reduced. Atracurium and its derivative, *cis*-atracurium, undergo enzymatic ester hydrolysis and spontaneous nonenzymatic (Hoffman) degradation with minimal renal excretion of the parent compound. Their elimination half-life, clearance, and duration of action are not affected by renal failure,[59] nor have they been reported to cause prolonged clinical effects in ESRD. These characteristics strongly recommend the use of atracurium and *cis*-atracurium in patients with renal disease. One potential concern is that an atracurium metabolite, laudanosine, causes seizures in experimental animals and may accumulate with repeated dosing or continuous infusion.[60] This, however, has not been realized in intensive care patients with renal failure receiving prolonged infusions of atracurium.[61] Consistent with its greater potency and lower dosing requirements, *cis*-atracurium metabolism results in lower laudanosine blood levels than does atracurium in ESRD patients.[62]

The pharmacokinetics of vecuronium were initially reported as unchanged in renal failure, but it was later demonstrated that its duration of action was prolonged as a result of reduced plasma clearance and increased elimination half-life.[63] In addition, the active metabolite, 3-desmethylvecuronium, was shown to accumulate in anephric patients receiving a continuous vecuronium infusion who subsequently had prolonged

neuromuscular blockade.[64] An intubating dose would be expected to last ~50% longer in patients with ESRD.[63]

Rocuronium, a rapid-onset muscle relaxant, has a pharmacokinetic profile in normal subjects similar to that of vecuronium.[65] Single-dose pharmacokinetic studies in patients with renal failure have reported conflicting results. Szenhradszky et al.[66] reported that renal failure increased the volume of distribution and elimination half-life of rocuronium, but had no effect on its clearance. Cooper et al.[67] found that clearance was reduced and duration of block widely variable in patients with renal failure, although mean duration of clinical relaxation and spontaneous recovery was not statistically different from that in control subjects. Wide variation in the duration of neuromuscular block has been reported by others, who also found that repeated maintenance doses of rocuronium were well tolerated in patients with ESRD.[68]

The short-acting muscle relaxant mivacurium is enzymatically eliminated by plasma pseudocholinesterase at a somewhat slower rate than succinylcholine. Low pseudocholinesterase activity correlates with slower recovery from a bolus dose of mivacurium in anephric patients.[56,69,70] The maintenance infusion dose has been reported to be both lower[69] and similar[70] to that in normal control subjects.

The pharmacokinetics of clinically available anticholinesterases are affected by renal failure.[71] They have a prolonged duration of action in ESRD because of their heavy reliance on renal excretion. The anticholinergic agents atropine and glycopyrrolate, used in conjunction with the

anticholinesterases, are similarly excreted by the kidney.[72] Therefore, no dosage alteration of the anticholinesterases is required when antagonizing neuromuscular blockade in patients with reduced renal function.

PRESERVATION OF RENAL FUNCTION

Preventing renal failure in surgical patients is preferable to treating established ARF, given the poor outcome of these patients. To prevent ARF, the clinician must first identify those patients who are particularly at risk for perioperative renal damage and then focus on preserving renal function in that group. Certain patient-based indicators, nephrotoxin exposures, and surgical procedures are known risk factors for postoperative ARF (Table 35-5). Identifying these factors prior to surgery allows the anesthesiologist an opportunity to devise an anesthetic plan emphasizing renal preservation.

TABLE 35-5 Risk Factors For Postoperative Renal Failure

Hepatic transplantation
Renal transplantation

Partial nephrectomy

Patient-Based Risk Factors for Acute Renal Failure

Large, prospective studies of preoperative patient-based risk factors for ARF are lacking. Most often, retrospective reviews of ARF in surgical patients have revealed conflicting data that may be pertinent to a select patient population, but cannot be generalized to a larger group of patients. Novis et al.[73] published a review of the available prospective and retrospective studies examining patient-based risk factors for postoperative renal failure. Their report serves as the basis for the following discussion on preoperative risk factors, which can be easily identified with history, physical examination, and appropriate laboratory screening tests.

8 The single most reliable predictor of postoperative renal dysfunction is preoperative renal dysfunction.[73] Elevated BUN or creatinine levels, a history of renal dysfunction, or other evidence of preexisting renal problems successfully predict postoperative ARF. It is likely that preexisting renal disease predisposes patients to further renal insult, but it may also make further loss of function easier to recognize.[73] The presumption, of course, is that it is essential to preserve what renal function the patient has. The alternative (frank renal failure) is potentially catastrophic. Identifying patients with preexisting renal dysfunction requires appropriate screening of BUN and creatinine in those who have other renal risk factors (history of renal problems, cardiac disease, or sepsis) or who are facing high-risk surgical procedures.

Preoperative cardiac dysfunction is another important predictor of postoperative ARF.[73] Shusterman et al.[74] identified heart failure as a risk factor in a mixed, surgical–medical population. Specifically, evidence of left ventricular dysfunction or elevated pulmonary capillary wedge pressure has predictive value in identifying patients at risk for ARF. This is intuitively obvious when one considers that poor cardiac output reduces RBF and increases the potential for renal vasoconstriction and ischemic injury. If left ventricular dysfunction is confirmed, medical management should be optimized before surgery whenever possible. Perioperative invasive monitoring can be helpful in managing fluid administration, oliguria, respiratory dysfunction, or further deterioration in cardiac performance.

Volume depletion has been reported to be a risk factor for ARP in both medical and surgical patients.[74] As with heart failure and sepsis, hypovolemia may induce renal vasoconstriction and render the kidney vulnerable to nephrotoxin exposure or further reduction in oxygen delivery. Patients with diabetes mellitus (and microangiopathy) are particularly prone to developing ARF when they become volume depleted.[74]

Cholestatic jaundice has long been suspected to be a risk factor for postoperative ARF.[75] Patients with severe cirrhosis and ascites or hepatic failure are clearly predisposed to renal dysfunction as a result of portal vein sepsis. In up to 75% of patients with hepatic failure, associated renal dysfunction/failure (hepatorenal syndrome) develops.[76]

Twenty-five percent of patients presenting for liver transplantation have some degree of renal

dysfunction; posttransplantation, this percentage rises to almost 70%.[77] Preoperative serum creatinine levels can predict short-term survival of liver transplant recipients.[78]

Numerous investigators cite advanced age as a risk factor for postoperative ARF.[73] Patients who are elderly are frequently found to have reduced GFR, RBF, and renal reserve, making them less able to withstand a renal insult.[79] They also have

a high incidence of cardiovascular disease and flow-limiting renal arterial atherosclerosis, which may account for their apparent increased risk of ARF. One study has convincingly demonstrated that advanced age increases the risk of ARF due to aminoglycoside toxicity.[74] However, age as an isolated risk factor has not been shown to predict postoperative ARF.[73]

Other risk factors for postoperative ARF were reviewed by Novis et al.,[73] but could not be conclusively shown to be significant. These included aortic aneurysm, acute bacterial endocarditis, decreased serum albumin, malignancy, emergency surgery, and previous cardiac surgery.

Perioperative Assessment of Renal Function

Although an accurate preoperative assessment of renal function is important in identifying high-risk patients, it would be advantageous to be able to differentiate prerenal azotemia from early ATN and predict impending ARF. Kellen et al.[27] examined the ability of commonly used renal function measures to predict and diagnose early ARF in critically ill patients. The findings of their meta-analysis of the specificity, sensitivity, and positive predictive value of renal function tests are summarized in Table 35-6.

TABLE 35-6 Clinical Usefulness of Renal Function Tests

▪RENAL FUNCTION TEST	▪DISTINGUISH ATN VERSUS PRA	▪PREDICT EARLY ATN	▪COMMENTS
Urine flow rate	Poor	Poor	
Urine-specific gravity	Poor	Poor	Many nonrenal factors
Urine osmolality	Poor	Poor	Many nonrenal factors

Urine/plasma creatinine, BUN	Poor	Poor	
Urine Na^+	Poor	Poor	
Fractional excretion Na^+	Good in late ATN	Poor	

Free water clearance	—	Good with Ccr	Less sensitive than Ccr
Ccr	Good	Good	24-hr collection

ATN, acute tubular necrosis; BUN, blood urea nitrogen; Ccr, creatinine clearance; PRA, prerenal azotemia.

Kellen et al. found that urine flow rate, specific gravity, and osmolality are poor indicators of renal dysfunction because they are influenced by many nonrenal variables. Serum creatinine and BUN are good screening tools for preoperative renal dysfunction, but they are late warning signs of reduced GFR. A sizable loss of GFR may occur before serum creatinine and BUN levels become abnormal (see Fig. 35-6). Unfortunately, creatinine and BUN are influenced by nonrenal variables such as catabolic rate and muscle mass, making isolated serum determinations unreliable in a rapidly changing scenario of critical illness. This is also true for tests based on creatinine and urea levels, such as urine-to-plasma ratios of these compounds. Urine sodium excretion should increase when tubular injury results in a loss of reabsorptive ability, but in the acute setting, isolated urine sodium (urine Na^+) values are more accurate reflectors of the composition of resuscitative fluids than tubular function. Fractional excretion of sodium (percentage of filtered sodium excreted) can reliably distinguish prerenal azotemia from established ATN, but it is unable to serve as an early indicator or predictor of ARF. Free water clearance (CH_2O) measures the diluting–concentrating ability of the kidney and should reflect tubular integrity. As a predictor of impending ARF, however, CH_2O cannot be used by itself and should be combined with a creatinine clearance (Ccr) determination.[80] It would appear that Ccr, as a sole indicator of imminent ARF, is the best test available to the clinician.[27]

Ccr is a direct reflection of GFR and may be either measured or calculated. Measured determination requires that urine and plasma creatinine (cr) levels be obtained and that the urine volume for 24 hours be collected and measured, such that

$$\text{Ccr} = \frac{\text{Urine cr} \times \text{Urine volume}}{\text{Plasma cr}}$$

Traditionally, the need for a 24-hour urine collection has limited the usefulness of Ccr in the acute situation. However, a 2-hour Ccr correlates reasonably well with the standard 24-hour collection in critically ill surgical patients [81] and nonoliguric intensive care patients.[82] A major advantage of the abbreviated Ccr determination is that it facilitates sequential monitoring of renal function during periods of rapidly changing patient status. Therapeutic interventions directed at improving renal function may be quickly assessed in this way.

Measured Ccr remains the most reliable predictor of renal dysfunction in critically ill surgical patients, regardless of the urine collection duration. The ideal renal function monitor would provide real-time data using noninvasive, easily transportable, and interpretable technology. Real-time monitoring of renal function is under development using ultrasonography[83] and nuclear medicine[84] technology.

Nephrotoxins and Perioperative Acute Renal Failure

Nephrotoxin exposure is a common occurrence in hospitalized patients and frequently plays a role in etiology of ARF in this population. Nephrotoxins may take the form of drugs, nontherapeutic

chemicals, heavy metals, poisons, and endogenous compounds; a partial list is found in Table 35-1. The nephrotoxins most likely to contribute to renal dysfunction/failure in the perioperative period are certain antimicrobial and chemotherapeutic–immunosuppressive agents, radiocontrast media, nonsteroidal anti-inflammatory drugs (NSAIDs), and the endogenous heme pigments myoglobin and hemoglobin. These diverse groups of renal toxins share a common pathophysiologic characteristic: they disturb either renal oxygen delivery or oxygen utilization and thereby promote renal ischemia.

Antimicrobial and chemotherapeutic–immunosuppressive agents are effective for their designed purpose because they are cellular toxins. When these drugs are filtered, reabsorbed, secreted, and eventually excreted by the kidney, toxic concentrations in renal cells can be realized.[85] The aminoglycoside antibiotics (neomycin, gentamicin, tobramycin, amikacin) and amphotericin B are particularly difficult to avoid because they are effective antimicrobials, with few available alternatives.[86]

They are filtered into the proximal tubule and, when reabsorbed into intracellular lysosomes, inhibit mitochondrial phosphorylation and deplete tubular cells' ATP stores. Their effect can be additive to other nephrotoxic factors, causing impairment of kidney function. Hypovolemia, fever, renal vasoconstriction, and concomitant therapy with other nephrotoxic agents should be avoided. Electrolyte disorders such as hypercalcemia, hypomagnesemia, hypokalemia, and metabolic acidosis can further enhance toxic effect on the kidney.

Cyclosporin A and tacrolimus are similarly indispensable agents, but in combination with other nephrotoxins and clinical factors, they cause both acute and chronic renal injury in transplant recipients.[87]

Radiocontrast media pose a threat to the renal function of patients with diabetic nephropathy, preexisting renal vasoconstriction (heart failure, hypovolemia), or renal insufficiency.[88] Radiocontrast dye effects on renal function develop 24 to 48 hours after exposure and peak at 3 to 5 days. Measures that can prevent ARF or lessen the severity of renal damage include prehydration, smaller contrast doses, and withholding of other nephrotoxins, such as NSAIDs. Elective surgery should be postponed until the effects of dye resolve. There is some evidence that pretreatment with N-acetylcysteine can prevent radiocontrast nephropathy in patients with renal insufficiency.[89]

NSAIDs produce reversible inhibition of prostaglandin synthesis and are well-known nephrotoxins.[90] Except in cases of massive overdose, NSAIDs produce renal dysfunction only in patients with coexisting renal hypoperfusion or vasoconstriction. Advanced age, hypovolemia, end-stage hepatic disease, heart failure, sepsis, renal insufficiency, and major surgery are risk factors for development of NSAID-induced ARF.[86] Of particular interest to anesthesiologists is *ketorolac*, a parenterally administered NSAID. Ketorolac may predispose critically ill and elderly patients to ischemic ARF and acute, life-threatening hyperkalemia when given perioperatively.[86]

Myoglobin and hemoglobin are both capable of causing ARF in the context of critical surgical illness. Myoglobin seems to be a more potent nephrotoxin than hemoglobin because it is more readily filtered at the glomerulus and can be reabsorbed by the renal tubules, where it inhibits nitric oxide and induces medullary vasoconstriction and ischemia.[2,91] Hypovolemia and acidemia potentiate the toxicity of both pigments. Reduced intravascular volume causes a decrease in RBF and GFR, which results in a smaller volume of tubular fluid with a relatively higher concentration of pigment. Myoglobin and hemoglobin dissociate more easily to ferrihemate (a potent nephrotoxin) in acidic tubular fluid. There is also evidence suggesting that pigment precipitation inside the tubular lumen is enhanced under acidotic conditions and that tubular obstruction plays a role in the pathogenesis of ARF.[91,92]

Myoglobinuric renal failure occurs in the clinical setting of massive rhabdomyolysis that may follow from a number of insults. The most common causes of massive rhabdomyolysis in surgical patients are major crush, thermal, or electrical injuries, acute muscle ischemia due to arterial occlusion or compartment syndrome, malignant hyperpyrexia, extreme lithotomy position, and hyperlordotic position.[92,93,94,95] Potassium, phosphorus, and creatinine are released in large quantities from the

necrotic muscle. The clinical picture of myoglobinuric ARF is one of oligoanuria, rapidly rising creatinine, and life-threatening hyperkalemia. Unfortunately, the diagnosis of rhabdomyolysis is not straightforward, and a high index of suspicion is necessary to identify patients at risk for ARF. A creatine phosphokinase level of >15,000 U/L is predictive of hyperkalemic ARF and a high risk of death.[96]

Hemoglobinuric ARF usually results from massive hemolysis in association with renal hypoperfusion, as seen during exposure to extracorporeal circulation or cardiopulmonary bypass (CPB). Major transfusion reactions that occur in hypovolemic, acidemic, septic, or hemodynamically unstable patients may lead to renal injury, but rarely does isolated hemoglobinemia cause renal failure.[92]

Preventive treatment of pigmenturia-induced ARF is directed at increasing RBF and tubular (urine) flow while correcting any existing acidosis. These goals are accomplished by expanding the intravascular fluid volume with crystalloid infusion, stimulating an osmotic diuresis with mannitol, and increasing urine pH with alkali therapy.[97] Adequate systemic resuscitation from shock cannot be overemphasized as a prerequisite for preventing ARF, especially in massive crush injuries and electrical burns. Forced mannitol–alkali diuresis is indicated as the second step in preventive treatment of myoglobinuric renal failure, with urine flow rates of up to 300 mL/hr and urine pH of 6.5 advocated for patients with massive crush injuries.[97]

The nephrotoxicity of volatile agents remains debatable. Inhalation anesthetics such as enflurane, isoflurane, and sevoflurane can generate free fluoride ions during their metabolism, which (when levels are >150 μg/L) may cause polyuric ARF by interfering with tubular concentrating ability. However, peak fluoride levels during administration of these agents seldom reach toxic levels, and there are few reports describing only enflurane-induced nephrotoxicity.[98] The potential of sevoflurane-induced nephrotoxicity has been related to production of compound A during prolonged, low gas flow, sevoflurane anesthesia.[99] There are not enough data to support sevoflurane-induced renal injury in the human population, even during low gas flow anesthesia. However, maintaining fresh gas flow of at least 2 L/min to inhibit compound A formation during sevoflurane anesthesia is recommended.[100]

High-Risk Surgical Procedures

Several common surgical procedures can place renal function at risk. These include surgery of the heart and aorta, trauma surgery, and hepatic transplantation. Renal transplantation poses other special problems for renal preservation and is discussed in more detail in Chapter 53.

Emergency surgery has been reported as a possible risk factor for ARF, with trauma surgery figuring as a prominent subgroup of emergency procedures.[73] ATN is the preeminent renal lesion associated with trauma, and it may be produced by a number of ischemic mechanisms. Most often, hypovolemic shock, pigmenturia, MOF, or exogenous nephrotoxins are responsible for sequential or simultaneous insults to the kidney.[101] ARF that develops in the trauma patient may be characterized by either an early, oliguric picture related to inadequate volume resuscitation, or a later, often nonoliguric syndrome associated with MOF, nephrotoxin exposure, or sepsis.[102] The outcomes of these two posttraumatic ARF scenarios are dramatically different. The early form is associated with up to 90% mortality, whereas only 20 to 30% of patients die with nonoliguric ARF.[103] Not surprisingly, trauma victims with preexisting renal insufficiency experience higher mortality than previously healthy patients.[104]

9 Preventing ARF in patients presenting for emergency surgery begins with proper management of intravascular volume depletion and shock. Restoring euvolemia and maintaining cardiac output, systemic oxygen delivery, and RBF obviate renal vasoconstriction. Urine flow, once established, is maintained at ⩾0.5 mL/kg/hr. Invasive hemodynamic monitoring may be required to guide intraoperative management of ongoing cardiovascular instability due to surgical manipulation, blood loss, fluid shifts, and anesthetic effects. Intraoperative transesophageal echocardiography provides excellent assessment of left and right ventricular function, as well as therapeutic guidance of fluid resuscitation.

Nephrotoxin exposure should be kept to a minimum in the unstable trauma victim. Radiocontrast media, NSAIDs, and myoglobin pose the greatest threat in this patient group. There is no place for either furosemide or mannitol therapy in the early, resuscitative phase of trauma management, except in the case of head injury with elevated intracranial pressure or when massive rhabdomyolysis is suspected. After surgery, 1- or 2-hour Ccr determinations can help identify patients with impending ARF.[80]

Vascular surgery requiring aortic clamping has deleterious effects on renal function regardless of the level of clamp placement. Suprarenal clamping results in an attenuated ATN-like lesion.[105] Infrarenal clamping causes a smaller, short-lived reduction in GFR and is associated with a lower risk of ARF, whereas surgery involving the thoracic aorta has a 25% incidence of renal failure.[106] Two major predictors of ARF following aortic surgery appear to be preexisting renal dysfunction and perioperative hemodynamic instability.[107] Olsen et al.[21] reported that in a large series of patients undergoing abdominal aortic aneurysm repair, overall incidence of ARF was 12%. Patients who had emergency surgery for ruptured aneurysm had a very high incidence of hemodynamic instability, and ARF developed in 26%; in contrast, elective aortic surgery was associated with good hemodynamic control and a 4% incidence of renal failure. Atheromatous renal artery emboli and prolonged aortic clamp time may contribute to ischemic renal injury.

Efforts to improve renal outcome in aortic surgery should begin in the preoperative period by identification of patients with renal dysfunction. Ideally, these high-risk patients should not receive radiocontrast media or other nephrotoxins in the immediate preoperative period.

An endovascular approach to major aortic surgery has gained popularity. The etiology of renal dysfunction after endovascular and open repair of aortic aneurysm is multifactorial (renal ischemia, atheroembolism, hemodynamic instability). Although hemodynamic changes during endovascular procedures on the aorta may be less dramatic than those accompanying open repair, prevalence of renal complications is similar.[108] During endovascular procedures, patients are exposed to a substantial amount of radiocontrast dye, which can exacerbate postoperative renal dysfunction, especially in those with preexisting renal insufficiency. The long-term incidence of renal insufficiency/failure (followed up to 24 months postoperatively) is similar after endovascular and open repair of aortic aneurysm.[108,109] It is important that before endovascular procedures, patients are adequately hydrated and the total dose of radiocontrast dye is limited.

Most efforts to preserve renal function in aortic surgery have centered on diuretic and renal vasodilator therapy. Unfortunately, is little to support the use of either mannitol or low-dose dopamine to prevent the renal injury associated with aortic surgery. Indeed, a clinical study of infrarenal aortic clamping found that combined mannitol and low-dose dopamine treatment was no more effective in preventing renal dysfunction than volume expansion with saline.[110] Although other investigators have demonstrated an increase in urine flow rate with low-dose dopamine in sick postoperative patients,[111] evidence that this can preserve renal function during aortic surgery is lacking. Nifedipine prevented a postoperative decrease in GFR in a small, placebo-controlled study of aortic surgery patients.[112] Larger outcome trials are needed to confirm this preliminary finding. Insulin-like growth factor-1 has been shown to speed healing in experimental ischemic ARF,[113] and to improve renal function in patients with ESRD[114] and in those undergoing aortic or renal artery surgery.[115] A synthetic form of ANP may be useful in managing established oliguric ARF,[116] but it has not been used prophylactically in high-risk surgical patients. Fenoldopam, a selective dopamine-1 receptor agonist, shows great promise as a renal protective agent and should be the subject of future perioperative studies.[117]

Cardiac operations requiring CPB can be expected to result in renal dysfunction or failure in up to 7% of patients.[118,119,120,121,122] Preoperative renal dysfunction is a major risk factor for postoperative ARF in this population,[118,121,122,123] yet patients with preoperative CRF appear to tolerate surgery and CPB well.[119] Renal hypoperfusion is considered the primary pathogenic mechanism involved in precipitating ARF. Preoperative left ventricular dysfunction[121,122,124] and duration of CPB[118,121,122] are associated with post–CPB renal failure.

Early experience with non-CPB (“off pump”) coronary artery bypass grafting (CABG) suggests that

it offers better renal preservation than the traditional, "on-pump" technique.[125] However, despite the fact that pulsatile CPB suppresses plasma renin activity, postoperative renal function in patients with normal kidneys undergoing pulsatile or nonpulsatile CPB was equivalent.[126]

There are reports that patients on hemodialysis recover more quickly after off-pump than on-pump CABG.[127] Higgins et al.[128] found that preoperative renal function is an important predictor of postoperative renal morbidity and mortality in patients undergoing cardiac surgery. In particular, a preoperative serum creatinine level above 1.9 mg/dL was associated with a high prevalence of postoperative renal complications.[128]

When CPB is used, mannitol can protect against hemoglobin-induced ARF, promote urine flow, and reduce renal cell swelling.[129] Dopamine has been used as a renal vasodilator in cardiac surgery with mixed success. Costa et al.[130] administered low-dose dopamine during CPB to patients with preoperative renal dysfunction and were able to induce a saluresis without affecting GFR or protecting the kidney from ischemic injury. Dopexamine has been shown to improve Ccr and systemic oxygen delivery in cardiac surgery patients,[131] but studies examining the renal protective effects of fenoldopam, ANP, and insulin-like growth factor-1 in this population are not yet available.

As previously discussed, patients with hepatic failure or cholestatic jaundice are particularly susceptible to renal dysfunction. When conjugated bilirubin exceeds 8 mg/dL, endotoxins from the gastrointestinal tract are absorbed into the portal circulation, causing intense renal vasoconstriction. Intravenous mannitol and/or oral administration of bile salts in the preoperative period seem to limit renal dysfunction in patients with cholestatic jaundice. This probably accounts for the high incidence of ARF after liver transplantation and biliary surgery.[75,132,133,134] Renal dysfunction/failure may occur in up to two-thirds of liver transplant recipients.[77] Many transplantation candidates have overt hepatorenal syndrome, asymptomatic renal dysfunction, or underlying renal vasoconstriction. When such patients are exposed to intraoperative hemodynamic instability, massive transfusion, and nephrotoxins, ARF frequently follows.[133,134] Both preoperative and postoperative renal dysfunction contribute to early and long-term mortality.[78,133,135,136] Maintenance of adequate intravascular volume and aggressive management of hypoperfusion are basic tenets of anesthetic care of the liver transplant recipient, but investigators have also sought a role for low-dose dopamine. Low-dose dopamine has been shown to be no better than preoperative hydration in preserving renal function in patients with obstructive jaundice.[137]

Perioperative sepsis is a common cause of renal dysfunction. The mechanism of kidney damage in sepsis is multifactorial and includes hypotension, vasomotor nephropathy, and effects of endotoxins. During sepsis, renal autoregulation is impaired. Decrease in RBF, GFR, sodium excretion, and urine flow is related to hypotension-induced activation of the neurohormonal cascade, including renin-angiotensin system, vasopressin, and thromboxane.[138]

ANESTHESIA FOR ENDOUROLOGIC PROCEDURES

Medical care continues to evolve toward nonoperative or minimally invasive surgical procedures. Incisional surgery in urology is being replaced by endoscopic procedures in which endoscopes are passed along natural pathways (e.g., urethra, ureter) or through small incisions.[139] Economic considerations, patient convenience, and advances in instrumentation have all supported the trend toward endoscopy in urologic surgery (Table 35-7).

TABLE 35-7 Common Endourologic Procedures

Cystourethroscopy
Internal optical urethrotomy
Ureteroscopy

Placement of ureteral stent
Distal stone manipulation/laser lithotripsy
Transurethral resection of the prostate
Transurethral incision of the prostate
Balloon dilation of the prostate
Transurethral resection of bladder tumors
Percutaneous nephrostomy, nephroscopy, and nephrolithotomy

Cystourethroscopy and Ureteral Procedures

Cystourethroscopy is commonly used to examine and treat lower urinary tract disease. It provides direct visualization of the anterior and posterior urethra, bladder neck, and bladder. In the past, cystourethroscopy was performed with rigid endoscopes. General or regional anesthesia was required for patient comfort. In 1973, the flexible endoscope was introduced, which can be gently passed over anatomic angles with less patient discomfort.[140] For brief cystoscopic procedures, 5 to 10 mL of lubricant anesthetic jelly (2% lidocaine hydrochloride jelly) can be instilled into the urethra preoperatively.[141] This local anesthetic technique provides adequate anesthesia for many patients undergoing simple cystoscopy. For longer or more extensive procedures, conscious sedation techniques using a wide variety of sedative–hypnotic, anxiolytic, and analgesic drugs have been shown to combine excellent patient comfort and operating conditions with rapid patient recovery.[142,143] If general anesthesia is required for cystoscopy or urethral procedures, laryngeal mask airways are an alternative to the traditional facemask.

Numerous therapeutic procedures may also be performed using endoscopic techniques. Strictures of the bladder neck or urethra are treated with internal optical urethrotomy, which uses a "cold knife" to excise the scar. Ureteroscopy is an extension of cystoscopic techniques, providing access to the upper urinary tract and kidney for diagnostic endoscopy and biopsy, removal of ureteral and renal calculi, passage of a ureteral stent, dilatation and incision of strictures, fulguration of tumors, and laser treatments.[139] Ureteroscopy usually requires dilatation of the ureteral orifice and intramural ureter, often necessitating regional or general anesthesia.

Transurethral Resection of the Prostate

Benign prostatic hyperplasia (BPH) is the most common benign tumor in men and refers to regional nodular growth that occurs in the prostate gland as men age.[144] The prostate is a pear-shaped gland that surrounds the urethra at the base of the bladder (Fig. 35-7). Because of its anatomic position, hypertrophy of the prostate gland can compress the proximal urethra, resulting in urinary retention. BPH is responsible for the majority of urinary symptoms in men older than the age of 50 and results in need for prostatectomy in approximately one-third of all men who live to age 80.[145]

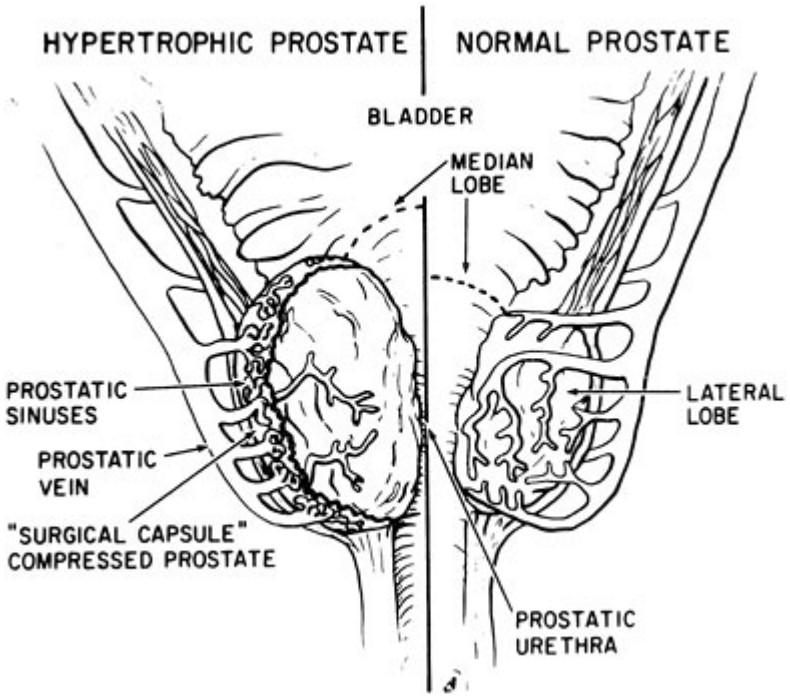

FIGURE 35-7. Anatomy of the normal and hypertrophic prostate gland. (Reprinted from Stoelting RK, Barash PG, Gallagher TJ: Advances in Anesthesia, p. 379, Chicago, Year Book Medical Publishers, 1986.)

Transurethral resection of the prostate (TURP) is the primary treatment for symptomatic BPH. This procedure commences with an initial cystoscopy to rule out concomitant disease and evaluate the size of the prostate gland.[146] The resectoscope, a specialized instrument with an electrode capable of both coagulating and cutting tissue, is then introduced through a modified cystoscope into the bladder, and the tissue protruding into the prostatic urethra is resected. Continuous irrigation of the bladder and prostatic urethra is required to maintain visibility, distend the operative site, and remove dissected tissue and blood.[147]

The prostate gland contains a rich plexus of veins that can be opened during surgical resection (see Fig. 35-7). If the pressure of the irrigating fluid during TURP procedures exceeds venous pressure, intravascular absorption of the fluid may occur via these open venous sinuses. The need for large volumes of irrigating fluid during the procedure and the potential for absorption of this fluid into the intravascular space may result in unique perioperative complications.

Irrigating Solutions for Transurethral Resection of the Prostate

The ideal irrigating fluid for use during TURP would be isotonic and nonhemolytic if absorbed. In addition, it would be nonelectrolytic to disperse the electrical current, transparent to allow clear visibility for the surgeon, nonmetabolized, nontoxic, rapidly excreted, and inexpensive.[148] A variety of irrigating solutions are available for transurethral procedures (Table 35-8), but most are hypoosmolar (normal serum osmolality is 280 to 300 mOsm/L) and acidic (pH of 4.5 to 6.5).[149]

TABLE 35-8 Properties of Commonly Used Irrigating Solutions For Transurethral Resection Procedures

·SOLUTION	·OSMOLALITY (mOsm/L)	·ADVANTAGES	·DISADVANTAGES

Distilled water	0	Improved visibility	Hemolysis
			Hemoglobinemia
			Hemoglobinuria
			Hyponatremia
Glycine (1.5%)	200	Less likelihood of transurethral resection syndrome	Transient postoperative visual syndrome
			Hyperammonemia
			Hyperoxaluria
Sorbitol (3.3%)	165	Same as glycine	Hyperglycemia, possible lactic acidosis
			Osmotic diuresis
Mannitol (5%)	275	Isosmolar solution	Osmotic diuresis
		Not metabolized	Possibility of acute intravascular volume expansion

Adapted with permission from Krongrad A, Droller MJ: Complications of transurethral resection of the prostate. In Marshall FF (ed): Urologic Complications: Medical and Surgical, Adult and Pediatric, 2nd ed, p 305. St. Louis, Mosby–Year Book, 1990.

Distilled water was the irrigating solution used by urologists in the past because it was nonconductive and interfered least

with surgical visibility. However, because of its low tonicity, water absorbed into the circulation can cause massive intravascular hemolysis, hemoglobinemia, and renal failure, and result in dilutional hyponatremia.[150] Distilled water can be used for transurethral procedures that do not open venous sinuses, such as cystoscopy and transurethral resection of bladder tumor, but it is no longer used in TURP procedures.

Solutes such as sorbitol, mannitol, glycine, urea, and glucose have been added to water to make its osmolality closer to that of plasma[148] (see Table 35-8). It is essential that the anesthesiologist be aware of the type of irrigating solution being used during an endoscopic procedure, because absorption of this fluid can be associated with numerous perioperative complications. Electrolyte solutions such as Ringer's lactate or normal saline should not cause electrolyte imbalance if absorbed into the circulation, but they cannot be used in conjunction with an electrocautery device

because they are ionized and able to conduct electrical currents. Sorbitol is metabolized to fructose, and use of this solution can produce hyperglycemia. Glycine is a nonessential amino acid that is normally present in the circulation. It is metabolized in the liver by oxidative deamination into ammonia and glyoxylic acid.[151] Depressed mental status and coma secondary to hyperammonemia have been reported following TURP procedures in which glycine was used as the irrigating solution.[151,152] Blood ammonia levels as high as 834 μM/L (normal 11 to 35 μM/L) have been documented, although the central nervous system depression was transient in these patients and they recovered within 24 to 48 hours.[152] Other investigators have observed development of hyperoxaluria in association with glycine irrigation.[153]

Visual disturbances, including blurred vision and transient blindness, have been reported following TURP procedures with glycine-containing irrigation fluid.[154] Loss of vision after transurethral procedures was traditionally believed to be secondary to cerebral edema from the hypervolemia and hyponatremia that developed as irrigating fluid was absorbed. However, when a centrally acting mechanism, such as cerebral edema, is the cause of visual impairment, patients have normal pupillary light reflexes. A review of patients with blindness after TURP revealed that some had sluggish or nonreactive pupils, suggesting an anterior pathway disturbance rather than cerebral edema.[154] Glycine acts as an inhibitory neurotransmitter in the brain, spinal cord, and retina. Elevated serum glycine levels could exert an inhibitory action on the retina and result in transient blindness consistent with the clinical picture seen in these patients.[154] It would appear that the visual disturbance after TURP may have more than one etiology.

Transurethral Resection Syndrome

Transurethral resection (TUR) syndrome (water intoxication syndrome) is a general term used to describe a wide range of neurologic and cardiopulmonary symptoms that occur when irrigating fluid is absorbed during TUR procedures, especially TURP. Its principal components are respiratory distress secondary to volume expansion from rapid intravascular absorption of the irrigating fluid, dilution of electrolytes and proteins by the electrolyte-free irrigating fluid, and symptoms related to the type of irrigating solution used.[148,155,156]

The average amount of irrigating fluid absorbed during TURP is ~20 mL/min of resection time.[150,157] The volume of fluid absorbed during the procedure can be estimated with the following formula[155]:

$$\text{Volume absorbed} = \frac{\text{preoperative serum } Na^+}{\text{postoperative serum } Na^+ \times \text{ECF}} - \text{ECF}$$

where ECF is extracellular fluid volume.

10 The amount of irrigation fluid absorbed during the procedure is directly related to the number and size of venous sinuses opened, duration of resection, hydrostatic pressure of the irrigating fluid, and venous pressure at the irrigant–blood interface.[147] To prevent excessive fluid absorption, it is recommended that resection time be limited to <1 hour and that the bag of irrigating fluid be suspended no more than 30 cm above the operating table at the beginning of the resection and 15 cm in the final stages of resection.[147,157] Investigations have demonstrated that ethanol-labeled irrigating fluid can be used to accurately assess the degree of fluid absorption during TUR procedures by measuring the ethanol content of the patient's exhaled breath.[158] Clinical manifestations of TUR syndrome range from mild (restlessness, nausea, shortness of breath, dizziness) to severe (seizures, coma, hypertension, bradycardia, cardiovascular collapse). In the awake patient with a regional block, a classic triad of symptoms has been described that consists of an increase in both systolic and diastolic pressures associated with an increase in pulse pressure, bradycardia, and mental status changes.[148,149] During general anesthesia, many of the more subtle signs of TUR syndrome are obscured, making early diagnosis more difficult. The initial hypertension and bradycardia are the result of acute volume overload, which may

lead to left heart failure, pulmonary edema, and cardiovascular collapse.[159] With the continued absorption of electrolyte-free irrigation fluid, dilutional hyponatremia and cerebral edema develop. The acute decrease in serum sodium concentration is responsible for many of the signs and

symptoms of TUR syndrome[148] (Table 35-9).

TABLE 35-9 Signs and Symptoms Associated With Acute Changes in Serum Na^+ Levels

▪SERUM Na^+	▪CENTRAL NERVOUS SYSTEM CHANGES	▪ELECTROCARDIOGRAM CHANGES
120 mEq/L	Confusion	Possible widening of QRS complex
	Restlessness	
115 mEq/L	Somnolence	Widened QRS complex
	Nausea	Elevated ST segment
110 mEq/L	Seizures	Ventricular tachycardia or fibrillation
	Coma	

Adapted with permission from Jensen V: The TURP syndrome. Can J Anaesth 38:90, 1991.

Symptoms related to absorption of a specific irrigating solution during the procedure may further complicate TUR syndrome. For example, if excessive amounts of glycine are absorbed, the patient may become encephalopathic secondary to high blood ammonia concentrations. Likewise, absorption of large volumes of sorbitol may produce hyperglycemia and coma, especially in diabetic patients.

Prompt intervention is necessary when neurologic or cardiovascular complications of TUR procedures are recognized (Table 35-10). Oxygenation, ventilation, and circulatory support must be ensured, and other potentially treatable conditions such as diabetic coma, hypercarbia, or drug interactions should be considered.[148] The surgeon should be informed of a change in the patient's status so the procedure can be terminated as quickly as possible. Treatment with hypertonic saline has been associated with development of demyelinating central nervous system lesions due to rapid increases in plasma osmolality and should be reserved for patients with severe, life-threatening symptoms.[160] Three percent sodium chloride solution should be infused at a rate no greater than 100 mL/hr and discontinued as soon as the serum sodium is >120 mEq/L. Once this goal is reached, treatment can continue with fluid restriction and diuretic therapy. The rate at which serum sodium is increased should not exceed 12 mEq/L in a 24-hour period.[160]

TABLE 35-10 Treatment of The Transurethral Resection Syndrome

Ensure oxygenation and circulatory support.
Notify surgeon and terminate procedure as soon as possible.
Consider insertion of invasive monitors if cardiovascular instability occurs.

Send blood to laboratory for electrolytes, creatinine, glucose, and arterial blood gases.
Obtain 12-lead electrocardiogram.
Treat mild symptoms (with serum Na^+ concentration >120 mEq/L) with fluid restriction and loop diuretic (furosemide).
Treat severe symptoms (if serum Na^+ <120 mEq/L) with 3% sodium chloride IV at a rate <100 mL/hr.
Discontinue 3% sodium chloride when serum Na^+ >120 mEq/L.

Other Complications of Transurethral Resection of the Prostate

Bleeding comes from either open venous sinuses or unrecognized arterial bleeding sites and typically ranges from 2 to 4 mL/min during the resection.[147] Blood loss is difficult to assess because of mixing with the irrigating fluid. Therefore, serial hemoglobin or hematocrit levels and the patient's vital signs should be evaluated to determine the need for transfusion.[149] The incidence of intraoperative blood transfusion is reported to be ~2.5%.

Abnormal bleeding after TURP occurs in <1% of resections[147] and may be caused by release of thromboplastin, which is found in high concentrations in prostate cancer cells.[149] This thrombogenic stimulus can produce disseminated intravascular coagulation. Treatment of this condition is supportive and may include transfusion of coagulation factors and platelets.[161] Another cause of postoperative bleeding after TURP is release of tissue plasminogen activators from the prostate. These factors activate the coagulation system and convert plasminogen to plasmin, which in turn causes fibrinolysis.

Perforation of the prostatic capsule occurs in ~1 to 2% of patients undergoing TURP, usually resulting in extraperitoneal extravasation of fluid.[149,162] This complication occurs more commonly during transurethral resection of the bladder, and management of this problem is discussed in that section of this chapter.

Fever in the perioperative period suggests bacteremia secondary to spread of bacteria through open prostatic venous sinuses. Hypothermia can occur if large volumes of room-temperature irrigating fluids are not warmed to body temperature. Body temperature decreases ~1°C/hr of surgery, and shivering occurs in 16% of patients who receive room-temperature irrigation fluids; hypothermia does not develop if the irrigation solution is warmed to body temperature (95 to 100° F).[163]

Anesthetic Techniques for Transurethral Resection of the Prostate

Regional anesthesia has long been considered the anesthetic technique of choice for TURP and is used in >70% of these procedures in the United States.[164] It allows the patient to remain awake, which should facilitate early diagnosis of TUR syndrome or extravasation of irrigation fluid. Some studies have demonstrated decreased blood loss when TURP procedures are performed using regional anesthesia, whereas others have found no difference in blood loss between regional and general anesthesia.[165,166]

Bowman et al.[167] found that only 15% of patients receiving spinal anesthesia for TURP required any pain medication other than acetaminophen, whereas the need for analgesics was increased approximately fourfold after general anesthesia.

A prospective study comparing the effect of general versus spinal anesthesia on cognitive function after TURP found a significant decrease in mental status in both groups at 6 hours after surgery, but no differences in mental function at any time in the first 30 days after surgery.[168] Perioperative morbidity and mortality among patients older than 90 years of age who underwent TURP did not depend on the type of anesthesia used.[169] A study of the occurrence of perioperative myocardial ischemia in patients undergoing transurethral surgery, assessed by Holter monitoring, determined that both the incidence and duration of myocardial ischemia increased following TUR surgery, but there was no difference between general or spinal anesthesia.[170] A second study confirmed these findings and concluded that presence of short-duration silent myocardial ischemia did not correlate with adverse outcome in elderly patients undergoing TURP procedures.[171] Thus, it appears that TURP can be performed safely with either type of anesthesia, and the choice of anesthetic technique should be tailored to the individual patient.

If spinal or epidural anesthesia is used for the procedure, a T10 dermatome anesthetic level is needed to block the pain from bladder distention by the irrigating fluid. Spinal anesthesia is usually preferred over lumbar epidural anesthesia because sacral segments are sometimes inadequately blocked with lumbar epidural techniques. Local anesthesia has also been used for TURP procedures in patients with small to moderate size prostate glands, with limited success.[172]

Morbidity and Mortality After Transurethral Resection of the Prostate

An American Urological Association (AUA) cooperative study evaluated postoperative complications in 3,885 patients after TURP[162]; average patient age was 69 years, and most patients (>75%) had coexisting medical problems that involved many of the major organ systems. The prevalence of complications in the intraoperative period was 6.9%. These included bleeding requiring transfusion (2.5%), TUR syndrome (2%), cardiac dysrhythmias (1%), and extravasation of irrigating fluid (0.9%). No intraoperative deaths occurred. Immediate postoperative problems following TURP occurred in 18% of patients, with the most common being failure to void. Other common postoperative problems were bleeding, clot retention, and infection. Patients at an increased risk for perioperative morbidity after TURP were those with large prostate glands (>45 g), resection times exceeding 90 min, acute urinary retention, or age >80 years.

Despite the high incidence of coexisting medical problems in patients undergoing TURP, 30-day mortality has declined over the years. In 1962, it was 2.5%, whereas the AUA cooperative study evaluating these procedures during 1978 to 1987 reported a much lower mortality of 0.2%, even though patient age and amount of prostate tissue resected had not changed from earlier surveys.[162] An evaluation of 181,161 TURP Medicare beneficiaries between 1991 and 1997 revealed a 30-day mortality of 0.39% for those ages 65 to 69 years. Age-specific mortality for those older than age 70 years was compared with 1984 to 1990 mortality and was also found to be lower (Table 35-11).[173]

TABLE 35-11 Thirty-Day Mortality Rate Following Transurethral Resection of the Prostate

	·BPH COHORTS (95% CI)	
·PT. AGE	·1991–1997	·1984–1990
65–69	0.39 (0.32–0.46)	0.39 (0.34–0.44)
70–74	0.52 (0.45–0.59)	0.67 (0.61–1.74)

75–79	0.90 (0.81–100)	1.10 (1.01–1.19)
80–84	1.34 (1.19–1.48)	1.92 (1.76–2.07)
85+	2.52 (2.26–2.78)	3.54 (3.26–3.82)
BPH, benign prostatic hyperplasia; CI, confidence interval.		

The Future of Transurethral Resection of the Prostate

TURP began to decline in 1987 for all age groups older than 65 years, likely because of less invasive medical and surgical treatments, changes in reimbursement, and greater involvement of patients in the decision-making process.[173] Less invasive surgical treatments include balloon dilatation, prostate stents, transurethral incision of the prostate, and laser prostatectomy. These procedures can usually be done on an outpatient basis, decrease the risk of TUR syndrome, and may be preferred for elderly patients with significant comorbidity risk factors.[174]

Transurethral Resection of Bladder Tumors

Bladder cancer is the second most common urologic malignancy, with nearly 50,000 new cases diagnosed in the United States each year.[175,176] Superficial transitional cell carcinoma accounts for ~90% of bladder cancers. In diagnosing and treating this cancer, most patients undergo endoscopic transurethral resection.[175,176] This procedure can be performed with either regional or general anesthesia. If a regional anesthetic is employed, an anesthetic level to T10 is required to block the pain associated with bladder distention. If the bladder tumor lies near the obturator nerve, the electrocautery may cause the thigh muscles to contract violently, resulting in inadvertent bladder perforation, regardless of whether general or regional anesthesia is used.[177] General anesthesia with addition of a muscle relaxant is the preferred technique when this is anticipated or occurs intraoperatively.

Complications During Transurethral Resection of the Bladder

Perforation of the bladder has been reported during transurethral surgery.[178] This can result in intraperitoneal or extraperitoneal extravasation of the fluid used to irrigate the bladder. Clinical diagnosis of bladder perforation is simplified if the procedure is performed under regional anesthesia. The conscious patient describes sudden, severe abdominal pain, often associated with referred pain from the diaphragm to the shoulder.[150,178] Associated symptoms include pallor, sweating, abdominal rigidity, nausea, and vomiting. If extravasation is suspected, the operation should be terminated as quickly as possible. Small perforations with minimal intraperitoneal leakage rarely cause hemodynamic changes and can usually be managed with catheter drainage and diuretics. The consequences of a large intraperitoneal accumulation of irrigating fluid (especially sterile water) can be life threatening. Open laparotomy for drainage and bladder perforation repair is recommended in these cases.[150,178,179]

Extracorporeal Shock Wave Lithotripsy

In the United States, the annual incidence of urolithiasis is 16.4 per 10,000 persons, and it is estimated that 12% of the

population will experience calculus disease in their lifetime.[180] This disease is three times more common in men than women, with a peak age incidence in the third to fourth decade of life.[181] Several therapeutic modalities exist for surgical treatment of urinary calculi. The final treatment decision is based on the size of the stone being treated (<4.0 mm usually pass spontaneously), location in the urinary tract, and composition.[181]

Introduction of extracorporeal shock wave lithotripsy (SWL) in 1980 dramatically changed the management of urolithiasis. Before development of this modality, open surgical removal was the most common technique for treating urethral and renal calculi.[182] Now, only 5% of all urinary calculi require open surgical procedures. SWL has the advantages of being a minimally invasive technique that is performed on an outpatient basis and is associated with minimal perioperative morbidity and a significant reduction in treatment costs.[183]

Technical Aspects of Shock Wave Lithotripsy

Lithotripters have four main components: an energy source, focusing device, coupling medium, and multiplane stone localization system. The original, first-generation lithotripter was the Dornier HM-3, which required the patient to be placed in a hydraulically supported gantry chair and immersed in a water bath (Fig. 35-8). Its energy source is a spark plug generator that creates an explosive impact and transmits high pressures (shock waves) to the water when discharged. An ellipsoidal reflector aims the shock waves at a focal point. Two fluoroscopes are oriented so their beam paths intersect at the focal point above the ellipsoidal reflector, and the patient's position in the tub is adjusted so the calculus is centered in these beam paths.[184] The water bath transmits the shock wave to the patient. It serves as the coupling medium, allowing the shock wave to pass into the body without dissipation because the acoustic impedance of body tissue is close to that of water.[183]

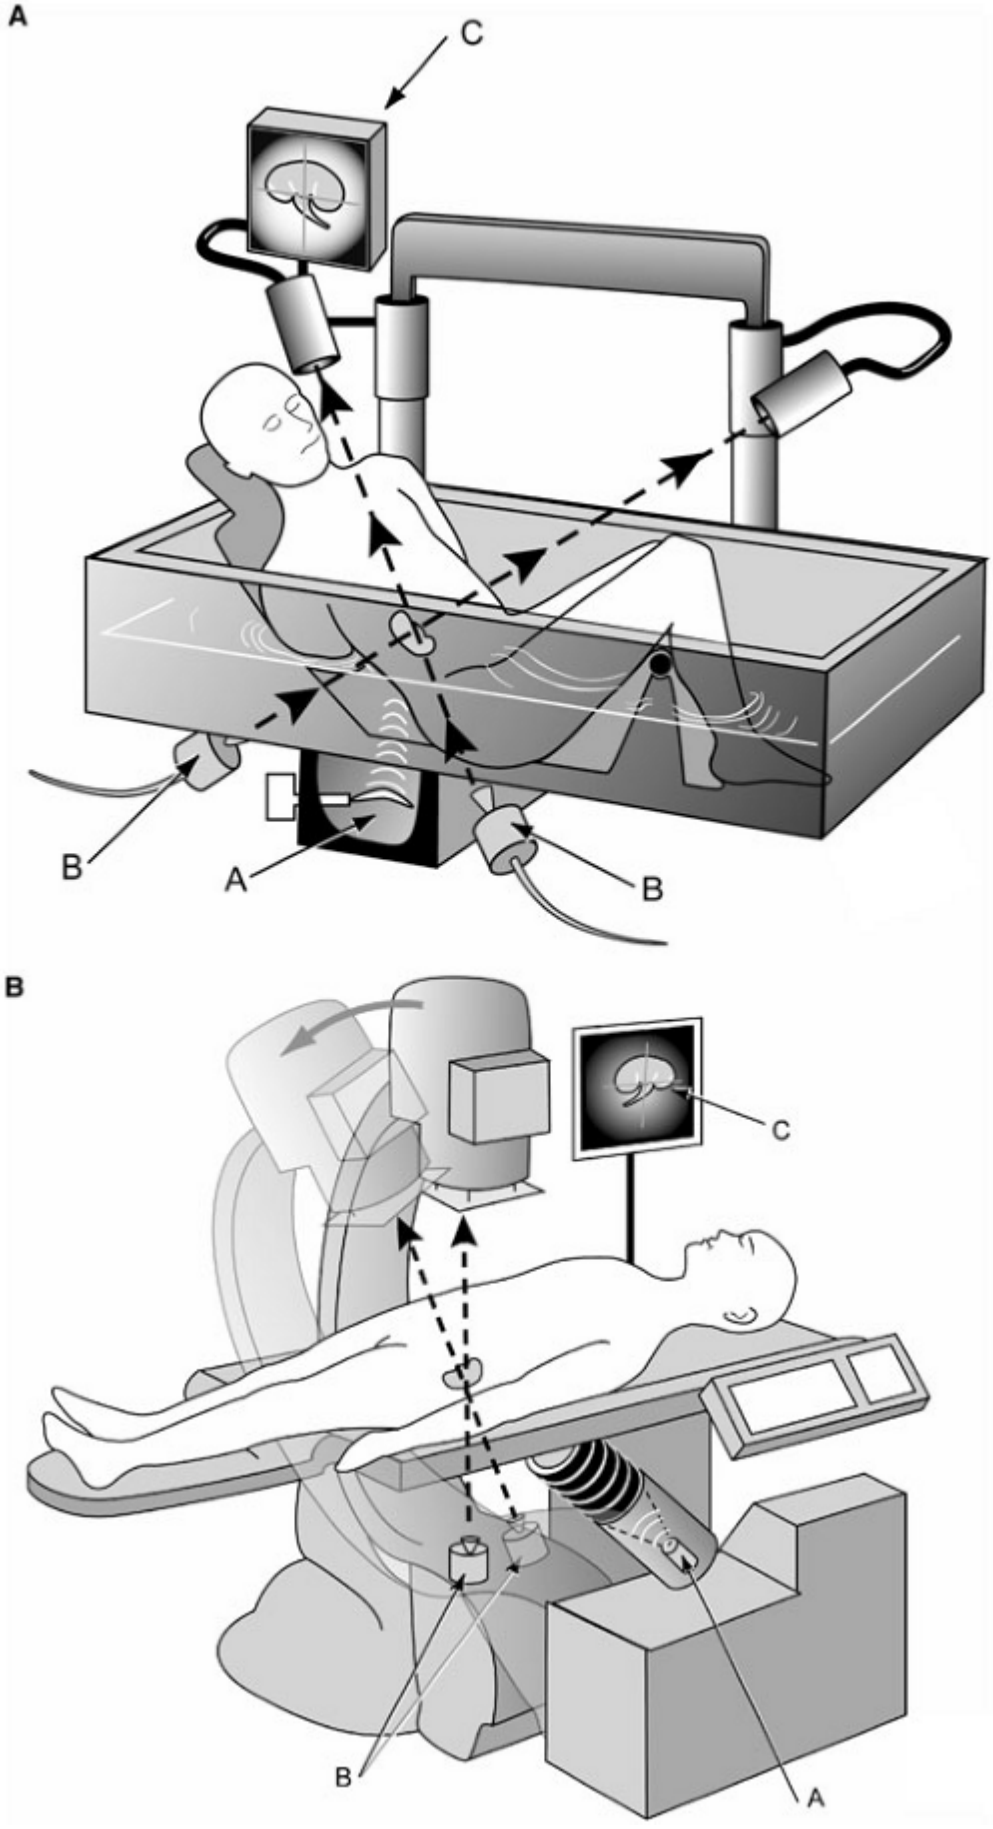

FIGURE 35-8. Schematics of patient positioned in **(A)** first-generation water bath immersion and **(B)** second-generation non-water bath lithotripter. A, energy source; B, multiplane fluoroscopy; C, focusing device. (Reprinted The Cleveland Clinic Foundation Copyright © 2004.)

Initial SWL treatments were associated with ventricular ectopic beats and even ventricular tachycardia.[185] It was postulated that these dysrhythmias were caused by stimulation of the myocardium when shock waves were delivered during the repolarization phase of the heart. To avoid this problem, shock waves can be synchronized and triggered off the electrocardiogram to occur 20 milliseconds after the R wave during the refractory period of the heart.[185] The average treatment on the Dornier HM-3 lithotripter uses 1,500 to 2,000 shocks.[183]

Physiologic Effects of Immersion Lithotripsy

Placing a patient into the water bath during lithotripsy produces a number of physiologic alterations in the cardiopulmonary system, with immersion causing peripheral venous compression that results in increased central blood volume (Table 35-12). Central venous pressure (CVP) and pulmonary capillary wedge pressure increases are linearly related to depth of immersion, with immersion to the clavicles increasing CVP by 10 to 14 cm H_2O.[186] Despite the increase in venous return during immersion, some patients experience hypotension as a result of vasodilatation from the warm water.[187] Placing a patient in water to the level of the clavicles increases the work of breathing and can result in respirations becoming shallow and rapid because of extrinsic pressure on the upper abdomen and thorax, which causes a decrease in vital capacity and functional reserve capacity.[188] Continuous monitoring of hemodynamics, respiratory gas exchange, and oxygenation should be used in all patients undergoing SWL, but are of paramount importance in patients with cardiopulmonary disease. In these patients, immersion should be achieved in a gradual fashion, or the procedure can be performed with minimal immersion so only the shock wave entry site is covered with water. Alternatively, a nonimmersion (second-generation or third-generation) lithotripter may be used.

TABLE 35-12 Cardiopulmonary Changes on Immersion During Lithotripsy

▪SYSTEM	▪VARIABLE	▪DIRECTION OF CHANGE
Cardiovascular	Central blood volume	Increased
	Central venous pressure	Increased
	Pulmonary artery pressure	Increased
Respiratory	Pulmonary blood flow	Increased
	Vital capacity	Decreased
	Functional residual	Decreased
	Tidal volume	Decreased
	Respiratory rate	Increased

Problems involving temperature regulation may occur during immersion SWL, especially in elderly patients with impaired thermoregulatory systems. Water in the lithotripter tub should be maintained in the temperature range of 35.8 to 37.5°C, and temperature monitoring should be used in every patient.[189]

Modifications of the original Dornier HM-3 have produced second-generation and third-generation lithotripters with several advantages[182] (see Fig. 35-8). Newer devices generate shock waves within a "shock tube" coupled to the body surface with a water cushion. This eliminates the water bath and all problems associated with patient immersion in water. They also have decreased power, causing less pain; however, most patients still require IV sedation or a "light" general anesthetic during treatment. One disadvantage of the newer lithotripters is that by decreasing power, efficiency of stone fragmentation is reduced, and thus the prevalence of retreatment is higher.[182]

Patient Selection and Complications of Shock Wave Lithotripsy

Absolute and relative contraindications to SWL are listed in Table 35-13. It was initially believed that presence of a cardiac pacemaker was a contraindication secondary to electrical interference from the shock wave energy's ability to inhibit, reprogram, or damage the pacemaker.[183] However, a review of 142 SWL treatments in pacemaker-dependent patients found a low (<1%) incidence of major pacemaker complications, with only one pacemaker deprogrammed during the treatment period.[190] Based on these findings, patients with pacemakers are considered acceptable candidates for lithotripsy provided that certain precautions are taken, including (1) preoperative determination of the type of pacemaker and its functional status; (2) availability of a magnet or programming device in the operating room, along with a person skilled in its use; (3) availability of an alternative pacing device; and (4) positioning of the patient so the pacemaker is not in the shock wave path. SWL can be performed safely in patients with an automatic implantable cardioverter-defibrillator with appropriate precautions and deactivation of the unit during lithotripsy.[191]

TABLE 35-13 Contraindications to Extracorpeal Shock Wave Lithotripsy

Absolute contraindications	Obstruction distal to the renal calculiBleeding disorder or anticoagulation Pregnancy
Relative contraindications	Large calcified aortic or renal artery aneurysms

	Untreated urinary tract infection
	Pacemaker or AICD implant
	Morbid obesity
AICD, automatic implantable cardioverter-defibrillator.	

Renal parenchymal damage is believed to be responsible for the hematuria that occurs in nearly all patients, whereas subcapsular hematoma is seen in only 0.5% of patients after lithotripsy.[182] These problems usually resolve spontaneously, and bleeding that requires transfusion is rare.[192] Transient renal failure after SWL has been reported; however, there is no evidence that lithotripsy is associated with permanent renal dysfunction.

After treatment, many patients complain of flank pain, which may be severe for several days.[192,193] Petechia and soft-tissue swelling can be seen at the entry site of the shock wave, especially in thin patients treated with first-generation lithotripters. Up to 10% of patients have significant urinary tract colic, occasionally requiring hospitalization and opioid analgesics. Broken stone fragments can also collect in the ureter and form a column of stone, which is commonly referred to as *steinstrasse* or "stone street." If *steinstrasse* results in total ureteral obstruction, rising creatinine levels, or severe pain, the patient may require an endoscopic procedure with ureteral stent placement to relieve the obstruction.[192]

SWL may be problematic in children or patients of small stature (height <48 in.) because of position in the immersion lithotripter chair and a higher risk of pulmonary contusion by shock waves.[194] Lungs of small patients can be shielded by foam padding during the treatment to help prevent this complication.

Other potential complications following lithotripsy include damage to adjacent organs by the shock waves.[182] Several cases of pancreatitis and transient gastrointestinal injury have been reported. Approximately 1% of patients have septic

complications after SWL. Brachial plexus injuries have also occurred from improper positioning of patients in the lithotripter chair. Despite the wide array of potential complications, mortality after SWL was only 0.02% in a review of more than 62,000 patients.[182] It appears that with proper patient selection and cautious intraoperative management, most patients can safely undergo lithotripsy procedures.

Radiation and auditory exposure of anesthesiology personnel during SWL appears to be safe with proper precautions. These include avoiding direct patient contact during fluoroscopy.[195,196]

Anesthetic Techniques for Shock Wave Lithotripsy

Shock wave impact and propagation through the skin and viscera are responsible for the pain experienced during SWL.[197]

The initial approach to anesthesia for lithotripsy on the Dornier HM-3 used either a regional or general technique. General anesthesia offers the advantages of controlling patient ventilation and movement, rapid induction of anesthesia, and quicker recovery from anesthesia compared with epidural anesthesia.[198] However, patients have to be positioned in the lithotripter chair while

unconscious, increasing the risk of peripheral nerve injuries. With regional anesthesia, the patient is awake and cooperative during transport, simplifying patient positioning. Regional anesthetic techniques for this procedure require a sensory level of T6. Neurologic damage has been reported after SWL when air was introduced into the epidural space during epidural anesthesia.[199]

Conscious sedation techniques have been developed for use during lithotripsy.[193,200] Monk et al.[193] examined the use of propofol and fentanyl or midazolam and alfentanil for intravenous sedation during treatments on the Dornier HM-3. Both sedative–analgesic combinations provided good treatment conditions and were associated with a high degree of patient satisfaction. When this intravenous sedation technique was compared with epidural anesthesia for the same procedures, anesthesia and recovery times were significantly shortened and hospital costs decreased with use of IV sedation.[193] Local anesthetic infiltration of the flank alone or in combination with intercostal blocks and topical application of local anesthetic cream have also been used during lithotripsy on the Dornier HM-3 to decrease intravenous analgesic requirements.[197,201] Although both local anesthetic techniques produced cutaneous analgesia, intravenous analgesics were still required for intraoperative patient comfort.

SWL has revolutionized the standard of treatment of nephrolithiasis. Currently, general or regional anesthesia is used with first-generation lithotripters, and conscious sedation or "light" general anesthesia is used with the second-generation or third-generation devices.

Percutaneous Renal Procedures

Percutaneous nephrostomy (PCN) is commonly performed to diagnose and treat a wide variety of urologic problems, including relief of renal obstruction, stone removal, biopsy of tumors, and ureteral stent placement.[139] During a PCN procedure, a needle-guidewire-catheter sequence technique is used to enter the renal collecting system under fluoroscopic guidance to establish access and drainage of the kidney. This procedure is performed with the patient prone, and local anesthesia with intravneous sedation is used for analgesia.[139] PCN involves passing an endoscope through the nephrostomy tract. Percutaneous nephrolithotomy, a procedure to remove renal calculi too large to be treated with lithotripsy, is one of the most common urologic endosurgical procedures, requiring dilatation of a nephrostomy tract and usually general or regional anesthesia.

Although percutaneous surgical techniques are considerably less invasive than open surgical procedures, a variety of complications can occur.[202] During insertion of the nephrostomy tube, trauma to the spleen, liver, or kidney can result in acute blood loss necessitating an emergency open surgical procedure. Colon injury has been reported if a retrorenal colon overlies the lower pole of the kidney.[139] Pleural injury may occur during nephrostomy tube placement when access is created above the twelfth rib or the kidney lies in a more cephalad position than normal. Nephrostomy tract dilatation causes bleeding in most patients, with hemoglobin declining an average of 1.2 g/dL. If excessive intraoperative bleeding occurs, it is wise to stop the procedure and insert a large-caliber nephrostomy tube or high-pressure balloon nephrostomy catheter to tamponade the bleeding.[202] In a study of 50 patients undergoing PCN for stone removal, prevalence of complications was 12%, with pleural effusion and hydropneumothorax being the most common problems encountered.[203]

During nephroscopy procedures, continuous irrigation of fluid through the endoscope is necessary to prevent blood and debris from obscuring the surgeon's vision. If a significant discrepancy exists between the amount of irrigating fluid infused and output from the patient, then clinical evaluation of the patient for extravasation of irrigation fluid into the retroperitoneal, intraperitoneal, intravascular, or pleural spaces is warranted. Intravenous absorption of irrigation fluid during percutaneous renal procedures can create a situation similar to that seen with TUR syndrome, in which electrolyte abnormalities and fluid overload can occur. Because electrocautery is rarely used during percutaneous renal procedures, the preferred irrigating solution is 0.9% sodium chloride.[204] If an electrocautery device is needed, irrigation fluid is temporarily changed to a nonelectrolyte solution.

LASER SURGERY IN UROLOGY

Laser therapy has been shown to be effective in treating a multitude of urologic problems, including condyloma acuminatum of the external genitalia and urethra; ureteral stricture or bladder neck contracture; interstitial cystitis; BPH; ureteral calculi, and superficial carcinoma of the penis, bladder, ureter, and renal pelvis.[205] Major advantages of laser surgery over traditional surgical approaches include minimal blood loss,

decreased postoperative pain, and tissue denaturation, a process that reduces risk of tumor implantation.

Because lasers are an integral part of urologic surgery, understanding the indications and limitations of each type of laser is essential.[206] The *carbon dioxide (CO_2) laser* produces intense heat with vaporization, but has minimal tissue penetration and is unable to penetrate water. Thus, its use is limited to treating cutaneous lesions of the external genitalia. The *argon laser* is poorly absorbed by water, but is selectively absorbed by hemoglobin and melanin, making it useful for procedures in the bladder requiring coagulation of bleeding sites. The *pulsed dye laser* generates a pulsed output and is useful for destroying ureteral calculi. One of the most versatile and widely used lasers in urologic surgery is the *Nd-YAG laser.*[205] This device produces deep tissue penetration via protein denaturation with minimal vaporization. It can be used in water or urine without loss of effectiveness and delivered with a fiber-optic laser delivery system for endourologic surgery. Excellent results have been reported after treatment of lesions of the penis, urethra, bladder, ureters, and kidneys. The *KTP-532 laser* is a frequency-doubled Nd-YAG laser that does not penetrate tissue as deeply as the Nd-YAG but has a better cutting effect.[206] It is extremely effective in treating urethral strictures and bladder neck contractures.

Safety issues assume paramount importance during laser surgery. Damage to the eye is the potential injury that requires the greatest attention because both direct and reflected laser beams can cause eye injury.[207] Protective goggles with appropriate filtering lenses are available for each type of laser, and laser equipment should not be activated until all operating room personnel and the patient are wearing glasses. Although less critical than eye damage, inadvertent thermal injury to the skin may also occur during laser treatments. Thermal injuries are avoidable if the laser is placed in the "standby" mode when not in operation and is activated only by the surgeon performing the procedure. During CO_2 laser therapy for condyloma acuminatum, the plume (smoke) from the vaporization of tissue contains active human papilloma virus particles.[208] To avoid inhalation of infectious agents, all operating room personnel involved in CO_2 laser procedures for genital lesions should wear protective laser masks that prevent small particles from being inhaled. In addition, the laser plume should be removed from the operating room with a smoke evacuation system.

UROLOGIC LAPAROSCOPY

Urologic laparoscopy techniques are minimally invasive and have rapidly gained acceptance because they are associated with decreased postoperative pain, shorter hospital stays, lower hospital costs, and more rapid convalescence than open surgical procedures.[139] Laparoscopic procedures performed in urology include diagnostic procedures for evaluating undescended testis, orchiopexy, varicocelectomy, bladder suspension, pelvic lymphadenectomy, nephrectomy, partial nephrectomy, nephroureterectomy, adrenalectomy, prostatectomy, and cystectomy.

Unique cardiopulmonary changes may occur during laparoscopic surgery (see Chapter 38). Physiologic alterations during laparoscopy are often related to the surgical technique itself, in particular, the creation of the pneumoperitoneum and absorption of insufflating gas.[209] A wide variety of intraoperative complications are also possible during laparoscopy (Table 35-14). Occurrence of complications for large laparoscopy series is reported to range from 0.6 to 2.4%, with approximately one-third being cardiopulmonary in nature.[210]

Laparoscopic urologic procedures differ from conventional laparoscopy in several respects. Many structures in the genitourinary system are extraperitoneal (i.e., pelvic lymph nodes, bladder, ureters, adrenal glands, kidneys), and urologists often prefer extraperitoneal insufflation during laparoscopic surgery on these organs. Several studies have reported that CO_2 absorption is

greater with extraperitoneal (76%) compared with intraperitoneal (15 to 25%) insufflation.[211]

Some laparoscopic procedures in urology, namely, cystectomy and nephrectomy, tend to be lengthy. Prolonged insufflation times during these procedures increase the amount of CO_2 absorbed and also necessitate use of general anesthesia to guarantee patient comfort. Increased absorption of CO_2 during extraperitoneal laparoscopic techniques mandates that the anesthesiologist carefully monitor and adjust ventilation to maintain normocarbia. Oliguria has been associated with prolonged duration of pneumoperitoneum during laparoscopic nephrectomy surgery.[212] A possible mechanism for intraoperative oliguria during laparoscopic surgery is an increase in stress hormone levels, such as ADH.[213] Intraoperative oliguria is often treated with fluid administration; thus, it is important that the anesthesiologist be aware that oliguria during prolonged laparoscopic procedures may not reflect intravascular volume depletion.

RADICAL CANCER SURGERY

Most major, open surgical procedures in urology are performed to treat cancer of the prostate, bladder, or kidney. These procedures are often lengthy and require intraoperative patient positions associated with significant impact on cardiorespiratory function. Radical urologic surgery also carries a potential for hemorrhage and large intraoperative blood and fluid requirements. In addition, patients undergoing these procedures are often elderly with preexisting medical conditions.

Radical Prostatectomy

Prostate cancer is the most commonly diagnosed cancer in men, as well as the second most common cause of prostate-related mortality in American men.[214] Localized prostate cancer

(stage A or B) is treated with radical prostatectomy, radioactive implants, or radiation therapy. In the United States, men with clinically localized prostate cancer whose life expectancy is 10 years or longer tend to undergo radical prostatectomy, whereas patients older than 70 years of age or with a life expectancy of less than 10 years usually opt for radiation therapy or observation. The outcome of the two approaches is similar.[215]

Radical prostatectomy can be performed by a perineal, retropubic, or laparoscopic surgical approach. The anesthetic technique for radical prostatectomy is influenced by whether an open or laparoscopic surgical approach is planned. The surgical procedure involves en bloc removal of the entire prostate gland, seminal vesicles, ejaculatory ducts, and a portion of the bladder neck, while attempting to preserve nerves controlling sexual function. After en bloc removal of these structures, the remaining bladder neck is anastomosed to the membranous urethra over an indwelling urethral catheter. Limited pelvic lymphadenectomy is usually performed during the procedure to aid in cancer staging.[216]

Proponents of radical perineal prostatectomy claim it is associated with less intraoperative blood loss, better exposure for the vesicourethral anastomosis, and a shorter convalescent time than with retropubic prostatectomy.[217] During a radical perineal prostatectomy, the patient is positioned in the exaggerated lithotomy position, slight flexion of the trunk, and a Trendelenburg tilt. This extreme lithotomy position compresses abdominal contents on the diaphragm and may cause respiratory embarrassment. Rhabdomyolysis with secondary ARF has also been reported after perineal prostatectomy in the exaggerated lithotomy position.[93,94,95] These reports suggest muscle damage is probably secondary to ischemia of the muscles in the elevated legs or the lumbar and pelvic muscles that were compressed by the exaggerated position. Lower-extremity nerve injury due to intraoperative leg positioning is another potential complication of the lithotomy position. In the exaggerated lithotomy, most anesthesiologists prefer either general or a combined epidural–general anesthetic for the procedure.[164]

Radical retropubic prostatectomy is performed through a midline lower abdominal incision, with the patient in a slight hyperextended supine position to distance the symphysis pubis from the umbilicus. General or regional (epidural or spinal) anesthesia with sedation may be used for this procedure. If regional anesthesia is used, a sensory block of T6–T8 is adequate.[164] Advocates of

general anesthesia believe it provides greater intraoperative patient comfort, improved airway control, faster onset, and a more controllable duration of action. Other anesthesiologists suggest that regional anesthesia is preferable for radical retropubic prostatectomy. Epidural anesthesia and analgesia has been described to favorably affect operative blood loss, postoperative pain control, and patient activity level after surgery.[218,219,220] A review of the current literature reveals no difference in patient mortality between regional and general anesthesia for radical prostatectomy.[220,221]

Preoperative administration of erythropoietin, preoperative autologous blood donation, acute normovolemic hemodilution, and intraoperative cell salvage are recommended perioperative techniques to avoid allogenic blood transfusion in radical retropubic prostatectomy. Autologous blood donation (3 U) versus preoperative erythropoietin and acute normovolemic hemodilution versus acute normovolemic hemodilution alone have been compared to determine which blood conservation strategy for radical retropubic prostatectomy was most efficient.[222] The authors concluded that all three blood conservation strategies resulted in similar allogenic blood exposure, but acute normovolemic hemodilution was the least costly technique. The need for allogenic blood transfusion in patients who participate in autologous blood donation is reported to be 0 to 14% and is similar to that in patients who do not donate blood (2.4 to 11%).[223]

Another technique to prevent allogenic blood transfusion for radical retropubic prostatectomy is intraoperative cell salvage. Gray et al.[224] evaluated the safety of this technique compared with preoperative autologous blood donation. They concluded that intraoperative cell salvage using leucocyte reduction filters in radical retropubic prostatectomy resulted in higher preoperative hematocrit levels with a low occurrence (3% versus 14%) of allogenic blood transfusion. Intraoperative cell salvage did not appear to be associated with increased risk of any early biochemical cancer progression. The safety of intraoperative cell salvage in malignant fields has not been clearly established, but there is some evidence that it is safe.[225,226]

General anesthesia is the technique of choice for laparoscopic prostatectomy. Endotracheal intubation with muscle relaxation provides a secure airway with controlled ventilation during pneumoperitoneum to facilitate the surgical procedure. Pulmonary implications of laparoscopy include management of decreased compliance and increased $PaCO_2$ produced from CO_2 absorption during pneumoperitoneum. It may be advisable to insert an intra-arterial catheter to facilitate arterial blood gas measurement and to monitor arterial pressure during the procedure. Major cardiovascular complications during CO_2 pneumoperitoneum include dysrhythmia and CO_2 embolism.[227]

Laparoscopic prostatectomy may take longer to perform than conventional open surgery, but less blood loss, shorter hospital stay, and quicker return of normal patient function is expected. Uncontrollable hemorrhage can occur, however, so at least one large-bore intravenous catheter should be inserted.

The head-down (Trendelenburg) position is used in perineal, retropubic, and laparoscopic prostatectomy surgery. This position produces physiologic changes in the cardiopulmonary and cerebrovascular systems in proportion to the degree of head-down tilt[228] (see Chapter 23). Head-down positioning during open prostatectomy procedures places the operative site in the pelvis above the heart, creating a gravitational gradient between the prostatic fossa and the heart. If the prostatic venous network is opened while the patient is in this position, then venous air embolism may occur.[229,230] The most common intraoperative problem during radical prostatectomy is hemorrhage.[216] Massive blood loss may occur if one of the branches of the hypogastric vein is inadvertently torn during pelvic lymphadenectomy or transection of the dorsal venous complex. With the potential for rapid blood loss, invasive monitoring or echocardiography may be needed to further assess cardiac filling pressures and overall hemodynamic status in patients with severe preexisting cardiopulmonary disease.

Length of hospital stay for radical retropubic prostatectomy is currently expected to be 2 to 3 days with an open procedure and 1 to 2 days with the laparoscopic approach. Choice of anesthesia for future radical prostatectomy surgeries may depend on whether a specific surgical approach (open

versus laparoscopic) is determined to deliver superior patient outcome.

Radical Cystectomy

The standard of care for treating muscle-invasive bladder cancer is a radical cystectomy.[231] In men, this surgery involves en bloc removal of the bladder, prostate, seminal vesicles, and proximal urethra. In women, it is necessary to remove the bladder, urethra, and anterior vaginal wall, as well as to perform a total hysterectomy and bilateral salpingo-oophorectomy. At completion of the procedure, a urinary diversion is performed, most commonly as an ileal or colon conduit.

Significant intraoperative hemorrhage can occur, suggesting the need for large-bore intravneous access and invasive

monitoring (arterial line and CVP) for intraoperative management. This intraperitoneal procedure is similar to a major bowel procedure, resulting in increased fluid requirements. The urinary diversion also prolongs the procedure, and most anesthesiologists find that the additional length and extent of surgery mandate a general or combined general–epidural anesthetic.[164] Patients with bladder cancer may have been treated with chemotherapy before their procedure. The most commonly used chemotherapeutic agents are methotrexate, vinblastine, cisplatinum, and doxorubicin. The anesthesiologist should be aware of prior use of any chemotherapeutic agent so any possible drug toxicity can be elucidated. In particular, doxorubicin has cardiotoxic effects, methotrexate may cause hepatic toxicity, and both cisplatinum and methotrexate are associated with neurotoxicity and renal injury.

Radical Nephrectomy

Renal cell carcinoma accounts for ~3% of all adult malignancies.[232] Surgery is the only effective treatment, with radical or partial nephrectomy the treatment of choice. Radical nephrectomy involves en bloc removal of the kidney and surrounding fascia, the ipsilateral adrenal gland, and the upper ureter. The tumor extends into the vena cava in ~5% of patients, and aggressive surgical therapy is warranted if there is no evidence of metastasis. On occasion, CPB and circulatory arrest have been used to treat extensive caval tumor invasion.

The kidney can be approached through a lumbar, transabdominal, or thoracoabdominal incision.[164] If a lumbar approach is used, the patient is placed in the flexed lateral decubitus position with the operative side up and the mechanical kidney support elevated beneath the twelfth rib. General anesthesia or combined epidural–general anesthesia is used for patients placed in the "kidney position" because the position is extremely uncomfortable. It may also predispose patients to nerve damage or cardiopulmonary alterations (see Chapter 23). During radical nephrectomy procedures, the anesthesiologist needs to be prepared for acute blood loss because of the proximity of the kidney to large blood vessels. The patient also needs to be adequately hydrated to optimize blood flow to the remaining kidney and to prevent hypotension from inferior vena caval compression during positioning. Pneumothorax can occur during surgery if the chest is inadvertently entered. A chest radiograph should be obtained in the postanesthesia care unit if a pneumothorax is suspected. Venous air embolisms are also possible during nephrectomy procedures if the positioning places the operative site above the heart.

Radical Surgery for Testicular Cancer

Although testicular cancer accounts for only 1% of all cancers in men, it is the most common malignancy in men between 15 and 34 years of age.[233] All intratesticular masses are considered cancerous until proven otherwise, and radical orchiectomy is performed for both definitive diagnosis and as the initial step of most treatment regimens. Either regional or general anesthesia can be used for this procedure.

Subsequent treatment depends on the stage and histology of the testicular tumor. Potential treatment options include observation, radiation to the inguinal and retroperitoneal areas,

chemotherapy, or retroperitoneal lymph node dissection. Because chemotherapy regimens change frequently, the National Cancer Institute's CancerNet website (http://www.cancernet. nci.nih.gov) carries current treatment protocols for each type and stage of testicular cancer.

Prior to surgery, the anesthesiologist should identify the chemotherapeutic agents used and be aware of the side effects of these drugs. One commonly used chemotherapeutic agent, bleomycin, is an antitumor antibiotic used against germ cell tumors of the testis. Its use is associated with pulmonary toxicity, and there are numerous reports of postoperative respiratory failure after retroperitoneal lymph node dissection in patients treated with it.[234,235] The onset of respiratory failure usually occurs 3 to 10 days after surgery. Risk factors for postoperative respiratory distress include preoperative evidence of pulmonary injury, recent exposure to bleomycin (within 1 to 2 months), a total dose of bleomycin >450 mg, or a Ccr of <35 mL/min.[235] Although intraoperative exposure to hyperoxia (inspired oxygen concentrations >30%) has been linked to postoperative pulmonary toxicity, this relationship is controversial.[234,235] A retrospective study found that intravenous fluid management, including blood transfusion, was the most significant factor affecting postoperative pulmonary morbidity and clinical outcome.[234] The authors recommend that intravenous fluid administration consist primarily of colloid and be limited to the minimum volume necessary to maintain hemodynamic stability and adequate renal output.

Chapter 36

Anesthesia and Obesity

Babatunde O. Ogunnaike

Charles W. Whitten

KEY POINTS

1	Many morbidly obese patients have clinically significant obstructive sleep apnea (OSA), which in the long term can result in the obesity hypoventilation syndrome (OHS). OSA predisposes to airway difficulties during anesthesia.
2	Angina or exertional dyspnea may rarely present because morbidly obese patients often have limited mobility and may appear asymptomatic even when they have significant cardiovascular disease.
3	Nonalcoholic fatty liver disease and elevated liver function tests (mostly elevated ALT) are seen in a significant number of obese patients. Despite these histologic and enzymatic changes, no clear correlation exists between abnormalities of routine liver function tests and the capacity of the liver to metabolize drugs.
4	Rhabdomyolysis is sometimes seen in morbidly obese patients undergoing prolonged operative procedures. Unexplained elevations in serum creatinine and creatine phosphokinase (CPK) levels or complaints of buttock, hip, or shoulder pain in the postoperative period may indicate that rhabdomyolysis has occurred.
5	Patients scheduled for repeat bariatric surgery may have long-term vitamin and nutritional abnormalities, which can lead to acute postgastric reduction surgery (APGARS) neuropathy, a polynutritional multisystem disorder characterized by protracted postoperative vomiting, hyporeflexia, and muscular weakness.
6	Morbid obesity is a major independent risk factor for deep venous thrombosis (DVT) and sudden death from acute postoperative pulmonary embolism. Subcutaneous heparin reduces the risk of DVT; however, low molecular weight heparins are currently popular for thromboembolism prophylaxis because of their bioavailability when injected subcutaneously.
7	Neck circumference has been identified as the single best predictor of problematic intubation in morbidly obese patients. A larger neck circumference is associated with the male sex, a higher Mallampati score, grade 3 views at

	laryngoscopy, and obstructive sleep apnea.
8	Forearm blood pressure is a fairly good predictor of upper arm blood pressure in most patients, but in obese patients, forearm measurements with a standard cuff may overestimate both systolic and diastolic blood pressures.
9	The head-elevated laryngoscopy position (HELP) elevates the obese patient's head, upper body, and shoulders above the chest to the extent that an imaginary horizontal line connects the sternal notch with the external auditory meatus to better improve laryngoscopy and intubation.

TABLE 36-1 Determinants of Dosing For Intravenous Drugs in The Obese Patient

·DRUG	·DOSING	·COMMENTS
Propofol	Induction: IBW Maintenance: TBW	Systemic clearance and V_D at steady state correlates well with TBW. High affinity for excess fat and other well-perfused organs. High hepatic extraction and conjugation relates to TBW.
Thiopental	TBW	Increased V_D. Increased blood volume, cardiac output, and muscle mass. Increased absolute dose. Prolonged duration of action.
Midazolam	TBW	Central V_D increases in line with body weight. Increased absolute dose. Prolonged sedation because higher loading doses needed to achieve adequate serum concentrations.
Succinylcholine	TBW	Plasma cholinesterase activity increases in proportion to body weight. Increased absolute dose.
Vecuronium	IBW	Recovery may be delayed if given according to TBW because of increased volume of distribution and impaired hepatic clearance.
Rocuronium	IBW	Faster onset and longer duration of action. Pharmacokinetics and pharmacodynamics not altered in obese subjects.
Atracurium	TBW	Absolute clearance, V_D, and elimination half-life

Cisatracurium		do not change. Unchanged dose per unit body weight without prolongation of recovery because of organ independent elimination.
Fentanyl Sufentanil	TBW Induction: TBW Maintenance: IBW	Increased V_D and elimination half-time which correlates positively with the degree of obesity. Distributes as extensively in excess body mass as in lean tissues. Dose should account for total body mass. Fentanyl dosing based on a derived pharmacokinetic mass correlates better with clearance.
Remifentanil	IBW	Systemic clearance and V_D corrected per kg of TBW—significantly smaller in the obese. Pharmacokinetics are similar in obese and nonobese patients. Age and lean body mass should be considered for dosing.
IBW, ideal body weight; TBW, total body weight; V_D, volume of distribution.		
Adapted from Ogunnaike BO, Jones SB, Jones DB *et al*: Anesthetic considerations for bariatric surgery. Anesth Analg 95:1793, 2002.		

OBESITY

Obesity is a condition of excessive body fat with adverse health implications, including increased risk for hypertension, coronary artery disease, hyperlipidemia, diabetes mellitus, gall bladder disease, degenerative joint disease, obstructive sleep apnea (OSA), and psychological and socioeconomic impairment. *Obesity* defines an abnormally high percentage of body weight as fat while *overweight* means an increased body weight above a standard related to height.

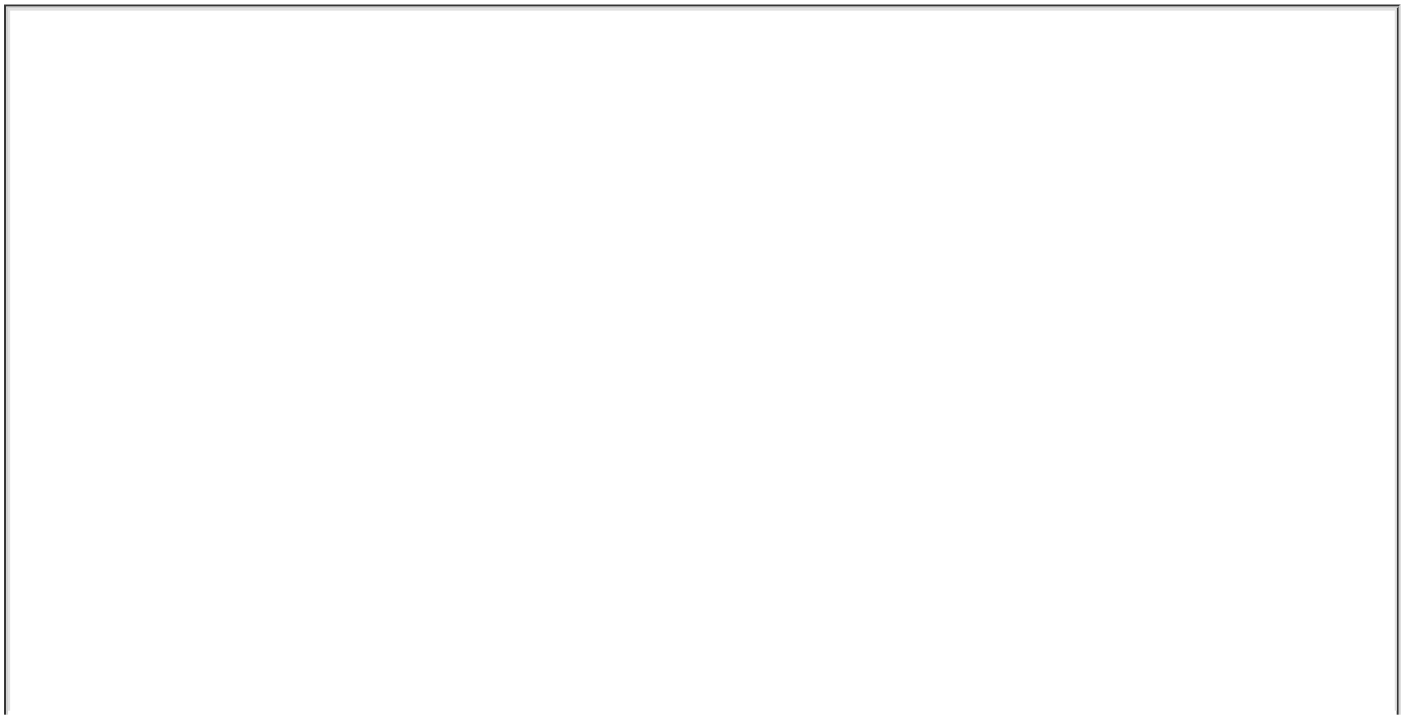
Varying pathophysiologic consequences are associated with the anatomic distribution of body fat. In *android* (central) obesity, adipose tissue is located predominantly in the upper body (truncal distribution) and is associated with increased oxygen consumption and increased incidence of cardiovascular disease. In *gynecoid* (peripheral) obesity, adipose tissue is located predominantly in the hips, buttocks, and thighs. This fat is less metabolically active so it is less closely associated with cardiovascular disease. Intra-abdominal fat is particularly associated with cardiovascular risk and left ventricular dysfunction.

Ideal body weight (IBW) is the weight associated with the lowest mortality rate for a given height and gender and can be estimated using Broca's index:

IBW (kg) = height (cm) – *x;* where *x* is 100 for adult males and 105 for adult females. In clinical practice, *body mass (Quetelet's) index* (BMI) is used to estimate the degree of obesity

$$\text{BMI} = \frac{\text{body weight (kg)}}{\text{height}^2\text{ (m)}}$$

Obesity and *morbid obesity* are BMI >30 and 40 kg/m^2, respectively, while BMI >55 kg/m^2 denotes *super morbid obesity*. BMI differentiates obese from nonobese adults and it reliably measures



body fat because it adjusts for height while strongly correlating with body weight; however, it cannot distinguish between overweight and overfat as heavily muscled people can be easily classified as overweight using BMI. Other factors such as age and fat distribution should therefore be taken into consideration, among other health risk predictors that utilize the concept of BMI. Weight loss reduces the risk associated with obesity and men are at a higher risk than women for a given level of obesity. Immediate preoperative weight loss has not been shown to reduce overall perioperative morbidity and mortality.

Body circumference indices such as waist circumference, waist-to-height ratio, and waist-to-hip ratio can identify patterns of obesity (e.g., android obesity) and correlate strongly with mortality and the risk for developing obesity-related diseases. Waist circumference strongly correlates with abdominal fat and is an independent risk predictor of disease. A waist circumference exceeding 102 cm (40 in) in men and 89 cm (35 in) in women indicates increased risk in overweight and obese individuals. A waist-to-hip ratio (WHR) >0.9 in women and >1.0 in men is associated with a higher risk of morbidity and mortality than a more peripheral distribution of body fat (WHR <0.75 in women and <0.85 in men). Alcohol encourages central (android) fat.

Pathophysiology of Obesity

Respiratory System

Fat accumulation on the thorax and abdomen decreases chest wall and lung compliance. Decreased lung compliance is partially explained by increased pulmonary blood volume because of an overall increase in blood volume as more volume is required to perfuse the additional body fat. Polycythemia from chronic hypoxemia contributes to increased total blood volume. Increased elastic resistance and decreased compliance of the chest wall further reduces total respiratory compliance while supine, leading to shallow and rapid breathing, increased work of breathing, and limited maximum ventilatory capacity. Respiratory muscle efficiency is below normal in obese individuals. Decreased pulmonary compliance leads to decreased functional residual capacity (FRC), vital capacity (VC), and total lung capacity (TLC). Reduction in FRC is primarily a result of reduced expiratory reserve volume (ERV) but the relationship between FRC and closing capacity (CC), the volume at which small airways begin to close, is adversely affected (Fig. 36-1). Residual volume and CC are unchanged. Reduced FRC can result in lung volumes below CC in the course of normal tidal ventilation, leading to small airway closure, ventilation-perfusion mismatch, right-to-left shunting, and arterial hypoxemia. Anesthesia worsens this situation such that up to a 50% reduction in FRC occurs in the obese anesthetized patient compared with 20% in the nonobese. Forced expiratory volume in one second (FEV_1) and forced vital capacity (FVC) are usually within normal limits.

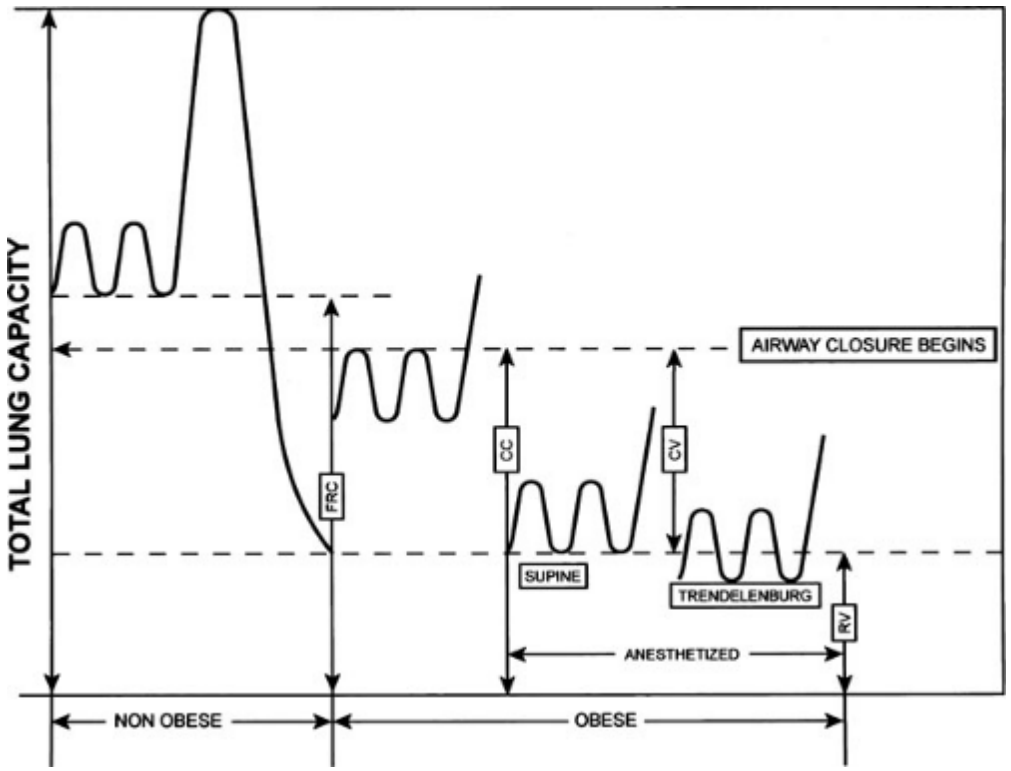


FIGURE 36-1. Effects of obesity, positioning, and anesthesia on lung volumes. FRC, functional residual capacity; CC, closing capacity; CV, closing volume; RV, residual volume.

Obesity increases oxygen consumption and carbon dioxide production because of the metabolic activity of excess fat and the increased workload on supportive tissues. The body attempts to meet these metabolic demands by increasing both cardiac output and alveolar ventilation. Basal metabolic activity is usually within normal limits in relation to body surface area and normocapnia is usually maintained by an increase in minute ventilation. This requires increased oxygen

consumption because most obese patients retain their normal response to hypoxemia and hypercapnia. Arterial oxygen tension in morbidly obese patients and breathing room air is lower than that predicted for similarly aged nonobese subjects in both sitting and supine positions. Chronic hypoxemia may lead to pulmonary hypertension and cor pulmonale.

1 **Obstructive Sleep Apnea.** Up to 5% of obese patients have clinically significant *obstructive sleep apnea*. OSA is characterized by frequent episodes of apnea or hypopnea during sleep, snoring, and daytime symptoms, which include sleepiness, impaired concentration, memory problems, and morning headaches. Apnea is defined as 10 seconds or more of total cessation of airflow despite continuous respiratory effort against a closed glottis. A 50% reduction in airflow or a reduction sufficient enough to cause a 4% decrease in arterial oxygen saturation defines hypopnea. Resultant physiologic abnormalities include hypoxemia, hypercapnia, pulmonary and systemic vasoconstriction, and secondary polycythemia (from recurrent hypoxemia), which is associated with an increased risk of ischemic heart disease and cerebrovascular disease.[1] Right ventricular failure can occur from hypoxic pulmonary vasoconstriction. Respiratory acidosis is initially limited to sleep with a return to normal homeostasis during the awake state.

Long-term OSA can lead to the *obesity hypoventilation (Pickwickian) syndrome* (OHS), which is seen in 5 to 10% of morbidly obese patients. Prolonged OSA results in altered control of breathing, with central apneic events as the main feature. This leads to increasing reliance on hypoxic drive for ventilation. The main ventilatory impairment of OHS is alveolar hypoventilation independent of intrinsic lung disease in a patient with obesity, daytime hypersomnolence, hypercapnia, hypoxemia, and polycythemia. Right ventricular failure eventually ensues. These

patients also have an increased sensitivity to respiratory depressant effects of general anesthetics.

Cardiovascular System

2 Total blood volume is increased in the obese, but on a volume-to-weight basis, it is less than in nonobese individuals (50 mL/kg compared with 70 mL/kg). Most of this extra volume is distributed to the fat organ. Renal and splanchnic blood flows are increased. Cardiac output increases with increasing weight by as much as 20 to 30 mL/kg of excess body fat because of ventricular dilatation and increases in stroke volume. The resulting increased left ventricular wall stress leads to hypertrophy, reduced compliance, and impairment of left ventricular filling (diastolic dysfunction) with elevated left ventricular and diastolic pressure and pulmonary edema, but when left ventricular wall thickening fails to keep pace with dilatation, systolic dysfunction ("obesity cardiomyopathy") results with eventual biventricular failure (Fig. 36-2). Obesity accelerates atherosclerosis. Symptoms such as angina or exertional dyspnea occur only occasionally because morbidly obese patients often have very limited mobility and may appear asymptomatic even when they have significant cardiovascular disease.

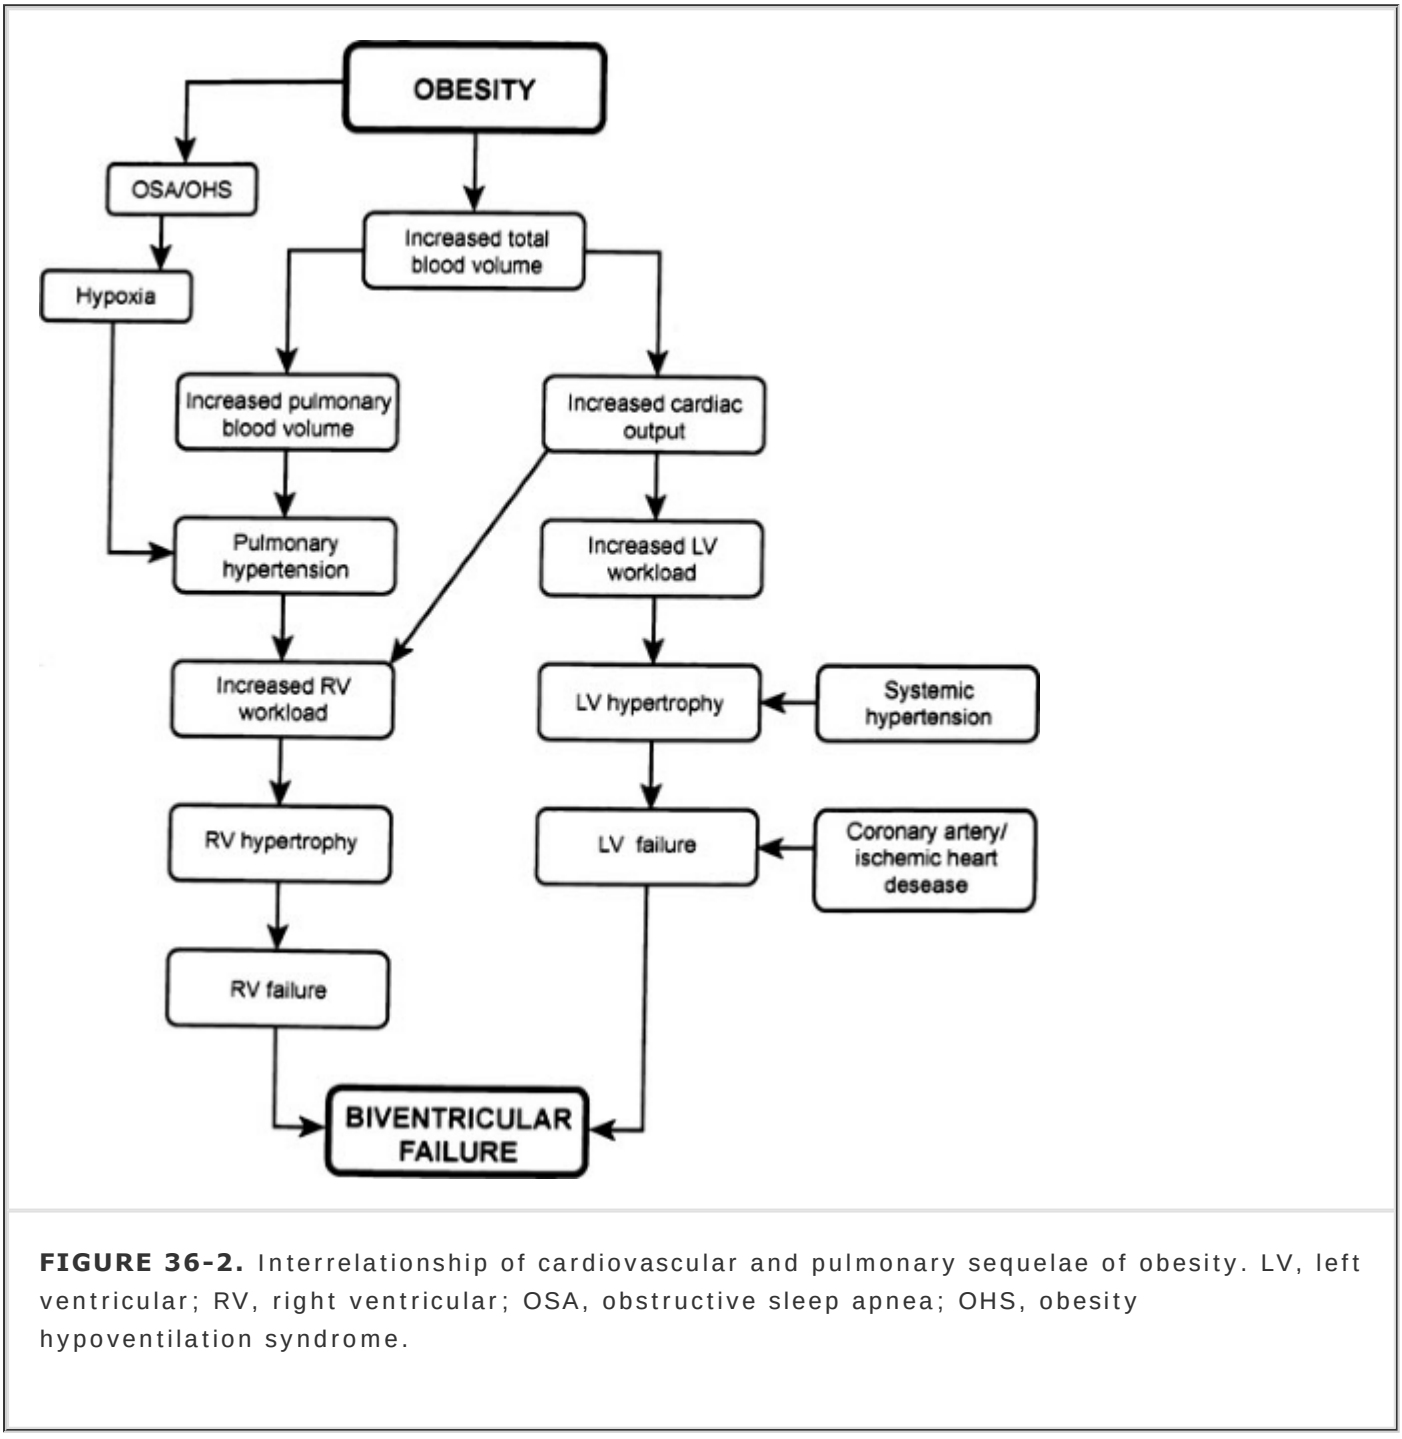

FIGURE 36-2. Interrelationship of cardiovascular and pulmonary sequelae of obesity. LV, left ventricular; RV, right ventricular; OSA, obstructive sleep apnea; OHS, obesity hypoventilation syndrome.

Blood flow to fat is 2 to 3 mL/100 g of tissue. An excess of fat requires an increase in cardiac output, to parallel an increase in oxygen consumption, leading to a systemic arteriovenous oxygen difference that remains normal or slightly above normal. Intraoperative ventricular failure may occur from rapid

intravenous fluid administration (indicating left ventricular diastolic dysfunction), negative inotropy of anesthetic agents, or pulmonary hypertension precipitated by hypoxia or hypercapnia. Dysrhythmias can also be caused by hypoxia, hypercapnia, electrolyte imbalance, coronary artery disease, increased circulating catecholamines, OSA, myocardial hypertrophy, and fatty infiltration of the conduction system.

Cardiac output rises faster in response to exercise in the morbidly obese and is often associated with a rise in left ventricular end-diastolic pressure and pulmonary capillary wedge pressure. Similar changes occur during the perioperative period, which should prompt a low threshold for performing detailed cardiac investigations. Many obese patients have mild to moderate hypertension, with a 3- to 4-mm Hg increase in systolic and a 2-mm Hg increase in diastolic arterial pressure for every 10 kg of weight gained. Normotensive obese patients have reduced systemic vascular resistance (SVR), which rises with the onset of hypertension. Their expanded blood volume causes an increased cardiac output with a lower calculated SVR for the same level of arterial blood pressure.

Gastrointestinal System

Gastric volume and acidity are increased, hepatic function altered, and drug metabolism adversely affected by obesity. Most fasted morbidly obese patients presenting for elective surgery have gastric volumes in excess of 25 mL and gastric fluid pH less than 2.5 (the generally accepted volume and pH indicative of high risk for pneumonitis should regurgitation and aspiration occur). Delayed gastric emptying occurs because of increased abdominal mass that causes antral distension, gastrin release, and a decrease in pH with parietal cell secretion. An increased incidence of hiatal hernia and gastroesophageal reflux also increase aspiration risk.

Gastric emptying has been said to be actually faster in the obese, especially with high energy content intake such as fat emulsions, but because of their larger gastric volume (up to 75% larger), the residual volume is larger. Both the faster gastric emptying and the larger gastric volume can be partially reversed by weight loss.[2] Nonpremedicated, nondiabetic fasting obese surgical patients who are free from significant gastroesophageal pathology are significantly less likely to have high volume, low pH gastric contents than are lean patients at the time of general anesthetic induction after routine preoperative fasting.[3] They should follow the same fasting guidelines as nonobese patients and be allowed to drink clear liquids until up to 2 hours before elective surgery. Up to 300 mL of clear liquid 2 hours before elective surgery in the fasting obese patient does not adversely affect the pH and volume of gastric contents at induction of anesthesia.[4]

3 Peculiar morphologic and biochemical abnormalities of the liver that are associated with obesity include fatty infiltration (high prevalence of nonalcoholic fatty liver disease), inflammation, focal necrosis, and cirrhosis. Fatty infiltration reflects the duration rather than the degree of obesity. Histological and liver function test abnormalities are relatively common in the obese, but clearance is usually not reduced. Abnormal liver function tests are seen in up to one-third of obese patients who have no evidence of concomitant liver disease, of which increased alanine aminotransferase (ALT) is most frequently seen. Weight loss results in sustained improvement in liver enzymes in direct proportion to the extent of weight reduction.[5] Despite these histologic and enzymatic changes, no clear correlation exists between routine liver function tests and the capacity of the liver to metabolize drugs.[6] Morbidly obese patients who have undergone intestinal bypass surgery have a particularly high prevalence of hepatic dysfunction and cholelithiasis, which is also common in the general obese population and of which abnormal cholesterol metabolism is partially to blame.

Renal and Endocrine Systems

Impaired glucose tolerance in the morbidly obese is reflected by a high prevalence of type II diabetes mellitus as a result of resistance of peripheral fatty tissues to insulin. Greater than 10% of obese patients have an abnormal glucose tolerance test, which predisposes them to wound infection and an increased risk of myocardial infarction during periods of myocardial ischemia.[7] Exogenous insulin may be required perioperatively even in obese patients with type II diabetes mellitus to oppose the catabolic response to surgery. Abnormal serum lipid profiles explain the high prevalence of ischemic heart disease.

Obesity is associated with glomerular hyperfiltration as evidenced by increased renal plasma flow (RPF) and increased glomerular filtration rate (GFR). Excessive weight gain increases renal tubular resorption and impairs natriuresis through activation of the sympathetic and renin–angiotensin system as well as physical compression of the kidney. With prolonged obesity, there may be a loss of nephron function, with further impairment of natriuresis and further increases in arterial pressure. Obesity-related glomerular hyperfiltration decreases after weight loss, which decreases the incidence of overt glomerulopathy.[8,9]

Airway

Anatomic changes of obesity that affect the airway include limitation of movement of the atlantoaxial joint and cervical spine by upper thoracic and low cervical fat pads; excessive tissue folds in the mouth and pharynx; short thick neck; suprasternal, presternal, and posterior cervical fat; and a very thick submental fat pad. All these factors contribute to potential difficult airway management. The history obtained from the patient and examination of previous records may help predict airway difficulties. OSA predisposes to airway difficulties during anesthesia. Obese patients with OSA have excess pharyngeal tissue deposited in their lateral pharyngeal walls, which may not be noticed during routine airway examination. Even with the presence of these anatomic and pathologic changes, the magnitude of BMI does not seem to have much influence on the difficulty of laryngoscopy. Such difficulty correlates better with increased age, male sex, temperomandibular joint (TMJ) pathology, Mallampati classes 3 and 4, history of OSA, and abnormal upper teeth.[10]

PHARMACOLOGY

The volume of the central compartment in which drugs are first distributed remains unchanged in obese patients, but absolute body water content and lean body and adipose tissue mass are increased, affecting lipophilic and polar drug distribution. The volume of distribution (V_D) in obese patients is affected by reduced total body water, increased total body fat, increased lean body mass (LBM), altered protein binding, increased blood volume, increased cardiac output, increased blood concentrations of free fatty acids, triglycerides, cholesterol, and alpha-1-acid glycoprotein, lipophilicity of the drug, and organomegaly.[11] Increased distribution of a drug prolongs its elimination half-life even when clearance is unchanged or increased. Hyperlipidemia and an increased concentration of alpha-1-acid glycoprotein may affect protein binding, leading to a reduction in free drug concentration. Plasma albumin and total plasma protein concentration and binding are not significantly changed by obesity, but when compared to normal weight individuals, a relative increase in plasma protein binding may be evident. Splanchnic blood flow, blood volume, cardiac size, cardiac output, organ adipose tissue, and LBM are all increased in obese patients. In contrast to the expected decrease in bioavailability of orally administered medication because of increased splanchnic blood flow in obese people, there is no

significant difference in absorption and bioavailability when comparing obese and normal weight subjects. Drugs that undergo phase I metabolism (oxidation, reduction, hydrolysis) are generally unaffected by changes induced by obesity while phase II reactions (glucuronidation, sulfation) are enhanced. Acetylation, a phase II reaction, is, however, unaltered.[11]

Histologic abnormalities of the liver are common in the obese, with concomitant deranged liver function tests, but drug clearance is not usually affected. Renal clearance of drugs is increased in

obesity because of increased renal blood flow and glomerular filtration rate.[8,9] Increase in GFR is an important contributing factor to proteinuria, a commonly cited renal abnormality in obese patients.[9] As a result of both increased GFR and increased tubular secretion, drugs such as cimetidine and aminoglycoside antibiotics that depend on renal excretion may require increased dosing. Highly lipophilic substances such as barbiturates and benzodiazepines show significant increases in V_D for obese individuals.[11] These drugs have a more selective distribution to fat stores and therefore a longer elimination half-life but with comparable clearance values to normal people. Less lipophilic compounds have little or no change in V_D with obesity. Exceptions to this rule include the highly lipophilic drugs digoxin, procainamide, and remifentanil.[12,13,14] Drugs with weak or moderate lipophilicity can be dosed on the basis of IBW or LBM. About 20 to 40% of an obese patient's increase in total body weight can be attributed to an increase in LBM. Adding 20% to the estimated IBW dose of hydrophilic medications is sufficient to include the extra lean mass. Nondepolarizing muscle relaxants can be dosed in this manner.

Specific Intravenous Agents (Table 36-1)

1. **Thiopental:** Prolonged somnolence with thiopental is expected because it is highly lipophilic and has a larger V_D in the obese patient. However, increased blood volume, cardiac output, and muscle mass necessitates an increase in the initial induction dose.
2. **Propofol:** There is no difference in initial V_D between obese and nonobese patients with propofol. Increased

   V_D at steady state and increased clearance offsets any increase in elimination half-life without evidence of accumulation. Total clearance and V_D at steady state correlate to body weight during maintenance infusion. The dose should be increased based on lean body weight. Propofol has high affinity for excess fat and other well-perfused organs. High hepatic extraction and conjugation relates to total body weight.[15]
3. **Benzodiazepines:** Benzodiazepines persist long after discontinuation because they are highly lipophilic drugs with a larger V_D in obese patients. Midazolam, although considered short acting, has the potential for prolonged sedation in obese patients because larger initial doses are required to achieve adequate serum concentrations.
4. **Neuromuscular Blocking Agents:** Pseudocholinesterase activity increases linearly with increasing weight and larger extracellular fluid compartment; therefore, the dose of succinylcholine should be increased somewhat. Nondepolarizing muscle relaxants should be administered according to lean body weight to prevent delayed recovery because of increased V_D and impaired hepatic clearance. The pharmacokinetics and pharmacodynamics of rocuronium are not altered by obesity in female subjects; however, in the general obese population, the onset time is shorter and duration slightly prolonged.[16,17] The V_D, absolute clearance, and elimination half-life of atracurium are unchanged and dosing can be based on actual body weight without prolongation of recovery because of organ function–independent breakdown.[18] Cisatracurium duration may be prolonged in light of more recent references.
5. **Opioids:** Application of nonweight-scaled pharmacokinetic models for fentanyl derived from normal-weight patients overestimates the plasma concentration of fentanyl as body weight increases from normal to morbid obesity. Fentanyl dosing based on a derived pharmacokinetic mass (derived pharmacokinetic body weight for dosing) is clinically more useful than that based on total body weight because of the strong linear correlation between this pharmacokinetic mass and total body clearance.[20] Sufentanil is highly lipid soluble; therefore, it has an increased V_D and a prolonged elimination half-life that correlates positively with the degree of obesity. It distributes extensively in excess body fat as in lean tissues; therefore, dosing should account for total body mass. Pharmacokinetic parameters derived from nonobese subjects accurately predict plasma sufentanil concentrations in morbidly obese subjects, but at the morbidly obese range, overestimation of plasma sufentanil concentration rises with increasing BMI.[21] Remifentanil pharmacokinetics are more

closely related to lean body mass than to total body weight; therefore, dosing should be based on ideal body weight.[12]

Increased blood volume in the obese patient decreases the plasma concentrations of rapidly injected intravenous drugs. Fat, however, has poor blood flow, and doses calculated on actual body weight could lead to excessive plasma concentrations. Calculating initial doses based on lean body weight with subsequent doses determined by pharmacologic response to the initial dose is a reasonable approach.[22] Repeated injections may accumulate in fat, leading to a prolonged response because of subsequent release from this large depot.

MEDICAL THERAPY FOR OBESITY

Medications used to treat obesity are formulated to reduce energy intake, increase energy utilization, or decrease absorption of nutrients. Indications for drug treatment include a BMI $\geqslant$30 kg/m^2 or a BMI between 27 and 29.9 kg/m^2 in conjunction with an obesity-related medical complication. The combination of phentermine and fenfluramine (Phen-Fen) was popular for the treatment of obesity until it became evident that it was associated with valvular heart disease and pulmonary hypertension.

Sibutramine and orlistat are newer antiobesity medications approved for long-term use. Sibutramine inhibits the reuptake of norepinephrine to increase satiety after the onset of eating rather than reduce appetite. It does not promote the release of serotonin unlike fenfluramine and dexfenfluramine, which primarily increase the release of serotonin in brain synapses and also inhibit reuptake to cause anorexia. These differences in mechanisms of action may explain why thus far there have been no reports of sibutramine causing cardiac valvular lesions. Because sibutramine does not deplete neural synapses of catecholamines, dangerous hypotension unresponsive to indirectly acting vasopressors, as seen with fenfluramine and dexfenfluramine, does not generally occur.[23] The most frequent adverse effects of sibutramine include dry mouth, insomnia, anorexia, and constipation. Sibutramine also results in transient dose-related increases in systolic and diastolic blood pressure by an average of 2 to 4 mmHg and a slight increase in heart rate of 3 to 5 bpm.[24]

Orlistat blocks the absorption and digestion of dietary fat by binding lipases in the gastrointestinal (GI) tract. Cardiovascular risk factors associated with obesity, including blood pressure, waist circumference, fasting blood glucose levels, and lipid profile, all improve with orlistat treatment.[25] Low density lipoprotein (LDL) and total cholesterol levels also decrease. Gastrointestinal complaints of oily spotting, liquid stools, fecal urgency, flatulence, and abdominal cramping are most common and are induced by fat malabsorption. Chronic dosing of orlistat results in an increase in warfarin's anticoagulant effect because of decreased absorption of vitamin K.[26] This leads to an abnormal prothrombin time (PT) with a normal partial thromboplastin time (PTT), because of deficiency of clotting factors II, VII, IX, and X. The resulting coagulopathy should be corrected 6 to 24 hours before elective surgery with a vitamin K analogue such as phytonadione and fresh frozen plasma for emergency surgery or active bleeding.

BARIATRIC SURGERY

Bariatric surgery encompasses a variety of surgical procedures used to treat morbid obesity. They are classified as malabsorptive, restrictive, or combined. *Malabsorptive procedures* (jejuno-ileal bypass and biliopancreatic diversion) are rarely used today. *Restrictive procedures* include the vertical banded gastroplasty (VBG) and the adjustable gastric banding (AGB). Roux-en-Y gastric bypass (RYGB) combines gastric restriction with a minimal degree of malabsorption. VBG, AGB, and RYGB can all be performed laparoscopically, albeit with difficulty in patients weighing >180 kg, because of technical considerations.

Gastric restriction (gastroplasty) creates a small upper pouch (15 to 30 mL) in the stomach, which restricts food intake and communicates with the remainder of the stomach through a narrow channel, or stoma. RYGB, the most commonly performed bariatric procedure in the United States, involves anastomizing the proximal gastric pouch to a segment of the proximal jejunum, bypassing

most of the stomach and the entire duodenum (Fig. 36-3). It is the most effective bariatric procedure to produce safe short- and long-term weight loss in severely obese patients. With RYGB, patients lose an average of 50 to 60% excess body weight and show a BMI decrease of approximately 10 kg/m^2 during the first 12 to 24 postoperative months. Type II diabetes resolves in the majority of patients.[27] Adjustable gastric banding is a restrictive gastric operation usually done by a minimally invasive laparoscopic approach.

An adjustable inflatable band is placed around the proximal stomach to limit stomach capacity (Fig. 36-4). The band can be made tighter or less so by adding or removing saline with adjustments made to meet patients' individual weight loss needs.

Laparoscopic bariatric surgery is minimally invasive with less postoperative pain, lower morbidity, and faster recovery. It is performed through five or six small abdominal incisions while pneumoperitonem is used to create a working space and gravity displacement for the abdominal viscera. Operative trauma is reduced when compared to open procedures, because the need for mechanical retraction of the abdominal wall is eliminated and because the surgical incision is smaller. Patients appreciate laparoscopic bariatric surgery because it reduces postoperative pain and the duration of convalescence.[28] Accumulation of “third-space” fluid, which correlates with the extent of surgical trauma, is significantly lower after laparoscopic RYGB than after open RYGB.[28] Laparoscopic gastric bypass patients also have a reduced incidence of wound infection and an early return to daily activities.

Profound muscle relaxation is important during laparoscopic bariatric procedures to facilitate ventilation and to maintain an adequate working space for visualization and safe manipulation of laparoscopic instruments. It also facilitates extraction of excised tissues. Collapse of the pneumoperitoneum and tightening of the patient's musculature around port sites are early indications of inadequate muscle relaxation.[29]

Laparoscopic bariatric surgery requires maneuvering the operating table into various surgically favorable positions. These maneuvers could contribute to a very large patient slipping off the operating table, with disastrous consequences. The use of a malleable “bean-bag,” in addition to belts and straps, may help to keep the patient secured. Anesthesia personnel may be asked to facilitate the proper placement of an intragastric balloon to help the surgeon size the gastric pouch and also facilitate performance of leak tests with saline or methylene blue through a nasogastric (NG) tube. Care should be taken to ensure a tight seal of the endotracheal tube cuff, otherwise aspiration of saline or methylene blue can occur. All endogastric tubes should be completely removed (not just merely pulled back into the esophagus) before gastric division to avoid unplanned stapling and transection of these devices (Fig. 36-5). After the gastric pouch is created, blind insertion of an NG tube should be avoided by viewing the laparoscope monitor and carefully watching to avoid disruption of the anastomosis.[29] Cephalad displacement of the diaphragm and carina from a pneumoperitoneum during laparoscopy can cause a firmly secured endotracheal tube to displace into a main-stem bronchus.[30]

Radiograph of postoperative gastrograffin swallow. **A.** Transected end of nasogastric (NG) tube left in the gastric remnant. **B.** New properly placed NG tube replacing the transected one. (Reprinted with permission from Ogunnaike BO, Jones SB, Jones DB *et al*: Anesthetic considerations for bariatric surgery. Anesth Analg 95;1801, 2002.)

4 Rhabdomyolysis is more common in morbidly obese patients undergoing laparoscopic procedures when compared to the open procedure. Long duration of surgery is one of the risk factors. Unexplained elevations in serum creatinine and

creatine phosphokinase (CPK) levels or complaints of buttock, hip, or shoulder pain in the postoperative period should raise suspicion of rhabdomyolysis and should be investigated. Serum CPK measured pre- and postoperatively aids in early diagnosis and treatment, which helps reduce further complications such as myoglobinuric acute renal failure that can be as high as 30% with serum CPK >5,000 IU/L.[31]

Gastric electrical stimulation by means of an implantable gastric stimulator (IGS) is a newer weight-loss procedure being performed laparoscopically. Electrical impulses stimulate smooth muscles of the stomach to stop peristalsis so that the patient feels full.[32] A lead with two electrodes implanted in the lesser curvature of the stomach is connected to an electrical pulse generator implanted subcutaneously on the abdominal wall (Fig. 36-6). Implications of this procedure for the anesthesiologist include possible lead dislodgement from violent stomach contractions during postoperative nausea and vomiting. The stimulating pulses emitted by the IGS can be picked up on the electrocardiogram (ECG), which may lead to false readings. The IGS can also be adversely affected by defibrillation, electrocautery, lithotripsy, magnetic resonance imaging, and therapeutic radiation.

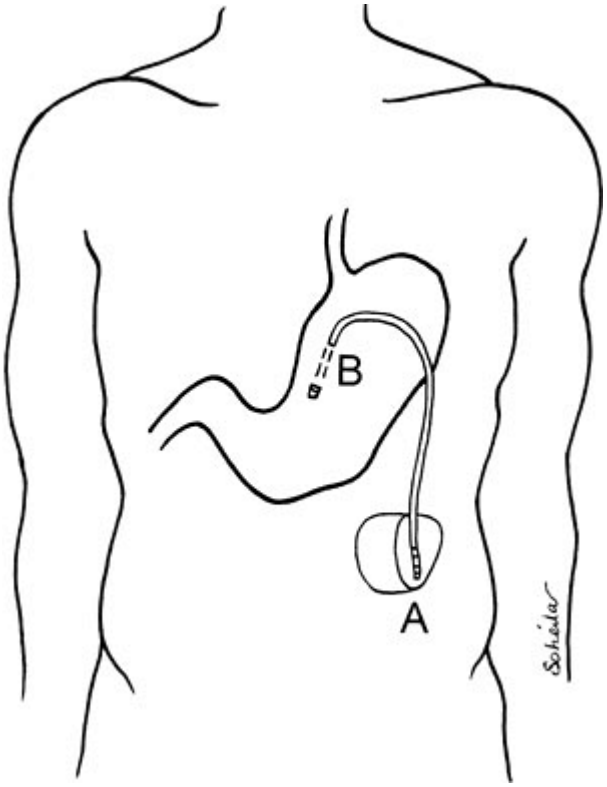

FIGURE 36-6. Illustration of the implantable gastric stimulator (IGS). A pulse generator **(A)** implanted subcutaneously sends impulses to a lead with two electrodes **(B)** implanted in the lesser curvature of the stomach.

PREOPERATIVE CONSIDERATIONS

Preoperative Evaluation

Attention should focus on issues peculiar to the obese patient including evaluation of the cardiorespiratory systems and the airway. Previous anesthetic experiences as detailed by the patient and previous anesthetic records are useful sources of information.

Obese patients should be evaluated for systemic hypertension, pulmonary hypertension, signs of right and/or left ventricular failure, and ischemic heart disease. Signs of cardiac failure such as elevated jugular venous pressure (JVP), added heart sounds, pulmonary crackles, hepatomegaly, and peripheral edema may all be difficult to detect because of masking by excess adiposity. Pulmonary hypertension is fairly common in this patient population because of the chronicity of their pulmonary impairment. The most common features of pulmonary hypertension are exertional dyspnea, fatigue, and syncope (which reflect an inability to increase cardiac output during activity). Tricuspid regurgitation on echocardiography is the most useful confirmatory test of pulmonary hypertension but should be combined with clinical evaluation.[33] An ECG may demonstrate signs of right ventricular hypertrophy such as tall precordial R waves, right axis deviation, and right ventricular strain. The higher the pulmonary artery pressure the more sensitive the ECG. Chest radiographs may show evidence of underlying lung disease and prominent pulmonary arteries.

5 Patients scheduled for repeat bariatric surgery may have long-term metabolic and nutritional abnormalities that should be investigated during the preoperative visit. Common deficiencies include vitamin B_{12}, iron, calcium, and folate. Vitamin and nutritional deficiencies can lead to a collective form of postoperative polyneuropathy, known as acute postgastric reduction surgery (APGARS) neuropathy, a polynutritional multisystem disorder characterized by protracted postoperative vomiting, hyporeflexia, and muscular weakness.[34] Differential diagnoses of this

disorder include thiamine deficiency (Wernicke's encephalopathy, beriberi), vitamin B_{12} deficiency, and Guillain-Barré syndrome. APGARS neuropathy should cause anesthesiologists to pay close attention to dosing and monitoring neuromuscular blocking agents. Electrolyte and coagulation indices should be checked before surgery, particularly in poorly compliant or acutely ill patients because chronic vitamin K deficiency can lead to coagulation abnormalities. Administration of a vitamin K analog or fresh frozen plasma may be needed.

Evidence of OSA and OHS should be sought preoperatively because they are frequently associated with difficult laryngoscopy. OSA patients on a continuous positive airway pressure (CPAP) device at home should be instructed to bring it with them to the hospital as it may be needed postoperatively. The possibility of invasive monitoring, prolonged intubation, and postoperative mechanical ventilation should be discussed with the patient. Arterial blood gas measurement will help evaluate ventilation, as well as the need for perioperative oxygen administration and postoperative ventilation. Routine pulmonary function tests (PFTs) and liver function tests (LFTs) are not cost-effective in asymptomatic obese patients. Blood glucose abnormalities should be corrected if present.

Concurrent, Preoperative, and Prophylactic Medications

Patients' usual medications should be continued until the time of surgery with the possible exception of insulin and oral hypoglycemics. Antibiotic prophylaxis is important because of an increased incidence of wound infections in the obese.[35] Anxiolysis and prophylaxis against both aspiration pneumonitis and deep vein thrombosis (DVT) should be addressed at premedication. Oral benzodiazepines are reliable for anxiolysis and sedation. Intravenous midazolam can also be titrated in small doses for anxiolysis during the immediate preoperative period. Pharmacologic intervention with H_2-receptor antagonists, nonparticulate antacids, or proton pump inhibitors will reduce gastric volume, acidity, or both, thereby reducing the risk and severity of aspiration pneumonitis.

6 Morbid obesity is a major independent risk factor for sudden death from acute postoperative pulmonary embolism (PE). Subcutaneous heparin 5,000 IU administered before surgery and repeated every 8 to 12 hours until the patient is fully

mobile reduces the risk of DVT. Four important risk factors, namely venous stasis disease, BMI $\geqslant$ 60, truncal obesity, and obesity hypoventilation syndrome (OHS)/sleep apnea syndrome (SAS), are significant in the development of postoperative venous thromboembolism, and if present, preoperative prophylactic placement of an IVC filter should be considered.[36] Many bariatric surgeons prefer low-dose unfractionated heparin as their method of thromboprophylaxis.[37] Use of a protocol for heparin dosing in gastric bypass patients, as opposed to a fixed dose, is preferred. Dosing based on height and weight initially, and then adjusted based on peak antifactor Xa activity, results in better thromboprophylaxis and few side effects.[38] Low molecular weight heparins (LMWH) have gained popularity for thromboembolism prophylaxis during bariatric surgery because of their bioavailability when injected subcutaneously. Enoxaparin, 40 mg, injected subcutaneously every 12 hours rather than the often recommended 30 mg every 12 hours decreases the incidence of postoperative DVT without an increase in bleeding complications.[39] It has also been suggested that enoxaparin dosing in the obese be varied with age and lean body mass.[40]

AIRWAY

7 Neck circumference has been identified as the single biggest predictor of problematic intubation in morbidly obese patients.[41] The probability of a problematic intubation is approximately 5% with a 40-cm neck circumference compared with a 35% probability at 60-cm neck circumference. A larger neck circumference is associated with the male sex, a higher Mallampati score, grade 3 views at laryngoscopy, and OSA.

INTRAOPERATIVE CONSIDERATIONS

Positioning

Specially designed tables or two regular operating tables may be required for safe anesthesia and surgery in obese patients. Regular operating tables have a maximum weight limit of approximately 205 kg, but operating tables capable of holding up to 455 kg, with a little extra width to accommodate the extra girth, are available. Electrically operated or motorized tables facilitate maneuvering into various surgically favorable positions. Strapping obese patients to the operating table in combination with a malleable bean bag helps keep them from falling off the operating table. Particular care should be paid to protecting pressure areas because pressure sores and neural injuries are common in this group. Brachial plexus and lower extremity nerve injuries are frequent. A documented association between ulnar neuropathy and increasing BMI quoted as much as one-third incidence of ulnar neuropathy in patients with a BMI $\geqslant$38 kg/m^2 compared with only 1% in the control group.[42]

Supine positioning causes ventilatory impairment and inferior vena cava and aortic compression in obese patients. FRC and oxygenation are decreased further with supine positioning. Trendelenburg positioning, often required during bariatric procedures, further worsens FRC and should be avoided if possible. Simply changing the obese patient from a sitting to supine position can cause a significant increase in oxygen consumption, cardiac output, and pulmonary artery pressure. The head-up reverse Trendelenburg position provides the longest safe apnea period (SAP) during induction of anesthesia.[43] The extra time gained may help preclude hypoxemia if intubation is delayed. Both intraoperative positive end-expiratory pressure (PEEP) and reverse Trendelenburg positions significantly decrease alveolar–arterial oxygen tension difference and increase total respiratory compliance to a similar degree in the obese, but reverse Trendelenburg position results in lower airway pressures. Both, however, decrease cardiac output significantly, which partially counteracts the beneficial effects on oxygenation.[44] Prone positioning, when required in the obese patient, should be correctly performed with freedom of abdominal movement to prevent detrimental effects on lung compliance, ventilation, and arterial oxygenation. Prone positioning increases intra-abdominal pressure, worsening IVC and aortic compression and further decreasing FRC. Lateral decubitus positioning allows for better diaphragmatic excursion and should be favored over prone positioning whenever the surgical procedure permits.

Monitoring

Invasive arterial pressure monitoring may be indicated for the super morbidly obese patient, for those patients with cardiopulmonary disease, and for those patients where the noninvasive blood pressure cuff may not fit properly. Blood pressure measurements can be falsely elevated if a cuff is too small. Cuffs with bladders that encircle a minimum of 75% of the upper arm circumference or, preferably, the entire arm, should be used. Forearm measurements with a standard cuff overestimate both systolic and diastolic blood pressures in obese patients.[45] Central venous and pulmonary artery catheters can be used in patients with significant cardiopulmonary disease or in patients undergoing extensive surgery where significant fluid shifts are anticipated. Central venous catheterization may also be required for intravenous access, which can be problematic in this patient population, although insertion of peripheral lines is almost always successful.[46]

Induction, Intubation, and Maintenance

Adequate preoxygenation is vital in obese patients because of rapid desaturation after loss of consciousness because of increased oxygen consumption and decreased FRC. Application of positive pressure ventilation during preoxygenation decreases atelectasis formation and improves oxygenation in morbidly obese patients.[47] Four vital capacity breaths with 100% oxygen within 30 seconds have been suggested as superior to the usually recommended 3 minutes of 100% preoxygenation in obese patients.[48] Larger doses of induction agents may be required by obese patients because blood volume, muscle mass, and cardiac output increase linearly with the degree of obesity. An increased dose of succinylcholine is necessary because of an increase in activity of pseudocholinesterase. Any of the intravenous induction agents can be used after taking into

consideration problems peculiar to individual patients.

9 If a difficult intubation is anticipated, awake intubation utilizing topical or regional anesthesia is a prudent approach. During awake intubation, sedative–hypnotic medications should be reduced to a minimum. If endotracheal intubation under general anesthesia is selected, hypoxia and aspiration of gastric contents should be prevented at all costs. An experienced colleague who is immediately available or, better still, in the room during induction and airway management can help with mask ventilation or attempts at intubation. A surgeon capable of accessing the airway surgically should be readily available. Towels or folded blankets under the shoulders and head can compensate for the exaggerated flexed position of posterior cervical fat (Fig. 36-7). The object of this maneuver, known as “stacking,” is to position the patient so that the tip of the chin is at a higher level than the chest to facilitate laryngoscopy and

intubation. The head-elevated laryngoscopy position (HELP) is a step beyond stacking. It significantly elevates the obese patient's head, upper body, and shoulders above the chest to the extent that an imaginary horizontal line connects the sternal notch with the external auditory meatus to better improve laryngoscopy and intubation.[49] To facilitate proper HELP placement, the preformed Troop Head Elevation Pillow® (C&R Enterprises, Frisco, TX) in combination with a standard intubation pillow can be used in place of folded towels or blankets (Fig. 36-8A and 36-8B). The advantage of the preformed pillow is that it can be prepositioned, inserted, and removed much faster with less effort than that required to build and dismantle a ramp made from blankets and towels.[50]

FIGURE 36-7. “Stacking” using towels and blankets.

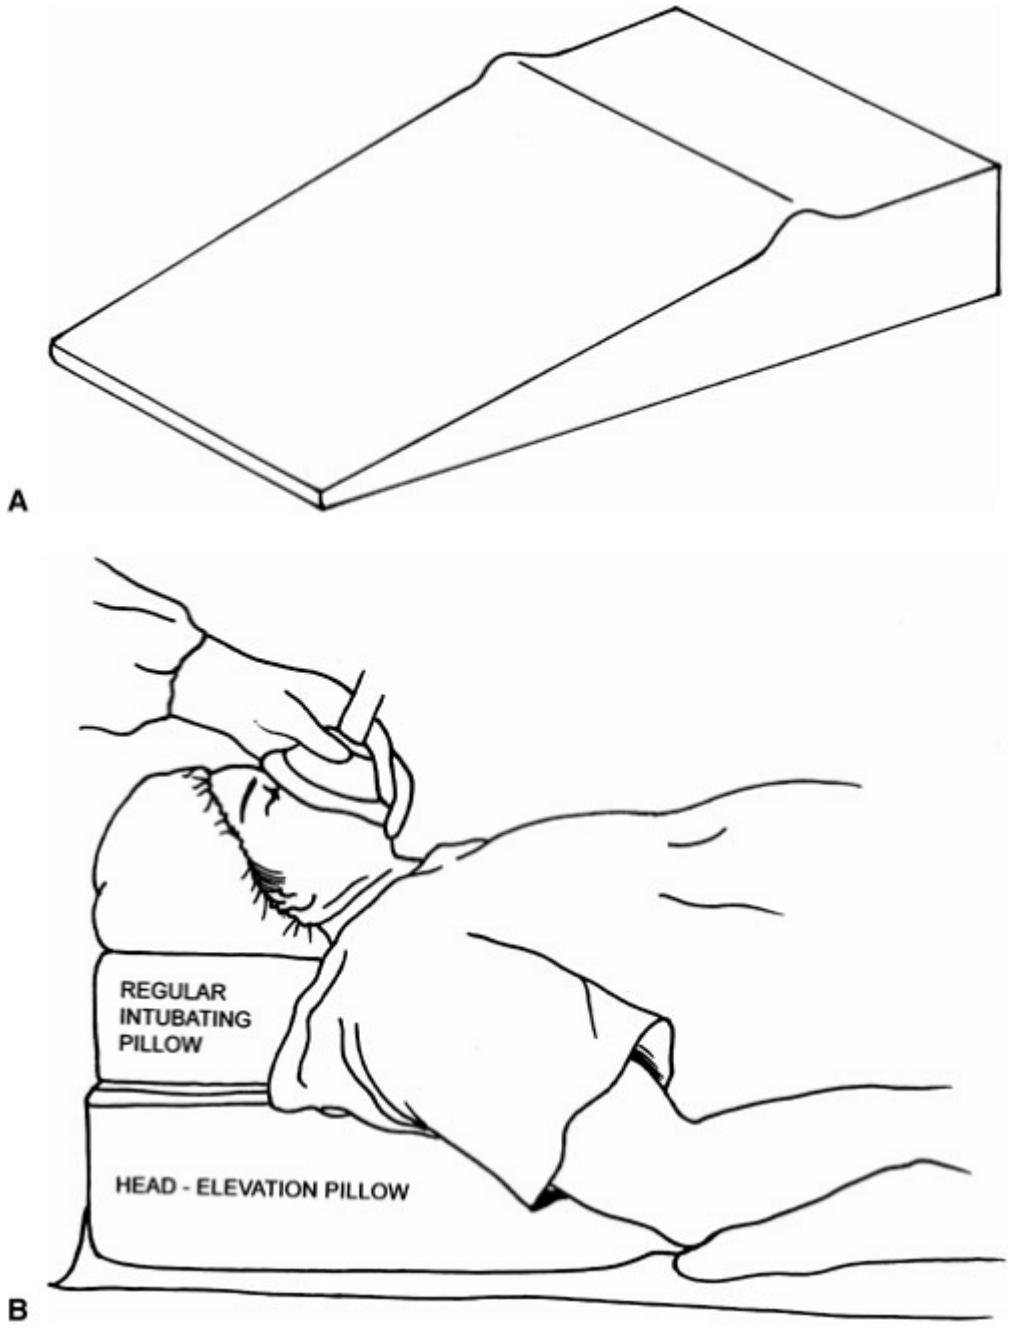

FIGURE 36-8. A. The preformed head elevation pillow. **B.** Proper head-elevated laryngoscopy position (HELP) placement with the head elevation pillow combined with a standard intubating pillow as described in the text.

Continuous infusion of a short-acting intravenous agent, such as propofol, or any of the inhalational agents or a combination may be used to maintain anesthesia. Desflurane, sevoflurane, and isoflurane are minimally metabolized and are therefore useful agents in the obese patient, with desflurane possibly providing better hemodynamic stability.[51] Sevoflurane provides rapid recovery, good hemodynamic control, infrequent incidence of nausea and vomiting, and prompt regaining of psychological and physical functioning when compared to isoflurane.[52] Metabolism of volatile anesthetics is greater in obese than in normal-weight patients, which is reflected by a greater increase in serum inorganic fluoride, including with sevoflurane, whose biotransformation has not been shown to result in significant differences in plasma fluoride levels nor differences in pre- and postoperative liver function and renal function tests between obese and nonobese patients.[53] A potentially hepatotoxic reductive pathway metabolizes halothane in obese patients, resulting in an increased incidence of “halothane hepatitis.” Fortunately, halothane is rarely

needed in modern-day practice. Evidence does not support the suggestion that significant delayed recovery and awakening from volatile

anesthetic agents occurs in obese patients when compared to the nonobese. Rapid elimination and analgesic properties make nitrous oxide an attractive choice for anesthesia in obese patients, but high oxygen demand in this patient population limits its use.

Short-acting opioids at the lowest possible dose, combined with a low solubility inhalation anesthetic, facilitate a more rapid emergence without increasing opioid-related side effects.[54] Cisatracurium possesses an organ-independent elimination profile and is a favorable nondepolarizing muscle relaxant for use during maintenance of anesthesia. Vecuronium and rocuronium are also useful choices. Dexmedetomidine, an alpha-2 agonist with sedative and analgesic properties, provides hemodynamic stability without myocardial depression. It has no clinically significant adverse effects on respiration, which makes it an attractive agent for use as an anesthetic adjunct in obese patients.[55] Furthermore, it reduces the postoperative opioid analgesic requirements and their subsequent detrimental respiratory depressant effects.[56]

Ventilatory tidal volumes greater than 13 mL/kg offer no added advantages during ventilation of anesthetized morbidly obese patients. Increasing tidal volumes further only increases the peak inspiratory airway pressure, end-expiratory (plateau) airway pressure, and lung compliance without significantly improving arterial oxygen tension.[57] Arterial oxygenation during laparoscopy in morbidly obese patients is affected mainly by body weight and not body position, pneumoperitoneum, or mode of ventilation, and oxygenation is not significantly improved by increasing either the respiratory rate or tidal volume.[58] Positive end-expiratory pressure is the only ventilatory parameter that has consistently been shown to improve respiratory function in obese subjects.[59] PEEP may, however, decrease venous return and cardiac output.

Excess adipose tissue may mask peripheral perfusion, making fluid balance difficult to assess. Blood loss is usually greater in the obese than in the nonobese for the same type of surgery, because technical difficulties of accessing the surgical site necessitate larger incisions and more extensive dissection. Early infusion of colloids and blood products may be necessary because obese patients are less able to compensate for small volumes lost, but rapid infusion of excessive amounts should be avoided because preexisting congestive cardiac failure is common in the obese.

Regional Anesthesia

A regional technique is a useful alternative to general anesthesia in the morbidly obese patient as it may help avoid potential intubation difficulties. It can, however, be technically difficult because of inability to identify usual bony landmarks. A peripheral nerve stimulator with an insulated needle may be of use. Central neuraxial block is easier in the lumbar region because the midline in this area has a thinner layer of fat than other areas of the spinal column. Longer needles and the sitting position are other useful tools that facilitate induction of central neuraxial anesthesia. Ultrasound[60] and fluoroscopy[61] can be used to guide the needle or continuous infusion catheter into the epidural space. Low current electrical epidural stimulation through an epidural catheter, to achieve trunk or limb movement, can also be used for confirmation of epidural catheter placement.[62] Epidural vascular engorgement and fatty infiltration reduce the volume of the space, making dose requirements of local anesthetics for epidural anesthesia 20 to 25% less in obese patients. Subarachnoid blocks are not technically as difficult as epidural blocks but the height of a subarachnoid block in obese patients can be unpredictable because it may spread considerably upward within a short time, causing cardiovascular and respiratory embarrassment. A continuous catheter subarachnoid block therefore seems an attractive choice that allows careful titration of the local anesthetic to desired effect and level.[63]

Combined epidural and balanced general anesthesia allows for better titration of anesthetic drugs, use of larger oxygen concentration, and optimal muscle relaxation. It also allows for continuation of postoperative analgesia through the same catheter used to provide surgical anesthesia, thereby facilitating early postoperative mobilization.

POSTOPERATIVE CONSIDERATIONS

Emergence

Prompt extubation reduces the likelihood that the morbidly obese patient, who may have underlying cardiopulmonary disease, will become ventilator dependent. The patient should be preferably extubated in the semirecumbent position, which has less adverse effect on respiration. Supplemental oxygen should be administrated after extubation. Lifting devices such as the HoverMatt® (Patient Handling Technologies, Allentown, PA) and the Patient Transfer Device (PTD®; Alimed, Dedham, MA) are useful for transporting morbidly obese patients onto or off the operating table. The PTD can be combined with the Walter Henderson Maneuver (Fig. 36-9) to safely and gently transfer obese patients onto their postoperative beds.[64]

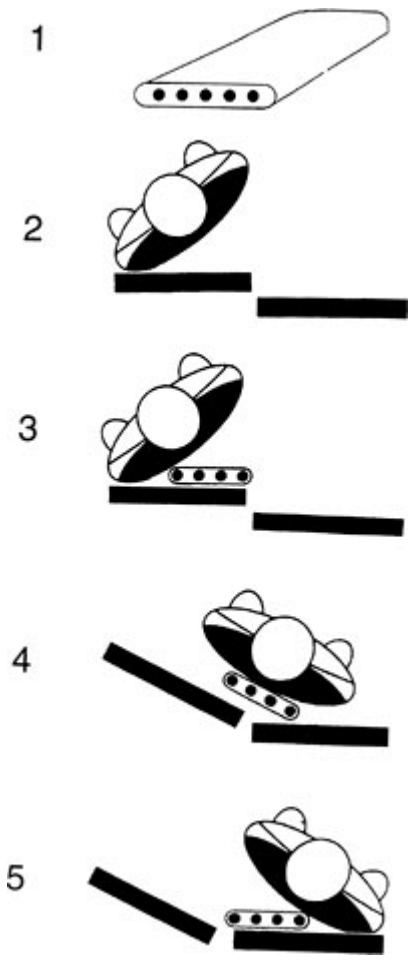

FIGURE 36-9. Illustration of the Walter Henderson maneuver. 1 = Patient Transfer Device—PTD® (a.k.a. patient roller); 2 = patient tilted to slip roller under; 3 = roller slipped under patient; 4 = table tilted to roll patient downhill onto bed; 5 = patient rolled onto bed. (Reprinted with permission from Ogunnaike BO, Whitten CW: In response to Rosenblatt MA, Reich DL, Roth R *et al* [Letter]. Anesth Analg 98;1809, 2004.)

There is an increased incidence of atelectasis in morbidly obese patients after general anesthesia, which persists into the postoperative period.[65] Consequently, initiation of continuous positive airway pressure (CPAP) or bi-level positive airway pressure (Bi-PAP) has been advocated to combat airway obstruction. Postoperative CPAP does not increase the incidence of major anastomotic leakage after gastric bypass surgery despite a theoretical risk.[66] The obese patient may avoid taking deep breaths because of pain after abdominal surgery. Adequate analgesia and a properly fitted elastic binder for abdominal support may encourage them to cooperate with early

ambulation and deep breathing exercises with the aid of incentive spirometry. Pulse oximetry and arterial blood gases should be monitored appropriately.

Postoperative Analgesia

Perioperative use of regional anesthesia and analgesia reduces the incidence of postoperative respiratory complications. Epidural analgesia with local anesthetics, opioids, or both is an effective form of analgesia. Intrathecal opioid is also a viable option. Potential advantages of epidural analgesia in obese patients include prevention of DVT, improved analgesia, and earlier recovery of intestinal motility. Lesser oxygen consumption and decreased left ventricular stroke work are other benefits. PCA morphine is equivalent to low thoracic/high lumbar continuous infusions of bupivacaine/fentanyl epidural analgesia in morbidly obese patients undergoing gastric bypass surgery with regards to the quality of pain control at rest, the frequency of nausea and pruritius, the time to ambulation, time to return of GI function, and the length of hospital stay.[67] Multimodal analgesia (incisional local anesthetic infiltration plus PCA) was found to produce lower pain scores when compared to epidural anesthesia and analgesia and postoperative PCA for gastric bypass surgery. In addition, infiltration analgesia as part of a multimodal regimen offers a simple, safe, and inexpensive alternative to epidural analgesia alone.[68] A combination of intraoperative nonopioid analgesics and anesthetic adjuvants (ketorolac, clonidine, ketamine, lidocaine, magnesium sulfate, and methylprednisolone) that produce analgesia by mechanisms different from opioids decreases sedation during recovery from anesthesia and reduces postoperative morphine requirements when compared to intraoperative fentanyl anesthesia in morbidly obese patients.[69] Delayed respiratory depression is one of the known complications of central neuraxial opioids. When this is coupled with a potentially difficult airway in the obese patient, closer monitoring in a step-down or intensive care unit is a wise choice until this complication is no longer a threat.

RESUSCITATION

The possible need for cardiopulmonary resuscitation should be entertained during anesthesia for the morbidly obese. Of concern are the equipment and technical aspects of resuscitation. Chest compressions may not be effective and mechanical compression devices may be required. The maximum 400 joules of energy on regular defibrillators is sufficient for the morbidly obese,[70] because their chest wall is usually not much thicker, but the higher transthoracic impedance from the fat may obligate several attempts. The laryngeal mask airway (LMA)® and the esophageal tracheal Combitube® are temporary supraglottic airway devices that are useful during resuscitation of the obese. Tracheostomy and percutaneous cricothyrotomy are time-consuming and technically difficult options in such emergency situations. Fiberoptic or retrograde wire intubation may be quicker alternatives in the absence of, or inadequate ventilation with, supraglottic devices.

Chapter 37

Anesthesia and Gastrointestinal Disorders

Babatunde O. Ogunnaike

Charles W. Whitten

KEY POINTS

1	The difference between the lower esophageal sphincter (LES) pressure and gastric pressure is "barrier pressure," which is more important than the LES tone in the production of gastroesophageal reflux.
2	Epidural analgesia that includes local anesthetics has been most effective in minimizing postoperative ileus. Other beneficial adjuncts include minimally invasive surgery, early enteral nutrition, and early mobilization.
3	Carcinoid crises can be precipitated by physical or chemical stimulation, stress, tumor necrosis from hepatic artery ligation or embolization, chemotherapy, and succinylcholine-induced fasciculations, which can potentially trigger mediator release. Octreotide effectively treats intraoperative carcinoid crises.

GASTROINTESTINAL DISORDERS

Esophagus

The adult esophagus extends from the cricophargyngeal sphincter at the level of the C6 vertebra to the gastroesophageal (GE) junction. An inner circular layer surrounded by an outer longitudinal layer makes up the musculature. The upper one-third of the inner circular muscle is striated while the lower two-thirds are smooth.

The cricopharyngeus muscle, one of the two inferior muscles of the pharynx, together with the circular fibers of the upper esophagus, acts as the functional *upper esophageal sphincter* (UES) at the pharyngoesophageal junction. The UES extends from one side of the cricoid arch to the other and is continuous with the circular muscular coat of the esophagus. This sphincter is in a state of tonic contraction with a resting pressure of 15 to 60 cm H_2O, preventing air from entering the esophagus under normal circumstances. The UES also helps prevent aspiration by sealing off the upper esophagus from the hypopharynx in conscious healthy patients. UES function is impaired during both normal sleep and anesthesia. Most anesthetic agents, except ketamine, will reduce UES tone and increase the likelihood of regurgitation of material from the esophagus into the hypopharynx. Impaired swallowing and reduction in tone of the UES from partial neuromuscular blockade increase the risk of aspiration.[1] Video manometry studies have shown a significant delay in relaxation of the UES following contraction of the inferior constrictor muscle during partial

neuromuscular blockade, suggesting that conscious patients in the recovery room may still be at risk of aspiration even with clinically adequate neuromuscular transmission.[2] Subhypnotic concentrations of intravenous (IV) and inhalational anesthetics increase the incidence of pharyngeal dysfunction.[3] Both intrinsic and extrinsic nerves supply the esophagus. The intrinsic nerve supply includes the myenteric plexus of Auerbach (which lies between the outer longitudinal and middle circular layers of muscle) and the submucosal plexus of Meissner (which lies between the circular layer and the mucosa). The extrinsic nerve supply is derived from parasympathetic fibers from the vagi with sympathetic fibers from the superior and inferior cervical and fourth and fifth thoracic sympathetic ganglia.

The border between the stomach and esophagus is formed by the *lower esophageal sphincter* (LES). It is a band of circular

muscle fibers surrounding the lower end of the esophagus and has a resting tone of 10 to 15 cm H_2O with an approximate length of 3 cm. The left margin of the lower esophagus makes an acute angle with the gastric fundus and contraction of the right crus of the diaphragm forms a sling around the abdominal esophagus. The LES, the major barrier to gastroesophageal reflux, is histologically similar to the rest of the esophagus but functionally different. The LES appears as an area of increased pressure on gastroesophageal manometry. During swallowing, the LES is relaxed whereas there is peristalsis in the remainder of the esophagus. The major physiological derangement in gastroesophageal reflux is a reduction in LES pressure. The sphincteric pressure is affected by both the intrinsic nerve plexus and by gastrin released by the mucosa of the gastric antrum in response to the presence of acid. Gastrin increases the sphincter pressure, as well as α-adrenergic agents, acetylcholine, serotonin, histamine, and pancreatic polypeptide. Dopamine, secretin, glucagons, and *β*-adrenergic agents decrease the LES sphincter pressure among other factors (Table 37-1).

TABLE 37-1 Factors Affecting Lower Esophageal Sphincter Tone

▪DECREASE TONE	▪INCREASE TONE	▪NO CHANGE IN TONE
• Inhaled anesthetics • Opioids • Anticholinergics—atropine, glycopyrrolate • Thiopental • Propofol • β-agonists • Ganglion blockers • Tricyclic antidepressants • Secretin • Glucagon • Cricoid pressure • Obesity • Hiatal hernia • Pregnancy	• Anticholinesterases—neostigmine, edrophonium • Cholinergics • Acetylcholine • Succinylcholine • α adrenergic stimulants • Antacids • Metoclopramide • Gastrin • Serotonin • Histamine • Pancreatic polypeptide • Metoprolol	• H_2-receptor antagonists—cimetidine, ranitidine • Nondepolarizing muscle relaxants—atracurium, vecuronium • Propranolol

1 The difference between the LES pressure and gastric pressure is "barrier pressure" and is more important than the LES tone in the production of gastroesophageal reflux. Adequately high intragastric pressure can overcome the LES and lead to reflux. This is unlikely in healthy individuals whose LES pressure usually rises in response to increased intragastric pressure. Low to

normal barrier pressures are characteristic of patients with gastroesophageal reflux with no distinct cut-off point. Vagal denervation does not seem to affect the active function or resting tone of the LES but reduced tone can be clinically seen with obesity, hiatal hernia, and pregnancy. Anesthetic agents that may reduce the barrier pressure, thereby reducing LES pressure, include thiopental, propofol, opioids, anticholinergics, and inhaled anesthetics, while antiemetics, cholinergics, antacids, and succinylcholine increase LES pressure. Nondepolarizing muscle relaxants and H_2-receptor antagonists have no effect on LES pressure. Cricoid pressure in both conscious and unconscious patients decreases LES tone as a result of a significant reduction in esophageal barrier pressure while gastric pressure remains normal.[4] The evidence that succinylcholine increases LES tone, while cricoid pressure decreases LES tone, makes the necessity for application of cricoid pressure during a rapid sequence induction questionable.

Stomach

Digestion begins in the stomach by mixing of ingested food with gastric secretions. It is very distensible with the capacity to store large amounts of material (up to 1.5 L of fluid) without a significant increase in intragastric pressure. Electrical activity that originates at a "pacemaker" located near the midpoint of the greater curvature of the stomach initiates mechanical activity that spreads toward the pylorus. Pyloric relaxation, in response to the waves of gastric activity, expels gastric contents into the duodenum in small amounts.

Obesity, bedridden states, pregnancy, shock, trauma, and pain are examples of pathologic states associated with high gastric content volume. Bowel handling during laparotomy increases gastric emptying time for up to 24 hours. Gastric secretion is predominantly hydrochloric acid with a pH of between 1.0 and 3.5, high potassium content, and a rate of production of about 50 to 100 mL per hour. A gastric volume of 0.4 mL/kg and gastric pH of <2.5 increase the risk and severity of aspiration pneumonitis; however, the volume of fluid aspirated does not necessarily relate to the volume in the stomach. Adequately starved patients have been anesthetized with greater than 0.5 mL/kg gastric volumes without evidence of aspiration. There is a dose-response relationship in the severity of aspiration pneumonitis for both gastric volume and acidity that directly reaches the lung. Human breast milk predisposes to an increased severity of aspiration pneumonitis when compared to other types of milk. Soy-based formula causes a less severe form of acute lung injury than human milk or dairy formula.[5]

Protective Airway Reflexes

The main protective airway reflexes include (1) Apnea with laryngospasm, which causes closure of both the false and true vocal cords. Prolonged laryngospasm maintains the true cords in spasm while the false cords relax. (2) Coughing, which is a brief period of inspiration followed by a forceful expiratory effort. Expiration is accompanied by wider opening of the false cords than inspiration. (3) Expiration reflex, which induces a closure of the false cords preceded by sudden opening of the glottis. It is a forceful expiration without prior preceding inspiration. (4) Spasmodic panting is a reflex involving the glottis

opening and closing rapidly and involves shallow breathing at approximately 60 breaths per minute for less than 10 seconds. These reflexes, except for laryngospasm, can be blunted by opioids such as fentanyl. Premedicated and anesthetized patients, and the elderly, have reduced airway reflexes, putting them at an increased risk for perioperative aspiration pneumonitis.[6]

REDUCING PERIOPERATIVE ASPIRATION RISK

This involves the control of gastric contents (volume and acidity) and prevention of pulmonary aspiration (e.g., cricoid pressure and cuffed endotracheal intubation). Controlling gastric volume and acidity helps minimize the effects of aspiration if it occurs (Table 37-2).

TABLE 37-2 Methods To Reduce The Risk of Regurgitation and Pulmonary Aspiration

1. Minimize intake
   Adequate preoperative fasting
   Clear liquids only if necessary
2. Increase gastric emptying
   Prokinetics (e.g., metoclopramide)
3. Reduce gastric volume and acidity
   Nasogastric tube
   Nonparticulate antacid (e.g., sodium citrate)
   H_2-receptor antagonists (e.g., famotidine)
   Proton pump inhibitors (e.g., lansoprazole)
4. Airway management and protection
   Cricoid pressure
   Cuffed endotracheal intubation
   Esophageal-tracheal combitube®
   Proseal LMA®

LMA, laryngeal mask airway.

Control of Gastric Contents

Control of gastric contents involves (1) minimizing intake, (2) increasing gastric emptying with prokinetics, and (3) reducing gastric volume and acidity with a nasogastric tube, antacids, H_2-receptor antagonists, and proton pump inhibitors (PPIs). Clear liquids can be administered to children and adults up to 2 and 3 hours respectively prior to anesthesia without increased risk for regurgitation and aspiration.[7] Gastric emptying is slower for milk than for clear liquids. Human breast milk is cleared more rapidly than other milk products.[8] Altered physiological states (e.g., pregnancy and diabetes mellitus) and GI pathology (e.g., bowel obstruction and peritonitis) adversely affect the rate of gastric emptying, thereby increasing aspiration risk. The extent of delayed gastric emptying with diabetes mellitus correlates well with the presence of autonomic neuropathy, but not with age, duration of disease, preprandial HbA_{1C}, or peripheral neuropathy. The time difference in the delay between diabetic and healthy patients ranges from 30 minutes to 2 hours.[9] The American Society of Anesthesiologists (ASA) recommends a fasting period of 4 hours for breast milk, 6 hours for both nonhuman milk and infant formula, and also 6 hours for a light solid meal.[7]

Reduction of gastric acidity can be achieved with the aid of H_2-receptor antagonists and PPIs, which also reduce gastric volume. Famotidine effectively reduces gastric volume and increases gastric pH better than ranitidine given a few hours before surgery.[10] The PPIs rabeprazole, lansoprazole, and omeprazole are most effective when given in two successive doses, in the evening before and on the morning of anesthesia.[11,12] When given in a single dose, rabeprazole and lansoprazole should be administered on the morning of anesthesia as they are not sufficiently effective when given the previous night, but single-dose omeprazole can be given on the previous night because it is not as effective when given on the morning of anesthesia.[11,12,13] Sodium citrate, best administered within 1 hour preoperatively in a dose of 15 to 30 mL, increases gastric pH to greater than 2.5, and when combined with metoclopramide (10-mg IV), it reduces gastric contents to less than 25 mL. A nasogastric (NG) tube can be used to reduce gastric volume prior to induction of anesthesia, especially in an emergency situation, but also in elective patients with a high risk of regurgitation and aspiration. Presence of an NG tube does not guarantee an empty stomach and may impair the function of the LES and UES, but it does not diminish the effectiveness of cricoid pressure.[14] The NG tube also provides a direct connection to the outside for passive drainage of gastric contents and is best left in place and open to freely drain during

induction of anesthesia.

Prevention of Pulmonary Aspiration

Cricoid pressure may be used to occlude the upper end of the esophagus to prevent passive regurgitation of gastric contents and decrease the risk of pulmonary aspiration during rapid sequence induction intubation technique. The technique has not been subjected to outcome analysis as to its effectiveness in patients. Also, application of cricoid pressure reduces LES tone and may cause the esophagus to be displaced to the side rather than to be compressed.[15] Application of cricoid pressure was first described by Sellick in 1961. He wrote that, "the maneuver consists in temporary occlusion of the upper end of the esophagus by backward pressure of the cricoid cartilage against the bodies of the cervical vertebrae."[16] It was described as compression generated with downward pressure exerted by the forefinger while the thumb and middle finger prevent lateral displacement of the cricoid ring (Fig. 37-1). Compression in the backward and upward direction has since been found to improve laryngoscopy. The force applied to the cricoid cartilage should be sufficient to prevent aspiration but not so great as to cause airway obstruction or allow the possibility of esophageal rupture if vomiting occurs. The recommended force is estimated to range between 20 and 44 newtons (N); however, cricoid deformation occurs at 44 N with associated cricoid occlusion, vocal cord closure, and difficult ventilation. A force of 1 N will give a mass of 1 kilogram an acceleration of 1 meter per second per second (i.e., 1 N = 1 kg ms^{-2}). Cricoid occlusion may also occur at 20 N and 30 N but to a lesser degree.[17] Cricoid deformation, vocal cord closure, and associated difficult ventilation may be caused by improperly applied cricoid pressure. Awake patients experience pain, coughing, and retching with pressures greater than 20 N, so this amount of force should be applied only after loss of consciousness. A reasonable approach is to apply 10 N force to the cricoid in the awake state and increase to 30 N after loss of consciousness.[14] Cricoid pressure by itself, before laryngoscopy and intubation, increases the incidence of hypertension and tachycardia during induction of anesthesia.[18] The upward and backward direction of application of cricoid pressure has been associated with improved laryngoscopy but with a reduction in manual

ventilatory tidal volumes, suggesting that the upward direction should be omitted if ventilation becomes necessary and continue application of pressure in the backward direction only.[19] Cricotracheal injury, active vomiting, and unstable cervical spine are some contraindications to cricoid pressure. Uncommon complications include esophageal rupture and cricoid ring fracture. In cases of failure to intubate, cricoid pressure may impede ventilation and should be released.[20]

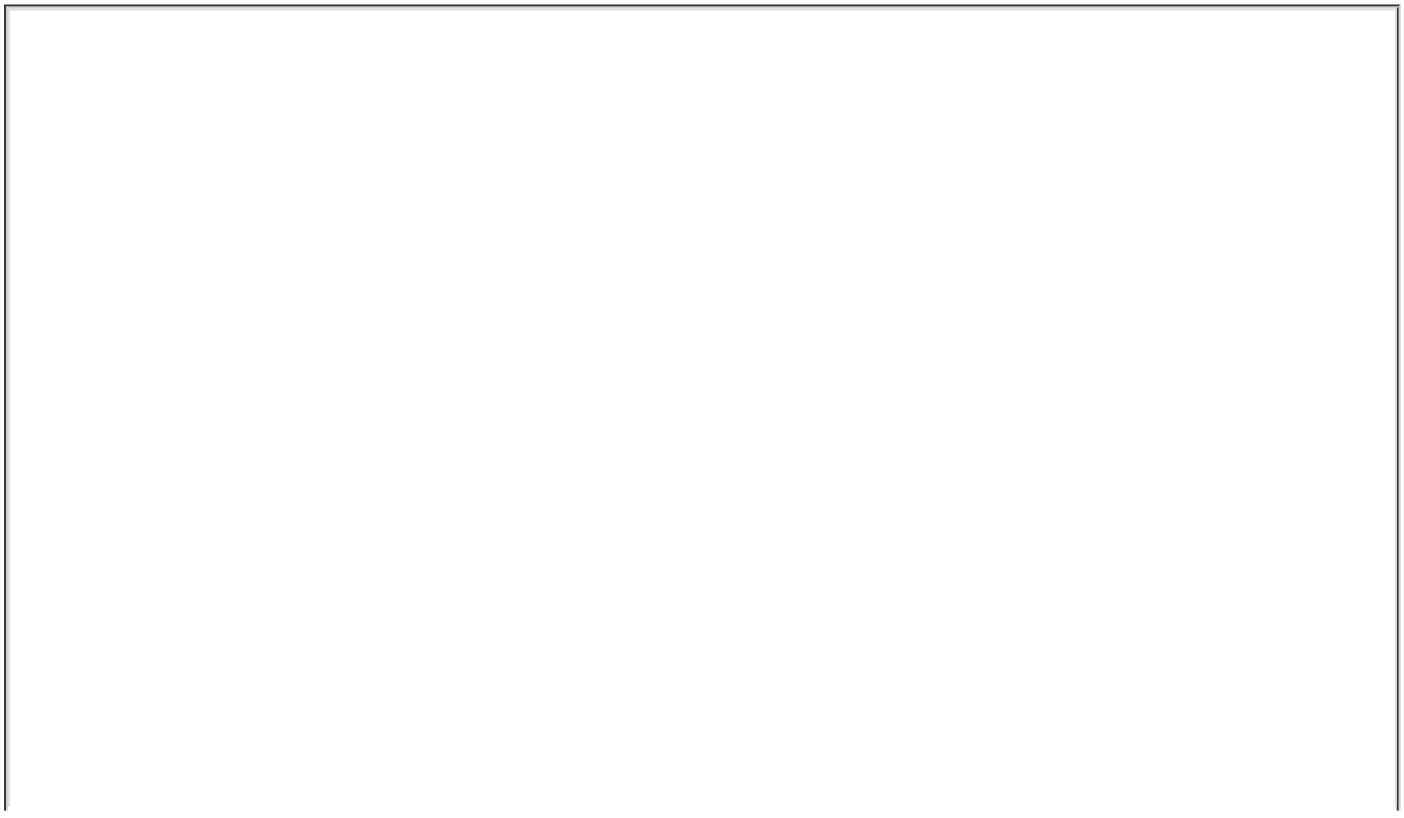

FIGURE 37-1. Cricoid pressure (Sellick's maneuver). Pressure is exerted by the forefinger while the thumb and middle finger prevent lateral displacement of the cricoid ring.

Bimanual cricoid pressure (Fig. 37-2), described as counterpressure with a hand beneath the cervical vertebrae to support the neck, minimizes the distortions of the position of the head and the alignment of the trachea, which can complicate cricoid pressure performed with one hand. A hyperextended vertebral column forms an arch based on the scapulae fixed below and a mobile rotating occiput above. The cricoid forms the apex of this arch, which if disrupted, complicates the maintenance of an unobstructed airway and good glottic view at laryngoscopy. Significant cricoid pressure with the neck extended tends to collapse the arch by downward apical pressure, making the occipital base of the arch rotate and causing the head to flex on the neck, reducing the glottic view with the tongue blocking the pharynx. The use of two hands balances pressure, facilitates the "sniffing" position, and aids laryngoscopy and intubation. Caution should be exercised with this technique in patients with suspected cervical spine trauma or fracture, cervical spine arthritis, immobile neck, and laryngotracheal pathology. No difference in laryngoscopic view has been found in some patients with bimanual cricoid pressure when compared to the single-handed technique.[21]

FIGURE 37-2. Bimanual cricoid pressure. Counterpressure with a hand beneath the cervical vertebrae supporting the neck and minimizing distortions of the head position.

Airway Protection

Cuffed endotracheal intubation tube is the mainstay of prevention of regurgitated material from reaching the trachea and lungs. The high-volume low-pressure cuffs in current widespread use may not completely prevent regurgitated material from reaching the airway. Leakage from the subglottis via the longitudinal folds of the cuff into the trachea can be prevented by cuff lubrication.[22] Of the other airway devices used, the laryngeal mask airway (LMA) reduces barrier pressure at the LES with an increased incidence of reflux in comparison with the cuffed endotracheal tube.[23] The use of the LMA with unusual positions, such as the lithotomy position, increases the incidence of GE reflux.[24] Other studies have found no evidence of regurgitation in LMA-anesthetized patients during either mechanical or spontaneous ventilation.[25,26] Some LMA devices have an esophageal vent for passage of a nasogastric tube and through which regurgitated material can pass to the outside. An incorporated dorsal cuff also allows for provision of a better seal around periglottic tissues. These improvements may help to better isolate the airway from the GI tract.

THE INTESTINES

The small intestine (SI) is the site of most of the absorption of fluids and nutrients from the GI tract. Parasympathetic stimulation and antagonism increases and decreases the activity of the SI respectively. Suppression of sympathetic activity increases SI activity while stimulation results in a decrease. Bowel denervation results in minimal change in intestinal activity, lending credence to

the possibility that humoral secretions (e.g., somatostatin and pancreatic polypeptides) play a major role in intestinal activity. Hypokalemia, peritonitis, and laparotomy all suppress intestinal activity for up to 48 hours. In addition, laparotomy decreases SI absorptive ability.

Absorption is the predominant function of the colon. A pacemaker in the transverse colon controls colonic motility. The vagus nerve supplies neural control to the colon down to the splenic flexure after which the sacral parasympathetic outflow takes over. Sympathetic supply is from T_{6-10}, which decreases colonic motility when stimulated in contrast to parasympathetic stimulation, which increases motility. Neostigmine increases colonic activity while morphine and other opioids decrease both activity and tone.

Splanchnic Blood Flow

Splanchnic blood flow is influenced predominantly by the autonomic nervous system. Alpha-adrenergic stimulation leads to vasoconstriction and ß-2 adrenergic stimulation causes vasodilation. Stimulation of dopaminergic receptors produces vasoconstriction, which predominates over the mild vasodilation produced by ß-2 adrenergic stimulation. Parasympathetic stimulation increases metabolism, which increases blood flow. Autoregulation normally maintains blood flow to the small intestine. With prolonged sympathetic stimulation, there is an initial decrease in blood flow, which is not sustained because of an "escape" phenomenon in the mesenteric circulation whereby the blood flow gradually increases toward normal after a few minutes. Severe stress induces the release of vasoconstrictors including vasopressin, angiotensin II, and catecholamines, which all reduce visceral blood flow. Reduced blood flow results in sympathetic stimulation, which preferentially diverts blood to the muscularis while reducing mucosal perfusion.

It is difficult to maintain adequacy of blood flow after colonic resection, especially in the sigmoid region. This is not usually a problem with small intestinal or stomach surgery. Hypoxia, inadequate oxygen carrying capacity from anemia or impairment of blood supply, may lead to further reductions in oxygen supply, causing ischemia at the anastomotic suture line and consequent anastomotic damage. Splanchnic vascular resistance increases with severe hemorrhage, which helps divert blood flow to other vital organs. Hypocapnia significantly reduces splanchnic blood flow while hypercapnia does the opposite; therefore, hyperventilation to produce hypocapnia is better avoided during colonic surgery and in the perioperative period. Neostigmine reduces mesenteric blood flow because of induced exaggerated contraction. Atropine partially offsets the blood flow reduction. Morphine decreases splanchnic vascular resistance thereby increasing splanchnic blood flow, an effect that can be reversed by naloxone. Thoracic epidural block reduces mean colonic serosal red cell flux and inferior meseneteric artery flow in proportion to a reduction in the mean arterial blood pressure, a situation that does not improve with fluid resuscitation but responds to vasopressor therapy.[27]

Postoperative Anastomotic Leakage

Anastomotic leakage after colon surgery can be related to patient factors (anemia, comorbidity), surgical factors (bowel preparation, operative expertise), and anesthesia- and pain management–related factors (morphine, epidural analgesia, neostigmine).[28] Anesthesia-related factors increase the incidence of anastomotic dehiscense by increasing intestinal motility and intraluminar pressure. In addition, epidural analgesia may reduce blood supply to the anastomotic site. No statistically significant difference in the incidence of anastomotic leakage has been observed in comparing epidural local anesthetics or opioids to intravenous opioids.[29] Neostigmine is an anticholinesterase that increases parasympathetic activity, which increases bowel peristalsis. Vagotomy reduces this effect. Postoperative use of neostigmine after bowel anastomosis has generated controversy as a result of the suggestion that it increases the incidence of anastomotic disruption because of its prokinetic effect. Neostigmine increases the frequency and magnitude of colonic pressure waves, an effect that can be magnified by bowel disease. Anticholinergics like atropine and glycopyrrolate reduce these effects. Prokinetics like metoclopramide have been associated with colonic anastomotic dehiscence during the early postoperative period,[30] however,

clinical observations and animal studies have largely discounted the suggestions that neostigmine has a deleterious effect on bowel anastomosis.[31]

Postoperative Ileus

2 Multiple mechanisms contribute to ileus after intestinal surgery. Abdominal pain activates a spinal reflex that inhibits GI motility, which is further inhibited by the stress of surgery that induces sympathetic hyperactivity. Other contributing factors include excessive handling of bowel, parenteral opioids, electrolyte imbalance, immobility, lack of enteral feeding, and intestinal wall swelling from excessive fluid administration.[32] Thoracic epidural blockade of sympathetic outflow increases GI parasympathetic activity with subsequent increased motility. Low thoracic and lumbar epidural blockade are not as beneficial for minimizing postoperative ileus as is upper thoracic epidural blockade. The colon, beyond the splenic flexure, and the rectum receive their parasympathetic supply from sacral nerve roots and are therefore more susceptible to ileus when lumbar epidural blockade is initiated. Opioids depress GI motility through μ-opioid receptors within the bowels, an effect that can be reversed by naloxone. Epidural analgesia that includes local anesthetics has been most effective in minimizing postoperative ileus. Minimally invasive surgery (including laparoscopy) reduces inflammatory responses, thereby reducing ileus; as does early enteral nutrition and early mobilization.[33]

Mesenteric Traction Syndrome

The mesenteric traction syndrome consists of sudden tachycardia, hypotension, and cutaneous hyperemia occurring during mesenteric traction. In addition, PaO_2 decreases.[34] Clinical features suggest the syndrome results from a release of vasoactive amines (mainly prostacyclin [PGI_2]) from the mesenteric vascular bed because the hemodynamic changes coincide with an increase in plasma concentrations of 6-keto-prostaglandin F_1 (a stable metabolite of prostacyclin) and thromboxane B_2 (a stable metabolite of thromboxane). In addition, even traction of the small intestine can cause histamine release from the mesenteric mast cells. Nonsteroidal anti-inflammatory drugs and aspirin, which inhibit cyclooxygenase, significantly ameliorate these clinical features, further suggesting a prostacyclin-mediated etiology. Intravenous ketorolac has been successfully used to treat persistent hypotension and flushing associated with mesenteric traction syndrome.[35] Prophylactic administration of H_1 and H_2 antihistamines also reduce the incidence of dysrhythmias because of the mesenteric traction syndrome. In addition, they reduce the need for stabilizing interventions.[34] Significant decreases in mean arterial pressure related to central and/or autonomic nervous reflexes occur during operations on upper abdominal viscera.[36] These hypotensive responses to visceral traction appear to be transmitted along afferent fibers contained within the splanchnic nerves. However, deafferentation of the splanchinc nerves, as occurs with epidural anesthesia, does not influence prostacyclin release, hypotension, or hypoxemia during mesenteric traction, lending further credence that prostacyclin is involved in the etiology of the syndrome.

Nitrous Oxide and the Bowel

Because nitrous oxide is 30 times more soluble than nitrogen in blood, nitrous oxide diffuses into gas-containing body cavities from the bloodstream faster than the nitrogen in those cavities can diffuse out into circulation. This can contribute to excessive distension of gas-containing bowels, possible bowel ischemia,[37] and increased difficulty with surgical exposure. Factors that determine the extent of distension include the amount of gas within the bowel, the duration of nitrous oxide administration, and the concentration of nitrous oxide used. There is a linear increase in bowel cavity size with time during administration of nitrous oxide such that after about 4 hours a 100 to 200% increase in gaseous bowel volume is observed with nitrous oxide anesthesia.[38] Use of 80% nitrous oxide can potentially result in a fivefold increase in bowel gas, whereas use of a 50% concentration can result in no more than a doubling of bowel gas. Nitrous oxide is best avoided in situations when the bowels are distended. On the other hand, use of low concentrations of nitrous oxide during elective abdominal operations where no significant amount of gas is present in the

bowels is reasonable.[39,40]

CARCINOID TUMORS

Carcinoid tumor was so named for its resemblance to carcinoma. It was earlier recognized as a slow-growing benign small intestinal tumor capable of metastasis, but with a good prognosis. The GI tract is the usual site of origin of carcinoid tumors, which are derived from enterochromaffin cells but can be found in any tissue derived from the endoderm. Intestinal carcinoid (appendix and ileum) is the usual source of metastasis.[41] Carcinoid tumors are usually asymptomatic, although nonspecific symptoms such as abdominal pain, diarrhea, intermittent intestinal obstruction, and GI bleeding are occasionally seen. Nonmetastatic carcinoid tumors secrete hormones that are usually transported to the liver through the portal vein where they are subsequently inactivated. Although symptoms are sometimes caused by mechanical effects of the tumors, most symptoms are produced by the effects of hormones and substances secreted into the GI tract or into the systemic circulation. Carcinoid tumors, especially those arising in the midgut, secrete a variety of hormones, mediators, and biogenic amines including large quantities of serotonin that produce increased platelet serotonin levels and increased urinary levels of 5-hydroxy-indole-acetic-acid (5-HIAA), a metabolite of serotonin. Other secreted substances include histamine, substance P, catecholamines (including dopamine), bradykinin, tachykinin, motilin, corticotrophin, prostaglandins, kallikrein, and neurotensin. Bradykinin produces cutaneous flushing, bronchospasm and hypotension while serotonin causes hypertension or hypotension. Histamine also produces flushing.

Carcinoid Syndrome

Metastatic carcinoid tumor releases vasoactive peptides into the systemic circulation, which leads to signs and symptoms collectively known as the *carcinoid syndrome*. It generally indicates the presence of pulmonary or hepatic metastasis, although access to the systemic circulation can occur without hepatic metastasis. Carcinoid syndrome occurs when massive amounts of circulating hormones produced by the tumor reach the systemic circulation. It occurs in approximately 20% of patients with carcinoid tumors.[41] The overall clinical manifestations of carcinoid syndrome include cutaneous flushing of the head, neck, and upper thorax (most common); bronchoconstriction; hypotension; diarrhea; and carcinoid heart disease. Hypertension can also occur. Serotonin increases the chronotropic and inotropic activity of the heart, and when coupled with vasoconstriction, will lead to hypertension. The diagnosis of carcinoid syndrome can be confirmed by urinary excretion of 5-HIAA, and serial values of this metabolite can be used to monitor tumor progression. A 24-hour urine sample with >30 mg of 5-HIAA suggests carcinoid syndrome. There is, however, no correlation between the blood level of serotonin and the severity of symptoms. Serotonin increases the tone and motility of the jejunum causing diarrhea, which is the major feature of increased serotonin level.

Carcinoid Heart Disease

Carcinoid heart disease is seen in up to 60% of patients with carcinoid syndrome. Cardiac involvement combines with flushing and diarrhea to make up the classic "carcinoid triad." Cardiac involvement is usually right-sided, affecting tricuspid and pulmonary valves. Left-sided cardiac involvement is rare. Tricuspid regurgitation is the predominant finding, although tricuspid stenosis and pulmonary valve regurgitation or stenosis can also occur. The pathology is described as tricuspid and/or pulmonary valve fibrosis with retraction and fixation of the leaflets leading to regurgitation.[42] Intramyocardial metastases and cardiac dysrhythmias are also seen. Over 50% of carcinoid deaths are a result of cardiac failure. The predominance of right-sided cardiac lesions suggests that the substances secreted from liver metastasis into the hepatic vein never reach the left side of the heart because of pulmonary metabolism. Carcinoid plaques damage valvular integrity and are caused by fibroblast proliferation and valvulitis because of the actions of serotonin and tachykinin on platelets and endothelium. The now banned appetite-suppressant drugs fenfluramine and dexfenfluramine interfere with serotonin metabolism to produce cardiac valve lesions similar to carcinoid valvular lesions.[43] Patients with carcinoid heart disease have

higher levels of serum serotonin and urinary 5-HIAA, but it is debatable whether serotonin is responsible for the cardiac lesions. Also, treatment that reduces 5-HIAA excretion does not lead to regression of cardiac lesions.

Perioperative Management of the Carcinoid Patient

Complete surgical excision is the most effective treatment for carcinoid tumors. Chemotherapy results are marginal at best. Biotherapy with interferon and octreotide may reduce tumor bulk and attenuate the release of vasoactive amines. Management should focus on blocking histamine and serotonin receptors and avoidance of drugs that facilitate mediator release from tumor cells. Mediator release can be triggered by opioids and muscle relaxants that release histamine, including succinylcholine, mivacurium, atracurium, and d-tubocurarine. Epinephrine, norepinephrine, histamine, dopamine, and isoproterenol have also been known to provoke carcinoid crises. Perioperative management should include acquisition of the knowledge and severity of the specific features of the syndrome in each specific patient. Therapy should be directed at preventing the release of mediator substances from the tumor or antagonizing their effects. There is a positive correlation between the presence of carcinoid heart disease or high urinary output of 5-HIAA and postoperative complications.[44] Patients with carcinoid may have diarrhea and high gastric output.[45] Therefore, fluid resuscitation may be required, and serum electrolytes and glucose should be measured at regular intervals.

Many carcinoid tumor specimens contain somatostatin receptors. Somatostatin is a GI regulatory peptide that reduces the production and release of gastropancreatic hormones. It reduces the amount of serotonin released from carcinoid tumors, which subsequently reduces the levels of urinary 5-HIAA. Somatostatin has a very short half-life of about 3 minutes and must therefore be given as infusion. Octreotide is a synthetic somatostatin analogue with approximately 50 times the half-life of somatostatin and is useful in treatment of symptoms and perioperative management of carcinoid syndrome. It has a half-life of approximately 2.5 hours. Subcutaneous octreotide at a dose of 50 to 500 mcg every 8 hours can be titrated to effect for relief of symptoms or prevention of hypotension. Alternatively, 10 to 100 mcg IV can be administered slowly 1 hour preoperatively. Preoperative preparation should also include 100 mg octreotide subcutaneously three times daily in the preceding 2 weeks and, if necessary, should be weaned slowly over 1 week postoperatively. Preoperative anxiolytics should be administered to prevent stress-triggered release of serotonin, and patients receiving octreotide preoperatively should continue with their normal dose on the morning of surgery. A combination of H_1- and H_2-blocking drugs can be used to block the effects of histamine. Histamine release is most likely to occur with gastric carcinoids; therefore, antihistamines may not be needed for carcinoid tumors originating in other areas.[41] H_2-blockers, diphenhydramine, and steroids inhibit the action of bradykinin.

3 Carcinoid crises can be precipitated by physical or chemical stimulation, stress, or tumor necrosis from hepatic artery ligation or embolization or chemotherapy. Succinylcholine-induced fasciculations can potentially trigger mediator release. Octreotide effectively treats intraoperative carcinoid crises. An octreotide infusion at a rate of 50 to 100 mcg/hr can be administered during surgery and if more is required, intravenous boluses of 25 to 100 mcg can be administered to the desired effect. Aprotinin, a kallikrein inhibitor, may be employed for hypotension if there is a refractory response to octreotide.[46]

Availability of newer titratable and short-acting anesthetic agents precludes the use of potentially histamine-releasing and longer acting anesthetic agents. Any of the currently available induction agents and muscle relaxants including propofol, etomidate, vecuronium, cisatracurium, and rocuronium can be used successfully. Caution should be exercised with drugs such as thiopental and succinylcholine that can release histamine. The short-acting synthetic opioids sufentanil, alfentanil, fentanyl, and remifentanil are all acceptable for use.[47] All current inhalation agents can be used successfully; however, desflurane may be the better choice in patients with liver metastasis because of its low rate of metabolism. Increased levels of serotonin have been associated with delayed awakening from general anesthesia. Administration of octreotide prior to manipulation of the tumor will attenuate adverse hemodynamic responses. Use of epidural

analgesia in patients that have been adequately treated with octreotide is a safe technique provided the local anesthetic is administered in a graded manner with careful hemodynamic monitoring and a diluted concentration of local anesthetic is used.[47] The sympathetic blockade produced by epidural or spinal anesthesia may worsen hypotension, which can be minimized by dosing the epidural catheter with opioids or dilute local anesthetic solutions. Intraoperative hypotension from sympathetic blockade should be treated with volume expansion and intravenous infusion of octreotide rather than with sympathomimetics like ephedrine, which can trigger release of vasoactive substances from carcinoid tumors. Octreotide infusion can also be used for intraoperative hypertension in combination with increasing doses of volatile anesthetic. Ondansetron, a serotonin antagonist, is a useful and logical antiemetic choice.

Invasive arterial blood pressure monitoring may be necessary during the intraoperative management of patients with carcinoid syndrome because of rapid changes in hemodynamic variables. Other useful monitors may include central venous or pulmonary artery catheters and transesophageal echocardiography (TEE). Intense hemodynamic monitoring and octreotide administration should continue into the postoperative period as secretion of vasoactive substances can still occur from residual tumor or metastasis. Emotional and physical stress that can trigger vasoactive substance release can be minimized by effective postoperative analgesia.

Chapter 38

Anesthesia for Minimally Invasive Procedures

Anthony J. Cunningham

Cathal Nolan

KEY POINTS

1	Minimal-access surgical procedures produce significantly less trauma than conventional open procedures, with the potential advantages of reduced postoperative pain, shorter hospital stays, more rapid return to normal activities, and significant cost savings.
2	Laparoscopic cholecystectomy is increasingly being performed in older patients with coexisting cardiopulmonary disease. Careful perioperative monitoring of ASA III and IV patients is advised during peritoneal insufflation.
3	Minimal-access surgical techniques are now routine for cholecystectomy, Nissen fundoplication for refractory gastroesophageal reflux disease, splenectomy, and adrenalectomy.
4	The physiological consequences of laparoscopy relate to the combined effects of intraperitoneal insufflation of carbon dioxide (CO_2) to create a pneumoperitoneum, alteration of patient position, and the effects of systemic absorption of carbon dioxide.
5	The principal physiologic responses are an increase in systemic vascular resistance (SVR), mean arterial blood pressure (MAP), and myocardial filling pressures, accompanied by an initial fall in cardiac index (CI), with little change in heart rate.
6	Pneumoperitoneum, changes in patient position, reductions in cardiac output, and systemic carbon dioxide absorption influence splanchnic, renal, and cerebral blood flow during minimal-access procedures.
7	The direct mechanical effects of pneumoperitoneum in reducing splanchnic circulation may be counterbalanced by the direct splanchnic vasodilating effects of carbon dioxide.

8	Although laparoscopic cholecystectomy is considered a minimally invasive procedure, it is associated with intra-abdominal, incisional, and shoulder pain after surgery.
9	A multimodal analgesic regimen combining opioids, non-steroidal anti-inflammatory drugs (NSAIDs), and local anesthetic infiltration may be most effective, allowing reduction of opioid dose and minimizing side effects.
10	The selective 5HT3 receptor antagonist ondansetron may provide effective prophylaxis against postoperative emesis following laparoscopic procedures.
11	Intraoperative complications may arise because of the physiologic changes associated with patient positioning and pneumoperitoneum creation. Traumatic injuries during blind trocar insertion, extraperitoneal insufflation, pneumothorax, and gas embolism are additional risks.
12	Caution is urged, however, against overenthusiastic ambulatory laparoscopic cholecystectomy, as early discharge may lead to occasional delays in diagnosis and management of postoperative complications.

MINIMAL ACCESS INTRA-ABDOMINAL GYNECOLOGIC PROCEDURES

1 Over the past decade, there has been an enormous expansion in the use of minimally invasive surgical procedures that aim to minimize the trauma of the interventional process but still achieve a satisfactory therapeutic result.[1] Minimal-access surgical procedures produce significantly less trauma than conventional open procedures, with the potential advantages of reduced postoperative pain, shorter hospital stays, more rapid return to normal activities, and significant cost savings.[2]

Laparoscopic cholecystectomy was first described in 1987 by Phillipe Mouret; the first series was reported by Perissat et al[3] and the technique was introduced into the United States in 1988 by Reddick and Olsen.[4] Laparoscopic cholecystectomy rapidly emerged as an alternative to traditional open cholecystectomy. It is now a routinely performed procedure and has replaced conventional open cholecystectomy as the procedure of choice for symptomatic cholelithiasis.[5,6] The evolution of laparoscopic cholecystectomy has represented a departure from traditional surgical development. Few prospective randomized controlled trials comparing laparoscopic and open procedures have been performed. Public expectation and perception of the superiority of minimally invasive techniques led to poorly controlled and audited introduction of laparoscopic surgical procedures. However, a significant body of experience and literature has emerged in the 1990s confirming the safety and efficacy of laparoscopic cholecystectomy. Several studies demonstrated that the introduction of laparoscopic cholecystectomy was associated with significant growth in cholecystectomy rates, possibly because of patient demand and lower surgical threshold. However, in 43 tertiary-care university-affiliated Veteran Administration Medical Centers participating in the National Veterans Affairs Surgical Risk Study 1991–1993, the number of cholecystectomies remained stable and the proportion of patients with acute cholecystitis, emergent cholecystectomies, and technically difficult procedures did not change significantly.[7]

2 Increasingly laparoscopic cholecystectomy is being performed in older patients with coexisting

cardiopulmonary disease, in pregnancy, in morbid obesity, and in pediatric patients. Laparoscopy produces significant physiological changes associated with peritoneal insufflation and alteration in patient position, which can have a major impact on cardiopulmonary function, particularly in American Society of Anesthesiologists (ASA) class III or IV patients. Specific intraoperative complications as a result of traumatic injuries and gas embolism may also occur and present significant challenges in anesthetic management. The duration of some procedures, the risk of vascular or visceral injury, and difficulty in evaluating blood loss add to the anesthetic challenge.

3 Increasing surgical experience and improvements in instrumentation, including developments in optics, laser, and electrosurgical technology, has resulted in an expansion of both the range of surgical procedures performed by the laparoscopic approach[8,9,10,11] and the patient population to whom such procedures are offered. Laparoscopic techniques have been applied not only in gastrointestinal (gastric, colonic, splenic, hepatic) but also in gynecologic (hysterectomy) and urologic (nephrectomy) surgery. Public expectation and technology developments have fueled these changes. The physiologic effects of intraperitoneal carbon dioxide insufflation combined with variations in patient positioning can have a major impact on cardiorespiratory function, particularly in elderly patients with comorbidities. Intraoperative complications may include traumatic injuries associated with blind trocar insertion, gas embolism, pneumothorax, and surgical emphysema associated with extraperitoneal insufflation. Appropriate monitoring and a high index of suspicion can result in early diagnosis of and treatment of complications.

SURGICAL TECHNIQUE

Laparoscopic operative techniques involve intraperitoneal insufflation of carbon dioxide. Techniques for pneumoperitoneum creation include insufflation after insertion of the Veress needle infra-umbilicus or open laparoscopy involving dissection through the linea alba and opening of the peritoneum under direct vision.[12] The Veress needle consists of a blunt-tipped, spring-loaded inner stylet and sharp outer needle that penetrates the tissue layers of the abdominal wall. The abdominal wall may be elevated by hand or by clamps placed on the margins of the umbilicus. The Veress needle is inserted at an angle of 45 to 90 degrees depending on operator preference, patient habitus, and previous lower abdominal surgery. The aortic bifurcation lies directly beneath the umbilicus, especially if the Trendelenburg position has already been established. Most practitioners insert the needle and trocar directed toward the pelvis with the patient still horizontal, with or without elevating the anterior abdominal wall. Once inserted, a number of tests are used to test for correct needle placement within the peritoneal cavity, including hanging drop of saline or “hiss test” of gas being sucked into peritoneum upon elevation of anterior abdominal wall.

Hasson, in 1971, described a technique for open insertion of the trocar, thereby guaranteeing pneumoperitoneum and avoiding dangers of blind trocar insertion.[13] Perone confirmed the efficacy of this technique in 585 patients, 173 of whom (29.5%) had undergone previous abdominal surgery. No technical failure or major complications (major vascular injury, bowel or urinary tract trauma) were reported.[14] Modern laparoscopic insufflators automatically terminate gas flow when a preset intra-abdominal pressure (IAP) of 10- to 15 mm Hg is reached. An access port is then inserted in place of the needle to maintain insufflation during surgery. A video laparoscope, inserted through the port, allows visualization of the operative field. Additional access ports are inserted through a number of small skin incisions, which allow the introduction of surgical dissection instruments.

Patient position during minimal-access procedures varies. Patients are usually placed in the Trendelenburg position for laparoscopic gynecologic procedures while laparoscopic cholecystectomy usually involves change to a steep reverse Trendelenburg (rT), with left lateral tilt to facilitate retraction of the gallbladder fundus and to minimize the diaphragmatic dysfunction associated with the induced pneumoperitoneum. The cystic duct and artery are identified and ligated. The diseased gallbladder is dissected from the hepatic bed and removed through the periumbilical cannula. Despite concerns about technical difficulties because of tissue edema and inflammation, acute cholecystitis is no longer considered a contraindication to laparoscopic cholecystectomy.[15] The conversion rate to an open procedure is, however, high, particularly in

older patients with a history of biliary disease and acute gangrenous gallbladder.[16]

Physiological Effects of Laparoscopy

4 The physiological consequences of laparoscopy relate to the combined effects of intraperitoneal insufflation of carbon dioxide (CO_2) to create a pneumoperitoneum, alteration of patient position, and the effects of systemic absorption of carbon dioxide. In addition, reflex increase in vagal tone and arrhythmias can develop.

Cardiovascular Effects

The hemodynamic response to peritoneal insufflation has been well described and depends on the interaction of factors including the IAP achieved[17], patient positioning[18], neurohumoral response[19], and patient factors including cardiorespiratory status[20] and intravascular volume[21] (Table 38-1).

TABLE 38-1 Hemodynamic Effects of Laparoscopy

·PATIENT FACTORS
Preexisting cardiorespiratory status
Intravascular volume
·INTRA-ABDOMINAL PRESSURE
·PATIENT POSITION
·SYSTEMIC CO_2 ABSORPTION
·NEUROHUMORAL RESPONSES

5 The principal physiologic responses are an increase in systemic vascular resistance (SVR), mean arterial blood pressure (MAP), and myocardial filling pressures, accompanied by an initial fall in cardiac index (CI), with little change in heart rate[22,23,24] (Table 38-2).

TABLE 38-2 Summary of Hemodynamic Changes

·CARDIAC OUTPUT
Variable-decreased–depending on CO_2 insufflation/patient position/measurement technique
·CARDIAC FILLING

Venous return—reduced—pooling in extremities
Left ventricular end-diastolic volume—reduced
Intrathoracic pressure—increased
Right atrial and pulmonary artery occlusion pressures—increased during insufflation
▪HEART RATE
Unchanged/minimal increase
▪ARTERIAL PRESSURE
Increased mechanical/neurohumoral (catecholamines, renin-angiotensin/vasopressin)
▪SYSTEMIC AND PULMONARY VASCULAR RESISTANCE
Increased mechanical/neurohumoral (catecholamines, renin-angiotensin/vasopressin)

A characteristic phasic hemodynamic response is described with initial reduction in cardiac index after CO_2 insufflation and subsequent recovery.[23] Using flow-directed pulmonary artery catheters in healthy patients during laparoscopic cholecystectomy, Joris and colleagues[24] observed a significant (35 to 40%) reduction in CI with induction of anesthesia and rT positioning, which was further decreased to 50% of baseline following peritoneal insufflation. Gradual restoration of CI and reduction of SVR occurred. A similar phasic hemodynamic response to pneumoperitoneum was observed by Branche and colleagues[25] using echocardiographic assessment. Left ventricular fractional area of shortening decreased significantly immediately after insufflation and returned to preinsufflation value after 30 minutes of pneumoperitoneum.

Mechanical Effects of Pneumoperitoneum

6 Increased IAP associated with pneumoperitoneum may compress venous capacitance vessels causing an initial increase, followed by a sustained decrease in preload.[25] Compression of the arterial vasculature increases afterload and may result in a marked increase in calculated SVR.[23] Cardiac index may be significantly reduced and the magnitude of this effect is proportional to the intra-abdominal pressure achieved. In healthy subjects undergoing laparoscopic cholecystectomy, Dexter et al[27] using transesophageal Doppler found that cardiac output was depressed to a maximum of 28% at an insufflation pressure of 15 mm Hg but was maintained at an insufflation pressure of 7 mm Hg. In an animal model, Ishizaki et al[18] report the threshold IAP that had minimal effects on hemodynamic function was $\leqslant$12 mm Hg and recommend this pressure limit to avoid cardiovascular compromise during CO_2 insufflation.

Neurohumoral Response

Potential mediators of the increased SVR observed during pneumoperitoneum include vasopressin and catecholamines. Hypercapnia and pneumoperitoneum are likely to cause stimulation of the

sympathetic nervous system and catecholamine release.[27,28] A number of investigators have reported activation of the renin–angiotensin system with vasopressin production.[25,26,27] Joris and colleagues[24] observed a marked increase in plasma vasopressin immediately after peritoneal insufflation in healthy patients and the profile of vasopressin release paralleled the time course of changes in SVR. A fourfold increase in plasma renin and aldosterone concentrations correlating with increases in MAP was reported by O'Leary and colleagues[28]. The time course of vasopressin release paralleling observed changes in CI and SVR suggest a possible cause-and-effect relationship.

CO_2 ABSORPTION

7 Significant hypercapnia and acidosis may occur during laparoscopy as a result of CO_2 absorption.[29] Hypercapnia may cause a decrease in myocardial contractility and lower arrhythmia threshold. The anticipated direct vascular effect of hypercapnia, producing arteriolar dilation and decreased SVR, is modulated by mechanical and neurohumoral responses including catecholamine release.

Effect of Patient Position

Intraperitoneal insufflation of CO_2 for laparoscopic cholecystectomy is performed with the patient in a horizontal or 15- to 20-degree Trendelenburg position. The patient's position is then changed to a steep rT position with left lateral tilt to facilitate retraction of the gallbladder fundus and to minimize diaphragmatic dysfunction (Fig. 38-1).[11] Patient

position may have significant effects on the hemodynamic consequences of pneumoperitoneum. In a series of 13 patients undergoing laparoscopic cholecystectomy, Cunningham and colleagues[19] using TOE monitoring reported a significant reduction in left ventricular end-diastolic area on assumption of rT position, indicating reduced venous return. Left ventricular ejection fraction was maintained throughout in these otherwise healthy patients. However, such changes in left ventricular loading conditions might have adverse consequences in patients with cardiovascular disease. The pattern of changes in cardiac output and arterial pressures in those with mild to severe cardiac disease are similar to otherwise healthy patients.[32] However, quantitatively these changes appear to be more marked.[29]

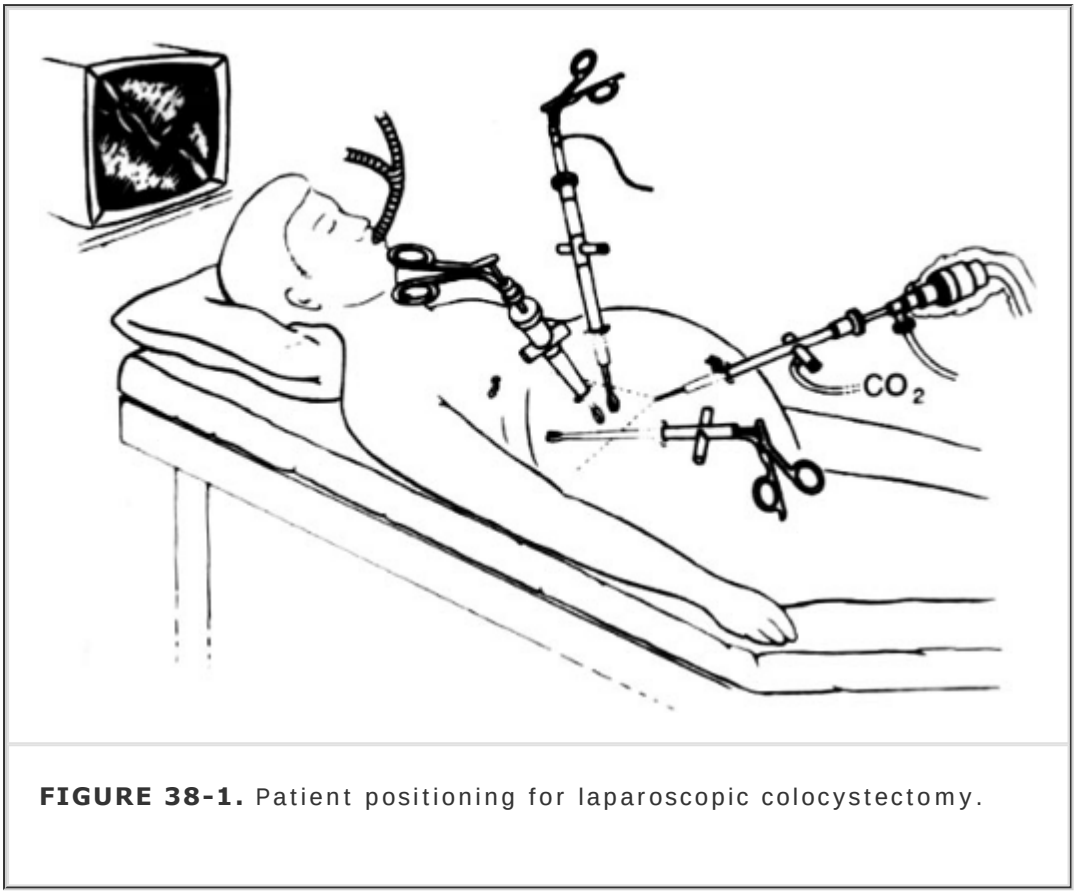

FIGURE 38-1. Patient positioning for laparoscopic colocystectomy.

Increased IAP and the head-up position results in reduced femoral vein blood flow, lower limb venous stasis, predisposing to thromboembolism.[29]

RESPIRATORY EFFECTS

Mechanical

Changes in pulmonary function during abdominal insufflation include reduction in lung volumes, decrease in pulmonary compliance, and increase in peak airway pressure.[30,31,32] Reduction in functional residual capacity (FRC) and lung compliance associated with supine positioning and induction of anesthesia is further aggravated by CO_2 insufflation and cephalad shift of the diaphragm during head-down tilt[30,33] Hypoxemia because of reduction in FRC is uncommon in healthy patients during laparoscopy.[34] However, reduction in FRC may result in significant hypoxemia because of ventilation-perfusion mismatch and intrapulmonary shunting in obese patients or in patients with preexisting pulmonary disease.[35]

GAS EXCHANGE EFFECTS—CO_2 ABSORPTION

Surgical exposure and access is facilitated during laparoscopic surgery by peritoneal gas insufflation. CO_2 is the insufflation gas of choice for laparoscopic surgery. Unlike nitrous oxide (N_2O), it does not support combustion and therefore can be used safely with diathermy. Compared to helium, the high blood solubility of CO_2 and its capability for pulmonary excretion reduces the risk of adverse outcome in the event of gas embolism.[36] CO_2 insufflation into the peritoneal cavity increases arterial carbon dioxide tension[30] ($PaCO_2$), which is managed by increasing minute ventilation.

The absorption of gas from the peritoneal cavity depends on its diffusibility, the absorption area, and vascularity of insufflation site. Carbon dioxide absorption

is greater during extraperitoneal (pelvic) insufflation than during intraperitoneal insufflation. Mullet and colleagues[37] examined end-tidal CO_2 ($ETCO_2$) and pulmonary CO_2 elimination during CO_2 insufflation for laparoscopic cholecystectomy and pelviscopy. CO_2 absorption reached a plateau within 10 minutes after initiation of intraperitoneal insufflation, but continued to increase

slowly throughout extraperitoneal insufflation. During uneventful pneumoperitoneum creation, $PaCO_2$ progressively rises to reach a plateau 15 to 30 minutes after insufflation. Any significant subsequent increase in $PaCO_2$ should prompt a search for a cause, either independent of or related to CO_2 insufflation, such as CO_2-subcutaneous emphysema.

The resulting rise in $PaCO_2$ is unpredictable, particularly in patients with severe pulmonary disease. Wittgen and colleagues[38] observed significant decreases in pH and decreases in $PaCO_2$ in ASA III patients during pneumoperitoneum, and these patients had significantly higher minute ventilation requirements and peak airway pressures. Furthermore, $ETCO_2$ levels may not correlate with arterial concentrations in this patient population. The $PETCO_2$ gradient remained stable during laparoscopy in ASA III patients[38], while other investigators have found $PETCO_2$ gradient to be variable in patients with cardiopulmonary disease.[37] Therefore, $ETCO_2$ may not be a reliable index of $PaCO_2$ during CO_2 insufflation in this patient population.

Splanchnic, Renal, and Cerebral Blood Flow

Pneumoperitoneum, changes in patient position, reductions in cardiac output, and systemic carbon dioxide absorption influence splanchnic, renal, and cerebral blood flow during minimal-access procedures (Table 38-3).

TABLE 38-3 Regional Hemodynamics

▪SPLANCHNIC
Unchanged—mechanical pneumoperitoneum compression balanced by hypercarbic vasodilatation
▪RENAL
Glomerular filtration—reduced
Renal plasma flow—reduced
Urine output—reduced during pneumoperitoneum/recovery following deflation
▪CEREBRAL
Cerebral blood flow velocity—increased
Intracranial pressure—increased

The clinical consequences of these changes depend largely on the patient's preexisting status. The direct mechanical effects of pneumoperitoneum in reducing splanchnic circulation may be counterbalanced by the direct splanchnic vasodilating effects of carbon dioxide. Notwithstanding occasional reports of mesenteric ischemia following laparoscopy,[39] the effects of pneumoperitoneum on the splanchnic circulation are not clinically significant. The mechanical compressive effects of pneumoperitoneum may account for the more than 50% reduction in glomerular filtration, renal plasma flow, and urine output during laparoscopic cholecystectomy.[40]

Urine output increases significantly following pneumoperitoneum deflation. Cerebral blood flow velocity and intracranial pressure both increase during CO_2 pneumoperitoneum, with implications for patients with intracranial mass lesions undergoing minimal access surgery.[41]

ANESTHETIC TECHNIQUE

Anesthetic technique for intra-abdominal general surgical and gynecologic procedures has been mostly limited to general anesthesia. Diagnostic laparoscopic procedures have been performed under spinal anesthesia,[42,43] and successful performance of laparoscopic cholecystectomy under continuous epidural anesthesia has been reported in patients with chronic respiratory disease[44] including cystic fibrosis.[45] However, the high level of sympathetic denervation required, the frequent need for change of patient position, and the mandatory pneumoperitoneum may be associated with adverse ventilatory and circulatory responses complicating perioperative management.

Airway Management

Endotracheal intubation and controlled mechanical ventilation comprise the accepted anesthetic technique to reduce the increase in $PaCO_2$ and avoid ventilatory compromise because of pneumoperitoneum and initial Trendelenburg position.[46] The laryngeal mask airway (LMA) has been used widely during pelvic laparoscopy. Continuous esophageal pH[47],[48] and clinical monitoring[49],[50] failed to detect gastroesophageal reflux in patients undergoing gynecologic laparoscopy using LMA. However, this evidence cannot be extrapolated to upper abdominal laparoscopy, and high intra-abdominal pressures during laparoscopic cholecystectomy may increase the risk of passive regurgitation of gastric contents. Cuffed endotracheal tube placement minimizes the risk of acid aspiration should reflux occur.

Choice of neuromuscular blocking drug depends on anticipated duration of surgery and the individual drug side effect profile. Reversal of residual neuromuscular blockade with neostigmine has been reported to increase the incidence of postoperative nausea and vomiting (PONV) following laparoscopy compared with spontaneous recovery,[50] and some practitioners avoid its use. However, other investigators have found no effect on the incidence of PONV associated with the use of neostigmine,[51] and specifically, in patients undergoing outpatient gynecological laparoscopy, use of neostigmine and glycopyrrolate did not increase the incidence or severity of PONV.[52] Even minor degrees of residual neuromuscular blockade can produce distressing symptoms and must be avoided. Therefore any benefit from omitting neostigmine must be balanced against the risk of inadequate reversal of neuromuscular blockade.

Monitoring

Standard intraoperative monitoring is recommended for all patients undergoing minimal-access procedures. Invasive hemodynamic monitoring may be appropriate in ASA III or IV patients to monitor the cardiovascular response to pneumoperitoneum and position changes and to institute therapy.[45] $ETCO_2$ is most commonly used as a noninvasive indicator of $PaCO_2$ in assessing the adequacy of ventilation during laparoscopic procedures. Wahba and colleagues[54] found that increasing minute ventilation by 12 to 16% maintained $PaCO_2$ close to preinsufflation levels, and that $ETCO_2$ provided a reasonable approximation of $PaCO_2$ in healthy patients undergoing laparoscopic cholecystectomy. McKinstry et al[55] similarly observed equal and proportional increases in $ETCO_2$ and $PaCO_2$ following CO_2 insufflation in healthy patients. In contrast, patients with preexisting cardiopulmonary disease sustained significant increases in $PaCO_2$ during CO_2 insufflation that were not reflected by comparable increases in $ETCO_2$.[37] Online compliance and pressure-volume loop monitoring may be helpful in diagnosing complications resulting in increase airway pressure, such as bronchospasm, endobronchial intubation, and pneumothorax.

Preoperative pulmonary function tests showing low forced expiratory and vital capacity volumes and high ASA status may predict those patients at risk for development of hypercapnia and acidosis during laparoscopic cholecystectomy.[40] For such patients it would seem prudent to monitor $PaCO_2$ at times during the procedure to avoid adverse outcome. Persistent refractory

hypercapnia or acidosis may require deflation of the pneumoperitoneum, lowering of the insufflation pressure, or conversion to an open procedure.

Nitrous Oxide

The use of N_2O during laparoscopic procedures has been controversial as a result of concerns regarding its ability to diffuse into bowel lumen causing distension and to increase postoperative nausea. As N_2O is more soluble than nitrogen (N_2), a closed air-containing space may accumulate N_2O more rapidly than it can eliminate N_2. Eger and Saidman[56] noted an increase of more than 200% in intestinal luminal size after 4 hours of N_2O breathing. The safety and efficacy of N_2O, specifically during laparoscopic cholecystectomy, were investigated

by Taylor et al.[65] Surgical conditions during procedures lasting 70 to 80 minutes were identical regardless of whether N_2O was used. In particular, bowel distension did not increase over time in those patients who received N_2O and surgeons were unable to distinguish between patients who had received N_2O compared to air. In a laboratory experimental study, N_2O was shown to diffuse into a CO_2 pneumoperitoneum and the N_2O fraction exceeded 29%, a level that can support combustion, within two hours.[66] The clinical risk associated with prolonged laparoscopy remains unclear. However, in practice, leakage of intraperitoneal gas and replacement with fresh CO_2 is likely to reduce risk.

Although N_2O can contribute to PONV, Muir and colleagues,[67] in a large randomized, blind study, found no association between the use of N_2O and the subsequent development of PONV. Omission of N_2O failed to reduce the occurrence of PONV after laparoscopic cholecystectomy[65] or pelvic laparoscopy.[68] As conclusive evidence is lacking demonstrating a significant effect of N_2O on the incidence of postoperative emesis after laparoscopic cholecystectomy, any benefit from its elimination must be balanced against the potential increased risk of awareness.

Analgesia

Opioids remain an important component of a balanced general anesthetic technique for minimal-access procedures. Concern has been raised regarding narcotic-induced spasm of the sphincter of Oddi,[69] leading to misinterpretation of intraoperative cholangiographic findings during laparoscopic cholecystectomy. Many opioids, including fentanyl, have been implicated and there are conflicting reports regarding the relative effect of individual opioids.[70,71] Opioid-induced spasm of the sphincter of Oddi may be antagonized by several drugs including glucagon[71] and naloxone.[72]

8 Although laparoscopic cholecystectomy is considered a minimally invasive procedure, it is associated with intra-abdominal, incisional, and shoulder pain after surgery.

9 A multimodal analgesic regimen combining opioids, nonsteroidal anti-inflammatory drugs (NSAIDs), and local anesthetic infiltration may be the most effective approach, allowing reduction of opioid dose, thereby minimizing side effects. The intraperitoneal route of administration of local anesthetics is simple, does not involve central neuraxial block, and may be particularly suited to ambulatory anesthesia.[73] Of 13 clinical trials in a systematic review of intraperitoneal administration of bupivacaine 50 to 200 mg in volumes of 10 to 100 mL, significant reduction in overall pain occurred in seven trials but not in the other six.[74] Joris and colleagues[76] found that visceral pain accounted for most of the discomfort after laparoscopic cholecystectomy and was not attenuated by intraperitoneal administration of 80 mL of 0.125% bupivicaine.

10 PONV is a common and distressing symptom following laparoscopy. Reduction of opioid dose with multimodal analgesia regimes may reduce the incidence of PONV. The selective 5HT3 receptor antagonist ondansetron was reported to provide effective prophylaxis against postoperative emesis following laparoscopic procedures.[76] Other investigators found no difference in antiemetic efficacy between ondansetron and cyclizine in patients undergoing ambulatory laparoscopy.[77] The timing of ondansetron administration was found to be significant, with administration at the end of surgery producing a significantly greater antiemetic effect compared to preinduction dosing.[78]

SPECIFIC INTRAOPERATIVE COMPLICATIONS

Intraoperative complications during minimal-access procedures as a consequence of creation and maintenance of carbon dioxide pneumoperitoneum are included in Table 38-4.

TABLE 38-4 Intraoperative Complications

·VASCULAR INJURIES
Veress needle/trocar insertion—aorta, inferior vena cava, iliac vessels, retroperitoneal hematoma
·GASTROINTESTINAL
Veress needle/trocar insertion—small and large bowel, liver and spleen, mesenteric
·CARDIAC ARRHYTHMIAS
Hypercarbia
Reflex increased vagal tone—peritoneal stretch
·SUBCUTANEOUS EMPHYSEMA
Intentional extraperitoneal insufflation—inguinal hernia repair/pelvic lymphadenectomy
Unintentional-accidental extraperitoneal CO_2 insufflation
·PNEUMOTHORAX/PNEUMOMEDIASTINUM/PNEUMOPERICARDIUM
Embryonic defects
Diaphragm defects—aortic/esophageal hiatus
Pleural tears
Emphysematous bullae rupture
CARBON DIOXIDE EMBOLISM
Direct needle placement in vessel—induction of pneumoperitoneum

Gas insufflation into abdominal organ—hysteroscopy

Major vascular injuries may occur during surgical instrumentation, particularly during insertion of the Veress needle or trocars. The incidence of vascular injury during upper abdominal laparoscopy is reported to be approximately 0.03% to 0.06%[79] and has decreased with increasing surgical experience. Hemorrhage may occur because of insertion of the Veress needle or trocar into major intra-abdominal vessels[80] or because of injury to abdominal wall vasculature.[81] Disruption or avulsion of the cystic or hepatic artery may cause major bleeding during laparoscopic cholecystectomy. Concealed bleeding, particularly into the retroperitoneal space, may result in delayed diagnosis of vascular injury, which may be indicated initially by unexplained hypotension. The anesthesiologist may therefore play a crucial role in early diagnosis of this potentially fatal complication of laparoscopic procedures.[82] Uncontrollable hemorrhage requires immediate conversion to an open procedure to control bleeding and repair the vascular injury. Other reported intra-abdominal injuries associated with trocar insertion include gastrointestinal tract perforations, hepatic and splenic tears, and mesenteric lacerations.[83] Unrecognized gastrointestinal (GI) injuries may be associated with significant morbidity and mortality. Risk factors for GI injuries include gastric distension and adhesions because of previous abdominal surgery. Placement of the Veress needle using a minilaparotomy approach[84] should be considered in patients at increased risk.

Cardiac Arrhythmias

Arrhythmias during laparoscopic procedures may be multifocal and include hypercapnia as a result of intraperitoneal CO_2 insufflation and increased vagal tone following peritoneal stretching, especially associated with light levels of anesthesia. Bradycardia, cardiac arrhythmias, and asystole have all been reported.[84]

Inadvertent Extraperitoneal Insufflation

Access to the peritoneal cavity is achieved during laparoscopy by blind insertion of the Veress needle through a small subumbilical incision. Extraperitoneal insufflation of CO_2 may occur if the needle tip lies in the subcutaneous, preperitoneal, or retroperitoneal tissue during insufflation. The reported incidence of this complication varies from 0.4 to 2%.[85] As there is a continuum of fascial planes, extensive subcutaneous emphysema can develop involving the abdomen, chest, neck, and groin. Subcutaneous emphysema is indicated by the development of crepitus over the abdominal wall. Increased CO_2 absorption may cause a sudden rise in $ETCO_2$ and significant hypercapnia and respiratory acidosis has been reported in association with subcutaneous emphysema because of extraperitoneal insufflation.[86,87] In most cases, no specific intervention is required and the subcutaneous emphysema resolves soon after the abdomen is deflated. Careful surgical technique during Veress needle insertion and verification of intraperitoneal location prior to insufflation[88] will reduce the incidence of these complications.

Pneumothorax, Pneumomediastinum, and Pneumopericardium

Pneumothorax has been reported during both intraperitoneal and extraperitoneal laparoscopic procedures,[34,90] and although rare, is a potentially life-threatening complication. During laparoscopic cholecystectomy, pneumothorax has occurred during Veress needle or trocar insertion, CO_2 insufflation, or gallbladder dissection.[91]

The suggested mechanisms include tracking of insufflated CO_2 around the aortic and esophageal hiatuses of the diaphragm into the mediastinum with subsequent rupture into the pleural space. Passage of gas through anatomic defects in the diaphragm occurring at the outer crus or through a congenital defect at the pleuroperitoneal hiatus (patent pleuroperitoneal canal) is also a likely mechanism.[92] Tension pneumothorax has been described during laparoscopic cholecystectomy[93,94] and has been attributed to such a congenital diaphragmatic defect. Alternatively, rupture of a lung bulla or bleb could produce a tension pneumothorax independent of the pneumoperitoneum.

Clinical signs are variable. Pneumothorax may be undetected intraoperatively, or may present as unexplained increased airway pressure, hypoxemia–hypercapnia, surgical emphysema, or, if tension pneumothorax occurs, severe cardiovascular compromise with profound hypotension. Maintaining a high index of suspicion will facilitate early diagnosis and treatment, which can be life saving. If pneumothorax is suspected, a chest radiograph should be obtained to confirm the diagnosis. In the event of hemodynamic instability or clinical evidence of tension pneumothorax, immediate abdominal deflation and chest tube decompression are indicated prior to chest radiograph. Further management depends on hemodynamic status. If the patient remains stable, the abdomen may be insufflated and the procedure continued. Small pneumothoraces detected at the end of surgery and not associated with hemodynamic compromise may be treated conservatively. CO_2 in the pleural cavity is rapidly resorbed following deflation of the abdomen obviating the need for chest tube placement.

Pneumomediastinum and pneumopericardium have also been reported during laparoscopic procedures. Hasel[95] reports three cases of extravasation of CO_2 during laparoscopic cholecystectomy resulting in subcutaneous emphysema, associated with pneumomediastinum, pneumothorax, and ocular emphysema, all of which resolved spontaneously over 24 hours. High IAPs during insufflation may have contributed to these complications. Management depends on the degree of hemodynamic compromise that results. Deflation of the pneumoperitoneum and close observation is adequate in many patients.[91]

Gas Embolism

Serious adverse intraoperative events attributed to gas embolism during laparoscopic procedures are widely reported.[96,97] Venous CO_2 embolism in these cases was associated with profound hypotension, cyanosis, and asystole after creation of the pneumoperitoneum. The proposed mechanisms of gas embolism include inadvertent intravenous placement of the Veress needle, passage of CO_2 into abdominal wall and peritoneal vessels during insufflation, or into open vessels on the liver surface during gallbladder dissection. Signs and severity of effects of CO_2 embolism are variable and may include hypotension with cardiovascular collapse, hypoxemia, detection of a “mill-wheel” murmur, and an associated decrease in $ETCO_2$ because of reduction in pulmonary blood flow. Paradoxical embolism through a probe-patent foramen ovale or an atrial septal defect[98] may result in cerebral CO_2 embolism.

The incidence of gas embolism during laparoscopy is unclear. Using transesophageal echocardiography, Derouin and colleagues[99] reported CO_2 embolism occurring in 69% of patients during laparoscopic cholecystectomy but without significant cardiopulmonary effects. In contrast Wadhwa and colleagues, using precordial Doppler, did not observe any gas embolism in 100 patients undergoing gynecologic laparoscopic procedures.[101]

Appropriate monitoring and maintenance of a high index of suspicion can result in early detection and prevention of serious adverse sequelae from CO_2 embolism.

POSTOPERATIVE CONSIDERATIONS

It has been suggested that laparoscopic surgery reduces postoperative pulmonary complications by avoiding the restrictive pattern of respiration that usually follows upper abdominal surgery. Although there have been few prospective randomized trials comparing laparoscopic and open cholecystectomy,

many early studies[82,101] report a lower incidence of pulmonary complications with the laparoscopic approach. Diaphragmatic dysfunction occurs following laparoscopic cholecystectomy and may last for up to 24 hours postoperatively.[102,103] Visceral afferents originating in the gallbladder area or somatic afferents arising from the abdominal wall that exert an inhibitory action on phrenic discharge may cause this diaphragmatic dysfunction.[91] However, although spirometric measures of lung function are decreased following both procedures, compared with patients undergoing open cholecystectomy, the laparoscopic approach was associated with 30 to 38% less impairment of postoperative pulmonary function including FRC, forced expiratory volume in 1 second (FEV_1), and vital capacity.[93] In addition, global respiratory muscle strength is greater 24 and 48 hours after laparoscopic compared with open cholecystectomy as determined by mouth pressure measurements during maximal inspiratory and expiratory efforts.[94]

Increased IAP during pneumoperitoneum has been reported to cause venous stasis that can increase the potential for deep vein thrombosis and pulmonary embolism (PE). The reported incidence of fatal PE following laparoscopic cholecystectomy (0.016%) is lower than after open surgery (0.8%).[95] Measures to reduce venous stasis such as graduated elastic compression stockings are indicated in the perioperative period. Minimal tissue trauma with laparoscopic techniques, facilitating early postoperative ambulation, also reduces risk.

Bile duct injuries are more common after laparoscopic compared with open cholecystectomy[96] and tend to be more extensive and located higher in the duct system. Pain and jaundice associated with bile collections are typical presenting features in the postoperative period. MacFadyen et al[96] analyzed a total of 114,005 laparoscopic cholecystectomies performed in the United States from 1989 to 1995. Major bile duct injuries occurred in 561 patients (0.5%). The common bile duct/common hepatic duct were most frequently injured (61.8%), and the majority of injuries required a surgical drainage procedure with either biliary-enteric anastomosis (41.8%) or T-tube placement (27.5%).

AMBULATORY LAPAROSCOPIC CHOLECYSTECTOMY

12 The minimally invasive nature of laparoscopic surgery facilitating earlier mobilization, and feeding, and reduced hospital stay has extended the range of procedures that can be performed on a day-case basis to include laparoscopic cholecystectomy. Some centers report successful same-day discharge for laparoscopic cholecystectomy in 68 to 94% of patients.[109,110,111] Concerns have been raised regarding the safety of outpatient laparoscopic cholecystectomy. In a series of 506 patients undergoing this procedure, 7.5% experienced postoperative complications, 61% of which had not become evident by 24 hours.[112] In an Australian report of 725 laparoscopic procedures, there was a 1.37% incidence of intensive care unit (ICU) admission.[113] Surgical complications were associated with delayed diagnosis and longer ICU admissions. Therefore, caution is urged against overenthusiastic ambulatory laparoscopic cholecystectomy based on the logical if unproven assumption that early discharge will lead to occasional delays in diagnosis and management of postoperative complications.

VIDEO-ASSISTED THORACIC SURGERY (VATS)

Video-assisted thoracic surgery (VATS) presents new challenges for the surgeon and anesthesiologist. Potential advantages include less postoperative pain, improved postoperative pulmonary function, shorter hospitalization, and earlier return to work.[115] Applications of VATS include lobectomy, pneumonectomy, esophagectomy, and pericardial resection (Table 38-5). More innovative applications include implantation of the implantable cardioverter–defibrillator, excision of mediastinal masses, transthoracic endoscopic sympathectomy for the treatment of upper limb

hyperhydrosis, and painful causalgias and splanchnicectomy (celiac plexus block) for intractable pain from pancreatic cancer and pancreatitis. VATS has been reported in the management of multiple diseases of the thoracic spine, including disc herniation, disc space abscesses, and spinal deformities.[116]

Abscess drainage

Anesthetic techniques for thoracoscopy were reviewed by Horswell.[117] Most VATS are performed under general anesthesia with one-lung ventilation (OLV) provided through a double-lumen endobronchial tube placed in the left main stem bronchus and verified bronchoscopically (Fig. 38-2). Anesthesia is maintained by a combination of intravenous (IV) and inhaled agents. A radial artery cannula is usually placed for continuous blood pressure measurement and blood gas analysis.

Continuous pulse oximetry and end-tidal carbon dioxide tension ($PETCO_2$) are measured. Postoperative pain is managed by patient-controlled opioid analgesia, NSAIDs, or regional techniques. VATS-assisted placement of paravertebral catheters during thoracoscopic procedures has been reported in the management of postoperative pain.

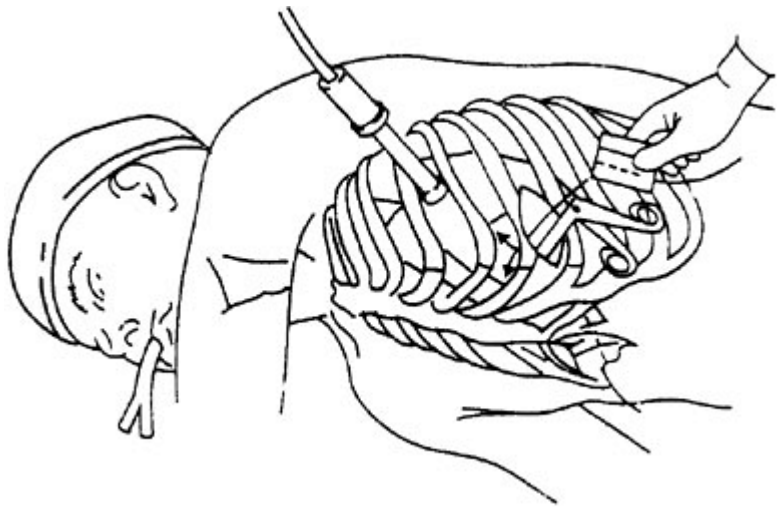

FIGURE 38-2. Patient positioning for thorascopic surgery.

SUMMARY

Laparoscopic cholecystectomy has proven to be a major advance in the treatment of patients with

symptomatic gallbladder disease. The minimal-access nature of the surgical insult results in less pain and less postoperative ileus, facilitating faster recovery, shorter hospital stay, and more rapid return to normal activities.

General anesthesia and controlled ventilation comprise the accepted anesthetic technique to control arterial carbon dioxide tension. There is no conclusive evidence demonstrating a significant effect of N_2O on surgical conditions during laparoscopic cholecystectomy or on the incidence of postoperative emesis. Opioids remain an important component of a balanced anesthetic technique for laparoscopic cholecystectomy. A multimodal analgesic regimen combining opioids, NSAIDs, and local anesthetic infiltration may be the most effective approach, allowing a reduction of opioid dose, thereby minimizing side effects. Postoperative nausea and vomiting is common and requires appropriate prophylaxis and treatment.

The physiologic changes associated with patient positioning and pneumoperitoneum creation may cause significant cardiorespiratory compromise, particularly in ASA III and IV patients, and careful monitoring during CO_2 insufflation is recommended. Intraoperative complications may also arise because of traumatic injuries sustained during blind trocar insertion, CO_2 embolism, extraperitoneal insufflation and surgical emphysema, pneumothorax, and pneumomediastinum. Increasingly laparoscopic cholecystectomy is being performed in pregnancy, morbid obesity, and in older patients with coexisting cardiopulmonary disease presenting significant challenges in anesthetic management. Appropriate monitoring and maintenance of a high index of suspicion can result in early diagnosis of complications and prevent serious adverse sequelae.

Increasing surgical experience and improvements in instrumentation, including developments in optics, laser, and electrosurgical technology, has resulted in an expansion of both the range of surgical procedures performed by the laparoscopic approach to include gastrointestinal (gastric, colonic, splenic, hepatic), gynecologic (hysterectomy), and urologic (nephrectomy) procedures.

KEY POINTS

1	The hepatic buffer response, in which the hepatic artery blood flow changes reciprocally with changing portal venous flow, is the mechanism by which total oxygen delivery to the liver is maintained. This response is limited in its ability to compensate during conditions of hypoperfusion, inflammation, or shock.
2	Hepatitis associated with volatile anesthetics is rare overall and is most commonly associated with halothane. The disorder appears to be immune mediated and is best avoided by eliminating halothane from clinical use.
3	Because of the liver's central role in the inflammatory response, the metabolic demands greatly increase whenever acute-phase proteins are being produced. These demands occur when hepatic oxygen delivery is likely to be compromised, placing the liver in a highly vulnerable situation.
4	The risk of developing perioperative hepatic dysfunction varies with the preexisting hepatic reserve status; presence of comorbid conditions; and the type, duration, and location of surgery. Commonly employed general and regional anesthetic techniques impart minimal additional stress to the liver.
5	Currently, there is no commonly available hepatic replacement therapy for acute liver failure. The most effective support for the liver, maintaining adequate perfusion and oxygenation, as well as avoiding secondary toxic insults, must occur before it fails.

The liver occupies the center of a diverse spectrum of vital physiologic functions and plays an essential role in maintaining perioperative homeostasis. Patients with advanced liver disease are at high risk of excessive morbidity and mortality following surgery due to failure of one or more of these essential functions. For example, the normal liver moderates the hypotensive response to acute blood loss and hypovolemia through its reservoir function, and helps minimize blood loss through synthesis of coagulation factors and degradation of fibrinolytic substances. Failure of these functions contributes to intraoperative and postoperative hypoperfusion, tissue ischemia, and activation of the systemic inflammatory response, setting the stage for the postoperative development of multisystem organ failure. The liver is the primary regulatory site for metabolism.

After oral intake, all nutrients are brought to the liver for processing, followed by controlled distribution to extrahepatic tissues. The liver also helps sustain energy supplies during fasting, is the site of synthesis of almost all the body's proteins, plays a central role in the individual's defense against infection, and modulates inflammatory processes. Predictable termination of the pharmacologic effects of many anesthetic agents depends on the liver for metabolic biotransformation into inactive products that can be eliminated.

The liver is a remarkably resilient organ, with unparalleled regenerative capacity and substantial physiologic reserves. Normal function may be present in humans when as much as 80% of the organ has been resected. Insidious hepatic diseases such as chronic hepatitis C can progress silently and destroy the majority of the liver before symptoms develop. Identifying patients with marked limitation of hepatic reserve, but without overt hepatic failure is important, but often difficult. A careful preoperative history and physical examination will help identify patients in whom laboratory evaluation of liver function is appropriate. These patients are often at increased risk for perioperative morbidity and mortality, including development of overt liver dysfunction postoperatively, particularly after major procedures.

As therapy for chronic hepatic diseases improves and the number of patients with chronic hepatitis C continues to rapidly increase, it can be expected that the number of patients with moderate-to-severe liver disease presenting for surgery will rise. These patients may be at extremely high risk for perioperative complications, and it is essential that the anesthesiologist understands the interactions between liver disease, surgical procedures, and anesthetic interventions so an appropriate therapeutic plan can be developed and implemented to optimize patient outcome.

HEPATIC ANATOMY

The liver is the largest gland in the human body with a median weight of 1.8 kg in men and 1.4 kg in women.[1] The liver is covered by peritoneum (Glisson's capsule), except for the gallbladder bed, the inferior vena cava (IVC), the bare area, and the porta hepatis. At the porta hepatis, the connective tissue of the capsule is continuous with the fibrous sheath, which invests the portal vessels and ducts. The capsular peritoneum reflects onto the diaphragm and continues as the parietal peritoneum. The reflections form various ligaments (coronary, triangular, and falciform), which firmly attach the liver to the anterior abdominal wall and diaphragm.

Lobes Versus Segments of the Liver

The customary division of the liver into the right, left, caudate, and quadrate lobes is derived from the topographic anatomy, with the falciform ligament separating the right and left lobes (Fig. 39-1). This anatomic description does not correspond to the branches of the liver's vascular supply and therefore is of limited clinical and physiologic significance. The liver can be divided on a different plane into right and left hemilivers, which have their own blood supplies and duct drainage. The liver can be further divided into a total of eight functionally independent segments, each with its own vascular inflow and outflow, and biliary drainage (Fig. 39-2). The segmental division of the liver was devised by Couinaud, based on the divisions of the portal vein, and more recently modified by Strasberg, based on the more consistent divisions of the hepatic artery and biliary ducts.[2] This anatomic arrangement facilitates limited segmental resection of the liver with relatively bloodless surgical dissection along the planes between segments, and thereby prevents major disruption of hepatobiliary function. With current imaging techniques, radiologists can construct precise, three-dimensional models of a patient's liver, defining the segmental location of lesions and their relation to the vasculature. Such information can help the surgeon decide on the most appropriate operative approach, while enhancing the resectability of a variety of lesions and improving outcome for patients undergoing operations for neoplasm or trauma.[3]

Vascular Supply of the Liver

The liver receives about 25% of the cardiac output, and therefore, has an average blood flow

between 100 and 130 mL/minute per 100 g. There are two major sources of blood to the liver: the hepatic artery and the portal vein. The common hepatic artery arises from the celiac trunk and sends off the cystic artery before entering the liver (Fig. 39-3). The portal vein is formed by the confluence of the splenic and superior mesenteric veins, and receives blood from the entire digestive tract, spleen, pancreas, and gallbladder. The hepatic artery delivers about 25% of the total hepatic blood flow but nearly 50% of the hepatic oxygen delivery. The portal vein provides the remaining 75% of total hepatic blood flow and 50% of hepatic oxygen delivery. Because portal venous blood has already perfused the preportal organs (stomach, intestines, spleen, and pancreas) (see Fig. 39-3), it is partially deoxygenated and enriched with nutrients and other substances absorbed from the gastrointestinal tract.

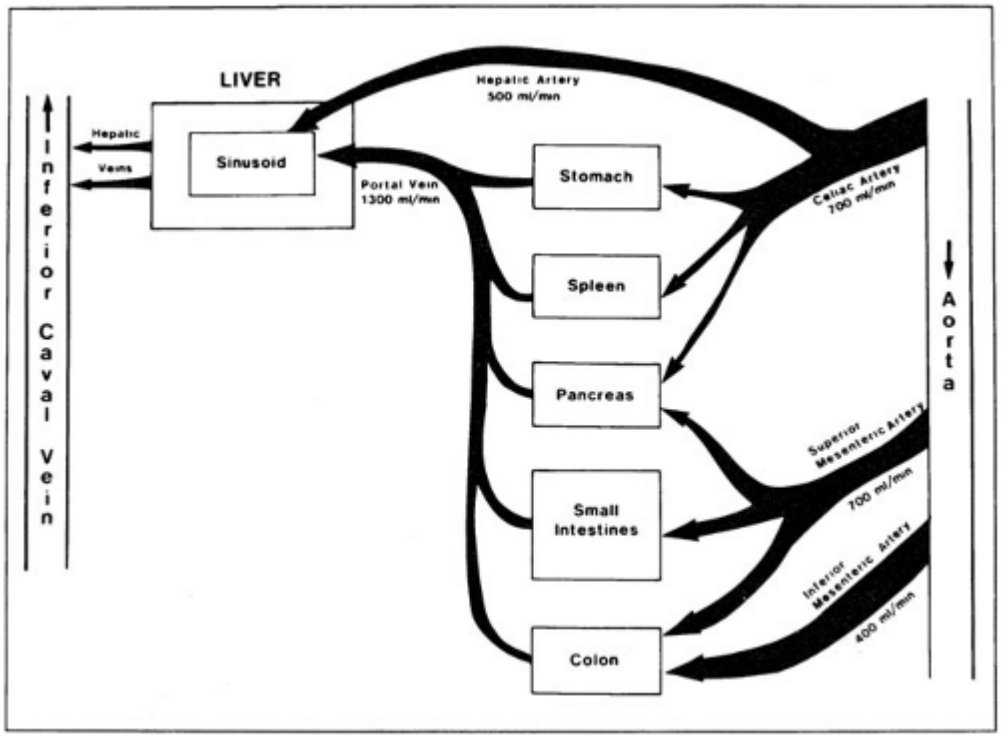

FIGURE 39-3. Schematic representation of splanchnic circulation. (Reprinted with permission from Gelman S: Effects of anesthetics on splanchnic circulation. In Altura BM, Halevy S [eds]: Cardiovascular Action of Anesthetics and Drugs Used in Anesthesia, p 127. Basel, Karger, 1986.)

The portal vein has numerous tributaries, which are usually of little importance (see Fig. 39-1). When patients develop portal hypertension, however, these normally rudimentary connections form large portosystemic shunts, permitting portal

venous blood to return to the systemic circulation without traversing the liver. These shunts produce many of the pathologic findings and severe complications of portal hypertension (e.g., esophageal varices).

Intrahepatic Circulation

The portal vein and hepatic artery enter the liver at the porta hepatis, where the larger bile ducts join and accompany them. Both vessels bifurcate into left and right branches, which arborize in parallel while diminishing in caliber as they penetrate the hepatic parenchyma to end as terminal hepatic arterioles and portal venules (Fig. 39-4). Most terminal vessels drain directly into the hepatic sinusoids, delivering substrates to, and removing products from, adjacent parenchymal cells. Before this, some arteriolar blood flows through the peribiliary capillary plexus, which plays a major role in bile secretion and absorption (see Fig. 39-4). Hepatic arterial pressure is similar to

aortic pressure, while the mean portal vein pressure is approximately 6 to 10 mm Hg. These two afferent vascular systems merge in the sinusoids where the pressure is normally 2 to 4 mm Hg above that of the IVC. The hepatic sinusoids connect the terminal portal vessels with the hepatic venules. The continuity of the sinusoidal wall is interrupted by fenestrations, which facilitate transfer of solutes to the space of Disse for uptake by hepatocytes. Flow through the sinusoids is influenced by several factors, the most important of which may be local control by shrinking or swelling of endothelial and Kupffer cells.

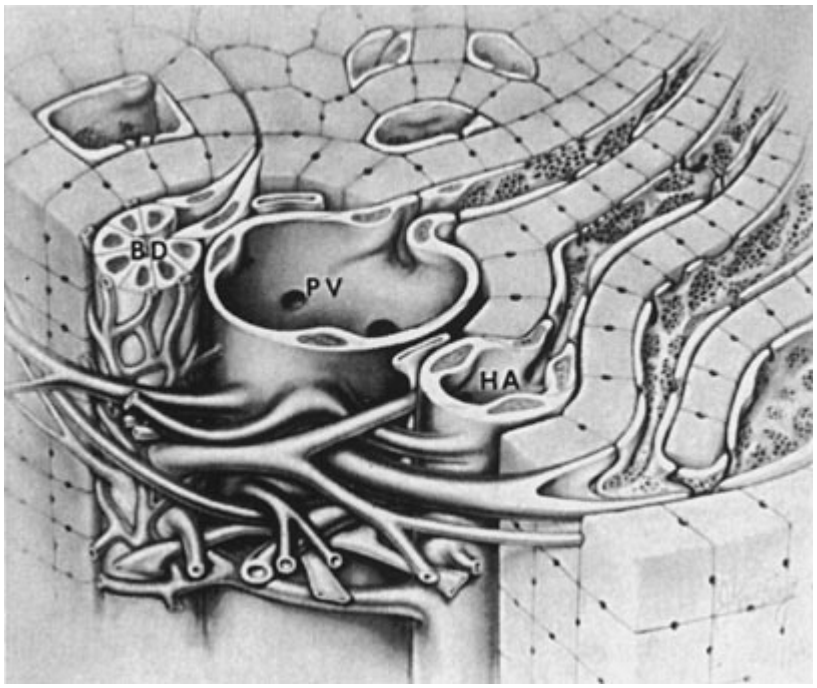

FIGURE 39-4. Relationship of branches of the portal vein (PV), hepatic artery (HA), and bile duct (BD). Notice the peribiliary capillary plexus that envelops the bile ducts. These three structures constitute a portal triad, which is a transverse section of a portal canal. (Reprinted with permission from Jones AL: Anatomy of the normal liver. In Zakim D, Boyer T [eds]: Hepatology: A Textbook of Liver Disease, 3rd ed, p 3. Philadelphia, WB Saunders, 1996.)

Blood drains from the hepatic sinusoids into the central vein and then flows through sublobular veins that join to form one of the three major hepatic veins (right, middle, and left) (Fig. 39-5). A short extrahepatic segment joins each major hepatic vein to the IVC. The caudate lobe drains directly into the IVC through small posterior caudate veins. If thrombosis of the major hepatic veins occurs (Budd-Chiari syndrome), the caudate veins become the key to drainage of hepatic blood into the IVC.

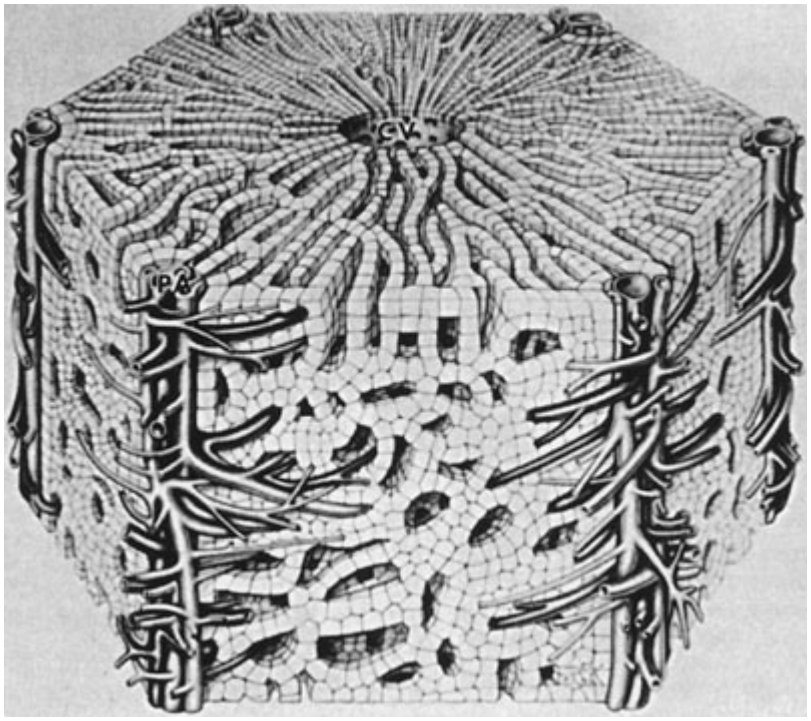

FIGURE 39-5. Schematic view of liver lobule: The central vein (CV) lies in the center of the figure surrounded by anastomosing cords of block-like hepatocytes. About the periphery of this schema are six portal areas (PAs) consisting of branches of the portal vein, the hepatic artery, and the bile duct. (Reprinted with permission from Jones AL: Anatomy of the normal liver. In Zakim D, Boyer T [eds]: Hepatology: A Textbook of Liver Disease, 3rd ed, p 3. Philadelphia, WB Saunders, 1996.)

Hepatic Microanatomy: Classic Liver Lobule Versus Acinar Lobule

The functional units of the liver have defied delineation. The organization of the hepatic parenchyma has been conceptualized in two contrasting models: Kierman's classic lobule and Rappaport's acinus.[4] Each model can successfully explain some of the pathologic and physiologic processes in the liver, but neither explains them all.

The classic liver lobule is hexagonal on cross section, with six vertically aligned portal canals at the corners and a hepatic venule (central vein) in its center (see Fig. 39-5). Each canal contains connective tissue, lymphatics, nerves, and a portal triad (terminal branches of portal vein, hepatic artery, and bile duct). A lobule consists of an array of anastomosing cords of hepatocytes, separated by vascular channels (lacunae) that radiate from the six portal areas and converge on the hepatic venule at the center of the hexagon. The lacunae contain the capillaries (sinusoids), which are lined by endothelium and scattered Kupffer cells, which protrude into the sinusoidal lumen.

A lacunar labyrinth penetrates the entire lobule, except for the first row of hepatocytes in contact with the portal tract (the limiting plate), where a near continuous wall of hepatocytes separates the interior of the lobule from the portal canal.

Human livers do not have well-defined interlobular connective tissue, making it difficult to visualize the classic lobule. The quest to identify the boundaries of the classic lobule led to the discovery of circumferential terminal hepatic arterioles, portal venules, and bile ductules. Reasoning that these encircling vessels supply segments of contiguous classic lobules that lie

between two terminal hepatic venules, Rappaport developed the acinus lobule (acinus) concept.[4] The simple liver acinus is a small parenchymal mass, irregular in size and shape, and arranged around a central axis consisting of a terminal hepatic arteriole, portal venule, bile ductule, lymph vessels, and nerves (Fig. 39-6). Blood enters the center of the acinus and flows centrifugally to the hepatic venules. In contrast to the direction of blood flow, bile flows in the opposite direction from perivenular hepatocytes to the portal tract bile ducts.

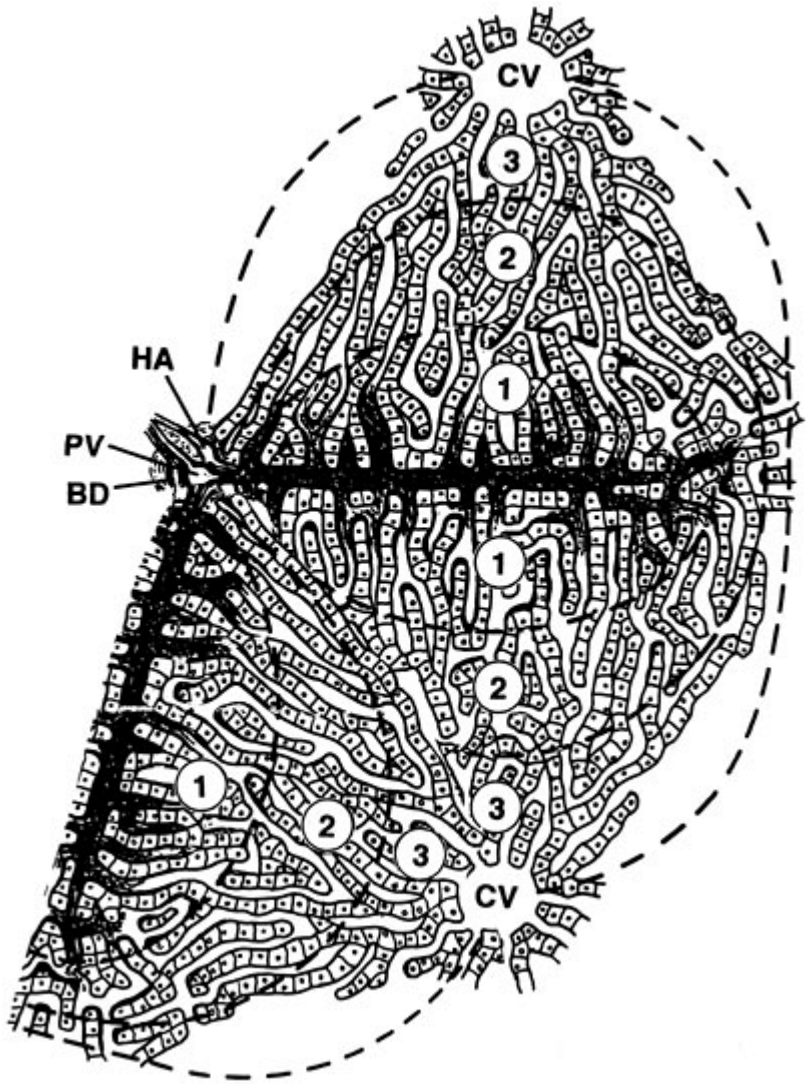

FIGURE 39-6. Blood supply of the simple liver acinus. The oxygen tension and the nutrient level of the blood in sinusoids decrease from zone 1 through zone 3. Note that the lower left side of the figure also depicts zones 1, 2, and 3 in a portion of an adjacent acinar unit. BD, bile duct; HA, hepatic artery; PV, portal vein; CV, central vein. (Reprinted with permission from Jones AL: Anatomy of the normal liver. In Zakim D, Boyer T [eds]: Hepatology: A Textbook of Liver Disease, 3rd ed, p 3. Philadelphia, WB Saunders, 1996.)

The simple liver acinus lies between two (or more) terminal hepatic venules. The terminal hepatic venule is therefore at the center of a classic liver lobule, but at the periphery of several simple liver acini. The dividing line between adjacent acini would be the watershed of biliary drainage (i.e., distinct acini empty their biliary secretions into distinct axial bile ducts). The conceptual advantage of the acinus concept is that the blood supply and biliary drainage of a portion of parenchyma reside in the same portal tract, whereas multiple portal vein branches and arteries supply each classic lobule.

The physiologic functions of the liver are performed at the liver cell plate, where interaction between the blood and hepatocytes occurs. The liver cell plates are formed by cords of

hepatocytes extending as one-cell-thick plates, 12 to 25 hepatocytes in length, between two vascular structures, the portal tract and the terminal hepatic venule. The liver cell plate receives unidirectional perfusion from the portal tract to the hepatic venule via the hepatic sinusoids. This structural organization allows an orderly interaction between blood and hepatocytes. There is a zonal relationship between the cells that constitute the lobule or acinus and their blood supply (see Fig. 39-6). Periportal hepatocytes located close to the terminal vascular branches of the portal vein and hepatic artery are the first to be supplied with oxygen and nutrients (zone 1). The perivenular (centrilobular) area, which is most distant from these terminal vascular branches, has the least resistance to metabolic and anoxic damage (zone 3). The intermediate area is termed zone 2. The oxygen content and nutritive value of the blood progressively decreases as blood flows from zone 1 to zone 3.

The sequential perfusion of hepatocytes in the liver cell plate allows a progressive qualitative and quantitative modification of the composition of sinusoidal blood as it traverses the liver. There are ultrastructural differences between hepatocytes located in zones 1 and 3, and these hepatocytes attain different functional capabilities. Hepatocytes in zone 1 contain numerous large mitochondria and have the highest concentrations of Krebs cycle enzymes. These cells are adapted for high oxidative activities such as gluconeogenesis, beta-oxidation of fatty acids, amino acid catabolism, ureagenesis, cholesterol synthesis, and bile acid secretion. Zone 3 hepatocytes are relatively anaerobic. Smooth endoplasmic reticulum is more abundant in these cells. Zone 3 is a primary site for glycolysis and lipogenesis. It is also the site for general detoxification and biotransformation of drugs, chemicals, and toxins. The anaerobic milieu of zone 3, however, is also its Achilles heel because these cells are exquisitely susceptible to injury from systemic hypoperfusion and hypoxemia. Sharply defined zone 3 necrosis is also characteristic of injury resulting from accumulation of toxic products of biotransformation as seen in toxicity from acetaminophen and halothane.

Innervation of the Liver

The liver is predominantly innervated by two plexuses that enter at the hilum and supply both sympathetic and parasympathetic nerve fibers. The anterior plexus surrounds the hepatic artery and is composed of postganglionic sympathetic fibers from the celiac ganglia and parasympathetic fibers from the anterior vagus nerve. The posterior plexus surrounds the portal vein and bile duct, and is formed from branches of the right celiac ganglia and posterior vagus. Sympathetic nerve fibers predominate and form a rich perivascular plexus around large hilar blood vessels, and follow these vessels to each lobule to reach the sinusoids and hepatocytes. Stimulation of the sympathetic fibers alters hemodynamics and metabolism of the liver. Hepatic vascular resistance increases and blood volume decreases, whereas glycogenolysis and gluconeogenesis increase, producing an increase in the blood glucose concentration. Parasympathetic stimulation increases glucose uptake and glycogen synthesis.

Hepatic Lymphatic System

The site of hepatic lymph formation is uncertain, but the most accepted hypothesis is that lymph is formed by filtration of plasma through the sinusoids into the perisinusoidal space of

Disse. This lymph travels through the periportal space of Mall (between the limiting plate and portal connective tissue), permeates the connective tissue, and drains into the lymphatic vessels of the portal canal. About 80% of hepatic lymph then travels through a rich plexus of lymphatic channels that surround the hepatic arteries, portal vein, and bile ducts until converging to form 12 to 15 lymph vessels that exit the porta hepatis and ultimately drain into the thoracic duct. The remaining 20% of hepatic lymph either leaves the liver through lymphatic vessels that accompany the hepatic veins to the IVC, or drain via lymphatic trunks within the coronary, triangular, and falciform ligaments that pierce the diaphragm and anastomose with esophageal and retrosternal lymph nodes. Portal hypertension and increased hepatic venous pressure can markedly increase hepatic lymph flow and lead to transudation through the hepatic capsule into the peritoneal cavity, producing ascites.

REGULATION OF HEPATIC BLOOD FLOW

Blood flow and oxygen supply to the liver are regulated to fulfill two separate demands. The first is to supply the liver itself with necessary energy substrates and oxygen for its own maintenance needs. The second is from the rest of the body, for which the liver provides vital services. Although the liver as a whole receives 25% of the cardiac output, regional blood flow within the organ is such that certain areas are highly prone to ischemia. The hepatic circulation is regulated by both intrinsic (regional microvascular) and extrinsic (neural and hormonal) mechanisms.[5]

Intrinsic Circulatory Regulation

1 The liver lacks the ability to directly regulate portal venous flow; therefore, regional microvascular regulatory mechanisms must operate almost exclusively by modulating hepatic arteriolar tone. The primary mechanism by which this occurs is called the hepatic arterial buffer response, whereby hepatic arterial flow varies reciprocally with changes in portal venous flow. This response is limited, however, to a 50% reduction of portal venous flow and a corresponding twofold increase in hepatic artery flow. Fortunately, because the hepatic artery carries higher oxygen content, this is an effective mechanism for protecting the liver from ischemic insults.

The hepatic buffer response appears to be mediated via adenosine. Presumably, this potent arteriolar dilator is synthesized at a constant rate and continuously secreted in the vicinity of the terminal hepatic arterioles and portal venules.[5] As flow through the portal vein decreases, less of the perivascular adenosine is "washed out," leading to its accumulation around hepatic arterioles. The result is increased arteriolar dilatation and an increase in hepatic arterial flow. Conversely, an increase in portal vein flow decreases the periarteriolar adenosine, leading to a corresponding decrease in hepatic artery flow.

The hepatic arterial system undergoes flow autoregulation when the liver is very active metabolically (postprandial), but not during the fasted state. The metabolic state modifies the composition of portal venous and systemic blood, thereby influencing hepatic blood flow. Decreases in pH and O_2 content, or increases in PCO_2 of the portal blood promote increases of hepatic arterial flow.[6] Postprandial hypersomolarity can increase both hepatic arterial and portal venous blood flow, but this effect would not be relevant in fasted patients. Thus, hepatic flow autoregulation is not likely to be an important mechanism during most anesthetics, given that they are performed in fasted patients.

Extrinsic Circulatory Regulation

Extrinsic factors regulate blood flow through the portal vein indirectly by modulating the tone of arterioles in the preportal splanchnic organs. Portal venous pressure (normally 7 to 10 mm Hg), therefore, reflects both splanchnic arteriolar tone and intrahepatic resistance to flow. Portal venules (presinusoidal sphincters) affect the distribution of blood flow to the sinusoids; however, the hepatic venules (postsinusoidal sphincters) control venous resistance in the liver. Extrinsic mechanisms modulate this postsinusoidal tone, with the sympathetic nervous system as the primary physiologic regulator. Stimulation of α_1-adrenergic receptors increases vascular tone, leading to constriction and a reduction in both blood flow and blood volume in the sinusoids.

Hepatic arteriolar tone is the main determinant of resistance in the hepatic arterial tree. Blood flow through the liver decreases with stimulation of certain arteriolar receptors (α_1-adrenergic and type 1 dopaminergic) and increases with activation of others (β_2-adrenergic).

Humoral Regulators

Myriad humoral substances alter liver blood flow, including gastrin, glucagon, secretin, bile salts, angiotensin II, vasopressin, and catecholamines. In addition, during inflammatory or septic states, cytokines, interleukins, and other inflammatory mediators have been implicated in the alteration of normal splanchnic and hepatic blood flow. Of the systemic hormones, epinephrine is most likely to attain concentrations producing vasoactive effects. Both α-adrenergic and β-adrenergic

receptors exist in the hepatic arterial bed, whereas the portal vasculature has only α receptors. An injection of epinephrine directly into the hepatic artery causes vasoconstriction (α_1-adrenergic effect), followed by vasodilitation (β_2-adrenergic effect). When injected into the portal vein, epinephrine produces only vasoconstriction. During activation of the sympathetic nervous system, the hepatic circulatory effects of epinephrine and norepinephrine far exceed those of dopamine, which probably has little if any importance as a physiologic modulator of the hepatic circulation. Glucagon induces a graded, long-lasting dilation of hepatic arterioles; it also antagonizes arterial constrictor responses to a wide range of physiologic stimuli, including stress-induced sympathoadrenal outflow. Angiotensin II markedly constricts both hepatic arterial and portal beds, and significantly reduces mesenteric outflow; the result is a substantial decrease in total hepatic blood flow. Vasopressin also intensely constricts splanchnic vessels, markedly reducing flow into the portal vein. This action accounts for the efficacy of high-dose vasopressin (0.2 to 0.4 U/minute intravenously) to alleviate portal hypertension and decrease bleeding from esophageal varices. The splanchnic and hepatic effects of low-dose (0.02 to 0.04 U/minute intravenously) vasopressin for endogenous vasopressin deficiency replacement therapy in sepsis remain controversial. Animal studies document splanchnic vasoconstriction and increases in lactate; however, human studies, although supporting positive renal effects, have documented inconsistent benefits on splanchnic perfusion and hepatic function.[7,8]

MAJOR PHYSIOLOGIC FUNCTIONS OF THE LIVER

Blood Reservoir

The liver is a vital reservoir of blood in humans. It contains nearly 25 to 30 mL of blood per 100 g of tissue, which represents 10 to 15% of the total blood volume. The autonomic

innervation of the liver, coupled with neurohumoral input from the systemic circulation, allows for rapid, precise control of the reservoir volume. Intense sympathetic nervous system stimulation (e.g., pain, hypoxia, hypercarbia) abruptly decreases hepatic blood flow and blood volume; 80% of the hepatic blood volume (approximately 400 to 500 mL) can be expelled within a matter of seconds.

Anesthetics that suppress sympathetic nervous system outflow impair this reservoir function and predispose the patient to circulatory decompensation when significant decreases of intravascular volume occur without immediate replacement. Severe liver disease exacerbates the hypotensive effects of hypovolemia by impairing vasoconstrictor responses to catecholamines. A total failure of vasoconstriction not only incapacitates the splanchnic reservoir, but also prevents the redirection of blood flow from skeletal muscle beds and splanchnic tissues to the heart and brain.

Regulator of Blood Coagulation

The liver helps maintain normal blood clotting in numerous ways. It is responsible for the synthesis of factors involved in coagulation, anticoagulation, and fibrinolysis. All procoagulation factors derive from the liver, with the exception of the endothelial product, Von Willebrand factor (VIIIvWF). Although factor VIII clotting factor is produced mostly by hepatocytes, it is also produced in endothelial cells, and adequate functional levels of this factor are often present in patients with liver disease. Precursor proteins for vitamin K-dependent coagulation are synthesized in the liver. Vitamin K catalyzes the activation of these factors (II, VII, IX, and X). Vitamin K_1 absorption depends on bile secretion into the gastrointestinal tract and transformation to active vitamin K_2 by the action of gut bacteria. Vitamin K deficiency results in the production of nonfunctional factors II, VII, IX, and X. The liver also modulates platelet production through the synthesis of thrombopoietin.

The liver synthesizes anticoagulant factors such as antithrombin III, proteins C and S, and fibrinolytic factors. The liver is also responsible for clearance of activated coagulation factors, fibrinolysins, and tissue plasminogen activators. Appropriate clearance of these activated factors is essential for prevention or control of fibrinolytic states.

Endocrine Organ

The liver has important endocrine functions. It synthesizes and secretes essential hormones, including insulin-like growth factor-1 (IGF-1), angiotensinogen, and thrombopoietin. IGF-1, formerly called somatomedin, mediates the peripheral actions of hormones produced by other endocrine glands. Angiotensinogen is a precursor of angiotensin II, playing a major role in the regulation of fluid and electrolyte balance. Thrombopoietin stimulates bone marrow precursor cells to differentiate into platelet-generating megakaryocytes.

The liver is also a principal site of hormone biotransformation and catabolism. Thyroxine (T_4) is actively taken up by the liver, where it is converted to tri-iodothyronine (T_3). In addition, the liver synthesizes thyroid-binding globulin. Thus, the liver can influence the distribution of thyroid hormones between intracellular and extracellular compartments. Corticosteroids, aldosterone, estrogen, androgens, insulin, and antidiuretic hormone are all inactivated by the liver. The interaction of altered hormone levels and diminished hepatic synthesis of hormone-binding globulins with altered metabolism and receptor regulation leads to significant endocrine abnormalities in patients with liver disease.

Erythrocyte Breakdown and Bilirubin Excretion

Bilirubin is an end product of heme degradation. About 300 mg is formed daily, with approximately 75% of bilirubin precursors derived from breakdown of the heme moiety of hemoglobin from senescent erythrocytes by the reticuloendothelial system, and the remainder from breakdown of nonerythrocytic hemoproteins, including cytochrome P450. After reticuloendothelial cells phagocytize senescent erythrocytes and separate the protein portion of hemoglobin from the heme moiety, the heme is oxidized by the microsomal heme oxygenase system to biliverdin. Biliverdin is then rapidly converted to unconjugated bilirubin, which is then released into the bloodstream, where it avidly binds to albumin while being transported to the liver. The albumin–bilirubin complex passes through fenestrations in the sinusoidal-lining cells to enter into the space of Disse where direct contact with the hepatocyte plasma membrane occurs. Binding proteins on the plasma membrane dissociate the unconjugated bilirubin from albumin before uptake into the hepatocyte where the bilirubin binds to cytoplasmic protein and is transported to the endoplasmic reticulum. The bilirubin is then conjugated with carbohydrate moieties, especially glucuronic acid. This reaction is catalyzed by the enzyme uridine diphosphate-glucuronyl transferase; this water-soluble conjugated bilirubin is actively excreted into bile canaliculi, and only a small portion enters the plasma. Conjugated bilirubin passes unchanged through the biliary tree and proximal small intestine. In the terminal ileum and large intestine, bacteria convert most of the conjugated bilirubin to urobilinogen. The intestinal mucosa reabsorbs some urobilinogen, which reaches the liver by mesenteric blood. The liver efficiently extracts the urobilinogen and returns it to the intestine (enterohepatic circulation). Eighty percent of urobilinogens are excreted in the stool. Ten percent is excreted in the urine, and the rest is reabsorbed.

The liver also scavenges free hemoglobin from blood, helping conserve body iron. It synthesizes haptoglobin, which forms complexes with dimers of free intravascular hemoglobin. Receptors on hepatocytes remove these complexes from plasma and thereby prevent the loss of hemoglobin dimers in the urine.

Metabolic Functions of the Liver

Receiving blood from the intestine through the portal vein, the liver is ideally positioned to play a major role in the regulation of carbohydrate, protein, and lipid metabolism. The liver is also the major site for catabolism of various hormones involved in regulating metabolism, including insulin, glucagon, glucocorticoids, thyroxin, and growth hormone.

Carbohydrate Metabolism

The liver plays an important role in maintaining euglycemia. The normal liver receives the dietary carbohydrate intake through the portal circulation. Following a carbohydrate-containing meal,

hyperglycemia is prevented by insulin-mediated hepatic extraction of glucose from the portal blood. Excess glucose in the liver is converted to glycogen. The liver can maximally store approximately 75 g of glycogen, which, when broken down, can provide up to 24 hours of available glucose. During fasting, hypoglycemia is initially prevented by glucagon-mediated glycogenolysis: glycogen stores are rapidly mobilized and converted to glucose, which is released into the circulation.

Once glycogen stores are depleted, the continued production of glucose requires muscle catabolism to provide the liver

with amino acids. Through the process of gluconeogenesis, certain amino acids (e.g., alanine) undergo oxidative deamination and are converted to glucose. More limited amounts of glucose may be formed by conversion from lactate and glycerol. In patients with chronic liver disease, hyperglycemia occurs commonly because portosystemic shunting allows direct entry of glucose-rich portal venous blood into the systemic circulation. Hypoglycemia is a late manifestation of advanced liver disease, and when present, a variety of mechanisms may be involved, including impaired glycogen storage, glycogenolysis, and gluconeogenesis. Hypoglycemia may also be seen in patients with large hepatocellular carcinomas secondary to increased glucose uptake by the tumor.

Lipid Metabolism

The liver is the major site of synthesis of fatty acids from excess sugar, protein, and lipid. Fatty acids in the liver are esterified to form triglycerides, cholesterol esters, and phospholipids, and are incorporated into lipoproteins for transport to storage sites in adipocytes. Fatty acids are vital for cellular function because they represent a major energy source for heart and skeletal muscle. Cholesterol is an essential constituent of biological membranes and an important precursor of steroid hormones, vitamins, and bile acids. The body pool of cholesterol in the adult is kept fairly constant by balancing absorption and endogenous synthesis with metabolism and excretion. The liver plays a central role in cholesterol and lipoprotein metabolism. It regulates uptake and excretion of cholesterol and synthesizes the various enzymes and apoproteins needed for cholesterol transport. Biliary secretion of cholesterol and its degradation product, bile acid, represents the major mechanism for elimination of cholesterol from the body.

In the fasted state, fatty acid beta-oxidation to acetylcoenzyme A (acetyl-CoA) in the liver is markedly stimulated by increased glucagon secretion. Acetyl-CoA is further oxidized to carbon dioxide and water or converted to ketone bodies, which are important fuels for extrahepatic organs (e.g., brain, muscle, kidney). Liver dysfunction may result in significant disturbances of cholesterol and lipoprotein metabolism.

Amino Acid Metabolism

The liver is the major site of protein and amino acid metabolism. After ingestion of protein, proteolytic enzymes in the digestive tract efficiently hydrolyze ingested proteins, yielding free amino acids that are absorbed by the gut and transported to the liver via the portal vein. Several distinct sinusoidal membrane transport systems then convey the amino acids into the hepatocyte. When necessary, the liver is able to synthesize the nonessential amino acids and use them to synthesize a large number of biologically essential proteins.

Protein catabolism occurs primarily in the liver. Proteins enter the hepatocyte through endocytosis and are then degraded into their component amino acids in the lysosomes. These may then form substrates for glucose production through gluconeogenesis, enter lipid metabolic pathways, or be further catabolized via transamination and deamination to form keto-acids, ammonia (NH_3), and glutamine. The urea cycle converts ammonia and most other nitrogenous excretory products into urea, which is excreted by the kidney. Patients with significant liver dysfunction may not have the capacity to eliminate nitrogen equivalents adequately through the urea cycle. Consequently, the serum ammonia level rises and hepatic encephalopathy may develop. Because urea is synthesized in the liver, a normal or low blood urea nitrogen concentration in patients with advanced liver

disease provides no assurance that glomerular filtration rate (GFR) is normal.

Synthesis of Important Proteins

The liver produces a vast assortment of proteins with important extrahepatic functions. Hepatocytes synthesize albumin; acute-phase proteins; all the coagulation factors and their inhibitors, except for factor VIII; ceruloplasmin; and most of the alpha-globulins and beta-globulins. Albumin accounts for nearly 10% of the protein synthesized by the liver. It constitutes about 60% of total plasma protein and is the primary determinant of the colloid oncotic pressure. Approximately 40% of the total exchangeable albumin pool is located intravascularly, and its serum half-life is about 20 days. This long half-life is one reason why the serum albumin level is not a reliable indicator of the liver's residual synthetic capacity in acute hepatic disease. The serum albumin level is affected by disturbances in synthesis, catabolism, and distribution. The normal liver synthesizes albumin at a rate of approximately 200 g/kg per day. Synthesis may be affected by several factors, including liver disease, dietary availability of amino acids, hormonal balance, plasma oncotic pressure, and heavy alcohol intake. Albumin serves as an important transport vehicle for metabolites (e.g., unconjugated bilirubin, heme, fatty acids), hormones (e.g., thyroxine, cortisol), and metals. Albumin also binds to a variety of pharmacologic agents; therefore, hypoalbuminemia has important consequences for the pharmacokinetics and pharmacodynamics of commonly administered drugs.

Immunologic Function

The liver is the largest organ in the reticuloendothelial system. Sinusoidal and perisinusoidal cells of the liver defend the body against microbial invaders and modulate inflammatory and immune responses to foreign materials. Pit cells, sparsely located in the perisinusoidal spaces, possess natural killer and neuroendocrine activities. Kupffer cells may constitute up to 10% of the total hepatic mass. These tissue macrophages police sinusoidal blood flow, filtering out toxins, bacteria, and debris that gain access from the gastrointestinal tract. They are aggressively involved in immune surveillance, participating in phagocytosis, cytolysis, and antigen presentation to T cells, and also may be involved in regulation of T-cell proliferation. Kupffer cells produce a variety of inflammatory mediators and cytokines that initiate and modulate both local and systemic effects of hepatic injury. Impairment of Kupffer cell function may be an important harbinger of sepsis or multiorgan system failure, particularly in the setting of severe gastrointestinal pathology or splanchnic ischemia.

Pharmacokinetics

Drug metabolism is primarily a hepatic event. The liver influences the plasma concentration and systemic availability of most orally and parenterally administered drugs. Through its synthesis of drug-binding proteins, the liver affects the partitioning of drugs into the various compartments of the body (apparent volume of distribution, V_d). Plasma proteins, especially albumin and α_1-acid glycoprotein, act as sinks to decrease free drug concentrations. Consequently, changes in the concentration of plasma proteins often modify dose–response relationships of drugs.

Hepatic clearance is the sum of all processes by which the liver eliminates a drug from the body. Hepatic biotransformation refers to the metabolism of drugs by hepatocytes with the goal of changing them into inactive water-soluble substances that can be excreted into the bile or urine for elimination from the body. A series of reactions that have been classified as phase

1 and phase 2 participate in these processes. Most drugs contain lipophilic functional groups to facilitate penetration of membrane barriers, thereby expediting gastrointestinal absorption. These same lipophilic groups inhibit excretion, owing to a high degree of protein binding and renal tubular reabsorption. By converting lipophilic substances to metabolites that can be excreted, hepatic enzymes detoxify drugs and terminate their pharmacologic activity. In general, phase 1 reactions (oxidation, reduction, *N*–dealkylation) modify structural features of drugs to render them more polar than the original compound. Most phase I reactions involve the participation of a group of cytochrome P450 isozymes, which are localized in the hepatic microsomes. In phase 2

reactions, catalyzed by transferase enzymes, the water solubility of the product is enhanced beyond that achieved by phase 1 reactions alone. The chemical groups generated by phase 1 reactions serve as receptors for conjugation with polar substances such as sulfate, glucuronic acid, and glutathione. The products of phase 2 reactions are usually less toxic and less biologically active than those of the parent compound. Phase 1 reactions are much more susceptible to inhibition by advanced age or hepatic diseases than are phase 2 reactions.

The ability of the liver to metabolize a drug is referred to as its intrinsic metabolic clearance.[9] Intrinsic clearance, which reflects the fraction of the delivered drug load that is metabolized or extracted during a single pass through the liver, provides the basis for classifying drugs as high-, intermediate-, or low-clearance compounds. High-clearance drugs (e.g., lidocaine, diphenhydramine, or metoprolol) are so efficiently metabolized that their hepatic clearance approaches the rates at which they traverse the liver (i.e., total hepatic blood flow) (Fig. 39-7). Therefore, hepatic blood flow determines the liver's ability to eliminate high-clearance drugs. Low-clearance drugs (e.g., diazepam), however, are metabolized at rates that are usually far below their flow rates through the liver; therefore, their hepatic clearances are relatively independent of hepatic blood flow (see Fig. 39-7). Factors that increase the free fraction of drugs (e.g., hypoalbuminemia) are much more consequential for low-extraction than high-extraction drugs. The clearance of low-extraction drugs increases almost linearly as the free fraction increases (Fig. 39-8). Patients with significant liver disease may have marked alterations of pharmacokinetics and pharmacodynamics. Portosystemic shunts allow orally administered drugs to bypass the liver, thereby reducing first-pass clearance. This and the reduction in total hepatic blood flow seen in patients with liver disease prolong the terminal half-life and increases the systemic effects of high-extraction drugs. The dosage of these agents should be reduced by as much as 50%. Hypoalbuminemia causes an increase in the free plasma drug concentration, not only increasing drug effects, but also facilitating elimination of compounds with low hepatic extraction ratios. The volume of distribution of some drugs will be increased in patients with hypoalbuminemia and ascites.

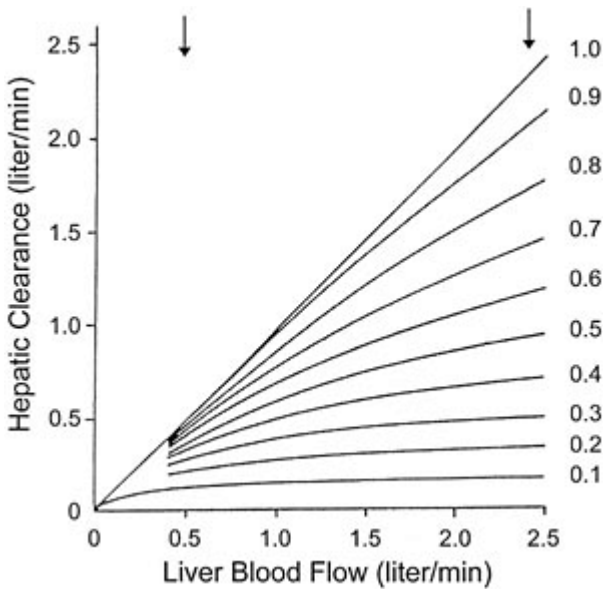

FIGURE 39-7. Relationship between hepatic clearance (*ordinate, on left*) and liver blood flow (*abscissa*) as determined by the extraction ratios (ERs) of the drug (*ordinate, on right*). Hepatic clearances of compounds with low extraction ratios are nearly independent of liver blood flow, whereas the clearances of compounds with high extraction ratios vary almost directly with changes in hepatic blood flow. The *arrows* indicate the normal physiologic range of liver blood flow. (Reprinted with permission from Wilkinson GR, Shand DG: A physiological approach to hepatic drug clearance. Clin Pharmacol Ther 18:377, 1975.)

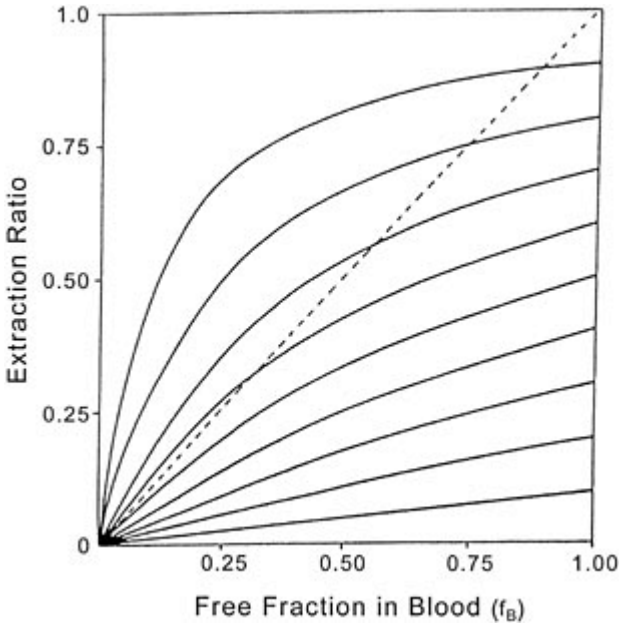

FIGURE 39-8. Relationship between hepatic extraction and fraction of unbound drug in blood: increasing free fraction (more unbound drug) usually produces increased extraction. This phenomenon is of greater importance for low-extraction drugs (with almost a direct linear change in extraction ratio with increasing free fraction) than for high-extraction drugs because the latter are almost completely cleared, regardless of extent of binding (nonrestrictive binding). The hepatic clearance (CL) reflects the changes in extraction ratio (E) if blood flow (Q) is constant (CL = Q·E). (Reprinted with permission from Wilkinson GR, Shand DG: A physiological approach to hepatic drug clearance. Clin Pharmacol Ther 18:377, 1975.)

The complex and poorly quantifiable effects of hepatic dysfunction on drug disposition may render pharmacokinetic, and even pharmacodynamic, predictions precarious. The rational selection of medications for patients with severe liver dysfunction mandates a careful risk–benefit analysis that integrates both pharmacodynamic and pharmacokinetic concerns. At times, cirrhotic patients with coexisting diseases will be better served by use of a hepatically cleared agent (superior efficacy, fewer untoward effects) than by one whose clearance is primarily extrahepatic. In such cases, careful titration of medication is imperative to achieve the desired pharmacologic responses with minimal adverse effects.

ASSESSMENT OF HEPATIC FUNCTION

Laboratory Evaluation of Hepatic Function

A broad array of biochemical tests is available to assess the multiple functions of the liver and evaluate patients with suspected or established liver disease (Table 39-1).[10] Although

collectively called "liver function tests" (LFTs), many (e.g., aspartate aminotransferase [AST] and alanine aminotransferase [ALT]) do not assess a function of the liver but rather are indicative of liver cell injury or dysfunction. LFTs are used to screen for the presence of liver disease, suggest a general category of disease as the etiology, assess prognosis, and monitor the effectiveness of therapy. Many of the routine tests are not specific for liver disease; however, when combined in a battery of tests, the sensitivity and specificity for liver disease is high.

TABLE 39-1 Blood Tests and the Differential Diagnosis of hepatic dysfunction

	·BILIRUBIN OVERLOAD (HEMOLYSIS)	·PARENCHYMAL DYSFUNCTION	·CHOLESTASIS
Aminotransferases	Normal	Increased (may be normal or decreased in advanced stages)	Normal (may be increased in advanced stages)
Alkaline phosphatase	Normal	Normal	Increased
Bilirubin	Unconjugated	Conjugated	Conjugated
Serum proteins	Normal	Decreased	Normal (may be decreased in advanced stages)
Prothrombin time	Normal	Decreased (may be normal in early stages)	Normal (may be prolonged in advanced stages)
Blood urea nitrogen	Normal	Normal (may be decreased in advanced stages)	Normal
Sulfobromophthalein/indocyanine green	Normal	Retention	Normal or retention
From Gelman S: Anesthesia and the liver. In Barash P, Cullen B, Stoelting, R (eds): Clinical Anesthesia, 3rd ed, p 1011. Philadelphia, Lippincott- Raven, 1997.			

LFTs can be classified into several broad categories. These include tests that reflect (1) hepatocellular damage; (2) obstructed bile flow; (3) hepatic synthetic function; (4) hepatic uptake, conjugation, and excretion; and (5) other aspects of liver function.

Indices of Hepatocellular Damage

Increased serum activities of AST (formerly, serum glutamic oxalacetic transaminase or SGOT) and ALT (formerly, serum glutamic pyruvic transaminase or SGPT) are detected when there is hepatocellular injury and necrosis. Serum levels of AST and ALT are elevated in almost all types of hepatic disease. ALT is localized primarily to the liver, whereas AST is present in a wide variety of tissues, including liver, heart, skeletal muscle, kidney, and brain. An isolated elevation of the AST level is typically seen in cardiac or muscle disease. Mild elevations of ALT and AST (less than 3-

fold) are seen in fatty liver, nonalcoholic steatohepatitis, drug toxicity, and chronic viral hepatitis. Larger increases (3- to 22-fold) are seen in patients with acute hepatitis or exacerbation of chronic hepatitis (alcoholic hepatitis). The highest concentrations are seen in drug-induced or toxin-induced hepatocellular necrosis (including anesthetics), severe viral hepatitis, and ischemic hepatitis complicating circulatory shock.

AST and ALT levels do not correlate with prognosis. A declining level may reflect either recovery from injury or a poor prognosis because of a paucity of surviving hepatocytes. The serum AST/ALT ratio may be helpful diagnostically. A ratio of >2 is characteristically found in alcoholic liver disease, while in viral hepatitis the ratio is typically <1.

Lactate dehydrogenase (LDH) is usually included in liver biochemistry panels. Markedly increased serum levels may be seen in hepatocellular necrosis, shock liver, or hemolysis associated with liver disease. However, LDH has poor diagnostic specificity for liver disease and even measurement of LDH isoenzymes has limited clinical usefulness.

Glutathione S-transferase (GST) is found in multiple organs, but plasma elevation of isoenzyme B is a sensitive indicator of liver damage. GST is rapidly released into the circulation following hepatic injury, and because of its short plasma half-life (90 minutes), monitoring of plasma GST concentrations permits rapid identification of continuing or resolving cellular damage. GST is most abundant in centrolobular (zone 3) hepatocytes, which are most susceptible to injuries from circulatory disturbances and toxic products of drug metabolism.[11] Following such injuries, GST elevations may be disproportionately greater than increases of serum transaminases, which are more highly localized to the periportal (zone 1) hepatocytes.

Indices of Obstructed Bile Flow

Alkaline phosphatase (AP) is a family of isoenzymes found in multiple organs, including the liver, bone, kidney, intestines, placenta, and leukocytes. In healthy individuals, most circulating AP originates from the liver or bone. In the liver, AP is concentrated in the microvilli of the bile canaliculi and the sinusoidal surface of hepatocytes. Elevations of serum AP disproportionate to changes of AST and ALT occur with intrahepatic or extrahepatic obstruction to bile flow. It is a highly sensitive test for assessing the integrity of the biliary system. Elevated serum levels of AP may also result from infiltrative liver diseases such as metastatic cancer. Mildly elevated levels of serum AP are nonspecific and may be seen in cirrhosis, hepatitis, or congestive heart failure. The liver is the source of an elevated AP in the majority of cases, but in up to one-third, no evidence of liver disease is found. During pregnancy, AP can nearly double from placental release of the enzyme.

5′-Nucleotidase (5′NT) is an alkaline phosphatase that degrades specific nucleotides. Although it is present in most human tissues, elevated serum levels are believed to be solely of hepatobiliary origin and may reflect the detergent action of bile salts on plasma membranes, which is needed for release of the enzyme into the circulation. 5′NT is markedly increased with intrahepatic or extrahepatic biliary obstruction, with more modest increases seen with other hepatocellular

disorders. Serum levels correlate closely with AP levels, and because serum 5′NT is so specific for liver diseases, it is used to determine if an elevated serum AP level is of hepatic origin.

Gamma glutamyl transferase (GGT) is a membrane-bound enzyme widely distributed in a variety of tissues, including the liver. It is found in high concentrations in epithelial cells lining biliary ductules. Serum GGT is the most sensitive laboratory indicator of biliary tract disease. However, because it is ubiquitous, an elevated GGT has limited usefulness due to its poor specificity and has largely been replaced by 5′NT measurements to determine if an elevated AP is of hepatic origin.

Bilirubin is an endogenous organic anion derived primarily from the degradation of hemoglobin released from aging red blood cells. Measurement of serum bilirubin levels is central to the evaluation of hepatobiliary disorders. Serum levels of bilirubin are determined by the van den Bergh reaction, which separates bilirubin into two fractions: a water-soluble direct-reacting form representing conjugated bilirubin and a lipid-soluble indirect-reacting form representing

unconjugated bilirubin.

Serum bilirubin levels are measured to confirm the severity of jaundice and to determine the extent of its conjugation. Hyperbilirubinemia has a wide variety of causes (Table 39-2) and is classified as either predominantly unconjugated or predominantly conjugated. Serum concentrations of unconjugated bilirubin between 1 and 4 mg/dL usually indicate a disorder of bilirubin metabolism, such as excessive production (hemolysis), impaired transport into hepatocytes, or defective conjugation by hepatocytes. Even in cases of severe hemolysis, the total serum bilirubin is rarely above 5 mg/dL in the presence of normal liver function. Serum bilirubin levels above 5 mg/dL, or lower levels in association with other LFT abnormalities, usually signify the presence of liver disease. Conjugated hyperbilirubinemia results from impaired intrahepatic excretion of bilirubin or extrahepatic obstruction. With complete biliary tract obstruction, the maximal serum bilirubin level will rarely exceed 35 mg/dL due to renal excretion of conjugated bilirubin. Therefore, total bilirubin levels above 35 mg/dL usually signify severe parenchymal liver disease in association with hemolysis or renal failure.

TABLE 39-2 Causes of Hyperbilirubinemia

·UNCONJUGATED (INDIRECT)
Excessive bilirubin production (hemolysis) Immaturity of enzyme systems   Physiologic jaundice of newborn   Jaundice of prematurity Inherited defects   Gilbert's syndrome   Crigler-Najjar syndrome Drug effects
·CONJUGATED (DIRECT)
Hepatocellular disease (hepatitis, cirrhosis, drugs) Intrahepatic cholestasis (drugs, pregnancy) Benign postoperative jaundice, sepsis Congenital conjugated hyperbilirubinemia   Dubin-Johnson syndrome   Rotor's syndrome Obstructive jaundice Extrahepatic (calculus, stricture, neoplasm) Intrahepatic (sclerosing cholangitis, neoplasm, primary biliary cirrhosis)
From Friedman L, Martin P, Munoz S: Liver function tests and the objective evaluation of the patient with liver disease. In Zakim D, Boyer T (eds): Hepatology: A Textbook of Liver Disease, 3rd ed, p 791. Philadelphia, WB Saunders, 1996, with permission.

Indices of Hepatic Synthetic Function

The liver synthesizes and releases a variety of proteins, including albumin and the coagulation factors. Measurement of serum albumin level and assays of coagulation function are the most widely used methods for assessing hepatic synthetic function. Proper interpretation of these tests

requires an understanding of the patient's clinical status. Many factors influence the serum albumin level independent of hepatic synthesis. Protein-losing enteropathy, burns, nephrotic syndrome, increased vascular permeability, nutritional deficiency, increased catabolism, and fluid retention can all depress serum albumin levels. A decreasing serum albumin concentration indicates worsening hepatic function in patients with chronic liver disease if none of these other factors is present. Because the half-life in serum is as long as 20 days, the serum albumin level is not a reliable indicator of hepatic protein synthesis in acute liver disease.

In contrast, the prothrombin time (PT) and international normalized ratio (INR) are sensitive indicators of severe hepatic dysfunction (whether patients have acute or chronic liver disease) because of the short half-life of factor VII. However, because most of the coagulation factors are present in quantities that far exceed requirements for normal coagulation, mild-to-moderate hepatic disease may not be detected by measurement of the PT. In acute or chronic hepatocellular disease, the PT may be a useful prognostic indicator. A progressively increasing PT is usually ominous in patients with acute hepatocellular disease, suggesting an increased likelihood of acute hepatic failure. Prolongation of the PT also suggests a poor long-term prognosis in chronic liver disease.

PT depends on normal hepatic synthesis of clotting factors and sufficient uptake of vitamin K. Absorption of vitamin K from the gastrointestinal tract requires adequate biliary secretion of bile salts. In patients with obstructive jaundice, a prolonged PT may be a manifestation of vitamin K deficiency rather than of impaired hepatic synthetic function. Prolongation of the PT is not specific for liver disease. It may result from congenital coagulation factor deficiencies, disseminated intravascular coagulopathy, vitamin K deficiency, or the use of drugs that antagonize the prothrombin complex, such as Coumadin.

Indices of Hepatic Blood Flow and Metabolic Capacity

Elimination of the dye indocyanine green (ICG) from the blood provides an estimate of hepatic perfusion and hepatocellular function because it is highly extracted (70 to 95% by the liver following an intravenous injection). Acute changes in hepatic circulation and function can be detected by this test and the ICG method has been a standard technique for comparing effects of various anesthetics on hepatic blood flow.

Hepatic function can also be assessed with substances that are metabolized selectively by the liver. Lidocaine is metabolized by oxidative N-demethylation to monoethylglycinexylidide (MEGX). Its concentration 15 to 30 minutes after intravenous injection of a single dose of lidocaine can be used as a quantitative measure of liver function. The MEGX test may have prognostic value in patients with end-stage liver disease; in one study of well-compensated cirrhotic patients, this test was able to identify patients at increased risk for

developing postoperative complications following hepatic resection for carcinoma.[12]

Additional metabolic tests for assessing hepatic function include antipyrine clearance from plasma, aminopyrine breath test, caffeine breath test, galactose elimination capacity, and the maximum rate of urea synthesis. These tests have not gained wide acceptance in the United States, and their precise role in clinical practice remains uncertain.

Miscellaneous Tests

Several other laboratory tests are available for the diagnosis of liver disease but provide no specific information about hepatic function. These include specific serologic tests for hepatitis viruses, autoantibody measurements useful for the diagnosis of primary biliary cirrhosis and the classification of autoimmune hepatitis; specific protein measurements (ceruloplasmin, ferritin, α1-antitrypsin, and α-fetoprotein) useful for the diagnosis of Wilson's disease; hemochromatosis; α1-antitrypsin deficiency and hepatocellular carcinoma, respectively; and serum ammonia often followed in patients with, or at risk for, developing hepatic encephalopathy.

Hepatobiliary Imaging

Selection of the most appropriate hepatobiliary imaging technique in a patient depends on the clinical presentation (history, physical examination, and LFT results), an understanding of the uses and limitations of each technique, and whether the test is for diagnosis alone or for therapeutic intervention as well.

Plain radiography has a limited role in the evaluation of hepatobiliary disease. Abdominal radiographs can be useful for calcified or gas-containing lesions that may be overlooked or misinterpreted by ultrasonography. These lesions include calcified gallstones, chronic calcific pancreatitis, gas-containing liver abscesses, portal venous gas, and emphysematous cholecystitis.

Ultrasonography is the most commonly used hepatobiliary imaging technique. It has the advantages of low cost, portability, and avoidance of the use of ionizing radiation. Ultrasonography is the primary screening test for hepatic disease, gallstones, and biliary tract disease that may be suspected because of symptoms, abnormal LFT, hepatomegaly, jaundice, or suspicion of a mass lesion. It is the best method for detecting gallstones and confirming the presence of extrahepatic biliary obstruction. It also may be useful for determining the thickness of the gallbladder wall, detecting the presence of ascites, demonstrating portal or hepatic vein thrombosis, evaluating the patency of portosystemic shunts in patients with recurrent variceal bleeding after shunt surgery, and directing thin-needle biopsy of hepatic mass lesions. Its major limitations are its dependence on the operator's skill and its inability to penetrate bone or air (including bowel gas), which may prevent complete examination of the abdominal organs.

A variety of radioisotopes can be used to study the anatomy and function of the liver and biliary system. Radioisotope scanning of the liver seldom provides a precise diagnosis, and these tests have largely been supplanted by ultrasonography and computed tomography (CT) scanning. However, radioisotope scanning of the biliary tract remains an important investigative tool in patients with suspected acute cholecystitis. Radioisotopes that are cleared rapidly by hepatocytes and excreted into bile permit rapid visualization of the biliary tract. Visualization of the gallbladder rules out obstruction of the cystic duct, while visualization of the biliary tree and common bile duct without the gallbladder confirms obstruction of the cystic duct and presence of cholecystitis.

CT is a complementary examination to ultrasonography and provides information on liver texture, gallbladder disease, bile duct dilatation, and mass lesions of the liver and pancreas. It provides better and more complete anatomic definition than ultrasonography and is less operator dependent. Lesions can be biopsied under CT guidance. The disadvantages of CT scanning are radiation exposure and cost.

The role of magnetic resonance imaging (MRI) for the evaluation of hepatobiliary disease is continually evolving. The algorithm for noninvasive biliary imaging has been markedly altered by the development of magnetic resonance cholangiopancreatography, which has dramatically reduced the need for direct cholangiography for visualization of the bile and pancreatic ducts, and for delineating the most proximal extent of biliary tract obstruction when planning for operative resection or drainage.

Percutaneous transhepatic cholangiography (THC) involves the direct percutaneous injection, through a 22-gauge needle, of contrast into bile ducts in the liver under fluoroscopic guidance. THC may be used to determine the level and cause of biliary obstruction, confirm the presence of cholestasis without obstruction, and evaluate whether a proximal cholangiocarcinoma is surgically resectable. THC can be used for balloon dilation of biliary strictures via a catheter inserted through the tract, for placement of an internal stent to relieve obstruction, or for placement of an external drain.

Endoscopic retrograde cholangiopancreatography (ERCP) uses endoscopy to visualize the ampulla of Vater and guide insertion of a guidewire and catheter through the ampulla to permit selective injection of contrast material into the pancreatic and common bile ducts, which are then imaged radiographically. ERCP has the advantage over THC of not requiring dilation of the biliary tree to

achieve a very high procedural success rate. ERCP is the imaging technique of choice in patients with choledocholithiasis because a sphincterotomy and stone extraction can often be performed. Stones can also be removed with this technique in patients with acute cholangitis and severe gallstone pancreatitis. ERCP also permits biopsies, brushings, balloon dilation, and stent insertion to relieve biliary obstruction caused by tumors.

Liver Biopsy

Liver biopsy continues to have a central role in the evaluation of patients with suspected liver disease because it provides the only means of determining the precise nature of hepatic damage (necrosis, inflammation, steatosis, or fibrosis). Liver biopsy plays a key role in the evaluation of otherwise unexplained abnormalities of liver enzymes in patients with or without hepatomegaly. It is used in patients with chronic hepatitis to determine the nature and extent of hepatic injury and degree of inflammation, which for patients with chronic hepatitis C, will be used to determine if antiviral therapy should be initiated. Liver biopsy is also an important tool for determining the etiology of abnormal LFT in the post liver transplant patient (see chapter 53). The presence of coagulopathy (e.g., PT that is 3 seconds greater than control, platelet count <60,000 cells/μL), however, contraindicates percutaneous liver biopsy, although transjugular liver biopsy can be performed safely in these patients.

HEPATIC AND HEPATOBILIARY DISEASES

Classification of Liver Diseases

For the purposes of the following discussion, liver diseases are divided into two large heterogeneous groups: parenchymal diseases (e.g., viral hepatitis, steatohepatitis, cirrhosis) and cholestatic diseases (e.g., intrahepatic and extrahepatic biliary

obstruction). Some diseases are characterized by features of both parenchymal dysfunction and cholestasis.

Prevalence of Hepatobiliary Disease

More than 100 distinct hepatic diseases have been described. Currently, nearly 10% of the American population (25 million) has some form of hepatobiliary disease. Hepatitis B or C afflicts more than 5 million Americans. About 50% of those with hepatitis C may develop cirrhosis, which currently accounts for between 13,000 to 15,000 deaths each year. Alcoholic liver disease remains a problem, becoming severe in 10 to 15% of those who consume large amounts of alcohol over a prolonged period.

PARENCHYMAL DISEASES

Viral Hepatitis

Acute hepatitis usually results from a viral infection, although it may also be caused by drugs and toxins. Viral hepatitides are important causes of perioperative hepatic dysfunction. The diagnosis of viral hepatitis depends on the appearance of clinical signs and symptoms, laboratory findings, serologic assays, and, on occasion, liver biopsy. During the incubation period, patients are often asymptomatic and may undergo surgical procedures. When increased ALT and AST and/or jaundice develop postoperatively, it is essential that a comprehensive serologic evaluation be performed to document the viral origin for the liver damage.

Classic acute hepatitis is caused by one of five viruses: hepatitis A (HAV), hepatitis B (HBV), hepatitis C (HCV), hepatitis D (HDV, delta), and hepatitis E (HEV). In the United States, approximately 50% of reported cases of acute viral hepatitis are caused by HBV, 30% by HAV, and 20% by HCV. Chronic hepatitis can occur following HBV, HCV, and HDV infections. All five types of viral hepatitis have similar clinical and laboratory features. Patients may remain asymptomatic,

develop influenza-like symptoms, became jaundiced, or develop acute hepatic failure.

HAV infection (infectious hepatitis) is a highly contagious enterovirus transmitted by the intake of fecal-contaminated food. It is not transmitted by blood transfusion. Viremia is present for several days prior to the onset of clinical symptoms. Virus is shed in stool for 14 to 21 days before the onset of jaundice. Patients are usually not infectious after 21 days. There are no chronic carriers, and chronic liver disease does not occur. Fulminant hepatic failure is rare (0.14 to 2%) in the absence of preexisting liver disease. Patients with HBV who acquire a HAV infection typically have an uncomplicated clinical course. In contrast, 41% of patients with chronic hepatitis C who acquire a HAV superinfection progress to fulminant hepatitis with a 35% fatality rate.[13]

HBV is primarily transmitted through percutaneous inoculation of infected serum or blood products. HBV is present in the serum and body secretions of most patients early in the course of acute hepatitis B. The surface coat of the virus is composed of a polypeptide that acts as the major hepatitis B surface antigen (HBsAg). Development of serum antibodies to HbsAg (anti-HbsAg) confirms immunity. Individuals who have detectable HbsAg for more than 6 months have a chronic HBV infection.

HCV (formerly, non-A, non-B hepatitis), which was discovered in 1989, was the major cause of transfusion-related hepatitis until the 1990s. It is also transmitted by percutaneous inoculation of infected serum or blood products, occupational exposure to blood or blood products, and intravenous drug abuse. Hepatitis C is the most common bloodborne infection in the United States; it accounts for 40% of chronic liver disease. Fortunately, serologic tests for HCV now exist. Because of their use in screening donated blood, HCV has almost been eliminated as a cause of posttransfusion hepatitis. HDV is an RNA strand that coinfects with and requires the helper function of HBV for its replication and expression. HDV may be acquired simultaneously with HBV or may be a superinfection of a patient with prior HBV infection. HBV and HDV coinfection substantially increases the likelihood of fulminant hepatitis and death.

HEV is an enterically transmitted virus that has epidemiologic features resembling HAV. HEV infections occur primarily in Asia, Africa, and Central America.

Other important but infrequent causes of viral hepatitis include cytomegalovirus, Epstein-Barr virus, and herpes simplex. These viruses typically produce benign, anicteric disease and often escape detection preoperatively. However, in rare circumstances, particularly in immunocompromised patients, they can disseminate, causing acute hepatitis, fulminant hepatic failure, and death.[14]

Acute viral hepatitis occurs after an incubation period that varies with the specific virus involved. The mean incubation period for HAV is 4 weeks, for HBV 12 weeks, and for HCV 7 weeks. Clinical disease is often heralded by the development of constitutional symptoms such as anorexia, nausea, vomiting, and low-grade fever. Dark urine and clay-colored stools usually precede the onset of jaundice. At this point, the liver may be enlarged and tender. Recovery usually takes weeks to months. Many patients with acute viral hepatitis never become clinically jaundiced. AST and ALT levels begin to rise during the prodromal phase and usually reach a peak between 400 to 4,000 IU when the patient is clinically jaundiced. Serologic tests are the mainstay for the diagnosis of viral hepatitis. The diagnosis of hepatitis A is based on the detection of serum immunoglobulin M (IgM) antibody to the HAV capsid or HAV RNA in stool during acute illness; recovery is associated with immunoglobulin G anti-HAV antibody, which confers long-lasting immunity to recurrent HAV infection. The diagnosis of HBV infection is usually made by identifying HbsAg in serum. HbsAg may be present in serum as early as 7 days after HBV infection. Infrequently, levels of HbsAg are too low to be detected during acute HBV infection, and in such cases, the diagnosis can be established by the identification of IgM antibody to the HBV core antigen (IgM anti-Hbc). Hepatitis Be antigen (HbeAg) follows the pattern of HbsAg, and recovery is heralded by the disappearance of this antigen, while persistence of HbeAg identifies patients whose blood remains infective. Development of antibody to HbsAg (anti-Hbs) is seen in recovered patients.

The serologic diagnosis of hepatitis C can be made by demonstrating the presence in serum of

anti-HCV or the presence of HCV RNA. HBD infection can be identified by demonstrating the presence of anti-HDV antibody.

Nonviral Hepatitis

Toxin and Drug-Induced Hepatitis

Acute hepatitis may follow the ingestion, inhalation, or parenteral administration of pharmacologic and chemical agents. Drugs and chemicals that are directly toxic to the liver (carbon tetrachloride, acetaminophen, α-amanitin from the toxic mushroom, *Amanita phalloides*) predictably produce dose-dependent liver injury. Each of these direct hepatotoxins produces a pattern of histologic injury that is reasonably

characteristic and reproducible. Clinical manifestations of liver injury usually occur within 1 to 2 days of exposure. Acetaminophen not only causes fulminant hepatic failure following ingestion of extremely large doses (suicide attempts), but can also produce chronic liver injury with analgesic doses in susceptible individuals (malnutrition, chronic alcoholism).[15]

Other drugs (nonsteroidal anti-inflammatory agents, volatile anesthetics, antibiotics, antihypertensives, anticonvulsants) infrequently cause liver injury. These idiosyncratic drug reactions are unpredictable, and the response is not dose dependent. Hepatitis may develop during or shortly after exposure to the drug, but more commonly, clinical signs of liver dysfunction occur 2 to 6 weeks after initiation. Treatment of toxin-induced and drug-induced hepatitis is largely supportive. Failure to discontinue the offending drug promptly may result in progressive hepatitis and death. Hemodialysis may be useful following ingestion of *Amamita phalloides*, whereas *N*-acetylcysteine is used to treat patients with potentially hepatotoxic ingestions of acetaminophen. Liver transplantation may be lifesaving in patients with fulminant hepatitis, resulting from toxin or drug ingestion.

Toxic Acute Hepatitis and Volatile Anesthetics

Halothane was introduced in the United States in 1958; concerns linking this agent to acute hepatitis were raised shortly thereafter. To determine the incidence of massive hepatic necrosis after halothane anesthesia, the Committee on Anesthesia of the National Academy of Sciences launched one of the largest epidemiologic studies ever completed: the National Halothane Study.[16] From 1959 to 1962, 856,000 anesthetics were retrospectively reviewed. The incidence of fulminant hepatic necrosis terminating in death associated with halothane was found to be 1 per 35,000 anesthetics. The incidence of nonfatal hepatitis, however, may be as low as 1 in 3,000.[17] The association prompted a dramatic decrease in the use of halothane, especially in adult patients. Other volatile anesthetic agents have been reported to cause hepatitis, but at a much lower rate (Table 39-3).

TABLE 39-3 Relationship Between Metabolism of Volatile Halogenated Agents and Anesthetic-Induced Hepatitis

·AGENT	·YEAR INTRODUCED IN UNITED STATES	·NO. OF CASES OF HEPATITIS	·PERCENTAGE OF ANESTHETIC METABOLIZED	·FLUOROACETYL METABOLITES
Halothane	1958	>500	20–46	Yes
Enflurane	1972	~50	2.5–8.5	Yes

Isoflurane	1981	6	0.2–2	Yes
Desflurane	1993	1	0.02	Yes
Sevoflurane	1995	3	2–5	No

From Mushlin PS, Gelman S: Liver dysfunction after anesthesia. In Benumof JL, Saidman LJ (eds): Anesthesia and Perioperative Complications, 2nd ed, p 440. St Louis, Mosby, 1999, with permission.

The classic presentation of volatile anesthetic-associated hepatitis includes fever, anorexia, nausea, chills, myalgias, and rash, followed by the appearance of jaundice 3 to 6 days later. The syndrome characteristically develops after minor uneventful procedures of brief duration (<30 minutes). Overt jaundice indicates severe disease and portends a mortality rate as high as 40%. Other predictors of poor prognosis include a short latency between the anesthetic and the onset of symptoms, certain demographic factors (age >40, obesity), and severe hepatic dysfunction.[18]

The single most important risk factor for halothane hepatitis is prior exposure to halothane. Previous exposure has also been reported as a factor in isoflurane-associated hepatitis.[19] Of the patients who develop jaundice after halothane, 71 to 95% have had at least one prior exposure to this agent.[20] Severe reactions occur nearly 10 times more often in patients who have had multiple exposures to halothane than in those having their first halothane anesthetic.[21]

Demographic factors also provide important information about the risk of developing halothane hepatitis. Obese women appear to be more likely than their nonobese counterparts to contract halothane hepatitis. The disease may also have a genetic basis.[22] Some ethnic groups, such as Mexican Americans, seem to be at greater risk, and chromosomal differences have been noted between patients who recovered from halothane hepatitis and halothane-treated patients who never had the disease.[23,24] For reasons that are not yet clear, age is also a significant risk factor. Approximately 50% of the cases of halothane-associated fulminant hepatic failure occur in patients older than 50, whereas children are highly resistant to the development of halothane hepatitis.[21,25,26] The rare cases documented in children have involved multiple exposures to halothane.[27] Notably, neither preexisting liver disease nor concomitant administration of medication has been identified as a risk factor for halothane hepatitis.

Although the incidence of hepatitis appears to correlate with the degree of metabolism of the various agents, the paucity of cases reported with anesthetics other than halothane has cast doubt that any of these anesthetics was actually involved in the hepatic complications (see Table 39-3).

The observation that halothane hepatitis is associated with repeated exposure has led investigators to postulate an immune reaction. Of the halothane taken up during anesthesia, 20 to 46% is metabolized, compared with 2.5 to 8.5% for enflurane, 2 to 5% for sevoflurane, 0.2 to 2% for isoflurane, and 0.02% for desflurane.[28,29,30] Each anesthetic, with the exception of sevoflurane, is oxidized via cytochrome P450 2E1 to yield highly reactive intermediates that bind covalently (acylation) to a variety of hepatocellular macromolecules (Fig. 39-9). Halothane anesthesia induces both neoantigens (arising via the reaction of TF-acetyl chloride with hepatic proteins) and autoantigens (lacking TF-acetyl adducts).[31,32,33,34,35] Presumably, the TF-acetyl moiety acts as a hapten and enhances the immune recognition of the carrier protein. In susceptible people, these altered hepatic proteins may trigger an immunologic response that causes massive hepatic necrosis.[36]

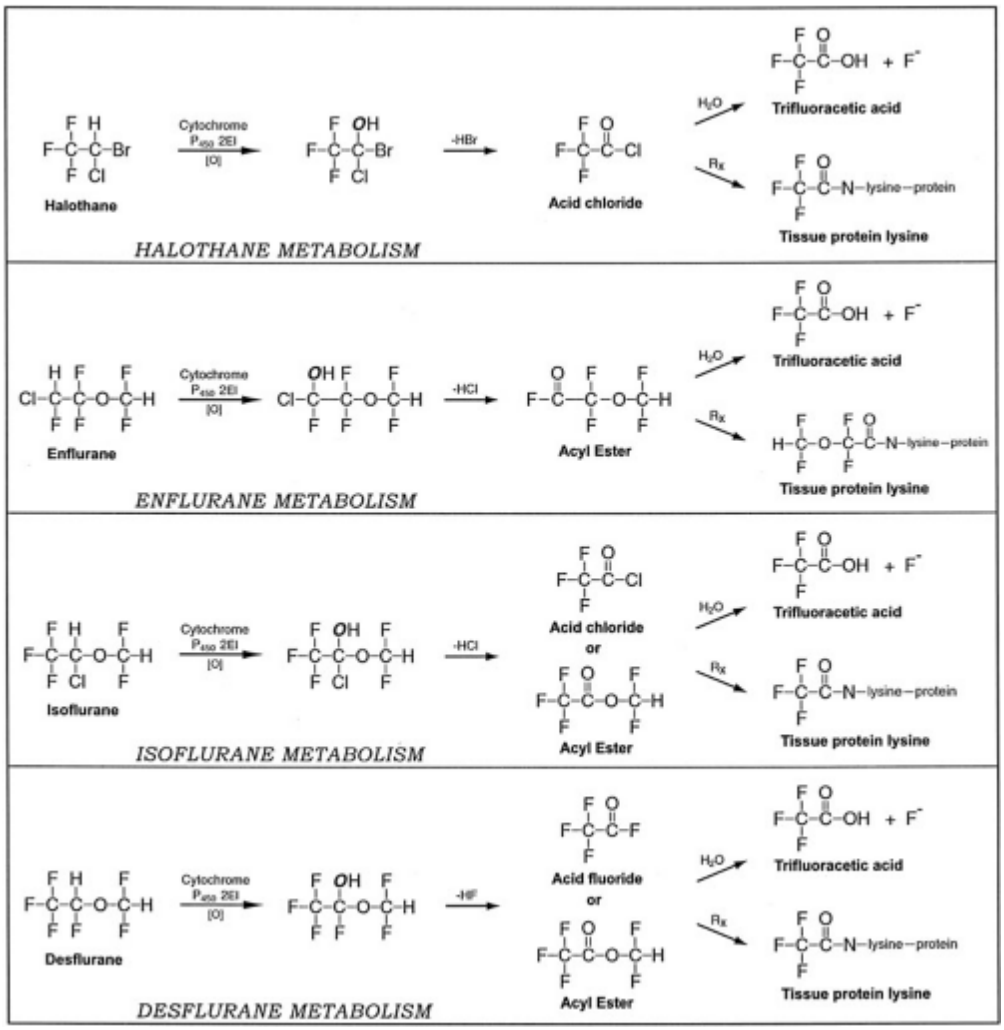

FIGURE 39-9. Proposed pathways of cytochrome P450 2E1-catalyzed metabolism of halothane, enflurane, isoflurane, and desflurane that are involved in the production of highly reactive intermediates that acylate hepatic proteins. The acylated moieties of the liver proteins appear to function as haptens to elicit an immune response. Sevoflurane metabolism is not included in this figure (see Fig. 39-10) because there is no evidence that it produces an acylating intermediate. (Modified with permission from Mushlin PS, Gelman S: Liver dysfunction after anesthesia. In Benumof JL, Saidman LJ [eds]: Anesthesia and Perioperative Complications, 2nd ed, p 442. St Louis, Mosby, 1999; modified from Frink EJ Jr: The hepatic effects of sevoflurane. Anesth Analg 81[suppl 6]:S46, 1995; Kenna JG, Jones RM: The organ toxicity of inhaled anesthetics. Anesth Analg 81[suppl 6]:S51, 1995.)

Halothane hepatitis is idiosyncratic, affecting only a tiny fraction of those anesthetized with this agent. Neither the incidence nor the severity of the reaction correlates with the dose

of halothane administered. The disease has a latency of days, unlike the hepatic injury produced by severe hypoxia or a potent cytotoxin, which typically appears within hours of the insult. Moreover, it is usually accompanied by laboratory findings that are characteristic of an immunologically mediated disorder, such as peripheral eosinophilia, circulating immune complexes, organ nonspecific autoantibodies, and antibodies that bind to antigens isolated from halothane-treated animals (rabbits).[37,38] Approximately 70% of patients have antibodies that recognize neoantigens (TF-acetyl-modified epitopes), and 90% have antibodies that recognize autoantigens (non–TF-acetyl–modified epitopes). Therefore, preoperative testing for halothane antibodies might identify patients at risk for developing hepatitis, whereas postoperative testing could help determine if halothane was the likely cause of unexplained postoperative hepatitis.

totally sensitive or specific for detecting the disease. The ELISA test for antibodies has been reported to be approximately 75% sensitive and 88% specific.[33] Obviously, the easiest way to avoid the risk of halothane-induced hepatitis is to avoid the use of halothane completely, especially in adults. Fortunately, alternative agents are readily available; thus, there has been decreased interest in developing preoperative tests.

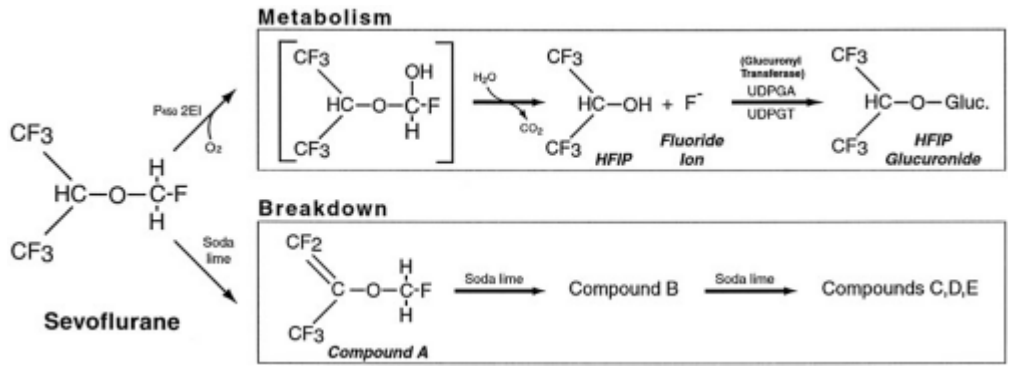

FIGURE 39-10. Cytochrome P450 2E1-catalyzed biotransformation of sevoflurane produces inorganic fluoride and hexafluoroisopropanol (HFIP). The liver rapidly metabolizes HFIP to HFIP-glucuronide. Sevoflurane also undergoes breakdown in soda lime, yielding compound A, which is nephrotoxic but does not appear to be hepatotoxic. (Modified with permission from Mushlin PS, Gelman S: Liver dysfunction after anesthesia. In Benumof JL, Saidman LJ [eds]: Anesthesia and Perioperative Complications, 2nd ed, p 442. St Louis, Mosby, 1999; modified from Frink EJ Jr: The hepatic effects of sevoflurane. Anesth Analg 81[suppl 6]:S46, 1995.)

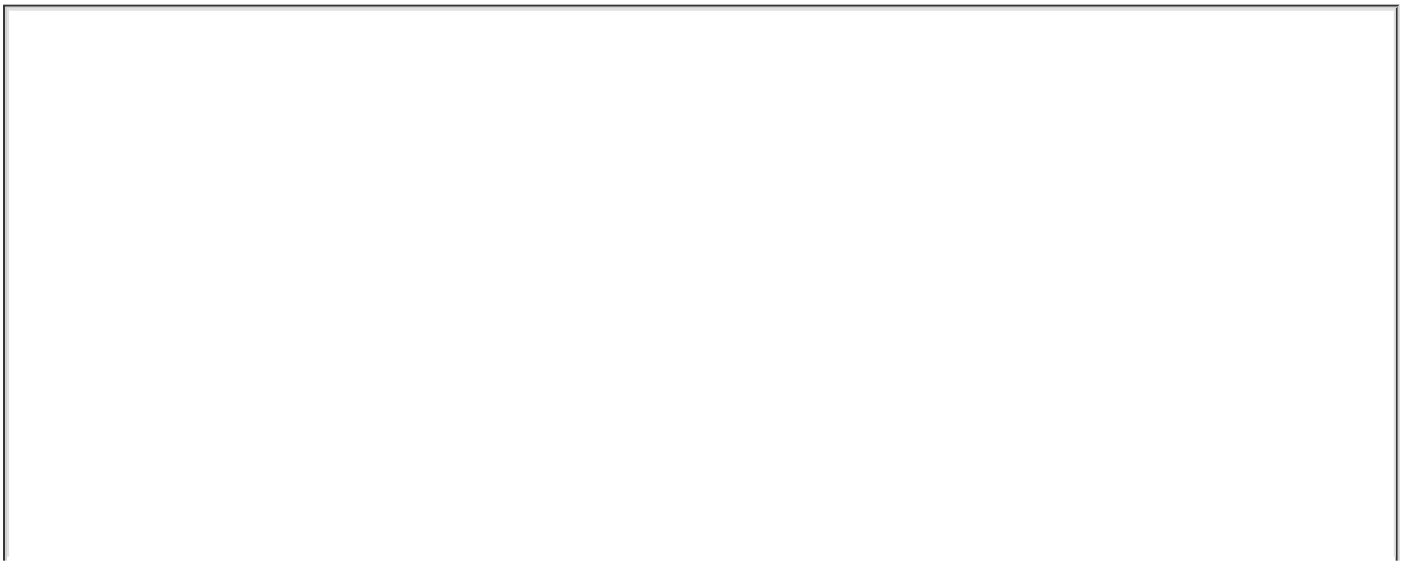
2 Other volatile agents besides halothane also have immunogenic potential. Enflurane metabolism produces acyl adducts (difluoromethoxydifluoroacetyl halide) that are similar, but not identical, to those derived from halothane (TF-acetyl halide). Nonetheless, antibodies isolated from patients with halothane hepatitis can bind to hepatic proteins that contain enflurane-induced adducts (neoantigens).[39]

Isoflurane metabolism also yields highly reactive intermediates (TF-acetyl chloride; acyl ester) that bind covalently to hepatic proteins (see Fig. 39-9). The likelihood that isoflurane causes hepatitis via production of these intermediates appears to be extremely low, however, as just 0.2% of the isoflurane taken up into the body is actually metabolized. Only trace amounts of isoflurane-derived adducts are bound to hepatic proteins following isoflurane anesthesia.

Desflurane, which is similarly biotransformed to trifluoroacyl metabolites, appears even less likely than isoflurane to cause immune injury because only 0.02 to 0.2% of this agent is metabolized (1/1,000th that of halothane). Desflurane metabolites are usually undetectable in plasma, except after prolonged administration. Furthermore, although antibodies from patients with halothane hepatitis clearly react with proteins isolated from halothane-treated or enflurane-treated rats, they do not appear to react with hepatic proteins from desflurane-treated or isoflurane-treated rats.[36]

Sevoflurane is metabolized more extensively than is isoflurane or desflurane, slightly less than enflurane, and much less than halothane.[40] The metabolism of sevoflurane (primarily via cytochrome P450 2E1) is rapid (1.5 to 2 times faster than enflurane), and produces detectable plasma concentrations of fluoride and hexafluoroisopropanol (HFIP) within minutes of initiating the

anesthetic. The liver conjugates most of the HFIP with glucuronic acid, which is then excreted by the kidney (Fig. 39-10). An important distinction between sevoflurane and the other volatile agents is that sevoflurane produces neither highly reactive metabolites nor fluoroacetylated liver proteins.[29] There is no evidence that any sevoflurane metabolites cause severe hepatic injury.



At present, the preponderance of evidence supports the immune theory (via TF-acetyl-hapten) of halothane-induced hepatitis. Nonetheless, it is conceivable that the antigen–antibody responses that accompany anesthesia-induced hepatitis are the result of the hepatic injury, rather than the cause. Most (if not all) patients anesthetized with halothane form the same or similar TF-acetylated liver proteins, but few develop halothane hepatitis. In fact, pediatric anesthesiologists, like halothane hepatitis patients, have been shown to have higher serum autoantibody levels of P450 2E1 than general anesthesiologists and controls, possibly because of their increased occupational exposure to anesthetics. The female pediatric anesthesiologists in this study had higher levels of P450 2E1 autoantibodies than all other anesthesiologists.[41] Despite one female anesthesiologist demonstrating evidence of hepatic injury in the aforementioned study, there are no reports of fulminant halothane hepatitis attributable to occupational exposure. Explanations for these observations, which proponents of the hapten theory must reconcile, include the following: only a few of the TF-acetyl proteins are actually immunogenic, the triggering of an immune response requires a critical threshold of TF-acetylated proteins (antigenic threshold), and only a small fraction of patients are genetically susceptible to these antigens.

Volatile Agents and Hepatic Blood Flow and Oxygen Delivery

Insofar as all halogenated anesthetic agents depress cardiac output and most surgical procedures stimulate a stress response with resultant catecholamine-induced vasoconstriction, it is predictable that hepatic blood flow and oxygen delivery will decrease during general anesthesia with volatile agents. The degree to which hepatic metabolic demands are also depressed with the various agents determines the relative impact on the hepatic supply–demand relationship, and consequently, the potential of each agent for causing hepatic ischemia.

Other perioperative conditions also contribute to hepatic blood flow, oxygen delivery, and metabolic requirements: hemoglobin concentration, oxygen saturation, systemic inflammation, volume status, and temperature. Additional insults such as direct hepatic trauma and hepatotoxic drug exposure, as well as occult preexisting hepatic insufficiency, can obscure the independent effects of the volatile agent.

Both animal and human studies indicate that halothane is more likely than other inhaled anesthetics to produce liver injury, probably because it causes the most cardiovascular and respiratory depression, as well as the greatest reduction in hepatic arterial flow (Fig. 39-11). Consequently, halothane is the most likely of the clinically used vapors to produce, or exacerbate, hepatic hypoxia when blood flow to the liver is critically limited and the adequacy of the oxygen supply-to-demand balance is in question.

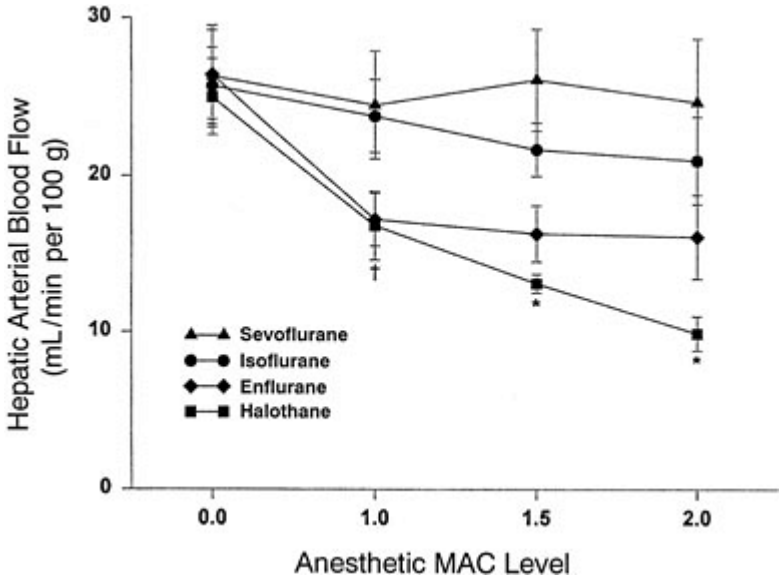


FIGURE 39-11. Dose-dependent effects of inhaled anesthetics on hepatic arterial flow in chronically instrumented dogs in the absence of a surgical stress. Sevoflurane and isoflurane preserve hepatic arterial flow even at the higher minimum alveolar concentration (MAC) levels. *Differs from sevoflurane and isoflurane at same MAC values ($p < .05$). †Differs from sevoflurane at same MAC value ($p < .05$). (Reprinted with permission from Frink EJ Jr: The hepatic effects of sevoflurane. Anesth Analg 8[suppl 6]:S46, 1995.)

Excluding halothane, enflurane decreases hepatic blood flow and splanchnic perfusion more than any other halogenated vapor in clinical use. It induces dose-dependant decreases in portal venous blood flow and either reduces or leaves unchanged hepatic arterial blood flow.[42,43] Splanchnic perfusion decreases in parallel with decreased mean arterial pressure and cardiac output. Enflurane also increases splanchnic oxygen extraction, and lowers both hepatic venous and mixed venous oxygen saturation.

Desflurane decreases hepatic blood flow in both experimental and clinical settings. Administration of 1 minimum alveolar concentration (MAC) desflurane to patients prior to skin incision reportedly decreases hepatic blood flow by 30% (measured by ICG), similar to the reduction associated with 1 MAC of halothane or isoflurane.[44] Desflurane can markedly reduce oxygen delivery to the liver and small intestine without producing comparable reductions of hepatic oxygen uptake or hepatic and mesenteric metabolism. Therefore, desflurane anesthesia may decrease the oxygen reserve capacity of both the liver and the small intestine.

Isoflurane is much less likely than halothane or enflurane to cause or contribute to hepatic injury. It undergoes minimal biodegradation, and preserves hepatic blood flow[45] and oxygen delivery even during open laparotomy.[46]

Sevoflurane anesthesia usually preserves blood flow and oxygen delivery to the liver, even in the presence of positive-pressure ventilation.[47] Patients having elective operations under sevoflurane anesthesia (1 or 2 MAC) experience significant reductions in mean arterial blood pressure, but maintain the hepatic blood flow at preanesthetic levels. Animal data suggest that the hepatic arterial buffer response remains intact.[48] Sevoflurane appears to be the most effective of the inhaled anesthetics for maintaining both blood flow and oxygen delivery to the liver. Thus, it is less likely than either halothane or enflurane to induce liver injury and is no more toxic than desflurane or isoflurane. Its metabolic products are less reactive, and therefore probably less injurious, than those resulting from halothane, enflurane, isoflurane, or even desflurane.[49] Sevoflurane better preserves hepatic blood flow and oxygen delivery than halothane, enflurane, or desflurane; its effects on hepatic perfusion and metabolic function are similar to those of

isoflurane.

Other than sevoflurane, desflurane is the least likely of the halogenated vapors to cause severe hepatic injury, based on the immune theory of anesthesia-induced hepatitis. Nonetheless, desflurane produces a greater reduction of hepatic blood flow and oxygen delivery than either isoflurane or sevoflurane. Hence, it may be more likely than the latter agents to cause liver injury in the setting of marginal hepatic oxygenation.

Other Anesthetics and Hepatic Function

Nitrous Oxide

Nitrous oxide produces a mild increase in sympathetic nervous system tone. Consequently, one would expect mild vasoconstriction of the splanchnic vasculature, leading to a decrease in portal blood flow, and mild vasoconstriction of the hepatic arterial system. In addition, N_2O is a known inhibitor of the enzyme methionine synthase, which could potentially produce toxic hepatic effects. Even brief exposures to N_2O at concentrations used clinically are sufficient to produce time-related decreases in methionine synthase activity in the livers of animals and humans, and prolonged exposure will induce a functional vitamin B_{12} deficiency.[50] Whether the resultant abnormalities in folate and methionine metabolism actually injure the liver is unclear. In a survey of more than 60,000 dentists and chairside assistants, Cohen and coworkers found a higher prevalence of liver disease in professionals who were chronically exposed to nitrous oxide: 1.7-fold higher in dentists, and 1.6-fold higher in their assistants.[51] Other studies suggest that N_2O-containing anesthetics do not cause liver injury in the absence of impaired hepatic oxygenation. In one study, no hepatocellular injury resulted from up to 4 hours of anesthesia with 67% N_2O (in oxygen) and infusions of methohexital.[52] In another, no hepatic dysfunction developed when patients with mild alcoholic hepatitis received N_2O-opioid or N_2O-enflurane anesthetics for peripheral or superficial operations.[53] There is no convincing evidence that nitrous oxide per se causes hepatotoxicity in the absence of a precarious oxygen supply–demand ratio in the liver.[54]

Nonopioid Sedative-Hypnotic Agents

Because it is a sympathomimetic agent, ketamine may produce a moderate increase in serum concentrations of some liver enzymes.[55] Patients anesthetized with ketamine infusion plus oxygen show a dose-dependent increase in biochemical markers of hepatic injury.[56] Despite these findings, it remains unclear whether ketamine causes liver dysfunction by exerting direct hepatotoxic effects, by altering hepatic metabolism, or by

increasing serum catecholamines, which would be expected to decrease hepatic blood flow and oxygen delivery.

Other intravenous agents, such as propofol, etomidate, and midazolam, have not been shown to alter hepatic function significantly in patients undergoing minor operative procedures. Although very large doses of thiopental (>750 mg) may cause hepatic dysfunction, usual induction doses have little effect on the liver.[57]

Opioids

Opioids have little effect on hepatic function, provided they do not impair hepatic blood flow and oxygen supply. All opioids increase tone of the common bile duct and the sphincter of Oddi, as well as the frequency of phasic contractions, leading to increases in biliary tract pressure and biliary spasm. The effect on the sphincter of Oddi does not favor one opioid over another and is not considered an absolute contraindication to narcotic analgesia, even in cases of pancreatitis.[58]

NONPHARMACOLOGIC CAUSES OF PERIOPERATIVE LIVER DYSFUNCTION

Inflammation and Sepsis

3 The liver occupies a central position in the inflammatory response, especially when the inflammation is secondary to intra-abdominal sepsis. Because of its location downstream from the splanchnic circulation, bacteria, endotoxin, and proinflammatory cytokines (IL-1, IL-6, and TNF-α) are carried directly to the liver. These interact with sinusoidal Kupffer cells and stimulate hepatocytes to decrease production of certain proteins (mainly albumin), called negative acute-phase reactants, and increase production of others (mainly C-reactive protein and serum amyloid A), called acute-phase reactants. In addition, especially following blunt trauma and burns, complement and coagulation factor production also increase in the liver. Some, such as C-reactive protein and serum amyloid A, up to 30,000-fold, greatly increase the liver's metabolic demands (Fig. 39-12). With inflammation, the resulting changes in systemic vascular resistance; regional blood flow distribution; tissue oxygen extraction; coagulation status; glucose, fat, and protein metabolism; and catecholamine sensitivity can be far reaching and profound.[59] In sepsis, hepatic arterial flow changes in a biphasic manner: an initial transient decrease followed by a marked and sustained increase in flow. The increase in hepatic artery flow occurs independent of changes in portal venous flow, suggesting a dysregulation of the physiologic hepatic arterial buffer response.[60] In sepsis, and inflammation in general, hypovolemia and splanchnic hypoperfusion are common, predictably decreasing oxygen delivery to the liver.

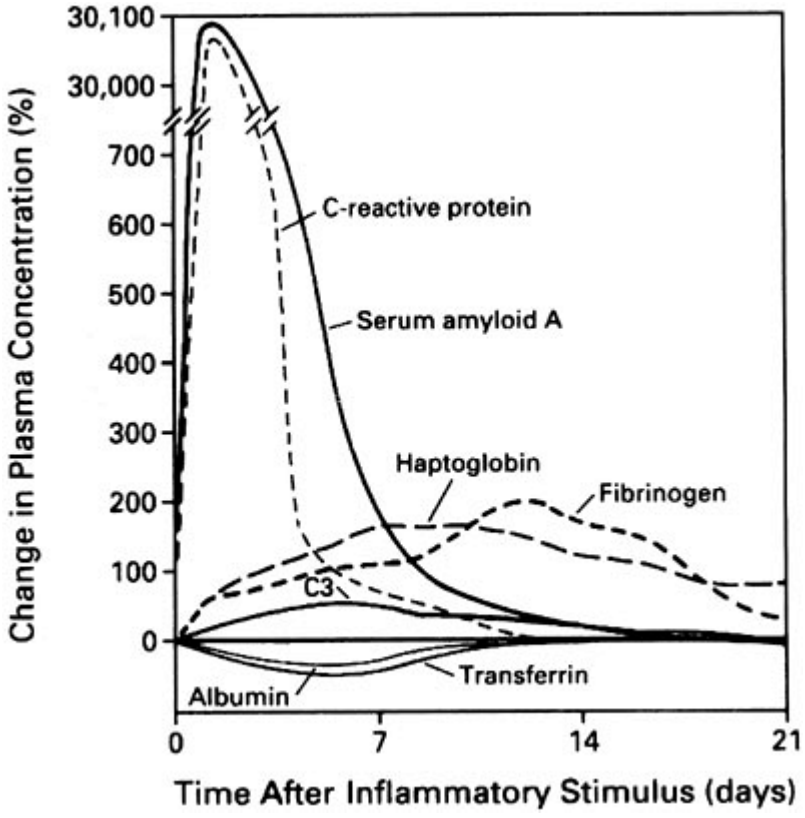

FIGURE 39-12. Characteristic patterns of change in plasma concentrations of some acute-phase proteins after a moderate inflammatory stimulus. (Reprinted with permission from Giltin JD, Colten HR. Molecular biology of the acute phase plasma proteins. In: Pick E, Landy M [eds]: Lymphokines. Vol. 14., pp. 123–153. San Diego, CA, Academic Press, 1987.)

Hypoxia and ischemia

The liver is exquisitely sensitive to hypoxia. In one study, patients with chronic lung disease whose blood oxygen content fell below 9 mL/dL all developed liver injury without developing overt myocardial or cerebral damage.[61] The detrimental effects of oxygen deprivation on perioperative

hepatic function can occur independent of anesthetic techniques.[62] In addition, if moderate hypotension occurs, a hepatitis-like illness (ischemic hepatitis) may follow. Patients develop jaundice, systemic symptoms, and large increases of serum transaminases, which may persist for 3 to 11 days. Liver biopsy shows centrilobular necrosis with little or no inflammatory response.[63]

Patients with ischemic hepatitis typically have a history of inadequate systemic perfusion, along with marked increases of serum aminotransferases. The increases are usually of greater magnitude than those associated with viral hepatitis. Prolonged shock or sepsis can cause extreme liver injury; a hepatic lobe or the entire liver may become infarcted, even in the absence of portal venous or hepatic arterial occlusion.[64] The mechanism of ischemic hepatitis is unknown, but it may involve free radical production because hepatocytes contain very high concentrations of xanthine oxidase. Ischemia and reperfusion increase xanthine oxidase activity; this enzyme catalyzes the oxidation of purines to uric acid and the associated reduction of O_2 to superoxide anion, which initiates toxic free radical reactions.

Cardiac Disease

Severe congestive heart failure may be associated with liver dysfunction.[65] The most common cause is ischemic hepatitis from decreased hepatic blood flow secondary to low cardiac output. Cardiac cirrhosis (fibrosis) may result from prolonged recurrent congestive heart failure. Acute liver failure is more likely to occur in patients with preexisting cirrhosis, severe chronic heart failure, or sustained hepatic ischemia, although passive hepatic congestion and fulminant hepatocellular necrosis has been reported from acute, severe elevations of central venous pressures.[67]

Surgical Stress

The surgical stress response includes stimulation of the sympathetic nervous system, activation of the renin-angiotensin-aldosterone system, and the nonosmotic release of vasopressin;

each of these responses may compromise the splanchnic circulation. These effects may persist for many hours or even days after surgery. Laboratory studies indicate that laparotomy, in particular, induces marked mesenteric vasoconstriction and decreases gastrointestinal and hepatic blood flow; acute hypophysectomy and administration of an angiotensin II antagonist can abolish these changes.[67] In addition to the surgical stress response, laparotomy independently decreases blood flow through the intestine and the liver, probably as a result of traction and manipulation of the viscera.[68]

Although reducing the surgical stress response and minimizing tissue injury and inflammation, laparoscopic procedures are not entirely benign with respect to the liver. The increased intra-abdominal pressures induced with insufflation appear to significantly decrease splanchnic perfusion and hepatic blood flow.[69]

Procedures performed under cardiopulmonary bypass, with low-flow states and nonpulsatile perfusion, can aggravate preexisting hepatic dysfunction. Administration of catecholamines to improve cardiac performance, either before or after bypass, may decrease hepatic oxygen delivery. Hypothermia during cardiopulmonary bypass probably limits the hepatic injury caused by the abnormal hemodynamics. Hypotension and hemorrhage decrease portal blood flow, but the hepatic arterial buffer response and pressure-flow autoregulation tend to preserve hepatic arterial flow and oxygen delivery. Perfusion at 28°C increases portal flow and slightly decreases hepatic arterial flow. A pump flow rate of 2.4 L/minute per m^2 maintains total blood flow to the liver better than does a rate of 1.2 L/minute per m^2. Only at low rates does pulsatile flow appear to be more advantageous than nonpulsatile perfusion in terms of hepatic blood flow.[70]

CHRONIC HEPATITIS

Chronic hepatitis refers to a group of liver disorders of varying etiologies and severity in which hepatic inflammation and necrosis continue for at least 6 months. Chronic hepatitis was previously

classified based on liver biopsy as chronic persistent or chronic active hepatitis. When this early classification was devised, chronic persistent hepatitis was considered to have a good prognosis, whereas chronic active hepatitis was considered a progressive disorder with a poor outcome. However, the prognostic value of these histologic distinctions has been found to be limited; thus, this classification has been supplanted by one based on cause, grade, and stage. Clinical and serologic features allow the establishment of an etiology for chronic hepatitis caused by HBV, HBV plus HDV, HCV, autoimmune hepatitis, drug-associated chronic hepatitis, and a category of cryptogenic chronic hepatitis. Histologic features on liver biopsy are necessary for grading and staging chronic hepatitis. The grade is determined by an assessment of the degree of necrosis and inflammation, and the stage reflects the level of progression of the disease, which is determined by an assessment of the degree of fibrosis.

Patients with chronic HBV infection who are asymptomatic and have normal serum transaminases are called HbsAg carriers. Those with chronic HBV infection who have clinical, laboratory, or pathologic evidence of chronic hepatic disease are diagnosed as chronic hepatitis B. An estimated 0.2 to 0.5% of the American population are chronic carriers of HbsAg. These HBV carriers are at risk for developing cirrhosis and hepatocellular carcinoma. The goal of treatment of chronic hepatitis B is to eradicate HBV infection, and thereby prevent the development of cirrhosis and hepatocellular carcinoma. Current therapy of chronic hepatitis B has limited long-term efficacy and does not yet achieve these goals. However, available therapies can suppress HBV replication and lead to laboratory and histologic improvement.[71,72] The decision to initiate treatment depends on balancing the patient's age, severity of disease, likelihood of response, and potential adverse effects and complications. Treatment is not recommended for inactive HbsAg carriers. To date, three drugs have been approved for treatment of chronic hepatitis B: injectable interferon α, and two oral agents, lamivudine and adefovir.[73]

Chronic HCV infection follows acute HCV infection in 85% of patients; an estimated 1.8% of the United States population are carriers of HCV. Although the progression of chronic hepatitis C infection to cirrhosis is characteristically slow, end-stage liver disease due to HCV-associated cirrhosis is the most common indication for liver transplantation. At least six distinct genotypes of HCV have been identified by nucleotide sequencing, and differences exist among these genotypes in responsiveness to antiviral therapy. Chronic HCV infection is usually treated with the combination of ribavirin and interferon.[74]

Autoimmune hepatitis is a chronic disease characterized by a wide spectrum of clinical symptoms, seroimmunologic manifestations, and continued hepatocellular necrosis and inflammation, which often progresses to cirrhosis. Extrahepatic features of autoimmunity, seroimmunologic abnormalities, and association with other autoimmune disorders all support an autoimmune pathogenesis. The clinical and laboratory features of autoimmune hepatitis are often similar to those described for chronic hepatitis. Patients with autoimmune hepatitis, however, usually have hypergammaglobulinemia, rheumatoid factor, and other circulating autoantibodies. Immunosuppressive therapy using corticosteroids with or without azathioprine is the mainstay of treatment and leads to symptomatic, clinical, biochemical, and histologic improvement, along with increased survival.

Fatty Liver Disease

Nonalcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease in the United States.[75] NAFLD is defined as fat accumulation in the liver exceeding 5% by weight.[76] It has been estimated that up to 24% of American adults have NAFLD. It usually becomes manifest in the fifth and sixth decades of life and is more common in women.[77] The two major risk factors for NAFLD are type II diabetes and obesity. In a consecutive autopsy series, 70% of obese patients had fatty liver. Among type II diabetics, it is estimated that 75% have some form of fatty liver.

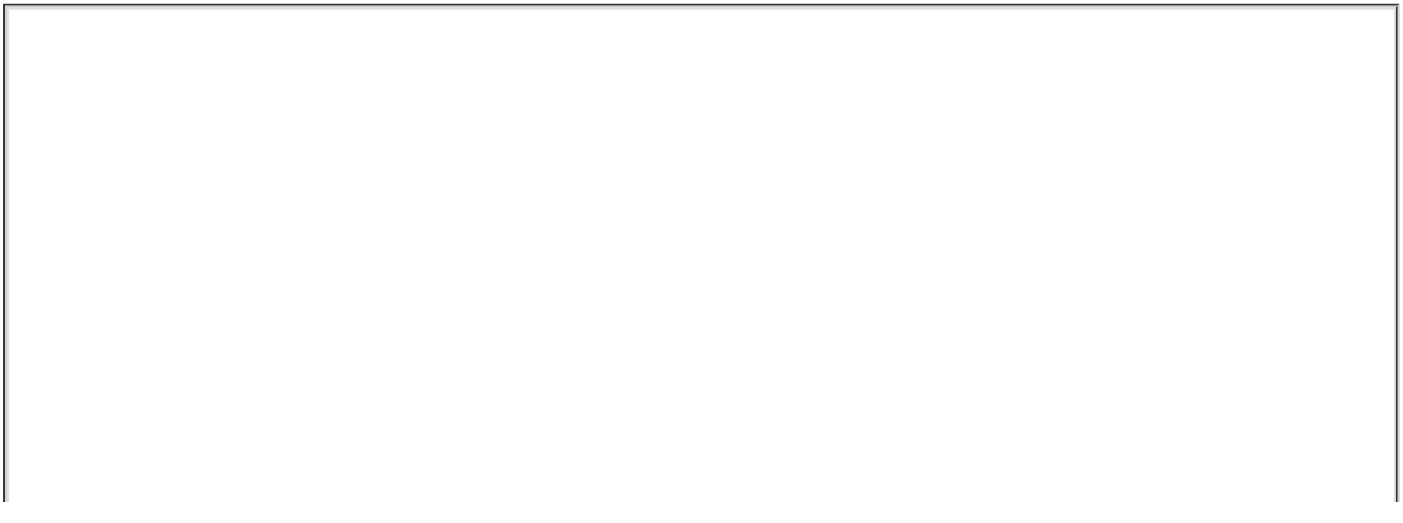
NAFLD includes a spectrum of hepatic pathology that ranges from fatty liver (steatosis) at its most clinically indolent extreme to the intermediate stage of nonalcoholic steatohepatitis (NASH), characterized by steatosis with lobular inflammation and perisinusoidal fibrosis, to its most severe

form, cirrhosis. NAFLD is now believed to be responsible for most cases of what was once classified as cryptogenic cirrhosis, a form that accounts for half of the annual liver-related deaths.

Most patients with NAFLD are asymptomatic, and the presence of an abnormality is often detected by abnormal LFT or hepatomegaly on a routine physician's office visit. The most common LFT abnormality is a 2- to 5-fold elevation of the AST and ALT. The AST/ALT ratio is reported to be <1 in 65 to 90% of patients with NAFLD, which distinguishes it from alcohol-related liver injury.

The pathophysiology of NAFLD is unknown, but present data suggest a multihit hypothesis in which common initial insults promote hepatic steatosis (e.g., obesity, subclinical insulin resistance), and the increased hepatic fat appears to stress the hepatocyte and render it more vulnerable to subsequent insults. This eventually produces some degree of hepatocyte necrosis, which promotes the accumulation of inflammatory cells within

the liver (NASH). In some patients, a fibrotic response predominates, leading to cirrhosis.



The natural history of NAFLD varies according to its histologic type. Patients with steatosis alone usually have a benign clinical course. Significant adverse clinical sequelae, however, occur in patients with NASH and cryptogenic cirrhosis.

There are no proven treatments for NAFLD. Exercise and diet are recommended. Several studies have reported beneficial effects of bariatric surgery when NAFLD is secondary to obesity. When the disease is advanced, the patient is often a poor candidate for liver transplantation due to comorbid conditions such as obesity and the complications of diabetes.

Alcoholic Liver Disease

Alcoholic liver disease is defined by the development of three types of liver damage following chronic heavy alcohol consumption: (1) steatosis (fatty liver), (2) alcoholic hepatitis, and (3) cirrhosis.[78] The clinical features and laboratory values frequently do not distinguish among these because compensatory mechanisms can mask extensive liver disease. A liver biopsy is often necessary to arrive at a definitive diagnosis.

Alcoholic steatosis occurs commonly after ingestion of moderate to large amounts of alcohol for even a short period of time. When severe, patients may be symptomatic, with malaise, nausea, anorexia, weakness, abdominal discomfort, and tender hepatomegaly. Mild transaminase and AP elevations may be present. Alcoholic steatosis is usually a benign disorder, and the liver abnormalities will usually resolve with abstinence from alcohol. In contrast, alcoholic hepatitis is a precursor of cirrhosis. Although symptoms may overlap with those of alcoholic steatosis, patients with alcoholic hepatitis may be febrile and jaundiced. There may be up to a 10-fold elevation of the aminotransferases with the AST level characteristically higher than the ALT. Hypoalbuminemia, prolongation of the PT, and marked elevations of the AP may be present. Treatment of alcoholic hepatitis consists of abstinence from alcohol, bed rest, and intake of a normal or high protein diet if hepatic encephalopathy is not present. Corticosteroids are often used to treat patients with severe alcoholic hepatitis, although their use for this indication remains controversial. It should be noted that alcohol abusers have a 2- to 3-fold increase in perioperative morbidity (Fig. 39-13).[79]

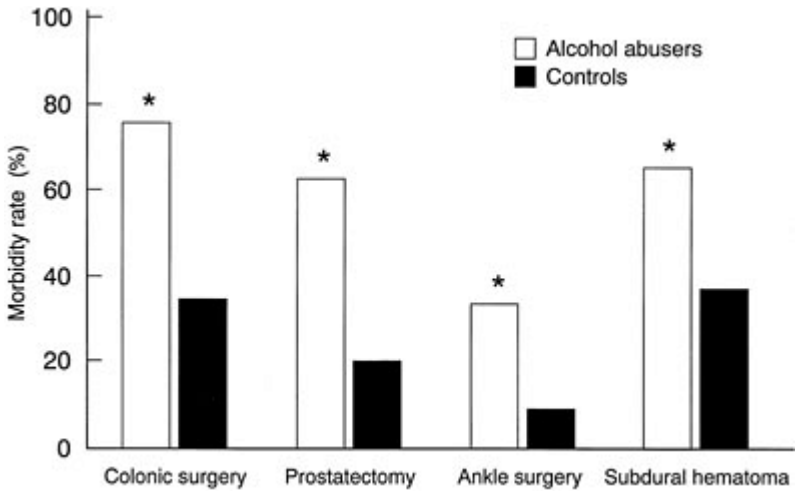


FIGURE 39-13. Prospective studies of postoperative morbidity in alcohol abusers and control subjects. $^{*}p < 0.05$ vs. control subjects. (Reprinted with permission from Tonnesen H, Kehlet H: Preoperative alcoholism and postoperative morbidity. Br J Surg 86:869, 1999.)

CIRRHOSIS: A PARADIGM FOR END-STAGE PARENCHYMAL LIVER DISEASE

This section discusses the pathophysiology of parenchymal liver disease, typified by hepatic cirrhosis, as it relates to anesthesia. Cirrhosis affects more than 3 million Americans and is the twelfth leading cause of death. The most frequent etiologies of cirrhosis in the United States are chronic hepatitis C infection and alcoholism. The most common symptoms are anorexia, weakness, nausea, vomiting, and abdominal pain. Signs include hepatosplenomegaly, ascites, jaundice, spider nevi, and metabolic encephalopathy. Advanced parenchymal hepatic disease alters the function of nearly every organ and body system.

Cardiovascular Abnormalities

Characteristically, patients with cirrhosis and portal hypertension have a hyperdynamic circulation with a high cardiac output, low peripheral vascular resistance, low to normal arterial blood pressure, normal to increased stroke volume, normal filling pressures, and a mildly elevated heart rate (Table 39-4).[80] The total blood volume is usually increased, but with an altered distribution in which the central "effective" blood volume is decreased, while the splanchnic bed is hypervolemic. Extensive arteriovenous collateralization occurs in many organs and tissues, leading to increased oxygen tension and saturation of the peripheral and mixed venous blood, and a decrease in the arteriovenous oxygen content difference. The mechanism by which these collaterals develop is complex and not completely understood, but may be related to increased plasma levels of glucagon and vasoactive intestinal polypeptide, which can induce peripheral vasodilation, decrease vascular resistance, and increase arteriovenous shunting. Glucagon also reduces the vascular responsiveness to infused catecholamines and other vasopressors in experimental animals.[81] Nitric oxide may also be an important mediator of the hyperdynamic changes that occur in cirrhosis and portal hypertension. Data from normal subjects and patients with cirrhosis reveal a positive correlation between exhaled concentrations of nitric oxide and cardiac index (Fig. 39-14).[82] Some causes of liver disease are also associated with cardiomyopathy (alcoholic liver disease, hemochromatosis); these patients may develop signs and symptoms of congestive heart failure, including decreased peripheral blood flow.

TABLE 39-4 Cardiovascular Function in Hepatic Cirrhosis

Decreased vascular resistance (peripheral vasodilation, increased arteriovenous shunting)
Increased cardiac output
Maintained arterial blood pressure, filling pressures, and heart rate (deterioration is late)
Blood volume maintained or increased, but redistributed (splanchnic hypervolemia, central hypovolemia)
Possible cardiomyopathy
Increased O_2 content in mixed venous blood; decreased difference in the O_2 contents of arterial and venous blood
Diminished responsiveness to catecholamines
Increased blood flow in splanchnic (extrahepatic), pulmonary, muscular, and cutaneous tissues
Decreased total hepatic blood flow
  Maintained hepatic arterial blood flow
  Decreased portal venous blood flow
Maintained or decreased renal blood flow

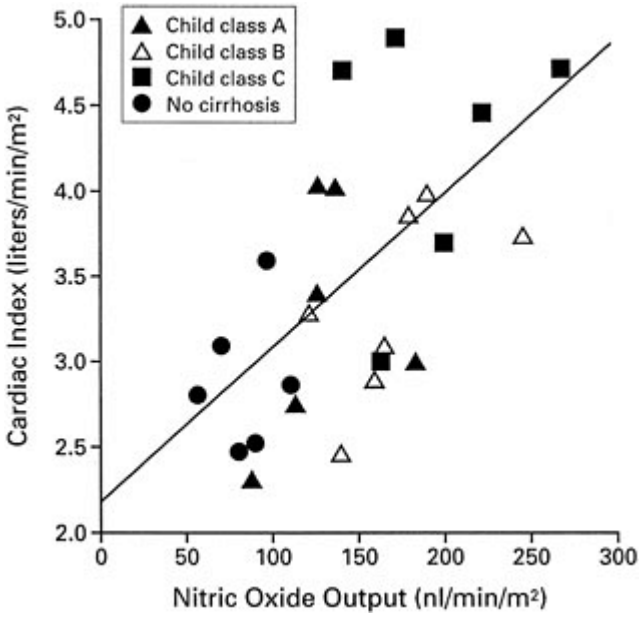

FIGURE 39-14. Relationship between nitric oxide in exhaled air and the cardiac index in 25 patients who had either normal hepatic function or cirrhosis with varying degrees hepatic dysfunction. (Severity of liver dysfunction increases progressively from Child class A to class C.) A positive correlation exists between nitric oxide output (expressed in nanoliters per minute per square meter of body surface area) and cardiac index (expressed in liters per minute per square meter). $r = 0.62$ and $p < 0.001$. (Reprinted with permission from Matsumoto A, Ogura K, Hirata Y *et al:* Increased nitric oxide production in the exhaled air of patients with decompensated cirrhosis. Ann Intern Med 123:110, 1995.)

Hepatic Circulatory Dysfunction

Portal hypertension can complicate the course of many chronic liver diseases but is a hallmark of end-stage cirrhosis. Portal hypertension is a pathologic increase in portal venous pressure,

resulting in the formation of portosystemic collaterals, which develop by dilatation and hypertrophy of preexisting vascular channels. It plays an important role in the pathogenesis of ascites and hepatic encephalopathy, leads to the development of esophageal varices, and contributes to the enhanced susceptibility to bacterial infections and altered drug metabolism found in these patients.

In patients with cirrhosis, portal hypertension may result from increased vascular resistance to portal blood flow, which is believed to be the initial factor responsible for an increase in portal pressure. In cirrhotics, this increased resistance occurs mainly in the hepatic sinusoids. Subsequently, increased portal venous inflow occurs as a result of marked splanchnic arteriolar vasodilation. Several humeral vasodilators have been suspected of contributing to splanchnic hyperemia, including glucagon, prostacyclin, endotoxin, and nitric oxide.[83] Eventually, the majority of the blood entering the portal system flows through the collateral circulation, and under these circumstances, the resistance of these vessels markedly influences portal pressure. As portal blood flow to the liver decreases substantially, hepatic arterial flow remains the same or increases. Thus, although the total circulation of the liver decreases, the hepatic oxygen supply is preserved. This decrease in total hepatic blood flow has pharmacokinetic implications that have been previously discussed.

Variceal Hemorrhage

Gastroesophageal variceal hemorrhage is probably the most dreaded complication of portal hypertension. Varices are portosystemic collaterals formed after preexisting vascular channels have been dilated by portal hypertension. They permit the passage of splanchnic venous blood from the high-pressure portal venous system to the low-pressure azygos and hemiazygous veins. Gastroesophageal varices are present in 40 to 60% of cirrhotics, and 25 to 35% of these will bleed. Up to 30% of initial bleeding episodes are fatal, and as many as 70% of survivors of an initial hemorrhage will have a recurrence.[84]

Variceal ruptures typically present as acute severe upper gastrointestinal hemorrhage. Prompt aggressive fluid resuscitation, blood transfusion, and correction of hemostatic abnormalities are essential, and are usually implemented in an intensive care unit. Endotracheal intubation for airway protection is frequently necessary. Empiric pharmacologic therapy (e.g., with octreotide) is indicated in situations in which variceal bleeding is likely. Subsequent esophagogastroduodenoscopy will define the site of bleeding and permit endoscopic therapy if appropriate.

Treatment of patients with gastroesophageal varices includes prevention of the initial bleeding episode (primary prophylaxis), control of active hemorrhage, and prevention of recurrent bleeding after a first episode (secondary prophylaxis).[85]

The goal of pharmacologic treatment is to reduce portal and intravariceal pressures. The nonselective beta-blockers, propranolol and nadolol, are effective agents for primary prophylaxis as they produce sustained decreases in portal venous pressure and decrease the risk of bleeding by 40 to 50%. Isosorbide mononitrate added to a beta-blocker may not only produce a further decrease in portal pressure, but also cause increased side effects. Endoscopic band ligation is an acceptable option for primary prophylaxis in patients at high risk for variceal bleeding who cannot tolerate medical therapy.

Patients with acute gastrointestinal bleeding of probable variceal origin are initially treated with intravenous somatostatin or its synthetic analogue octreotide. These drugs stop variceal hemorrhage in up to 80% of patients by reducing portal pressure. The variceal origin of the bleeding is then confirmed endoscopically, and the varices are subsequently treated either by band ligation or sclerotherapy. Current endoscopic therapies are capable of stopping bleeding in approximately 90% of patients.

If variceal bleeding persists or recurs despite endoscopic and pharmacologic therapy, balloon tamponade with a Sengstaken-Blakemore or Minnesota tube may be attempted. These modified nasogastric tubes are infrequently used, but when applied properly, achieve hemostasis in most

cases. Because rebleeding frequently occurs after balloon decompression, it should be used as a rescue technique and a bridge to more definitive treatment.

Transjugular intrahepatic portal systemic shunt (TIPS) was introduced in the 1990s, and its use has nearly eliminated the need for emergency shunt surgery. TIPS has become the preferred therapy for most bleeding patients who are not controlled by other nonoperative therapies. TIPS effectively decompresses the portal venous circulation with low short-term mortality, but late TIPS failure rates are high.[86]

A surgical portocaval shunt is considered in cases of continued hemorrhage or recurrent bleeding that cannot be controlled by endoscopic and pharmacologic means, and when TIPS is not available or technically feasible. When performed emergently, mortality approaches 40% but is substantially less when the procedure can be performed electively. Liver transplantation is often offered to patients with Childs B and C cirrhosis soon after or even before they bleed from varices. Secondary prophylaxis with nonselective beta-blockers, plus isosorbide mononitrate and band ligation of varices, reduces the incidence of rebleeding.

Pulmonary Dysfunction

A variety of disorders may produce hypoxemia in patients with advanced cirrhosis, including intrinsic cardiopulmonary

disorders such as congestive heart failure, interstitial lung disease, obstructive airway disease, pleural effusions, and pulmonary vascular disease (Table 39-5). Fluid retention may cause interstitial edema, airway edema, and large volume ascites, all of which may contribute to the development of hypoxemia through ventilation-perfusion mismatch and intrapulmonary shunting from compression of the basal regions of the lung.

TABLE 39-5 Hypoxemia in Patients with Cirrhosis

Intrapulmonary shunting caused by intrapulmonary vascular dilatations (precapillary or arteriovenous)
Ventilation-perfusion mismatch caused by impaired hypoxic pulmonary vasoconstriction, pleural effusions, ascites, and diaphragm dysfunction
Decreases in pulmonary diffusion capacity secondary to increased extracellular fluid, interstitial pneumonitis, and/or pulmonary hypertension

In the absence of primary lung disease, the major causes of arterial hypoxemia in patients with advanced cirrhosis may be intrapulmonary vascular dilatations (IPVDs). The clinical triad of chronic liver disease, increased alveolar-arterial oxygen gradient, and evidence of IPVDs is defined as the hepatopulmonary syndrome (HPS). IPVD encompasses two types of vascular abnormalities: (1) vascular dilatation at the precapillary level close to the alveoli, and (2) vascular dilatation resulting in larger arteriovenous communications that may or may not be in proximity to gas exchange units.[87] Supplemental oxygen significantly increases the PaO_2 when precapillary IPVD is contributing to hypoxemia, but has minimal effects when larger arteriovenous communications are the primary etiology of hypoxemia. The pathogenesis of IPVD in HPS is incompletely understood, but enhanced pulmonary production of nitric oxide likely plays a role.

IPVD is most commonly detected using contrast-enhanced echocardiography. In normal patients,

injection of microbubbles results in transient echogenicity in the right heart with no contrast in the left heart. Patients with dilated precapillary pulmonary vessels show delayed opacification in the left atrium approximately three to six contractions after visualization of the right ventricle.[87]

As many as 40% of patients with cirrhosis have detectable IPVD, and up to 15% have hypoxemia and functional limitation.[88] Survival of patients with HPS is reduced compared with cirrhotic patients of similar Child-Pugh class without HPS. Severe hypoxemia from HPS increases intraoperative and postoperative risks in liver transplantation. IPVD often resolves completely after liver transplantation.

Hepatic hydrothorax occurs in 4 to 10% of cirrhotic patients. These patients characteristically have pleural effusions in the absence of cardiopulmonary disease, secondary to transfer of ascitic fluid from the peritoneal cavity into the pleural space through diaphragmatic defects.[89] The initial treatment of hepatic hydrothorax consists of sodium restriction, diuretics, and thoracentesis; TIPS may be required in refractory cases. Because most of these patients have end-stage liver disease, liver transplantation becomes the preferred treatment if the previous options fail.[89]

Portopulmonary hypertension refers to the development of pulmonary artery hypertension in patients with portal hypertension. It is usually defined as a mean pulmonary artery pressure >25 mm Hg with a normal pulmonary capillary wedge pressure and an elevated pulmonary vascular resistance (>120 dyne/second per cm^{-5}). Portopulmonary hypertension affects between 4 to 6% of patients referred for liver transplantation. Patients with mean pulmonary artery pressures >35 mm Hg are considered to be high-risk transplant candidates.[90]

Ascites, Renal Dysfunction, and the Hepatorenal Syndrome

Ascites and Edema

Ascites is the most common of the major complications of cirrhosis. Nearly 50% of cirrhotic patients develop ascites within 10 years of being diagnosed.[91] Because 50% of cirrhotic patients with ascites die within 3 years, the development of ascites is a clear indication for evaluation for liver transplantation.

The pathogenesis of ascites in cirrhosis is complex and not completely understood. Sodium and water retention plays a key role. Three theories have evolved over time to explain the enhanced sodium and water avidity in patients with cirrhosis. Initially, the "underfilling" theory was proposed. The primary abnormality with this theory is cirrhosis-related hepatic venous block and portal hypertension leading to formation of ascites. This transudation of fluid decreases the effective intravascular volume. The neurohumoral response to "ineffective" plasma volume triggers the kidney to retain sodium and water. Thus, the underfilling hypothesis explains renal sodium retention as a secondary rather than a primary phenomenon (Fig. 39-15).

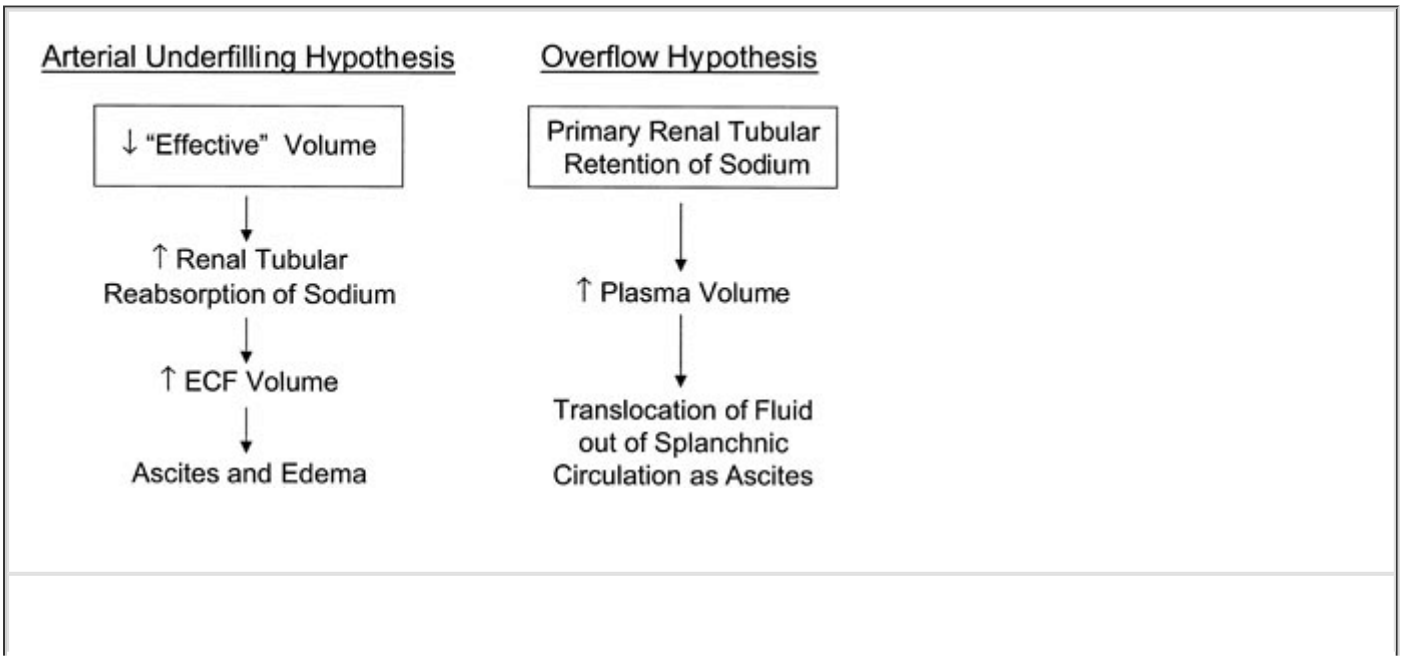

FIGURE 39-15. The presumed sequences of events that result in ascites formation according to the arterial underfilling hypothesis and the overflow hypothesis. The proposed primary disorders are shown in the boxes. According to the underfilling hypothesis, cirrhosis induces abnormal Starling forces in the portal venous circulation that cause an unfavorable distribution of the circulating blood volume (decreased effective blood volume). The diminished "effective" volume constitutes an afferent signal to the renal tubules to augment salt and water reabsorption. The attempt to replenish the diminished effective volume results in an expansion of the total blood volume to values far in excess of normal, with resultant ascites and edema formation. The overflow hypothesis holds that the primary disorder is retention of excessive sodium by the kidneys. In the setting of abnormal Starling forces in the portal venous bed, the expanded plasma volume is sequestered preferentially in the peritoneal sac. ECF, extracellular fluid. (Reprinted with permission from Epstein M: Renal functional abnormalities in cirrhosis: Pathophysiology and management. In Zakim D, Boyer TD [eds]: Hepatology: A Textbook of Liver Disease, p 448. Philadelphia, WB Saunders, 1982.)

Subsequent studies determined that total blood volumes were increased in cirrhotic patients with ascites, and this finding led to the proposal of the "overflow" hypothesis to explain the development of ascites in cirrhotics.[92] The primary abnormality with this proposal is sodium and water retention induced by a hepatorenal reflex promoted by portal hypertension. The resulting hypervolemia and increased portal pressure produces "overflow" ascites. Thus, this hypothesis contends that renal sodium retention and plasma volume expansion, rather than

plasma volume reduction, are responsible for ascites formation (see Fig. 39-15).

The "peripheral arterial vasodilation hypothesis" was proposed by Schrier and associates in 1988.[93] This theory contends that the primary event leading to sodium and water retention in cirrhosis is splanchnic arterial vasodilation secondary to portal hypertension induced production of vasodilatory mediators such as nitric oxide. At this phase of the disease, ascites has not yet developed, and a hyperdynamic circulation helps maintain systemic perfusion. With disease progression, this compensatory mechanism becomes insufficient to maintain circulatory homeostasis. Enlargement of the intravascular compartment decreases the effective arterial blood volume. Arterial blood pressure decreases, leading to baroreceptor activation, which stimulates three vasoconstrictor systems: the sympathetic nervous system, the renin-angiotensin-aldosterone system, and the nonosmotic release of vasopressin. Renal sodium and water retention increases and contributes to the development of ascites.

The most important initial treatment for patients with ascites resulting from cirrhosis is reduction of sodium intake and diuretic therapy. Fluid intake should be restricted to approximately 1,000 mL per day if the patient also has dilutional hyponatremia.[94] If the patient has significant anasarca, there is no limit to the amount of edema that can be safely mobilized. However, once the edema has resolved, 0.5 kg is probably a reasonable daily maximum weight loss, as ascitic fluid is much more slowly mobilized than edema. The diuretics of choice are either spironolactone or amiloride. Furosemide should be used with caution because of the risk of excessive diuresis, which may lead to potentially serious complications including renal failure of prerenal origin, precipitation of hepatorenal syndrome, hyponatremia, hypokalemia, and encephalopathy.

Refractory ascites occurs in 5 to 10% of ascitic patients and is defined as a lack of response to high dose of diuretics (spironolactone, 400 mg/day plus furosemide 160 mg/day).[95] The main clinical features include marked abdominal distension, frequent recurrence of ascites after paracentesis, an increased risk of developing hepatorenal syndrome, and a poor prognosis. Repeated large-volume paracentesis with use of plasma volume expanders is the most widely accepted therapy for refractory ascites.[96] Removal of large amounts of ascitic fluid without the administration of plasma volume expanders is associated with paracentesis-induced circulatory dysfunction (PICD), characterized by reduction of effective arterial blood volume due to shift of

intravascular fluid to the peritoneal cavity, with progressive reaccumulation of ascites and marked activation of the renin-angiotensin-aldosterone system.[97]

The hemodynamic status of patients with tense ascites who undergo rapid total paracentesis without fluid resuscitation typically improves for the first 3 hours following the procedure, as a result of release of compression of the IVC and right atrium. Cardiac output increases, whereas pulmonary artery wedge pressure is unchanged and right atrial pressure decreases.[97] Other studies have demonstrated that along with the early increase in cardiac output, there is a decrease in plasma renin and aldosterone levels, a decrease in serum creatinine and BUN, and reduced portal pressures.[98] However, these beneficial effects are transient.

After 3 hours, the hemodynamic status is determined by the development of a relative hypovolemia caused by progressive reaccumulation of ascites. Twenty-four hours after total paracentesis, there is a significant decrease in cardiac output and cardiac filling pressures, accompanied by increased plasma renin and aldosterone concentrations. This effect is prevented by intravenous albumin infusion.[99] Although the use of albumin in this setting remains controversial because of its high cost and the lack of documented improvement in survival, albumin has a greater protective effect on the circulatory system than other expanders. More recent studies suggest that 50% of the plasma expander should be infused immediately after paracentesis, and the other half, 6 hours later.[100] The prevalence of PICD also depends on the amount of ascitic fluid removed because it is an uncommon complication following a low-volume paracentesis. It can be anticipated that similar hemodynamic changes may occur following emergent laparotomy in patients with tense ascites.

Placement of a peritoneal-venous shunt (Le Veen or Denver) was the first treatment specifically designed for patients with refractory ascites. Le Veen introduced the first prosthesis in 1974. It consists of a perforated intra-abdominal tube connected via a one-way valve to a second tube that traverses the subcutaneous tissue to the jugular vein. This creates a continuous passage of ascites into the systemic circulation. Poor long-term patency and excessive complications have led to the near abandonment of this procedure. A TIPS procedure is effective for preventing recurrence of ascites in patients with refractory ascites. TIPS decreases the activity of sodium-retaining mechanisms and improves the renal response to diuretics. This procedure is better than repeated large-volume paracentesis for the long-term control of ascites, but it has several disadvantages, including a high rate of shunt stenosis, which can lead to recurrence of ascites; a high incidence of severe hepatic encephalopathy; a high cost; and lack of availability in some centers. Survival is not improved by TIPS compared with repeated large-volume paracentesis. Thus, TIPS is not considered the first-line treatment for refractory ascites. Liver transplantation may also be a consideration in these patients.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) is characterized by the spontaneous infection of ascitic fluid in the absence of an intra-abdominal source of infection. Its prevalence among patients with ascites ranges between 10 and 30%. SBP is diagnosed when there are $\geqslant$250 polymorphonuclear (PMN) cells/mm^3 of ascitic fluid. Bacterascites is diagnosed when there are positive ascitic fluid cultures and the neutrophil count is <250 cells/mm^3. SBP develops secondary to translocation of bacteria from the intestinal lumen to regional lymph nodes with subsequent bacteremia and infection of the ascitic fluid. Aerobic Gram-negative bacteria are most commonly isolated, but Gram-positive isolates are being recovered with increasing frequency. Ascitic fluid should be obtained by paracentesis and should be directly inoculated into blood culture bottles at the bedside rather than be cultured by conventional methods. Prospective clinical trials have demonstrated that cultures will be positive in approximately 80% of instances with the former approach versus 50% with the latter in patients with $\geqslant$250 PMN cells/mm^3 of ascitic fluid.

Because ascitic fluid PMN count can be assessed much more rapidly than cultures and accurately determines who can benefit from empiric antibiotic coverage, patients with a PMN count $\geqslant$250 cells/mm^3 in a clinical setting that is compatible with ascitic fluid infection should receive empiric antibiotic therapy. Delaying antibiotic therapy until positive ascitic fluid cultures are present likely

increases the risk of the patient developing severe sepsis. Patients with ascitic PMN counts <250 cells mm^3 with clinical signs or symptoms of infection should also be treated with empiric antibiotics until ascitic culture results are available. Cefotaxime, a third-generation cephalosporin, appears to be the antibiotic of choice for suspected SBP because it covers 95% of the responsible flora, including the three most common isolates, which are *Escherichia coli*, *Klebsiella pneumonia*, and the pneumococcus.

In a retrospective analysis of 252 episodes of SBP, renal insufficiency developed in 33%.[101] The renal dysfunction was transient in 25%, stable in 33%, and progressive in 42%. The

overall mortality for an episode of SBP was 24%, but was 54% versus 9% in those with and without the development of renal insufficiency. The development of renal impairment is therefore an important clinical event in the course of SBP. Sepsis-induced decrease in the effective arterial blood volume with subsequent baroreceptor-mediated stimulation of the renin-angiotensin and sympathetic nervous systems, and vasopressin release contribute toward the development renal dysfunction. Direct stimulation of renal vasoconstrictors by endotoxin may also play a role. Sort and associates demonstrated in a randomized, controlled clinical trial of 126 patients with SBP that interventions directed at maintaining effective arterial blood volume (1.5 g/kg albumin within 6 hours of diagnosis of SBP followed by 1 g/kg on day 3) were associated with a significant decrease in development of HRS, and in both the in-hospital and 30-day mortality rates.[102] Data do not exist regarding the efficacy of lower doses of albumin or other plasma volume expanders in preventing HRS.

Long-term antibiotic prophylaxis with a quinolone is recommended following resolution of SBP because there is an estimated 70% probability of recurrence within the first year, and antibiotic prophylaxis has a beneficial effect on patient survival. Short-term quinolone prophylaxis is also recommended for patients with low-protein ascites and gastrointestinal bleeding because bleeding increases bacterial translocation and SBP.

Pathogenesis of Renal Dysfunction

The three main renal functional abnormalities in cirrhosis are reduction in sodium excretion, reduction in free water excretion, and a decrease in renal perfusion and glomerular filtration.[94]

The arterial vasodilation characteristic of cirrhosis, with its associated decrease in effective plasma volume, leads to baroreceptor-mediated activation of the sympathetic nervous system. This causes the kidney to release renin, which results in an increased production of angiotensin II and aldosterone. Both aldosterone and increased sympathetic nervous system outflow enhance tubular sodium resorption. In addition, through their vasoconstrictive actions, norepinephrine and angiotensin II cause a redistribution of renal blood flow, which further decreases sodium elimination.

Water homeostasis is disturbed in up to 75% of patients with advanced cirrhosis and ascites (decompensated cirrhosis). In these patients, water retention, increased total body water, and dilutional hyponatremia develop when fluid intake exceeds the impaired renal capacity to excrete free water. Reduced glomerular filtration secondary to impaired perfusion, elevated vasopressin levels caused by nonosmotic hypersecretion and decreased metabolic clearance, and impaired renal production of prostaglandin E2 also contribute to the impairment of free water excretion.

The major consequence of reduced sodium excretion is the development of edema and ascites. When free water clearance becomes significantly reduced, dilutional hyponatremia develops. The main consequence of decreased renal perfusion and GFR is development of the hepatorenal syndrome.

Hepatorenal Syndrome

HRS is a functional prerenal failure that occurs in up to 10% of patients with advanced cirrhosis and ascites, and less commonly in patients with acute liver failure. HRS is characterized by intense vasoconstriction of the renal circulation, low glomerular filtration, preserved renal tubular

function, and normal renal histology.

HRS may be diagnosed after other causes of renal failure are ruled out. The International Ascites Club has suggested five major criteria to confirm the diagnosis of HRS: (1) chronic or acute liver disease with advanced hepatic failure and portal hypertension; (2) a low GFR as assessed by serum creatinine >1.5 mg/dL or creatinine clearance below 40 mL/min; (3) absence of shock, ongoing bacterial infection, fluid losses, or treatment with nephrotoxic drugs; (4) no sustained improvement in renal function after oral diuretic withdrawal and plasma volume expansion; and (5) less than 500 mg/day proteinuria with no ultrasonographic evidence of parenchymal renal disease or urinary obstruction.[103]

HRS has been classified clinically into two types based on its intensity and presentation. Type 1 HRS is characterized by progressive oliguria and a rapid rise in the serum creatinine concentration. Type 1 HRS develops in 5% of cirrhotics hospitalized for acute upper gastrointestinal bleeding, 30% of those admitted for SBP, 10% of patients with ascites treated with total paracentesis, and 25% of patients with severe acute alcoholic hepatitis.[104] SBP commonly precipitates the development of type 1 HRS. The prognosis of type 1 HRS is poor, with a median survival of less than 1 month without therapeutic intervention. Type 2 HRS is usually seen in patients with refractory ascites, and is characterized by a moderate and more stable impairment of renal function.

Pathophysiologically, intense renal vasoconstriction is the final consequence of extreme vasodilation of the splanchnic arterial circulation that reduces the effective arterial blood volume (that sensed by the central arterial circulation). The resulting abnormal distribution of arterial volume is associated with reduced flow to all extrasplanchnic areas, including the kidneys. Splanchnic arterial vasodilation is related to an increased level of both endothelial (prostacyclin and nitric oxide) and nonendothelial vasodilators (e.g., glucagon). Increased activity of both the renin-angiotensin and sympathetic nervous systems mediate the renal vasoconstriction, as well as other intrarenal vasoconstrictor factors such as endothelin, adenosine, and leukotrienes.[105]

Until more recently, the development of type 1 HRS was considered to be an irreversible clinical condition, which in the absence of an emergent liver transplant, was associated with rapid progression to death. Because HRS develops as a consequence of splanchnic arterial vasodilation, drugs that produce splanchnic vasoconstriction have been proposed for treatment of this condition. Several different vasoconstrictors (vasopressin analogs, catecholamines), usually combined with albumin infusion, have been evaluated in small nonrandomized clinical trials. Vasoconstrictor therapy results in an increased arterial blood pressure, near-normalization of the activity of the major endogenous vasoconstrictor systems, and marked increases in renal plasma flow, GFR, and urine volume in approximately two-thirds of patients. These studies have demonstrated that a prolonged improvement in circulatory function, with 1 to 2 weeks of administration of intravenous albumin and vasoconstrictors, is required to reverse HRS, with a lag between the normalization of systemic circulation and the improvement in renal perfusion and GFR. Recurrence of HRS in responding patients after withdrawal of therapy is uncommon.[106,107]

Octreotide, an inhibitor of the release of gastrointestinal vasodilator peptides such as glucagon and vasoactive intestinal peptide, when combined with midodrine and intravenous albumin, has been shown to have beneficial effects on renal function in a clinical study of five patients with type 1 HRS.[107]

Patients showing an improvement in renal function after vasoconstrictor therapy survive significantly longer than patients who do not respond. Treatment with vasoconstrictors may thus increase the likelihood that patients with HRS will survive long enough to undergo liver transplantation. Transplant survival may be significantly reduced in cirrhotic patients with preoperative renal failure. Reversal of HRS with vasoconstrictor therapy is, therefore, an important tool in patients waiting for a liver transplant.

Acute Renal Failure and Acute Tubular Necrosis

Cirrhotic patients are also at risk for developing acute renal failure from acute tubular necrosis (ATN), especially following infection or hypotensive episodes. ATN occurs more frequently after surgical procedures to relieve obstructive jaundice than it does following similar operations on nonjaundiced patients. The impaired vasoconstrictor response to hypovolemia seen in patients with hepatic parenchymal disease and obstructive jaundice limits the normal redistribution of splanchnic blood to the central circulation that occurs with hemorrhage. Therefore, even moderate hemorrhage may produce severe hypotension and cause ATN. In addition, conjugated bilirubin appears to be toxic to renal tubules and may contribute to the development of ATN in jaundiced patients.

The differential diagnosis of acute azotemia in patients with liver disease is outlined in Table 39-6. Of note is the remarkable similarity of the urinary characteristics of prerenal azotemia and HRS. Prompt detection and treatment of hypovolemia may rapidly improve renal function in prerenal azotemia, but this response does not if HRS is present.

TABLE 39-6 Differential Diagnosis Of Acute Azotemia In Patients With Liver Disease: Important Differential Urinary Findings

	▪PRERENAL AZOTEMIA	▪HEPATORENAL SYNDROME	▪ACUTE RENAL FAILURE(ACUTE TUBULAR NECROSIS)
Urinary sodium concentration	<10 mEq/L	<10 mEq/L	>30 mEq/L
Urine-to-plasma creatinine ratio	>30:1	>30:1	<20:1
Urinary osmolality	Exceeds plasma osmolality by at least 100 mOsm	Exceeds plasma osmolality by at least 100 mOsm	Equal to plasma osmolality
Urinary sediment	Normal	Unremarkable	Casts, cellular debris

Hematologic and Coagulation Disorders

The liver is the site of synthesis of all clotting factors with the exception of von Willebrand factor (vWF), an endothelial product. Anticoagulant (antithrombin III, proteins C and S), and fibrinolytic factors are also products of the liver. Acute or chronic liver disease results in a variable level of impairment of hemostasis from multiple causes: decreased production of coagulation and inhibitor factors, synthesis of dysfunctional clotting factors, quantitative and qualitative platelet defects, vitamin K deficiency, decreased clearance of activated factors, hyperfibrinolysis, and disseminated intravascular coagulation.

Vitamin K is an essential cofactor for the production in the liver of factors II, VII, IX, and X, and

also proteins C and S. The precursors of vitamin K-dependent coagulation factors are also synthesized in the liver. Vitamin K is needed for conversion of these factors to active forms by gamma carboxylation of glutamic acid residues in the amino-terminal region of the precursors. The carboxylated residues permit the binding of calcium ions that are essential for their functional activity.

Vitamin K is a fat-soluble vitamin requiring bile salts for absorption from the intestines. Thus, deficiency of the vitamin K-dependent factors results when there is impaired bile secretion from either intrahepatic or extrahepatic cholestasis.

Thrombocytopenia occurs in approximately 30 to 64% of patients with advanced chronic liver disease; however, the platelet count is rarely less than 30,000 cells/μL, and spontaneous bleeding is uncommon. The primary cause of thrombocytopenia in cirrhosis is portal hypertension-induced splenomegaly because up to 90% of circulating platelets may be sequestered in the enlarged spleen. Decreased hepatic synthesis and serum levels of the cytokine thrombopoietin are also believed to have a causative role in cirrhotics with thrombocytopenia. Increased destruction of platelets by immune mechanism; coexistent, low-grade, disseminated intravascular coagulation; sepsis; and direct suppression of bone marrow thrombopoiesis by ethanol, folate deficiency, and other drugs may all contribute to the development of thrombocytopenia in patients with chronic liver disease.

Dysfibrinogenemia is the most common qualitative abnormality of clotting factors in patients with liver disease. The abnormal functioning of fibrinogen is caused by an increased degree of sialylation of the molecule. This produces abnormal polymerization of fibrin monomers and leads to a disproportionate prolonged thrombin time, despite mild prolongation of the PT and partial thromboplastin (PTT) and normal amount of fibrinogen.

Hyperfibrinolysis is a common finding in patients with advanced liver disease and results from decreased hepatic clearance of plasminogen activator. This complication may be documented by the finding of decreased whole blood euglobulin clot lysis time, with elevated levels of D-dimer, fibrin, and fibrinogen degradation products.

Diagnosing disseminated intravascular coagulation in cirrhotic patients is difficult. The diagnosis is suggested when there is a known triggering event associated with progressive worsening of coagulation test results and platelet counts, as well as a disproportionate reduction of factor V with a concomitant decreased level of a previously normal factor VIII.

Disorders of coagulation rapidly develop in patients with severe acute liver failure because of the brief half-life of some of the clotting factors. Factors II, V, VII, IX and X are all reduced in acute liver failure. As a consequence, the PT and INR become markedly elevated, serving as prognostic indicators and predictors of the need for transplantation. Reduced concentrations of the vitamin K-dependent factors are due predominantly to a combination of decreased hepatic synthesis and increased consumption of coagulation factors, rather than to vitamin K deficiency.

Thrombocytopenia is also a frequent finding in patients with acute liver failure with platelet counts below 100,000 cells/μL, developing in approximately 66% of patients at some point in their clinical course.

Quantitative and qualitative abnormalities of fibrinogen are also seen, and there is often evidence of excessive thrombin

activity, increased fibrinogen turnover, and fibrinolysis, but the relative contributions of disseminated intravascular coagulopathy and impaired hepatic synthesis/clearance to the development of hemostatic abnormalities in acute liver failure remains unclear.

Spontaneous bleeding occurs infrequently in patients with advanced liver disease, and prophylactic treatment is not generally required. Bleeding, however, accounts for 60% of all deaths in cirrhotics having abdominal surgery; therefore, correction of coagulation abnormalities is appropriate prior to major surgical procedures and invasive diagnostic studies. A PT prolonged by >3 seconds or a platelet count of <50,000 cells/μL are considered contraindications to elective

surgery.[108]

Perioperative management includes blood component therapy guided by laboratory studies. Fresh frozen plasma contains all the clotting factors, and administration of 10 to 20 mL/kg will usually correct the PT to nearly normal levels, but the effect lasts for no more than 12 to 24 hours. Vitamin K may improve the PT in patients with cholestatic disease. In these instances, 10 mg subcutaneous vitamin K should be given for 3 consecutive days. Platelets should be infused prophylactically prior to elective surgery when the platelet count is less than 60,000 cells/μL.[109]

Endocrine Disorders

The presence of advanced cirrhosis invariably leads to abnormal regulation and function of multiple endocrine systems. The prevalence and severity of endocrine dysfunction are increased in diseases such as hemochromatosis, in which both the liver and endocrine organs are damaged by a common pathophysiologic process. Cirrhotic patients often have abnormal glucose utilization. The mechanism of this phenomenon is rather complex and includes increased fatty acid concentration in the plasma, which antagonizes the effects of insulin on glucose uptake by skeletal muscles. In addition, plasma levels of growth hormone and glucagon are often increased, and undoubtedly contribute to the glucose intolerance and other derangements of intermediary metabolism that occur in patients with hepatic dysfunction. Patients with cirrhosis are also prone to hypoglycemia. This may reflect glycogen depletion secondary to malnutrition or alcohol-induced glycogenolysis and interference with gluconeogenesis. Severe cirrhosis may also impair hepatic conversion of lactate to glucose.

Abnormal metabolism of sex hormones causes gonadal dysfunction in both men and women. Men undergo feminization, often developing gynecomastia along with a decrease in the size of their testes and prostate gland. The frequency of impotence increases, and sperm counts typically decrease. Women with liver dysfunction commonly exhibit oligomenorrhea or amenorrhea.

Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a complex reversible metabolic encephalopathy presenting as a wide spectrum of neuropsychiatric abnormalities in patients with hepatocellular failure and/or increased portal-systemic shunting. The clinical manifestations are highly variable and range from minimal changes in personality or altered sleep patterns without overt signs of HE (minimal HE), to confusion, lethargy, somnolence, and coma. Thirty to 60% of cirrhotics have at least minimal HE. Several well-recognized factors can precipitate HE in patients with cirrhosis who were previously stable (Table 39-7). A large dietary protein load, gastrointestinal hemorrhage, constipation, hypokalemia, diuretics, and azotemia produce an increased blood ammonia level. Surgery, associated with anesthesia and dehydration, can precipitate an episode of HE because of decreased hepatic perfusion. Sepsis can precipitate HE through increased ammonia production due to protein catabolism, impaired hepatic perfusion, and the effects of cytokines on the central nervous system. Psychoactive drugs can also precipitate HE. The diagnosis has to be made on the basis of clinical findings. Several other conditions that may present in a similar fashion must be excluded, including chronic subdural hematoma, Wernicke's encephalopathy, and electrolyte disturbances.

TABLE 39-7 Factors That May Precipitate Hepatic Encephalopathy

·PRECIPITATING FACTOR	·POSSIBLE MECHANISMS
Excessive dietary protein	Increased ammonia production

Constipation Gastrointestinal bleeding Infection Azotemia	
Diarrhea and vomiting Diuretic therapy Paracentesis	Dehydration with electrolyte and acid-base imbalance, increased ammonia generation, and decreased hepatic perfusion, increasing blood ammonia level
Hypoxia Hypotension Anemia Hypoglycemia	Adverse effect on liver and brain function
Sedatives/hypnotics	Action at the $GABA_A$/benzodiazepine receptor complex
Creation of portal-systemic shunt	Reduced hepatic metabolism

It is commonly believed that HE is caused by substances that under normal circumstances are efficiently metabolized by the liver, rather than by insufficient synthesis of substrates essential for normal neurologic function. This notion is consistent with the development of HE in patients following portosystemic bypass who do not have significant intrinsic liver disease. More than 20 different compounds have increased blood concentrations when liver function is impaired. Of these, ammonia has been considered the most important factor in the genesis of HE. Ammonia is produced in the intestine by catabolism of proteins, amino acids, and biogenic amines. Forty percent is derived from intestinal bacterial metabolism of nitrogenous substances, and most of the remainder from digestion of dietary protein. The concentration of ammonia in portal venous blood is high, and a high degree of extraction occurs in the liver where the ammonia is converted to urea and glutamine. This detoxification is impaired in cirrhotics as a result of impaired conversion by the liver and marked portal-systemic shunting. Increased ammonia levels in blood result in increased diffusion of ammonia into the brain. Variation in the transfer of ammonia across the blood-brain barrier may explain the poor relationship between the blood ammonia level and the degree of hepatic encephalopathy. Ammonia has many deleterious effects on brain function. Although this ion seems to play a central role, the clinical features of HE differ from those of pure ammonia intoxication, and therefore, other mechanisms must be involved.

The clinical and neurophysiologic manifestations of HE seem to reflect a global depression of central nervous system

function caused by an increase in inhibitory neurotransmission. The observation of an improvement in mental status after the administration of flumazenil, a benzodiazepine receptor antagonist, in some patients with advanced HE who have not taken benzodiazepines supports a role for an increased GABAergic tone. One possible mechanism is an increased availability of agonist ligands of the GABA receptor complex. These are called natural benzodiazepines and bind to the benzodiazepine site of the GABA receptor. Natural benzodiazepines accumulate in the brains of patients with HE, and it has been suggested that they may induce a decrease in consciousness.

Other putative mechanisms include the effects of a group of potentially neurotoxic compounds of

colonic origin (mercaptans, short-chain fatty acids, manganese), impairment of cerebral energy metabolism, gliopathy secondary to astrocyte swelling, and disruption of the blood-brain barrier. Patients with liver failure have an increase in plasma levels of aromatic amino acids and a decrease in branched-chain amino acids. It has been proposed that this imbalance enhances the entry of aromatic amino acids into the brain and that these are channeled into the synthesis of abnormal biogenic amines, which are released along with, or instead of, normal neurotransmitters. These *false neurotransmitters* (octopamine, phenylethanolamine) are relatively inactive. However, this hypothesis has not been supported by in vivo or postmortem studies. Administration of intravenous branched-chain amino acids does not produce beneficial effects in acute HE.

The main principles of treatment of HE have not been evaluated by randomized clinical trials but rather have been accepted on the basis of clinical observation.[110,111] Most episodes of HE in patients with cirrhosis are initiated by an identifiable precipitating factor. Because effective methods exist to control most of these, a key component of the treatment of HE is to identify and treat the precipitating cause. Often, the elimination of these factors leads to an improvement without need for any additional therapy. If no precipitating factor can be identified or if rapid improvement does not occur with treatment, therapy should be initiated to reduce the production and absorption of ammonia. Dietary protein intake should be restricted, to an extent dependent on the severity of HE. However, severe restriction of dietary protein is no longer recommended because of the adverse effects of severe malnutrition on liver function and short-term prognosis.[112]

Lactulose (*B*-galactosidofructose) is a nonabsorbable disaccharide that is not broken down by intestinal enzymes following oral administration, but is metabolized by enteric bacteria in the cecum to lactate and acetate. This produces a reduction of ammonia absorption from the large intestine (because it is converted to ammonium) and net movement of NH_3 from the blood into the bowel. In addition, lactulose enhances the growth of non–urease-producing bacteria, thereby reducing the bacterial production of ammonia, and it also has cathartic activity.

Neomycin is an alternative to lactulose for patients who do not tolerate the disaccharide or have unsatisfactory results. It reduces the intestinal production of ammonia by reducing the population of urease-producing bacteria and may also have nonbacterial effects. Prolonged use should be avoided because of possible toxicity from the small amount of drug that is absorbed. Neomycin is as effective as lactulose.

Zinc deficiency is common in cirrhotics due to increased urinary excretion and malnutrition. Two of the five enzymes responsible for the metabolism of ammonia to urea are zinc dependent; thus, it has been suggested that zinc deficiency contributes to the development of HE. Whether zinc supplementation in this population is beneficial has not been established. Flumazenil, a selective antagonist of the central benzodiazepine receptor, produces a transient improvement in the mental status of some patients with HE, but has no sustained benefits. The dopamine agonists, bromocriptine and levodopa, were introduced to restore the decreased activity of central neurotransmitters caused by false neurotransmitters. Although the false neurotransmitter hypothesis is now questioned, these drugs may help chronic HE patients with extrapyramidal manifestations, which are believed to develop as a result of manganese accumulation in the basal ganglia.

It appears clear that encephalopathic changes are associated with clinically important alterations in pharmacodynamics and pharmacokinetics of various medications. For example, cerebral uptake of benzodiazepines increases substantially, which may reflect an increase in the density or affinity of benzodiazepine receptors or a leaky blood-brain barrier. Drugs administered to patients with advanced hepatic disease require careful titration against effect.

Orthotopic liver transplantation cures HE. Medical management for HE is mainly used for patients who do not yet meet the criteria for liver transplantation, who are waiting for a transplant, or who are not transplant candidates. Without transplantation, overt HE in the patient with chronic liver disease has a poor prognosis, with a survival rate of 42% at 1 year and 23% at 3 years.

Uncommon Causes of Cirrhosis

Wilson's Disease

Wilson's disease (hepatolenticular degeneration) is a hereditary disease characterized by decreased hepatocellular excretion of copper into the bile and decreased binding of copper to apoceruloplasmin, resulting in hepatic copper accumulation, hepatic injury, and decreased ceruloplasmin levels in the blood. Eventually, copper is released into the bloodstream and is deposited in various organs, especially the brain, cornea, and kidneys. Untreated, it is a lethal disease with progressive lenticular degeneration, accompanied by chronic liver disease leading to cirrhosis.[113] Wilson's disease has an autosomal recessive pattern of inheritance. Homozygotes have a defect of the hepatic enzyme required for transmembrane transport of copper into the bile. Wilson's disease occurs worldwide with an average prevalence of approximately 30 affected individuals per million population. It can present clinically as liver disease, as a progressive neurologic disorder, or as a psychiatric illness.

The clinical presentation of liver dysfunction in patients with Wilson's disease can range from asymptomatic, with only biochemical evidence of damage, to fulminant liver failure requiring urgent liver transplantation for survival. Histologically, steatosis and focal hepatocellular necrosis occur early, with progression to fibrosis and cirrhosis, which is present in most untreated patients by the second decade of life. Neurologic dysfunction typically becomes evident later than liver disease. Tremors, gait disturbances, and slurring of speech are common manifestations, simulating Parkinson's disease. Kayser-Fleischer rings are a pathognomonic sign but are present in only 50 to 62% of patients with Wilson's disease at the time of diagnosis.[113] They represent copper deposition in Decemet's membrane of the cornea and usually require a slit-lamp examination for their identification.

A combination of clinical findings and biochemical testing is necessary to establish the diagnosis of Wilson's disease. Recognition of Kayser-Fleischer rings, increased liver copper concentrations on percutaneous biopsy samples, reduced concentration of ceruloplasmin in the blood, and increased urinary copper excretion can point to the correct diagnosis prior to development of neurologic symptoms. A hepatic copper content of $\geqslant$250 μg/g dry weight is the best biochemical evidence for Wilson's disease. The combination of a blood ceruloplasmin

level <200 mg/L associated with the presence of Kayser-Fleischer rings is also diagnostic.

Lifelong pharmacologic treatment is given to symptomatic patients or to those with active disease. The oral chelating drugs D-penicillamine or trientine bind copper and thereby promote urinary excretion. Liver transplantation corrects the underlying hepatic defect, but is reserved for patients with decompensated liver disease unresponsive to medical therapy and for patients presenting with fulminant hepatic failure.

Hereditary Hemochromatosis

Hemochromatosis is a hereditary disease characterized by excessive iron absorption from the duodenum and subsequent tissue deposition producing organ damage, which is frequently irreversible. Hemochromatosis may be the most common autosomal-recessive genetic disease in Caucasians. It is estimated that 1 in 10 to 20 Caucasians carry the disease gene, and 1 in 400 are homozygotes who are at risk of clinical disease. It is currently impossible to predict whether and to what extent the mutation will be expressed and, in a small percentage of homozygotes, laboratory evidence of altered iron metabolism never develops.[114]

Hemochromatosis occurs when intestinal absorption of dietary iron exceeds bodily needs. The primary site for regulating iron absorption is in duodenal mucosa cells. Duodenal iron absorption is normally minimized when body iron stores are increased. In hemochromatosis, this step is inappropriately controlled, and although iron overload is present, enterocytes continue to transfer unneeded iron into the bloodstream. A gradual and progressive expansion of the plasma iron compartment occurs that produces an increased transferrin-saturation value (the earliest

detectable biochemical abnormality in hemochromatosis).

Symptomatic organ involvement usually does not begin until the fourth or fifth decade of life, and reflects injury induced by parenchymal iron deposition. The nonspecific initial symptoms often found in these patients, such as unexplained weakness, lethargy, and arthralgias, makes consideration of hemochromatosis unlikely. Subsequently, liver disease often predominates and may range from transaminitis to end-stage cirrhosis with signs of portal hypertension. Hepatomegaly is the most common physical finding on presentation, found in 80% of patients, followed by increased skin pigmentation in 75%.[115] Once the patient has developed cirrhosis, the chances of developing hepatocellular carcinoma are increased 200-fold.

In addition to hepatic infiltration, iron deposition frequently affects: (1) islet cells of the pancreas producing diabetes mellitus; (2) the pituitary gland, producing hypogonadotrophic hypogonadism, impotence, and hypothyroidism; (3) the myocardium, frequently with dysrhythmias, while up to one-third of untreated patients die of cardiac failure; and (4) the skin, with a characteristic bronze discoloration.

Thanks to increasingly early diagnosis, the classic triad of cirrhosis, diabetes mellitus, and bronze skin is now rare in adult-onset hemochromatosis. The best diagnostic test is the serum transferrin saturation level, which is normally less than 50%. In the absence of significant liver disease, which would lead to decreased hepatic transferrin synthesis, a transferrin saturation level consistently greater than 62% is associated with a greater than 90% chance of hemochromatosis. Suggestive laboratory results should be followed by a liver biopsy; the presence of substantial stainable iron in parenchymal liver cells is characteristic of hemochromatosis.

Once the diagnosis is confirmed by liver biopsy, the patient should be treated by repeated phlebotomy to remove excess iron from tissues and the blood. If initiated early in the course of the disease, organ damage can be prevented and survival improved. Established organ damage cannot be reversed, but progression can be slowed.

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) accounts for up to 2% of worldwide deaths from cirrhosis. It is a chronic progressive cholestatic liver disease of unknown etiology that most commonly affects middle-age women. Genetic factors play a role in the development of PBC, but it is not inherited in a simple dominant or recessive pattern. PBC is characterized by portal inflammation, destruction of the small intrahepatic bile ducts, and progressive scarring. It commonly presents as unexplained hepatomegaly or an elevated alkaline phosphatase level in an asymptomatic patient. Fatigue and pruritus are often the initial symptoms. Jaundice is a late manifestation of the disease. The antimitochondrial antibody test is positive in 95% of patients and is relatively specific for the disease. There is a strong association between PBC and other autoimmune diseases. The diagnosis should be confirmed by percutaneous liver biopsy, which also provides staging and prognostic data. The median survival of symptomatic patients is approximately 7 years. There is no generally accepted effective medical treatment, although cholestyramine may alleviate pruritus. Liver transplantation is the only treatment that improves survival.[116]

α-1-Antitripsin Deficiency

Patients with homozygous deficiency of serum α-1-antitrypsin (α-1-AT) develop a slowly progressive liver disease that most commonly progresses to asymptomatic cirrhosis, which may be complicated by the development of hepatocellular carcinoma. Adult patients with this disorder often have emphysema. The molecular basis for the disease is related to a single nucleic acid substitution. The diagnosis is suggested by the presence of hepatomegaly, mild LFT abnormalities, and the absence of α-1-AT on serum protein electrophoresis. The diagnosis is confirmed by direct measurement of serum α-1-AT and/or demonstration of characteristic periodic acid-Schiff-positive, diastase-resistant globules adjacent to portal tracts on liver biopsy.

Budd-Chiari Syndrome

Budd-Chiari syndrome is a heterogeneous group of disorders characterized by outflow obstruction of blood, from the liver to the right heart. The pathologic processes responsible for the syndrome can be categorized into three groups: those that affect the hepatic venules, those obstructing the major hepatic veins, and those preventing the flow of blood from the hepatic veins into the right atrium.[117]

Hepatic veno-occlusive disease refers to obstruction of hepatic venous outflow at the level of the central or sublobular veins. Cytotoxic agents used in preparation of patients for bone marrow transplantation are the most common causes of the disease in the United States. Obstruction of the major hepatic veins is most commonly related to an underlying hypercoagulable state, including myeloproliferative disorders or malignancies that involve the hepatic veins either directly or by extension of tumor thrombus. Obstruction of the IVC proximal to the right atrium is commonly the result of either a membranous intracaval web or caval thickening.

Obstruction of venous outflow results in increased hepatic sinusoidal pressure and portal hypertension. Hepatic venous stasis and congestion causes hypoxic damage to adjacent hepatic parenchymal cells and cells lining the sinusoids. Hepatocyte necrosis develops in centrilobular regions followed by fibrosis, nodular regeneration, and ultimately, cirrhosis.

The clinical presentation is highly variable, and depends on the extent and rapidity of hepatic vein occlusion and on the development of a collateral circulation to decompress the

sinusoids. Symptoms include right upper quadrant tenderness secondary to hepatomegaly and abdominal distension due to ascites. Laboratory evaluation usually reveals modest alteration in liver function tests and low serum albumin. Rarely, fulminant liver failure occurs if there is rapid and complete occlusion of the hepatic veins and secondary thrombosis of the portal vein as the result of hepatic outflow obstruction.

A variety of noninvasive tests can be used to support the diagnosis of Budd-Chiari syndrome. Doppler ultrasonography of the liver is the most cost-effective radiographic tool for initial evaluation when the syndrome is suspected. It will reveal absent or diminished hepatic venous blood flow, thrombosis of the IVC, and liver and spleen enlargement. CT and MRI scanning are more expensive alternatives. Once the diagnosis is suggested by its clinical features and noninvasive radiographic evaluation, venography with cannulation of the hepatic veins is usually performed. The diagnosis is confirmed by a "spiderweb." If appropriate, a number of interventional procedures can then be performed, including thrombolytic therapy and balloon angioplasty.[117]

Untreated, Budd-Chiari syndrome will result in death within months to years. Therapy includes medical management and relief of hepatic venous outflow obstruction to prevent further hepatic injury or liver transplantation in selected patients, especially those with fulminant liver failure.

Medical therapy is limited primarily to anticoagulation and thrombolysis. The latter is considered in patients with acute onset of the syndrome, especially if angiography reveals fresh thrombus in the hepatic veins and IVC. The thrombolytic agent is infused directly into the thrombosed vein for approximately 24 hours. Percutaneous transluminal angioplasty of localized segments of narrowed hepatic veins or inferior vena caval webs may result in dramatic improvement, although the risk of restenosis is high. This may be prevented with intravascular metal stent placement.

The mainstay of therapy involves surgical intervention. By relieving sinusoidal hypertension, portosystemic shunting may reverse hepatic necrosis and prevent the development of cirrhosis. The most commonly used technique is a side-to-side portocaval shunt. Liver transplantation is usually reserved for those patients with decompensated cirrhosis, fulminant hepatic failure, or failure of a portosystemic shunt.[117]

HEPATOCELLULAR CARCINOMA

Primary hepatocellular carcinoma (HCC) is one of the most common tumors in the world and the third most frequent cause of death from cancer. It occurs in the United States with an incidence of 2.4 individuals per 100,000 population. HCC usually arises in a cirrhotic liver. Cirrhosis secondary to chronic viral hepatitis accounts for the large majority of HCC worldwide but only 30 to 40% of

reported cases in America. Thus, there are many individuals in whom no obvious cause can be identified. Inherited metabolic diseases, including hemochromatosis, α-1-antitrypsin deficiency, and Wilson's disease, are well known to be risk factors for the development of HCC. Another implicated factor is alcohol. Alcoholic cirrhosis may clearly result in HCC, but it is uncertain whether alcohol is directly carcinogenic or whether associated hepatocellular injury and regeneration, iron accumulation, or coexistent hepatitis C infection is responsible.

HCC may escape early clinical detection because it occurs in patients with underlying cirrhosis, and the clinical findings may suggest progression of the underlying disease. The most common presenting complaint is abdominal pain, and the most frequent finding on physical examination is an abdominal mass. Serum alpha fetoprotein (AFP) values are greater than 500 µg/L in about 70 to 80% of patients with HCC. Unfortunately, AFP has a low specificity and levels may be elevated in pregnancy, germ cell tumors, and acute or chronic hepatitis. Hepatic ultrasound has greater sensitivity and specificity than AFP levels when used for HCC screening. Three imaging procedures are in common use for diagnosing HCC, ultrasonography, helical CT, and MRI. The sensitivity and specificity of radiologic studies for detection of HCC is unknown.

Chemoembolization is widely used for treatment of HCC. No studies have shown a long-term survival advantage in treated versus untreated patients. Surgical resection offers a chance for cure; however, few patients have a resectable tumor at the time of presentation. Patients with two or fewer lesions, each smaller than 5 cm, which are encapsulated and have no evidence of macroscopic vascular invasion are the best candidates for hepatic resection. Operative mortality in cirrhotics is approximately 10%.[118] Liver transplantation may be considered as a therapeutic option for patients who have a single lesion ⩽5 cm or three or fewer lesions ⩽3 cm. Survival after transplantation in these groups is similar to that of patients transplanted for nonmalignant disease.

PREGNANCY-RELATED DISORDERS

Well-known disorders of pregnancy that can cause fulminant hepatic failure during the third trimester or in the immediate postpartum period include acute fatty liver of pregnancy (AFLP) and the HELLP syndrome (Hemolysis, Elevated Liver enzymes, Low Platelets). In addition, parturients are unusually susceptible to morbidity and mortality from hepatitis E infection and herpes simplex hepatitis.

Acute Fatty Liver of Pregnancy

AFLP occurs in the late stages of pregnancy. Although severe cases are rare (frequency of 1/6,659 deliveries in a 1999 report), it is now recognized to exist in a broad clinical spectrum ranging from mild to severe hepatic disease. The pathogenesis is unclear, but an association between inherited defects in beta-oxidation of fatty acids and AFLP is now well established. Some affected patients have an inherited long-chain 3-hydroxyacyl-CoA dehydrogenase deficiency, which causes a defect in intramitochondrial beta-oxidation of fatty acids. Other patients with AFLP have a defect in beta-oxidation caused by deficiency of carnitine palmitoyltransferase I.

Affected women usually present in the third trimester with symptoms related to hepatic failure. Initial symptoms are variable, and include nausea, vomiting, abdominal pain, and encephalopathy. Modest elevations of serum transaminases (<750 U/L) are usual. Jaundice is common as is laboratory evidence of renal dysfunction and leukocytosis. Prolongation of the prothrombin time and other laboratory findings of disseminated intravascular coagulation are often present and help distinguish AFLP from HELLP syndrome. Severely affected patients have complications typical of any form of fulminant hepatic failure, including hepatic coma and renal failure. Some patients are asymptomatic, with the diagnosis made during evaluation of abnormal liver function tests. Imaging techniques have not been consistently useful for confirming the diagnosis of AFLP. Although a liver biopsy can be diagnostic, it is often contraindicated because of coagulopathy. Therefore, the diagnosis of AFLP is clinical. When a biopsy is available, the characteristic histologic finding is microvesicular fatty infiltration most prominent in the central zone, with sparing of the periportal hepatocytes.

When AFLP is diagnosed, delivery of the fetus is expedited, usually by induction of labor or, occasionally, cesarean section, because AFLP improves in response to termination of pregnancy. After delivery, maximal supportive care is required as the liver recovers. Most affected women recover completely, although severe cases may require prolonged intensive care. On rare occasions, liver transplantation has been necessary. Recurrence of AFLP with future pregnancy is uncommon.

Preeclampsia and Hellp Syndrome

HELLP syndrome was defined by Weinstein in 1982. It is now recognized to be a common and potentially ominous complication of preeclampsia, affecting 10% of women with this disorder, and 20% of women with severe preeclampsia. The presence of HELLP syndrome is associated with an increased risk of maternal (1%) and perinatal (up to 20.4%) death.[119] The diagnosis of HELLP syndrome is made clinically by the presence of signs of preeclampsia and laboratory evidence of hemolysis (elevated serum LDH level, schistocytes and burr cells on peripheral smear), elevated serum transaminases due to ischemic hepatocellular necrosis (up to several thousand IU), and thrombocytopenia (<100,000 cells/μL). Hyperbilirubinemia occurs in approximately 40% of cases of HELLP, and may be caused by hemolysis and liver dysfunction. The presence of full-blown coagulopathy is rare and should raise concern for the presence of hepatic failure caused by AFLP. It should be noted that there is considerable disagreement in the medical literature about the diagnostic criteria for the HELLP syndrome.[119]

Liver biopsy is rarely warranted, but when performed, the specimens usually demonstrate periportal hemorrhage and fibrin deposition with periportal hepatic necrosis. Both macrovesicular and microvesicular fat are present, but steatosis is usually modest and is unlike the pericentral microvesicular fat seen in AFLP. The liver involvement in HELLP syndrome is most frequently misdiagnosed as viral hepatitis, although thrombocytopenia is an uncommon finding in the latter disease. AFLP also should be considered, but is usually associated with more severe liver failure and not necessarily with thrombocytopenia. All affected patients should be considered to have severe preeclampsia. Once the diagnosis is made, management is primarily supportive. There is a consensus of opinion that prompt delivery is indicated if the syndrome develops beyond 34 weeks' gestation or earlier if life-threatening morbidity develops in the mother. When HELLP syndrome develops prior to 34 weeks' gestation, management is controversial with the choice of either providing supportive care with close monitoring of mother and fetus until the fetus is mature, or administration of corticosteroids to accelerate fetal lung maturity followed by delivery after 24 hours.[119]

In most affected patients, all abnormalities associated with preeclampsia and HELLP syndrome resolve after delivery, leaving no hepatic sequelae. Rarely, the condition worsens progressively after delivery with further diminution of the platelet count and development of sepsis with multisystem organ failure.

Hepatic Rupture, Hematoma, and Infarct

These conditions occur in preeclampsia and may be the extreme end of the spectrum of HELLP syndrome. Patients with spontaneous rupture of the liver present close to term with abdominal pain and distension, as well as cardiovascular collapse. The rupture results from extravasation of blood, presumably from one or several microscopic areas of periportal hemorrhage with subsequent separation of Glisson's capsule from the liver surface and eventual capsule rupture. The diagnosis depends on a high index of suspicion and identification of hemoperitoneum on abdominal ultrasonography, CT scan, or MRI. If the rupture goes undiagnosed, death results for both mother and fetus. Aggressive management is essential, with vigorous hemodynamic support, rapid delivery of the fetus, and surgical repair of the liver. Some patients may have a contained subcapsular hematoma without frank rupture into the peritoneum. These patients may be managed expectantly with serial hepatic CT scans.

Hepatic infarction typically occurs in the third trimester and presents with right upper quadrant

pain, fever, leukocytosis, and marked elevations of serum transaminases. The infarcts can be seen on abdominal CT scan. Management is supportive.

CHOLESTATIC DISEASE

Cardiovascular Dysfunction

The presence of bile salts in circulating blood (cholemia) can impair myocardial contractility.[120] Cholemia also blunts the response to norepinephrine, angiotensin II, and isoproterenol, probably by interfering with their binding to membrane receptors.[121] Less severe hemodynamic perturbations occur in patients with biliary obstruction than in those with cirrhosis. However, the pattern of the pathophysiologic change is remarkably similar: increases in peripheral vasodilatation, cardiac output, and portal venous pressure, and a decrease in portal venous blood flow.

Coagulation Disorders

Cholestatic disease predisposes the patient toward development of coagulopathy primarily related to vitamin K deficiency. During even brief episodes of biliary obstruction, coagulopathy can result from a deficiency of coagulation factors whose activation depends on the presence of vitamin K. Absorption of vitamin K depends on the excretion of bile into the gastrointestinal tract. Long-lasting biliary obstruction can cause liver injury, with subsequent deterioration in the hepatic synthesis of proteins, including coagulation factors. Usually, the coagulation disorders are moderate, and parenteral vitamin K corrects the problem. If this treatment is not fully effective, one should suspect that the disease is not purely cholestatic and that hepatic parenchymal injury exists. If such patients need urgent surgery, the coagulopathy will require immediate treatment with fresh frozen plasma. The failure of parenteral vitamin K to correct a prolonged prothrombin time typically indicates the presence of severe hepatic parenchymal dysfunction and portends a poor prognosis.

PERIOPERATIVE MANAGEMENT PREOPERATIVE

Hepatic Evaluation and Preparation

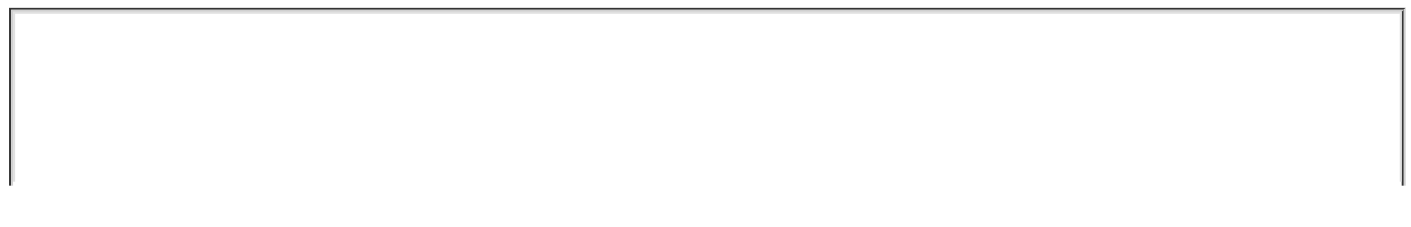
As with any preoperative evaluation, the history, physical exam, and laboratory tests are the initial modalities employed. While obtaining the history, inquiry should be made about risk factors and the presence of symptoms attributable to chronic liver disease. The history should include questions about prior episodes of jaundice and their relationship to surgical procedures and the anesthetic techniques used, blood product transfusions, use of alcohol and other recreational drugs, current

medications (including herbal preparations), family history of jaundice or liver disease, travel history, and an occupational history (exposure to hepatotoxins). In the review of systems, the patient should be asked about easy bruising, anorexia, weight loss or gain, fatigue, nausea, vomiting, pain with fatty meals, pruritus, abdominal distension, and episodes of gastrointestinal bleeding.

The usage of prescription, over-the-counter medications, and herbal preparations is ubiquitous. Polypharmacy is unfortunately the rule, rather than the exception, especially in elderly and debilitated patients who undergo major operations. Thus, the capacity of pharmacologic agents to injure the liver is an important perioperative concern. Some 500 to 1,000 therapeutic agents have been implicated in causing a broad spectrum of liver diseases.[122] These diseases may be classified in accordance with whether the drug produces primarily direct cell toxicity (necrosis), cholestasis, or steatosis. Most forms of drug-induced liver disease are benign and of little consequence (e.g., estrogen-induced cholestasis), producing only transient alterations of LFT. Severe drug toxicities, which are typically dose related (acetaminophen), or idiosyncratic (halothane), are responsible for 15 to 30% of cases of fulminant hepatic failure and 20 to 50% of cases of chronic nonviral

hepatitis. Moreover, when drug reactions produce hepatocellular necrosis, the estimated case fatality approaches 50%.

Drugs known to produce hepatocellular injury and centrilobular necrosis include acetaminophen, isoniazid, and methyldopa. Other cytotoxic drugs include oxyphenisatin, rifampin, papaverine, phenytoin, indomethacin, monoamine oxidase inhibitors, and amitriptyline. The use of dantrolene for treatment of muscle spastic disorders has been associated with the development of hepatic failure in patients receiving the drug for more than 60 days. Cholestatic reactions often result from drugs such as chlorpromazine, phenylbutazone, and androgenic and anabolic steroids. In at least one case, erythromycin (ethylsuccinate form) has caused hepatic failure that had initially been attributed to halothane administration.



A drug's potential to cause hepatotoxicity is influenced by various pharmacologic (other drugs) or pathophysiologic (hepatitis) factors. For example, the combination of trimethoprim and sulfamethoxazole is nearly five times more frequently associated with hepatotoxicity than sulfamethoxazole alone. By inducing hepatic microsomal drug-metabolizing systems, some drugs can markedly increase the injurious potential of others by altering their metabolism to favor the production of toxic metabolites. For example, phenobarbital increases the hepatotoxicity of various drugs, including chemotherapeutic agents (methotrexate) and antibiotics (tetracycline).[123]

Ethanol is obviously an important hepatotoxin. Although elective surgery is not contraindicated in patients with alcoholic steatosis, the mortality from acute alcoholic hepatitis, even without surgery, is significant. Animal studies indicate that alcohol ingestion increases the likelihood that centrilobular necrosis will develop after halothane anesthesia, which may relate to the ability of ethanol to increase hepatic hypoxia. Therefore, if alcoholic hepatitis is suspected, further examination of liver function is warranted before performing an elective operation.

The physical examination of the patient with chronic liver disease is particularly valuable because the patient may appear ill before there is laboratory evidence of hepatic dysfunction. The examination should focus on signs such as scleral icterus, jaundice, ascites, splenomegaly, palmar erythema, gynecomastia, asterixis, testicular atrophy, spider angiomata, petechiae, and ecchymosis. The liver may be enlarged with a tender soft and smooth edge if the patient has hepatitis, or firm and nodular with cirrhosis or malignancy. Patients with chronic hepatitis often have extrahepatic manifestations, including arthritis, skin rashes, and thyroiditis.

Acute liver failure has a distinct clinical presentation. Typically, nonspecific symptoms such as nausea and malaise are followed by the rapid onset of jaundice and subsequently altered mental status, which may progress to coma with clinical and radiologic evidence of cerebral edema.

If no suspicion of liver dysfunction arises from a thorough history and physical exam, then laboratory tests for liver function do not need to be routinely sent because of the low prevalence of disease. Routine testing may yield false-positive results, engendering patient anxiety and prompting the performance of expensive, unnecessary, and potentially dangerous invasive tests. If, however, hepatic dysfunction is known or suspected, then the degree of dysfunction should be quantified by applying either the Child-Pugh or Model of End-stage Liver Disease (MELD) scoring system. A dilemma arises when a patient without any risk factors or stigmata of liver disease is found to have one more abnormal LFT abnormalities on a recent blood test (e.g., routine yearly employment health assessment). The prudent action may be to delay surgery and repeat the tests later. This conservative approach helps ensure a patient is not in the early stages of a disease process (e.g., hepatitis) that may abruptly worsen and may minimize the medical-legal risk for the anesthesiologist. Acute hepatitis (viral, alcoholic, ischemic, or drug related) is associated with increased perioperative risk and mortality. For nonemergent procedures, supportive care allowing an improvement in their overall condition will diminish their perioperative risk. Therefore, in the presence of acute hepatic disease, elective surgery should be postponed (Fig. 39-16).

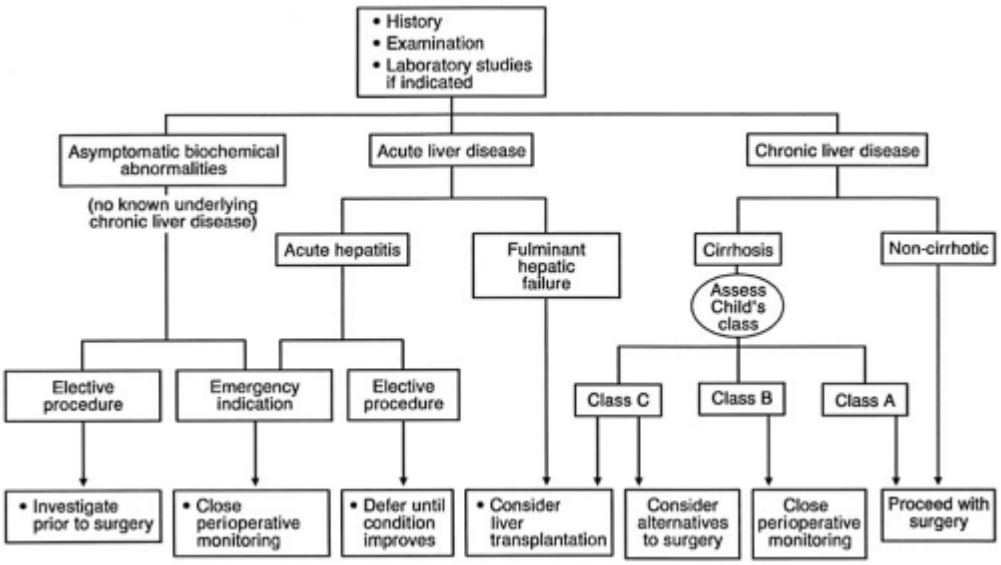


FIGURE 39-16. Preoperative approach to patient with known or suspected liver disease. (Modified with permission from Patel T: Surgery in the patient with liver disease. Mayo Clin Proc 74:593, 1999.)

Perioperative Risk Associated with Acute and Chronic Liver Disease

Because of our limited ability to support a failing liver, the perioperative risks associated with acute and chronic liver disease present significant challenges.[124] The increased surgical morbidity and mortality associated with varying degrees of liver insufficiency have been described in detail for over four decades.[125,126,127,128,129,130] What remains less clear, however, is whether perioperative outcomes can be improved with proactive interventions.

Regardless of the etiology, an increased magnitude of liver dysfunction is associated with a higher probability of morbidity and mortality.[131] Thus, it is important to quantify and grade preoperative liver dysfunction. Most risk assessment studies about liver disease address expected life span in reference to the prioritization of candidates for liver transplant. In 1999, a new classification system called MELD was designed to predict the outcome of decompressive therapy for portal hypertension.[132] MELD integrates weighted values of three parameters: serum bilirubin, INR, and serum creatinine:

MELD score = $0.957 \times \log_e$ (creatinine mg/dL) + $0.378 \times \log_e$ (bilirubin mg/dL) + $1.120 \times \log_e$ (INR) + 0.643

The model was developed from prospective data. MELD has since been adopted by the United Network of Organ Sharing in the United States to prioritize patients for liver transplantation.

Child and Turcotte first described their classification system in 1964.[125] They selected five parameters—serum albumin, serum bilirubin, ascites, encephalopathy, and nutritional status—each graded at one of three levels of severity, and combined to generate an assignment to one of three classes (A to C). Mortality was assessed following portosystemic shunt operations. In 1972, Pugh modified the Child-Turcotte system, replacing the subjective assessment of nutritional status with the more objective PT (Table 39-8).[133]

TABLE 39-8 Modified Child-Pugh Score

·PRESENTATION	·POINTS[a] ·1	·2	·3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Prothrombin time			
Seconds prolonged	<4	4–6	>6
International normalized ratio	<1.7	1.7–2.3	>2.3
Bilirubin (mg/dL)[b]	<2	2–3	>3
Ascites	Absent	Slight–moderate	Tense
Encephalopathy	None	Grade I–II	Grade III–IV

[a]Class A = 5–6 points; B = 7–9 points; C = 10–15 points.

[b]Cholestatic diseases (e.g., primary biliary cirrhosis) produce bilirubin elevations that are disproportionate to the hepatic dysfunction. Thus, the following adjustments should be made: assign 1 point for a bilirubin level of 4 mg/dL; points for bilirubin concentrations between 4 and 10 mg/dL; and 3 points for bilirubin >10 mg/dL.

From Kamath PS: Clinical approach to the patient with abnormal liver test results. Mayo Clin Proc 71:1089, 1996, with permission.

It is important to note that surgical mortality from hepatic shunt and transplant procedures is less than that from other major surgery.[134,135] In 1997, Rice et al. reported a retrospective analysis of 40 consecutive patients over a 5-year period undergoing general anesthesia for surgery, including 28 abdominal procedures, 2 coronary artery bypass grafts, 5 orthopaedic procedures, and 5 miscellaneous procedures.[129] By multiple logistic regression analysis, an INR greater than 1.6 and encephalopathy were associated with a greater than 10- and 35-fold increased mortality risk, respectively. However, Child classification and Pugh score failed to predict 30-day mortality. Also in 1997, Mansour and associates studied mortality of patients with liver disease undergoing abdominal surgery.[130] Their retrospective analysis from a single institution reported operative 30-day mortality on 92 cirrhotic patients during a 12-year period. Types of surgery were divided into four categories: cholecystectomy, hernia repair, gastrointestinal, and miscellaneous procedures. Twenty-six percent of operations were performed as emergencies. Child class A was associated with 10% mortality, class B with 30%, and class C with 82%. Gastrointestinal procedures and emergent operations were associated with the highest mortality. For comparison, the 3-month mortality in patients hospitalized for liver complications but not undergoing surgery was 4% for Child class A, 14% for class B, and 51% for class C.

MELD score has shown comparable prediction of short-term, nonoperative mortality in advanced

cirrhosis when compared with the Child classification. Except for liver transplantation and shunt procedures, MELD is not commonly used to predict perioperative morbidity and mortality.[136]

The scoring of liver disease is only one component of evaluating perioperative risks. Other considerations are the patient's age; coexisting diseases; and the type, location, and duration of the surgery. Accurate assessment and communication of perioperative risks is an essential condition of informed consent.

4 Scant data exist to support lengthy preoperative admissions for "optimization," especially for patients with mild hepatic dysfunction having minor operative procedures. Patients with severe or long-standing hepatic dysfunction, however, may benefit from aggressive inpatient correction of certain abnormalities. Liver-related conditions that may benefit from preoperative correction or optimization include ethanol dependency, coagulopathy, malnutrition, anemia, SBP, and hepatic encephalopathy.[137] Esophageal varices can be treated as previously discussed. Preoperative coagulopathy warrants particular attention. Ideally, coagulation abnormalities should be corrected preoperatively, and this should help minimize intraoperative blood loss and thereby decrease the risk of major complications, including development of postoperative HRS. Significant coagulation abnormalities must be corrected prior to performing a spinal or epidural anesthetic. Increased PT or INR in patients with either cholestasis or obstructive jaundice may respond to a few days of vitamin K therapy, but if unsuccessful or if the urgency of surgery does not allow adequate time for a response, administration of fresh frozen plasma is indicated. Platelet transfusion should be considered for patients with evidence of platelet dysfunction or thrombocytopenia (<100,000 cells/μL).

Minor operations do not cause postoperative liver dysfunction in healthy patients. Even patients with marginal hepatic function usually tolerate peripheral procedures without hepatic complications, including those who receive halothane anesthesia.[138] A randomized study in patients with mild alcoholic hepatitis compared spinal versus general anesthesia (enflurane plus N_2O plus opioid) and found no anesthesia-related differences in values of LFTs following peripheral or superficial surgery.[139]

Major operations (especially laparotomy) are often associated with hepatic dysfunction or injury. The magnitude of the abnormality depends more on the type of operation than on a particular anesthetic technique.[140] Nonetheless, hepatic dysfunction subsequent to major surgery is rarely of concern in healthy patients. In contrast, patients with advanced hepatic disease (marginal hepatic function) who undergo major operations, such as laparotomy, have extremely high postoperative morbidity and mortality.[141] These patients are probably unable to tolerate the surgical stress, which contributes to decreased hepatic oxygen supply.

Medications needed to control the myriad complications of severe liver disease should be continued throughout the perioperative period. Preoperative sedatives, when indicated, should be used in lower doses because of the marked derangements in pharmacokinetics and pharmacodynamics associated with advanced liver disease. These patients may have a full stomach, even if they have not taken food or fluid for several hours, because of hiatal hernia, massive ascites, and decreased gastric and intestinal motility. Therefore, premedication may include an H_2-receptor blocker, metoclopramide, as well as sodium citrate.

Anticipated Pharmacokinetic and Pharmacodynamic Alterations

Drugs administered to patients with advanced hepatic disease require careful titration against effect. It appears clear that encephalopathic changes are associated with clinically important alterations in the pharmacodynamics and pharmacokinetics of various medications. For example, cerebral uptake of benzodiazepines increases substantially, which may reflect an increase in the density or affinity of benzodiazepine receptors or a leaky blood-brain barrier. Data concerning the pharmacokinetics of midazolam in patients with advanced liver disease are conflicting. One study demonstrated a significant decrease in clearance and elimination half-life, whereas another study demonstrated only slightly impaired disposition in cirrhotic patients.[142,143] The pharmacokinetics of

single doses of sufentanil and propofol were found to be similar in cirrhotic patients and those with normal hepatic function, although some differences in elimination time were observed.[144,145] Such findings imply that administering infusions or multiple doses of certain intravenous drugs can result in prolonged pharmacologic effects because of impaired hepatic elimination in patients with advanced hepatic disease. The differences in the results of these studies are probably a consequence of certain differences in the binding proteins, as well as in the accumulation of endogenous binding inhibitors such as bilirubin. These findings might explain a smaller degree of midazolam protein binding in cirrhotic individuals, with a subsequent increase in the free fraction of the drug and enhancement of the pharmacologic effect in cirrhotic patients.

For thiopental, total plasma clearance and total apparent volume of distribution at the steady state are unchanged in cirrhotic patients. Therefore, the elimination half-life is not prolonged.[146] Thiopental has a low extraction ratio, so its clearance is independent of hepatic blood flow. Nonetheless, decreases in plasma protein binding, which are often unpredictable, may cause excessive pharmacologic responses to standard doses of the various agents used to induce anesthesia.

The plasma clearance of fentanyl is significantly lower in cirrhotic patients than in control subjects. The total apparent volume of distribution does not change, but the elimination half-life increases owing to decreased plasma clearance. With alfentanil, the free fraction also increases, and this agent exerts prolonged and pronounced effects in cirrhotic patients with advanced liver disease.[147]

The data regarding morphine pharmacokinetics in cirrhotic patients are contradictory. For example, Patwardhan and associates reported that the pharmacokinetics of morphine in cirrhotic patients and healthy people are similar. They suggested that the "reported intolerance to the central effects of morphine cannot be explained by impaired drug elimination and increased availability of morphine to cerebral receptors."[148] Other investigators, however, reported that the clearances of free morphine and its metabolites are decreased and their half-lives prolonged in cirrhotic patients compared with healthy control subjects.[149]

Although hepatic disease often produces substantial pharmacokinetic changes, it can also lead to important pharmacodynamic alterations. Patients with cirrhosis, particularly those with hepatic encephalopathy, are much more sensitive to sedatives (e.g., opioids, benzodiazepines) than are healthy people. For example, at equal plasma concentrations of diazepam, more pronounced encephalographic alterations occur in those with severe hepatic disease than in healthy people.[150] By contrast, pharmacologic responses to some medications decrease in patients with cirrhosis and portal hypertension as a result of the pathophysiologic changes associated with the disease. Increases in plasma concentrations of certain vasodilatory substances antagonize responses to catecholamines and other vasoconstrictors. Patients, as well as animals with portal hypertension, have elevations of plasma glucagon, which substantially reduces the responses of a variety of blood vessels to catecholamines.[81,83] Thus, while patients with advanced liver disease often require reduced doses of central nervous system depressants, they

require increased doses of catecholamine or addition of a nonadrenergic vasoconstrictor (vasopressin) when such therapy is needed to support blood pressure.

INTRAOPERATIVE

Monitoring and Vascular Access

In addition to using the routine array of monitors required by the American Society of Anesthesiologists (ASA), the need for invasive monitoring and degree of vascular access will be dictated by the severity of the liver disease and type of surgery. For severely ill patients or major operative procedures, cannulation of an artery is important for direct and continuous blood pressure monitoring, as well as for periodic determinations of blood gases, electrolytes, hematocrit, and other laboratory data as needed during surgery. Because patients with advanced liver disease may present with multiple complex hemodynamic abnormalities, a central venous

catheter, or even a pulmonary artery catheter may be of utility for confirming diagnoses of hypovolemia, abdominal compartment syndrome, distributive shock, or congestive heart failure, as well as for following responses to therapeutic intervention and for monitoring trends as the case progresses. In addition, because coagulopathies can accompany even mild hepatic insufficiency, the surgical bleeding encountered may be far in excess of that anticipated based on normal circumstances. Large-bore vascular access is encouraged for all but the most minor of procedures. Intraoperative monitoring of coagulation status presents formidable challenges; baseline values may be abnormal despite lack of bleeding. Intraoperative PT, PTT, and platelet count usually take too long for results to be of much utility during a large blood-loss operation. Assessing the activated clotting time and thromboelastography may be helpful, although clinical assessment remains the standard for intraoperative diagnosis of coagulopathy.[151]

Selection of Anesthetic Technique

For most cases, the presence of liver disease will not alter the choice of anesthetic technique based on other common considerations. Regional anesthesia is generally the preferred technique in patients without coagulation abnormalities who are undergoing peripheral surgery. However, it would be difficult to justify using regional anesthesia or analgesia for patients with overt coagulopathies or for those having major or lengthy operations. Local anesthesia with sedation is usually the least invasive for relatively minor procedures, such as sclerotherapy. Adequate sedation is essential to minimize sympathetic stimulation and resultant decreases in hepatic blood flow and oxygen delivery. A short-acting benzodiazepine, such as midazolam combined with remifentanil, or a low dose of fentanyl, will usually provide sedation, anxiolysis, and analgesia. As mentioned, patients with advanced hepatic disease have extensive pharmacodynamic and pharmacokinetic abnormalities, so each medication should be titrated carefully to achieve the desired effect.

Induction of General Anesthesia

Rapid-sequence induction (or awake intubation of the trachea) is indicated in patients perceived to be at risk for aspiration pneumonitis (full stomach). All widely used intravenous induction agents have been administered to patients with advanced hepatic disease. For patients who do not require rapid-sequence induction, careful titration of the anesthetic will minimize hemodynamic lability while achieving the desired anesthetic effect. Succinylcholine is a reasonable choice to facilitate endotracheal intubation, after screening for the usual contraindications (e.g., prolonged immobility or critical illness, hyperkalemia). Although severe liver dysfunction can markedly decrease cholinesterase activity and may prolong the effect of succinylcholine somewhat, this rarely causes a clinical problem. When using nondepolarizing neuromuscular blocking agents to induce anesthesia, consider that the initial dose to achieve total relaxation may be higher than in healthy patients. This increased dose requirement results primarily from pharmacokinetic alterations and pertains to relaxants such as rocuronium, atracurium, and pancuronium, but not to vecuronium.

Maintenance of Anesthesia

Intraoperative liver injury can develop from oxygen deprivation, the stress response, drug toxicity, blood transfusion, and infection. An impairment of hepatic oxygen supply can occur at any step in the process of delivering oxygen to the liver. Hypoxic hypoxia may result from inadequate FIO_2, right-to-left-shunting, or

$$\dot{V}/\dot{Q}$$

mismatch. Anemic hypoxia may develop when the oxygen-carrying capacity of the blood (hematocrit) is inadequate. Circulatory hypoxia may result from systemic (hypovolemia, arterial hypotension, reduction in cardiac output) or regional (decrease in hepatic blood flow and oxygen supply) hemodynamic disorders. Delivery of blood and oxygen to the liver may decrease owing to systemic circulatory disturbances, surgical manipulation of the liver or adjacent structures, or from endogenous vasoconstrictors (e.g., renin-angiotensin, catecholamines, antidiuretic hormone).

Anesthetics, exogenous vasoconstrictors, and other medications that impair electron transport or cellular metabolism could also induce histotoxic hypoxia.

In addition to ensuring adequate blood flow and oxygen supply, one must always consider the oxygen supply–demand relations in the liver. Experimental data indicate that severe surgical stress during fentanyl (moderate dose) anesthesia can produce a somewhat higher hepatic oxygen supply and uptake than an identical stress during isoflurane anesthesia; this results in similar values of hepatic oxygen supply–uptake ratio with the two anesthetics.[152] Taking this into consideration, the guiding principle is to maintain adequate pulmonary and cardiovascular function, including cardiac output, blood volume, and perfusion pressures. One should strive to prevent arterial hypotension by adequate blood and volume replacement, and by avoidance of relative overdoses of anesthetics or other blood pressure-lowering drugs. Vasodilation, a reduced perfusion pressure, and a decrease in blood velocity will inevitably increase oxygen extraction in all tissues, including those in the preportal area. A decrease in blood velocity and increased oxygen extraction will cause a decrease in venous oxygen content—in this case, decreased oxygen content in the portal venous blood. A reduction in portal blood oxygen content or flow usually leads to a compensatory increase in hepatic arterial flow. Thus, hepatic injury after moderate systemic arterial hypotension is a relatively rare event. However, in the presence of severe liver dysfunction, the ability of autoregulatory mechanisms to increase hepatic arterial blood flow may be diminished or abolished. Therefore, with severe hepatic disease, the hepatic arterial blood flow may not increase appropriately when portal blood flow or oxygen content decreases. This might lead to hepatic oxygen deprivation. Thus, the lesson is clear: take all precautions to avoid arterial hypotension and low cardiac output states.

A particular challenge exists when the operative procedure is on the splanchnic tissues or on the liver itself. In these cases, one objective is to minimize potential for hemorrhage by decreasing the portal blood pressures. Judicious limitation of fluids during the operative resection to maintain a low CVP (<5 mm Hg) has been associated with significantly decreased blood loss, while maintaining renal function in a retrospective analysis of hepatic resection cases.[153]

When performing general anesthesia, it seems prudent to avoid halothane, and possibly enflurane, because they cause the most prominent decreases in hepatic blood and oxygen supply, and are associated with the highest incidences of postoperative hepatic dysfunction. Isoflurane and probably sevoflurane appear to be the anesthetics of choice for inhalational anesthesia. Nitrous oxide does not appear to be associated with major hepatic complications in patients with advanced liver disease, despite its abilities to produce sympathomimetic effects and to limit the maximum oxygen content of arterial blood.

Consideration for the clinical use of halothane should take into account the following issues and concerns:

1. In children, halothane hepatitis is extremely uncommon, even after repeated exposures to halothane.
2. In adults, the disease rarely occurs after a single exposure to halothane; repeated anesthetics, however, especially in obese, middle-age women, over a brief period (<6 weeks) seem to substantially increase the risk of the disease.
3. No totally reliable tests exist for detecting halothane hepatitis or susceptibility to the disease.
4. Halothane can markedly decrease hepatic blood flow and oxygen supply, and often causes mild, transient liver injury.
5. Halothane anesthetics have potential legal liability implications, which may plague anesthesiologists whenever unexplained hepatic dysfunction develops in the postoperative period.

Why use halothane? The main advantages of halothane over other agents appear to be its low cost and its utility as an inhalational induction agent. However, when potential legal costs are factored into the equation, the cost–benefit analysis might actually favor the elimination of halothane from anesthesia practice.[118] Sevoflurane has emerged as the alternative inhalation induction agent of choice.

Opioids are reasonable to include in the anesthetics of patients with hepatic disease. Despite certain pharmacokinetic concerns (decreased clearance and prolonged half-life), fentanyl is probably the opioid of choice. Interestingly, fentanyl neither decreases the hepatic oxygen or blood supply nor prevents an increase in hepatic oxygen requirements when used in moderate doses. Therefore, the oxygen supply–demand relation in the liver is no better with a fentanyl-based anesthetic than during anesthesia with isoflurane.[152] It seems that anesthetic management using inhaled agents (especially isoflurane or sevoflurane) alone or in combination with nitrous oxide, and small doses of fentanyl would be the method of choice, provided that adequate hemodynamic parameters are maintained. Many other agents also have favorable risk–benefit profiles for patients with advanced hepatic disease.

Because substantial alterations in pharmacokinetics occur in patients with advanced hepatic disease, dose requirements for a variety of medications can be unpredictable. For example, the hepatic clearance of lidocaine may be increased by more than 300% and benzodiazepines by more than 100%. Drugs that bind to proteins usually have a decreased volume of distribution, so a lower initial dose would be required. The volume of distribution of other agents, such as muscle relaxants, may increase substantially for various reasons, including an increase in γ-globulin concentration or the presence of edema. These factors appear to account for the so-called "resistance" to such agents and explain why the initial dose requirements of these medications are increased in cirrhotic patients. However, subsequent dose requirements may be decreased, and drug effects prolonged, owing to decreases in hepatic blood flow and impaired hepatic clearance, and possible concurrent renal dysfunction. Advanced hepatic disease does not appear to significantly affect the pharmacokinetics of vecuronium, although some dose-dependent pharmacokinetic alterations may occur. These alterations may be the result of a limited hepatic uptake capacity, which is usually exceeded at doses greater than 0.15 mg/kg. At lower doses, hepatic dysfunction does not affect the pharmacokinetics or duration of action of vecuronium.[154]

Severe hepatic dysfunction per se does not contraindicate the use of any specific muscle relaxant. Atracurium (and cis-atracurium) have a theoretical advantage because their elimination occurs mainly by Hofmann decomposition, making their clearance relatively independent of renal or hepatic function. Despite elimination and clearance profiles, which match those in healthy patients, the volumes of distribution of these agents are larger in cirrhosis and, accordingly, the distribution half-life is shorter in patients with hepatorenal dysfunction compared with normal individuals. The only situation that appears to prolong the elimination half-life of atracurium is marked metabolic acidosis, which may decrease the rate of Hofmann decomposition.[155]

The pharmacokinetics of many muscle relaxants in conditions of cholestasis and obstructive jaundice may be altered: prolonged duration of action has been demonstrated.[156] However, especially when postoperative ventilation is planned, any nondepolarizing agent can be used successfully. Titration of any relaxant must be made according to transcutaneous nerve stimulation monitoring. Although pharmacokinetic studies in patients with hepatic cirrhosis provide interesting data that are helpful in understanding the pathogenic aspects of chronic liver disease, the results do not necessarily have significant value for predicting the safety of a drug. The degree of hepatic dysfunction affects the degree of pharmacokinetic disorder, and both are dynamic processes that may vary during the course of a procedure; therefore, the best way to avoid complications when administering medications is to titrate to effect.

Fluids and Blood Products

Standard indications for intravascular resuscitation and transfusion of blood products apply to the patient with hepatic insufficiency. No prospective data exist, demonstrating superiority of either a crystalloid-based or colloid-based resuscitation strategy. Because of this lack of conclusive data,

the choice of fluid continues to engender spirited opinion and debate. Clearly, colloids represent a higher cost, and some may contribute to coagulopathy, especially at higher doses; however, despite these limitations and lack of documented benefit, they remain the resuscitation fluid of choice for some practitioners.[157] Normovolemic hemodilution has been described as a blood conservation technique for hepatic resections with some success, but is not routinely used for nonhepatic cases in patients with liver insufficiency.[158]

Monitoring of central filling pressures may assist in administering proper fluid therapy and maintaining renal perfusion. The contents of infused solutions should be initially selected and then adjusted based on periodic determinations of serum electrolyte concentrations.

Vasopressors

Patients with hepatic disease, either parenchymal or cholestatic, have peripheral vasodilatation, systemic shunting,

and a reduced sensitivity to vasopressor drugs. The exact reason for the decreased pressor sensitivity is unclear. However, data from in vitro and in vivo experiments indicate that bile acids contribute to the vasodilatation and hypotension that often occur in patients with biliary obstruction.[120] Conceivably, a decreased responsiveness to vasoactive substances (including catecholamines) is responsible for the interesting and clinically important observation that patients with biliary obstruction are often intolerant of even small blood losses. A moderate loss (10%) of blood volume in animals with experimentally induced biliary obstruction causes severe (~50%) arterial hypotension. Intact animals respond to such blood loss with an approximately 15% decrease in blood volumes in both the pulmonary and splanchnic vascular beds. Animals with biliary obstruction have only a 7% decrease of their pulmonary blood volume and no change in splanchnic blood volume.[121] If we can extrapolate these results to humans, patients with biliary obstruction would have an impaired hemodynamic response to blood loss. An impairment of the ability to translocate blood from pulmonary and splanchnic blood reservoirs to the systemic circulation would render patients highly susceptible to arterial hypotension from bleeding. Furthermore, the results would indicate the urgency of expeditiously replacing perioperative volume losses in this patient population. The anesthesiologist should be aware that biliary decompression can be accompanied by severe cardiovascular collapse.[159]

POSTOPERATIVE

Liver Dysfunction and Management

Postoperative liver dysfunction is common but rarely severe (Table 39-9). Although it is usually asymptomatic, it may progress to overt liver failure on rare occasions. Mild, transient increases in serum concentrations of hepatic enzymes are often detectable within hours of surgery, but do not usually persist for more than 2 days. Such subclinical hepatocellular injury occurs in as many as 20% of patients who receive enflurane anesthesia, and in nearly 50% of those receiving halothane. Jaundice rarely occurs in healthy patients following minor operations, but appears in up to 20% of patients after major surgical procedures.[160] Jaundice is typically the earliest sign of serious hepatic or hepatobiliary dysfunction, and therefore, requires prompt medical attention. Marked increases of serum aminotransferase activities are an ominous finding, reflecting extensive hepatocellular necrosis.

TABLE 39-9 Causes of Postoperative Liver Dysfunction

Hepatocellular	Drugs Anesthetics Ischemia

	Shock, hypotension, iatrogenic injury Viral hepatitis
Cholestasis	Benign postoperative cholestasis Sepsis Bile duct injury Drugs Antibiotics, antiemetics Choledocholithiasis or pancreatitis Cholecystitis Gilbert syndrome

Some cases of severe postoperative liver dysfunction are apparent hours after surgery (e.g., with hypoxic injury), whereas other cases are delayed in onset for days to weeks (e.g., with anesthesia-induced hepatitis). With severe postoperative liver dysfunction, residual liver function may fall below a critical threshold, leading to the development of hepatic encephalopathy. If encephalopathy occurs within 2 weeks of the onset of jaundice or within 8 weeks of the initial manifestation of hepatic disease, the disorder is defined as fulminant hepatic failure. Fulminant hepatic failure has a variety of causes.[161] The mortality rate from fulminant hepatic failure correlates with the severity of encephalopathy. The shorter the interval between the appearance of jaundice and presentation of encephalopathy, the worse the prognosis.

5 Successful treatment of patients with fulminant hepatic failure requires the clinician to make prompt and accurate predictions about the outcome of the disease. Proper recognition of reversible disease obviates unnecessary orthotopic liver transplantation (OLT). Irreversible cases of fulminant hepatic failure require immediate identification. Otherwise, the severe complications of fulminant hepatic failure that develop may render patients unacceptable candidates for OLT. Several bioartificial liver (BAL) devices are in various stages of development to provide "liver replacement therapy."[162] Most use porcine or human hepatocytes as a bridge to transplantation or regeneration. Other artificial liver devices are based on albumin dialysis and are undoubtedly effective in removing protein-bound toxins, and uncontrolled evidence shows some survival benefit. Although initial animal studies demonstrated survival benefit of BAL devices, to date, no prospective randomized trial has shown improved survival using these devices.[163]

Hemolysis and Transfusion

Reabsorption of large surgical or traumatic hematomas and transfusions of red blood cells are major causes of postoperative jaundice in the absence of overt hepatocellular dysfunction. At least 10% of transfused erythrocytes hemolyze within the initial 24 hours following a blood transfusion (the bilirubin load is about 250 mg per unit transfused). A normal liver readily clears the bilirubin that results from mild hemolysis. With severe hemolysis, the excessive bilirubin leads to unconjugated hyperbilirubinemia, which persists until the liver conjugates and excretes the excess bilirubin. Excessive bilirubin loads can also result from severe hemolytic disorders, including hemoglobinopathies (e.g., sickle cell disease) or derangements of erythrocyte metabolism (e.g., glucose-6-phosphate dehydrogenase [G6PD] deficiency). These problems may be seen in the perioperative period as a result of hypovolemia, hypoxia, hypothermia or stress, exacerbations of sickle cell disease, or G6PD deficiency. Other causes of significant hemolysis include transfusion reactions and prosthetic cardiac valves.

CAUSES OF POSTOPERATIVE LIVER DYSFUNCTION UNRELATED TO PERIOPERATIVE FACTORS

Asymptomatic and Preexisting Hepatic Injury

Although postoperative liver dysfunction can clearly result from anesthetic or surgical interventions, it is often unrelated to perioperative factors. For example, it can arise from

preexisting liver disease that has escaped preoperative detection. According to a study by Schemel, the prevalence of acute, asymptomatic liver disease in a healthy-appearing surgical population may approach 0.25%.[164] During a 1-year period, Schemel and coworkers performed multiple laboratory screening tests in 7,620 patients (ASA Physical Status I) scheduled for elective surgical procedures. Eleven of these patients (approximately 1 per 700) were found to have abnormal increases of AST, ALT, and LDH, and the proposed surgeries were cancelled. All 11 proved to have overt hepatic disorders (infectious mononucleosis, viral hepatitis, cirrhosis, or alcoholic hepatitis), and three later became clinically jaundiced (overall incidence of jaundice of 1:2,540). If any of these three patients actually received a halogenated anesthetic, with the subsequent development of overt hepatic disease between the 6th and 14th postoperative days, their diseases may well have been diagnosed erroneously as anesthesia-induced hepatitis. None of the 7,609 patients who underwent anesthesia and surgery exhibited laboratory evidence of preexisting hepatic disease, and none developed unexplained postsurgical jaundice. Another clinical study has documented a prevalence of unsuspected preoperative hepatic dysfunction similar to that reported by Schemel.([165]) Thus, it appears that approximately 1 of every 2,500 healthy patients who undergo surgery and anesthesia may have clinically significant postoperative liver dysfunction that is totally unrelated to surgery or anesthesia, and that a preexisting disease is more likely than an anesthetic agent to cause severe postoperative liver dysfunction.

Congenital Disorders

Gilbert's syndrome (familial unconjugated hyperbilirubinemia) is the most common cause of jaundice in the United States. It is a benign metabolic disorder characterized by a decrease in the activity of the hepatic enzyme bilirubin glucuronyltransferase, which is required for hepatocyte uptake of unconjugated bilirubin. Affected individuals may have modest increases in their unconjugated bilirubin level preoperatively, but become jaundiced postoperatively secondary to exacerbation of the condition by commonly occurring postoperative factors such as stress, fasting, fever, and infection. The diagnosis is suggested by the combination of clinical (jaundice without dark urine) and laboratory (unconjugated hyperbilirubinemia) abnormalities.

Crigler-Najjar syndrome (congenital nonhemolytic jaundice) is a much less common congenital disorder that exhibits either an absence (type 1) or marked decrease (type 2) of bilirubin glucuronyltransferase producing unconjugated hyperbilirubinemia. Surgical and anesthesia-related problems are apparently minimal in patients with either Gilbert's or Crigler-Najjar syndrome.

Conjugated bilirubin is excreted into the bile by a rate-limited, energy-requiring mechanism. Dubin-Johnson and Rotor's syndromes are congenital disorders that exhibit a defect in the biliary excretory mechanism, resulting in an increased conjugated bilirubin level. Surgery can exacerbate these abnormalities.

CONCLUSION: PREVENTION AND TREATMENT OF POSTOPERATIVE LIVER DYSFUNCTION

Identifying patients at high risk for developing liver dysfunction or for having an exacerbation of preexisting liver disease is of utmost importance for minimizing the morbidity and mortality in such patients. Thus, a careful preoperative evaluation is required to detect preexisting liver disease and to identify important risk factors for anesthesia-induced hepatic injury. Perioperative physicians who are armed with an understanding of the interactions among liver disease, surgical procedures, the physiologic stress response, and anesthetic interventions can formulate and orchestrate therapeutic plans to optimize patient outcome.

When liver abnormalities are recognized preoperatively, it is prudent to defer elective procedures until the course of the disease can be determined. For operations that cannot be deferred,

clinically significant pathophysiologic changes associated with the liver disease (e.g., coagulopathy, fluid and electrolyte abnormalities) should be corrected as soon as practical.

Which anesthetic technique best preserves the function of the liver? The choice of anesthesia is usually an insignificant issue for peripheral or minor surgery (operations that do not affect splanchnic blood flow), even in patients with severe liver disease. Regional anesthetic techniques, when appropriate (e.g., absence of coagulopathy), are often preferred because they minimize the cardiovascular and pulmonary perturbations associated with anesthesia. In addition, at least for certain types of procedures such as laparoscopic cholecystectomy, the addition of epidural anesthesia to a general anesthetic technique may decrease the circulating levels of endogenous catecholamines by mitigating the surgical stress response.[166] This effect seems to persist into the postoperative period, when epidural pain management is maintained.[167] The selection of pharmacologic anesthetic agents may also have important implications, especially in patients undergoing major operations. A rational approach to general anesthesia would include the use of agents that preserve cardiac output and do not adversely affect the oxygen supply–demand relationships of the liver (e.g., isoflurane, sevoflurane, fentanyl, remifentanil). Throughout the perioperative period, medications must be carefully titrated to achieve the desired pharmacologic effects while minimizing untoward effects; this can be challenging because pharmacokinetics and pharmacodynamics of many drugs are often unpredictable in patients with hepatobiliary dysfunction.

A primary goal during the maintenance of anesthesia is to ensure the adequacy of splanchnic, hepatic, and renal perfusion, especially in patients with severe liver disease who undergo major abdominal operations. Although well tolerated in the absence of liver disease, hepatic hypoperfusion in patients recovering from infectious hepatitis or chronic alcoholics can have devastating consequences. These patients may be highly susceptible to hepatic ischemia because of critically compromised liver blood flow, impaired pressure-flow autoregulation, and a dysfunctional hepatic arterial buffer response. In such cases, invasive monitoring of the circulation may be indicated so acute hypoperfusion can be rapidly detected and expeditiously treated.

Although anesthesia-induced hepatitis rarely occurs, we must remain aware of the association between this disorder and the use of halogenated vapors. As halothane usage for inhalation inductions and general anesthesia maintenance is increasingly supplanted by sevoflurane, the incidence of this complication decreases with each passing year.[168] In the final analysis, completely avoiding the use of halothane is perhaps the single most effective way to decrease the incidence of anesthesia-induced hepatitis.

When postoperative hepatic injury occurs, the mainstay of therapy is supportive. A thorough search is required to identify any reversible cause of the injury. The hepatotoxic potentials of all medications merit consideration. Discontinue any medication that is suspect. Investigate all potential sources of sepsis because the presence of sepsis mandates rapid, aggressive therapy. Consider extrahepatic biliary obstruction in the differential diagnosis because this may require prompt surgical intervention. In some cases, identifying the pathogen or

documenting the type of hepatic injury requires a percutaneous liver biopsy. Judicious use of biochemical tests and imaging studies, which can help delineate hepatocellular from cholestatic dysfunction, usually shortens the list of diagnostic possibilities and provides useful prognostic information.

Unfortunately, fulminant hepatic failure is often survived only with orthotopic liver transplantation. Given that organ donors are far fewer than those in need, many must endure our currently inadequate means of supporting this essential organ when it fails. Caring for patients whose liver is failing can be a frustrating endeavor. Perhaps the future holds promise for a supportive intervention as dialysis has provided for renal failure. In the mean time, our efforts at mitigating the tragedy of liver failure will continue to be best directed at prevention.

Chapter 40

Anesthesia for Orthopaedic Surgery

Terese T. Horlocker

Denise J. Wedel

KEY POINTS

1	Orthopaedic surgery is well suited to neuraxial and peripheral regional anesthetic techniques. Improved surgical outcomes have increased their popularity.
2	The frequency of neurologic injuries following scoliosis correction is approximately 1%, with half of these resulting in partial or complete paraplegia. Neurophysiologic monitoring and the wake-up test are often used to monitor spinal cord integrity.
3	Orthopaedic procedures are frequently associated with significant blood loss. The anesthesia care provider must be knowledgeable of blood salvage techniques, induced hypotension, and normovolemic hemodilution to decrease blood loss and transfusion requirements.
4	Visual changes, including blindness, may occur following major spine surgery.
5	Continuous brachial plexus infusions may be used during hospitalization or at home with disposable pumps.
6	Proper positioning for orthopaedic procedures is paramount to providing optimal surgical conditions, as well as avoiding potential stretch and compression injuries.
7	Neuraxial and peripheral continuous blockade improve surgical outcome, including increased joint range of motion and decreased hospital stay, following total knee replacement.
8	Orthopaedic patients are at high risk for thromboembolic complications, with the highest risk reported among hip fracture patients.

9	Regional anesthetic techniques reduce the risk of thromboembolism. However, they do not currently replace the need for pharmacologic prophylaxis.

Surgical procedures involving bone, muscle, and related soft tissues require similar monitoring and anesthetic techniques, regardless of the patient's age. For example, many orthopaedic surgical procedures lend themselves to the use of regional anesthesia. Regional anesthetic techniques allow intraoperative surgical anesthesia and postoperative pain relief, and create a further subspecialty within orthopaedic anesthesia. Another seemingly trivial but vitally important part of orthopaedic anesthesia is patient positioning. Unusual patient positioning is a common feature in orthopaedic cases. Experience and specific knowledge are required to produce optimal surgical conditions and avoid potential injuries. Orthopaedic procedures are frequently associated with major blood loss. The orthopaedic anesthesiologist must be experienced in techniques that decrease these risks, must be able to use intraoperative hypotension and blood salvage techniques, and must be able to manage transfusion-related complications. The orthopaedic surgical patient is also at risk for deep venous thrombosis and pulmonary embolus. Knowledge of the current pharmacologic and mechanical methods of thromboprophylaxis is required to prevent the occurrence of these thromboembolic complications. Likewise, potential interactions between anticoagulants and anesthetic drugs or regional anesthetic techniques must be thoroughly understood to reduce the risk of perioperative bleeding.

Knowledge of specific orthopaedic surgical techniques, including duration, extent, predicted blood loss, and associated complications, is invaluable for providing the best possible

patient care. Orthopaedic surgical patients usually require early mobilization and rehabilitation, both of which can be expedited by appropriate selection of anesthetic techniques and management of postoperative analgesia. In this chapter, we discuss the various aspects of orthopaedic anesthesia, emphasizing the anesthetic techniques and patient management issues unique to this practice.

PREOPERATIVE ASSESSMENT

The anesthesiologist's preoperative assessment is crucial to the formulation and execution of the anesthetic plan. The patient must be evaluated for preexisting medical problems, previous anesthetic complications, potential airway difficulties, and considerations relating to intraoperative positioning. This evaluation, coupled with an appreciation of the surgeon's needs, is used to formulate the anesthetic plan.

Patients with *coronary artery disease* pose unique problems to the anesthesiologist. Overall, patients undergoing orthopaedic procedures are considered at intermediate risk for cardiac complications perioperatively. However, it is often difficult to assess exercise tolerance or a recent progression of cardiac symptoms because of the limitations in mobility induced by the underlying orthopaedic condition. As a result, pharmacologic functional cardiovascular testing may be warranted based on clinical history. Perioperative cardiac morbidity may be decreased by the

initiation of beta-blockade.[1]

Many patients undergoing orthopaedic surgery have *rheumatoid arthritis.* Systemic manifestations of this disease include pulmonary, cardiac, and musculoskeletal involvement. Particularly significant to the anesthesiologist is involvement of the cervical spine, temporomandibular joint, and larynx. Rheumatoid involvement of the cervical spine may result in limited neck range of motion, which interferes with airway management. Atlantoaxial instability, with subluxation of the odontoid process, can lead to spinal cord injury during neck extension. Patients with rheumatoid arthritis are often on chronic steroid therapy and may require perioperative steroid replacement.

Preoperative evaluation should include a focused *physical examination.* Patients should be assessed for limitation in mouth opening or neck extension, adequacy of thyromental distance (measured from the lower border of the mandible to the thyroid notch), and state of dentition. The heart and lungs should be auscultated. In addition, the site of proposed injection for regional anesthesia should be assessed for evidence of infection and anatomic abnormalities or limitations. At this time, the patient should also be evaluated for any potential positioning difficulties related to arthritic involvement of other joints or body habitus.

CHOICE OF ANESTHETIC TECHNIQUE

Many orthopaedic surgical procedures, because of their localized peripheral site, lend themselves to regional anesthetic techniques. Neural structures may be blocked at the peripheral nerve, plexus, or neuraxial level. Regional anesthetics offer several advantages over general anesthetics among these patients, including improved postoperative analgesia, decreased incidence of nausea and vomiting, less respiratory and cardiac depression, improved perfusion via sympathetic block, reduced blood loss, and decreased risk of thromboembolism. It is important to explain these benefits and encourage regional anesthesia where appropriate. The regional technique and local anesthetic solution used depend on a variety of factors, including duration of surgery, length of desired postoperative analgesia, and indication for postoperative sympathectomy. Likewise, any patient who has an absolute contraindication to regional anesthesia (patient refusal, infection at the site of needle placement, systemic anticoagulation) is a candidate for general anesthesia. The risks and benefits of regional and general anesthesia are discussed in the following sections.

SURGERY TO THE SPINE

Spinal Cord Injuries

Spinal injury occurs at a rate of 11,000 cases per year. Approximately one-half of these are at the cervical level. The examination of a person with a suspected spinal cord injury begins with a prompt neurologic examination and a rapid assessment for possible injury to other systems. Cervical injuries are frequently associated with head injury, thoracic fractures with pulmonary and cardiovascular injury, and lumbar fractures with abdominal and long bone injuries. The patient should be examined immediately for signs of respiratory insufficiency, airway obstruction, rib fractures, and chest wall or facial trauma.

Serial neurologic examination is necessary to assess function of the spinal cord above the level of the fracture. The fifth cervical segment is perhaps the most important in providing clinical evidence of cervical spinal injury. This segment controls motor function of the deltoid, biceps, brachialis, and brachioradialis muscles. If these muscles are flaccid, the fifth cervical nerve is involved, and there will be partial diaphragmatic paralysis. A complete lesion at the fourth cervical segment is not compatible with survival unless artificial respiration is initiated. Spinal shock occurs acutely and results in complete cessation of spinal cord functions below the level of the lesion. This results in flaccid paralysis, loss of visceral and somatic sensation, and paralytic ileus. Vasopressor reflexes are also lost. Spinal shock may persist from a few days to 3 months.

Surgical treatment of spinal cord injuries is based on the presence or absence of neurologic function and the radiographic evaluation of vertebral displacement and instability. Patients with unstable spines who are not quadriplegic or paraplegic may become so during transport or

positioning for surgery.

Tracheal Intubation

Airway management is critical in patients with cervical spinal cord injury. The most common cause of death with acute cervical spinal cord injury is respiratory failure. All patients with severe trauma or head injuries should be assumed to have an unstable cervical fracture until proven otherwise radiographically. During transport, the patient should be moved on a spine board with the neck immobilized to prevent further injury. Awake fiberoptic-assisted intubation may be necessary, with general anesthesia induced only after voluntary upper- and lower-extremity movement is confirmed. Blind nasotracheal intubation may be used if there is no evidence of facial or basal skull fractures. In a truly emergent situation, oral intubation with direct laryngoscopy is the usual approach. The trachea should be intubated with minimum flexion or extension of the neck.

Respiratory Considerations

Ventilatory impairment increases with the higher level of spinal injury. A high cervical lesion that includes the diaphragmatic segments (C4–C5) results in respiratory failure, and death occurs unless artificial pulmonary ventilation is used. Lesions between C5 and T7 cause significant alterations in respiratory function, owing to the loss of abdominal and intercostal

support. The indrawing of flaccid thoracic muscles during inspiration produces paradoxical respirations, resulting in a vital capacity reduction of 60%. Inability to cough and effectively clear secretions results in atelectasis and infection.

Cardiovascular Considerations

During spinal shock, there is loss of sympathetic vascular tone below the injury. If the cardioaccelerator fibers (T1–T4) are damaged, bradycardia results. Therefore, hemorrhagic shock may not produce a compensatory tachycardia in these patients; the rate may remain at 40 to 60 beats/min. Monitoring of central venous or pulmonary artery pressures may be necessary as an aid to fluid management in a patient with a high cervical lesion. Autonomic instability should be treated with vasoconstrictors, vasodilators, and positive chronotropic drugs as needed.

Succinylcholine-Induced Hyperkalemia

Hyperkalemia may develop after administration of succinylcholine to a patient with spinal cord injury. The amount of potassium released depends on the extent of the patient's motor deficit. It is usually safe to administer succinylcholine for the first 48 hours. After that time, there is a proliferation of acetylcholine receptors in muscle, and they become supersensitive to depolarizing muscle relaxants.[2] The increases in serum potassium are maximal between 4 weeks and 5 months after spinal injury. Serum potassium levels may increase from normal to as high as 14 mEq/L, causing ventricular fibrillation or cardiac arrest. Therefore, succinylcholine should be avoided in all spinal cord-injured patients after 48 hours. There are no contraindications to the nondepolarizing agents.

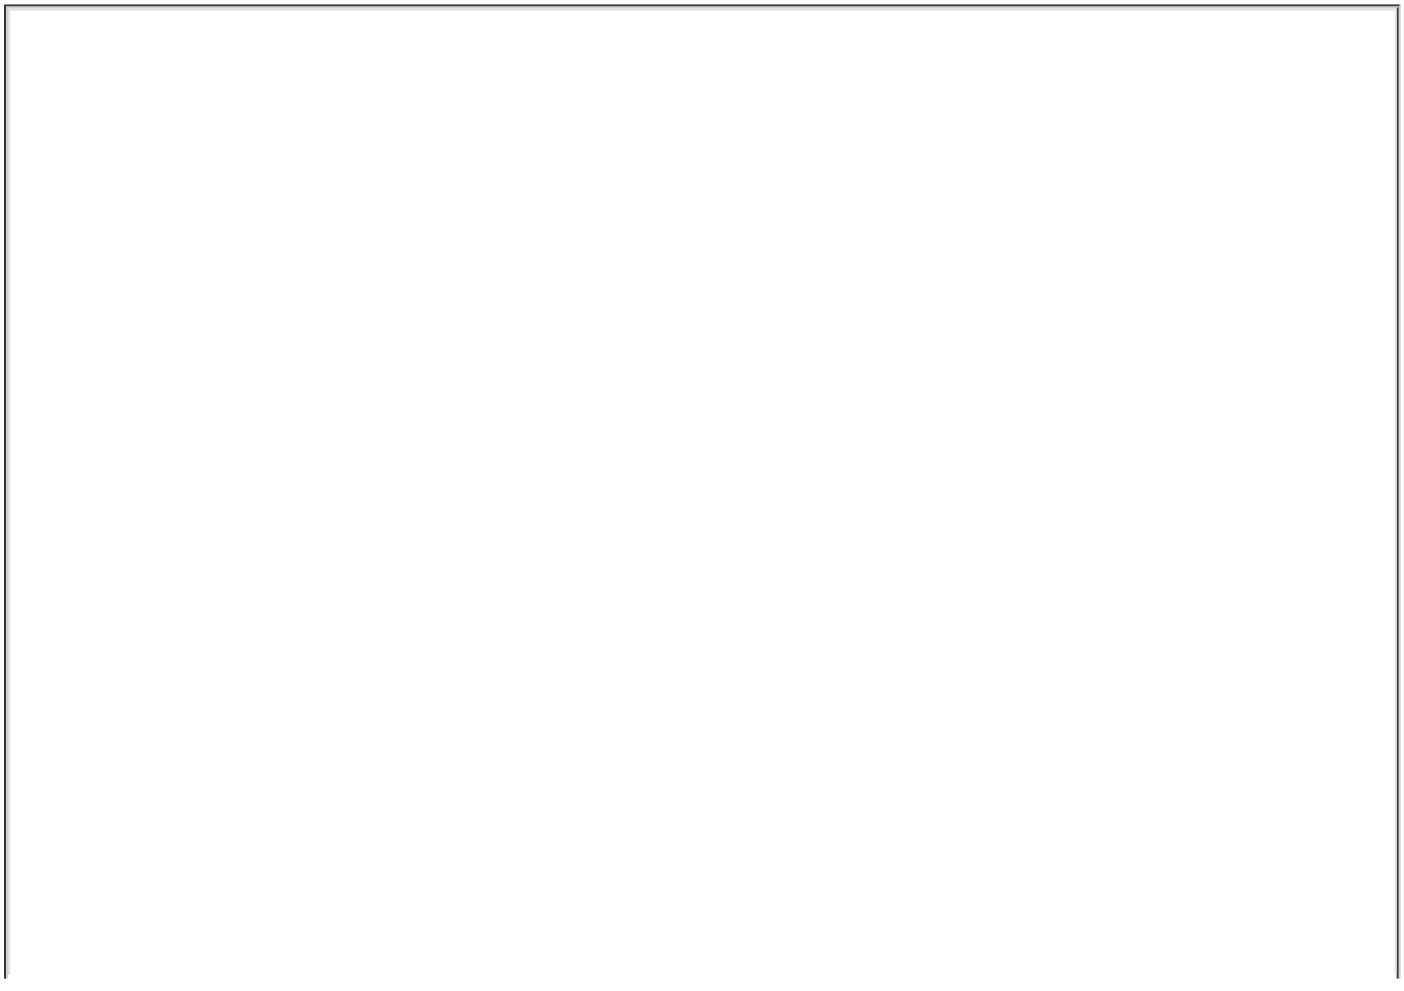
Temperature Control

Disruption of the sympathetic pathways carrying temperature sensation, and subsequent loss of vasoconstriction below the level of injury, causes spinal cord-injured patients to be poikilothermic. Maintenance of normal temperature can be achieved by applying exogenous heat to the skin, increasing ambient air temperature, warming intravenous fluids, and humidifying gases.

Maintaining Spinal Cord Integrity

All patients with spinal cord trauma should be considered to have compromised spinal cords, and an important component of anesthetic management is the preservation of spinal cord blood flow.

Blood pressure and intravascular volume should be maintained within normal levels to ensure adequate spinal cord perfusion pressure. Sustained hypotension may worsen neurologic deficits. Hyperventilation should be avoided because hypocarbia decreases spinal cord blood flow.



Autonomic Hyperreflexia

After recovery from spinal shock, 85% of patients exhibit autonomic hyperreflexia when there has been complete cord transection above T5. The syndrome, which can also occur with injuries at lower levels, is characterized by severe paroxysmal hypertension with bradycardia (baroreceptor reflex), dysrhythmias, and cutaneous vasoconstriction below, and vasodilation above, the level of the injury. The episode is typically precipitated by distention of the bladder or rectum, but can be induced by any noxious stimulus. Many patients with spinal injuries and autonomic hyperreflexia will report characteristic headaches with bladder distention. The lack of supraspinal inhibition allows the sympathetic outflow below the lesion to react to the stimulus unopposed. If autonomic hyperreflexia occurs, it should be treated by removal of the stimulus, deepening anesthesia, and administration of direct-acting vasodilators. Untreated, the hypertensive crisis may progress to seizures, intracranial hemorrhage, or myocardial infarction.

Scoliosis

Scoliosis is a deformity of the spine resulting in lateral curvature and rotation of the vertebrae, as well as deformity of the rib cage (Fig. 40-1). The incidence of scoliosis predominantly reflects the incidence of idiopathic scoliosis, which

represents 75 to 90% of cases. The remaining 10 to 25% of cases are associated with neuromuscular diseases and congenital abnormalities, including congenital heart disease, trauma, and mesenchymal disorders. A diagnosis of scoliosis in a patient should therefore include a family history and physical examination, with particular attention to the respiratory, cardiac, and neuromuscular systems. The severity of scoliosis is defined by the angle of scoliosis, or *Cobb angle*. Surgical correction is performed for Cobb angles greater than 50 degrees, with the intent of halting progression of respiratory and cardiac dysfunction.

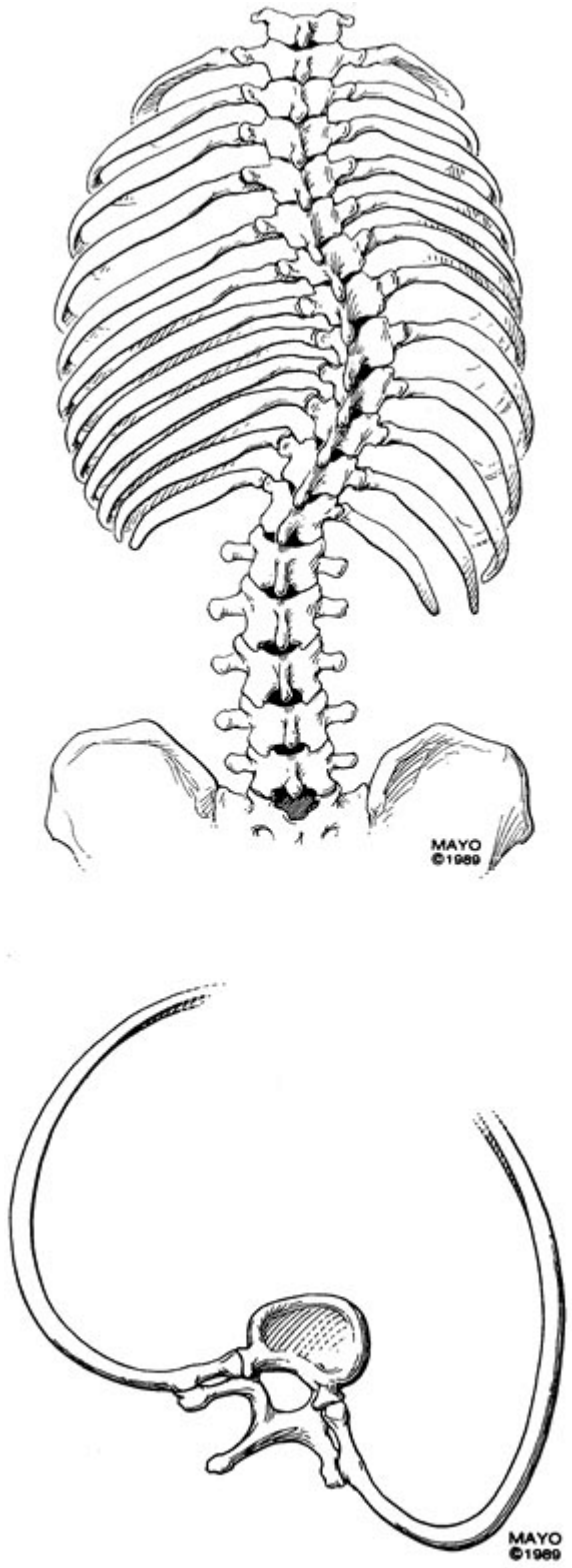


FIGURE 40-1. Deformity of the vertebrae and rib cage in scoliosis. Primary curvature occurs most frequently in the thoracic and lumbar regions. The vertebral bodies are wedge shaped, and the posterior angles of the ribs are shallow on the side of concavity. On the convex side, the rib angles are more acute. (Reprinted with permission from Horlocker TT, Cucchiara RF, Ebersold MJ: Vertebral column and spinal cord surgery. In Cucchiara RF, Michenfelder JD [eds]: Clinical Neuroanesthesia, p 325. New York, Churchill Livingstone, 1990.)

Pulmonary Considerations

Scoliosis has profound effects on the respiratory and cardiovascular systems (Fig. 40-2). In

patients with untreated scoliosis, respiratory failure and death usually occur by 45 years of age. Vital capacity appears to be a reliable prognostic indicator of perioperative respiratory reserve. Postoperative ventilation will most likely be required for patients with a vital capacity less than 40% of predicted. Although the long-term effect of scoliosis repair is to halt the decline in respiratory function, pulmonary function acutely deteriorates for 7 to 10 days after surgery.

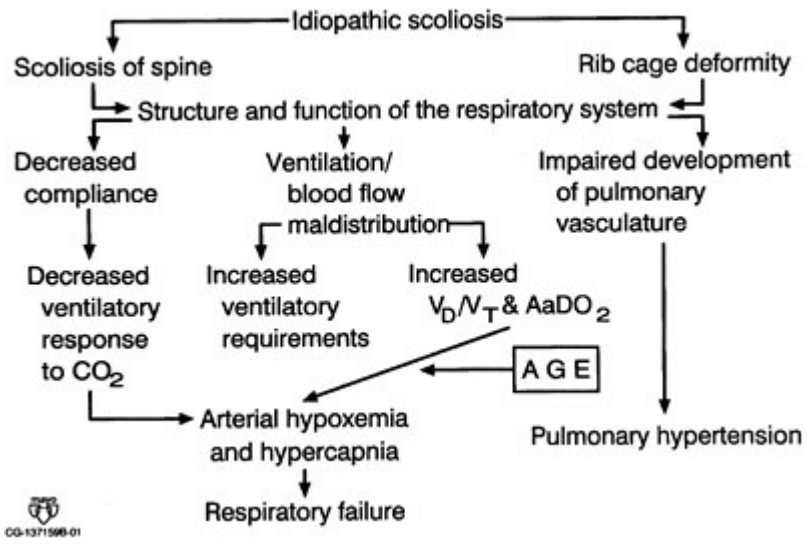

FIGURE 40-2. The factors in idiopathic scoliosis that contribute to respiratory function abnormalities and failure. (Reprinted with permission from Kafer ER: Respiratory and cardiovascular functions in scoliosis. Bull Eur Physiopathol Respir 13:299, 1977.)

The primary abnormality in gas exchange is ventilation–perfusion maldistribution, which contributes to hypoxemia. However, hypercapnia develops with increasing age as compensatory mechanisms fail. Prolonged hypoxia, hypercapnia, and pulmonary vascular constriction may result in irreversible pulmonary vascular changes and pulmonary hypertension. In general, the prognosis of scoliosis associated with neuromuscular disease is worse than that of idiopathic scoliosis. These patients frequently need postoperative ventilatory support.

Cardiovascular Considerations

Cardiovascular function is also affected in patients with scoliosis. At autopsy, these patients exhibit right ventricular hypertrophy and hypertensive pulmonary vascular changes. Prolonged alveolar hypoxia due to hypoventilation and ventilation–perfusion mismatch eventually causes irreversible vasoconstriction and pulmonary hypertension. Scoliosis is also associated with congenital heart conditions, including mitral valve prolapse, coarctation, and cyanotic heart disease, suggesting a common embryonic insult or collagen defect.

Surgical Approach and Positioning

The prone position is used for the posterior approach to the spine. Pressure points should be carefully padded. An orthopaedic frame, such as the Jackson table or Wilson frame, can be used to free the chest and abdomen. In correct prone positioning for thoracolumbar spine surgery, the head is turned, the neck is slightly flexed, and the arms are anteriorly flexed and abducted to reduce tension on the brachial plexus (Fig. 40-3). If only one arm is abducted, the head should be laterally rotated toward the ipsilateral arm to prevent stretch injury to the brachial plexus. Because rotation of the neck in patients with cervical spondylosis may alter carotid or vertebral circulation and compromise the spinal cord, patients should be evaluated for neck pain or neurologic symptoms with neck rotation before surgery. The chest and iliac crest are supported by chest rolls or other supports to leave the abdomen free. Breasts should be positioned medially to avoid traumatic injury. The dependent ear and eye should be checked frequently during surgery to

avoid injury and ischemia. Necrosis of the dependent ear cartilage may occur if the pinna is doubled back on itself. Eyes should be taped closed to avoid corneal abrasion, which occurs in the dependent eye with a frequency of 0.17%.

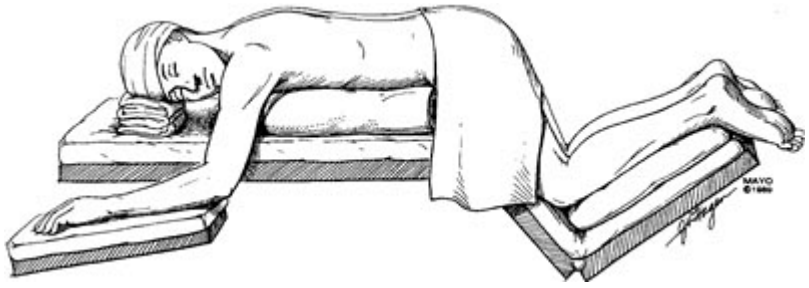

FIGURE 40-3. Prone position. The head is turned with the dependent ear and eye protected from pressure. Chest rolls are in place, the arms are brought forward without hyperextension, and the knees are flexed. (Reprinted with permission from Horlocker TT, Cucchiara RF, Ebersold MJ: Vertebral column and spinal cord surgery. In Cucchiara RF, Michenfelder JD [eds]: Clinical Neuroanesthesia, p 325. New York, Churchill Livingstone, 1990.)

The anterior approach to the spine is achieved with the patient in the lateral position, usually with the convexity of the curve uppermost. Removal of one or more ribs may be necessary for adequate surgical exposure. Likewise, placement of a double-lumen endotracheal tube, with collapse of the lung on the operative side may be required for surgery above T8. Thus, the thoracolumbar approach for anterior spinal fusion may be associated with more postoperative respiratory insufficiency than posterior fusion due to lung and diaphragmatic manipulation.

Combined anterior and posterior spinal procedures yield higher union rates and greater correction in patients undergoing scoliosis correction. It remains unclear whether these two major procedures should be performed on the same day or whether the posterior fusion should be delayed to allow the patient to recover from the anterior (first) procedure. Furthermore, the actual timing of the second procedure remains controversial. Although the degree of correction and the arthrodesis rates are similar for one-stage or two-stage procedures, the morbidity and number of complications, such as increased blood loss and transfusion requirements, decreased nutritional parameters, and longer hospital stays, may be increased for staged procedures.[3] However, these results are not consistent.[4] Because the risk of significant complications is present with either same-day or staged anterior–posterior fusion, prospective studies are needed to clarify this issue.

Anesthetic Management

The primary aim of preoperative evaluation of patients with scoliosis is to detect the presence and extent of cardiac or pulmonary compromise. Respiratory reserve is assessed by exercise tolerance, vital capacity, and arterial blood gases. Cardiac studies are performed as indicated to optimize preoperative cardiovascular status. A brief neurologic examination will document preexisting neurologic deficits. Finally, cervical mobility and upper airway anatomy are assessed to discover any potential airway or positioning difficulties. Patients should also be encouraged to participate

in preoperative autologous blood donation. Usually four or more units of blood can be collected in the month before surgery.

Anesthetic considerations for surgical correction of scoliosis by *spinal fusion and instrumentation* include management of a patient in the prone position, hypothermia secondary to a long procedure with an extensive exposed area, and replacement of blood and fluid losses, which may be extensive.[5] More recently, attention has been focused on the maintenance of spinal cord integrity, the prevention and treatment of venous air embolism (VAE), and reduction of blood loss through hypotensive anesthetic techniques.

Monitoring

Adequate monitoring and venous access are essential in management of patients undergoing spinal fusion and instrumentation. The radial artery is cannulated for direct blood pressure measurement and assessment of blood gases. A central venous catheter is helpful in evaluating blood and fluid management, and can be used to aspirate air if VAE occurs. Patients with evidence of pulmonary hypertension, or severe coexistent cardiovascular or pulmonary disease, may require a pulmonary artery catheter. Neurophysiologic monitoring, such as the use of somatosensory-evoked potentials (SSEPs), motor-evoked potentials (MEPs), or electromyography, assists in prompt diagnosis of neurologic changes and early intervention in situations of potential neurologic ischemia. The wake-up test may also be used to confirm neurologic dysfunction in the presence of changes in MEP or SSEP waveforms.

Degenerative Vertebral Column Disease

Spinal stenosis, spondylosis, and spondylolisthesis are all forms of degenerative vertebral column disease. It is not unusual for more than one of these degenerative changes in the spine to occur concomitantly, leading to a more rapid progression of neurologic symptoms and the need for surgical intervention.

Surgical Approach and Positioning

Cervical laminectomy is performed in the prone, lateral, or sitting position, whereas thoracolumbar laminectomy is usually performed prone. Considerations for positioning a prone patient have been previously discussed. Patients undergoing cervical laminectomy should be assessed before surgery for cervical range of motion and the presence of neurologic symptoms during flexion, extension, or rotation. Fiberoptic-assisted intubation may be necessary in patients with severely limited cervical movement. With the anterior approach, the surgical incision approximates the anterior border of the sternocleidomastoid muscle, and is therefore near critical anatomic structures. Lateral retraction of the carotid artery may endanger blood flow to the brain, particularly in the elderly patient.[6] Retraction of the esophagus and trachea medially may cause pharyngeal laceration, laryngeal edema, and recurrent laryngeal nerve paralysis. Cerebrospinal fluid leaks and trauma to the vertebral artery have also been reported.

The use of the sitting position for cervical laminectomy has become increasingly popular. Blood flows away from the site of operation, producing a clear operative field and better surgical exposure. In this position, the patient sits with head, arms, and chest supported. The patient must be carefully positioned and dependent areas padded to prevent compression injuries to nerves and skin. Extreme cervical flexion may obstruct the airway. Hypotension can be minimized by gradual attainment of the sitting position. A disadvantage of the sitting position is the increased occurrence of VAE. Although the incidence of VAE in sitting posterior fossa cases is 40%, the incidence is only 5 to 25% in sitting cervical spine procedures.[7] This decreased incidence may alter the need for a central venous pressure catheter.

Anesthetic Management

Either general or neuraxial anesthesia may be safely administered for relatively uncomplicated lower thoracic and lumbar spine surgery. However, general anesthesia is preferred for essentially

all thoracic and cervical procedures because of the high spinal level that would be required with a regional technique. The advantages of regional anesthesia include a reduction in blood loss and improved operating conditions by contraction of epidural vasculature. Both spinal and epidural techniques have been described. Epidural catheters may be placed under direct vision by the surgeon to provide intraoperative anesthesia and postoperative analgesia. Likewise, the accessibility of the dural sac facilitates intrathecal reinjection by the surgeon for extended procedures. Despite these considerations, most spine surgery is performed under general anesthesia. General anesthesia ensures airway access, is associated with greater patient acceptance, and can be used for prolonged operations. Succinylcholine should be avoided if there are progressive neurologic deficits because of the possible hyperkalemic response.

Spinal Cord Monitoring

Paraplegia is one of the most feared complications of spinal surgery. The incidence of neurologic injuries associated with scoliosis correction is 1.2%, with partial or complete paraplegia occurring in one-half of cases. When patients awaken paraplegic, neurologic recovery is unlikely, although immediate removal of instrumentation improves the prognosis. It is therefore essential that any intraoperative compromise of spinal cord function be detected as early as possible and reversed immediately. The two methods developed to accomplish this are the wake-up test and neurophysiologic monitoring.

The *wake-up test*, first described by Vauzelle et al,[8] consists of the intraoperative awakening of patients after completion of spinal instrumentation. Surgical anesthesia is typically provided with a balanced technique of nitrous oxide, a volatile drug, and opioids, although use of opioids and a short-acting volatile anesthetic (e.g., sevoflurane) alone is also possible. The opioids are important to provide analgesia while the patient is awake and to permit the patient to tolerate the endotracheal tube. During the 30 to 45 minutes before intraoperative wake-up, the volatile anesthetic and muscle relaxants are discontinued and the patient is allowed to gradually awaken. The patient is addressed by name and asked to move both hands, and after a positive response, both feet. Patients usually respond within 5 minutes. If there is satisfactory movement of the hands, but not the feet, the distraction on the rod is released one notch, and the wake-up test repeated. Although recall of the event

occurs in only 0 to 20% of patients and is rarely viewed as unpleasant,[9] it is important to describe what will transpire to the patient before surgery so anxiety will be minimized if the patient is fully aware. It is extremely rare for a patient who was neurologically intact when awakened during surgery to have a neurologic deficit on completion of the procedure. However, certain hazards of the wake-up test do exist and include recall, pain, air embolism, dislocation of spinal instrumentation, and accidental tracheal extubation or removal of intravenous and arterial lines.

An adjunct or alternative to the wake-up test is neurophysiologic monitoring. Neurophysiologic monitoring, including SSEPs, MEPs, and electromyography, is also discussed in Chapter 24. Somatosensory stimulation follows the dorsal column pathways of proprioception and vibration: pathways supplied by the posterior spinal artery. The motor pathway, which is supplied by the anterior spinal artery, is not monitored. MEPs, in contrast, monitor motor pathways but are technically more difficult to use. Muscle relaxants cannot be used in patients having MEP monitoring. It is of critical importance to note that postoperative paraplegia has occurred in at least one patient with preserved intraoperative SSEPs.[10]

Acute alterations in SSEP amplitude or latency signify spinal cord compromise and may be the result of direct trauma, ischemia, compression, or hematoma. If changes occur, it is recommended that surgery be discontinued, blood pressure returned to normal or 20% above normal, and volatile agents decreased or discontinued. Arterial blood gases may be drawn to rule out a metabolic derangement. If the waveform does not return to normal, the surgeon should release distraction on the cord. A wake-up test is often performed at this time definitely to exclude neurologic deficits. In addition to neural injury, SSEPs are altered by volatile anesthetics, hypercarbia, hypoxia, hypotension, and hypothermia.[11,12]

Blood Loss

3 Most of the blood loss in spinal instrumentation and fusion occurs with decortication and is proportional to the number of vertebral levels decorticated.[13] Blood loss and transfusion requirements may be reduced through proper positioning and the use of intraoperative blood salvage, induced hypotension, intraoperative hemodilution, and the administration of aprotinin, although reported results are inconsistent.[14,15,16] However, induced hypotension is not without risk, and has been reported to cause cord ischemia and neurologic deficit, including blindness.[18,19,20] The various agents used to induce hypotension in scoliosis surgery include trimethaphan, nitroglycerin, sodium nitroprusside, volatile anesthetics, calcium channel blockers, and α-antagonists and β-antagonists.[21] The volatile agents provide anesthesia and hypotension. However, all volatile anesthetics produce a dose-dependent deterioration of evoked potential waveforms. Therefore, a combination of intravenous hypotensive agents and volatile anesthetics is frequently used.

Finally, patients undergoing major spine surgery may acquire a perioperative coagulopathy from dilution of coagulation factors and/or platelets or fibrinolysis. The mechanisms of the coagulopathy and the role of coagulation testing during these procedures are poorly defined. However, it appears that a significant deviation from normal values of either the prothrombin time, or the activated partial thromboplastin time, are predictive of bleeding and may be used to guide transfusion therapy.[22]

Another rare etiology of bleeding during spine surgery is trauma to the aorta, vena cava, or iliac vessels. Unexplained hypotension or signs of hypovolemia without obvious blood loss should alert the anesthesiologist to this possibility.

Visual Loss After Spine Surgery

4 Unilateral and bilateral blindness have been reported in case reports and small series after spinal surgery.[18,19,20] The diagnoses included optic neuropathy, retinal artery occlusion, and cerebral ischemia. Most cases were associated with complex instrumented fusions.[19] Although no definitive risk factors have been identified, many cases were associated with significant (prolonged) intraoperative hypotension, anemia, large intraoperative blood loss, and prolonged surgery.[20] However, these conditions are present during many major spine procedures, without visual sequelae. Therefore, actual risk factors remain unidentified at this time (see Chapter 5).

Venous Air Embolus

VAE is a catastrophic event that may occur during spine surgery. The large amount of exposed bone and the elevated location of the surgical incision relative to the heart predispose to VAE. The use of capnography, mass spectrometry, and precordial Doppler are noninvasive, yet effective, in detecting VAE. VAE can occur in all positions associated with laminectomies because the wound is above the cardiac level. Incidences of VAE (defined by aspiration of air through a central venous catheter) in patients undergoing neurosurgical procedures in the sitting, supine, prone, and lateral positions are 25, 18, 10, and 8%, respectively.[7] The actual incidence of VAE in scoliosis surgery is unknown; however, six cases have been reported in the literature, four of which were fatal.[23,24,25,26] The presenting sign in all cases was unexplained hypotension and an increase in the end-tidal nitrogen concentration. The anesthesiologist, therefore, should be aware of the possibilities of VAE because prompt diagnosis and treatment increase patient survival. If VAE is suspected, the wound should be irrigated with saline, nitrous oxide discontinued, and vasopressors administered. Massive embolism may necessitate turning the patient supine and initiating cardiopulmonary resuscitation.

Postoperative Care

Most patients undergoing posterior spinal fusion can be extubated immediately after the operation if the procedure was relatively uneventful and preoperative vital capacity values were acceptable. Residual opioid or muscle relaxant may lead to hypoventilation or apnea, especially in patients

with an associated neuromuscular disease. Some patients who have experienced considerable blood loss and who have received large amounts of intravenous fluids, particularly if they were prone, may have severe facial edema that renders immediate tracheal extubation unwise. Aggressive postoperative pulmonary care, including incentive spirometry, is necessary to avoid atelectasis and pneumonia. Continued hemorrhage in the postoperative period is another concern. Careful monitoring of systemic and central venous pressures, urine output, and wound drainage is essential. Neurologic status must also be monitored closely for deterioration.

Postoperative analgesia is typically provided by systemic opioids. However, wound instillation with local anesthetic or injection of intrathecal morphine is associated with improved pain scores and decreased side effects in the early postoperative period.[27,28]

Epidural and Spinal Anesthesia After Major Spine Surgery

Previous spinal surgery has been considered to represent a relative contraindication to the use of regional anesthesia. The presence of postoperative spinal stenosis or other degenerative changes in the spine or preexisting neurologic symptoms may preclude the use of regional anesthesia in these patients. Likewise, many of these patients experience chronic back pain and are reluctant to undergo epidural or spinal anesthesia, fearing exacerbation of their preexisting back complaints. Finally, postoperative anatomic changes make needle or catheter placement more difficult and complicated after major spinal surgery; needle insertion can be accomplished only at nonfused segments.

Spread of epidural local anesthetic following spinal surgery may be affected by adhesions, producing an incomplete or "patchy" block. Obliteration of the epidural space may increase the incidence of dural puncture and make subsequent epidural blood patch placement impossible. Several retrospective studies have demonstrated that epidural anesthesia may be successfully performed in patients with previous spinal surgery; however, successful catheter placement was possible on the first attempt in only 50% of patients, even with an experienced anesthesiologist. In addition, although adequate epidural anesthesia was eventually produced in 40 to 95% of patients, there appeared to be a higher incidence of traumatic needle placement, inadvertent dural puncture, and unsuccessful epidural needle or catheter placement, especially if spinal fusion extended to L5–S1.[29,30,31]

Spinal anesthesia may produce a more reliable block and cause less trauma than epidural anesthesia. Although needle placement may be more difficult or traumatic in these patients, the spread of local anesthetic in the subarachnoid space and quality of block would not be affected. A spinal anesthetic may be more desirable after spinal surgery because the technique does not depend on a subjective loss of resistance, but instead has a definite end point—the presence of cerebrospinal fluid.

SURGERY TO THE UPPER EXTREMITIES

Orthopaedic surgical procedures to the upper extremity are well suited to regional anesthetic techniques. In addition to intraoperative anesthesia, brachial plexus and peripheral nerve blocks may be used in the treatment and prevention of reflex sympathetic dystrophy. Continuous catheter techniques provide postoperative analgesia and allow early limb mobilization. Conversely, although the benefits of regional anesthesia in this patient population are well established, orthopaedic surgical procedures often involve peripheral nerves with preexisting deficits, such as ulnar nerve transposition and carpal tunnel release. In addition, the operative site may be adjacent to neural structures, as with total shoulder arthroplasty or fractures of the proximal humerus. The decision to perform regional anesthesia in a patient with preexisting neurologic deficits or who is at risk for perioperative neuropraxia should be made on an individual basis after discussion with the patient and surgeon. Meticulous regional anesthetic technique with appropriate use of local anesthetic solutions and vasoconstrictors, careful patient positioning, and serial postoperative neurologic examinations may reduce the incidence of neurologic dysfunction.

Local anesthetic selection is based on the duration and degree of sensory or motor block required.

Although prolonged blockade of the lower extremities interfere with ambulation and therefore delay outpatient discharge, persistent upper-extremity block is not a contraindication to hospital dismissal. However, the patient should be informed of the anticipated duration of analgesia during the postoperative visit and instructed to protect the blocked extremity until block resolution.

Surgery to the Shoulder and Upper Arm

Reconstructive shoulder surgery, including total shoulder arthroplasty and rotator cuff repair, presents unique management and positioning considerations to the anesthesiologist. For example, 4% of patients undergoing total shoulder arthroplasty have a documented postoperative neurologic deficit, including 3% of patients with injury to the brachial plexus. The level of injury is at the level of the nerve trunks, which is the level at which an interscalene block is performed, making it impossible to determine the etiology of the nerve injury (surgical versus anesthetic). Most of these nerve injuries represent a neurapraxia; 90% resolve in 3 to 4 months.[32] In addition, nerve injury often occurs in association with upper-extremity trauma. Radial nerve palsy is identified in up to 18% of patients with humeral shaft fractures, whereas injury to the axillary nerve and brachial plexus is associated with proximal humerus fractures. However, the significant incidence of neurologic deficits demonstrates the importance of clinical examination before regional anesthetic techniques in these patients.

Surgical Approach and Positioning

Surgical procedures to the upper arm and shoulder are typically performed with the patient in the "beach chair" position. The patient is flexed at the hips and knees and placed in a 10- to 20-degree reverse Trendelenburg position to promote venous return. The patient is shifted laterally to the edge of the operating table to allow unrestricted surgical access to the upper extremity. The patient's head, neck, and hips must be secured to prevent additional lateral movement. The head and neck must remain firmly supported by the operating table and secured in a neutral position; excessive rotation or flexion of the head away from the operative side results in stretch injury to the brachial plexus. Care also must be taken to avoid pressure on the eyes and ears. All airway connections should be tightened and possibly reinforced with tape because after surgical draping, access to the patient's face and airway is limited. Hypotension and bradycardia, which occur in up to 20% of cases, can be minimized by gradual assumption of the beach chair position, hydration, and administration of atropine or beta-blockade.

A tourniquet cannot be used during proximal upper-extremity surgical procedures, and significant blood loss may occur. Therefore, arterial cannulation may be helpful for direct blood pressure measurement and monitoring of intraoperative hemoglobin concentrations during total shoulder arthroplasty and reduction of humeral fractures. In theory, VAE may occur during surgical procedures to the shoulder because the operative site is higher than the heart. However, this complication has not been reported in the literature. Patients with a documented right-to-left shunt may be monitored with a precordial Doppler to allow prompt diagnosis and treatment of VAE.

Anesthetic Management

Surgery to the shoulder and humerus may be performed under regional or general anesthesia.[33] With careful positioning and appropriate sedation, interscalene or supraclavicular blockade alone can provide excellent surgical anesthesia. However, general anesthesia or a combination of regional and general anesthesia is often chosen because of limited access to the patient's airway during these surgical procedures. Interscalene brachial plexus block may be performed before surgical incision or

after postoperative upper-extremity neurologic function has been determined. Although preoperative interscalene block reduces the intraoperative requirement of volatile anesthetic and opioids, and in theory provides preemptive analgesia, postoperative evaluation of neurologic function will not be possible until block resolution.

Interscalene block should be performed with caution in patients with a preexisting brachial plexopathy because of the risk of perioperative exacerbation of neurologic deficits. The ipsilateral diaphragmatic paresis and 25% loss of pulmonary function produced by interscalene block also contraindicates this block in patients with severe pulmonary disease.[34] The reduction in pulmonary function is present for the duration of the interscalene block.

Surgery to the Elbow

Surgical procedures to the distal humerus, elbow, and forearm are commonly performed under regional anesthetic techniques. Infraclavicular and supraclavicular approaches to the brachial plexus are the most reliable and provide consistent anesthesia to the four major nerves of the brachial plexus: median, ulnar, radial, and musculocutaneous. However, the small but definite risk of pneumothorax associated with supraclavicular and infraclavicular blocks usually makes this approach unsuitable for outpatient procedures. Typically, the pneumothorax occurs 6 to 12 hours after hospital discharge; therefore, a postoperative chest radiograph is not helpful. Although chest tube placement is advised for pneumothorax greater than 20% of lung volume, the lung may also be reexpanded with a small Teflon catheter under fluoroscopic guidance, eliminating the need for hospital admission. The axillary approach to the brachial plexus eliminates the risk of pneumothorax and reliably provides adequate anesthesia for surgery near the elbow.[35]

Surgery to the Wrist and Hand

Surgery to the distal forearm, wrist, and hand may be performed under general or regional anesthesia. Brachial plexus block provides comprehensive and consistent regional anesthesia for the distal upper extremity.[36] Although the brachial plexus may be successfully blocked at several sites, the interscalene approach is seldom used for wrist and hand procedures because incomplete anesthesia of the ulnar nerve is noted in 15 to 30% of patients. In addition, although the supraclavicular approach results in blockade of all four major nerves, the risk of pneumothorax reduces its suitability for outpatient procedures. Therefore, the axillary approach is most commonly used for surgical procedures to the forearm, wrist, and hand.

Minor hand procedures such as carpal tunnel release, reduction of phalanx fractures, and superficial wound debridements may require only local infiltration or peripheral blockade at the midhumeral, elbow, or wrist level. Inflation of an upper arm tourniquet in these patients causes significant discomfort in 45 to 60 minutes and limits the duration of the surgical procedure. Intravenous regional anesthesia (Bier block) using a double tourniquet permits more extensive surgery and longer tourniquet times than distal peripheral block, but does not provide postoperative analgesia.

Continuous Brachial Plexus Anesthesia

5 Brachial plexus catheters may be inserted using interscalene, infraclavicular, and axillary approaches. However, the axillary approach is most common. A 20-gauge catheter is advanced 5 to 10 cm through a medium-gauge needle after elicitation of a paresthesia (or motor response if the nerve stimulator technique is used), and 45 to 50 mL of local anesthetic is injected. Although *analgesia* is produced in all nerve distributions, the block may not provide satisfactory surgical *anesthesia*, even with administration of more potent local anesthetic solutions. Therefore, for surgical procedures, the continuous brachial plexus block is often supplemented with a general anesthetic. After surgery, the catheters may be left indwelling for 4 to 7 days without adverse effects. A continuous infusion of local anesthetic solution, such as bupivacaine 0.125%, prevents vasospasm and increases circulation after limb replantation or vascular repair. More concentrated solutions result in complete sensory block and allow early joint mobilization after painful surgical procedures to the elbow. Ambulatory (at-home) applications provide superior analgesia with fewer side effects than conventional systemic analgesic therapy.[37]

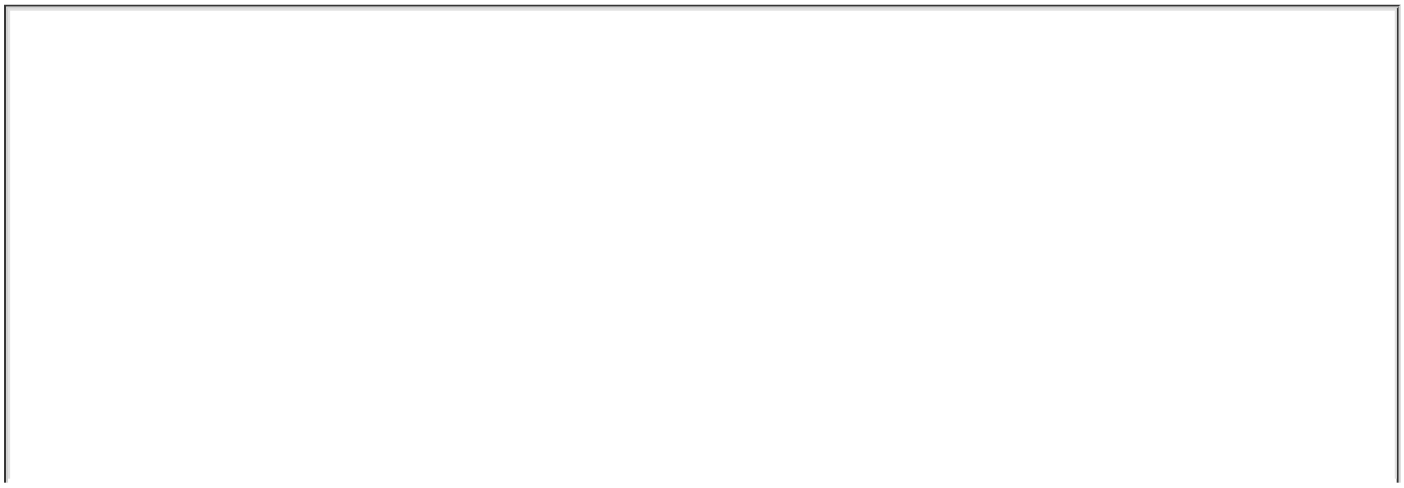
SURGERY TO THE LOWER EXTREMITIES

Although orthopaedic procedures to the lower extremity may be performed under both general and

regional anesthesia, the ability to provide superior postoperative analgesia, rapid postoperative rehabilitation, and reduced cost of medical care may result from thoughtfully implemented regional anesthetic and analgesic techniques.

Multiple studies demonstrate significantly reduced intraoperative blood loss during total hip arthroplasty (THA) completed under central neuraxial blockade compared with general anesthesia.[38] The reasons for this reduction are unproved but may be influenced by the decrease in mean arterial pressure, blood flow redistribution to larger-caliber vessels, and locally reduced venous pressure. Decreased postoperative blood loss can be demonstrated when the epidural local anesthetic is continued for analgesia. Likewise, postoperative pulmonary thromboembolism (PTE) from deep venous thrombosis (DVT) is an important cause of morbidity and mortality in orthopaedic surgical patients. Historical investigations reported a decreased incidence of DVT and PTE in patients whose surgery was conducted under regional anesthesia.[39,40] However, these patients did not receive anticoagulants. The potential benefit of regional anesthesia in reducing thromboembolic complications is discussed later in this chapter.

Surgery to the Hip



More than 200,000 total hip replacements are performed annually in North America. Patients undergoing surgical procedures to the hip for arthritic conditions typically are elderly and often have preexisting medical conditions that may affect perioperative outcome. In addition, because hospital costs appear to be directly related to the length of hospital stay, anesthetic techniques associated with improved recovery and reduced complications may decrease the total hospital costs among these patients.

Surgical Approach and Positioning

6 The lateral decubitus position is frequently used to facilitate surgical exposure for THA, whereas the fracture table is often used for repair of femur fractures. In transferring the patient from the supine to lateral decubitus position, care must be taken to maintain the head and shoulders in a neutral position. The patient is supported while the position is secured with hip rests or other mechanical devices. The dependent arm is abducted and placed on a padded arm rest; a rolled towel or wrapped intravenous fluid bag is placed in the axilla to avoid

compression of the brachial plexus and vascular structures. The upper arm is placed on a padded over-arm board.

Positioning on the fracture table (Fig. 40-4) also requires adequate personnel to move the patient, with one person assigned to apply traction to the fractured limb. The fracture table affords two advantages: maintenance of traction on the fractured extremity, allowing manipulation for closed reduction and fixation; and access to the fracture site for radiography in several planes. The patient must be carefully monitored for hemodynamic changes during positioning, whether under regional or general anesthesia. Care must be taken to pad the perineal post before positioning the patient's pelvis. Usually, the arm ipsilateral to the fractured hip is placed on an arm board or in a sling to keep it from obstructing the fluoroscopic view.

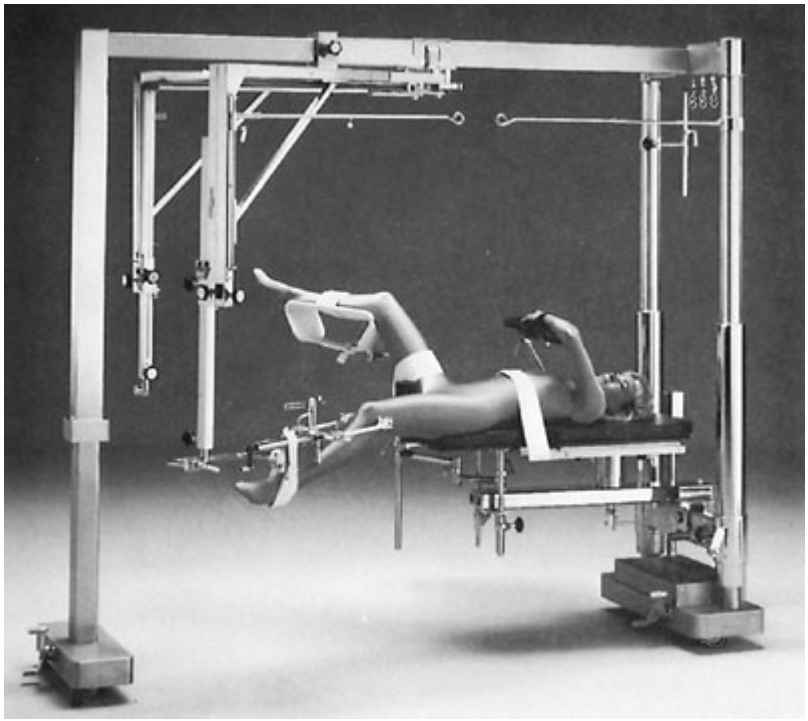


FIGURE 40-4. The fracture table. The patient must be moved carefully with continuous traction on the fractured limb. The ipsilateral arm is positioned on an arm board or sling without stretching the brachial plexus. (Courtesy of Midmark Corporation, Versailles, OH.)

Anesthetic Technique

Regional anesthetic techniques are well suited to procedures involving the hip. Central neuraxial blockade, including spinal and epidural blockade, is commonly used. Regional anesthesia may be instituted with the patient sitting or in the lateral decubitus position. Both hypobaric and isobaric spinal anesthetic solutions are effective. Adequate intravenous hydration before placing the spinal block protects against a precipitous drop in blood pressure that can occur secondary to sympathetic blockade and peripheral vasodilation. Epidural blockade also provides excellent surgical anesthesia. Placement of a catheter allows prolonged anesthesia as well as postoperative analgesia. More recently, both single-dose and continuous lumbar plexus techniques have been performed to provide postoperative analgesia in patients undergoing major hip surgery. Psoas compartment block was associated with decreased postoperative pain and facilitated hospital discharge in a series of 660 patients.[41] The lumbar plexus block also contributes to the intraoperative anesthetic, allowing decreased dosing of volatile agents, opioids, and/or spinal anesthetic solutions.

Blood Loss

Regional anesthetic techniques reduce blood loss in patients undergoing hip surgery. Deliberate hypotension can also be used with general anesthesia as a means of reducing surgical blood loss and has been recommended when the benefits can be expected to outweigh the risks.[42] Diltiazem, nitroprusside with and without captopril, beta-blockers, and nitroglycerin have also been used to induce hypotension.

Total Knee Arthroplasty

More than 300,000 total knee arthroplasties are performed annually in North America. Patients undergoing total knee arthroplasty (TKA) experience significant postoperative pain. Failure to provide adequate analgesia impedes aggressive physical therapy and rehabilitation, which is

critical to maintaining joint range of motion and potentially delays hospital dismissal. Thus, the anesthesiologist must devise a plan for not only intraoperative anesthesia, but also postoperative analgesia.

Surgical anesthesia for operative procedures on the knee in which a tourniquet will be used requires blockade of all four nerves (femoral, lateral femoral cutaneous, obturator, and sciatic nerves) innervating the leg. Although it is possible to perform major knee surgery under peripheral nerve blocks, more often a femoral three-in-one or lumbar plexus (psoas) block is combined with a spinal or general anesthetic. This is less difficult technically, reduces the amount of local anesthetic (and associated systemic toxicity), and provides postoperative analgesia for 12 to 24 hours. Continuous lumbar plexus and sciatic techniques allow for prolonged postoperative analgesia.

Regional anesthetic techniques that can be used for surgical procedures about the knee include neuraxial and peripheral leg blocks. Spinal anesthesia can be accomplished with hyperbaric or isobaric solutions, although the latter are favored by most orthopaedic anesthesiologists. Injection of hyperbaric solutions often results in a higher level of sensory and motor blockade than needed for the surgical procedure, with subsequent earlier offset of anesthesia. Epidural blockade offers the advantage of a continuous catheter technique that can be continued into the postoperative period. These procedures are often associated with significant postoperative pain, particularly when continuous-motion machines are applied to the affected joint.

7 Although numerous methods of providing postoperative analgesia after total knee arthroplasty have been reported, the optimal technique based on efficacy, number/type of side effects, surgical outcome, and resource utilization is unknown. Several studies have suggested that aggressive postoperative regional analgesic techniques maintained for 48 to 72 hours result in a shorter rehabilitation period and increased joint mobility compared with conventional systemic opioids.[43,44]

Positioning

The supine position optimizes surgical exposure during knee arthroscopy or arthroplasty, lower-extremity amputations, and procedures to the tibia and fibula. Care must be taken to cushion the extremities and bony prominences.

Knee Arthroscopy and Anterior Cruciate Ligament Repair

Outpatient knee surgery may be performed under a variety of regional anesthetic techniques. Traditionally, neuraxial or general anesthesia is used. Because diagnostic knee arthroscopy is a relatively minor procedure that may be performed under local anesthesia with sedation, the performance of a single-dose or continuous lower-extremity block is probably not warranted in the majority of patients. The optimal anesthetic technique would allow rapid operating suite turnover and patient

recovery, excellent operating conditions, and minimal side effects. Unfortunately, each approach is associated with advantages and disadvantages. For example, concerns over transient neurologic symptoms propelled a search for an alternative to intrathecal lidocaine; to date, its reliable sensory and motor block (of limited duration) have not been duplicated. Bupivacaine has a low incidence of transient neurologic symptoms. However, the time to hospital discharge following administration of low-dose bupivacaine (5 to 7.5 mg) with fentanyl (10 µg) may be as long as 3 hours. Epidural 2-chloroprocaine may be an alternative to spinal lidocaine, but experience remains limited. Finally, general anesthesia is associated with nausea and vomiting, side effects prevalent in the patient population undergoing knee arthroscopy. Meta-analyses have failed to demonstrate a clinically significant difference in patient outcome with respect to anesthetic technique.[45]

ACL repair is also performed as an outpatient procedure. However, the surgery is more extensive than knee arthroscopy and postoperative pain may be significant. The anesthetic considerations are similar to those of diagnostic knee arthroscopy with the addition of providing substantial analgesia. Although few data exist on the use of lower-extremity blocks for patients undergoing

ACL repair, one study suggests that lumbar plexus block (combined with a spinal or sciatic block) dramatically reduces postoperative opioids requirements and opioid-related side effects.[46] Patients may be discharged home with an indwelling femoral catheter to provide sustained pain relief for 48 hours.[47] Thus, for outpatient procedures, the complexity/duration of the surgical procedure will determine the usefulness of peripheral blocks compared with neuraxial or general anesthesia.

Surgery to the Ankle and Foot

Innervation of the foot is provided by the femoral nerve (via the saphenous nerve) and by the sciatic nerve (via the posterior tibial, sural, and deep and superficial peroneal nerves). Therefore, central neuraxial blockade and peripheral nerve blocks at the upper leg, knee, or ankle are appropriate regional anesthetic techniques for foot surgery. The selection of the regional technique is based on the surgical site, use of a calf or thigh tourniquet, degree of weight bearing/ambulation, and the need for postoperative analgesia. For example, inflation of a thigh tourniquet for longer than 15 to 20 minutes necessitates a general or neuraxial anesthetic, regardless of surgical site. Common surgical procedures and considerations regarding the choice of regional technique are discussed in Table 40-1.[48]

TABLE 40-1 Anesthetic Techniques For Common Foot and Ankle Operations

	▪ANESTHETIC TECHNIQUES FOR COMMON FOOT AND ANKLE OPERATIONS		
	▪SURGICAL PROCEDURE	▪REGIONAL TECHNIQUE	▪COMMENTS
Forefoot[a]	Hallux valgus	Metatarsal, ankle, popliteal blockade	Sural nerve block not necessary for surgery
	Amputations	Ankle, popliteal blockade	Popliteal blockade is the technique of choice in the presence of infection or swelling
Midfoot[a]	Transmetatarsal amputations	Popliteal, ankle blockade	
Hindfoot[a]	Ankle arthroscopy	Spinal, epidural or general anesthesia	Operation typically requires good muscle relaxation for manipulation; thigh tourniquet
	Achilles tendon repair	Spinal, epidural, or popliteal blockade	Spinal or epidural anesthesia whenever thigh tourniquet is required
	Triple arthrodesis	Spinal or epidural	Neuraxial technique preferred for bone graft harvesting; popliteal blockade for postoperative analgesia

[a]Femoral or saphenous block required if the incision extends to the medial aspect of the foot or ankle.

From Hadzic A, Vloka JD: Anesthesia for ankle and foot surgery. Tech Reg Anesth Pain Manage 3:113, 1999.

The distal surgical site and the ability to block the pain pathways at multiple sites give regional anesthesia an advantage over general anesthesia for surgery to the ankle and foot. Peripheral blockade avoids the cardiovascular and respiratory side effects, as well as the urinary retention associated with neuraxial and general anesthesia. Often, patients undergoing lower-extremity peripheral techniques may be discharged directly from the operating room to the outpatient nursing station, reducing recovery time and charges. The use of long-acting local anesthetics and the addition of epinephrine or clonidine allow prolongation of postoperative analgesia. However, additional onset time is required with bupivacaine and ropivacaine. Mepivacaine and lidocaine may be more appropriate in the ambulatory setting, where fast-onset and reliable surgical anesthesia is essential. The main disadvantage of peripheral blocks is the technical expertise required for consistent success; neuraxial techniques are a suitable alternative.

Postoperative Analgesia

Systemic Analgesics

Systemic opioids remain a popular postoperative regimen for major orthopaedic surgery because they are relatively simple to administer, safe, and cost-effective. Delivery of opioids using patient-controlled analgesia (PCA) devices results in improved analgesia, decreased total opioid consumption, and increased patient and nurse satisfaction. However, the pain after total joint replacement, particularly total knee arthroplasty, is severe. Adequate analgesia achieved with systemic opioids is frequently associated with side effects, including sedation, nausea, and pruritus. Anti-inflammatory medications and acetaminophen are valuable adjuvants to systemic opioids. The

addition of nonopioid analgesics reduces opioid use, improves analgesia, and decreases opioid-related side effects.

Neuraxial and Peripheral Blockade

Studies have demonstrated that epidural analgesia or peripheral nerve blocks provide better pain relief and faster postoperative rehabilitation than intravenous PCA with morphine after total joint replacement. For example, after total knee arthroplasty, patients receiving epidural analgesia or continuous femoral three-in-one block reported lower pain scores, better knee flexion, faster ambulation, and shorter hospital stays compared with patients who received intravenous PCA morphine.[43,44] These landmark studies demonstrate the long-term effects of an aggressive postoperative analgesic technique following orthopaedic surgery—continuous femoral and epidural analgesia hastened rehabilitation and improved joint mobility. An additional relevant result of these investigations is the finding that continuous femoral block provided a quality of analgesia and surgical outcomes similar to that of continuous epidural analgesia, but was associated with

fewer side effects. These studies support the movement toward continuous peripheral technique as the optimal analgesic method following total knee arthroplasty.

Intra-Articular Injection

Intra-articular injections of local anesthetics, opioids, or combinations have become routine for perioperative pain management after arthroscopic knee surgery. A number of reports enthusiastically recommend the use of this technique; however, the results remain conflicting.[49,50] Comparison of reports is difficult because of variability in underlying anesthetic techniques, different dosages and concentrations of local anesthetic, and lack of control groups. The safety of injecting large volumes of intra-articular bupivacaine has been ascertained,[51] and side effects are rare after intra-articular doses of morphine. Because these techniques are simple and low risk and seem to afford pain relief under some conditions, they will likely be continued.

MICROVASCULAR SURGERY

Microvascular surgery includes both replantation, the reattachment of a completely severed body part, and revascularization, the reestablishment of blood flow through a severed body part. Most replantation surgery involves the upper extremity. Anesthetic management in microvascular surgery includes maintenance of blood flow through microvascular anastomoses, positioning considerations associated with a long surgical procedure during which the patient must lie completely still, and replacement of blood and fluid losses, which may be extensive.

Maintenance of blood flow through microvascular anastomoses is paramount to limb or graft viability. Blood flow may be improved by increasing the perfusion pressure, preventing hypothermia, and using vasodilators and sympathetic blockade. Microvascular perfusion pressure depends on both adequate intravascular volume and oncotic pressure. Blood loss during microvascular surgery is typically continual and insidious. Unrecognized bleeding and migration of intravascular fluid into the third space reduce microvascular perfusion pressure, and must be corrected. However, overzealous use of crystalloid results in generalized edema, including the replanted body part, whereas excessive transfusion of blood products increases blood viscosity and therefore decreases flow. Evidence suggests that use of phenylephrine to support blood pressure does not jeopardize blood flow to the tissue being replanted.[52] Rheologically, the oxygen-carrying capacity of blood is optimized with a hematocrit of 30%. Arterial cannulation allows frequent assessment of hemoglobin levels and acid-base status, as well as direct blood pressure measurement.

Body temperature is also a determinant of blood flow. Hypothermia not only results in peripheral vasoconstriction, but causes sympathetic activation, shivering, increased oxygen demand, a leftward shift of the oxygen–hemoglobin dissociation curve, and altered coagulation. Therefore, hypothermia must be prevented in microvascular surgical patients. The operating room temperature should be increased to 21°C, intravenous solutions should be warmed,[53] and the patient covered with a forced-air warming blanket.

The use of vasodilators has also been studied in the treatment of perioperative vasospasm. Local anesthetics and papaverine, applied topically, may be used to provide relaxation of vascular smooth muscle in the intraoperative setting.[54] All the volatile anesthetics are potent vasodilators and can increase tissue blood flow 200 to 300%, even at typical expired anesthetic concentrations. Direct-acting vasodilating agents, such as sodium nitroprusside, trimethaphan, and hydralazine, produce vasodilation but do not prevent vasospasm due to direct surgical stimulation. Nitroprusside has been shown to reduce perfusion in a microvascular free flap.[52] In addition, the volatile anesthetics and intravenous agents may also result in hypotension and decreased microvascular perfusion pressure. Regional anesthetic techniques provide sympathectomy and vasodilation to the proximal (innervated) segment of an extremity, but have no effect on vasospasm in the replanted (denervated) tissue. Antithrombotics (heparin), fibrinolytics (streptokinase, urokinase, low molecular weight dextran), and smooth muscle relaxants (papaverine, local anesthetics) are also used to preserve blood flow in microvascular anastomoses.

Microvascular surgery may be performed under regional or general anesthesia. Regional anesthesia has several advantages over general anesthesia. The sympathectomy associated with local anesthetic blockade results in vasodilation and increased blood flow. A single-injection regional anesthetic technique may be of insufficient duration for many microvascular procedures. However, placement of an indwelling catheter (intrathecal, epidural, or axillary) provides extended intraoperative anesthesia and continuous postoperative analgesia. General anesthesia ensures airway access and reduces the possibility of patient movement during critical surgical events. A combination of general and continuous regional anesthesia allows prolonged intraoperative anesthesia and postoperative analgesia, reduces the amount of inhalational agent, and increases the patient's acceptance of lengthy surgical procedures. However, regardless of anesthetic technique, conditions that stimulate vasospasm or vasoconstriction, such as pain, hypotension, and hypovolemia, must be avoided. Whether administration of a vasopressor with vasoconstrictive qualities or addition of epinephrine to local anesthetic solutions may decrease anastomotic blood flow is controversial.[52]

PEDIATRIC ORTHOPAEDIC SURGERY

Pediatric patients present with a variety of orthopaedic conditions, including congenital deformities, traumatic injuries, infections, and malignancies. Anesthetic management of the pediatric orthopaedic patient involves not only the usual pediatric patient considerations, such as airway management, fluid replacement, and maintenance of body temperature, but also the unique concerns associated with orthopaedic surgery. Coexisting neuromuscular conditions, such as arthrogryposis or myelomeningocele, may predispose pediatric orthopaedic patients to latex allergy and malignant hyperthermia. In addition, patient positioning and the use of regional techniques for

intraoperative anesthesia and postoperative analgesia must be considered.

Regional techniques are readily adaptable to the pediatric orthopaedic patient. Often, regional anesthetic procedures are technically easier to perform on children because the relative lack of subcutaneous tissue facilitates identification of bony and vascular landmarks as well as spread of local anesthetic solutions. The advantages of regional anesthesia in children are similar to those in adults and include earlier ambulation and hospital discharge, decreased incidence of nausea and vomiting, and prolonged postoperative analgesia. However, pediatric patients often are not considered candidates for regional techniques. The preoperative visit is essential in building a patient–parent–physician relationship and establishing an anesthetic plan. The use of preoperative and preblock sedation (oral and intranasal midazolam, intramuscular ketamine, and rectal methohexital) decreases anxiety and increases acceptance of regional anesthesia in the pediatric patient.

Orthopaedic procedures may be performed with children anesthetized with regional, general, or a combination of anesthetic techniques. The patient's age, operative site and positioning, and surgical duration are important factors in selection of an anesthetic. Children older than 7 years of age may tolerate a primary regional anesthetic technique, whereas younger children may benefit from a general or combination regional/general anesthesia. Neural blockade may be initiated after induction of general anesthesia and before surgical incision, to provide possible preemptive analgesia, or, on completion of the surgical procedure, to extend the duration of postoperative analgesia.

Surgical procedures to the lower extremity may be safely and successfully performed under caudal, epidural, and spinal anesthesia.[55] However, the anatomic differences between the pediatric and adult spine and spinal cord must be appreciated.[56] In addition, femoral, lateral femoral cutaneous, and sciatic nerve blocks allow prolonged anesthesia and analgesia to the blocked extremity, but often require additional intraoperative supplementation with intravenous or inhalational agents.[57]

Upper-extremity procedures may be performed with any of the anesthetic techniques previously described for adults. The superficial location of the brachial plexus, decreased neural diameter,

and rapid diffusion of local anesthetics contribute to the high success rate, which approaches 100%, even with a variety of techniques.[58] Blockade of the brachial plexus is usually accomplished with perivascular, sheath, or nerve stimulator techniques in children younger than 7 years of age because elicitation of paresthesias is regarded as uncomfortable (and therefore unacceptable) by the younger pediatric patients. Intravenous regional (Bier) block is particularly useful in the pediatric population for limited procedures such as closed reduction of forearm fractures. The use of local anesthetic eutectic creams minimizes patient discomfort during intravenous catheter placement.

OTHER CONSIDERATIONS

Anesthesia for Nonsurgical Orthopaedic Procedures

Many orthopaedic procedures requiring anesthesia are carried out in areas other than the operating room. These include cast and dressing changes in pediatric patients, pin removal, hip and shoulder relocation, closed reduction of fractures, and joint manipulations. Although some of the minor procedures require only light sedation, those procedures involving bone and joint manipulation usually require a full anesthetic intervention. It is critically important that patients undergoing these procedures be managed with the same careful attention afforded those scheduled for a standard operating room. Regional anesthesia, usually with a short-acting local anesthetic, can be a good choice for these procedures, especially when the patient wants to leave the hospital on the same day with minimal residual anesthetic effects.

Regional Anesthesia in the Outpatient Setting

Hospital discharge criteria generally include successful oral intake, ambulation, and voiding by the patient. Thus, patients who have undergone a neuraxial technique will not be discharged until complete block resolution (although the requirement to void is somewhat controversial). Return of full neurologic function may be less important immediately after peripheral nerve blocks. Persisting peripheral or plexus blockade provides excellent pain relief and increased blood flow to the surgical site, both of which may be desirable side effects. However, the risk of accidental nerve trauma in an anesthetized extremity is theoretically higher outside the hospital environment. The patient should be informed of the risks and instructed in appropriate care of the extremity. Patients who are unable or unwilling to comply with recommended medical care may not be good candidates for regional anesthesia techniques and/or should be fully recovered before discharge.

In all cases, a follow-up telephone call on the first postoperative day should include questions concerning residual areas of neural blockade or altered neural function, such as paresthesias. Any patient concerns regarding the anesthetic or surgery should also be discussed. Patients with indwelling plexus or peripheral catheters should be queried regarding the presence of residual block, signs of local anesthetic toxicity, and catheter migration.[37,47] Following spinal anesthesia or accidental dural puncture during epidural anesthesia, the patient should be informed of the risk of postspinal headache and given a contact person in the anesthesia department to call if problems arise.

Tourniquets

Tourniquets are often used to minimize blood loss and provide a bloodless operating field. The cuff should be applied over limited padding or none at all. Appropriate selection of tourniquet cuff size and inflation pressure is paramount in reducing the risk of neuromuscular injury related to tourniquet ischemia. The cuff should be large enough to comfortably circle the limb to ensure circumferentially uniform pressure. The point of overlap should be placed 180 degrees from the neurovascular bundle because there is some area of decreased compression at the overlap point. The width of the inflated cuff should be more than half the limb diameter. Before tourniquet inflation, the limb should be elevated for approximately 1 minute and tightly wrapped with an elastic bandage distally to proximally.

Opinions differ as to the pressure required in tourniquets to prevent bleeding. In general, a cuff pressure 100 mm Hg above a patient's measured systolic pressure is adequate for the thigh, and 50 mm Hg above systolic pressure is adequate for the arm, with the understanding that if hypertensive episodes occur, the cuff pressure should be increased. Bleeding from the surgical site after cuff inflation may rarely be due to inadequate occlusion of the major arterial inflow, which is corrected by cuff reapplication and use of the proper degree of inflation. Bleeding during tourniquet inflation is more commonly due to intramedullary blood flow in the long bones, particularly in the skeletally immature, and to small arterial vessels between the two bones of distal extremities. Overinflation of the tourniquet does *not* resolve these problems. Likewise, the duration of safe tourniquet inflation is unknown. Recommendations range

from 30 minutes to 4 hours. Five minutes of intermittent perfusion between 1- and 2-hour inflations, followed by repeated exsanguination through elevation and compression, may allow more extended use.[59]

Damage to underlying vessels, nerves, and skeletal muscles has been reported following tourniquet inflation.[60] Injury is a function of both inflation pressure and duration of inflation.[61,62] Direct pressure from the cuff is more damaging than the ischemia distally.[61,63] Arterial spasm, venous thrombosis, and nerve injury are all demonstrable after several hours. Clinical examination, electromyography, and effluent blood analysis all show completely reversible changes for inflations of 1 to 2 hours, which is the basis for the recommendation of this period as the safe duration for tourniquet use; longer inflation times are associated with prolonged or irreversible changes in neurologic and/or muscular function.[64]

Transient systemic metabolic acidosis and increased arterial carbon dioxide levels have been demonstrated after tourniquet deflation, and do not cause deleterious effects in healthy patients.[65,66] Measurable changes include a 10 to 15% increase in heart rate, a 5 to 10% increase in serum potassium, and a rise of 1 to 8 mm Hg in carbon dioxide tension in blood. Prolonged inflation or the simultaneous release of two tourniquets may produce clinically significant acidosis, particularly in patients with an underlying acidosis due to other causes. Tourniquet release has also been associated with cerebral embolic phenomena.[67]

When a pneumatic tourniquet is used with regional anesthetic techniques, some patients complain of dull, aching pain or become restless, even though seemingly adequate analgesia exists for the operation itself. Patient discomfort usually appears approximately 45 minutes after the tourniquet is inflated and becomes more intense with time. No satisfactory explanation for its genesis has been found. Current explanations involve pain transmission through both A delta and C fibers, and its modulation in the dorsal horn synapses. The C (slow pain) fibers recover faster as the block wanes. Analogous phenomena may be observed at the same time point during general anesthesia. Evidence of lightening anesthesia (increase in blood pressure and pulse rate) may appear even though the same concentrations of anesthetic are being delivered.[68,69] The definitive treatment for tourniquet pain is release of the tourniquet. Relief of pain is prompt and complete. During surgery, however, opioids and hypnotics are usually effective.

Fat Embolus Syndrome

Fat embolus syndrome (FES) is associated with multiple traumatic injuries and surgery involving long bone fractures.[70] Risk factors include male gender, age (20 to 30 years), hypovolemic shock, intramedullary instrumentation, rheumatoid arthritis, THA using the technique of cementing femoral stems designed for press-fit application, and bilateral total knee surgery. The incidence of FES in isolated long bone fractures is 3 to 4%, and the mortality rate associated with this condition is significant, ranging from 10 to 20%.

Clinical and laboratory signs of FES have been classified by Gurd[71] as major or minor (Table 40-2), with a diagnosis requiring at least one major and four minor criteria, as well as the exclusion of other posttraumatic causes of hypoxemia. Major signs of the syndrome include the presence of axillary or subconjunctival petechiae, significant hypoxemia, central nervous system depression in excess of that expected due to the level of hypoxemia, and pulmonary edema. Classified as minor

signs are tachycardia, hyperthermia, retinal fat emboli on funduscopic examination, urinary fat globules, an unexplained decrease in hematocrit or platelets, an increased erythrocyte sedimentation rate, and fat globules in the sputum. Symptoms usually occur 12 to 40 hours after the injury and can range from mild dyspnea to frank coma. Decreased arterial oxygen tension is the most consistent abnormal laboratory value. Fulminant episodes can occur within hours of the traumatic injury, causing severe hypoxemia, respiratory failure, and severe neurologic impairment. Disseminated intravascular coagulation can also occur in conjunction with FES. Not all trauma patients who have demonstrated evidence of fat emboli fit the criteria for diagnosis of FES. Two theories are hypothesized to explain the mechanism of this syndrome: the mechanical theory and the biochemical theory. The mechanical theory proposes that long bone trauma results in release of fat droplets that enter the vascular system through torn veins. These droplets are transported to the pulmonary vascular bed where they act as microemboli. The biochemical theory can be divided into two mechanisms: toxic and obstructive. The toxic mechanism proposes that free fatty acids released at the time of trauma directly affect pneumocytes in the lung and cause adult respiratory distress syndrome. This effect would be enhanced by the trauma-induced release of catecholamines, which would result in further mobilization of free fatty acids. The obstructive theory hypothesizes that an unspecified chemical event at the site of the fracture releases mediators that affect lipid solubility, resulting in coalescence of lipids and consequent embolization. Some or all these theories may play a role in development of FES. Other predisposing or aggravating factors such as shock, hypovolemia, sepsis, or disseminated intravascular coagulation may be required to trigger the conversion of fat emboli to FES.

TABLE 40-2 Criteria for Diagnosis of Fat Embolus Syndrome

▪MAJOR
Axillary/subconjunctival petechiae
Hypoxemia (PaO_2 < 60 mm Hg; FIO_2 < 0.4)
Central nervous system depression (disproportionate to hypoxemia)
Pulmonary edema
▪MINOR
Tachycardia (>110 beats/min)
Hyperthermia
Retinal fat emboli
Urinary fat globules
Decreased platelets/hematocrit (unexplained)

Increased erythrocyte sedimentation rate
Fat globules in sputum
Diagnosis of fat embolus syndrome requires at least one sign from the major and four signs from the minor criteria categories.
From Gurd AR: Fat embolism: An aid to diagnosis. J Bone Joint Surg Br 52:732, 1970, with permission.

8 Appropriate treatment of FES requires early recognition of the syndrome, reversal of possible aggravating factors such as hypovolemia, early surgical stabilization of fracture sites, and aggressive respiratory support. Corticosteroid therapy is controversial but may be beneficial. Other pharmacologic interventions, including heparin and dextran, have not been shown to be effective in treating FES.

Methyl Methacrylate

Methyl methacrylate is an acrylic bone cement used during arthroplastic procedures. Insertion of this cement is associated with sudden onset of hypotension in some patients. This

hypotension has been attributed to absorption of the volatile monomer of methyl methacrylate, embolization of air and bone marrow during femoral reaming, lysis of blood cells and marrow induced by the exothermic reaction, and conversion of methyl methacrylate to methacrylate acid. Adequate hydration and maximizing inspired oxygen concentration minimize the hypotension and hypoxemia that can accompany cementing of the prosthesis. Because air can be entrained during this procedure, nitrous oxide should be discontinued several minutes before this point.

Deep Venous Thrombosis and Pulmonary Embolus

Orthopaedic surgical procedures are associated with a variety of complications due to embolic phenomena. Reported emboli occurring during and after surgery include fat, cement, air, and thrombus. These may be caused by multiple factors such as positioning, fracture of long bones, injection of cement under pressure, and predisposing medical conditions. VAE can occur in orthopaedic surgical patients undergoing spinal surgery in the prone position and shoulder surgery in the sitting position, and is discussed earlier in this chapter.

Venous thromboembolism is a major cause of death after surgery or trauma to the lower extremities. Without prophylaxis, venous thrombosis develops in 40 to 80% of orthopaedic patients, and 1 to 28% show clinical or laboratory evidence of pulmonary embolism. Fatal pulmonary embolism occurs in 0.1 to 8% of patients[72] (Table 40-3). The incidence of fatal pulmonary embolism is highest in patients who have undergone surgery for hip fracture. Although fatal pulmonary embolism may be the most common preventable cause of hospital death, many physicians fail to use prophylaxis appropriately because of concern about bleeding complications from anticoagulation. Effective thromboprophylaxis requires knowledge of clinical risk factors in individual patients, such as advanced age, prolonged immobility or bed rest, prior history of thromboembolism, cancer, preexisting hypercoagulable state, and major surgery. In many patients, multiple risk factors may be present, and the risks are cumulative. After identification of the risk of thromboembolism, an assessment may be made regarding the risks and benefits of physical or pharmacologic techniques used to prevent thromboembolic complications.

TABLE 40-3 Venous Thromboembolism Prevalence After Major Orthopaedic Surgery

	·DEEP VENOUS THROMBOSIS[a]		·PULMONARY EMBOLISM	
·PROCEDURE	·TOTAL(%)	·PROXIMAL(%)	·TOTAL(%)	·FATAL(%)
Total hip replacement	42–57%	18–36%	0.9–28%	0.14–2.0%
Total knee replacement	41–85%	5–22%	1.5–10%	0.1–1.7%
Hip fracture surgery	46–60%	23–30%	3–11%	2.5–7.5%

[a]Total or proximal deep venous thrombosis prevalence based on the use of mandatory venography in prospective randomized clinical trials in which patients received either prophylaxis or a placebo.

From Geerts WH, Pineo GF, Heit JA *et al*: Prevention of venous thromboembolism: The seventh ACCP conference on antithrombotic and thrombolytic therapy. Chest 126(3 suppl):338S, 2004, with permission.

Antithrombotic Prophylaxis

Patients undergoing major orthopaedic surgery are at high risk for thromboembolism. Thromboprophylaxis is based on identification of risk factors. Guidelines for antithrombotic therapy, including selection of pharmacologic agent, degree of anticoagulation desired, and duration of therapy continue to evolve.[72] Recommendations from the Seventh American College of Chest Physicians in 2004 are based on prospective randomized studies that assess the efficacy of therapy, using contrast venography or fibrinogen leg scanning to diagnose asymptomatic thrombi (Table 40-4).

TABLE 40-4 Antithrombotic Regimens To Prevent Thromboembolism In Orthopaedic Surgical Patients

·HIP AND KNEE ARTHROPLASTY AND HIP FRACTURE SURGERY

- LMWH[a] started 12 hr before surgery or 12 to 24 hr after surgery, or 4 to 6 hr after surgery at half the usual dose and then increasing to the usual high-risk dose the following day
- Fondaparinux (2.5 mg started 6 to 8 hr after surgery)
- Adjusted-dose warfarin started preoperatively or the evening after surgery (INR target, 2.5; INR range, 2.0 to 3.0)
- Intermittent pneumatic compression is an alternative option to anticoagulant prophylaxis in patients undergoing total knee (but not hip) replacement

·SPINAL CORD INJURY
• LMWH once primary hemostasis is evident • Intermittent pneumatic compression is an alternative option when anticoagulation is contraindicated early after the injury • During the rehabilitation phase, conversion to adjusted-dose warfarin (INR target, 2.5; INR range, 2.0 to 3.0)
·ELECTIVE SPINE SURGERY
• Routine use of thromboprophylaxis, apart from early and persistent mobilization, not recommended
·KNEE ARTHROSCOPY
• Routine use of thromboprophylaxis, apart from early and persistent mobilization, not recommended
INR, international normalized ratio; LMWH, low molecular weight heparin.
[a]Use with caution in patients receiving neuraxial anesthesia/analgesia. Enoxaparin and dalteparin are LMWH approved by the U.S. Food and Drug Administration.
From Geerts WH, Pineo GF, Heit JA *et al*: Prevention of venous thromboembolism: The seventh ACCP conference on antithrombotic and thrombolytic therapy. Chest 126(3 suppl):338S, 2004, with permission.

Multiple thromboprophylaxis regimens for patients undergoing total joint replacement and hip fracture surgery have

been studied. Although aspirin, subcutaneous unfractionated heparin, and the presence of a neuraxial block are more efficacious than placebo, the risk of thromboembolism remains significant, and a higher level of anticoagulation is required. In addition, although adjusted-dose administration of unfractionated heparin (to attain an activated partial thromboplastin time in the upper normal range) is effective, most orthopaedic surgeons consider adjusted-dose heparin prophylaxis impractical. Rather, administration of low molecular weight heparin (LMWH), warfarin, or fondaparinux is recommended. Similar recommendations are made for patients with acute spinal cord injury. Conversely, other orthopaedic patients are considered low risk, and no pharmacologic prophylaxis is warranted.

Neuraxial Anesthesia and Analgesia in the Patient Receiving Antithrombotic Therapy

9 Several studies show a decrease in the incidence of both DVT and PTE in patients undergoing hip surgery under epidural[38,39,40] and spinal[73,74,75] anesthesia. Similar findings have been reported for knee surgery performed under epidural anesthesia.[76,77] Proposed mechanisms for this effect include (1) rheologic changes resulting in hyperkinetic lower-extremity blood flow, reducing

venous stasis and preventing thrombus formation; (2) beneficial circulatory effects from epinephrine added to the local anesthetic solutions; (3) altered coagulation and fibrinolytic responses to surgery under central neural blockade, resulting in a decreased tendency for blood to clot and better fibrinolytic function[78]; (4) the absence of positive-pressure ventilation and its concomitant effects on circulation; and (5) direct local anesthetic effects such as decreased platelet aggregation. It is important to note that most of the studies examining the value of epidural and spinal anesthesia in preventing DVT and PTE involved patients who were not receiving currently recommended pharmacologic prophylaxis.

Despite the advantages of neuraxial techniques, patients receiving perioperative anticoagulants and antiplatelet medications are often not considered candidates for spinal or epidural anesthesia/analgesia because of the risk of neurologic compromise from expanding spinal hematoma. The actual incidence of neurologic dysfunction resulting from hemorrhagic complications associated with neuraxial blockade is unknown; however, the incidence cited in the literature is estimated to be less than 1 in 150,000 epidural and less than 1 in 220,000 spinal anesthetics.[79] The frequency of spinal hematoma is increased in patients who receive perioperative anticoagulation.[80] The more recent introduction of more efficacious anticoagulants and antiplatelet agents has further increased the complexity of patient management. Anesthesiologists must balance the risk of thromboembolic and hemorrhagic complications.

Spinal hematoma was considered a rare complication of neuraxial blockade until the introduction of LMWH as a thromboprophylactic agent in the 1990s. The calculated incidence (approximately 1 in 3,000 epidural anesthetics), along with the catastrophic nature of spinal bleeding (only 30% of patients had good neurologic recovery)[81] warranted an alternate approach to analgesic management following total hip and knee replacement. Although psoas compartment and femoral catheters are suitable (if not superior) alternatives to neuraxial infusions, there are no investigations that examine the frequency and severity of hemorrhagic complications following plexus or peripheral blockade in anticoagulated patients. All cases of major bleeding (significant decreases in hemoglobin and/or blood pressure) associated with nonneuraxial techniques occurred after psoas compartment or lumbar sympathetic blockade and have involved heparin, LMWH, warfarin, and thienopyridine derivatives. These cases suggest that significant blood loss, rather than neural deficits, may be the most serious complication of nonneuraxial regional techniques in the anticoagulated patient. Additional information is needed to make definitive recommendations. The current information focuses on neuraxial blocks and anticoagulants (Table 40-5).[82] Conservatively, these neuraxial guidelines may be applied to plexus and peripheral techniques. However, this may be more restrictive than necessary.

TABLE 40-5 Neueraxial Anesthesia and Analgesia in the Orthopaedic Patient Receiving Antithrombotic Therapy

▪LMWH
Needle placement should occur 10–12 hr after a dose. Indwelling neuraxial catheters are allowed with once (but not twice daily) dosing of LMWH. In general, it is optimal to place/remove indwelling catheters in the morning and administer LMWH in the evening to allow normalization of hemostasis to occur prior to catheter manipulation.
▪WARFARIN
Adequate levels of all vitamin K-dependent factors should be present during catheter placement and removal. Patients chronically on warfarin should have normal INR prior to performance of regional technique. Monitor prothrombin time and INR daily. Remove

catheter when INR <1.5.
·FONDAPARINUX
Neuraxial techniques are not advised in patients who are anticipated to receive fondarinux perioperatively.
·NONSTEROIDAL ANTI-INFLAMMATORY DRUGS
No significant risk of regional anesthesia-related bleeding is associated with aspirin-type drugs. However, for patients receiving warfarin or LMWH, the combined anticoagulant and antiplatelet effects may increase the risk of perioperative bleeding. In addition, other medications affecting platelet function such as the thienopyridine derivatives and glycoprotein IIb/IIIa platelet receptor inhibitors should be avoided.
INR, international normalized ratio; LMWH, low molecular weight heparin.
Adapted from Horlocker TT, Wedel DJ, Benzon H *et al*: Regional anesthesia in the anticoagulated patient: Defining the risks (the second ASRA consensus conference on neuraxial anesthesia and anticoagulation). Reg Anesth Pain Med 28:172, 2003.

In summary, thromboembolism is a serious complication of total joint replacement. The development of new antithrombotic drugs, mechanical devices, and postoperative rehabilitation regimens is paramount in improving patient outcome. Neuraxial and peripheral techniques, which allow for early ambulation and earlier hospital discharge may prove to be an integral component of patient care. However, at this time, they do not replace the need for pharmacologic thromboprophylaxis.

Chapter 41

Anesthesia and the Endocrine System

Jeffrey J. Schwartz

Stanley H. Rosenbaum

KEY POINTS

1	Asymptomatic or mild hypothyroidism does not appear to significantly increase anesthetic risk and is not a contraindication to surgery. Moderate to severe hypothyroidism should be corrected before surgery to prevent multisystem complications.
2	The major risk of anesthesia in the poorly controlled thyrotoxic patient is thyroid storm, which must be aggressively treated with beta-blockers, iodide, and antithyroid drugs.
3	Patients who have received corticosteroids for more than 1 week in the past year may have adrenal suppression and should receive supplemental steroids in the perioperative period.
4	Preoperative preparation of the pheochromocytoma patient with alpha-blockers decreases intraoperative hemodynamic instability.
5	Tumor manipulation is associated with severe hypertension that should be treated aggressively with nitroprusside, phentolamine, or other rapidly acting vasodilators.
6	The major perioperative risks to the diabetic patient come from coexisting disease, especially coronary artery disease. Coexisting disease must be aggressively sought and optimized.
7	Maintenance of blood glucose levels near euglycemia appears to reduce cardiac, wound, neurologic, and septic complications.
8	Patients with acromegaly may be difficult intubations that cannot be anticipated by physical examination.

THYROID GLAND

The thyroid gland secretes thyroid hormones, thyroxine (T_4), and 3,5,3′-1-tri-iodothyronine (T_3), which are the major regulators of cellular metabolic activity. Thyroid hormones exert a variety of actions by regulating the synthesis and activity of various proteins. They are necessary for proper cardiac, pulmonary, and neurologic function during both health and illness.

Thyroid Metabolism and Function

The production of thyroid hormone is initiated by the active uptake and concentration of iodide in the thyroid gland (Fig. 41-1). Dietary iodine is reduced to iodide in the gastrointestinal (GI) tract. Circulating iodide is taken up by the thyroid gland, where it is then bound to tyrosine residues to form various iodotyrosines. After organification, monoiodotyrosine or diiodotyrosine is coupled enzymatically by thyroid peroxidase

to form either T_3 or T_4. These hormones are attached to the thyroglobulin protein and stored as colloid in the gland. The release of T_3 and T_4 from the gland is accomplished through proteolysis from the thyroglobulin and diffusion into the circulation. Thyrotropin (thyroid-stimulating hormone or TSH) is produced in the anterior pituitary gland, and its secretion is regulated by thyrotropin-releasing hormone, produced in the hypothalamus. TSH is responsible for maintaining the uptake of iodide and proteolytic release of thyroid hormone. Excess iodine inhibits the synthesis and secretion of thyroid hormone. Circulating thyroid hormone inhibits thyroid-releasing hormone and TSH secretion in a negative feedback loop. The thyroid gland is solely responsible for the daily secretion of T_4 (80 to 100 µg/day). The half-life of T_4 in the circulation is 6 to 7 days.

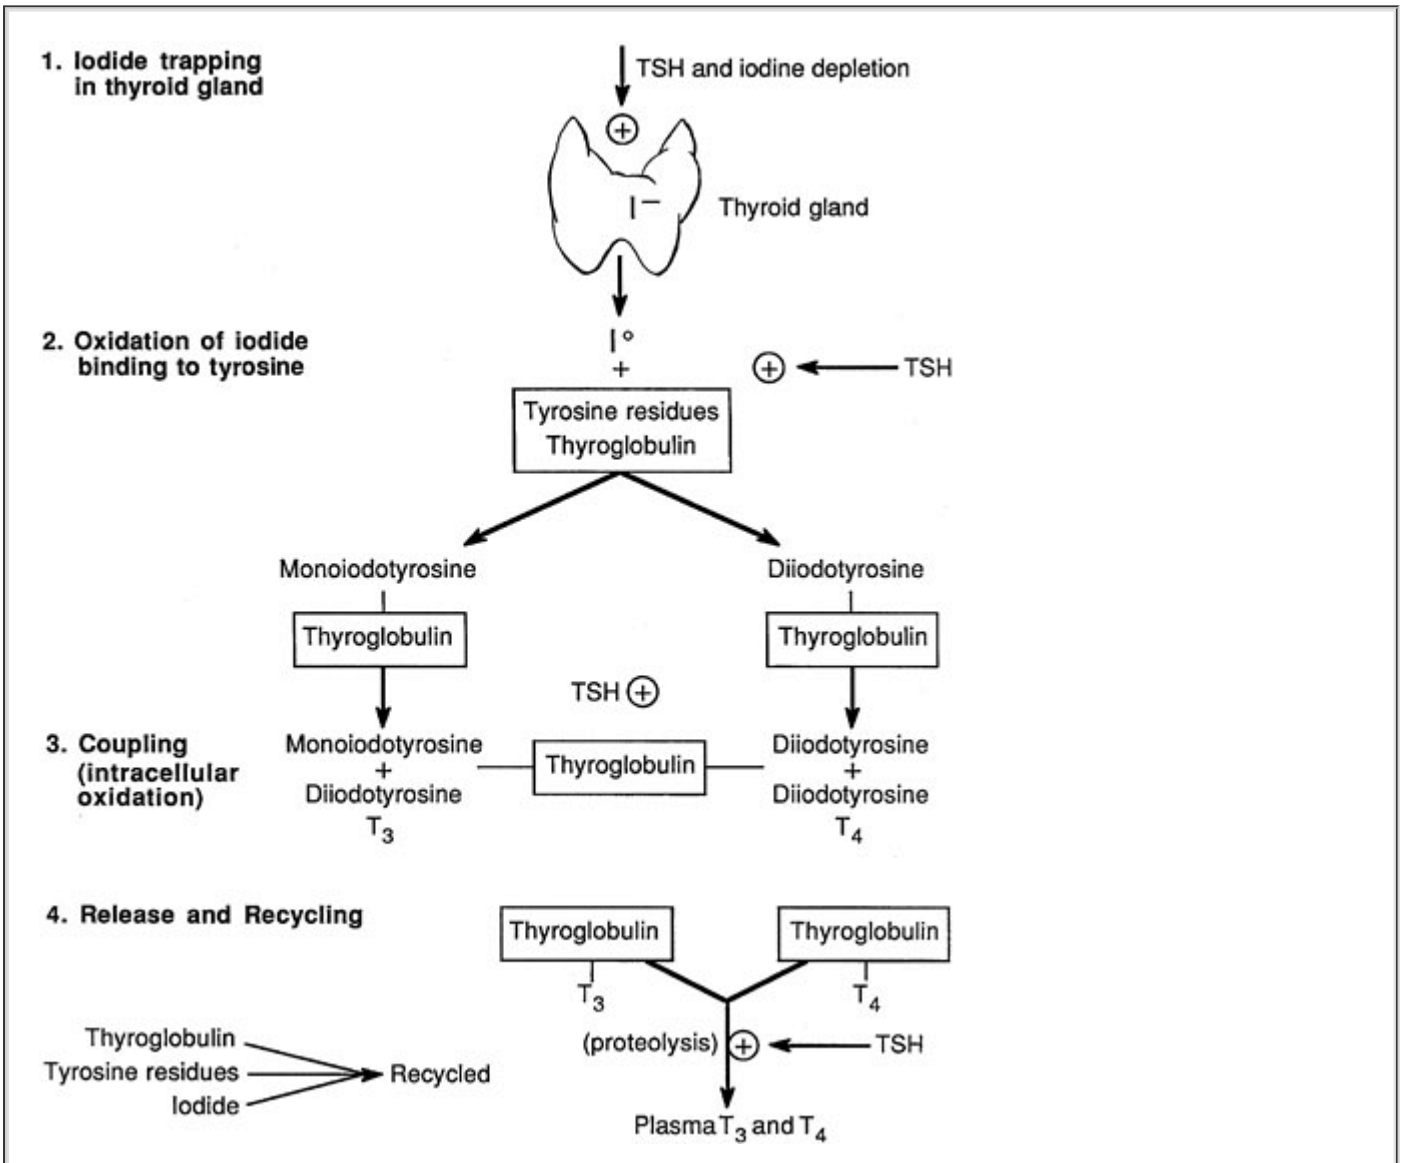

FIGURE 41-1. Thyroid hormone biosynthesis consists of four stages: (1) organification, (2) binding, (3) coupling, and (4) release. TSH, thyroid-stimulating hormone; T_3, triiodothyronine; T_4, thyroxine.

Approximately 80% of T_3 is produced by the extrathyroidal deiodination of T_4 and 20% by direct thyroid secretion. The half-life of T_3 is 24 to 30 hours. Most of the effects of thyroid hormones are mediated by the more potent and less protein-bound T_3. The degree to which these hormones are protein bound in the circulation is the major factor influencing their activity and degradation. T_4 is metabolized by monodeiodination to either T_3 or reverse T_3 (rT_3). T_3 is biologically active, whereas rT_3 is inactive. The major fraction of circulating hormone is bound to thyroid-binding globulin (TBG), with a smaller fraction bound to albumin and thyroid-binding prealbumin. Less than 0.1% is present as free, unbound hormone. Changes in serum-binding protein concentrations have a major effect on total T_3 and T_4 serum concentrations. The plasma normally contains 5 to 12 µg/dL of T_4 and 80 to 220 ng/dL of T_3. Many drugs can affect thyroid function, including amiodarone and dopamine.[1]

Although the thyroid hormone is important to many aspects of growth and function, the anesthesiologist is most often concerned with the cardiovascular manifestations of thyroid disease. Thyroid hormones affect tissue responses to sympathetic stimuli and increase the intrinsic contractile state of cardiac muscle. β-Adrenergic receptors are increased in number, and cardiac α-adrenergic receptors are decreased by thyroid hormone.

Tests of Thyroid Function

Serum Thyroxine

The serum T_4 assay is the standard screening test for evaluation of thyroid gland function (Table 41-1). The total T_4 is elevated in approximately 90% of patients with hyperthyroidism, and it is low in 85% of those who are hypothyroid. The concentration of T_4 is measured by radioimmunoassay (RIA). The serum T_4 concentration is influenced by thyroid hormone protein-binding capacity. An increase or decrease in TBG levels or in protein binding may therefore alter the total T_4 but not the concentration of the free T_4. Because of the effect of TBG on circulating total T_4, T_4 levels should never be used alone to evaluate thyroid disease. Elevations in the TBG concentration are the most common cause of hyperthyroxinemia in euthyroid patients. Increases in TBG due to acute liver disease, pregnancy, or drugs (oral contraceptives, exogenous estrogens, clofibrate, opioids) may be responsible. Because a total T_4 can be misleadingly high in euthyroidism or normal in hypothyroidism, some measure of free thyroid hormone activity (free T_4) must also be used.

TABLE 41-1 Tests of Thyroid Gland Function

	·T_4	·T_3	·THBR	·TSH
Hyperthyroidism	Elevated	Elevated	Elevated	Normal or low
Primary hypothyroidism	Low	Low or normal	Low	Elevated

Secondary hypothyroidism	Low	Low	Low	Low
Sick euthyroidism (decreased peripheral conversion of T_4 to T_3)	Normal	Low	Normal	Normal
Pregnancy	Elevated	Normal	Low	Normal

T_4, total serum thyroxine; T_3, serum triiodothyronine; THBR, thyroid hormone-binding rate; TSH, thyroid-stimulating hormone.

Serum Triiodothyronine

The serum T_3 is also measured by RIA. Serum T_3 levels are often determined to detect disease in patients with clinical evidence of hyperthyroidism in the absence of elevations of T_4. T_3 may be the only thyroid hormone produced in excess. T_3 concentrations may be depressed by factors that impair the peripheral conversion of T_4 to T_3 (sick euthyroid syndrome). In 50% of hypothyroid patients, the serum T_3 concentration is low; in the remaining 50%, it is normal.

Tests for Assessing Thyroid Hormone Binding

It is necessary to find some measure of thyroid-binding proteins, mostly TBG, to interpret correctly total thyroxine levels. The "T uptake" test measures the ability of the patient's serum to bind exogenously introduced T_4 and reflects the amount of TBG and the extent of T_4 saturation on TBG. The T uptake is inversely related to the degree of unsaturation of TBG. The T uptake can be used to calculate the T_4-binding capacity, which is directly related to the degree of unsaturation of TBG. The T uptake or T_4-binding capacity can be used to calculate the estimated free T_4 or free T_4 index, which reflects the free T_4 concentration in the blood independent of binding proteins.

Thyroid-Stimulating Hormone

The RIA for this hormone has proved most useful in detecting patients who are hypothyroid. It is often higher than 20 μIU/mL in primary hypothyroidism (normal, 8 μIU/mL). Current assays are sensitive enough to diagnose hyperthyroidism by depressed levels of TSH. A condition characterized by elevated TSH and normal T_4 may represent subclinical hypothyroidism. A low TSH level in a clinically hypothyroid patient indicates disease at the pituitary or hypothalamic level. The goal of thyroid replacement therapy is to normalize TSH levels.[2] Starvation, fever, stress, corticosteroids, and T_3 or T_4 can all depress TSH levels.

Radioactive Iodine Uptake

The thyroid gland has the ability to concentrate large amounts of inorganic iodide. The oral administration of radioactive iodine (^{131}I) can be used to indicate thyroid gland activity. Thyroid uptake is elevated in hyperthyroidism unless the hyperthyroidism is caused by thyroiditis, in which case the uptake is low or absent. Because of overlap in values, it is difficult to distinguish euthyroid from hypothyroid people. Radioactive iodide uptake may be increased by a variety of factors, including dietary iodine deficiency, renal failure, and congestive heart failure. Because uptake is under TSH control, elevated free T_4 levels and corticosteroids decrease radioactive iodide uptake. Functioning ("hot") thyroid tissue is rarely malignant. Nonfunctioning ("cold") tissue may be malignant or benign.

Hyperthyroidism

Hyperthyroidism results from the exposure of tissues to excessive amounts of thyroid hormone (Table 41-2). The most common etiology is the multinodular diffuse goiter of Graves' disease. This typically occurs between the ages of 20 and 40 years, and is predominant in women. Most of these patients demonstrate a syndrome characterized by diffuse glandular enlargement, ophthalmopathy, dermopathy, and clubbing of the fingers. A thyroid-stimulating autoantibody may be present. Thyroid adenoma is the second most common cause. Another cause of increased thyroid hormone synthesis is thyroiditis. Subacute thyroiditis frequently follows a respiratory illness and is characterized by a viral-like illness with a firm, painful gland. This type of thyroiditis is frequently treated with

anti-inflammatory agents alone. Rarely, subacute thyroiditis may occur in a patient with a normal-size, painless gland. Hashimoto's thyroiditis is a chronic autoimmune disease that usually produces hypothyroidism but may occasionally produce hyperthyroidism. Hyperthyroidism may also be associated with pregnancy, ^{131}I therapy, thyroid carcinoma, trophoblastic tumors, or TSH-secreting pituitary adenomas. Iatrogenic hyperthyroidism may follow thyroid hormone replacement or may occur after iodide exposure (angiographic contrast media) in patients with chronically low iodide intake (Jod-Basedow phenomenon). The antiarrhythmic agent amiodarone is iodine rich and is another cause of iodine-induced thyrotoxicosis.[3]

Iodine induced
TSH, thyroid-stimulating hormone.

The major manifestations of hyperthyroidism are weight loss; diarrhea; skeletal muscle weakness and stiffness; warm, moist skin; heat intolerance; and nervousness. Cardiovascular manifestations include increased left ventricular contractility and ejection fraction, tachycardia, elevated systolic blood pressure, and decreased diastolic blood pressure. Hypercalcemia, thrombocytopenia, and a mild anemia may be present. Elderly patients may present with heart failure, atrial fibrillation, or other cardiac dysrhythmias. They may also present with apathetic hyperthyroidism characterized by depression and withdrawal, without the usual systemic signs or symptoms.

Treatment and Anesthetic Considerations

The most important goal in managing the hyperthyroid patient is to make the patient euthyroid before any surgery, if possible. The drugs propylthiouracil and methimazole are thiourea derivatives that inhibit organification of iodide and the synthesis of thyroid hormone.[4] Propylthiouracil also decreases the peripheral conversion of T_4 to T_3. Normal thyroid glands usually contain a store of hormone that is large enough to maintain a euthyroid state for several months, even if synthesis is abolished. Therefore, hyperthyroid patients are unlikely to be regulated to a euthyroid state with antithyroid drugs alone in less than 6 to 8 weeks. Toxic reactions from these drugs are uncommon, but include skin rash, nausea, fever, agranulocytosis, hepatitis, and arthralgias.

Inorganic iodide inhibits iodide organification and thyroid hormone release—the Wolff-Chaikoff effect. Iodide is also effective in reducing the size of the hyperplastic gland and has a role in the preparation of the patient for emergency thyroid surgery. Antithyroid drugs should be started before iodide treatment because of the possibility of worsening the thyrotoxicosis.

β-Adrenergic antagonists are effective in attenuating the manifestations of excessive sympathetic activity and should be used in all hyperthyroid patients unless contraindicated. β-Adrenergic blockade alone does not inhibit hormone synthesis, but propranolol does impair the peripheral conversion of T_4 to T_3 over 1 to 2 weeks. Propranolol given over 12 to 24 hours decreases tachycardia, heat intolerance, anxiety, and tremor. Any beta-blocker may be used, and long-acting agents may be more convenient. The combination of propranolol (in doses titrated to effect) plus potassium iodide (two to five drops every 8 hours) is frequently used before surgery to ameliorate cardiovascular symptoms and reduce circulating concentrations of T_4 and T_3. Preoperative preparation usually requires 7 to 14 days. Heart failure secondary to poorly controlled paroxysmal atrial fibrillation may improve with slowing of the ventricular rate, but abnormalities of left ventricular function secondary to hyperthyroidism may not be corrected with the use of β-antagonists. If a hyperthyroid patient with clinically apparent disease requires emergency surgery, β-adrenergic blockade should be administered to achieve a heart rate less than 90 beats/min.

Beta-blockers do not prevent thyroid storm. Glucocorticoids such as dexamethasone (8 to 12 mg/day) are used in the management of severe thyrotoxicosis because they reduce thyroid hormone secretion and the peripheral conversion of T_4 to T_3.

Iopanoic acid, a radiographic contrast agent that decreases peripheral conversion of T_4 and releases iodine that inhibits synthesis, is useful for emergency preparation.

Radioactive iodine therapy is an effective treatment for some patients with thyrotoxicosis.[5] It should not, however, be administered to patients who are pregnant because it crosses the placenta and may destroy the fetal thyroid. A side effect of RIA therapy is hypothyroidism; 10 to 60% of cases occur in the first year of therapy, and an additional 2% occur per year thereafter.

A variety of anesthetic techniques and drugs have been used for hyperthyroid patients undergoing surgery. All antithyroid medications are continued through the morning of surgery. The goal of intraoperative management in the hyperthyroid patient is to achieve a depth of anesthesia that prevents an exaggerated sympathetic response to surgical stimulation, while avoiding the administration of medication that stimulates the sympathetic nervous system. Pancuronium should be avoided. It is best to avoid using ketamine, even when a patient is clinically euthyroid. Hypotension that occurs during surgery is best treated with direct-acting vasopressors rather than a medication that provokes the release of catecholamines. The incidence of myasthenia gravis is increased in hyperthyroid patients; thus, the initial dose of muscle relaxant should be reduced, and a twitch monitor should be used to titrate subsequent doses. Regional anesthesia is an excellent alternative when appropriate; however, epinephrine-containing solutions should be avoided.

1 *Thyroid storm* is a life-threatening exacerbation of hyperthyroidism that most commonly develops in the undiagnosed or untreated hyperthyroid patient because of the stress of surgery or nonthyroid illness.[6] Operating on an acutely hyperthyroid gland may provoke thyroid storm, although this is probably not due to mechanical release of hormone.[7] Its manifestations include hyperthermia, tachycardia, dysrhythmias, myocardial ischemia, congestive heart failure, agitation, and confusion. It must be distinguished from, or considered with, pheochromocytoma, malignant hyperthermia, and light anesthesia. Although free T_4 levels are often markedly elevated, no laboratory test is diagnostic. Treatment involves large doses of propylthiouracil and supportive measures to control fever and restore intravascular volume. Hemodynamic monitoring (pulmonary artery catheter, arterial catheter) is especially useful in guiding the treatment of patients with significant left ventricular dysfunction (Table 41-3). Again, it is essential to remove or treat the precipitating event.

TABLE 41-3 Management of Thyroid Storm

Administer IV fluids.
Administer sodium iodide, 250 mg PO or IV q6h.
Administer propylthiouracil, 200–400 mg PO or via NGT q6h.
Administer hydrocortisone, 50–100 mg IV q6h.
Administer propranolol, 10–40 mg PO q4–6h, or esmolol infusion to treat hyperadrenergic signs.

Cooling blankets and acetaminophen and meperidine (25–50 mg) IV q4–6h may be used to prevent shivering.
Use digoxin for heart failure especially in the presence of atrial fibrillation with rapid ventricular response.
IV, intravenous(ly); PO, oral(ly); NGT, nasogastric tube.

Anesthesia for Thyroid Surgery

Subtotal thyroidectomy as an alternative to prolonged medical therapy is used less frequently now than in the past. Indications include failed medical therapy, underlying cancer, and symptomatic goiter. It is usually performed under general endotracheal anesthesia, although the use of the laryngeal mask airway is increasing.[8] Use of a laryngeal mask airway allows real-time visualization of vocal cord function because the patient is allowed to breathe spontaneously. Limited thyroidectomy may also be performed under bilateral superficial cervical plexus block. The anesthesiologist must be prepared to manage an unexpected difficult intubation because the incidence of difficult intubation during goiter surgery is 5 to 8%.[9] Thyroid cancer increases the risk, but the size of the goiter is not predictive. Airway obstruction is a potential problem in the patient with a large substernal goiter, although rarely a problem with goiters exclusively in the neck. Evidence of significant airway obstruction or tracheal deviation or narrowing may warrant inhalation induction or awake fiberoptic intubation. The complications after subtotal thyroidectomy include recurrent laryngeal nerve damage, tracheal compression secondary to hematoma or tracheomalacia, and hypoparathyroidism. Hypoparathyroidism secondary to the inadvertent surgical removal of parathyroid glands is most frequently seen after total thyroidectomy. The symptoms of hypocalcemia develop within the first 24 to 96 hours after surgery.[10] Laryngeal stridor progressing to laryngospasm may be one of the first indications of hypocalcemic tetany. The intravenous administration of calcium chloride or calcium gluconate is warranted in this situation. Magnesium levels should also be monitored and corrected if low. Bilateral recurrent laryngeal nerve injury is an extremely rare injury and necessitates reintubation. Unilateral nerve injury is more common and is often transient.[11] Unilateral damage to the recurrent laryngeal nerve is characterized by hoarseness and a paralyzed vocal cord, whereas bilateral injury causes aphonia. It is wise to evaluate vocal cord function before and after surgery by laryngoscopy or by asking the patient to phonate by saying the letter "e". Routine postoperative visualization of the vocal cords is not warranted. Postoperative extubation of the trachea should be performed under optimal conditions. Intraoperative laryngeal nerve injury or collapse of the tracheal rings from previous weakening may mandate emergency reintubation.

Hypothyroidism

Hypothyroidism is a relatively common disease (0.5 to 0.8% of the adult population) that results from inadequate circulating levels of T_4 or T_3, or both.[12] The development of hypothyroidism is often slow and progressive, making the clinical diagnosis difficult, especially in the more subtle cases. Hypofunctioning of the thyroid gland has many causes (Table 41-4). Primary failure of the thyroid gland refers to decreased production of thyroid hormone, despite adequate TSH production, and accounts for 95% of all cases of thyroid dysfunction. The remainder is caused by either hypothalamic or pituitary disease (secondary hypothyroidism) and is associated with other pituitary deficiencies.

A lack of thyroid hormone produces a variety of signs and symptoms. These early findings are often nonspecific and difficult to recognize. A history of RIA therapy, external neck irradiation, or the presence of a goiter is helpful in diagnosis. There is a generalized reduction in metabolic activity, resulting in lethargy, slow mental functioning, cold intolerance, and slow movements. The cardiovascular manifestations of hypothyroidism reflect the importance of thyroid hormone for myocardial contractility and catecholamine function. These patients exhibit bradycardia, decreased cardiac output, and increased peripheral resistance.[13] The accumulation of a cholesterol-rich pericardial fluid produces low voltage on the electrocardiogram (ECG). Heart failure only rarely occurs in the absence of coexisting heart disease. Angina pectoris itself is unusual in hypothyroidism but can appear when thyroid hormone treatment is initiated. Ventilatory responsiveness to hypoxia and hypercapnia is depressed in hypothyroid patients. This depression is potentiated by sedatives, opioids, and general anesthesia. Postoperative ventilatory failure

requiring prolonged ventilation is rarely seen in hypothyroid patients in the absence of coexisting lung disease, obesity, or myxedema coma. Other abnormalities found in hypothyroidism include anemia, coagulopathy, hypothermia, sleep apnea, and impaired renal free water clearance with hyponatremia. Decreased gastrointestinal motility can compound the effect of postoperative ileus. In long-standing or severe disease, the stress response may be blunted and adrenal depression may occur.

Treatment and Anesthetic Considerations

Treatment of symptomatic hypothyroidism is with hormone replacement therapy.[14] Controversy remains regarding the preoperative anesthetic management of the hypothyroid patient. Although it seems logical, given the multisystem effects of thyroid hormone, to recommend that all hypothyroid surgical candidates be restored to a euthyroid state before surgery, such a recommendation is, in general, based on individual case reports. There have been few controlled studies to support the position that most hypothyroid patients are unusually sensitive to anesthetic drugs, have prolonged recovery times, or have a higher incidence of cardiovascular instability or collapse.

2 No increase in serious complications in patients with mild or moderate hypothyroidism undergoing general anesthesia has been noted.[15] One study[16] noted a higher incidence of intraoperative hypotension and postoperative GI and neuropsychiatric complications in mild and moderately hypothyroid patients undergoing noncardiac surgery, but still noted there were no compelling clinical reasons to postpone surgery in these patients. Surgery in severely hypothyroid patients should be postponed when possible until these patients are at least partially treated.

The management of hypothyroid patients with symptomatic coronary artery disease has been a subject of particular controversy.[17] The need for thyroid hormone replacement therapy must be weighed against the risk of precipitating

myocardial ischemia. Several studies and a literature review found no differences in the frequency of intraoperative or postoperative complications when mild or moderately hypothyroid patients underwent cardiac surgery. In symptomatic patients or unstable patients with cardiac ischemia, thyroid replacement should probably be delayed until after coronary revascularization.

There appears to be little reason to postpone elective surgery in patients who have mild or moderate hypothyroidism. Thyroid replacement therapy is, however, indicated for patients with severe hypothyroidism or myxedema coma and for pregnant patients who are hypothyroid. Untreated hypothyroidism in pregnant patients is associated with an increased incidence of spontaneous abortion and mental and physical abnormalities in the offspring.

A number of anesthetic medications have been used without difficulty in hypothyroid patients. Although ketamine has been proposed as the ideal induction agent, thiopental has also been used in the hypothyroid patient. The maintenance of anesthesia may be safely achieved with either intravenous or inhaled anesthetics. There appears to be little if any decrease in the minimum alveolar concentration for volatile agents. Regional anesthesia is a good choice in the hypothyroid patient, provided the intravascular volume is well maintained. Monitoring is directed toward the early recognition of hypotension, congestive heart failure, and hypothermia. Scrupulous attention should be paid to maintaining normal body temperature.

Myxedema coma represents a severe form of hypothyroidism characterized by stupor or coma, hypoventilation, hypothermia, hypotension, and hyponatremia. This is a medical emergency with a high mortality rate (25 to 50%), and as such, requires aggressive therapy (Table 41-5). Only lifesaving surgery should proceed in the face of myxedema coma. Intravenous thyroid replacement is initiated as soon as the clinical diagnosis is made. An intravenous loading dose of T_4 (sodium levothyroxine, 200 to 300 µg) is given initially and followed by a maintenance dose of T_4, 50 to 200 mg/day intravenously.[18] Alternatively, T_3 may be used because it has a more rapid onset. Improvements in heart rate, blood pressure, and body temperature may occur within 24 hours. However, replacement therapy with either form of thyroid hormone may precipitate myocardial ischemia. There is also an increased likelihood of acute primary adrenal insufficiency in these

patients, and they should receive stress doses of hydrocortisone. Steroid replacement continues until normal adrenal function can be confirmed.

TABLE 41-5 Management of Myxedema

Tracheal intubation and controlled ventilation as needed
Levothyroxine, 200–300 µg IV over 5–10 min initially, and 100 µg IV q24h
Hydrocortisone, 100 mg IV, then 25 mg IV q6h
Fluid and electrolyte therapy as indicated by serum electrolytes
Cover to conserve body heat; no warming blankets

IV, intravenous(ly).

PARATHYROID GLANDS

Calcium Physiology

The normal adult body contains approximately 1 to 2 kg of calcium (Ca^{2+}), of which 99% is in the skeleton.[19] Plasma calcium is present in three forms: (1) a protein-bound fraction (50%); (2) an ionized fraction (45%); and (3) a diffusible but nonionized fraction (5%) that is complexed with phosphate, bicarbonate, and citrate. This division is interesting because it is the ionized fraction that is physiologically active and homeostatically regulated. The normal total serum calcium concentration is 8.8 to 10.4 mg/dL. Albumin binds approximately 90% of the protein-bound fraction of calcium, and total serum Ca^{2+} consequently depends on albumin levels. In general, an increase or decrease in albumin of 1 g/dL is associated with a parallel change in total serum Ca^{2+} of 0.8 mg/dL. The serum ionized Ca^{2+} concentration is affected by temperature and blood pH through alterations in Ca^{2+} protein binding to albumin. Acidosis decreases protein binding (increases ionized Ca^{2+}), and alkalosis increases protein binding (decreases ionized Ca^{2+}). The concentration of free Ca^{2+} ion is of critical importance in regulating skeletal muscle contraction, coagulation, neurotransmitter release, endocrine secretion, and a variety of other cellular functions. As a consequence, the maintenance of serum Ca^{2+} concentration is subject to exquisite hormonal control by parathyroid hormone (PTH) and vitamin D (Fig. 41-2).

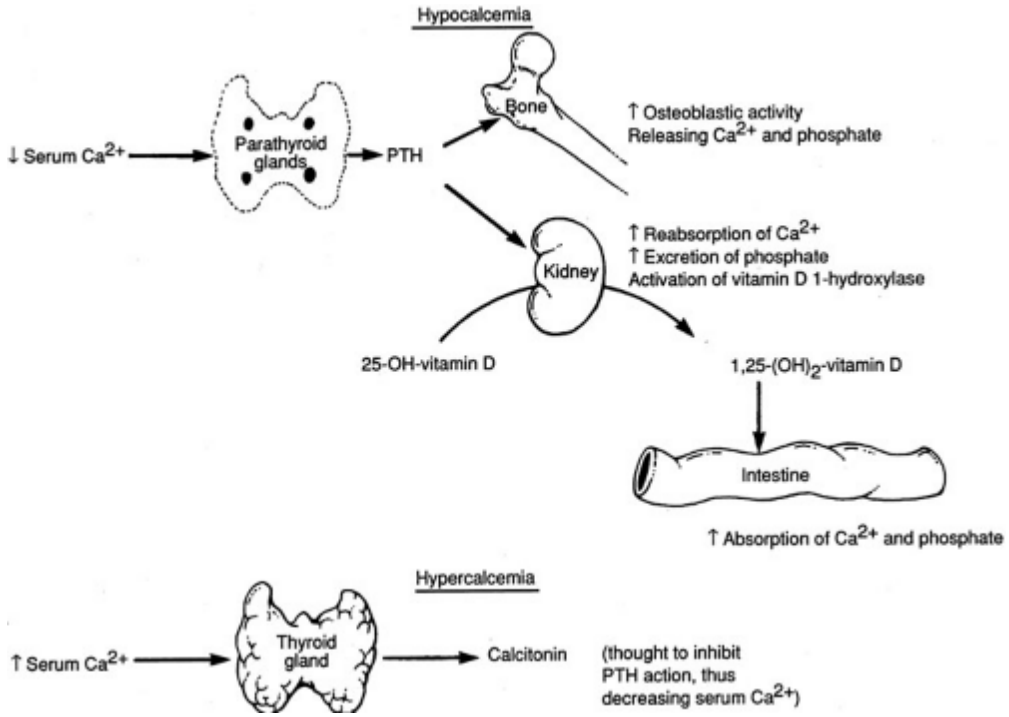

FIGURE 41-2. Parathyroid hormone (PTH) and vitamin D metabolism and action. (From McClatchey KD: Clinical Laboratory Medicine, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Parathyroid hormone acts to maintain the extracellular fluid Ca^{2+} concentration through direct effects on bone resorption and renal Ca^{2+} resorption at the distal tubule, and indirectly through its effects on the synthesis of 1,25-dihydroxyvitamin D. The renal effects of PTH include phosphaturia and bicarbonaturia, in addition to enhanced Ca^{2+} and magnesium resorption. Most evidence suggests that rapid changes in blood Ca^{2+} levels are due primarily to hormonal effects on bone and, to a lesser extent, to renal Ca^{2+} clearance, whereas maintenance of Ca^{2+} balance depends more on the indirect effects of the hormone on intestinal calcium absorption.

Parathyroid hormone secretion is primarily regulated by the serum ionized Ca^{2+} concentration. This negative feedback mechanism is exquisitely sensitive in maintaining calcium levels in a normal range. Release of PTH is also influenced by phosphate, magnesium, and catecholamine levels. Acute hypomagnesemia directly stimulates PTH release, whereas chronic magnesium depletion appears to inhibit proper functioning of the parathyroid gland. The plasma phosphate concentration has an indirect influence on PTH secretion by causing reciprocal changes in the serum ionized Ca^{2+} concentration.

Vitamin D is absorbed from the GI tract and can be produced enzymatically by ultraviolet irradiation of the skin. Vitamin D (cholecalciferol) is made from cholesterol metabolites and is inactive. Calciferol is hydroxylated in the liver to 25-hydroxycholecalciferol (25-OHD) and in the kidney is further hydroxylated to 1,25-dihydroxycholecalciferol [1,25 $(OH)_2D$] or 24,25-dihydroxycholecalciferol [24,25$(OH)_2D$]. 25-OHD is the major circulating form of vitamin D. The synthesis of this hormone is not regulated by a hormone or by Ca^{2+} or phosphate levels. 1,25$(OH)_2D$ and 24,25$(OH)_2D$ are the major active metabolites of vitamin D, and their production is reciprocally regulated at the kidney. Hypocalcemia and hypophosphatemia cause an increased production of 1,25$(OH)_2D$ and a decreased production of 24,25$(OH)_2D$. 1,25$(OH)_2D$ stimulates bone, kidney, and intestinal absorption of calcium and phosphate. Vitamin D deficiency can lead to decreased intestinal absorption of Ca^{2+} and secondary hyperparathyroidism.

Hyperparathyroidism

Primary hyperparathyroidism is most commonly due to a benign parathyroid adenoma (90% of cases) or hyperplasia (9%) and very rarely to a parathyroid carcinoma. Primary hyperparathyroidism may also exist as part of a multiple endocrine neoplastic (MEN) syndrome. Hyperplasia usually involves all four glands. Although most patients with primary hyperparathyroidism are hypercalcemic, most are asymptomatic

at the time of diagnosis. When symptoms occur, they usually result from the hypercalcemia that accompanies the disease. Primary hyperparathyroidism occurring during pregnancy is associated with a high maternal and fetal morbidity rate (50%). The placenta allows the fetus to concentrate calcium, promoting fetal hypercalcemia and leading to hypoparathyroidism in the newborn. Pregnant women with primary hyperparathyroidism should be treated with surgery.

Hypercalcemia is responsible for a broad spectrum of signs and symptoms. Nephrolithiasis is the most common manifestation, occurring in 60 to 70% of patients. Polyuria and polydipsia are also common complaints. An increase in bone turnover may lead to generalized demineralization and subperiosteal bone resorption; however, only a small group of patients (10 to 15%) have clinically significant bone disease. Patients may experience generalized skeletal muscle weakness and fatigability, epigastric discomfort, peptic ulceration, and constipation. Psychiatric manifestations include depression, memory loss, confusion, or psychosis. Between 20 and 50% of patients are hypertensive, but this usually resolves with successful treatment of the disease. Cardiac function is enhanced in the early stages of hypercalcemia. Calcium flux into the cells is reflected in the plateau phase of the action potential (phase 2). As extracellular calcium increases, the inward flux is more rapid, and phase 2 is shortened. The corresponding ECG change is a shorter QT interval. Cardiac contractility may increase until a level between 15 and 20 mg/dL is reached. At this point, there is a prolongation of the PR segment and QRS complex that can result in heart block or bundle-branch block. Bradycardia also occurs.

An elevated serum Ca^{2+} concentration is a valuable diagnostic indicator of primary hyperparathyroidism. The serum phosphate concentration is nonspecific, with many patients having normal or near-normal levels. The reported incidence of hyperchloremic acidosis varies widely in primary hyperparathyroidism, but most patients usually have a serum chloride concentration in excess of 102 mEq/L. Rarely does a patient with hypercalcemia secondary to ectopic PTH production (malignancy) present with hyperchloremic acidosis. The definitive diagnosis of primary hyperparathyroidism is made by RIA demonstration of an elevation in PTH levels in the presence of hypercalcemia. An elevated nephrogenous cyclic adenosine monophosphate is noted in more than 90% of patients with primary hyperparathyroidism.

Hypercalcemia may also result from the ectopic production of PTH or PTH-like substances from lung, genitourinary, breast, GI, and lymphoproliferative malignancies. Tumors may also produce hypercalcemia through direct bone resorption or the production of osteoclast-activating factor. In the absence of a clinically obvious neoplasm, there may be difficulty in differentiating between PTH-producing malignancies and primary hyperparathyroidism. PTH fragments from malignant tissue differ from native PTH and aid in distinguishing between ectopic PTH production and primary hyperparathyroidism.

Secondary hyperparathyroidism represents an increase in parathyroid function as a result of conditions that produce hypocalcemia or hyperphosphatemia. Chronic renal disease is a common cause of hyperphosphatemia (due to decreased phosphate excretion) and decreased vitamin D metabolism. The hypocalcemia that results leads to an increased production of PTH. GI disorders accompanied by malabsorption may also lead to a secondary increase in parathyroid activity. Tertiary hyperparathyroidism refers to the development of hypercalcemia in a patient who has had prolonged secondary hyperparathyroidism that has caused adenomatous changes in the parathyroid gland and unregulated PTH.

Treatment and Anesthetic Considerations

Surgery is the treatment of choice for the patient with symptomatic disease. Considerable

controversy, however, surrounds the choice of treatment in the asymptomatic patient. It is not clear that mild primary hyperparathyroidism decreases longevity. Surgery is often chosen over medical therapy because it offers definitive treatment and is generally safe.

Preoperative preparation focuses on the correction of intravascular volume and electrolyte irregularities. It is particularly important to evaluate the patient with chronic hypercalcemia for abnormalities of the renal, cardiac, or central nervous systems. Emergency treatment of hypercalcemia is undertaken before surgery, when the serum Ca^{2+} concentration exceeds 15 mg/dL (7.5 mEq/L). Lowering of the serum Ca^{2+} concentration is initially accomplished by expanding the intravascular volume and establishing a sodium diuresis. This is achieved with the intravenous administration of normal saline and furosemide. Rehydration alone is capable of lowering the serum Ca^{2+} level by $\geqslant$2 mg/dL. Hydration dilutes the serum Ca^{2+}, and a sodium diuresis promotes Ca^{2+} excretion through an inhibition of sodium and Ca^{2+} resorption in the proximal tubule. Hypokalemia and hypomagnesemia may result. Another element in the treatment of hypercalcemia is the correction of hypophosphatemia. Hypophosphatemia increases GI absorption of Ca^{2+}, stimulates the breakdown of bone, and impairs the uptake of Ca^{2+} by bone. Low serum phosphate levels impair cardiac contractility and may contribute to congestive heart failure. Hypophosphatemia also causes skeletal muscle weakness, hemolysis, and platelet dysfunction.

Other medications that have a role in lowering the serum Ca^{2+} include bisphosphonates, mithramycin, calcitonin, and glucocorticoids. Bisphosphonates are pyrophosphate analogs that inhibit osteoclast action. They are the drugs of choice for severe hypercalcemia. Toxic effects include fever and hypophosphatemia. Mithramycin, a cytotoxic agent, inhibits PTH-induced osteoclast activity and can lower the serum Ca^{2+} levels by $\geqslant$2 mg/dL in 24 to 48 hours. Toxic effects include azotemia, hepatotoxicity, and thrombocytopenia. Calcitonin is useful in transiently lowering the serum Ca^{2+} level 2 to 4 mg/dL through direct inhibition of osteoclastic bone resorption. The advantages of calcitonin are that side effects are mild (urticaria, nausea) and the onset of activity is rapid. Calcitonin resistance usually develops within 24 to 48 hours. Glucocorticoids are effective in lowering the serum Ca^{2+} concentration in several conditions (sarcoidosis, some malignancies, hyperthyroidism, vitamin D intoxication) through their actions on osteoclast bone resorption, GI absorption of calcium, and the urinary excretion of calcium. Glucocorticoids are usually of no benefit in the treatment of primary hypercalcemia. Finally, hemodialysis or peritoneal dialysis can be used to lower the serum Ca^{2+} level when alternative regimens are ineffective or contraindicated.

There is no evidence that a specific anesthetic drug or technique has advantages over another. A thorough knowledge of the clinical manifestations attributable to hypercalcemia is of the greatest value in choosing an anesthetic technique. Special monitoring is usually not required. Because of the unpredictable response to neuromuscular blocking drugs in the hypercalcemic patient, a conservative approach to muscle paralysis makes sense. There is an increased requirement for vecuronium, and probably all nondepolarizing muscle relaxants, during onset of neuromuscular blockade.[20] Careful positioning of the osteopenic patient is necessary to avoid pathologic bone fractures.

Anesthesia for Parathyroid Surgery

General anesthesia is most commonly used, but cervical plexus block and local anesthesia with hypnosis have been used successfully.[21] Postoperative complications include recurrent laryngeal nerve injury, bleeding, and transient or complete hypoparathyroidism. Unilateral recurrent laryngeal nerve injury is characterized by hoarseness and usually requires no intervention. Bilateral recurrent laryngeal nerve injury is a rare complication, producing aphonia and requiring immediate tracheal intubation. After successful parathyroidectomy, a decrease in the serum Ca^{2+} level should be observed within 24 hours. Patients with significant preoperative bone disease may have hypocalcemia after removal of the PTH-secreting glands. This “hungry bone” syndrome comes as a result of the rapid remineralization of bone.[22] Thus, serum Ca^{2+}, magnesium, and phosphorus levels should be closely monitored until stable. The serum Ca^{2+} nadir usually occurs within 3 to 7

days.

Hypoparathyroidism

An underproduction of PTH or resistance of the end-organ tissues to PTH results in hypocalcemia (<8 mg/dL). The normal physiologic response to hypocalcemia is an increase in PTH secretion and $1,25(OH)_2D$ synthesis with an increase in Ca^{2+} mobilization from bone, GI absorption, and renal tubule reclamation. The most common cause of acquired PTH deficiency is inadvertent removal of the parathyroid glands during thyroid or parathyroid surgery. Other causes of acquired hypoparathyroidism include ^{131}I therapy for thyroid disease, neck trauma, granulomatous disease, or an infiltrating process (malignancy or amyloidosis). Severe hypomagnesemia (<0.8 mEq/L) from any cause can produce hypocalcemia by suppressing PTH secretion and interfering with PTH action. Renal insufficiency leads to phosphorus retention and impaired $1,25(OH)_2D$ synthesis, and this results in hypocalcemia. These patients are commonly treated with vitamin D, which increases intestinal calcium absorption and suppresses secondary increases in PTH secretion. Hypocalcemia due to pancreatitis and burns results from the suppression of PTH and from the sequestration of calcium.

Clinical Features and Treatment

The clinical features of hypoparathyroidism are a manifestation of hypocalcemia. Neuronal irritability and skeletal muscle spasms, tetany, or seizures reflect a reduced threshold of excitation. Latent tetany may be demonstrated by eliciting Chvostek's or Trousseau's sign. Chvostek's sign is a contracture of the facial muscle produced by tapping the facial nerve as it passes through the parotid gland. Trousseau's sign is contraction of the fingers and wrist after application of a blood pressure cuff inflated above the systolic blood pressure for approximately 3 minutes. Other common complaints of hypocalcemia include fatigue, depression, paresthesias, and skeletal muscle cramps. The acute onset of hypocalcemia after thyroid or parathyroid surgery may manifest as stridor and apnea. Cardiovascular manifestations of hypocalcemia include congestive heart failure, hypotension, and a relative insensitivity to the effects of β-adrenergic agonists. Delayed ventricular repolarization results in a prolonged QT interval on the ECG. Although prolongation of the QT interval may be a reliable sign of hypocalcemia in an individual patient, the ECG is relatively insensitive for the detection of hypocalcemia.

The treatment of hypoparathyroidism consists of electrolyte replacement. The objective is to have the patient's clinical symptoms under control before anesthesia and surgery. Hypocalcemia caused by magnesium depletion is treated by correcting the magnesium deficit. Serum phosphate excess is corrected by the removal of phosphate from the diet and the oral administration of phosphate-binding resins (aluminum hydroxide). The urinary excretion of phosphate can be

increased with a saline volume infusion. Ca^{2+} deficiencies are corrected with Ca^{2+} supplements or vitamin D analogs. Patients with severe symptomatic hypocalcemia are treated with intravenous calcium gluconate (10 to 20 mL of 10% solution) given over several minutes and followed by a continuous infusion (1 to 2 mg/kg/hr) of elemental Ca^{2+}. The correction of serum Ca^{2+} levels should be monitored by measuring serum Ca^{2+} concentrations and following clinical symptoms. When oral or intravenous calcium is inadequate to maintain a normal serum ionized calcium level, vitamin D is added to the regimen.

ADRENAL CORTEX

The adrenal cortex functions to synthesize and secrete three types of hormones. Endogenous and dietary cholesterol is used in the adrenal biosynthesis of glucocorticoids (cortisol), mineralocorticoids (aldosterone and 11-deoxycorticosterone), and androgens (dehydroepiandrosterone). Cortisol and aldosterone are the two essential hormones, whereas adrenal androgens are of relatively minor physiologic significance in adults. The major biologic effects of adrenal cortical hyperfunction or hypofunction occur as a result of cortisol or aldosterone excess or deficiency. Abnormal function of the adrenal cortex may render a patient

unable to respond appropriately during a period of surgical stress or critical illness.

Glucocorticoid Physiology

Cortisol (hydrocortisone) is the most potent endogenous glucocorticoid and is produced by the inner portions of the adrenal cortex. Cortisone is a glucocorticoid produced in small amounts. Cortisol is produced under the control of adrenocorticotropic hormone (ACTH; corticotropin), a polypeptide synthesized and released by the anterior pituitary gland. Glucocorticoids exert their biological effects by diffusing into the cytoplasm of target cells and combining with specific high-affinity receptor proteins.

The daily production of endogenous cortisol is approximately 20 mg. The maximal output is 150 to 300 mg/dL. Most of the circulating hormone is bound to the α-globulin transcortin (cortisol-binding globulin). It is the relatively small amount of free hormone that exerts the biological effects. Endogenous glucocorticoids are inactivated primarily by the liver and are excreted in the urine as 17-hydroxycorticosteroids. Cortisol is also filtered at the glomerulus and may be excreted unchanged in the urine. Although the rate of cortisol secretion is decreased by approximately 30% in the elderly patient, plasma cortisol levels remain in a normal range because of a corresponding decrease in hepatic and renal clearance.

Cortisol secretion is directly controlled by ACTH, which in turn is regulated by the corticotropin-releasing factor (CRF) from the hypothalamus. ACTH is synthesized in the pituitary gland from a precursor molecule that also produces β-lipotropin and β-endorphin. The secretion of ACTH and CRF is governed chiefly by glucocorticoids, the sleep–wake cycle, and stress. Cortisol is the most potent regulator of ACTH secretion, acting by a negative feedback mechanism to maintain cortisol levels in a physiologic range. ACTH release follows a diurnal pattern, with maximal activity occurring soon after awakening. This diurnal pattern of activity occurs in normal subjects and in those with adrenal insufficiency. Psychological or physical stress (trauma, surgery, intense exercise) also promotes ACTH release, regardless of the level of circulating cortisol or the time of day.

Cortisol has multiple effects on intermediate carbohydrate, protein, and fatty acid metabolism, as well as maintenance and regulation of immune and circulatory function. Glucocorticoids enhance gluconeogenesis, elevate blood glucose, and promote hepatic glycogen synthesis. The catabolic effect of glucocorticoids is partially blocked by insulin. The net effect on protein metabolism is enhanced degradation of muscle tissue and negative nitrogen balance. In supraphysiologic amounts, glucocorticoids suppress growth hormone secretion and impair somatic growth. The anti-inflammatory actions of cortisol relate to its effect in stabilizing lysosomes and promoting capillary integrity. Cortisol also antagonizes leukocyte migration inhibition factor, thus reducing white cell adherence to vascular endothelium and diminishing leukocyte response to local inflammation. Phagocytic activity does not decrease, although the killing potential of macrophages and monocytes is diminished. Other diverse actions include the facilitation of free water clearance, maintenance of blood pressure, a weak mineralocorticoid effect, promotion of appetite, stimulation of hematopoiesis, and induction of liver enzymes.

Mineralocorticoid Physiology

Aldosterone is the most potent mineralocorticoid produced by the adrenal gland. This hormone binds to receptors in sweat glands, the alimentary tract, and the distal convoluted tubule of the kidney. Aldosterone is a major regulator of extracellular volume and potassium homeostasis through the resorption of sodium and the secretion of potassium by these tissues. The major regulators of aldosterone release are the renin–angiotensin system and serum potassium (Fig. 41-3). The juxtaglomerular apparatus that surrounds the renal afferent arterioles produces renin in response to decreased perfusion pressures and sympathetic stimulation. Renin splits the hepatic precursor angiotensinogen to form the decapeptide, angiotensin I, which is then altered enzymatically by converting enzyme (primarily in the lung) to form the octapeptide angiotensin II. Angiotensin II is the most potent vasopressor produced in the body. It directly stimulates the adrenal cortex to produce aldosterone. The renin–angiotensin system is the body's most important

protector of volume status. Other stimuli that increase the production of aldosterone include hyperkalemia and, to a limited degree, hyponatremia, prostaglandin E, and ACTH.

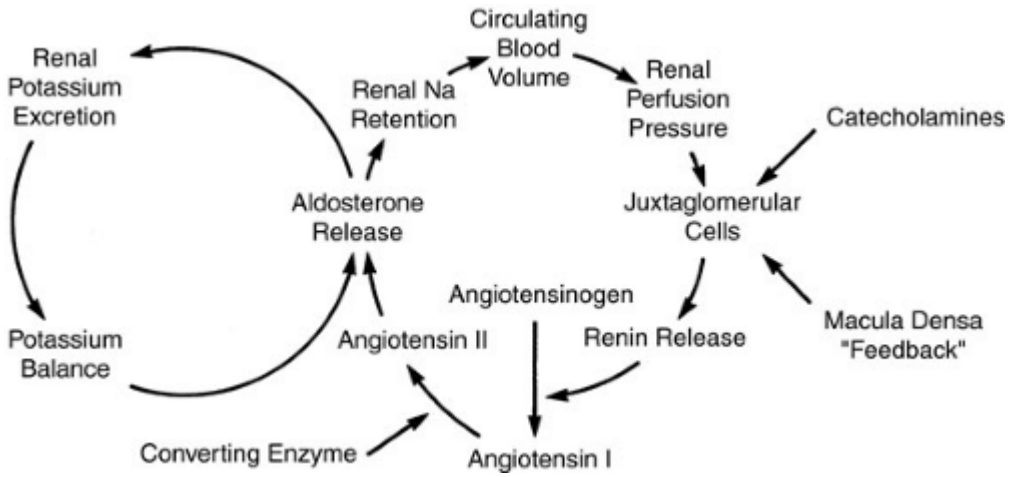

FIGURE 41-3. The interrelationship of the volume and potassium feedback loops on aldosterone secretion. (Reprinted with permission from Petersdorf RG [ed]: Harrison's Principles of Internal Medicine, 10th ed. New York, McGraw-Hill, 1983.)

Glucocorticoid Excess (Cushing's Syndrome)

Cushing's syndrome, caused either by the overproduction of cortisol by the adrenal cortex or exogenous glucocorticoid therapy, results in a syndrome characterized by truncal obesity, hypertension, hyperglycemia, increased intravascular fluid volume, hypokalemia, fatigability, abdominal striae, osteoporosis, and muscle weakness. Most cases of Cushing's syndrome that occur spontaneously are due to bilateral adrenal hyperplasia secondary to ACTH produced by an anterior pituitary microadenoma or nonendocrine tumor (e.g., of the lung, kidney, or pancreas). The primary overproduction of cortisol and other adrenal steroids is caused by an adrenal neoplasm in approximately 20 to 25% of patients with Cushing's syndrome. These tumors are usually unilateral, and approximately half are malignant. When Cushing's syndrome occurs in patients older than 60 years of age, the most likely cause is an adrenal carcinoma or ectopic ACTH produced from a nonendocrine tumor. Finally, an increasingly common cause of Cushing's syndrome is the prolonged administration of exogenous glucocorticoids to treat a variety of illnesses.

The signs and symptoms of Cushing's syndrome follow from the known actions of glucocorticoids. Truncal obesity and thin extremities reflect increased muscle wasting and a redistribution of fat in facial, cervical, and truncal areas. Impaired calcium absorption and a decrease in bone formation may result in osteopenia. Sixty percent of patients have hyperglycemia, but overt diabetes mellitus occurs in less than 20%. Hypertension and fluid retention are seen in most patients. Profound emotional changes ranging from emotional lability to frank psychosis may be present. An increased susceptibility to infection reflects the immunosuppressive effects of corticosteroids. Hypokalemic alkalosis without distinctive physical findings is common when adrenal hyperplasia is caused by ectopic ACTH production from a nonendocrine tumor.

The laboratory diagnosis of hyperadrenocorticism is based on a variable elevation in plasma and urinary cortisol levels, urinary 17-hydroxycorticosteroids, and plasma ACTH. Once the diagnosis is established, simultaneous measurement of plasma ACTH and cortisol levels can determine whether the Cushing's syndrome is due to primary pituitary or adrenal disease.[23] Alternatively, a dexamethasone suppression test can be used. Patients with pituitary adenomas frequently show

depression in cortisol and 17-hydroxycorticosteroid levels when a high dose of dexamethasone is administered because the tumor retains some negative feedback control, while adrenal tumors do not.

Anesthetic Management

General considerations for the preoperative preparation of the patient include treating hypertension and diabetes and normalizing intravascular fluid volume and electrolyte concentrations. Diuresis with the aldosterone antagonist spironolactone helps mobilize fluid and normalize the potassium concentration. Careful positioning of the osteopenic patient is important to avoid fractures. Intraoperative monitoring is planned after evaluation of the patient's cardiac reserve and consideration of the site and extent of the proposed surgery. When either unilateral or bilateral adrenalectomy is planned, glucocorticoid replacement therapy is initiated at a dose equal to full replacement of adrenal output during periods of extreme stress (see Steroid Replacement During the Perioperative Period section). The total dosage is reduced by approximately 50% per day until a daily maintenance dose of steroids is achieved (20 to 30 mg/day). Hydrocortisone given in doses of this magnitude exerts significant mineralocorticoid activity, and additional exogenous mineralocorticoid is usually not necessary during the perioperative period. After bilateral adrenalectomy, most patients require 0.05 to 0.1 mg/day of fludrocortisone (9-α-fluorohydrocortisone) starting around day 5 to provide mineralocorticoid activity. Slightly higher doses may be needed if prednisone is used for glucocorticoid maintenance because it has little intrinsic mineralocorticoid activity. The fludrocortisone dose is reduced if congestive heart failure, hypokalemia, or hypertension develops. For the patient with a solitary adrenal adenoma, unilateral adrenalectomy may be followed by normalization of function in the contralateral gland over time. Treatment plans should therefore be individualized, and adjustments in dosage may be necessary. The production of glucocorticoids or ACTH by a neoplasm may not be eliminated if the tumor is unresectable. These patients often need continuous medical therapy with steroid inhibitors such as metyrapone to control their symptoms.

There are no specific recommendations regarding the use of a particular anesthetic technique or medication in patients with hyperadrenocorticism. When significant skeletal muscle weakness is present, a conservative approach to the use of muscle relaxants is warranted. Etomidate has been used for temporizing medical treatment of severe Cushing's disease because of its inhibition of steroid synthesis.

Mineralocorticoid Excess

Hypersecretion of the major adrenal mineralocorticoid aldosterone increases the renal tubular exchange of sodium for potassium and hydrogen ions. This leads to hypertension, hypokalemic alkalosis, skeletal muscle weakness, and fatigue. Possibly as many as 1% of unselected hypertensive patients have primary hyperaldosteronism. The increase in renal sodium reabsorption and extracellular volume expansion is in part responsible for the high incidence of diastolic hypertension in these patients. Patients with primary hyperaldosteronism (Conn's syndrome) characteristically do not have edema. Secondary aldosteronism results from an elevation in renin production. The diagnosis of primary or secondary hyperaldosteronism should be entertained in the nonedematous hypertensive patient with persistent hypokalemia who is not receiving potassium-wasting diuretics. Hyposecretion of renin that fails to increase appropriately during volume depletion or salt restriction is an important finding in primary aldosteronism. The measurement of plasma renin levels is useful in distinguishing primary from secondary hyperaldosteronism. It is of limited value in differentiating patients with primary aldosteronism from those with other causes of hypertension because renin activity is also suppressed in approximately 25% of patients with essential hypertension.

Anesthetic Considerations

Preoperative preparation for the patient with primary aldosteronism is directed toward restoring the intravascular volume and the electrolyte concentrations to normal. Hypertension and

hypokalemia may be controlled by restricting sodium intake and administration of the aldosterone antagonist spironolactone. This diuretic works slowly to produce an increase in potassium levels, with dosages in the range of 25 to 100 mg every 8 hours. Total body potassium deficits are difficult to estimate and may be in excess of 300 mEq. Whenever possible, potassium should be replaced slowly to allow equilibration between intracellular and extracellular potassium stores. The usual complications of chronic hypertension need to be assessed.

Adrenal Insufficiency (Addison's Disease)

The undersecretion of adrenal steroid hormones may develop as the result of a primary inability of the adrenal gland to elaborate sufficient quantities of hormone or as the result of a deficiency in the production of ACTH.

Clinically, primary adrenal insufficiency is usually not apparent until at least 90% of the adrenal cortex has been destroyed. The predominant cause of primary adrenal insufficiency used to be tuberculosis; however, today, the most frequent cause of Addison's disease is idiopathic adrenal insufficiency secondary to autoimmune destruction of the gland. Autoimmune destruction of the adrenal cortex causes both a glucocorticoid and a mineralocorticoid deficiency. A variety of other conditions presumed to have an autoimmune pathogenesis may also occur concomitantly with idiopathic Addison's disease. Hashimoto's thyroiditis in association with autoimmune adrenal insufficiency is termed *Schmidt's syndrome.* Other possible causes of adrenal gland destruction include certain bacterial, fungal, and advanced HIV infections; metastatic cancer; sepsis; and hemorrhage. Secondary adrenal insufficiency occurs when the anterior pituitary fails to secrete sufficient quantities of ACTH. Pituitary failure may result from tumor, infection, surgical ablation, or radiation therapy.

Patients receiving chronic corticosteroid therapy will not generally have frank adrenal insufficiency, but may have hypothalamic-pituitary-adrenal (HPA) suppression and may develop acute adrenal insufficiency during the stress of the perioperative period. Adrenal insufficiency is a common finding in critically ill surgical patients with hypotension requiring vasopressors.[24]

Clinical Presentation

The cardinal symptoms of idiopathic Addison's disease include chronic fatigue, muscle weakness, anorexia, weight loss, nausea, vomiting, and diarrhea. Hypotension is almost always encountered in the disease process. Female patients may exhibit decreased axillary and pubic hair growth due to the loss of adrenal androgen secretion. An acute crisis can present as abdominal pain, severe vomiting and diarrhea, hypotension, decreased consciousness, and shock. Diffuse hyperpigmentation occurs in most patients with primary adrenal insufficiency and is secondary to the compensatory increase in ACTH and β-lipotropin. These hormones stimulate an increase in melanocyte production. Mineralocorticoid deficiency is characteristically present in primary adrenal disease; as a result, there is a reduction in urine sodium conservation. Hyperkalemia may be a cause of life-threatening cardiac dysrhythmias. Adrenal insufficiency secondary to pituitary disease is not associated with cutaneous hyperpigmentation or mineralocorticoid deficiency. Salt and water balance is usually maintained unless severe fluid and electrolyte losses overwhelm the subnormal aldosterone secretory capacity. Organic lesions of pituitary origin require a diligent search for coexisting hormone deficiencies. Acute adrenal insufficiency from inadequate replacement of steroids on chronic steroid therapy is rare and can present as refractory, distributive shock. In critically ill patients, adrenal insufficiency may not present with classic symptoms. The clinical picture may resemble that of sepsis without a source of infection.[25] A high degree of suspicion must be maintained if the patient has cardiovascular instability without a defined cause.[26,27]

Diagnosis

The patient's pituitary-adrenal responsiveness should be determined when the diagnosis of primary or secondary adrenal insufficiency is first suspected. Biochemical evidence of impaired adrenal or pituitary secretory reserve unequivocally confirms the diagnosis. Patients who are

clinically stable may undergo testing before treatment is initiated. Those believed to have acute adrenal insufficiency should receive immediate therapy.

Plasma cortisol levels are measured before and 30 and 60 minutes after the intravenous administration of 250 µg of synthetic ACTH. In patients with adequate adrenal reserve, plasma cortisol rises at least 7 mg/dL (or to a total of 18 mg/dL) 60 minutes after the injection of the synthetic ACTH.[28] Patients with adrenal insufficiency usually demonstrate little or no adrenal response.

Treatment and Anesthetic Considerations

Normal adults secrete about 20 mg of cortisol (hydrocortisone) and 0.1 mg of aldosterone per day. Glucocorticoid therapy is usually given twice daily in sufficient dosage to meet physiologic requirements. A typical regimen may consist of prednisone, 5 mg in the morning and 2.5 mg in the evening, or hydrocortisone, 20 mg in the morning and 10 mg in the evening. The daily glucocorticoid dosage is typically 50% higher than basal adrenal output to cover the patient for mild stress. Replacement dosages are adjusted in response to the patient's clinical symptoms or the occurrence of intercurrent illnesses. Mineralocorticoid replacement is also administered on a daily basis; most patients require 0.05 to 0.1 mg/day of fludrocortisone. The mineralocorticoid dose may be reduced if severe hypokalemia, hypertension, or congestive heart failure develops, or it may be increased if postural hypotension is demonstrated.

Secondary adrenal insufficiency often occurs in the presence of multiple hormone deficiencies. A decrease in ACTH production results in the decreased secretion of cortisol and adrenal androgens, but aldosterone control by more dominant mechanisms remains intact. A liberal salt diet is encouraged. Glucocorticoid substitution follows the same guidelines previously outlined for primary adrenal insufficiency.

Immediate therapy of acute adrenal insufficiency is mandatory, regardless of the etiology and consists of electrolyte resuscitation and steroid replacement (Table 41-6). Initial therapy begins with the rapid intravenous administration of an isotonic

crystalloid solution (D_5NS). One hundred milligrams of hydrocortisone is administered as an intravenous bolus over several minutes. Steroid replacement is continued during the first 24 hours with 100 mg intravenous hydrocortisone given every 6 hours. If the patient is stable, the steroid dose is reduced starting on the second day. After adequate fluid resuscitation, if the patient continues to be hemodynamically unstable, inotropic support may be necessary. Invasive monitoring is extremely valuable as a guide to both diagnosis and therapy.

TABLE 41-6 Management of Acute Adrenal Insufficiency

Hydrocortisone 100 mg IV bolus followed by hydrocortisone 100 mg q6h for 24 hr
Fluid and electrolyte replacement as indicated by vital signs, serum electrolytes, and serum glucose

Steroid Replacement During the Perioperative Period

Perioperatively, patients with adrenal insufficiency and those with HPA suppression from chronic steroid use require additional corticosteroids to mimic the increased output of the normal adrenal gland during stress. The normal adrenal gland can secrete up to 200 mg of cortisol per day or more during the perioperative period. During periods of extreme stress, the adrenal gland may be exogenously stimulated to secrete between 200 and 500 mg/day of cortisol.[29] The pituitary-adrenal axis is usually considered to be intact if a plasma cortisol level of greater than 22 mcg/dL is measured during acute stress. The degree of adrenal responsiveness has been correlated with the duration of surgery and the extent of surgical trauma. The mean maximal plasma cortisol level measured during major surgery (colectomy, hip osteotomy) was 47 mcg/dL. Minor surgical procedures (herniorrhaphy) resulted in mean maximal plasma cortisol levels of 28 mcg/dL. Adrenal activity may also be affected by the anesthetic technique used. Regional anesthesia is effective in postponing the elevation in cortisol levels during surgery of the lower abdomen and extremities.[30] Deep general anesthesia may also suppress the elevation of stress hormones such as ACTH and cortisol during the surgical procedure.

Although symptoms indicative of clinically significant adrenal insufficiency have been reported during the perioperative period, these clinical findings have rarely been documented in direct association with glucocorticoid deficiency.[31] There is evidence in adrenally suppressed primates that subphysiologic steroid replacement causes perioperative hemodynamic instability and increased mortality.

3 Identifying which patients require steroid supplementation can be difficult. Provocative testing with ACTH stimulation is too costly to justify compared with the risk of brief steroid supplementation. HPA suppression can occur after five daily doses of prednisone 20 mg or more. Recovery of HPA function occurs gradually and can take up to 9 to 12 months. HPA suppression can occur with topical, regional, and inhaled steroids. Alternate-day therapy decreases the risk of HPA suppression.[32]

The clinical problem is how much steroid to give. There is no proven optimal regimen for perioperative steroid replacement (Table 41-7). A "low-dose" cortisol replacement program using an intravenous infusion of 25 mg of cortisol before the induction of anesthesia, followed by a continuous infusion of cortisol (100 mg) in the next 24 hours has been advocated[33] (Fig. 41-4). This low-dose cortisol replacement program was used in patients with proven adrenal insufficiency and resulted in plasma cortisol levels as high as those seen in healthy control subjects subjected to a similar operative stress. One study with a limited number of patients found no problems with cardiovascular instability if patients received their usual dose of steroids.[34] Although the low-dose approach appears logical, many clinicians are unwilling to adopt this regimen until further trials have been undertaken in patients receiving physiologic steroid replacement. A popular regimen calls for the administration of 200 to 300 mg of hydrocortisone per 70 kg body weight in divided doses on the day of surgery. The lower dose is adjusted upward for longer and more extensive surgical procedures. Patients who are using steroids at the time of surgery receive their usual dose on the morning of surgery and are supplemented at a level that is at least equivalent to the usual daily replacement. Glucocorticoid coverage is rapidly tapered to the patient's normal maintenance dosage during the postoperative period. Although no conclusive evidence supports an increased incidence of infection or abnormal wound healing when supraphysiologic doses of supplemental steroids are used acutely, the goal of therapy is to use the minimal drug dosage necessary to adequately protect the patient.

TABLE 41-7 Management Options for Steroid Replacement in The Perioperative Period

Hydrocortisone 25 mg IV at time of induction followed by hydrocortisone infusion 100 mg

over 24 hr
Hydrocortisone 100 mg IV before, during, and after surgery
IV, intravenous(ly).

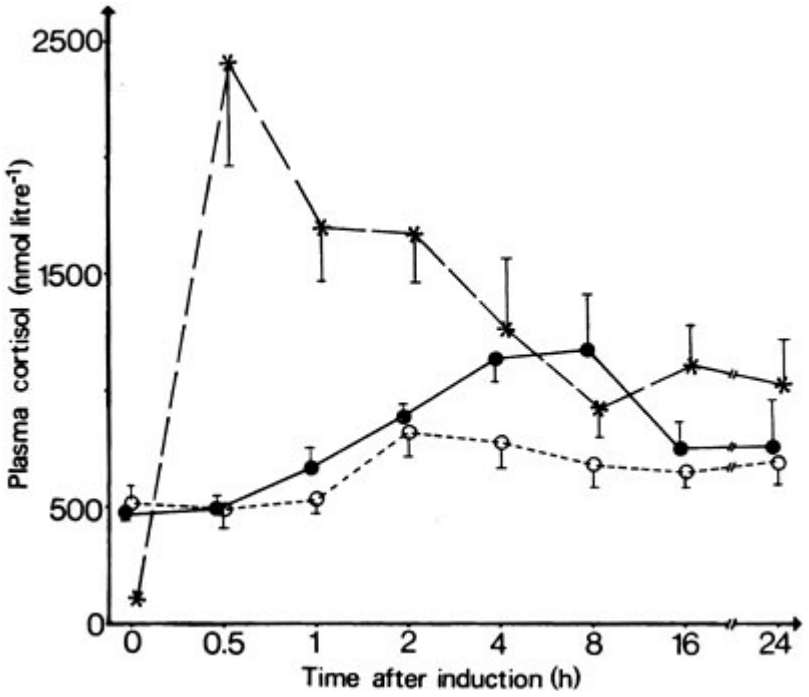

FIGURE 41-4. Plasma cortisol concentrations (mean ± SEM) were measured in three groups of patients undergoing elective surgery. Group I control patients, *n* = 8 (*closed circles*), had never received corticosteroids. Group II patients, *n* = 8 (*open circles*), received preoperative corticosteroids with a normal response to preoperative adrenocorticotropic hormone (ACTH; corticotropin) stimulation testing. These patients and control patients received no corticosteroid substitution during the perioperative period. Group III, *n* = 6 (*asterisks*), consisted of patients receiving long-term corticosteroid therapy with an abnormal response to ACTH stimulation testing during the perioperative period. These patients (group III) received intravenous (IV) cortisol, 25 mg, after the induction of anesthesia plus a continuous IV infusion of cortisol, 100 mg, during the next 24 hours. Plasma cortisol levels in group III were significantly lower than in the other two groups before the induction of anesthesia. After IV administration of cortisol to group III patients, plasma concentrations were significantly higher than in groups I and II for the next 2 hours ($p < .01$). Thereafter, the mean plasma concentrations were similar for all groups. There were no clinical signs of circulatory insufficiency in any group. Br J Anaesth 53:949, 1981.)

Exogenous Glucocorticoid Therapy

The therapeutic use of supraphysiologic doses of glucocorticoids has expanded, and the anesthesiologist should be familiar with the various preparations (Table 41-8). Dexamethasone, methylprednisolone, and prednisone have less mineralocorticoid effect than cortisone or hydrocortisone. Prednisone and methylprednisolone are precursors that must be metabolized by the liver before anti-inflammatory activity can occur and should be used cautiously in the presence of liver disease.

TABLE 41-8 Glucocorticoid Preparations

·GENERIC NAME	·ANTI-	·MINERALOCORTICOID	·APPROXIMATE

	INFLAMMATORY		EQUIVALENT DOSE(mg)
·SHORT ACTING			
Hydrocortisone	1.0	1.0	20.0
Cortisone	0.8	0.8	25.0
Prednisone	4.0	0.25	5.0
Prednisolone	4.0	0.25	5.0
Methylprednisolone	5.0	—	4.0
·INTERMEDIATE ACTING			
Triamcinolone	5.0	—	4.0
·LONG ACTING			
Dexamethasone	30.0	—	0.75
Relative milligram comparisons with cortisol. The glucocorticoid and mineralocorticoid properties of cortisol are set as 1.0.			

Mineralocorticoid Insufficiency

Isolated mineralocorticoid insufficiency has been reported as a congenital biosynthetic defect, after unilateral adrenalectomy for removal of an aldosterone-secreting adenoma, during protracted heparin therapy, and in patients with a deficiency in renin production. This syndrome is commonly seen in patients with mild renal failure and long-standing diabetes mellitus. A feature common to all patients with hypoaldosteronism is a failure to increase aldosterone production in response to salt restriction or volume contraction.

Most patients present with hypotension, hyperkalemia that may be life threatening, and a metabolic acidosis that is out of proportion to the degree of coexisting renal impairment. Patients with low renin secretion, hypoaldosteronism, and renal dysfunction respond to ACTH stimulation. Nonsteroidal anti-inflammatory drugs, which inhibit prostaglandin synthesis, may further inhibit renin release and exacerbate the condition. Patients with isolated hypoaldosteronism are given fludrocortisone orally in a dose of 0.05 to 0.1 mg/day. Patients with low renin secretion usually require higher doses to correct the electrolyte abnormalities. Caution should be observed in patients with hypertension or congestive heart failure. An alternative approach in these patients is the administration of furosemide alone or in combination with mineralocorticoid.

ADRENAL MEDULLA

The adrenal medulla is derived embryologically from neuroectodermal cells. As a specialized part of the sympathetic nervous system, the adrenal medulla synthesizes and secretes the catecholamines epinephrine (80%) and norepinephrine (20%). Preganglionic fibers of the sympathetic nervous system bypass the paravertebral ganglia and pass directly from the spinal cord to the adrenal medulla. The adrenal medulla is analogous to a postganglionic neuron, although the catecholamines secreted by the medulla function as hormones, not as neurotransmitters.

The synthesis of norepinephrine begins with hydroxylation of tyrosine to dopa (Fig. 41-5). This rate-limiting step in catecholamine biosynthesis is regulated so synthesis is coupled to release. In the adrenal medulla and in those rare central neurons using epinephrine as a neurotransmitter, most of the norepinephrine is converted to epinephrine by the enzyme phenylethanolamine-*N*-methyltransferase. It is likely that the capacity of the adrenal medulla to synthesize epinephrine

is influenced by the flow of glucocorticoid-rich blood from the adrenal cortex through the intra-adrenal portal system because it is known that high concentrations of glucocorticoid are able to induce the enzyme phenylethanolamine-*N*-methyltransferase.

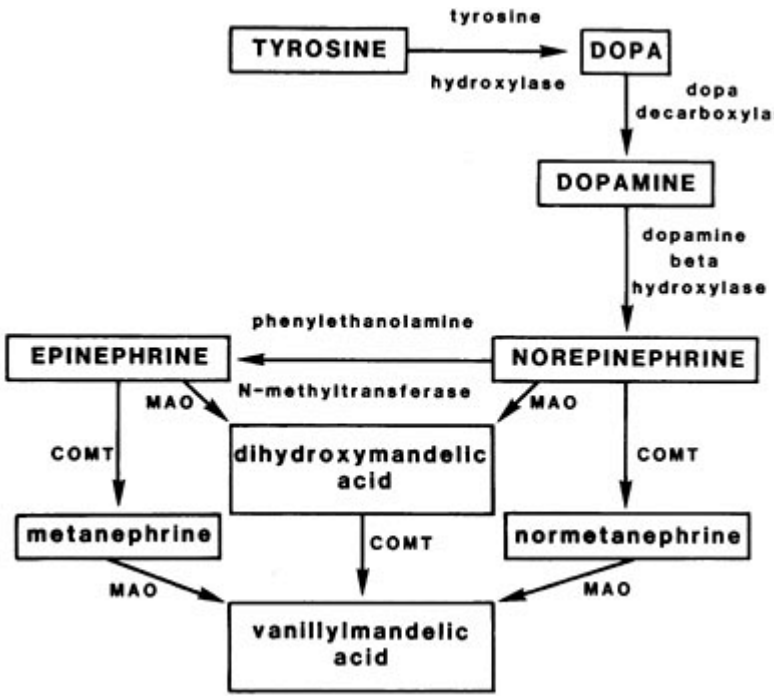

FIGURE 41-5. The synthesis and metabolism of endogenous catecholamines. COMT, catechol-*O*-methyltransferase; MAO, monoamine oxidase. (Reprinted with permission from Stoelting RK, Dierdorf SF [eds]: Anesthesia and Co-existing Disease. New York, Churchill-Livingstone, 1983.)

In the adrenal medulla, catecholamines are stored in chromaffin granules complexed with adenosine triphosphate and Ca^{2+}. The normal adrenal releases epinephrine and norepinephrine by exocytosis in response to stimulation by preganglionic sympathetic neurons. The circulatory half-life (10 to 30 seconds) of these catechols is considerably longer than the brief receptor activity of norepinephrine released as a neurotransmitter from postganglionic sympathetic nerve endings. Biotransformation of circulating norepinephrine and epinephrine is accomplished chiefly by the enzyme catechol-*O*-methyltransferase, located in the liver and kidney. Monoamine oxidase is of less importance in the metabolism of circulating catechols. Metanephrine and vanillylmandelic acid (VMA) are the major end products of catecholamine metabolism. These metabolites and a small

amount of unchanged catecholamine (1%) appear in the urine.

The outflow of postganglionic sympathetic neurotransmitters and circulating catecholamine from the adrenal medulla is coordinated by higher cortical centers connected to the brainstem. The intrinsic activity of the brainstem sympathetic areas is modulated by higher cortical functions, emotional reactions (anger, fear), and various physiologic stimuli, including changes in the physical and chemical properties of the extracellular fluid (hypoglycemia, hypotension). The adrenal medulla and sympathetic nervous system are often stimulated together in a generalized fashion, although many physiologic conditions exist in which they act independently.

Pheochromocytoma

The only important disease process associated with the adrenal medulla is pheochromocytoma. These tumors produce, store, and secrete catecholamines. Most pheochromocytomas secrete both epinephrine and norepinephrine, with the percentage of secreted norepinephrine being greater than that secreted by the normal gland. Although pheochromocytomas occur in less than 0.2% of hypertensive patients, it is important to aggressively evaluate the patient with clinically suspect symptoms because surgical extirpation is curative in more than 90% of patients and complications are often lethal in undiagnosed cases.[35] Postmortem series have reported high perioperative mortality rates in undiagnosed patients undergoing relatively minor surgical procedures. Most deaths are from cardiovascular causes. Perioperative morbidity is related to tumor size and the degree of catecholamine secretion.[36]

Most (85 to 90%) pheochromocytomas are solitary tumors localized to a single adrenal gland, usually the right. Approximately 10% of adults and 25% of children have bilateral tumors. The tumor may originate in extra-adrenal sites (10%), anywhere along the paravertebral sympathetic chain; however, 95% are located in the abdomen, and a small percentage is located in the thorax, urinary bladder, or neck. Malignant spread of these highly vascular tumors occurs in approximately 10% of cases.

In approximately 5% of cases, this tumor is inherited as a familial autosomal dominant trait. It may be part of the polyglandular syndrome referred to as MEN type IIA or IIB. Type IIA includes medullary carcinoma of the thyroid, parathyroid hyperplasia, and pheochromocytoma; Type IIB consists of medullary carcinoma of the thyroid, pheochromocytoma, and neuromas of the oral mucosa. Pheochromocytomas may also arise in association with von Recklinghausen's neurofibromatosis or von Hippel-Lindau disease (retinal and cerebellar angiomatosis). The pheochromocytoma of the familial syndromes is rarely extra-adrenal or malignant. Bilateral tumors occur in approximately 75% of cases. When these patients present with a single adrenal pheochromocytoma, the chances of subsequent development of a second adrenal pheochromocytoma are sufficiently high that bilateral adrenalectomy should be considered. Every member of a MEN family should be considered at risk for pheochromocytoma.

Clinical Presentation

Pheochromocytoma may occur at any age, but it is most common in young to midadult life. The clinical manifestations are mainly due to the pharmacologic effects of the catecholamines released from the tumor. These tumors are not innervated, and catecholamine release is independent of neurogenic control. Most patients have sustained hypertension, although occasionally it is paroxysmal.[37] When true paroxysms occur, the blood pressure may rise to alarmingly high levels, placing the patient at risk for cerebrovascular hemorrhage, heart failure, dysrhythmias, or myocardial infarction. Headache, palpitations, tremor, profuse sweating, and either pallor or flushing may accompany an attack. Pheochromocytoma can masquerade as malignant hyperthermia. Physical examination of the patient with pheochromocytoma may be unrevealing during the period between attacks unless the patient presents with symptoms and signs of sequelae related to long-standing hypertension. A catecholamine-induced cardiomyopathy may manifest as myocarditis accompanied by heart failure and cardiac dysrhythmias. Paroxysms are commonly not associated with clearly defined events but may be precipitated by displacement of the abdominal contents or, in the case of a bladder tumor, by micturition.

Diagnosis

Biochemical determination of free catecholamine concentration and catecholamine metabolites in the urine is the most common screening test used to establish the diagnosis of pheochromocytoma.[38] Urinary VMA and unconjugated norepinephrine and epinephrine levels are measured in a 24-hour urine collection and are expressed as a function of the creatinine clearance. Excess production of catecholamines is diagnostic for pheochromocytoma. Free catecholamines represent less than 1% of the originally released hormone, and urinary levels are not always elevated to a significant degree. Hence, differentiation from normal subjects may be difficult. A change in the ratio of unconjugated epinephrine to norepinephrine may be the only biochemical finding. Certain drugs interfere with urinary assays, and some patients with paroxysmal hypertension have normal values between attacks.

Although routine laboratory data are unlikely to provide specific diagnostic insight, the ECG, chest radiograph, and complete blood cell count can provide valuable information to the clinician who entertains the diagnosis. Left ventricular hypertrophy and nonspecific T-wave changes are two of the more common ECG findings. Evidence of acute myocardial infarction or tachyarrhythmia has also been reported. The chest radiograph may reveal cardiomegaly, and the blood count often shows an elevated hematocrit consistent with a reduced intravascular volume and hemoconcentration. Standardized imaging methods such as computed tomography and magnetic resonance imaging (MRI) are used in the noninvasive localization of these tumors.[39] Improvements in imaging may obviate the need for abdominal exploration or venous sampling to localize the tumor in selected patients.[40] Ultrasound and MRI are especially useful in pregnant patients. ^{131}I-Metaiodobenzylguanidine (^{131}I-MIBG) scintigraphy is also effective in localizing recurrent or

extra-adrenal masses. Arteriography must be performed with extreme care in these patients because a hypertensive crisis can be precipitated.

Anesthetic Considerations

Preoperative Preparation. The reduction in perioperative mortality rates from a high of 45% to between 0% and 3% with the excision of pheochromocytoma is followed the introduction of α-antagonists for preoperative therapy. Perioperative blood pressure fluctuations, myocardial infarction, congestive heart failure, cardiac dysrhythmias, and cerebral hemorrhage all appear to be reduced in frequency when the patient has been treated before surgery with alpha-blockers and the intravascular fluid compartment has been reexpanded. Extended treatment with α-antagonists is also effective in treating the clinical manifestations of catecholamine myocarditis. However, alpha-blocker therapy has never been studied in a controlled way, and there are some groups that question its necessity in light of the availability of potent titratable vasodilators for intraoperative use.[41] A list of drugs frequently used in the management of pheochromocytoma is given in Table 41-9.

TABLE 41-9 Drugs Used in The Management of Pheochromocytoma

▪DRUG	▪ACTION	▪PREOPERATIVE BLOOD PRESSURE CONTROL	▪PRESSOR CRISIS	▪COMMENT
Phentolamine	Nonselective α-antagonist	—	1–5 mg IV; 0.5–1 mg/min IV	Short duration of action ~5 min

Phenoxybenzamine	Nonselective α-antagonist	20 mg/d PO up to 160 mg/d in divided doses	—	Long half-life; may accumulate
Doxazosin (terazosin dosing similar)	Selective α_1-antagonist	1 mg/d PO up to 8 mg/d PO	—	First-dose phenomena; may cause syncope
Propranolol	Nonselective β-antagonist	40 mg/d PO up to 480 mg/d in divided doses to control tachycardia	1–2 mg IV bolus	Should never be given without first creating α-blockade
Atenolol	Selective β_1-antagonist	50–100 mg/d PO	—	Long-acting drug eliminated; unchanged by kidney
Esmolol	Selective β_1-antagonist	—	250–500 mcg/kg/min IV loading followed by maintenance infusion 25–250 mcg/kg/min	Short acting; elimination half-life ~9 min
Labetalol	α-antagonist and β-antagonist	200 mg/d PO in divided doses up to 800 mg/d	10 mg IV bolus	A much weaker alpha-blocker than beta-blocker; may cause hypertensive response
Nitroprusside	Direct vasodilator	—	0.5–1.5 mcg/kg/min initially, increased to maximum of 8 mcg/kg/min; titrate to effect	Powerful vasodilator; short acting

Magnesium sulfate	Direct vasodilator and membrane stabilizer	—	2–4 g IV bolus followed by 1–2 g/hr and additional 1–2 g boluses as needed	May potentiate neuromuscular blockade
Nicardipine	Calcium channel antagonist		1–2 mcg/kg/min increased to 7.5 mcg/kg/min; titrate to effect	
α-Methyltyrosine	Inhibitor of biosynthesis of catecholamine	1–4 g/d PO in divided doses	~	Suitable for patients not amenable to surgery; may be nephrotoxic
IV, intravenous(ly); PO, oral(ly).				

α-Adrenergic blockade is initiated once the diagnosis of pheochromocytoma is established. Phenoxybenzamine, a long-acting (24 to 48 hours), noncompetitive presynaptic (α_2) and postsynaptic (α_1) blocker, has traditionally been used at doses of 10 mg every 8 hours. Increments are added until the blood pressure is controlled and paroxysms disappear. Most patients need between 80 and 200 mg/day. The absorption after oral administration is variable, and side effects are common. Certain cardiovascular reflexes, such as the baroreceptor reflex, are blunted, and postural hypotension is common. Selective competitive α-1-blockers, such as doxazosin, terazosin, and prazosin, have also been used effectively. Because postural

hypotension can be pronounced with the commencement of therapy, the initial 1-mg dose is given at bedtime. Postural changes are also seen with maintenance therapy. A comparison of patients with pheochromocytoma receiving phenoxybenzamine and prazosin has shown both drugs to be equally effective in controlling the blood pressure. Although the optimal period of preoperative treatment has not been established, most clinicians recommend beginning α-blockade therapy at least 10 to 14 days before the proposed surgery; however, periods as short as 3 to 5 days have been used.[42] During this time, the contracted intravascular volume and hematocrit return toward normal, and the blood pressure is stabilized. Despite the real possibility of hypotension after vascular isolation of the tumor, most clinicians continue alpha-blockers up until the morning of surgery.

β-Adrenergic blockade is occasionally added after α-blockade has been established. This addition is considered in patients with persistent tachycardia or cardiac dysrhythmias that may be caused by nonselective α-blockade or epinephrine-secreting tumors. Beta-blockers should not be given until adequate α-blockade is ensured to avoid the possibility of unopposed α-mediated vasoconstriction. There is no clear preoperative advantage of one β antagonist over another,

although the short half-life of esmolol may allow better control of heart rate and arrhythmias in the perioperative setting. Labetalol, a β-adrenergic antagonist with α-blocking activity, is effective as a second-line medication, but can increase blood pressure when this drug is used alone.

α-Methyl tyrosine is an agent that inhibits the enzyme tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis. This medication is currently reserved for patients with metastatic disease, or for situations in which surgery is contraindicated and long-term medical therapy is required. When α-methyl tyrosine is used in combination with α-adrenergic-blocking agents, there is a significant reduction in catecholamine biosynthesis.

Unrecognized pheochromocytoma during pregnancy may be life threatening to the mother and fetus. Although the safety of adrenergic-blocking agents during pregnancy has not been established, these agents probably improve fetal survival in pregnant patients with pheochromocytoma. The trend is to perform surgery during the first trimester or at the time of cesarean delivery. There is no reason to terminate an early pregnancy, but the patient should be aware of the risk of spontaneous abortion resulting from abdominal surgery to remove the tumor.[43]

Perioperative Anesthetic Management. Symptomatic patients continue to receive medical therapy until tachycardia, cardiac dysrhythmias, and paroxysmal elevations in blood pressure are well controlled. If it is not possible to initiate α-blocking therapy before surgery, or if the patient has received less than 48 hours of intensive treatment, it may be necessary to infuse nitroprusside during the induction of anesthesia. A low-dose infusion is often initiated in anticipation of the marked blood pressure elevations that can occur with laryngoscopy and surgical stimulation.

Improvements in imaging now allow most patients with solitary tumors without evidence of metastases or local invasion to undergo a laparoscopic retroperitoneal approach. If the surgeon needs to assess for bilateral disease or the dissection is too difficult, then the procedure can be converted to an open one. During laparoscopic surgery, creation of the pneumoperitoneum may cause release of catecholamines and large changes in hemodynamics that can be controlled with a vasodilator.[44]

5 Although there is no clear advantage to one anesthetic technique over another, drugs that are known to liberate histamine are avoided. Because of the potential for ventricular irritability, halothane is not administered. A potent sedative-hypnotic, in combination with an opioid analgesic, is used for induction. It is extremely important to achieve an adequate depth of anesthesia before proceeding with laryngoscopy to minimize the sympathetic nervous system response to this maneuver. Maintenance is provided with an opioid analgesic and a potent inhalation agent. Manipulation of the tumor may produce marked elevations in blood pressure. Acute hypertensive crises are treated with intravenous infusions of nitroprusside or phentolamine. Phentolamine is a short-acting α-adrenergic antagonist that may be given as an intravenous bolus (2 to 5 mg) or by continuous infusion. Tachydysrhythmia is controlled with intravenous boluses of propranolol (1-mg increments) or by a continuous infusion of the ultrashort-acting selective β_1-adrenergic antagonist esmolol. The disadvantage of long-acting beta-blockers may be persistence of bradycardia and hypotension after the tumor is removed. Even esmolol may be problematic because there are cases of cardiac arrest after clamping of the venous drainage in patients on large doses of esmolol. Almost every vasodilator has been tried and recommended as an adjuvant to control hypertension. Magnesium sulfate given as an infusion with intermittent boluses has successfully controlled blood pressure.[45] Nicardipine, nitroglycerin, diltiazem, fenoldopam, and prostaglandin E_1 have all been used anecdotally. The reduction in blood pressure that may occur after ligation of the tumor's venous supply can be dangerously abrupt and should be anticipated through close communication with the surgical team. Restitution of any intravascular fluid deficit is the initial therapy in this situation. After replenishment of the intravascular volume, if the patient remains hypotensive, phenylephrine is administered. After surgery, catecholamine levels return to normal over several days. Approximately 75% of patients become normotensive within 10 days.

DIABETES MELLITUS

Diabetes mellitus (DM) is the most commonly occurring endocrine disease found in surgical patients.[46] Twenty-five to 50% of diabetics will require surgery. It has a broad spectrum of severity, and its manifestations can be altered in reaction to the patient's metabolic stress. Although the most serious complications of DM are related to its character as a chronic disease, it can cause difficulties in the short-term management of acute illness. Occasionally, DM remains clinically inapparent until exacerbated by the stress of trauma or surgery.

The principles of the treatment of DM will be easier to understand if we review the physiology of glucose metabolism and the stress response, and then consider some of the specific pathologic entities that comprise the clinical picture of DM.

Classification

DM is primarily a disease of glucose metabolism; however, it has numerous manifestations and interactions with a large range of hormonal and endocrinologic functions. Despite a variety of etiologic factors, its hallmark is a deficiency, either absolute or relative, in the amount of insulin effect to the tissues.

DM is often divided into two broad types. Type I, formerly called insulin-dependent diabetes mellitus, is distinguished from type II, formerly called non–insulin-dependent diabetes mellitus. The patient with type I DM typically experiences the onset of disease early in life.[47] Consequently, this form is also referred to as juvenile-onset diabetes. In general, the patient with type I DM is not obese, had an abrupt onset of the disease, and has very low levels of circulating insulin.

Disease in these patients cannot be controlled with diet or oral hypoglycemic agents; rather, it mandates treatment with insulin. Patients in this group are often difficult to maintain in good glucose balance, are more likely to become ketotic, and are likely to sustain the end-organ complications of diabetes if they live long enough.

Patients with type II DM, also called adult-onset diabetes, typically experience a gradual onset of the disease later in life. They are often obese and have some resistance to the effects of insulin. They may have normal or even elevated levels of insulin. In milder forms, this version of diabetes can often be treated with diet or oral hypoglycemic agents. Because these patients are relatively resistant to ketosis, their disease may be clinically inapparent until exacerbated by the stress of surgery or intercurrent illness.

This classification of DM is only a generalization. The milder, type II form occasionally occurs in young people, and many older adults acquire a severe and brittle form of type I. Secondary DM can be a result of a disease that damages the pancreas and thus impairs insulin secretion. Pancreatic surgery, chronic pancreatitis, cystic fibrosis, and hemochromatosis can damage the pancreas and impair insulin secretion sufficiently to produce clinical DM. DM can result from one of the endocrine diseases that produces a hormone that opposes the action of insulin. Hence, a patient with a glucagonoma, pheochromocytoma, or acromegaly may be diabetic. An increased effect of glucocorticoids, either from Cushing's disease or steroid therapy, may also oppose the effect of insulin enough to elicit clinical diabetes and would certainly complicate the management of preexisting diabetes. Gestational diabetes is a common medical problem of pregnancy and may presage future type II DM.

Physiology

Insulin has multiple and complex interactions with lipid, protein, and glucose metabolism. For our purposes, it is easiest to regard the effects of insulin on glucose metabolism as primary and to view its effects on other metabolic functions only as they relate to glucose.

Insulin is a small protein produced by the β cells of the islets of Langerhans in the pancreas. Normal production in the adult human is approximately 40 to 50 U/day. Insulin acts through receptor sites on cells. The half-life of insulin in the circulation is only a few minutes. However, it

may clinically appear to have a longer duration of action, owing to delays in binding and release from the cellular receptors. These facts lead us to the important principle that once a high level of insulin saturates all the binding sites, insulin will not have a more potent effect, just a more long-lasting effect. This is crucial to understanding insulin therapy, which is discussed in the following paragraphs.

Insulin is metabolized in the liver and kidney. In patients with hepatic dysfunction, the loss of gluconeogenesis and a prolongation of insulin effect increase the risk of hypoglycemia. Renal disease may prolong the action of insulin, is another risk factor for hypoglycemia, and is an important consideration in managing the use of exogenous insulin in diabetic patients.

Insulin release is related to a number of events. First is the direct effect of glucose and amino acids to stimulate insulin release. The mechanism involves interaction with hormones from the GI tract released during enteral feeding. The autonomic nervous system, also through vagal stimulation, increases insulin release, as does β-adrenergic stimulation and α-adrenergic blockade.

The most fundamental action of insulin is to stimulate increased cellular uptake of glucose. This is particularly important in skeletal muscle cells, where muscle activity also increases glucose uptake and is an important variable in the management of the physically active diabetic patient. The brain and liver are exceptions where insulin does not affect glucose transport. Hence, the diabetic patient has hyperglycemia because of inadequate cellular uptake of glucose. Along with glucose, potassium enters the cells under the influence of insulin, so the diabetic patient is also likely to have an imbalance of potassium concentrations across cell membranes.

Other important metabolic functions of insulin include the stimulation of glycogen formation, as well as the suppression of gluconeogenesis and lipolysis. The patient with insulin deficiency has low glycogen stores and active gluconeogenesis. This implies that in the diabetic patient, due to an absence of glycogen, protein must be broken down to make glucose. Insulin also increases the uptake of amino acids into muscle cells. Hence, an insulin deficiency leads to catabolism and negative nitrogen balance.

Fat metabolism is also abnormal in the diabetic state, with acceleration of lipid catabolism and increased formation of ketone bodies. A deficiency of insulin leads to increased fatty acid liberation from adipose tissue. These fatty acids have multiple metabolic effects, including interference with carbohydrate phosphorylation in muscle, which leads to further hyperglycemia. Low concentrations of insulin, which may be inadequate to prevent hyperglycemia, are often sufficient to block lipolysis. This effect explains the common clinical situation in which a patient is hyperglycemic without being ketotic.

Glucagon is a polypeptide released from the α cells of the pancreas, and acts both to stimulate the release of insulin and oppose some of the effects of insulin. Hence, it has both a direct and an indirect ability to increase circulating glucose levels. In some patients, after total pancreatic resection, glucose balance is not as poor as might be expected because of the concomitant absence of glucagon. Glucagon release is stimulated by hypoglycemia, as well as by epinephrine and cortisol, and is suppressed by glucose ingestion.

The metabolic effects of stress are intricately involved with the same pathways as those involved in DM. During stress, elevations in the circulating levels of cortisol, glucagon, catecholamines, and growth hormone all act to cause hyperglycemia. In addition, glucagon and α-adrenergic stimulation exert a suppressive effect on insulin release. Mild hyperglycemia may occur in the stressed patient who does not have DM. In the diabetic patient, stress makes the diabetes more difficult to control. In a patient with minimal or subclinical DM before the stressful episode, the glucose balance may become difficult to manage during the stress-related event.

Treatment

Patients with type I DM require insulin to survive. Further, the risk of microvascular complications can be decreased if tight glycemic control maintains near-normal levels of blood glucose. Patients may be on a range of doses of both short-acting and intermediate-acting insulin, with doses given

one to six times per day, depending on the desire for tight control.

Patients with type II DM may initially be treated with diet control and exercise. If this fails to control glucose levels or the diabetes worsens, therapy with an oral agent is indicated.[48] Sulfonylureas enhance β-cell insulin secretion. Metformin is a biguanide that enhances the sensitivity of both hepatic and peripheral tissues to insulin.[49] Rosiglitazone (Avandia) and pioglitazone (Actos) are thiazolidinediones that also increase insulin sensitivity. α-Glucosidase inhibitors decrease postprandial glucose absorption. If oral agents cannot maintain acceptable glucose levels, insulin is used.

Anesthetic Management

6 Successful management of the diabetic patient depends as much, if not more, on the proper management of the chronic complications of the disease as on acute glycemic management.

Preoperative

A thorough preoperative search must be done for end-organ complications of DM. In addition to a thorough history and physical, a recent ECG, blood urea nitrogen, potassium, creatinine, glucose, and urinalysis are essential.

Atherosclerosis develops earlier and is more widespread in diabetic patients compared with nondiabetics. Manifestations include coronary artery disease, peripheral vascular disease, cerebrovascular disease, and renovascular disease. The incidence of postoperative myocardial infarction is increased in diabetic patients, and the complication rate is higher. Coronary artery disease can manifest at a young age or atypically in type I diabetics. Silent myocardial ischemia and infarction occur more commonly in diabetic patients, perhaps because of sensory neuropathy of the visceral afferents to the heart. DM may be associated with a cardiomyopathy in the face of angiographically normal coronary arteries, possibly with diffuse disease in arteries too small to be visualized. The American College of Cardiology (ACC)/American Heart Association guidelines recognize DM as an intermediate risk factor when evaluating patients for noncardiac surgery.

In up to 40% of juvenile patients with DM presenting for renal transplantation, laryngoscopy can be difficult.[50] This may be due to diabetic stiff joint syndrome, a frequent complication of type I DM, leading to decreased mobility of the atlanto-occipital joint. The "prayer sign," an inability to approximate the palmar surfaces of the interphalangeal joints, is associated with stiff joint syndrome and may predict difficult laryngoscopy.

Diabetic nephropathy eventually occurs in up to 40 to 50% of patients with DM. Albuminuria usually precedes a steady decline in renal function.

Diabetic patients with autonomic neuropathy are at increased risk for intraoperative hypotension, requiring vasopressor support, and perioperative cardiorespiratory arrest.[51,52,53] There may be an exaggerated pressor response to tracheal intubation.[54] Autonomic function may be tested by measuring the beat-to-beat variation in heart rate during breathing, heart rate response to a Valsalva maneuver, and orthostatic changes in diastolic blood pressure and heart rate. Autonomic neuropathy predisposes to intraoperative hypothermia.[55]

Diabetic patients may have delayed gastric emptying as a result of diabetic autonomic neuropathy, and therefore, they may be at increased risk of aspiration. Autonomic function tests can predict the presence of solid food particles in gastric contents but not increased gastric volume or acidity.[56] Metoclopramide may be useful in emptying the stomach of solid food.

It is axiomatic that the patient should attain the best possible preoperative metabolic control. If the patient's glucose level has been unstable, especially with episodes of hypoglycemia, adjustment of insulin therapy is required. Traditionally, oral hypoglycemics have been held before surgery because of fear of hypoglycemia in the fasted patient. With today's shorter-acting agents, this may be unnecessary because the risk is much reduced. Metformin should be discontinued preoperatively because it has been associated with severe lactic acidosis during episodes of

hypotension, poor perfusion, or hypoxia. Unless the patient has a surgical emergency, patients with diabetic ketoacidosis or hyperosmolar coma should receive intensive medical management before coming to the operating room (see Emergencies section).

Intraoperative

The details of the anesthetic plan depend intimately on the end-organ complications. Invasive monitoring may be indicated for the patient with heart disease, awake intubation may be necessary if a difficult intubation is predicted, fluid management and drug choices may depend on renal function, and aspiration must be considered if there is gastroparesis.

Blood glucose levels should be measured before and after surgery. The need for additional measurements is determined by the duration and magnitude of surgery, as well as the brittleness of the diabetes. Hourly measurements are reasonable in high-risk patients.

On the basis of a preoperative osmotic diuresis, the diabetic patient may reach the operating room with clinically significant dehydration. In addition to the usual principles of perioperative fluid management, it is important to note the amount of glucose administered intravenously to avoid a massive overdose of glucose. The standard glucose dosage for an adult patient is 5 to 10 g/hr (100 to 200 mL of 5% dextrose solution hourly). It is best to monitor and record the dextrose administered separately from the fluids given. It would be wrong to give large amounts of dextrose (contained in the intravenous solutions) just because that patient needed vigorous fluid replacement. If this happens, the patient is likely to be extremely hyperglycemic in the postanesthesia care unit. It is difficult to determine the proper dose of insulin to correct this iatrogenic hyperglycemia, so prolonged observation and therapy may be required.

Monitoring of the patient who arrives in the operating room with significant metabolic impairment, such as diabetic ketoacidosis, is similar to management in the medical intensive care unit, including hourly determinations of blood glucose, arterial pH, electrolytes, and fluid balance. Frequent reassessments with medical consultation as necessary guide the use of fluids; electrolytes, especially potassium; insulin; phosphate; and glucose.

Another area of patient monitoring that is extremely important in the diabetic patient is positioning on the operating table. Injuries to the limbs or nerves are more likely in the patient who arrives in the operating room already compromised by diabetic peripheral vascular disease or neuropathy. The peripheral nerves may already be partly ischemic and therefore particularly vulnerable to pressure or stretch injuries.[57]

Glycemic Goals

7 Traditionally, intraoperative glucose management has been a laissez-faire approach, where mild hyperglycemia would not be treated unless blood glucose was greater than 200 to 250 mg/dL or even higher. It was widely believed that short-term, mild hyperglycemia was not detrimental and the risk from inadvertent hypoglycemia too great. Over the past few years, there has been increasing evidence that even mild hyperglycemia is associated with increased perioperative morbidity, and tight control to achieve euglycemia can reduce complications in many groups of medical and surgical patients.

One study looked at 1,548 critically ill surgical patients, many of whom had cardiac surgery, and found that patients who had conventional therapy as opposed to intensive insulin therapy (goal 80 to 110 mg/dL) had increased risk of sepsis, renal failure, neuropathy, and mortality.[58] One study of 3,500 diabetic patients undergoing coronary artery bypass graft (CABG) surgery found decreased mortality and infections in patients who received continuous insulin infusions.[59] Similarly, a study of 141 diabetic patients undergoing CABG surgery found improved survival, decreased episodes of recurrent ischemia, and fewer recurrent wound infections in those who received a glucose-insulin-potassium infusion to maintain

blood glucose less than 200 mg/dL.[60] This study was notable because tight control began during the intraoperative period and continued for 12 hours afterward. Hyperglycemia exacerbates

neuronal ischemic damage. Patients undergoing surgical procedures associated with cerebral ischemia such as intracranial surgery, carotid endarterectomy, and cardiopulmonary bypass may benefit from euglycemia.[61] On the strength of these and other studies,[62,63] there is a growing trend toward recommending tight control of glucose in critically ill and perioperative patients. The American College of Endocrinology has published a position paper stating that the goal for maintaining blood glucose should be less than 110 mg/dL.[64]

There are limitations in applying these data to the intraoperative period. Most of the studies looked at glucose control over days to weeks. The specific importance of the few hours of the intraoperative period is not addressed, although it is reasonable to assume good intraoperative metabolic control will help achieve good postoperative metabolic control. Further, these studies included heterogeneous populations undergoing a variety of procedures. The majority of studies are in cardiac surgical patients. Some studies had diabetics and nondiabetics. It may be possible to stratify the risk and select patients for intensive therapy. As the desired glycemic end point gets lower, the incidence of hypoglycemia will increase. Although no complications have been reported from hypoglycemia during intensive therapy, outside the rigid protocols and monitoring of a study there may be serious neurologic complications.

The mechanisms by which intensive insulin therapy reduces complications are likely multifactorial. Hyperglycemia impairs neutrophil, fibroblast, and endothelial function. Insulin decreases inflammation and reduces fatty acids, which can have detrimental effects on myocardial metabolism.

Therefore, it seems reasonable to keep perioperative glucose levels lower than in the past, certainly below 200 mg/dL, and probably close to 110 mg/dL. Further studies may identify which patients will benefit from resource-intensive, tight control and provide empirical or consensus guidelines for managing intraoperative glucose.

Management Regimens

There is no consensus about the optimal way to manage perioperative metabolic changes in diabetic patients; many options are available. Factors to consider in selecting a plan include the type of DM, how aggressively euglycemia will be sought, whether the patient takes insulin, whether the surgery is minor and in an ambulatory unit, whether the surgery is elective or an emergency, and the ability of hospital resources to safely administer a complex plan. The goal of any regimen should be to minimize metabolic derangements and, most obviously, to avoid hypoglycemia.

Type I Diabetes

Type I diabetics require insulin or they will rapidly develop ketoacidosis and its complications. This can be given by administering one-half to two-thirds of the patient's usual intermediate-acting insulin subcutaneously on the morning of surgery. In addition to this basal insulin, a regular insulin sliding scale (RISS) can be added and titrated to blood glucose measurement.[65] Alternatively, an insulin infusion of 0.5 to 2 U/hr (100 U regular insulin in 1,000 mL normal saline at 5 to 20 mL/hr) can meet basal metabolic needs and be adjusted to maintain blood glucose at the desired level.[66] With either method, a slow glucose infusion (D5W at 75 to 125 mL/hr) will prevent hypoglycemia while the patient is fasting. Some authorities recommend a combination glucose-insulin or glucose-insulin-potassium infusions.

Type Ii Diabetes

The hospitalized type II diabetic may find glucose control improved because of stricter dietary control. Fasting patients will not have postprandial hyperglycemia. Sulfonylureas should be held while the patient is NPO (nothing per mouth) to decrease the risk of hypoglycemia and because they interfere with the cardioprotective effect of ischemic preconditioning. Metformin should probably also be held, especially if there is a risk of decreased renal function perioperatively because of a risk of lactic acidosis. Thiazolidinediones can be continued because they do not predispose to hypoglycemia. α-Glucosidase inhibitors should be held because they only work when

taken with meals. For type II patients on oral agents alone, RISS can be added to titrate blood glucose levels.

Patients on chronic insulin can be treated similarly to the type I patient by giving one-half the usual NPH dose the morning of surgery, supplemented by a RISS, or an insulin infusion titrated to blood glucose. The use of a RISS as the sole method of control is to be discouraged because it can predispose to wide glucose variations.[67]

At Yale-New Haven Hospital, the Department of Medicine has implemented an effective insulin infusion protocol designed to achieve strict glycemic control in medical intensive care unit patients.[68] It emphasizes the need to consider the current blood glucose value, as well as the rate of change of blood glucose level when adjusting the infusion.

Postoperatively, as the patient resumes oral intake, therapy can be transitioned to the patient's chronic regimen. Type II diabetics who have had gastric bypass can have rapid resolution of their glucose intolerance, and will often need their oral agents and insulin reduced or even discontinued in the postoperative period. This effect appears to be due to changes in the enteric hormones such as glucose-dependent insulinotropic polypeptide and glucagon-like peptide-1, rather than weight loss.[69]

Emergencies

Patients may present with metabolic instability, or it may develop perioperatively. Stress, trauma, and infection may all lead to increased insulin requirements and insulin resistance.

Hyperosmolar Nonketotic Coma

An occasional elderly patient with minimal or mild DM may present with remarkably high blood glucose levels (>600 mg/dL) and profound dehydration. Such patients usually have enough endogenous insulin activity to prevent ketosis; even with blood sugar concentrations of 1,000 mg/dL, they are not in ketoacidosis. Presumably, it is the combination of an impaired thirst response and mild renal insufficiency that allows the hyperglycemia to develop. The marked hyperosmolarity may lead to coma and seizures, with the increased plasma viscosity producing a tendency to intravascular thrombosis. It is characteristic of this syndrome that the metabolic disturbance responds quickly to rehydration and small doses of insulin. One to 2 L of normal saline, or equivalent, should be infused over 1 to 2 hours if there are no cardiovascular contraindications. Insulin, by bolus or infusion, should be administered. With rapid correction of the hyperosmolarity, cerebral edema is a risk, and recovery of mental acuity may be delayed after the blood glucose level and circulating volume have been normalized.

Diabetic Ketoacidosis

If the diabetic patient has insufficient insulin effect to block the mobilization and metabolism of free fatty acids, the metabolic byproducts acetoacetate and β-hydroxybutyrate accumulate.[70]

These ketone bodies are organic acids and cause a metabolic acidosis with an increased unmeasured anion gap. Clinically, the patient often presents because of intercurrent illness, trauma, or the untoward cessation of insulin therapy. Although hyperglycemia is almost always present, the degree of hyperglycemia does not correlate with the severity of the acidosis. Blood sugar levels are often in the 300 to 500 mg/dL range. The patient is always dehydrated because of the combination of the hyperglycemia-induced osmotic diuresis and the nausea and vomiting typical of this syndrome. Because leukocytosis, abdominal pain, GI ileus, and mildly elevated amylase levels are all common in ketoacidosis, an occasional patient is misdiagnosed as having an intra-abdominal surgical problem.

Treatment of diabetic ketoacidosis includes insulin administration and fluid and electrolyte replacement (Table 41-10). An intravenous bolus of 10 to 20 U of insulin achieves rapid maximal effect. Further insulin can be administered by intravenous infusion or intermittent bolus every 30 to 60 minutes. When blood glucose levels decrease below 250 mg/dL, glucose should be added to

the intravenous fluid while insulin therapy continues. Fluid requirements can be marked; 1 to 2 L of normal saline, or equivalent, should be given over 1 to 2 hours. Further deficits can be replaced more gradually. Potassium replacement is a key concern in patients with diabetic ketoacidosis. Because of the diuresis, the total body potassium stores are reduced. However, acidosis by itself causes a shift of potassium ions out of the cell. Thus, the serum potassium concentration may be normal or even slightly elevated while the patient is acidotic. As soon as the metabolic acidosis is corrected, the potassium ions shift back into the cells. Consequently, the serum potassium concentration can decline acutely. Therefore, early and vigorous potassium replacement is required in these patients, with the exception of those patients in renal failure. Hypophosphatemia also occurs with the correction of the acidosis and, if severe, may cause impairment of ventilation, resulting from skeletal muscle weakness in the vulnerable patient. Instead of diabetic ketoacidosis, the diabetic patient with a metabolic acidosis may have lactic acidosis, which results from poor tissue perfusion or sepsis. It is diagnosed by the presence of an increased serum lactate concentration without an elevated ketone concentration.

TABLE 41-10 Management of Diabetic Ketoacidosis

- Regular insulin 10 U IV bolus followed by an insulin infusion nominally at (blood glucose/150) U/hr
- Isotonic IV fluids as guided by vital signs and urine output; anticipate 4–10 L deficit
- When urine output is >0.5 mL/kg/hr, give potassium chloride 10–40 mEq/hr (with continuous ECG monitoring when the rate is greater than 10 mEq/hr)
- When serum glucose decreased to 250 mg/dL, add dextrose 5% at 100 mL/hr
- Consider sodium bicarbonate to correct pH < 6.9

ECG, electrocardiogram; IV, intravenous(ly).

Diabetic ketoacidosis must also be distinguished from the syndrome of alcoholic ketoacidosis. This typically occurs in the poorly nourished alcoholic patient after acute intoxication. Except for the presence of chemical ketoacidosis, alcoholic ketoacidosis is not clinically related in any way to DM. The alcoholic patient may be hypoglycemic or mildly hyperglycemic. The predominant ketone in this syndrome is β-hydroxybutyrate, which tends to react less sensitively in the standard laboratory nitroprusside reaction measurement of ketones. Hence, the diagnosis may be obscured. Administration of dextrose and parenteral fluids is the specific treatment for alcoholic ketoacidosis; insulin is not indicated (except in the rare circumstance in which the patient also has clear-cut DM).

Hypoglycemia

Hypoglycemia is the clinical occurrence most feared in the management of diabetic patients. The precise level at which symptomatic hypoglycemia occurs is variable. The normal, fasted patient may have blood sugar levels lower than 50 mg/dL without symptoms. However, the diabetic patient who has a chronically elevated blood sugar level may be symptomatic at levels significantly above this glucose concentration. Hypoglycemia is almost impossible to diagnose clinically in the unconscious patient.

In the awake patient, hypoglycemia often produces central nervous system changes ranging from light-headedness to coma with seizures. Often, the patient recognizes the symptoms and can tell that the blood sugar is low before any overt clinical signs develop. With hypoglycemia, there is a reflex catecholamine release that produces overt sympathetic hyperactivity causing tachycardia, lacrimation, diaphoresis, and hypertension. In the anesthetized patient, these signs of

sympathetic hyperactivity can easily be misinterpreted as inadequate or "light" anesthesia. In the anesthetized, sedated, or seriously ill patient, the mental changes of hypoglycemia are also unrecognizable. Furthermore, in patients being treated with β-adrenergic blocking agents or in patients with advanced diabetic autonomic neuropathy, the sympathetic hyperactivity of hypoglycemia may be obscured. Thus, the clinical diagnosis of hypoglycemia in the surgical patient may be difficult to make, and only a high degree of suspicion and frequent blood glucose checks can prevent this complication.

Hypoglycemia is more likely to occur in the diabetic surgical patient if insulin or sulfonylureas are given without supplemental glucose. With renal insufficiency, the action of insulin and oral hypoglycemic agents is prolonged.

PITUITARY GLAND

The pituitary gland is located below the base of the brain in a bony structure called the sella turcica. The pituitary gland and the hypothalamus together form a central unit that regulates the release of various hormones. The pituitary gland is divided into two components. The anterior pituitary (adenohypophysis) secretes prolactin, growth hormone, gonadotropins (luteinizing hormone and follicle-stimulating hormone), TSH, and ACTH. The posterior pituitary (neurohypophysis) secretes the hormones vasopressin and oxytocin. Hormone release from the anterior and posterior pituitary is regulated by the hypothalamus. Regulatory peptides or preformed hormones from the hypothalamus are transported to the pituitary gland through vascular or tissue connections.

Anterior Pituitary

Hyposecretion of anterior pituitary hormones is usually due to compression of the gland by tumor. This may begin as an isolated deficiency, but it usually develops into multiglandular dysfunction. Male impotence or secondary amenorrhea in the woman is an early manifestation of panhypopituitarism. Panhypopituitarism after postpartum hemorrhagic shock (Sheehan's syndrome) is due to necrosis of the anterior pituitary gland. Radiation therapy delivered to the sella turcica or nearby structures and surgical hypophysectomy are other causes of

panhypopituitarism. Panhypopituitarism is treated with specific hormone replacement therapy, which should be continued in the perioperative period. Stress doses of corticosteroids are necessary for patients receiving steroid replacement due to inadequate ACTH.

The hypersecretion of various anterior pituitary hormones is usually caused by an adenoma. Excess prolactin secretion with galactorrhea is a common hormonal abnormality associated with pituitary adenoma. Cushing's disease may occur secondary to excess ACTH production, and gigantism or acromegaly may occur as a consequence of excess growth hormone production in the child or adult, respectively. Excessive secretion of TSH is rare.

8 Acromegaly in the adult patient may pose several problems for the anesthesiologist.[71] Excess hypertrophy occurs in skeletal, connective, and soft tissues.[72] The tongue and epiglottis are enlarged, making the patient susceptible to upper airway obstruction. The incidence of difficult intubation is 20 to 30%, and it is difficult to predict which patients will be difficult.[73] Hoarseness may reflect thickening of the vocal cords or paralysis of a recurrent laryngeal nerve due to stretching. Dyspnea or stridor is associated with subglottic narrowing. Peripheral nerve or artery entrapment, hypertension, and DM are other common findings. The anesthetic management of these patients is complicated by distortion of the facial anatomy and upper airway. Induction of general anesthesia may put the patient at increased risk if mask fit or vocal cord visualization is impaired. When the preoperative history suggests upper airway or vocal cord involvement, it is prudent to consider intubation of the trachea while the patient is awake.

Posterior Pituitary

The posterior pituitary, or neurohypophysis, is composed of terminal nerve endings that extend

from the ventral hypothalamus. Vasopressin (antidiuretic hormone or ADH) and oxytocin are the two principal hormones secreted by the posterior pituitary. Both hormones are synthesized in the supraoptic and paraventricular nuclei of the hypothalamus. They are bound to inactive carrier proteins, neurophysins, and transported by axons to membrane-bound storage vesicles located in the posterior pituitary. ADH is a nonapeptide that circulates as a free peptide after its release. The primary functions of ADH are the maintenance of extracellular fluid volume and regulation of plasma osmolality. Oxytocin elicits contraction of the uterus and promotes milk secretion and ejection by the mammary glands.

Vasopressin

ADH promotes resorption of solute-free water by increasing cell membrane permeability to water alone. The target sites for ADH are the collecting tubules of the kidneys. A decrease in free water clearance causes a decrease in serum osmolality and a corresponding increase in circulating blood volume. Under normal conditions, the primary stimulus for the release of ADH is an increase in serum osmolality.

Osmoreceptors located in the hypothalamus are sensitive to changes in the normal serum osmolality of as little as 1% (normal osmolality is approximately 285 mOsm/L). Stretch receptors in the left atrium and perhaps pulmonary veins, which are sensitive to moderate reductions in the blood volume, are also capable of stimulating ADH secretion. The need to restore plasma volume may at times override osmotic inhibition of ADH release. Various physiologic and pharmacologic stimuli also influence the secretion of ADH. Positive-pressure ventilation of the lungs, stress, anxiety, hyperthermia, β-adrenergic stimulation, and any histamine-releasing stimulus can promote the release of ADH.

ADH also has other actions. It can increase blood pressure by constricting vascular smooth muscle. This activity is most significant in the splanchnic, renal, and coronary vascular beds, and provides the rationale for administering exogenous vasopressin in the management of hemorrhage due to esophageal varices. Caution must be taken when this drug is used in patients with coronary artery disease. ADH (even in small doses) can precipitate myocardial ischemia through vasoconstriction of the coronary arteries. It is unclear whether selective arterial infusion is safer than systemic administration with regard to cardiac and vascular side effects. ADH is also often used in vasodilatory shock as an adjuvant to other pressor agents.

ADH also promotes hemostasis through an increase in the level of circulating von Willebrand factor and factor VIII. Desmopressin (DDAVP), an analog of ADH administered to patients after cardiopulmonary bypass in a dose of 0.3 μg/kg, significantly decreased blood loss and reduced transfusion requirements compared with a group of patients who did not receive the drug. DDAVP is also frequently used to reverse the coagulopathy of renal failure.

Diabetes Insipidus

This disorder results from inadequate secretion of ADH or resistance on the part of the renal tubules to ADH (nephrogenic diabetes insipidus). Failure to secrete adequate amounts of ADH results in polydipsia, hypernatremia, and a high output of poorly concentrated urine. Hypovolemia and hypernatremia may become so severe as to be life threatening. This disorder usually occurs after destruction of the pituitary gland by intracranial trauma, infiltrating lesions, or surgery. Patients in whom diabetes insipidus develops secondary to severe head trauma or subarachnoid hemorrhage often have impending brain death.[74] The treatment of diabetes insipidus depends on the extent of the hormonal deficiency. During surgery, the patient with complete diabetes insipidus receives an intravenous infusion of aqueous ADH (100–200 mU/hr), combined with administration of an isotonic crystalloid solution. The serum sodium and plasma osmolality are measured on a regular basis, and therapeutic changes are made accordingly. ADH may also be given intramuscularly (as vasopressin tannate in oil). DDAVP administered intranasally has prolonged antidiuretic activity (12 to 24 hours) and is associated with a low incidence of pressor effects. As a consequence of the large outpouring of ADH in response to surgical stress, patients with a residually functioning gland usually do not need parenteral ADH during the perioperative

period unless the plasma osmolality rises above 290 mOsm/L. Nonhormonal agents that have efficacy in the treatment of incomplete diabetes insipidus include the oral hypoglycemic chlorpropamide (200 to 500 mg/day). This drug stimulates the release of ADH and sensitizes the renal tubules to the hormone. Hypoglycemia is a serious side effect that limits the usefulness of the drug. Clofibrate, a hypolipidemic agent, is also capable of stimulating ADH release and has been used in the outpatient setting. None of these medications is effective in the patient with nephrogenic diabetes insipidus. Paradoxically, the thiazide diuretics exert an antidiuretic action in patients with this disorder.

Inappropriate Secretion of Antidiuretic Hormone

The inappropriate and excessive secretion of ADH may occur in association with a number of diverse pathologic processes, including head injuries, intracranial tumors, pulmonary infections, small cell carcinoma of the lung, and hypothyroidism. The clinical manifestations occur as a result of a dilutional hyponatremia, decreased serum osmolality, and a reduced urine output with a high osmolality. Weight gain, skeletal muscle

weakness, and mental confusion or convulsions are presenting symptoms. Peripheral edema and hypertension are rare. The diagnosis of the syndrome of inappropriate ADH (SIADH) secretion is one of exclusion, and other causes of hyponatremia must first be ruled out. The prognosis is related to the underlying cause of the syndrome.

The treatment of patients with mild or moderate water intoxication is restriction of fluid intake to 800 mL/day. Patients with severe water intoxication associated with hyponatremia and mental confusion may require more aggressive therapy, with the intravenous administration of a hypertonic saline solution. This may be administered in conjunction with furosemide. Caution must be observed in patients with poor left ventricular function. Isotonic saline is substituted for hypertonic solutions once the serum sodium is brought into a safe range. Too-rapid correction of hyponatremia may induce central pontine myelinolysis and cause permanent brain damage. Serum sodium should not be raised by more than 12 mEq/L in 24 hours. Other drugs that may be used in the patient with SIADH are demeclocycline and lithium. Demeclocycline interferes with the ability of the renal tubules to concentrate urine and is frequently used in outpatients. Lithium usually is not used because of the high incidence of toxicity.

ENDOCRINE RESPONSE TO SURGICAL STRESS

Anesthesia, surgery, and trauma elicit a generalized endocrine metabolic response characterized by an increase in the plasma levels of cortisol, ADH, renin, catecholamines, and endorphins, and by metabolic changes such as hyperglycemia and a negative nitrogen balance.[75,76] Various neural and humoral factors (e.g., pain, anxiety, acidosis, local tissue factors, hypoxia) play a role in activating this stress response.

The induction of anesthesia increases the levels of circulating catecholamines and is a form of metabolic stress. Regional anesthesia may block part of the metabolic stress response during surgery, probably by blockade of the neural communications from the surgical area. It is theorized that the persistently high levels of circulating catecholamines in trauma and critical illness lead to stress hyperglycemia through a direct inhibition of insulin release. Bypass of the gut hormonal actions in patients receiving intravenous glucose feedings, especially if given in large amounts, contributes to the impairment of insulin release during illness and can create a particularly difficult management problem for diabetic patients.

Endorphins are a group of endogenous peptides with opioid activity that have been isolated from the central nervous system. It is well documented that β-endorphin is released from the anterior pituitary, where it is contained as part of β-lipoprotein, a 91-chain amino acid, which is a cleavage product of the precursor peptide for ACTH. Large increases in the central nervous system and plasma concentrations of endorphins in response to emotional or surgical stimuli suggest that these substances play a role in the body's response to stress. These substances modulate painful stimuli by binding to opiate receptors located throughout the brain and spinal cord.

Numerous experiments have focused on the stress response and its relationship to the depth of anesthesia. Regional anesthesia and general anesthesia appear to blunt the release of various stress hormones during the period of surgical stimulation in a dose-dependent fashion. Historically, anesthesiologists have relied on the indirect measurement of hemodynamic variables such as blood pressure and heart rate to evaluate the level of autonomic activity in response to anesthesia and surgery. It is assumed that the physiologic manifestations of stress are potentially harmful, especially in patients with limited functional reserve. As such, our anesthetic techniques and pain management strategies are designed to limit this neurohormonal response, in the hope of providing the patient with some benefit. Further investigations are needed to assess the impact of these efforts on perioperative morbidity and mortality.

Chapter 42

Obstetric Anesthesia

Alan C. Santos

Ferne R. Braveman

Mieczyslaw Finster

KEY POINTS

1	As oxygen consumption increases during pregnancy, the maternal cardiovascular system adapts to meet the metabolic demands of a growing fetus.
2	Airway edema may be particularly severe in women with preeclampsia, in patients placed in the Trendelenburg position for prolonged periods, or with concurrent use of tocolytic agents.
3	A rapid-sequence induction of anesthesia, application of cricoid pressure, and intubation with a cuffed endotracheal tube are required for all pregnant women receiving general anesthesia after the first trimester.
4	The driving force for placental drug transfer is the concentration gradient of free drug between the maternal and fetal blood.
5	For cesarean section, the choice of anesthesia depends on the urgency of the procedure, in addition to the condition of the mother and fetus.
6	The case fatality rate (maternal mortality) with general anesthesia is 16.7 times greater than that with regional anesthesia.
7	By virtue of age and gender, as well as reduced epidural pressure after delivery, pregnant women are at a higher risk for developing postdural puncture headache (PDPH).
8	Pregnancy and parturition are considered "high risk" when accompanied by conditions unfavorable to the well-being of the mother, fetus, or both.
9	Preeclampsia is classified as severe if it is associated with severe hypertension, proteinuria, or end-organ damage.

10	Antepartum hemorrhage occurs most commonly in association with placenta previa.
11	Heart disease during pregnancy is a leading nonobstetric cause of maternal mortality.
12	Substance abuse with cocaine has the greatest implications for anesthetic management because it causes a heightened sympathetic state.
13	Fetal asphyxia develops as a result of interference with maternal or fetal perfusion of the placenta.
14	There is an increased incidence of adverse obstetric outcome, particularly after nonobstetric operations during the first trimester.

PHYSIOLOGIC CHANGES OF PREGNANCY

During pregnancy, there are major alterations in nearly every maternal organ system. These changes are initiated by hormones secreted by the corpus luteum and placenta. The mechanical effects of the enlarging uterus and compression of surrounding structures play an increasing role in the second and third trimesters. This altered physiologic state has relevant implications for the anesthesiologist caring for the pregnant patient. The most relevant changes, involving hematologic, cardiovascular, ventilatory, metabolic, and gastrointestinal functions, are considered in Table 42-1.

TABLE 42-1 Summary of Physiologic Changes of Pregnancy at Term

▪VARIABLE	▪CHANGE	▪AMOUNT
Total blood volume	Increase	25–40%
Plasma volume	Increase	40–50%
Fibrinogen	Increase	50%
Serum cholinesterase activity	Decrease	20–30%
Cardiac output	Increase	30–50%
Minute ventilation	Increase	50%

Alveolar ventilation	Increase	70%
Functional residual capacity	Decrease	20%
Oxygen consumption	Increase	20%
Arterial carbon dioxide tension	Decrease	10 mm Hg
Arterial oxygen tension	Increase	10 mm Hg
Minimum alveolar concentration	Decrease	32–40%

Hematologic Alterations

Increased mineralocorticoid activity during pregnancy produces sodium retention and increased body water content.[1] Thus, plasma volume and total blood volume begin to increase in early gestation, resulting in a final increase of 40 to 50% and 25 to 40%, respectively, at term. The relatively smaller increase in red blood cell volume (20%) accounts for a reduction in hemoglobin (to 11 to 12 g/dL) and hematocrit (to 35%).[1] The leukocyte count ranges from 8,000 to 10,000 per mm^3 throughout pregnancy, whereas the platelet count remains unchanged. Plasma fibrinogen concentrations increase during normal pregnancy by approximately 50%, whereas clotting factor activity is variable.[2] Serum cholinesterase activity declines to a level of 20% below normal by term and reaches a nadir in the puerperium. However, it is doubtful that moderate succinylcholine doses lead to prolonged apnea in otherwise normal circumstances.[3] Total plasma protein concentration declines to less than 6 g/dL at term, whereas the total amount in the circulation increases.[4] The albumin–globulin ratio declines because of the relatively greater reduction in albumin concentration. A decrease in serum protein concentration may be clinically significant in that the free fractions of protein-bound drugs can be expected to increase.

Cardiovascular Changes

As oxygen consumption increases during pregnancy, the maternal cardiovascular system adapts to meet the metabolic demands of a growing fetus. Decreased vascular resistance due to estrogens, progesterone, and prostacyclin may be the initiating factor.[5] Lowered resistance is found in the uterine, renal, and other vascular beds; at term, there is an increase in heart rate (15 to 25%), and cardiac output (up to 50%) above that of the nonpregnant state. Arterial blood pressure decreases slightly because the decrease in peripheral resistance exceeds the increase in cardiac output. Additional increases in cardiac output occur during labor (when cardiac output may reach 12 to 14 L/min) and also in the immediate postpartum period due to added blood volume from the contracted uterus.

From the second trimester, aortocaval compression by the enlarged uterus becomes progressively more important, reaching its maximum at 36 to 38 weeks, after which it may decrease as the fetal head descends into the pelvis.[6] Studies of cardiac output, measured with the patient in the supine position during the last weeks of pregnancy, have indicated a decrease to nonpregnant levels; however, this decrease was not observed when patients were in the lateral decubitus position.[6] Supine hypotensive syndrome, which occurs in 10% of pregnant women because of venous occlusion, results in maternal tachycardia, arterial hypotension, faintness, and pallor. Compression of the lower aorta in this position may further decrease uteroplacental perfusion and result in fetal asphyxia. Therefore, uterine displacement or lateral pelvic tilt should be applied

routinely during the second and third trimesters of pregnancy.

Changes in the electrocardiogram may also occur. Left axis deviation results from the upward displacement of the heart by the gravid uterus, and there is also a tendency toward premature atrial contractions, sinus tachycardia, and paroxysmal supraventricular tachycardia.

Ventilatory Changes

Increased extracellular fluid and vascular engorgement may not only lead to edema of the extremities, but may also compromise the upper airway. Many pregnant women complain of difficulty with nasal breathing, and the friable nature of the mucous membranes during pregnancy can cause severe bleeding, especially on insertion of nasopharyngeal airways or nasogastric and endotracheal tubes. Airway edema may be particularly severe in women with preeclampsia, in patients placed in the Trendelenburg position for prolonged periods, or with concurrent use of tocolytic agents. It may also be difficult to perform laryngoscopy in obese, short-necked parturients with enlarged breasts. Use of a short-handled laryngoscope has proved helpful.

The level of the diaphragm rises as the uterus increases in size, and is accompanied by an increase in the anteroposterior and transverse diameters of the thoracic cage. From the fifth month, the expiratory reserve volume, residual volume, and functional residual capacity (FRC) decrease, the latter to 20% less than in the nonpregnant state. Concomitantly, there is an increase in inspiratory reserve volume so total lung capacity remains unchanged. In most pregnant women, a decreased FRC does not cause problems, but those with preexisting alterations in closing volume as a result of smoking, obesity, or scoliosis may experience early airway closure with advancing pregnancy, leading to hypoxemia. The Trendelenburg and supine positions also exacerbate the abnormal relationship between closing volume and FRC. The residual volume and FRC return to normal shortly after delivery.

Progesterone-induced relaxation of bronchiolar smooth muscle decreases airway resistance, whereas lung compliance remains unchanged. Minute ventilation increases from the beginning of pregnancy to a maximum of 50% above normal at term.[7] This is accomplished by a 40% increase in tidal volume and a 15% increase in respiratory rate. Dead space does not change significantly, and thus alveolar ventilation is increased by 70% at term. After delivery, as blood progesterone levels decline, ventilation returns to normal within 1 to 3 weeks.[8]

Metabolism

Basal oxygen consumption increases during early pregnancy, with an overall increase of 20% by term.[7] However, increased alveolar ventilation leads to a reduction in the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) to 32 mm Hg and an increase in the partial pressure of oxygen in arterial blood (PaO_2) to 106 mm Hg. The plasma buffer base decreases from 47 to 42 mEq/L, and therefore, the pH remains practically unchanged. The maternal uptake and elimination of inhalational anesthetics is enhanced because of the increased alveolar ventilation and decreased FRC.[8] However, the decreased FRC and increased metabolic rate predispose the mother to development of hypoxemia during periods of apnea/hypoventilation, such as may occur during airway obstruction or prolonged attempts at tracheal intubation.[9]

Human placental lactogen and cortisol increase the tendency toward hyperglycemia and ketosis, which may exacerbate preexisting diabetes mellitus. The patient's ability to handle a glucose load is decreased, and the transplacental passage of glucose may stimulate fetal secretion of insulin, leading in turn to neonatal hypoglycemia in the immediate postpartum period.[10]

Gastrointestinal Changes

Enhanced progesterone production may cause slower absorption of food. Gastric secretions are more acidic and lower esophageal sphincter (LES) tone is decreased. Controversy exists as to when a pregnant woman becomes at risk for aspiration. A delay in gastric emptying can be demonstrated by the end of the first trimester,[11] whereas other studies suggest that gastric

emptying is not delayed in pregnancy.[12] Earlier studies showing delayed emptying in the first trimester may have been a result of the patients' pain, anxiety, or opioid administration.[11]

3 The risk of regurgitation on induction of general anesthesia depends, in part, on the gradient between the LES and intragastric pressures. In most patients, the gradient increases after succinylcholine administration because the increase in LES pressure exceeds the increase in intragastric pressure. However, in parturients with "heartburn," the LES tone is greatly reduced.[13] The efficacy of prophylactic nonparticulate antacids is diminished by inadequate mixing with gastric contents, improper timing of administration, and the tendency for antacids to increase gastric volume. Administration of histamine (H_2) receptor antagonists, such as cimetidine and ranitidine, requires careful timing. A good case can be made for the administration of intravenous metoclopramide before elective cesarean section. This dopamine antagonist hastens gastric emptying and increases resting LES tone in both nonpregnant and pregnant women.[14] However, conflicting reports have appeared on its efficacy and on the frequency of side effects such as extrapyramidal reactions and transient neurologic dysfunction.[15] Although no routine prophylactic regimen can be recommended with certainty, it is the authors' preference to administer at least a nonparticulate antacid before cesarean section and to use regional anesthesia whenever possible. A rapid-sequence induction of anesthesia, application of cricoid pressure, and intubation with a cuffed endotracheal tube are required for all pregnant women receiving general anesthesia from the twelfth week of gestation.[12] These recommendations also pertain to women in the immediate postpartum period because there is uncertainty as to when gastric volume returns to normal.

Altered Drug Responses

The minimum alveolar concentration (MAC) for inhalational agents is decreased by 8 to 12 weeks' gestation and may be related to an increase in progesterone levels.[16] In addition, lower doses of local anesthetic are needed per dermatomal segment of epidural or spinal block. This has been attributed to an increased spread of local anesthetic in the epidural and subarachnoid spaces, which occurs as a result of epidural venous engorgement. An increased neural sensitivity to local anesthetics has also been suggested, which may be mediated by progesterone.[17]

PLACENTAL TRANSFER AND FETAL EXPOSURE TO ANESTHETIC DRUGS

Most drugs, including anesthetic agents, readily cross the placenta. Several factors influence the placental transfer of drugs, including physicochemical characteristics of the drug itself, maternal drug concentrations in the plasma, properties of the placenta, and hemodynamic events within the fetomaternal unit.

Drugs cross biologic membranes by simple diffusion, the rate of which is determined by the Fick principle, which states that:

$$Q/t = KA\ (C_m - C_f)/D$$

where Q/t is rate of diffusion, K is diffusion constant, A is surface area available for exchange, C_m is concentration of free drug in maternal blood, C_f is concentration of free drug in fetal blood, and D is thickness of diffusion barrier.

The diffusion constant (K) of the drug depends on physicochemical characteristics such as molecular size, lipid solubility, and degree of ionization. Compounds with a molecular weight of less than 500 daltons are unimpeded in crossing the placenta, whereas those with molecular weights of 500 to 1,000 daltons are more restricted. Most drugs commonly used by the anesthesiologist have molecular weights that permit easy transfer.

If blood flow to the fetal side of the placenta can be measured, as in some animal models, calculating the placental clearance may be a more appropriate way of expressing drug transfer to the fetus.

Drugs that are highly lipid soluble cross biological membranes more readily, and the degree of ionization is important because the nonionized moiety of a drug is more lipophilic than the ionized

one. Local anesthetics and opioids are weak bases, with a relatively low degree of ionization and considerable lipid solubility. In contrast, muscle relaxants are less lipophilic and more ionized, and their rate of placental transfer is therefore more limited. The relative concentrations of drug existing in the nonionized and ionized forms can be predicted from the Henderson-Hasselbalch equation:

pH = pKa + log(base)/(cation)

The ratio of base to cation becomes particularly important with local anesthetics because the nonionized form penetrates tissue barriers, whereas the ionized form is pharmacologically

active in blocking nerve conduction. The pKa is the pH at which the concentrations of free base and cation are equal. For the amide local anesthetics, the pKa values (7.7 to 8.1) are sufficiently close to physiologic pH that changes in maternal or fetal biochemical status may significantly alter the proportion of ionized and nonionized drug present (Fig. 42-1). At equilibrium, the concentrations of nonionized drug in the fetal and maternal plasma are equal. In the case of the acidotic fetus, a greater tendency for drug to exist in the ionized form, which cannot diffuse back across the placenta into the maternal plasma, causes a larger total amount of drug to accumulate in the fetal plasma and tissues. This is the mechanism for the phenomenon termed *ion trapping*.[18]

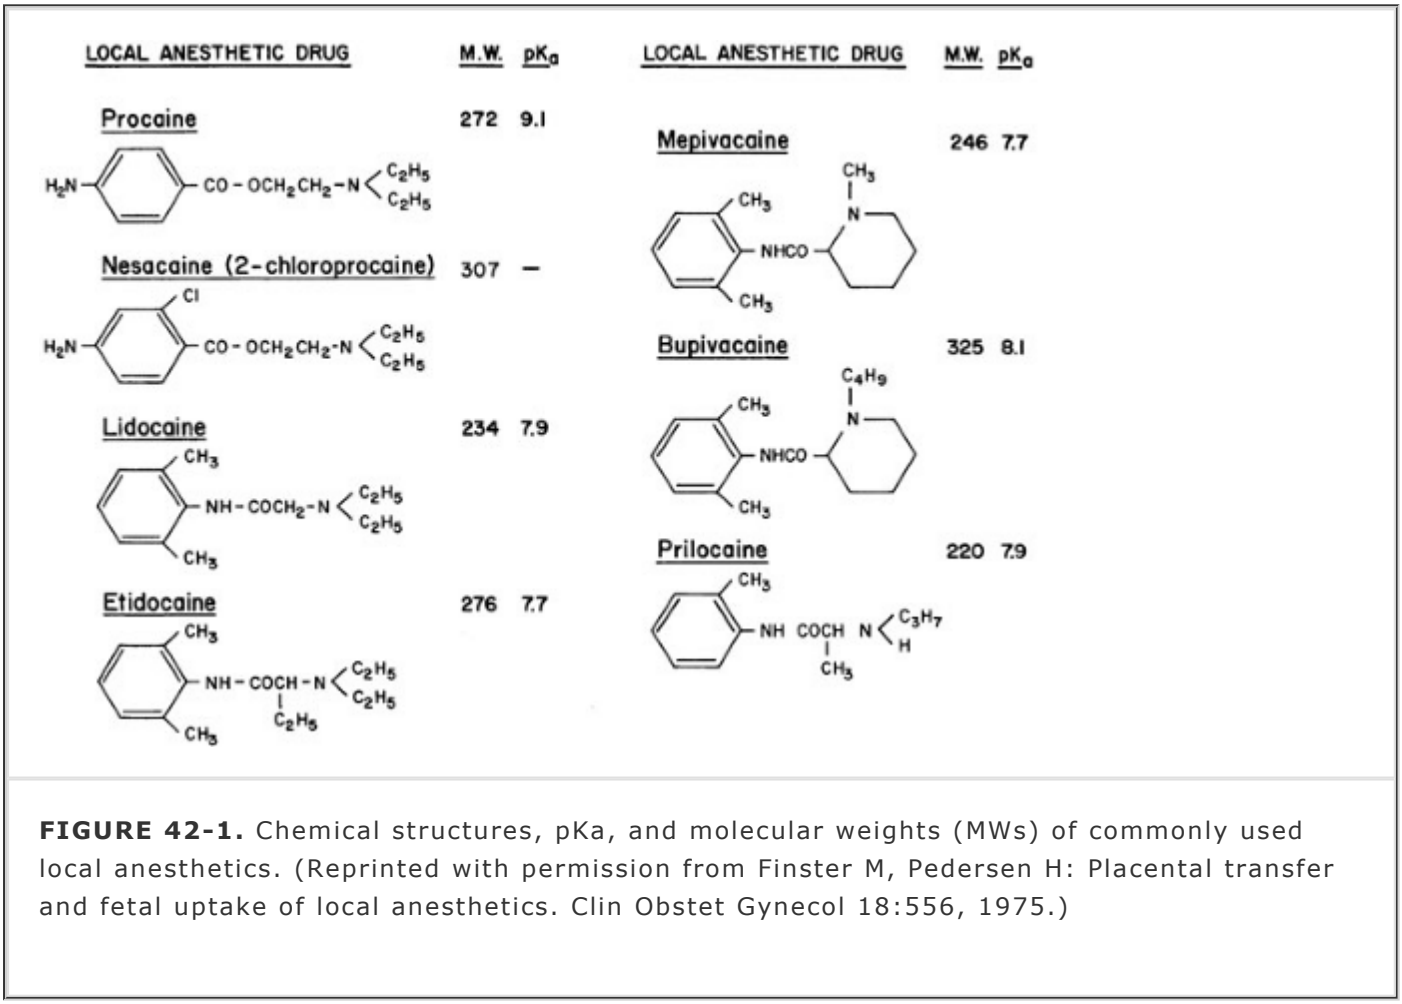

FIGURE 42-1. Chemical structures, pKa, and molecular weights (MWs) of commonly used local anesthetics. (Reprinted with permission from Finster M, Pedersen H: Placental transfer and fetal uptake of local anesthetics. Clin Obstet Gynecol 18:556, 1975.)

The effects of maternal plasma protein binding on the rate and amount of drug transferred to the fetus are not so well understood. Animal studies have shown that the transfer rate is slower for drugs that are extensively bound to maternal plasma proteins, such as bupivacaine.[19] In sheep, the low fetomaternal ratio of bupivacaine plasma concentrations has been attributed to the difference between fetal and maternal plasma protein binding, rather than to extensive fetal tissue uptake.[20] However, if enough time is allowed for fetomaternal equilibrium to be approached, substantial accumulation of highly protein-bound drugs, such as bupivacaine, can occur in the fetus.[21]

4 As already stated, the driving force for placental drug transfer is the concentration gradient

of free drug between the maternal and fetal blood. On the maternal side, the following factors interact: the dose administered, the mode and site of administration, and, in the case of local anesthetics, the use of vasoconstrictors. The rates of distribution, metabolism, and excretion of the drug, which may vary at different stages of pregnancy, are equally important. In general, higher doses result in higher maternal blood concentrations. The absorption rate varies with the site of drug injection. Compared with other forms of administration, an intravenous bolus results in the highest blood concentrations. It was believed that intrathecal administration of local anesthetics resulted in negligible plasma concentrations because of the small doses used and the relatively poor vascularity of this area. However, spinal anesthesia may also result in significant maternal and umbilical venous plasma concentrations of drug.

Increased maternal blood concentrations after repeated administration of a drug greatly depend on the dose and frequency of reinjection, in addition to the kinetic characteristics of the drug. The elimination half-life of amide local anesthetic agents is relatively long so repeated injection may lead to accumulation in the maternal plasma[22] (Fig. 42-2). In contrast, 2-chloroprocaine, an ester local anesthetic, undergoes rapid enzymatic hydrolysis in the presence of pseudocholinesterase. After epidural injection, the mean half-life in the mother was shown to be approximately 3 minutes; after reinjection, 2-chloroprocaine could be detected in the maternal plasma for only 5 to 10 minutes, and no accumulation of this drug was evident[23] (Fig. 42-3).

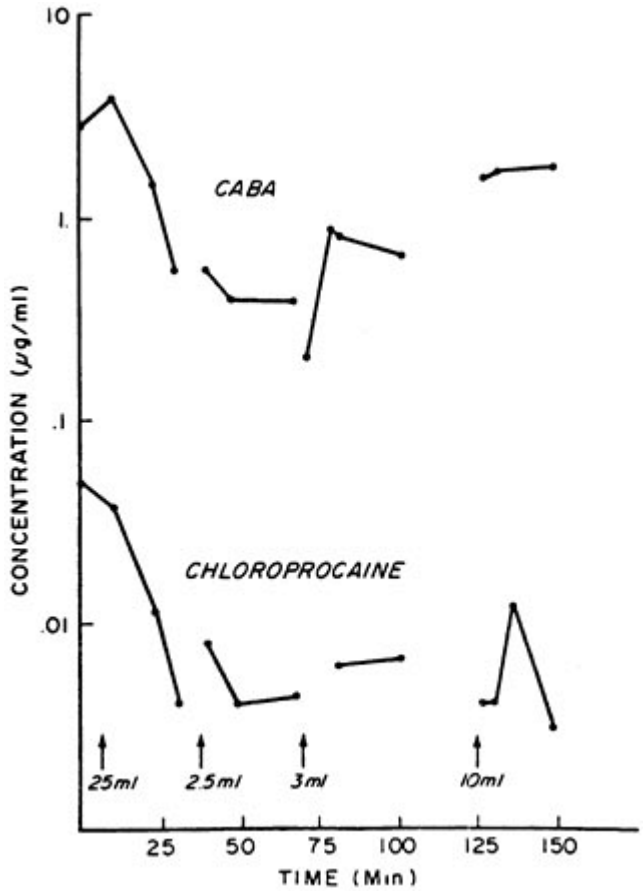

FIGURE 42-3. Plasma concentrations of chloroprocaine and chloroaminobenzoic acid (CABA) in a typical patient after epidural anesthesia (multiple injections) for vaginal delivery. (Reprinted with permission from Kuhnert BR, Kuhnert PM, Prochaska AL *et al*: Plasma levels of 2-chloroprocaine in obstetric patients and their neonates after epidural anesthesia. Anesthesiology 53:21, 1980.)

Pregnancy is associated with physiologic changes that may influence maternal pharmacokinetics and the action of anesthetic drugs. These changes may be progressive during the course of gestation and are often difficult to predict. Alterations in ventilation and lung volumes have a significant effect on the rate of uptake and excretion of inhalation agents. Of most concern to the anesthesiologist is a 20% reduction in FRC.[7] As a result, the equilibration time between the alveolar and inspired concentrations of inhalation agents is shortened.

Placenta

Maturation of the placenta can affect the rate of drug transfer to the fetus, as the thickness of the trophoblastic epithelium decreases from 25 to 2 mm at term. Uptake and biotransformation of anesthetic drugs by the placenta would decrease the amount transferred to the fetus. However, placental drug uptake is limited, and there is no evidence to suggest that this organ metabolizes any of the agents commonly used in obstetric anesthesia.

Hemodynamic Factors

Any factor decreasing placental blood flow, such as aortocaval compression, hypotension, or hemorrhage, can decrease drug delivery to the fetus. During labor, uterine contractions intermittently reduce perfusion of the placenta. If a uterine

contraction coincides with a rapid decline in plasma drug concentration after an intravenous bolus injection, by the time perfusion has returned to normal, the concentration gradient across the

placenta has been greatly reduced. When women were given an intravenous injection of diazepam, administered at the onset of contraction in one group and during uterine diastole in the other, less drug was found in infants born to mothers in the former group.[24]

Several characteristics of the fetal circulation delay equilibration between the umbilical arterial and venous blood, and thus delay the depressant effects of anesthetic drugs (Fig. 42-4). The liver is the first fetal organ perfused by umbilical vein blood, which carries drug to the fetus. Substantial uptake by this organ has been demonstrated for a variety of drugs, including thiopental, lidocaine, and halothane. During its transit to the arterial side of the fetal circulation, the drug is progressively diluted as blood in the umbilical vein becomes admixed with fetal venous blood from the gastrointestinal tract, the lower extremities, the head and upper extremities, and, finally, the lungs. Because of this unique pattern of fetal circulation, continuous administration of anesthetic concentrations of nitrous oxide during elective cesarean sections caused newborn depression only if the induction-to-delivery interval exceeded 5 to 10 minutes. Rapid transfer of inhalational agents, including halothane, enflurane, and isoflurane, result in detectable umbilical arterial and venous concentrations after 1 minute.[25] Because of the rapid decline in maternal plasma drug concentrations, administration of thiopental or thiamylal as a single bolus injection not exceeding 4 mg/kg was followed by fetal arterial concentrations of barbiturate below a level that would result in neonatal depression[26] (Fig. 42-5).

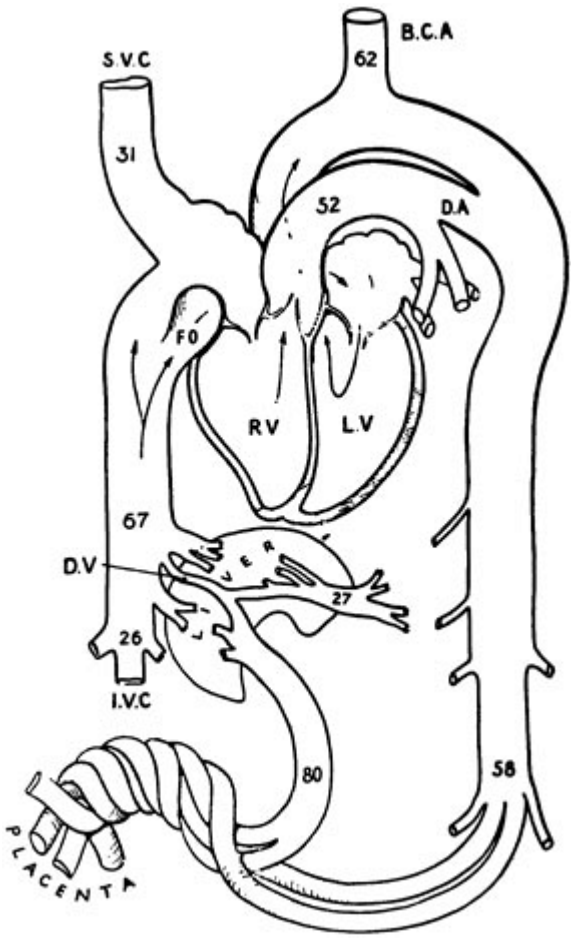

FIGURE 42-4. Diagram of the circulation in the mature fetal lamb. The numerals indicate the mean oxygen saturation (%) in the great vessels of six lambs: right ventricle (RV), left ventricle (LV), superior vena cava (SVC), inferior vena cava (IVC), brachiocephalic artery (BCA), foramen ovale (FO), ductus arteriosus (DA), ductus venosus (DV). Fetal regional blood flow changes can also affect the amount of drug taken up by individual organs. For example, during asphyxia and acidosis, a greater proportion of the fetal cardiac output perfuses the fetal brain, heart, and placenta. Infusion of lidocaine resulted in increased drug uptake in the heart, brain, and liver of asphyxiated baboon fetuses compared with nonasphyxiated control fetuses.[27]

Fetus and Newborn

Any drug that reaches the fetus undergoes metabolism and excretion. In this respect, the fetus has an advantage over the newborn in that it can excrete the drug back to the mother once the concentration gradient of the free drug across the placenta has been reversed. With the use of local anesthetics, this may occur even though the total plasma drug concentration in the mother may exceed that in the fetus because there is lower protein binding in fetal plasma.[20] There is only one drug, 2-chloroprocaine, that is metabolized in the fetal blood so rapidly that even in acidosis, substantial accumulation in the fetus is avoided.[23]

In both the term and the preterm newborn, the liver contains enzymes essential for the biotransformation of amide local anesthetics. A study comparing the pharmacokinetics of lidocaine among adult ewes and lambs (fetal and neonatal) showed that the metabolic clearance in the newborn was similar to, and renal clearance greater than, that in the adult.[28] Nonetheless, the elimination half-life was prolonged in the newborn. This was attributed to a greater volume of distribution and tissue uptake of the drug so at any given time the neonate's liver and kidneys were exposed to a smaller fraction of lidocaine accumulated in the body. Similar results were reported in another study involving lidocaine administration to human infants in a neonatal intensive care unit.[29] Prolonged elimination half-lives in the newborn compared with the adult have been noted for other amide local anesthetics.

The question remains whether the fetus and newborn are more sensitive than adults to the depressant and toxic effects of drugs. Laboratory investigations have shown that the newborn is, in fact, more sensitive to the depressant effects of opioids. The relative central nervous and cardiorespiratory toxicity of several local anesthetics has been studied in adult ewes and lambs (fetal and neonatal).[30] The doses required to produce toxicity in the fetus and newborn were greater than those required in the adult. In the fetus, this difference was attributed to placental clearance of drug into the mother and better maintenance of blood gas tensions during convulsions, whereas in the newborn, a larger volume of distribution is probably responsible for the higher doses needed to induce toxic effects.

Bupivacaine has been implicated as a possible cause of neonatal jaundice because its high affinity for fetal erythrocyte membranes may lead to a decrease in filterability and deformability, rendering them more prone to hemolysis. However, a more recent study has failed to show increased bilirubin production in newborns whose mothers received bupivacaine for epidural anesthesia during labor and delivery.[31] Finally, neurobehavioral studies have revealed subtle changes in newborn neurologic and adaptive function. In the case of most anesthetic agents, these changes are minor and transient, lasting for only 24 to 48 hours.

ANESTHESIA FOR LABOR AND VAGINAL DELIVERY

Most women experience moderate to severe pain during parturition. In the first stage of labor, pain is caused by uterine contractions, associated with dilation of the cervix and stretching of the lower uterine segment. Pain impulses are carried in visceral afferent type C fibers accompanying the sympathetic nerves. In early labor, only the lower thoracic dermatomes (T11–T12) are affected, but with progressing cervical dilation in the transition phase, adjacent dermatomes may be involved and pain referred from T10 to L1. In the second stage, additional pain impulses due to distention of the vaginal vault and perineum are carried by the pudendal nerves, composed of lower sacral fibers (S2–S4).

Well-conducted obstetric analgesia, in addition to relieving pain and anxiety, may benefit the mother. Pain may result in maternal hypertension and reduced uterine blood flow. During the first and second stages of labor, epidural analgesia blunts the increases in maternal cardiac output, heart rate, and blood pressure that occur with painful uterine contractions and "bearing-down" efforts.[32] In reducing maternal secretion of catecholamines, epidural analgesia may convert a previously dysfunctional labor pattern to normal. Maternal analgesia may also benefit the fetus by eliminating maternal hyperventilation, which often leads to a reduced fetal arterial oxygen tension because of a leftward shift of the maternal oxygen-hemoglobin dissociation curve.

The most frequently chosen methods for relieving the pain of parturition are psychoprophylaxis, systemic medication, and regional analgesia. Inhalational analgesia, conventional spinal analgesia, and paracervical blockade are less commonly used. General anesthesia is rarely necessary, but may be indicated for uterine relaxation in some complicated deliveries.

Psychoprophylaxis

The philosophy of prepared childbirth maintains that lack of knowledge, misinformation, fear, and anxiety can heighten a patient's response to pain and consequently increase the need for analgesics. The most popular method of prepared childbirth is that introduced by Lamaze. It provides an educational program on the physiology of parturition and attempts to diminish cortical pain perception by encouraging responses such as specific patterns of breathing and focused attention on a fixed object.[33] However, labors do vary in length and intensity; thus, it is realistic to encourage the mother in the Lamaze method, while recognizing individual variations in pain tolerance and need for pain relief. Of course, medication should not be withheld if required. Neonatal outcome appears to be similar for women who deliver infants solely with the Lamaze technique and for women who receive appropriate supplementary analgesia.

Systemic Medication

The advantages of systemic analgesics include ease of administration and patient acceptability. However, the drug, dose, time, and method of administration must be chosen carefully to avoid maternal or neonatal depression. Drugs used for systemic analgesia are opioids, tranquilizers, and occasionally ketamine.

Opioids

Meperidine is the most commonly used systemic analgesic and is reasonably effective in ameliorating pain during the first stage of labor. It can be administered by intravenous injection (effective analgesia in 5 to 10 minutes) or intramuscularly (peak effect in 40 to 50 minutes). The major side effects are a high incidence of nausea and vomiting, dose-related depression of ventilation, orthostatic hypotension, and the potential for neonatal depression. Meperidine may cause transient alterations of the fetal heart rate (FHR), such as decreased beat-to-beat variability and tachycardia. Among other factors, the risk of neonatal depression is related to the interval from the last drug injection to delivery. The placental transfer of an active metabolite, normeperidine, which has a long elimination half-life in the neonate (62 hours), has also been implicated in contributing to neonatal depression and subtle neonatal neurobehavioral dysfunction.

Experience with the newer synthetic opioids such as fentanyl, alfentanil, and remifentanil has been limited. Although they are potent, their use during labor is restricted by their short duration of action. For example, a single intravenous injection of fentanyl, up to 1 μg/kg, results in prompt pain relief without severe neonatal depression.[34] These drugs offer an advantage when analgesia of rapid onset but short duration is necessary (e.g., with forceps application). For more prolonged analgesia, fentanyl or remifentanil can be administered with patient-controlled delivery devices. Patient-controlled analgesia administration of opioid does carry with it the potential for drug accumulation and the risk of neonatal depression.[35] Opioid agonists–antagonists, such as butorphanol and nalbuphine, have also been used for obstetric analgesia. These drugs have the proposed benefits of a lower incidence of nausea, vomiting, and dysphoria, as well as a "ceiling effect" on depression of ventilation. Butorphanol 1 to 2 mg or nalbuphine 10 mg by intravenous or intramuscular injection are probably most popular. Unlike meperidine, these are biotransformed into inactive metabolites and have a ceiling effect on depression of ventilation. A potential disadvantage is a high incidence of maternal sedation.

Naloxone, a pure opioid antagonist, should not be administered to the mother shortly before delivery to prevent neonatal ventilatory depression because it reverses maternal analgesia at a time when it is most needed and, in some instances, has caused maternal pulmonary edema and even cardiac arrest. If necessary, the drug should be given directly to the newborn intramuscularly (0.1 mg/kg).

Ketamine

Ketamine is a potent analgesic. However, it may also induce unacceptable amnesia that may interfere with the mother's recollection of the birth. Nonetheless, ketamine is a useful adjuvant to incomplete regional analgesia during vaginal delivery or for obstetric manipulations. In low doses (0.2 to 0.4 mg/kg), ketamine provides adequate analgesia without causing neonatal depression. In higher doses, ketamine may induce general anesthesia. Thus, constant communication is required with the patient to ensure she is awake and able to protect her airway.

Regional Analgesia

Regional techniques provide excellent analgesia with minimal depressant effects on mother and fetus. The regional techniques most commonly used in obstetric anesthesia include central neuraxial blocks (spinal, epidural, and combined spinal/epidural or CSE), paracervical and pudendal blocks, and, less frequently, lumbar sympathetic blocks (LSBs). Hypotension resulting from sympathectomy is the most frequent complication that occurs with central neuraxial blockade. Therefore, maternal blood pressure should be monitored at regular intervals, typically

approximately 15 to 20 minutes after the initiation of the block and at routine intervals thereafter. The use of regional analgesia may be contraindicated in the presence of severe coagulopathy, acute hypovolemia, or infection at the site of needle insertion. Chorioamnionitis itself, without frank sepsis, is not a contraindication to central neuraxial blockade in obstetrics.

Epidural Analgesia

Epidural analgesia may be used for pain relief during labor and vaginal delivery, and converted to anesthesia for cesarean delivery, if required. Effective analgesia during the first stage of labor may be achieved by blocking the T10–L1 dermatomes with low concentrations of local anesthetic and/or with the use of opioids, which have their effect at the opioid receptors in the dorsal horn of the spinal cord. For the second stage of labor and delivery, because of pain due to vaginal distention and perineal pressure, the block should be extended to include the S2–S4 segments.

Because of ethical considerations and methodological difficulties, it is difficult to design clinical studies to examine the effects of epidural analgesia on the progress of labor and mode of delivery. The first stage of labor may be slightly prolonged by epidural analgesia. However, this is not of clinical significance, provided aortocaval compression is avoided.[36,37,38,39,40] There has been concern that early initiation of epidural analgesia during the latent phase of labor (2 to 4 cm cervical dilation) in nulliparous women may result in a higher incidence of dystocia and cesarean delivery.[38,39,40,41] However, this has largely been dispelled by several large, randomized, prospective studies. Chestnut et al.[36,37] demonstrated that there was no significant difference in the incidence of cesarean delivery between nulliparous women having epidural analgesia initiated during the latent phase (<4 cm dilation) compared with control group whose analgesia was initiated during the active phase. Similarly, other investigators have demonstrated that epidural analgesia was not associated with an increased incidence of cesarean delivery compared with patient-controlled intravenous analgesia in nulliparous women.[39,40] However, a prolongation of the second stage of labor has been reported in nulliparous women, possibly owing to a decrease in expulsive forces or malposition of the vertex.[36,37,38,39,40,41] Thus, with use of epidural analgesia, the American College of Obstetricians and Gynecologists have redefined an abnormally prolonged second stage of labor as greater than 3 hours in nulliparous and 2 hours in multiparous women. Prolongation of the second stage may be minimized by the use of an ultradilute local anesthetic solution in combination with opioid. Long-acting amides such as bupivacaine, ropivacaine, or levobupivacaine are most frequently used because they produce excellent sensory analgesia while sparing motor function, particularly at the low concentrations used for epidural analgesia during labor. Analgesia for the first stage of labor may be achieved with 5 to 10 mL of bupivacaine, ropivacaine, or levobupivacaine (0.125 to 0.25%), followed by a continuous infusion (8 to 12 mL/hr) of 0.0625% bupivacaine or levobupivacaine, or 0.1% ropivacaine. Addition of fentanyl 1 to 2 µg/mL or sufentanil 0.3 to 0.5 µg/mL is often required and will allow for more dilute local anesthetic solutions to be administered. During the delivery, the sacral dermatomes may be blocked with 10 mL of 0.5% bupivacaine, 1% lidocaine, or, if a rapid effect is required, 2% chloroprocaine, in the semirecumbent position. Many parturients have adequate analgesia, particularly if epidural analgesia has been in place for a long interval, and thus do not require an additional dose of local anesthetic at the time of delivery.

There is controversy regarding the need for a test dose when using an ultradilute solution of local anesthetic.[42] Because catheter aspiration is not always diagnostic, some authors believe a test dose should be administered to improve detection of an intrathecally or intravascularly placed catheter (see Lumbar Epidural Anesthesia section under Cesarean Section).

Patient-controlled epidural analgesia (PCEA) is a safe and effective alternative to conventional bolus or infusion techniques. Maternal satisfaction is excellent and demands on anesthesia manpower reduced.

Spinal Analgesia

A single subarachnoid injection for labor analgesia has the advantages of a fast and reliable onset of neural blockade, but repeated intrathecal injections may be required for a long labor, thus increasing the risk of postdural puncture headache (PDPH). Spinal analgesia with fentanyl 10 µg or sufentanil 2 to 5 µg, alone or in combination with 1 mL isobaric bupivacaine 0.25%, may be appropriate in the multiparous patient whose anticipated course of labor does not warrant a catheter technique (duration 1.5 hours). Although infrequent, a potential disadvantage of a single-shot spinal is that the duration of labor, even in a rapidly progressing multiparous woman, may be longer than anticipated. Furthermore, if the woman requires an urgent cesarean delivery, a new anesthetic will need to be initiated. However, spinal anesthesia (a "saddle block") is a safe and effective alternative to general anesthesia for instrumental delivery.

Combined Spinal/Epidural Analgesia

CSE is an ideal analgesic technique for use during labor. CSE combines the rapid, reliable onset of profound analgesia resulting from spinal injection with the flexibility and longer duration associated with a continuous epidural technique. After identification of the epidural space using a conventional (or specialized) needle, a longer (127-mm), pencil-point spinal needle is advanced into the subarachnoid space through the epidural needle. After intrathecal injection, the spinal needle is removed, and an epidural catheter is inserted. Intrathecal injection of fentanyl 10 to 20 µg or sufentanil 2.5 to 5 µg, alone or more commonly in combination with 1 mL of isobaric bupivacaine 0.25%, produces profound analgesia lasting for 90 to 120 minutes with minimal motor block. Although opioid alone may suffice for the early latent phase, addition of bupivacaine is usually necessary for satisfactory analgesia during advanced labor. An epidural infusion of bupivacaine 0.03 to 0.0625% with added opioid may be started within 10 to 20 minutes of spinal injection. Alternatively, the epidural component may be activated when necessary. Women with hemodynamic stability and preserved motor function who do not require continuous fetal monitoring may ambulate with assistance. Before ambulation, women should be observed for 30 minutes after intrathecal or epidural drug administration to assess maternal and fetal well-being.

The most common side effects of intrathecal opioids are pruritus, nausea, vomiting, and urinary retention. Rostral spread resulting in delayed respiratory depression is rare with fentanyl and sufentanil, and usually occurs within 30 minutes of injection. Transient nonreassuring FHR patterns may occur because of uterine hyperstimulation, presumably as a result of a rapid decrease in maternal catecholamines, or because of hypotension after sympatholysis. Fetal bradycardia may occur in the absence of uterine hyperstimulation or hypotension and is unrelated to uteroplacental insufficiency. The incidence of fetal heart rate abnormalities may be greater in multiparous women with rapidly progressing, painful labors.[43] However, the incidence of emergency cesarean delivery is no greater after CSE than after conventional epidural analgesia.[44]

PDPH is always a risk after intrathecal injection. However, it has been demonstrated that the incidence of cephalalgia is

no greater with CSE than with standard epidural analgesia.[45] Unintentional intrathecal catheter placement through the dural puncture site is also extremely rare after use of a 26-gauge spinal needle for CSE.[45] The potential exists for epidurally administered drug to leak into the subarachnoid space after dural puncture, particularly if large volumes of drug are rapidly injected. Indeed, epidural drug requirements are approximately 30% less with CSE than with standard lumbar epidural techniques.[46]

Mothers in early labor may particularly benefit from CSE. In early labor, spinal opioid may provide sufficient analgesia without the need for local anesthetic and almost always allows the woman to ambulate because there is no motor block—although ambulation has little effect, positive or negative, on the course of labor.[47] Because the epidural component of a CSE is not initially tested, a CSE should be used with caution in those women who may require an urgent cesarean section and are most at increased risk, such as a morbidly obese parturient with a poor airway.

Paracervical Block

Although paracervical block effectively relieves pain during the first stage of labor, the technique has fallen out of favor because it was associated with a high incidence of fetal asphyxia and poor neonatal outcome, particularly with the use of bupivacaine. This may be related to uterine artery constriction or increased uterine tone. The technique is basically simple and involves a submucosal injection of local anesthetic at the vaginal fornix, near the neural fibers innervating the uterus.

Paravertebral Lumbar Sympathetic Block

Paravertebral LSB is a reasonable alternative when contraindications exist to central neuraxial techniques. LSB interrupts the painful transmission of cervical and uterine impulses during the first stage of labor.[48] Although there is less risk of fetal bradycardia with LSB compared with paracervical blockade, technical difficulties associated with the performance of the block and risks of intravascular injection have decreased its use in standard practice.

Pudendal Nerve Block

The pudendal nerves, derived from the lower sacral nerve roots (S2–S4), supply the vaginal vault, perineum, rectum, and parts of the bladder. The nerves are easily anesthetized transvaginally where they loop around the ischial spines. Ten milliliters of local anesthetic deposited behind each sacrospinous ligament can provide adequate anesthesia for outlet forceps delivery and episiotomy repair.

Inhalation Analgesia

Inhalation analgesia is easily administered and, although it does not relieve pain completely, it may make uterine contractions more tolerable. During delivery, a combination of inhalation analgesia with a pudendal block or infiltration of the perineum with a local anesthetic may be satisfactory. A particular advantage of inhalation analgesia is that the desired level of analgesia can be easily and rapidly titrated. However, a major disadvantage of inhalational analgesia is the need for a waste gas scavenging system. Nitrous oxide, 50% by volume, is the most commonly used inhalation agent for analgesia during labor. However, the analgesia provided by intermittently self-administered 50% nitrous oxide alone has been shown to be equivalent to that of a placebo.[49]

General Anesthesia

General anesthesia is rarely used for vaginal delivery, and precautions against gastric aspiration must always be observed (see General Anesthesia section under Cesarean Section). It may be required when time constraints prevent induction of regional anesthesia. Potent inhalation drugs (1.5 to 2.0 MAC for short periods) can provide uterine relaxation for obstetric maneuvers such as second twin delivery, breech presentation, or postpartum manual removal of a retained placenta. After obstetric manipulation is completed, an intravenous infusion of oxytocin 10 to 20 U should be commenced to promote uterine contraction. In current practice, intravenous nitroglycerin (50 to 500 µg) has replaced the need for general anesthesia for uterine relaxation.

ANESTHESIA FOR CESAREAN SECTION

5 The most common indications for cesarean section include failure to progress, nonreassuring fetal status, cephalopelvic disproportion, malpresentation, prematurity, prior cesarean delivery, and prior uterine surgery involving the corpus.[50] The choice of anesthesia depends on the urgency of the procedure, in addition to the condition of the mother and fetus. After a comprehensive discussion of the risks and benefits of all anesthesia options, the mother's wishes should be considered.

Regional Anesthesia

A 1992 survey of obstetric anesthesia practices in the United States revealed that most patients undergoing cesarean section do so under spinal or epidural anesthesia.[51] Regional techniques have

several advantages: they lessen the risk of gastric aspiration, avoid the use of depressant anesthetic drugs, and allow the mother to remain awake during delivery.[52] It has also been suggested that operative blood loss is less with regional than general anesthesia. In elective cesarean sections, the duration of antepartum anesthesia does not affect neonatal outcome provided there is no protracted aortocaval compression or hypotension. The risk of hypotension is greater than during vaginal delivery because the block must extend to at least the T4 dermatome. Proper positioning and prehydration with up to 20 mL/kg of a crystalloid solution is recommended.[53] If hypotension occurs despite these measures, left uterine displacement should be increased, the rate of intravenous infusion augmented, and intravenous ephedrine 10 to 15 mg administered incrementally, or phenylephrine 20 to 50 µg, may be used.

Spinal Anesthesia

Subarachnoid block is probably the most commonly administered regional anesthetic for cesarean delivery because of its speed of onset and reliability. It has become an alternative to general anesthesia for emergency cesarean section.[54] Hyperbaric 0.75% bupivacaine, 1.6 to 1.8 mL, is perhaps the most commonly used local anesthetic lasting approximately 120 to 180 minutes. Using 0.75% hyperbaric bupivacaine, Norris[55] showed that it is not necessary to adjust the dose of drug based on the patient's height. Hemodynamic monitoring during cesarean section should be similar to that used for other surgical procedures. Before delivery, oxygen should be routinely administered to optimize fetal oxygenation.

Despite an adequate dermatomal level for surgery, women may experience varying degrees of visceral discomfort, particularly during exteriorization of the uterus and traction on abdominal viscera. Improved perioperative analgesia can be provided with the addition of fentanyl 6.25 µg or 0.1 mg of preservative-free morphine to the local anesthetic solution. Fentanyl is short acting and provides little additional postoperative analgesia. However, morphine 0.1 mg, in addition to intraoperative anesthesia, will also provide anesthesia into the postoperative period. Nausea and vomiting may be alleviated by the administration of metoclopramide. Maternal sedation should be avoided if possible.

Lumbar Epidural Anesthesia

In contrast to spinal anesthesia, epidural anesthesia is associated with a slower onset of action and a larger drug requirement to establish an adequate sensory block. The advantages are a reduced risk of PDPH and the ability to titrate the local anesthetic through the epidural catheter. To avoid inadvertent intrathecal or intravascular injection, correct placement of the epidural catheter is essential. This is especially a concern when administering the large doses of local anesthetic required for cesarean delivery.

Aspiration of the epidural catheter for blood or cerebrospinal fluid is not reliable for detection of catheter misplacement. Thus, administration of a test dose has become popular. A small dose of local anesthetic, lidocaine 45 mg or bupivacaine 5 mg, produces a readily identifiable sensory and motor block if injected intrathecally. Addition of epinephrine (15 µg) with careful hemodynamic monitoring may signal intravascular injection if followed by a transient increase in heart rate and blood pressure. However, the use of an epinephrine test dose is controversial because false-positive results do occur in the presence of uterine contractions. In addition, epinephrine may reduce uteroplacental perfusion. Electrocardiography and application of a peak-to-peak heart rate criterion may improve detection.[56] Rapid injection of 1 mL of air with simultaneous precordial Doppler monitoring appears to be a reliable indicator of intravascular catheter placement.[57] A negative test, although reassuring, does not eliminate the need for fractional administration of local anesthetic.

The most commonly used agents are 2-chloroprocaine 3% and lidocaine 2% with epinephrine 1:200,000. Adequate anesthesia is usually achieved with 15 to 25 mL of the solution, given in divided doses. Alternatively, 0.5% bupivacaine, ropivacaine or levobupivacaine may be used if a prolonged block is desired. The patient should be monitored as with spinal anesthesia. Because of

its extremely high rate of metabolism in maternal and fetal plasma, 2-chloroprocaine provides a rapid-onset, reliable block with minimal risk of systemic toxicity. It is the local anesthetic of choice in the presence of fetal acidosis and when a preexisting epidural block is to be rapidly extended for an urgent cesarean section. There has been controversy as to whether chloroprocaine antagonizes the effects of spinally administered opioids or whether the chloroprocaine block recedes so rapidly before the full onset of neuraxial morphine analgesia. Transient neurologic deficits after massive inadvertent intrathecal administration of the drug have occurred with the formulation containing a relatively high concentration of sodium bisulfite, at a low pH.[58] The most recent formulation of 2-chloroprocaine contains no additives and is packaged in an amber vial to prevent oxidation. Bupivacaine 0.5% provides profound anesthesia for cesarean section of slower onset but longer duration of action. Considerable attention has been focused on the drug since it was reported that unintentional intravascular injection could result not only in convulsions, but also in almost simultaneous cardiac arrest, with patients often refractory to resuscitation.[59] The greater cardiotoxicity of bupivacaine (and etidocaine) compared with other amide local anesthetics has been well established.[60] Lidocaine has an onset and duration intermediate to those of 2-chloroprocaine and bupivacaine. The need to include epinephrine in the local anesthetic solution to ensure adequate lumbosacral anesthesia may be of concern in women with maternal hypertension and uteroplacental insufficiency.

Prolonged postoperative pain relief can be provided by epidural administration of an opioid, such as preservative free morphine 3 to 4 mg. PCEA is another option. Delayed respiratory depression is rare, but it may occur with the use of morphine; thus, the patient must be monitored carefully in the postoperative period.

General Anesthesia

General anesthesia may be necessary when contraindications exist to regional anesthesia or when time precludes central neuraxial blockade. General anesthesia with a potent halogenated agent may also be useful in situations where uterine relaxation will facilitate delivery, as with some types of breech presentation, transverse lie, or in women with multiple gestation who may not tolerate regional blocks owing to dyspnea and supine hypotension syndrome. General anesthesia should be used cautiously in women with asthma, upper respiratory tract infection, obesity, or a history of difficult tracheal intubation. Preoperative airway evaluation is particularly important in pregnant women because inability to intubate the trachea and provide effective ventilation is the leading cause of maternal death related to anesthesia.[51] Airway assessment should include removal of all oral jewelry in anticipation of the need for general anesthesia.[52] If airway difficulties are anticipated, a regional anesthetic technique should be considered or an awake tracheal intubation performed. Premedication is usually not necessary, except for oral administration of 15 to 30 mL of a nonparticulate antacid within 30 minutes of induction of anesthesia and an H_2 receptor antagonist administered intravenously. The patient should be positioned with a wedge in place to prevent aortocaval compression. Routine monitoring should be the same as with regional anesthetic techniques and should comply with national standards.

To minimize the risk of hypoxemia during induction, denitrogenation for 3 to 5 minutes with a tight-fitting mask is essential. In an emergency, four deep breaths with 100% oxygen suffice. A "defasciculating" dose of a nondepolarizing muscle relaxant is not necessary. Rapid-sequence induction is performed with thiopental (4 mg/kg), propofol (2 mg/kg), ketamine (up to 1 mg/kg), or a combination of thiopental (2 to 3 mg/kg) and ketamine (0.5 mg/kg), followed by succinylcholine (1 to 1.5 mg/kg) to facilitate intubation. Succinylcholine is the preferred muscle relaxant. However, when its use is contraindicated, rocuronium (0.6 mg/kg) is an acceptable alternative. Cricoid pressure is applied by a trained assistant until the airway is properly secured with a cuffed endotracheal tube. If there is difficulty in securing the airway, cricoid pressure should be maintained throughout, and the mother ventilated with 100% oxygen before a subsequent attempt at tracheal intubation is made. It is safer to allow the mother to awaken and to reassess the method of induction than to persist with traumatic efforts at tracheal intubation, which may result in loss of the airway because of edema and bleeding (Fig. 42-6). Once placement of the endotracheal tube is confirmed, with capnography and auscultation, the obstetrician may

with incision. If difficulty is encountered in securing the airway, it should be managed according to the American Society of Anesthesiologists algorithm for difficult airway (Fig. 42-6). It is crucial to maintain ventilation/oxygenation by mask ventilation and cricoid pressure, if necessary, by other means such as the laryngeal mask airway.[61,62] In the predelivery interval, anesthesia is maintained with a 50:50 mixture of nitrous oxide in oxygen and 0.5 MAC of a potent agent. Severe maternal hyperventilation should be avoided because it may reduce uterine blood flow. A few minutes before delivery is anticipated, the concentration of the potent agent may be increased temporarily to 2 MAC, if uterine relaxation is desired to facilitate delivery, or nitroglycerin may be used.

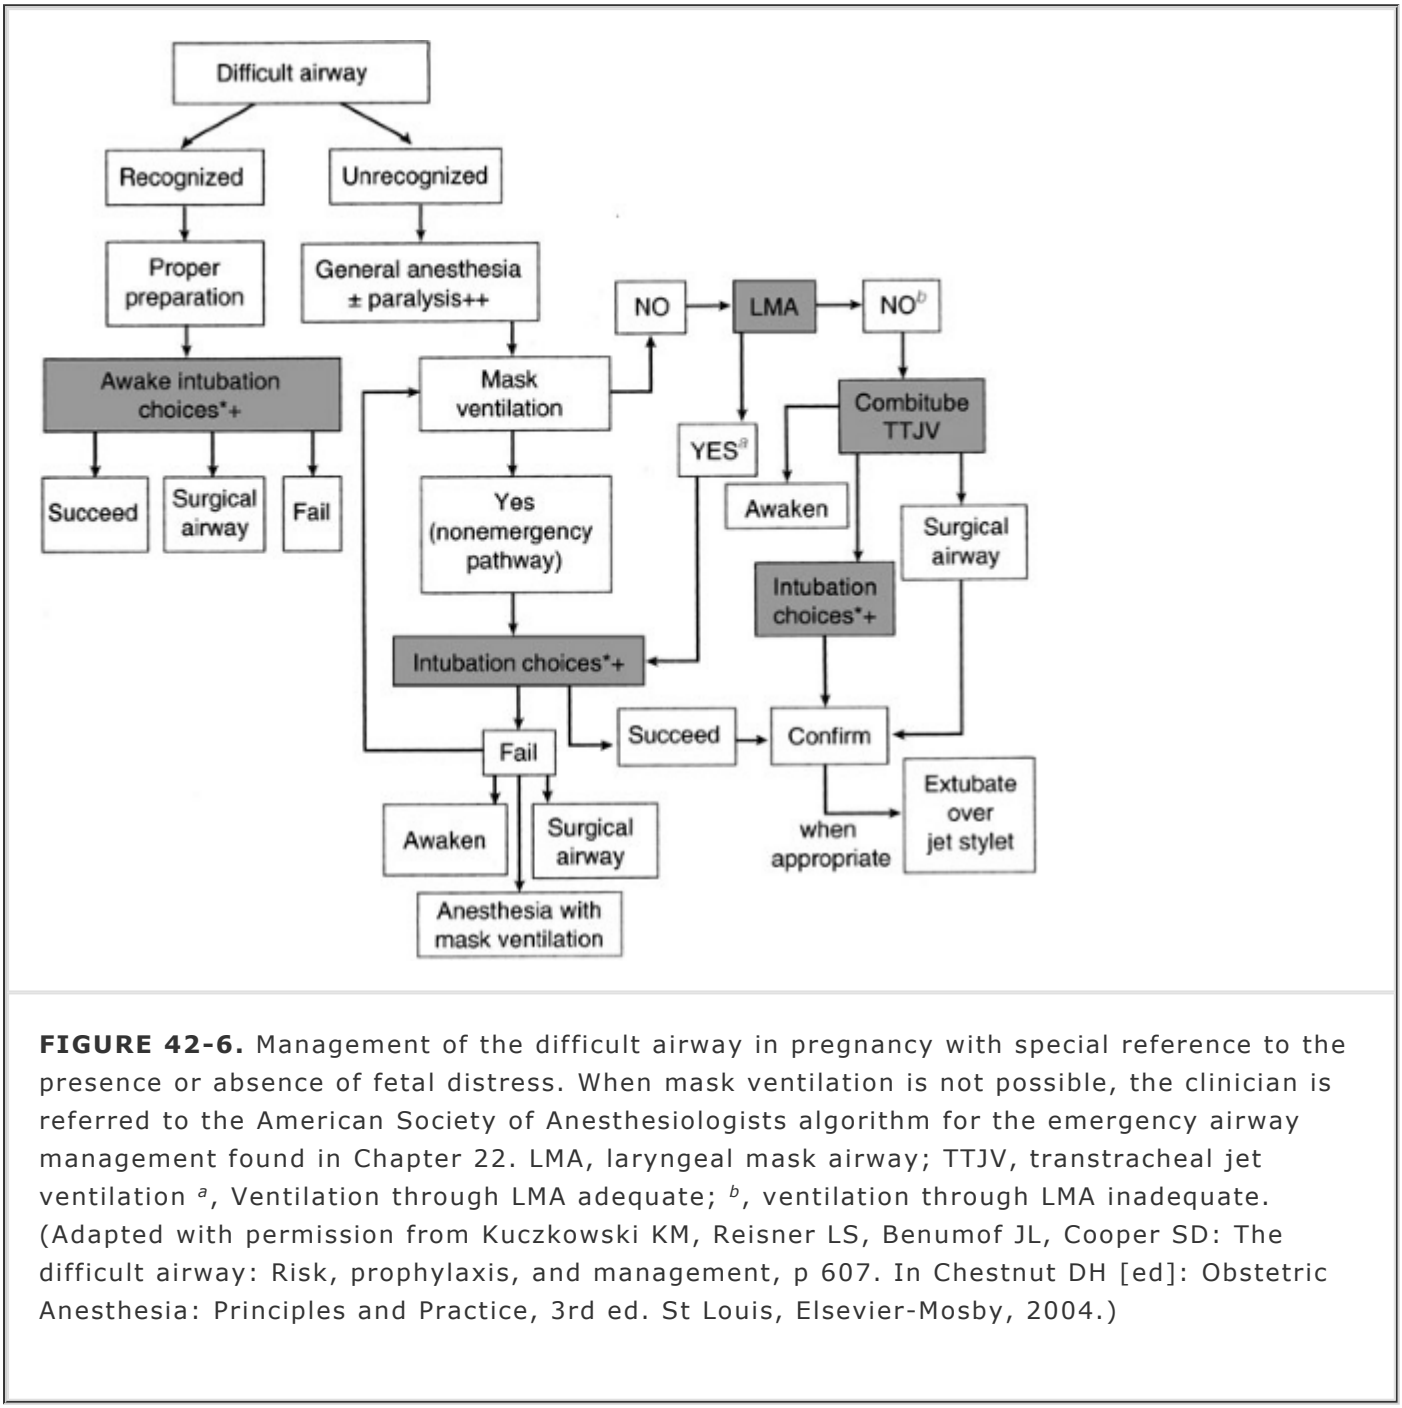

FIGURE 42-6. Management of the difficult airway in pregnancy with special reference to the presence or absence of fetal distress. When mask ventilation is not possible, the clinician is referred to the American Society of Anesthesiologists algorithm for the emergency airway management found in Chapter 22. LMA, laryngeal mask airway; TTJV, transtracheal jet ventilation [a], Ventilation through LMA adequate; [b], ventilation through LMA inadequate. (Adapted with permission from Kuczkowski KM, Reisner LS, Benumof JL, Cooper SD: The difficult airway: Risk, prophylaxis, and management, p 607. In Chestnut DH [ed]: Obstetric Anesthesia: Principles and Practice, 3rd ed. St Louis, Elsevier-Mosby, 2004.)

The newborn's condition after cesarean section with general anesthesia is comparable with that seen with regional techniques.[63] The uterine incision-to-delivery interval seems to be more important to neonatal outcome than the induction of anesthesia-to-delivery interval. Lower Apgar scores at 1 minute and acidosis were reported in cases in which the uterine incision-to-delivery time interval exceeded 180 seconds, whereas anesthesia for up to 30 minutes before delivery appears to have no adverse effects on the infant.[64] In contrast, with use of nitrous oxide 70 to

75% in oxygen, neonatal depression has been reported to occur within approximately 10 minutes of anesthesia. Increasing the FIO_2 to 50% has the additional benefit of increasing the fetal PaO_2.[57]

After delivery of the infant, 20 U of oxytocin should be added to the infusion and anesthesia is deepened with an opioid and benzodiazepine, as necessary. At the end of the procedure, the mother's trachea is extubated once she is awake and extubation criteria have been met. The usual blood loss at a cesarean section is 750 to 1,000 mL, and transfusion is rarely necessary.

ANESTHETIC COMPLICATIONS

Maternal Mortality

A study of anesthesia-related deaths in the United States between 1979 and 1990 revealed that the case fatality rate with general anesthesia was 16.7 times greater than that with regional anesthesia. Most anesthesia-related deaths were a result of cardiac arrest due to hypoxemia when difficulties securing the airway were encountered.[65,66] Pregnancy-induced anatomic and physiologic changes, such as reduced FRC, increased oxygen consumption, and oropharyngeal edema, may expose the patient to serious risks of desaturation during periods of apnea and hypoventilation (see Physiologic Changes of Pregnancy).

Pulmonary Aspiration

The risk of inhalation of gastric contents is increased in pregnant women, as discussed previously, particularly if difficulty is encountered establishing the airway. Measures to decrease the risks of aspiration include comprehensive airway evaluation, prophylactic administration of nonparticulate antacids, and preferred use of regional anesthesia. Occasionally, general anesthesia may be unavoidable in obstetric anesthesia practice, and therefore, awake intubation may be indicated in women in whom airway difficulties are anticipated.

Hypotension

Regional anesthesia may be associated with hypotension. The risk of hypotension is lower in women who are in labor compared with nonlaboring women.[67] Maternal prehydration up to 20 mL/kg of lactated Ringer's solution before initiation of regional anesthesia and avoidance of aortocaval compression after induction may decrease the incidence of hypotension.[53] It has been demonstrated that for effective prevention of hypotension, the blood volume increase from preloading must be sufficient to result in a significant increase in cardiac output.[68] This was possible only with the administration of hetastarch, 0.5 to 1 L.[68] Nonetheless, controversy exists regarding the efficacy of volume loading in the prevention of hypotension.[69] If hypotension does occur despite prehydration, therapeutic measures include increased displacement of the uterus, rapid infusion of intravenous fluids, titration of intravenous ephedrine (5 to 10 mg) or phenylephrine (20 to 50 µg), oxygen administration, and placement of the patient in the Trendelenburg position. Continued vigilance and active management of hypotension can prevent serious sequelae in both mother or neonate.[67]

Total Spinal Anesthesia

High or total spinal anesthesia is a rare complication of intrathecal injection that occurs after excessive cephalad spread of local anesthetic in the subarachnoid space. Unintentional intrathecal administration of epidural medication as a result of dural puncture or catheter migration may also result in this complication. Left uterine displacement, placement in the Trendelenburg position, and continued fluid and vasopressor administration may be necessary to achieve hemodynamic stability. Rapid control of the airway is essential, and endotracheal intubation may be necessary to ensure oxygenation without aspiration.

Local Anesthetic-Induced Seizures

Unintended intravascular injection or drug accumulation after repeated epidural injection can result in high serum levels of local anesthetic. Rapid absorption of local anesthetic from highly vascular sites of injection may also occur after paracervical and pudendal blocks.

Resuscitation equipment should always be available when any major nerve block is undertaken. Intravenous access, airway equipment, emergency drugs, and suction equipment should be immediately accessible. To avoid systemic toxicity of local anesthetic agents, strict adherence to recommended dosages, methods to detect misplaced needles and catheters, and fractional administration of the induction dose are essential.

Despite these precautions, life-threatening convulsions and, more rarely, cardiovascular collapse may occur. Seizure activity should be treated with intravenous thiopental 50 to 100 mg or diazepam 5 to 10 mg; larger doses may enhance local anesthetic-induced myocardial depression. The maternal airway should be secured and oxygenation maintained. If cardiovascular collapse does occur, cesarean delivery may be required to relieve aortocaval compression and to ensure the efficiency of cardiac massage.[70]

Postdural Puncture Headache

7 By virtue of age and gender, pregnant women are at a higher risk for developing PDPH. In addition, after delivery, the reduced epidural pressure increases the risk of cerebrospinal fluid leakage through the dural opening.

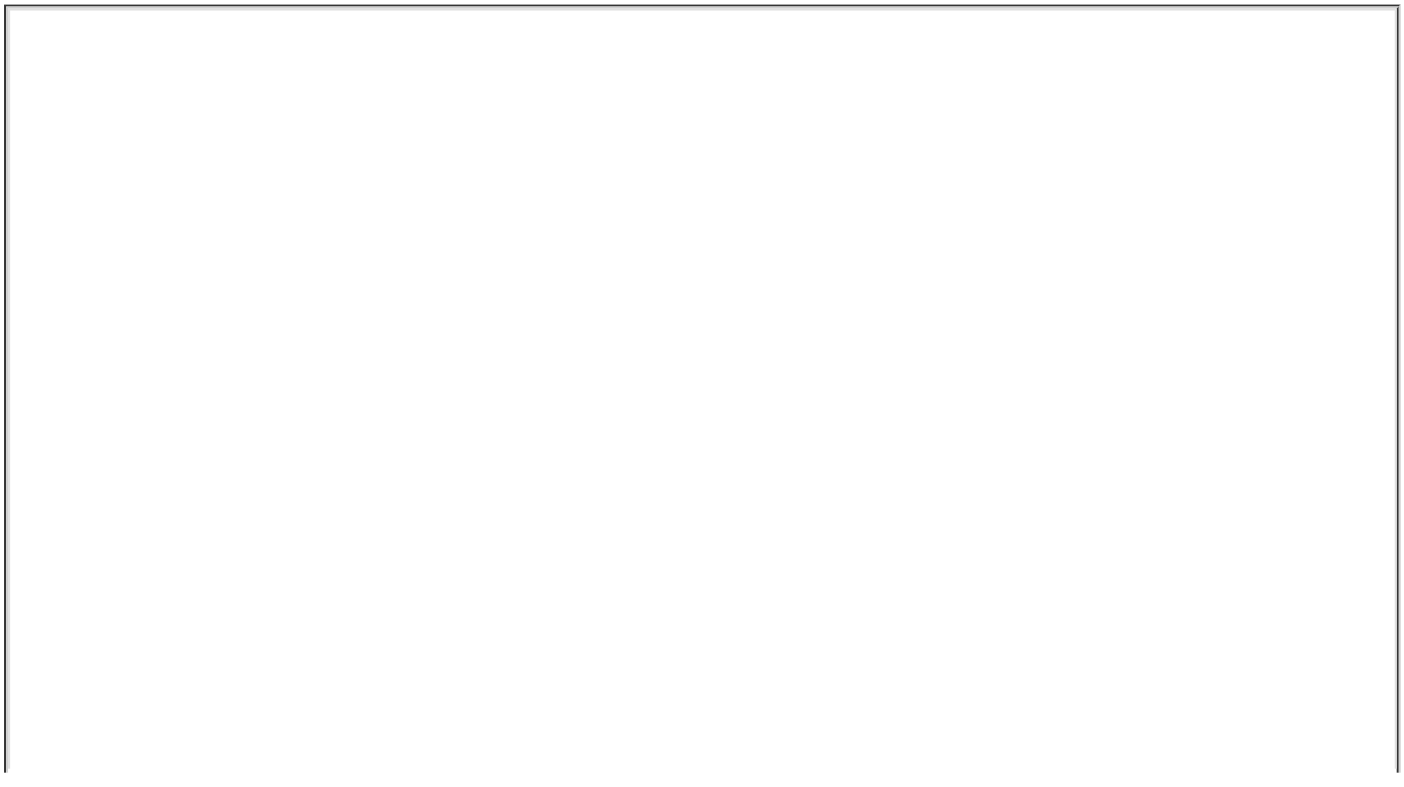
The frequency of PDPH is related to the diameter of the dural puncture, ranging from in excess of 70% after use of 16-gauge needles to less than 1% with the smaller 25- or 26-gauge spinal needles. The incidence of cephalalgia is reduced with the use of atraumatic pencil-point needles (Whitacre or Sprotte), which are believed to separate the dural fibers, rather than the diamond-shaped (Quincke) cutting needles. Conservative treatment is indicated in the presence of mild to moderate discomfort, and includes bed rest, hydration, and simple analgesics. Caffeine (500 mg intravenously or 300 mg orally) or theophylline have also been used in treatment of PDPH. Severe headache that does not respond to conservative measures is best treated with autologous blood patch. Using aseptic technique, 10 to 15 mL of the patient's blood is injected into the epidural space close to the site of dural puncture. This procedure may be repeated as necessary and is associated with excellent success rates. If an epidural catheter is in place after delivery, there is sufficient evidence to support the efficacy of injecting 15 to 20 mL of autologous blood may be injected through the catheter before removal.[71]

Nerve Injury

Neurologic sequelae of central neuraxial blockade, although rare, have been reported. Pressure exerted by a needle or catheter on spinal nerve roots produces immediate pain and requires repositioning. Infections such as epidural abscess or meningitis are rare and may be a manifestation of systemic sepsis. Epidural hematoma can also occur, usually in association with coagulation defects. Nerve root irritation may have a protracted recovery, lasting weeks or months. Peripheral nerve injury as a result of instrumentation, lithotomy position, or compression by the fetal head may occur even in the absence of neuraxial technique.[72]

MANAGEMENT OF HIGH-RISK PARTURIENTS

8 Pregnancy and parturition are considered "high risk" when accompanied by conditions unfavorable to the well-being of the mother, the fetus, or both. Maternal problems may be related to pregnancy, such as preeclampsia–eclampsia and other hypertensive disorders of pregnancy, or antepartum hemorrhage resulting from placenta previa or abruptio placentae. Diabetes mellitus; cardiac, chronic renal, neurologic, or sickle cell disease; and asthma, obesity, and drug abuse are not related to pregnancy but are often affected by it. Prematurity (gestation of less than 37 weeks), postmaturity (42 weeks or longer), intrauterine growth retardation, and multiple gestation are fetal conditions associated with risk. During labor and delivery, fetal



malpresentation (breech, transverse lie), placental abruption, compression of the umbilical cord (prolapse, nuchal cord), precipitous labor, or intrauterine infection (prolonged rupture of membranes) may increase the risk to the mother or the fetus.

In general, the anesthetic management of the high-risk parturient is based on the same maternal and fetal considerations as the management of healthy mothers and fetuses. These include maintenance of maternal cardiovascular function and oxygenation, maintenance and possibly improvement of uteroplacental blood flow, and creation of optimal conditions for a painless, atraumatic delivery of an infant without significant drug effects. However, there is less room for error because many of these functions may be compromised before the induction of anesthesia. For example, significant acidosis is prone to develop in fetuses of diabetic mothers when delivered by cesarean section with spinal anesthesia complicated by even brief maternal hypotension.[10] Because the high-risk parturient may have received a variety of drugs, anesthesiologists must be familiar with potential interactions between these drugs and the anesthetic drugs they plan to administer.

Preeclampsia–Eclampsia

Hypertensive disorders, which occur in approximately 7% of all late pregnancies, are among the major causes of maternal mortality. Preeclampsia is diagnosed on the basis of development of hypertension with proteinuria. The added appearance of convulsions makes for the diagnosis of eclampsia. Preeclampsia–eclampsia is a disease unique to human pregnancy, occurring predominantly in young nulliparas. Symptoms usually appear after the twentieth week of gestation, occasionally earlier than that if in association with a hydatidiform mole. The condition requires the presence of a trophoblast but not a fetus.

The origin of preeclampsia–eclampsia is unknown. Many of the symptoms associated with preeclampsia, including placental ischemia, systemic vasoconstriction, and increased platelet aggregation, may result from an imbalance between the placental production of prostacyclin and thromboxane (Figs. 42-7 and 42-8). During normal pregnancy the placenta produces equivalent quantities of these prostaglandins, whereas in preeclamptic pregnancy, there is seven times more thromboxane than prostacyclin.[73] Endothelial cell injury is central to the development of preeclampsia. This injury occurs as a result of reduced placental perfusion leading to a production and release of substances (possibly lipid peroxidases), and causing endothelial cell injury. Abnormal endothelial cell function contributes to an increase in peripheral resistance and other abnormalities noted in preeclampsia through a release of fibronectin, endothelin, and other substances.

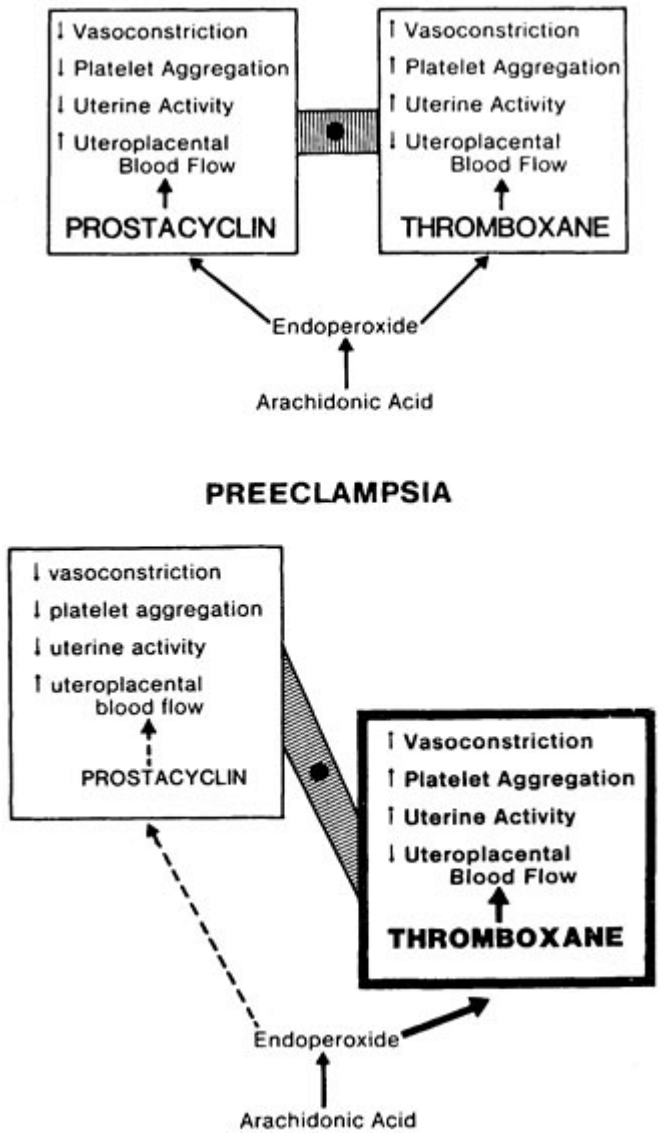

FIGURE 42-8. Comparison of the balance in the biological actions of prostacyclin and thromboxane in normal pregnancy with the imbalance of increased thromboxane and decreased prostacyclin in preeclamptic pregnancy. (Reprinted with permission from Walsh SW: Preeclampsia: An imbalance in placental prostacyclin and thromboxane production. Am J Obstet Gynecol 152:335, 1985.)

Placental ischemia related to preeclampsia results in a release of uterine renin and an increase in angiotensin activity (see Fig. 42-7). This would lead to a widespread arteriolar vasoconstriction, causing hypertension, tissue hypoxia, and endothelial damage. Adherence of platelets at sites of endothelial damage would result in coagulopathies, occasionally in disseminated intravascular coagulation. Enhanced angiotensin-mediated aldosterone secretion would lead to an increased sodium reabsorption and edema. Proteinuria, another symptom of preeclampsia, may also be attributed to placental ischemia, which would lead to local tissue degeneration and a release of thromboplastin with subsequent deposition of fibrin in constricted glomerular vessels, as well as increased permeability to albumin and other plasma proteins. Furthermore, there is believed to be a decreased production of prostaglandin E, a potent vasodilator secreted in the trophoblast, which normally would balance the hypertensive effects of the renin–angiotensin system. The HELLP syndrome is a particular form of severe preeclampsia characterized by *h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelet count (thrombocytopenia). In contrast to preeclampsia, elevations in blood pressure and proteinuria may be mild.

9 Preeclampsia is classified as severe if it is associated with any of the following:

1. Severe hypertension
    a. Systolic blood pressure of 160 mm Hg
    b. Diastolic blood pressure of 110 mm Hg
2. Severe proteinuria of 5 g/24 hr

3. Evidence of severe end-organ damage
    a. Refractory oliguria (400 mL/24 hr)
    b. Cerebral or visual disturbances
    c. Pulmonary edema or cyanosis
    d. Epigastric pain
    e. Intrauterine growth retardation

In severe preeclampsia–eclampsia, all major organ systems are affected because of widespread vasospasm. Global cerebral blood flow is not diminished, but focal hypoperfusion may occur. Indeed, postmortem examination has revealed hemorrhagic necrosis in the proximity of thrombosed precapillaries, suggesting intense vasoconstriction. Cerebral edema and small foci of degeneration have been attributed to hypoxia. Petechial hemorrhages are common after the onset of convulsions. Symptoms related to these changes include headache, vertigo, cortical blindness, hyperreflexia, and convulsions. The extent of blood pressure elevation correlates poorly with the incidence of seizures, which are commonly generalized. Cerebral hemorrhage and edema are the leading causes of death in preeclampsia–eclampsia, together accounting for approximately 50% of deaths.

In the eyes, intense arteriolar constriction may result in blurred vision, even temporary blindness. Heart failure may occur in severe cases as a result of peripheral vasoconstriction and increased blood viscosity secondary to hemoconcentration. Changes described in autopsy specimens include left ventricular hypertrophy, subendocardial hemorrhages, cloudy swelling, and fatty and hyaline degeneration.

Decreased blood supply to the liver may lead to periportal necrosis of variable extent and severity. Subcapsular hemorrhages account for the epigastric pain encountered in severe cases. Rarely, there is rupture of the overstretched liver capsule and massive hemorrhage into the abdominal cavity. Hepatic function tests show elevated plasma levels of aspartate aminotransferase, lactate dehydrogenase, and alkaline phosphatase, whereas bilirubin is unaltered.

In the kidneys, there is swelling of glomerular endothelial cells and deposition of fibrin, leading to a constriction of the capillary lumina. Renal blood flow and glomerular filtration rate decrease, resulting in reduced uric acid clearance and, in severe cases, reduced clearance of urea and creatinine. As already stated, oliguria and proteinuria are among the characteristic symptoms of severe preeclampsia. The severity of renal involvement is reflected in the degree of proteinuria, which may reach nephrotic levels of 10 to 15 g/24 hr.

A mild degree of pulmonary ventilation–perfusion imbalance has been reported in severe cases. It is not believed to be clinically important because the arterial oxygen tension was within normal limits. In contrast, airway edema, which may also occur in severe preeclampsia, is of great concern because it may lead to respiratory embarrassment and difficulty in tracheal intubation. Pulmonary edema is commonly found at autopsy. It may result from heart failure, circulatory overload, or aspiration of gastric contents during convulsions.

In the placenta, a reduction in intervillous blood flow may result from vasoconstriction or the development of occlusive lesions in decidual arteries, despite the elevated maternal blood pressure. Histologic examination of the placenta often reveals nodular ischemia and varying stages of infarction. Necrosis of the supporting tissues may lead to a rupture of fetal cotyledonary vessels and hemorrhage. If the hemorrhage is extensive, it may extend retroplacentally, initiating the process of abruption. Reduced placental blood flow leads to chronic fetal hypoxia and malnutrition. The risks of intrauterine growth retardation, premature birth, and perinatal death are substantially higher than in normal pregnancies and correlate with the severity of preeclampsia.

Although preeclampsia is accompanied by exaggerated retention of water and sodium, a shift of fluid and proteins from the intravascular into the extravascular compartment may result in hypovolemia, hypoproteinemia, and hemoconcentration. This phenomenon may be further aggravated by proteinuria. The risk of uteroplacental hypoperfusion and poor fetal outcome correlates with the degree of maternal plasma and protein depletion. The mean plasma volume in women with preeclampsia was found to be 9% less than normal, and in those with severe disease it was as much as 30 to 40% below normal.[66] The inverse relationship between the intravascular volume and the severity of hypertension was confirmed with measurements of central venous pressure (CVP; Fig. 42-9). Patients with a diastolic pressure of 110 mm Hg may have a CVP as low as –4 cm H_2O and may require careful hydration to increase the CVP. A significant reduction in maternal plasma volume may precede the clinical appearance of preeclampsia in previously normotensive patients.

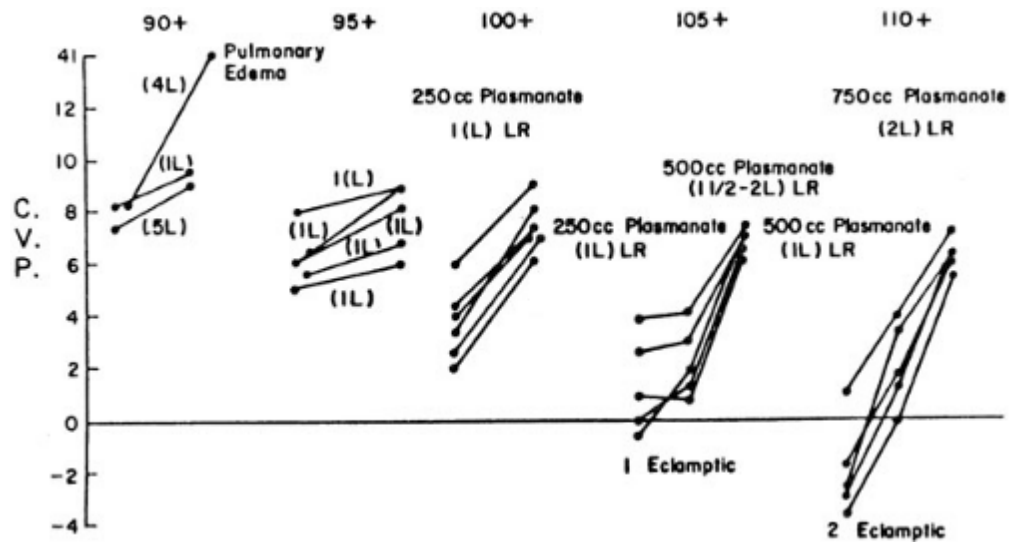

FIGURE 42-9. Initial central venous pressure (CVP) measurements (three or more recordings of maternal diastolic pressure) and intravenous volume replacement required to attain the range of 6 to 8 cm H_2O in five groups of women with preeclampsia classified according to the severity of the disease (by diastolic BP). LR, lactated Ringer's solution. (Reprinted with permission from Joyce TH III, Debnath KS, Baker EA: Preeclampsia: Relationship of CVP and epidural analgesia. Anesthesiology 51:S297, 1979.)

Hemodynamic changes in preeclampsia may vary with the progression of the disease, whether patients are in labor or have received therapy. Earlier studies, using pulmonary artery flow-directed catheters, suggested patients with severe preeclampsia were in a hyperdynamic state. However, these investigations were performed when patients were in labor or in the postpartum period, after treatment had been instituted. More

recently, hemodynamic data were obtained in 10 preeclamptic and 4 healthy pregnant women near term who were not in labor[75] (Table 42-2). In the preeclamptic women, measurements were made

before treatment, after volume expansion, and after vasodilation was achieved with a continuous intravenous infusion of dihydralazine. Initial measurements revealed a low pulmonary capillary wedge pressure, a low cardiac index, a high systemic vascular resistance, and an increased heart rate, indicating the existence of a low-output state in untreated preeclamptic women. Volume expansion resulted in a significant increase in pulmonary capillary wedge pressure and cardiac index, whereas the systemic vascular resistance and maternal heart rate decreased. The mean arterial pressure was significantly reduced, mainly because of a decrease in systolic pressure. Subsequent infusion of dihydralazine did not alter the capillary wedge pressure but led to an additional increase in cardiac index and a decrease in systemic vascular resistance. These data indicate that careful volume expansion may improve maternal tissue perfusion in severe preeclampsia.

TABLE 42-2 Hemodynamic Variables (Mean and Range) in Preeclamptic Patients and Control Subjects

	▪PREECLAMPTIC PATIENTS (n = 10)					
▪VARIABLE	▪INITIAL	▪AFTER VOLUME EXPANSION	p[a]	▪AFTER VASODILATION	p[b]	▪CONTROL SUBJECTS (n = 4)
Diastolic blood pressure (mm Hg)	106 (100–120)	102 (90–120)	NS	85 (75–100)	<.01	77 (70–90)
Mean arterial pressure (mm Hg)	121 (113–136)	116 (103–136)	<.02	102 (97–116)	<.01	95 (93–106)
Heart rate (beats/min)	100 (90–130)	81 (60–110)	<.02	82 (70–100)	NS	84 (70–90)
Pulmonary capillary wedge pressure (mm Hg)	3.3 (1–5)	8 (7–10)	<.01	8 (7–9)	NS	9 (6–12)
Systemic vascular resistance (dyne/sec/cm^5)	1,943 (1,480–2,580)	1,284 (1,073–1,600)	<.01	947 (782–1,028)	<.01	886 (805–1,021)
Cardiac index (L/min/m^2)	2.75 (1.97–3.33)	3.77 (3.26–4.05)	<.01	4.40 (3.94–5.00)	<.01	4.53 (3.96–4.97)

NS, not significant. Wilcoxon signed-rank test (two-tailed).

Simultaneous determinations of CVP and pulmonary capillary wedge pressure were obtained in another group of 18 patients with severe preeclampsia.[76] In approximately half of the cases, there was a linear relation between the two modalities, but even in these women it was difficult to predict the pulmonary capillary wedge pressure from the CVP because of wide interindividual variations.

Adherence of platelets at sites of endothelial damage may result in consumption coagulopathy. Thrombocytopenia is the most frequent finding. It is usually mild, with the platelet count in the range of 100,000 to 150,000 per mm^3. The use of high dose steroids (>24 mg of beta or dexamethasone in 24 hours) to accelerate fetal lung maturity has been shown in a retrospective study to prevent a further decrease in platelet count or even increase platelet count in women with HELLP[77] (Fig. 42-10). Elevated levels of fibrin degradation products are found less frequently, and plasma fibrinogen concentrations remain normal unless there is a placental abruption. Prolongation of prothrombin and partial thromboplastin times indicates consumption of procoagulant. Bleeding time is no longer considered a reliable test of clotting.

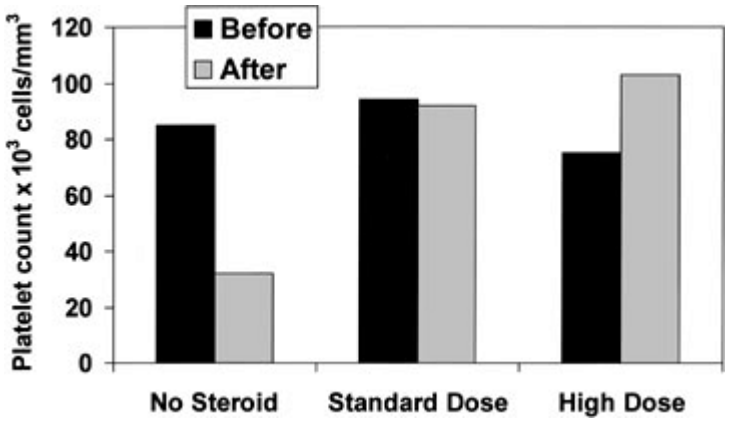

FIGURE 42-10. Mean platelet count in women with HELLP syndrome without steroids, and before and after standard steroid (<24 mg/day) and high steroid (>24 mg/day) therapy. (Adapted from O'Brien JM, Milligan DA, Barton JR. Impact of high dose corticosteroid therapy for patients with HELLP [hemolysis, elevated liver function tests, and low platelets] syndrome. Am J Obstet Gynecol 183:921, 2000.)

General Management

Because the origin of preeclampsia–eclampsia is not known, management is symptomatic, until such time as the obstetrician determines that delivery is appropriate for the fetus. The definitive treatment of preeclampsia–eclampsia remains delivery of the fetus and placenta. The goals are to prevent or control convulsions, improve organ perfusion, normalize blood pressure, and correct clotting abnormalities. Mild cases may be managed expectantly with bed rest, antihypertensive medication, and fetal surveillance until the pregnancy is closer to term. Delivery is indicated in refractory cases, if there is nonreassuring fetal status or if the pregnancy is already close to term. In severe cases, aggressive management should continue for at least 24 to 48 hours after delivery.

The mainstay of anticonvulsant therapy in the United States is magnesium sulfate. Although its efficacy in preventing seizures has been well substantiated, its mechanism of action remains controversial. The patient usually receives an intravenous loading dose of 4 g in a 20% solution, administered

over 5 minutes. Therapeutic blood levels are maintained by continuous infusion of 1 to 2 g/hr. In addition to its anticonvulsant properties, by causing mild peripheral arterial vasodilation, magnesium sulfate may affect the maternal hemodynamic state. Magnesium ions cross the placenta readily, and may lead to fetal and neonatal hypermagnesemia. There is poor correlation between magnesium concentrations in the umbilical cord blood and the incidence of low Apgar scores and depression of ventilation at birth, which are more likely due to fetal asphyxia and prematurity.

Magnesium potentiates the duration and intensity of action of depolarizing and nondepolarizing muscle relaxants by decreasing the amount of acetylcholine liberated from the motor nerve terminals, diminishing the sensitivity of the endplate to acetylcholine, and depressing the excitability of the skeletal muscle membrane. Magnesium may also increase the severity of hypotension under regional anesthesia and make it more difficult to treat. Judicious hydration with a balanced salt solution may be required to replace intravascular volume. In all cases, careful monitoring of arterial pressure and urine output should be started as soon as possible. In severe cases, invasive central pressure monitoring may be required.[76] A pulmonary artery catheter is preferred in patients with pulmonary edema, refractory hypertension, or oliguria.[76] Monitoring should also be carried out in the postpartum period, preferably in the recovery room or intensive care setting.

Antihypertensive therapy in preeclampsia is used to lessen the risk of cerebral hemorrhage in the mother while maintaining, even improving, tissue perfusion. Plasma volume expansion combined with vasodilation fulfills these goals.[75] Hydralazine is the most commonly used vasodilator in preeclampsia because it increases uteroplacental and renal blood flows. It can be administered orally, intramuscularly, or intravenously. Nitroprusside, a potent vasodilator of resistance and capacitance vessels, with an immediate but evanescent action, is useful in preventing dangerous elevations in systemic and pulmonary artery blood pressure during laryngoscopy and intubation, and is ideal for treatment of hypertensive emergencies. Nitroprusside infusion can be decreased gradually in the interim as a longer-acting agent, such as hydralazine, begins to take effect. Infusion rates of nitroprusside less than 5 to 10 mg/kg/min, depending on the length of administration, can be maintained without undue risk of cyanide toxicity to the mother and fetus. Other agents used to control maternal blood pressure in preeclampsia include nitroglycerin and labetalol, a nonselective beta-blocker with some α_1-blocking effects.

Consumption coagulopathy may require corrective measures such as infusion of fresh whole blood, platelet concentrates, fresh frozen plasma, and cryoprecipitate. The administration of conduction anesthesia is contraindicated in patients with severe coagulopathy because of the increased risk of an epidural hematoma, leading to permanent neurologic damage.

Anesthetic Management

Epidural anesthesia (or CSE) for labor and delivery should no longer be considered contraindicated, provided there is no severe clotting abnormality or plasma volume deficit.[78] In volume-repleted patients positioned with left uterine displacement, regional anesthesia does not cause an unacceptable reduction in blood pressure and leads to a significant improvement in placental perfusion.[79] With the use of radioactive xenon, it was shown that the intervillous blood flow increased by approximately 75% after the induction of epidural analgesia (10 mL of bupivacaine 0.25%).[80] The total maternal body clearance of amide local anesthetics may be prolonged in preeclampsia, and repeated administration of these drugs can lead to higher blood concentrations than in normotensive patients.[81]

For cesarean section, the sensory level of regional anesthesia must extend to T3–T4, making adequate fluid therapy and left uterine displacement even more vital. In two more recent studies, the incidence of hypotension, perioperative fluid and ephedrine administration, and neonatal conditions were found to be similar in preeclamptic women who received either epidural or spinal anesthesia for cesarean delivery.[82,83]

General anesthesia in preeclamptic patients has its particular hazards. Rapid-sequence induction of anesthesia and intubation of the trachea necessary to avoid aspiration are occasionally difficult because a swollen tongue, epiglottis, or pharynx distorts the anatomy. In patients with impaired coagulation, laryngoscopy and intubation of the trachea may provoke profuse bleeding. Marked systemic and pulmonary hypertension occurring at intubation and extubation enhance the risk of cerebral hemorrhage and pulmonary edema (Fig. 42-11). However, these hemodynamic changes can be minimized with appropriate antihypertensive therapy, such as administration of labetalol or nitroprusside infusion. The use of ketamine and ergot alkaloids should be avoided. As already mentioned, magnesium sulfate may prolong the effects of all muscle relaxants through its actions on the myoneural junction. Therefore, relaxants should be administered with caution (using a nerve stimulator) to avoid overdosage. General anesthesia may be necessary in acute emergencies, such as abruptio placentae, and in patients who do not meet the criteria for regional anesthesia.

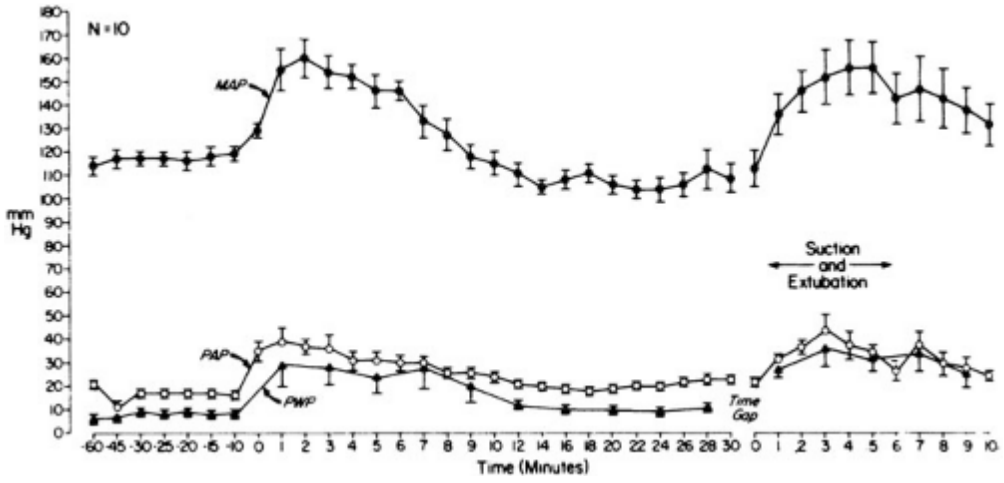

FIGURE 42-11. Mean and SE of mean arterial pressure (MAP), mean pulmonary artery pressure (PAP), and pulmonary wedge pressure (PWP) in patients with severe preeclampsia receiving thiopental and nitrous oxide (40%) with 0.5% halothane anesthesia for cesarean section. Can Anaesth Soc J 27:389, 1980.)

Antepartum Hemorrhage

10 Antepartum hemorrhage occurs most commonly in association with placenta previa (abnormal implantation on the lower uterine segment and partial to total occlusion of the internal cervical os) or abruptio placentae. Placenta previa occurs in 0.1 to 1.0% of all pregnancies, resulting in up to a 0.9% incidence of maternal and a 17 to 26% incidence of perinatal mortality. Placenta previa may be associated with abnormal fetal presentation, such as transverse lie or breech. It should be suspected whenever a patient presents with painless, bright red vaginal bleeding, usually after the seventh month of pregnancy. The diagnosis is confirmed by ultrasonography. If the bleeding is not profuse and the fetus is immature, obstetric management is conservative to prolong pregnancy. In severe cases, or if the fetus is mature at the onset of symptoms, prompt delivery is indicated, usually by cesarean section. An emergency hysterectomy may be required because of severe hemorrhage, even after delivery of the placenta, because of uterine atony. The risk of severe hemorrhage after attempted removal of a placenta previa is greatly increased in patients who have undergone prior uterine surgery, including cesarean section. This is due to a higher incidence of placenta accreta, which results from the penetration of myometrium by placental villi. After one previous cesarean delivery, placenta accreta was reported to occur in 20 to 25% of patients with placenta previa, and after four or more prior cesarean sections, the incidence is greater than 67%.[84]

Abruptio placentae occurs in 0.2 to 2.4% of pregnant women, usually in the final 10 weeks of gestation and usually in association with hypertensive diseases. Complications include Couvelaire uterus (when extravasated blood dissects between the myometrial fibers), renal failure, disseminated intravascular coagulation, and anterior pituitary necrosis (Sheehan's syndrome). The maternal mortality rate is high (1.8 to 11.0%), and the perinatal mortality rate is even higher, in excess of 50%. The diagnosis of abruptio placentae is based on the presence of uterine tenderness and hypertonus, as well

as vaginal bleeding of dark, clotted blood. Bleeding may be concealed if the placental margins have remained attached to the uterine wall. If the blood loss is severe (>2 L), there may be changes in the maternal blood pressure and pulse rate indicative of hypovolemia. Fetal movements may increase during acute hypoxia or decrease if hypoxia is gradual. Fetal bradycardia and death may ensue. Management of milder cases of abruption includes artificial rupture of amniotic membranes and oxytocin augmentation of labor, if required. In the presence of nonreassuring fetal status, an emergency cesarean section may be performed.

The anesthesiologist is involved in both maternal resuscitation and provision of anesthesia. This may include establishment of invasive monitoring (an arterial and a central venous catheter are usually adequate) and blood volume replacement, preferably through 14- or 16-gauge cannulae. If clotting abnormalities are present, fresh frozen plasma, cryoprecipitate, and platelet concentrates may be required. The anesthesiologist also performs the traditional role of providing appropriate anesthesia for a cesarean section or a cesarean hysterectomy. The choice of anesthetic technique depends on the anticipated duration of surgery, maternal condition and volume status, the potential for coagulopathy and urgency of the procedure. General anesthesia is indicated in the presence of uncontrolled hemorrhage and/or severe coagulation abnormalities.[85] However, continuous epidural anesthesia has been successfully used for hysterectomy in planned, controlled situations.[85]

Heart Disease

11 Heart disease during pregnancy occurs in 0.4 to 4.1% of patients and is a leading nonobstetric cause of maternal mortality, with a mortality rate ranging from 0.4% among patients in class I or II of the New York Heart Association's functional classification to 6.8% among those in classes III and IV. The following lesions pose the greatest risk for the mother: pulmonary hypertension, particularly with Eisenmenger's syndrome; mitral stenosis with atrial fibrillation; tetralogy of Fallot; Marfan's syndrome; and coarctation of the aorta. Cardiac decompensation and death occur most commonly at the time of maximum hemodynamic stress, that is, in the third trimester of pregnancy, during labor and delivery, and particularly during the immediate postpartum period. During labor, cardiac output increases above antepartum levels.

Between contractions, this increase is approximately 15% in the early first stage, approximately 30% during the late first stage, approximately 45% during the second stage, and after delivery 30 to 50%. With each uterine contraction, approximately 200 mL of blood is squeezed out of the uterus into the central circulation. Consequently, stroke volume, cardiac output, and left ventricular work increase, and each contraction consistently increases cardiac output by 10 to 25% above that of uterine diastole. The greatest change occurs immediately after delivery of the placenta, when cardiac output increases to an average of 80% above prepartum values, and in some patients, it may increase by as much as 150%. These changes in cardiac output can be reduced by administration of regional anesthesia. In patients managed with continuous caudal anesthesia, cardiac output increased only 24% above prepartum control values during the second stage and 59% immediately postpartum.[30] A multidisciplinary approach is best when managing patients with complicated cardiac disease. All members of the team should be aware of the management plan for when the patient arrives in labor or requires a cesarean section. For the anesthesiologist, it is particularly important to know how the hemodynamic consequences of different anesthetic techniques could adversely affect mothers with specific cardiac lesions.

PRETERM DELIVERY

Preterm labor and delivery present a significant challenge to the anesthesiologist because the mother and the infant may be at risk. The definition of prematurity was altered to distinguish between the preterm infant, born before the thirty-seventh week of gestation is completed, and the small-for-gestational-age infant, who may be born at term but whose weight is more than 2 standard deviations below the mean. Although preterm deliveries occur in 8 to 10% of all births, they account for approximately 80% of early neonatal deaths. In general, the

mortality and morbidity rates are higher among preterm infants than among small-for-gestational-age infants of comparable weight. Severe problems, including respiratory distress syndrome, intracranial hemorrhage, hypoglycemia, hypocalcemia, and hyperbilirubinemia, are prone to develop in preterm infants. Fortunately, with improved neonatal intensive care, severe, lasting impairment, such as cerebral palsy, mental retardation, or chronic lung disease, has become infrequent among the survivors.

Obstetricians frequently try to inhibit preterm labor to enhance fetal lung maturity. Delaying delivery by even 24 to 48 hours may be beneficial if glucocorticoids are administered to the mother. Various agents have been used to suppress uterine activity (tocolysis), including ethanol, magnesium sulfate, prostaglandin inhibitors, β-sympathomimetics, and calcium channel blockers. β-Adrenergic drugs, such as ritodrine and terbutaline, are the most commonly used tocolytics. These agents are initially administered by an intravenous infusion at the rate of 0.05 to 0.1 mg/min for ritodrine and 0.01 mg/min for terbutaline. Their predominant effect is β_2 receptor stimulation, resulting in myometrial inhibition, vasodilation, and bronchodilation. Numerous maternal complications may occur: hypotension, hypokalemia, hyperglycemia, myocardial ischemia, pulmonary edema, and death.[86] Complications also may occur because of interactions with anesthetic drugs and techniques. With the use of regional anesthesia, peripheral vasodilation caused by β-adrenergic stimulation increases the risk of hypotension. Acute prehydration must be managed carefully to avoid pulmonary edema. General anesthesia may be associated with increased risks of hemodynamic instability in the presence of preexisting tachycardia, hypotension, and hypokalemia. Caution should be exercised with use of halothane (cardiac dysrhythmias), atropine, and pancuronium (tachycardia). In nonemergent situations, delay of anesthesia by at least 3 hours from the cessation of tocolysis allows β-mimetic effects to dissipate. Potassium supplementation is usually not necessary because the intracellular potassium concentration is normal, despite a reduction in serum concentrations.

It has become axiomatic that the premature infant is more vulnerable than the term newborn to the effects of drugs used in obstetric analgesia and anesthesia. However, there have been few systematic studies to determine the maternal and fetal pharmacokinetics and dynamics of drugs throughout gestation. There are several postulated causes of enhanced drug sensitivity in the preterm newborn: less protein available for drug binding; higher levels of bilirubin, which may

compete with the drug for protein binding; greater drug access to the central nervous system (CNS) because of a poorly developed blood-brain barrier; greater total body water and lower fat content; and a decreased ability to metabolize and excrete drugs. However, these deficiencies of the preterm infant should not be as serious as we have been led to believe. Although the serum albumin and α_1-acid glycoprotein concentrations are lower in the preterm fetus, this would primarily affect drugs that are highly bound to these proteins. However, most drugs used in anesthesia exhibit only low to moderate degrees of binding in the fetal serum: approximately 50% for etidocaine and bupivacaine, 25% for lidocaine, 52% for meperidine, and 75% for thiopental.

The placenta efficiently eliminates fetal bilirubin. Thus, the hyperbilirubinemia of prematurity normally occurs in the postpartum period. With the exception of diazepam, bilirubin does not compete with anesthetic drugs because most are bound to other serum proteins (e.g., meperidine and local anesthetics to α_1-acid glycoproteins). It seems likely that the human blood-brain barrier develops substantially in early gestation. Thus, factors such as tissue affinity changes may account for differences between immature and mature brain uptake of highly lipid-soluble drugs.

Greater total body water in the preterm fetus results in a greater volume of distribution for drugs. Thus, to achieve equal blood concentrations, the immature fetus must receive a greater amount of drug transplacentally than the mature fetus. A study of age-related toxicity of lidocaine in sheep showed that the greater the volume of distribution, the greater the dose required to achieve toxic blood concentrations of the drug.[30] Decreased ability to metabolize or excrete drugs, associated with prematurity, is certainly not a universal phenomenon. In a study comparing the pharmacokinetics of lidocaine in preterm newborns and adults, plasma clearance was similar in both groups.[29] Neonates excreted much more unchanged lidocaine than did adults. Similarly, although meperidine metabolism is more limited in the neonate than in the adult, urinary excretion of the unchanged drug is greater in the neonate.

Another factor is gestational changes in maternal serum albumin and α_1-acid glycoprotein concentrations, which tend to decrease. Serial determinations of protein binding of diazepam, phenytoin, and valproic acid in maternal serum, performed in early (8 to 16 weeks), middle (17 to 32 weeks), and late pregnancy, showed a progressive increase in the unbound fraction of these drugs.[87] This increases drug availability for placental transfer. Placental permeability itself increases as pregnancy progresses because of the increased area and decreased thickness of tissue barriers.

In a largely ignored, prospective study of more than 1,000 premature labors, during which mothers received meperidine alone or with scopolamine, medication had no effect on the perinatal death rate, the incidence of respiratory distress syndrome, Apgar scores, the need for resuscitation, and the incidence of severe neurologic defects within 1 year.[88]

Therefore, it appears that in selection of the anesthetic drugs and techniques for delivery of a preterm infant, concerns regarding drug effects on the newborn are far less important than prevention of asphyxia and trauma to the fetus. For labor and vaginal delivery, well-conducted epidural anesthesia is advantageous in providing good perineal relaxation. The anesthesiologist should ascertain that the fetus is neither hypoxic nor acidotic before induction of epidural blockade. Asphyxia results in a redistribution of fetal cardiac output, which increases oxygen delivery to vital organs such as the brain, heart, and adrenals. These changes in the preterm fetus may be better preserved with bupivacaine or chloroprocaine than with lidocaine.[89,90] Preterm infants with breech presentation are usually delivered by cesarean section. General anesthesia with uterine relaxation, provided by a halogenated drug, facilitates delivery of the aftercoming head. If regional anesthesia is used, nitroglycerin should be available for uterine relaxation.

HIV AND AIDS

HIV infection is tragically not an uncommon occurrence in women of reproductive age. Fortunately, the use of combination antiretroviral therapy has improved the long-term outlook for women with HIV. Unfortunately, some of these women will become pregnant. There is no evidence that pregnancy itself accelerates the progression of the disease. However, there is compelling interest to prevent vertical transmission of HIV from mother to fetus. Neonatal detection is

difficult because maternal antibody can persist in the neonate for up to 18 months. The factors associated with increased vertical transmission are a high viral load (or AIDS), rupture of amniotic membranes, coexisting sexually transmitted disease, chorioamnionitis, and obstetric interventions, such as with amniocentesis or cervical cerclage. The greatest success in reducing vertical transmission has been with combination antiretroviral therapy to reduce the maternal viral load and elective cesarean delivery prior to

rupture of membranes/labor. Intravenous antiretroviral therapy usually administered prior to delivery.

The choice of anesthetic technique should be based on maternal condition, obstetric considerations, and patient desires. There has been concern that regional anesthesia may spread HIV infection to the CNS or accelerate the course of the disease. However, spread of HIV to the CNS occurs rapidly after initial infection, and there is no evidence linking the use of regional anesthesia (epidural or spinal) to progression of the disease.[91,92] A PDPH should be managed conservatively with caffeine, theophylline, or sumatriptan. If these modalities fail, an epidural blood patch (EBP) may be considered. There has been concern that an EBP, particularly if the viral load is high, may accelerate neurologic symptoms of the disease. In a more recent case series of six patients with HIV infection and PDPH requiring EBP, there was no evidence of acceleration of HIV symptoms.[93]

SUBSTANCE ABUSE

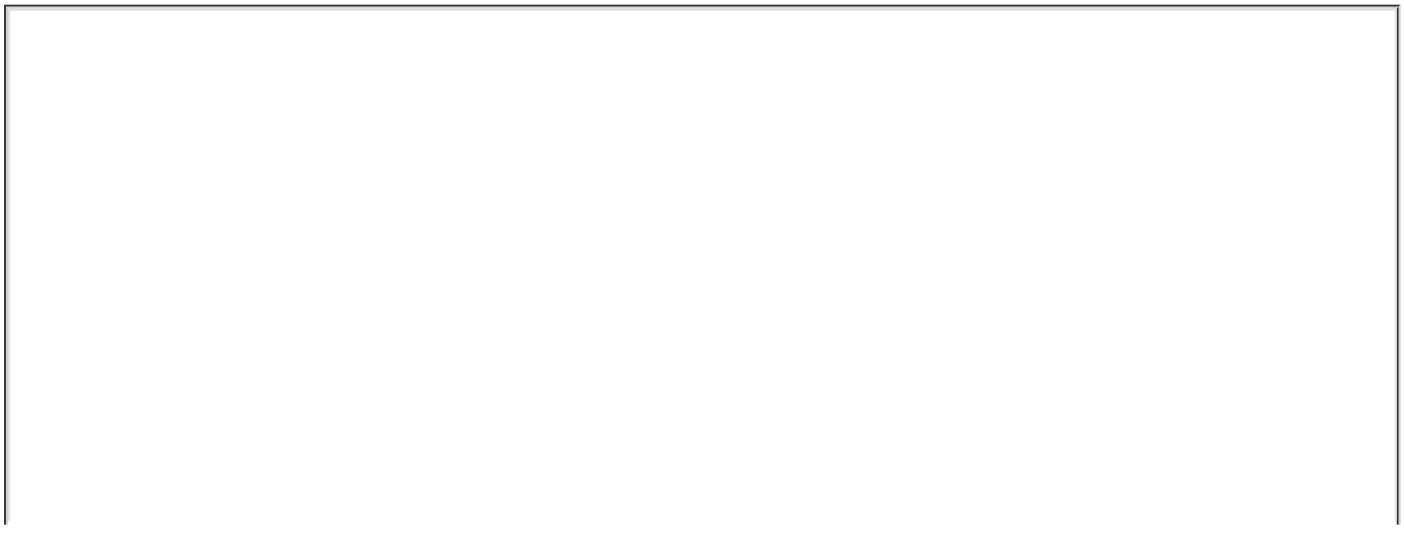
12 Substance abuse with amphetamines, ecstasy, opioid, marijuana, or cocaine is also not uncommon among women of reproductive age. Of these, cocaine has the greatest implications for anesthetic management because it causes a heightened sympathetic state. Women abusing cocaine generally display euphoria, tachycardia, and hypertension. More serious manifestations may include seizure and coma, myocardial infarction, pulmonary edema, or subarachnoid hemorrhage. Sudden death may occur due to a lethal ventricular arrhythmia. For the fetus as well, maternal cocaine use is harmful. For instance, cocaine use in the first trimester may cause congenital anomalies. Later in pregnancy, cocaine use may be associated with premature labor, intrauterine growth retardation, and nonreassuring fetal status due to uteroplacental insufficiency or placental abruption. Therapy is supportive primarily aimed at controlling CV and CNS consequences of cocaine use. Pure β-antagonist drugs should be avoided because of the potential for worsening hypertension due to unopposed pure α-receptor stimulation by cocaine. The choice of anesthetic depends on maternal and fetal condition, the planned procedure (vaginal delivery or cesarean section), and urgency. General anesthesia may be associated with uncontrolled hypertension/tachycardia and life-threatening arrhythmias in women using cocaine.[94] Regional anesthesia is not without its hazards. Cocaine is a local anesthetic, and systemic toxicity may be additive when using amide local anesthetics for epidural anesthesia. Chronic cocaine use may also be associated with thrombocytopenia. The incidence and severity of hypotension related to regional anesthesia may be greater in cocaine using parturients compared with controls, and hypotension may be more difficult to treat.[94]

FETAL AND MATERNAL MONITORING

The development of biophysical and biochemical monitoring of the fetus during labor and delivery has had a tremendous impact on obstetric practice since the early 1970s. Monitoring procedures are now performed routinely, and it is important that the anesthesiologist understand the basic principles of the technology, as well as the interpretation of results, because they relate to both mother and fetus.

During the same period, there has been an explosion in monitoring technology in the fields of anesthesiology and intensive care. The mother with serious medical problems requiring intensive care or the one whose infant is delivered in an operating room under an anesthesiologist's care is subject to the same standards of monitoring as any other surgical patient. It is generally agreed that the use of intensive peripartum monitoring is appropriate in a high-risk pregnancy. In contrast, patients with routine labor are frequently observed in the same way that patients were

many generations ago (i.e., with intermittent blood pressure readings). With the growing sophistication of electronic devices, and specifically the science of telemetry, we can look forward to better surveillance of both mother and fetus without the loss of maternal freedom and activity that monitoring currently entails.



Biophysical Monitoring

A fetal monitor is a two-channel recorder of FHR and uterine activity. In the direct system, the fetal ECG is obtained from an electrode attached to the presenting part. Intrauterine pressure is measured continuously with a transducer connected to a saline-filled catheter that is inserted transcervically. Direct monitoring is quantitative but requires rupture of the membranes and a cervical dilation of at least 1.5 cm. In addition, the presenting part must dip into the true pelvis. Indirect fetal monitoring uses data obtained from transducers secured to the mother's abdomen with adjustable straps. Ultrasound cardiography is the most commonly used indirect method of obtaining FHR signals. Uterine activity is monitored with a tocodynamometer triggered by the changing shape of the uterus during the contraction. Indirect monitoring is mostly qualitative. Its advantage is that it can be applied without rupture of membranes, even before the onset of labor.

The following variables are considered when fetal well-being is determined: baseline heart rate, beat-to-beat variability, periodic patterns, and uterine activity. The baseline FHR is measured between contractions and ranges between 120 and 160 beats/min in the normal fetus. An acceleration of FHR in response to fetal stimulation, such as during vaginal examination or fetal capillary blood sampling, is a reassuring sign that the fetus is not acidotic. Persistently elevated rates may be associated with chronic fetal distress, maternal fever, or administration of drugs such as ephedrine and atropine. Abnormally low rates may be encountered in fetuses with congenital heart block or as a late occurrence during the course of fetal hypoxia and acidosis.

The baseline FHR variability, which is normally present, reflects the beat-to-beat adjustments of the parasympathetic and sympathetic nervous systems to a variety of internal and external stimuli. Fetal CNS depression by asphyxia may decrease baseline variability. Therefore, a smooth FHR tracing may be an ominous finding. However, drugs can also decrease FHR variability by depressing mechanisms in the CNS that integrate cardiac control (tranquilizers, opioids, barbiturates, anesthetics) or by blocking the transmission of control impulses to the cardiac pacemaker (atropine). In contrast, ephedrine administration may increase beat-to-beat variability.

Periodic FHR patterns consist of decelerations or accelerations of relatively brief duration in association with uterine contractions (Fig. 42-12). There are three major forms of FHR deceleration: early, late, and variable. Early decelerations are U shaped, with the heart rate usually not decreasing to less than 100 beats/min. The fetal heart begins to slow with the onset of the contraction, the low point coincides with the peak of the contraction, and the rate usually returns to the baseline as the uterus relaxes. This type of deceleration has been attributed to fetal head compression, leading to increased vagal tone. It is not ameliorated by increasing fetal oxygenation but is blocked by atropine administration. Early decelerations are transient and well tolerated by the fetus because there is no systemic hypoxemia or acidosis.

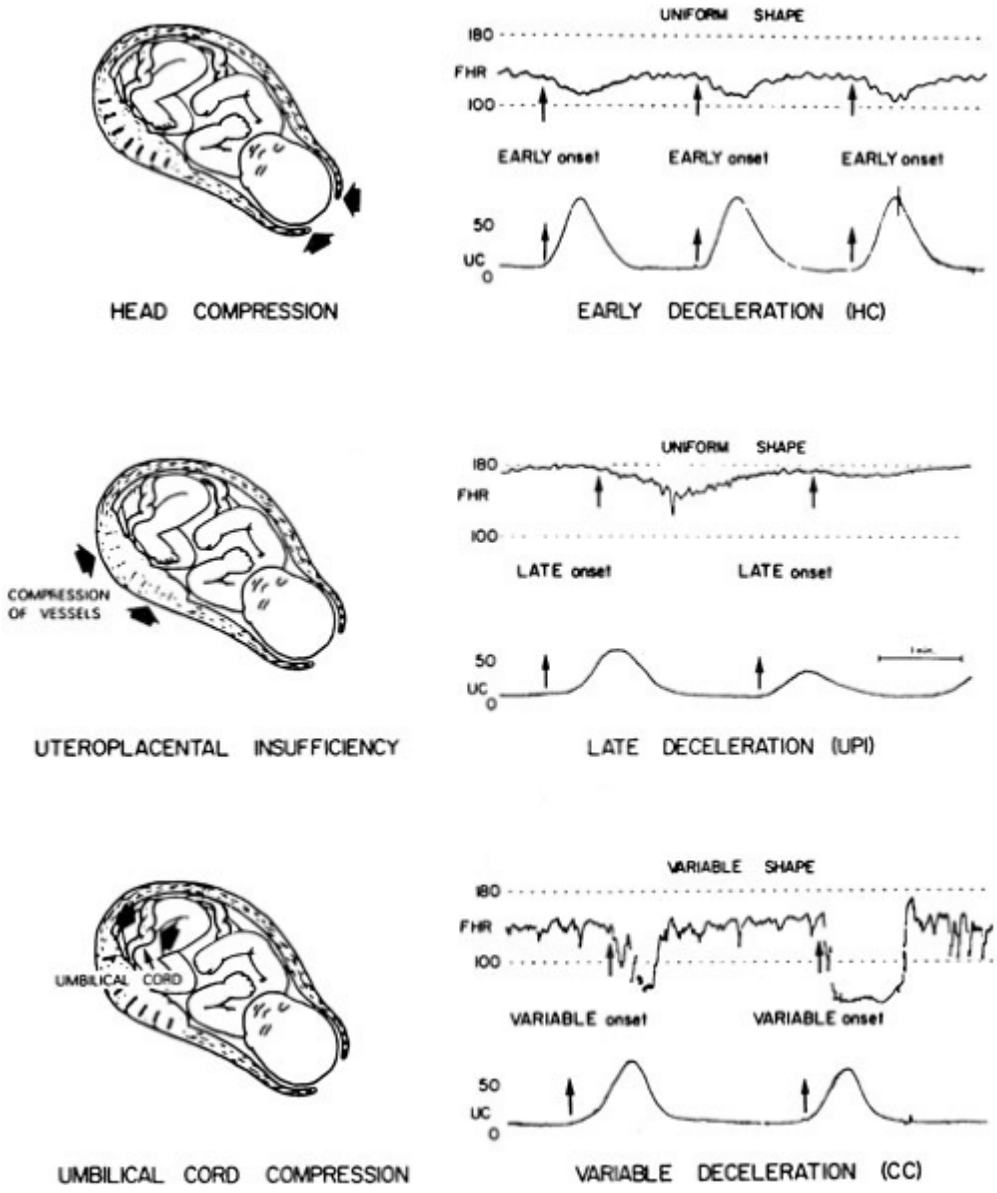


FIGURE 42-12. Classification and mechanism of fetal heart rate patterns. (Reprinted with permission from Hon EH: An Introduction to Fetal Heart Rate Monitoring, p 29. New Haven, CT, Harty Press, 1969.)

Late decelerations are also U shaped. However, they begin 20 to 30 seconds or more after the onset of uterine contraction,

and the low point of the deceleration occurs well after the peak of the contraction. Myocardial ischemia resulting from uteroplacental insufficiency is believed to cause late decelerations. Late deceleration can be corrected by improving fetal oxygenation, which may be accomplished with oxygen administration to the mother, correction of maternal hypotension, or aortocaval compression, or by taking measures that reduce uterine activity. If late decelerations are repetitive, continuous, and progressive in severity, there is a significant correlation with fetal acidosis, and delivery may be required.

Variable decelerations, which result from umbilical cord compression, are the most common periodic patterns observed in the intrapartum period. They are variable in shape and onset, with the rate usually decreasing to less than 100 beats/min and >15 beats/min below baseline. Although the initial FHR changes are of reflex origin, if the cord compressions are frequent or prolonged, fetal asphyxia may result in direct myocardial depression.

A prolonged deceleration is defined as a FHR decrease lasting longer than 2 minutes but less than 10 minutes. All decelerations should be quantified based on deviation from baseline and duration.[95]

Cervical dilation and descent of the presenting part during the first stage of labor result primarily from uterine contractions. During the active phase, contractions should occur every 2 to 3 minutes, with peak intrauterine pressures of 50 to 80 mm Hg and resting pressures of 5 to 20 mm Hg. Uterine activity may be abnormally elevated in association with abruptio placentae or the injudicious use of oxytocics. Tetanic uterine contractions have been reported after the use of methoxamine, a pure α-adrenergic agonist. In the first and second trimesters of pregnancy, increased uterine tone may occur with ketamine in doses greater than 1.1 mg/kg. At term, ketamine does not appear to have this effect.

Poor uterine contractility may result from overdistention (polyhydramnios, multiple pregnancy) or aortocaval compression. During early labor, administration of opioids, sedatives, or regional anesthesia may delay the onset of the active phase by diminishing uterine activity. However, regional anesthesia instituted during the active phase has no untoward effects on uterine activity as long as hypotension and the supine position are avoided. The addition of epinephrine to a local anesthetic solution may have a dose-related inhibitory effect on uterine activity.

Fetal Pulse Oximetry

Fetal pulse oximetry (FPO) is a newer technique to evaluate intrapartum fetal oxygenation. Currently, it remains an adjunct to electronic FHR monitoring. The fetal pulse oximeter is currently being used when the electronic FHR monitor shows a nonreassuring FHR tracing or if the tracing is unreliable (i.e., fetal arrhythmia). Fetal O_2 saturation between 30% and 70% is considered normal. Saturation readings consistently <30% for a prolonged period of time (i.e., 10 to 15 min) are suggestive of fetal acidemia. Fetal blood scalp sampling and/or prompt obstetric intervention may be indicated.

As of September 2001, the American College of Obstetrics and Gynecology failed to endorse the routine use of the FPO in

clinical practice related to concerns over increased health costs without clear-cut improvement in obstetric outcome. Others suggest that simultaneous monitoring with a combination of fetal ECG and FPO is easily feasible, and reliable in indicating signs of intermittent hypoxia.[96]

Biochemical Monitoring

Before labor, the normal fetus is neither hypoxic nor acidotic. During labor, many events, including repeated uterine contractions, cord compression, aortocaval compression, and maternal hypotension from any cause, may decrease uteroplacental blood flow sufficiently to produce fetal hypoxia and acidosis. Acidosis associated with short-term placental hypoperfusion primarily results from carbon dioxide accumulation (respiratory acidosis). With prolonged asphyxia, hypercarbia is accompanied by metabolic acidosis resulting from anaerobic metabolism. Thus, fetal acid-base indices, such as PCO_2 and base deficit, usually reflect the degree and duration of asphyxia.

Assessment of fetal acid-base status became possible in the early 1960s, with the development of a fetal capillary blood sampling technique. Blood is usually obtained from the scalp, but it may also be sampled from the breech. It is collected into a heparinized glass capillary tube, and pH, PCO_2, PO_2, and base deficit are determined immediately with an appropriate electrode system adapted to the small sample size.

This technique has been validated in animal and clinical studies. It has been shown that fetal blood values obtained from the scalp of fetal monkeys are closely correlated with those in simultaneously obtained samples from the carotid artery and jugular vein.[97] A fetal capillary blood pH of 7.25 is the lowest limit of normal. A pH below 7.20 indicates fetal acidosis, and values between 7.20 and 7.24 are considered preacidotic. The last predelivery fetal pH correlated with the Apgar score at 1 or 2 minutes after birth.[98,99] Ninety-two percent of infants scored 7 or better

when the pH was above 7.25. With the pH below 7.16, 80% of infants scored 6 or less.[88] In general, when the pH is normal immediately before delivery, it can be assumed the infant will be in good condition. However, there is a small incidence of false-positive and false-negative results. In one study, normal pH was associated with low Apgar scores (false-positive results) in approximately 10% of cases[99] (Fig. 42-13). In approximately 8% of cases (false-negative results), a vigorous infant was born despite a low capillary scalp pH. The major factors contributing to false-positive outcomes are administration of sedative drugs or anesthetics, infection, airway obstruction, and congenital anomalies. False-negative outcomes are usually associated with maternal acidosis, which may occur after prolonged labor, excessive muscular activity, or inadequate fluid and caloric intakes. Obtaining a maternal sample (arterial or free-flowing venous blood) for the evaluation of the acid-base status helps identify this group. If fetal acidosis is of maternal origin, the mother's blood shows a large base deficit value, and the difference between the fetal and maternal base deficit values is small. In contrast, fetal acidosis resulting from prolonged asphyxia is reflected in a large fetal, but normal maternal, base deficit value; consequently, the difference in base deficit values is large. Fetal acidosis of maternal origin can be treated by correcting the maternal acid-base imbalance.

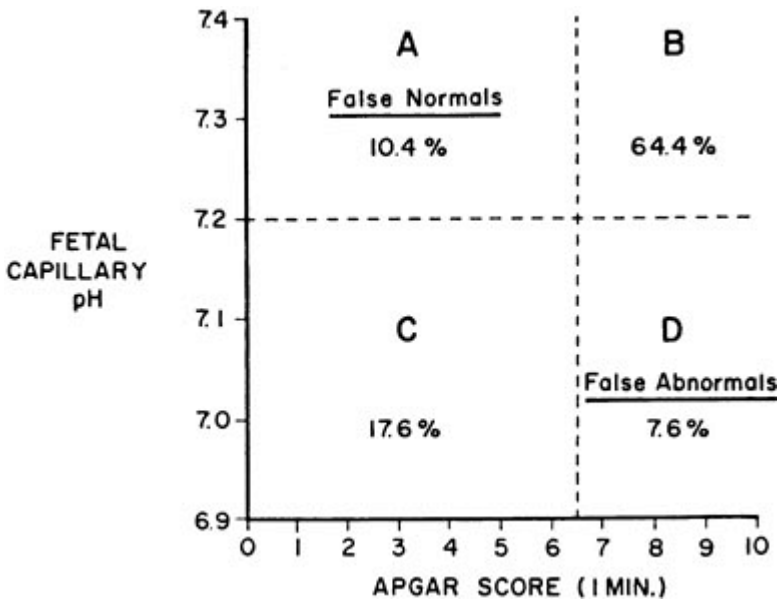

FIGURE 42-13. Fetal pH as an index of infant's condition at birth in 355 patients during labor. *Segment A:* depressed infants with normal pH; *segment B:* vigorous infants with normal pH; *segment C:* depressed infants with low pH; *segment D:* vigorous infants with low pH. NEWBORN RESUSCITATION IN THE DELIVERY ROOM

Of the approximately 3.5 million infants born in the United States each year, 6% require resuscitation in the delivery room. Among those weighing 1,500 g or less, the incidence is approximately 80%. The following factors may contribute to depression of the newborn: drugs used in labor or during delivery, including anesthetic agents; trauma of precipitate labor and operative obstetrics; and birth asphyxia (i.e., hypoxia and hypercapnia with acidosis).

Fetal Asphyxia

13 Fetal asphyxia, the best-studied cause of neonatal depression, usually develops as a result of interference with maternal or fetal perfusion of the placenta. As stated previously, the normal fetus is neither hypoxic nor acidotic before labor. Experimental data have revealed that

transplacental gradients for pH and PCO_2 are approximately 0.05 pH units and 5 mm Hg, respectively. Although oxygen tension is low, oxygen saturation is relatively high (80 to 85%) by virtue of the shift to the left of the fetal oxyhemoglobin dissociation curve.

During labor, uterine contractions decrease the blood flow through the intervillous space of the placenta or may stop it completely. On the fetal side, cord compression occurs during the final stages of approximately one-third of vaginal deliveries. Thus, mild degrees of hypoxia and acidosis occur even during normal labor and delivery, and play an important role in initiation of ventilation. On average, healthy, vigorous infants (at birth) have an oxygen saturation of 21%, a pH of 7.24, and a PCO_2 of 56 mm Hg.

Severe fetal asphyxia occasionally develops as a result of fetal and maternal complications, such as a tight nuchal cord, prolapsed cord, premature separation of the placenta, uterine hyperactivity, or maternal hypotension. During asphyxia, changes in blood gases and hydrogen ion concentration are rapid. The decrease in pH results from accumulation of carbon dioxide and end products of anaerobic glycolysis. After oxygen stores are exhausted, the ability of fetal brain and myocardium to derive energy from anaerobic metabolism is essential for survival. However, anaerobic glycolysis is pH dependent, and its rate is greatly diminished when the pH decreases below 7.0. Other untoward effects of severe hypoxia and acidosis include depression of the myocardium resulting from a decrease in its

responsiveness to catecholamines; a shift to the right of the fetal oxyhemoglobin dissociation curve, resulting in reduced oxygen-carrying capacity; and an increase in pulmonary vascular resistance, which plays an important role during circulatory readjustment after birth.

Ventilatory and cardiovascular responses to controlled experimental asphyxia have been investigated extensively in newborn monkeys (Fig. 42-14). During the initial phase of asphyxia, the unanesthetized animal exhibits respiratory efforts that increase in depth and frequency for up to 3 minutes. This period, called primary hyperpnea, is followed by primary apnea, which lasts for approximately 1 minute. Rhythmic gasping then begins and is maintained at a fairly constant rate of approximately 6 gasps/min for 4 to 5 minutes. Thereafter, the gasps become weaker and slower. Their cessation at approximately 8.5 minutes after the onset of asphyxia marks the beginning of secondary apnea. Administration of opioids and systemic anesthetic agents to the mother can abolish the period of primary hyperpnea and prolong primary apnea.

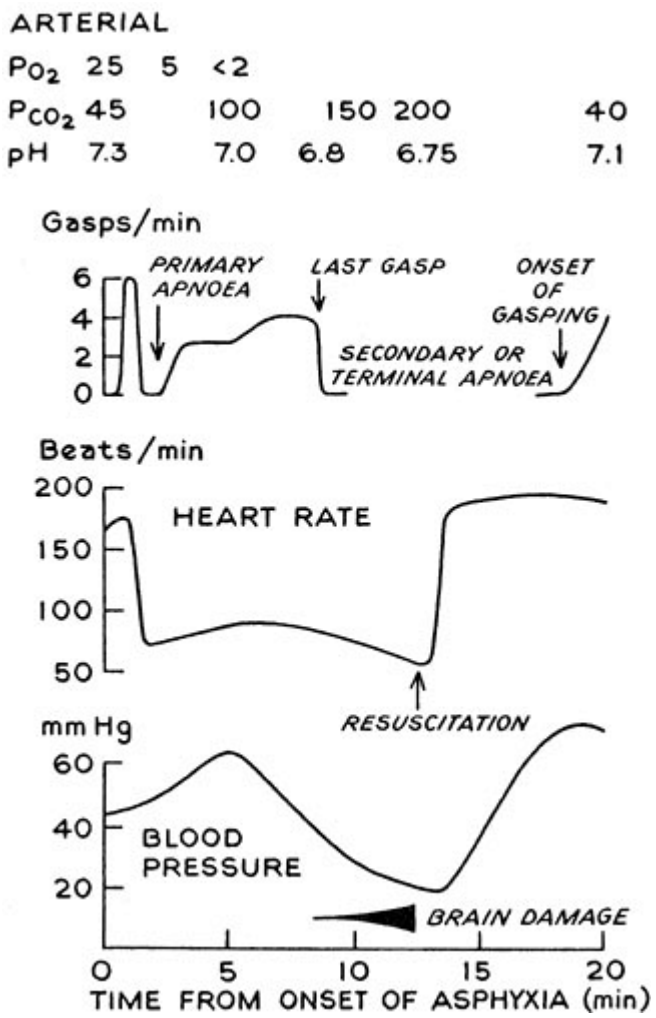

FIGURE 42-14. Schematic diagram of changes in rhesus monkeys during asphyxia and with resuscitation by positive-pressure ventilation. Brain damage was assessed by histologic examination some weeks or months later. (Reprinted with permission from Dawes GS: Foetal and Neonatal Physiology: A Comparative Study of the Changes at Birth, p 149. Chicago, Year Book Medical, 1968.)

There is a linear relationship between the duration of asphyxia and the onset of gasping and rhythmic spontaneous breathing. In the newborn monkey, for each minute of asphyxia beyond the last gasp, 2 additional minutes of artificial ventilation is required before gasping begins again and 4 minutes before rhythmic breathing is established.[100] This indicates that the longer artificial ventilation of the lungs is delayed during secondary apnea, the longer it will take to resuscitate the infant. Furthermore, in the newborn monkey, prolongation of asphyxia for 4 minutes beyond the last gasp is accompanied by extensive damage to brainstem nuclei, whereas animals resuscitated before the last gasp show little or no brain damage. Thus, a relatively short delay in resuscitation can have serious sequelae.

Neonatal Adaptations at Birth

During this period, and through the early hours and days of life, many morphologic and functional changes take place, with the cardiovascular and ventilatory systems undergoing the most dramatic alterations. In the normal newborn, two events occur almost simultaneously, and within seconds of delivery: the end of umbilical circulation through the placenta and expansion of the lungs. These events change the fetal circulation toward the adult type. Survival of the neonate depends primarily on prompt expansion of the lungs and establishment of effective ventilation.

The onset of ventilation and expansion of the lungs dilates the pulmonary vascular bed, resulting in decreased resistance and a significant increase in pulmonary blood flow. Pulmonary vascular resistance decreases as oxygen tension increases and carbon dioxide levels decrease. As soon as pulmonary perfusion increases, the foramen ovale, which is a communication between the inferior vena cava and the left atrium, undergoes functional closure because of pressure changes across the valve of the foramen (see Fig. 42-4). Cessation of the umbilical circulation reduces pressure in the inferior vena cava and right atrium, whereas the increase in pulmonary blood flow increases venous return and pressure in the left atrium. The ductus arteriosus does not constrict abruptly or completely after birth; functional closure may take hours, even days. Thus, shunting may still occur in the neonatal period, its direction depending on relative resistances in the pulmonary and systemic vascular beds. The smooth muscle of the ductus arteriosus constricts in response to increased oxygen tension in the newborn's blood. Catecholamines, which exist in increased concentrations in the newborn, particularly during the first 3 hours of life, also constrict the ductus arteriosus. In contrast, prostaglandins PGI_2 and PGE_2, produced by the wall of the ductus arteriosus, relax the ductal smooth muscle. Administration of prostaglandin synthesis inhibitors to fetal animals promotes constriction of the ductus arteriosus.

Cardiac output and its distribution also increase; left ventricular output increases ~150 to 400 mL/kg/min, whereas right ventricular output increases less significantly. Cardiac output changes closely parallel the increase in oxygen consumption. The redistribution of cardiac output also leads to increases in myocardial, renal, and gastrointestinal blood flow, and decreases in cerebral, adrenal, and carotid flow.

During fetal life, respiratory gas exchange takes place through the placenta. Delivery of the infant's trunk relieves the thoracic compression that occurs as the infant passes through the birth canal, and the thorax and the lungs expand. Most infants initiate respiratory efforts a few seconds after birth. After the first inspiration, a cry usually results as the infant exhales against a partially closed glottis, thus increasing intrathoracic pressure significantly. Negative pressures in excess of 40 cm H_2O bring about the initial entry of air into fluid-filled alveoli. In the mature, normal neonate, the lungs expand almost completely after the first few breaths, and the pressure–volume changes achieved with each respiration resemble those of the adult. After lung expansion, the FRC approximates 70 mL in the term newborn and changes little over the first 6 days of life. The tidal volume varies between 10 and 30 mL, the breathing frequency ranges from 30 to 60 breaths/min, and minute ventilation exceeds 500 mL. After delivery and prompt lung expansion, reoxygenation is rapid, but it takes 2 or 3 hours to achieve a relatively normal acid-base balance, primarily by pulmonary excretion of carbon dioxide. By 24 hours, the healthy

neonate has reached the same acid-base state as that of the mother before labor.

Resuscitation

The delivery room must be prepared for adequate and prompt treatment of severe neonatal depression at birth. All members of the delivery room team should be trained in resuscitation methods because both mother and infant may encounter difficulty simultaneously. Every piece of apparatus necessary for emergency resuscitation should be checked carefully before delivery (Table 42-3). An overview of resuscitation in the delivery room is provided in >Fig. 42-15.

TABLE 42-3 Resuscitation Equipment in the Delivery Room

Radiant warmer
Suction with manometer and suction trap
Suction catheters
Wall oxygen with flow meter
Resuscitation bag (⩽750 mL)

Infant facemasks
Infant oropharyngeal airways
Endotracheal tubes, 2.5, 3.0, 3.5, and 4.0 mm
Endotracheal tube stylets
Laryngoscope(s) and blade(s)
Sterile umbilical artery catheterization tray
Needles, syringes, three-way stopcocks
Medications and solutions 1:10,000 Epinephrine
Naloxone hydrochloride
Sodium bicarbonate
Volume expanders

Initial Treatment and Evaluation of All Infants

Immediately after delivery, the infant should be held head down while the cord is clamped and cut. The infant should then be placed supine under a radiant heat source, with the head kept low with a slight lateral tilt, and the skin should be dried promptly. A nurse or assistant should listen to the heartbeat immediately, indicating the rate by finger movement. If help is not available, the rate can be detected from pulsation of the umbilical cord. At the same time, the resuscitator should aspirate the mouth, pharynx, and nose with a catheter. This suction should be brief, not exceeding 30 seconds. Slapping the infant's soles lightly or rubbing its back frequently aids in initiating a deep breath or cry. The initial appraisal of the newborn should start from the moment of birth, with particular attention paid to the first few breaths and the evenness and ease of respiration. Most infants are vigorous and cough or cry within seconds of delivery. Their heart rate is above 100 beats/min. The administration of free-flowing oxygen rapidly improves their

oxygenation and decreases pulmonary vascular resistance. Mildly to moderately depressed infants constitute the largest group requiring some form of resuscitation at birth. These infants are pale or cyanotic, have not established sustained respiration even at 1 minute after delivery, and may be nearly flaccid. However, their heart rate is usually above 100 beats/min. The severely depressed infant is flaccid, unresponsive, and pale, and may often have a heart rate below 100 beats/min. The scoring system introduced by Apgar is a useful method of clinically evaluating the infant, particularly at 1 and 5 minutes after delivery (Table 42-4).

TABLE 42-4 Apgar Scores

·SIGN	·0	·1	·2
Heart rate	Absent	<100 beats/min	>100 beats/min
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion of extremities	Active motion
Reflex irritability	No response	Grimace	Cough, sneeze, or cry
Color	Pale, blue	Body pink, extremities blue	Completely pink

Treatment of Moderately Depressed Infants

If initial resuscitative methods, including rubbing the back or slapping the feet once or twice, have produced no response, that is, the infant is apneic or its heart rate remains below 100 beats/min, positive-pressure ventilation by bag and mask should be instituted at a rate of 40 breaths/min. The initial breath may require pressures of 30 to 40 cm H_2O. Subsequently, the inflation pressures should be reduced to 15 to 20 cm H_2O in an infant with normal lungs. A small plastic oropharyngeal airway may be needed to maintain patency of the upper airway. If after 15 to 30 seconds of ventilation the heart rate is below 60 beats/min, or maintained between 60 and 80 beats/min, chest compressions should be initiated.[101]

Treatment of Severely Depressed Infants

Ventilation should be established without delay. The glottis should be inspected immediately with the laryngoscope. If meconium or thick meconium-stained mucus has been aspirated into the trachea, it should be suctioned out at once through an endotracheal tube before the lungs are inflated. It is usually possible to accomplish this within 1 to 2 minutes of delivery. Severely depressed infants may require 3 to 8 minutes of artificial ventilation before a spontaneous gasp is taken. The endotracheal tube can be removed as soon as quiet and sustained respiration is established.

Use of Cardiac Massage

If the blood pressure or heart rate is unduly low at the beginning of resuscitation, positive-pressure ventilation is unlikely to be successful unless cardiac massage is used. Chest

compressions should be provided if heart rate is less than 60 beats/min, despite adequate ventilation for 30 seconds. The technique preferred by the authors consists of intermittent compression of the lower third of the sternum. The ratio of chest compression to ventilation should be approximately 3:1 or 100 compressions to 30 breaths per min. Cardiac massage and ventilation should be maintained until the heart rate exceeds 100 beats/min.

Rapid Correction of Acidosis

Sodium bicarbonate use is not recommended during brief cardiopulmonary resuscitation. The hyperosmolarity and CO_2 generated may be detrimental to cerebral and myocardial function. After ensuring adequate ventilation and perfusion, severe acidosis (pH < 7.0 or a base deficit > 15 mEq/mL) may need to be corrected. For that purpose, a 3.5F or 5F catheter should be inserted, under sterile conditions, into the umbilical vein and advanced until the tip of the catheter is just below the skin level. A solution of sodium bicarbonate, 0.5 mEq/mL (4.2%), is then infused over at least 2 minutes, up to a total dose of 2 mEq/mL (Fig. 42-16).

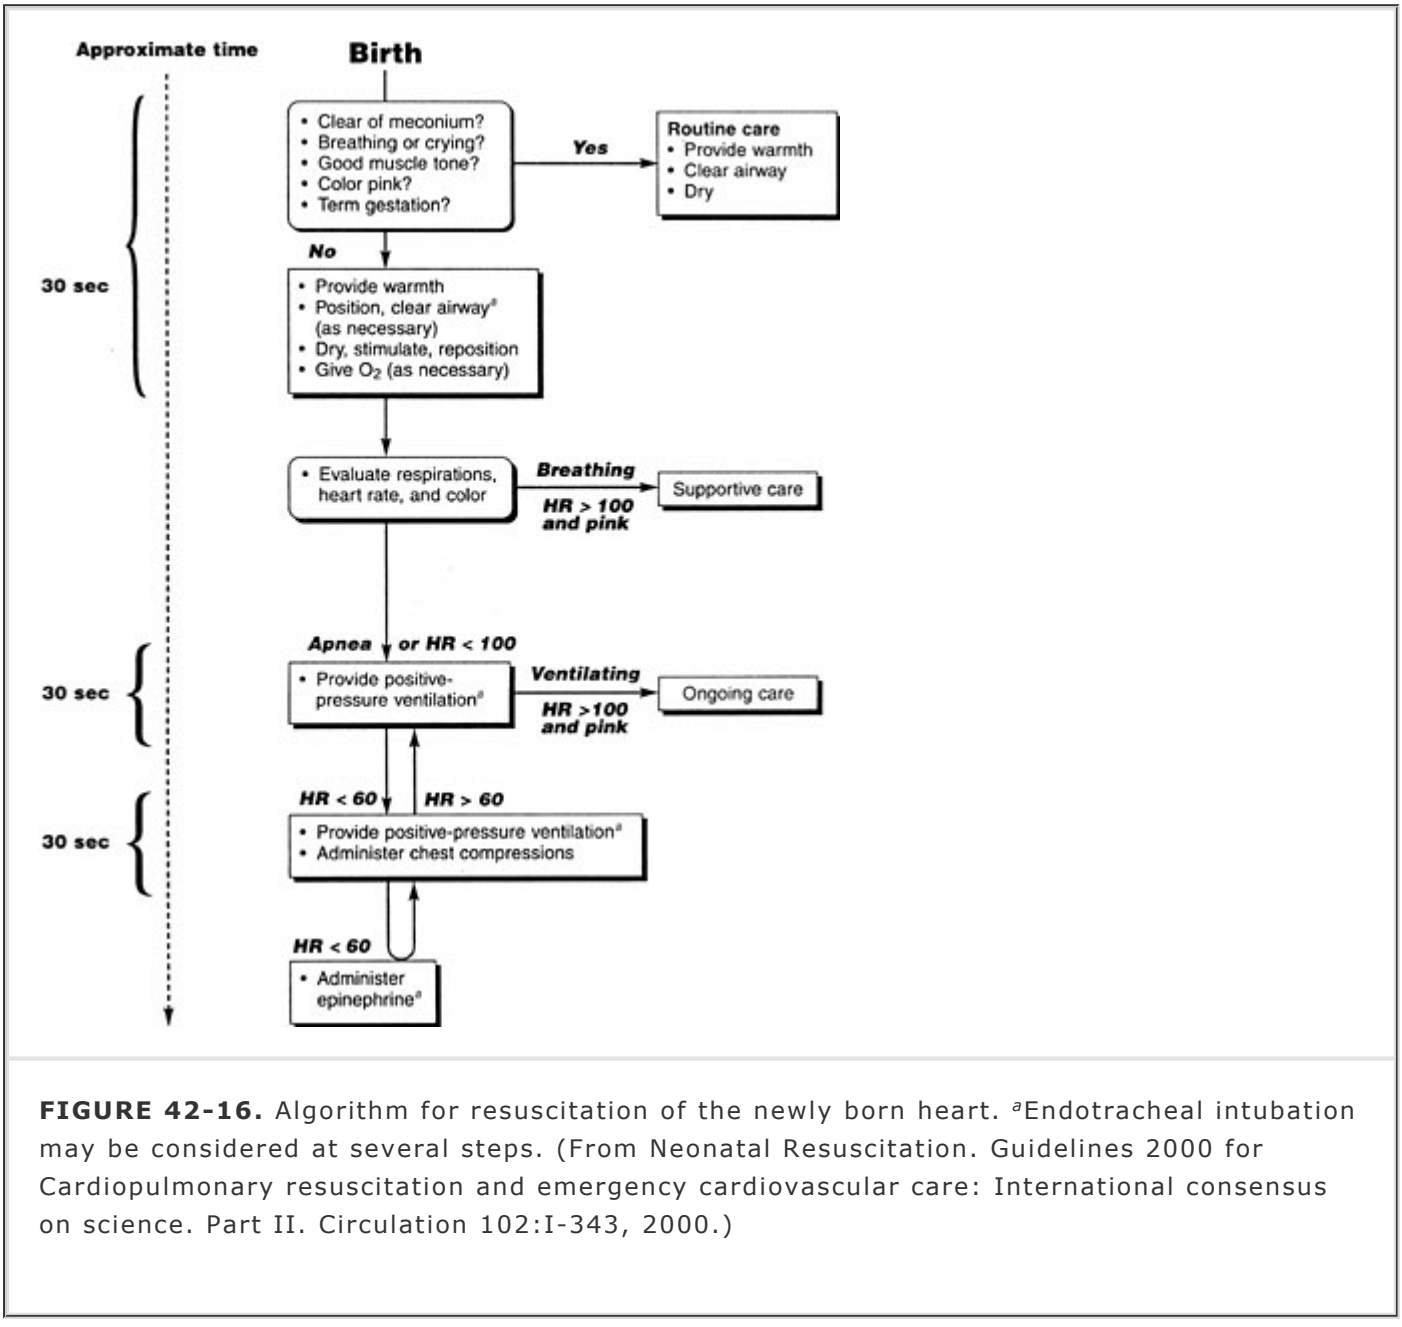

FIGURE 42-16. Algorithm for resuscitation of the newly born heart. [a]Endotracheal intubation may be considered at several steps. (From Neonatal Resuscitation. Guidelines 2000 for Cardiopulmonary resuscitation and emergency cardiovascular care: International consensus on science. Part II. Circulation 102:I-343, 2000.)

Other Drugs and Fluids

If it is believed that persistent depression has resulted from maternal opioid medication, naloxone should be given after adequate ventilation has been established (Table 42-5). The recommended dose of 0.1 mg/kg may be injected intravenously, intramuscularly, subcutaneously, or by

endotracheal tube. The initial dose may be repeated as needed. Naloxone should be avoided in infants born to opioid-addicted mothers so as not to precipitate acute withdrawal. A severely asphyxiated newborn might require cardiotonic drugs during early resuscitation. Epinephrine should be used to treat asystole or persistent bradycardia despite 30 seconds of effective ventilation and external cardiac massage. A dose of 0.1 to 0.3 mL/kg of a

1:10,000 solution should be injected intravenously or by endotracheal tube, and repeated every 5 minutes if necessary.

TABLE 42-5 Therapeutic Guidelines for Neonatal Resuscitation

·DRUG OR VOLUME EXPANDER	·CONCENTRATION TO ADMINISTER	·PREPARATION (BASED ON RECOMMENDED CONCENTRATION)	·DOSAGE	·ROUTE/RATE
Epinephrine	1:10,000	1 mL in a syringe Can dilute 1:1 with normal saline if given IT	0.1–0.3 mL/kg	IV or IT Give rapidly
Volume expanders	Whole blood 5% solution	40 mL to be given by syringe or IV drip	10 mL/kg	Give over 5–10 min
	Normal saline			
	Lactated Ringer's			
Sodium bicarbonate	0.5 mEq/mL (4.2% solution)	20 mL in a syringe or two 10-mL prefilled syringes	2 mEq/kg	IV Give slowly over at least 2 min (1 mEq/kg/min)
Naloxone hydrochloride	Narcan	2 mL in a syringe	0.5 mL/kg	IV, IM, SC, or IT
	Neonatal 0.02 mg/mL			Give rapidly

IM, intramuscular(ly); IV, intravenous(ly); IT, intratracheal(ly); SC, subcutaneous(ly).

Hypovolemia frequently follows severe birth asphyxia because a greater than normal portion of fetal blood remains in the placenta. The infant appears pale and has low arterial pressure, tachycardia, and tachypnea. Acute blood volume expansion may be accomplished with the intravenous administration of the following solutions over 5 to 10 minutes: O negative blood, cross-matched with the mother's blood, 10 mL/kg; and normal saline or lactated Ringer's solution, 10 mL/kg. Albumin is no longer indicated because it is associated with increased mortality.

Diagnostic Procedures

After the neonate is successfully resuscitated and stabilized, several diagnostic procedures are indicated. To rule out choanal atresia, each nostril should be obstructed. Because newborns must breathe through their noses, occlusion of the nostril on the patent side causes respiratory obstruction. To rule out esophageal atresia, a suction catheter is inserted into the stomach. Gastric contents are aspirated; volume in excess of 12 mL after vaginal delivery and 20 mL after cesarean section may result from an abnormality of the upper gastrointestinal tract.

ANESTHESIA FOR NONOBSTETRIC SURGERY IN THE PREGNANT WOMAN

Approximately 1.6 to 2.2% of pregnant women undergo surgery for reasons unrelated to parturition.[102,103] Apart from trauma, the most common emergencies are abdominal, involving torsion or rupture of an ovarian cyst and acute appendicitis,

but breast tumors are not uncommon, as are serious conditions such as intracranial aneurysms, cardiac valvular disease, and pheochromocytoma. Surgery to correct an incompetent cervix with Shirodkar or McDonald sutures is more related to the pregnancy itself.

When the necessity for surgery arises, anesthetic considerations are related to the alterations in maternal physiologic condition with advancing pregnancy, the teratogenicity of anesthetic drugs, the indirect effects of anesthesia on uteroplacental blood flow, and the potential for abortion or premature delivery. The risks must be balanced to provide the most favorable outcome for mother and child.

Five major studies have attempted to relate surgery and anesthesia during human pregnancy to fetal outcome as determined by anomalies, premature labor, or intrauterine death.[102,103,104,105,106] Although they failed to correlate surgery and anesthetic exposure with congenital anomalies, all of them demonstrated an increased incidence of fetal death, particularly after operations during the first trimester. No particular anesthetic agent or technique was implicated, and it seemed that the condition that necessitated surgery was the most relevant factor, with fetal mortality greatest after pelvic surgery or procedures performed for obstetric indications (i.e., cervical incompetence).

Two studies deserve mention. A review was taken of the entire population of the province of Manitoba, Canada, between the years 1971 and 1978.[105] State health insurance records were used to identify approximately 2,500 pregnant women who had undergone surgery during this period. Each patient was matched with a woman of similar age, living in the same area, with a pregnancy-related condition but no surgical intervention. As in earlier studies, there was no increase in the incidence of congenital anomalies in the offspring of mothers who had had surgery. However, there was an increased risk of spontaneous abortion in women who had received general anesthesia during the first or second trimesters, which was most evident after gynecologic operations. Few of the surgical group had had procedures to treat cervical incompetence, suggesting that factors other than the obstetric condition itself might be important. The results also might have been influenced by the fact that a small number of gynecologic procedures were performed with anesthesia other than general so the effect of the surgical site alone could not be distinguished. The authors emphasized a multiplicity of factors other than choice of anesthetic agent (e.g., diagnostic radiologic procedures, antibiotics, analgesics, infection, decreased uterine perfusion, stress) that might have been responsible for the increased risk of abortion.

The largest study to date regarding reproductive outcome after surgery during pregnancy is a Swedish registry review covering the years 1973 to 1981.[106] During this period, there were a total of 720,000 births, 5,405 of them after anesthesia and surgery during pregnancy. The results of this study are reassuring in that there was no increased incidence of congenital anomalies or stillbirths among infants exposed in utero to maternal surgery and anesthesia. However, in this group there was an increased frequency of very low and low birth weights, and of deaths within 168 hours after delivery. The reasons for this are unclear and are not related to any specific type of operation. The authors postulated that the maternal illness itself may have been a major contributor to adverse neonatal outcome.

Direct Effects of Anesthetic Agents on Embryo and Fetus

The idea that surgical anesthesia, although deemed necessary for the patient, might have detrimental effects on the growth and development of the human fetus has led to a great deal of investigation, both in vitro and in experimental animals. These studies present difficulties in interpretation because the concentrations of anesthetic and the duration of exposure are frequently far in excess of what is clinically used and because most of the studies were performed in lower animals.

Animals exposed to toxic substances and anesthetics show a dose-related response, the first change being decreased fertility and increased fetal death. The teratogenic effects between species and also within the same species vary significantly. The developmental stage is crucial, with dramatic sensitivity to exposure at certain times and little or no effect at a later time. The period of organogenesis is most critical. In humans, it corresponds to the fifteenth to fifty-sixth days of gestation.

Many congenital malfunctions show a pattern of multifactorial inheritance. In this mode, maldevelopment may result from a combination of factors in one person, such as hereditary predisposition, sensitivity to a given drug, and exposure at a vulnerable time in development. There are numerous other factors contributing to the potential teratogenicity of anesthesia. The cytotoxicity of anesthetic agents is closely associated with biodegradation, which, in turn, is influenced by oxygenation and hepatic blood flow. Thus, the complications associated with anesthesia, such as maternal hypoxia, hypotension, administration of vasopressors, hypercarbia, hypocarbia, and electrolyte disturbances, may possibly be a greater cause for concern as regards teratogenesis than the use of the agents themselves. Hypoxia is certainly a well-documented teratogen in the incubating chick embryo.[107] The role of maternal carbohydrate metabolism on embryonic development is also important. For example, the effects of 48 hours of fasting and administration of insulin to pregnant rats have included a large number of skeletal deformities.[108]

Experimental evidence on exposure to specific drugs and agents is highlighted briefly, with the consideration that it is difficult to extrapolate laboratory data to the clinical situation in humans. Large numbers of patients must be exposed to a suspected teratogen before its safety can be ascertained. Complicating factors include the frequency of maternal exposure to a multiplicity of drugs; the difficulty in separating the effects of the underlying disease process and surgical treatment from those of the drug administered; differing degrees of risk with stage of gestation; and the variety, rather than the consistency, of anomalies that appear in association with one agent. Of the premedicants, anticholinergics have not been found to be teratogenic, whereas tranquilizers and sedatives such as phenothiazines and barbiturates produce anomalies in some species.[109] Several reports have described a specific relationship between diazepam and oral clefts, but another study has not confirmed this.[110,111] Intravenous agents such as thiopental, methohexital, and ketamine in doses normally used in the operating room have not been associated with birth defects. Only one study has shown musculoskeletal deformities involving the joints after infusion of a muscle relaxant (*d*-tubocurarine) in the chick embryo between the seventh and fifteenth day of incubation.[112] Local anesthetics have not been shown to be teratogenic in animals or humans. Halogenated inhalation drugs have produced conflicting results. Pregnant rats exposed to halothane 0.8% for 12 hours at various times during gestation have increased incidences of anomalous skeletal development and fetal death.[113] Other investigators

have failed to show teratogenic effects of halothane in rats, rabbits, and mice exposed to subanesthetic concentrations for brief periods. Subanesthetic concentrations of enflurane do not appear to be teratogenic.[114] However, mice exposed to 1% enflurane for 4 hr/day on days 6 to 15 of gestation showed an increased incidence of cleft palates and minor skeletal and visceral abnormalities.[103] In a subsequent study by the same authors, teratogenic changes after exposure to 0.6% isoflurane in mice were similar to those found with enflurane, but the incidence of cleft palate was six times more frequent (12% vs. 1.9%).[115] Cleft palate readily develops in mice, and its occurrence as an isolated finding suggests that this might be a species-specific response. To clarify the results from earlier studies, rats were exposed to 0.75 MAC halothane, isoflurane, or enflurane; 0.55 MAC nitrous oxide; or a known teratogen, retinoic acid, for two 6-hour periods at three different stages of pregnancy.[116] No major morphologic abnormalities occurred in any of the anesthetic-exposed groups.

Nitrous oxide has been the most extensively investigated agent since the 1955 observation that leukopenia developed in patients with tetanus after they inhaled nitrous oxide for several days. Numerous studies have demonstrated significant effects on fetal growth, skeletal development, and death rate in both pregnant rats and incubating chicks exposed to concentrations of between 50% and 80%, for periods ranging from hours to days.[117] The question arises as to whether adverse effects at such high doses resulted from the anesthetic itself or from the accompanying physiologic derangements.

Although the mechanism of the teratogenic effect of nitrous oxide has not been determined, it may be related to the inhibitory effect of the agent on methionine synthetase activity and vitamin B_{12}. A dose-dependent decrease in both maternal and fetal methionine synthetase activity occurred in pregnant rats receiving 10% or 50% nitrous oxide for periods ranging from 60 to 240 minutes.[118] It is possible that failure of this enzyme to convert homocysteine to the essential amino acid methionine may lead to abnormalities of myelination of nerve fibers (Fig. 42-17). Furthermore, inhibition of methionine synthesis results in decreased thymidine production, which in turn can lead to decreased DNA synthesis and inhibition of cell division. Because there is evidence that nitrous oxide adversely affects methionine synthetase activity, it has been recommended that it not be administered to pregnant women in the first two trimesters. However, a more recent human study demonstrated no significant changes in plasma methionine concentrations after anesthesia with 60 to 70% nitrous oxide for up to 4 hours.[119] Two other reviews of exposure to this agent, this time for cervical cerclage procedures, showed no effects on fetal outcome.[120,121] Further, in the already mentioned Swedish birth registry study, nitrous oxide was administered to almost all 2,929 patients receiving general anesthesia without adverse fetal consequences.[106] In rats, the teratogenic effects of nitrous oxide could be prevented by the concomitant administration of isoflurane or halothane.[122] It is controversial whether pretreatment with folinic acid, the concentration of which is

reduced when methionine synthetase is inhibited, affords protection against the effects of nitrous oxide.[122] Because a single exposure to anesthetic agents seems unlikely to result in fetal abnormality, the selection of agent should be based on specific surgical requirements.

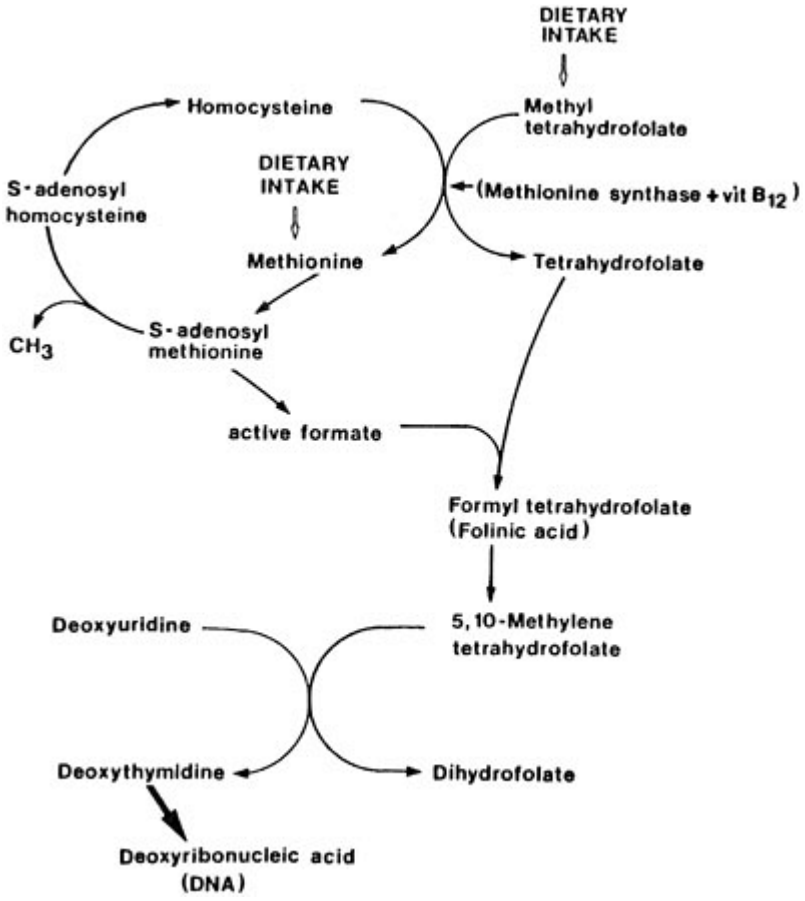

FIGURE 42-17. Abridged metabolic map showing the relationship between methionine and deoxythymidine syntheses. (Reprinted with permission from Nunn JF: Interaction of nitrous oxide and vitamin B_{12}. Trends Pharmacol Sci 5:225, 1984.)

Indirect Effects of Agents and Techniques

The adequacy of the uteroplacental circulation, so vital to the well-being of the fetus, is easily affected by drugs and anesthetic procedures. As discussed previously, perfusion of the intervillous space of the placenta may be diminished consequently on maternal systemic hypotension, which in turn may result from the use of epidural or spinal anesthesia, from aortocaval compression with the patient in the supine position, or from hemorrhage. Similarly, increased uterine activity may result in reduced placental perfusion. Thus, the use of α-adrenergic drugs to correct maternal hypotension and anesthetics such as ketamine (in doses above 1 mg/kg) may produce increased uterine tone sufficient to endanger the fetus. Severe hyperventilation of the mother may also reduce uterine blood flow. Finally, it has been shown in experimental animals that epinephrine or norepinephrine infusion results in decreased uterine blood flow and deterioration of fetal condition. Maternal pain and apprehension may similarly affect the fetus.[123]

Practical Suggestions

It is generally agreed that only surgeries that cannot be delayed for months, including emergency surgery, should be performed during pregnancy, particularly in the first trimester. The possibility of pregnancy should be considered in all female surgical patients of reproductive age. Based on the maternal and fetal hazards already described, the following approach to anesthesia seems indicated:

1. The patient's apprehension should be allayed as much as possible by personal reassurance

during the preanesthetic visit and by adequate sedation and premedication.

2. Pain should be relieved whenever present.
3. An antacid, 15 to 30 mL, should be administered within half an hour before induction of anesthesia. Ranitidine and metoclopramide may be useful.
4. Beginning in the second trimester, uterine displacement must be maintained at all times.
5. Hypotension related to spinal or epidural anesthesia should be prevented as much as possible by rapid intravenous infusion of crystalloid solution before induction. If the mother becomes hypotensive, ephedrine or phenylephrine should be promptly administered intravenously.
6. General anesthesia should be preceded by careful denitrogenation.
7. The risk of aspiration should be minimized by application of cricoid pressure and rapid tracheal intubation with a cuffed tube.
8. To reduce fetal hazard, particularly during the first trimester, it appears preferable to choose drugs with a long history of safety; these drugs include thiopental, morphine, meperidine, muscle relaxants, and low concentrations of nitrous oxide.
9. Avoid maternal hyperventilation and monitor end-expiratory $PaCO_2$ or arterial blood gases.
10. FHR may be monitored continuously or intermittently throughout surgery and anesthesia, provided that placement of the transducer does not encroach on the surgical field[113] (this becomes technically feasible from the sixteenth week of pregnancy). The decision to monitor the fetus should be made in conjunction with the obstetrician based on the severity of maternal disease, the potential for fetal jeopardy and whether the fetus is viable or not. Uterine tone may also be monitored with an external tocodynamometer if the uterus reaches the umbilicus or above.
11. Monitoring of uterine activity should be continued after operation, and tocolytic agents may be required.
12. Special procedures such as hypothermia and induced hypotension might be necessary to facilitate surgery, despite the potential fetal hazard. It is reassuring to know that there was successful fetal outcome after both procedures for intracranial operations.[114] There are numerous reports of cardiopulmonary bypass being performed during pregnancy, with generally good maternal and fetal results.[115,116]

Chapter 43

Neonatal Anesthesia

Frederic A. Berry

Barbara A. Castro

KEY POINTS

1	Understanding the physiologic changes that occur during the transition from fetal to neonatal life is crucial to the anesthetic management of the neonate. The circulatory, pulmonary, hepatic, and renal systems are all affected.
2	Persistent pulmonary hypertension (PPH) is a pathologic condition that can be primary but is often secondary to other conditions, including meconium aspiration, sepsis, congenital diaphragmatic hernia, or pneumonia. Understanding the pathophysiologic characteristics of PPH helps guide therapy.
3	Knowledge of the major anatomic differences between the infant and adult airway helps one understand why the infant's airway is often described as “anterior” and why airway management may be challenging. These differences include a relatively large tongue, a higher glottis with anterior slanting vocal folds, a larger occiput, and a narrowing at the cricoid ring.
4	Four important physiologic factors account for the rapid rate of desaturation observed in neonates. These include an increase in oxygen consumption, a high closing volume, a high ratio of minute ventilation to FRC, and a pliable rib cage.
5	Careful attention must be given to the choice of anesthetic agents and dosing of such agents in the neonatal population. Ongoing maturational changes in the renal and hepatobiliary systems, which occur during the first 30 days of life, will affect the metabolism and elimination of many anesthetic agents.
6	Although a host of anesthetic techniques are available, including regional, multiple factors are considered when choosing an anesthetic plan for the neonate. These include the surgical requirements, the need for postoperative ventilation, the cardiovascular stability of the neonate, and the anticipated method of postoperative pain control.
7	Special considerations must be addressed when planning an anesthetic for a neonate. Some of the most common and controversial issues include the risk of postoperative apnea and the use of caffeine in treatment and prophylaxis, the

	role of oxygen concentration in the development of retinopathy of prematurity, and the neurodevelopmental effects of anesthetic agents on the developing brain.
8	True surgical emergencies are uncommon in the neonatal period. Knowledge of conditions with comorbidities, such as tracheoesophageal fistula, omphalocele, and congenital diaphragmatic hernia, and a thorough preoperative evaluation and stabilization of such neonates cannot be overemphasized.

PHYSIOLOGY OF THE INFANT AND THE TRANSITION PERIOD

The first year of life is characterized by an almost miraculous growth in size and maturity. The body weight alone changes by a factor of three, and there is no other period in extrauterine life when changes occur so rapidly. Before birth, fetal growth and development depend on the genetic composition of the fetus, the mother's placental function, and potential exposure to chemicals or infectious agents that can affect mother, fetus, or both. The journey down the birth canal (or through the abdominal wall)—called the most dangerous trip in a person's life—ends the fetal period, and the newborn must adapt to extrauterine life. This change from fetal to extrauterine life is called the period of transition or adaptation.

The infant is considered a newborn in the first 24 hours of life. This chapter focuses on the neonatal period, which is defined as the first 30 days of extrauterine life and includes the newborn period. The most significant part of transition occurs in the first 24 to 72 hours after birth. All systems of the body change during transition, but the most important to the anesthesiologist are the circulatory, pulmonary, hepatic, and renal systems. The circulatory and pulmonary systems are so interdependent that they are discussed together.

Transition of the Cardiopulmonary System

Fetal Circulation

Fetal circulation is characterized by the presence of three main shunts (Fig. 43-1A). These shunts are the placenta, foramen ovale, and ductus arteriosus. The placenta oxygenates the blood, which then courses up the inferior vena cava into the right atrium. The right atrium is divided by a structure called the crista dividends so this relatively well-oxygenated blood is shunted from the right atrium through the foramen ovale into the left atrium, thereby bypassing the right ventricle and the pulmonary vascular bed. This blood, the best oxygenated in the fetus, progresses from the left atrium to the left ventricle and out the ascending aorta to provide oxygenation for the brain and upper extremities. Blood returns from the upper body to the right heart by the superior vena cava, where it is directed

by the crista dividends into the right ventricle, from which it is then pumped out the pulmonary artery. The relatively low pressure in the left atrium and the high pressure in the right atrium result in the foramen ovale being open. The pulmonary vascular bed has a high vascular resistance because the alveoli are relatively closed and filled with fluid, and the blood vessels are compressed. In addition, decreased PaO_2 and low pH increase pulmonary vascular resistance. The ductus arteriosus represents a low-resistance system because it is dilated secondary to a low PaO_2. Therefore, the blood that leaves the right ventricle by the pulmonary artery is shunted

preferentially (90%) through the ductus arteriosus and down the descending aorta, whereas only 10% of the output of the right ventricle flows through the pulmonary artery into the pulmonary vascular bed. The pulmonary vascular bed requires only enough blood flow to ensure growth and development of the lungs, including surfactant production.

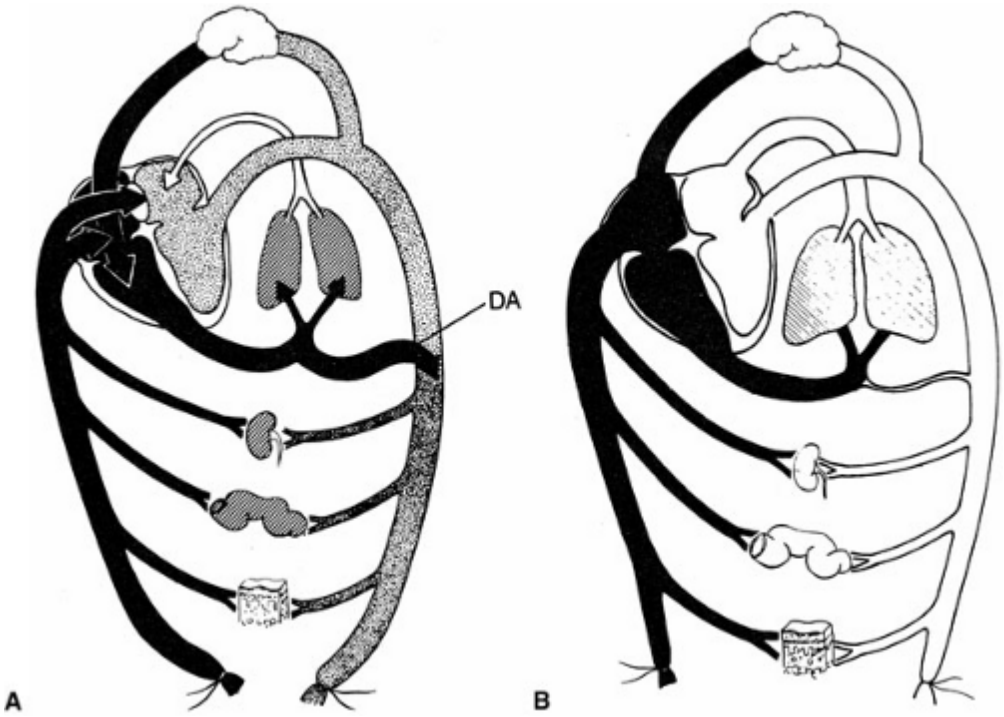

FIGURE 43-1. A. Schematic representation of the fetal circulation. Oxygenated blood leaves the placenta in the umbilical vein (*vessel without stippling*). Umbilical vein blood joins blood from the viscera (represented here by the kidney, gut, and skin) in the inferior vena cava. Approximately half of the inferior vena cava flow passes through the foramen ovale to the left atrium, where it mixes with a small amount of pulmonary venous blood, and this relatively well-oxygenated blood (*light stippling*) supplies the heart and brain by way of the ascending aorta. The other half of the inferior vena cava stream mixes with superior vena cava blood and enters the right ventricle (blood in the right atrium and ventricle has little oxygen, which is denoted by *heavy stippling*). Because the pulmonary arterioles are constricted, most of the blood in the main pulmonary artery flows through the ductus arteriosus (DA) so the descending aorta's blood has less oxygen (*heavy stippling*) than does blood in the ascending aorta (*light stippling*). **B.** Schematic representation of the circulation in the normal newborn. After expansion of the lungs and ligation of the umbilical cord, pulmonary blood flow and left atrial and systemic arterial pressures increase. When left atrial pressure exceeds right atrial pressure, the foramen ovale closes so all inferior and superior vena cava blood leaves the right atrium, enters the right ventricle, and is pumped through the pulmonary artery toward the lung. With the increase in systemic arterial pressure and decrease in pulmonary artery pressure, flow through the ductus arteriosus becomes left to right, and the ductus constricts and closes. The course of circulation is the same as in the adult. (Reprinted with permission from Phibbs R: Delivery room management of the newborn. In Avery GB [ed]: Neonatology, Pathophysiology and Management of the Newborn, p 184. Philadelphia, JB Lippincott, 1981.)

1 Clamping of the umbilical cord and initiation of ventilation produce enormous circulatory changes in the newborn (Fig. 43-1B). The transition of the alveoli from a fluid-filled to an air-filled state results in a reduced compression of the pulmonary alveolar capillaries with a reduction in pulmonary vascular resistance over the first several hours of life. However, it takes 3 to 4 days for the pulmonary vascular resistance to decrease to normal levels. Nitric oxide is an integral part

of the reduction in pulmonary vascular resistance; its clinical use is discussed later in the chapter. The initial moderate decrease in pulmonary vascular resistance is accompanied by constriction of the ductus arteriosus secondary to oxygenation. This results in an increase in pulmonary blood flow and an increase in left atrial pressure so the foramen ovale functionally closes. Closure of these two neonatal shunts (i.e., the ductus arteriosus and the foramen ovale) is initially only a functional closure. Both shunts usually close permanently in the first several months of life. However, an autopsy study of normal hearts has demonstrated a 30% incidence of patent foramen ovale during the first 30 years of life and a 20% incidence for people 30 years of age and older.[1]

Transition of the Pulmonary System

The pulmonary system transition occurs more quickly than the circulatory system. The primary event is the initiation of ventilation, which changes the alveoli from a fluid-filled to an air-filled state. During the first 5 to 10 minutes of extrauterine life, normal ventilatory volumes develop and normal tidal ventilation is established. The initial negative intrathoracic pressures that the newborn generates are often in the range of 40 to 60 cm H_2O. By 10 to 20 minutes of life, the newborn has achieved its near-normal functional residual capacity (FRC) and the blood gases are well stabilized. Table 43-1 lists the normal blood gases for the various periods of life. One study in preterm infants older than 26 weeks' gestational age demonstrated that a single dose of dexamethasone given within 2 hours of delivery resulted in lower ventilator settings and a higher mean blood pressure during the first week of life.[2] In addition, fewer infants in this group received indomethacin to treat a patent ductus arteriosus (PDA).

TABLE 43-1 Normal Blood Gas Values in the Neonate

SUBJECT	AGE	PO_2 mm Hg	PCO_2 mm Hg	pH
Fetus (term)	Before labor	25	40	7.37
Fetus (term)	End of labor	10–20	55	7.25
Newborn (term)	10 min	50	48	7.20
Newborn (term)	1 hr	70	35	7.35
Newborn (term)	1 wk	75	35	7.40
Newborn (preterm, 1,500 g)	1 wk	60	38	7.37

Patent Ductus Arteriosus

A study by Reller et al.[3] demonstrated that a PDA on or beyond the fourth day of life is abnormal, regardless of gestational age. Prematurity, unless complicated by acute asphyxia or the respiratory distress syndrome, is not a risk factor for persistent PDA. In their study, 95% of premature infants, regardless of gestational age, had closure of the ductus by day 4. The incidence of a PDA in premature infants with respiratory distress syndrome without a history of birth asphyxia was 11%, a percentage that is somewhat less than is commonly assumed.

Persistent Pulmonary Hypertension

2 The pulmonary circulation is extremely sensitive to oxygen, pH, and nitric oxide. Figure 43-2 illustrates the correlation of the mean pulmonary artery pressure with age during the first 3 days of life. Hypoxia and acidosis, along with inflammatory mediators, may cause pulmonary artery pressure either to persist at a high level or, after initially decreasing, to increase to pathologic levels. The result is termed *persistent pulmonary hypertension* (PPH). The pathophysiologic characteristics of

pulmonary hypertension comprise a spectrum, ranging from normal pulmonary vasculature to abnormal pulmonary vasculature that is characterized by extension of smooth muscle into the distal respiratory units (Fig. 43-3). Vasoconstriction of the muscle in the blood vessels of the pulmonary vascular bed results in pulmonary hypertension with a right-to-left shunt through the foramen ovale and/or the ductus arteriosus (Fig. 43-4).

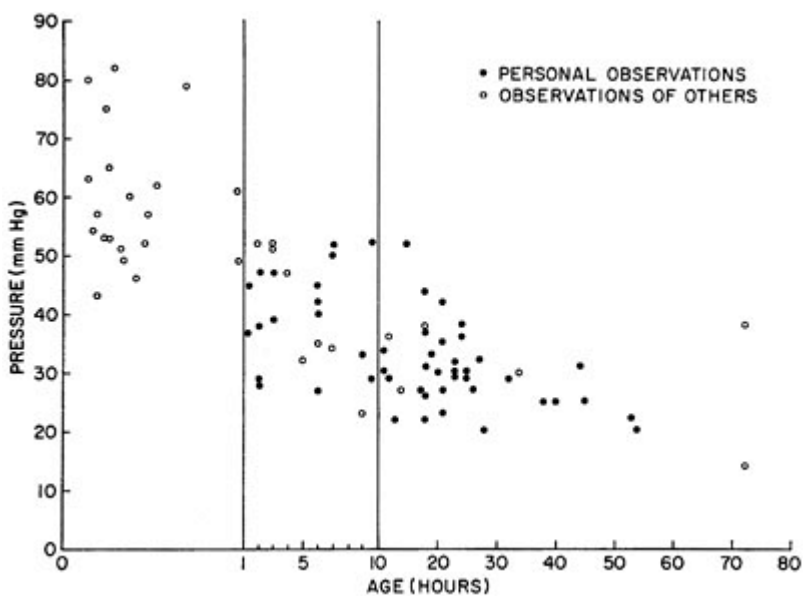

FIGURE 43-2. Correlation of mean pulmonary arterial pressure with age in 85 normal-term infants studied during the first 3 days of life. (Reprinted with permission from Emmanouilides GC, Moss AJ, Duffie ER, Adams FH: Pulmonary arterial pressure changes in human newborn infants from birth to 3 days of age. J Pediatr 65:327, 1964.)

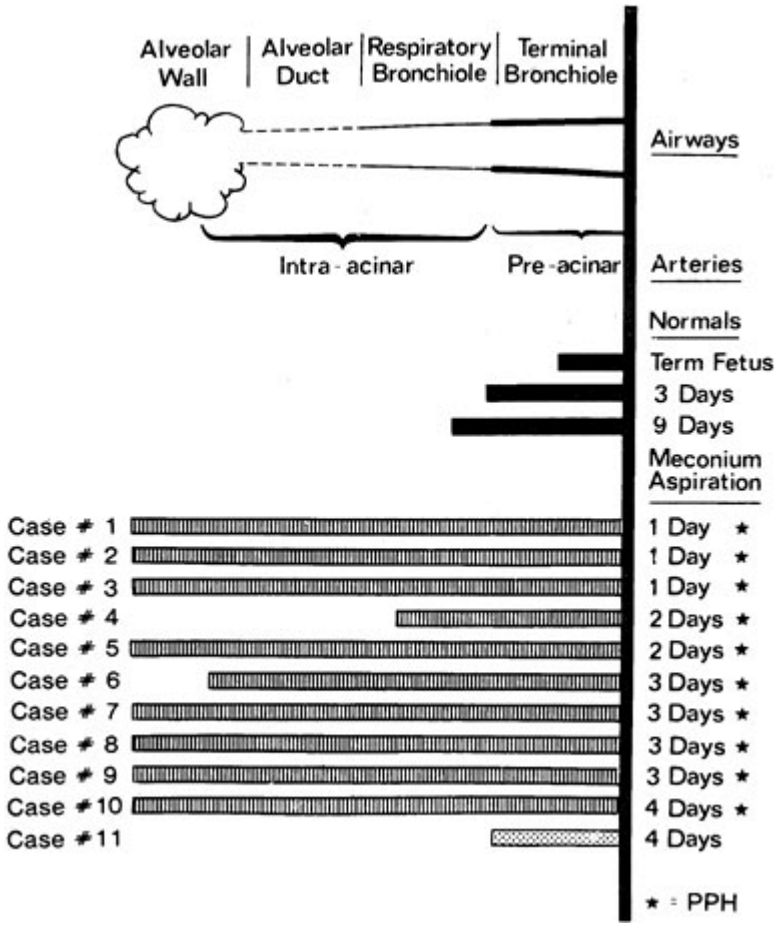

FIGURE 43-3. Diagram of muscle extension along pulmonary arterial branches (*shaded bars*). In the normal newborn, virtually no intra-acinar artery is muscular. In 9 of 10 infants with meconium aspiration and persistent pulmonary hypertension (PPH), muscle extended into the most peripheral arteries; the infant with meconium aspiration without PPH (case # 11) had normal intra-acinar arteries. (Reprinted with permission from Murphy JD, Vawter GF, Reid LM: Pulmonary vascular disease in fetal meconium aspiration. J Pediatr 104:758, 1984.)

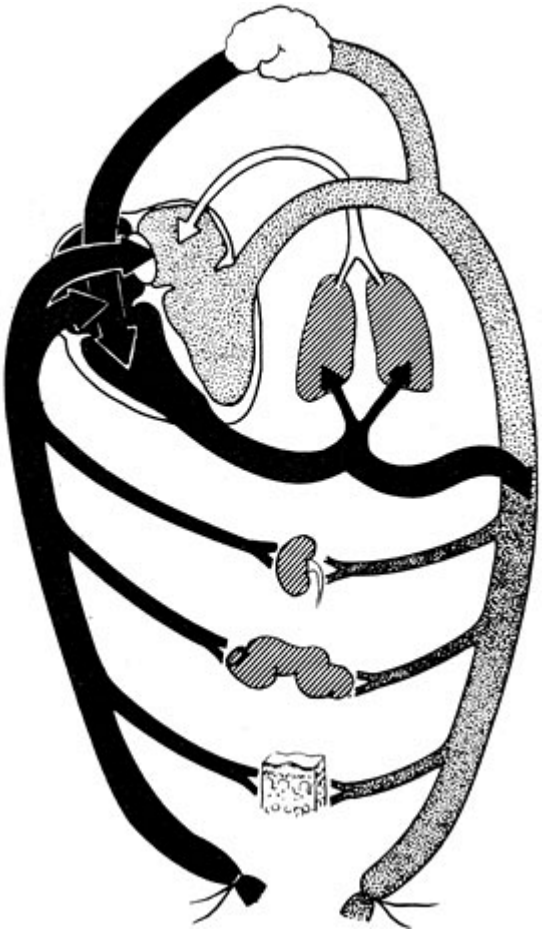

FIGURE 43-4. Schematic representation of the circulation in an asphyxiated newborn with incomplete expansion of the lungs. Pulmonary vascular resistance is high, pulmonary blood flow is low (note the small caliber of the pulmonary vein), and flow through the ductus arteriosus is high. With little pulmonary venous flow, left atrial pressure decreases below right atrial pressure, the foramen ovale opens, and vena cava blood flows through the foramen into the left atrium. This partially venous blood flows to the brain by the ascending aorta. The descending aorta blood that flows to the viscera has less oxygen than that of the ascending aorta (*heavy stippling*) because of the right-to-left flow through the ductus arteriosus. The circulation is the same in the fetus, except there is no oxygenated blood in the inferior vena cava from the umbilical vein. (Reprinted with permission from Phibbs R: Delivery room management of the newborn. In Avery GB [ed]: Neonatology, Pathophysiology and Management of the Newborn, p 184. Philadelphia, JB Lippincott, 1981.)

Problems of PPH or hypoxemic respiratory failure involve not only preterm, but also term infants. PPH may be primary with no recognized etiology, or it may be secondary to meconium aspiration, sepsis, pneumonia, respiratory distress, and congenital diaphragmatic hernia (CDH). Currently, the basic treatment depends on the degree of respiratory failure and the response to therapy. The goals of therapy are to achieve a PaO_2 between 50 and 70 mm Hg and a $PaCO_2$ between 40 and 60 mm Hg. There have been major changes in therapy since the 1990s, with the introduction of surfactant, high-frequency ventilation, inhaled nitric oxide, and extracorporeal membrane oxygenation (ECMO). The technique and degree of intervention depend on the response to supportive care. Surfactant and various ventilatory techniques are used as the first-line treatment. These techniques include intermittent mandatory ventilation, assist control ventilation, and proportional assist ventilation.[4,5,6] Studies with proportional assist ventilation demonstrate that gas exchange can be maintained with smaller transpulmonary pressure changes, which may reduce the incidence of chronic lung disease in low-birth-weight infants.[6]

Meconium Aspiration

Interference with the normal maternal placental circulation in the third trimester may cause fetal hypoxia. Fetal hypoxia can result in an increase in the amount of muscle in the blood vessels of the distal respiratory units. Figure 43-3 illustrates the muscle increase found in blood vessels of a series of 11 infants who died of PPH.[7] Chronic fetal hypoxia leads to the passage of meconium in utero. The fetus breathes in utero so the meconium mixed with amniotic fluid enters the pulmonary system. Meconium aspiration can be a marker of chronic fetal hypoxia in the third trimester. This condition is different from the meconium aspiration that occurs during delivery. This meconium at birth is thick and tenacious, and mechanically obstructs the tracheobronchial system. Meconium aspiration syndrome leads to varying degrees of respiratory failure, which can be fatal in spite of all treatment modalities.

Until relatively recently, tracheal intubation and suctioning were recommended for all infants with frank meconium aspiration or meconium staining (approximately 10% of newborns). Now a more conservative approach should be used because routine intubation may cause unnecessary respiratory complications.[8,9,10] Routine oropharyngeal suctioning of

meconium is recommended immediately at the time of delivery, but tracheal intubation and suctioning should be performed selectively, depending on the condition of the infant. Infants with a high Apgar score (i.e., 7-9) need no additional airway management. Infants with a low Apgar score or who are clinically obstructed with meconium should have the appropriate resuscitative measures taken.

Transition and Maturation of the Renal System

The fetal kidneys and the fetal lungs have certain similarities. During the fetal period, both have a relatively low blood flow compared with that during the newborn and neonatal periods because both organs need only enough blood flow for growth and development. The maternal placenta removes fetal waste material. The major function of the fetal kidneys is the production of urine; this contributes to the formation of amniotic fluid, which is important for the normal development of the fetal lung, and acts as a shock absorber for the fetus. The fetal kidney is characterized by a low renal blood flow (RBF) and glomerular filtration rate (GFR).[11] There are four major reasons for the low RBF and GFR: low systemic arterial pressure, high renal vascular resistance, low permeability of the glomerular capillaries, and the small size and number of glomeruli. The low systemic arterial pressure and high vascular resistance are the two characteristics that are similar to those found in the fetal lung. This results in a low RBF, which in turn results in a low GFR. Transition changes the first two factors: the systemic arterial pressure increases and the renal vascular resistance decreases. Again, this is similar to what occurs in the lung. The other two factors are changed through maturation. The limited ability of the newborn's kidney to concentrate or dilute urine results from the low GFR at birth. However, during the first 3 to 4 days, the circulatory changes increase RBF and GFR and improve the neonate's ability

to concentrate and dilute the urine. The maturation continues, and by the time the normal full-term infant is 1 month of age, the kidneys are approximately 60% mature. This is sufficient renal function to handle almost any contingency.

The neonatal kidney does have certain limitations. The renin-angiotensin-aldosterone system is the primary compensatory system for the reabsorption of sodium and water to compensate for the loss of plasma, blood, gastrointestinal tract fluid, and third-space fluid. Aldosterone facilitates the reabsorption of sodium in the distal tubule. The immature tubular cells cannot completely reabsorb sodium under the stimulus of aldosterone so the neonate continues to excrete sodium in the urine, even in the presence of a severe sodium defect. For this reason, the neonate is considered an “obligate sodium loser.” In the mature state, the distal tubule can reabsorb essentially all the sodium so the urine has less than 5 to 10 mEq of sodium per liter of urine. In the neonate, this number may be as high as 20 to 25 mEq of sodium per liter of urine.

Fluid and Electrolyte Therapy in the Neonate

The inability of the neonatal distal tubule to respond fully to aldosterone results in the obligatory sodium loss in the urine. Therefore, intravenous fluids in the neonate must contain sodium. Most operations on neonates involve loss of blood and extracellular fluid, which must be replaced with a fluid of similar electrolyte content (i.e., a balanced salt solution such as lactated Ringer's or Plasmalyte).

The other problems of the neonate are those of appropriate glucose administration. Infants of diabetic mothers and those small for gestational age have particular problems with hypoglycemia. These infants need to have their blood glucose values monitored. Neonates who are scheduled for surgery and have been receiving hyperalimentation fluids or supplementary glucose must continue to receive that fluid during surgery or must have their glucose levels monitored because of concerns of hypoglycemia. There is no consensus on the issue of what constitutes hypoglycemia.[12] This concern must be balanced against the potential augmentation of ischemic injury by the administration of glucose leading to hyperglycemia. Interestingly, in a more recent study in infants undergoing cardiac surgery, low glucose concentrations tended to relate to electroencephalographic seizures, and high glucose concentrations were not associated with worse neurodevelopmental outcomes. The authors concluded that avoiding hypoglycemia was preferable to restricting glucose in infants having cardiac surgery.[13]

Premature infants and neonates must receive full-strength balanced salt solution for the replacement of third-space and blood losses during the perioperative period.[14] There is a misconception that these infants cannot tolerate the salt load; therefore, they are often given hypotonic fluids. It is not unusual to see premature infants with postoperative sodium values of 125 to 130 mEq/L. Alone, these levels may not be a major problem, but when added to the residual effects of muscle relaxants and antibiotics in a sick infant, they may result in depression of neuromuscular function.

ANATOMIC AND MATURATIONAL FACTORS OF NEONATES AND THEIR CLINICAL SIGNIFICANCE

Anatomy of the Neonatal Airway

3 The anatomic and maturational factors unique to the neonatal airway have far-reaching clinical implications (Fig. 43-5). Neonates are obligate nose breathers; therefore, anything that obstructs the nares compromises the neonate's ability to breathe. For this reason, choanal atresia is a life-threatening surgical problem for the neonate. The large tongue occupies relatively more space in the infant's airway and makes it difficult to conduct a laryngoscopic examination and intubate the infant's trachea. In the normal adult, the glottis is at the level of C5. In the full-term infant, the glottis is at the level of C4, and in the premature infant, it is at the level of C3. The combination of a large tongue and a relatively high glottis means that on laryngoscopic examination it is more difficult to establish a line of vision between the mouth and larynx; there is relatively more tissue in less distance. Therefore, the infant's larynx appears to be anterior. When combined with the anterior-slanting vocal cords, the result is a more difficult laryngoscopic examination and intubation. Application of cricoid pressure by the anesthesiologist or an assistant improves visualization of the neonate's larynx. If the anesthesiologist's hand is large enough, cricoid pressure can be applied with the little finger (Fig. 43-6).

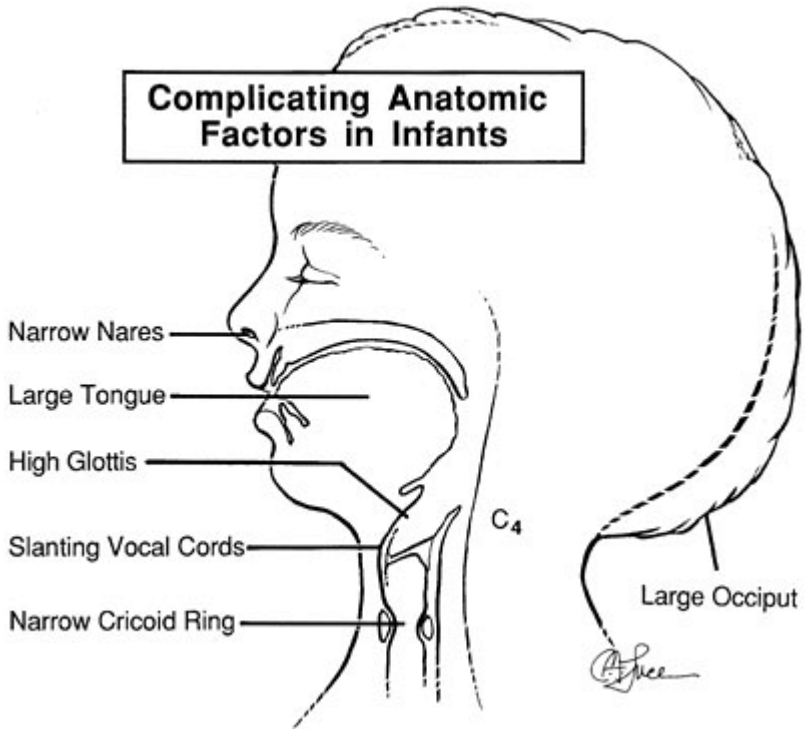

FIGURE 43-5. Complicating anatomic factors in infants. (Modified with permission from Smith RM: Anesthesia for Infants and Children, 4th ed, p 16. St Louis, Mosby, 1980.)

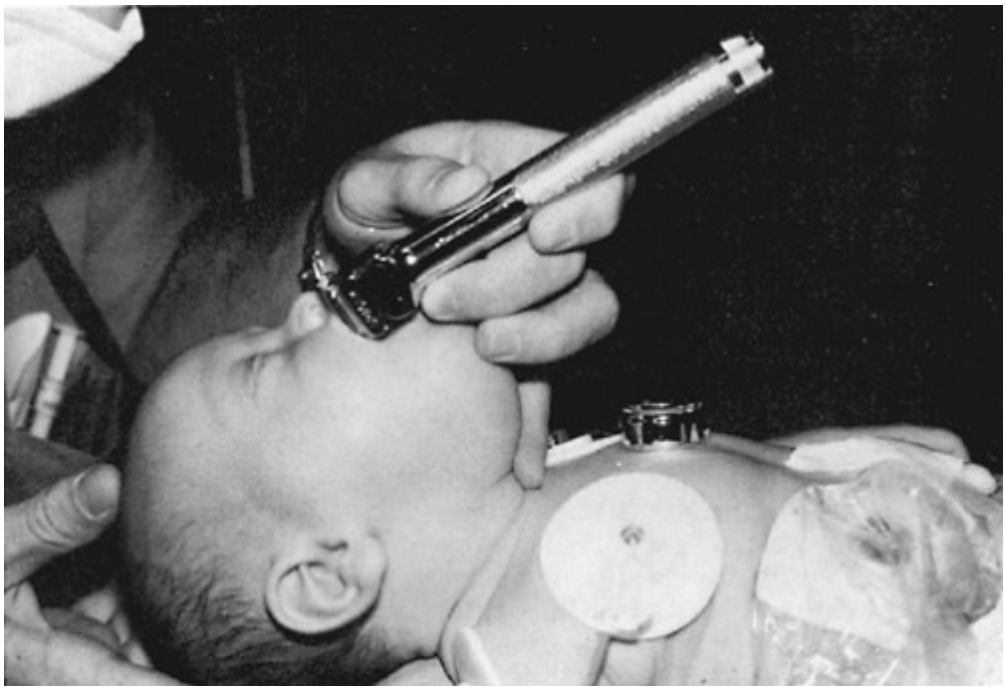

FIGURE 43-6. Cricoid pressure applied with little finger. (Reprinted with permission from Physiology and surgery of the infant. In Berry FA [ed]: Anesthetic Management of Difficult and Routine Pediatric Patients, Fredrick A. Berry Chapter 5 Physiology and Surgery of the Infant. p 129. New York, Churchill Livingstone, 1990.)

A narrow cricoid ring is significant because it means that the narrowest portion of the neonate's

airway is not the vocal cords but the cricoid ring. In the mature state, the airway from the vocal cords down the trachea is of equal dimensions (Fig. 43-7), and if the endotracheal tube passes comfortably through the vocal cords, it will not be tight within the cricoid cartilage. However, the neonate's laryngeal structures resemble a funnel; even though the endotracheal tube may pass through the vocal cords, which are at the midpoint of the funnel, the endotracheal tube may be tight within the cricoid ring. This tight fit may cause temporary or permanent damage to the cricoid cartilage, resulting in short-term or long-term airway difficulties.

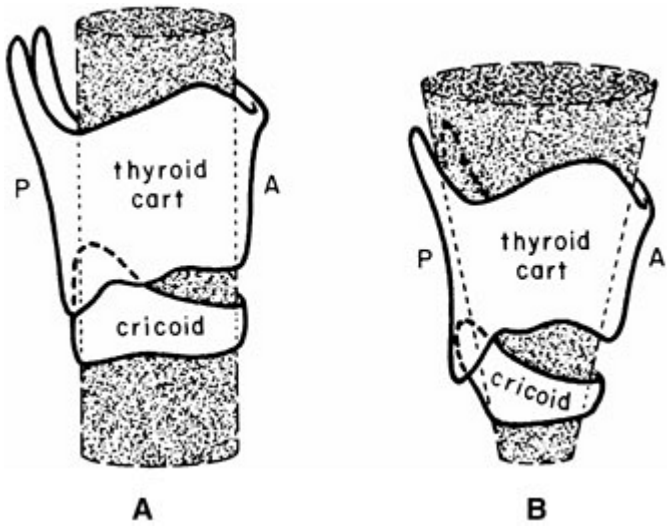

FIGURE 43-7. Configuration of the adult (**A**) versus the infant larynx (**B**). The adult larynx has a cylindrical shape. The infant larynx is funnel shaped because of the narrow, undeveloped cricoid cartilage. (Reprinted with permission from The pediatric airway. In Ryan JF, Charles J. Coté and I. David Todres [eds]: A Practice of Anesthesia for Infants and Children, 2nd ed, p 61. Orlando, FL, Grune & Stratton, 1992.)

Finally, the infant has a large occiput so the head flexes forward onto the chest when the infant is lying supine with its head in the midline (Fig. 43-8A). Extreme extension can also obstruct the airway, so a midposition of the head with slight extension is preferred for airway maintenance. This is accomplished by placing a small roll at the base of the neck and shoulders (Fig. 43-8B).

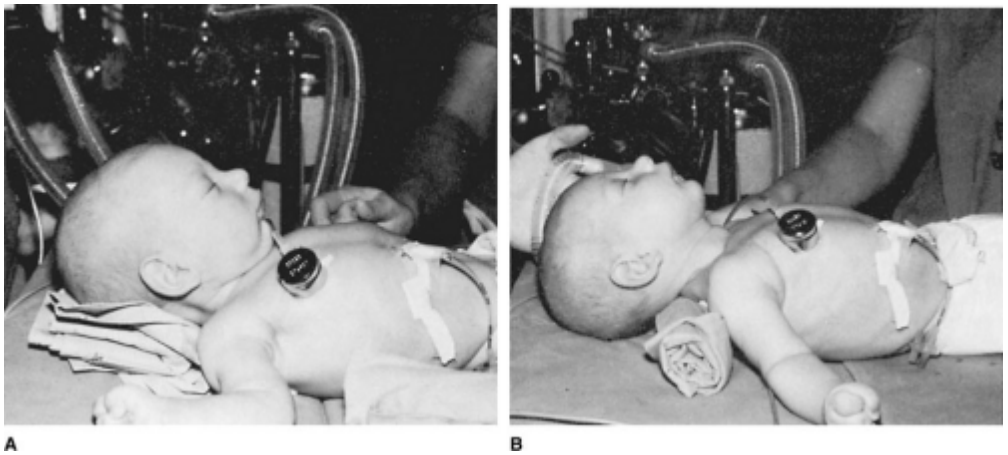

FIGURE 43-8. A. Pad placed under occiput in an attempt to achieve a “sniffing” position obstructs the infant's airway. **B.** Pad is placed under infant's neck to improve the airway

patency and for laryngoscopic examination.

The Pulmonary System

4 Anatomically and physiologically, the neonate's pulmonary system differs in at least four respects from that of the adult: high oxygen consumption, high closing volumes, high ratio of minute ventilation to FRC, and pliable ribs. The oxygen consumption of the infant is 7 to 9 mL/kg/min, whereas in the adult it is 3 mL/kg/min. Therefore, varying degrees of airway obstruction have more impact on oxygen delivery and reserve in the neonate and in the infant in the mature state.

The high closing volumes of the neonate's lungs are within the range of the normal tidal volume (Fig. 43-9). Closing volumes are the lung volumes at which alveoli close, resulting in the shunting of blood by a closed alveolus. If an infant experiences mild laryngospasm and a reduction in lung volume, the high closing volume contributes to shunting of blood and rapid desaturation. When a high oxygen consumption is combined with a high closing volume in the presence of laryngospasm, the rapidity with which desaturation occurs is breathtaking not only for the infant, but also for the anesthesiologist. When coughing and breath-holding occur with an endotracheal tube in place, the situation is not much different because there is an inability to ventilate the alveoli. Positive pressure ventilates the large airways, but there is no oxygen delivery to the closed alveoli. Therefore, even though an endotracheal tube may be in the appropriate anatomic location, severe desaturation can occur in infants who are lightly anesthetized and are coughing on the

endotracheal tube. At times, because of inability to oxygenate the infant, it might be incorrectly believed that the endotracheal tube has come out of the trachea. The high intrathoracic pressure along with hypoxia, which increases pulmonary vascular resistance, may well cause right-to-left shunting either through the ductus arteriosus or through the foramen ovale. Management of the patient in this situation entails deepening the anesthesia or paralysis. This can be done with either small intravenous doses of succinylcholine, 0.5 mg/kg, or intravenous lidocaine, 1.5 mg/kg. Caution must be taken not to exceed this dose of lidocaine in the neonate.

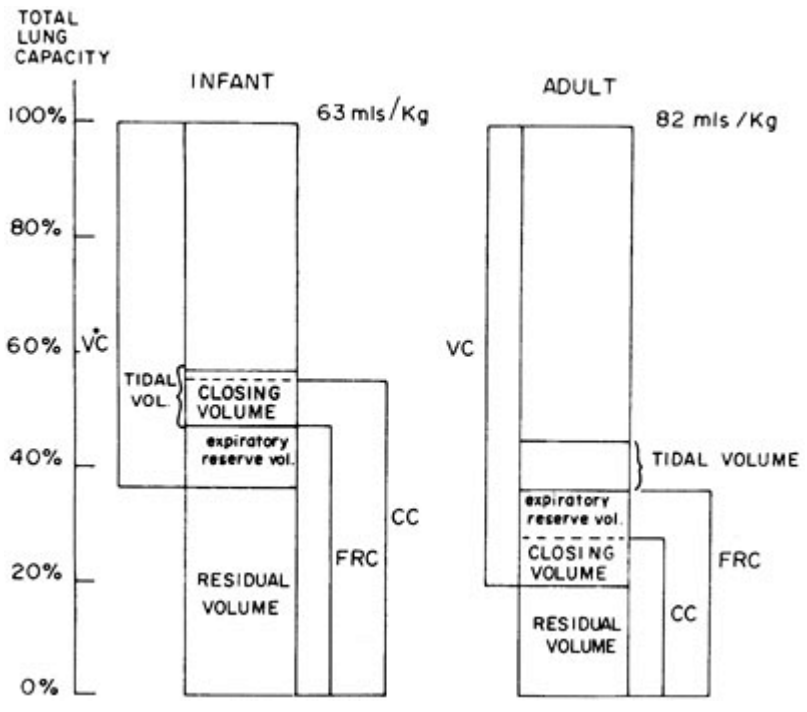

FIGURE 43-9. Static lung volumes of infants and adults. (Reprinted with permission from

Smith CA, Nelson NM: Physiology of the Newborn Infant, 4th ed, p 207. Springfield, IL, Charles C Thomas, 1976.)

The third unique pulmonary feature of the neonate is the high ratio of minute ventilation to FRC, which is similar to that of the term pregnant woman but occurs for different reasons. The pregnant woman has a reduction in FRC because of elevation of the diaphragm by the uterus. The neonate has increased alveolar ventilation because of the need to increase oxygen

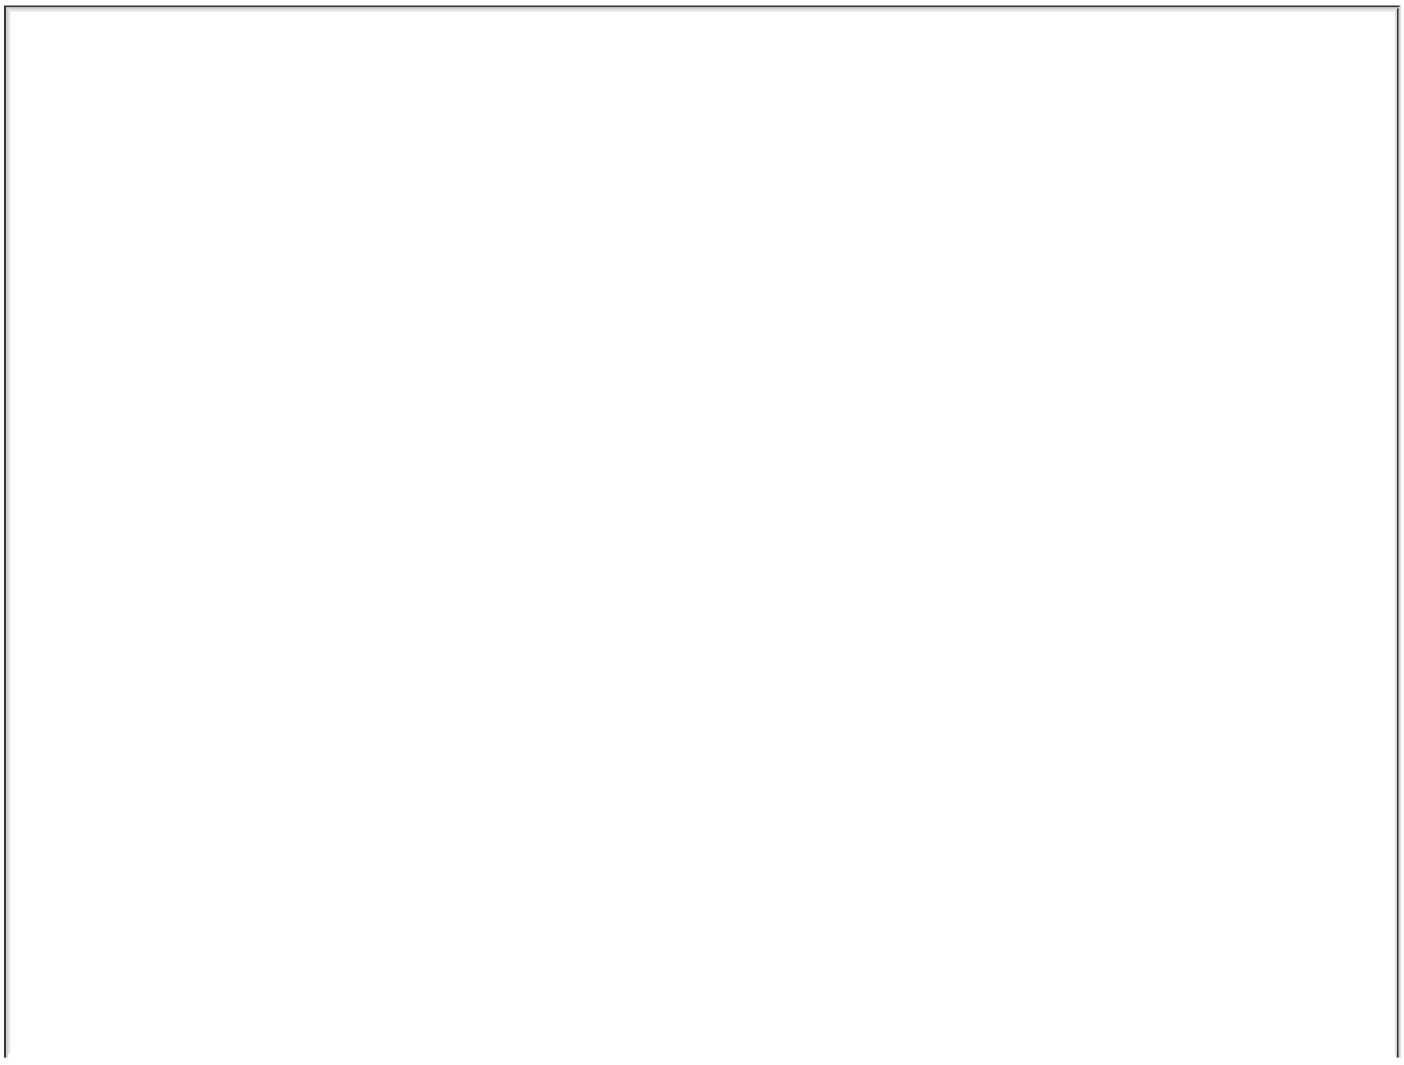
delivery secondary to the high oxygen consumption. Table 43-2 compares the normal respiratory values for newborns and adults.

TABLE 43-2 Comparison of Normal Respiratory Values in Infants and Adults

▪PARAMETER	▪INFANT	▪ADULT
Respiratory frequency	30–50	12–16
Tidal volume (mL/kg)	7	7
Dead space (mL/kg)	2–2.5	2.2
Alveolar ventilation (mL/kg/min)	100–150	60
Functional residual capacity (mL/kg)	27–30	30
Oxygen consumption (mL/kg/min)	7–9	3

The tidal ventilation for an infant is the same, in milliliters per kilogram, as for the adult; therefore, with oxygen consumption that is three times greater, the respiratory rate must be three times greater, which results in alveolar ventilation that is three times greater. Consequently, the ratio of minute ventilation to FRC is 5:1 in the neonate, whereas in adults it is 1.5:1. The clinical implication of the high ratio of minute ventilation to FRC is that there is a much more rapid induction of inhalational anesthesia, as well as more rapid awakening. The more rapid induction of anesthesia also results from a higher percentage of the neonate's body weight consisting of vessel-rich tissues.

The fourth anatomic difference of the neonate is a pliable rib cage. When increased minute ventilation is needed, which requires an increase in respiratory frequency or tidal volume, the pliable ribs of the neonate are a disadvantage. The neonate's diaphragm is the major ventilatory muscle. To increase oxygen delivery by either an increase in frequency or excursion, the contraction of the diaphragm results in greater negative intrathoracic pressures. In older infants and children with a fixed rib cage, this results in an increase in air movement. However, with a pliable rib cage, the resulting increase in negative intrathoracic pressure results in retractions of ribs, as well as retraction in the subcostal and supraclavicular area. This results in less efficient ventilation and a high-energy price for the effort involved. This is one of the reasons why neonates are susceptible to fatigue with airway obstruction, pneumonia, and any other conditions



that result in interference with pulmonary function.

There are two types of muscles: type 1, slow-twitch, high-oxidative muscles, which are necessary for sustained muscle activity; and type 2, fast-twitch, low-oxidative muscles, which have an immediate but short activity.[15] The development of type 1 muscles is necessary for sustained ventilatory activity. The premature infant has 10% type 1 and the newborn 25% type 1 muscles in the diaphragm, which is the primary muscle for ventilation. The infant's diaphragm achieves maturity of type 1 muscles at approximately 8 months of age. At that point, he or she has approximately 55% type 1 muscles. The intercostal muscles are the other ventilatory muscles. The premature infant has 20% type 1 intercostal muscles and the newborn, 46%. The age of maturity for these muscles is 2 months, when type 1 muscles comprise 65% of the total.

The Cardiovascular System

Heart and Sympathetic Nervous System

The ability of the neonate's immature cardiovascular system to respond to stress is limited by the relatively low contractile mass per gram of cardiac tissue, which results in a limited ability to increase myocardial contractility and a reduction in ventricular compliance.[16] The clinical implication of this limited compliance of the ventricle means that, although there may be some ability to increase stroke volume, it is extremely limited. Therefore, any increase in cardiac output must be accomplished by an increase in heart rate. For this reason, the infant is said to be rate dependent for its cardiac output. Thus, any slowing of the heart rate is reflected in a reduction in cardiac output. This is why bradycardia has such serious consequences for the infant. Hypoxia is a major cause of bradycardia in the neonate. Even in the absence of stress, the neonatal heart has limited ability to increase cardiac output compared with the mature heart (Fig. 43-10). The resting cardiac output of the immature heart is close to the maximal cardiac output, so there is a limited reserve. The mature heart can increase cardiac output by 300%, whereas the immature heart can only increase cardiac output by 30 to 40%.

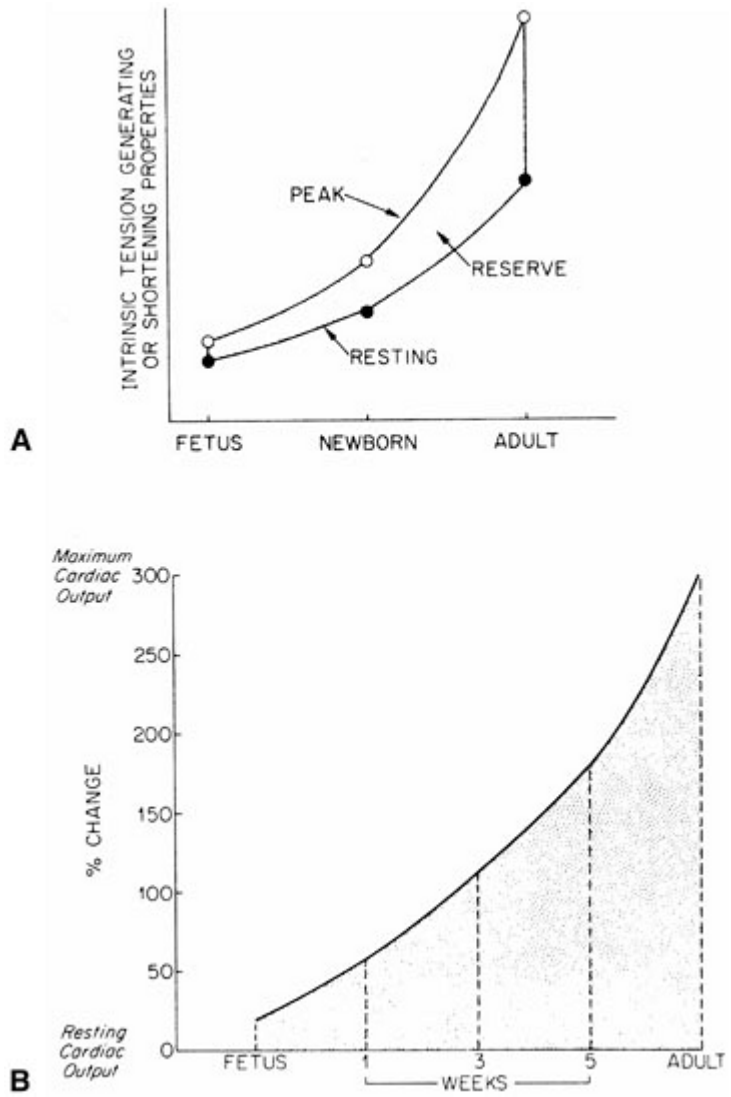


FIGURE 43-10. Schema of reduced cardiac reserve in fetal and newborn animal hearts compared with adult hearts. **A.** In the newborn infant, resting cardiac muscle performance is close to a peak of ventricular function because of limitations in diastolic, systolic, and heart rate reserve. **B.** Similarly, pump reserve early in life is limited by these factors and by much higher resting cardiac output relative to body weight, compared with that in adults. (Reprinted with permission from Friedman WF, George BL: Treatment of congestive heart failure by altering loading conditions of the heart. J Pediatr 106:700, 1985.)

In summary, the neonatal heart has some significant limitations. The resting cardiac output is much higher relative to body weight than in the adult because of the higher O_2 consumption per kg body weight. Stimulation of the myocardium produces a limited increase in contractility and cardiac output. The sympathetic nervous system, which usually provides the important chronotropic and inotropic support to the mature circulation during stress, is severely limited in the neonate because of immaturity.

Baroresponse

Neonates have immature baroreceptors. The baroreceptor is responsible for the reflex tachycardia that occurs in response to hypotension. Therefore, the immaturity of this reflex would limit the neonate's ability to compensate for hypotension. In addition, the baroresponse of the neonate is more depressed than that of the adult at the same level of anesthesia.

ANESTHETIC DRUGS AND THE NEONATE

Anticholinergic Drugs

There is controversy about the need for routine premedication with anticholinergics. The neonate is at risk for developing bradycardia due to increased vagal activity. This may manifest during induction, with suctioning, during laryngoscopy, or after administration of succinylcholine. Because of these concerns, many anesthesiologists routinely administer anticholinergics either before or during surgery to infants younger than 6 months of age. We administer anticholinergics only for specific indications. One of the major indications for anticholinergics is to reduce secretions. The management of a difficult infant airway can be simplified by reducing secretions. The dose of atropine in the neonate is 0.02 mg/kg; for glycopyrrolate, it is 0.01 mg/kg. These drugs can be administered orally, rectally, intravenously, or intramuscularly.

Inhalational Agents

Nitrous oxide is usually considered a reasonably benign anesthetic drug from the standpoint of the cardiovascular system. However, in adult patients, when nitrous oxide is combined with opioids, the cardiac index and arterial pressure decrease because of myocardial depression. Nitrous oxide has mild depressant effects on systemic hemodynamics in sedated infants, similar to those reported in adults, but does not produce the elevations in pulmonary artery pressure and pulmonary vascular resistance that are seen in adults. Therefore, it appears that nitrous oxide is a reasonable drug in neonates if there is no concern for expanding gas pockets within the body (i.e., pneumocephalus, intestinal obstruction, pneumothorax) and no need for a high FIO_2 to maintain saturation.

All the volatile anesthetics affect the cardiovascular system. Halothane has little effect on peripheral vascular resistance; therefore, the decrease in blood pressure that accompanies the administration of halothane results from myocardial depression.[17] However, isoflurane, desflurane, and sevoflurane decrease systemic vascular resistance so the major effect on blood pressure is a decrease in peripheral vascular resistance.[18]

Neuromuscular Blocking Agents

Neuromuscular blocking agents (NMBAs) are frequently used during neonatal anesthesia to facilitate tracheal intubation, assist with controlled ventilation, relax abdominal musculature, and ensure immobility. Factors that influence the choice of agent include the time of onset, duration of action, cardiovascular effects, and mechanism of clearance/elimination.

Succinylcholine

Succinylcholine, the only depolarizing muscle relaxant available, has the most rapid onset time of all the NMBAs. The neonate and infant have a larger extracellular fluid volume leading to a larger volume of distribution and an increased dose requirement compared with children and adults.[19] The recommended intravenous dose of succinylcholine for neonates and infants is 3 mg/kg, compared with 2 mg/kg in children, with an onset time of 30 to 45 seconds and duration of 5 to 10 minutes. The recommended intramuscular dose of succinylcholine is 4 mg/kg, with an onset time of 3 to 4 minutes and duration of approximately 20 minutes. Caution should be exercised when administering a second dose of succinylcholine because this can lead to vagally mediated bradycardia or sinus arrest. Pretreatment with atropine is recommended.

The more recent succinylcholine controversy has called into question the use of succinylcholine in male children younger than 8 years of age.[20] The reports of hyperkalemia with cardiac arrest in such children with unrecognized muscular dystrophy has led some clinicians to take the position that succinylcholine should not be used routinely for this group of patients. The occurrence of this problem is somewhere in the range of 1 in 250,000 anesthetics, with a mortality rate of 50%. However, succinylcholine is still recommended in rapid-sequence situations, a potentially difficult

airway, or if there are airway emergencies with a developing desaturation. In the emergency airway situation, the clinician should not wait to use succinylcholine until the patient becomes severely desaturated and bradycardic. When it is evident that a neonate is obstructed by laryngospasm or any other reason and no progress is made in ventilation, then either intramuscular or intravenous succinylcholine should be administered. The anesthesiologist must know how to recognize and treat hyperkalemia.[21] Hyperkalemia can be recognized by peaked T waves. However, the clinician may not see this particular electrocardiographic change because it occurs 2 to 3 minutes after drug administration, when the anesthesiologist is attending to the airway. The hyperkalemia interferes with conduction, leading to a bradycardia and, if severe enough, cardiac arrest. The drug of first choice is epinephrine 5 to 10 µmg/kg. One of the actions of epinephrine is to stimulate the sodium–potassium pump and cause the potassium to reenter the cell, thereby reducing the serum level. If there is no response at this dose level, it should be increased incrementally until there is a response. Magnesium has been described as a treatment for hyperkalemia because it also antagonizes the effects of hyperkalemia, as does calcium.[22] The use of sodium bicarbonate to treat any metabolic acidosis that may occur with arrest is also believed to be useful because alkalosis decreases hyperkalemia. At the same time, the patient should be hyperventilated to reduce the CO_2, thereby encouraging a respiratory alkalosis.

Nondepolarizing Agents

5 The neonate's neuromuscular junction is more sensitive to nondepolarizing muscle relaxants, and the neonate has a larger volume of distribution because of a large extracellular fluid volume. These two effects tend to balance each other so, roughly speaking, the dose of a nondepolarizing muscle relaxant for an infant is similar to that for a child on a milligram per kilogram basis. The ongoing organ maturation, which continues during the neonatal period, has a tremendous impact on the metabolism and clearance of the nondepolarizing agents. As a result, there is considerable variability and unpredictability in the duration of action of these agents in the neonatal period. Dosing should be titrated to effect and, when possible, guided by monitoring neuromuscular function with a nerve stimulator.

Rocuronium appears to be the drug of choice among the intermediate-acting, nondepolarizing muscle relaxants. The dose of rocuronium is 0.6 mg/kg. The length of action of rocuronium in the neonate is similar to that in the older infant or child following an equipotent dose.[23] However, if a larger dose of rocuronium, 1.0 to 1.2 mg/kg, is administered to avoid using succinylcholine during a rapid-sequence induction, then rocuronium will be a relatively long-acting muscle relaxant. Rocuronium is metabolized by the liver; however, unlike vecuronium there are no active metabolites. Rocuronium has mild vagolytic properties and may slightly increase heart rate.

Although vecuronium is considered an intermediate-acting muscle relaxant in children and adults, in infants younger than 1 year of age it is considered a long-acting muscle relaxant.[24] The duration of action of vecuronium is approximately twice that observed in children because of liver immaturity. Vecuronium undergoes primarily hepatic metabolism with production of active metabolites that are dependent on renal excretion. The recommended dose of vecuronium is 0.1 to 0.15 mg/kg with an onset time of 90 seconds and duration of action of 60 to 90 minutes in the neonate. Even with increased doses, vecuronium has no effect on the cardiovascular system.[25]

Pancuronium is a long-acting NMBA with a pharmacokinetic profile similar to vecuronium. The recommended dose of 0.1 to 0.15 mg/kg has an onset time of 120 seconds and duration of 60 to 75 minutes. Unlike vecuronium, however, pancuronium primarily undergoes renal excretion. Pancuronium has vagolytic and sympathomimetic actions that cause tachycardia and an increase in blood pressure.[26] If a neonate is moribund or in shock, or there is concern about the volume status, then pancuronium may well be the muscle relaxant of choice. However, in a relatively normal neonate with a normal blood pressure and normal blood volume, the use of pancuronium may result in hypertension, which has the potential to increase blood loss and increase the risk of hemorrhage in the extremely premature neonate.

Reversal Agents

Due to the unpredictable nature of the NMBAs in the neonatal population, as well as the inability to accurately assess neuromuscular function in many situations, it has become common practice to reverse all nondepolarizing NMDAs in neonates. The two commonly used reversal agents are edrophonium and neostigmine. Edrophonium in a dose of 1 mg/kg achieves a 90% reversal of a neuromuscular block in 2 minutes, whereas neostigmine in a dose of 0.07 mg/kg requires 10 minutes for a 90% reversal of neuromuscular block. This difference in time to peak effect allows the anesthesiologist to decide which agent is needed. A word of caution: when edrophonium is used to reverse neuromuscular blockade, the effect is so rapid that atropine should be administered before the edrophonium; some believe that atropine is superior to glycopyrrolate for this reversal. The dose of atropine is 0.01 to 0.02 mg/kg. Neostigmine is a suitable alternative for reversal of nondepolarizing muscle relaxants in neonates. The muscarinic effects of neostigmine can be blocked with atropine or glycopyrrolate (0.01 mg/kg), and the drugs can be given concurrently. The two advantages of edrophonium over neostigmine are a more rapid reversal and fewer muscarinic side effects.

Opioids

Opioids are mild vasodilators but have little direct effect on cardiac function. Cholinergic side effects of fentanyl may decrease the heart rate. If the neonate is hypovolemic, the administration of opioids may decrease blood pressure. However, if the infant is adequately volume resuscitated, the administration of opioids should have little effect on the blood pressure.[27,28]

A study of the dose-response relationship of fentanyl in neonates undergoing surgery demonstrated that, in doses of 10 to 12.5 µg/kg, fentanyl produced a stable hemodynamic state and reliable anesthesia as determined by the heart rate and blood pressure.[28] The doses were given in increments of 2.5 µg/kg. In all infants in the study, heart rate and systolic blood pressure decreased with the administration of fentanyl. One of the concerns with the administration of opioids in neonates is the altered pharmacokinetics and pharmacodynamics.[29,30] In one study, 25 to 50 µg/kg of fentanyl resulted in unpredictable respiratory effects and, in some neonates, postoperative respiratory depression. There was a prolonged metabolism of the fentanyl, particularly in those with increased intra-abdominal pressure. This was believed to be due to a reduction in liver blood flow and hence metabolism of fentanyl—evidence of altered pharmacokinetics. In addition, it also appeared that newborns were more sensitive at the same plasma level to the respiratory depressant effects of fentanyl—evidence of altered pharmacodynamics.

Traditionally, morphine has been avoided in neonates because of adverse side effects, including respiratory depression. On a pharmacokinetic basis, morphine has been shown to have a longer half-life and decreased plasma clearance in neonates compared with children and adults. Pharmacodynamically, the plasma concentration of morphine required to produce adequate analgesia is higher in neonates than infants and children. Studies have failed to detect morphine-6-glucuronide, a metabolite of morphine with potent analgesic properties, in neonates. This has been attributed to the immaturity of the neonate's liver.[31]

Intravenous Agents

Ketamine has unique cardiovascular effects.[32] Its action is centrally mediated through the sympathetic nervous system, and it can cause a release of norepinephrine. Ketamine in vitro has negative inotropic effects. However, on balance, ketamine can override the depressant effects on the myocardium and overall results in support of the cardiovascular system. Therefore, ketamine is a useful agent for the infant who has an unstable cardiovascular system or in whom there is some question about volume repletion. The intravenous induction dose of ketamine is 1 to 2 mg/kg in titrated doses, followed by 0.5 to 1 mg/kg every 15 to 30 minutes.

ANESTHETIC MANAGEMENT OF THE NEONATE

The anesthesiologist has a host of anesthetic techniques from which to choose and can tailor the anesthetic to the requirements of the surgery and the condition of the neonate. The three major factors to consider in selecting an anesthetic technique are (1) whether it is anticipated that the neonate will be extubated at the end of surgery or shortly thereafter, (2) the need to control blood pressure, and (3) the need for postoperative pain relief. The drugs and techniques available to achieve these goals are many, and include inhalational anesthetics, regional techniques, muscle relaxants, opioids, and ketamine. If extubation is anticipated at the end of surgery or shortly thereafter, the anesthetic must be tailored so there are minimal residual effects from inhalational agents and muscle relaxants, thereby allowing the infant to be awake and in control of its airway reflexes, which promotes early extubation. The use of a regional anesthesia technique, such as a caudal technique, reduces the need for inhalational agents, opioids, and muscle relaxants. There are great advantages to using a combined general and regional technique when early extubation is anticipated. Yet, if the management plan is to leave the infant intubated and ventilated for a longer time, then the choice of anesthetic technique and muscle relaxant depends on other factors, such as the need to control blood pressure and the length of postoperative ventilation.

The neonate who is moribund or who has a severely compromised cardiovascular status needs resuscitation. The use of ketamine or opioids and a muscle relaxant can be advantageous when caring for the hemodynamically unstable infant. The normal full-term neonate has a systolic blood pressure between 60 and 70 mm Hg. For purposes of controlled hypotension, a blood pressure of 50 to 60 mm Hg is desired. As the neonate's status improves, anesthetic drugs may be titrated. Nitrous oxide can be added, providing oxygenation is closely monitored and expansion of any gas pocket in the body is considered. In the case of intestinal obstruction, the use of air along with appropriate concentrations of oxygen and a volatile drug is indicated.

Tracheal Intubation

One of the frequently asked questions about the anesthetic management of neonates is whether tracheal intubation is routinely needed or if the airway and ventilation can be managed with the laryngeal mask airway. The answer to this question depends on the skill of the anesthesiologist and the surgical procedure, but in most clinical situations, the neonate should be intubated because of various anatomic and physiologic considerations. If the anesthesiologist is skilled and the surgery is short, intubation may not be necessary and a laryngeal mask airway can be used. Another question is whether to control the ventilation of all neonates. If the overall condition of the neonate is healthy and the procedure is short, then spontaneous ventilation is certainly acceptable. However, if the neonate is

debilitated, has had a relatively long-standing illness, has circulatory instability, and requires muscle relaxation for the surgery, then intraoperative controlled ventilation of the lungs is indicated.

Opinion on whether to perform an awake tracheal intubation in the neonate has changed in the last several years. There is concern that awake tracheal intubation causes hypertension and that the hypertension

can rupture the fragile intracerebral vessels, particularly in premature infants. There are times when awake tracheal intubation would seem to be the technique of choice, such as in neonates who are critically ill and need resuscitation.

Topical anesthesia is used to reduce laryngospasm during intubation with volatile agents. Topical anesthesia of the larynx may be achieved with 4 to 5 mg/kg of 2% lidocaine sprayed on the larynx and vocal cords. Lidocaine 2% is preferred to higher concentrations in these small infants because it is easier to control the dose.

The question of extubation of the trachea is considerably easier to answer. The awake state is associated with control of the airway reflexes. Partially anesthetized infants are susceptible to laryngospasm and its associated apnea. Laryngospasm, apnea, and high oxygen consumption are a

devastating combination. Therefore, the trachea should be extubated when the neonate is awake. An awake neonate opens his or her eyes, grasps the endotracheal tube, and cries. Crying cannot be heard because of the endotracheal tube but can be readily visualized. Any of these findings indicates that the infant is ready for extubation. If there is any doubt, however, the neonate should remain intubated until the clinician feels comfortable that the neonate can be extubated.

Impact of Surgical Requirements on Anesthetic Technique

Blood loss and muscle relaxation are two areas of concern for the surgeon and anesthesiologist. Parents and health care workers are also concerned about the transmission of AIDS and hepatitis through transfusions of blood and blood products. The use of blood and blood products should be minimized whenever possible. One way to minimize blood replacement is to minimize blood loss. This can be achieved through the control of blood pressure by the various anesthetics and muscle relaxants. Volatile anesthetics reduce blood pressure by 20 to 30%. Blood replacement is indicated if the neonate has demonstrated circulatory instability and considerable blood loss is anticipated. However, if the neonate is basically healthy, the anticipated blood loss is 25 to 30% of the blood volume, and the final hemoglobin is in the range of 8 to 9 g/dL, then blood transfusion probably can be avoided. The anesthesiologist can tailor the anesthetic to control the blood pressure and thereby reduce blood loss.

Uptake and Distribution of Anesthetics in Neonates

Various reasons for the faster uptake of anesthetics in infants have been proposed: (1) the ratio of alveolar ventilation to FRC is 5:1 in the infant and 1.5:1 in the adult; (2) in the neonate, more of the cardiac output goes to the vessel-rich group of organs, which includes the heart and brain; (3) the neonate has a greater cardiac output per kilogram of body mass; and (4) the infant has a lower blood gas partition coefficient for volatile anesthetics. One not well-recognized factor that may result in higher concentrations of volatile anesthetics being administered to infants has to do with the use of nonrebreathing systems such as the Bain or a Mapleson “D” circuit. When an adult circle system is used with infant tubes and bag, the clinician experienced with this equipment is used to reading the inspired, end-tidal, and dialed concentrations of the volatile anesthetic. In the circle system, the inspired concentration is a result of the combination of the end-tidal concentration that is rebreathed through the soda lime absorber and the dialed concentration. The inspired concentration is always lower than the dialed concentration, unless the flow rates are so high that a nonrebreathing system has been created. In the nonrebreathing system, the dialed concentration is the inspired concentration. Clinicians who use both systems are accustomed to these subtle differences. However, if the clinician switches back and forth between the circle system and a nonrebreathing circuit, but does so infrequently, there is a danger of not recognizing the possibility of excessive overpressure of volatile anesthetics with the nonrebreathing systems.

Anesthetic Dose Requirements of Neonates

Neonates and premature infants have lower anesthetic requirements than older infants and children.[33] The easiest way to remember the MAC values is that the MAC value in the mature state (i.e., late teenager or adult) is the same as for a full-term infant. By 6 months of age, the MAC value has increased by 50%. In the premature infant, the MAC value decreases by 20 to 30%.[33,34] The reasons for the lower MAC requirements are believed to be an immature nervous system, progesterone from the mother, and elevated blood levels of endorphins, coupled with an immature blood-brain barrier. The neonate has an immature central nervous system with attenuated responses to nociceptive cutaneous stimuli. These responses rapidly mature in the first several months of an infant's life, along with an increase in the MAC. Progesterone has been shown to reduce the MAC of the pregnant mother. The newborn infant has elevated progesterone levels, similar to those of the mother. Elevated levels of β-endorphin and β-lipotropin have been demonstrated in infants in the first few days of postnatal life. Endorphins do not cross the blood-brain barrier in adults; however, it is believed that the neonate's blood-brain barrier is more permeable and that endorphins might well pass into the central nervous system, thus elevating the pain threshold and reducing the MAC requirement.

Regional Anesthesia

There has been a tremendous increase in the use of regional anesthesia in children. In general, the regional techniques are combined with general anesthesia to permit early extubation and provide postoperative pain relief. Early extubation is possible because the use of regional anesthetic techniques eliminates the need for intraoperative narcotics in neonates, reduces or eliminates the need for muscle relaxants, and reduces the concentration of volatile agents needed for relaxation. Spinal anesthesia has been reported to be effective when used as the sole anesthetic technique in premature and high-risk infants, but this technique requires excellent cooperation between the anesthesiologist and an experienced surgeon. Even at a dose of 0.5 mg/kg, the effects of tetracaine last only approximately 90 minutes in the neonate. Total spinal anesthesia, produced either with a primary spinal technique or secondary to an attempted epidural puncture, presents as respiratory insufficiency rather than as hypotension because of the lack of sympathetic tone in infants.[35] The exact mechanism for the lack of cardiovascular change with spinal anesthesia in infants and young children is not clear. One study suggests that the sympatholysis is offset by a decrease in parasympathetic activity, resulting in the withdrawal of cardiac vagal activity. The overall effect is no change in heart rate and blood pressure.[36] The first indication of a high spinal is falling oxygen saturation rather than a falling blood pressure. Sedation can be added to regional anesthesia but may cause problems of apnea in ex-premature infants.

The techniques of caudal, spinal, brachial plexus, and other blocks should be considered in all neonates. Caudal epidural block is frequently used for abdominal and thoracic surgery in neonates. There are several different techniques described for performing a caudal. We prefer the 22-gauge, short-bevel needle; the caudal space is identified both by the loss of resistance and the ease of administering the anesthetic. Once the sacrococcygeal membrane is penetrated and there is a loss of resistance, gentle aspiration is applied to the needle to determine if there is blood or cerebrospinal fluid (CSF). Injection of the anesthetic is then attempted. If there is difficulty in injecting the solution, the tip of the needle is not in the caudal space and it needs to be repositioned. If the anesthetic can be injected easily, this confirms placement in the epidural space. The needle is not advanced up the caudal canal after proper placement in the caudal epidural space has been accomplished. In one study that uses Longwell catheters for the caudal epidural, the catheter is advanced up the caudal canal.[37] They report an intravenous injection incidence of approximately 6% with this technique. Epinephrine is added to local anesthetic solutions for the purposes of determining if there is an intravascular injection of the anesthetic. Evidence of an intravascular injection includes (1) peaked T waves (which may be of relatively short duration, e.g., 30 seconds), and (2) increase in heart rate. The other technique to minimize the potential difficulties of an intravascular injection is to fractionate the dose by dividing the dose into three aliquots and waiting approximately 20 to 30 seconds between each aliquot before continuing the injection.

Caudal anesthesia is particularly effective at reducing the concentrations of volatile anesthetics needed, as well as relaxants and opioids. In addition, a single-injection caudal anesthetic can provide analgesia for 6 to 8 hours. The two local anesthetics currently in use are 0.25% bupivacaine or 0.2% ropivacaine. Epinephrine is added to local anesthetics to assist in determining if there has been an intravenous injection. The amount of epinephrine added should result in a 1:200,000 dilution of epinephrine (5 µmg/mL). Although ropivacaine has not been approved for use in infants, it does have several theoretical advantages. Because it is used in a concentration of 0.2%, compared with 0.25% for bupivacaine, less drug is being administered per milliliter of injectate. In addition, ropivacaine has been reported to be less cardiodepressant than equipotent doses of bupivacaine. If a caudal catheter is placed, an infusion of ropivacaine can be administered and provide analgesia for several days. Current recommendations for infusions in neonates and young infants are for an initial loading dose of 0.2 to 0.25 mg/kg; after 1 to 2 hours, an infusion can be begun in a dose of 0.2 mg/kg/hr. For older infants, toddlers, and children, the dosage range is 0.4 to 0.5 mg/kg/hr. The addition of clonidine, 1.0 to 2.0 µg/kg, to local anesthetic for caudal block has prolonged the duration of analgesia in small children.[38] However, there has been some controversy as to whether the addition of clonidine has contributed

to postoperative apnea in neonates and preterm infants.[39,40]

Another block that has become popular is a simple ring block of the penis for circumcision. Bupivacaine 0.25% is injected subcutaneously in a ring about the base of the penis. This way, there is no danger of causing a hematoma, which occasionally occurs with a penile block.

Postoperative Ventilation

The choice of an anesthetic drug should also be determined by the need for postoperative management of ventilation and by the drug's effects on the circulation. If the surgical procedure or the neonate's condition is such that postoperative ventilation is likely, the prolonged respiratory effects of opioids or any other drug are of little concern. However, if the surgical procedure is relatively short and by itself does not require postoperative ventilation, the clinician should carefully select drugs, as well as doses of anesthetic drugs and relaxants, that will not necessitate prolonged postoperative ventilation or intubation. Postoperative ventilation places the neonate at added risk because of the problems associated with mechanical ventilation, the trauma to the subglottic area, and the potential development of postoperative subglottic stenosis or edema. However, if there is any question about the neonate's ability to maintain protective airway reflexes or normal ventilation after anesthesia, the neonate should be returned to the recovery room or newborn intensive care unit with the trachea intubated, and either ventilated or treated with a small amount of positive end-expiratory pressure (PEEP) (2 to 4 cm H_2O).

Postoperative Pain Management

The concepts of postoperative pain management are well known to most anesthesiologists. The use of intraoperative epidural anesthesia followed by postoperative epidural local anesthetics or opioids has been popular in older children and adults, and these techniques are being applied to neonates. In addition, most neonatologists are experienced with the intravenous administration of opioids for patient comfort. Each technique has its own risks and benefits.

SPECIAL CONSIDERATIONS

Maternal Drug Use During Pregnancy

Maternal cocaine and marijuana use during pregnancy leads to a host of problems for the neonate. These drugs result in a reduced catecholamine reuptake, which may result in the accumulation of catecholamines. This has circulatory effects on the uterus, the umbilical blood vessels, and the fetal cardiovascular system. The three major problems affecting the infant are premature birth, intrauterine growth retardation, and cardiovascular abnormalities, including low cardiac output.[41,42] The cardiac output and stroke volume are reduced on the first day of life but return to normal by the second day. The clinical implication of this finding is that in infants of these mothers it may be advantageous to postpone any surgery until the second or third day of life. There is an increase in structural cardiovascular malformations and electrocardiographic abnormalities. The most frequent lesions are peripheral pulmonic stenosis, right ventricular conduction delay, right ventricular hypertrophy, and ST segment and T-wave changes.

Respiratory Distress Syndrome

Because of the enormous technical ability of the neonatologist and the resources of neonatal intensive care units (NICUs), many small infants survive who need surgery. One of the frequent problems of these infants is the occurrence of the respiratory distress syndrome secondary to a deficiency of surfactant. Respiratory distress syndrome is not an all-or-none disease; there are varying degrees of the disease and various treatments

for it. Exogenous surfactant has been widely used in premature infants of low birth weight either to prevent or to treat respiratory distress syndrome.[43] As a result, fewer infants now die of this entity, and the incidence of bronchopulmonary dysplasia in survivors has fallen. However, the use of exogenous surfactant appears to have had little impact on other complications of prematurity

such as PDA, necrotizing enterocolitis (NEC), or intraventricular hemorrhage.

Postoperative Apnea

A major concern with surgery in neonates is the development of apnea in the postoperative period. The infants at highest risk are those born prematurely, those with multiple congenital anomalies, those with a history of apnea and bradycardia, and those with chronic lung disease. The etiology of this apnea is multifactorial. Decreased ventilatory control and hyporesponsiveness to hypoxia and hypercarbia may be potentiated by anesthetic agents. Respiratory muscle fatigue may also play a role because neonates have a smaller percentage of type I fibers in their diaphragm and intercostal muscles. Hypothermia and anemia may also contribute to the development of postoperative apnea.[44,45,46,47] The treatment of postoperative apnea may be as simple as tactile stimulation with “blow by” oxygen. However, some infants require prolonged intubation and ventilatory support. Infants with life-threatening apnea and bradycardia before surgery may be on central nervous system stimulants. Caffeine and theophylline both act by increasing central respiratory drive and lowering the threshold of response to hypercarbia, as well as stimulating contractility in the diaphragm. Caffeine is favored because of its wider therapeutic margin and decreased propensity for toxicity. Administering caffeine prophylactically to infants at risk of postoperative apnea to ensure adequate serum levels may prevent the need for prolonged periods of postoperative ventilatory support. The recommended loading dose is 10 mg/kg caffeine base.[48,49,50]

Those infants at high risk for development of postoperative apnea may benefit from the use of a regional anesthetic as opposed to general anesthesia. Multiple studies have shown that spinal anesthesia without supplemental sedation decreases the incidence of postoperative apnea and bradycardia in high-risk infants. Once supplemental sedation is used, inhalation or ketamine, this advantage is lost.[51,52]

The question remains as to which infant should be admitted and monitored after outpatient surgery and for how long. The most conservative approach is to monitor all infants younger than 60 weeks postconceptual age for 24 hours after surgery.[44] Many reports show that the incidence of significant apnea and bradycardia is highest in the first 4 to 6 hours after surgery, but they have been reported up to 12 hours after surgery. In addition, the incidence of apnea directly correlates to postconceptual age. Therefore, the most widely accepted guideline is to monitor all infants younger than 50 weeks' postconceptual age for at least 12 hours after surgery, even infants who have had a spinal as their sole anesthetic.[45,46]

Retinopathy of Prematurity

Advances in neonatal medicine have led to the survival of extremely premature infants (i.e., infants weighing <1,000 g and infants <28 weeks' gestation). These infants are at high risk for development of retinopathy of prematurity (ROP).[53] ROP is a common cause of blindness in these extremely premature infants. Although the exact etiology is unknown, variations in arterial oxygenation (hypoxia or hyperoxia) and prolonged exposure to bright light are believed to play a significant role. Hyperoxic vasoconstriction of retinal vessels, induction of vascular endothelial growth factor, and damage to spindle cells by oxygen-free radicals are some of the currently supported hypotheses in the pathogenesis of ROP.[54] Advances in the treatment of ROP have followed the advances in neonatal care that led to the increased incidence of ROP. ROP is staged as follows:

Stage 1: Presence of a demarcation line between vascularized and avascularized retina

Stage 2: Presence of a demarcation line that has height, width, and volume (ridge)

Stage 3: Presence of a ridge with extraretinal fibrovascular proliferation

Stage 4: Partial retinal detachment

Stage 5: Total retinal detachment

The early stages are treated with cryotherapy or laser. These treatments may be performed with sedation in the NICU or under general anesthesia in the operating room. The later stages require retinal surgery (scleral buckle or vitrectomy) to be performed under general anesthesia.[55] In addition, the anesthesiologist may be called on to anesthetize an infant with ROP for an unrelated surgery, such as hernia repair, ventriculoperitoneal shunt, or central line placement.

The question the anesthesiologist faces is what inspired oxygen concentration is safe under general anesthesia. There are no studies that document some threshold PaO_2 above which ROP develops. In addition, there are no studies that document the length of time that the PaO_2 has to remain above some threshold number. A study by Flynn et al.[56] suggested that the longer time the premature infant had a documented TCO_2 (transcutaneous oxygen) above 80 mm Hg, the higher the incidence of ROP. The guidelines for the administration of oxygen in premature infants is a goal of 50 to 80 mm Hg.[57] An oxygen saturation of 90 to 95% represents a PaO_2 of somewhere between 60 and 80 mm Hg. Therefore, it seems reasonable to try to maintain an oxygen saturation of 95% with minimal inspired oxygen while these premature infants are under general anesthesia. If the infant is experiencing episodes of hypotension or problems with ventilation, then attempts to micromanage the oxygen saturation should be secondary to the management of the primary problems. However, if an infant is stable, it might be appropriate to dilute the inspired oxygen with room air, nitrogen, or nitrous oxide until the saturation is in the neighborhood of 95%.

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is defined as the sudden death of an infant younger than 1 year of age that remains unexplained after complete autopsy, death scene investigation, and review of family history. SIDS is the most frequent cause of death in infants between the ages of 1 month and 1 year. Death from SIDS is relatively rare in the first month of life, with the peak occurring at the third to fourth months of life. Premature infants are known to be at increased risk. However, studies have failed to prove a relationship between apnea of prematurity and SIDS.[58] Data from the Collaborative Home Infant Monitoring Evaluation (CHIME) study suggest that preterm infants are at increased risk of having at least one extreme event until about 43 weeks' postconceptual age (PCA) compared with term infants. However, given the peak timing of SIDS deaths, these extreme events are not likely to be precursors to SIDS.[59] Epidemiologic studies suggest that the risk factors for SIDS include low birth weight, maternal smoking, maternal cocaine use, young maternal age, low socioeconomic status, and African American race.[60] There is currently no evidence that general anesthesia triggers SIDS.[61]

The relationship between infant sleep position and SIDS was evaluated in the early 1990s. It was noted that there was a 50% reduction of SIDS rates in those countries where there was a decline in prone positioning of infants. As a result, the American Academy of Pediatrics recommended that all well infants at term with no other problems be placed either on their side or on their back when sleeping.[62,63]

SIDS remains a mystery in many ways. Multiple theories have been proposed over the years, including the “infant apnea syndrome.” Many current theories focus on abnormalities of cardiorespiratory control during sleep states. In addition, more recent evidence suggests an abnormality in the maturational process of brainstem nuclei, particularly the arcuate nucleus. As a result, it is believed that these infants lack the normal homeostatic mechanisms necessary to respond to exogenous stressors during sleep.[64] A separate theory focuses on abnormalities in autonomic control during obstructive sleep events in infants at risk.[65]

Neurodevelopmental Effects of Anesthetic Agents

Parents will frequently ask whether anesthesia will harm their infant. More recent studies suggesting that anesthetic agents may be harmful to the developing brain are inconclusive. These

studies primarily performed in animals were done with prolonged exposure to high doses of agents; therefore, correlation to humans is difficult, and further investigation is warranted.[66]

SURGICAL PROCEDURES IN NEONATES

Surgical procedures in neonates are arbitrarily divided into two periods: those performed in the first week and those performed in the first month. Except for gastroschisis, which should be attended to within 12 to 24 hours, there are really no acute emergency operations in the neonate. This means that a period of 2 to 3 days can be allowed for stabilization or transport to an appropriate pediatric center for treatment. There is more to neonatal emergency surgery than just the immediate anesthetic and surgical procedure. Many of these infants require the support services of specialized nursing units, pediatric radiologists, pediatric intensive care physicians, and so forth. Managed care considerations should never take precedence over the appropriate care of infants and children.

Surgical Procedures in the First Week of Life

The five most frequent major surgical procedures performed in the first week of life are for CDH, omphalocele and gastroschisis, tracheoesophageal fistula (TEF), intestinal obstruction, and meningomyelocele. Some of these conditions, such as CDH, omphalocele and gastroschisis, and meningomyelocele, are obvious at birth. It may take hours or days for a TEF or intestinal obstruction to become manifest.

Two confounding factors in neonatal surgery are prematurity and associated congenital anomalies. The presence of one congenital anomaly increases the likelihood of another congenital anomaly. In conditions such as TEF, the mortality rate from the associated congenital heart defect is far higher than that from the surgical correction of the TEF. Prematurity, particularly when associated with the respiratory distress syndrome, may adversely affect surgical outcome. The use of surfactant in the treatment of the respiratory distress syndrome has greatly increased the number of survivors and has decreased the complexity of the issues of the infant with a combination of TEF and the respiratory distress syndrome. A neonatologist should be consulted in the case of any neonate with a congenital defect who is considered for surgery. The most serious associated congenital lesion is that of the cardiovascular system. Approximately 25 to 30% of infants with CDH have a cardiac anomaly,[67] whereas approximately 15 to 25% of infants with TEF have an associated congenital cardiac anomaly.[68]

Congenital Diaphragmatic Hernia

CDH occurs with an incidence of approximately 1 in 4,000 live births. Traditionally, the mortality rate from CDH was in the range of 40 to 50%. The new strategy of permissive hypercapnia and delayed surgical repair has resulted in survival rates of >75% in some centers. However, the morbidity remains high in survivors. A brief discussion of the embryologic characteristics of CDH will help the clinician understand the potentially enormous postoperative problems that may be encountered. It will become evident that the defect is more than a hernia of the diaphragm.

Early in fetal development, the pleuroperitoneal cavity is a single compartment. The gut is herniated or extruded to the extraembryonic coelom during the ninth to tenth weeks of fetal life (Fig. 43-11). During this period, the diaphragm develops to separate the thoracic and abdominal cavities (Fig. 43-12). The development of the diaphragm is usually completed by the seventh fetal week. In the ninth to tenth weeks, the developing gut returns to the peritoneal cavity. If there is delay or incomplete closure of the diaphragm, or if the gut returns early and prevents normal closure of the diaphragm, a diaphragmatic hernia will develop, producing varying degrees of herniation of the intestinal contents into the chest. The left side of the diaphragm closes later than the right side, which results in the higher incidence of left-sided diaphragmatic hernias (foramen of Bochdalek). Approximately 90% of hernias detected in the first week of life are on the left side.

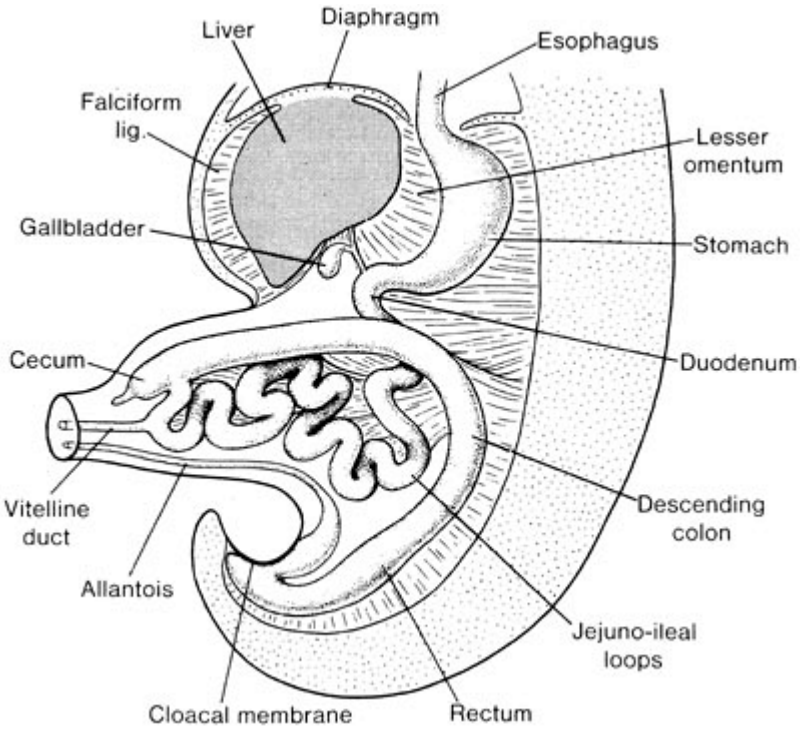

FIGURE 43-11. Umbilical herniation of the intestinal loops in an embryo of approximately 8 weeks' gestation (crown-rump length, 35 mm). Coiling of the small intestinal loops and formation of the cecum occur during the herniation. (Reprinted with permission from Langman J, Body cavities and serous membranes. In Sadler TW: Langman's Medical Embryology, 5th ed, p 150. Baltimore, Williams & Wilkins, 1985.)

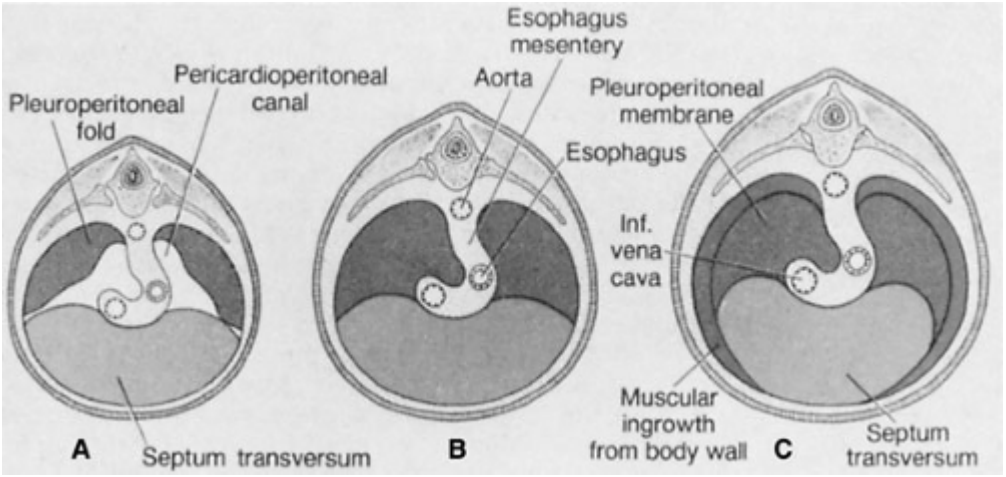

FIGURE 43-12. Schematic drawings illustrating the development of the diaphragm. **A.** The pleuroperitoneal folds appear at the beginning of the sixth week. **B.** The pleuroperitoneal folds have fused with the septum transversum and the mesentery of the esophagus in the seventh week, thus separating the thoracic cavity from the abdominal cavity. **C.** In a transverse section at the fourth month of development, an additional rim derived from the body wall forms the most peripheral part of the diaphragm. (Reprinted with permission from Langman J, Body cavities and serous membranes. In Sadler TW: Langman's Medical Embryology, 5th ed, p 147. Baltimore, Williams & Wilkins, 1985.)

The clinical presentation and the outcome from a diaphragmatic hernia are varied. At one end of the spectrum, the diaphragmatic hernia may develop early in fetal life so the abdominal contents compress the developing lung bud, resulting in an extremely small, hypoplastic lung. In severe cases, bilateral hypoplastic lungs may be found, with no chance for survival. At the other end of the spectrum, a moderately small diaphragmatic hernia may develop later in fetal life so the lung is normal but compressed by the abdominal viscera. In between is a large range of possibilities. At the mild end of the scale, the infant might have a relatively normal pulmonary vascular bed with varying degrees of PPH that may rapidly revert to normal. At the more serious end of the spectrum are severe pulmonary hypoplasia and abnormal pulmonary vasculature with a low chance for survival. As a result, there is an irreducible mortality rate associated with CDH; some infants will just not survive no matter what treatment is provided.

After closure of the pleuroperitoneal membrane, muscular development of the diaphragm occurs. Incomplete muscularization of the diaphragm results in the development of a hernia sac because of intra-abdominal pressure. The condition is known as eventration of the diaphragm, and the diaphragm may extend well up into the thoracic cavity. The other possibility is that the innervation of the diaphragm is incomplete and the muscle atonic. Eventration of the diaphragm is usually not symptomatic in the first week of life.

Antenatal Diagnosis

The diagnosis of CDH can be made prenatally by fetal ultrasonography or ultrafast fetal magnetic resonance imaging. Antenatal diagnosis has led to the identification of a “hidden mortality” in CDH, fetuses who did not survive gestation and neonates who died before diagnosis. One of the hopes of prenatal diagnosis is to identify predictors of poor postnatal outcome. Various factors have been proposed, including early gestation diagnosis, severe mediastinal shift, polyhydramnios, a small lung-to-thorax transverse area ratio, and the herniation of liver or stomach. New techniques in fetal surgery, such as temporary fetal tracheal occlusion, may prove beneficial to fetuses with CDH who are identified to be at risk for not surviving to term.[69,70] The other obvious advantage of prenatal diagnosis is that plans can be made for maternal or neonatal

transport to a center with advanced neonatal critical care.

Clinical Presentation

Because the infant's status immediately at birth is determined primarily by the oxygenation by the placenta, the 1-minute Apgar score may well be normal. The occurrence of symptoms depends on the degree of herniation and interference with pulmonary function. At times, the degree of interference is so great that the neonate's clinical condition begins to deteriorate immediately, whereas in other situations it may be several hours before the infant's condition is fully appreciated. In the severely involved newborn, the initial clinical findings are usually classic and readily discerned. The infant has a scaphoid abdomen secondary to the absence of intra-abdominal contents, which have herniated into the chest (Fig. 43-13). Breath sounds on the affected side are reduced or absent. The diagnosis can be confirmed with a radiograph. Immediate supportive care entails tracheal intubation and control of the airway, along with decompression of the stomach. Excessive airway pressure carries a high risk for pneumothorax and worsening of a bad situation.

FIGURE 43-13. Infant with congenital diaphragmatic hernia. Note scaphoid abdomen.

Preoperative Care

CDH was traditionally treated as a surgical emergency. The infants were taken immediately to surgery for decompression and repair. The thought was that removing the abdominal viscera from the thorax would allow for reexpansion of the atelectatic lung and improved oxygenation. However, as the pathophysiology of CDH was more clearly defined—pulmonary hypoplasia associated with a hyperreactive pulmonary vasculature—a strategy of preoperative stabilization with delayed surgical repair was adopted.

The stabilization of an infant with CDH may require multiple treatment modalities. The use of aggressive ventilation strategies to induce hyperventilation alkalosis has been

abandoned secondary to the high incidence of iatrogenic lung injury. Conventional ventilation with permissive hypercapnia is now favored. The goal is to maintain preductal arterial saturation above 85% using peak inspiratory pressures below 25 cm H_2O and allowing the PCO_2 to rise to 45 to 55 mm Hg.[71,74] High-frequency oscillatory ventilation has been used in place of conventional ventilation in an attempt to reduce barotrauma, but has not been shown to improve survival.[72] The Neonatal Inhaled Nitric Oxide Study Group (NINOS) was unable to demonstrate a beneficial effect for inhaled nitric oxide in infants with CDH and hypoxic respiratory failure unresponsive to aggressive conventional therapy, although it may have some benefit post-ECMO.[73] Neonates born

with CDH may also have a component of surfactant deficiency, and studies have shown improvement in oxygenation in those infants given surfactant prophylactically.[72]

The use of ECMO in infants with CDH was initiated in the mid-1980s. Since then, more than 2,000 infants with CDH have been placed on ECMO. Despite extensive literature on the subject, there remains an ongoing debate as to whether ECMO improves survival in neonates with CDH. The Congenital Diaphragmatic Hernia Study Group analyzed data from the multicenter CDH Registry and determined that ECMO improves the survival rate in CDH neonates with a predicted high risk of mortality (⩾80%) based on birth weight and 5-minute Apgar score.[75]

Perioperative Care

Because delayed surgical repair of CDH is now the norm, neonates with CDH frequently present to the operating room already intubated and on some form of ventilatory support. Despite a period of preoperative stabilization, some infants still have a component of reactive pulmonary hypertension. The goals of ventilatory management are to ensure adequate oxygenation and avoid barotrauma. Any sudden deterioration in oxygen saturation with or without associated hypotension should raise suspicion of pneumothorax. It is important to avoid hypothermia because this increases the oxygen requirement and could precipitate pulmonary hypertension. Blood loss and fluid shifts are usually not a problem, although maintenance of intravascular volume is essential to avoid acidosis, which could also precipitate pulmonary hypertension.

The anesthetic technique chosen depends on the size of the defect and the anticipated postoperative respiratory status. In those infants who will remain intubated after surgery, inhalational agents and narcotics may be used as tolerated. In those infants with a small defect who present to the operating room with little or no respiratory distress, it may be beneficial to avoid intraoperative narcotics and provide regional analgesia in anticipation of extubation. The use of nitrous oxide should be avoided, particularly in those situations in which abdominal closure could be difficult. Muscle relaxation is often needed to facilitate abdominal closure.

Some centers are performing repairs of CDH while the neonate is on ECMO. This may be performed in the operating room or in the NICU. The anesthetic technique usually consists of narcotics with muscle relaxation. Surgical repair while on ECMO can be associated with significant bleeding, making fluid management more challenging and increasing the mortality rate.

Postoperative Care

Most infants with CDH require intensive postoperative care. Recovery depends on the degree of pulmonary hypertension and pulmonary hypoplasia. It was previously believed that pulmonary hypoplasia was responsible for most deaths; however, it is now believed that potentially reversible pulmonary hypertension may be responsible for as much as 25% of reported deaths.[76]

There is evidence to suggest that cardiac development is impaired in infants with CDH. Relative left ventricular hypoplasia with an attenuated muscle mass and cavity size have been described. Many studies have confirmed that a calculated left ventricular mass less than 2 g/kg on pre-ECMO echocardiography was predictive of subsequent death.[77]

Omphalocele and Gastroschisis

Although omphalocele and gastroschisis sometimes appear similar and may be confused, they have entirely different origins and associated congenital anomalies.[78] During the fifth to tenth weeks of fetal life, the abdominal contents are extruded into the extraembryonic coelom, and the gut returns to the abdominal cavity at approximately the tenth week (see Fig. 43-11). Failure of part of or all the intestinal contents to return to the abdominal cavity results in an omphalocele that is covered with a membrane called the *amnion*. The amnion protects the abdominal contents from infection and the loss of extracellular fluid. The umbilical cord is found at approximately the apex of the sac (Fig. 43-14). Gastroschisis, in contrast, develops later in fetal life, after the intestinal contents have returned to the abdominal cavity. It results from interruption of the omphalomesenteric artery, which results in ischemia and atrophy of the various layers of the

abdominal wall at the base of the umbilical cord. The gut then herniates through this tissue defect (Fig. 43-15). The degree of herniation may be slight, or major amounts of the abdominal viscera may be found outside the peritoneal cavity. The umbilical cord is found to one side of the intestinal contents. The intestines and viscera are not covered by any membrane and therefore are highly susceptible to infection and loss of extracellular fluid. There is a high incidence of associated congenital anomalies with omphalocele, but not with gastroschisis. The Beckwith-Wiedemann syndrome consists of mental retardation, hypoglycemia, congenital heart disease, a large tongue, and an omphalocele. Congenital heart lesions are found in approximately 20% of infants with omphalocele. Other associated congenital defects are found with gastroschisis and omphalocele; most involve the gastrointestinal

tract and consist primarily of intestinal atresia or stenosis and malrotation.

Antenatal Diagnosis

Alpha-fetoprotein (AFP) is a normal protein present in fetal tissues during fetal development. Closure of the abdominal wall and the neural tube (see Meningomyelocele section) prevents release of large quantities of this protein into the amniotic fluid. High levels of AFP in the amniotic fluid can cross the placenta and be detected in maternal blood. Thus, abnormal levels of AFP in the mother raise concerns over the possibility of either an abdominal wall defect or a neural tube defect in the fetus, as do high levels of AFP in fluid obtained during amniocentesis. Ultrasonography is reliable in helping diagnose either condition.

Preoperative Care

There is controversy over the appropriate mode of delivery, vaginal or cesarean section, in parturients in whom the antenatal diagnosis has been made. Advocates of operative delivery maintain that it is necessary to prevent trauma to the exposed bowel and that it allows better coordination of the various medical specialties needed for immediate surgical management of the defect. Advocates of vaginal delivery point out that most infants with abdominal wall defects are born without injury to the bowel. The aspect of delivery room care unique to an infant with gastroschisis is the need to protect the exposed bowel and minimize fluid and temperature loss. This is best achieved by “bagging” the neonate by placing its lower body in a sterile, clear plastic bag. The bag is then filled with warm saline and a drawstring is used to tighten the bag against the infant's body.

Preoperative stabilization of the neonate with an abdominal wall defect includes management of respiratory insufficiency, establishment of adequate intravenous access, and an assessment for associated congenital anomalies. Respiratory failure at birth in infants with omphalocele is a significant predictor of mortality.[79] Lung hypoplasia and abnormal thoracic development may be significant in infants with large omphaloceles. A difficult airway can be anticipated in the patient

with Beckwith-Wiedemann syndrome.

Surgery is not urgent in the neonate with an omphalocele, and can be delayed for several days until the infant is assessed and stabilized. In those infants with severe respiratory distress or congenital heart disease who are too unstable for surgery, nonsurgical treatment with topical antiseptics and delayed closure is an option.

Perioperative Care

The two major perioperative concerns are fluid loss and ventilation. The fluid volume management of the infant often entails administration of large amounts of full-strength, balanced salt solution. The adequacy of the peripheral circulation and urine output is an indicator of the adequacy of the volume resuscitation. Both conditions may present an intraoperative challenge to the anesthesiologist because with an omphalocele, after the amniotic membrane is removed, large volumes of fluid may transude or exude from the exposed abdominal viscera. The fluid that is lost is extracellular fluid, which should be replaced with full-strength, balanced salt solution. An arterial line is often used for blood pressure monitoring and frequent blood gas monitoring to assess acid-base status.

If the defect in the abdominal wall is small, a primary repair of the deficit can be accomplished. However, with a large defect, it may be difficult to return the abdominal viscera to the peritoneal cavity because the muscle and peritoneum are underdeveloped. Because of concern for the increase in the volume of gas in the intestine, nitrous oxide should not be used. Muscle relaxation is necessary to allow closure of the abdomen. With moderate-size abdominal wall defects, it may not be possible to close the peritoneum, but there may be sufficient skin to close the defect. With large defects, the peritoneal cavity may be too small to contain the viscera, and attempted closure can impair circulation to the bowel, kidneys, and lower extremities, as well as compromise respiration. A pulse oximeter probe on the foot can be helpful in monitoring circulation to the lower extremities during abdominal wall closure.

Attempts have been made to find objective criteria by which to determine whether the infant will tolerate primary closure of the defect, and to avoid or minimize the circulatory and ventilatory problems. One study that measured intragastric pressure in infants who underwent primary closure found that if the intragastric pressure was 20 mm Hg or more, the infant needed reoperation and placement of a Dacron silo (Fig. 43-16) within 24 hours of the primary closure.[80] If the intragastric pressure was less than 20 mm Hg, the defect was successfully closed primarily. Intragastric pressure is measured by placing a nasogastric tube in the stomach and using a column of saline to measure the pressure.

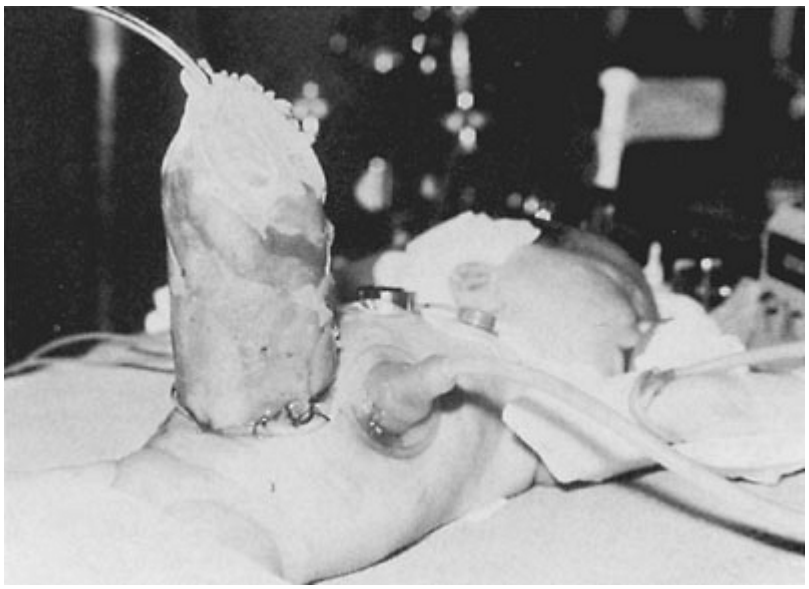

FIGURE 43-16. Dacron silo for extruded viscera. (Reprinted with permission from Berry FA, Physiology and surgery of the infant. In Berry FA [ed]: Anesthetic Management of Difficult and Routine Pediatric Patients, p 154. New York, Churchill Livingstone, 1990.)

If primary closure is impossible, a silo is incorporated into the abdominal wall to contain and cover the abdominal viscera. The repair is then staged from this point onward. Every 2 or 3 days, the size of the silo is reduced, in much the same fashion that a tube of toothpaste is squeezed. The infant may feel some degree of discomfort as the peritoneum and skin are stretched. Small doses of ketamine, 0.5 to 1.0 mg/kg, are titrated as the silo is reduced. The infant is allowed to breathe spontaneously and without intubation. Oxygen saturation should be monitored with a pulse oximeter, and the infant's pulse and blood pressure are also monitored. These measurements help the surgeon and anesthesiologist determine the appropriate silo reduction that allows adequate ventilation and circulation. This is a situation that requires clinical judgment. After several stages of silo reduction, the final operation is complete closure of the abdominal wall defect under full anesthesia with complete muscle relaxation.

Postoperative Care

The postoperative care of infants with omphalocele or gastroschisis is critical. Some need tracheal intubation and assisted ventilation of the lungs for as long as 3 to 7 days. Additional complications include postoperative hypertension and edema of the extremities. The increased abdominal pressure can reduce the circulation to the kidneys, which results in a release of renin. Renin activates the renin-angiotensin-aldosterone system, which is believed to cause the hypertension.

Tracheoesophageal Fistula

The treatment of esophageal atresia and TEF can be both challenging and satisfying for the anesthesiologist. Death in the perioperative period typically results from prematurity or from an associated congenital heart defect. TEF occurs in approximately 1 in 3,000 live births. Approximately 85% consist of a fistula from the distal trachea to the esophagus and a blind proximal esophageal pouch. In 10% of cases, there is a blind proximal esophageal pouch with no TEF (Fig. 43-17). The embryologic defect results from imperfect division of the foregut into the anteriorly positioned larynx and trachea and the posteriorly positioned esophagus; the division should occur between the fourth and fifth weeks of intrauterine life. Fifty percent of affected infants have associated congenital anomalies, of which approximately 15 to 25% involve the cardiovascular system.

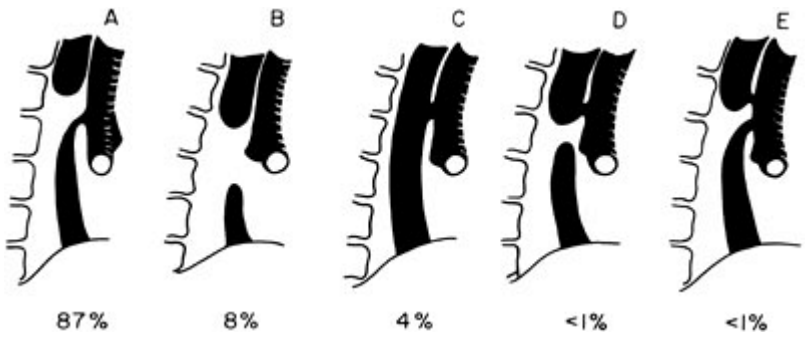

FIGURE 43-17. Diagrams of the five most commonly encountered forms of esophageal atresia and tracheoesophageal fistula, shown in order of frequency. (Reprinted with permission from Herbst JJ: Gastrointestinal tract. In Behrman RE, Kleigman RM, Nelson WE, Vaughan WC III [eds]: Nelson Textbook of Pediatrics, 14th ed, p 942. Philadelphia, WB Saunders, 1992.)

Clinical Presentation

Atresia of the esophagus leads to inability of the fetus to swallow amniotic fluid and the subsequent development of polyhydramnios. Ultrasound may well raise the possibility of a congenital anomaly. For that reason, if polyhydramnios is present, attempts should be made to pass a nasogastric tube shortly after delivery. Passing a nasogastric tube is not routine in the delivery room; therefore, the diagnosis may not become apparent until the infant is fed. Cyanosis and choking with oral feedings should raise suspicion.

There are two major complications of esophageal atresia with a distal tracheal fistula: aspiration pneumonia and dehydration. The presence of a distal TEF increases the likelihood of reflux of gastric juice up the esophagus and into the pulmonary system. Dehydration results from the fact that the proximal esophagus does not communicate with the stomach. Therefore, preoperative preparation of these infants is aimed at evaluation and treatment of the pulmonary system, as well as at ensuring adequate hydration and electrolyte balance. Rarely, the degree of reflux and pneumonia is so great that a gastrostomy must be performed to protect the pulmonary system, and a period of several days is needed to improve the general condition of the infant. However, if the infant is in good condition, primary repair can be performed at 24 to 48 hours. This consists of ligation of the fistula and a primary repair with approximation of the two ends of the esophagus.

Anesthetic Considerations

The presence of a gastrostomy reduces the potential for reflux of gastric juice during the surgical procedure. If a gastrostomy is present, the gastrostomy tube should be open to air and left at the head of the table under the anesthesiologist's observation to avoid kinking and obstruction.

There are two approaches to tracheal intubation after induction of anesthesia. One is to use an inhalation induction, followed by topical spray of lidocaine and intubation while the infant is breathing spontaneously. The other technique is to use an intravenous or inhalation induction and intubate the trachea after muscle paralysis. This technique may lead to distention of the fistula and stomach with excessive positive-pressure ventilation. When controlled ventilation of the lungs is used, attempts must be made to minimize the distention of the stomach and the potential for reflux. If a gastrostomy tube is in place, the point is moot. Alternatively, because the fistula is usually located just above the carina on the posterior wall of the membranous trachea, the endotracheal tube can be placed just distal to the TEF. To do this, the endotracheal tube is inserted until it enters one or the other main-stem bronchi. This is judged by unilateral expansion of the chest and unilateral breath sounds. The endotracheal tube is then slowly withdrawn until bilateral chest movement and breath sounds are confirmed.

The endotracheal tube might inadvertently enter the fistula, when the infant is turned or during surgical manipulation. This should be suspected if there is increased difficulty in ventilation of the lungs, as well as decreased oxygen saturation and end-tidal CO_2. Because these findings may also be present when the lung is packed away to perform the surgery and because there are other explanations for these findings, intubation of the fistula should always be included in the differential diagnosis. Any time ventilation is difficult and desaturation is occurring, the surgeon must stop the procedure while the situation is clarified. The surgeon will be able to palpate the tip of the tube in the fistula if this is the problem.

The localization and isolation of H-type fistulas can be difficult. In this situation, bronchoscopy is

surgeon, the fistula is identified, and a guidewire is fed through the fistula tract into the esophagus. The infant is then intubated, with care taken not to dislodge the guidewire. Once intubated esophagoscopy is performed, the guidewire is visualized and brought out through the mouth. In this way, the surgeon can use fluoroscopy to determine the level of the fistula and decide whether a cervical or thoracic approach is necessary. During surgery, the anesthesiologist can apply traction to the wire loop to facilitate the localization of the fistula by the surgeon.[81]

Postoperative Care

Although there have been great advances in the treatment of TEF and esophageal atresia, postoperative care can be complicated by associated congenital heart disease, respiratory distress syndrome, and a need for continued postoperative ventilation. The compression of the lung for several hours, along with preexisting aspiration pneumonia in some of these infants, suggests the need in the more difficult cases for a short period of postoperative ventilation, or at least intubation with PEEP, as the most conservative technique for postoperative airway management. Some infants are in excellent condition at the time of surgery with no complicating factors, and therefore, should be considered for extubation immediately at the end of surgery or shortly thereafter. If extubation of the trachea is planned for the end of surgery, the anesthetic technique must be tailored accordingly. Caudal anesthesia as part of the technique is useful in these situations, reducing the concentration of maintenance volatile anesthetics, the amount of muscle relaxants, and the need for intraoperative narcotics.

A high percentage of infants with esophageal atresia have residual difficulties of the tracheobronchial tree and esophagus for many years. These include tracheomalacia, gastroesophageal reflux, esophageal stricture, and recurrent fistulas.

Intestinal Obstruction

Obstruction of the gastrointestinal system can be arbitrarily divided into obstruction of the upper gastrointestinal tract (i.e., duodenum) and obstruction of the lower gastrointestinal tract (i.e., terminal ileum, colon, imperforate anus). Obstruction of the upper gastrointestinal tract is usually evident within the first 24 hours of life, when the institution of feedings leads to vomiting, whereas obstruction of the lower gastrointestinal tract becomes evident somewhere between 2 and 7 days of age as the infant becomes progressively distended, little or no stool is passed, and there is vomiting.

Upper Gastrointestinal Tract Obstruction

If there has been persistent vomiting, this usually means that a deficit of fluids or electrolytes will develop in the infant. The stomach contains approximately 100 to 130 mEq/L of sodium and 5 to 10 mEq/L of potassium. The greatest deficit is for sodium. Another major concern in the infant with upper gastrointestinal tract obstruction is aspiration of gastric contents.

The anesthetic management of these patients is directed toward ensuring adequate relaxation for abdominal exploration, repair of the congenital defect, and closure of the abdomen. Nitrous oxide can be used in high intestinal obstruction because there is essentially no gas in the gastrointestinal tract. The next concern is whether the infant's trachea should be extubated at the end of surgery. If the infant is robust, extubation of the trachea at the end of surgery can be anticipated. The preferred technique is for general anesthesia combined with caudal epidural anesthesia. This allows light levels of volatile agent and minimal muscle relaxant use, resulting in an early extubation. Opioids are not administered until the postoperative period. However, if the infant is moderately debilitated or if the surgical incision is extensive, a period of postoperative intubation with PEEP may well be indicated, particularly if moderate doses of opioids have been used.

Lower Gastrointestinal Tract Obstruction

The problems associated with lower gastrointestinal tract obstruction usually develop within 1 to 7 days after birth. It may take this long for the lesion to become evident because it is low in the gastrointestinal tract. An imperforate anus should be recognizable shortly after birth. Some of these infants may have vomiting secondary to the obstruction, which poses a problem for fluid and electrolyte management. An enormous amount of fluid can be sequestered within the intestinal tract. This fluid is essentially extracellular fluid and has high sodium content. Therefore, these infants should be prepared carefully for surgery and have a serum sodium level of at least 130 mEq/L and a urine volume of 1 to 2 mL/kg/hr.

Nitrous oxide should not be used in any infant who has gaseous distention of the intestine, which is easily determined from the preoperative radiograph. Providing adequate muscle relaxation for surgery can be accomplished with various anesthetic techniques, such as volatile anesthesia, muscle relaxants, and caudal epidural block.

The criteria for tracheal extubation at the end of surgery are the same as those described for upper gastrointestinal tract obstruction. When in doubt, leave the tracheal tube in place with PEEP.

Meningomyelocele

Clinical Presentation

Myelomeningocele is the most common congenital primary neural tube defect, occurring in approximately 1 of every 1,000 live births. It results from failure of neural tube closure during the fourth week of gestation. Neural tube defects can be identified on prenatal ultrasound. Elevated maternal serum AFP detects 50 to 90% of open neural tube defects but has a false-positive rate of 5%. Amniotic fluid AFP is more reliable. Evidence also supports a relation between folic acid deficiency and the development of neural tube defects.

By definition, the lesion involves both the meninges and neural components, as compared with a meningocele, which does not contain neural elements. The infant is born with a cystic mass on the back comprising a neural placode, arachnoid, dura, nerve tissue and roots, and CSF. The lesion most commonly occurs in the lumbosacral or sacral region. The bony canal is also malformed, leading to multiple orthopaedic problems as the child matures. Urologic complications correlate with the level of the spinal lesion.

Most infants born with myelomeningocele have an associated anomaly of the brainstem known as the Arnold-Chiari II (Chiari II) malformation. The Chiari II malformation is characterized by caudal displacement of the cerebellar vermis through the foramen magnum, caudal displacement of the medulla oblongata and the cervical spine, kinking of the medulla, and obliteration of the cisterna magna. Hydrocephalus requiring shunting develops in approximately 90% of infants with myelomeningocele. In contrast, only 20% of patients have symptoms of brainstem dysfunction as a result of the Chiari II malformation, but the mortality rate among those symptomatic patients is high. Complications of brainstem dysfunction include stridor, apnea and bradycardia, aspiration pneumonia, sleep-disordered breathing patterns, vocal cord paralysis, lack of coordination, and spasticity. If the symptoms are not

improved by shunting, posterior fossa decompression is necessary.[82,83,84]

The infant with a myelomeningocele is usually operated on within the first 72 hours of life. This reduces the risk for development of ventriculitis or progressive neurologic deficits. Most centers close the defect and place a shunt at the same time. However, some centers may delay placement of a shunt until the infant shows symptoms of hydrocephalus. There is some evidence that intrauterine repair of myelomeningocele may decrease the morbidity associated with the Chiari II malformation and brainstem dysfunction.[85]

Preoperative Care

The safest route of delivery of an infant with a myelomeningocele remains controversial. Some question whether labor and vaginal delivery can adversely affect neurologic outcome. However, there are studies suggesting no difference in neurologic deficits between infants delivered vaginally or by cesarean section.

The preoperative stabilization period focuses on the prevention of infection, maintenance of extracellular fluid volume, and assessment for other congenital anomalies. The exposed neural placode is susceptible to trauma, leakage, and infection. The infant is usually placed in the prone position, and the placode is covered with saline-soaked gauze to prevent desiccation. Because of the high risk of infection, antibiotic therapy is initiated in the preoperative period. Rupture of the cyst on the back can lead to ongoing CSF leakage. This fluid is replaced with full-strength balanced salt solution. The infant is also assessed for any potentially life-threatening congenital anomalies.

Perioperative Care

The high prevalence of clinical latex allergy and latex sensitization in children with myelomeningocele has drawn much attention. Studies show that the prevalence increases with increasing age. It is believed that an early, intense exposure to the allergen, as occurs with frequent surgery and bladder catheterization, contributes to this high prevalence. As a result, these infants are now labeled as latex sensitive and cared for in a latex-free environment.[86]

Positioning is critical in the infant with myelomeningocele. For induction of anesthesia, the infant may be placed supine with the defect resting in a “donut” to minimize trauma. Alternatively, the induction can be performed with the infant in the lateral position, although this makes intubation more challenging. The infant is turned prone for surgery. Rolls are positioned to ensure the abdomen and chest are free, avoiding pressure on the epidural venous plexus to minimize bleeding and allowing for adequate ventilation.

In most instances, the infant has an intravenous line placed before surgery and an intravenous induction is performed. Succinylcholine may be used to facilitate intubation without risking hyperkalemia.[87] Because increased intracranial pressure is rarely present before closure of the defect, inhalational induction is an alternative in the infant with difficult intravenous access. Identification of neural tissue may require nerve stimulation, and therefore, muscle relaxants are avoided. Narcotics are used with caution in these infants because of the abnormal response to hypoxia and hypercarbia, predisposing to apnea and bradycardia. The effects of general anesthesia in association with the abnormalities of respiratory control may warrant a prolonged period of respiratory support in some infants with myelomeningocele.

Regional anesthesia has been reported as a safe alternative to general anesthesia in the neonate with myelomeningocele. Viscomi et al.[88] successfully administered tetracaine spinals to 14 infants undergoing repair of myelomeningocele. In this small series, there was no evidence of anesthetic-induced neurologic damage. Two of the 14 infants had a postoperative respiratory event (1 transient apnea/bradycardia and 1 brief desaturation with bradycardia). Both of these infants had received intraoperative midazolam for sedation.

Postoperative Care

These infants must be monitored closely in the postoperative period. Respiratory complications, including stridor, apnea and bradycardia, cyanosis, and respiratory arrest, may develop after surgery in these infants with known brainstem abnormalities and potential disorders of central respiratory control. In addition, those infants who were not shunted during repair may show signs of hydrocephalus, including lethargy, vomiting, seizures, apnea and bradycardia, or cardiovascular instability. These infants need to return to the operating room for insertion of a shunt.

Hydrocephalus

Hydrocephalus may occur after closure of a meningomyelocele because of the Arnold-Chiari malformation. The cranial sutures in the neonate are open so intracranial pressure increases are blunted or minimized. However, infants with hydrocephalus eventually have an increase in head size and sometimes in intracranial pressure, resulting in lethargy, vomiting, and cardiorespiratory problems. The anesthetic approach and the technique for tracheal intubation depend on the infant's condition. The major concern is protection of the airway and control of intracranial pressure. Awake tracheal intubation, crying, struggling, and straining can increase intracranial pressure. A rapid-sequence induction of anesthesia to control the airway and intracranial pressure is preferred. Volatile drugs, nitrous oxide, and opioids are all reasonable choices for maintenance of anesthesia. Noninvasive intracranial pressure measurements in neurologically normal preterm neonates have shown a decrease in intracranial pressure with all drugs, including ketamine, fentanyl, and isoflurane. The failure of volatile anesthetics and ketamine to increase intracranial pressure as in adults is attributed to the compliance of the neonate's open-sutured cranium. After surgery, the trachea of these infants should remain intubated, and they should receive PEEP if they were experiencing periods of apnea or bradycardia before surgery because of the intracranial abnormalities. If not, the trachea can be extubated as soon as the protective reflexes have recovered.

Surgical Procedures in the First Month of Life

Surgical procedures in the first month also are considered emergent, or at least urgent, surgery. The six most frequent surgical procedures in the first month are exploratory laparotomy for NEC, inguinal hernia repair, correction of pyloric stenosis, PDA ligation, a shunt procedure for hydrocephalus, and placement of a central venous catheter.

Necrotizing Enterocolitis

Necrotizing enterocolitis is a disease that primarily affects premature infants who have survived the first days of life. One of the theories about NEC is that earlier, more rapid feeding places infants at greater risk for development of NEC. The incidence

of NEC among very-low-birth-weight infants varies between 5 and 15%.[89,90]

The exact pathophysiology of NEC has yet to be determined.[91] The condition is characterized by a cascade of pathologic events, beginning with an immature intestine that has a decreased ability to absorb substrate, leading to stasis. Stasis encourages bacterial proliferation, which leads to local infection. The picture is complicated by further pooling of fluid. The ischemia and infection may lead to necrosis of the intestinal mucosa, followed by perforation. The perforation leads to gangrene, fluid loss, peritonitis, septicemia, and disseminated intravascular coagulation. The first signs that NEC may be developing are abdominal distention, irritability, and the development of metabolic acidosis. NEC is primarily a medical disease and is treated by cessation of oral intake, administration of antibiotics, fluid and electrolyte therapy, and recently the insertion of a peritoneal drain. In nonresponsive cases, the infant becomes more septic with severe peritonitis, and the only solution is to perform an exploratory laparotomy to remove the gangrenous bowel and create an ileostomy.

The preoperative problems are an acute abdomen with severe peritonitis, necrosis, and gangrene of the intestine; septicemia; metabolic acidosis; and hypovolemia. These neonates may also have a coagulopathy. Preparation of the patient is directed toward these problems. Often the septicemia, coupled with the distended abdomen and the overall clinical deterioration of the infant, also necessitates the use of intubation and ventilation in the NICU. The anesthetic requirements are continuation of resuscitation, provision of abdominal relaxation for the surgery, and careful titration of anesthetic drugs. These infants are often so critically ill that they tolerate minimal anesthesia. One choice is to start with small doses of ketamine, 0.5 to 1 µg/kg. This can be administered every 20 to 30 minutes. If the condition improves, fentanyl, 2 to 3 µg/kg, can be administered, up to a total dose of 10 to 12 µg/kg. If the infant's condition improves dramatically, small doses of volatile drug can also be added. The use of nitrous oxide should be avoided

because of the gas pockets in the abdomen.

These infants are among the most challenging cases in pediatric anesthesia. Monitoring of intra-arterial pressure and arterial blood gases has usually been started in the NICU. The fluid loss can be enormous. They need full-strength, balanced salt solution for maintenance of blood pressure and urine output. If the hematocrit is below 30 to 35%, blood should be administered. These infants are returned to the NICU, and their postoperative care is coordinated carefully with the surgeon, neonatologist, or pediatrician.

Inguinal Hernia Repair in the Neonate

The development of a hernia in the premature infant or neonate is a different clinical problem from the development of a hernia in an infant older than 1 year of age.[92,93] In one study of 100 infants younger than 2 months of age who needed inguinal hernia repair, 30% were premature, 42% had a history of respiratory distress syndrome, 16% had been ventilated, and 19% had congenital heart disease.[92] Furthermore, 31% of the infants had incarcerated hernias, 9% had an intestinal obstruction, and 2% had gonadal infarction. These data preclude waiting until a premature infant or neonate is 6 months or 1 year of age before performing “elective” surgery. The potential for emergent or urgent intervention is so great that surgical repair should be accomplished within a reasonable amount of time after an inguinal hernia is discovered. The “reasonable” time depends on the infant's condition. If the infant is normal and has no other life-threatening medical problems, repair can be done within several days or weeks. If the infant has another problem, the waiting period should be sufficient to stabilize the infant's condition.

Anesthetic Techniques for Hernia Repair

Surgical procedures below the umbilicus can be performed with either general or regional anesthesia. The choice of whether to do general or regional depends on the preference of the surgeon and/or the anesthesiologist. Regional anesthesia can be used entirely for the surgery or as an adjunct to reduce general anesthetic requirements and provide postoperative analgesia. Other methods of providing intraoperative anesthesia and postoperative analgesia include the ilioinguinal-iliohypogastric nerve block or local infiltration. Ilioinguinal-iliohypogastric nerve block with 0.25% bupivacaine or 0.2% ropivacaine, with epinephrine, can be administered shortly after the induction of general anesthesia; it affords excellent postoperative analgesia without the need for opioids.

Pyloric Stenosis

Pyloric stenosis is a relatively frequent surgical disease of the neonate and infant. It can appear as early as the second week of life. The pathologic characteristics include hypertrophy of the pyloric smooth muscle with edema of the pyloric mucosa and submucosa. This process, which develops over a period of days to weeks, leads to progressive obstruction of the pyloric valve, causing persistent vomiting. The vomiting leads to varying losses of fluids and electrolytes. Pediatricians are now adept at the early diagnosis of pyloric stenosis with ultrasound, so it is rare to find an infant with severe fluid and electrolyte derangements. However, an infant is occasionally seen whose problem has developed slowly over a period of weeks, resulting in severe fluid and electrolyte derangements. The stomach contents contain sodium, potassium, chloride, hydrogen ions, and water. The classic electrolyte pattern in infants with severe vomiting is a hyponatremic, hypokalemic, and hypochloremic metabolic alkalosis with a compensatory respiratory acidosis. The anesthesiologist, pediatrician, and surgeon are all responsible for preparing these infants for surgery. Pyloric stenosis is a medical emergency and should not be converted into an anesthetic nightmare by premature surgical repair before adequate fluid and electrolyte homeostasis has been achieved. The infant should have normal skin turgor, and the correction of the electrolyte imbalance should produce a sodium level that is greater than 130 mEq/L, a potassium level that is at least 3 mEq/L, a chloride level that is greater than 85 mEq/L and increasing, and a urine output of at least 1 to 2 mL/kg/hr. These patients need a resuscitation fluid of full-strength, balanced salt solution and, after the infant begins to urinate, the addition of

potassium.

Anesthetic Management

One of the concerns in the anesthetic management of patients with pyloric stenosis is the aspiration of gastric contents. A large orogastric tube is passed, and the stomach contents are aspirated.[94] This procedure greatly reduces the quantity of gastric fluid. Intubation of the trachea can be done while the patient is awake or after induction of anesthesia, which is preferred by most clinicians. The infant will most likely have an intravenous line in place for hydration. A rapid-sequence induction is performed using succinylcholine or rocuronium for muscle relaxation. Cricoid pressure is applied as soon as tolerated, and the infant's trachea is intubated. If an intravenous line is not present and cannot be placed with reasonable ease, then a careful inhalation induction can be done using sevoflurane. An intravenous line should be started as soon as possible;

however, if this is not accomplished, intubation can be facilitated by intramuscular succinylcholine or airway topicalization. Anesthesia can be maintained by almost any technique the clinician prefers. The point to remember is that surgeons need muscle relaxation twice: when they deliver the pylorus at the beginning of surgery and when they replace the pylorus into the abdomen at the end of surgery, shortly before closing the peritoneum. Administration of a caudal anesthetic (1.25 mL/kg of 0.25% ropivacaine with epinephrine) after the induction of general anesthesia with tracheal intubation provides intraoperative relaxation, reduces the anesthetic requirement, and provides postoperative analgesia without the need for narcotics. Controlled ventilation reduces or eliminates the need for muscle relaxants for this surgery. The infant's trachea should remain intubated until he or she is awake with eyes opened and is reaching for the endotracheal tube, or is crying. These infants do not appear to be at increased risk of postoperative apnea.[95]

Ligation of a Patent Ductus Arteriosus

As the number of small premature infants who survive has increased, so also has the number of infants who have PDA with heart failure and respiratory failure. Prostaglandins relax the smooth muscle of the ductus so it cannot constrict. Indomethacin, a prostaglandin synthetase inhibitor, is administered to encourage closure of the ductus. However, indomethacin is often unsuccessful in the small premature infant because of the lack of muscle within the ductus. Infants with a PDA and heart failure need maximal medical management with fluid restriction and diuretics. These infants are at special risk because of the reduced blood volume and precarious cardiopulmonary system. Fentanyl with pancuronium is a frequent choice for anesthesia. The clinician must be prepared to augment volume rapidly with 10 to 15 mL/kg of lactated Ringer's solution. If the lactated Ringer's solution accompanies the administration of 20 to 25 µg/kg of fentanyl and pancuronium, the pressure changes are minimal and the infant will be appropriately anesthetized. The tracheas of these infants usually remain intubated and the lungs ventilated in the postoperative period, so concern about the length of action of muscle relaxants and opioids is minimized.

A new technique for closing the PDA in low-birth-weight infants has been developed, called video-assisted ligation of the PDA.[96] Under general anesthesia, four small thoracotomy incisions are made that allow the insertion of an endoscope and various other instruments to ligate the PDA. The operation is accomplished without either spreading the ribs or cutting muscles, thereby offering a minimally traumatic and safe technique for the surgery. This operation has been accomplished both in the operating room and in the NICU; where the surgery is performed is more of a “turf” issue than a technical one.

Placement of a Central Venous Catheter

The use of a central venous catheter for monitoring serum electrolytes for hyperalimentation and for administering medications is increasing. It can be placed either as part of the surgical procedure or at some other time as a separate procedure. The three major concerns in central venous catheter placement are airway management, pneumothorax, and bleeding. The airway should be secured by an endotracheal tube in small infants because of the difficulty in sharing the

head, neck, and upper chest with the surgeon and as an adjunct for treating complications such as pneumothorax and bleeding. The anesthetic technique depends on the infant's condition. A pneumothorax may occur with attempts at subclavian vein puncture. The first indication of trouble may be a decreasing oxygen saturation, hypotension, or difficulty with ventilation of the lungs. Because a fluoroscope is often used for central venous catheter placement, it can be used rapidly to diagnose a pneumothorax. If not, the chest should be rapidly aspirated for both diagnostic and therapeutic reasons. Bleeding is an unusual but serious complication of central venous catheter placement. It usually becomes manifest in the perioperative period as a hemothorax or as hypovolemia with a decreasing hematocrit or blood pressure. The question of whether an infant needs an intravenous catheter placed before proceeding with a central line has never been answered. The reason for the central line is usually that the infant has no veins and the clinician is left with a trade-off between prolonged attempts at starting an intravenous catheter versus proceeding without an intravenous line to obtain central venous line placement. The subclavian approach has a higher incidence of problems than an external or internal jugular approach. An intravenous catheter should be started when possible if it can be done within a reasonable time (i.e., 15 to 20 minutes). If not, then central catheter placement continues as described previously, without an intravenous catheter, after discussion and agreement with the surgeon.

Chapter 44

Pediatric Anesthesia

Joseph P. Cravero

Zeev N. Kain

KEY POINTS

1	There are numerous specific anatomic, physiologic, and psychological issues that should be understood prior to anesthetizing pediatric patients.
2	A child with an upper respiratory infection (URI) or who is recovering from a URI is at increased risk to develop laryngospasm, bronchospasm, oxygen desaturation, and postoperative atelectasis and croup.
3	Children with obstructive sleep apnea (OSA) may obstruct with the use of preoperative sedative premedication during the induction process. Muscle relaxants should be used carefully.
4	Healthy children undergoing elective minor surgery require no laboratory evaluation.
5	The American Society of Anesthesiologists has issued practice guidelines regarding preoperative fasting. Solids are prohibited within 6 to 8 hours of surgery (generally after midnight), formula within 6 hours, breast milk within 4 hours of surgery, and clear liquids within 2 hours of surgery.
6	Oral midazolam is the most commonly used sedative premedicant.
7	Mask induction of general anesthesia remains the most common induction technique for pediatric anesthesia.
8	Succinylcholine is recommended in situations where ultrarapid onset and short duration of action is of paramount importance (laryngospasm), when relaxation is required, or when intravenous access is not available and intramuscular administration is required.
9	Perioperative fluid and blood product management for pediatric patients must take into account fluid deficits, translocation of fluids and blood loss during

	surgery, and maintenance fluid requirements.
10	Appropriate airway management remains the single most important aspect of delivering safe pediatric anesthesia.
11	The most commonly used form of regional anesthesia in children is the *caudal block*. This technique can provide postoperative analgesia following a wide variety of lower abdominal and genitourinary surgical procedures.
12	Recovery of the young child in the postanesthesia care unit (PACU) includes management of hypothermia, nausea and vomiting, and postoperative pain.

1 The provision of safe anesthesia for the pediatric patient requires a clear understanding of the anatomic, psychological, physiologic, and pharmacologic differences between patients in different age epochs from newborn to adolescent. These distinctive features form the basis for the techniques and pharmacology outlined in this chapter. A partial listing of the most important differences is presented in Table 44-1. Consideration of these differences when providing anesthesia care to children is critical to achieving high-quality and efficient care. Given its brief nature, this chapter focuses on only the most salient issues relating to anesthesia delivery for pediatric patients. The reader should note that relevant topics such as neonatal anesthesia, pediatric pharmacology, and pediatric equipment are covered elsewhere in this textbook.

TABLE 44-1 Anatomic and Physiologic Distinctions Between Adults and Pediatric Patients

·PHYSICAL OR PHYSIOLOGIC VARIABLE	·CONTRAST BETWEEN CHILD AND ADULT	·ANESTHETIC IMPLICATION
Head size	Much larger head size relative to body	Consider roll under shoulders or neck for optimal intubation positioning
Tongue size	Larger size relative to mouth	Makes airway appear slightly anterior; oral airways particularly helpful during mask ventilation
Airway shape	Narrowest diameter is below the glottis at cricoid level in children	Uncuffed tubes can make seal when appropriately sized in children younger than 8 years of age

Respiratory physiology	Oxygen consumption is two to three times greater in infants than adults. FRC ranges from 8–13 cm^3 ≈ 1/3 as large as adults	Oxygen desaturation is extremely rapid following apnea
Cardiac physiology	Relatively fixed stroke volume in neonates and infants	Bradycardia must be treated aggressively in young age groups; consider atropine prior to airway management; heart rates less than 60 require circulatory support
Renal function	Limited GFR at birth; does not reach adult levels until late infancy; total body water and % extracellular fluid are increased in the infant	Prolonged duration of action for hydrophilic drugs, particularly those that are renally excreted
Hepatic function	P450 system not fully developed in neonates and infants; liver blood flow decreased in newborns	Prolonged excretion for drugs, depending on hepatic metabolism
Body surface area	Larger surface-to-body ratio in newborns/infants/toddlers	Heat loss more prominent problem for these age groups
Psychological development	0–6 mo—stress on family 8 mo–4 yr—separation anxiety 4–6 yr—misconceptions of surgical mutilation 6–13 yr—fear of not "waking up" ⩾13 yr—fear of loss of control, body image issues	Changes the manner in which each patient and family should be approached; must address issues with personal and systemic strategies

FRC, functional residual capacity; GFR, glomerular filtration rate.

THE PREOPERATIVE EVALUATION

The preoperative evaluation and preparation of the child for surgery is an integral part of the perioperative process. The preoperative evaluation of the pediatric patient should consist of all pertinent maternal history, birth and neonatal history, review of systems, physical examination and evaluation of height, weight, and vital signs. Preoperative use of bronchodilators, steroids, and chemotherapeutic agents has significant implications for the anesthetic management. The use of herbal medication, as well as other alternative and complementary medicine modalities, also has to be assessed.[1] Special attention should be paid to the existence of congenital malformations in the child and family. Issues such as anesthetic risks, anesthetic plans, recovery, and postoperative analgesia and discharge must be discussed in detail. Indeed, a more recent study found that most parents were interested in receiving all information about the surgery *and*, as a

result of the detailed discussion regarding anesthetic plans and risks, the parents were not overly anxious.[2]

It is important to appreciate that anesthesia and surgery cause an enormous amount of stress and hardship on both the child and parents. Anxiety in children undergoing surgery is characterized by subjective feelings of tension, apprehension, nervousness, and worry, and may be expressed in many forms.[3]

Some children verbalize their fears explicitly, whereas for others anxiety is expressed only behaviorally. Many children look scared, become agitated, breathe deeply, tremble, stop talking or playing, and may start to cry. These behaviors, which may prolong the induction of anesthesia, could give children some sense of control in the situation and thereby diminish a damaging sense of helplessness.[3] Coping with this preoperative stress requires consistent communication between the child, the parents, and all health care providers involved in the perioperative period. Because parental anxiety increases a child's anxiety,[4] preoperative preparation should include the entire family.[5] Both behavioral and pharmacological interventions can be used to address the issue of preoperative anxiety in children and their parents. Behavioral interventions include tours of the operating room, written and audiovisual materials, coloring books, and patient care representatives skilled in the preoperative preparation of children.[6] To date, most studies suggest that preoperative preparation programs reduce anxiety and enhance coping in children.[6] Some hospitals allow parents to be present for the induction of anesthesia in their child, but the efficacy of this intervention is uncertain and the availability of such programs is limited.[6,7,8,9,10] Also, other nonpharmacological interventions such as music and acupuncture have been shown to reduce the anxiety of parents and children in the perioperative settings.[11,12] Pharmacological interventions such as midazolam are effective treatment for preoperative anxiety and are discussed later in this chapter. The anesthesiologist should also be aware that more recent research has documented that a child's fear on the day of surgery might extend beyond the immediate operative period.[13] About 50% of all children undergoing routine outpatient surgery present at 2 weeks postoperatively with new-onset anxiety, nighttime crying, enuresis, separation anxiety, temper tantrums, and sleep or eating disturbances.[4] Most of these behaviors disappear within 3 to 4 weeks postoperatively. It is important for the primary health care provider to be aware of these behaviors and to assure the parents that these behavioral changes are self-limited. Children with postoperative behavioral changes that persist beyond 3 to 4 weeks after surgery should be referred to a trained mental health provider.

Coexisting Health Conditions

Upper Respiratory Infection

2 Multiple investigations have found that a child with an upper respiratory infection (URI) or who is recovering from a URI is at increased risk to develop laryngospasm, bronchospasm, oxygen desaturation, and postoperative atelectasis and croup.[14,15] Although these complications usually do not cause significant morbidity in otherwise healthy children, they may be significant in children with underlying conditions such as asthma and sickle cell disease. More recent studies indicated that children with asthma, infants and young children with bronchopulmonary dysplasia, children younger than 1 year of age, children with sickle cell disease, children who live in a household

that includes smoking parents, and children who are to undergo bronchoscopy are at a higher risk of developing perioperative morbidity if suffering from a URI.[14] Patients in these categories should be carefully assessed, and strong consideration should be given to postponing elective surgery. It is unclear how long surgery should be delayed following a URI, however, because bronchial hyperreactivity may exist for up to 7 weeks after a URI.[16] The final decision would take into account the risk–benefit ratio of the surgical procedure. Finally, mask anesthetic, but not laryngeal mask airway, was clearly shown to be associated with a significantly lower rate of perioperative complications as compared with endotracheal tube and thus should be used

whenever possible with these children.

Obstructive Sleep Apnea

3 Severe adenotonsillar hypertrophy with obstructive sleep apnea (OSA) is a frequent indication for children to undergo tonsillectomy and adenoidectomy. Postoperatively, patients with severe OSA may exhibit worsening of their obstructive symptoms secondary to tissue edema, altered response to carbon dioxide, and residual anesthetic and analgesic agents.[17] Although most children who undergo tonsillectomy and adenoidectomy can be discharged home following 4 hours of postanesthesia care unit (PACU) observation, children with severe OSA may require postoperative observation in the hospital. Such issues have to be discussed a priori with the family and the surgeon.

Asthma

It is well established that children with asthma should be under optimal medical care prior to undergoing general anesthesia and surgery.[18] In fact, the more active the disease, as indicated by recent asthma symptoms, drug usage, and recent treatment in an emergency department, the greater probability of perioperative complications.[19] All oral and inhaled medications, such as corticosteroids and beta agonists, should be continued up to and including the day of surgery. More recent data have indicated that administration of inhaled short-acting beta agonists prior to induction of anesthesia eliminates the increase in airway pressure that is typically associated with intubation in asthmatic patients.[20]

The Former Preterm Infant

There are multiple concerns related to the perioperative period of preterm infants. Three frequent problems are the impact bronchopulmonary dysplasia might have on the patient's perioperative course, the presence of anemia, and the possibility of postoperative apnea. Bronchodilators and inhaled corticosteroids, which many of these patients require, affect treatment, and should be continued up to and including the day of surgery. The parents should be questioned about the need for oxygen therapy at home, and recent hematocrit data should be available. In fact, many institutions require preoperative hematocrit for all infants younger than 2 months of age. Data also indicate that former preterm infants are more likely to develop postoperative apnea following general anesthesia.[21,22] Reports indicate that risk of postoperative apnea is inversely related to postconceptional age, and that infants with a history of apnea and bradycardia, respiratory distress, and mechanical ventilation may be at increased risk.[23] Although which infants should be admitted to the hospital following anesthesia is controversial, the age generally is believed to be younger than 52 to 60 weeks' postconceptual age.[23] Arrangements for overnight hospital monitoring should be made for any child considered to be at significant risk for postoperative apnea.

Laboratory Evaluation

4 It is currently the standard of care that healthy children undergoing elective minor surgery require no laboratory evaluation, and thus can be spared the anxiety and pain of blood drawing.[24] Indeed, blood chemistry analyses are usually performed only for indications, such as measurement of ionized potassium in children on digoxin or diuretics. The arbitrary hemoglobin value of 10 g/dL has been cited for infants older than 3 months, with higher values for the younger infants, depending on gestational age and general health status. Children whose hemoglobin values are less than this arbitrary standard should have the cause of their anemia investigated and corrected. Outside this subgroup, there is little evidence that testing for hematocrit levels is helpful in the management of routine pediatric outpatients. Patients with sickle cell anemia or other hemoglobinopathies require special preoperative preparation. Routine chest radiographs and urinary analysis are also unnecessary. Coagulation screening has been among the most debated of all laboratory tests. Although an undiagnosed coagulopathy could result in serious surgical morbidity, commonly used screening tests, such as bleeding time and prothrombin time, do *not* reliably predict abnormal perioperative bleeding.[25] Laboratory testing

should only be considered in children in whom either the history or medical condition suggests a possible hemostatic defect, in patients undergoing surgical procedures that might induce hemostatic disturbances (e.g., cardiopulmonary bypass), when the coagulation system is particularly needed for adequate hemostasis, and in patients for whom even minimal postoperative bleeding could be critical.

Although teratogenicity of anesthetic agents has not been firmly established, a determination of whether a female patient is pregnant should be ascertained before the administration of anesthesia. This may be a difficult task because parents might decline a request for a pregnancy test, and a reliable menstrual and sexual history may be difficult to obtain from an adolescent when a relationship of confidentiality with medical personnel has not been previously established. Because there are no clear national guidelines, whether pregnancy screening of all female patients of childbearing age before the administration of anesthesia is routine or selective is a matter of policy at individual facilities.

Preoperative Fasting Period

5 The risk of aspiration pneumonia in children is well recognized, and more recent reports found an incidence of about 1 in 10,000 for this clinical phenomenon.[26] These reports also indicate that the outcome of children who developed aspiration pneumonia is excellent, unless these children had some major underlying problem such as abdominal or thoracic trauma.[26] As the importance of this issue is recognized, the American Society of Anesthesiologists issued practice guidelines regarding preoperative fasting. Solids are prohibited within 6 to 8 hours of surgery (generally after midnight), formula within 6 hours, breast milk within 4 hours of surgery, and clear liquids within 2 hours of surgery.[27] Indeed, liquids such as apple or grape juice, flat cola, and sugar water may be encouraged up to 2 hours prior to the induction of anesthesia because their consumption has been shown to decrease the gastric residual volume. It is important to note that some institutions have chosen to make the fasting period for clear liquids for 2 to 4 hours because this longer fasting time allows for flexibility in patient

scheduling. This issue of fasting time is important because the younger the child, the smaller the glycogen stores, and the more likely the occurrence of hypoglycemia with prolonged intervals of fasting. For this reason, fasting time should be reduced based on the previous recommendation. Regardless of the length of preoperative fasting, there still exists a defined population of children who are at an increased risk for regurgitation and aspiration of stomach contents. This group of children includes children with delayed gastric emptying times, and abdominal pathology associated with ileus, vomiting, or electrolyte disorders.

Preoperative Sedatives

Sedation before surgery is an effective method for decreasing anxiety that is widely used for young children (Table 44-2).[7,28] The primary goals of premedication in children are to facilitate a smooth and anxiety-free separation from the parents and induction of anesthesia. Other effects that may be achieved by pharmacological preparation of the patient include amnesia, anxiolysis, prevention of physiologic stress, and analgesia. In addition, children who are sedated before coming to the operating room may have fewer stress-related behavioral changes in the immediate postoperative time compared with groups of patients who receive no sedation (Fig. 44-1).

TABLE 44-2 Premedication

▪MEDICATION	▪ROUTE	▪DOSE mg/kg	▪TIME TO ONSET (min)	▪ELIMINATION HALF-LIFE T½ (hr)
Midazolam	Oral	0.25–1.0	10	2

	Intranasal	0.2–0.3	<10	2–3
	Rectal	0.3–1.0	10	2–3
Ketamine	Oral	3.0–6.0	10	2–3
	Intranasal	3.0–5.0	<10	3
	Rectal	5.0–6.0	20–30	3
Clonidine	Oral	0.002–0.004	45	8–12

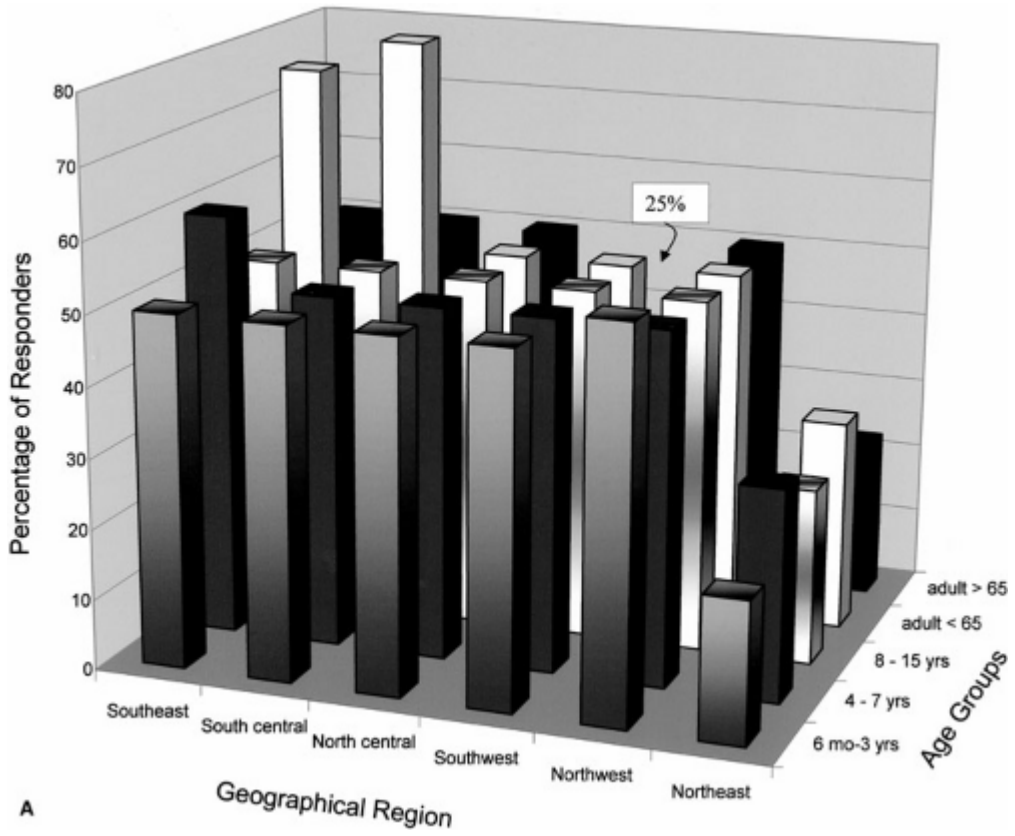

FIGURE 44-1. A. Frequency of sedative premedication practice in the United States as of 2002. **B.** Frequency of sedative premedication practice in the United States as of 1996. Data reported are medians (range, 0–100%). (From Kain ZN, Caldwell-Andrews AA, Krivutza DM *et al*: Trends in the practice of parental presence during induction of anesthesia and the use of preoperative sedative premedication in the United States, 1995–2002: Results of a follow-up national survey. Anesth Analg 98[5]:1252, 2004.)

Oral

Midazolam is the most commonly used sedative premedicant used in the United States.[29] It has rapid onset and predictable effect, without causing cardiorespiratory depression. In a dose of 0.5 to 0.75 mg/kg, midazolam peaks approximately 30 minutes after administration, and its effect lasts approximately 30 minutes.[28] Midazolam has short duration that generally does not delay emergence from general anesthesia or discharge from the PACU. Although serious side effects after oral midazolam are uncommon, strict adult supervision is necessary in children who receive this drug. Midazolam has been shown to be superior to parental presence in decreasing perioperative stress for patients and families.[30] Midazolam can be reversed with flumazenil, which antagonizes benzodiazepines competitively. The initial recommended dose in children is 0.05 mg/kg given intravenously in a titrated fashion of up to 1.0 mg total.[31]

Oral ketamine has also been used as a sedation medication in doses of 5 to 6 mg/kg for children 1 to 6 years of age.[28] Maximal sedation occurred within 20 minutes. Investigators also evaluated a combination of ketamine and midazolam as an oral sedative premedication mixture. Funk et al reported that the combination of midazolam and ketamine administrated orally had a 90% success rate of satisfactory anxiolysis compared with less than 75% with either drug alone.[32] Nausea and vomiting rates were slightly increased in children who received oral ketamine.

Oral transmucosal fentanyl represents the first commercial attempt to deliver medication to children by the transmucosal oral route and was shown to sedate children prior to induction of anesthesia.[28] Its sedative effect is often, however, heralded by facial pruritus, higher incidence of postoperative nausea and vomiting, and arterial oxygen desaturation.[33] Thus, this drug is not currently used routinely in the perioperative settings.

Finally, clonidine is an α_2 agonist that, when given in combination with atropine, produces satisfactory preoperative sedation, easy separation from parents, and mask acceptance within 30 minutes.[33] Orally administrated clonidine in a dose of 4 µg/kg has been demonstrated to reliably cause sedation, decrease anesthetic requirements, and decrease requirement for postoperative analgesics. It also attenuates the hemodynamic response to tracheal intubation. With the recommended dose, perioperative hypotension is not observed.[28]

Nasal

A major disadvantage of intranasally administered sedative medications is that *most* children cry upon administration because it transiently irritates the nasal passages. Rapid absorption and avoidance of first-pass hepatic metabolism of medications are advantages of this route of administration. When required, midazolam can be administered intranasally in a dose of 0.2 mg/kg. The use of sufentanil and other sedatives intranasally has been abandoned because of untoward side effects.

Rectal

Rectal administration of midazolam in doses of 0.5 to 1.0 mg/kg effectively reduces the anxiety of children prior to induction.[28] Care must be taken, however, that the medication is not expelled immediately on placement. Both methohexital and thiopental have also been used in rectal formulations in a dose of 25 mg/kg. Onset of sedation requires approximately 10 minutes. Respiratory depression and oxygen desaturation may occur because of variable absorption of the medication in the rectum.

Intramuscular

Parenteral administration of sedation may be the only alternative in a child who refuses to cooperate with other modalities. Intramuscular midazolam in a dose of 0.3 mg/kg provides anxiolysis in 5 to 10 minutes. Ketamine in an intramuscular dose

of 3 to 4 mg/kg provides a quiet and breathing, yet minimally responsive, patient in approximately 5 minutes.

ANESTHETIC AGENTS

Potent Inhalation Agents

Mask Induction Pharmacology

7 Mask induction of general anesthesia remains the most common induction technique for pediatric anesthesia the United States. Although inhalation induction of anesthesia is safe, the incidence of bradycardia, hypotension, and cardiac arrest during this form of induction is higher in infants younger than 1 year of age than in older children and adults.[34] This difference in outcome is due to the extremely rapid uptake of inhalation agents in infants compared with adults as a result of the much greater ratio of alveolar ventilation to functional residual capacity and the altered distribution of cardiac output. In addition, high inspired concentrations (overpressure) are often used early in induction, yielding high tissue concentrations of anesthetic that can lead to severe cardiac depression and junctional rhythms.[35] In light of these facts, mask induction of anesthesia in this age group should be accompanied by monitoring of blood pressure, electrocardiogram (ECG), oxygenation, and ventilation.

Minimal Alveolar Concentration

The minimum alveolar concentration (MAC) of anesthetic required in pediatric patients differs with age. There is actually a small increase in MAC between birth and 2 to 3 months of age, which represents the age of highest MAC requirement. After that time, MAC slowly decreases with age. For sevoflurane, the change in MAC is marked—with a value of approximately 2.5% for young infants compared with 2% for adolescents and adults.[36]

Intracardiac Shunts

Children with unrepaired or partially repaired congenital heart malformations may safely undergo inhaled induction of anesthesia. Although intracardiac shunts can, in theory, alter the uptake of anesthetic agents and affect the speed of induction, this is rarely clinically evident. A right-to-left shunt slows the

inhaled induction of anesthesia because anesthetic concentration in the arterial blood increases more slowly. A left-to-right shunt should have the opposite effect; volatile agent induction is more rapid because the rate of anesthetic transfer from the lungs to the arterial blood is increased. In practice, decreased delivery of anesthetic to the target tissues largely negates the increased uptake with this type of shunt.

Inhaled Agents for Induction of Anesthesia

The only two potent anesthetic agents currently in use that are compatible with inhaled induction are sevoflurane and halothane.[37] Both of these agents have acceptable odor and can be used for smooth inhaled induction in children. Sevoflurane dominates this market in the United States where its advantages—including rapid onset and relatively *less frequent* junctional bradycardia associated with its use—are perceived as worth its added cost over halothane.[38] Some of these (clinically noted) differences may, in fact, be due to vaporizer design owing to the fact that it is possible to deliver a much higher MAC multiple of halothane versus sevoflurane.[39] Halothane has been shown to have a greater depressive effect on the myocardial contractility than sevoflurane during standard inhaled induction techniques.[40,41]

Inhaled Agents—General Points on Maintenance and Recovery in Pediatric Patients

The safety and efficacy of sevoflurane for maintenance of anesthesia in children has been established in hundreds of studies. Intubation and laryngeal mask airway (LMA) insertion under deep sevoflurane anesthesia has also been reported.[42,43,44,45] The rapid and extensive pulmonary

elimination of sevoflurane minimizes the amount of anesthetic available for metabolism. In vivo studies suggest that only about 5% of the sevoflurane dose is metabolized by the hepatic cytochrome P4502E1 isoenzyme to hexafluoroisopropanol (HFIP) with the release of inorganic fluoride and carbon dioxide. Fluoride is primarily excreted in the urine, and no evidence of toxic levels or renal injury has been found in children after exposure to sevoflurane.[46]

Sevoflurane undergoes ex vivo degradation reaction in the clinical setting through direct contact with CO_2 absorbents (i.e., soda lime or Baralyme) in the anesthesia circuit. This reaction produces pentafluoroisopropenyl fluoromethyl ether (PIFE), also known as compound A, and trace amounts of pentafluoromethoxy isopropyl fluoromethyl ether (PMFE or compound B). Mean maximum concentrations in pediatric patients with soda lime are about half those found in adults. Although the level of compound A at which toxicity occurs is not known, sevoflurane use with fresh gas flows of 1 L/minute appears to be safe in children. Finally, although emergence from anesthesia is more rapid with sevoflurane than with more soluble agents such as halothane or isoflurane, there is a growing literature supporting the fact that agitation behaviors in children on emergence are more common with this agent. The exact reason for this disturbance is not known, but there is evidence that it may occur with or without pain as a factor.[47,48,49] The use of various medications to decrease the problem of

emergence agitation after sevoflurane (including midazolam, ketorolac, fentanyl, propofol, and dexmedetomidine) have been reported.[50,51,52,53,54] Careful attention to pain control and supportive environments are indicated.

Halothane has a long history of safety and efficacy as an inhaled agent for pediatric anesthesia. Although there has been some concern regarding sensitization of the myocardium to catecholamines, there is little problem in the absence of hypercarbia or light anesthesia.[55] Up to 10 µg/kg of epinephrine may be used with minimal risk of cardiac dysrhythmia in the absence of hypercarbia.

Halothane can cause myocardial depression. This effect is exaggerated in young children and in those who are hypovolemic. Addition of muscle relaxants to a lighter halothane anesthetic (in conjunction with regional anesthetic techniques or opioids) can ameliorate this effect.

Isoflurane also has a long track record as a safe and efficacious agent for maintenance of anesthesia in infants and children. Like halothane, it decreases blood pressure in pediatric patients. Although myocardial depression in children is less than that caused by halothane, isoflurane reduces peripheral vascular resistance, whereas halothane does not. (In neonates, equal myocardial depression has been demonstrated with both drugs.[56] The major disadvantage of isoflurane is its pungent odor and high incidence of laryngospasm when this agent is used for inhaled induction of anesthesia. It should not be used for inhaled induction of anesthesia.

Desflurane is also a safe and effective agent for anesthesia[57] in infants and children. Unfortunately (like isoflurane), an unacceptable incidence of coughing, increased secretions, and laryngospasm preclude its use as a mask induction agent.[58] Although desflurane appears to be associated with faster initial awakening when used as a maintenance anesthetic agent in pediatric patients, studies have shown no difference between halothane and desflurane in time to discharge after ambulatory surgery. As is the case with sevoflurane, emergence agitation has been reported with desflurane use in children.[47]

Intravenous Agents

Sedative Hypnotics

Sedative hypnotic agents may be employed after inhaled induction of anesthesia (e.g., to deepen anesthesia for airway management), or they may be used as primary induction and maintenance agents in children who have an intravenous catheter in place. Intravenous line placement may be made easier for the awake patient through the use of topical anesthetics such as the eutectic mixture of local anesthetics, topical liposomal lidocaine cream, or lidocaine iontophoresis.[59,60] As with inhaled agents mentioned previously, the doses of intravenous agents used in infants and

toddlers will often need to be increased by 25 to 40% to obtain the same level of sedation/anesthesia in children as compared with adults.

Propofol, thiopental, methohexital, etomidate, midazolam, and ketamine have all been used to produce effective intravenous induction of anesthesia or sedation in infants and children. Methohexital, midazolam, and ketamine have also been used through the rectal administration, whereas midazolam (in particular) and ketamine have been shown to have useful oral and intramuscular applications. In this chapter, we discuss only the two agents; the other drugs are reviewed in detail in other chapters of this text and elsewhere.

Propofol is the most widely reported agent for induction and maintenance of anesthesia or sedation in children. Its use is limited to the operating room environment and brief sedation outside the operating room as prolonged use in the intensive care environment (although not well understood) is believed to be linked to acidosis, heart failure, and several fatalities.[61,62] Propofol induction doses range from 3 to 4 mg/kg for children younger than 2 years of age to approximately 2.5 to 3 mg/kg for older children, whereas maintenance of anesthesia requires 200 to 300 mcg/kg per minute.[63] Onset is rapid, but may be accompanied by some random movement and cough. Bag-mask ventilation is generally easily performed. Pain on injection of propofol is marked. This problem may be minimized by infusing the largest vein possible and running carrier fluid as rapidly as possible. Other techniques for minimizing pain include small doses of lidocaine preceding or mixed with the propofol bolus, fentanyl premedication, ketamine premedication, and nitrous oxide inhalation at the time of propofol infusion.[64] Propofol will cause mild to moderate decreases in blood pressure when used at recommended doses.[65]

The emergence profile of propofol in children shows clear advantages over other intravenous agents and inhaled anesthetics. Emergence from deep sedation/anesthesia is clearly faster than that from most other sedative agents and most inhaled agents, especially after prolonged administration. In addition, although time to awakening may not be faster than sevoflurane or desflurane, the emergence from propofol is associated with less nausea and vomiting, and is accompanied by less emergence agitation so readiness for discharge is at least as rapid.[66]

Although it was first described 40 years ago, ketamine has been increasingly reported for use in anesthesia, procedural sedation, and sedation in the intensive care environment for children. It is the only agent that offers both hypnosis *and* analgesia. Other unique aspects include the fact that ketamine preserves airway reflexes, maintains respiratory drive, increases endogenous catecholamine release, and results in bronchodilation and pulmonary vasodilation. Induction doses of 1 mg/kg intravenously yields effective analgesia and sedation with rapid onset. Intramuscular doses of 3 to 4 mg/kg result in a similar state with significant analgesia appropriate for minor procedures such as intravenous catheter starts or fracture manipulation.[67] Simultaneous administration of an anticholinergic will minimize oral secretions. Emergence can be marked by diplopia, occasional disturbing dreams, and nausea/vomiting, although these are less common in children than in adults.[68] The use of concomitant midazolam 0.025 to 0.50 mg/kg to decrease some of these side effects has a mixed record of success and should not be considered reliable.

Opioids

Opioids are important elements of balanced anesthesia and sedation in children. Their use for surgical anesthesia will decrease MAC of inhaled agents, smooth hemodynamics during airway management or stimulating procedures, and provide postoperative analgesia. Usual recommended doses include fentanyl 0.5 to 1.0 mcg/kg, morphine 0.10 mg/kg, sufentanil 0.1 mcg/kg, and alfentanil 50 to 100 µg/kg. Remifentanil has also been shown to be an effective part of anesthesia and sedation protocols for a variety of procedures at 0.25 to 1.0 µg/kg per minute.[69,70] It should be noted that due to its short half-life, remifentanil does not offer effective postoperative analgesia when used in this manner.

Chest wall rigidity is not uncommon when administering bolus opioids, especially to drug-naïve neonates and infants. This effect can severely impair respiration, and providers must be prepared to provide muscle relaxation and general airway support when delivering these medications in this

manner. Opioids are also well known to depress central respiratory effort. Newborns and infants younger than 6 months are particularly susceptible to this effect due the immature blood-brain barrier and increased levels of free drug. These facts highlight the need to carefully monitor pediatric patients given opioids; however, they do not argue for withholding pain medications. In fact, after 6 months of age, there is evidence that infants and children are no more susceptible to central depression due to opioids than adults given equivalent doses.[71] It should be noted that opiate delivery via patient-controlled analgesia is well studied and effective in most developmentally normal patients 5 years of age or older.[72] Other modalities such as nurse-controlled analgesia and parent-controlled analgesia are also employed in some centers.[73]

Muscle Relaxants

8 Succinylcholine has been used as part of pediatric anesthesia and airway management for more than 60 years. When given in a dose of 1.5 to 2.0 mg/kg, it produces excellent intubating conditions (reliably) in 60 seconds. Recovery occurs in 6 to 7 minutes. Succinylcholine can also be given intramuscularly at 4 mg/kg in emergencies when intravenous access is not available. Its use is absolutely contraindicated in a variety of patients, particularly in those with muscular dystrophy, recent burn injury, spinal cord transection, and/or immobilization, as well as any child with a family history of malignant hyperthermia because of the risk of rhabdomyolysis, hyperkalemia, masseter spasm, and malignant hyperthermia. In addition, the drug is currently listed as relatively contraindicated for use in all children by the U.S. Food and Drug Administration (FDA). This is due to the infrequent but well-reported cases where succinylcholine has been inappropriately administered to children with risk factors (usually) that are not clinically apparent or unappreciated. The requirement for succinylcholine has also been decreased by the availability of fast-acting nondepolarizing agents such as rocuronium. For these reasons, succinylcholine can only be recommended in situations where ultrarapid onset and short duration of action is of paramount importance (laryngospasm), or when relaxation is required or intravenous access is not available and intramuscular administration is required.

All nondepolarizing muscle relaxants used in adults are effective for pediatric patients. Because they have a larger percentage of total body water and larger extracellular fluid volume, neonates and young infants have a larger volume of distribution for these hydrophilic drugs than older children and adults. In contrast, these patients are slightly more sensitive to these drugs. The result is a pharmacokinetic and pharmacodynamic profile where the recommended doses of these agents are identical for children and adults, but the duration of action tends to be slightly longer (Table 44-3). In selecting a particular drug for a clinical scenario, one must consider the possible side effects of each medication, its route of metabolism, and the possible duration of action. For instance, pancuronium has a vagolytic effect that may be desirable in many neonates; however, it is renally excreted and therefore may have a markedly extended duration of action in this patient group where glomerular filtration rate is relatively decreased. Rocuronium has the fastest onset of action in this class (60 to 90 seconds for a 1 mg/kg dose) and is generally the choice for rapid-sequence intubation.

TABLE 44-3 Onset, Duration, Cardiovascular Effects, Cost, and Special Considerations of Nonc Blocking Agents in Children

The need for reversal of muscle blockade should be carefully considered in each patient. The risks associated with inadequate ventilation in small children are great, especially in cases where the work of breathing may be increased, as is the case with intercurrent illness and chest/abdominal procedures. Muscle twitch should be monitored and reversal agents (i.e., neostigmine 0.05 mg/kg with 0.015 mg/kg of atropine or 0.01 mg/kg glycopyrrolate) administered if residual weakness is detected. Clinical signs of adequate strength for ventilation in this age group include the ability to flex the hips.

Antiemetics

Postoperative nausea and vomiting are among the most common causes of prolonged recovery stays and unanticipated hospitalization in children. Unfortunately, this is a complex clinical problem to manage, with many factors influencing its frequency. Postoperative nausea and vomiting (PONV) is particularly prominent after certain surgeries, such as orchidopexy, strabismus surgery, and tonsillectomy. In addition, certain age groups such as adolescent females are much more prone to postoperative nausea and vomiting than when compared with young infants. There is no one therapy that is universally

accepted as safe and effective. In fact, all antiemetic therapies for children are only shown to have efficacy in high-risk groups and surgeries; their use in lower-risk situations is suspect. The type of anesthetic employed for a particular surgery will also influence the incidence of PONV. For instance, when propofol is used in place of inhaled agents as the primary anesthetic, there is evidence that PONV is less common, particularly for high-risk surgeries such as tonsillectomy.[74] Opiate-based anesthetics are, conversely, more often associated with PONV.

All the antiemetics used in adults, including phenothiazines, antihistamines, anticholinergics, benzamides, butyrophenones, and 5-HT(3) antagonists, have been used in children and (to one extent or the other) have been shown to have some effectiveness. The 5-HT(3) antagonists are generally considered equivalent as a group; however, ondansetron has been most thoroughly studied in children, and at 0.05 to 0.15 mg/kg, has been found to be effective in tonsillectomy and strabismus models.[75] Its effectiveness as a "rescue" medication is not proven. Dexamethasone 0.15 to 1.0 mg/kg appears to be effective in limiting PONV after oral pharyngeal surgery (tonsillectomy), but there is much less data on its use in other types of procedures.[76]

Complete reviews of antiemetic use in children are available;[77,78] however, droperidol deserves special mention. Its use and effectiveness in children as an antiemetic is well documented.[79] However, in 2003, the FDA issued a report warning of prolonged QT syndrome and possible torsades de pointes with its use, suggesting prolonged monitoring (6 hours) for patients given this drug. A black box warning has been placed on this medication to this effect. The frequency of this problem in children is unknown but is believed to be extremely low; nevertheless, use of the drug has decreased significantly in light of this warning.

Unfortunately, the issue of antiemetic efficacy and cost effectiveness remains largely unanswered in spite of the hundreds of studies that exist concerning their use in children. The use of at least one of the drugs mentioned previously with known antiemetic action is indicated for surgeries associated with a high incidence of nausea and vomiting, especially in high-risk age groups. In addition, the practice of *requiring* patients to eat and/or drink prior to discharge will only increase PONV rates and does not appear to improve outcomes. Likewise, the use of pain control modalities in lieu of opioids (acetaminophen or nonsteroidal anti-inflammatory drugs [NSAIDs], and regional anesthesia) will likely decrease the overall risk of PONV.

FLUID AND BLOOD PRODUCT MANAGEMENT

9 Perioperative fluid and blood product management for pediatric patients must take into account fluid deficits, translocation of fluids and blood loss during surgery, and maintenance fluid requirements. A patient's fluid deficit prior to starting a case can be simply calculated by multiplying his or her calculated maintenance requirement by the number of hours since the last PO fluid intake. The calculation for maintenance fluids depends directly on metabolic demand; each calorie of energy expended requires 1 mL of H_2O for metabolism. Relating this energy requirement to patient weight results in an hourly fluid requirement that may be estimated as in Table 44-4.

TABLE 44-4 Maintenance Fluid Requirements for Pediatric Patients

·WEIGHT (kg)	·HOURLY FLUID	·24-hr FLUID
<10	4 mL/kg	100 mL/kg
11–20	40 mL + 2 mL/kg > 10 kg	1,000 mL + 50 mL/kg > 10 kg
>20	60 mL + 1 mL/kg > 20 kg	1,500 mL + 20 mL/kg > 20 kg

Immediate intravascular volume expansion may be accomplished with a 10 cc/kg bolus of isotonic fluid. The balance of the calculated fluid deficit can be provided over 1 or 2 hours and is often provided in the form of isotonic fluid or a 5% dextrose solution in 0.9% normal saline. There is

conflicting data concerning the need for glucose-containing solutions in this setting. In our current era with liberalized recommendations for intake of clear fluids (generally up to 2 hours prior to surgery), there is little evidence of hypoglycemia in children due to fasting prior to surgery. Indeed, most children who are given non–glucose-containing fluids during surgery actually experience a rise in blood glucose due to sympathetic activation. Hyperglycemia has been documented in children given 5% dextrose solutions to replace deficits or fluid losses intraoperatively. This is particularly problematic for patients with intracranial injury where hyperglycemia may result in worsening outcomes. In addition, hyperosmolar diuresis caused by significant hyperglycemia may also confuse diuretic and fluid therapy. In contrast, life-threatening *hypo*glycemia would be undetectable on clinical grounds under anesthesia.

To optimize fluid administration and glucose delivery, a balanced salt solution containing 2.5% glucose may be used (although not commercially available). Another approach would be to provide 5% dextrose in 0.45% normal saline (D_5 0.45 NS) for maintenance, piggybacked into a balanced salt solution for the deficit and third-space fluid. The exact composition of fluids used is less important than being aware of the issue of glucose control.[80] Intraoperative monitoring of blood glucose is appropriate for newborns, former premature infants, and any high-risk pediatric patients.

Surgical manipulation is associated with the isotonic transfer of fluids from the extracellular fluid compartment to the nonfunctional interstitial compartment. Estimated third-space loss during intra-abdominal surgery varies from 6 to 15 mL/kg per hour, whereas in intrathoracic surgery it is less (4 to 7 mL/kg per hour), and during intracranial or cutaneous surgery, it is negligible (1 to 2 mL/kg per hour). These third-space losses should be estimated and replaced on an hourly basis. These losses are derived from extracellular fluid; therefore, it is important to replace them with a balanced salt solution to avoid hyponatremia that would result from using hypotonic replacement. Lactated Ringer's solution is frequently used as normal saline contains an excessive chloride and acid load for infants.

Indications for blood or blood component therapy in pediatric patients are not always clear cut. Decisions must be based on considerations of the patient's blood volume, preoperative hematocrit, general medical condition, ability to provide oxygen to tissues, the nature of the surgical procedure, and the risks

versus benefits of transfusion. All blood loss should be measured as accurately as possible and accounted for with some form of volume replacement to maintain intravascular volume and perfusion. If an isotonic solution is chosen to replace some element of blood loss it should be given in a ratio of 3 mL of solution for each milliliter of blood lost.

Many major procedures in children will be accompanied by significant blood loss and require transfusion of red blood cells and other blood products. In these cases, calculation of acceptable blood loss is vital to any replacement plan. The concept of the maximum allowable blood loss (MABL) takes into account the patient's total blood volume, starting hematocrit, and estimated "target" hematocrit—that which represents the lowest acceptable hematocrit for this patient considering age and comorbid conditions. In general, blood volume is estimated at 100 mL/kg for the preterm infant, 90 mL/kg for the term infant, 80 mg/kg for the child 3 to 12 months of age, and 70 mg/kg for the patient older than 1 year of age. These estimates of blood volume can be used in calculating the individual patient's blood volume by multiplying the child's weight by the estimated blood volume (EBV) per kilogram:

$$\text{MABL} = \frac{\text{EBV} \times (\text{starting hematocrit} - \text{target hematocrit})}{\text{starting hematocrit}}$$

As the MABL is approached, the patient's hematocrit should be checked to confirm estimated blood losses and volumes.

Packed red blood cells have a hematocrit between 55 and 70%. On average, 1 mL/kg of packed red blood cells increases the hematocrit by 1.5%. Units of blood can be subdivided into pediatric packs of 50 to 100 mL; thus, the remainder of a single unit is not wasted. Administration of other

products such as cryoprecipitate or fresh frozen plasma should be based on laboratory evidence of coagulopathy and aimed at replacement of identifiable deficiencies of factors relating to hemostasis. Rapid administration of citrated blood products (particularly fresh frozen plasma) can result in hypocalcemia and hypothermia. Although under most circumstances, mobilization of calcium and hepatic metabolism of citrate are sufficiently rapid to prevent precipitous decreases in ionized calcium, infants have smaller stores of calcium.

As always, the end point of fluid and blood therapy is adequate blood pressure, tissue perfusion, and urine volume (0.5 to 1 mL/kg per hour). Careful attention to these goals through the examination of clinical (e.g., capillary refill time, urine output) and laboratory (e.g., blood gases) examination are more important than adherence to any one particular clinical protocol.

AIRWAY MANAGEMENT

10 Appropriate airway management remains the single most important aspect of delivering safe pediatric anesthesia. At any age, operative cases can be performed with facemask, LMA, or endotracheal tube placement. The choice of airway will depend on the age of the child, the time since last PO intake, coexisting illness, and the procedure to be performed. Each case must be considered on its own merits, but trends and guidelines have been established:

1. As a general rule, endotracheal tubes are preferred for premature infants and most neonates due to the slightly greater difficulty of providing effective facemask ventilation under appropriate levels of anesthesia and the risk of filling the stomach with air while providing mask ventilation.
2. Cases where recent oral intake or pathology (e.g., pyloric stenosis or intestinal obstruction) raise the probability that the stomach contains food or acid (and therefore risk aspiration injury) and are best managed with a rapid-sequence induction and intubation, regardless of age.
3. LMAs come in a range of full sizes and half sizes, and can be employed in infants, toddlers, and older children for almost any procedure that does not involve opening the abdomen or thoracic cavity. Although their use is standard for lower-extremity, inguinal, cutaneous, or eye procedures, comfort with this airway for oral procedures such as tonsillectomy/adenoidectomy varies from center to center. Use of the LMA in neonates and premature infants is less common, and depends on provider experience and preference. Aspiration and laryngospasm with the airway in place are not common but are possible, and plans to quickly manage these events must always be in place.[81] The LMA has become a critical part of the difficult airway algorithm for pediatric patients. This device can be used to ventilate patients where conventional mask ventilation is difficult, as well as to provide a conduit for fiberoptic–assisted intubation.
4. Because the narrowest portion of the pediatric airway is at the level of the cricoid cartilage (and is therefore round), uncuffed tubes can be used and will create a functional seal when appropriately sized.[82] Several formulas have been used for tube selection in children older than 1 year of age, the most common being (16 + age)/4 or variations thereof. One may also estimate the size by comparing the size of the fifth digit or of a nostril. Once the tube is in place, it should be checked to determine at what pressure air can escape around the tube. Air should leak out at no higher than 20 to 25 cm H_2O to minimize risk of postextubation croup. Cuffed tubes can also be safely used in children by selecting a tube 0.5 mm smaller in internal diameter than the uncuffed choice.[82] Care should be taken to check the pressure in the cuff to assure it does not exceed 20 cm H_2O.
5. Intubation in children can be safely accomplished after inhaled induction with or without the use of muscle relaxant. Intubating conditions after 3 minutes of 8% sevoflurane or a dose of propofol and opiate[43,83] may produce acceptable views of the larynx. In fact, a recent survey of pediatric anesthesiologists revealed the majority do not use muscle relaxants for elective surgery.[84] The use of muscle relaxants should be based on the specific issues related to the

child and the procedure to be performed.

PEDIATRIC BREATHING CIRCUITS

Much has been written about the advantages and disadvantages of various anesthesia circuits for use in pediatric patients (see Chapter 21). Pediatric circuit design has been directed to the physiology of the neonate and ways of reducing the work of breathing while preventing rebreathing. Nonrebreathing circuits minimize the work of breathing because they have no valves to be opened by the patient's respiratory effort. In addition, because the total volume of the circuit is less, the partial pressure of inhaled agent increases faster. Compression and compliance volumes are also decreased compared with a standard breathing circuit.

A number of combinations of the simple T-piece tubing, reservoir bag, and sites of fresh gas entry and overflow are

possible. Mapleson classified the various combinations into five types. The Jackson Rees modification is functionally identical to the Mapleson D, as are coaxial systems. Carbon dioxide is removed most effectively in the D configuration when controlled ventilation is used, whereas spontaneous ventilation is most effective in the A system.

Circle breathing systems can also be used effectively in infants and children. Newer anesthesia machines use valves with much less resistance than older models. In addition, most neonates and small infants (for whom resistance would be the biggest problem) are ventilated mechanically during surgery, making work of breathing a nonissue. Dead space in these systems is no more than that of the Mapleson circuits.

MONITORING

Monitoring decisions for pediatric patients are similar in many respects to those in adults. The pediatric patient should be monitored continuously with precordial or esophageal stethoscope. This simple device allows the anesthesiologist to detect changes in the rate, quality, and intensity of the heart sounds. Pulse oximetry, capnography, blood pressure (measured, *appropriately* sized cuffs), temperature, and ECG should also be monitored routinely in children as in adults. More invasive or sophisticated monitoring should be used in appropriate circumstances. One should note that patient pathophysiology may contribute to an increased gradient between end-tidal and arterial CO_2 measurements, usually by increasing shunt (V/Q mismatch) and increasing dead space (V_D/V_T). That is, in children with cyanotic congenital heart disease, $ETCO_2$ underestimates $AaCO_2$ as venous blood passes directly into the arterial circulation *without* going through the lungs.[57] Low tidal volumes, rapid respiratory rates, and changing intrapulmonary shunts make $ETCO_2$ accuracy also inaccurate for infants and premature neonates with respiratory distress syndrome. It is important to note that transesophageal echocardiography has become an important tool for intraoperative assessment of cardiac function, flow defects, cardiac morphology, and adequacy of repair during and after surgical procedures for congenital heart disease. Although placement of the probe in the anesthetized infant is usually the responsibility of the anesthesiologist, interpretation of the echocardiogram occurs in collaboration between surgeons, cardiologists and anesthesiologists. Finally, the use of pulmonary artery catheters (Swan-Ganz) is quite limited in the pediatric population because of size issues and because of the fact that left-sided and right-sided pressures are similar.

PAIN MANAGEMENT AND REGIONAL ANESTHESIA

It is important for the health care provider to note that children experience pain, just like adults, regardless of their age. More recent studies indicate that neonates have considerable maturation of pain transmission by 26 weeks' gestation and respond to injury with specific behavior and with autonomic, hormonal, and metabolic signs of stress and distress.[85] In fact, more recent data indicate that extreme pain experienced during the neonatal period may have lifelong lasting adverse effects.[85,86] Pain in children can be assessed by self-reporting, observational, and

physiological assessment tools.[85,87] Although self-reporting pain is considered the gold standard, this assessment methodology cannot be used in infants, younger children, and children who suffer from developmental delay.[86] In these children, the clinicians often need to rely on parental report.[87] Children older than 4 to 6 years of age can usually self-report pain using a face scale. Younger children are usually assessed using a behavioral or physiologic-behavioral scale.[87]

The most common oral analgesic used in children continues to be acetaminophen (Table 44-5). This medication has been shown to be safe and efficacious in neonates and older children. Doses of 10 to 15 mg/kg orally every 4 hours.[88] The plasma concentrations effective for fever control and analgesia are 10 to 20 µg/mL.[89] Rectal administration is associated with delayed and erratic absorption; single doses of 35 to 45 mg/kg generally produce therapeutic plasma concentrations.[85] Subsequent rectal doses, however, should not exceed 20 mg/kg, and the interval between doses should be extended to at least 6 to 8 hours. The rectal route of administration can be particularly effective for children with no intravenous access, such as pressure-equalizing ear tube placement.

TABLE 44-5 Management of Postoperative Pain

	·DOSE			·MAXIMAL DAILY DOSE	
·DRUG	·PATIENTS <60 kg (mg/kg)	·PATIENTS ⩾60 kg (mg)	·INTERVAL (hr)	·PATIENTS <60 kg (mg/kg)	·PATIENTS ⩾60 kg (mg)
Acetaminophen	10–15	650–1,000	4	100[a]	4,000
Ibuprofen	6–10	400–600[b]	6	40[b,c]	2,400[b]
Naproxen	5–6[b]	250–375[b]	12	24[b,c]	1,000[b]
Aspirin[d]	10–15[b,d]	650–1,000[b]	4	80[b-d]	3,600[b]

[a]The maximal daily doses of acetaminophen for infants and neonates are a subject of current controversy. Provisional recommendations are that daily dosing should not exceed 75 mg/kg per day for infants, 60 mg/kg per day for term neonates and preterm neonates of more than 32 weeks of postconceptional age, and 40 mg/kg per day for preterm neonates 28 to 32 weeks of postconceptional age. Fever, dehydration, hepatic disease, and lack of oral intake may all increase the risk of hepatotoxicity.

[b]Higher doses may be used in selected cases for treatment of rheumatologic conditions in children.

[c]Dosage guidelines for neonates and infants have not been established.

[d]Aspirin carries a risk of provoking Reye's syndrome in infants and children. If other analgesics are available, aspirin should be restricted to indications for which an

antiplatelet or antiinflammatory effect is required, rather than being used as a routine analgesic or antipyretic in neonates, infants, or children. Dosage guidelines for aspirin in neonates have not been established.

From Berde CB, Sethna NF: Analgesics for the treatment of pain in children. N Engl J Med 347:1094, 2002.

Ketorolac has been shown to be an effective and safe analgesic for pediatric patients.[85,90] It may be administered intramuscularly (0.75 mg/kg) or intravenously with a loading dose of 1 mg/kg followed by a maintenance dose of 0.5 mg/kg every 6 hours. Ketorolac has the disadvantage of prolonging bleeding time because of its effect on platelet aggregation. As with other NSAIDs, ketorolac should be avoided in patients with preexisting nephropathy or bleeding diathesis. Ibuprofen is the most popular NSAID given orally to children. It comes in several palatable preparations. When given in the recommended oral dose of 10 mg/kg, it has similar analgesic effects as acetaminophen or ketorolac. Gastrointestinal side effects are uncommon.

The safety and efficacy of patient-controlled analgesia for children as young as 6 years has been shown.[91] Although routinely used in Children's Hospitals, this technique is to be used *only* by highly trained medical personnel who are knowledgeable in pediatric pain management. For infants and children younger than 6 years of age, nurse-controlled analgesia is now widely used as a pain management modality. Finally, it should be noted that although parent-controlled analgesia is now accepted in palliative care, its use for postoperative pain is controversial because of the potential for overdosing.

Regional Anesthesia

Chapters 25 and 26 discuss regional anesthesia and analgesia in detail. Most regional anesthetic techniques can be useful for children undergoing anesthesia and surgery.[92] Because of obvious developmental and cognitive issues, regional techniques are rarely used as a sole anesthetic and most often used as adjuncts to general anesthesia and to provide postoperative analgesia.[92] Regional anesthetic techniques may also be used as the sole anesthetic in premature infants at risk for postoperative apnea undergoing abdominal or lower-extremity procedures (spinal/epidural). Simple techniques such as ilioinguinal-iliohypogastric nerve block, ring block of the penis, or caudal block can be useful for common pediatric surgical procedures.[92] Direct local infiltration of surgical wounds can also be helpful. The types of blocks that can be used safely in children are limited only by the skill of the anesthesiologist.

Because of the unique anatomic and physiologic considerations, strict attention must be paid to the dose of local anesthetic, dose of epinephrine, and technique of administration. More sophisticated techniques such as continuous caudal or epidural analgesia using combinations of opioids and local anesthetics are useful for inpatients after thoracic, abdominal, or lower-extremity procedures. These regional techniques are usually used in combination with general anesthesia (catheters are placed after the child is induced), and the regional block is maintained for postoperative pain control. Close postoperative monitoring of the child must take place when these continuous infusions are used.[93]

11 The most commonly used form of regional anesthesia in children is the *caudal block*. This technique can provide postoperative analgesia following a wide variety of lower abdominal and genitourinary surgical procedures. Usually, bupivacaine 0.175% solution in a dose of 1 mg/kg

is used, and if larger volumes are needed, the use of 0.125% is recommended. Postoperative analgesia typically lasts 4 to 6 hours and is not associated with a motor paralysis. This route can be used for either a single-dose injection or for catheter advancement for continuous infusion.[94]

Spinal anesthesia may be used for procedures involving surgical dermatomes below T_6. It is important to note that the dural sac migrates cephalad during the first year of life and in a neonate it is at S_3, whereas over the age of 1 year it is at the S_1 level.[92] The sitting position may be especially helpful in neonates to maintain midline needle position and free flow of spinal fluid. It may be easier for the novice assistant to hold the infant more securely in the lateral decubitus position. As mentioned previously, spinal anesthetic is a particularly good option for premature infants who undergo surgery because the incidence of postoperative apnea has been shown to be reduced in these infants with the use of this technique.[94]

Epidural anesthesia can be used to provide postoperative analgesia for thoracic, lumbar, and sacral dermatomes. In young children, the epidural space can be reached easily by the caudal approach with less risk of dural puncture than with thoracic or lumbar approaches. This approach is ideal for analgesia/anesthesia of lumbar and sacral nerve roots. Higher dermatomes can be reached by either using a lumbar approach or increasing drug volume, or threading a catheter several centimeters into the epidural space.[92]

POSTANESTHESIA CARE

12 Recovery of the young child in the PACU can be hindered by a variety of challenges. Hypothermia is a common perioperative problem, particularly in infants and young children. The inability to regulate body temperature under general anesthesia, cold large operating rooms, and continued heat loss are major reasons for hypothermia. Although minor hypothermia (34 to 36°) has not been found to influence the recovery period,[95] it is best to restore normothermia prior to discharge from the PACU. More significant hypothermia can result in increased oxygen consumption, cardiovascular manifestations of hypothermia,[96] prolonged metabolism and excretion of anesthetic drugs, and delayed wound healing.

Nausea and vomiting occur frequently after eye or ear surgery but can occur after any surgical procedure or anesthetic. More recent studies quote an overall incidence of 20 to 30%,[6] whereas others have found that the problem is even more widespread (39 to 73%).[97] The physiologic mechanisms for postoperative nausea include central causes (opiates), gastrointestinal malfunction (ileus or gastric distention), the surgical procedure itself (eye and ear, most commonly), and postoperative pain.[98] Control of nausea and vomiting no longer remains purely within the domain of the PACU, but begins in the selection of agents/techniques used for anesthesia.[99] For example, induction and maintenance of anesthesia with propofol-air-oxygen is associated with only a 23% incidence of nausea and vomiting, as compared with a 50% incidence using halothane-N_2O-droperidol for strabismus surgery.[100] Pretreatment with ondansetron 0.15 mg/kg, droperidol 0.075 mg/kg, or metoclopramide 0.15 mg/kg has been successful in reducing nausea and vomiting for patients at higher risk, such as those undergoing tonsillectomy or strabismus repair. Ondansetron, a selective serotonin antagonist, is particularly effective in reducing postoperative nausea and vomiting when used prophylactically. Although more expensive than other antiemetics, its significant efficacy makes it cost effective when used for procedures with a high incidence of nausea and vomiting.

Special attention should be paid to the treatment of pain in the PACU. Although pain self-report is considered the best assessment modality in older children, physiologic responses such as tachycardia, hypertension, nausea, vomiting, and agitation may be important indicators of analgesic needs in the preverbal child. Intravenous opiates such as fentanyl or morphine are used most commonly to treat moderate to severe pain in the PACU. Carefully titrated intravenous narcotics present few untoward effects.

Finally, many children are terrified in the recovery room. They awaken in a strange place with unfamiliar people and may be disoriented from residual effects of the anesthesia. Some

children may experience nightmares, develop enuresis, or have behavioral problems after a

surgical procedure.[101] Measures taken to calm and comfort the child may reduce the incidence of these sequelae and aid in the overall recovery. Many institutions have found that allowing parents to soothe the child during recovery is beneficial.

Chapter 45

Anesthesia for the Geriatric Patient

Stanley Muravchick

KEY POINTS

1	Aging is a physiologic process associated with decreased functional reserve and an increase in the variability of clinical signs and symptoms.
2	At a cellular level, normal aging may be largely due to declining mitochondrial bioenergetics and the deleterious effects of oxidative stress.
3	Physiologic reserve provides a margin of safety that allows elderly surgical patients to meet the increased demands imposed by illness, surgical trauma, infection, and wound healing.
4	Decreased tissue elasticity, reduced lean tissue mass, neuronal attrition, and a loss of autonomic homeostasis explain much of the measurable physical decline associated with normal aging.
5	Aging is associated with a decline in anesthetic requirements and an increase in the duration of clinical effect for drugs that require organ-based elimination.
6	Adverse drug effects and other forms of perioperative morbidity are more common in older surgical patients than in younger adults.
7	In older adults, a higher likelihood of perioperative mortality and major adverse outcome are largely the result of age-related disease and site of surgery rather than of chronological age itself.

Advances in nutrition, public health, education, and social services have produced major changes in human longevity in industrialized societies, and elderly patients now account for more than one-half of all hospital care days in the United States. In addition, almost one-third of all surgical patients are 65 years of age or older, and an even larger fraction is anticipated in the next two decades. Therefore, unless intentionally limited to pediatrics or obstetric patients, every anesthesiologist in contemporary practice must acquire expertise in geriatric medicine. The following sections define the current concepts of aging that are relevant to anesthetic practice. They discuss the distinction between aging and age-related disease, present strategies useful for perioperative assessment of the elderly patient, and summarize practical aspects of anesthetic

management and the perioperative care of geriatric surgical patients.

CONCEPTS OF AGING AND GERIATRICS

1 As they age, adults exhibit an increasingly varied array of physical responses to concurrent disease states. These, in turn, reflect life-long exposure to environmental and socioeconomic conditions, and to the accumulated stigmata of prior traumatic injuries and medical therapies. Prolonged longevity also enables complete expression of intrinsic genetic qualities as subtle physiologic manifestations. Therefore, extreme variability of signs, symptoms, and physical presentation among older patients is an essential characteristic of geriatric medicine. Currently, however, there is no consensus as to when the “geriatric” era begins in human subjects or whether any single physiologic marker can identify an “elderly” patient. Therefore, establishing a rigid and finite chronological definition of the term “geriatric” has little medical value other than for administrative, actuarial, or epidemiologic applications. For clarity and consistency, however, the terms “elderly” and “geriatric” are used synonymously in this chapter to describe human subjects who are 65 years of age or older. The term “aged” will be used to describe individuals older than 80 years.

“Life span” is a species-specific biological parameter that quantifies maximum attainable individual age under optimal conditions. Human life span has remained nearly constant at about 120 years for the past 20 centuries, but this is only a brief epoch on the evolutionary scale and human life span may actually be increasing slightly.[1] In contrast, the term “life expectancy” describes typical longevity under prevailing conditions, and this has changed dramatically during short periods in history. More recent advances in medical science and health care have increased the relative “agedness” of voting populations in democratic societies to the point that the economics of health care for the elderly have, for the first time, assumed roles of major social and political importance.

Most studies of human aging are cross-sectional studies that measure physiologic parameters simultaneously in young and elderly subjects. Although straightforward in design and

execution, even a comprehensive cross-sectional approach may not identify patients with subtle manifestations of disease. In addition, cross-sectional experimental design cannot be controlled for cohort-specific factors such as nutritional and environmental history, and the “young” and “old” patient groups being compared often differ not only in age, but also in their overall ethnic, anatomic, and biochemical characteristics for genetic background, or for prior exposure to infectious agents. Many changes now known to be due to age-related disease have, in the past, been attributed erroneously to aging. Therefore, data from cross-sectional studies rarely permit unambiguous conclusions regarding the effect of age itself on a measured parameter.

Longitudinal studies of aging, in contrast, require the investigator to obtain repeated measurements in each individual subject over several decades. Each subject therefore generates his or her own “young adult” control value for comparison with subsequent measurements. If any of the subjects in a longitudinal study eventually manifest signs of age-related disease, their data points can be excluded from the study, thereby leaving behind a smaller but more homogeneous group of healthy elderly subjects. Although difficult and expensive to organize and maintain, long-term longitudinal studies have produced substantial amounts of extremely valuable data related to human aging.

2 The mechanisms that control the aging process remain unknown. The impressive consistency of observed life span does not necessarily imply that there is a “biological clock” for each species. Instead, age-related decline in organ and tissue function may simply be the inevitable accumulation of nonspecific degenerative phenomena. Declining mitochondrial bioenergetics may be the underlying mechanism for age-related deterioration of cellular and organ function.[2] Throughout adulthood, increasing levels of oxygen-derived free radicals or “reactive oxygen species” create oxidative stress within the mitochondria, and disrupt the structural and enzymatic machinery of oxidative phosphorylation. As the ability to scavenge these byproducts of aerobic metabolism declines, it creates a “vicious cycle of aging” within the mitochondria (Fig. 45-1).

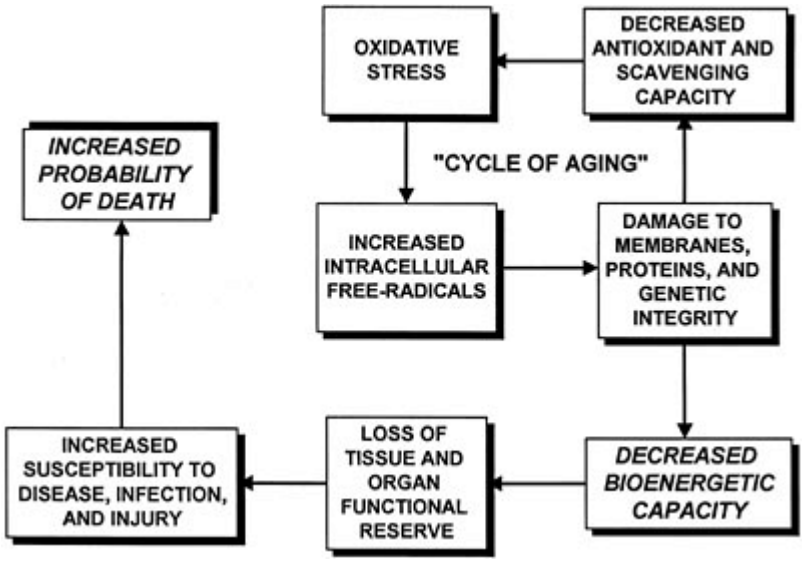

FIGURE 45-1. At a cellular level, there may be a self-sustaining “cycle of aging” within mitochondria in which oxidative stress damages the metabolic machinery needed to provide adequate bioenergetic capacity for full organ system functional reserve.

Viewed from this perspective, the unique life span demonstrated by each species could be explained as the net result of interaction between the genetically determined biochemical and physiologic attributes of each species, as well as the randomly destructive environmental factors that produce disorder in biological systems. Two recent observations support this concept. First, the cellular resistance to oxidative stress has been shown to be intrinsically involved in both aging and longevity,[3] and second, mitochondrial DNA mutation has produced phenotypic aging in laboratory animals.[4]

AGING AND ORGAN FUNCTION

Contemporary definitions of aging remain conceptual rather than quantitative. The implied consequence of aging in all species is an increasing probability of death as a function of time. Aging manifests itself in mammalian species as degenerative changes in both the structure and the functional capacity of organs and tissues. At one time, global age-related physiologic degeneration was depicted as a linear decline of maximal function beginning in young adulthood and continuing inexorably downward thereafter. However, a more contemporary analysis describes nonlinear change in maximal organ function that first becomes apparent following the years that represent the peak of somatic maturation, in the fourth decade of human life (Fig. 45-2). Additional decrements of function during the middle adult years appear to be relatively subtle, but subsequently become progressively more dramatic during the traditional years of geriatric senescence, the seventh decade of life and beyond. Elderly patients who maintain greater than average functional capacities are considered “physiologically young.” When organ function declines at an earlier age than usual, or at a more rapid rate, elderly patients appear to be “physiologically old.”

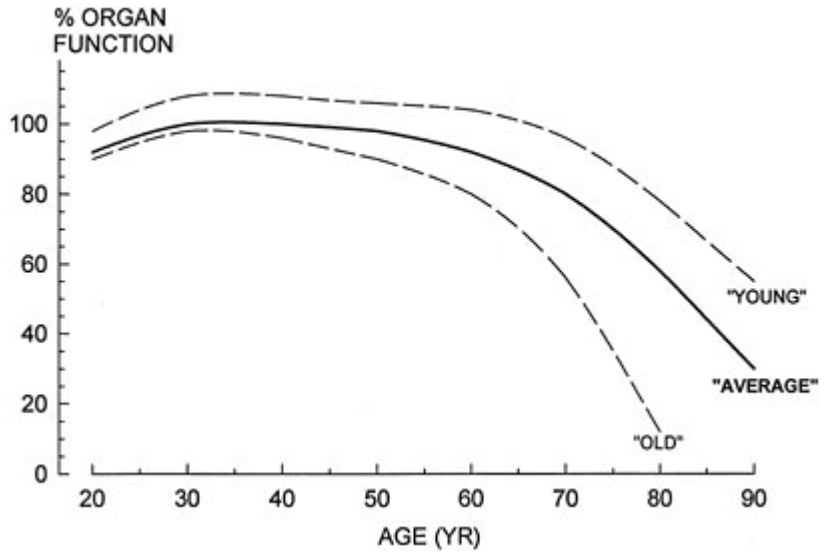

FIGURE 45-2. Differences in the rate at which maximal organ system functions decline with increasing age, and, to a lesser extent, differences in initial functional levels explain the inevitable variability seen in geriatric patients commonly described as physiologically “younger” or “older” than average.

Nevertheless, the competence of integrated organ system function varies greatly from one elderly patient to the next, even in the absence of disease, and is significantly altered by activity level, social habits, diet, and genetic background. In all healthy geriatric patients, however, maximum organ system function is greater than basal demand at all ages. The difference between maximal organ system capacity and basal function represents organ system functional reserve (Fig. 45-3). Organ system functional reserve is the “safety margin” available to meet, for example, the additional demands for cardiac output, carbon dioxide excretion, or protein synthesis imposed on the patient by trauma or disease, or by surgery and convalescence.

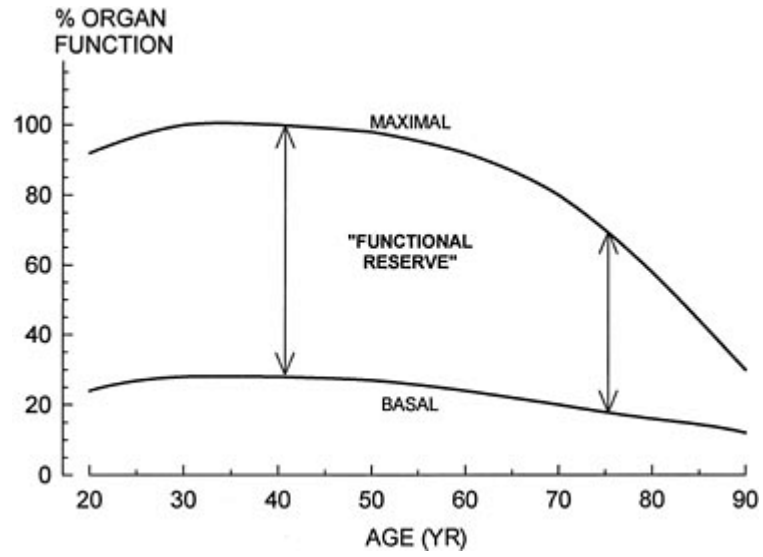

FIGURE 45-3. For any organ system, “functional reserve” represents the difference between basal (minimal) and maximal organ system function. The age-related decline in functional reserve may not be clinically apparent until demands made on the organ system are increased by stress, disease, polypharmacy, or surgical intervention.

Increased susceptibility of elderly patients to stress-induced and disease-induced organ system dysfunction is a defining characteristic of physiologic aging. Consequently, preoperative

testing in the elderly patient is most effective when it provides the anesthesiologist with a quantifiable assessment of organ system reserve. Testing should be clinically directed according to symptoms and complaints referable to age-related disease or functional decline, suggesting erosion of physiologic homeostasis. Cardiopulmonary functional reserve can be assessed clinically using various exercise or aerobic stress tests, but currently there are no comparable techniques for assessment of hepatic, immune, or nervous system functional reserve.

CARDIOPULMONARY FUNCTION

The aging heart increases output to meet imposed metabolic demands as needed within the limits of its maximal capacity. Consequently, the modest decrease in resting cardiac index observed in most healthy elderly subjects should not be considered as evidence of degenerative cardiovascular change. Rather, it represents an appropriate integrated response to the reduced requirements for perfusion and metabolism that occur with age-related atrophy of skeletal muscle and the loss of tissue mass in major organs with high intrinsic metabolic rates. From the perspective of integrated cardiovascular function, skeletal muscle energy expenditure and maximal breathing capacity, aging simply produces a progressively smaller “aerobic machine.”

Under conditions of submaximal demand, myocardial contractility appears to remain uncompromised by increasing age at least until the eighth decade.[5] The heart, unlike other major organs, does not atrophy with age. Short-term demands for increased cardiac output are met at first by modest increases in heart rate, and then by increasing left ventricular end-diastolic volumes and pressures, changes that produce progressively larger stroke volumes. Because aging reduces the inotropic and chronotropic responses to adrenergic stimulation and beta-agonists, maximal heart rate is age limited, and unlike young adults, older adults exhibit little enhancement of ejection fraction under these conditions.

The aging left ventricle is also thicker and less elastic than its younger counterpart, exhibiting symmetric hypertrophy and an increase in collagen cross-linking in the myocardial cytoskeleton to which the myocytes are attached.[6] Cross-linking may reflect the buildup of advanced glycation end

products produced by the chemical transformation of sugar moieties normally found in tissues.[7] Whatever the precise mechanism, the stiffer ventricle and atrium do not undergo complete relaxation until relatively late in diastole, and passive ventricular filling, which occurs during the early phase of diastole, is significantly reduced (Fig. 45-4). The progressive change in tissue quality imposes a form of diastolic dysfunction that makes the elderly depend more on the synchronous atrial contraction of sinus rhythm for complete ventricular filling.[8] Therefore, small decreases in venous return, such as those produced by positive-pressure ventilation, surgical hemorrhage, or venodilator drugs, may significantly compromise stroke volume when even minor cardiac dysrhythmias are present.

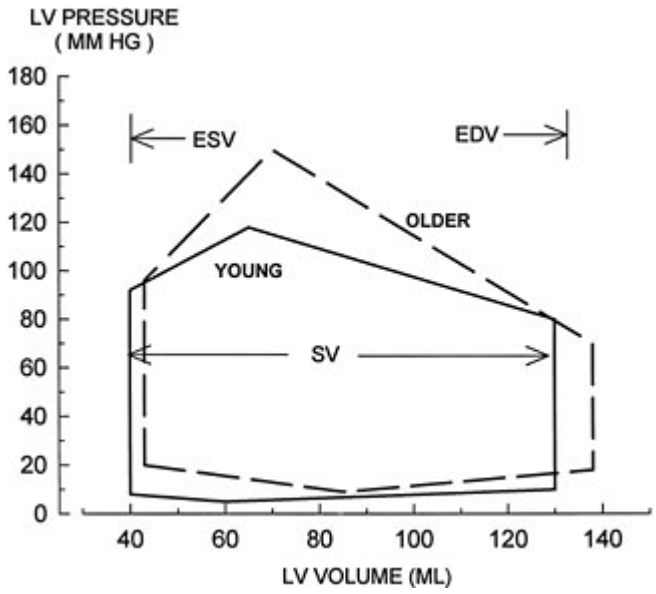

FIGURE 45-4. Left ventricular (LV) cardiac pressure–volume loops for fit subjects who are young (*solid line*) and elderly (*broken line*). Subjects who are elderly have a slightly higher end-diastolic ventricular volume (EDV) and larger end-diastolic stroke volume (ESV), as well as slightly elevated intracavitary pressures throughout the cardiac cycle due to increased myocardial stiffness and delayed active relaxation during diastole. SV, stroke volume.

Systolic hypertension with increased arterial pulse pressure is common in the geriatric population. It is a major cardiovascular risk factor[9] caused by a gradual increase in large artery stiffness due to fibrotic replacement of elastic tissues during the adult years. This reduces the ability of the aorta and large arteries to store hydraulic energy, and increases vascular impedance to ejection of stroke volume. The end result of these changes is a progressive and sustained rise in left ventricular wall tension and myocardial workload that produces symmetric ventricular hypertrophy. Because vascular impedance is a frequency-dependent form of hydraulic resistance, increased impedance to the ejection of stroke volume occurs in older adults, even when systemic vascular resistance is unchanged.[10] Increased vascular stiffness and loss of arterial cross-sectional area also increase the reflection of arterial pressure waves that produces the familiar “ringing” characteristics of radial artery waveform tracings in geriatric patients.

4 Age-related loss of tissue elasticity occurs in the lung and the cardiovascular system. There is an increase in fibrous connective tissue within the lung parenchyma, as well as degeneration and cross-linking of lung elastin. Therefore, all elderly individuals eventually demonstrate some degree of emphysema-like increases in lung compliance. However, calcification and stiffening of the costochondral joints of the thorax reduce chest wall compliance, so net pulmonary compliance is essentially unchanged.[11] Nevertheless, loss of lung elastic recoil is the primary anatomic mechanism by which aging exerts deleterious effects on pulmonary gas exchange. Breakdown of alveolar septae also reduces total alveolar surface area, increasing both anatomic and alveolar dead space. These changes are nonuniform and severely disrupt the normal

and perfusion within the lungs, increasing both shunting and physiologic dead space. Small airway patency, normally maintained by elastic recoil, may also be compromised and closing capacity typically becomes greater than the volume of the lung at rest.[12]

Vital capacity is significantly and progressively compromised[13] because residual lung volume increases at the expense of inspiratory and expiratory reserve volumes (Fig. 45-5). Although the strength and endurance of the ventilatory apparatus remain adequate to meet moderate demands,[14] skeletal calcification and increased airway resistance increase work of breathing in subjects who are elderly and predispose them to acute postoperative ventilatory failure.[15] Moment-to-moment neural control of ventilation and the responses to changes in pH and respiratory gases appear to be essentially unchanged. Overall, pulmonary function in older adults during general anesthesia is best described as progressive ventilation–perfusion mismatch due to the deterioration of alveolar architecture and to anesthetic-induced depression of active hypoxic pulmonary vasoconstriction. The cardiovascular and ventilatory response to imposed hypoxia or hypercarbia is also delayed in onset and is smaller in geriatric patients.[16]

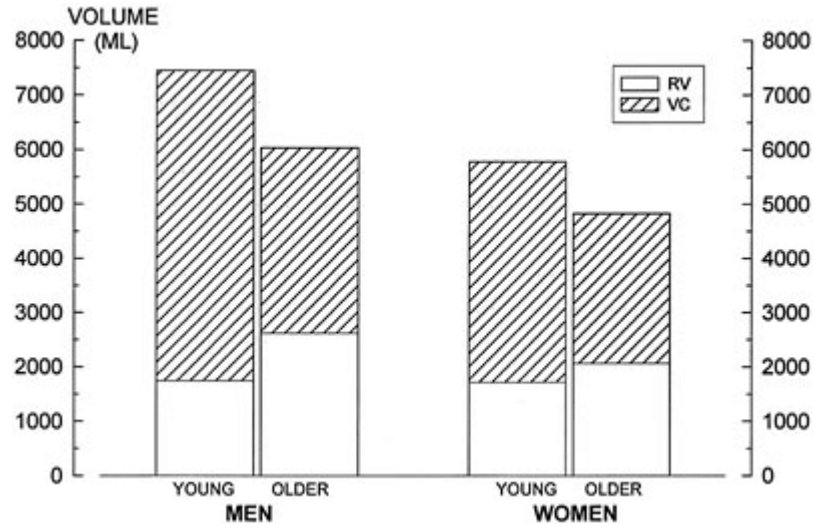

FIGURE 45-5. Total lung capacity, the sum of vital capacity (VC) and residual volume (RV), falls slowly in older adults of either gender. VC, however, the exchangeable gas volume, is markedly compromised by increases in thoracic rigidity and loss of ventilatory muscle power. RV increases because intrinsic lung elastic recoil is progressively reduced.

Opioid-induced rigidity of the chest wall occurs more frequently in older adults than in younger adults. The threshold stimulus magnitude needed for vocal cord closure is markedly elevated, increasing the risk of pulmonary injury due to aspiration of gastric contents in older patients, especially if level of consciousness is depressed. Consequently, geriatric surgical patients are clearly at increased risk of unrecognized respiratory failure in the typical postoperative setting of residual anesthetic depression and the use of opioids for pain management.

PHARMACOKINETICS, HEPATORENAL, AND IMMUNE FUNCTION

Hepatic enzyme activities are comparable to those of young adults, but liver tissue mass declines about 40% by the age of 80 years, and hepatic blood flow is proportionally reduced.[17] Loss of perfused hepatic tissue mass largely explains the reduced rates of plasma clearance and prolonged clinical effects of narcotics and many other xenobiotics in geriatric subjects.[18] In general, age-related differences in the binding of drugs to plasma proteins do not affect pharmacokinetics significantly in a clinical context. However, hepatic metabolism and drug biotransformation may be altered unpredictably in this patient subpopulation because of sustained exposure to the intense

polypharmacy of age-related chronic disease. In addition, the hepatic synthetic reserve needed for wound healing or response to sepsis may be inadequate, especially if associated with arterial hypotension, low cardiac output, hypothermia, or any form of direct hepatic injury.

Almost one-third of renal tissue mass is lost by the eighth decade, and renal blood flow decreases by about 10% per decade beginning in early adulthood (Fig. 45-6). Atrophy is especially marked in the renal cortex, although the extent of parenchymal loss is often masked by diffuse interstitial fibrosis and a reciprocal increase in intrarenal fat. More than one-third of the glomeruli and tubular structures disappear in the elderly, and in some of the remaining glomeruli, sclerosis impairs effective filtration by producing tubular diverticuli and dysfunctional continuity between afferent and efferent glomerular arterioles.[19] The renal cortex suffers the greatest reduction in vascularity, with relative sparing of the medulla. Shifting perfusion from cortex to medulla produces a slight compensatory increase in filtration fraction in subjects who are elderly.[20] Serum creatinine concentration remains normal because loss of skeletal muscle mass imposes a progressively smaller creatinine load, and glomerular filtration rate is sufficient to avoid uremia and maintain normal plasma osmolarity and electrolyte concentrations.[21] Geriatric surgical patients do not appear to require a unique fluid replacement protocol, but their renal functional reserve is rarely adequate to withstand gross disruptions of water and electrolyte balance. Water retention through antidiuretic hormone secretion is less efficient than in young adults, and excretion of free water is delayed. Diminished thirst, poor diet, and the use of diuretic agents to decrease age-related hypertension also predispose debilitated, elderly surgical patients with chronic disease to intravascular and intracellular dehydration.

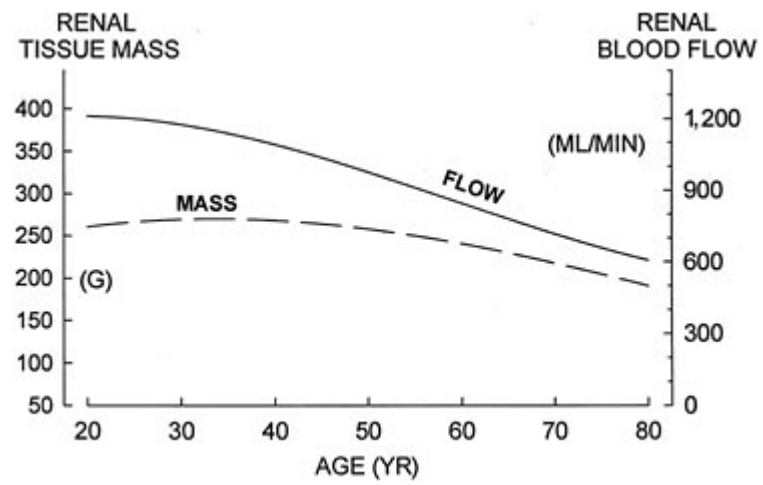

FIGURE 45-6. Renal blood flow (*solid line*) declines more rapidly than does renal tissue mass (*broken line*) with increasing age. Glomerular filtration rate (not shown) falls somewhat more slowly than plasma flow because filtration fraction actually increases in some individuals who are elderly.

Aging appears to have little effect on macrophage and other phagocytic activity, but even fit subjects who are elderly exhibit evidence of decreased immune responsiveness.[22] There is shrinkage of thymic mass and progressive alteration of thymus cellular composition. Older adults have decreased B-cell and T-cell lymphocyte activity, as well as depressed serum titers of immunoglobulin E, depressed skin response to allergens, and impaired delayed hypersensitivity. Older adults are particularly predisposed to streptococcal pneumonia, meningitis, and septicemia. Sepsis is second only to respiratory failure as a cause of morbidity and mortality in trauma patients who are elderly.[23]

METABOLISM AND BODY COMPOSITION

Particularly in men, aging produces a progressive and generalized loss of skeletal muscle mass and atrophy of other metabolically active tissues in brain, liver, and kidney. Reciprocal increases in the lipid fraction of total body mass during the middle adult years are typical but extremely variable in magnitude. In general, changes in body composition reduce basal metabolic requirements by 10 to 15% compared with young adults. Reduction in body heat production and impairment of thermoregulatory vasoconstriction[24] place surgical patients who are elderly at increased risk for inadvertent intraoperative hypothermia. In fact, intraoperative core temperature decreases at a rate twice as great as that observed in young adults under comparable conditions,[25] and the time needed for spontaneous postoperative rewarming increases in direct proportion to patient age.[26] Because muscle and liver provide storage for carbohydrates, aging is also associated with impairment of the ability to handle a glucose challenge, even though the timing and the magnitude of insulin release appear to remain normal. Age-related glucose intolerance therefore may also reflect progressive impairment of insulin function or antagonism of its effect on target tissues.[27] Fluid replacement with glucose-containing solutions in patients who are elderly should be limited to environments that permit frequent measurement of blood sugar levels.

After the young adult years, men gain adipose tissue and lose skeletal muscle mass, changes that eventually result in the loss of 10 to 15% of their total body water (Fig. 45-7). In men who are aged, continuing loss of muscle and central organ atrophy eventually produces a significant decline in total body weight, often to levels less than those of young adulthood. In women, however, muscle and bone loss due to osteoporosis are largely offset by increasing body fat; therefore, total body weight usually returns toward, but rarely falls below, young adult values. Virtually all age-related changes in body water in men and women are limited to the intracellular compartments. Plasma volume, red cell mass, and extracellular fluid volumes are usually well maintained in nonhypertensive elderly individuals who maintain their habits of daily physical activity. Decreases in circulating blood volume are typical only in the bed-ridden and deconditioned elderly or those with essential hypertension.[28]

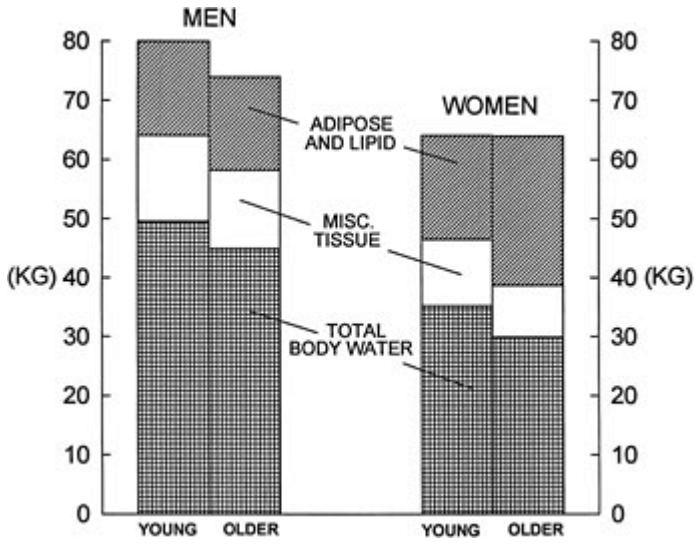

FIGURE 45-7. Age-related changes in body composition are gender specific. In women, total body mass remains constant because increases in body fat (*upper shaded segment*) offset bone loss (*middle segment*) and intracellular dehydration (*lower shaded segment*). In men, body mass declines despite maintenance of body lipid and skeletal tissue elements because accelerating loss of skeletal muscle and other components of lean tissue mass produces marked contraction of intracellular water (*lower shaded segment*).

CENTRAL NERVOUS SYSTEM

Aging reduces brain size. Average adult brain mass is about 20% less by the age of 80 years than respective values measured postmortem in young adults.[29] The fraction of intracranial volume occupied by brain tissue falls from 92 to 82% over the same time period, with the most rapid reduction in gray matter tissue mass and the greatest rate of compensatory increase in cerebrospinal fluid occurring after the sixth decade. Aging, in effect, produces a form of low-pressure hydrocephalus. Most of the tissue loss reflects attrition of neurons because there is little decline in the number of glial cells that normally constitute almost half of total brain mass. Neuron loss is highly selective according to type and region, the rate of loss varies greatly at different ages, and some degree of neuronal regeneration may occur at any age.[30] In general, the most metabolically active, highly specialized neuronal subpopulations, particularly those that synthesize neurotransmitters, appear to suffer the most severe degree of attrition. The residual neutropil also develops a markedly simplified pattern of synaptic interconnection.[31]

These and other age-related changes within the brain and spinal cord are well described anatomically but their functional significance remains unclear. In the healthy elderly individual, decreased cerebral blood flow is a consequence, not a cause, of brain tissue atrophy, and it falls in proportion to reduced brain tissue mass. The mechanisms that couple regional cortical and subcortical perfusion to local variation of metabolic demands are maintained and the blood-brain barrier is functionally intact. Aging does not impair autoregulation of cerebrovascular resistance to changes in arterial blood pressure, and the cerebral vasoconstrictor response to hyperventilation remains intact in the healthy geriatric patient.[32]

As in other organ systems, it may be difficult to distinguish between aging and age-related nervous system disease. Many forms of “senile” dysfunction may eventually be established as age-related disease, and conversely, it has become increasingly clear that most neurodegenerative disorders and normal aging neurons share declining mitochondrial bioenergetics and rising levels of oxidative stress as common characteristics.[33] Nevertheless, most studies suggest that “crystallized intelligence,” such as language skills and personality, do not decline with increasing age. General knowledge, comprehension, and long-term memory are well maintained even in individuals who are aged if they remain physically fit and mentally active. It remains unclear whether “fluid intelligence” and other cognitive functions that require immediate processing or rapid retrieval suffer intrinsic deterioration or whether they are compromised by age-related limitation of attention span. In general, however, anatomic and functional redundancy within the central nervous system appears to compensate adequately for attrition of cellular elements, reduction of neurotransmitter concentrations, and simplification of neuronal interconnections within the neuropil that occur in the aging brain.

PERIPHERAL NERVOUS SYSTEM

The threshold intensities of stimuli needed to initiate all forms of perception, including vision, hearing, touch, joint position sense, smell, peripheral pain, and temperature increase during senescence. This process of progressive age-related deafferentation is due, at least in part, to degenerative changes within specialized sense organs such as the pain-generating

Meissner's corpuscles in skin. However, there are also age-related changes at central sites of pain processing such as the thalamus and throughout peripheral pathways for conduction of pain impulses. In addition, attrition of the individual nerve fibers within afferent conduction pathways in both the peripheral nervous system and spinal cord reduce the velocity and amplitude of evoked sensory potentials. Peripheral motor nerve conduction velocity decreases steadily throughout adulthood, and impairment of efferent corticospinal transmission increases the latency between intention and onset of motor activity.

Isometric muscle strength appears to be well maintained, but failing proximodistal protoplasmic transport in aging motor neurons reduces the myotrophic support normally provided to skeletal muscle. Mitochondrial volume within skeletal muscle cells is reduced, and neurogenic skeletal muscle atrophy[34] causes the dynamic strength and steadiness of skeletal muscle in the extremities

to decline 20 to 50% by the age of 80 years. Reduced neurotrophic support also produces disseminated neurogenic atrophy at the neuromuscular junction.[35] The postjunctional muscle membrane thickens, and atypical “extrajunctional” cholinoceptors appear on the skeletal muscle surface.[36] The increase in the total number of cholinoceptors at each end plate and in the surrounding areas of the muscle cell surface may mask the age-related decline in the number and the density of motor neuron and end-plate units.

AUTONOMIC NERVOUS SYSTEM

As in other parts of the peripheral nervous system, neurons in sympathoadrenal pathways are subject to significant cellular attrition. In addition, adrenal tissues atrophy and cortisol secretion declines at least 15% by the age of 80. Nevertheless, plasma concentrations of norepinephrine are two- to fourfold higher in subjects who are elderly than in younger adults during sleep, at rest, and even in response to exercise-induced physical stress.[37] High plasma levels of catecholamines are rarely apparent clinically in patients who are elderly, however, because aging markedly and progressively depresses beta-adrenergic end-organ responsiveness.[38] The response to beta agonists such as isoproterenol are markedly reduced. In effect, aging produces “endogenous beta-blockade.” There appears to be little change in alpha adrenoceptor or muscarinic cholinoceptor activity in older adults and no intrinsic changes in the basic contractile properties of peripheral vascular smooth muscle.[39]

Nevertheless, the integrated autonomic reflex responses that maintain cardiovascular and metabolic homeostasis are progressively impaired in individuals who are elderly.[40] This may explain the increased incidence and severity of arterial hypotension seen in older patients following anesthetic induction. Baroreflex responsiveness, the vasoconstrictor response to cold stress, and beat-to-beat heart rate responses following postural change in subjects who are elderly become progressively less rapid in onset, smaller in magnitude, and less effective in stabilizing blood pressure under a variety of circumstances.[41] The autonomic nervous system in the elderly patient is effectively “underdamped,” and is characterized by wider variation from homeostatic set points and delayed restabilization during hemodynamic stress.[42]

ANALGESIC AND ANESTHETIC REQUIREMENTS

The net effect of the age-related structural and functional changes within the nervous system described previously on pain-related neurologic function remains controversial. The study of amplification, modulation, and selectivity of afferent input within the spinal cord, thalamus, and other locations within the aging nervous system does not yet permit broad generalizations regarding aging and perception of pain.[43] Perceived intensity of pain perioperatively is extremely unpredictable and appears to depend far more on anxiety, personality, and the prospect of long-term debility than on age itself.[44] Nevertheless, parenteral morphine requirements are clearly inversely related to patient age and essentially independent of body weight.[45] Similarly, when a fixed dose and volume of local anesthetic is used, higher levels of sensory blockade occur in patients who are elderly than in young patients undergoing spinal anesthesia.[46] Segmental dose requirements for epidural analgesia are similarly reduced,[47] and more cephalad levels of neural blockade carry a greater risk of hypotension in the elderly.[48] Overall, however, the differences are small and considered to be clinically insignificant by some investigators.[49]

5 The effect of nervous system aging on requirements for general anesthesia is less controversial. Between young adulthood and the geriatric era, relative minimum alveolar concentration (MAC) values for the newer inhalational agents decline by as much as 30%,[50,51] the same decrement seen with older anesthetics (Fig. 45-8). The mechanisms producing age-related increases in sensitivity to anesthetic agents remain unknown, but the consistency of this phenomenon for anesthetic agents with markedly different chemical characteristics suggests that it reflects a fundamental neurophysiologic process. Declining neuronal bioenergetics due to mitochondrial genetic mutation or to age-related oxidative stress have both been recently shown to reduce anesthetic requirement.[52,53]

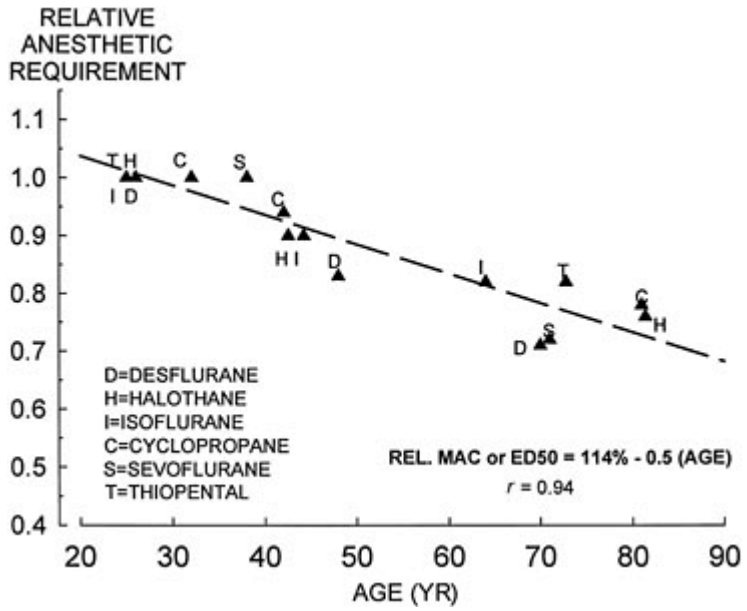

FIGURE 45-8. The age-related decline in relative anesthetic requirement (minimum alveolar concentration [MAC] or ED50) in unsedated human subjects is a consistent characteristic reported for a wide variety of inhaled and injected anesthetic agents.

The data for the effect of aging on the pharmacodynamics, or dose requirements, for opioids, barbiturates, and benzodiazepines are less consistent than that for inhalational anesthetics. There is considerable controversy as to whether the clinically apparent age-related increase in the potency of these drugs is truly a pharmacodynamic (drug sensitivity) phenomenon or whether it simply reflects age-related changes in “alpha” or early-phase redistribution pharmacokinetics (molecular drug disposition). Plasma drug concentrations immediately after intravenous injection are often higher in subjects who are elderly than in young adults.[54] This may reflect delayed intercompartmental transfer of drug rather than a decreased initial volume of distribution.[55] In any case, the concentrations of short-acting intravenous agents in plasma change so rapidly, and in such a complex manner, that the traditional two-compartment

pharmacokinetic model may be of little value for studying the early or “alpha-phase” behavior of these drugs and their subsequent redistribution in subjects who are elderly.[56]

Interpretation of data from clinical studies of intravenous agents is further complicated by difficulty in defining the anesthetic end point in a process that, in contrast to the conditions under which MAC is determined, does not represent pharmacokinetic equilibrium. Therefore, both onset and duration of clinical effects can be influenced by pharmacodynamic or pharmacokinetic processes. Clinical experience suggests that there are significant age-related reductions in the dose requirements for thiopental,[57] as well as virtually all other agents that depress consciousness. Most studies also suggest that aging increases brain sensitivity to narcotics,[58,59] with insignificant pharmacodynamic effects for barbiturates or etomidate.[60] Overall, there is a complex interaction between subtle changes in pharmacodynamics and altered “alpha-phase” redistribution pharmacokinetics due to age-related hemodynamic factors that must be characterized for each drug to predict the implications of aging for clinical drug action and drug dosage.[61]

Despite the inevitable loss of skeletal muscle mass in subjects who are elderly, the median effective doses (ED50) and steady-state plasma concentrations required for half-maximal neuromuscular-blocking effect (EC50) remain virtually unchanged or may actually increase slightly in the patient who is elderly.[62] Although the elderly have reduced skeletal muscle mass, disseminated neurogenic atrophy at the neuromuscular junction allows proliferation of

extrajunctional cholinoceptors, and thereby may require increased local concentrations of neuromuscular-blocking drugs to produce competitive blockade. Maximal relaxant effect is clearly delayed in onset relative to that produced in young adults.[63,64] Duration of neuromuscular blockade is also markedly prolonged for relaxants with hepatic or renal elimination because plasma clearance declines with increasing age.[65,66] However, antagonism of the effects of blocking drugs and recovery of neuromuscular transmission should be unchanged. As in younger adults, the intensity of neuromuscular blockade at time of or “reversal” by neostigmine or edrophonium, not patient age, determines the speed and the completeness of recovery of neuromuscular transmission.

PERIOPERATIVE MANAGEMENT AND OUTCOME

6 There probably are no healthy patients who are “too old” for anesthesia, even ambulatory surgical procedures.[67] Age-related disease, and not aging itself, largely determines the morbidity and mortality that characterizes an elderly surgical population,[68,69,70] although advanced age itself may have additional negative prognostic significance if associated with severe multiple organ system dysfunction. Following orthopaedic surgery, the speed and extent to which a patient who is elderly recovers full function has also been shown to depend on functional level prior to surgery.[71] Morbidity and mortality rates, therefore, are higher in elderly surgical patients largely because this surgical patient subpopulation has a greater incidence and severity of concurrent disease, and greater exposure to invasive medical interventions, than do younger adults. Polypharmacy also produces an age-related increase in adverse drug reactions that complicate perioperative management (Fig. 45-9).

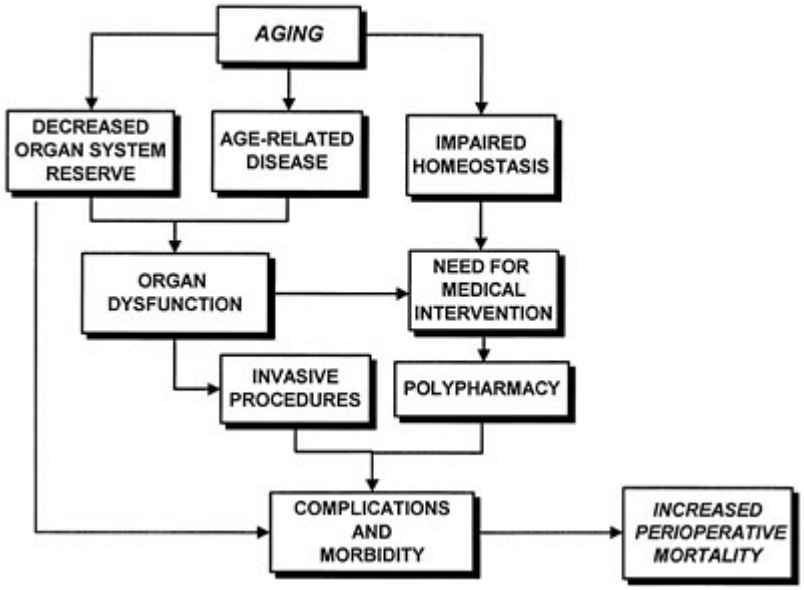

FIGURE 45-9. Increased rates of perioperative morbidity and mortality in surgical patients who are elderly can be attributed primarily to interactions between age-related decreases in organ system reserve, a high prevalence of disease in the elderly, and the inherent risk associated with therapy and surgical intervention.

7 The probability of a serious pulmonary or hemodynamic complication after surgery is determined both by the site of operation and by the patient's physical status (Fig. 45-10). Many members of the geriatric surgical population summarily “cleared” for major surgery by medical consultants on empirical clinical grounds may later be found to have mild to severe cardiopulmonary functional deficits.[72] Adverse outcomes in geriatric surgical patients show a relative predominance of disorders of cardiac rate or rhythm,[73] myocardial ischemia, or general hemodynamic instability. Pulmonary complications, infections and sepsis, and renal failure also contribute significantly to morbidity.[74] In-hospital postoperative complications have also been

identified as having negative prognostic implications with regard to long-term survival.[75] Consequently, adequate time for diagnosis, treatment, and preparation of the anesthetic plan is essential if the rate and severity of complications are to be reduced.[76]

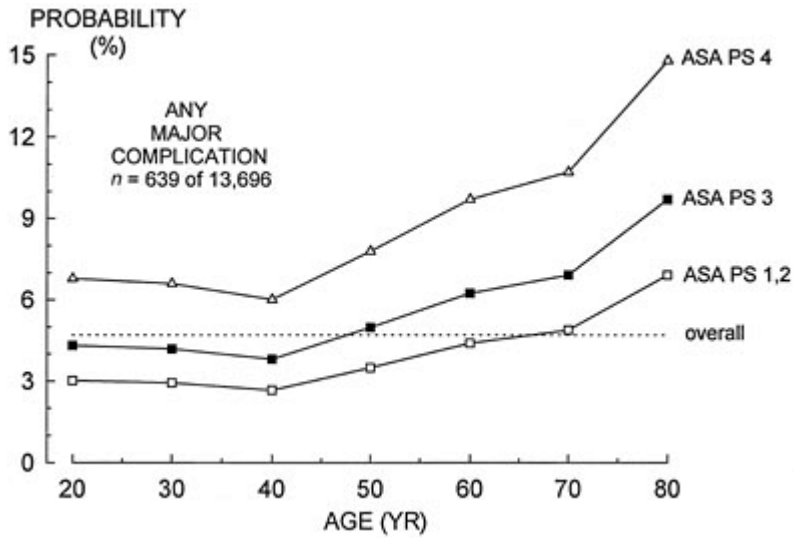

FIGURE 45-10. The probability of adverse postoperative outcome increases gradually with age across middle adulthood. Analyzed prospectively from a large series of randomized patients, preexisting cardiovascular or pulmonary disease and physical status (*solid lines*) were found to be the primary determinants of perioperative morbidity, although the widening of the separation between physical status lines shown here suggests that age itself may further amplify the negative prognostic value of impaired physical status in surgical patients who are well into the geriatric era.[68]

Elderly patients at low risk may be able to proceed without further testing or preparation, and intermediate-risk patients are now believed to benefit substantially from perioperative beta-blockade.[77] For the elderly surgical patient at high cardiac risk, coronary angiography prior to elective major surgery may be indicated.[78] Newer inhalational agents such as sevoflurane and desflurane appear to be the agents of choice to

preserve left ventricular function after cardiopulmonary bypass in high-risk, elderly coronary surgery patients.[79] Nevertheless, although many clinical studies have shown that some perioperative complications are associated more frequently with one form of anesthesia than another,[80,81] it may not be possible to determine whether there is a single “best” anesthetic for patients who are elderly.[82]

No single anesthetic technique or agent appears to have universal advantage for the elderly surgical patient with regard to survival. Neither regional anesthesia nor general anesthesia has clearly demonstrable superiority of outcome in patients who are elderly, although one or the other may be preferred for use in specific procedures[83] or certain patients for other medical reasons.[84] In fact, the intraoperative period of anesthetic management is often only a small component of a prolonged, difficult, and complex hospital course. Nevertheless, more recent preliminary studies suggest that there may be value in careful titration of the depth of surgical anesthesia in older adults to the minimum value needed to avoid awareness. In older surgical patients, deeper maintenance anesthetic levels are associated with higher 1-year postoperative death rates.[85] Male gender and subnormal body mass index may be additional cofactors that, along with prolonged deep levels of anesthesia, increase long-term mortality in the geriatric surgical patient population.[86]

Prompt and complete postoperative recovery of mental function is particularly important in

patients who are elderly if mentation is already compromised by age-related disease or drug therapy. The use of newer intravenous agents such as remifentanil[87,88] and cisatracurium[89] minimize dependence on organ system functional reserve for drug elimination.[90] Newer inhalation agents such as sevoflurane and especially desflurane[91] also provide more rapid recovery of consciousness in the adult who is aged than was possible with isoflurane.[92] There is less nausea and vomiting in older adults[93] after general anesthesia but a greater likelihood of prolonged postoperative confusion.[94] Full recovery of psychomotor function is somewhat delayed in older patients, even after typically brief outpatient anesthesia with propofol.[95] Local anesthesia or regional techniques, if they can be comfortably performed without heavy intravenous sedation, may significantly improve postoperative mental function immediately after surgery, although there is no clinical evidence of long-term benefits to this approach.[96] In addition, nerve palsies, residual paresthesias, and other neurapraxias associated with regional anesthesia occur more often than in young adults.[97,98,99]

Even when anesthetic management of the older patient is appropriate and surgical convalescence uncomplicated, full return of cognitive function to preoperative levels after a prolonged general anesthetic may require up to 2 weeks.[100] Perioperative environmental factors such as chronic medication and drug interaction,[101] disorientation due to sensory deprivation, or the disruption of normal routine needed to maintain “implicit” memory[102] have been identified as factors that predispose older surgical patients to “delirium.”[103] However, the neurophysiologic or pharmacologic explanation for persistent disruption of nervous system function remains unknown. Psychometrically defined postoperative cognitive dysfunction can be demonstrated 3 months after apparently uncomplicated surgery in 10 to 15% of patients 60 years of age or older who have had major procedures and a hospital stay of 4 or more days.[104] This suggests that, at least in older adults with reduced central nervous system functional reserve, either the process of general anesthesia itself or the drugs used to produce it may produce residual neurologic dysfunction or perhaps even injury.[105] Impairment of learning long after the pharmacologic effects of anesthetic agents are dissipated has been clearly demonstrated in older laboratory animals given uncomplicated conventional general anesthesia.[106,107]

The physical management of patients who are elderly in the operating room and afterward also requires specific precautions. Aged skin and bones are fragile, joints are stiff, and their range of motion is limited, especially if compromised by age-related arthritic processes. The elderly surgical patient therefore requires gentle and expert routine care if traumatic injuries from improper positioning, bandaging, or enforced bed rest are to be avoided. Avoiding hypothermia is important; however, active heating devices in contact with poorly perfused skin or connective tissue pressure points can quickly produce ischemic lesions requiring surgical treatment. In all patients who are elderly, postoperative bleeding diatheses or hypercoagulable states and bacterial infection are more frequent than in younger adults. Because of diastolic dysfunction and increased ventricular stiffness, rates of intravenous fluid administration that would be modest for young adults may produce dangerous increases in atrial and pulmonary artery pressures in geriatric patients, precipitating congestive heart failure or pulmonary edema.

Whatever anesthetic approach is selected, surgical tissue injury produces extensive neuroendocrine and sympathoadrenal stress. Suppression of excessive sympathetic activity promotes prompt rewarming, wound healing, and a reduced period of increased cardiovascular and pulmonary demands. Careful attention to need for analgesia may eliminate the long periods of emotional stress due to persistent surgical pain sometimes imposed on geriatric patients because of exaggerated fears of opioid side effects. To some extent, “ageism” may influence caregivers to withhold diagnostic or therapeutic measures that would be offered routinely to a younger adult.[108] Untreated pain and related emotional stress itself may also significantly impair immune responsiveness in older adults and increase the risk of perioperative infection.[109] Therefore, an anesthetic plan that includes postoperative epidural sympathectomy and analgesia, or a parenteral sympathetic modulator such as dexmedetomidine,[110] may be of special value in the elderly surgical patient.

Overall, however, patients who are elderly and aged do not require a “special” kind of anesthetic. A well-conducted anesthetic of any type is a safe and appropriate anesthetic plan if attention to

dosage and careful assessment of anesthetic depth are used.[111] Good perioperative care of the geriatric patient simply requires the highest standards of diagnosis and control of preexisting disease, as well as clinical vigilance and meticulous delivery of anesthetic and postoperative care.

Chapter 46

Anesthesia for Ambulatory Surgery

J. Lance Lichtor

KEY POINTS

1	All individuals, whether young or old, deserve a careful preoperative history and physical examination.
2	Patients of American Society of Anesthesiologists (ASA) physical status III or IV patients are appropriate candidates for ambulatory surgery, providing their systemic diseases are medically stable.
3	Particularly when midazolam is combined with fentanyl, adult patients can remain sleepy for up to 8 hours.
4	Most surgeons that direct their patient's choice of anesthetic choose regional anesthesia, yet delay in establishing a block and unpredictable success detract from their enthusiasm. Unnecessary delays can be obviated by performing the block preoperatively in a preoperative holding area.
5	For those patients who do receive spinal anesthesia, it is incumbent on the anesthesiologist and the facility to have follow-up with telephone calls to ensure no disabling symptoms of headache have developed.
6	When the bispectral index (BIS) or other guide of anesthetic depth is used, the difference between drugs and wake-up times may not be as great.
7	Nausea, with or without vomiting, is probably the most important factor contributing to a delay in discharge of patients and an increase in unanticipated admissions of both children and adults after ambulatory surgery.
8	Inhalation agents are associated with an increased risk of postoperative nausea and vomiting (PONV), particularly in the early stages of recovery.
9	Combination therapy is probably the most effective way to control PONV.

10	BIS or another guide of anesthetic depth can decrease the incidence of awareness.

The first ether anesthetic was given for ambulatory surgery. James M. Venable, a school teacher, had a small cystic tumor removed from the back of his neck by Dr. Crawford W. Long on the evening of March 30, 1842, after school was dismissed. The patient described the procedure in this way: “I commenced inhaling the ether before the operation was commenced and continued it until the operation was over. I did not feel the slightest pain from the operation and could not believe the tumor was removed until it was shown to me.”[1] The modern concept of an independent surgical center for outpatients was popularized in the early 1970s by Wallace Reed. Since then, ambulatory surgery has been so well accepted that the majority of patients currently return home within 24 hours of an operative procedure. Because of this fact, anesthesiologists have had to refine the method of performing anesthesia so the anesthetic is not responsible for hindering a patient from returning to normal activities.

Cost savings partially prompted the original ambulatory centers. In the late 1960s, in Arizona, an uninsured barber's two children needed myringotomies, which in those days meant 2 days of hospitalization before the procedure.[2] The surgeons, astounded by how many haircuts they would receive instead of payment, began the cost-reducing measure of ambulatory surgery. Patient selection today is based on the desire to reduce cost while maintaining quality of care, so morbidity from the procedure or preexisting disease is no greater than if the patient were hospitalized. The length and complexity of operations performed in an ambulatory setting have increased, especially with the arrival of many new procedures. In the past, only patients with American Society of Anesthesiologists (ASA) physical status class I or II were candidates for ambulatory surgery. Today, patients classified as ASA physical status III or IV and whose systemic disease is medically stable are considered for procedures as outpatients. Preoperative screening, preferably in a clinic or by telephone, is essential both for reduction of patient anxiety and to ensure medical management is appropriate. Specific laboratory tests that should be performed before these operations are discussed elsewhere (see Chapter 18).

In this chapter, we review the patients and procedures suitable for ambulatory surgery, as well as how to manage anesthesia for outpatients.

PLACE, PROCEDURES, AND PATIENT SELECTION

Ambulatory surgery occurs in a variety of settings. Some centers are within a hospital or in a freestanding satellite facility that is either part or independent of a hospital. Physicians' offices may also serve for procedures. The independent facilities are often for-profit and not located in rural or inner-city areas. Although freestanding, independent facilities continue to grow, although some consumers prefer care in units affiliated with hospitals.

Procedures appropriate for ambulatory surgery are those associated with postoperative care that is easily managed at home and with low rates of postoperative complications that require intensive

physician or nursing management. The definition of a low rate of postoperative complication depends on the relative aggressiveness of the facility, surgeon, patient, and payer. For example, procedures that postoperatively result in intense pain may be treated with continuous regional techniques that are continued at home, whereas in other settings these procedures are limited to inpatients.

Lists of ambulatory procedures quickly become outdated simply because they exclude certain procedures that in a short time may become routine in ambulatory settings. In 1986, a patient would have been hospitalized for cholecystectomy but not for cataract extraction. When laparoscopic cholecystectomy was first introduced, a much higher percentage of patients required open cholecystectomy afterward, hence inpatient admission. Now, this procedure is commonly performed as an outpatient procedure, particularly when patients are generally healthy, live nearby, and when an uneventful operative procedure is anticipated. Procedure costs can be significantly reduced when a hospital stay is avoided.

Length of surgery is not a criterion for ambulatory procedures because there is little relationship between length of anesthesia and recovery. Patients undergoing longer procedures, though, should have their operations earlier in the day. The need for transfusion is also not a contraindication for ambulatory procedures. Some patients undergoing liposuction as outpatients, for example, are given autologous blood. Some surgeons, however, are uneasy about performing transfusion-requiring operations in an ambulatory setting because blood loss is a factor in unexpected hospital admission after surgery.[3]

Preterm infants (gestation age 37 weeks) who are younger than 50 weeks' postconceptual age should not be discharged from an ambulatory surgery center for at least 23 hours after a procedure because they are at risk of developing apnea even without a history of apnea. Although some have found that spinal anesthesia without the use of other drugs intraoperatively or postoperatively is not associated with apnea; one study of 62 premature and former-premature infants who underwent surgery using spinal anesthesia, postoperative apnea was seen in 5 of 55 premature infants.[4] In a pooled study of 255 former preterm infants who underwent general anesthesia, taken from eight previously published studies from four institutions, it was seen that apnea was strongly and inversely related to gestational and postconceptual age, apnea at home, and anemia (Fig. 46-1).[5] Yet, apnea varied dramatically in different institutions: it was highest in those institutions that used continuous recording devices, compared with those that used impedance pneumography and nursing observation. Nonetheless, apnea may not be apparent up to 12 hours after anesthesia. Anemia (hematocrit <30%) was also predictive of apnea, yet the number of patients with anemia was small and they tended to be younger.

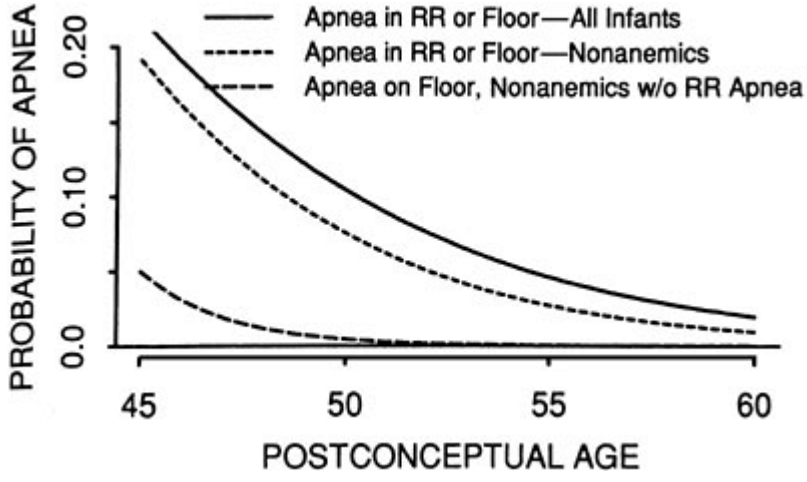

FIGURE 46-1. The risk for apnea after surgery is a function of gestational age, hematocrit, and the presence of apnea in the postanesthesia care unit (PACU). The predicted probability for apnea by weeks postconception is shown for all infants (*solid line*), nonanemic infants

(*irregular line*), and infants who were not anemic and did not have apnea in the PACU (*broken line*).[5] (Reprinted with permission from Coté CJ, Zaslavsky A, Downes JJ *et al*: Postoperative apnea in former preterm infants after inguinal herniorrhaphy. A combined analysis. Anesthesiology 82:809, 1995.)

Some techniques have been tried to eliminate postoperative apnea in infants to allow them to go home on the same day of a procedure. When caffeine 10 mg/kg was administered immediately after induction of anesthesia, no preterm infants younger than or at 44 conceptual weeks of age developed postoperative apnea.[6]

1 At the other extreme of life, advanced age alone is not a reason to disallow surgery in an ambulatory setting. Age, however, does affect the pharmacokinetics of drugs. Even short-acting drugs such as midazolam and propofol have decreased clearance in older individuals. In addition, age may be a factor that affects the likelihood of unanticipated admission. In a study of 169 patients (of 3,152 patients), age was a factor that influenced unanticipated admission.[7] In a study of outcome after 6,000 procedures, some for patients older than 90 years, longer recovery time was not correlated with older age.[8] In a study of more than 6,000 patients undergoing ambulatory surgery, age was not a predictor of return; however, patients younger than 40 years of age who returned after ambulatory procedures were more likely to be treated in the emergency room, whereas patients older than 65 years were more likely to be hospitalized.[9] When age, gender, duration, and type of surgery were adjusted, hypertension, obesity, smoking, asthma, and gastroesophageal reflux were medical conditions that were associated with perioperative adverse events related to ambulatory anesthesia.[10] Admission, by itself, is not necessarily bad if it results in a better quality of care or uncovers the need for more extensive surgery. With proper patient selection for ambulatory procedures, which are usually elective, the incidence of readmission should be very low. Most medical problems that older individuals may experience after ambulatory procedures are not caused by age, but by specific organ dysfunction. For that reason, all individuals, whether young or old, deserve a careful preoperative history and physical examination.

2 Whatever their age, ambulatory surgery is no longer restricted to patients of ASA physical status I or II. Patients of ASA physical status III or IV are appropriate candidates, providing their systemic diseases are medically stable. In a review of ASA III patients who were compared with ASA I or II patients undergoing outpatient surgery, no significant increase in unplanned admissions, unplanned contact with health

professionals, and postoperative complications was found.[11] Certainly, not all life-threatening diseases have been studied as to how appropriate such patients with these diseases might be if they were to undergo ambulatory surgery. Yet, of those patients with such diseases who have been studied, the disease label itself does not seem to preclude an ambulatory surgical procedure. For example, in a review of 258 morbidly obese patients who underwent outpatient surgery, compared with patients who were not morbidly obese, there was not a greater incidence of unplanned admissions, minor complications, or unplanned contact with health care professionals.[12] Patients with diagnosed obstructive sleep apnea who underwent nonotorhinolaryngolic procedures were not found to have a greater risk for unanticipated hospital admission or for other adverse perioperative events.[13] Certainly, though, preexisting medical illness is a factor in both intraoperative difficulties and postoperative complications that require unexpected patient admission.[10] Patients who undergo ambulatory surgery should have someone to take them home and stay with them afterward to provide care. Before the procedure, the patient should receive information about the procedure itself, where it will be performed, laboratory studies that will be ordered, and dietary restrictions. The patient must understand that he or she will be going home on the day of surgery. The patient, or some responsible person, must ensure all instructions are carried out. Once at home, the patient must be able to tolerate the pain from the procedure, assuming adequate pain therapy is provided. The majority of patients are satisfied with early

discharge, although a few prefer a longer stay in the hospital. Patients for certain procedures such as laparoscopic cholecystectomy or transurethral resection of the prostate should live close to the ambulatory facility because postoperative complications may require their prompt return. “Reasonable” distance and time for the patient to get care if problems arise are not easily defined. This issue must be addressed by each facility and by each patient, and depends on the type of surgery to be performed.

PREOPERATIVE EVALUATION AND REDUCTION OF PATIENT ANXIETY

Each outpatient facility should develop its own method of preoperative screening to be conducted before the day of surgery. The patient may visit the facility, or staff members may telephone to obtain necessary information about the patient, including a complete medical history of the patient and family, the medications the patient is taking, and the problems the patient or the patient's family may have had with previous anesthetics. In a study of the usefulness of a preoperative screening telephone call, patients were less likely to cancel surgery if they had been screened beforehand.[14] The screening may uncover the need for transportation to the facility or the need for child care. The process also provides the staff with an opportunity to remind patients of arrival time, suitable attire, and dietary restrictions (e.g., nothing to eat or drink after midnight, no jewelry or makeup). Staff members can determine whether a responsible person is available to escort the patient to and from the facility and care for the patient at home after surgery. The screening is the ideal time for the anesthesiologist to talk with the patient, but if that is not possible, the anesthesiologist may review the screening record to determine whether additional evaluation by other consultants is necessary and if laboratory tests must be obtained.

Automated history-taking may also prove beneficial during the screening of a patient. Computerized questionnaires or checklists with plastic overlays automate the taking of patient histories, flag problem areas, and suggest laboratory tests to be ordered. Such devices can also be used in a surgeon's office, both to guide the surgeon in the selection of laboratory tests and to serve as a medical summary for the anesthesiologist. Such devices are particularly useful to control the cost of preoperative testing. They enable test ordering based on information obtained from a patient's responses to health questions, thus eliminating requests for tests that are not warranted by history or physical examination.

Another important reason for preoperative screening is to help alleviate a patient's anxiety. Preoperative reassurance from nonanesthesia staff and the use of booklets also reduce preoperative anxiety. However, use of booklets is less effective than a preoperative visit by the anesthesiologist. Audiovisual instructions also reduce preoperative anxiety.

For children, information modeling and coping-based programs have been shown to reduce anxiety and enhance coping, particularly during the preoperative period. A child's anxiety seems to be maximally reduced if the effort to reduce it is made before surgery. However, behavior during induction, in the postanesthesia care unit (PACU), or postoperatively does not seem to be affected by this effort.

Upper Respiratory Tract Infection

A patient might be seen several days before surgery without any contraindication to the upcoming procedure. However, on the day of surgery, the patient may have an upper respiratory infection (URI). One study of 1,078 children 1 month to 18 years of age examined risk factors for adverse respiratory events in children with URIs.[15] The authors could find no difference in laryngospasm or bronchospasm if the children had active URIs, a URI within 4 weeks, or no symptoms. But children with active or recent URIs had more episodes of breath holding, incidences of desaturation <90%, and more respiratory events compared with children without symptoms (Fig. 46-2). Independent risk factors for adverse respiratory events in children with URIs included use of an endotracheal tube (versus use of a laryngeal mask airway [LMA] or facemask), a history of prematurity, a history of reactive airway disease, a history of paternal smoking, surgery involving the airway, presence of copious secretions, and nasal congestion. Generally, if a patient with a URI has a

normal appetite, does not have a fever or an elevated respiratory rate, and does not appear toxic, it is probably safe to proceed with the planned procedure.

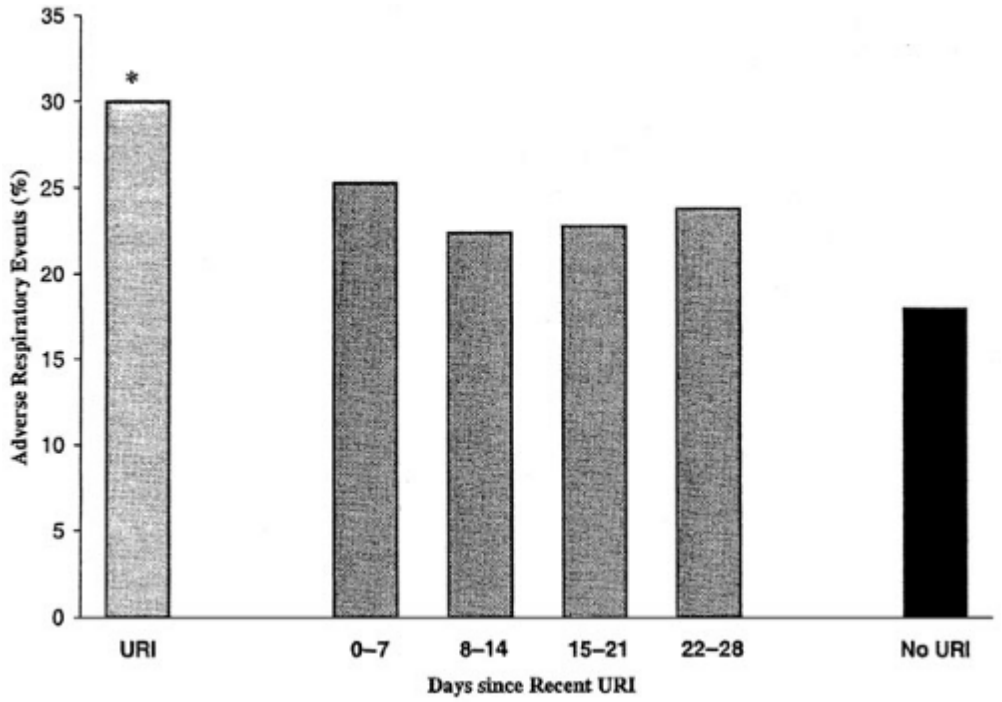

FIGURE 46-2. Adverse respiratory events are similar between children with an upper respiratory infection (URI) and a recent URI, and this similarity persists for at least 4 weeks after the URI.[15] *$P < .05$ vs. no URI. (Reprinted with permission from Tait AR, Malviya S, Voepel-Lewis T *et al*: Risk factors for perioperative adverse respiratory events in children with upper respiratory tract infections. Anesthesiology 95:299, 2001.)

Restriction of Food and Liquids Before Ambulatory Surgery

To decrease the risk of aspiration of gastric contents, patients are routinely asked not to eat or drink anything (non per os [NPO] or “nothing by mouth”) for at least 6 to 8 hours before surgery. However, prolonged fasting can be detrimental to a patient. One study actually showed that infants who fasted longer had greater drops in intraoperative blood pressure (Fig. 46-3).[16] No trial has shown that a shortened fluid fast increases the risk of aspiration. Gastric volumes are actually less when patients are allowed to drink some fluids before surgery. Admittedly, though, the majority of studies have not been specifically performed in individuals who are at an increased risk for aspiration. An excellent review of this topic has been published.[17]

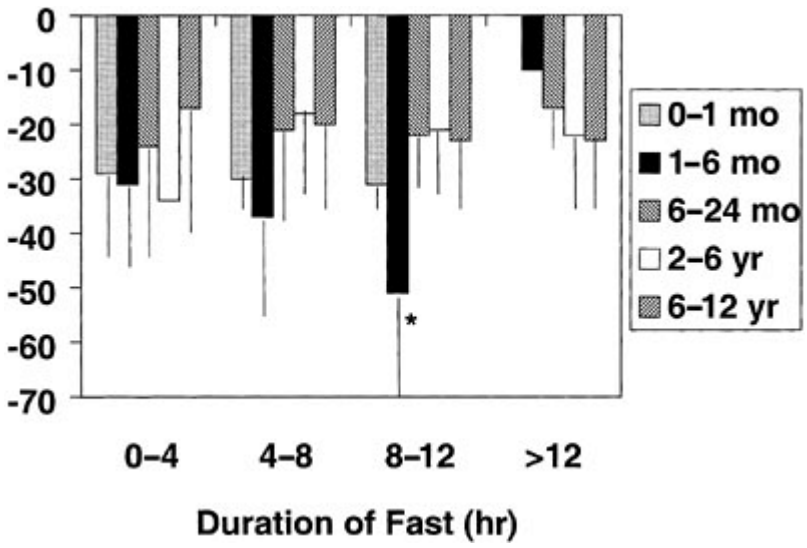

FIGURE 46-3. Blood pressure is lower in children 1 to 6 months of age who fast more than 8 hours, compared with those who fast for less than 4 hours.[16] Illustrated are changes in systolic blood pressure from baseline to the time when 2 minimum alveolar concentration halothane was reached in 250 infants and children. *P < .05 vs. 0- to 4-hour fasting group. (Reprinted with permission from Friesen RH, Wurl JL, Friesen RM: Duration of preoperative fast correlates with arterial blood pressure response to halothane in infants. Anesth Analg 95:1572, 2002.)

The ASA has published practice guidelines for preoperative fasting.[18] The guidelines allow a patient to have a light meal up to 6 hours before an elective procedure. In one survey of anesthesiologists' practice in an outpatient setting based on the practice guidelines, only 35% of those surveyed said that

their institution had a policy that would allow a light breakfast 6 hours before elective surgery, although 65% said they would proceed without delay.[19] The guidelines support a fasting period for clear liquids of 2 hours for all patients. Coffee is not transparent but is free of particulate matter and is accepted as a clear liquid. Coffee drinkers should follow fasting guidelines but should be encouraged to drink coffee prior to their procedure because physical signs of withdrawal (e.g., headache) can easily occur.[20] Some surgeons are not aware of these guidelines, so some patients are still fasting for longer periods of time. There is some evidence that shorter periods of preoperative fasting are accompanied by less postoperative nausea and vomiting (PONV). Yet, it is unclear whether rehydration during surgery is equivalent to a shorter fast before surgery in relation to PONV.

To ensure patients are optimally medically managed before their outpatient surgery, given the fact that clear liquids can be taken up to 2 hours before surgery, patients should be encouraged to take their chronic medications.

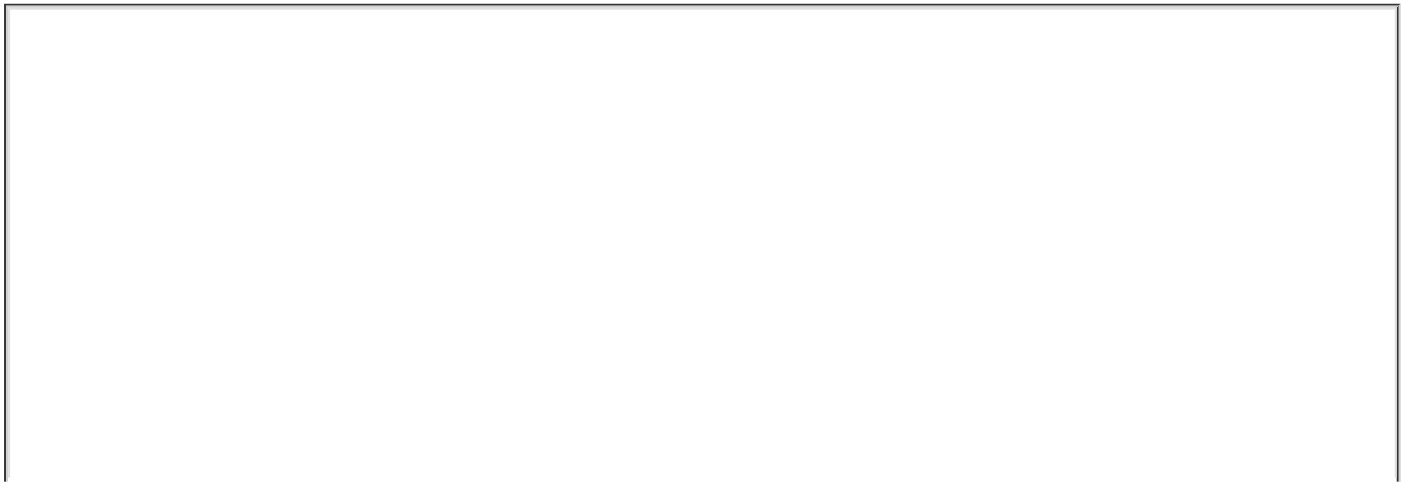
MANAGING THE ANESTHETIC: PREMEDICATION

The outpatient is not that different from the inpatient undergoing surgery. In both, premedication is useful to control anxiety, postoperative pain, nausea, and vomiting, and to reduce the risk of aspiration during induction of anesthesia. Because the outpatient is going home on the day of surgery, the drugs given before anesthesia should not hinder recovery afterward. Most premedicants do not prolong recovery when given in appropriate doses for appropriate indications, although drug effects may be apparent even after discharge.

Controlling Anxiety

Clearly, some patients scheduled to undergo surgery are anxious, and they are probably anxious long before they come to the outpatient area. However, not all outpatients are anxious. For example, insomnia and anxiety are related, and in a study of sleep characteristics of outpatients before elective surgery, no differences in sleep quality between patients before surgery and a community control group was seen.[21] Indeed, physicians often tend to overestimate the level of anxiety that patients are actually experiencing.[22] Some operations can certainly generate more anxiety than others. The need to remove dentures is also associated with increased preoperative stress. If in doubt about patient anxiety, ask the patient: visual analog scales are also easy to use and are an accurate tool to assess anxiety.[23]

Like adults, children should have some idea of what to expect during a procedure. But much of a child's anxiety before surgery concerns separation from a parent or parents. A child is more likely to demonstrate problematic behavior from the



time of separation from parents to induction of anesthesia if a procedure has not been explained preoperatively. Parents and children need to be involved in some preoperative discussions together so the anxiety of the parents is not transmitted to the child. The transmission of anxiety is at least as problematic as is the separation itself (e.g., experiences of children being left with baby-sitters). If the parents are calm and can effectively manage the physical transfer to a warm and playful anesthesiologist or nurse, premedication is not necessary. Semisedation may be awkward, and recovery after premedication may be prolonged. If a child is accompanied by a parent during the induction of anesthesia, the child's anxiety can be reduced.

Although historically many classes of drugs (e.g. barbiturates, antihistamines) have been used to reduce anxiety and induce sedation, benzodiazepines are currently the drugs most commonly used. Propofol also has some anxiety reduction properties.

Benzodiazepines

Midazolam is the benzodiazepine most commonly used preoperatively. It can be used intravenously and orally. In adults, it can be used to control preoperative anxiety and, during a procedure alone or in combination with other drugs, for intravenous sedation. For children, oral midazolam in doses as small as 0.25 mg/kg produces effective sedation and reduces anxiety.[24] With this dose, most children can be effectively separated from their parents after 10 minutes and satisfactory sedation can be maintained for 45 minutes.

3 Fatigue associated with the effects of anxiolytics may delay or prevent the discharge of patients on the day of surgery, although more frequently patients are not discharged because of the effects of the operation. With regard to anesthesia effects, patients normally stay in the hospital not because they are too sleepy but because they are nauseous. In adults, particularly when midazolam is combined with fentanyl, adult patients can remain sleepy for up to 8 hours (Fig. 46-4).[25] Although children may be sleepier after oral midazolam, discharge times are not affected.[26]

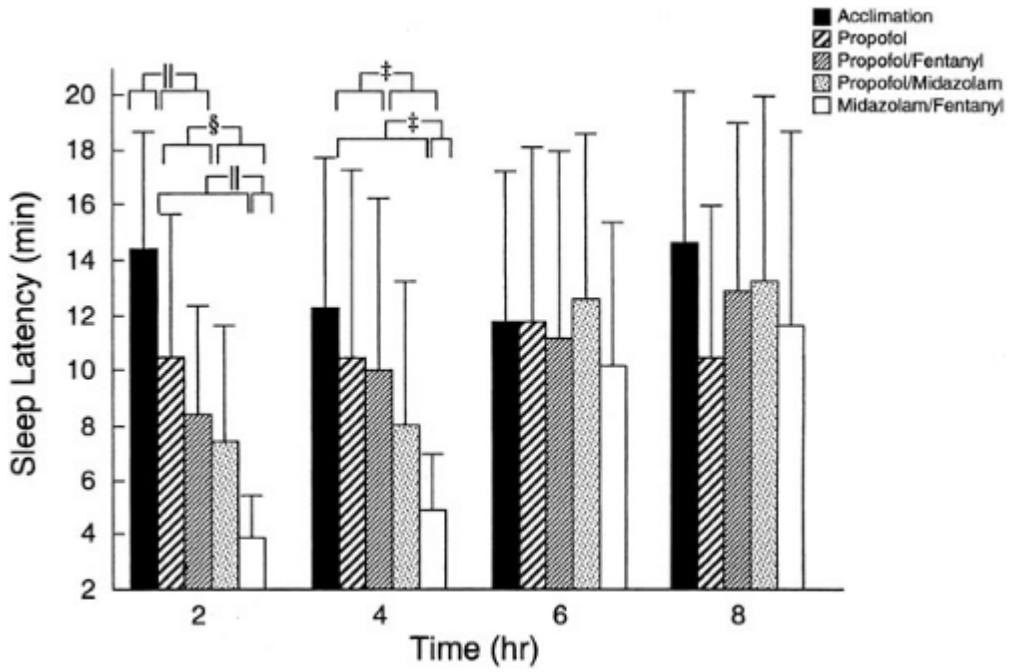


FIGURE 46-4. Patients can remain sleepy after receiving midazolam and fentanyl, even 8 hours after drug administration.[25] The abscissa represents time (hours) after sedation. The ordinate represents sleep latency (i.e., time to fall asleep). Data are the mean time to fall asleep. An individual is sleepier if less time is required to fall asleep. Subjects receiving the midazolam and fentanyl combination were much sleepier than the same subjects receiving other types of sedation. Although not seen in the figure, up to 8 hours after sedation, some subjects were still sleepier than before they received drug. (Reprinted with permission from Lichtor JL, Alessi R, Lane BS: Sleep tendency as a measure of recovery after drugs used for ambulatory surgery. Anesthesiology 96:878, 2002.)

Oral diazepam is useful to control anxiety in adult patients, either the day before surgery or the day of surgery and before an intravenous line has been inserted. Indeed, in one study, investigators believed that after 5 mg oral diazepam, it was easier to insert an intravenous catheter.[27]

At proper doses, neither midazolam nor diazepam place patients at any additional risk for cardiovascular and respiratory depression. Decreased oxygen saturation has also been reported after injection of midazolam. Routine administration of supplemental oxygen with or without continuous monitoring of arterial oxygenation is recommended whenever benzodiazepines are given intravenously. This precaution is important not only when midazolam is given as a premedicant, but also when it is used alone or with other drugs for conscious sedation.The potential for amnesia after premedication is another concern, especially for patients undergoing ambulatory surgery. Anterograde amnesia certainly occurs, but benzodiazepines actually facilitate retrograde memory.[28] For midazolam, amnesia is a function of serum concentration and the effects on memory are separate from the effects on sedation.[29] In addition, amnesia is not simply an effect of drug administration, but, among other factors, it is also a function of stimulus intensity.

Opioids and Nonsteroidal Analgesics

Opioids can be administered preoperatively to sedate patients, control hypertension during tracheal intubation, and decrease pain before surgery. Meperidine (but not morphine or fentanyl) is sometimes helpful in controlling shivering in the operating room (OR) or PACU, although treatment is usually instituted at the time of shivering and not in anticipation of the event. The effectiveness of opioids in relieving anxiety is controversial and probably nonexistent, particularly

in adults.

Opioids are useful in controlling hypertension during tracheal intubation. Opioid premedication prevents increases in systolic pressure in a dose-dependent fashion. After tracheal intubation, systolic, diastolic, and mean arterial blood pressures sometimes decrease below baseline values.

Preoperative administration of opioids or nonsteroidal anti-inflammatory drugs (NSAIDs) is also useful for controlling pain in the early postoperative period. Controlled-release oxycodone 10 mg, for example, when given before surgery, was

effective in managing pain after laparoscopic tubal ligation surgery and was even associated with less PONV.[30] Celecoxib, up to 400 mg, is effective in reducing postoperative pain.[31] When celecoxib 200 mg was compared with rofecoxib 50 mg, rofecoxib was more effective.[32] Ibuprofen or acetaminophen can be given rectally to children around the time of induction. Nonsteroidal analgesics are associated with less nausea compared with narcotics.[33] If rectal acetaminophen is used, an initial loading dose of 40 mg/kg is appropriate; subsequent doses of 20 mg/kg every 6 hours can be used.[34]

Preoperative sedation is not needed for every patient. The following is our practice when patients require drugs to relieve anxiety. For the patient who has been seen at least 24 hours before a scheduled procedure and expresses a desire for medication to relieve anxiety or has anxiety that cannot be relieved with comforting, oral diazepam, 2 to 5 mg 70 kg^{-1} body weight, is prescribed for the night before and at 6:00 AM on the day of surgery (even if surgery is scheduled for 1:00 PM or later). Patients seen for the first time in the preoperative holding area who seem to need medication, midazolam, 0.01 mg/kg, is administered intravenously, or the patient is brought into the OR and propofol, 0.7 mg/kg, is injected intravenously. For children, when necessary, oral midazolam, 0.5 mg/kg, is administered in the preoperative holding area.

Controlling the Risk of Aspiration

Patients who undergo ambulatory surgery may be at some small risk for aspiration of gastric contents, although this risk is no greater than for inpatients. At greater risk for aspiration are pregnant or morbidly obese patients or patients with hiatal hernia. Preoperative anxiety probably has no effect on gastric acidity for individuals without a history of duodenal ulcer. H_2 receptor antagonists, such as cimetidine and ranitidine, omeprazole, sodium citrate, or metoclopramide, can be used to control the risk of aspiration.

INTRAOPERATIVE MANAGEMENT: CHOICE OF ANESTHETIC METHOD

There are several choices among anesthetic methods: general anesthesia, regional anesthesia, and local anesthesia. Regional and local anesthesia can be used with or without sedation. Except for obstetric cases for which regional anesthesia may be safer than general anesthesia, all three types are otherwise equally safe. However, even for experienced anesthesiologists, there is a failure rate associated with regional anesthesia.

Certainly, some procedures are possible only with a general anesthetic. For others, the preference of patients, surgeons, or anesthesiologists may determine selection. Cost may be a factor: the cost of sedation is usually less than the cost of a general anesthetic. Time to recovery may also influence the choice of anesthetic method. For example, in a study of adult patients undergoing strabismus surgery with either propofol sedation and local anesthesia or general anesthesia with inhalation agents, time to leave the hospital was much less after sedation.[35] For some procedures such as arthroscopy, patients might prefer a regional anesthetic simply because they are curious.[36] Postoperative pain is less after regional anesthesia, and this is discussed in more detail later in this section. Also, with regional anesthesia or sedation, some of the side effects of general anesthesia can be avoided, although no form of medical care is without side effects. Whenever drugs are given that affect memory, patients might have complaints that they do not remember after the procedure. In addition, with regional anesthesia, more time is required to place a block than it takes to induce a general anesthetic, and the success rate with regional anesthesia is not

100%. In one survey of orthopaedic surgeons, the majority of surgeons that direct their patient's choice of anesthetic choose regional anesthesia, yet delay in establishing a block and unpredictable success detracted from their enthusiasm (Fig. 46-5).[37] In most instances after regional anesthesia, PACU time is shorter, and patients can frequently bypass the first phase of the PACU.

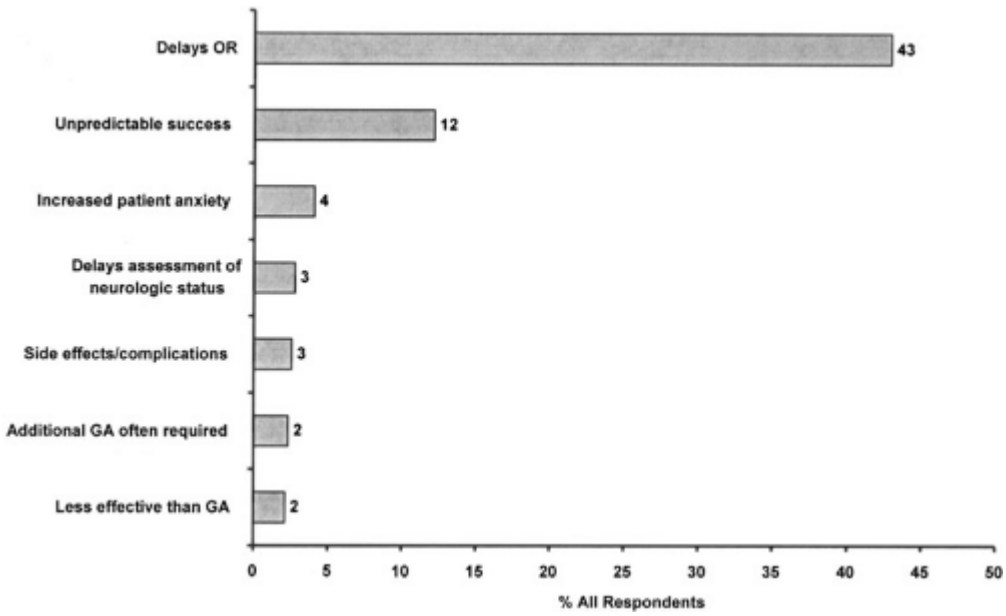

FIGURE 46-5. Operating room (OR) delays are the major reasons orthopaedic surgeons do not favor regional anesthesia.[37] GA, general anesthesia. (Reprinted with permission from Oldman M, McCartney CJ, Leung A *et al*: A survey of orthopedic surgeons' attitudes and knowledge regarding regional anesthesia. Anesth Analg 98:1486, 2004.)

One adverse effect associated with spinal anesthesia is headache, but headaches are also experienced by patients after general anesthesia. Especially when smaller spinal needles are used, the incidence of headache after either technique may be similar. In one study, after either method of anesthesia, incidence of headache ranged between 11 and 15%.[38] In that study, backache was higher (26%) after spinal anesthesia than general anesthesia (4%). However, incidence of sore throat (24%) and nausea (22%) was higher after general anesthesia than spinal anesthesia (6% for both). Larger studies of patients undergoing ambulatory surgery are needed that compare sedation with regional and general anesthesia.

Regional Techniques

Local anesthesia and regional anesthesia have long been used for ambulatory surgery. As early as 1963, for example, 56% of ambulatory procedures were performed with the use of these techniques.[39] Regional techniques commonly used for ambulatory surgery, in addition to spinal and epidural anesthesia, include local infiltration, brachial plexus, and other peripheral nerve blocks, and intravenous regional anesthesia. General anesthesia can also be supplemented with regional nerve blocks.

4 Performing a block takes longer than inducing general anesthesia, and the incidence of failure is higher. Unnecessary delays can be obviated by performing the block beforehand in a preoperative holding area. Because a postoperative nursing intervention, usually associated with general anesthesia, is associated with a 27- to 45-minute delay, the increased setup time may be associated with a shorter time to discharge.[40] Postoperative pain control is best with regional techniques.

An occasional patient may experience syncope when the needle for the regional block is inserted.

In the experience of oral and maxillofacial surgeons in Massachusetts in the late 1990s, 1 of 160 patients fainted when local anesthesia was injected.[41] When sedation accompanies local anesthesia injection, the incidence of syncope is reduced. Patients usually experience less postoperative pain when local or regional anesthesia has been used. Patients may still have a numb extremity (e.g., after a brachial plexus block) but otherwise meet all criteria for discharge. In such instances, the extremity must be well protected with a sling, and patients must be cautioned to protect against injury because they are without normal sensations that would warn them of vulnerability. Reassurance that sensation will return should be provided.

Spinal Anesthesia

Spinal anesthesia is useful for ambulatory procedures in children born prematurely. The procedure is best performed with the child in the sitting position, head supported and somewhat extended, to prevent occlusion of the airway. Bupivacaine 0.5% isobaric, 1 mg/kg of tetracaine, 1 mg/kg, mixed with an equal volume of 10% dextrose, is injected into the L4–L5 interspace with a 22-gauge Quincke needle, 3.75 cm long. It is useful to apply a eutectic mixture of lidocaine and prilocaine (EMLA)

patch to the lumbar puncture site 1 hour before the procedure. Because a leg raised may drive the spinal higher, the child must be kept flat when, for example, the Bovie pad is placed on the back. Hypotension is less common after spinal anesthesia in infants than adults, and when it occurs, typically the spinal is high. An intravenous line can be started in a lower extremity after the spinal is in place, the extremity is anesthetized, and vasodilatation is present. Spinal anesthesia with a local anesthetic alone may not last long enough. In one study, when clonidine was added to bupivacaine, the length of spinal block increased from an average of 67 minutes to 111 minutes after 1 mcg/kg clonidine (Fig. 46-6).[42] See the previous discussion as to whether a neonate should be discharged home on the same day of a spinal anesthetic.

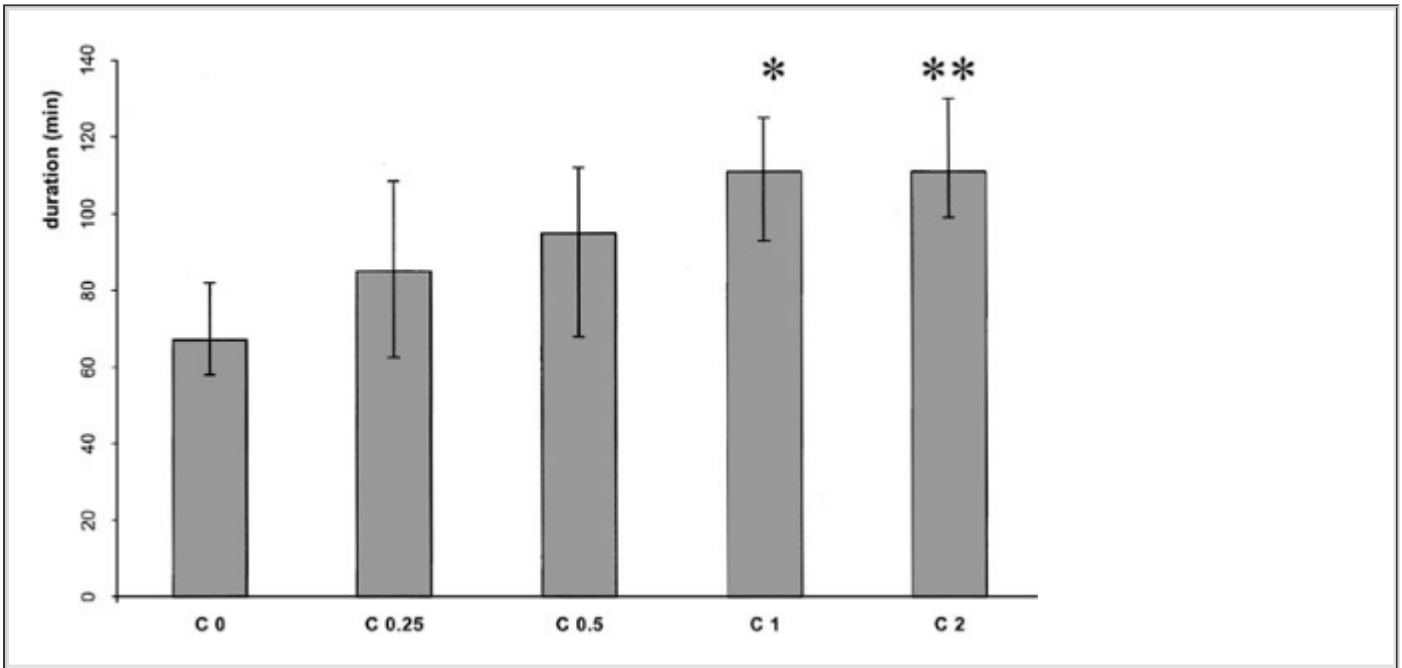

FIGURE 46-6. Clonidine prolongs spinal anesthesia in newborns.[42] Illustrated is the median duration of spinal block with 25 to 75% confidence intervals. C 0, spinal with 0.5% isobaric bupivacaine, 1 mg/kg; C 0.25, bupivacaine with 0.25 mcg/kg clonidine; C 0.5, C 1, and C 2, bupivacaine with 0.5, 1, and 2 mcg/kg clonidine, respectively. *$P < .003$; **$P < .006$ vs. C 0. (Reprinted with permission from Rochette A, Raux O, Troncin R *et al*: Clonidine prolongs spinal anesthesia in newborns: A prospective dose-ranging study. Anesth Analg 98:56, 2004.)

The use of spinal needles with pencil point, noncutting tips has prompted a resurgence of spinal anesthesia for ambulatory

surgery in adults. Epidural or spinal anesthesia is suitable for pelvic, lower abdominal, and lower-extremity surgery, but not for laparoscopic procedures, because most people have difficulty breathing in the head-down position with the abdomen distended with air. Motor block of the legs with either technique may delay a patient's ability to walk. However, the use of a short-acting local anesthetic through an epidural catheter, will minimize this problem while allowing the duration of anesthesia to match the sometimes unpredictable duration of surgery. Nausea is much less frequent after epidural or spinal anesthesia than after general anesthesia.

Different drugs and drug concentrations have been used for spinal anesthesia. Lidocaine and mepivacaine are ideal for ambulatory surgery because of their short duration of action, although lidocaine use has been problematic because of transient neurologic symptoms. In one study comparing patients who underwent knee arthroscopy with either 45 mg 1.5% mepivacaine or 60 mg 2% lidocaine, 22% of patients who received lidocaine had transient neurologic symptoms (back pain or dysesthesia).[43] The symptoms were treated by NSAIDs and resolved within 5 days; no patients who received mepivacaine developed transient neurologic symptoms. Chloroprocaine spinal anesthesia has rapid onset; in a study of nonpatient volunteers, after 40 mg 2-chloroporcaine (2-CP), the study participants could void after 110 minutes.[44] In that study, when 20 µg of fentanyl was included, regression time to L1 was lengthened and tourniquet tolerance was improved, although overall block length was minimally affected. Forty milligrams of preservative-free 2-CP produces a similar onset time and block height when compared with 40 mg lidocaine.[45] In that study, transient neurologic symptoms occurred in seven of eight volunteers who received lidocaine and in none of the volunteers who received 2-CP. Low-dose bupivacaine is useful for some outpatient procedures such as inguinal herniorrhaphy; yet, in one study, patients could not be discharged until almost 7 hours after block initiation.[46]

5 Although headache is a common complication of lumbar puncture, smaller-gauge needles result in a lower incidence of postdural puncture headache. For those patients who do receive spinal anesthesia, it is incumbent on the anesthesiologist and the facility to have follow-up with telephone calls to ensure no disabling symptoms of headache have developed. If the headache does not respond to bed rest, analgesics, and oral hydration, the patient must return to the hospital for a course of caffeine intravenous therapy or an immediate epidural blood patch.

Spinal anesthesia should not be avoided in ambulatory surgery patients simply because they may be more active postoperatively than inpatients. Bed rest does not reduce the frequency of headache. Indeed, early ambulation may decrease the incidence. Further study is needed to assess the relative risk–benefit ratio of spinal anesthesia as a technique for the ambulatory surgery patient.

Epidural and Caudal Anesthesia

Epidural anesthesia takes longer to perform than spinal anesthesia. Onset with spinal anesthesia is more rapid, although recovery may be the same with either technique. In one study of patients undergoing knee arthroscopy, spinal anesthesia with small-dose lidocaine and fentanyl was compared with 3% 2-CP administered in the epidural space: intraoperative conditions, discharge characteristics and times, and recovery profiles were similar.[47] Also, failure rates for the two techniques, although low, were the same. Some studies suggest that bicarbonate can be added to solutions for faster onset of epidural anesthesia. An advantage of the epidural block is that it can be performed outside the OR, and, after the surgical procedure is completed, the problem of postdural puncture headache is usually avoided.

Caudal anesthesia is a form of epidural anesthesia commonly used in children before surgery below the umbilicus as a supplement to general anesthesia and to control postoperative pain. Bupivacaine, 0.175 to 0.25%, or ropivacaine 0.2%, in a volume of 0.5 to 1.0 mL/kg, may be used; a safe maximal dose is 2.5 mg/kg. Epinephrine, 1:200,000, when added to the anesthetic solution, may allow earlier detection of intravenous, rather than epidural, injection. Other additives useful,

albeit controversial, for increasing duration of blockade include narcotics, ketamine, clonidine, and neostigmine.[48] The block may be more difficult in children, particularly those who weigh more than 10 kg and are obese, if landmarks for the block are difficult to locate. The block is usually administered while the child is anesthetized. After injection, the depth of general anesthesia can be reduced. Because of better pain control after a caudal block, children can usually ambulate earlier and be discharged sooner than without a caudal block. Pain control and discharge times are no different whether the caudal block is placed before surgery or after it was completed.

Nerve Blocks

Nerve blocks control pain during a surgical procedure; however, certain procedures are quite painful, and hospitalization can be required to control the pain. An exciting new area in outpatient surgery is where, instead of a needle, a catheter is placed that is then left in after the operation. Paravertebral somatic nerve block can be used for breast surgery followed by a continuous perineural infusion of local anesthetic at home for 24 to 48 hours.[49] Perineural catheters in the sciatic nerve through the popliteal fossa can be used to control pain after foot surgery.[50] Interscalene perineural catheters have been used for patients undergoing moderately painful shoulder surgery.[51] Continuous cervical paravertebral block may also be useful for analgesia after shoulder surgery: early return of motor function in the hand, wrist and elbow, which is seen with this block, may be useful for recovery after shoulder surgery (Fig. 46-7).[52] Patients must be taught about pump function, understand signs of

local anesthesia toxicity, and have someone else at home who can provide assistance. In addition, the patients must be able to communicate with someone by phone. The number of patients who have been sent home with catheters is not large. More study is needed, in order to demonstrate patient safely.

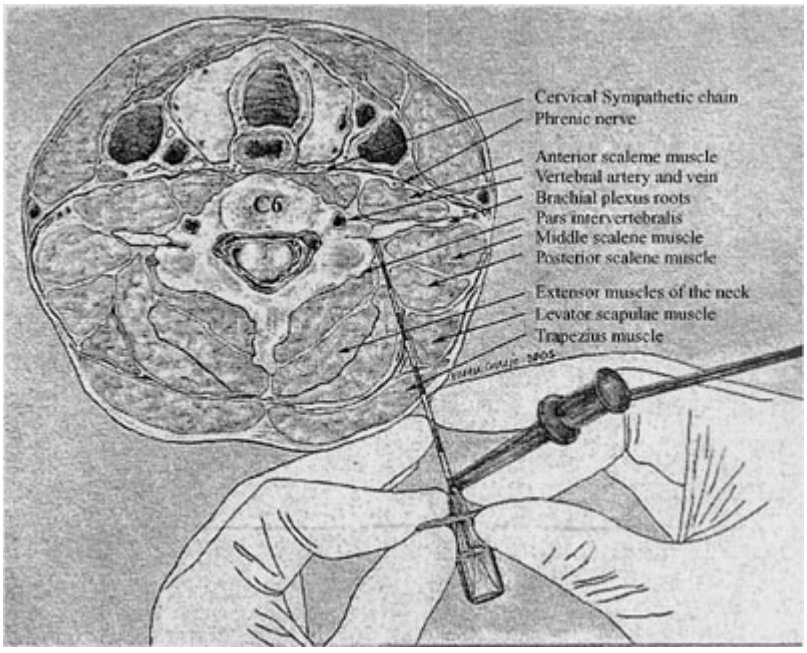

FIGURE 46-7. A continuous cervical paravertebral block can be placed prior to induction of anesthesia for shoulder surgery and can be left in place for up to 7 days after surgery.[52] The figure shows the path that the sheathed Tuohy needle follows, using the posterior approach, from the skin, and then between the trapezius and levator scapulae muscles to the paravertebral space. (Reprinted with permission from Boezaart AP, De Beer JF, Nell ML: Early experience with continuous cervical paravertebral block using a stimulating catheter. Reg Anesth Pain Med 28:406, 2003.)

In a survey mailed to members of the Society for Ambulatory Anesthesia in 2001, there was shown to be widespread use of axillary and interscalene blocks for surgery in the upper extremity, and ankle and femoral blocks for lower-extremity surgery.[53] Using different nerve blocks improves postoperative patient satisfaction: PONV and postoperative pain are less. Costs are also less. When nerve block was used for anterior cruciate legament repair reconstruction, one nonrandomized study of outpatients in a university setting showed that PACU admissions, hospital cost, and unexpected hospital admission were all reduced.[54] For knee arthroscopy, psoas compartment block or spinal anesthesia is superior to general anesthesia in terms of postoperative pain management and patient satisfaction.[55] After more complex knee surgery, patients who received femoral-sciatic nerve block required fewer nursing interventions for pain; and, if patients received either that block or only a femoral nerve block, unplanned hospital admissions were less compared with patients who underwent the procedure without a block.[56] In a comparison of patients who underwent either infraclavicular brachial plexus block or general anesthesia for upper-extremity surgery, after brachial plexus block more patients were able to bypass phase I PACU care, had less pain on PACU arrival, and were discharged home much sooner (Fig. 46-8).[57]

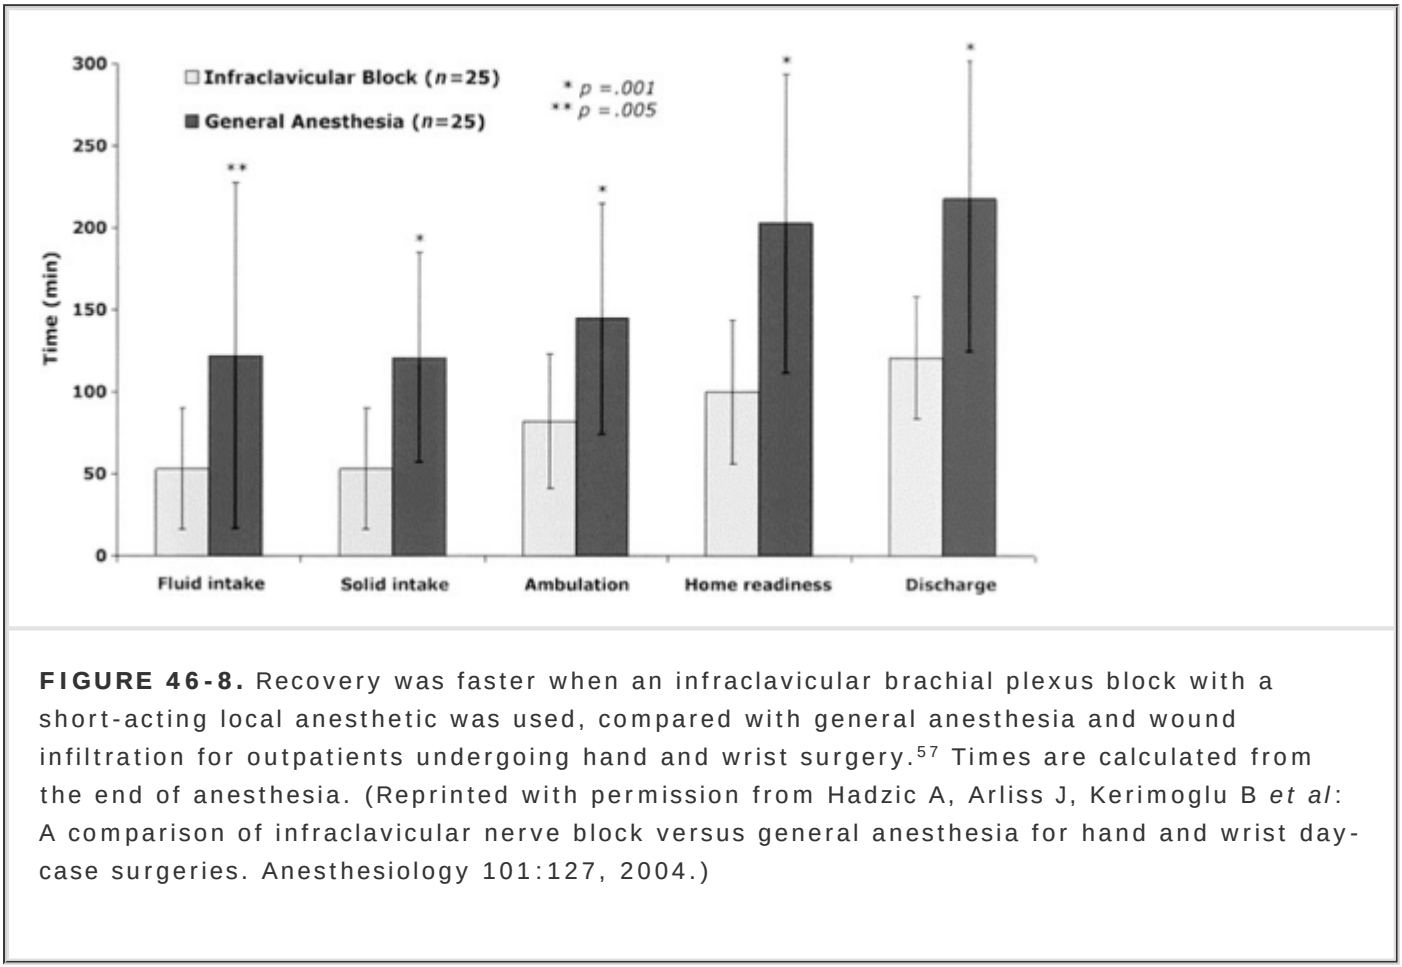

FIGURE 46-8. Recovery was faster when an infraclavicular brachial plexus block with a short-acting local anesthetic was used, compared with general anesthesia and wound infiltration for outpatients undergoing hand and wrist surgery.[57] Times are calculated from the end of anesthesia. (Reprinted with permission from Hadzic A, Arliss J, Kerimoglu B *et al*: A comparison of infraclavicular nerve block versus general anesthesia for hand and wrist day-case surgeries. Anesthesiology 101:127, 2004.)

Sedation and Analgesia

Many patients who undergo surgery with local or regional anesthesia prefer to be sedated and to have no recollection of the procedure. Sedation is important, in part, because injection with local anesthetics can be painful and lying on a hard OR table can be uncomfortable. Levels of sedation vary from light, during which a patient's consciousness is minimally depressed, to very deep, in which protective reflexes are partially blocked and response to physical stimulation or verbal command may not be appropriate. When patients are unsuitable for outpatient general anesthesia, surgery can often be performed if local or regional anesthesia is supplemented with conscious sedation. However, serious risk, such as death, is probably no different after sedation than after general anesthesia. Children who have surgery usually will not remain immobile unless they are deeply sedated or receive general anesthesia.

For adults, the proper dose might be selected by having the patient control dosage. Yet, at least

for ambulatory surgical procedures, patient-controlled sedation is not as popular as patient-controlled analgesia. This may be due to the fact that a member of the anesthesia care team must be continuously present anyway.

General Anesthesia

The drugs selected for general anesthesia determine how long patients stay in the PACU after surgery, and for some patients, whether they can be discharged to go home.

Induction

The popularity of propofol as an induction agent for outpatient surgery in part relates to its half-life: the elimination half-life of propofol is 1 to 3 hours, shorter than that of methohexital (6 to 8 hours) or thiopental (10 to 12 hours). Although the effect of drugs given for induction seems to be transient, these drugs can depress psychomotor performance for several hours. When induction doses of propofol and thiopental were

compared, psychomotor impairment in patients was evident for up to 5 hours after thiopental, but only for 1 hour after propofol.[58]

Pain on injection can be a problem with propofol. Pain is more likely on injection into dorsal hand veins and is minimized if forearm or larger antecubital veins are used. Some individuals, though, experience pain if the drug is injected into proximal larger veins. Nonetheless, thrombophlebitis does not appear to be a problem after intravenous administration of this agent, whereas it can be evident after thiopental. Intravenous lidocaine 0.2 mg/kg or 1% lidocaine mixed with propofol in a 10:1 volume ratio can be used to decrease the incidence and severity of pain.

Most children and some adults prefer not to have an intravenous catheter inserted before the start of anesthesia. Sevoflurane has a relatively low blood-gas partition coefficient and the speed of induction is similar to, albeit somewhat slower than, that of propofol. Induction with sevoflurane can be hastened when the patient is told to breathe out to residual volume, then take a vital capacity breath through a primed anesthesia circuit, and then hold the breath.

Parental presence is becoming more accepted during induction of anesthesia in children, even though scientific evidence of its advantages is not conclusive. Some studies show that children are less upset and have fewer behavioral changes after surgery if a parent is present during induction. Others have suggested that parents can become upset when they see their anesthetized child, who appears to be dead, albeit breathing and with a beating heart. Separation anxiety on the part of the parents is probably no different if the child is awake or asleep.

For short procedures, some patients may not require neuromuscular-blocking drugs; others may need brief paralysis (e.g., with succinylcholine) to facilitate tracheal intubation. Nondepolarizing drugs can be used to facilitate intubation and also during the procedure. Nondepolarizing drugs such as rapacuronium or rocuronium have rapid onset times that are similar to those with succinylcholine. Of course, paralysis is not needed to insert an endotracheal tube: drug combinations such as propofol, alfentanil, and lidocaine obviate the need for paralysis.[59] Succinylcholine should be used with caution in children because of the possibility of cardiac arrest related to malignant hyperthermia or unsuspected muscular dystrophy, particularly Duchenne's disease.

Maintenance

Although many factors affect the choice of agents for maintenance of anesthesia, two primary concerns for ambulatory anesthesia are speed of wake-up and incidence of postoperative nausea and vomiting.

Anesthesia Maintenance and Wake-Up Times. Time to recovery may be measured by various criteria; however, for an ambulatory center, a patient may be considered awake when able to leave the center. Actual discharge from an ambulatory center, though, may depend on

administrative issues, such as a written order from a surgeon or anesthesiologist. The time necessary before a patient can be taken from the OR after completion of surgery, or a patient's ability to skip the PACU and go directly to a step-down unit, may be directly related to the anesthetic and result in cost savings for an institution. Does choice of maintenance agent affect recovery after anesthesia? Propofol, desflurane, and sevoflurane have characteristics that make them ideal for maintenance of anesthesia for ambulatory surgery. Propofol has a short half-life and, when used as a maintenance agent, results in rapid recovery and few side effects. Desflurane and sevoflurane, halogenated ether anesthetics with low blood-gas partition coefficients, seem to be ideal for general anesthesia for ambulatory surgery. Sevoflurane, unlike desflurane, facilitates a smooth inhalation induction of anesthesia, the preferred technique to ensure rapid recovery of children in ambulatory surgery centers. For children who receive either sevoflurane or halothane, or halothane and then desflurane, for induction and maintenance of anesthesia, recovery times are significantly shorter after sevoflurane or desflurane.

6 It is important to distinguish between wake-up time and discharge time. For example, in one study of laparoscopic surgery, patients emerged from anesthesia with desflurane and nitrous oxide significantly faster than after propofol or sevoflurane and nitrous oxide, although the ability to sit up, stand, and tolerate fluids and the time to fitness for discharge were no different.[60] When the bispectral index (BIS) or other guide of anesthetic depth is used, the difference between drugs and wake-up times may not be as great. Conversely, if fast wake-up times can translate to bypass of phase I, there may be cost savings.

7 **Intraoperative Management of Postoperative Nausea and Vomiting.** Nausea, with or without vomiting, is probably the most important factor contributing to a delay in discharge of patients and an increase in unanticipated admissions of both children and adults after ambulatory surgery. Patients hate vomiting. In one survey taken before surgery, for example, patients rated vomiting as most undesirable and, if given $100, would spend the most money on that problem to prevent it (Fig. 46-9).[61] Women, especially those who are pregnant, have a higher incidence of PONV. Other risk factors include a previous history of motion sickness or postanesthetic emesis; surgery within 1 to 7 days of the menstrual cycle; not smoking; and procedures such as laparoscopy, lithotripsy, major breast surgery, and ear, nose, or throat surgery. The greater the number of risk factors, the greater risk for nausea or vomiting after surgery.[62]

8 Inhalation agents are associated with an increased risk of PONV, particularly in the early stages of recovery; postoperative narcotic use is associated with PONV more than 2 hours after surgery.[63]

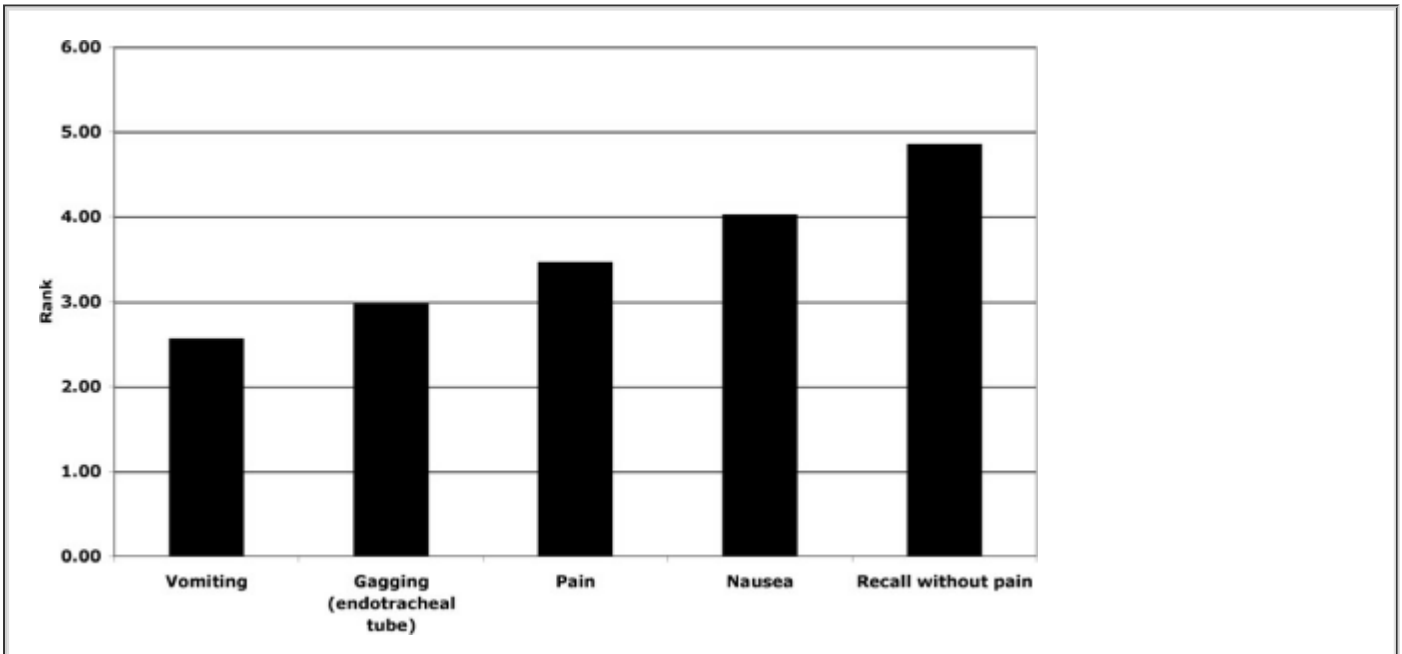

FIGURE 46-9. Patients were asked to rank 10 possible outcomes from most desirable to

most undesirable.[61] Illustrated, in relative rank order, are the top 5 undesirable outcomes; the lower the rank, the more undesirable is the outcome. (Adapted with permission from Macario A, Weinger M, Carney S, Kim A: Which clinical anesthesia outcomes are important to avoid? The perspective of patients. Anesth Analg 89:652, 1999.)

The vomiting pathway starts peripherally, where emetogens through enterochromaffin cells in the GI tract and/or other sensory neurons activate vagal afferents to the group of brainstem nuclei in the area postrema, the nucleus tractus solitarius, and the dorsal motor nucleus of the vagus. This area in the brain is otherwise known as the vomiting center. Although the pathways for vomiting are not completely understood, the area postrema is highly vascular, lacks a complete blood-brain barrier, and has receptors for neurotransmitters and hormones.[64] Receptor antagonists, specifically selective serotonin antagonists (ondansetron, dolasetron, and granisetron), have been shown to have similar efficacy to help alleviate this condition. Dopamine antagonists, antihistamines, and anticholinergic drugs are useful and are generally less expensive, but are associated with extensive side effects. NK_1 receptor antagonists may also be useful to control PONV. At the time of writing, although aprepitant, an NK_1 receptor antagonist, has been shown to be more effective than standard therapy (ondansetron and dexamethasone) after highly emetogenic chemotherapy (Fig. 46-10),[65] no publication has demonstrated the drug's effectiveness to control PONV. Other therapies useful in controlling PONV include acupuncture (Fig. 46-11),[66] supplemental fluid therapy,[67] clonidine (perhaps in part because it decreases anesthesia requirement),[68] and dexamethasone.[69,70] In one study, acupuncture therapy was effective in controlling both PONV and postoperative pain.[71]

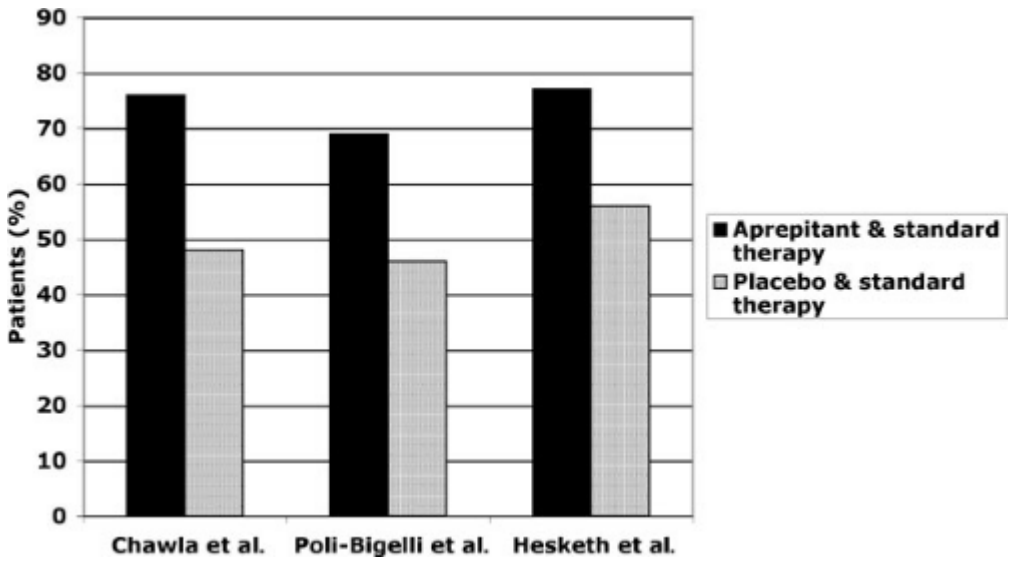

FIGURE 46-10. When oral aprepitant, compared with control, was combined with intravenous ondansetron and oral dexamethasone in adult patients who received one cycle cisplatin-based chemotherapy, based on three different multicenter randomized double-blind studies (Chawla et al,[90] Poli-Bigelli et al,[91] and Hesketh et al[92]); overall emetic events were significantly reduced (all $P < .01$) compared with standard therapy.[65] (Adapted with permission from Dando TM, Perry CM: Aprepitant: A review of its use in the prevention of chemotherapy-induced nausea and vomiting. Drugs 64:777, 2004.)

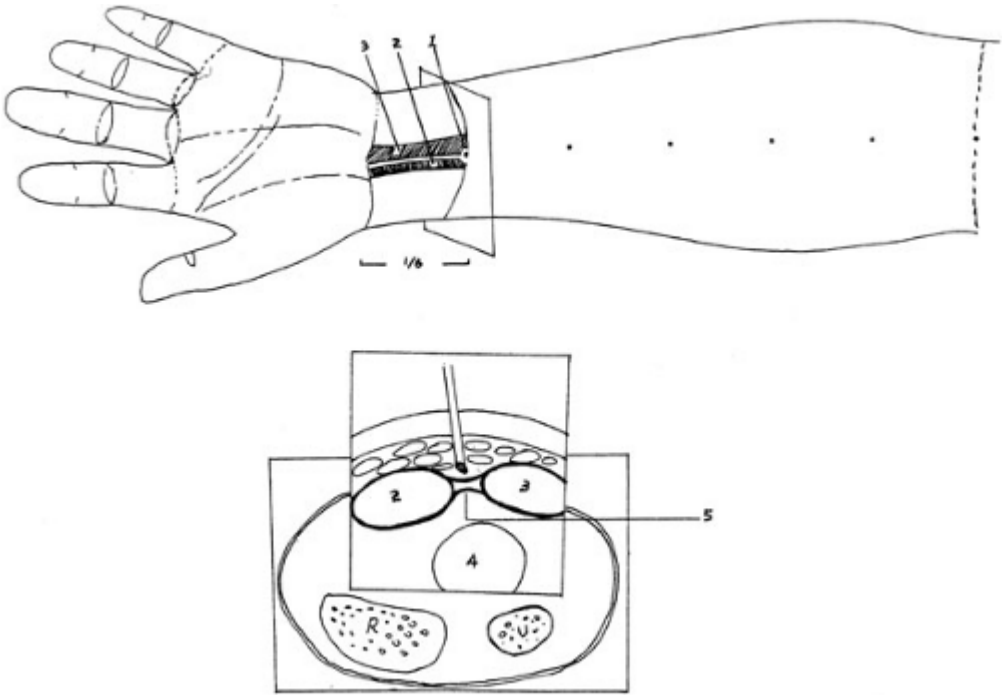

FIGURE 46-11. The P6 acupuncture point in relation to other hand structures is illustrated:[66] (1) P6 acupuncture point, (2) palmrois long tendon, (3) flexor carpi radialis tendon, (4) median nerve, (5) palmar aponeurosis. (Reprinted with permission from Wang SM, Kain ZN: P6 acupoint injections are as effective as droperidol in controlling early postoperative nausea and vomiting in children. Anesthesiology 97:359, 2002.)

9 Combination therapy is probably the most effective way to control PONV. In one study in children, for example, low-dose ondansetron and dexamethasone was more effective than high-dose ondansetron in reducing PONV.[72] In another study, the need for treatment of symptomatic PONV in the PACU was less when a total intravenous anesthetic without N_2O or paralysis, aggressive intravenous hydration, and three antiemetics

were used, compared with an inhalation-based anesthetic with paralysis and ondansetron, and with a third placebo group, which was treated similarly to the previous group but did not receive ondansetron.[73] In a third study of women after laparoscopic surgery, ondansetron with cyclizine was more effective in reducing postoperative vomiting and the need for a rescue antiemetic than ondansetron alone.[74] However, not all have found that combination therapy is more effective. For example, in a study of patients undergoing abdominal surgery, ondansetron with droperidol was not better than ondansetron alone.[75]

Because of its ability to decrease PONV, propofol is the best general anesthetic for ambulatory anesthesia. For example, in a study of 5,161 patients, propofol, compared with a volatile anesthetic, reduced nausea and vomiting by 19%; and nitrogen compared with nitrous oxide reduced the incidence by 12% (Fig. 46-12).[70] Despite the greater initial cost of propofol, overall costs may be less because treatment for nausea and vomiting is eliminated. In one study of patients undergoing office-based surgical procedures, patients received either propofol or sevoflurane for induction and maintenance.[76] Costs of drugs used for anesthesia were the same; yet, when wasted propofol

was also considered, propofol costs were greater by approximately $5 per patient. Overall, though, average cost per patient was lowest when propofol was used for both induction and maintenance, primarily because of the costs of treating nausea and vomiting ($46 for propofol induction and maintenance, $63 for propofol induction and sevoflurane maintenance, $72 for

sevoflurane induction and maintenance).

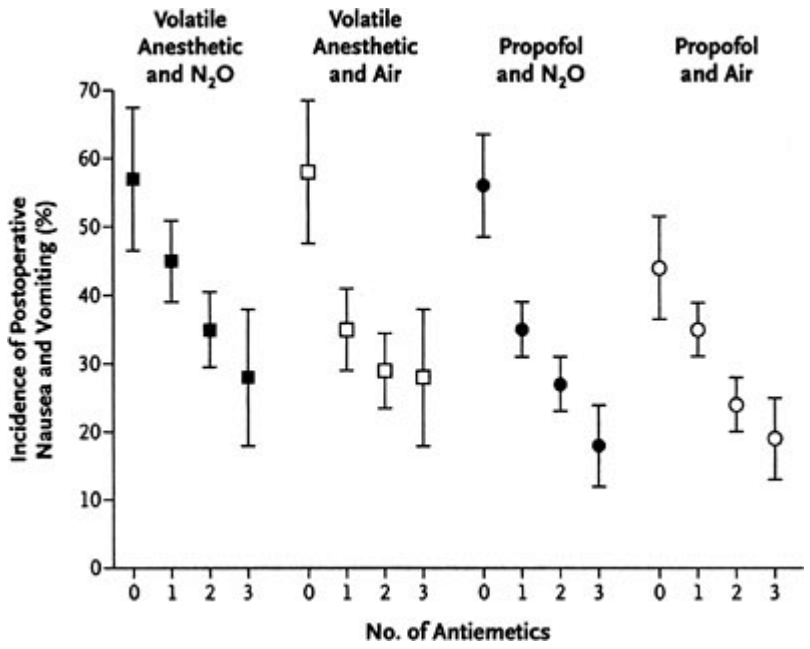

FIGURE 46-12. Postoperative nausea and vomiting (PONV) is least after a propofol anesthetic with air.[70] Illustrated is the incidence of PONV when different anesthetics and different numbers of prophylactic antiemetic treatments are administered. (Reprinted with permission from Apfel CC, Korttila K, Abdalla M *et al*: A factorial trial of six interventions for the prevention of postoperative nausea and vomiting. N Engl J Med 350:2441, 2004.)

The use of nitrous oxide for ambulatory anesthesia is an issue because the incidence of emesis may be greater after nitrous oxide than after other inhalation agents. Yet, many studies have shown that nitrous oxide can be used successfully for ambulatory anesthesia. A meta-analysis, designed to determine if nitrous oxide significantly reduced the odds of PONV, included 26 trials from 24 studies.[77] Overall, the use of nitrous oxide increased the risk of PONV by 28%. The maximal benefit of nitrous oxide avoidance was seen in female patients (46%).

Paralysis. Muscle paralysis for ambulatory anesthesia extends beyond the time of paralysis for intubation, particularly when nondepolarizing drugs have been used. The clinical effect of the nondepolarizing agent mivacurium, given as a bolus injection to 25% recovery, lasts 12 to 18 minutes, the shortest duration of effect for the neuromuscular blockers. The duration of action of rocuronium, vecuronium, rapacuronium, and atracurium ranges from 25 to 40 minutes. Because mivacurium depends on plasma cholinesterase for metabolism, recovery can be prolonged in the presence of atypical plasma cholinesterase. In patients with normal plasma cholinesterase levels, postoperative vomiting might be reduced if mivacurium does not have to be reversed. Reversal agents must be used unless there is no doubt that muscle relaxation has been fully reversed. When an ambulatory surgery case is expected to last more than 30 minutes, mivacurium may not be indicated. Particularly for children, in whom muscle relaxants generally have decreased potency, thereby enabling more rapid recovery, longer-acting drugs, such as pancuronium, may be used without sequelae.

Intraoperative Management of Postoperative Pain. Opioids, when given intraoperatively, are useful to supplement both intraoperative and postoperative analgesia. Fentanyl is probably the most popular drug, although all other available narcotics have been tried. All narcotics can cause nausea, sedation, and dizziness, which can delay a patient's discharge. Nonsteroidal analgesics are not effective as supplements during general anesthesia, although they are useful in controlling postoperative pain, particularly when given before skin incision. To control postoperative pain, combination therapy is most useful. For example, in a study of outpatients undergoing inguinal

hernia repair under general anesthesia, triple preincisional therapy that included rofecoxib, 50 mg PO, ketamine, 0.2 mg/kg intravenously, and local anesthetic field block reduced pain scores and analgesic use in the first 24 hours after discharge compared with a placebo group.[78] See also the previous discussion on opioids and nonsteroidal analgesics in the Opioids and Nonsteroidal Analgesics section.

10 **Depth of Anesthesia.** BIS monitors and entropy or auditory-evoked potential monitors are believed to decrease anesthesia

requirement without sacrificing amnesia during general anesthesia. Because less anesthesia is used, titration of anesthesia with these monitors results in earlier emergence from anesthesia. In a meta-analysis of BIS monitoring for ambulatory anesthesia, BIS monitoring was shown to reduce anesthetic use by 19%, with more modest decreases in PACU duration (4 min) and PONV (6%) (Fig. 46-13).[79] Results are even more modest, albeit mixed, in terms of later recovery end points. Because these monitors result in less use of anesthesia, there is the possibility that intraoperative awareness and myocardial ischemia might be increased. Sympatholytic drugs, instead of anesthesia, can be used to control autonomic responses to anesthesia. In fact, recovery is faster and side effects are fewer in ambulatory patients whose blood pressure is controlled by sympatholytics instead of inhalation agents.[80] In a study of almost 5,000 patients who underwent general anesthesia and who were paralyzed and/or were intubated, awareness was significantly reduced in the group of patients who were monitored with a BIS compared with the group who were not monitored with the BIS (Fig. 46-14).[81]

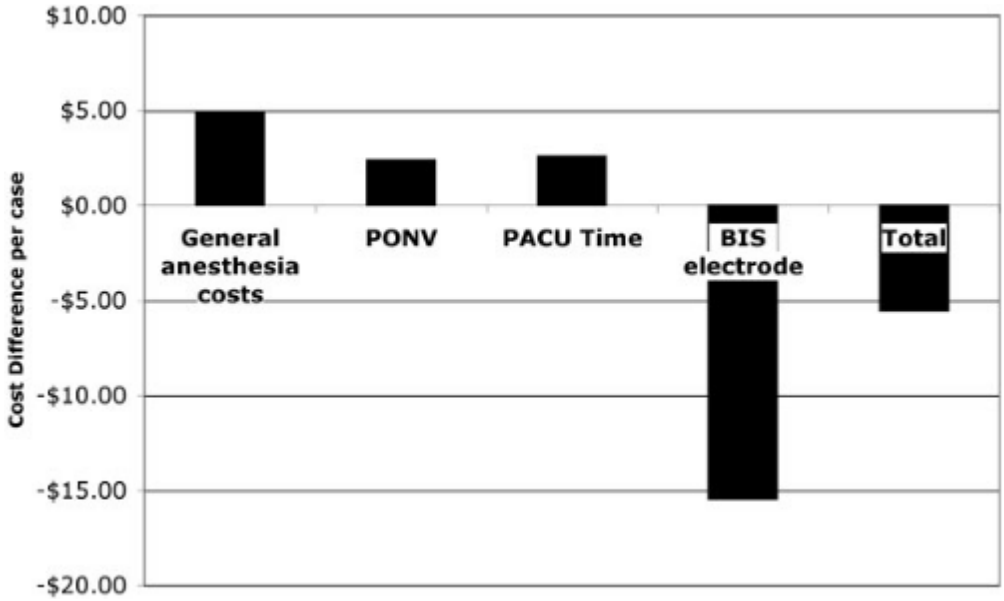

FIGURE 46-13. Bispectral index (BIS) monitoring reduces anesthetic consumption, cost to treat nausea and vomiting, and postanesthesia care unit (PACU) time; the cost of the electrode reverses cost savings.[79] The ordinate represents cost difference per case pooled from three studies (i.e., costs for the control group minus cost for the group that used BIS). The capital cost for the BIS monitor was not included. (Adapted with permission from Liu SS: Effects of bispectral index monitoring on ambulatory anesthesia: A meta-analysis of randomized controlled trials and a cost analysis. Anesthesiology 101:311, 2004.)

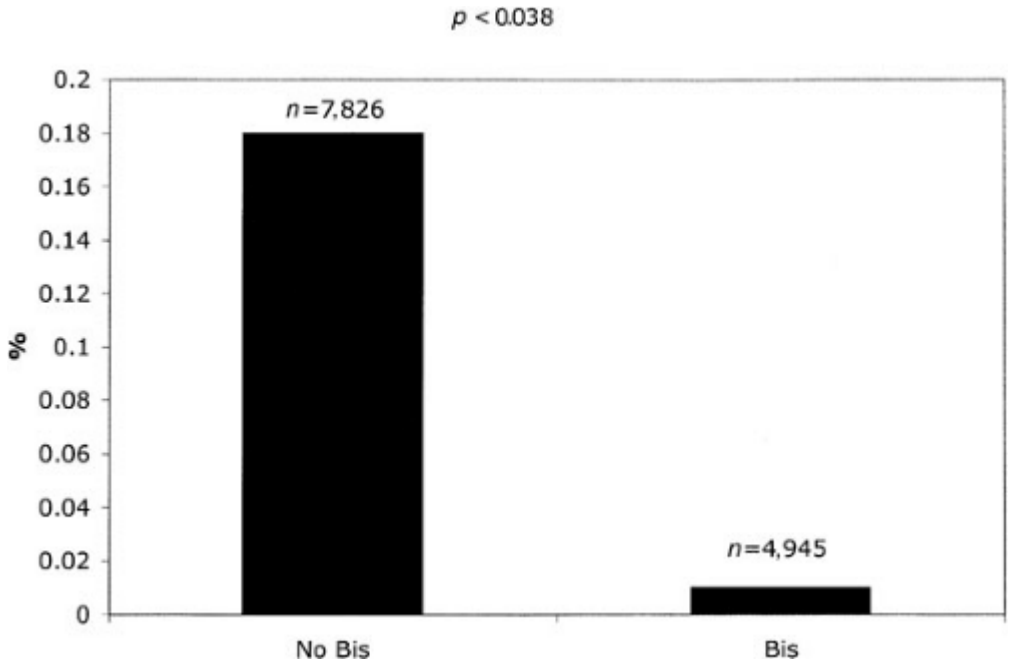

FIGURE 46-14. When a bispectral index (BIS) monitor is used, the incidence of awareness is reduced.[81] (Reprinted with permission from Ekman A, Lindholm ML, Lennmarken C, Sandin R: Reduction in the incidence of awareness using BIS monitoring. Acta Anaesthesiol Scand 48:20, 2004.)

Airways. Using a laryngeal mask airway (LMA), or similar type of airway, provides several advantages for allowing a patient to return to baseline status quickly. Muscle relaxants required for intubation can be avoided. Coughing is less than with tracheal intubation. Anesthetic requirements are reduced. Hoarseness and sore throat are also reduced. Overall, cost savings result with the use of LMAs. Because of gastric insufflation, though, nausea and vomiting may be greater. The use of the LMA has been described for laparoscopic procedures, although the potential for aspiration exists because of an inflated abdomen during laparoscopy.

MANAGEMENT OF POSTANESTHESIA CARE

Many recovery issues are part of patient selection and perioperative management and must be considered before the patient enters the PACU. Managing common problems in the PACU quickly and effectively is as important as appropriate patient selection and choice of anesthetic technique if the patient is to return home on the day of surgery. The three most common reasons for delay in patient discharge from the PACU are

drowsiness, nausea and vomiting, and pain. All three are a function of intraoperative management, but nausea, vomiting, and pain also can be treated in the PACU.

Reversal of Drug Effects

Reversal of muscle relaxants is not unique to the ambulatory surgery patient and is not discussed here. Reversal of opioids may sometimes be necessary. Flumazenil, a benzodiazepine receptor antagonist, has primarily been used to reverse the effects of sedation after endoscopy and spinal anesthesia. Reversal of psychomotor impairment with flumazenil is not complete, and the subjective experience of sedation is not necessarily attenuated. Reversal of amnesia with flumazenil is only partial, and the duration of the reversal effect may not be long enough to be clinically significant. Flumazenil should not be used routinely as a benzodiazepine antagonist, but may be used when sedation appears to be excessive. In addition, reversal of benzodiazepine-induced sedation by flumazenil should not replace appropriate ventilatory assistance and, if

necessary, placement of an endotracheal tube.

Nausea and Vomiting

Nausea and vomiting are the most common reasons both children and adults have protracted stays in the PACU or unexpected hospital admission due to anesthesia. Nausea and vomiting are also the most common adverse effect in patients in the PACU. Much research has been undertaken to study prophylactic treatment of this problem before surgery, as well as practice techniques in the OR that can minimize nausea and vomiting in the PACU. The treatment of this problem, once it occurs in the PACU, has not received as much study. Yet, there are a variety of drugs that are effective in treating the problem. The 5-HT3 antagonists seem particularly effective. For example, in one study of children who underwent strabismus surgery and were then nauseous during the first 3 hours after recovery from anesthesia, emesis-free episodes were greater after granisetron 40 mcg/kg (88%), compared with droperidol 50 mcg/kg (63%) or metoclopramide 0.25 mg/kg (58%).[82] Similar findings were seen in a study of patients who underwent laparoscopic cholecystectomy and then experienced PONV during the first 3 hours after their procedure: complete control was more commonly seen after granisetron 40 mcg/kg (88%), compared with droperidol 20 mcg/kg (60%) or metoclopramide 0.2 mg/kg (55%).[83] Hydroxyzine 25 mg is also effective. Midazolam and propofol, although more commonly used for sedation, have antiemetic effects that are longer in duration than their effects on sedation. For example, when patients in the PACU were nauseous and then received either propofol 15 mg, or midazolam 1 mg or 2 mg, subsequent nausea was no different than ondansetron 4 mg.[84] Other authors have also found that propofol 10 mg is effective. When a ReliefBand accustimulation device was compared with ondansetron for patients who were nauseous in the PACU after receiving metoclopramide or droperidol and undergoing laparoscopic surgery, nausea was most effectively treated with both the ReliefBand and ondansetron, although both therapies were equally effective individually in treating PONV.[85] If patients have already received ondansetron prophylaxis in the OR, and then are nauseous in the PACU, another repeat dose might not be effective: in a multicenter study of patients who received ondansetron 4 mg during an outpatient procedure that included nitrous oxide, and who were then nauseous in the PACU, complete response to treatment was no different if patients received either another dose of ondansetron 4 mg or placebo.[86] More work is obviously needed to study effective therapies for treatment PONV in the PACU. Finally, because pain may be associated with nausea, treatment of pain frequently decreases nausea.

Pain

Postsurgical pain must be treated quickly and effectively. It is important for the practitioner to differentiate postsurgical pain from the discomfort of hypoxemia, hypercapnia, or a full bladder. Factors that correlate with greater postoperative pain are younger age of patient, less serious illness, greater body mass index, operative site, and duration of surgery.[87] Medications for pain control should be given in small intravenous doses (e.g., 1 to 3 mg/70 kg morphine or 10 to 25 mcg/70 kg fentanyl). Intramuscular injection of opioid for pain control in the PACU is probably not necessary. Onset of action of drugs is faster after intravenous catheter administration than after oral administration. Control of postoperative pain may include administration of opioid analgesics or NSAIDs, which are not associated with respiratory depression, nausea, or vomiting. Fentanyl is the narcotic frequently used to control postoperative pain, although the effects of morphine last longer. Patients who receive fentanyl for pain control may require additional injections and go home no sooner compared with patients who receive morphine. Nonsteroidal medications, such as ketorolac or ibuprofen, can also effectively control postoperative pain and, compared with narcotics, can give pain relief for a longer period and are associated with less nausea and vomiting. NSAIDs can increase bleeding, although there is no evidence at this time of such a danger for most ambulatory surgery procedures. When swelling and pain are problematic postoperatively, NSAIDs can be more effective than opioids in relieving both.

We manage pain in both adults and children initially either with a short-acting opioid analgesic such as fentanyl (25 mcg/70 kg), or with an injection of ketorolac 30–60 mg/70 kg intramuscularly or intravenously. Fentanyl is repeated at 5-minute intervals until pain is

controlled. For children, we also use an elixir of acetaminophen containing codeine (120 mg acetaminophen, 12 mg codeine, in each 5 mL of solution). Five milliliters is administered to children between the ages of 3 and 6, and 10 mL to children between the ages of 7 and 12. Children are returned to parental care as soon as they are awake. We find frequently that infants younger than 6 months of age usually need to be reunited with their mothers for nursing (or bottle feeding) after a procedure not associated with severe pain. For older infants and young children in the PACU, acetaminophen, 60 mg per year of age (given orally or rectally), is commonly used to relieve mild pain. Intravenous fentanyl (up to a dose of 2 mcg/kg) is preferred for more severe pain. Meperidine (0.5 mg/kg) and codeine (1 to 1.5 mg/kg) can be given intramuscularly if an intravenous route has not been established.

Preparation for Discharging the Patient

In addition to the PACU, many ambulatory surgery centers in the United States have another area, often known as a phase II recovery room, where patients may stay until they are able to tolerate liquids, walk, and/or void. With the anesthetics that are typically used in ambulatory surgery ORs, patients who are awakened in the OR and are evaluated as 9 or 10 according to the modified Aldrete scoring system may be transferred directly to phase II recovery from the OR. Patients who undergo procedures under monitored anesthesia care can usually go straight to the phase II area from the OR. After general anesthesia, LMA use and pain control using nonopioid analgesics

facilitates fast-tracking. In one study, 35 to 53% of patients who underwent laparoscopic gynecologic surgery were able to bypass the PACU.[88] In that study, residual sedation was the most common reason the PACU was not bypassed. In another study of patients who underwent outpatient knee surgery, in the phase II recovery area, of those who bypassed the PACU, 31% required nursing interventions and were three times more likely to need a nursing intervention, compared with 16% who required a nursing intervention who first went to the PACU. Yet, discharge times were faster and unplanned hospital admissions were fewer if patients were able to bypass the PACU.[89]

Concerning discharge to home, some criteria for discharge have been created without scientific basis. One criterion is the ability to tolerate liquids before being discharged. Postoperative nausea may be greater if patients are required to drink liquids prior to discharge. Even though it is warranted after spinal or epidural anesthesia, the requirement that low-risk patients void before discharge may only lengthen stay in the hospital, particularly if patients are willing to return to a medical facility if they are unable to void. Practical criteria for patient discharge from the OR, from the PACU, and from the phase II recovery area are needed that in no way compromise patient safety. The value of psychomotor tests to measure different phases of recovery (except for research purposes) is questionable.

Although scoring systems may be used to guide transfer from the PACU to the phase II recovery room and from phase II recovery to home, they do little to test higher levels of function, such as the ability to use one's hands, to drive a car, or to remain alert long enough to drive. Patients may feel fine after they leave the hospital, but they should be advised against driving for at least 24 hours after a procedure. Patients and responsible parties should be reminded that the patient should not operate power tools or be involved in major business decisions for up to 24 hours. Once the patient leaves the medical facility, supervision may not be as good as it was in the hospital. Therefore, before a patient is discharged, dressings should be checked. It is wise to include the responsible person in all discharge instructions, which are best made available on printed forms.

Patients should also be informed that they may experience pain, headache, nausea, vomiting, or dizziness and, if succinylcholine was used, muscle aches and pains apart from the incision for at least 24 hours. A patient will be less stressed if the described symptoms are expected in the course of a normal recovery. Written instructions are important. The addition of written and oral education techniques at discharge has a significant impact on improving compliance.

For patients with a language barrier (e.g., in a population with a high percentage of immigrants),

consent forms, procedural explanation, and discharge information may have to be written in languages other than English and the services of an interpreter may be necessary. Nursing staff should assess the adult who will take the patient home to determine whether he or she is in fact a responsible person. A responsible person is someone who is physically and intellectually able to take care of the patient at home. Facilities should develop a method of follow-up after the patient has been discharged. At some facilities, staff members telephone the patient the next day to determine the progress of recovery; others use follow-up postcards. Whenever we become innovative in the management of our outpatients, we must assess how a cost-effective, “no frills” approach to care affects patient safety. We must determine what we can do for the patient who lives alone, for the patient whose responsible person is unable to manage his or her needs, for the patient without means of transportation, and for the patient with limited insurance coverage. Hospital beds can be set aside for patients who require observation. Patients in these beds after an ambulatory surgical procedure are still considered outpatients. They are charged for the hours spent in the observation area. Some hospitals have joined with management firms to build a hospital hotel or medical motel close to the hospital itself. The hotel, usually a nonmedical facility, offers the outpatient a comfortable, inexpensive, and convenient place to recuperate while being cared for by family or nurses. Home health care nursing may be appropriate after surgical procedures such as reduction mammoplasty, abdominoplasty, vaginal hysterectomy, and major open ligament repairs of the knee. The various services for management and/or observation of outpatients after surgery stand today where techniques for management of outpatients during surgery stood in the health care delivery system 20 years ago. Prospective studies are needed to assess the quality of care and the effect that these innovative approaches have on patient safety.

Patient, procedure, availability and quality of aftercare, and anesthetic technique must be individually and collectively assessed to determine acceptability for ambulatory surgery. A delicate balance must be maintained between the physical status of the patient, the proposed surgical procedure, and the appropriate anesthetic technique, to which must be added the expertise level of the anesthesiologist caring for a patient.

Anesthesia for ambulatory surgery is a rapidly evolving specialty. Patients once believed unsuitable for ambulatory surgery are now considered to be appropriate candidates. Operations once believed unsuitable for outpatients are now routinely performed in the morning so patients can be discharged in the afternoon or evening. The appropriate anesthetic management before these patients come to the OR, during their operation, and then afterward is the key to success. The availability of both shorter-acting anesthetics and longer-acting analgesics and antiemetics enables us to care for patients in ambulatory centers effectively.

Chapter 47

Monitored Anesthesia Care

Simon C. Hillier

Michael S. Mazurek

KEY POINTS

1	A comprehensive preanesthetic evaluation is a critical component of any monitored anesthesia care procedure. This is especially important because the patient population that presents for monitored anesthesia care has increasingly complex coexisting disease.
2	There is significant interpatient variability in response to sedative drug administration. Therefore, the safe provision of monitored anesthesia care requires the ability to immediately secure and maintain a patent airway and perform advanced life support techniques.
3	Sedation techniques should be modified to account for interpatient differences in age, general medical condition, and the particular requirements of the procedure. The sedation technique can be conceptually thought of as having hypnotic, anxiolytic, and analgesic components. Each component of the sedation technique should be adjusted as required accordingly.
4	In general, it is preferable to use drugs having a shorter duration of action to facilitate titration, earlier awakening, and a rapid return to street fitness.
5	It is important to titrate drugs carefully, remembering to allow time for the drug to achieve its effect prior to administering supplemental doses. Careful titration of drugs will reduce the likelihood of unintended general anesthesia with an unprotected airway and cardiorespiratory compromise.
6	It is prudent to gain experience and become comfortable with a small armamentarium of drugs. It is particularly important to appreciate the potential adverse synergistic effects of sedative drugs on the respiratory and cardiovascular systems.
7	The institutional standards for monitoring, record keeping and documentation, recovery room practice, quality assurance, and policy and procedure development for sedation and monitored anesthesia care should be no different than those for general anesthesia.

8

Sedation is frequently used as an adjunct to local or regional analgesic techniques. Therefore, it is important to be prepared to recognize and treat local anesthetic toxicity. It should be remembered that the usual premonitory signs of impending local anesthetic toxicity are obscured by concomitant administration of sedative drugs.

Anesthesiologists typically provide monitored anesthesia care to patients undergoing therapeutic or diagnostic procedures that would otherwise be uncomfortable or unsafe. The continuous attention of the anesthesiologist is directed at optimizing patient comfort and safety. Monitored anesthesia care usually involves the administration of drugs with anxiolytic, hypnotic, analgesic, and amnestic properties, either alone or as a supplement to a local or regional technique.

TERMINOLOGY

It is important to distinguish between "monitored anesthesia care" and "sedation/analgesia." *Sedation/analgesia* is the term currently used by the American Society of Anesthesiologists (ASA) in their Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists.[1] Monitored *anesthesia care* implies the potential for a deeper level of sedation than that provided by sedation/analgesia and is always administered by an anesthesiologist provider. The standards for preoperative evaluation, intraoperative monitoring, and continuous presence of a member of the anesthesia care team are no different from those for general or regional anesthesia.[2]

Conceptually, monitored anesthesia care is attractive because it should invoke less physiologic disturbance and allow a more rapid recovery than general anesthesia. It is instructive to review the ASA position statement approved by the House of Delegates in 1986 and last amended in 1998.[2] The ASA definition of monitored anesthesia care is as follows:

> *Monitored anesthesia care is a specific anesthesia service in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure.*
>
> *Monitored anesthesia care includes all aspects of anesthesia care—a preprocedure visit, intraoperative care and post procedure anesthesia management.*
>
> *During monitored anesthesia care, the anesthesiologist or a member of the anesthesia care team provides a number of specific services, including but not limited to:*

Monitoring of vital signs, maintenance of the patient's airway and continual evaluation of vital functions

Diagnosis and treatment of clinical problems which occur during the procedure

Administration of sedatives, analgesics, hypnotics, anesthetic agents or other medications as necessary to ensure patient safety and comfort

Provision of other medical services as needed to accomplish the safe completion of the

procedure

Monitored anesthesia care often includes the administration of doses of medications for which the loss of normal protective reflexes or loss of consciousness is likely. Monitored anesthesia care refers to those clinical situations in which the patient remains able to protect the airway for the majority of the procedure. If, for an extended period of time, the patient is rendered unconscious and/or loses normal protective reflexes, then anesthesia care shall be considered a general anesthetic.

Because monitored anesthesia care is a physician service provided to an individual patient and is based on medical necessity, it should be subject to the same level of reimbursement as general or regional anesthesia. Accordingly, the ASA Relative Value Guide provides for the use of proper basic procedural units, time units and age and risk modifier units as the basis for determining reimbursement.

The ASA also states that monitored anesthesia care should be requested by the attending physician and be made known to the patient, in accordance with accepted procedures of the institution. In addition, the ASA states that the service must include the following:

1. Performance of a preanesthetic examination and evaluation
2. Prescription of anesthetic care
3. Personal participation in, or medical direction of, the entire plan of care
4. Continuous physical presence of the anesthesiologist or, in the case of medical direction, of the resident or nurse anesthetist being medically directed
5. Proximate presence, or in the case of medical direction, availability of the anesthesiologist for diagnosis and treatment of emergencies

Furthermore, the ASA states that all institutional regulations pertaining to anesthesia services will be observed, and all the usual services performed by the anesthesiologist will be furnished, including but not limited to:

1. Usual noninvasive cardiocirculatory and respiratory monitoring
2. Oxygen administration, when indicated
3. Administration of sedatives, tranquilizers, antiemetics, narcotics, other analgesics, beta-blockers, vasopressors, bronchodilators, antihypertensives, or other pharmacologic therapy as may be required in the judgment of the anesthesiologist

PREOPERATIVE ASSESSMENT

1 The preoperative evaluation is an essential prerequisite to monitored anesthesia care and should be as comprehensive as that performed prior to any general or regional anesthetic (see Chapter 18). However, in addition to the usual evaluation for the patient who is planned to undergo general anesthesia, there are additional considerations unique to monitored anesthesia care that may ultimately determine the success or failure of the procedure. It is important to evaluate the patient's ability to remain motionless and, if necessary, actively cooperate throughout the procedure. Thus, it is important to evaluate the patient's psychological preparation for the planned procedure. It is also important to elicit the presence of coexisting sensorineural or cognitive deficits. These factors, or the inability to communicate with the patient, may on occasion make general anesthesia a more appropriate alternative. Verbal communication between physician and patient is very important for three reasons: (1) as a monitor of the level of sedation and cardiorespiratory function, (2) as a means of explanation and reassurance for the patient, and (3)

as a mechanism of communication when the patient is required to actively cooperate. Although cardiorespiratory disease is often an indication to perform a procedure using monitored anesthesia care rather than general anesthesia, there are occasions when cardiorespiratory disease may reduce the utility of monitored anesthesia care. For example, the presence of a persistent cough may make it difficult for the patient to remain immobile, which can be particularly dangerous during ophthalmologic or awake neurosurgical procedures. Attempts to attenuate coughing with sedation techniques are likely to be unsuccessful and potentially harmful because a significant level of anesthesia is required to abolish the cough reflex. Similarly, some patients with significant cardiovascular disease may experience orthopnea and be unable to lie flat for an extended period.

TECHNIQUES OF MONITORED ANESTHESIA CARE

2 A variety of medications are commonly administered during monitored anesthesia care with the desired end points being providing patient comfort, maintaining cardiorespiratory stability, improving operating conditions, and preventing recall of unpleasant perioperative events. It is helpful to delineate and individualize the goals for each patient to formulate an appropriate regimen that frequently involves the administration of either individual or combinations of analgesic, amnestic, and hypnotic drugs. There should be a minimal incidence of side effects, such as cardiorespiratory depression, nausea and vomiting, delayed emergence, and dysphoria, and there should be a rapid and complete recovery. Ideally, the patient should be able to communicate during the procedure. Clinical experience

suggests that a level of sedation that allows verbal communication is optimal for the patient's comfort and safety. If the level of sedation is deepened to the extent that verbal communication is lost, most of the advantages of monitored anesthesia care are lost, and the risks of the technique approach those of general anesthesia with an unprotected and uncontrolled airway. However, because monitored anesthesia care is provided by anesthesiologists, the range of sedation may be expanded to include significantly deeper sedation techniques than those provided by nonanesthesiologists during sedation/analgesia.

3 The preanesthetic evaluation and plan should strive to identify specific causes of, and provide specific therapy for, pain, anxiety, and agitation. Pain may be treated by local or regional analgesia, systemic analgesics, or removal of the painful stimulus. Anxiety may be reduced by the use of an anxiolytic such as a benzodiazepine and reassurance by the anesthesiologist. Patient agitation may be a result of pain or anxiety, but it is also vitally important to eliminate life-threatening factors such as hypoxia, hypercarbia, impending local anesthetic toxicity, and cerebral hypoperfusion. Other less ominous, but often overlooked, causes of discomfort and agitation include a distended bladder, hypothermia, hyperthermia, pruritus, nausea, positional discomfort, uncomfortable oxygen masks and nasal cannulae, intravenous cannulation site infiltration, a member of the surgical team leaning on the patient, and prolonged pneumatic tourniquet inflation.

Pharmacologic Basis of Monitored Anesthesia Care Techniques—Optimizing Drug Administration

4 The ability to predict the effects of the drugs in our armamentarium demands an understanding of their pharmacokinetic and pharmacodynamic properties. This understanding is a fundamental prerequisite for the design of an effective sedation regimen and greatly increases the probability of producing the desired therapeutic effect. Context-sensitive half-time, effect–site equilibration time, and anesthetic–sedative drug interactions are fundamental concepts that are particularly useful in the context of minimum alveolar concentration (MAC) and are discussed in some detail.

The ultimate objective of any dosing regimen is to deliver a therapeutic concentration of drug to its site of action, which is determined by the unique pharmacokinetic properties of that drug in that particular patient. The therapeutic response to a particular drug concentration is described by the pharmacodynamics of that particular patient–drug combination. There is a large degree of pharmacokinetic and pharmacodynamic variability, producing a significant variability in the dose-response relationship in clinical practice. Excessive sedation may result in cardiac or respiratory

depression. Inadequate sedation may result in patient discomfort and potential morbidity due to lack of cooperation. As a general principle, to avoid excessive levels of sedation, drugs should be titrated in small increments or by adjustable infusions rather than administered in larger doses according to predetermined notions of efficacy. In an ideal dosing regimen, an effective concentration of drug is achieved and then adjusted according to the magnitude of the noxious stimulus. If the noxious stimulus is increased or decreased, the concentration is increased or decreased accordingly. By the end of the procedure, the drug concentration should have decreased to a level compatible with rapid recovery. This approach requires the use of drugs that are easily titratable, such as propofol. When using drugs such as propofol, adjustable rate continuous infusions are the most logical method of maintaining a desired therapeutic concentration. When the traditional method of intermittent bolus administration is used, significant fluctuations in drug concentration occur. Under these circumstances, the plasma concentrations are either above or below the desired therapeutic range for a significant proportion of the procedure (Fig. 47-1). Continuous infusions are superior to intermittent bolus dosing because they produce less fluctuation in drug concentration, thus reducing the number of episodes of inadequate or excessive sedation. Administration of drugs by continuous infusion rather than by intermittent dosing also reduces the total amount of drug administered and facilitates a more prompt recovery.[3]

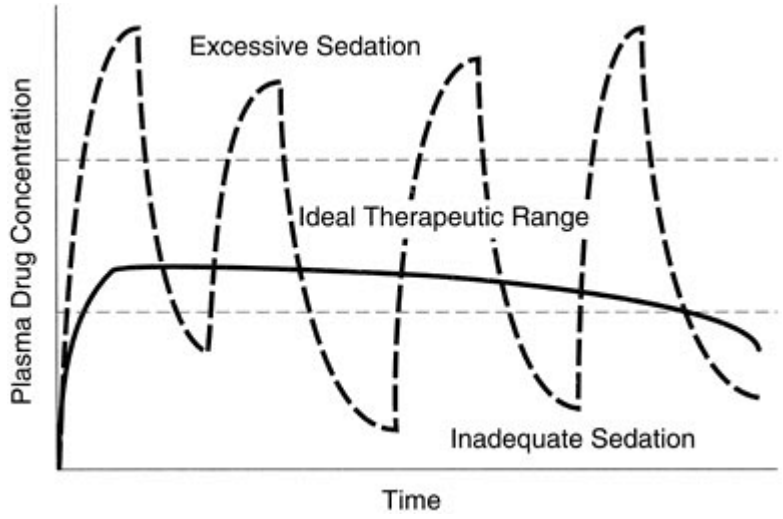

FIGURE 47-1. The changes in drug concentration during differing administration techniques. The *solid line* represents a continuous infusion of a drug. In this situation, the drug is maintained within the therapeutic range for most of the procedure. The *dashed line* represents the drug concentration resulting from intermittent bolus administration. The drug concentration is significantly above or below the desired therapeutic level for most of the procedure.

Distribution, Elimination, Accumulation, and Duration of Action

Following the administration of intravenous anesthetic drugs, the immediate distribution phase causes a brisk decrease in plasma levels as the drug is transported to the rapidly equilibrating vessel-rich group of tissues. There is a simultaneously occurring distribution of drug to the less well perfused tissues such as muscle and skin. Over time, the drug is also distributed to the poorly perfused tissues such as bone and fat. Although the latter compartments are poorly perfused, they may accumulate significant amounts of lipophilic drugs during prolonged administration. This peripheral depot may contribute to a delayed recovery when the drug is eventually released back into the central compartment after its administration is discontinued. Redistributive factors are important determinants of drug effect and influence the plasma

concentration of a drug in a time-dependent fashion.

The Elimination Half-Time

Until more recently, the elimination half-time was the predominant pharmacokinetic parameter used as the predictor of an anesthetic drug's duration of action. In everyday clinical practice, however, this parameter has not greatly enhanced our ability to predict anesthetic drug disposition. Only in single-compartment models does the elimination half-time actually represent the time required for a drug to reach half of its initial concentration after administration. This is because in a single-compartment model elimination is the only process that can alter drug concentration. Intercompartmental

distribution cannot occur because there are no other compartments for the drug to be distributed to and from. Most drugs in the anesthesiologist's armamentarium are lipophilic and are therefore more suited to multicompartmental modeling than single-compartment modeling. Similarly, other pharmacokinetic parameters such as distribution half-time, distribution volume, intercompartmental rate constants, etc., do not provide us with a practical means of predicting drug disposition. In multicompartmental models, the metabolism and excretion of some intravenous anesthetic drugs may have only a minor contribution to changes in plasma concentration when compared with the effects of intercompartmental distribution.

Context-Sensitive Half-Time

To improve the description and understanding of anesthetic drug disposition, the concept of context-sensitive half-time has been developed.[4] This concept has greatly improved our understanding of anesthetic drug disposition and is clinically applicable. The effect of distribution on plasma drug concentration varies in magnitude and direction over time and depends on the drug concentration gradients that exist between the various compartments. For example, during the early part of an infusion of a lipophilic drug, distributive factors will tend to decrease plasma concentrations as the drug is transported to the unsaturated peripheral tissues. Later, after the infusion is discontinued, drug will return from the peripheral tissues and reenter the central circulation. The relative effect on plasma concentrations of distributive processes versus elimination varies over time and from drug to drug. The context-sensitive half-time describes the time required for the plasma drug concentration to decline by 50% after terminating an infusion of a particular duration. This parameter is calculated by using computer simulation of multicompartmental models of drug disposition (Fig. 47-2). The context-sensitive half-time reflects the combined effects of distribution and metabolism on drug disposition. There are several interesting aspects of these data. First, the data confirm the clinical impression that as the infusion duration increases, the context-sensitive half-time of all the drugs increases; this phenomenon is not described in any way by the elimination half-life. The increase in context-sensitive half-time is particularly marked with fentanyl and thiopental. In the case of fentanyl, drug that is irreversibly eliminated from the plasma by hepatic clearance is immediately replaced by drug returning from the peripheral compartments. Thus, although fentanyl has a shorter elimination half-life than that of sufentanil (462 versus 577 minutes), its context-sensitive half-time is much greater than that of sufentanil after an infusion of duration longer than 2 hours. The storage and later release of fentanyl from peripheral binding sites delay the decline in plasma concentration that would otherwise occur. The context-sensitive half-times of all the drugs bear no constant relationship to their elimination half-times. Also compare the context-sensitive half-times of propofol and thiopental (Fig. 47-2). Although the context-sensitive half-times of propofol and thiopental are comparable following a brief infusion, the context-sensitive half-time of thiopental increases rapidly following all but the shortest infusions. This finding confirms the clinical impression that thiopental is not an ideal drug for continuous infusion during ambulatory procedures. The context-sensitive half-time of propofol is prolonged to a minimal extent as the infusion duration increases. After an infusion of propofol, the drug that returns to the plasma from the peripheral compartments is rapidly cleared by metabolic processes and is therefore not available to retard the decay in plasma levels. This difference between thiopental and propofol is attributable to (1) the high metabolic clearance of propofol compared with thiopental and (2) the

relatively slow rate at which propofol returns to the plasma from peripheral compartments.

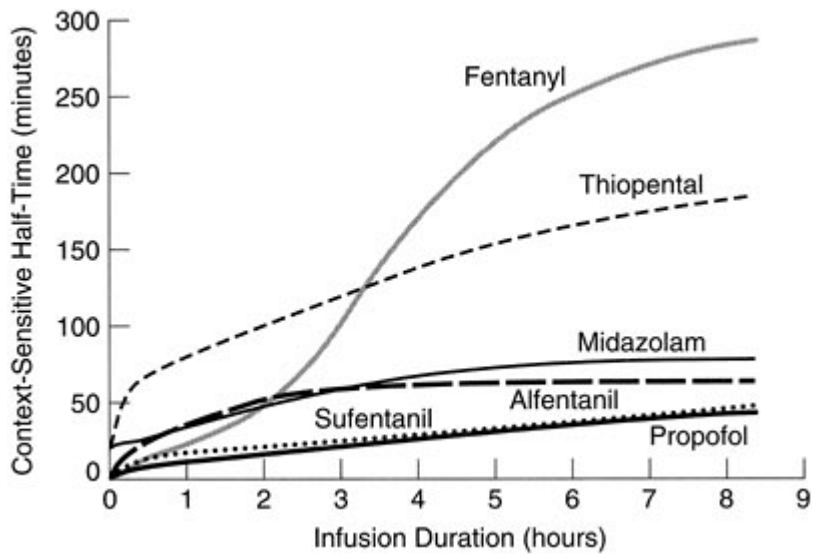

FIGURE 47-2. Context-sensitive half-times as a function of infusion duration. These data were generated from the computer model of Hughes et al.[4] It can be seen that the context-sensitive half-time of propofol demonstrates a minimal increase as the duration of the infusion increases. Also note that for infusions of short duration, sufentanil has a shorter half-time than alfentanil. (Reprinted with permission from Hughes MA, Glass PSA, Jacobs JR: Context-sensitive half-time in multicompartment pharmacokinetic models for intravenous anesthetic drugs. Anesthesiology 76:334, 1992.)

Alfentanil is the opioid that has, until more recently, been most frequently studied, described, and promoted in the context of ambulatory techniques. This is because alfentanil has a short elimination half-time, one-fifth that of sufentanil (111 versus 577 minutes). However, despite the longer elimination half-time of sufentanil, its context-sensitive half-time is actually less than that of alfentanil for infusions up to 8 hours in duration. This phenomenon is explained in part by the huge distribution volume of sufentanil. After termination of a sufentanil infusion, the decay in plasma drug concentrations is accelerated not only by elimination, but also by the continued redistribution of sufentanil into peripheral compartments. In contrast, the small distribution volume of alfentanil equilibrates rapidly; therefore, peripheral distribution of drug away from the plasma is not a significant contributor to the decay in plasma concentration after an infusion. The data derived from computer simulation by Hughes et al[4] show that the plasma decay of alfentanil is slower than that of sufentanil following infusions of similar duration to those used during conscious sedation. Thus, despite its short elimination half-time, alfentanil may not necessarily be superior to sufentanil for ambulatory sedation techniques.

How Does the Context-Sensitive Half-Time Relate to the Time to Recovery?

5 Although the context-sensitive half-time represents a significant advance in our ability to describe drug disposition, this parameter does not directly describe how long it will take the patient to recover from MAC. The context-sensitive half-time merely describes how long it will take for the plasma concentration of the drug to decrease by 50%. The time to recovery depends on other additional factors. The difference between the plasma concentration at the end of the infusion and the plasma concentration below which awakening can be expected is an obvious factor in determining time to recovery. For example, if the drug concentration is maintained at a level just above that required for awakening,

the time to recovery will be more rapid than after an infusion during which the drug concentration

is much greater than that required for awakening (Fig. 47-3). Furthermore, although context-sensitive half-time is a reflection of plasma drug decay, awakening from anesthesia is actually a function of effect–site (i.e., brain) concentration decay. Changes in effect–site concentration demonstrate a variable time lag behind changes in plasma drug concentration. Effect–site equilibration is a concept that is particularly relevant to intravenous sedation. When a drug is administered intravenously by bolus or infused rapidly, there is a delay before the onset of clinical effect. This delay occurs because the plasma is not usually the site of action but is merely the route by which the drug reaches its effect site. If some parameter of drug effect can be measured (e.g., power spectrum electroencephalographic [EEG] analysis in the case of opioids), the half-time of equilibration between drug concentration in the blood and the drug effect can then be determined.[5] This parameter is abbreviated $t_{1/2}k_{e0}$. Drugs with a short $t_{1/2}k_{e0}$ will equilibrate rapidly with the brain and have a shorter delay in onset than drugs that have a longer $t_{1/2}k_{e0}$. Thiopental, propofol, and alfentanil have short $t_{1/2}k_{e0}$ values compared with midazolam, sufentanil, and fentanyl. The $t_{1/2}k_{e0}$ allows predictions to be made of the time course of equilibration of the drug between the blood and the brain. A distinct time lag between the peak serum fentanyl concentration and the peak EEG slowing can be seen. In contrast, following alfentanil administration, the EEG changes closely parallel serum concentrations. The $t_{1/2}k_{e0}$ for fentanyl is 6.4 minutes compared with a $t_{1/2}k_{e0}$ of 1.1 minutes for alfentanil. If an opioid is required to blunt the response to a single brief stimulus, alfentanil might represent a logical choice over fentanyl. The $t_{1/2}k_{e0}$ is an important determinant of bolus spacing when titrating drugs to clinical effect. In the case of drugs such as midazolam, which have a relatively long equilibration time (midazolam $t_{1/2}k_{e0}$ = 0.97 to 5.6 minutes), boluses of drug should be spaced far enough apart to allow the full peak effect to be clinically appreciated before further drug administration to avoid inadvertent overdosing.[6,7] For example, even if the shortest quoted equilibration half-time for midazolam (0.9 minutes) is used, it will take 2.7 minutes for effect–site concentrations to be 87.5% equilibrated. Other factors are also important determinants of bolus size and spacing. For example, a low cardiac output will markedly delay drug arrival at the site of action. If sufficient time is not given for the drug to take effect before giving additional drug increments, significant cardiorespiratory compromise may occur. Furthermore, the effects of initial doses of most drugs in anesthetic practice are terminated by redistribution, which depends on blood flow to redistribution sites. If there is reduced blood flow to redistribution sites because of preexisting and iatrogenic decreases in cardiac output, the dangerous adverse effects of these drugs are likely to be not only delayed, but also markedly prolonged. An example of the previous scenario is the patient with a hemodynamic compromise caused by a tachydysrhythmia that requires sedation for cardioversion. Careful, well-spaced, small boluses of drug should be given to induce the appropriate level of sedation, bearing in mind that it may take several minutes for the full effect of a small bolus dose to become apparent.

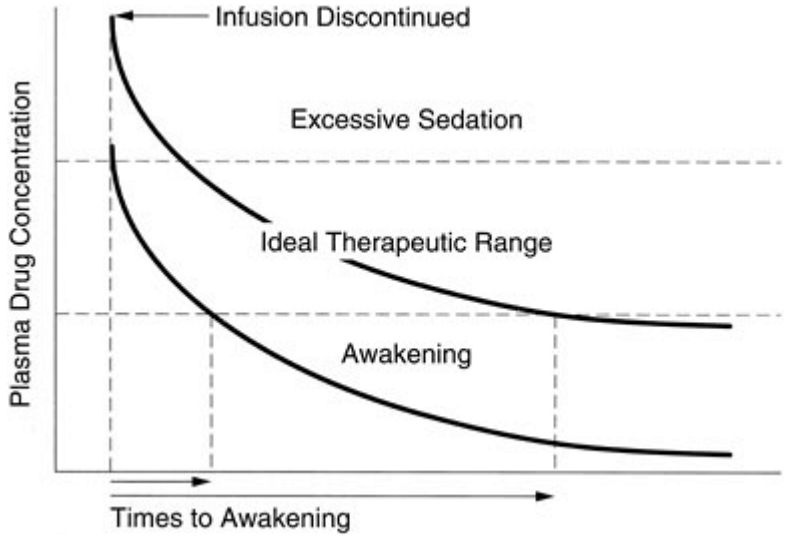

FIGURE 47-3. The context-sensitive half-time is not the sole determinant of the time it

takes for the patient to awaken. This parameter merely reflects the time taken for the plasma concentration of a drug to decrease by 50%. The time to awakening is determined in addition by the difference in concentration at the end of the procedure and the concentration below which awakening will occur.

DRUG INTERACTIONS IN MONITORED ANESTHESIA CARE

At the present time, no single inhaled or intravenous drug can provide all the components of MAC (i.e., analgesia, anxiolysis, hypnosis) with an acceptable margin of safety or ease of titratability. Therefore, patient comfort is usually maintained with a combination of drugs. By acting synergistically, combinations of drugs enable reductions in the dose requirements of individual drugs. For example, during general anesthesia, the combination of propofol and fentanyl by infusion has been shown to produce a more rapid recovery and better stress response abolition than the use of propofol alone.[8] However, synergistic interaction may also extend to the undesirable interactions of the drugs such as cardiorespiratory depression.

Drug interactions may have both a pharmacodynamic and a pharmacokinetic basis and may vary, depending on the combination of drugs being coadministered, the dose range over which these drugs are administered, and the specific clinical effect that is measured. For example, because fentanyl is primarily an analgesic rather than a hypnotic, it reduces propofol requirements for suppression of response to skin incision to a much greater degree than it reduces propofol requirements for induction of anesthesia.[9] In contrast, because midazolam has significant hypnotic properties, it displays significant synergism with propofol or thiopental when used to induce hypnosis.[10,11]

The plasma concentration of a drug at steady state that is required to abolish purposeful movement at skin incision in 50% of patients ($Cp_{ss}50$) is a measure of potency that is analogous to the familiar parameter of MAC of the volatile inhaled anesthetics. Intravenous anesthetic interactions may be evaluated by their effect on the $Cp_{ss}50$ in a manner analogous to the expression of the effects of opioids on volatile anesthetic requirements in terms of MAC reduction. For example, during general anesthesia, opioid requirements to suppress the responses to noxious stimuli are 10-fold higher when used as the sole agent compared to when they are used in conjunction with a nitrous oxide–potent inhaled vapor technique. This interaction persists at the lighter levels of anesthesia encountered during MAC. Therefore, in an ambulatory conscious sedation setting, it is likely that a rapid recovery would be facilitated by using opioids in combination with other agents (e.g., propofol/midazolam) rather than as the sole drug.

Drug interactions are dose dependent. For example, when fentanyl is combined with isoflurane, the greatest reduction in isoflurane MAC occurs within the analgesic concentration range of fentanyl (i.e., 1 to 2 ng/mL). At a fentanyl concentration of 1.7 ng/mL, the MAC of isoflurane is reduced by 50%.[12] Once the fentanyl concentration is increased beyond 3 ng/mL, there appears to be minimal further reduction with a maximum MAC reduction of 80%. Likewise, the MAC of desflurane is reduced by approximately 50% 25 minutes after a 3-μg/kg intravenous bolus of fentanyl.[13] However, when the fentanyl bolus is increased to 6 μg/kg, there is no significant further decrease in the MAC of desflurane. The interactions between propofol and opioids are important

because these agents are frequently used during MAC. When analgesic concentrations of fentanyl (0.6 ng/mL) are used in combination with propofol for anesthesia, the $Cp_{ss}50$ of propofol is reduced by 50% compared with when propofol is used as the sole agent.[11] However, when the dose of fentanyl is increased, there is no significant further reduction of the $Cp_{ss}50$ for propofol beyond a fentanyl concentration of 3 ng/mL.

Although the data presented previously pertain to patients under general anesthesia, these findings have important implications for monitored anesthesia care. These studies demonstrate

that the potentiating effects of opioids upon coadministered sedatives are pronounced within the dose range commonly used during MAC. Furthermore, the data suggest that the dose-response curve is likely to be steep within this dose range, thus supporting the clinical impression that significant increases in depth of sedation can occur with only modest increments in opioid or hypnotic/sedative dosage. The following clinical recommendations can be made: during MAC, the maximum benefit of opioid supplementation, in terms of potentiation of other administered sedatives, will accrue when the opioid is used in the analgesic dose range. Within this dose range, there is great potential for adverse cardiorespiratory interaction.

Opioid and benzodiazepine combinations are frequently used to achieve the components of hypnosis, amnesia, and analgesia. This drug combination displays marked synergism in producing hypnosis. Approximately 25% of the ED_{50} for each individual drug is required in combination to induce hypnosis in 50% of patients.[14] If the combination were simply additive, hypnosis would be induced in only approximately 25% of patients. Even subanalgesic doses of alfentanil (3 µg/kg) produce a profound reduction in midazolam requirements for hypnosis.[15] This synergism also extends to the unwanted effects of these drugs, producing the life-threatening complications of respiratory and cardiac depression.[16] Several fatalities have been reported after the use of midazolam, the majority of these being related to adverse respiratory events. In many of these cases, midazolam was used in combination with an opioid. The effects of midazolam and fentanyl upon respiratory function in healthy volunteers have been examined by Bailey et al.[17] Whereas midazolam produced no significant respiratory effects alone and fentanyl alone produced hypoxemia (oxyhemoglobin saturation 95%) in half of the subjects, the combination of midazolam 0.05 mg/kg and fentanyl 2.0 µg/kg resulted in hypoxemia in 11 of 12 subjects and apnea (no spontaneous respiratory effort for 15 seconds) in 6 of 12 subjects. The combination of midazolam and fentanyl places patients at high risk for developing hypoxemia and apnea. The respiratory depressant effects of this drug combination are likely to be even more significant in the patient with coexisting respiratory or central nervous system (CNS) disease or at the extremes of age. In clinical practice, the clinical advantages of the synergy between opioids and benzodiazepines for the maintenance of patient comfort should be carefully weighed against the disadvantages of the potentially adverse effect of this drug combination on the cardiovascular and respiratory systems.

SPECIFIC DRUGS USED FOR MONITORED ANESTHESIA CARE

Propofol

Propofol has many of the ideal properties of a sedative-hypnotic for use in MAC. Its pharmacokinetic profile (i.e., a context-sensitive half-time that remains short even after infusions of prolonged duration and a short effect–site equilibration time) makes it an easily titratable drug with an excellent recovery profile. The quality of recovery and the low incidence of nausea and vomiting make propofol particularly well suited to ambulatory MAC procedures. A significant body of experience with the use of propofol for MAC has emerged. Propofol has significant advantages compared with benzodiazepines when used as the hypnotic component of a MAC technique. Although midazolam has a relatively short elimination half-time, its context-sensitive half-time is approximately twice that of propofol. Whereas propofol is noted for the rapid return to clear-headedness, midazolam is often associated with prolonged postoperative sedation and psychomotor impairment, particularly in the elderly. Propofol in typical MAC doses (25 to 75 µg/kg/min) has minimal analgesic properties. However, the unique advantages of propofol can be exploited to the maximum when propofol is used to provide sedation when the analgesic component is provided by a local or regional analgesic technique. The use of propofol (50 to 70 µg/kg/min) to provide sedation (defined as sleep with preservation of the eyelash reflex and purposeful reaction to verbal or mild physical stimulation) as an adjunct to spinal anesthesia for lower limb surgery has been examined.[18] After termination of infusions of approximately 100 minutes in duration, patients regained consciousness in approximately 4 minutes. The authors also noted the ease with which general anesthesia could be induced if necessary by increasing the propofol infusion. The same group also compared propofol (60.5 µg/kg/min) to midazolam (4.3 µg/kg/min) as an adjunct to spinal anesthesia. The propofol group had faster immediate recovery than the midazolam group (2.3 versus 9.2 minutes to spontaneous eye opening). Furthermore,

psychomotor function was comparable to baseline values following propofol sedation but did not return to baseline until 2 hours after midazolam administration. White and Negus also compared propofol and midazolam sedation for local and regional anesthesia.[19] These investigators examined several recovery parameters and demonstrated that propofol produced less postoperative sedation, drowsiness, confusion, and clumsiness than midazolam, but that discharge times were similar. It should be noted that most investigators have shown that propofol does not reliably produce amnesia in subhypnotic doses.[20] Although recall of intraoperative events is generally believed to be undesirable, the lack of amnestic properties in propofol may be preferable when patients are required to remember important instructions they are given in the postoperative period.

The use of propofol for sedation has been examined in several diverse clinical settings, including propofol alone for upper gastrointestinal endoscopy[21] and magnetic resonance imaging in children,[22] with fentanyl for extracorporeal shock wave lithotripsy,[23] with alfentanil for transvaginal oocyte retrieval, and for sedation during the dental care to persons with mental and physical disabilities.[24,25]

There is a general clinical impression that patients recovering from propofol not only recover rapidly, but also often experience an increased sense of well-being. However, a study specifically addressing the issue of the subjective effects of low-dose propofol in volunteers could find no evidence for a euphoric effect of propofol.[26] The authors postulate that the sense of well-being arises from the feeling of relief that the procedure is over. This feeling of relief may be inhibited by the prolonged psychomotor impairment that often follows other anesthetic techniques.

General anesthesia with propofol is generally associated with less nausea and vomiting than most other anesthetic techniques. There is now evidence that even subhypnotic doses of propofol (a single 10-mg dose in an adult) also possess direct antiemetic properties.[27] Thus, it is likely that the beneficial effects of propofol on nausea and vomiting will be a feature of MAC techniques using this drug. In contrast, even during

low-dose infusions used for sedation, pain during injection of propofol may be troublesome in 33 to 50% of patients.[28,29] Several strategies for reducing the pain of propofol administration are described in Table 47-1.[30]

TABLE 47-1 Published Strategies for Reducing Pain on IV Injection of Propofol

Using larger veins in antecubital fossa
Decreasing the speed of injection
Injection into a fast-running IV
Diluting with 5% glucose or 10% intralipid
Adding lidocaine to propofol
Pretreating with lidocaine and venous occlusion
Pretreatment with opioid
Pretreatment with pentothal
Cooling to 4°C prior to injection
Injecting cooled saline (4°C) prior to injection
Discontinuing IV fluid administration during injection

IV, intravenous(ly).

Benzodiazepines

Benzodiazepines are commonly used during MAC for their anxiolytic, amnestic, and hypnotic

properties. Midazolam has now displaced diazepam as the most commonly used benzodiazepine for conscious sedation. The important differences between midazolam and diazepam are listed in Table 47-2.[31] Although midazolam has a short elimination half-time, there is often significant and prolonged psychomotor impairment following sedation techniques using midazolam as a significant component. With the more recent availability of propofol, midazolam may be better used in a modified role by using lower doses prior to the start of a propofol infusion to provide the specific amnestic and perhaps anxiolytic component of a "balanced" sedation technique, rather than as the major hypnotic component.[32] This allows the more evanescent and titratable propofol to provide the desired level of conscious sedation in an adjustable manner, according to the specific stimulus. The analgesic component, if required, of a balanced MAC technique could be provided by regional and local techniques or opioids. Again, when using opioids with benzodiazepines, the potential for significant respiratory impairment should be considered.

TABLE 47-2 Comparison of Important Properties of Midazolam and Diazepam

·MIDAZOLAM	·DIAZEPAM
Water soluble, does not require propylene glycol for solubilizing	Lipid soluble, requires propylene glycol for solubilizing
Nonvenoirritant, usually painless	Venoirritant, pain on injection
Thrombophlebitis rare	Thrombophlebitis common
Short elimination half-time (1–4 hr)	Long elimination half-time (>20 hr)
Clearance unaffected by H_2 antagonists	Clearance reduced by H_2 antagonists
Inactive metabolites (1-hydroxy-midazolam)	Active metabolites (desmethyl-diazepam, oxazepam)
Resedation unlikely	Resedation more likely

Clinical experience suggests that the dose of a particular benzodiazepine required to reach a desired clinical end point is reduced in the elderly compared with younger patients. This difference in dosing requirements in the elderly is due mainly to pharmacodynamic factors. This is demonstrated by the threefold decrease in plasma concentration of midazolam, at which 50% of patients would be expected not to respond to verbal command (Cp50) at 80 years of age compared with 40 years of age (Fig. 47-4).[33]

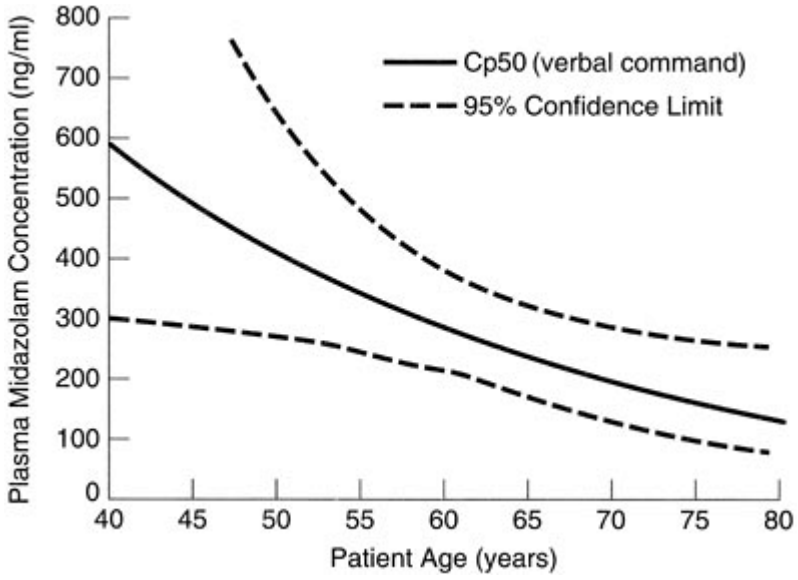

FIGURE 47-4. Midazolam Cp50 (the concentration at which 50% of subjects will fail to respond to a verbal command) as a function of age. There is a marked decrease in midazolam requirements as patient age increases. (Reprinted with permission from Jacobs JR, Reves JG, Marty J *et al*: Aging increases pharmacodynamic sensitivity to the hypnotic effects of midazolam. Anesth Analg 80:143,1995.)

Benzodiazepines are valuable components of MAC techniques because they enhance patient comfort, improve operating conditions, and provide amnesia. However, recovery of psychomotor and cognitive function may be significantly prolonged following benzodiazepine sedation, especially when compared with sedative–hypnotic techniques using propofol as the major component.[34] The specific benzodiazepine antagonist flumazenil provides the potential to improve the recovery profile of benzodiazepines by permitting the active termination of their sedative and amnestic effects without invoking adverse side effects. However, the potential for resedation remains an obstacle to the routine use of benzodiazepine reversal, particularly in patients undergoing ambulatory procedures. The effects of midazolam may recur up to 90 minutes following the administration of flumazenil.[35] Thus, it is possible that patients could be discharged prematurely to a less well-monitored area, or even out of the hospital in the case of ambulatory surgery, and later experience recurrence of benzodiazepine effects. An important additional issue is that of cost. The routine use of flumazenil-antagonized benzodiazepine sedation has a significant cost disadvantage. Ghouri et al.[35] demonstrated that flumazenil-antagonized midazolam sedation was more expensive than propofol sedation ($68.67 versus $27.80). Typical dose requirements are listed in Table 47-3.

TABLE 47-3 Recommended Regimen for Use of Flumazenil to Antagonize Benzodiazepine Effects

Initial recommended dose of 0.2 mg If desired level of consciousness is not achieved in 45 sec, repeat 0.2-mg dose Doses of 0.2 mg may need to be repeated every 60 sec until a maximum of 1 mg is administered Be aware of the potential for resedation

Opioids

Opioids are most logically used in the context of MAC to provide the specific analgesic component of a "balanced" technique rather than to provide the sedative component. Opioid

analgesics are indicated when regional or local anesthetic techniques are inappropriate or ineffective. Opioids may also play an important role during the initial injection of local anesthetic solution or during other periods of intense patient discomfort. Pain relief may be required for factors other than the procedure itself, such as uncomfortable positioning, propofol injection, pneumatic tourniquet pain, or other pain not relieved by the local anesthetic technique.

A typical circumstance in which the patient must briefly cooperate and remain motionless is during the placement of a retrobulbar block prior to ophthalmic procedures. Patient movement during block placement may increase the incidence of complications such as brainstem anesthesia and cardiac arrest. Retrobulbar block placement affords an excellent opportunity to study the effects of drugs on the response to a standardized, ethically acceptable, brief painful stimulus. The ideal drug for block placement would provide a brief period of intense analgesia, yet allow the patient to be awake and cooperative without causing cardiorespiratory depression, cause minimal nausea and vomiting, and not significantly prolong recovery.[36] Alfentanil (20 μg/kg) has a rapid onset and offset of intense analgesia, and was compared with methohexital (0.5 mg/kg) for retrobulbar block placement.[36] Patients receiving methohexital were unresponsive to verbal command at the time of block placement and demonstrated more movement on injection than those receiving alfentanil, who were mostly (87%) awake and cooperative at the time of injection. The authors noted that 1 of the 15 elderly patients who received alfentanil became apneic for 30 seconds, and suggested that the dose of opioids be reduced in the elderly. They also noted that the personnel performing the block were accustomed to the patient being "asleep" during methohexital sedation, but took some time to become at ease with the awake yet comfortable and cooperative patient who had received alfentanil.

The well-described phenomenon of patient awareness and subsequent recall of intraoperative events following high-dose opioid anesthesia is taken as evidence that opioids lack significant amnestic properties. However, when the effects of low-dose fentanyl on memory were specifically examined in volunteers, it was found that although the subjects appeared to be awake during the fentanyl infusion, there was significant memory impairment.[37] The degree of stimulation was probably less than that experienced by a patient undergoing a painful surgical procedure. Recall for a painful stimulus may not be impaired to the same degree as recall for the less noxious stimuli that the subjects of this study experienced.

Alfentanil appears to have a pharmacokinetic advantage for the treatment of discrete stimuli because of its short effect–site equilibration time, which allows rapid access of the drug to the brain and facilitates titration. However, sufentanil may have a more favorable recovery profile when used over a longer period of time because of its shorter context-sensitive half-time. In clinical practice, however, there is a marked interpatient variability in opioid pharmacokinetics and dynamics. This interpatient variability may be more significant than the interdrug differences, making it difficult to predict with any precision the effects of a given drug dose in an individual patient.

Remifentanil

In the context of monitored anesthesia care, the analgesic properties of opioids are extremely valuable. However, their adverse effects, including respiratory depression, muscle rigidity, and emesis, are undesirable in the spontaneously breathing patient with an

unprotected airway and significantly limit the ability to consistently provide effective analgesic doses. A further complicating issue is that the ability to predict the effect of a given dose of opioid in a particular patient is limited by significant interpatient pharmacokinetic and pharmacodynamic variability. This problem is usually overcome in practice by the cautious incremental administration of small, carefully spaced boluses or by titrating infusions to the desired effect.

Remifentanil has pharmacodynamic properties similar to those of other potent μ-opioid receptor agonists such as fentanyl and alfentanil. However, remifentanil is predominantly metabolized by nonspecific esterases generating an extremely rapid clearance and offset of effect.[38] The context-sensitive half-time of remifentanil is consistently short, 3 to 5 minutes, increasing to a minimal degree with the duration of the infusion. Furthermore, remifentanil has a short effect–site equilibration time ($t_{1/2}k_{e0}$) of 1.0 to 1.5 minutes. This $t_{1/2}k_{e0}$ is slightly longer than that of alfentanil (0.6 to 1.2 minutes), but much shorter than that of fentanyl (4 to 5 minutes) and morphine (~20 minutes), and makes the onset of effect after drug administration rapid, thus facilitating titration of effect during MAC.

In clinical practice, remifentanil has been used successfully as the analgesic component of sedation techniques for regional and local anesthesia. Its unique pharmacokinetic profile makes it well suited for ambulatory MAC techniques. Published experience with the use of remifentanil suggests that it is possible to titrate remifentanil administration to provide effective analgesia with minimal respiratory depression. The published data can be used to generate some practical clinical guidelines,[39] which are discussed as follows:

1. As with other potent opioids used during sedation techniques, the most logical therapeutic end point for remifentanil administration is effective analgesia and patient comfort rather than sedation. When opioids are titrated to preconceived levels of sedation rather than patient comfort, an unacceptable degree of respiratory depression may occur. Drugs such as propofol or midazolam can be used in combination with remifentanil to provide the hypnotic-amnestic component of the sedation technique, remembering that the concomitant administration of midazolam decreases remifentanil dose requirements by up to 50%.[40]
2. Published data suggest that bolus administration of remifentanil is associated with an increased incidence of respiratory depression and chest wall rigidity. Because these side effects are likely to be related to high peak concentrations of drugs, it is recommended that remifentanil boluses be administered slowly (over 30 to 90 seconds) or avoided completely by using a pure infusion technique. Furthermore, the administration of remifentanil boluses during the concomitant administration of remifentanil infusions is also associated with an increased incidence of respiratory depression, the most likely mechanism again being excessive peak drug concentrations. These episodes of respiratory depression are of significant concern, particularly in the spontaneously breathing patient with an unprotected airway. However, if promptly recognized, and the remifentanil administration is reduced or discontinued, they should resolve within approximately 3 minutes. Thus, despite the

pharmacokinetic advantages of remifentanil, the level of vigilance required for its administration should be no different from that for any other potent opioid. Although the offset time of remifentanil is rapid, it still requires the recognition of respiratory depression to trigger a downward adjustment in dosage. Similarly, the short $t_{1/2}k_{e0}$ of remifentanil suggests that sudden respiratory depression may occur in response to upward adjustments in dosage. Despite the potential for respiratory depression, the efficacy of remifentanil boluses during MAC has been investigated by several groups. The most logical scenario in which a bolus dose could be used is immediately prior to a brief but painful stimulus, such as placement of a retrobulbar block.[41] A bolus of 1 μg/kg over 30 seconds was administered 90 seconds prior to block placement. More than three-fourths of patients receiving remifentanil did not report any pain during subsequent block placement. However, 15% of the patients given a single bolus alone had significant respiratory depression (respiratory rates <8 breaths per minute), and 19% of those given a bolus followed by an infusion had significant respiratory depression.

3. The effects of coadministration of benzodiazepines and opioids are well documented. The addition of midazolam to provide the anxiolytic-sedative and amnestic components of a sedation technique has been shown to increase patient satisfaction and significantly reduce remifentanil dose requirements. The combination of remifentanil with midazolam significantly reduces patient anxiety when compared with the use of the opioid alone.[42] Even relatively low-dose midazolam (2 mg intravenously) produces significant reductions in remifentanil requirements and patient anxiety. During breast or lymph node biopsy, remifentanil infusion requirements were 0.065 μg/kg/min when preceded by midazolam compared with 0.123 μg/kg/min when used alone. The advantages of coadministration of small doses of midazolam include increased patient satisfaction, increased amnesia, decreased nausea and vomiting, and decreased anxiety. The disadvantages include a tendency toward increased respiratory depression, apnea, and excessive sedation.
4. Because most painful stimuli are of unpredictable duration and because the risk of adverse respiratory events is increased following bolus administration, the most logical method for the administration of remifentanil during MAC is by an adjustable infusion. This should ideally be preceded by a small bolus of midazolam. Most investigators have used infusion rates that start at 0.1 μg/kg/min approximately 5 minutes prior to the first painful stimulus. This initial "loading" infusion is then weaned to approximately 0.05 μg/kg/min to maintain patient comfort. The maintenance infusion is adjusted upward in response to pain or hemodynamic response or downward in response to excessive sedation, respiratory depression, or apnea. A typical incremental change in infusion rate is 0.025 μg/kg/min. The use of remifentanil infusions of 0.2 μg/kg/min is associated with an increased incidence of respiratory depression that is not necessarily associated with superior analgesia. As in the case of propofol administration, inadvertent interruption of remifentanil administration will result in abrupt offset of effect, which may result in patient discomfort, hemodynamic instability, and even morbidity due to patient movement. It is therefore important to ensure the drug delivery system is monitored carefully during the procedure. Remifentanil is supplied as a powder that must be reconstituted prior to use. It is particularly important when administering this drug to patients with an unsecured airway to ensure there are no errors in drug dilution that would result in inadvertent dosing errors.

Typical adult dose recommendations for opioids and other drugs discussed in the text are listed in Table 47-4.

TABLE 47-4 TYPICAL DOSE RANGES OF SEDATIVE, HYPNOTIC, AND ANALGESIC DRUGS

·DRUG	·TYPICAL ADULT IV DOSE RANGE (TITRATED TO EFFECT IN SMALL INCREMENTS)

·BENZODIAZEPINES	
Midazolam	1–2 mg prior to propofol or remifentanil infusion
Diazepam	2.5–10 mg (in 0.5–2 mg increments)
·OPIOID ANALGESICS	
Alfentanil	5–20-μg/kg bolus 2 min prior to stimulus
Fentanyl	0.5–2.0-μg/kg bolus 2–4 min prior to stimulus
Remifentanil	Infusion 0.1 μg/kg/min 5 min prior to stimulus
	Wean to 0.05 μg/kg/min as tolerated
	Adjust up or down in increments of 0.025 μg/kg/min
	Reduce dose accordingly when coadministered with midazolam or propofol
	Avoid boluses
·HYPNOTICS	
Propofol	250–500-μg/kg boluses
	25–75 μg/kg/min infusion
IV, intravenous(ly).	

Ketamine

Ketamine is a phencyclidine derivative, is an intense analgesic, and is frequently used as a component of pediatric sedation techniques.[43,44] When used in small doses (0.25 to 0.5 mg/kg), its use is associated with minimal respiratory and cardiovascular depression. Ketamine produces a dissociative state in which the eyes remain open with a nystagmic gaze. However, as the dose of ketamine increases, or when used in combination with other sedatives, a state of deep sedation and/or general anesthesia may be inadvertently achieved. Increased oral secretions make laryngospasm more likely. The fear of laryngospasm is the underlying rationale for the frequent administration of atropine or glycopyrrolate. Ketamine is frequently combined with a benzodiazepine to reduce the incidence of hallucinations associated with its use. However, this practice is controversial.[45] Patient movement may make ketamine less than ideal for procedures

pressure and is thus relatively contraindicated in patients with increased intracranial pressure and with glaucoma or open globe injuries. Although it has been suggested that airway reflexes are relatively preserved with ketamine, there is no convincing evidence to support this notion.

Ketamine can be administered orally, intramuscularly, or intravenously. The oral dose of ketamine is 4 to 6 mg/kg. The onset of action typically occurs within 20 to 30 minutes, and the duration of effect is between 60 to 90 minutes. The intramuscular dose is 2 to 4 mg/kg, with an onset of action of 5 to 10 minutes and a duration of action of 30 to 120 minutes. When administered via the intravenous route, ketamine should be given in small (0.25 to 1.0 mg/kg) increments, titrating to effect with an onset of action of 1 to 2 minutes and an approximate duration of 20 to 60 minutes.

Dexmedetomidine

Dexmedetomidine, like clonidine, is a selective alpha-2 receptor agonist. Stimulation of alpha-2 receptors produces sedation and analgesia, a reduction of sympathetic outflow, and an increase in cardiac vagal activity. The use of clonidine in the perioperative period is limited by its long half-life of 6 to 10 hours. However, dexmedetomidine has a much shorter half-life and greater alpha-2 receptor selectivity, thus limiting its peripheral vascular effects. Despite its alpha-2 selectivity, dexmedetomidine may still cause significant bradycardia and hypotension.[46] Dexmedetomidine does not depress respiratory function to the same extent as other classes of sedatives. Furthermore, patients sedated with dexmedetomidine are more easily aroused from a given level of sedation.

Dexmedetomidine has been used as sedative supplementation to regional anesthesia during carotid endarterectomy. Under these circumstances, there were fewer fluctuations from the desired sedation level when compared with the combination of midazolam, fentanyl, and propofol.[47] Dexmedetomidine has also been used successfully in both adult and pediatric patients for MAC during the awake portions of craniotomies requiring patient cooperation during mapping of cortical speech areas.[48,49] When compared with propofol, as a supplement to regional anesthesia, the target sedation level took longer to achieve with dexmedetomidine (25 versus 10 minutes).[50] However, the use of dexmedetomidine resulted in greater sedation, lower blood pressure, and improved analgesia in the recovery room when compared with propofol. Time to PACU discharge was not different between the groups.

Dexmedetomidine is most often delivered as an initial bolus followed by a continuous infusion. Initial bolus doses range from 0.5 to 1.0 µg/kg over 10 to 20 minutes, followed by a continuous infusion of 0.2 to 0.7 µg/kg per hour.

Patient-Controlled Sedation and Analgesia

Techniques that allow the direct patient control of the level of sedation may positively affect patient satisfaction.[51] The degree of sedation desired by the patient varies significantly, and the individual response to drugs is variable. Patient-controlled sedation (PCS) appears to be an attractive solution to this problem. One approach to PCS has been to use a conventional patient-controlled analgesia (PCA) delivery system set to deliver 0.7-mg/kg boluses of propofol with a 3-minute lockout period.[52] Other approaches include fixed-dose combinations of 0.5 mg midazolam and 25 µg fentanyl with a 5-minute lockout interval between doses.[53] This technique was as safe and effective as anesthesiologist-controlled drug delivery, but may be associated with greater postprocedure sedation.[54] The pharmacokinetic profile of alfentanil is ideal for the treatment of short, discrete episodes of pain. These properties have been exploited during vaginal ovum retrieval procedures, when ultrasonically guided needles are passed through the vaginal wall under monitored anesthesia care. Zelcer et al used a PCA delivery system to allow self-administration of alfentanil during this procedure.[55] After midazolam premedication and a loading dose of alfentanil, patients received 5-µg/kg boluses of alfentanil via the PCA pump with a mandatory 3-minute lockout period. Patient acceptability, alfentanil dosage, respiratory variables,

and pain scores were similar to those obtained with physician-controlled analgesia. From the limited data that are available, intraoperative PCA during monitored anesthesia care appears to be an effective alternative to physician-administered analgesia.

RESPIRATORY FUNCTION AND SEDATIVE-HYPNOTICS

During monitored anesthesia care, there is significant potential for respiratory compromise mediated via several important mechanisms. These include adverse effects on respiratory drive, either directly as a result of sedative-hypnotic or opioid administration or indirectly as a consequence of brainstem hypoperfusion resulting from hypotension, such as that occurring during spinal or epidural anesthesia. There may also be a marked increase in the work of breathing due to increased resistance to gas flow in the upper airway.[56] During sedation, it is likely that protective airway reflexes will be attenuated. In contrast, sedative doses of benzodiazepines appear to have variable effects on respiratory system mechanics, either decreasing, increasing, or having no effect on functional residual capacity.[57,58,59]

Sedation and Upper Airway Patency

The upper airway is located outside the thorax. During normal inspiration, the pressure within the upper airway is subatmospheric; thus, there is a tendency for the upper airway to collapse under the influence of the surrounding atmospheric pressure. However, in the normal subject this tendency for airway collapse is opposed by upper airway dilator muscle tone. These muscles probably both increase the diameter and reduce the compliance of the upper airway. An increase in upper airway dilator muscle tone occurs during inspiration, commencing just prior to diaphragmatic contraction.[60] Several studies have confirmed the importance of coordinated activation of the diaphragmatic and upper airway respiratory muscles in maintaining airway patency. Upper airway dilator muscle control appears to be extremely sensitive to sedative-hypnotic drug administration.[61] For example, sedative doses of midazolam have been reported to increase inspiratory subglottic airway resistance three- to fourfold.[62] Sedative doses of diazepam selectively suppress genioglossal muscle activity to a greater degree than diaphragmatic activity; furthermore, this effect is exaggerated in the elderly.[63] In all these examples, the increased upper airway resistance markedly increased the work of breathing. The response to this obstruction is a significant increase in intercostal and accessory muscle activity. However, this response is only partially effective because the increase in inspiratory force will further decrease intraluminal upper airway pressure, predisposing to further airway collapse. It is likely that these effects will be of greatest significance in patients with preexisting respiratory compromise, such as the elderly or those with chronic obstructive pulmonary disease. These patients often

have limited respiratory reserve and are unable to increase their respiratory muscle activity in response to the increased work of breathing induced by sedation and may become hypercarbic, acidotic, and hypoxic.

Sedation and Protective Airway Reflexes

Competent laryngeal and upper airway reflexes are required to protect the lower airway from aspiration. It is well documented that protective laryngeal and pharyngeal reflexes are depressed by anesthesia and sedation. Furthermore, it is also well documented that protective airway reflexes are compromised by advanced age and debilitation. Therefore, it is likely that significant depression of airway reflexes could occur during sedation in the patient who is elderly or debilitated. Aspiration of gastric contents could occur either in the operating room or during recovery, particularly if oral intake is allowed before the return of adequate upper airway protective reflexes. The time required for the return of protective reflexes varies considerably. Complete recovery of the swallowing reflex occurs approximately 15 minutes after the return of consciousness following propofol anesthesia.[64] However, the intravenous administration of 15 mg of diazepam has been shown to depress the swallowing reflex for up to 4 hours.[65] The swallowing reflex is significantly depressed for up to 2 hours following the administration of midazolam, despite the return to a normal state of consciousness.[66] In otherwise healthy adult male

volunteers, the inhalation of 50% nitrous oxide was associated with marked depression of the swallowing reflex.[67]

It is apparent from the sources quoted previously that the protective airway reflexes alone cannot be relied on to protect the lower airway from aspiration during sedation. Thus, patients who are deemed to be at risk from aspiration of gastric contents should be maintained at the lightest level of sedation possible. Ideally, the patient should be awake enough to recognize the regurgitation of gastric contents and be able to protect his or her own airway. If the ability of the patient to protect his or her own airway cannot be reliably guaranteed and regurgitation/aspiration is believed to be a significant risk, placement of a cuffed endotracheal tube under general or local anesthesia should be seriously considered.

Sedation and Respiratory Control

Clinical experience would lead most anesthesiologists to predict that the administration of sedative-hypnotic drugs is associated with the depression of respiratory drive. However, the findings of scientific studies in this area are often conflicting and confusing, on occasion finding minimal, if any, effects of sedative drugs on ventilatory responsiveness. However, it is important to note that in many cases the methods used to measure respiratory drive may affect the outcome of the study by stimulating the subject, thus attenuating the negative effect of the drug on respiratory drive. In clinical practice, it is likely that during regional anesthesia there is a degree of deafferentation that will potentiate the respiratory depressant effects of sedative-hypnotic drugs.[68] Most studies have demonstrated that opioids depress the ventilatory response to hypercapnia and hypoxia.[69] Reports of the effects of sedative doses of benzodiazepines on carbon dioxide responsiveness have shown variable results, including no significant effect[70] and clinically significant depression.[71] However, when opioids and benzodiazepines are used in combination, there appears to a consistent and marked negative effect on respiratory responsiveness.[17] Initial clinical investigation examining the combination of propofol and opioids has shown little potentiation of the adverse effects of opioids by sedative doses of propofol.[24]

SUPPLEMENTAL OXYGEN ADMINISTRATION

Hypoxia as a result of alveolar hypoventilation is a relatively common occurrence following the administration of sedatives, analgesics, and hypnotics. In the absence of significant lung disease, the administration of only modest concentrations of supplemental oxygen is frequently effective in restoring the patient's oxygen saturation to an acceptable level. This concept is well illustrated by reference to the familiar alveolar gas equation. An extreme example illustrates the point: an otherwise healthy adult male breathing room air receives a dose of an opioid that causes marked alveolar hypoventilation such that his alveolar PCO_2 is increased to 80 mm Hg. The alveolar gas equation predicts that his arterial PO_2 will fall to approximately 40 mm Hg as shown:

$PAO_2 = PIO_2 - PACO_2/R$

$PIO_2 = FIO_2 \times (P_B - PH_2O)$

$PIO_2 = 0.21 \times (760 - 47) = 150$ mm Hg

$PAO_2 = 150 - 80/0.8$

$PAO_2 = 50$ mm Hg

Assuming a normal A–a gradient, his PaO_2 will be 40 mm Hg, corresponding to an arterial oxygen saturation of 75%. If while initiating definitive therapy for hypoventilation this patient were to receive only a modest increase in inspired oxygen, a marked improvement in arterial saturation would be achieved:

FIO_2 increased to 28%

$PIO_2 = 0.28 \times (760 - 47) - 200$ mm Hg

$PAO_2 = 200 - 80/0.8$

PAO_2 = 100 mm Hg

This theoretical example serves to highlight several points. First, in isolated hypoventilation, modest increases in inspired oxygen are remarkably effective at restoring oxygen saturation to acceptable levels. However, a patient who is receiving minimal supplemental oxygen and has acceptable oxygen saturation may have significant undetected alveolar hypoventilation. Therefore, before making the decision to discharge patients to a less well-monitored environment without supplemental oxygen, it is useful to measure their oxygen saturation while breathing room air.

MONITORING DURING MONITORED ANESTHESIA CARE

American Society of Anesthesiologists Standards

The ASA standards for basic anesthetic monitoring are applicable to all levels of anesthesia care, including monitored anesthesia care. It is useful to review the components of the ASA standards that are pertinent to MAC as approved by the house of delegates on October 21, 1986, and subsequently amended on October 21, 1998.[72] (See Chapter 2, Table 2-1, for the current ASA standards.)

Communication and Observation

A conscientious and well-trained anesthesia caregiver is the single most vital monitor in the operating room. However, his or

her effectiveness will be markedly enhanced by the use of the basic quantitative and qualitative monitoring devices, which should be readily available in all operating rooms. It is important that the anesthesiologist continually evaluate the patient's response to verbal stimulation to effectively titrate the level of sedation and to allow the earlier detection of neurologic or cardiorespiratory dysfunction. Continuous visual, tactile, and auditory assessment of physiologic function should include observation of the rate, depth, and pattern of respiration; palpation of the arterial pulse; and assessment of peripheral perfusion by extremity temperature and capillary refill. In addition, the patient should be continually observed for diaphoresis, pallor, shivering, cyanosis, and acute changes in neurologic status.

Auscultation

Auscultation of heart and breath sounds has long been a vital component of monitoring during anesthesia. Placement of a precordial stethoscope near the sternal notch of a nonintubated patient provides important information concerning upper airway patency, as well as a continuous monitor of heart sounds and ventilation. Continuous precordial auscultation is an inexpensive, effective, and essentially risk-free process that serves an additional important purpose by bringing the anesthesia care provider closer to the patient. If access to the patient is limited during the procedure, FM wireless or infrared remote transmission systems are now commercially available.

Pulse Oximetry

No monitor of oxygen transport has had a greater impact on the practice of anesthesiology than the pulse oximeter.[73] Pulse oximetry is noninvasive, safe, and comfortable to the awake patient; it is also technically simple to apply and interpret, and allows continuous real-time monitoring of arterial oxygenation. The use of a quantitative measure of oxygenation is specifically mandated by the ASA standards for intraoperative monitoring. The important mechanisms whereby respiratory function may be compromised during monitored anesthesia care include the effects of sedatives and opioids on respiratory drive, upper airway patency, and protective airway reflexes. Additional important risk factors for arterial desaturation include obesity, preexisting upper airway obstruction and respiratory disease, the extremes of age, and the lithotomy position.[74] The fundamental importance of monitoring oxygenation during monitored anesthesia care can be appreciated from the closed-claim study of Caplan et al,[68] who examined 14 cases of sudden cardiac arrest in otherwise healthy patients who received spinal anesthesia. These major

anesthetic mishaps occurred before the routine adoption of pulse oximetry. One of the major findings of this study was that cyanosis frequently heralded the onset of cardiac arrest, suggesting that unappreciated respiratory insufficiency may have played an important role. Further support for the use of pulse oximetry comes from the ASA Committee on Professional Liability analysis of closed anesthesia claims, which reveals that respiratory events constitute the single largest source of adverse outcome. Furthermore, review of these cases suggests that pulse oximetry in combination with capnometry would have prevented the adverse outcome in the vast majority of cases.

Capnography

Although capnography is most effective in the intubated patient, some useful information may be obtained from a spontaneously breathing, nonintubated patient. Sidestream capnographs have been adapted for use with facemasks, nasal airways, and nasal cannulae, and have been used successfully during monitored anesthesia care.[75,76,77,78] Nasal cannulae for oxygen delivery have been modified to provide an integral port for respiratory gas sampling and are available commercially. Alternatively, capnograph sampling lines can be attached to shortened intravenous catheters and inserted inside nasal oxygen probes.

Cardiovascular System

At a minimum, the electrocardiogram (ECG) must be continually displayed, and the blood pressure measured and recorded at least every 5 minutes during monitored anesthesia care. The pulse should be monitored by palpation, oximetry, or auscultation. The selection of additional hemodynamic monitoring is usually determined more by the cardiovascular status of the patient than the magnitude of the procedure. Most procedures performed under monitored anesthesia care do not involve major hemorrhage, fluid shifts, or major physiologic trespass. Decisions concerning choice of monitoring for myocardial ischemia and other adverse hemodynamic events will need to be individualized on a case-by-case basis.

Temperature Monitoring and Management During Monitored Anesthesia Care

The value of temperature monitoring is well established during general anesthesia, the perioperative period being frequently complicated by hypothermia and hyperthermia. Although sedation techniques used during monitored anesthesia care do not generally trigger malignant hyperthermia, there is potential for significant inadvertent hypothermia, particularly during neuraxial anesthesia. Even MAC techniques unaccompanied by regional anesthesia are associated with hypothermia at the extremes of age, both the old and very young having impaired thermoregulatory mechanisms. The elderly also have markedly reduced muscle mass and therefore reduced basal heat production. Although the anesthesiologist may be able to exert some control over the ambient temperature in the operating room, he or she may be unable to influence the temperature at remote anesthetizing locations. Radiology suites are often maintained at lower temperatures to accommodate the computer systems that are used to reconstruct images. Radiant heating lamps, forced-air heaters, fluid warmers, or warming blankets, all common items in operating rooms, may be unavailable and unsuitable for use at remote locations. Forced-air heating has been shown to be an effective means of maintaining normothermia and can be combined with intravenous fluid warming.[79] Even mild perioperative hypothermia (i.e., 1 to 2°C) accompanying general anesthesia is associated with adverse myocardial outcomes, increased bleeding tendency and transfusion requirements, wound infections, and delayed wound healing and hospital discharge.[80] There is no evidence suggesting that the morbidity associated with perioperative hypothermia is any less during MAC than during general anesthesia. The morbidity associated with perioperative hypothermia is well described in high-risk patients; this is a group of patients that are likely to undergo procedures under monitored anesthesia care. When hypothermia is significant, shivering may interfere with the planned procedure, markedly increase oxygen requirements, and predispose susceptible patients to myocardial ischemia or respiratory insufficiency. The major thermoregulatory defenses against hypothermia include vasoconstriction,

shivering, and behavior. Vasoconstriction and shivering are impaired during major conduction anesthesia. Behavioral thermoregulation is impaired even in the conscious patient. Regional anesthesia

has major effects on thermoregulation.[81] Lower-extremity vasodilatation causes central cooling via a redistribution of heat from the core to the periphery. Afferent input to the hypothalamus from the warm peripheral compartment counteracts conflicting input from the cooling central compartment, thus delaying the initiation of compensatory thermoregulation. In the absence of reliable temperature monitoring, it is possible that the first indication of hypothermia would be the onset of shivering, by which time considerable central cooling may have occurred.

Frank and coworkers examined the issue of temperature monitoring and management during neuraxial anesthesia and found that temperature monitoring is significantly underused, with only one-third of patients being monitored.[82] Furthermore, the method that was most frequently used to monitor temperature may not accurately reflect core temperature, the most important determinant of thermoregulatory response and perioperative morbidity. Forehead skin surface was the most commonly monitored site. The accuracy of these devices for perioperative temperature monitoring remains controversial; they do not reliably detect malignant hyperthermia and are not sufficiently accurate for fever screening purposes in children.[83] Sessler recommended the use of a properly positioned axillary probe or intermittent oral temperature monitoring during neuraxial anesthetics.[81]

Patients will frequently complain of feeling too warm when covered by heavy drapes. Although malignant hyperthermia is rare during MAC, hyperthermia is still possible as a result of thyroid storm or malignant neuroleptic syndrome. The subjective sensation of hyperthermia may also be the first indicator of important adverse events in evolution such as hypoxia, hypercarbia, cerebral ischemia, local anesthetic toxicity, and myocardial ischemia.

Bispectral Index Monitoring During Monitored Anesthesia Care

The bispectral index (BIS) is a processed EEG parameter that was specifically developed to evaluate patient response during drug-induced anesthesia and sedation. Sedation monitoring is attractive because of the potential to titrate drugs more accurately, avoiding the adverse effects of both overdosing and underdosing. BIS monitoring has some potential advantages over conventional intermittent techniques of patient assessment. Conventional assessment involves patient stimulation at frequent intervals to determine the level of consciousness, requires patient cooperation, and is subject to testing fatigue. An example of a conventional assessment tool is the Observer's Assessment of Alertness/Sedation Scale (OAA/S; Table 47-5).[84] The BIS has been shown to be a useful monitor of drug-induced sedation and of recall in volunteers, and has been shown to correlate with OAA/S scores during propofol-induced sedation in patients undergoing surgery with regional anesthesia.[85] An increasing depth of sedation was associated with a predictable decrease in the BIS. Absence of recall was associated with BIS values less than 80. These findings correspond with those of Kearse et al, who found no intraoperative recall at BIS values less than 79 during midazolam-induced, isoflurane-induced, and propofol-induced sedation.[86] However, the inability to recall a nonnoxious stimulus such as a picture, as used in the previous studies, may not necessarily correspond to amnesia to noxious events such as surgical stimulation. Despite this caveat, Liu and coworkers suggested that using a combination of propofol and midazolam to achieve a BIS value less than 80 will minimize the possibility of intraoperative recall.[85] Although the use of BIS to monitor sedation is appealing, conventional assessment of sedation is an important mechanism whereby continuous patient contact is maintained. Ideally, BIS monitoring will be employed in the future as an adjunct to clinical evaluation rather than as the primary monitor of consciousness.

TABLE 47-5 Observer's Assessment of Alertness/Sedation Scale

·RESPONSIVENESS	·SPEECH	·FACIAL EXPRESSION	·EYES	·COMPOSITE SCORE
Responds readily to name spoken in normal tone	Normal	Normal	Clear, no ptosis	5 (Alert)
Lethargic response to name spoken in normal tone	Mild slowing or thickening	Mild relaxation	Glazed or mild ptosis (less than half the eye)	4
Responds only after name is called loudly or repeatedly	Slurring or prominent slowing	Marked relaxation (slack jaw)	Glazed and marked ptosis (half the eye or more)	3
Responds only after mild prodding or shaking	Few recognizable words			2
Does not respond to mild prodding or shaking				1 (Asleep)

Anesth Analg 84:185, 1997.

Preparedness to Recognize and Treat Local Anesthetic Toxicity

8 Monitored anesthesia care is often provided in the context of regional or local anesthetic techniques. It is vitally important that the anesthesiologist responsible for the patient has a high index of suspicion, and is fully prepared to recognize and treat local anesthetic toxicity immediately (see Chapter 17). This point deserves special emphasis, particularly in light of the fact that monitored anesthesia care is often provided to patients who are elderly or debilitated and deemed "unfit" for general anesthesia; these are the patients most likely to suffer adverse reactions to local anesthetic drugs. Even if the anesthesiologist does not perform the block personally, he or she is in a unique position to fulfill an important "preventive" role by advising the surgeon about the most appropriate volume, concentration, and type of local anesthetic drug or technique to be used.

Systemic local anesthetic toxicity occurs when plasma concentrations of drug are excessively high. Plasma concentrations will increase when the rate of entry of drug into the circulation exceeds the rate of drug clearance from the circulation. The

clinically recognizable effects of local anesthetics on the CNS are concentration dependent. At low concentrations, sedation and numbness of the tongue and circumoral tissues, as well as a metallic taste, are prominent features. As concentrations increase, restlessness, vertigo, tinnitus, and difficulty of focusing may occur. Higher concentrations result in slurred speech and skeletal muscle twitching, which often herald the onset of tonic-clonic seizures.

The conduct of monitored anesthesia care may modify the individual's response to the potentially toxic effects of local anesthetic administration and adversely affect the margin of safety of a regional or local technique. For example, a patient with compromised cardiovascular function may experience a further decline in cardiac output during sedation. The resultant reduction in hepatic blood flow will reduce the clearance of local anesthetics that are metabolized by the liver and have a high hepatic extraction ratio, thereby increasing the likelihood of achieving toxic plasma concentrations. A patient receiving sedation may experience respiratory depression and a subsequent increase in arterial carbon dioxide concentration. Hypercarbia adversely affects the margin of safety in several ways. By increasing cerebral blood flow, hypercarbia will increase the amount of local anesthetic that is delivered to the brain, thereby increasing the potential for neurotoxicity. By reducing neuronal axoplasmic pH, hypercarbia increases the intracellular concentration of the charged, active form of local anesthetic, thus also increasing its toxicity. In addition, hypercarbia, acidosis, and hypoxia all markedly potentiate the cardiovascular toxicity of local anesthetics. Furthermore, the administration of sedative-hypnotic drugs may interfere with the patient's ability to communicate the symptoms of impending neurotoxicity. However, the anticonvulsant properties of benzodiazepines and barbiturates may attenuate the seizures associated with neurotoxicity. In both of the previous circumstances, it is possible that the symptoms of cardiotoxicity will be the first evidence that an adverse reaction has occurred. Thus, appropriate treatment is delayed or inadvertent intravascular injection is continued because of the absence of any clinical evidence of neurotoxicity. Cardiovascular toxicity usually occurs at a higher plasma concentration than neurotoxicity, but when it does occur, it is usually much more difficult to manage than neurotoxicity. Although cardiotoxicity is usually preceded by neurotoxicity, it may occur de novo when bupivacaine is being used.

Sedation and Analgesia by Nonanesthesiologists

Although anesthesiologists have specific training and expertise to provide sedation and analgesia, in clinical practice these services are frequently provided by nonanesthesiologists. The specific reasons for nonanesthesiologist involvement differ from institution to institution and from case to case, and include convenience, availability, and scheduling issues; perceived lack of anesthesiologist enthusiasm; perceived cost issues; and perceived lack of benefit concerning patient satisfaction and safety when sedation and analgesia are provided by anesthesiologists. Despite our frequent noninvolvement in these cases, anesthesiologists are indirectly involved in the care of these patients by being required to participate in the development of institutional policies and procedures for sedation and analgesia. To assist anesthesiologists in this process, an ASA task force has developed practice guidelines for sedation and analgesia by nonanesthesiologists.[1]

Four levels of sedation are defined in the ASA practice guidelines, and include minimal sedation, moderate sedation, deep sedation, and general anesthesia. The practice guidelines emphasize that sedation and analgesia represent a continuum of sedation where patients can easily pass into a level of sedation deeper than intended. When monitoring a sedated patient during a procedure, it is important to recognize when a patient becomes more deeply sedated than intended so the care team can act appropriately to prevent cardiorespiratory compromise.

The guidelines emphasize the importance of preprocedure patient evaluation, patient preparation, and appropriate fasting periods. The importance of continuous patient monitoring is discussed: in particular, the response of the patient to commands as a guide to the level of sedation. The

appropriate monitoring of pulmonary ventilation, oxygenation, and hemodynamics is also discussed, and recommendations are made for the contemporaneous recording of these parameters. The task force strongly suggests that an individual other than the person performing the procedure be available to monitor the patient's comfort and physiologic status. Education and training of providers is recommended. Specific educational objectives include the potentiation of sedative-induced respiratory depression by concomitantly administered opioids, adequate time intervals between doses of sedative/analgesics to avoid cumulative overdosage, and familiarity with sedative/analgesic antagonists. The routine administration of supplemental oxygen is recommended. At least one person with advanced life support skills should be present during the procedure. This individual should have the ability to recognize airway obstruction, establish an airway, and maintain oxygenation and ventilation. The practice guidelines recommend that appropriate patient size emergency equipment be readily available, specifically including equipment for establishing an airway and delivering positive-pressure ventilation with supplemental oxygen, emergency resuscitation drugs, and a working defibrillator. The presence of reliable intravenous access until the patient is no longer at risk for cardiorespiratory depression will improve safety. Adequate postprocedure recovery care with appropriate monitoring must be provided until discharge. Certain high-risk patient groups (e.g., uncooperative patients; extremes of age; severe cardiac, pulmonary, hepatic, renal, or CNS disease; morbid obesity; sleep apnea; pregnancy; drug or alcohol abuse) will be encountered and the guidelines recommend that preprocedure consultation with anesthesiologists, cardiologists, pulmonologists, and so forth be performed *before* administration of sedation and analgesia by nonanesthesiologists.

CONCLUSION

Through the use of monitored anesthesia care, an often terrifying and painful procedure can be made safe and comfortable for the patient. Monitored anesthesia care presents an opportunity for our patients to observe us at work. For the anesthesiologist, monitored anesthesia care can provide a more prolonged and intimate level of care and reassurance to our patients that is in contrast to the more limited exposure that occurs during and after general anesthesia. Our airway management skills and our daily practice of applied pharmacology make us uniquely qualified to provide this service. Monitored anesthesia care presents us with an opportunity to display these skills and increase our recognition in areas outside the operating room. The availability of drugs with a more favorable pharmacologic profile allows us to tailor our techniques to provide the specific components of analgesia, sedation, anxiolysis, and amnesia with minimal morbidity and to facilitate a prompt recovery. As the population ages, increasing numbers of patients will become candidates for monitored anesthesia care. Significant advances in nonsurgical fields (e.g., interventional radiology) will increase the number of procedures that are ideally performed under monitored anesthesia care. It is our responsibility to clearly demonstrate to our nonanesthesia colleagues that anesthesiologist-provided

monitored anesthesia care contributes to the best outcome for our patients. If anesthesiologists are not willing or able to provide these services, others who are less qualified are prepared to assume that role.

Chapter 48

Trauma and Burns

Levon M. Capan

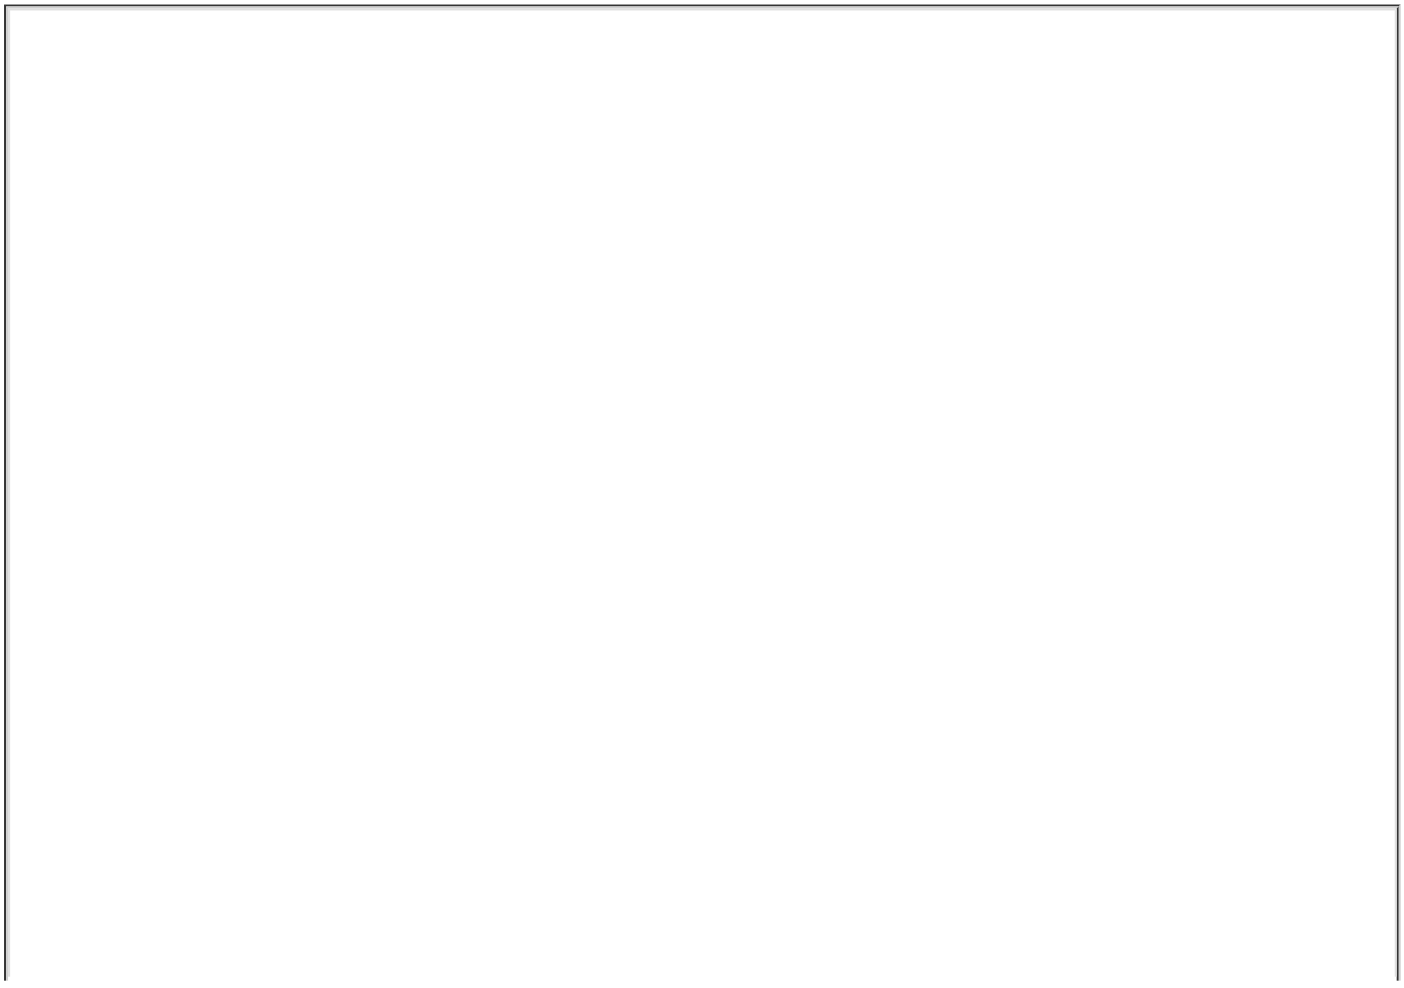
Sanford M. Miller

KEY POINTS

1	Initial evaluation of the trauma patient involves rapid overview, primary survey, and secondary survey.
2	Airway management is tailored to the type of injury, the nature and degree of airway compromise, and the patient's hemodynamic and oxygenation status.
3	Of the several causes that may alter respiration after trauma, tension pneumothorax, flail chest, and open pneumothorax are immediate threats to the patient's life, and therefore, require rapid diagnosis and treatment.
4	Hemorrhage is the most common cause of traumatic hypotension and shock.
5	Approximately 40% of deaths from trauma are caused by head injury.
6	The most important therapeutic maneuvers in head injury patients are aimed at maintaining cerebral perfusion pressure and oxygen delivery.
7	The objective in the evaluation of spinal trauma is to diagnose instability of the spine and the extent of neurologic involvement.
8	Penetrating neck injuries usually present with obvious clinical manifestations, whereas blunt cervical trauma may be more subtle.
9	Patients with three or more fractured ribs have a greater likelihood of pulmonary injury, higher injury severity score, and mortality rate than those with fewer rib fractures.
10	Blunt cardiac injury has replaced "myocardial contusion" and encompasses varying degrees of myocardial damage; coronary artery injury; and rupture of the cardiac free wall, septum, or a valve following blunt trauma.

11	Pelvic fractures result in major hemorrhage in 25% and exsanguination in 1% of patients.
12	Thermal trauma caused by flames in a closed space is likely to be associated with airway damage.
13	In burn victims, carbon monoxide (CO) inhalation is almost always associated with smoke inhalation, which increases the morbidity and mortality compared with CO toxicity alone.
14	Crystalloid solutions are preferred for resuscitation during the first day following a burn injury; leakage of colloids during this phase may increase edema.
15	Evaluation of the multiple trauma patient emergently transported to the operating room involves review of vital signs, oxygenation, preoperative fluid replacement, and confirmation of correct position and patency of a previously inserted endotracheal tube.
16	Anesthetic agents not only have direct cardiovascular depressant effects, but also inhibit compensatory hemodynamic mechanisms such as central catecholamine output and baroreflex (neuroregulatory) mechanisms, which maintain systemic pressure in hypovolemia.
17	Persistent hypotension following trauma is usually the result of one of four mechanisms: bleeding, tension pneumothorax, neurogenic shock, and cardiac injury.
18	The mortality rate after trauma increases with decreasing temperature.
19	Perioperative diagnosis of coagulopathy is often made by observing bleeding from wounds or puncture sites, rather than by interpretation of laboratory tests.
20	Intraoperative hyperkalemia may develop as a result of three mechanisms: alteration of cell membrane permeability, reperfusion injury, and rapid blood transfusion.
21	Reevaluation and optimization of the circulation, oxygenation, temperature, central nervous system function, coagulation, electrolyte and acid-base status, and renal function are the hallmarks of postoperative management.

Injuries are the most common cause of death in Americans between the ages of 1 and 45 years; more than 50% of all deaths in people between 5 and 34 years of age result from trauma.[1] There were nearly 145,000 deaths from trauma in 2001: the fourth most common cause of mortality



following heart disease (700,000), malignant neoplasms (554,000), and cerebrovascular disease (164,000).[1] The victim's quality of life may also be affected; approximately 80% of survivors of major trauma have significant functional limitation 12 and 18 months after injury.[2] The economic impact of trauma on society is also

enormous. In 2002, the estimated cost of unintentional injuries alone was $586 billion, including the costs of fatal and nonfatal injuries, employer costs, vehicle damage, and fire losses. The additional cost of lost quality of life is estimated as $1,272 billion, bringing the total annual cost of trauma to $1,858 billion.[3]

Approximately 75% of the hospital mortality from trauma occurs within 48 hours after admission,[4,5,6] most commonly from thoracic, abdominal or retroperitoneal, vascular, or central nervous system (CNS) injuries.[4,5] Hypoxia, systemic air embolism, and cardiac failure may also be direct or contributing factors.[5] Approximately one-third of these patients die within the first 4 hours after admission, representing the majority of operating room (OR) trauma deaths.[6,7] Of the remaining 25% of hospital deaths, 5 to 10% occur between the third and seventh day of admission, usually from CNS injuries,[4,6,7] and the rest in subsequent weeks, most commonly as a result of multiorgan failure.[5] Pulmonary thromboembolism and infectious complications may also contribute to mortality during this phase.[4,5]

INITIAL EVALUATION AND RESUSCITATION

The strategy of initial management can be defined as a continuous, priority-driven process of patient assessment, resuscitation, and reassessment. The general approach to evaluation of the acute trauma victim has three sequential components: rapid overview, primary survey, and secondary survey (Fig. 48-1). Resuscitation is initiated, if needed, at any time during this continuum. *Rapid overview* takes only a few seconds and is used to determine whether the patient is stable, unstable, dead, or dying. The *primary survey* involves rapid evaluation of functions that are crucial to survival. The "ABCs" of airway patency, breathing, and circulation are assessed. Then a brief neurologic examination is performed, and the patient is examined for any external injuries that might have been overlooked.

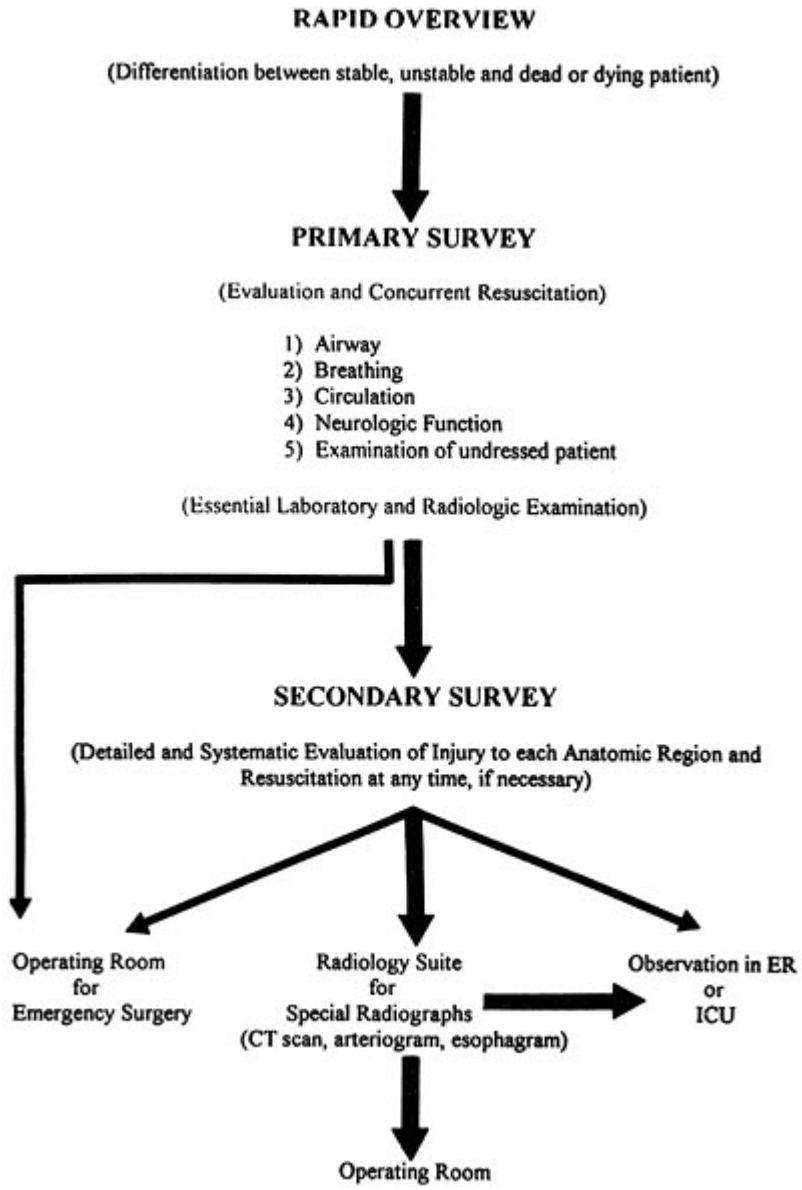


FIGURE 48-1. Clinical sequence for initial management of the major trauma patient. CT, computed tomography; ER, emergency room; ICU, intensive care unit.

The *secondary survey* involves a more elaborate systematic examination of the entire body to identify additional injuries. Radiographic and other diagnostic procedures may also be performed if the stability of the patient permits. Within this general framework the anesthesiologist, aside from managing the airway, contributes as part of the team to evaluation and resuscitation, while gathering information needed for possible future anesthetic management.

Injuries may be missed during initial evaluation and even during emergency surgery, resulting in significant pain, complications, residual disability, delay of treatment, or death.[8] Reported missed diagnoses include cervical spine, thoracoabdominal, pelvic, nerve, and external soft-tissue injuries, and extremity fractures. Some of these injuries may present during anesthesia, such as spinal cord damage during airway management in a patient with unrecognized cervical spine injury, massive intraoperative bleeding from an unrecognized thoracoabdominal injury during extremity surgery, or sudden intraoperative hypoxemia in a patient with unrecognized pneumothorax. A *tertiary survey* within the first 24 hours after admission (which may include a period of anesthesia) can potentially diagnose the majority of clinically significant injuries missed during initial evaluation,[8] by repeating the primary and secondary examinations and reviewing the results of radiologic and laboratory testing.

Airway Evaluation and Intervention

2 Airway evaluation involves the diagnosis of any trauma to the airway or surrounding tissues, recognition and anticipation of the respiratory consequences of these injuries, and prediction of the potential for exacerbation of these or other injuries by any contemplated airway management maneuvers. Although nontraumatic causes of airway difficulty, such as preexisting factors, may be present, only the management of trauma-related problems is discussed in this section.

Airway Obstruction

Airway obstruction is probably the most frequent cause of asphyxia and may result from posteriorly displaced or lacerated pharyngeal soft tissues, hematoma, bleeding, secretions, foreign bodies, or displaced bone or cartilage fragments. Bleeding into the cervical region may produce airway obstruction not only because of compression by the hematoma, but also from venous congestion and upper airway edema as a result of compression of neck veins. Signs of upper and lower airway obstruction include dyspnea, hoarseness, stridor, dysphonia, subcutaneous emphysema, and hemoptysis. Cervical deformity, edema, crepitation, tracheal deviation, or jugular venous distention may be present before these symptoms appear and may help indicate that specialized airway management techniques are required.

The initial steps in airway management are chin lift, jaw thrust, clearing of the oropharyngeal cavity, placement of an oropharyngeal or nasopharyngeal airway, and in inadequately breathing patients, ventilation with a self-inflating bag.

Immobilization of the cervical spine and administration of oxygen should be applied simultaneously. Blind passage of a nasopharyngeal airway or a nasogastric or nasotracheal tube should be avoided if a basilar skull fracture is suspected; it may enter the anterior cranial fossa.[9] A cuffed oropharyngeal airway or a laryngeal mask airway (LMA) may permit ventilation with a self-inflating bag, although neither provides protection against aspiration of gastric contents. If these measures do not provide adequate ventilation, the trachea must be intubated immediately using either direct laryngoscopy or a cricothyroidotomy, depending on the results of airway assessment.

Maxillofacial, neck, and chest injuries, as well as cervicofacial burns, are the most common trauma-related causes of difficult tracheal intubation. Airway assessment should include a rapid examination of the anterior neck for feasibility of access to the cricothyroid membrane. Tracheostomy is not desirable during initial management because it takes longer to perform than a cricothyroidotomy and requires neck extension, which may cause or exacerbate cord trauma in patients with cervical spine injuries. Conversion to a tracheostomy should be considered later to prevent laryngeal damage if a cricothyroidotomy will be in place for more than 2 to 3 days. Possible contraindications to cricothyroidotomy include age younger than 12 years and suspected laryngeal trauma; permanent laryngeal damage may result in the former, and noncorrectable airway obstruction may occur in the latter situation.

Proper placement by paramedics of devices such as an LMA, esophageal-tracheal combitube, or endotracheal tube should be confirmed by auscultation and capnography as soon as possible after the patient is admitted to the emergency department. Esophageal lacerations presenting as subcutaneous emphysema, pneumomediastinum, or pneumoperitoneum have been described as a result of the use of the combitube.[10]

Full Stomach

A full stomach is a background condition in acute trauma; the urgency of securing the airway often does not permit adequate time for pharmacologic measures to reduce gastric volume and acidity. Thus, rather than relying on these agents, the emphasis should be placed on selection of a safe technique for securing the airway when necessary: rapid-sequence induction with cricoid pressure for those patients without serious airway problems, and awake intubation with sedation

and topical anesthesia, if possible, for those patients who may present with serious airway difficulties. Posterior displacement of a vertebral bone fragment, with potential damage to the spinal cord, may result when cricoid pressure and manual inline stabilization (MIS) are applied to patients with cervical spine injuries.[11] Supporting the back of the neck with another hand may alleviate this problem.[12]

The probability of a full stomach precludes the use of an LMA, or any other device that does not protect the trachea, as a definitive airway in trauma patients. However, these devices can serve as a bridge for a brief period to reestablish airway patency or to facilitate intubation aided by a flexible fiberoptic bronchoscope. In patients with maxillofacial injuries, aspiration of pharyngeal blood or secretions is more likely than aspiration of gastric contents. If it can be inserted in these circumstances, an LMA may protect the lungs. Although positive-pressure ventilation may be used with the LMA, patients with pulmonary contusion, edema, or aspiration may be difficult to ventilate with this device. Difficulty may also be encountered when inserting an LMA in the presence of cricoid pressure and MIS of the cervical spine.[12,13] These problems may be somewhat circumvented with the intubating laryngeal mask (ILM); adequate ventilation is more likely, blind tracheal intubation is more successful, and an endotracheal tube as large as 8 mm can be placed through this device, as opposed to the maximum of 6 mm that can be passed through an LMA.[14] An important disadvantage of the ILM is that its metal part may exert considerable pressure against the cervical vertebrae, potentially exacerbating an unstable injury in this region.[15]

The selection of an airway management technique in the trauma patient may be affected by his or her hemodynamic condition. The presence of uncorrectable hypotension from hemorrhage, hypovolemia, or pericardial tamponade may necessitate omitting intravenous anesthetics from the rapid-sequence technique. Muscle relaxants alone may be sufficient. If only a mild to moderate degree of hypovolemia is present, reduced doses (30 to 50%) of intravenous anesthetics should be administered.[16] Although there is no evidence that the choice of intravenous agent affects outcome, ketamine and etomidate may confer advantages over thiopental and propofol. In equipotent doses in normovolemic patients, they produce less cardiovascular depression.[16] Although succinylcholine, with its short onset time and duration, is still the muscle relaxant of choice for rapid-sequence induction, rocuronium (0.9 to 1.2 mg/kg) has almost the same onset time and does not have the undesirable side effects associated with succinylcholine (e.g., increased intragastric, intraocular, and intracranial pressure [ICP]; potassium release in patients with burns and neurologic diseases). Bradycardia, dysrhythmias, and cardiac arrest have been described after succinylcholine in the presence of hypoxia and hypercarbia; some of these complications may also follow apparently uneventful intubation performed without succinylcholine.[17]

In agitated and uncooperative patients, topical anesthesia of the airway may be impossible, whereas administration of sedative agents may result in apnea or airway obstruction, with an increased risk of aspiration of gastric contents and inadequate conditions for tracheal intubation. After locating the cricothyroid membrane and denitrogenating the lungs, a rapid-sequence induction may be used to permit securing the airway with direct laryngoscopy or, if necessary, with immediate cricothyroidotomy. Personnel and material necessary to perform translaryngeal ventilation or cricothyroidotomy must be in place before induction of general anesthesia.[18]

Head, Open Eye, and Contained Major Vessel Injuries

The principles of tracheal intubation are similar for these injuries. Apart from the need to ensure adequate oxygenation and ventilation, these patients require deep anesthesia and profound muscle relaxation before airway manipulation. This helps prevent hypertension, coughing, and bucking, and thereby minimizes intracranial, intraocular, or intravascular pressure elevation, which can result in herniation of the brain, extrusion of eye contents, or dislodgment of a hemostatic clot from an injured vessel, respectively. The preferred anesthetic sequence to achieve this goal includes preoxygenation and opioid loading, followed by relatively large doses of an intravenous anesthetic and muscle relaxant. Hemodynamic responses to the opioid should be carefully monitored and promptly corrected. Systemic hypotension, ICP elevation, and decreased cerebral perfusion pressure (CPP; CPP = mean arterial pressure - ICP) may occur whether cerebral

autoregulation is present or absent in patients with head injuries, and if untreated can produce secondary ischemic insults.[19] Ketamine is probably contraindicated in patients with head and vascular injuries because it may increase both intracranial[20] and systemic vascular pressures; however, no significant increase in intraocular pressure (IOP) has been documented.[21] Any muscle

relaxant, including succinylcholine, may be used as long as the fasciculation produced by this agent is inhibited by prior administration of an adequate dose of a nondepolarizing muscle relaxant.[22] Alternatively, rocuronium can provide intubating conditions within 60 seconds with a dose of 1.6 to 2.0 mg/kg, although the neuromuscular blockade produced by this dose lasts approximately 2 hours.[23] Intravenous lidocaine has an attenuating effect on the pressor response to airway instrumentation, but it is mild and unpredictable. Of course, neither muscle relaxants nor intravenous anesthetics are indicated when initial assessment suggests a difficult airway. As in any other trauma patient, hypotension dictates either reduced or no intravenous anesthetic administration.

Cervical Spine Injury

Evidence of a serious new spinal cord injury or accentuation of existing neurologic abnormalities has been documented after intubation of patients with unsuspected cervical spine injuries.[24,25] Immobilization of the neck in a neutral position is indicated before airway management in all acute trauma patients with depressed consciousness, cervical pain, posterior midline cervical spine tenderness, extremity paresthesias, or focal neurologic deficits, and whenever the pain of other injuries is likely to mask the neck pain.[26] Additional risk factors that should increase suspicion are high-risk mechanisms of injury (falls, diving, high-speed motor vehicle accidents) and restricted active neck movement, particularly in rotation.[27] The combined use of a semirigid collar, sandbags placed on both sides of the head and neck, bindings, and a backboard provides the most reliable immobilization. For airway management purposes, however, MIS, with assistants holding the head and torso of the patient, is a practical and safe method if the neck is not otherwise reliably stabilized. A semirigid neck collar alone does not provide absolute protection. Protection of the neck should be maintained after tracheal intubation until a cervical spine injury has been ruled out.

Nasotracheal intubation carries the risks of epistaxis, failure of intubation, and the possibility of entry of the endotracheal tube into the cranial vault or the orbit if there is damage to the cranial base or the maxillofacial complex. Absence of the usual signs of cranial base fracture (Battle sign, raccoon eyes, or bleeding from the ear or the nose) cannot be relied on to exclude the possibility of its occurrence because with rapid prehospital transport these signs may not be immediately apparent. Orotracheal intubation with direct laryngoscopy is more desirable, although stabilization of the neck, which limits head extension, may make glottic visualization difficult. The incidence of inadequate exposure of the larynx increases from less than 3% in the general population to approximately 10% with immobilization of the neck.[28,29]

Other devices and techniques, including the McCoy laryngoscope, rigid fiberoptic laryngoscopes (Bullard or WuScope), flexible fiberoptic endoscope, light wand, translaryngeal (retrograde) intubation, and cricothyroidotomy, can be used to secure the airway in patients requiring cervical spine immobilization.[12] In most instances, successful, safe, and rapid tracheal intubation can be achieved with a conventional laryngoscope despite limited visualization of the larynx.[30] The McCoy laryngoscope is able to lift the epiglottis and may improve the laryngeal view: the cuff of a Fogarty catheter attached to the tip of this device may further improve exposure.[12,31] A gum elastic bougie passed through the endotracheal tube, or a satin-sheathed stylet placed through its Murphy aperture, may also be helpful; they can be inserted through the larynx more easily than the tube itself because their small diameter does not block the view of the glottis during direct laryngoscopy.[32] The WuScope provides a consistently good laryngeal view with a high rate of successful intubation and minimal neck movement.[30,33]

Flexible fiberoptic laryngoscopy and translaryngeal guided intubation (see Maxillofacial Injuries section) cause almost no neck movement, but blood or secretions in the airway, a long preparation time, and difficulty in their use in comatose, uncooperative, or anesthetized patients

reduce their utility during initial management.

Direct Airway Injuries

Direct airway damage can occur anywhere between the nasopharynx and the bronchi; sometimes more than one site may be involved, resulting in persistent airway dysfunction after one of the problems is corrected.[34]

Maxillofacial Injuries. In addition to soft-tissue edema of the pharynx and peripharyngeal hematoma, blood or debris in the oropharyngeal cavity may be responsible for partial or complete airway obstruction in the acute stage of these injuries. Occasionally, teeth or foreign bodies in the pharynx may be aspirated into the airway, causing some degree of obstruction, which may occur or be recognized only during attempts at tracheal intubation. Another problem is the dynamic nature of soft-tissue injuries in this region. A hematoma or edema in the face, tongue, or neck may expand during the first several hours after injury and ultimately occlude the airway. Serious airway compromise may develop within a few hours in up to 50% of patients with major penetrating facial injuries or multiple trauma, as a result of progressive inflammation or edema resulting from liberal administration of fluids.[35,36] Prophylactic intubation of the trachea or close and repeated examination of the upper airway may avert airway compromise before it occurs.

Fracture-induced encroachment on the airway or limitation of mandibular movement, pain, and trismus may limit mouth opening. Fentanyl in titrated doses of up to 2 to 4 µg/kg over a period of 10 to 20 minutes may produce an improvement in the patient's ability to open the mouth if mechanical limitation is not present.

The selection of an airway management technique in the presence of a maxillofacial fracture is based on the patient's presenting condition. Most patients with isolated facial injuries do not require emergency tracheal intubation. Surgery may be delayed for as long as a week with no adverse effect on the repair. Patients who present with airway compromise may be intubated using direct laryngoscopy; the decision about the use of anesthetics and muscle relaxants is based on the results of airway evaluation. When there is bleeding into the oropharynx, a flexible fiberoptic laryngoscope may be useless because of obstruction of the view. A retrograde technique, using a wire or epidural catheter passed through a 14-gauge catheter introduced into the trachea through the cricothyroid membrane, may be used if the patient can open his or her mouth. A surgical airway is indicated when there is airway compromise, when direct laryngoscopy has failed or is considered impossible, when the jaws will be wired, or when a tracheostomy will be performed anyway after definitive repair of the fracture. Nasogastric or nasotracheal intubation should be avoided when a basilar skull or maxillary fracture is suspected because of the possibility that the tube may enter the cranium or the orbital fossa. Hemorrhagic shock and life-threatening cranial, thoracic, and cervical spine injuries may accompany major facial fractures;[37] airway management must be tailored accordingly.[38] The likelihood of cranial injury increases in midface fractures involving the frontal sinus, as well as the orbitozygomatic and orbitoethmoid complexes.[39]

Cervical Airway Injuries. Injury to the cervical air passages can result from blunt or penetrating trauma. Clinical signs such as escape of air, hemoptysis, and coughing are present in almost all patients with penetrating injuries, facilitating the diagnosis. In contrast, major blunt laryngotracheal damage may be missed, either because the patient is asymptomatic or unresponsive, or because suggestive signs and symptoms are missed in the initial evaluation.[34] The typical presentation includes hoarseness, muffled voice, dyspnea, stridor, dysphagia, odynophagia, cervical pain and tenderness, ecchymosis, subcutaneous emphysema, and flattening of the thyroid cartilage protuberance (Adam's apple).[40] Whether the trauma is blunt or penetrating, attempts at blind tracheal intubation may produce further trauma to the larynx and complete airway obstruction if the endotracheal tube enters a false passage or disrupts the continuity of an already tenuous airway.[41,42] Thus, whenever possible, intubation of the trachea should be performed using a flexible fiberoptic bronchoscope or an airway should be established surgically. A computed tomography (CT) scan of the neck provides valuable information and should be performed before any airway intervention in all stable patients without respiratory and

hemodynamic compromise.

The strategy for tracheal intubation depends on the clinical presentation.[42] The tracheas of some patients with penetrating airway injuries, especially stab wounds, may be intubated through the airway defect without the need for anesthetics or optical equipment.[28] Patients with a normal airway on endoscopy can be intubated orotracheally under general anesthesia. The presence of cartilaginous fractures or mucosal abnormalities necessitates awake intubation with a fiberoptic bronchoscope or awake tracheostomy. Laryngeal damage precludes cricothyroidotomy. Tracheostomy should be performed with extreme caution because up to 70% of patients with blunt laryngeal injuries may have an associated cervical spine injury.[42] Uncooperative or confused patients may not tolerate awake airway manipulation. It may be best to transport these patients to the OR, induce anesthesia with inhalational agents, and intubate the trachea without muscle relaxants.[42] Episodes of airway obstruction during spontaneous breathing under an inhalational anesthetic can be managed by positioning the patient upright in addition to the usual maneuvers. In extreme situations such as near-complete transection of the larynx and trachea, femorofemoral bypass or percutaneous cardiopulmonary support may be considered.[43]

Thoracic Airway Injuries. Whereas penetrating trauma can cause damage to any segment of the intrathoracic airway, blunt injury usually involves the posterior membranous portion of the trachea and the mainstem bronchi, usually within approximately 3 cm from the carina. Pneumothorax, pneumomediastinum, pneumopericardium, subcutaneous emphysema, and a continuous air leak from the chest tube are the usual signs of this injury; they occur frequently but are not specific for thoracic airway damage. In patients intubated without the suspicion of a tracheal injury, difficulty in obtaining a seal around the endotracheal tube or the presence on a chest radiograph of a large radiolucent area in the trachea corresponding to the cuff suggests a perforated airway.[44] Other radiographic findings include a radiolucent line along the prevertebral fascia due to air tracking up from the mediastinum, peribronchial air or sudden obstruction along an air-filled bronchus, and the "dropped lung" sign when complete intrapleural bronchial transection causes the apex of the collapsed lung to descend to the level of the hilum.[45] Airway management is similar to that of cervical airway injury. Anesthetics, and especially muscle relaxants, may produce irreversible obstruction, presumably because of relaxation of structures that maintain the airway patent in the awake state; however, airway loss may also occur during attempts at awake intubation, often as a result of further distortion of the airway by the endotracheal tube, patient agitation, or rebleeding into the airway.[46]

After intubation of the trachea, the adequacy of the airway intervention is evaluated by clinical examination, capnography, and pulse oximetry. Pulmonary contusion, atelectasis, diaphragmatic rupture with thoracic migration of the abdominal contents, and pneumothorax may complicate the interpretation of chest auscultation. Likewise, CO_2 elimination may be decreased or absent in shock and cardiac arrest.

Management of Breathing Abnormalities

3 Of the several causes that may alter respiration after trauma, tension pneumothorax, flail chest, and open pneumothorax are immediate threats to the patient's life and therefore require rapid diagnosis and treatment. Hemothorax, closed pneumothorax, pulmonary contusion, diaphragmatic rupture with herniation of abdominal contents into the thorax, and atelectasis from a mucous plug, aspiration, or chest wall splinting can also interfere with breathing and pulmonary gas exchange and deteriorate into life-threatening complications.

Although cyanosis, tachypnea, hypotension, neck vein distention, tracheal deviation, and diminished breath sounds on the affected side are the classic signs of tension pneumothorax, neck vein distention may be absent in hypovolemic patients and tracheal deviation may be difficult to appreciate. The definitive diagnosis is established by chest radiograph; however, in hypoxemic and hypotensive patients, immediate insertion of a 14-gauge angiocatheter through the fourth intercostal space in the midaxillary line or, at times, through the second intercostal space at the midclavicular line is essential. There is no time for radiologic confirmation in this setting.

A flail chest results from comminuted fractures of at least three adjacent ribs or rib fractures with

associated costochondral separation or sternal fracture. An underlying pulmonary contusion with increased elastic recoil of the lung and work of breathing is the main cause of respiratory insufficiency or failure, and resulting hypoxemia.[47] It often develops over a 3- to 6-hour period, causing gradual deterioration of the chest radiograph and arterial blood gases (ABGs).[47] Coexisting hemopneumothorax, paradoxical chest wall movement, and/or pain-induced splinting may contribute to the gas exchange abnormalities. Repeated evaluation by physical examination, chest radiograph, and ABG determinations is essential for early recognition of these complications.

Without significant gas exchange abnormalities, chest wall instability alone is not an indication for respiratory support. There is evidence that liberal use of mechanical ventilation in the presence of a flail chest or pulmonary contusion increases the rate of pulmonary complications and mortality, and prolongs the hospital stay.[47] Effective pain relief by itself can improve respiratory function and often avoid the need for mechanical ventilation. For this purpose, continuous epidural analgesia with local anesthetics and opioids, preferably directed to thoracic segments, provides better pain relief and ventilatory function than parenteral opioids, reducing morbidity and mortality in elderly patients with chest wall trauma.[48] Other therapeutic measures include supplemental oxygen, continuous positive airway pressure (CPAP) of 10 to 15 cm H_2O by facemask, airway humidification, chest physiotherapy, incentive spirometry, bronchodilators, airway suctioning (using fiberoptic bronchoscopy, if necessary), and nutritional support.[47] Overzealous infusion of fluids may result in deterioration of oxygenation by worsening underlying pulmonary injury.[47]

In patients with pulmonary contusion, respiratory insufficiency or failure despite adequate analgesia, clinical evidence

of severe shock, associated severe head injury or injury requiring surgery, airway obstruction, and significant preexisting chronic pulmonary disease are indications for tracheal intubation and mechanical ventilation. Positive end-expiratory pressure (PEEP) should be used if ventilation is controlled. In intubated, spontaneously breathing patients, airway pressure release ventilation, in which spontaneous breathing is superimposed on mechanical ventilation by intermittent sudden, brief decrease of CPAP, provides improved $\dot{V}/\dot{Q}$ matching and systemic blood pressure, lower sedation requirements, greater O_2 delivery, and shorter periods of intubation.[47,49] Severe unilateral pulmonary contusion unresponsive to these measures may be treated by differential lung ventilation via a double lumen endobronchial tube. In bilateral severe contusions with life-threatening hypoxemia, high-frequency jet ventilation (HFJV) may enhance oxygenation and cardiac function, which may be compromised by concomitant myocardial contusion or ischemia.[50]

Systemic air embolism occurs mainly after penetrating lung trauma and blast injuries, and less frequently after blunt thoracic trauma that produces lacerations of both distal air passages and pulmonary veins[51]; positive-pressure ventilation after tracheal intubation may then result in entrainment of air into the systemic circulation. Hemoptysis, circulatory, and CNS dysfunction immediately after starting artificial ventilation, as well as detection of air in blood from the radial artery, establishes the diagnosis. Air bubbles may also be seen in the coronary arteries during thoracotomy. Surgical management involves immediate thoracotomy and clamping of the hilum of the lacerated lung. Respiratory maneuvers that minimize or prevent air entry into the systemic circulation include isolating and collapsing the lacerated lung by means of a double-lumen tube, or ventilation with the lowest possible tidal volumes via a single-lumen tube.[51] Transesophageal echocardiography (TEE) of the left side of the heart may permit visualization of air bubbles and their disappearance with therapeutic maneuvers.

Management of Shock

4 Hemorrhage is the most common cause of traumatic hypotension and shock. Other causes are abnormal pump function (myocardial contusion, pericardial tamponade, preexisting cardiac

disease, or coronary artery or cardiac valve injury), pneumothorax or hemothorax, spinal cord injury, and, rarely, anaphylaxis or sepsis (Table 48-1).

BP, blood pressure.

BP, blood pressure.

Evaluation of the severity of hemorrhagic shock in the initial phase is based on a few relatively insensitive and nonspecific clinical signs. For example, tachycardia, which is traditionally used as an index of hypovolemia, may be absent in up to 30% of hypotensive trauma patients because of increased vagal tone, chronic cocaine use, or other unknown reasons.[52] In contrast, by increasing catecholamine output, tissue injury, and associated pain may maintain tachycardia and normal or elevated systemic blood pressure in the presence of hypovolemia without necessarily increasing the cardiac index or tissue oxygen delivery.[53] In fact, in this situation an increase in intestinal vascular resistance and a decrease in splanchnic blood flow may occur, and if prolonged, may allow entry of intestinal microorganisms into the circulation and increase the likelihood of subsequent sepsis and organ failure.[54,55,56,57] Thus, equating a normal heart rate and systemic blood pressure with normovolemia during initial resuscitation may lead to loss of valuable time for treating an underlying occult hypovolemia or hypoperfusion. Nevertheless, heart rate, systemic blood pressure, pulse pressure, respiratory rate, urine output, and mental status remain the best available early clinical indicators of the severity of hemorrhagic shock[54] (Table 48-2).

TABLE 48-2 Advanced Trauma Life Support Classification of Hemorrhagic Shock[a]

	·CLASS I	·CLASS II	·CLASS III	·CLASS IV
Blood loss (mL)	⩽750	750–1,500	1,500–2,000	⩾2,000
Blood loss (% blood volume)	⩽15	15–30	30–40	⩾40
Pulse rate (per min)	<100	>100	>120	⩾140
Blood pressure	Normal	Normal	Decreased	Decreased
Pulse pressure	Normal or increased	Decreased	Decreased	Decreased
Respiratory rate	14–20	20–30	30–40	>35

(breaths/min)				
Urine output (mL/hr)	⩾30	20–30	5–15	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious and confused	Confused, lethargic
Fluid replacement (3:1 rule)[b]	Crystalloid	Crystalloid	Crystalloid + blood	Crystalloid + blood

[a]For a 70-kg male patient, based on initial presentation.

[b]The 3:1 rule is based on empiric observation that most patients require 300 mL balanced electrolyte solution for each 100 mL blood loss. Without other clinical and monitoring parameters, this guideline may result in excessive or inadequate fluid resuscitation.

Some of the proven markers of organ perfusion can be used during early management to set the goals of resuscitation. Of these, the base deficit, blood lactate level, and probably sublingual P_{CO2} (SLP_{CO2}) are the most useful and practical tools during all phases of shock, including the earliest. The base deficit reflects the severity of shock, the oxygen debt, changes in O_2 delivery, the adequacy of fluid resuscitation, and the likelihood of multiple organ failure and survival with reasonable accuracy in *previously healthy* adult and pediatric trauma patients.[58,59,60] A base deficit between 2 and 5 mmol/L suggests mild shock, between 6 and 14 mmol/L indicates moderate shock, whereas >14 mmol/L is a sign of severe shock. An admission base deficit in excess of 5 to 8 mmol/L correlates with increased mortality.[59,60] Thus, normalization of the base deficit is one of the end points of resuscitation.[61,62]

Elevation of the blood lactate level is less specific than base deficit as a marker of tissue hypoxia because it can be generated in well-oxygenated tissues by increased epinephrine-induced skeletal muscle glycolysis, accelerated pyruvate oxidation, decreased hepatic clearance of lactate, and early mitochondrial dysfunction.[63] All these conditions may be present in the trauma patient. Nevertheless, in most trauma victims an elevated lactate level correlates with other signs of hypoperfusion, rendering it an important marker of dysoxia and an end point of resuscitation.[64,65] The normal plasma lactate concentration is 0.5 to 1.5 mmol/L; levels above 5 mmol/L indicate significant lactic acidosis. The half-life of lactate is approximately 3 hours;[64] thus, the level decreases rather gradually after correction of the cause.[64] Failure to clear lactate within 24 hours after circulatory shock is a predictor of increased mortality.[65,66]

Sublingual capnometry is a new noninvasive addition to organ perfusion monitoring; it appears to indicate gut perfusion as reliably as gastric tonometry in hemorrhage, but with greater ease of use.[67,68] In trauma patients in the early phase of shock, it detected hemorrhage as accurately as base deficit and plasma lactate.[69] The device consists of a sublingual CO_2 sensor that directly measures mucosal P_{CO2}. The normal value for SLP_{CO2} is 45 to 50 mm Hg; elevated levels suggest

organ hypoperfusion.[69] The gradient between SLP_{CO2} and Pa_{CO2} may reflect organ perfusion more accurately, although in young trauma patients hyperventilation or hypoventilation does not seem to affect SLP_{CO2}.[69]

The response of the pulse and blood pressure to initial fluid therapy also aids in the assessment of hypovolemia.[54] In hypotensive and tachycardic patients, administration of lactated Ringer's (LR) solution, 2,000 mL over 15 minutes in adults or 20 mL/kg in children, should normalize the vital signs if hemorrhage is mild (10 to 20%). A transient improvement after fluid infusion suggests a 20 to 40% decrease in circulating volume or continuing blood loss. More crystalloids and possibly blood transfusion are required in these patients. If the vital signs do not respond to initial fluid resuscitation, there has probably been severe (>40%) severe blood loss or severe volume loss, which must be replaced by rapid infusion of crystalloids, colloids, and blood.

Bickell et al[70] challenged the conventional management of initial shock resuscitation; they showed that delaying fluid resuscitation until surgical control of bleeding in victims of penetrating trauma improved survival to hospital discharge and decreased the length of hospital stay. Vigorous fluid therapy increases arterial and venous pressures, dilutes clotting factors and platelets, and decreases blood viscosity, and thus may reinitiate bleeding already stopped by a soft thrombus. Although many experimental studies have confirmed the findings of Bickell et al, it has also become clear that withholding fluids completely can result in as much harm as vigorous resuscitation.[71] In contrast, slow fluid infusion with isotonic or hypertonic crystalloids, and preferably with packed red blood cells (PRBCs), titrated to lower than normal systemic pressure, had

beneficial effects on animal survival without tissue injury or organ failure.[71] Although there are substantial data to suggest that this "limited resuscitation" may be preferable to the current standard of care, proof of this is lacking. The only clinical study conducted subsequent to Bickell et al failed to demonstrate any decrease in mortality.[72] Thus, although this technique is far from being a standard of care, it emphasizes the useful fact that fluid administration in excess of that needed for achieving normovolemia prior to control of hemorrhage may be deleterious.

A reasonable transfusion threshold is a hematocrit below 25% for young, healthy patients and below 30% for older patients or those with coronary or cerebrovascular disease.[73] Preliminary data suggest that transfusion of PRBC units older than 14 days may prolong the length of hospital stay in moderately injured,[74] and may be an independent risk factor for multiple organ failure in severely injured patients.[75] Normally, type-specific blood can be available in less than 15 minutes for patients with severe hemorrhage. If the situation dictates immediate transfusion, type O, Rh (+) blood is satisfactory in most situations. O, Rh(-) blood should be given to women of childbearing age. However, because of the scarcity of Rh(-) blood, some women require an Rh(+) transfusion. The immunogenicity of the D antigen can be neutralized by administration of Rh immune globulin (anti-Rh antibody).

Rapid establishment of venous access with large-bore cannulae placed in peripheral veins that drain both above and below the diaphragm is essential for adequate fluid resuscitation in the patient who is severely injured. When vascular collapse and extremity injury impair access to arm or leg vessels, percutaneous cannulation of the internal jugular, subclavian, or femoral veins can be performed. Ultrasound guidance may be useful for cannulation of the internal jugular vein and may also be used for an infraclavicular approach to the axillary vein,[76] or to the cephalic or basilic veins at the midarm level.[77] If necessary, a cutdown to a saphenous or arm vein can be rapidly performed in older children and adults. In children younger than 5 years of age, intraosseous cannulation has a high success rate and a low incidence of complications. Infusion rates comparable with those obtained with intravenous lines are possible in small children, although a pressure infusion device may be necessary to achieve adequate flow.[78] A special screw-type needle or the needle of a 16- or 18-gauge angiocatheter is introduced into the bone marrow of the distal femur or proximal tibia at the level of its tuberosity. Care should be taken not to injure the epiphyseal plate during puncture. Proper placement is indicated by loss of resistance to fluid

injection or aspiration of marrow.

Patients who arrive in the emergency department in cardiac arrest require advanced cardiac life support. However, the success rate of external cardiac massage in hypovolemic trauma victims is likely to be low.[79] Emergency department thoracotomy not only permits performance of open cardiac massage, but also aids resuscitation efforts by allowing drainage of pericardial blood, control of cardiac and great vessel bleeding, application of a cross-clamp to the aorta, and rapid administration of fluids through a small Foley catheter introduced into the right atrium, or in desperate situations, through a large-bore catheter or introducer in the descending aorta. This procedure is not indicated in blunt torso trauma; the mortality rate is similar regardless of whether it is attempted.[80] In penetrating injuries, depending on the presenting condition of the patient, the initial success rate may be as high as 70%, but the neurologically intact hospital discharge rate is only 10 to 15%.[80,81]

EARLY MANAGEMENT OF SPECIFIC INJURIES

Head Injury

5 Approximately 40% of deaths from trauma are caused by head injury, and indeed, even a moderate brain injury may increase the mortality rate of patients with other injuries.[82] In nonsurvivors, progression of the damaged area beyond the directly injured region (secondary brain injury) can be demonstrated at autopsy.[83] The major factor in secondary injury is tissue hypoxia, which results in lactic acidosis; free radical generation; prostaglandin synthesis and release of excitatory amino acids (primarily glutamate); lipid peroxidation and breakdown of cell membranes; entry of large quantities of sodium, calcium, and water into the cells; and leakage of fluid from the blood vessels into the extracellular space.[84] This process results in brain edema, as well as both regional and global disturbances of the cerebral circulation. Thus, of all the possible insults to the injured brain, decreased oxygen delivery as a result of hypotension and hypoxia has the greatest detrimental impact[85,86,87] (Table 48-3).

TABLE 48-3 Effects on Outcome of Secondary Insults Occurring from Time of Injury Through Resuscitation[a]

SECONDARY INSULTS	NO. OF PATIENTS	% OF TOTAL PATIENTS	6-MONTH OUTCOME (%)		
			GOOD/MODERATE	SEVERE/VEGETATIVE	DEAD
Total cases	717	100	43.0	20.2	36.8
Neither	308	43.0	63.9	10.2	26.9
Hypoxia	161	22.4	50.3	21.7	28.0
Hypotension	62	11.4	32.9	17.1	50.0

Brain injury by itself does not cause hypotension in adults, except as a preterminal event. However, more than half of patients with severe head trauma have other injuries that render

approximately 15% of them hypotensive; approximately 30% are hypoxic on admission as a result of central respiratory depression or associated chest injuries.[84] Furthermore, exposure to these insults is likely to occur during any phase of the continuum of hospital care: in the radiology unit, the OR, the recovery room, the intensive care unit, or elsewhere. The most common early complications of head trauma are intracranial hypertension, brain herniation, seizures, neurogenic pulmonary edema, cardiac dysrhythmias, bradycardia, systemic hypertension, and coagulopathy.

Diagnosis

Mental impairment after trauma may have any of several etiologies. However, the possibility of hypoxia and shock must always be considered first. If consciousness remains depressed despite ventilation and fluid replacement, a head injury is assumed to be present, and the patient is managed accordingly. As noted, hypotension is the most important cause of death in the patient with head injury; Chesnut et al[85,88] demonstrated that a single episode of systolic blood pressure <90 mm Hg is associated with a 50% increase in mortality. Therefore, every effort should be made to support the blood pressure with fluids and vasopressors (preferably phenylephrine, which does not constrict cerebral vessels), and ensure adequate oxygenation *before* the unconscious patient is evaluated.[89] A baseline neurologic examination should be performed after initial resuscitation, but before any sedative or muscle relaxant agents are administered, and should be repeated at frequent intervals because the patient's condition may change rapidly. Anesthetic and adjunct drugs render an adequate neurologic examination impossible; thus, long-acting muscle relaxants, opioids, sedatives, or hypnotics should be given selectively.[90,91]

Consciousness can be initially assessed within a few seconds using the AVPU system (*a*lert; responds to *v*erbal stimuli; responds to *p*ain; *u*nresponsive; Table 48-4). More precise information is provided by the Glasgow Coma Scale[92] (GCS; see Table 48-4), which provides a standard means of evaluating the patient's neurologic status. In this test, the sum of the scores obtained for eye opening, verbal response, and motor activity correlates with the state of consciousness, the severity of the head injury, and the prognosis.[90,93] Assessment of motor function should be performed on the extremity that responds best. The limb affected by neurologic injury is examined, but the result is not considered in the GCS.

TABLE 48-4 Two-Level Initial Evaluation of Consciousness

▪LEVEL 1. AVPU SYSTEM A = Alert V = Responds to verbal stimuli P = Responds to painful stimuli U = Unresponsive

GCS ⩽ 8 = deep coma, severe head trauma, poor outcome	
GCS 9–12 = concious patient with moderate injury	
GCS > 12 = mild injury	

Dilatation and sluggish response of the pupil is a sign of compression of the oculomotor nerve by the medial portion of the temporal lobe (uncus). A maximally dilated and unresponsive "blown" pupil suggests uncal herniation under the falx cerebri. The presence of similar findings in ocular injuries makes interpretation of pupillary findings difficult when eye and head injuries coexist. However, the pupillary reaction to light is usually more sluggish in the patient with head injury.

CT scanning is used for the diagnosis of most acute head injuries. Positive CT findings after acute head injury include midline shift, distortion of the ventricles and cisterns, effacement of the sulci in the uninjured hemisphere, and the presence of a hematoma at any location in the cranial vault. Subdural hematomas usually have a concave border, whereas epidural hematomas present with a convex outline classically termed a *lenticular* configuration. Patients in coma (GCS < 8) have a 40% likelihood of an intracranial hematoma.[94] Those with a higher GCS score are less likely to have had intracranial bleeding, although it is now evident that the significant incidence

of this complication even in these patients necessitates a CT study, preferably with contrast enhancement.[87,95] Other benefits of CT scanning include detection of intracranial air and depressed skull fractures.

Management

6 The primary objective of the early management of brain trauma is to prevent or alleviate the secondary injury process that may follow any complication that decreases the oxygen supply to the brain, including systemic hypotension, hypoxemia, anemia, raised ICP, acidosis, and possibly hyperglycemia (serum glucose >200 mg/dL).[96] These insults cause exacerbation of trauma-induced cerebral ischemia and metabolic derangements, worsening the outcome.[88,97] *The most important therapeutic maneuvers in these patients are aimed at maintaining CPP and oxygen delivery.* The Brain Trauma Foundation and the American Association of Neurological Surgeons have published evidence-based guidelines for the treatment of patients with head injury.[87] Primary therapy includes normalization of the systemic blood pressure (mean blood pressure >80) and arterial oxygenation (SaO_2 >95); sedation and paralysis, if necessary; mannitol and possibly a loop diuretic to shrink the brain and decrease the ICP; and drainage of cerebrospinal fluid through a ventriculostomy catheter, if available.

Rapid and adequate restoration of the intravascular volume with isotonic crystalloid and, if necessary, with colloid solutions should be aimed at maintaining the CPP > 60 mm Hg, while attempting to minimize further brain swelling. LR solution, which is slightly hypotonic (Na^+ = 130 mEq/L, osmolality ~255 mOsm/L), may promote swelling in uninjured areas of the brain if it is given in large quantities. Edema tends to occur in injured brain regions regardless of the type of solution administered because of increased permeability of the blood-brain barrier. To minimize edema formation, it is wise to monitor serum osmolality and to replace LR solution with isotonic normal saline. If serum osmolality cannot be measured, this change can be made empirically after

3 L of LR solution.

Effective reduction in ICP can be provided, or at least aided, by administration of mannitol, an important part of the management of severe head injury. It is administered in boluses of 0.25 to 0.5 g/kg, repeated every 4 to 6 hours as needed to control the ICP.[87] In addition to its osmotic diuretic effect, this agent may improve cerebral blood flow (CBF) and O_2 delivery by reducing the hematocrit and thus the blood viscosity.[98] There is a risk of hypovolemia and resultant hypotension when therapeutic doses of mannitol are used. The aim in administration of this agent is a normal volume of mildly hypertonic (~295 mOsm/L) plasma. If the ICP elevation persists, additional doses of mannitol should be given with great care. Acute mannitol toxicity, manifested by hyponatremia, high serum osmolality, and a gap between calculated and measured serum osmolality >10 mOsm/L, may result when the drug is given in large doses (2–3 g/kg) or to patients with renal failure.[99] Hyponatremia in these patients results from intravascular volume expansion rather than sodium loss; thus, treatment with saline solutions is not appropriate. Because of a synergistic action between mannitol and loop diuretics in improving the ICP, addition of furosemide may be a safer and more effective treatment than increasing the dose of mannitol when intracranial hypertension persists.[100]

Until about 1995, hyperventilation to a $PaCO_2$ of 25 to 30 mm Hg was a mainstay of the therapy of head injury. However, brain ischemia, which is probably the most threatening consequence of head injury, is likely to occur during the first 6 hours after trauma,[101,102,103] even when the CPP is maintained above the generally recommended 60 to 70 mm Hg.[102,104] This hypoperfusion seems to be largely caused by increased cerebral vascular resistance, which may be enhanced by hyperventilation. Ward et al[105] showed that patients ventilated to a $PaCO_2$ of 24 mm Hg had a significantly worse outcome than did those maintained at a $PaCO_2$ of 35 mm Hg. However, some degree of hyperventilation may be necessary for short periods of time in patients who have severe injuries and elevated ICP that does not respond to normal ventilation and diuretics, although this should not be used during the first 24 hours following injury.[87,106] Its use after the initial phase should be based on monitoring of the ICP and, if available, the jugular bulb O_2 saturation ($SjvO_2$) and arteriovenous O_2 difference ($AVDO_2$).

Measurement of $SjvO_2$ is used in many centers as a guide to therapy of the patient with head injury.[107] A catheter is passed retrograde into the jugular bulb. The O_2 saturation may be measured with a cooximeter or continuously by means of a fiberoptic sensor. $SjvO_2$ of <50% is considered critical desaturation. $AVDO_2$ is a standard measure of the brain's oxygen supply–demand ratio. It is equal to $1.34 \cdot Hgb \cdot (SaO_2 - SjvO_2)$, and normally, is approximately 6. An increase in this value is a sign of insufficient blood flow, whereas a subnormal level indicates hyperemia. A reduction in ICP with elevation of CPP during treatment is reflected by a rise in $SjvO_2$ and a narrowing of the $AVDO_2$, presumably reflecting an improvement in the circulation to the brain.[107,108] Unfortunately, several shortcomings of the technique have hindered its universal acceptance. Because all the cerebral veins drain into the cavernous sinus and from there into the jugular bulbs, $AVDO_2$ measures only global O_2 consumption, which may well be different from the situation in the injured region. Indeed, Coles et al[102] demonstrated that a significant increase in the region of critical hypoperfusion resulting from hyperventilation was not necessarily associated with a correspondingly abnormal $SjvO_2$ or $AVDO_2$ (Fig. 48-2). Patient or catheter movement may also alter the measured $PjvO_2$. Thus, there may be a high proportion of inaccurate values—as high as nearly two-thirds in one study[109]—although more recent advances in the technique have probably reduced these errors. Cruz[110] suggested that jugular venous monitoring should be used only in sedated, paralyzed patients.

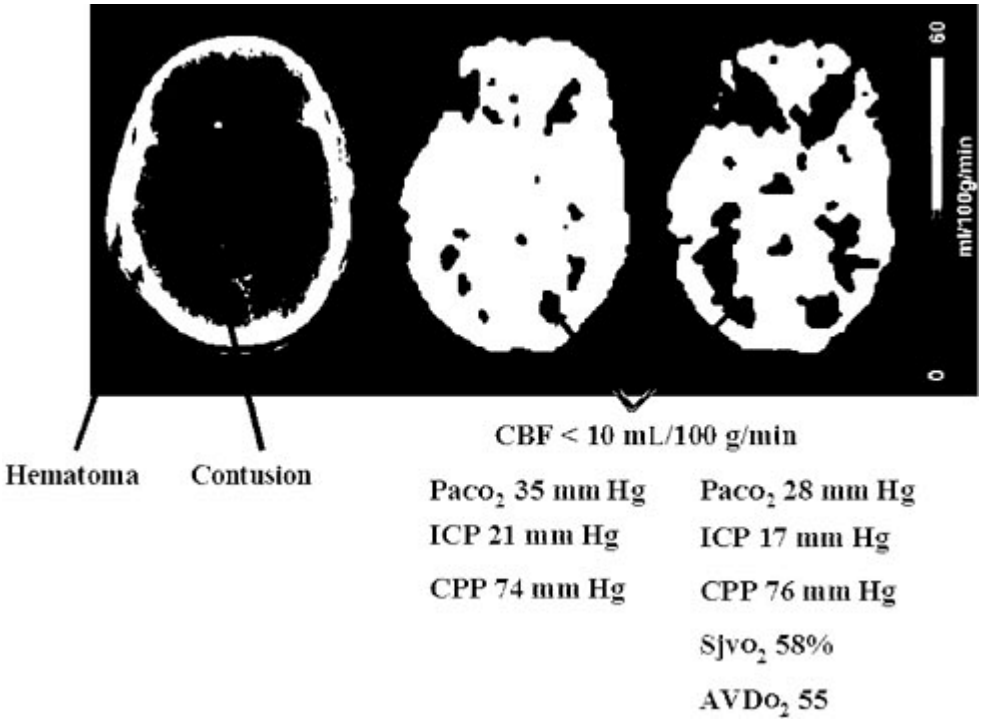

FIGURE 48-2. Effects of hyperventilation on cerebral blood flow (CBF). The left image is a computed tomography scan of the patient whose positron emission tomography scans are shown in the other two images. Note that there is a significant decrease in the CBF and an increase in the areas of hypoperfusion despite improvement in the intracranial pressure (ICP), and normal $SjvO_2$ and $AVDO_2$. CPP, cerebral perfusion pressure. (Adapted with permission from Coles JP: Regional ischemia after head injury. Curr Opin Crit Care 10:120, 2004.)

If the ICP remains elevated, pentobarbital (3 to 10 mg/kg given over 0.5 to 2.5 hours, followed by a maintenance infusion of 0.5 to 3.0 mg/kg/hr, aimed at a serum concentration between 2.5 and 4.0 mg/dL) may be required.[87,100] High-dose barbiturates, however, are of no value in the routine therapy of head injury and should be used only for refractory ICP elevation. Whether active normalization of elevated serum glucose (a common occurrence in the patient with head injury) has any salutary effect on outcome is not known. Of course, immediate surgical decompression, especially of epidural hematomas, is an important factor in reducing morbidity and mortality.

If the patient is hemodynamically stable, a CT scan is performed; the strictest attention should be paid to ensuring adequate oxygenation, ventilation, blood pressure, and ICP control during the procedure. If the patient is hemodynamically unstable or requires emergency surgery for associated injuries, and has a history suggesting a head injury even though a significant intracranial hematoma is unlikely on clinical grounds, intraoperative ICP monitoring is indicated to permit rapid detection of ICP elevation. Both intracranial hematomas and hemorrhage in other regions have a high surgical priority. In the multiple trauma victim, prioritization between the two is based on the severity of each injury. Because there is no time to obtain a CT scan of the head in patients with both profuse hemorrhage and brain herniation, the patient is brought directly to the OR for simultaneous control of the bleeding site and evacuation of the intracranial hematoma. The site of the craniotomy can be determined by a ventriculogram or an ultrasound examination with a pencil-tip probe; both tests may be performed under local anesthesia through a frontal burr hole.

The addition of relatively small volumes of hypertonic saline in concentrations between 3% (6 to 8 mL/kg) and 7.5% (4 mL/kg) followed by infusion of LR may be beneficial in multiple trauma

patients with head injury.[111,112] Hypertonic saline draws fluid from the intracellular space and, thus, in addition to restoring the blood volume, it reduces brain edema and prevents elevation of the ICP as effectively as 20% mannitol.[113,114] The intravascular volume expansion produced by hypertonic saline is transient; it can be prolonged by addition of 6% dextran-70 or hetastarch to the solution.[115] However, administration of hypertonic saline cannot be maintained for long periods. It may cause hypernatremia, hyperosmolality, or hyperchloremic acidosis, probably from renal bicarbonate loss secondary to increased levels of Cl^-. Serum concentrations of Na^+ and Cl^- and the patient's acid-base status should be followed, and the administration of hypertonic saline should be discontinued if plasma Na^+ reaches 160 mEq/L. Because of these considerations, the use of hypertonic saline is still considered experimental therapy.[116] Resuscitation with colloid solutions (hetastarch, pentastarch, pentafraction, human albumin 5% and 25%, or dextran) provides a sustained improvement in vital signs, but the increase in colloid osmotic pressure produced by these solutions may not have an important role in reducing brain edema.[117]

Several more recent studies seem to indicate that the outlook for patients with brain injury can be improved:

1. Cruz et al[118] and the Lund group[119] used widely different approaches, but the common factor in their treatments was not only maintenance of the CPP, but also avoidance, or at least limitation, of brain swelling. Cruz et al accomplished this by standard therapy augmented by monitoring the cerebral O_2 extraction ($CeO_2 = SaO_2 - SjvO_2$). Hyperventilation was used when this value decreased below the normal range of 24 to 42% to constrict the circulation and thus decrease the ICP. The Lund treatment involved a rather complex pharmacological approach, both to control blood pressure and ICP, and to limit edema formation.
2. The earlier definitive treatment is initiated, the better the outcome is likely to be.[120,121] Rudehill et al[120] demonstrated improvement in outcomes in a large series of patients when care was initiated by physicians at the accident scene.
3. Meanwhile, the wide variety of types and severities of injury, and of responses to treatment—both among different patients and in the same patient at different times—imply that therapeutic interventions must be individualized.[122,123,124] These latter aims may be met, at least partly, by carefully structured intensive care.[125,126] Therapeutic goals should be explicitly set, reviewed, and altered, if necessary, at every change of shift.

Indeed, early intervention and controlled management may explain much of the improvement in outcomes that has been obtained over the past 5 years, including the results obtained by Cruz et al and by the Lund group (Table 48-5**).** Individualized treatment is likely to result in further advances.

Spine and Spinal Cord Injury

Initial Evaluation

The objective in the evaluation of spinal trauma is to diagnose instability of the spine and the extent of neurologic involvement. Not stabilizing the spine in the first hours after a major accident until a definitive diagnosis is established risks converting a neurologically intact patient into a paraplegic or quadriplegic.[127] During transport to the hospital, the patient should be immobilized with a hard collar, a spine board, and tape. After admission, patients should not be left on a rigid spine board for longer than 1 hour, especially when they are paralyzed, because of the risk of decubitus ulcers.

In the conscious patient, the diagnosis is relatively easy: a history of a motor vehicle, industrial, or athletic accident or a fall; penetrating trauma resulting in a neurologic deficit below a specific spinal level; or pain and tenderness over the involved vertebrae strongly suggests a spine injury. Obviously, these symptoms are difficult to elicit in the comatose patient. In these circumstances, flaccid areflexia, loss of rectal sphincter tone, paradoxical respiration, and bradycardia in a hypovolemic patient suggest the diagnosis. In cervical spine trauma, an ability to flex but not to extend the elbow and response to painful stimuli above but not below the clavicle also indicate neurologic injury. Current guidelines consider absence of neck pain or paresthesia and a negative physical examination—lack of tenderness with palpation and during voluntary flexion and extension of the neck—in a neurologically intact, conscious patient as adequate indications for ruling out a cervical spine injury without further radiologic studies.[128,129,130] Alcohol intoxication and distracting associated injuries do not seem to alter

these criteria as long as the patient is alert, conscious, and able to concentrate.[131]

Depending on the degree of deficit, spinal cord injuries are categorized as *complete* or *incomplete.* Intact sensory perception over the sacral distribution and voluntary contraction of the anus (sacral sparing) are present in incomplete, but not in complete, injuries. There is practically no possibility of significant neurologic recovery in complete injury, whereas functional restoration may occur in up to 50% of patients after incomplete injuries.[132] In some patients the development of *spinal shock*, which is manifested by absolute flaccidity and loss of reflexes, precludes distinguishing between complete and incomplete injuries during the initial phase of treatment. Therefore, even in the absence of sacral sparing, the possibility of neurologic recovery dictates that all possible efforts be made at this time to prevent further damage and to preserve cord function. A similar principle applies to the evaluation of the level of injury. After the first few days, spinal cord edema subsides, and the final level is commonly a few segments lower than on initial presentation. Thus, early therapeutic efforts should not be abandoned even in the patient with a high-level injury, which carries a grim functional prognosis.

Spinal shock is probably caused by direct trauma to the spinal cord and usually subsides within days to weeks.[133] The term is frequently used as a misnomer for *neurogenic shock*, which is defined as hypotension and bradycardia caused by the loss of vasomotor tone and sympathetic innervation of the heart as a result of functional depression of the descending sympathetic pathways of the spinal cord. It is usually present after high thoracic and cervical spine injuries and improves within 3 to 5 days.

Radiologic Evaluation

For radiologic diagnosis of the cervical spine, the current strategy is based on the Eastern Association for the Surgery of Trauma guidelines, which recommend a standard three-view (anteroposterior, lateral, and open mouth) series of radiographs and examination of suspect or suboptimally visualized areas with limited, focused CT scans.[134] A more recent trend, however, is to use a helical CT scan with sagittal and coronal reconstruction as the primary diagnostic measure, in conjunction with plain radiographs.[135,136] The advantages of this approach include less reliance on plain films, which are frequently inadequate; almost 100% sensitivity in detecting the injury; the ability to scan other anatomic locations in the same session; and possibly reduced cost. However, the ability of a CT scan to diagnose ligamentous injuries is less than that of detecting fractures. Woodring and Lee[137] found that CT scans detected 90% of the fractures but only 54% of subluxation dislocations, whereas plain films identified only 58% of the fractures but 93% of subluxation dislocations. Newer CT techniques can partially overcome this problem. In fact, it has been suggested that cross-sectional imaging with either CT scanning or magnetic resonance imaging (MRI) should replace the flexion-extension series used to detect ligamentous injury in patients with cervical pain and tenderness but negative spine radiographs.[138] Apart from not being cost effective, flexion-extension films are inadequate when, as in many acute trauma patients, the range of motion of the neck is limited.[138,139]

It is important to recognize that enlargement of the prevertebral space in the neck on lateral films may be due to a retropharyngeal hematoma, which may cause tracheal deviation and tenderness,

and complicate airway management.[132] Any radiologic examination should be performed with the patient in the supine position until a spine injury is ruled out, so the risk of displacement of the fracture is minimized. When associated injuries dictate immediate management, radiographic diagnosis may have to be postponed for several hours or days as long as proper immobilization of the spine is maintained.

Initial Management

The spinal cord, a microcosm of the brain, is also vulnerable to a secondary injury process that may be a product of hypotension, hypoxia, and probably other physiologic complications.[140] Prompt recognition and aggressive treatment of these insults, which may also result from associated injuries, may minimize exacerbation of spinal cord lesions and improve the long-term outlook of patients with spinal cord injuries.[93,97,141]

Immobilization and Intubation. Maintenance of immobilization of the injured spine is of paramount importance. If a cervical spine fracture is suspected, immobilization or manual inline stabilization of the neck is necessary before the patient is moved. If the patient has a thoracic or lumbar injury, a careful log-rolling maneuver should be used.[142]

Any intubation technique is safe as long as the neck is held in a neutral position. Thus, a Macintosh laryngoscope may be used if manual inline stabilization of the neck is applied. Inline stabilization, however, decreases the visibility of the larynx in a large proportion of patients. If difficulties occur, it is better to choose an alternate technique rather than manipulate the neck more than a small amount. Cricoid pressure should be applied with great care in the patient with a possible cervical spine injury because it may produce undue motion of the spine if excessive force is used.[93]

Steroids. For several years, high-dose methylprednisolone has been used in many centers in an attempt to improve the outcome from spinal cord injuries. The drug is usually given as a bolus of 30 mg/kg within 8 hours of injury, followed in 1 hour by an infusion of 5.4 mg/kg/hr for the next 23 to 47 hours. The National Acute Spinal Cord Injury Studies (NASCIS-2 and NASCIS-3)[143,144,145] demonstrated some improvement in motor function in treated patients who had partial sensory and motor loss. The results were best in patients who received 24 hours of therapy starting within 3 hours of injury and those receiving 48 hours of treatment starting within 3 to 8 hours of injury. There was virtually no improvement in sensory scores in any of the groups. There was little or no difference from untreated patients in groups with more severe injuries or in those who were treated after 8 hours, and the long-term improvement in the functional status of most of the patients was at best moderate. Unfortunately, the results of these studies have not been duplicated in any other prospective or retrospective trials.[146,147,148]

Furthermore, steroid therapy is associated with an increased rate of sepsis, pneumonia, and days of intensive care and positive-pressure ventilation.[143,144,145,149] Given these results, the *Guidelines for the Management of Acute Cervical Spine and Spinal Cord Injuries*[130] state, "Treatment with methylprednisolone for either 24 or 48 hours is recommended as an option in the treatment of patients with acute spinal cord injuries that should be undertaken only with the knowledge that the evidence suggesting harmful side effects is more consistent than any suggestion of clinical benefit."

Respiratory Complications

Respiratory complications are common in all phases of the care of patients with spinal cord injury, and in the initial period, may be augmented by associated brain, neck, chest, or abdominal injury, alcohol intoxication, or the effects of self-administered or iatrogenic drugs. Injuries at C5 or lower are usually associated with normal tidal volumes because the function of the diaphragm is intact, whereas patients with levels at C4 or above may require permanent ventilatory assistance. Nevertheless, accessory respiratory muscle paresis may cause a significant loss of expiratory reserve even when the injury involves the lower spinal segments.[150,151]

Pulmonary edema is another significant cause of respiratory dysfunction. A severe catecholamine surge follows acute trauma to the spinal cord.[152] Although the resultant hypertension lasts for only a few minutes, its effects persist; it may produce both pulmonary capillary damage, as a result of shifting of a large portion of the blood volume into the pulmonary circulation, and left ventricular dysfunction. Overzealous fluid therapy to treat the patient's initial hypotension may lead to acute pulmonary edema when the sympathetic activity returns approximately 3 to 5 days after the injury.

Paradoxical respiration in the quadriplegic patient results from partial chest wall collapse during inspiration; it may produce limitation of the tidal volume and an increased risk of hypoventilation. The situation is aggravated when the patient is in an upright position. The diaphragm cannot maintain its normal domed shape, which is the only way it can contract efficiently, because the weight of the thoracic contents is not opposed by the normal tone of the abdominal muscles. Thus, in contrast to other diseases that produce respiratory insufficiency, the supine position improves respiration in persons with quadriplegia.[151]

Other causes of inadequate respiration in the early phase of spinal cord injury are aspiration of gastric contents, atelectasis, pneumonia, and bronchoconstriction. Management includes careful observation of the patient's breathing and preparation to ventilate the lungs and intubate the trachea at the first sign of respiratory depression.[151]

Severe bradycardia or dysrhythmias may result from unopposed vagal activity during tracheal intubation or suctioning: the patient must be preoxygenated, and atropine (0.4 to 0.6 mg) should be given before any instrumentation. If bradycardia develops during airway management, treatment includes additional atropine, glycopyrrolate, isoproterenol, or, if necessary, cardiac pacing.

Hemodynamic Management

Hemodynamic management of quadriplegic patients includes a complete assessment, with a pulmonary artery catheter, if necessary, as early as possible after injury. In as many as 25% of patients with cervical spinal cord injuries, left ventricular dysfunction may contribute to the hypotension.[153] Decreased preload can be treated with fluid infusion using cardiac function curves as a guide. In general, volume may be safely replaced to a central venous or pulmonary capillary wedge pressure (PCWP) of 18 mm Hg.[153] This avoids, or at least limits, the severity of the pulmonary edema described previously. Hypotension despite adequate fluid infusion, acidosis, or low mixed venous PO_2 requires treatment with inotropes such as dopamine.

Anesthetic Considerations

Any anesthetic technique compatible with the patient's general condition is satisfactory for the patient with spinal cord injury. Hypotension is common during anesthesia in quadriplegics. Placement of a central venous or pulmonary artery catheter may facilitate management of the patient's volume and blood pressure status.

Succinylcholine may produce a sudden, severe increase in serum K^+ in patients with spine injury. Levels as high as 14 mEq/L may be reached; the result may be irreversible ventricular dysrhythmias and cardiac arrest. Although succinylcholine is probably safe during the first week after injury, it is probably best to avoid it altogether in the paraplegic patient and to use rapid-onset nondepolarizing agents such as rocuronium when a rapid-sequence induction is required.

Neck Injury

Both penetrating and blunt trauma may injure the major structures in the neck: vessels, respiratory and digestive tracts, and nervous system. Hemorrhage, asphyxia, mediastinitis, paralysis, stroke, or death may result if these injuries are not promptly recognized and treated.

8 Penetrating neck injuries usually present with obvious clinical manifestations; blunt cervical trauma may be more subtle. Airway compromise or obstruction, brisk bleeding from the

wound site, an expanding pulsatile hematoma, and shock with or without external bleeding are obvious signs of cervical

vascular injury, and dictate immediate airway management and vascular control. Decreased or absent upper-extremity or distal carotid pulses, as well as carotid bruit or thrill, are pathognomonic for cervical arterial injury; however, these often do not require immediate surgery. Hemothorax, pneumothorax, and signs of air embolism are also suggestive. Respiratory distress, cyanosis, or stridor are obvious signs of airway injury and require immediate tracheal intubation. Other signs that strongly suggest airway injury are dysphonia, hoarseness, cough, hemoptysis, air bubbling from the wound, subcutaneous crepitus, laryngeal tenderness, pneumothorax, and hemothorax. Because of their dynamic nature, cervical airway injuries may rapidly progress to obstruction; the patient therefore should be observed carefully and the trachea intubated at the first sign of problems.

Esophageal injuries, whether in the neck or the chest, are insidious and difficult to diagnose. Dysphagia, odynophagia, hematemesis, subcutaneous crepitus, prevertebral air on a lateral cervical radiograph, and major concomitant injuries to other cervical structures suggest an esophageal injury and call for confirmation with an esophagram.

The neurologic manifestations of a penetrating neck injury vary depending on the injured structure. Partial spinal cord transection produces the Brown-Sequard syndrome with ipsilateral motor and contralateral sensory deficit below the injury. Complete spinal cord transection, depending on the level of injury, produces paraplegia or quadriplegia, usually with neurogenic shock. Occasionally, luminal occlusion of the carotid and vertebral arteries may lead to a hemispheric cerebrovascular accident; associated hypotension increases the likelihood of this event.

Patients with severe active bleeding, persistent hypotension, and air bubbling through the wound require immediate surgery without further diagnostic studies.[154] Controversy exists over the indications for surgical management of stable penetrating neck injuries. Mandatory exploration is associated with negative findings in approximately 70% of patients.[154] Thus, in many centers, patients are evaluated with noninvasive diagnostic tests and undergo surgery only when there are positive findings.[154]

Blunt cervical vascular injuries usually present with a hematoma that may compress the cervical veins, displace the airway, and produce pharyngeal and laryngeal congestion. Injury to an artery may produce an intimal tear, pseudoaneurysm, fistula, or thrombosis.[155] If a carotid or vertebral artery is involved, cerebral ischemia may occur. Often thrombosis develops gradually over minutes to a few hours, therefore, the appearance of neurologic symptoms is delayed in approximately 40% of patients.[155] Symptomatic patients may present with a cervical bruit, altered mental status, or lateralizing neurologic deficits including hemiparesis, transient ischemic attacks, amaurosis fugax, or Horner's syndrome. The mortality rate associated with blunt carotid injury varies between 15 and 28%, and 15 to 50% of survivors have neurologic deficits.[155,156] Identification of a blunt carotid injury in an asymptomatic patient using CT, magnetic resonance angiography, or four-vessel arteriography not only allows early institution of antiplatelet therapy, systemic anticoagulation, endovascular intervention, or surgical repair,[156,157] but also occasionally prevents the neurologic deficits that may follow surgery for associated injuries in an unprotected patient.

Airway injuries after blunt trauma are rare, but carry an overall mortality rate of 2%.[158] Their severity varies from a simple mucosal tear or hematoma to a comminuted laryngeal cartilage fracture or complete cricotracheal separation. They frequently require primary laryngeal repair or tracheostomy. Anesthetic management is not only complicated by relatively complex airway management problems[41,42,43] (discussed in the Airway Evaluation and Intervention section), but also with associated skull base, intracranial, open neck, cervical spine, esophageal, or pharyngeal injuries.[158]

Chest Injury

Although a high percentage of thoracic injuries can be treated conservatively, patients who need

surgery may have major intraoperative physiologic disturbances.

Chest Wall Injury

Rib fractures may produce pneumothorax or hemothorax, and both the frequency and severity of visceral injuries increase as the number of fractured ribs increases. Patients with three or more fractured ribs have a greater likelihood of hepatic and splenic injury, a higher mortality rate, a higher injury severity score, and longer intensive care unit (ICU) and hospital stays than those with fewer rib fractures.[159] Patients with lower rib fractures may have an underlying spleen or liver injury. Because of the large amount of energy required to fracture the first rib in its protected location, injury to this bone indicates severe underlying trauma, commonly to the aorta, the subclavian vessels, the heart, or the abdominal viscera, but also to the maxillofacial complex, the brain, or the spinal cord.[160] Scapular fractures also suggest severe injuries in other locations, especially the heart and lungs.[161] Sternal fractures are mainly encountered in elderly motor vehicle occupants wearing seat belts; they are usually not associated with serious trauma to the thoracic or abdominal viscera.[162]

The management principles for these injuries are similar to those previously described for flail chest, although the need for mechanical ventilation is less likely in single rib fractures than in a flail chest. Effective pain relief, preferably with continuous thoracic epidural anesthetics or opioids, is central to management.[48]

Pleural Injury

Closed pneumothorax most commonly develops as a result of lung puncture by a displaced rib fracture after blunt trauma, or by missile injuries or stab wounds. The presence of subcutaneous emphysema suggests coexisting pneumothorax, although this finding alone is not an indication for chest tube placement because it may be the result of other injuries. Tension pneumothorax involving >50% of a hemithorax presents with dyspnea, tachycardia, cyanosis, agitation, diaphoresis, neck vein distention, tracheal deviation, and displacement of the maximal cardiac impulse to the contralateral side.

The plain chest radiograph, routinely obtained during initial evaluation of all trauma victims, is essential for diagnosis. Although an upright film provides the best opportunity for detection of pneumothorax, this position may be impossible or contraindicated in patients who are experiencing major hemorrhage or those with suspected spine injury. Air in the pleural space tends to accumulate anteriorly in supine or semirecumbent patients, often in the anteromedial sulcus.[163] More recently, transthoracic ultrasound has been used for the diagnosis of pneumothorax. Normally, movement of the lung beneath the chest wall produces "comet tail" artifacts from echodense areas on the lung surface.[164] In the presence of pneumothorax, neither lung motion nor comet tails can be seen.[164] In a more recent study of blunt and penetrating trauma victims, ultrasound was more sensitive than a supine chest film, but did not detect all pneumothoraces. Further, ultrasound detection of rib and sternal fractures also appeared to be more accurate than the chest radiograph.[165] It was recommended that a chest film and the ultrasound can complement each other, but that chest CT be used as the definitive test.[166]

Brasel et al[167] suggested that a small closed pneumothorax can be safely managed by observation alone, without a chest tube, even in those patients who require positive-pressure ventilation, as long as continuing vigilance is maintained. However, based on an earlier study[168] and our own experience, we strongly believe that once diagnosed, a traumatic pneumothorax, no matter how small, should be treated with thoracostomy drainage before tracheal intubation and positive-pressure ventilation.

Bleeding intercostal vessels are responsible for most hemothoraces. Severe airway deviation may be produced by a hemothorax, although it is not as common as it is after a pneumothorax. Treatment consists of drainage with a 30 to 40F chest tube (26 to 32F is used for pneumothorax). Initial drainage of 1,000 mL of blood, or collection of >200 mL/hr for several hours, is an indication for thoracotomy. Additional indications for thoracotomy are a "white lung" appearance

on the anteroposterior chest radiograph; a continuous major air leak from the chest tube, which may result from a direct airway injury or major lung laceration; and evidence of pericardial tamponade. Hemodynamically stable patients with persistent bleeding of <150 mL · hr^{-1} are managed with video-assisted thoracoscopic surgery (VATS) to control bleeding.[169] This procedure requires placement of a double-lumen tube to collapse the lung on the involved side; it can also be useful in diagnosis of suspected diaphragmatic, cardiac, or mediastinal injuries; evaluation of some bronchopleural fistulas; and evacuation of clotted blood or an empyema that does not drain with a chest tube.[169] Use of VATS decreases the need for open thoracotomy and the number of negative explorations in trauma patients.[170]

Pulmonary Contusion

This entity often accompanies chest wall injury, but may also develop in isolation. Its management is discussed in the section on flail chest.

Penetrating Cardiac Injury

Pericardial tamponade, cardiac chamber perforation, and fistula formation between the cardiac chambers and the great vessels are the consequences of this type of trauma. Any penetrating wound of the chest, especially one within the "cardiac window" (midclavicular lines laterally, clavicles superiorly, and costal margins inferiorly), can cause this injury. Pneumopericardium visible on a plain chest radiograph after penetrating chest trauma should increase the suspicion, although it is not seen in all patients. Unstable patients require immediate sternotomy or left thoracotomy. Transthoracic echocardiography (TTE) can be used for screening stable patients,[171] but it may be inconclusive in obese patients and in those with pneumothorax; TEE provides an accurate diagnosis in these patients.[172] Of the alternative diagnostic measures, the central venous pressure (CVP) is not always accurate, and a subxiphoid pericardial window is invasive, must be performed in the OR under general anesthesia, takes longer, and cannot detect an intracardiac shunt.

Pericardial Tamponade

The classic findings of pericardial tamponade—tachycardia, hypotension, distant heart sounds, distended neck veins, pulsus paradoxus, or pulsus alternans—are difficult to appreciate or may be absent in a hypovolemic trauma patient. TTE or TEE can demonstrate blood in the pericardial sac and the presence of ventricular "diastolic collapse," which indicates at least a 20% reduction in cardiac output. Initial management consists of intravenous fluids and, if necessary, careful selection and titration of anesthetic agents, such as ketamine and etomidate, which produce relatively little myocardial depression. Evacuation of the pericardial blood by pericardiocentesis or surgery should be performed as soon as possible.

Blunt Cardiac Injury

10 This term has replaced "myocardial contusion" and encompasses varying degrees of myocardial damage; coronary artery injury; and rupture of the cardiac free wall, septum, or a valve following blunt trauma.[173] Myocardial injury consists of myofibrillar disintegration, edema, bleeding, or necrosis that, depending on its severity, presents as minor electrocardiogram (ECG) or enzyme abnormalities, complex arrhythmias, or cardiac failure caused by direct mechanical impact or indirectly by coronary occlusion. Arrhythmias last no more than a few days; ventricular wall motion abnormalities may persist for up to 1 year, but any increased risk of perioperative cardiac complications appears to last for no more than a month.

The prominent clinical findings are angina, sometimes responding to nitroglycerine, dyspnea, chest wall ecchymosis and/or fractures; dysrhythmias of any type; and right-sided or left-sided congestive heart failure. Orliaguet et al[173] proposed an algorithm for the diagnosis and treatment of several clinical scenarios caused by this injury (Fig. 48-3). The diagnosis is based on the 12-lead ECG, troponin I level, and echocardiography. The ECG is very sensitive, although not specific. A normal trace cannot rule out the diagnosis, but it is the best screening test. Common ECG

abnormalities include almost any type of arrhythmia, ST or T-wave changes, and conduction delays. Patients with a normal ECG undergoing minor surgery do not require any further testing. Patients with severe injuries need measurement of troponin I and TEE to diagnose any abnormalities caused by the cardiac injury (see Fig. 48-3). Troponin I has replaced serum creatine kinase and its MB fraction (CK-MB) because of its greater specificity for cardiac muscle damage. Echocardiography can demonstrate wall motion abnormalities, valve malfunction, hemopericardium, intracardiac thrombi, venous or systemic embolism, and end-diastolic and fractional ventricular wall area changes. It thus aids not only in the diagnosis of blunt cardiac injury, but also in

hemodynamic management. Treatment options depend on the diagnosis (see Fig. 48-3). They include antiarrhythmic agents, inotropes, fluid loading, HFJV to optimize cardiac function, and surgery for hemopericardium, valvular, or septal lesions, or coronary artery injury or disease.

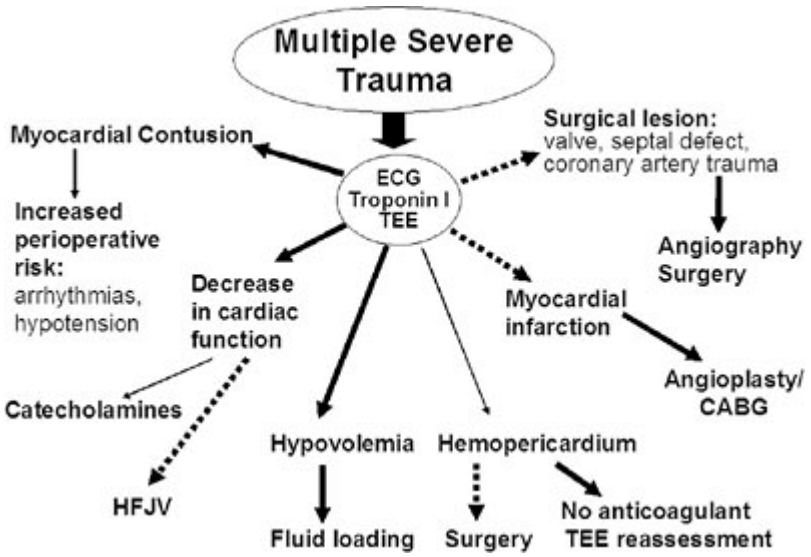

FIGURE 48-3. Algorithm for management of various clinical scenarios produced by severe blunt cardiac injury (BCI). Evaluation of severe multiple trauma induced BCI uses electrocardiogram (ECG), troponin I, and transesophageal echocardiography (TEE). *Arrows* represent the frequency of occurrence of each scenario and the frequency of management measures. *Thick arrows* represent high frequency, *thin arrows* low frequency, and *dotted arrows* very rare occurrences. CABG, coronary artery bypass graft; HFJV, high-frequency jet ventilation. (Adapted with permission from Orliaguet G, Ferjani M, Riou B: The heart in blunt trauma. Anesthesiology 95:544, 2001.)

Thoracic Aortic Injury

This injury occurs at the isthmus—the junction between the free and fixed portions of the descending aorta—in 90% of cases, and carries an 80% incidence of mortality in the first hour following injury. There may be no clinical findings in the emergency department (Table 48-6). Only 20 to 30% of patients with mediastinal widening actually have this injury, although the negative predictive value of the test is 98%.[174] Measuring the left mediastinal width ($\geqslant$6 cm) and its fraction of the total mediastinal width ($\geqslant$0.6) may increase the specificity and positive predictive value of the plain film.[175]

TABLE 48-6 Common Clinical, Radiographic, and Ultrasound Features of Thoracic Aortic Injuries

·CLINICAL	·RADIOGRAPHIC	·SPIRAL COMPUTED TOMOGRAPHY	·ULTRASOUND
Increased arterial pressure and pulse amplitude in upper extremities Decreased arterial pressure and pulse amplitude in lower extremities Absent or weak left radial artery pulse Osler's sign: discrepancy between left and right arm blood pressure Retrosternal or interscapular pain Hoarseness Systolic flow murmur over the precordium or medial to the left scapula Neurologic deficits in the lower extremities	Widened mediastinum Blurring of the aortic contours Widened paraspinal interfaces Opacified pulmonary window Broadened paratracheal stripe Displacement of the left main-stem bronchus Rightward deviation of the esophagus and trachea Left hemothorax Sternal and/or upper rib fractures	Mediastinal hematoma Aortic wall irregularity Intimal flap False aneurysm Pseudocoarctation Intramural hematoma Intraluminal clot or medial flap	Intimal flap Turbulent flow Dilated aortic isthmus Acute false aneurysm Intraluminal medial flap Hemothorax Hemomediastinum

More recent advances in contrast-enhanced spiral CT and ultrasound technologies permit reliable noninvasive diagnosis and have substantially decreased the need for biplanar aortography. Both CT and TEE are equally capable of diagnosing subadventitial aortic injuries that require surgical intervention.[176] CT is more likely to be used for diagnosis because introducing a TEE probe in an awake patient may be undesirable. Lesions of the intima and media that can be treated conservatively, and concomitant blunt cardiac injuries are much more likely to be detectable by TEE than CT.[176] Intraoperative TEE is especially useful for the anesthesiologist when other injuries require immediate surgery without time for CT examination of the chest. Aortography remains the examination of choice when the noninvasive studies are contraindicated or provide equivocal results. It also can demonstrate injuries to the branches of the aorta, which TEE cannot detect.[176]

Surgical prioritization when multiple injuries are present depends on the hemodynamic and neurologic status of the patient. Although the aorta should be repaired as early as possible, control of active hemorrhage from other sites and surgery for intracranial hematomas have a higher surgical priority, unless the aorta is leaking.[177] In most instances, a blood clot between the aorta and the mediastinal pleura occludes the vessel. Any disturbance of the tamponaded region

may reinitiate bleeding. A rapid flow of blood in a large artery tends to pull its endothelium with it and thus may rupture an injured vessel that is sealed with a clot or a hematoma. Such an increase in the aortic blood flow is usually caused by increased myocardial contractility; every effort should be made to prevent increased cardiac contractility and hypertension. Endovascular stent grafts have more recently been used in some centers for repair of thoracic aortic injuries, with an apparently reduced risk of paraplegia and the complications associated with thoracotomy.[178]

Diaphragmatic Injury

Injury to the diaphragm may permit migration of abdominal contents into the chest where they may compress the lung, producing abnormalities of gas exchange, or the heart, resulting in dysrhythmias and/or hypotension. Because the defect produced by blunt injury is larger than that resulting from a penetrating injury, migration of abdominal contents, which requires a defect of at least 6 cm in diameter, is also more common after blunt trauma.[179] The liver protects the right side of the diaphragm, thus traumatic herniation is more common on the left side.[179]

The best method of diagnosing a diaphragmatic hernia is laparoscopy, or in selected cases, VATS. Nevertheless, noting that the end of a nasogastric tube is above the diaphragm on the chest radiograph is a certain sign that the stomach is displaced into the chest. A chest radiograph that shows intestinal markings and lung compression, or a contrast-enhanced abdominal CT scan that includes the lower third of the thorax, also provide important information.[180] Failure to retrieve the instilled fluid during diagnostic peritoneal lavage (DPL) or drainage of DPL fluid from a thoracostomy tube also indicates this injury.[180]

Abdominal and Pelvic Injuries

Table 48-7 summarizes the strengths and weaknesses of the currently available diagnostic tools used for abdominal injuries.[181] Because of the unpredictable course of bullets in the body, exploratory laparotomy or, in selected cases, laparoscopy is required after any gunshot wound of the abdomen. Stab wounds may be managed with tractotomy to determine whether the peritoneum is involved. Laparoscopy, laparotomy, or DPL may be indicated after a positive tractotomy. In some hemodynamically stable patients, abdominal and flank gunshot
