It is a time-honored concept that the neck is responsible for much headache. Unfortunately, as with much of history, the good story is often ruined by the facts. While there is little doubt that there is a rich overlap between the innervation of intracranial pain-producing structures by the ophthalmic division of the trigeminal nerve and the posterior fossa and high cervical innervation by branches especially of the C_2 dorsal root,[92] causality is another issue. The Headache Classification Committee recognizes that head pain can arise from the neck and labels this cervicogenic headache.[6] The term has been used by others to define a syndrome[93] that is so poorly described as to be useless in practice.[94] Most patients with neck discomfort and headache referred to specialty practice have migraine. They will have neck stiffness or discomfort as a premonitory symptom that can clearly persist in all stages of the attack.[95] They may respond to local therapies, such as greater occipital nerve injection;[96] however, this implies no more than triggering, and is to be expected. The pursuit of neck pathology and the treatment of patients who have migraine by manipulative or physical means has no support in the controlled literature, and is rarely of long-lasting value. This not to say that the patient with clear neck pathology and pain does not exist; they do, and are very well treated by therapy aimed at the responsible neck pathology.

CHAPTER 62 ■ NONCARDIAC CHEST PAIN

RONNIE FASS

INTRODUCTION

Noncardiac chest pain (NCCP) is defined as recurring angina-like retrosternal chest pain of noncardiac origin. A patient's history and characteristics do not reliably distinguish between cardiac and esophageal causes of chest pain.[1] This is compounded by the fact that patients with a history of coronary artery disease (CAD) may also experience chest pain of noncardiac origin. The heightened awareness about the potentially devastating ramifications of chest pain may drive patients to seek medical attention despite a negative cardiac workup.[2] Furthermore, almost half of NCCP patients are not convinced by their negative cardiac diagnosis, and reassurance alone has proved to be an ungratifying therapeutic strategy.[3] Compared to patients with cardiac angina, those with NCCP are usually younger, less likely to have typical symptoms, and more likely to have a normal resting electrocardiogram.[4] Additionally, levels of anxiety of NCCP patients seen in a rapid access chest pain clinic significantly exceeded those of patients with cardiac angina and remained above community norms for at least 2 months after clinic visit.[5] NCCP patients view their condition as significantly less controllable and less understandable than those whose pain is of cardiac origin.[5]

NCCP may be the manifestation of nongastrointestinal (GI) or GI-related disorders (Fig. 62.1). An important step toward understanding of the underlying mechanisms of NCCP was the recognition that gastroesophageal reflux disease (GERD) is the most common contributing factor for chest pain. While chest pain has been considered an atypical manifestation of GERD, it is an integral part of the limited repertoire of esophageal symptoms. In patients with non–GERD-related NCCP, esophageal motility disorders and functional chest pain of presumed esophageal origin are the main underlying mechanism for symptoms. The Rome III Committee uses the term "functional chest pain of presumed esophageal origin" to describe recurrent episodes of substernal chest pain of visceral quality with no apparent explanation (Table 62.1). As with all other functional esophageal disorders, GERD and esophageal dysmotility should also be ruled out before the diagnosis is established.[6]

Up to 20% of the patients with functional chest pain exhibit other functional disorders, primarily irritable bowel syndrome (27%) and abdominal bloating (22%).[7] The mechanisms responsible for functional chest pain include abnormal mechanophysical properties of the esophagus, central and peripheral hypersensitivity, and psychological comorbidity (Table 62.2). The latter may include depression, anxiety, and somatization.

EPIDEMIOLOGY

Information about the epidemiology of NCCP in the United States and around the world is relatively scarce. The mean annual

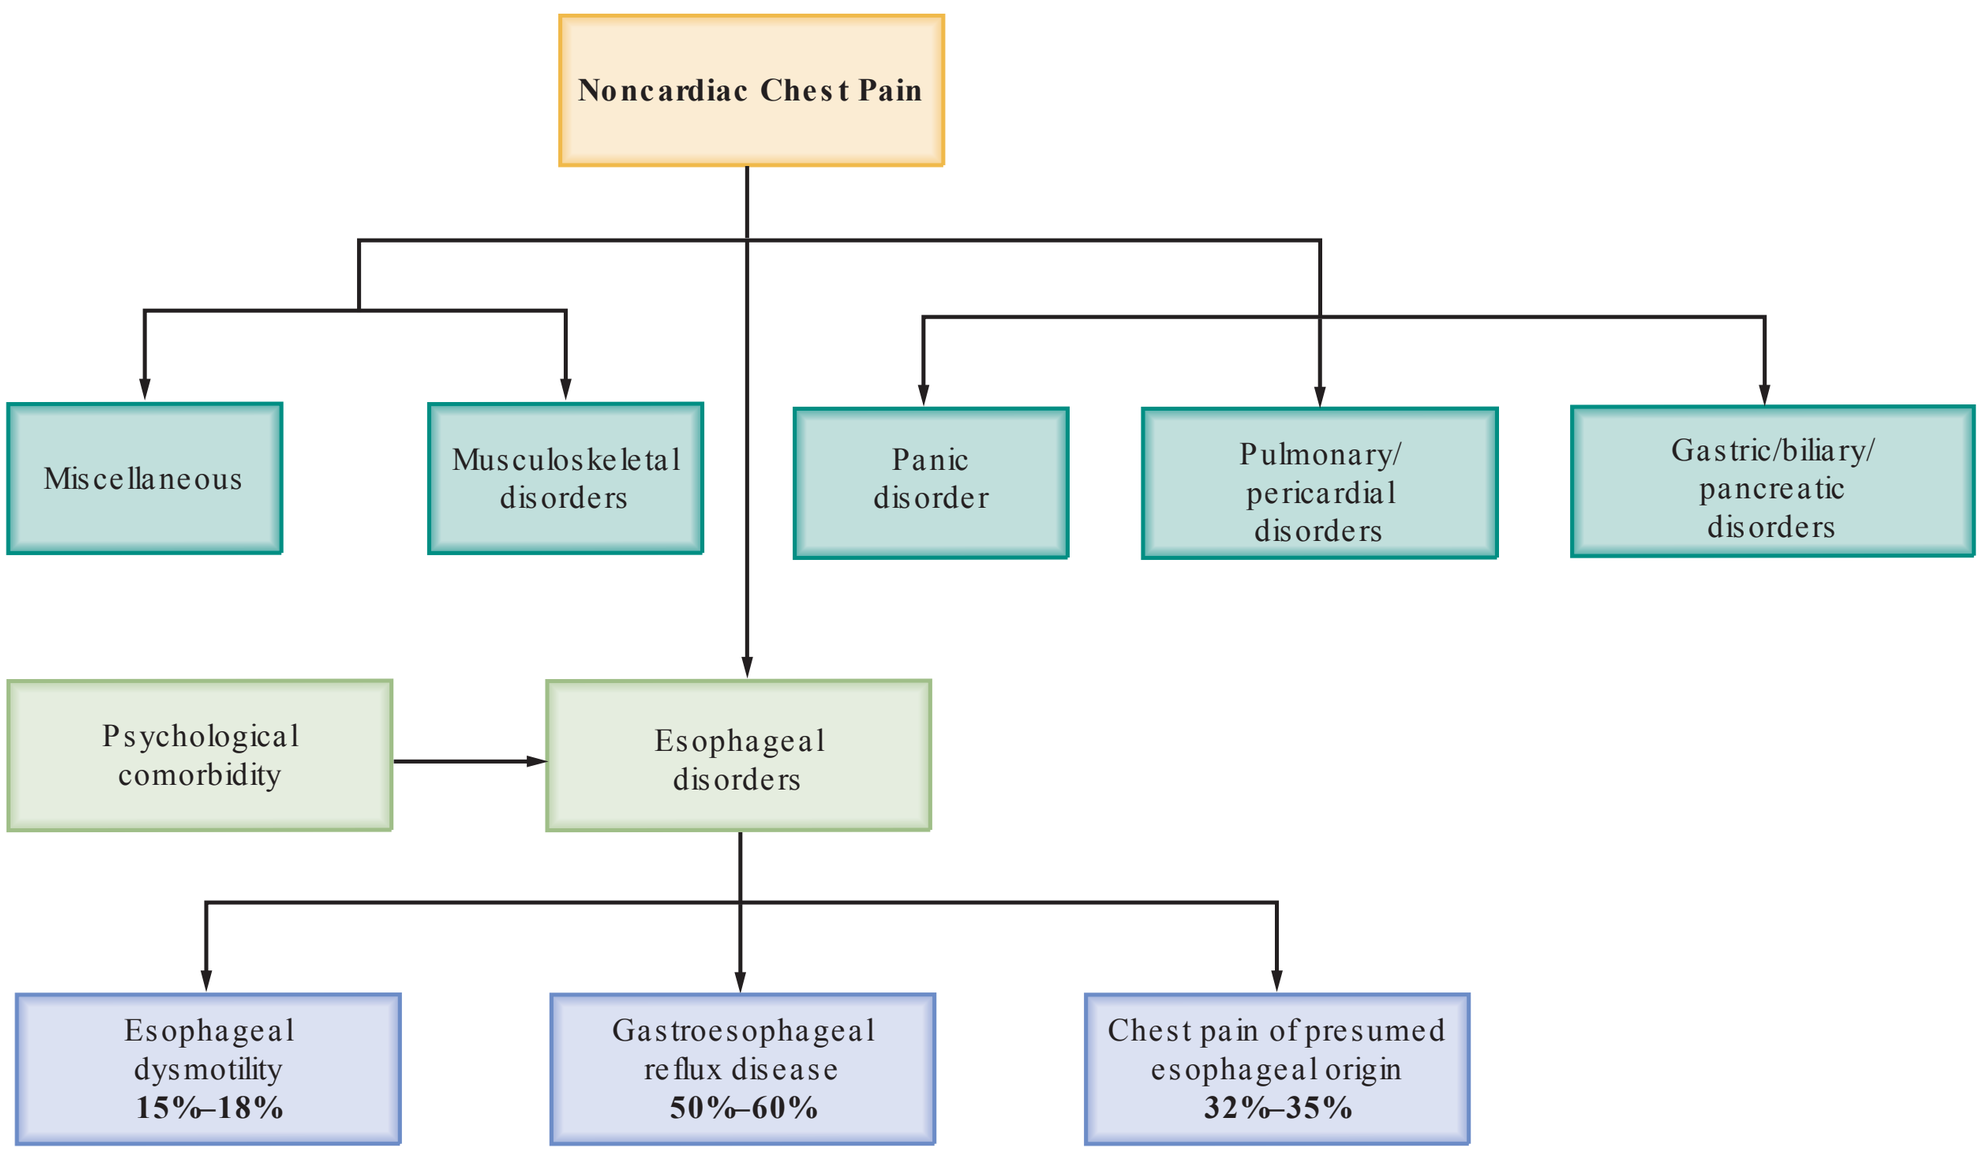

FIGURE 62.1 The different underlying mechanisms of NCCP.

TABLE 62.1

ROME III DIAGNOSTIC CRITERIA FOR FUNCTIONAL CHEST PAIN OF PRESUMED ESOPHAGEAL ORIGIN

Must include all of the following:
- Midline chest pain or discomfort that is not of burning quality
- Absence of evidence that gastroesophageal reflux is the cause of the symptom
- Absence of histopathology-based esophageal motility disorders

Criteria fulfilled for the last 3 months with symptoms onset at least 6 months prior to diagnosis.

TABLE 62.2

THE MAIN DIFFERENT PROPOSED UNDERLYING MECHANISMS OF FUNCTIONAL CHEST PAIN OF PRESUMED ESOPHAGEAL ORIGIN

- Abnormal mechanophysical properties
  - Hyperactive
  - ↓Compliance
- Visceral hypersensitivity
  - Peripheral and central sensitization
  - Altered central processing of visceral stimuli (altered autonomic activity)
- Psychological abnormalities
  - Panic attack
  - Anxiety
  - Depression

prevalence of NCCP in the general population is approximately 25%, making NCCP the most common atypical/extraesophageal manifestation of GERD. A recent nationwide population-based study from South America[8] found that the annual prevalence of NCCP was 23.5% and that NCCP has been equally reported by both genders. In this study, frequent typical GERD symptoms (at least once a week) were significantly and independently associated with NCCP. Another recent published epidemiological study demonstrated that the annual prevalence of NCCP in a Chinese population was 19%.[9]

Whilst females with NCCP tend to consult health care providers more often than men, the disorder affects both genders equally.[10] Additionally, females are more likely to present to hospital emergency departments with NCCP than males. However, there are no gender differences regarding chest pain intensity, although women tend to use terms like "burning" and "frightening" more often than men.[11]

Epidemiological studies report a decrease in the prevalence of NCCP with increasing age. Women under 25 years of age and those between 45 and 55 years of age have the highest prevalence rates.[12] Patients with NCCP are younger, consume greater amounts of alcohol, smoke more, and are more likely to suffer from anxiety than their counterparts with ischemic heart disease. Patients with NCCP continued to seek treatment on a regular basis after the diagnosis was established for both chest pain and other unrelated symptoms, but few were in contact with hospital services.[13]

A recent U.S.-based survey revealed that cardiologists manage by themselves about half of the patients diagnosed with NCCP. Of those NCCP patients that were referred, 45.9% were sent back to the primary care physician (PCP), and only 29.3% to a gastroenterologist (Fig. 62.2).[14]

In a survey of PCPs, Wong et al.[15] demonstrated that most NCCP patients were diagnosed and treated by PCPs (79.5%), without being referred to a gastroenterologist (Fig. 62.2). The most preferred subspecialty for the initial diagnostic evaluation

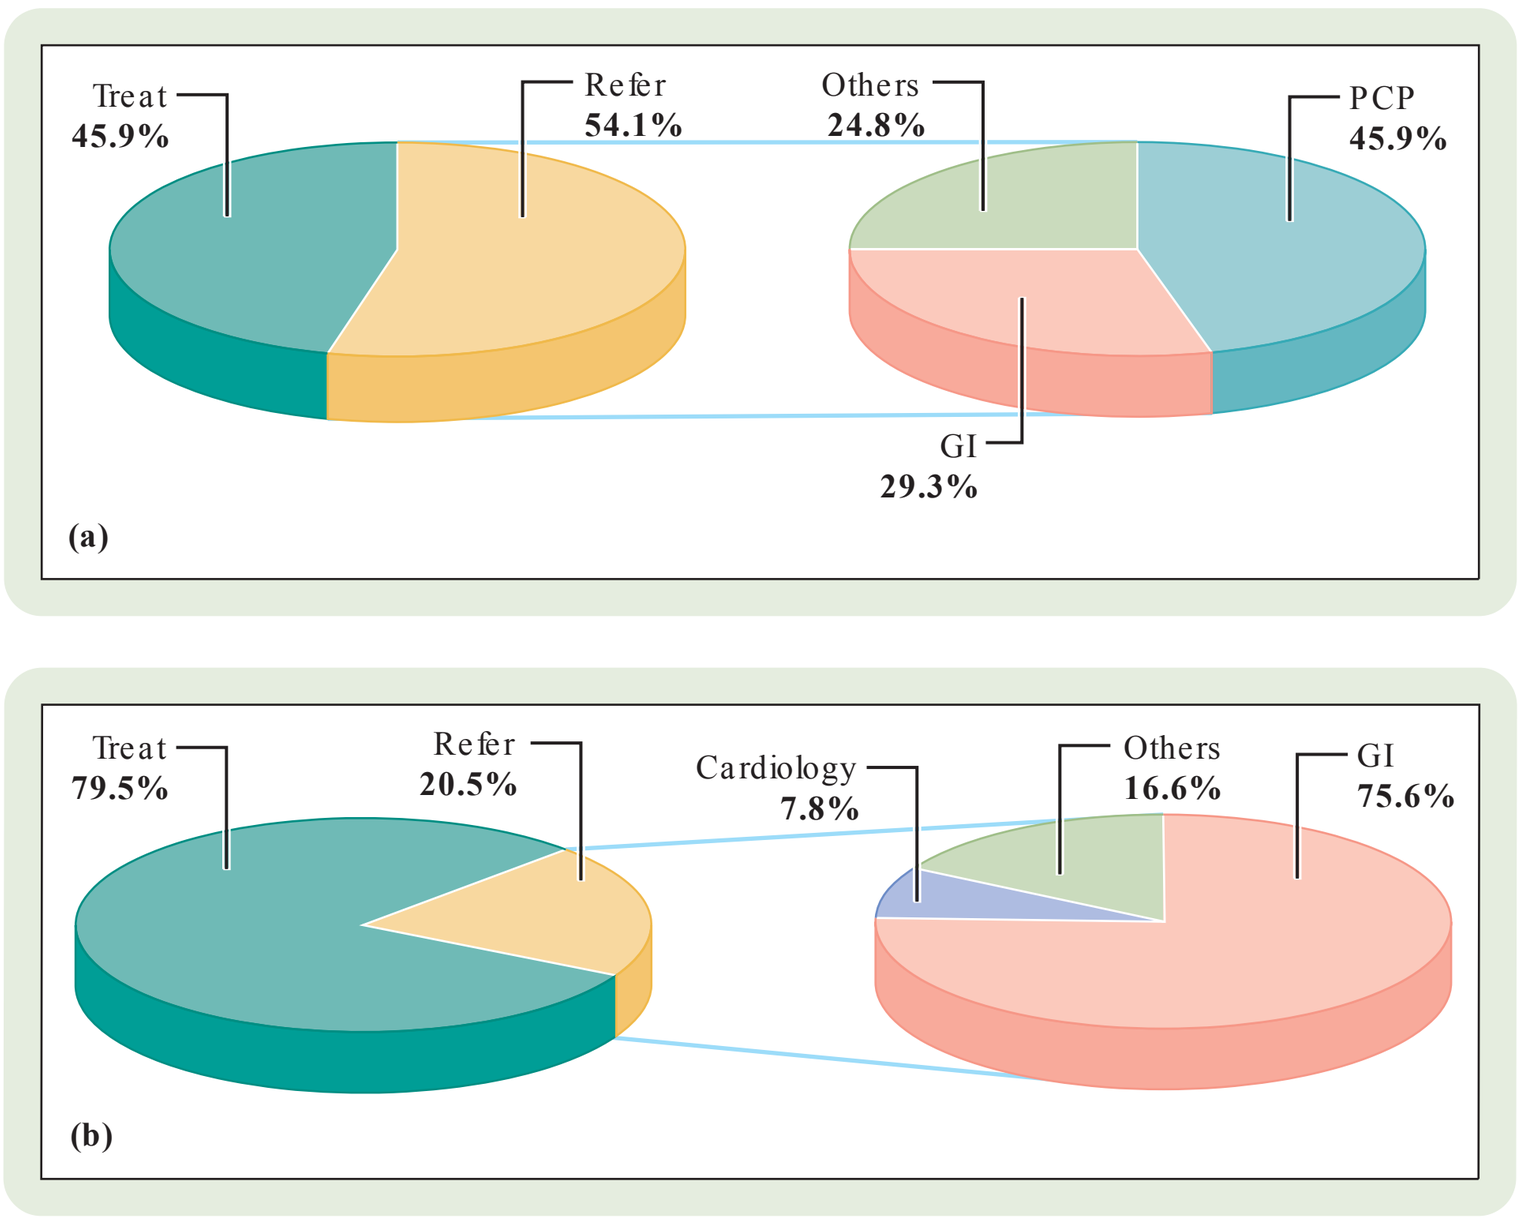

FIGURE 62.2 (A) A survey of 246 cardiologists determined that approximately half self-managed NCCP patients. (From Wong WM, Risner-Adler S, Beeler J, et al. Noncardiac chest pain: the role of the cardiologist—a national survey. *J Clin Gastroenterol* 2005;39:858–862, with permission.) **(B)** A similar survey of 205 primary care physicians demonstrated that the majority self-managed NCCP patients. (Redrawn after Wong WM, Risner-Adler S, Beeler J, et al. Noncardiac chest pain: the role of the cardiologist—a national survey. *J Clin Gastroenterol* 2005;39: 858–862.)

of a patient presenting with chest pain was cardiology (62%), followed by gastroenterology (17%). However, the mean percentage of such referrals was only 22%. The most preferred subspecialty for the further management of NCCP was gastroenterology (76%), followed by cardiology (8%). However, the mean percentage of the actual referral rate was 29.8% for gastroenterologists and 14% for cardiologists.[15] Eslick and Talley[16] assessed the types of health care professionals consulted for chest pain. In their study, the main health care professionals seen were PCPs (85%), cardiologists (74%), and gastroenterologists (30%).

NATURAL HISTORY

The long-term prognosis of NCCP patients is excellent and very few eventually succumb to CAD or other cardiovascular-related disorders. In a study that followed 46 NCCP patients over a period of 11 years, only 4.3% died from a cardiovascular-related event.[17] However, most of the NCCP patients continue to report episodes of long-term chest pain. In the previous study, 75% of the surviving NCCP patients continued to report chest pain 11 years later, and 34% reported chest pain symptoms weekly.[17] Furthermore, studies have demonstrated that many NCCP patients have long-term impaired functional status and utilize health care resources because of their chest pain.[18] In one study, the rates of work absenteeism and interruption to daily activities were 29% and 63%, respectively, over a 1-year period.[16]

PATHOPHYSIOLOGY

Gastroesophageal Reflux Disease

The most common cause of NCCP is GERD. Locke and colleagues have found that NCCP is more commonly reported by patients who experience heartburn symptoms at least weekly (37%) as compared with those who have infrequent heartburn (less than once a week) (30.7%) and those without any symptoms of GERD (7.9%).[10] In this study 5% of the individuals with NCCP reported severe or very severe heartburn symptoms.[10] In another community-based study the authors demonstrated that 53% of all patients with NCCP experience heartburn and 58% acid regurgitation.[12] Beedassy et al. evaluated 104 patients with NCCP and documented that 48% had an abnormal pH test.[19] While 52 patients reported chest pain during the pH study, only in 21% of them did the chest pain coincide with an abnormal pH test. Interestingly, only 10 of the 52 NCCP patients with chest pain during the pH test had a positive symptom index.[19] Of these 10 patients, however, 80% had an abnormal pH test indicating that patients with a positive symptom index are significantly more likely to have an abnormal pH test.[19] In contrast, Dekel et al. found that a positive symptom index is a relatively uncommon phenomenon in NCCP patients regardless if GERD was present or absent.[20] The authors pointed out that the low incidence of a positive symptom index in NCCP patients is due to a very low number of reported chest pain episodes during the pH study.

By using 24-hour esophageal pH monitoring and/or endoscopy, GERD can be demonstrated in up to 60% of all patients with NCCP.[21] However, esophageal mucosal injury is relatively uncommon in NCCP, affecting only up to 25% of the patients. The presence of an abnormal acid exposure and/or esophageal mucosal inflammation in patients with NCCP suggests an association with GERD. However, studies have shown that approximately 80% of the NCCP patients with abnormal pH test and/or endoscopy report marked improvement in their chest pain when proton pump inhibitors (PPI) are administered.[21–23]

It is still unclear why GERD leads to chest pain alone in some subjects and heartburn alone in others. Furthermore, it is not uncommon that some patients may experience both chest pain and heartburn as a result of gastroesophageal reflux. As with GERD, less than 5% of all acid reflux events are perceived by NCCP patients and, thus, result in chest pain, regardless of whether mucosal injury is present. The latter observation underscores the importance of peripheral and central factors in modulating perception of intra-esophageal stimuli, through brain–gut interactions, and thus the generation of chest pain.[24] Exposure to acid has been demonstrated to sensitize esophageal sensory afferents to subsequent mechanical stimuli, such as intra-esophageal balloon distension, raising the role of visceral hypersensitivity as an important mediating physiological mechanism.

Linked Angina

It is well known that the esophagus and the heart share similar sensory innervation and several studies have demonstrated that acidification of the distal esophagus may influence the flow of the coronary circulation.[25–27] Chauhan et al. have shown a reduction in coronary artery blood flow in response to acid perfusion into the distal esophagus in patients with syndrome X. Syndrome X is defined as typical chest pain and electrocardiographic changes suggestive of myocardial ischemia on stress test, but patent coronary arteries on angiogram.[24] The reduction in coronary blood flow was also associated with typical anginal pain, suggesting the presence of an esophagocardiac inhibitory reflex.[28] These findings were later confirmed by Rosztoczy et al. who showed a decrease in coronary artery blood flow in 19 out of 42 (45%) patients undergoing acid perfusion of the esophagus.[29]

Esophageal Dysmotility

Though often entertained as an etiology of NCCP in the absence of GERD, the role of esophageal dysmotility in NCCP is likely very limited. More than 70% of the patients with non–GERD-related NCCP have normal esophageal motility (Fig. 62.3).[29,30] Esophageal dysmotility when documented by esophageal manometry is rarely associated with reports of chest pain.[31] Studies have repeatedly shown that chest pain will often improve without any normalization of the esophageal motor disorder. Unlike GERD, in which PPIs are highly effective in alleviating symptoms, we are still devoid of pharmacological agents that can effectively treat esophageal dysmotility.[30] The latter further complicates our

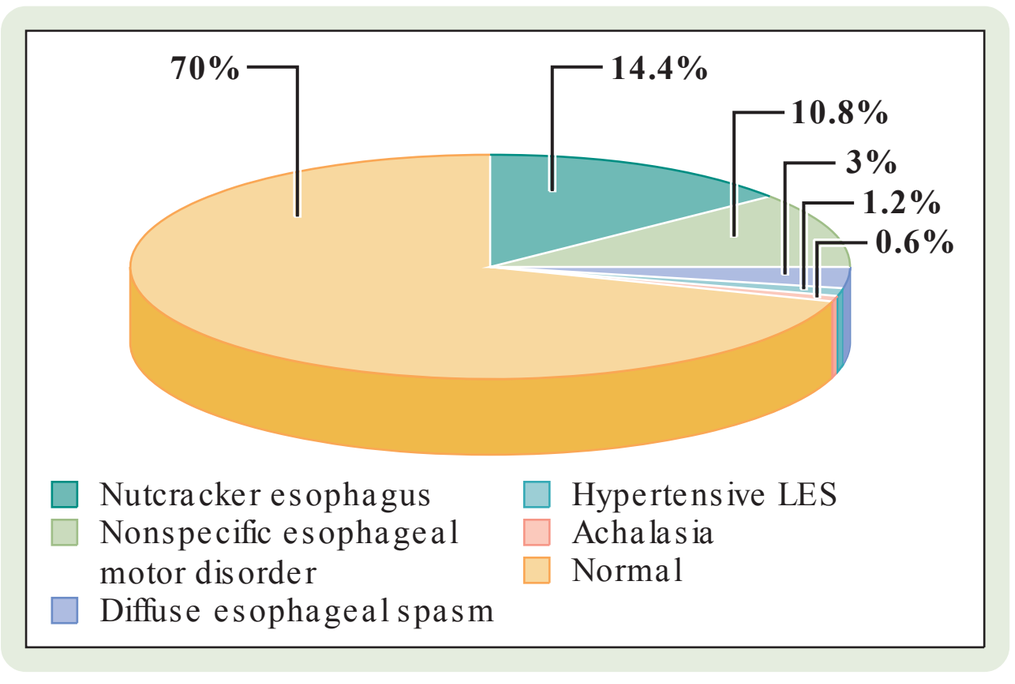

FIGURE 62.3 Distribution of esophageal motility abnormalities in NCCP patient without GERD (N = 910). (Redrawn after Katz PO, Dalton CB, Richter JE, et al. Esophageal testing of patients with noncardiac chest pain or dysphagia. Results of three years' experience with 1161 patients. *Ann Intern Med* 1987;106(4):593–597, with permission.)

ability to determine any relationship between chest pain and manometric findings. That being said, esophageal motility disorders still can be demonstrated in 30% of the patients with non–GERD-related NCCP.[30] Dekel et al. demonstrated, via the Clinical Outcomes Research Initiative Database, that hypotensive lower esophageal sphincter (LES) was the most common (61%) esophageal motor disorder found in patients with NCCP.[30] It has been suggested that this is due to an increased rate of GERD in these patients. Spastic esophageal motility disorders were shown to be the second most common cause with nutcracker esophagus affecting 10%, hypertensive LES affecting 10%, and diffuse esophageal spasm affecting 2% of the NCCP cases with esophageal dysmotility.[29] However, in another study of non–GERD-related NCCP, Katz et al. reported that nutcracker esophagus was the most common motor disorder documented during esophageal manometry followed by nonspecific esophageal motility disorders, diffuse esophageal spasm, hypertensive LES, and achalasia (Fig. 62.3).

The high prevalence of nutcracker esophagus in NCCP patients is intriguing. Nutcracker esophagus is defined manometrically as high amplitude contractions in the distal esophagus (>180 mm Hg) in the presence of a normally functioning LES. The general significance of nutcracker esophagus and specifically its role in NCCP has been an area of intense controversy.[32] Achem et al. demonstrated improvement in chest pain symptoms of patients with NCCP and nutcracker esophagus who received antireflux medical therapy.[32] In this study, esophageal manometry normalized only in a minority of the patients thus indicating that the underlying etiology of the chest pain was likely GERD rather than the nutcracker esophagus.[32] As a result of the weak correlation between documented esophageal dysmotility during manometry and chest pain, some have postulated that motility disorders serve more as a marker for a presently poorly understood esophageal abnormality which contributes to the underlying etiology of NCCP.[33] Consequently, one may argue that esophageal motor disorders, with the exception of achalasia, may have no direct etiological role in symptom generation of patients with NCCP and thus should not be pursued diagnostically or therapeutically.

Sustained Esophageal Contractions

High-frequency intraluminal ultrasonography, a technique useful for the evaluation of smooth muscle contraction, has been employed to assess the esophageal motor corollary of chest pain in NCCP patients.[34] By using high-frequency intraluminal ultrasonography, Balaban et al. have shown a close correlation between longitudinal muscle contractions and reports of chest pain.[34] When evaluating the 10 participating subjects, the authors demonstrated esophageal longitudinal muscle contractions preceding 18 of 24 spontaneous chest pain events. These muscle contractions cannot be detected by conventional esophageal pressure recordings that solely evaluate the esophageal circular muscle.[34] Balaban et al. further showed that edrophonium-induced chest pain was also preceded by sustained esophageal muscle contractions.[34] The authors also demonstrated that swallow-associated contractions of the longitudinal muscles lasted an average of 6.4 seconds whereas contractions associated with chest pain lasted a mean of 68.0 seconds.[35] Pehlivanov et al. demonstrated that the duration of the sustained esophageal muscle contractions might be correlated with the type of symptom perceived by patients. Shorter durations of these contractions were associated more with heartburn while longer durations were linked more with chest pain.[35] Furthermore, sustained esophageal muscle contractions were observed in patients who reported heartburn that was unrelated to an acid reflux event giving further credence to the hypothesis that sustained esophageal contractions are responsible for the generation of esophageal-related symptoms such as chest pain.[34] Unfortunately, high-frequency intraluminal ultrasonography is highly operator dependent and consequently may not always be an objective evaluative tool. None of the initial studies have been replicated by other investigators. While sustained esophageal muscle contractions appear to be predictable markers for chest pain, it is still unclear if they are the direct underlying mechanism or just an epiphenomenon.[36]

Visceral Hypersensitivity

The underlying mechanisms responsible for non–GERD-related NCCP remain to be fully elucidated. Numerous studies have consistently documented alteration in pain perception regardless of whether esophageal dysmotility was present or absent (Table 62.2).

Visceral hypersensitivity is a phenomenon in which the conscious perception of visceral stimulus is enhanced independent of the intensity of the stimulus.[37] Peripheral and central mechanisms have been proposed to be responsible for visceral hypersensitivity in patients with NCCP. It has been hypothesized that peripheral sensitization of esophageal sensory afferents leads to subsequently heightened responses to physiologic or pathologic stimuli of the esophageal mucosa.[37] Additionally, central sensitization at the brain level or the dorsal horn of the spinal cord may modulate afferent neural function and thus enhance perception of intraluminal stimuli.[21] What causes peripheral or central sensitization remains to be determined. Studies have shown that acute tissue irritation results in subsequent peripheral and central sensitization which is manifested as increased background activity of sensory neurons, the lowering of nociceptive thresholds, changes in stimulus response curves, and enlargements of receptive fields.[38] Peripheral sensitization involves the reduction of esophageal pain threshold and an increase in the transduction processes of primary afferent neurons.[39] Esophageal tissue injury, inflammation, spasm, or repetitive mechanical stimuli can all sensitize peripheral afferent nerves. The presence of esophageal hypersensitivity can be subsequently demonstrated long after the original stimulus is no longer present and the esophageal mucosa has healed. However, it is still unclear what factors are pivotal for the persistence of such esophageal hypersensitivity.

Several studies have demonstrated that patients with non–GERD-related NCCP have lower perception thresholds for pain. Richter et al. used balloon distension protocol in the distal esophagus and found that 50% of the patients with NCCP developed pain at volumes of 8 mL or less in comparison with 9 mL or more in healthy subjects who developed pain (Fig. 62.4).[40] The authors found no difference in the pressure-volume curve of the two groups as well as no difference in esophageal motility.[40] When the balloon was inflated to 10 mL, patients with a history of NCCP were more likely to experience pain (18/30) than the control subjects (6/30).[39] Barish et al. evaluated 50 patients with NCCP and 30 healthy volunteers using a graded balloon distension protocol.[39] Of the patients with NCCP, 56% (28/50) experienced their "typical" chest pain during balloon distension as compared with 20% (6/30) of the normal controls.[39] Of those with NCCP who experienced pain, 86% reported pain at volumes less than 80 mL.[41] There was no difference in esophageal tone between the two groups.

Rao et al. used impedance planimetry to evaluate 24 patients with NCCP and 12 healthy controls and demonstrated that during balloon distension those with NCCP had lower perception thresholds for first sensation, moderate discomfort, and pain in comparison to healthy controls.[41] Typical chest pain was reproduced in 83% of the NCCP patients.[41] In addition, the reactivity of the esophagus to balloon distension was increased in those with NCCP as was the pressure elastic modulus. Rao et al.[42] also performed graded balloon distensions of the esophagus using impedance planimetry in 16 consecutive patients with NCCP (normal esophageal evaluation) and 13 healthy control subjects.

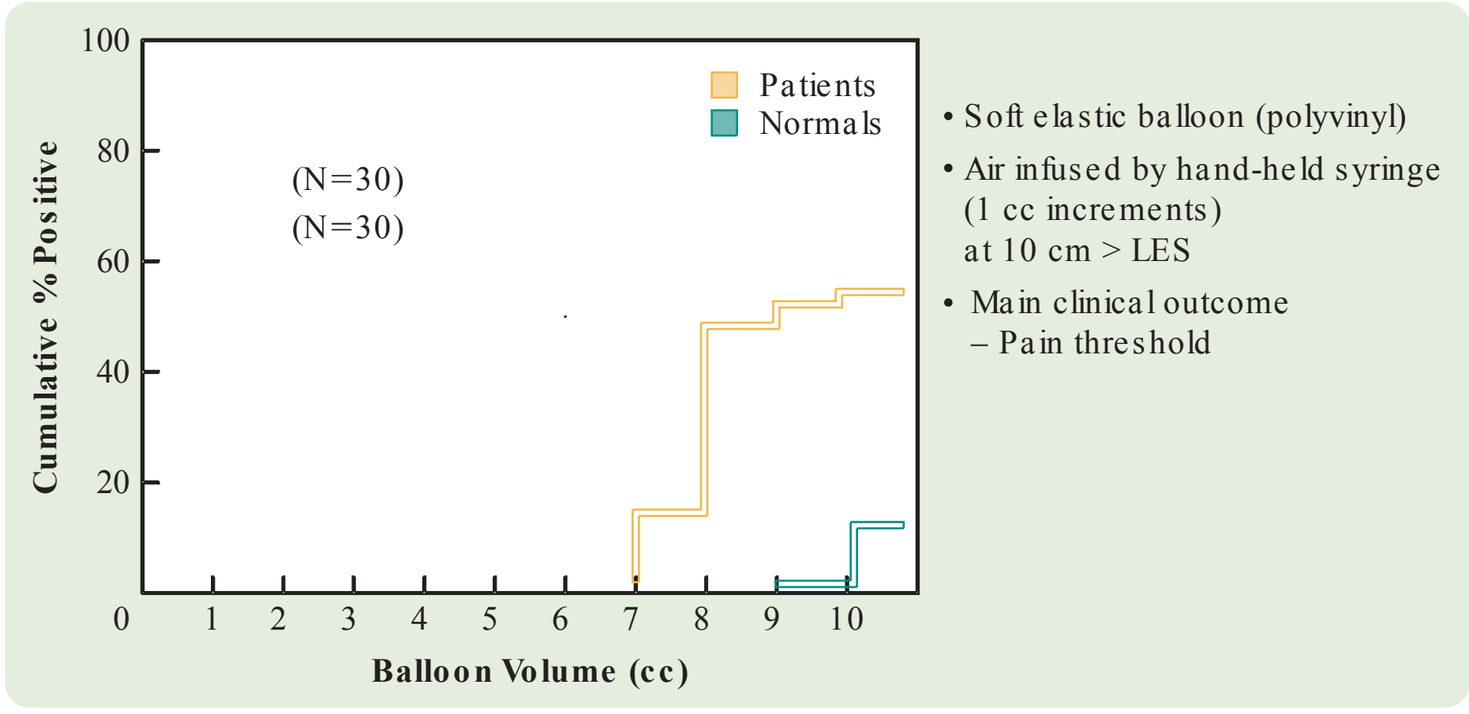

FIGURE 62.4 Pain thresholds in NCCP patients versus normal controls using a balloon distension protocol. (Redrawn after Richter JE, Barish CF, Castell DO. Abnormal sensory perception in patients with esophageal chest pain. *Gastroenterology* 1986;91(4):845–852, with permission.)

Patients who experienced chest pain during the balloon distension were subsequently restudied after receiving intravenous atropine. Balloon distensions reproduced chest pain at lower sensory thresholds than controls in most NCCP subjects. Similar findings were documented after atropine administration despite relaxed and more deformable esophageal wall. Thus, the investigators concluded that hypersensitivity, rather than motor dysfunction, is the predominant mechanism for functional chest pain (Fig. 62.5).

Sarkar et al.[43] recruited 19 healthy volunteers and 7 patients with NCCP. Hydrochloric acid was infused into the distal esophagus during a period of 30 minutes. Sensory responses to electrical stimulation were monitored within the acid-exposed distal esophagus and the nonexposed proximal esophagus both before and after infusion. In the healthy subjects, acid infusion into the distal esophagus lowered the pain threshold in the upper esophagus. Patients with NCCP already had a lower resting esophageal pain threshold than healthy subjects. After acid perfusion, their pain threshold in the proximal esophagus fell farther and for a longer duration than was the case for the healthy subjects (Fig. 62.6). Additionally, there was a decrease in the pain threshold of the anterior chest wall after acid infusion. This study demonstrated the development of secondary visceral hypersensitivity in the proximal esophagus by repeated acid exposure of the distal esophagus. The concurrent visceral and somatic pain hypersensitivity is, most likely, caused by central sensitization (increase in excitability of spinal cord and supraspinal neurons induced by activation of esophageal nociceptors in the area of the tissue injury). The patients with NCCP demonstrated both visceral hypersensitivity at the site of insult and at a distant, secondary site in the esophagus. However, it is unclear from the study what mechanism is responsible for the exaggerated secondary hypersensitivity and what initiates central sensitization in patients with NCCP. It is interesting to note that other studies[44] in NCCP, using similar human model of acute tissue irritation by acid infusion, showed no significant effect on pain thresholds.

Borjesson et al. also demonstrated that patients with NCCP have reduced sensitivity to esophageal balloon distension during simultaneous transcutaneous electrical nerve stimulation (TENS) as compared with healthy controls.[36,44] This further supports the role of visceral hypersensitivity in NCCP and suggests that the phenomenon is probably due to central sensitization.[45]

Mehta et al. also demonstrated that acid infusion into the distal esophagus reduces esophageal pain thresholds for balloon distension in patients with NCCP not previously sensitive to balloon distension or acid infusion.[46]

In one study, subjects underwent perfusion of the distal esophagus with either normal saline or 0.1N hydrochloric acid.[46] Perceptual responses to intraluminal esophageal balloon distension using an electronic barostat were recorded. Perfusion with acid was associated with a reduced sensation threshold (innocuous perception) and tended to reduce the pain threshold (aversive sensation). The study demonstrated short-term sensitization of mechanosensitive afferent pathways by transient exposure to acid. It was suggested that in patients with NCCP, acid reflux induces sensitization of the esophagus and this may subsequently alter the way in which otherwise normal esophageal distensions are perceived.[47]

Sarkar et al. evaluated 14 patients with GERD-related NCCP and 8 healthy controls. All subjects underwent an esophageal

electrical stimulation protocol in the proximal esophagus and those with NCCP demonstrated lower perception thresholds for pain than normal controls.[47] After a 6-week course of high-dose PPI (omeprazole 20 mg twice daily), however, there was an increase in the perception thresholds for pain during electrical stimulation in the group of patients with NCCP (Fig. 62.7).[47] This study demonstrated that patients with NCCP and evidence of GERD have a component of esophageal hypersensitivity that is responsive to high-dose PPI therapy.[47]

In another small study that enrolled 22 NCCP patients with documented nutcracker esophagus, the authors demonstrated that stepwise balloon distensions reproduced pain symptoms at a lower threshold in 90% of the NCCP patients as compared

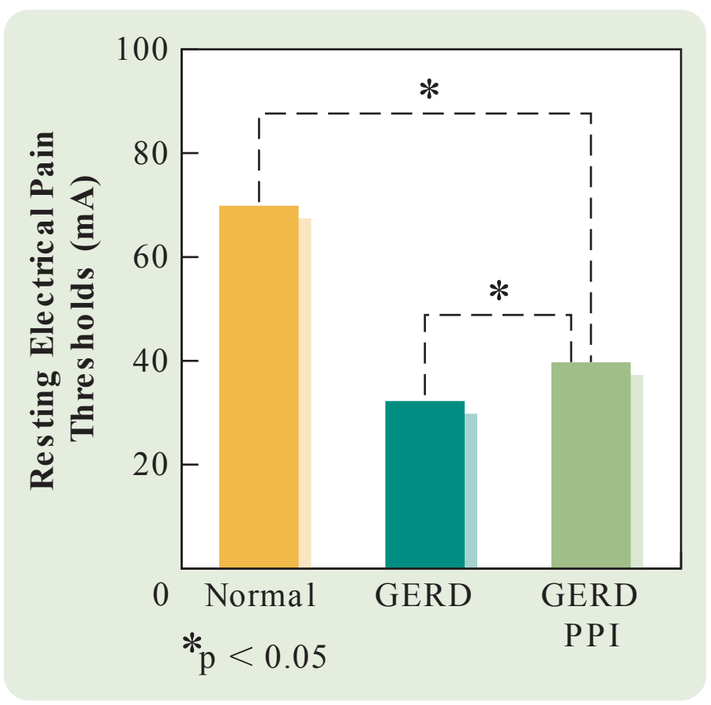

FIGURE 62.7 Patients with chest pain and occult GERD demonstrate visceral hypersensitivity that may be partially responsive to acid suppression with a PPI. (Redrawn after Sarkar S, Thompson DG, Woolf CJ, et al. Patients with chest pain and occult gastroesophageal reflux demonstrate visceral pain hypersensitivity which may be partially responsive to acid suppression. *Am J Gastroenterol* 2004;99(10):1998–2006, with permission.)

with 20% of the healthy controls.[48] It was concluded that patients with NCCP and nutcracker esophagus also exhibit visceral hypersensitivity. Additionally, the latter is the likely main underlying mechanism for patients' symptoms, rather than the presence of the high amplitude contractions (nutcracker esophagus). Unfortunately, the presence of GERD in these patients was not determined in this study.

Abnormal Cerebral Processing of Visceral Stimulation

Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have been increasingly used to evaluate brain–gut relationship in patients with esophageal disorders, primarily GERD and NCCP.

Kern et al. demonstrated, via fMRI, that slow infusion of 0.1N hydrochloric acid evokes a cerebral cortical response primarily in the posterior cingulate, parietal, and anteromesial frontal lobes prior to inducing heartburn.[49] Aziz et al., using PET scanning and a distal esophageal balloon distension protocol, examined the human brain loci involved in the process of esophageal sensation.[50] Both nonpainful and painful esophageal balloon distensions elicited bilateral activation along the central sulcus, the insular cortex, and the frontal and parietal operculum.[50] Painful esophageal balloon distensions, however, elicited an increased activation of these brain areas in addition to activation of the right anterior insular cortex (important in affective processing) and the anterior cingulate gyrus (important in pain processing and generating an affective and cognitive response to pain).[51]

During the early 1990s, investigators suggested that NCCP patients demonstrated altered central processing of intra-esophageal stimuli.[51] Investigators have used cerebral-evoked potentials as an objective measurement to assess the subjective sensation of pain of NCCP patients.[52] In response to esophageal balloon distension, evoked potential quality scores and amplitude of the major peaks increased significantly with increased sensation, both in NCCP patients and healthy controls. However, in the patients, quality score and amplitude of all four peaks of the evoked potentials were lower and latencies of two of the four peaks were longer than in the controls. The volumes of air required to produce the various sensations were lower in the patients. The investigators concluded that the results suggest that increased perception of esophageal distension in NCCP patients is caused by altered central processing of intra-esophageal events. Kamath et al. studied the effect of esophageal electrical stimulation on cortical evoked potentials in patients with NCCP. The authors demonstrated that in patients with NCCP the evoked potentials were of greater amplitude and the peak latencies were slightly longer than in controls.[37] The authors concluded that increased perception of esophageal stimulation in NCCP reflects an altered cortical processing of visceral sensation.

Hollerbach et al. studied 20 subjects (8 with NCCP, 12 healthy) and demonstrated an abnormal cerebral processing of esophageal stimuli in patients with NCCP. Cortical-evoked responses were lower in intensity during electrical esophageal stimulation in patients with NCCP in comparison to the healthy controls. Because of the smaller cortical-evoked potentials, it was hypothesized that the increased perception of esophageal stimuli might in fact be the result of enhanced cerebral processing of visceral sensory input rather than hypersensitive responses of visceral afferent pathways.[37]

Altered Autonomic Activity

Tougas et al. have performed several studies exploring autonomic nervous system function and its role in the pathogenesis of NCCP.

In one study, the investigators assessed autonomic activity, using spectral analysis of heart rate variability, before and during distal esophageal acidification of patients with NCCP and matched healthy controls.[53] Of those with NCCP, 68% developed angina-like symptoms during the esophageal acidification. These patients had a higher baseline heart rate and a lower baseline vagal activity than patients without acid sensitivity. During acid infusion, vagal cardiac outflow increased in acid-sensitive patients as compared with patients without acid sensitivity.[53] Additionally, Tougas et al. have also documented increased vagal activity in patients with NCCP during other intra-esophageal stimuli, both mechanical and electrical. These studies indicate that autonomic dysregulation may be present in at least a subset of patients with NCCP.[54] The authors further hypothesized that increased perception of esophageal stimulation may also reflect an exaggerated brainstem response. However, Tougas has hypothesized that in most cases in which both central and autonomic factors are involved, central factors will likely lead to autonomic dysregulation.[54]

Psychological Comorbidity

Studies have demonstrated that central factors, such as stress, psychological disorders, and others play an important role in enhancing perception of intraesophageal stimuli.[55] Stress has been noted to be an important factor in the generation and exacerbation of both functional and organic gastrointestinal disorders, including NCCP.[55] Certain stressful life events have been associated with the onset or symptom exacerbation of functional bowel disorders. Daily experiences of stress appear to have an important modulating effect on perception of intraluminal events and may alter perception thresholds for pain.[56]

Between 17% and 43% of the patients with NCCP are estimated to suffer from some type of psychological abnormality.[56] Psychological comorbidity can modulate esophageal perception and cause subjects to perceive low-intensity esophageal stimuli as being painful.[13,57–60] Anxiety, depression, neuroticism, and hypochondriac behavior have all been described in NCCP patients.[61–64] The findings, however, have been inconsistent when NCCP patients were compared to subjects with CAD, with some authors reporting increased anxiety and depression in NCCP patients while others reporting no significant difference between the two disorders.[65] In a recent study of 167 patients with NCCP and 32 with chest pain and CAD, there was no significant difference in the incidence of depression, anxiety, or neuroticism between the two groups.[65] The authors stated that the discrepancy of their results with previous findings might be secondary to different inclusion criteria or an overall low prevalence of current major depression.[65] The study also did find that panic disorder was more common in NCCP patients (41%) as compared to those with CAD.[66]

Among all esophageal symptoms, chest pain was shown to closely correlate with psychometric abnormalities. In some patients, chest pain is part of a host of symptoms that characterize panic attack.[66] Panic attack is a common cause for emergency room visits due to chest pain. In a large study that encompassed 441 consecutive ambulatory patients presenting with chest pain to the emergency department of a heart center, 25% were diagnosed as suffering from a panic attack.[67] While the reason for the observed association between NCCP and panic disorder remained to be fully understood, hyperventilation was demonstrated to precipitate chest pain in 15% of the patients with NCCP.[67] Additionally, it was demonstrated that hyperventilation could provoke reversible esophageal manometric abnormalities such as esophageal spasm (4%) and a nonspecific esophageal motor disorder (22%).[68] Furthermore, studies have demonstrated that hyperventilation may precipitate a panic attack.[69]

Anxiety and depression influence reports of pain and thus contribute to the pathophysiology of NCCP. Lantinga et al.[70] found that patients with NCCP had higher levels of neuroticism and psychiatric comorbidity before and after cardiac catheterization than did patients with CAD. This finding appears to have prognostic significance because these patients display less improvement in pain, more frequent pain episodes, greater social maladjustment, and more anxiety at 1-year follow-up than individuals with relatively low initial levels of psychosocial disturbances. In a large epidemiological study from England, a significant relationship between NCCP and psychiatric disorders was demonstrated in young adults.[71] Two independent variables were associated with chest pain: parental illness and fatigue during childhood.[14]

DIAGNOSIS OF NONCARDIAC CHEST PAIN

GERD-Related NCCP

There is no gold standard for diagnosing GERD-related NCCP. The currently available diagnostic tests to detect GERD in patients with NCCP include barium swallow, upper endoscopy, the acid perfusion test, ambulatory 24-hour esophageal pH monitoring, and the PPI test.

Barium Esophagram

Barium esophagram has very little use in the diagnosis of GERD. Barium esophagram has a low sensitivity (20%) for diagnosing GERD in general due to lack of anatomical and mucosal abnormalities in most of the GERD patients.[73] Furthermore, the significance of barium reflux during the procedure as a diagnostic for GERD is questionable. Johnston et al. found that the proportion of patients with an abnormal 24-hour esophageal pH study was similar to the proportion of patients with a normal 24-hour esophageal pH study who had spontaneous barium reflux during the test.[73] Additionally, spontaneous barium reflux has been demonstrated in up to 20% of healthy subjects.[74]

The role of barium esophagram is unclear in patients with GERD-related NCCP, primarily due to the rare presence of esophageal mucosal abnormalities. However, one may consider performing a barium esophagram as the initial diagnostic test in patients who report dysphagia in addition to chest pain.

Upper Endoscopy

Once a patient is referred to a gastroenterologist for evaluation of NCCP, if any alarm symptoms (decreased appetite, weight loss, dysphagia, odynophagia, hematemesis, and anemia) are present, an upper endoscopy is warranted to rule out mucosal abnormalities such as benign or malignant tumors, esophageal ulceration, or peptic stricture.

Upper endoscopy is the best test for identifying esophageal mucosal involvement in GERD (erosive esophagitis, stricture, ulcers, and Barrett esophagus). The diagnostic yield of upper endoscopy, esophageal manometry, and Bernstein testing was assessed in 100 consecutive patients being evaluated for NCCP. Upper endoscopy revealed grade II–IV esophagitis in only 24 patients (24%).[75] Frober et al.[76] investigated the clinical value of upper endoscopy in NCCP and found that only 15 (31%) of the patients had esophageal mucosal injury, with all but one having grade I erosive esophagitis.

Recently, Dickman et al.[77] evaluated upper GI findings in patients with noncardiac chest pain versus those with GERD using a national endoscopic database (Table 62.3). Of the NCCP group, 28.6% had hiatal hernia, 19.6% erosive esophagitis, 4.4% Barrett esophagus, and 3.6% stricture/stenosis. The prevalence of

TABLE 62.3

THE VALUE OF UPPER ENDOSCOPY IN CHEST PAIN PATIENTS AS COMPARED TO THOSE WITH REFLUX-RELATED SYMPTOMS USING A LARGE MULTICENTER CONSORTIUM

Findings	Chest pain group N = 3688 (%)	Reflux group N = 32,981 (%)	P Value
Barrett esophagus	163 (4.4%)	3,016 (9.1%)	<0.0001
Esophageal inflammation	715 (19.4%)	9,153 (27.8%)	<0.0001
Hiatal hernia	1,053 (28.6%)	14,775 (44.8%)	<0.0001
Normal	1,627 (44.1%)	12,801 (38.8%)	<0.0001
Stricture/stenosis	132 (3.6%)	1,223 (3.7%)	0.69

(From Dickman R, Mattek N, Holub J, et al. Prevalence of upper gastrointestinal tract findings in patients with noncardiac chest pain versus those with gastroesophageal reflux disease (GERD)-related symptoms: results from a national endoscopic database. *Am J Gastroenterol* 2007;102:1173–1179, with permission.)

these findings was significantly lower in the NCCP group as compared to the GERD group. The authors concluded that most of the endoscopic findings in NCCP patients were GERD related but less common as compared to GERD patients. Thus, the value of upper endoscopy in NCCP is very limited, because the findings are primarily related to GERD. Potentially, the test is indicated as a screening tool for Barrett esophagus in this specific patient population.

Ambulatory 24-hour Esophageal pH Monitoring

Ambulatory 24-hour esophageal pH monitoring with symptom correlation is still commonly used to evaluate patients with NCCP.[78] Approximately 50% to 60% of the NCCP patients have abnormal esophageal acid exposure or a positive symptom index alone. However, the presence of abnormal distal esophageal acid exposure during pH testing does not necessarily mean that the patient's chest pain is GERD related. Hewson et al.[78] examined 100 consecutive patients with NCCP and detected abnormal acid exposure in 48% of the patients. Of the 83 patients who had spontaneous chest pain during the study, 37 (46%) had abnormal reflux parameters and 50 (60%) had a normal study but a positive symptom index (calculated as the percentage of symptoms that are associated with acid reflux events). The authors concluded that 24-hour esophageal pH testing with symptom index (SI) is the single best test for evaluating patients with NCCP. In contrast, Dekel et al.[20] demonstrated that a positive SI is a relatively uncommon phenomenon in NCCP patients because most of the patients do not experience chest pain during the pH study.

The pH test is invasive, inconvenient to patients, costly, and not readily available for many physicians. Additionally, the yield of the test in NCCP has not been rigorously assessed. This is compounded by the rarity of chest pain symptoms during the test in many patients, making it difficult to determine the relationship between patients' symptoms and acid reflux events.[79]

Because of the introduction of the PPI therapeutic trial, the role of 24-hour esophageal pH testing in NCCP has markedly changed in the last decade. Presently, the test is commonly used to assess NCCP patients who failed an empirical therapy with a PPI.

The Wireless pH System

The wireless Bravo (Medtronic, Shoreview, MN) pH monitoring system is a "catheterless" pH system. It involves the attachment of a radiotelemetry pH capsule to the wall of the esophagus (per-oral or transnasal). It simultaneously measures pH and transmits data to a pager-sized receiver clipped onto the patient's belt, thereby circumventing the need for a nasally placed pH catheter, which is uncomfortable for many patients.[80] Unlike the traditional pH catheter system, the wireless pH system can collect data for up to 48 hours. The system was found to be well tolerated and reliable, and it provided reproducible results.[81]

Prakash and Clouse[82] found that by extending the recording time to 48 hours, using the wireless pH system, the number of subjects recording symptoms during the test increased by 6.8% and the number of symptoms available for association with an acid reflux event was doubled. The study also demonstrated that patients with NCCP benefited the most from extending the duration of the pH test. In another study, the same authors demonstrated that the wireless pH system increased the detection of NCCP patients with abnormal pH test and/or positive reflux-symptom association probabilities.[83]

The Proton Pump Inhibitor Test

The PPI test (or short therapeutic trial) is defined as a short course of high dose PPI for diagnosing GERD. This is a simple and noninvasive diagnostic tool for GERD. It is readily available and at the disposal of every PCP. Additionally, it increases the role of PCPs in evaluating and treating patients with different manifestations of GERD. It also offers significant cost savings when compared to the other diagnostic tests for GERD.

Empirical therapy with PPIs (usually offers 2–3 months of treatment with PPI) has often been used by physicians as the initial treatment of patients with typical or atypical manifestations of GERD. However, it is both impractical and costly for patients to complete several months or longer of acid suppression therapy before determining whether the medication is of benefit or not.[21]

The doses used in the PPI test have ranged from 40 mg to 80 mg daily for omeprazole; 30 mg to 60 mg daily for lansoprazole; and 40 mg daily for rabeprazole, over duration of treatment of 1 to 28 days, in patients with symptoms suggestive of GERD or NCCP.[88–101] In patients with laryngeal manifestations of GERD, the doses ranged from 40 mg to 80 mg omeprazole daily and the duration of treatment from 1 to 4 weeks.[84–87] By far, the most commonly used PPI in most of the PPI test trials is omeprazole, which has led to the term the "omeprazole test."[88–97] However, studies using other PPIs demonstrated that they are equally efficacious as short therapeutic trials.[98–100]

An important factor in determining the sensitivity of a PPI test is the definition of a positive test. In most studies, a symptom

score cutoff was used: if the symptom assessment score for heartburn, chest pain, or other symptoms improved by more than 50% to 75% (depending on the study) relative to baseline, the test was considered positive. As with any diagnostic test, the optimal cutoff is critical in defining test accuracy.[101] The symptom score cutoff values that were used among studies that evaluated PPI tests for GERD were chosen arbitrarily. Rarely, studies calculated the Receiver Operator Curve (ROC) by varying the percentage reduction in the symptom tested to ascertain the optimal value for detecting patients with GERD.[88,92,101] This cutoff point provides the greatest sensitivity, specificity, positive predictive value, and accuracy of the short therapeutic trial tested.

As with any other test, the sensitivity of a PPI test depends on the prevalence of the disease in the patient population that is evaluated. Obviously, the PPI test has minimal utility in patients with erosive esophagitis, in whom acid reflux is almost always the underlying cause. However, as the likelihood of a particular syndrome being attributable to reflux decreases, the potential value of a PPI test increases.

The diagnostic accuracy of the PPI test is limited by the lack of gold standard for the diagnosis of GERD. In the absence of gold standard, studies evaluating the PPI test have used a combination of upper endoscopy and ambulatory 24-hour esophageal pH monitoring as the closest one can get to a gold standard. Factors that may determine the sensitivity of the PPI test include type of antireflux medication used, dosage, treatment duration, definition of a positive test (symptom score cutoff, change in symptom grading, receiver operating characteristics curve analysis), and the GERD-related symptom evaluated.

Only one study attempted to compare the accuracy of the PPI test (omeprazole test) to 24-hour esophageal pH monitoring in diagnosing GERD.[102] The study used the presence of erosive esophagitis as indicative of GERD in patients who are not on aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). Thirty-five patients were included, and they underwent both pH testing and the PPI test (omeprazole 40 mg before breakfast and 20 mg before dinner). The PPI test was significantly more sensitive than total acid contact time during pH testing (83% vs. 60%, $p < 0.03$). The sensitivity of the pH test increased to 80% only after adding patients with positive SI, and patients with abnormal acid contact time, in the supine and/or erect positions despite normal total acid contact time. The authors concluded that the PPI test was at least as sensitive as ambulatory 24-hour esophageal pH monitoring in diagnosing GERD in patients with documented erosive esophagitis.

In different studies, the sensitivity of the PPI test for GERD-related NCCP ranged from 69% to 95% and the specificity from 67% to 86%.[88,95–97,103,104] The dosages of PPIs used ranged from 60 mg to 80 mg daily for omeprazole,[88,95–97] 30 mg to 90 mg for lansoprazole,[103,105] and 40 mg for rabeprazole.[106] The trial duration ranged from 1 to 28 days.[88,95–97,103,105,106]

In a double-blind placebo-controlled trial, 37 patients with NCCP were randomized to either placebo or high-dose omeprazole (40 mg before breakfast and 20 mg before dinner) for 7 days.[88] After a washout period and repeated baseline symptom assessment, patients crossed over to the opposite arm. The PPI test was considered positive if the chest pain improved by at least 50% after treatment. The combination of upper endoscopy and 24-hour esophageal pH monitoring was used as the gold standard. Sixty-two percent (23/37) of the patients had evidence of GERD: 7 had abnormal esophageal acid exposure by pH testing only, 8 had erosive esophagitis only, and 8 had both. Of the GERD-positive group, 78.3% had a positive PPI test and 22.7% had a positive placebo response. In contrast, of the GERD-negative group, 14.2% had a positive PPI test and 7.1% had a positive placebo response. Thus, the calculated sensitivity was 78.3%, specificity 85.7%, and the positive predictive value was 90%.[88] When different reductions in chest pain were evaluated as previously mentioned, the greater accuracy of predicting GERD-related NCCP was obtained with 65% symptom reduction, producing a sensitivity of 85.7% and specificity of 90.9%.[88] Using similar design, other investigators confirmed the usefulness of the PPI test for diagnosing GERD-related NCCP.[97,103] Furthermore, subsequent studies demonstrated that short therapeutic trials with PPIs other than omeprazole achieved similar efficacy for the diagnosis of GERD-related NCCP.[105,106] A study in the Chinese population showed that the PPI test, using lansoprazole 30 mg daily for a period of 4 weeks, was useful in diagnosing endoscopy-negative GERD-related NCCP.[103]

As with the PPI test in patients with classic GERD symptoms, the PPI test in NCCP has been recently scrutinized by two meta-analyses. In the first meta-analysis of randomized controlled trials (parallel group and crossover design), the authors evaluated the pooled risk ratio for continued chest pain after PPI therapy; overall number needed to treat; and pooled sensitivity, specificity, and diagnostic odds ratio for the PPI test versus reference standards.[107]

Eight studies were included in the PPI efficacy analysis. The pooled risk ratio for continued chest pain after PPI therapy was 0.54 (95% confidence interval [CI], 0.41–0.71). The overall number needed to treat was 3 (95% CI, 2–4). The pooled sensitivity, specificity, and diagnostic odds ratio for the PPI test versus 24-hour pH monitoring and upper endoscopy were 80%, 73%, and 13.83 (95% CI, 5.48–34.91), respectively. All studies were small, and there was evidence of publication bias or other small study effects. The authors concluded that PPI therapy reduces symptoms in NCCP and may be useful as a diagnostic test in identifying abnormal esophageal acid reflux. However, in this meta-analysis, the authors included a potpourri of diagnostic and therapeutic trials with a PPI in patients with NCCP. Many of these trials have little in common and often used different clinical endpoints. Of the eight studies that were included in the PPI efficacy analysis, two (25%) were published only in an abstract form.[95,106] Additionally, one study[108] focused on the value of the pH testing-derived parameter—the SI in patients with NCCP. The usage of an open label PPI test in this study was a secondary endpoint. Another study[103] was done exclusively in Chinese patients with nonerosive reflux disease-related NCCP. Furthermore, the latter study included a standard dose PPI given during a period of 1 month. One study[109] was an open label, empirical therapy in patients with NCCP, using omeprazole 40 mg in the evening during a period of 6 weeks. The studies differ significantly from each other in many clinical aspects, affecting the quality and reliability of the meta-analysis.

Wang et al. have also performed a meta-analysis of the PPI test in patients with NCCP.[110] Unlike the previous meta-analysis, the authors found only six studies that met inclusion criteria. The overall sensitivity and specificity of a PPI test were 80% (95% CI, 71% to 87%) and 74% (95% CI, 64% to 83%), respectively, compared with 19% (95% CI, 12% to 29%) and 77% (95% CI, 62% to 87%), respectively, in the placebo group. The PPI test showed significant higher discriminative power, with a summary diagnostic odds ratio of 19.35 (95% CI, 8.54–43.84) compared to 0.61 (95% CI, 0.20–1.86) in the placebo group. Thus, the authors concluded that the use of PPI treatment as a diagnostic test for detecting GERD in patients with NCCP has an acceptable sensitivity and specificity and could be used as an initial approach by PCPs to detect GERD in selected patients with NCCP.

There is evidence that when using the PPI test, there is a significant correlation between the extent of esophageal acid exposure in the distal esophagus as determined by ambulatory 24-hour esophageal pH monitoring and the change in symptom intensity score after treatment, suggesting that the higher the esophageal acid exposure, the greater the response to the PPI test in patients with GERD-related NCCP.[22]

Economic analysis also showed that the PPI test for GERD-related NCCP is a cost-saving approach primarily due to signifi-

cant reduction in the usage of various costly, invasive diagnostic tests.[88]

In patients with NCCP, the PPI test was evaluated using a cost minimization analysis.[88] The PPI test was found to save $573 per average patient with NCCP undergoing diagnostic evaluation. The test was associated with an 81% reduction in the number of upper endoscopies and 79% reduction in the number of ambulatory 24-hour esophageal pH tests. This significant reduction is due to the high positive predictive value of the PPI test for patients with GERD-related NCCP.

When a decision-analytic model utilizing Bayesian analysis was developed to compare the costs and outcomes of alternative diagnostic strategies for NCCP, noninvasive strategies utilizing the PPI test as the initial step resulted in significant cost savings as compared to invasive strategies. These cost savings were a direct result of a significant reduction in the utilization of invasive diagnostic tests that are of unproven utility in the diagnosis and subsequent management of patients with NCCP.[111]

Multichannel Intraluminal Impedance

The combination of an impedance catheter and a pH probe provides a unique opportunity to study physiologic and pathologic events within the esophagus and their relationship to symptoms. In addition, the recording assembly can disclose the characteristics of the gastric refluxate (acidic, weakly acidic, alkaline, gas, liquid, and mixed gas and liquid). The specific value of the multichannel intraluminal impedance plus pH sensor and the documentation of weakly acidic reflux in patients with NCCP remains to be elucidated.

The combined multichannel intraluminal impedance and manometry testing has been useful in determining bolus transport patterns, bolus transit parameters, and bolus clearance in patients with esophageal motor disorders and a variety of symptoms including chest pain.[112] The true value of this technique has not been specifically evaluated in patients with NCCP.

Esophageal Dysmotility

In approximately a third of the patients with non–GERD-related NCCP, various esophageal motility abnormalities have been described.[29,30,113] Thus, in NCCP, esophageal manometry is commonly performed if GERD has been excluded as the underlying cause.[8] The role of esophageal manometry in NCCP has evolved over the last few years, primarily due to lack of effective treatment for the various esophageal motility abnormalities. This was compounded by clinical evidence that patients with non–GERD-related NCCP reported symptom improvement on pain modulators regardless if esophageal dysmotility was present or absent (except for achalasia).[114] Consequently, the role of esophageal manometry in non–GERD-related NCCP appears to be limited to identifying the small number of patients with achalasia.[31]

Esophageal Manometry

Esophageal manometry is the best tool to detect motility disorders of the esophagus. Evaluation of the amplitude of the esophageal contraction wave, its configuration, and propagation as well as the function of the upper and lower esophageal sphincters may be provided.[115]

The relationship between motility abnormalities diagnosed in NCCP patients and chest pain remains controversial. In a large retrospective study of patients with NCCP, only 28% were found to have esophageal dysmotility during esophageal manometry.[29] Nutcracker esophagus was the most common motility disorder (48%) followed by nonspecific esophageal motility disorder (36%), diffuse esophageal spasm (10%), hypertensive LES (4%), and achalasia (2%).

In NCCP patients with esophageal dysmotility, some have stipulated that esophageal spasm, for example, may be the cause of chest pain either by distending the proximal segment of the esophagus (leading to activation of mechanoreceptors) or by producing myoischemia (activation of chemoreceptors).[116] However, in patients with NCCP, documented esophageal manometry abnormalities are rarely associated with symptoms. Therefore, some have suggested that maybe these abnormalities are not the direct cause of patients' chest pain but rather a marker of an underlying motor disorder.[117] Consequently, documenting the presence of an esophageal motility disorder during esophageal manometry (except achalasia) does not conclusively prove that it is the underlying cause of patients' chest pain. This should not be surprising, as this test assesses patients in a fasting, supine state, free of exogenous influences, and with a rapid succession of wet and/or dry swallows.

The role of high-resolution esophageal manometry in evaluating NCCP patients remains unknown.

Provocative Testing

In order to enhance the value of esophageal manometry in providing a definitive diagnosis, pharmacological provocative agents have been used to elicit chest pain while monitoring changes in esophageal amplitude contractions.

Edrophonium (Tensilon) Test

The edrophonium (Tensilon) test has been used pharmacologically to induce esophageal dysmotility and chest pain in patients with NCCP. Edrophonium is an anticholinesterase that increases cholinergic activity at muscarinic receptors.[118] The pharmacologic action of this short-acting drug is manifested within 30 to 60 seconds after injection and lasts an average of 10 minutes. The aim of the edrophonium test is to induce greater esophageal body amplitude contractions in the hope of provoking the patient's typical chest pain.[119] The test is performed by injection of either 80 mg/kg or 10 mg edrophonium intravenously (IV), immediately followed by 5 to 10 swallows of 5 to 10 mL of water over a period of 5 to 10 minutes. The pain occurs during swallowing within 5 minutes after the administration of the drug and disappears as the drug is quickly metabolized.[20] Overall, the side effects are minimal, and the antidote atropine is rarely required. Side effects include increased salivation, nausea, vomiting, and abdominal cramps.

The sensitivity of the edrophonium test is relatively low. Studies have shown that the edrophonium test is positive in approximately 30% of patients with normal baseline esophageal manometry.[120,121] Consequently, the usage of the edrophonium test has declined in the last decade.

Ergonovine Stimulation Test

The ergonovine stimulation test has been demonstrated to induce augmentation of esophageal contractions and chest pain in patients with NCCP. Ergonovine is a sympathomimetic agent of the ergot alkaloid group. The drug is reportedly as effective as edrophonium in the provocation of chest pain in NCCP patients, but the side effects are more common and could potentially be fatal (coronary artery spasm). Thus, ergonovine is rarely used today in clinical practice in the evaluation of NCCP.[20]

Pentagastrin Stimulation Test

Pentagastrin directly stimulates esophageal smooth muscle, especially in patients with primary esophageal dysmotility. Its sensitivity to inducing pain in patients with NCCP is low, and presently the drug is no longer used for NCCP provocative testing.[20]

SENSORY TESTING OF THE ESOPHAGUS

The esophagus, like the rest of the viscera, receives dual sensory innervation, traditionally referred to as parasympathetic and sympathetic because the sensory nerves are anatomically associated with the autonomic nervous system, but more properly based on the actual nerves, vagal and spinal (Fig. 62.8).[122] The vagal afferent neurons compose 80% of the vagal trunk and have cell bodies in the nodose ganglia.[123] Vagal afferents whose receptive fields are located in the esophageal smooth muscle layer are sensitive to mechanical distension, whereas polymodal (responding to multiple modalities of stimuli) vagal afferents with receptive fields in the mucosa are sensitive to various chemical or mechanical intraluminal stimuli, which, under normal circumstances, are not associated with conscious perception.[124] In general, vagal afferents do not play a direct role in visceral pain transmission at the level of the gut, except for certain types of vagal afferents that appear to have a pain modulatory effect.[125] Recent reports suggest that vagal afferents may also play a role in perception of esophageal distension.[125,126] In contrast, spinal afferents, which have their cell bodies in the dorsal root ganglia, are primarily acting as nociceptors and are central to the perception of discomfort and pain.[127] Spinal afferents with receptive fields in the muscle layer and serosa are primarily mechanosensitive. The intraepithelial nerve endings of spinal afferent are likely to be involved in mediating acid-induced pain during topical exposure to intraluminal acid.[21,128] Many of the afferents contain calcitonin gene-related peptide and substance P, which are neurotransmitters that are important in mediating visceral nociception.[123]

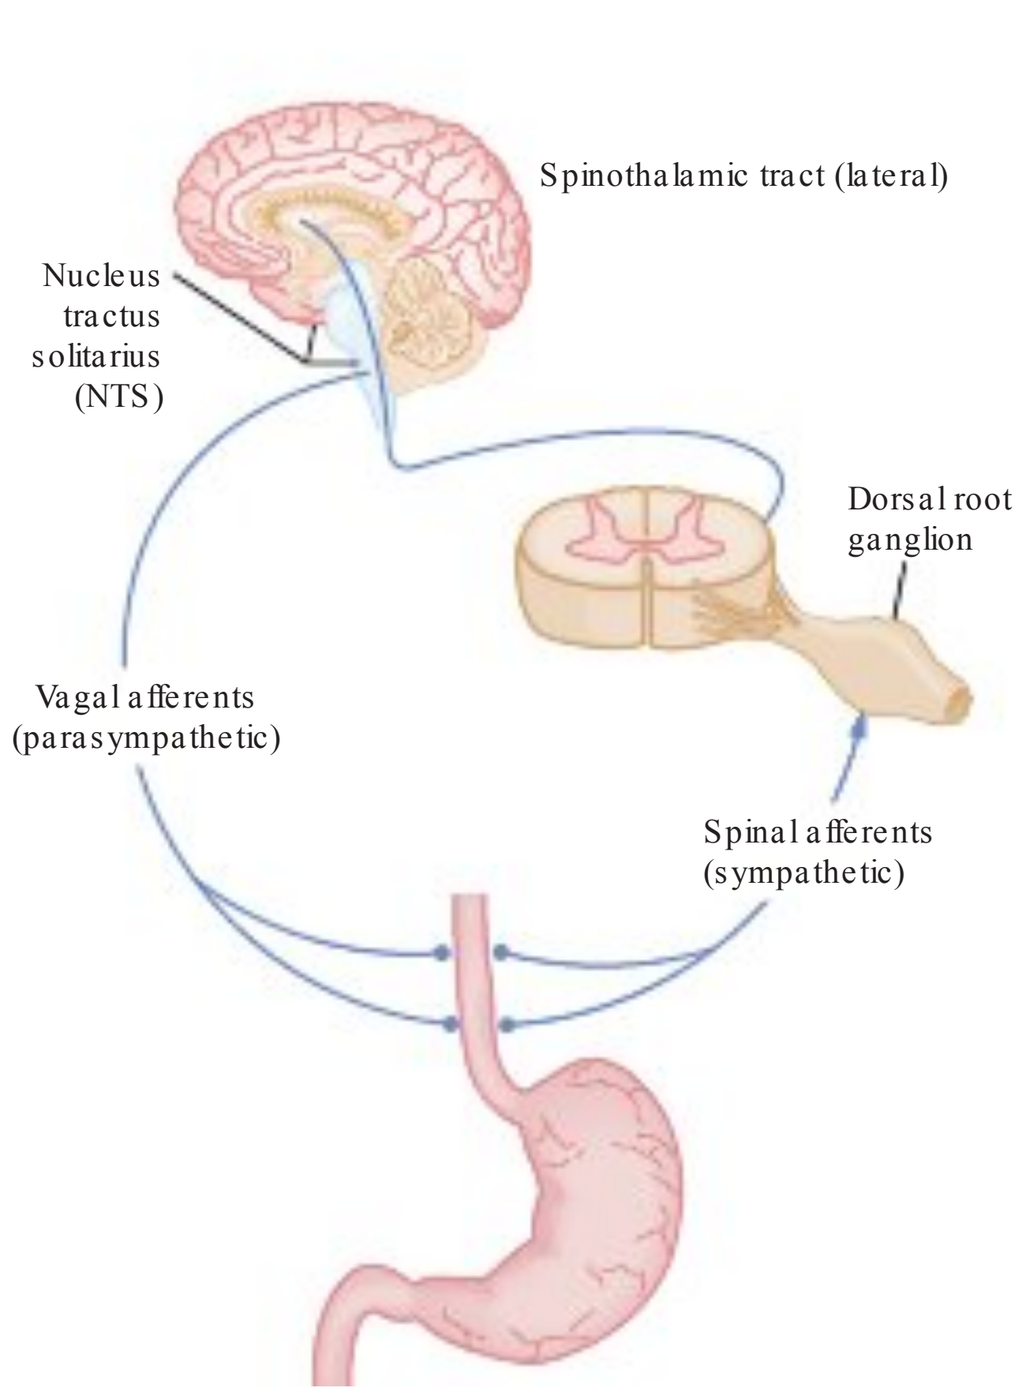

FIGURE 62.8 Esophageal sensory afferent pathways. (Redrawn after Fass R. Sensory testing of the esophagus. *J Clin Gastroenterol* 2004;38(8): 628–641, with permission.)

Data regarding cortical loci involved in processing of esophageal sensation in humans are relatively scarce.[129] Nonpainful esophageal balloon distensions elicit bilateral activation along the central sulcus, the insular cortex, and the frontal and parietal operculum.[50] In contrast, painful esophageal balloon distensions result in intense activation of the same areas and additional activation of the right anterior insular cortex (important in affective processing) and anterior cingulate gyrus (important in pain processing and generating an affective and cognitive response to pain).[135–137] Nonpainful infusion of 0.1N hydrochloric acid resulted in cerebral cortical activity that was concentrated in the posterior cingulate and the parietal and anteromesial frontal lobes.[49] The superior frontal lobe regions activated corresponded to Brodmann area 32, the insula, the operculum, and the anterior cingulate.

Chest pain symptoms may represent an activation of a common pathway in response to different intraesophageal stimuli. Different intraesophageal stimuli (e.g., acid and balloon distension) may elicit similar symptoms in different patients or different symptoms in the same patient.[21,130] Thus, esophageal symptoms such as heartburn or chest pain are not stimulus specific.

A recent study demonstrated that chest pain and heartburn may be provoked in normal subjects during esophageal balloon distension either in the proximal or distal portion of the esophagus.[21] Volume thresholds for heartburn and chest pain in both esophageal locations were similar, suggesting that, for a specific volume, some patients develop chest pain and others heartburn. Furthermore, volume thresholds for both chest pain and heartburn did not differ significantly at each esophageal location and between locations. In this study, esophageal balloon distension reproduced typical heartburn symptoms in some patients with documented GERD and chest pain in others. This study clearly demonstrates that balloon distension may result in different types of esophageal symptoms.

The mechanism by which an esophageal stimulus causes heartburn in some patients and chest pain in others remains poorly understood. Balaban and colleagues[34] have demonstrated a temporal correlation between sustained contractions of the esophageal longitudinal muscle and both spontaneous and provoked esophageal chest pain. In a subsequent study that assessed the temporal relationship between sustained esophageal longitudinal muscle contractions and heartburn,[35] the investigators suggested that shorter duration of the sustained esophageal contraction was associated with heartburn and longer duration with chest pain.

Perception of intraesophageal events, either physiologic or pathologic, is a complicated process that involves central and peripheral mechanisms. Several studies have shown that most intraesophageal stimuli are not perceived by subjects.[131] For example, less than 20% of all acid reflux events result in GERD symptoms, regardless of whether mucosal injury is present.[131] It is yet to be elucidated what factors determine perception of an intraesophageal event, leading to symptom generation. In GERD, it has been demonstrated that the actual hydrogen ion concentration (H^+) of the refluxate, the summation of several short reflux events, the distribution of acid along the esophagus (proximal migration), or the nadir or duration of acid reflux events.[129] Several studies have demonstrated that fat and other nutrients can modulate perception of intraluminal events that are mediated by gut neurotransmitters, hormones, or enzymes. Meyer and colleagues have shown that intraduodenal fat significantly shortened latency to onset of heartburn and intensified the perception of

acid-induced heartburn in subjects with GERD who underwent intraesophageal acid perfusion.[132]

Central neural mechanisms seem to have an important role in modulating esophageal perception also.[133] Psychological comorbidity (e.g., anxiety and depression) can modulate esophageal perception and cause subjects to perceive low-intensity esophageal stimuli (pathologic or physiologic) as being painful.[134] Another important factor is stress that seems to enhance perception of intraesophageal stimuli by reducing perception thresholds for pain.[135] Stress has recently emerged as an important factor in symptom generation and exacerbation of both functional and organic GI disorders.[136] Traditionally, stress is considered a domain of psychology and, thus, commonly lumped together with the role of psychiatric comorbidity.[55] However, recent developments in the understanding of brain–gut interactions in functional bowel disorders resulted in reassessment of the role of chronic stress in the pathophysiology and management of GI disorders such as NCCP. Certain stressful life events have been associated with the onset or symptom exacerbation of functional bowel disorders. In addition, daily experiences of stress seem to have an important modulating effect on perception of intraluminal events.

Other central factors, such as sleep quality, may also alter perception of intraesophageal events.[136a] Further research is needed to better define the brain–gut (or gut–brain) relationship as it relates to symptom generation in esophageal disorders.

Acid Perfusion Test (Bernstein Test)

The acid perfusion test was introduced as an objective method to identify esophageal chemosensitivity to acid.[137] A nasogastric tube was passed through the nares of a fasting, sitting subject and into the stomach.[137,138] After the gastric content was aspirated, the tube was withdrawn until it measured 30 cm from the nares to the tip.[138] This maneuver assumed that the solution would be delivered at a level near the junction of the upper and middle thirds of the esophagus. The tube was connected to an IV bottle. A control administration of 0.9% NaCl was perfused for 10 to 15 minutes at a rate of 6 to 7.5 mL per minute. This was followed by administration of 0.1N hydrochloric acid, at a similar rate, for 30 minutes or until discomfort was induced.[138] If symptoms appeared, the test was discontinued and saline solution was given.

The acid perfusion test was originally devised to distinguish between chest pain of cardiac and esophageal origin. However, since the initial description, many modifications have been made to the original Bernstein test. Although the basic principle of the test remained similar, many investigators have tried different acid perfusion rates, concentrations, and durations in the hope of increasing the sensitivity of the test.[78,139–145] Furthermore, some have even suggested the addition of bile salts to the acid solution.[146]

Many attempts were made to change the test from a qualitative to a quantitative tool. Time to onset of symptoms during acid perfusion was used to compare the extent of chemosensitivity to acid between GERD and Barrett patients.[147] Fass and colleagues[21] placed a manometry catheter 10 cm above the upper border of the LES to ensure sufficient exposure of the esophageal mucosa to acid. Saline was infused initially for 2 minutes and then without the patient's knowledge 0.1N hydrochloric acid was infused for 10 minutes at a rate of 10 mL per minute. Patients were instructed to report whenever their typical symptoms were reproduced. Esophageal chemosensitivity was assessed by both the latency until typical symptom perception was induced (expressed in seconds) and the total sensory intensity rating reported by the subject at the end of acid perfusion by using a verbal descriptor scale. The scale consisted of a 20-cm vertical bar flanked by descriptors of increasing intensity (no sensation, faint, very weak, weak, very mild, mild, moderate, barely strong, slightly intense, strong, intense, very intense, and extremely intense). Placement of words along the side of the scale was determined from their relative log intensity rating in a normative study.[148] The validity of these scales for assessing the perceived intensity of visceral sensations has been confirmed.[149]

An acid perfusion test intensity score (cm $\times$ seconds) was then calculated as follows: $I \times T/100$, where I is the total intensity rating at the end of acid perfusion and T is the duration of report of typical symptom perception during the test. For convenience, the score was divided by 100.

The test is highly specific but the sensitivity ranges from 6% to 60%.[150–157] A negative test has no clinical relevance and does not exclude esophageal origin.

Presently, the acid perfusion test is rarely performed in clinical practice because of its limited diagnostic value in NCCP and other esophageal disorders. Because of the low sensitivity and the emergence of noninvasive and highly sensitive modalities, such as the PPI test and empirical therapy with a PPI, many authors have considered the acid perfusion test to be obsolete.[78,158,159]

Electrical Stimulation

Electrical stimulation of the esophagus has been used by several research groups to study visceral perception and cortical responses to different intensities of intraesophageal stimuli. The technique has yet to be standardized and published protocols are difficult to compare.

Electrical stimulation of the esophageal mucosa is performed by using a 5-mm stainless steel electrode attached to a standard manometric catheter assembly.[160] The electrode is made from fine stainless steel wire wrapped around the end of the catheter and fixed with surgical silk.[161] The electrodes are connected to an electrical stimulator. The catheter assembly is then passed through the nostril and the electrode is placed in the esophagus. Electrical stimuli are applied repeatedly in a series of 24 stimuli (duration 200 μs at 0.2 Hz). A reference electrode is placed on the abdominal wall, 5 cm below the xiphoid process. Electrical stimulation of the upper and lower esophagus can be achieved by 2 pairs of silver/silver chloride bipolar ring electrodes located at 5 and 20 cm proximal to the tip of the catheter.[43]

The ascending stimulus paradigm includes stimuli that are delivered at a frequency of 0.2 Hz at intensities between 0 and 100 mA.[43] Severity and qualitative perceptual responses are usually assessed by a verbal descriptor.[162] Descriptors are used in ascending order of severity. Sensory threshold is the intensity (measured in mA) at which the participant reports faint sensation, and pain threshold is the intensity at which the participant reports an intense sensation.[43] A somewhat different stimulus paradigm is used in patients who undergo recording of cerebral evoked responses to esophageal electrical stimulation.[37]

Intraluminal Ultrasonography

High-frequency intraluminal ultrasonography has been introduced as a novel modality to study the relationship between esophageal motor events and symptoms. The technique has been a useful tool for evaluating smooth muscle contractions.[33] Esophageal ultrasonography can be performed continuously using a catheter-based probe, which allows direct visualization of changes in smooth muscle conformation.[34] The capability of intraluminal ultrasonography to evaluate changes in the thickness of the longitudinal muscle of the esophagus has been used to determine the relationship between esophageal symptoms and motor changes of the esophageal wall. Although the technique has yet to be standardized, investigators have used an esophageal catheter assembly that included a 12.5-MHz ultrasound trans-

ducer, solid-state pressure catheter, and monopolar antimony pH catheter.[34] The ultrasound transducer was placed 5 cm above the LES. The 24-hour recordings were analyzed every 2 seconds for a period of 2 minutes before and 30 seconds after the onset of the studied symptom. Rules for image analysis remain at the discretion of the investigator. Because of the limited number of centers that are proficient with this technique, image analysis is primarily operator dependent and interobserver and intraobserver agreements have yet to be determined.

Using intraluminal ultrasonography, Balaban and colleagues demonstrated that most chest pain episodes in patients with NCCP were preceded by sustained thickening of the esophageal smooth muscle wall due to longitudinal muscle contraction that was not detected by esophageal manometry catheter.[34] The same muscular changes were noted after edrophonium-induced chest pain. The authors suggested that the duration rather than the magnitude of the longitudinal muscle contraction is the determining factor for generating esophageal pain. In this study, swallow-associated longitudinal muscle contractions lasted an average of 6.4 seconds, whereas contractions associated with chest pain persisted for a mean of 68.0 seconds. Similar studies in patients with GERD revealed that the mean duration of sustained longitudinal muscle contractions during heartburn was 44.9 seconds.[35] The motor changes were also observed in patients who reported heartburn that was unrelated to acid reflux events, further supporting the investigator's hypothesis that this sustained esophageal muscle contraction is responsible for generation of esophageal symptoms, such as chest pain and heartburn.

Even though high-frequency intraluminal ultrasonography has been a valuable research tool to assess the biomechanics of the human esophagus, its exact role in evaluating esophageal-related symptoms has not been fully elucidated.[163] Initial studies provided intriguing data, but other investigators have yet to replicate these findings. Additionally, sustained contractions of the esophageal longitudinal muscle may represent an epiphenomenon that occurs with symptoms, rather than being the trigger for symptoms.

Balloon Distension

Balloon distension has been used primarily for research purposes to determine perception thresholds for pain. This modality has been used extensively in studies of various functional bowel disorders, most notably irritable bowel syndrome, functional dyspepsia, and NCCP.[40,164,165]

More than 40 years ago, intraesophageal balloon distension in humans was reported to produce pain referred to the chest.[166] Early data indicated that, in patients with documented ischemic heart disease, balloon distension of the esophagus produced pain indistinguishable from anginal pain, but without ECG changes.[167] This may be explained by convergence of sensory pathways at the level of spinal cord or in the midbrain. Despite this similarity in pain, it seems that esophageal balloon distension itself has no effect on coronary function or blood flow.[168]

Balloon distension was reintroduced during the mid-1980s in a seminal study that evaluated perception thresholds for pain in patients with NCCP.[40] The latex balloon was attached to a manometric catheter and filled with air. The balloon was positioned 10 cm above the LES and distended in a stepwise fashion using a handheld syringe.

A further development in the balloon distension technique was the introduction of a pump that was powered by compressed air.[39] The pump ensured inflations at a predetermined rate, which was difficult to achieve with a handheld syringe. However, neither system was able to provide concomitant pressure measurements that could have been helpful to determine whether the balloon remained within the esophageal lumen during each inflation. This was particularly critical in protocols that inflated balloons within the distal portion of the esophagus. Fass and colleagues[21] demonstrated that balloon distension in the esophagus resulted in phasic esophageal contractions that increased with increase in balloon volume. These powerful contractions, in association with shortening of the esophagus, may propel the balloon into the stomach without being recognized by the subject or the investigator. Concomitant pressure measurements would have been helpful to detect the migration of the balloon into the gastric fundus by demonstrating a sudden decrease in intraluminal pressure despite continued increase in the balloon's volume.

The introduction of the electronic barostat, a computer-driven volume-displacement device, has helped to ensure proper location of the balloon, regardless of inflation paradigm that was used.[169] The basic principle of the barostat is to maintain a constant pressure within the balloon/bag in the lumen despite muscular contractions and relaxations.[113,169] To maintain a constant pressure, the barostat aspirates air with contractions and injects air with relaxations. Presently, many prefer the use of a polyethylene bag to that of a latex balloon. Bags are infinitely compliant and show no increase in intra-bag pressure until about 90% of the maximum bag volume has been achieved.[169,170] In contrast, latex balloons resist inflation and thus show a rapid increase in intra-balloon pressure with small volumes of distension.[21,169,171] When the pressure increases above the elastance threshold, the balloon becomes plastic and accommodates large volumes of air with very little change in pressure.[169,170] For tubular organs in the GI tract, such as the esophagus, experts recommend the use of a cylindrical bag (rather than the spherical) with a fixed length.[21,169]

Barostats have been used extensively in studies evaluating rectosigmoid and gastric perception thresholds for pain. However, this technique has been rarely used to assess esophageal mechanosensitivity in humans. Unlike the rectum and the stomach, the esophagus does not serve as a storage organ, but rather as a conduit. Consequently, intraesophageal distensions do not mimic a normal, physiologic stimulus and thus perceptual responses to such a stimulus may have no scientific merit. This factor, in addition to the patient's difficulties in tolerating balloon distension, which commonly results in poor recruitment rates as well as the potential for esophageal perforation, have made esophageal balloon distensions by a barostat a less attractive research tool.

Various distension protocols have been used in different studies. Like any other technique that assesses esophageal sensation, balloon distension has yet to be standardized. Slow ramp distension is an ascending method that involves slow (rate varies from one study to another) increase in volume or pressure of the balloon usually until the desired perceptual response has been reported by the subject.[21,46,172] In contrast, phasic distensions are rapid inflations of the balloon that can be delivered in random sequence or double random staircase.[21,46] The latter includes two series of distension stimuli (staircases), and the computer alternates between the two staircases on a random basis.[21,169,172] With the tracking method, the barostat is programmed to deliver a series of intermittent phasic stimuli separated by interpulse rest period within an interactive stimulus tracking procedure.[21,173,174] If the subject indicates a sensation below the tracked intensity then the following stimulus will increase in pressure. If the subject reports the desired sensation, then the following pressure step is randomized to stay the same or decrease. The random element is placed to mask the relationship between ratings and subsequent stimulus change, and, therefore, decrease potential scaling bias.[39]

Quantification of perceptual responses depends on the characteristics of the mechanoreceptors in a specific region of the GI tract. Volume or pressure distension can be considered the most physiologic stimuli.[165,175] The most reliable reports of esophageal sensory thresholds are obtained during volume distension. Although the overall pressure-volume curve is linear, the pressure at any given volume may vary because of the presence or absence of a superimposed esophageal phasic contractions.[21] Despite this

physiologic phenomenon, other investigators rely primarily on pressure when performing balloon studies in the esophagus.

Commonly, qualitative and quantitative perceptual responses are evaluated during balloon distension studies. Qualitative perceptual responses include symptom reports in response to balloon distension, such as chest pain, heartburn, bloating, and fullness, among others.[21,176] Heartburn is a common sensation that occurs during balloon distension and may mimic the patient's typical heartburn symptom.[176] Quantitative perceptual responses are commonly obtained during slow-ramp distension and include the minimal distension volume or pressure at which the individual first reports moderate sensation (innocuous sensation), discomfort, and pain (aversive sensation).[21] Discomfort threshold is commonly defined as the first unpleasant esophageal sensation, and pain threshold is defined as the first sensation of pain.[21]

Pitfalls that may modify perceptual responses to balloon distension include the following: increased rate of balloon distension results in reported perception at lower volumes or pressures[177]; longer durations of balloon distension are more likely to elicit sensation than shorter durations[177]; elderly subjects demonstrate diminished visceral pain perception and female patients seem to have lower perception thresholds for pain compared with male patients[178–180]; and the proximal esophagus has been suggested to be more sensitive to chemical and mechanical stimuli than the distal esophagus.[21,181] Additionally, reduced sensitivity to intraluminal stimuli has been demonstrated in specific patient populations, such as those with Barrett mucosa or esophageal stricture.[147,182,183] A recent study demonstrated the development of secondary hypersensitivity in the adjacent portion of the esophagus that was not sensitized by a chemical stimulus (acid).[43]

Balloon studies are primarily designed to assess the presence of visceral hypersensitivity in various esophageal disorders. Early studies demonstrated that pain develops with balloon distension more frequently in NCCP patients than in normal control subjects and that their pain occurs at smaller volumes.[39,40,184] Short-term sensitization of mechanosensitive afferent pathways by transient exposure to irritants has been shown in both humans and animal models of visceral hypersensitivity.[45,185] Human studies that evaluated the effect of esophageal acid perfusion on perception of esophageal distension in healthy control subjects and patients with GERD had varying results.[45,73,186,187]

Mehta and colleagues[45] reported that perfusion of the esophagus with 0.1N hydrochloric acid for 30 minutes resulted in enhanced sensitivity to esophageal balloon distension. Similarly, Sarkar and colleagues[187] reported that acid perfusion into the distal esophagus was associated with the development of mechanical hypersensitivity in the proximal esophagus, which had not been exposed to acid, suggesting the development of secondary visceral hypersensitivity. Peghini and coworkers[73] found a lowering of the pain threshold to distension only in those individuals who were symptomatic during acid perfusion.[186] In contrast, DeVault[186] reported that a 15-minute acid perfusion had no significant effect on pain perception during esophageal distension. The mechanisms underlying the sensitizing effect of acute tissue irritation on visceral afferent pathways have been well characterized in the form of peripheral and central sensitization.[127] Such sensitization manifests as increased background activity of sensory neurons, the lowering of nociceptive thresholds, changes in stimulus response curves, and enlargement of receptive fields. During a noxious event, a series of counter-regulatory mechanisms are activated that are aimed at containing the development of both the acute and any long-lasting sensitization.[127]

Studies evaluating balloon distensions in patients with chronic acid exposure or esophageal mucosal injury are scarce. Fass and colleagues demonstrated that mild to moderate chronic tissue injury in GERD differentially affects mechanosensitive and chemosensitive afferent pathways.[21] GERD patients showed enhanced perception of acid perfusion but not of esophageal distension. Chemosensitivity but not mechanosensitivity was correlated with reflux symptoms and with the degree of endoscopically shown tissue injury at baseline. Trimble and coworkers evaluated patients with heartburn and excess reflux defined by abnormal upper endoscopy or 24-hour esophageal pH monitoring and compared them with patients with heartburn and a normal 24-hour pH test. The results demonstrated that the latter group had lower volume thresholds for perception of esophageal balloon distension and discomfort.[134] This study suggests that patients with typical heartburn who lack any evidence of excess acid are highly sensitive to mechanical stimuli.

Balloon distension has been commonly used to assess the effect of various drugs on esophageal sensory perception. Imipramine, octreotide, and nifedipine have all been shown to increase perception thresholds for pain in normal controls or patients with NCCP.[188–192]

Esophageal-Evoked Potentials

Cerebral evoked potentials reflect electrical activity of the brain in response to visual, auditory, somatosensory, and visceral stimuli. There is a clear relationship between stimulus frequency, using esophageal electrical stimulation, and amplitude of cerebral evoked potentials.[193] Studies have demonstrated that a significant and progressive decrease of evoked potential amplitudes is associated with increasing stimulus frequency. This suggests a rapid attenuation of the cerebral autonomic responses with increased frequency of electrical stimulation.[193] Furthermore, a stimulus intensity-response relationship has been shown in brain response to increasing stimulus intensity, which is probably explained by increased recruitment of afferent fibers.[193,194]

Balloon distension and electrical stimulation protocols have been used in studies assessing cerebral-evoked potentials in response to esophageal stimulation. It is unclear if one of the sensory testing methods is better than the other.

Esophageal balloon distension triggers a characteristic triphasic evoked potential.[195] Two negative peaks (N1 and N2) and 1 positive peak (P1) can be demonstrated. Latency is the time in milliseconds from the stimulus to the peak. There is a considerable intersubject variability but almost no intrasubject variability when recording cerebral-evoked potentials. Studies in normal subjects have shown significantly shorter latencies during balloon distension in the proximal esophagus as compared with the distal esophagus.[196]

Assessment of patients with NCCP, using the esophageal balloon distension paradigm, revealed that amplitude and quality of cerebral-evoked potentials increased with increasing sensation, while the latencies remained stable.[195] Additionally, the amplitude and quality of evoked potentials were lower in NCCP patients as compared with controls. Similar levels of sensation were produced by lower balloon volumes in NCCP patients.[193]

Esophageal stimulation and cerebral-evoked potentials may provide clues to the pathway and type of neurons involved in nociception.[197] Additionally, cerebral-evoked potentials were used to identify brain areas that are responsible for esophageal pain sensation.[198,199]

Brain Imaging

In addition to cortical-evoked potentials, other techniques have been increasingly used to evaluate the brain–gut relationship in patients with esophageal disorders. These techniques include PET and fMRI. The GI is intricately connected to the central nervous system by pathways that are continuously sampling and modulating gut function.[200]

PET scanning is an established method to study the functional neuroanatomy of the human brain.[201,202] Radio-labeled compounds allow the study of biochemical and physiologic processes

involved in cerebral metabolism.[200] Tomographic images represent spatial distribution of radioisotopes in the brain. Regional cerebral blood flow is studied with labeled water (H215O) and glucose metabolism with 18Fl-labeled fluorodeoxyglucose. Unlike PET, fMRI does not require radioisotopes and, hence, is considered a safer imaging technique. fMRI detects increases in oxygen concentration in areas of heightened neuronal activity.[195, 201,203] This imaging technique is best suited for locating the site but not the sequence or duration of neuronal activity. Overall, fMRI provides both anatomic and functional information.

Thus far, only a few studies have attempted to assess the cortical process of esophageal sensation in humans. Aziz and colleagues examined the human brain loci involved in the process of esophageal sensation using PET and distal esophageal balloon distension in eight healthy volunteers.[50] Nonpainful stimuli elicited bilateral activation along the central sulcus, insular cortex, and the frontal and parietal operculum. Painful stimuli resulted in intense activation of the same areas and additional activation of right anterior insular cortex and anterior cingulate gyrus. The former is important in affective processing while the latter is important in pain processing and generating an affective and cognitive response to pain.[204–206] In another study, Kern and colleagues evaluated activation of cerebral cortical responses to esophageal mucosal acid exposure by using an fMRI.[49] Ten healthy subjects underwent intraesophageal perfusion of 0.1N hydrochloric acid over 10 minutes. None of the study subjects reported GERD symptoms during acid perfusion. Cerebral cortical activity was concentrated in the posterior cingulate, parietal, and anteromesial frontal lobes. The superior frontal lobe regions activated in this study corresponded to Brodmann area 32, the insula, the operculum, and the anterior cingulate.

Further studies are needed to assess cerebral activation in patients with different esophageal disorders. In addition, it would be of great interest to determine whether there are differences in central processing of an intraesophageal stimulus in patients with NCCP, nonerosive reflux disease, or functional heartburn. It is also important to begin to examine the role of psychophysiologic states such as stress, anxiety, and depression and their effects on central nuclei involved with perception of esophageal stimuli.

Sensory Testing—Pitfalls in Study Design

Surprisingly, many studies using esophageal sensory testing to evaluate sensory perception thresholds are afflicted with design flaws that make interpretation of the results very difficult. Studies using balloon distension paradigms in the distal esophagus, without simultaneously measuring intra-esophageal pressure, are inherently flawed because of the tendency of the balloon to migrate into the stomach due to esophageal contraction and shortening in response to distension of the balloon. Other common pitfalls include using different rates of balloon distension or acid perfusion, different balloon distension paradigms, or more commonly using an inappropriate control group. For example, a study that compares esophageal sensory testing of patients with Barrett esophagus versus normal controls, and uses a younger control group, is likely to bias the study results. Patients with Barrett esophagus are commonly older, and age per se (being older) increases perception thresholds for pain.[182] Thus, it will be difficult to discern if the Barrett epithelium or the difference in age is responsible for patients' alteration in pain perception.

Studies that evaluate esophageal sensory testing in irritable bowel syndrome (IBS) patients, as compared with normal controls and use a more gender diverse control group, are also hard to interpret. IBS patients are commonly women and a control group that is composed of a significant number of men may bias the results toward the IBS group unrelated to the underlying disorder (IBS). Men, as compared with women, demonstrate an increase of perception thresholds for pain in response to esophageal stimuli.

Ensuring a similar study protocol and age as well as gender matched control group will reduce the potential bias in esophageal sensory testing studies. However, because of lack of standardization in study design, comparison between studies remains a difficult task.

TREATMENT

Treatment for NCCP should be targeted toward the specific underlying mechanism responsible for the patient's symptoms. Table 62.4 provides a general treatment plan for NCCP.

GERD-Related NCCP

Lifestyle modifications include elevation of the head of the bed, weight loss, smoking cessation, and avoidance of alcohol, coffee, fresh citrus juice, and other food products as well as medications that can exacerbate reflux such as opioids, benzodiazepines, and calcium-channel blockers.[207, 208] While these lifestyle modifications are commonly advocated as first line treatment in GERD patients, there is no evidence to support their efficacy in GERD-related NCCP. Regardless, enthusiasm about lifestyle modifications is very high among physicians, and thus it is highly likely that GERD-related NCCP subjects will be instructed to follow them.

The efficacy of histamine (H_2) receptor antagonists in controlling symptoms in patients with GERD-related NCCP has been shown to range from 42% to 52%.[209] In one study, cimetidine (unknown dose) and antacids were shown to be effective in only 42% of the patients with GERD-related NCCP who were followed for a period of 2 to 3 years.[210] Stepping down GERD therapy from a PPI to an H_2 receptor antagonist has been disappointing in GERD-related NCCP patients.

Omeprazole (Prilosec) 20 mg twice daily or placebo was administered over a period of 8 weeks to GERD-related NCCP patients in the only double-blind placebo-controlled trial that

TABLE 62.4

TREATMENT PLAN FOR NCCP

GERD-related NCCP	PPIs, double dose for at least 2 months
Dysmotility-related NCCP	• Achalasia: Medical, endoscopic, and surgical therapy • Nutcracker esophagus: Treat for GERD first. If no response, pain modulator • Spastic motility disorder: Pain modulator
Chest pain of presumed esophageal origin	Pain modulators, low dose, and at bedtime (long term)

has been performed.[211] Patients who received omeprazole had a significant reduction in both the number of days with chest pain and in their chest pain severity scores compared to the patients who received placebo. Thus far, most of the studies assessing the efficacy of PPIs in NCCP primarily utilized omeprazole. However, it is likely that all other PPIs would demonstrate similar efficacy. In fact, a recent open-label study with esomeprazole (Nexium) administered 40 mg once daily over a period of 1 month demonstrated complete resolution of symptoms in 57.1% of subjects with either NCCP or laryngeal manifestations of GERD.[212] In another open-label study, 85% of NCCP patients reported symptom relief or improvement after receiving PPI twice daily (different brands) for a period of 3 months.[213]

A retrospective review of patients' files revealed that PPIs reduce the number of chest pain episodes, emergency department visits, and hospitalizations due to chest pain in subjects with documented CAD.[214] It is likely that GERD-related symptoms contribute to the medical-seeking behavior of this patient population.

Patients with GERD-related NCCP should be treated with at least double the standard dose of PPI until symptoms remit, followed by dose tapering to determine the lowest PPI dose that can control symptoms. As with other extraesophageal manifestations of GERD, NCCP patients may require more than 2 months of therapy for optimal symptom control. Long-term maintenance PPI treatment has been shown to be highly effective.[215] Borzecki and colleagues[216] developed a decision tree to compare empiric treatments for NCCP patients with H_2 receptor antagonists or standard-dose PPI for 8 weeks with initial investigations (upper endoscopy or upper GI series). Empiric treatment was more cost-effective in the initial investigation strategy, with a cost of $849 per patient versus $2,187 per patient.

The value of antireflux surgery in GERD-related NCCP is unclear. Several studies have demonstrated a significant improvement in symptoms following laparoscopic fundoplication in patients with GERD-related NCCP. For instance, Patti and associates reported improvement in chest pain symptoms following laparoscopic fundoplication in 85% of patients with GERD-related NCCP.[217] In addition, Farrell and coworkers reported that 90% of NCCP patients who underwent antireflux surgery experienced improvement in chest pain and 50% reported complete symptom resolution.[218] In contrast, So and colleagues reported that after laparoscopic fundoplication, relief of atypical GERD symptoms (e.g., chest pain) was less satisfactory than relief of typical GERD symptoms (e.g., heartburn).[219] In their study, the authors evaluated symptom improvement with a questionnaire given 3 months and 12 months after antireflux surgery. Overall, heartburn was relieved in 93% of patients, whereas only 48% of patients reported relief of chest pain symptoms.

Non–GERD-Related NCCP

The treatment of non–GERD-related NCCP is primarily based on esophageal pain modulation (Table 62.5). An important development in this field was the recognition that NCCP patients with spastic esophageal motor disorders (except achalasia), as documented by esophageal manometry, are more likely to respond to pain modulators than to muscle relaxants. Unfortunately, no large, well-designed studies to assess pain modulators in patients with non–GERD-related NCCP have been performed thus far.

Several recent studies have shown that most NCCP patients are managed by cardiologists and PCPs who appear to know little about the role and treatment of esophageal hypersensitivity in NCCP.[15,14,220] Even gastroenterologists appeared somewhat uninformed about the role of visceral hypersensitivity in NCCP.[221]

Nitroglycerin and long-acting nitrates cause relaxation of GI smooth muscles by stimulating cyclic guanosine monophosphate (GMP)-dependent pathways. Several open-label studies have reported that nitrates improve symptoms and esophageal motility patterns in patients with chest pain and esophageal dysmotility. Several investigators reported symptomatic improvement in patients with diffuse esophageal spasm (DES), accompanied by normalization of esophageal motility during treatment with nitrates.[222,223] In one small study, five patients with DES experienced a 4-year clinical and manometric remission.[224] However, other studies have failed to demonstrate similar efficacy.[225,226] Long-acting nitrates in doses of 10 to 20 mg two to three times daily, as well as short-acting, sublingual nitrates for acute episodes of chest pain in NCCP patients, were used in these studies.

Overall, studies that evaluated the value of nitrates in NCCP have been limited by small numbers of patients and inconsistent results in regard to drug efficacy. A placebo-controlled trial that excludes patients with GERD has yet to be performed.

Since calcium plays an important role in esophageal muscle contraction, the role of calcium channel blocking agents in patients with NCCP and esophageal spastic motility disorders has been the focus of investigation. Nifedipine (10–30 mg, by mouth, three times a day) decreases the amplitude and duration of esophageal contractions in patients with nutcracker esophagus after only 2 weeks.[121] Unfortunately, the effect of the drug disappeared after 6 weeks of treatment with the complete recurrence of symptoms. Davies and associates used a placebo-controlled trial to assess the efficacy of nifedipine in the prevention of symptomatic episodes of esophageal spasm in eight NCCP patients over a 6-week period.[227] The authors were unable to find statistically significant differences in symptom improvement between the two therapeutic arms. In contrast, symptom improvement was noted in 20 NCCP patients with various esophageal motility disorders, including hypertensive LES, nutcracker esophagus, DES, and vigorous achalasia, treated with nifedipine (10 mg, by mouth, three times a day).[228] Nifedipine was also found to significantly decrease LES resting pressure, with a direct correlation to the plasma levels of drug.[229]

Diltiazem (60–90 mg, by mouth, four times a day) for 8 weeks significantly improved mean chest pain scores and esophageal motility studies in patients with nutcracker esophagus when compared to placebo.[230, 231] However, in a study evaluating eight patients with DES, the effect of diltiazem in relieving chest pain was not different from the effect of placebo, probably due to the small number of patients who participated in the study.[232]

Other calcium channel blockers have been evaluated in patients with primary esophageal motor disorders including verapamil, fendiline, nimodipine (Nimotop; Bayer, West Haven, CT), and nisoldipine (Sular; Sciele, Alpharetta, GA), with various effects on LES resting pressure and esophageal amplitude contractions. Regardless, calcium channel blockers appear to have a transient esophageal motor effect that translates to a short-lived improvement in symptoms, compounded by a variety of side effects such as hypotension, bradycardia, and pedal edema.

Sildenafil (Viagra; Pfizer, New York, NY) is a potent selective inhibitor of cyclic GMP-specific PDE5 (phosphodiesterase 5), which inactivates nitric oxide–stimulated GMP. Intracellular accumulation of the latter induces smooth muscle relaxation. The

drug has been shown to improve esophageal motility in patients with nutcracker esophagus or hypertensive LES by lowering LES resting pressure, reducing distal esophageal amplitude contractions, and prolonging the duration of LES relaxation.[233, 234] However, thus far, there have been no studies that specifically addressed NCCP patients, so the value of this compound in NCCP remains unknown. Additionally, the usage of this compound in NCCP will likely be limited by its cost and side effects.

The antispasmodic cimetropium bromide has been shown to be efficacious in eight NCCP patients with nutcracker esophagus when taken intravenously,[235] but clinical data regarding the efficacy of an oral formulation are still lacking. Hydralazine, an antihypertensive compound that directly dilates peripheral vessels, was shown to improve chest pain and dysphagia by decreasing the amplitude and duration of esophageal contractions in a small study of only five patients.[226] Overall, evidence to support the therapeutic benefit of anticholinergic agents for the treatment of NCCP remains very limited.

Pain Modulators

Visceral hypersensitivity is thought to be the primary underlying mechanism of patients with non–GERD-related NCCP, regardless of the presence or absence of esophageal motor disorder. Consequently, drugs that can alter esophageal pain perception have become the mainstay of therapy in these patients.

Several drugs have been shown to have a pain modulatory or a visceral analgesic effect, thus alleviating chest pain symptoms. These drugs include tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), theophylline, and trazodone.

Several studies have demonstrated that antidepressants have a visceral analgesic effect,[236] but they also appear to inhibit calcium channels and thus may have an additional muscle relaxant-like effect.[237] TCAs have both central neuromodulatory and peripheral visceral analgesic effects. Several clinical trials have found favorable TCA-related effects on esophageal pain perception in both healthy subjects and patients with NCCP.

Imipramine, administered at a dose of 75 mg daily, significantly increases the pain threshold of healthy men during intraesophageal balloon distension as compared to baseline.[238] In another study, 60 patients with NCCP and normal coronary angiography were randomized to receive clonidine (0.2 mg daily), imipramine (50 mg nightly), or placebo for a period of 3 weeks. Patients who received imipramine had a significant (52%) reduction in the frequency of chest pain episodes, independent of cardiac, esophageal, or psychiatric test results, suggesting that imipramine has a visceral analgesic effect on chest pain.[239] In contrast, amitriptyline failed to show an effect on both perception and esophageal compliance in subjects undergoing balloon distension protocol.[240]

Because of their anticholinergic side effects, TCAs are commonly administered at nighttime. Based on our experience, it is recommended that TCA doses are slowly titrated to a maximum of 50 mg daily. The incremental increase in dosing should be based on symptom improvement and development of side effects.

Trazodone (100–150 mg, by mouth, four times a day) for 6 weeks showed a significant improvement in the symptoms of patients with NCCP and esophageal dysmotility as compared to placebo.[241] However, esophageal motility abnormalities remained unchanged. A small, open-label study reported symptom control and improved esophageal motility in patients with NCCP and DES following treatment with both trazodone and clomipramine.[242]

A randomized trial assessing the effect of sertraline in patients with NCCP demonstrated a significant reduction in pain scores, regardless of concomitant improvement in psychological scores.[243] In addition, a recent study demonstrated that citalopram, given 20 mg intravenously in a single dose, reduced chemical and mechanical esophageal hypersensitivity without altering esophageal motility.[244]

Octreotide, a synthetic analog of somatostatin, has been shown to increase rectal and sigmoid perception thresholds for pain in IBS subjects, as well as healthy subjects.[245,246] It has been postulated that the effect of octreotide is mediated by the activation of somatostatin receptors at the spinal cord and/or the supraspinal level.

Octreotide, administered 100 mg subcutaneously, was found to significantly increase perception thresholds for pain as compared to placebo in healthy subjects undergoing intraesophageal balloon distension.[247] Unfortunately, due to cost and the lack of an oral formulation, octreotide is rarely utilized for NCCP in clinical practice.

Theophylline, a xanthine derivative, has been shown to inhibit adenosine-induced angina-like chest pain and adenosine-induced pain in other regions of the body.[248] A study using an esophageal balloon distension protocol and impedance demonstrated that intravenous theophylline increased thresholds for sensation and pain in 75% of patients with functional chest pain.[249] Similar results were documented in functional chest pain patients receiving oral theophylline for a period of 3 months. In another study, the same authors showed that oral doses of theophylline 200 mg twice daily was more effective than placebo in preventing chest pain in 19 patients with functional chest pain (Fig. 62.9).[250]

Alprazolam has been shown in a study to ameliorate chest pain at a mean dose of 4.3 mg daily in patients with NCCP and panic disorder.[251] In this study, 15 out of 20 patients reported at least a 50% reduction in panic attack episodes and a corresponding decline in the frequency of chest pain episodes. Clonazepam, given 1 to 4 mg daily, was also shown to be effective in the treatment of patients with NCCP and panic disorder.[252] The treatment of a functional disorder such as NCCP with benzodiazepines has been greatly discouraged, primarily due to the likelihood of becoming addicted to this class of drugs.

Serotonin (5-HT) is a neurotransmitter present in the central nervous system, enteric neurons, and particularly in enterochromaffin cells in the GI tract. It is involved in visceral perception and motor activity processes in the gastrointestinal tract.[253] Ondansetron, a 5-HT3 receptor antagonist that is used as an antiemetic, has been shown to increase esophageal perception thresholds for pain in patients with NCCP.[253] The selective 5-HT4 receptor agonist tegaserod has been demonstrated to reduce both chemoreceptor sensitivity to acid and mechanoreceptor sensitivity to balloon distension in patients with functional heartburn.[254] Thus far, there are no studies assessing the value of tegaserod in patients with non–GERD-related NCCP.

Endoscopic Treatment and Surgery for NCCP

Botulinum toxin (BOTOX; Allergan, Irvine, CA) interacts selectively with cholinergic neurons to inhibit the release of acetylcholine at the presynaptic terminals. Botulinum toxin injection into the LES has been used in several uncontrolled trials that included patients with NCCP and documented esophageal spastic motility disorder. Injecting botulinum toxin into the LES in a small, uncontrolled study resulted in 50% reduction of chest pain episodes in 72% of the subjects for a mean duration of 7.3 months (Fig. 62.10).[255]

Laparoscopic fundoplication relieves heartburn and acid regurgitation in most patients with GERD, but its effect on chest pain is less clear. DeMeester and associates[210] identified a temporal correlation between chest pain and acid reflux events in 12 of 23 patients with NCCP. Chest pain resolved in all 12 patients treated either by surgery (8 patients) or acid-reducing agents

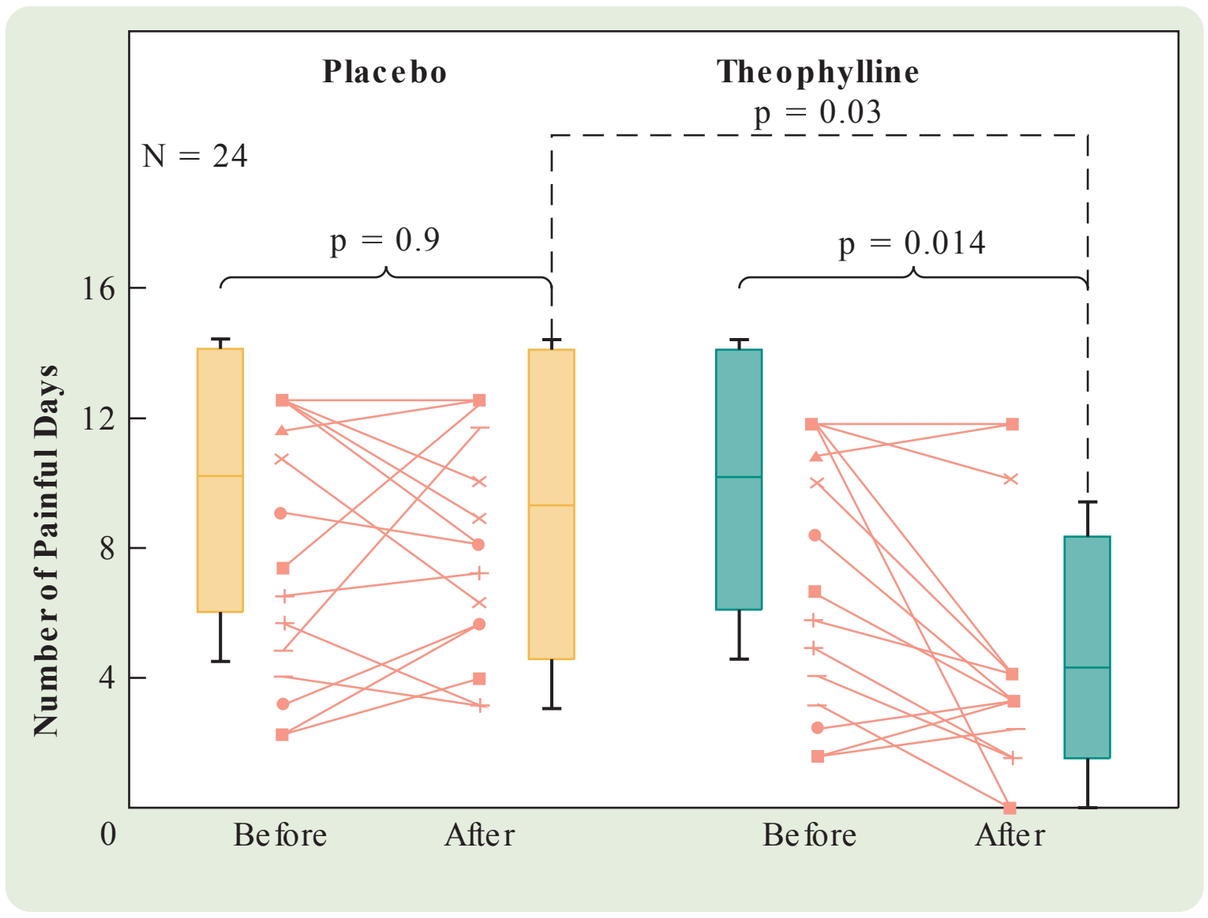

FIGURE 62.9 The effect of oral theophylline versus placebo on the number of painful days in each individual with non-GERD-related NCCP at baseline and after drug administration (200 mg twice daily for 4 weeks). Theophylline improves esophageal chest pain—a randomized, placebo-controlled study. *Am J Gastroenterol* 2007;102:930–938, with permission.)

(4 patients). Patti and coworkers[217] reviewed patients who complained of chest pain in addition to heartburn and acid regurgitation. Overall, chest pain improved in 85% of these patients after undergoing laparoscopic fundoplication for GERD. Improvement in chest pain increased to 96% in patients whose chest pain correlated with GERD most of the time. Farrell and colleagues[218] evaluated the effectiveness of antireflux surgery for patients with atypical manifestations of GERD. Chest pain improved in 90% of patients after laparoscopic fundoplication, with symptom resolution in 50% of patients. Although surgical studies demonstrated a high success rate of antireflux surgery in GERD-related NCCP patients, the patients included were carefully selected.

Very few studies to date have specifically evaluated the value of endoscopic treatment for GERD in patients with GERD-related NCCP. Liu et al., who treated 18 NCCP patients with endoluminal gastroplication, demonstrated short-term symptomatic response (6 months) in 72% of them.[256] During long-term follow-up (1–3 years) 75% of nonresponders became symptom free, and 40% of responders became symptomatic.

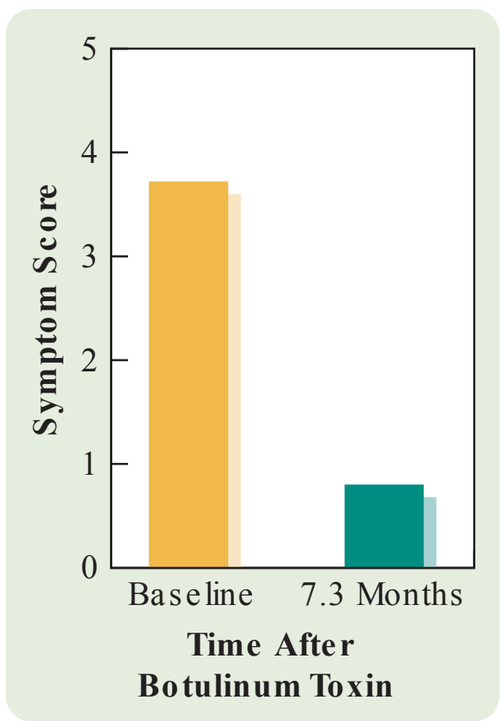

FIGURE 62.10 The effect of botulinum toxin injection in 29 non-GERD-related NCCP patients with spastic esophageal motility disorder. (Redrawn after Miller L, Pullela S, Parkman H, Smith. Treatment of chest pain in patients with noncardiac, nonreflux, nonachalasia spastic esophageal motor disorders using botulinum toxin injection into the gastroesophageal junction. *Am J Gastroenterol* 2002;97(7):1640–1646, with permission.)

Psychological Treatment

Psychological comorbidity, mainly depression and anxiety, is common in patients with NCCP. Psychotherapy may be helpful in the treatment of patients with NCCP, particularly those who also have hypochondriasis, anxiety, or panic disorder.

Several studies have demonstrated that patients with NCCP who are treated with cognitive-behavioral therapy report significant improvement in quality of life and reduction in chest pain symptoms. Additionally, cognitive-behavioral therapy has been successfully used for the treatment of NCCP patients without an existing panic disorder.[257] A study evaluating patients who were treated with cognitive-behavioral therapy reported that 48% of these patients remained pain free at 12-month follow-up, as compared to only 13% of the patients in the nonintervention group. Other psychological interventions that have been suggested to be effective in patients with NCCP include reassurance, education, relaxation techniques, breathing training, and biofeedback. Biofeedback was assessed in a study that compared it to primary care visits only in patients with NCCP.[258] Patients in the biofeedback group demonstrated a significantly lower symptom frequency and severity. However, a large group of patients assigned to the biofeedback arm (52%) did not complete the study.

Hypnotherapy has been recently evaluated in the treatment of NCCP patients. Jones and colleagues[259] reported an 80% improvement in symptoms, with a significant reduction in pain intensity, among patients who were receiving 12 sessions of hypnotherapy, compared to only a 23% symptom improvement in the control group (Fig. 62.11). The study concluded that hypnotherapy appears to have a role in treating NCCP and that further studies are needed.

Future Therapy

Future research in NCCP will continue to focus on mechanisms for pain and will attempt to identify new therapeutic modalities aimed to reduce visceral pain. Research will likely concentrate primarily on the role of central and peripheral sensitization in enhancing perception of intra-esophageal stimuli. Furthermore,

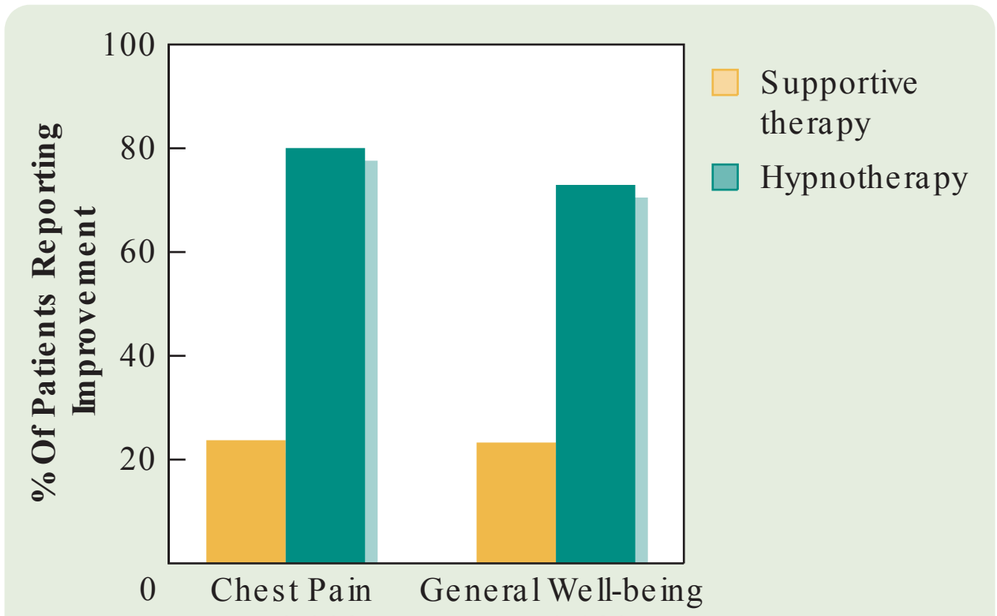

FIGURE 62.11 Percentage of patients reporting a global improvement in chest pain or general well-being with either hypnotherapy (N = 15) or supportive therapy (N = 13). (Redrawn after Jones H, Cooper P, Miller V, Smith. Treatment of non cardiac chest pain: a controlled trial of hypnotherapy. *Gut* 2006;55:1403–1408, with permission.)

currently available treatments for other functional GI disorders, such as IBS and nonulcer dyspepsia, may be tested in NCCP as well.

The serotonin-related drugs, such as 5-HT3 receptor antagonists and 5-HT4 receptor agonists, appear to have a pain-modulatory effect, probably by altering the initiation, transmission, or processing of extrinsic sensory information from the gastrointestinal tract. Phosphorylation of N-methyl-D-aspartate (NMDA) receptors expressed by dorsal horn neurons leads to central sensitization via an increase in their excitability and subsequent increase in receptive field size.[43] Potentially, this central sensitization may be prevented or even reversed by antagonism of NMDA receptors within the spinal cord.

Potential targets that are currently under consideration include vanilloid receptor ion channels, acid-sensing ion channels, sensory neuron-specific Na + channels, P2X purinoceptors, cholecystokinin (CCK) receptors, bradykinin and prostaglandin receptors, glutamate receptors, tachykinin, and calcitonin gene-related peptide receptors as well as peripheral opioid and cannabinoid receptors.[260,261] The peripheral opioid receptor agonists are of high interest because they may offer visceral analgesic effect without crossing the blood-brain barrier and thus affecting the CNS.

Spinal afferents, which may play a role in visceral nociception, express tachykinins that include substance P, neurokinins A and B, and neuropeptide K. Tachykinin receptor antagonists may confer a visceral analgesic effect that can be used in PPI-resistant patients. Neurokinin (NK)-1, NK-2, and NK-3 receptor antagonists were only evaluated in preclinical trials. Cholecystokinin receptor antagonists may alter visceral pain perception.[262]

Another important area that is likely to attract future attention when treating patients with NCCP is complementary and alternative therapeutic modalities that can interfere with the mind and body axis. Figure 62.12 provides a proposed management algorithm for NCCP.

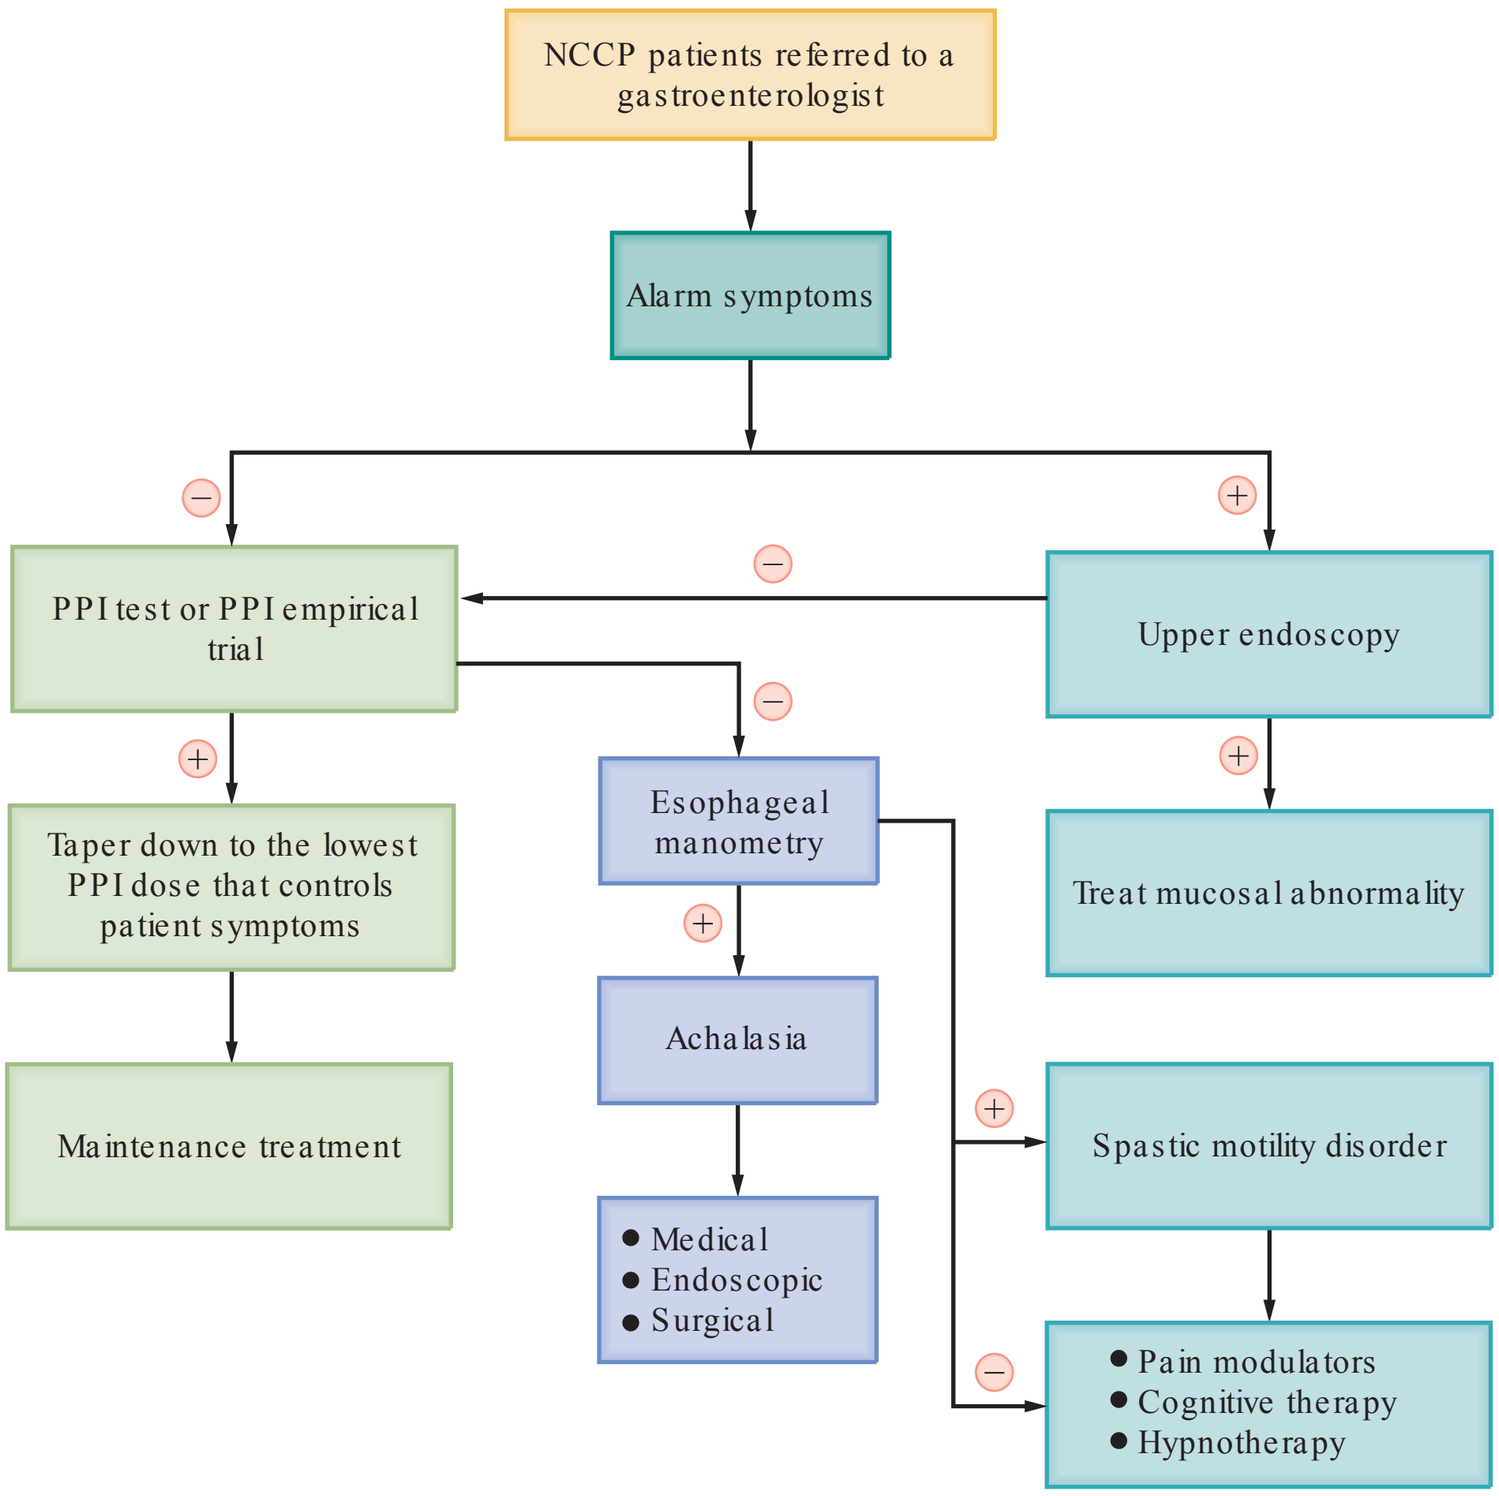

FIGURE 62.12 Proposed management algorithm for NCCP. (Redrawn after Fass R, Navarro-Rodriguez T. *J Clin Gastroenterol* 2008;42(5):636–646, with permission.)

CHAPTER 63 ■ ABDOMINAL, PERITONEAL, AND RETROPERITONEAL PAIN

EMERAN MAYER AND HENG WONG

INTRODUCTION

Abdominal pain can result from multiple peripheral and central causes, including injury to or inflammation of the gut, noxious (mechanical or chemical) viscerosensory stimuli, or central pain amplification. Whereas the former causes are generally associated with acute pain, the latter mechanism plays a prominent role in many chronic abdominal pain conditions, including functional gastrointestinal (GI) disorders (FGIDs) and chronic pancreatitis.

Abdominal pain can be divided into visceral and somatic components, which can occur in isolation or in combination during an episode of pain. Somatic and visceral pain have different characteristics which are clinically significant. Somatic pain arises from stimulation of the parietal peritoneum and accurately localizes to a specific part of the abdomen, while visceral pain has a diffuse nature and is experienced over a large portion of the abdomen. The teleological reason for this dichotomy is that somatic pain allows an organism to identify, appraise, and avoid a noxious stimulus. While this does not apply specifically in the case of peritoneal irritation, the parietal peritoneum has a similar embryological origin as somatic structures and therefore receives somatic innervation. In the case of a noxious visceral stimulus, the organism is unable to avoid the stimulus, and there is no functional reason to be able to accurately localize the site of visceral irritation. The responses to a visceral insult are largely autonomic and not consciously mediated by the organism. For example, during an episode of infective gastroenteritis, the response by way of vomiting and diarrhea is an attempt to expel the pathogen or toxin. In the case of ureteric obstruction by a calculus, the peristaltic contractions occur in an attempt to clear the obstruction.

KEY FEATURES IN THE DIAGNOSIS OF ABDOMINAL PAIN

Abdominal pain is a common problem experienced by children and adults alike and, as its potential causes are protean, diagnosis can often be a challenge. However, clinicians can frequently narrow down the potential causes to a few by taking a detailed history and performing a physical examination. In this section, the key features which help the decision-making process will be discussed.

First and foremost, it is crucial to distinguish between acute and chronic abdominal pain. While chronic pain reflects a chronic underlying disease process, the same cannot be said for acute pain. For example, an episode of acute pain may represent the first presentation of a chronic disease process such as the initial symptoms of functional dyspepsia. Alternatively, acute pain may represent a recurrence of a chronic disease which occurs intermittently and is interspersed with asymptomatic periods. A classic example would be that seen in irritable bowel syndrome (IBS) when patients may have symptom-free periods that may last from months to years. Lastly, it is also important to note that patients with chronic abdominal pain can also develop an unrelated acute cause of abdominal pain. For example, in a patient with IBS, an episode of acute abdominal pain may be due to a recurrence of IBS or may occur from an unrelated cause such an episode of diverticulitis or ureteric stone.

In this chapter, acute abdominal pain will be defined as acute pain of a nonrecurrent nature, while chronic abdominal pain will refer to either constant or recurrent pain that has occurred over a 3-month period. It must be emphasized that the distinction between acute and chronic abdominal pain is not always clear

TABLE 63.1

EXTRA-ABDOMINAL CAUSES OF ABDOMINAL PAIN

Cardiopulmonary
Ischemic heart disease
Pericarditis
Pneumonia
Pneumothorax
Pulmonary empyema

Metabolic/endocrinological
Acute intermittent porphyria
Addison's disease
Diabetic ketoacidosis
Hypercalcemia
Lead poisoning
Uremia

Miscellaneous
Familial Mediterranean fever
Narcotic withdrawal
Fractured ribs

as discussed in the preceding paragraph, and that this definition merely provides a framework for the discussion of the diagnosis of abdominal pain.

Lastly, one must bear in mind that there are a number of extra-abdominal causes presenting as abdominal pain that must be considered when evaluating both acute and chronic abdominal pain. Some of these causes are listed in Table 63.1.

Acute Abdominal Pain

Acute abdominal pain may occur as a result of life-threatening conditions, such as perforated viscera, to relatively benign diagnoses, such as acute gastroenteritis (Table 63.2). The main features relevant to the diagnosis of acute abdominal pain are discussed in this section and an example of the application of such information is illustrated in Figure 63.1.

Site of Pain

The location of pain is largely dependent on whether the pain originates from visceral or somatic structures. Pain from structures with somatic innervation, such the peritoneum, localize accurately to a specific location of the abdomen as the parietal peritoneum receives dense innervation by somatic spinal afferents. On the other hand, pain that originates from the viscera localizes poorly, is inconsistently localized in different patients, and is often experienced over a large portion of the abdomen. This is due to the relatively small number of mechanically sensitive spinal afferents innervating viscera which converge with somatic inputs onto the same spinal neurons at several spinal segments. In general, the perceived site of visceral pain corresponds to the embryological origin to the viscera: the embryological foregut (stomach, duodenum, pancreas, biliary tree), midgut (jejunum and ileum, ascending colon), and hindgut (descending, sigmoid, rectum) localize to the epigastrium, periumbilical area, and suprapubic region respectively.

The localization of visceral pain is illustrated in a study by Doran,[1] in which balloon distention of the bile duct of postcholecystectomy patients leads to epigastric pain in the majority of patients (47%), consistent with the expected localization of visceral pain of foregut origin. However, pain was described in the right upper quadrant and in the back in 18% and 16% of patients, respectively. Furthermore, 19% of patients experienced no pain at all.[1] This variation is seen in clinical practice where patients with acute choledocholithiasis frequently have epigastric pain, but a significant proportion have right upper quadrant pain.

In acute abdominal pain, there can be activation of both somatic and visceral pain afferents. For example, in acute appendicitis, the initial pain is poorly localized in the central abdomen even though the appendix is physically located in the right iliac fossa. At this stage, inflammation is limited to the appendix, and pain is transmitted predominantly via visceral afferents. Subsequently, as the inflammation progresses and involves the parietal peritoneum, the pain from acute appendicitis then becomes localized accurately to the right iliac fossa.

Abdominal pain may radiate to a site distant from the abdomen. Typical examples include the pain seen in acute cholecystitis, when right upper quadrant pain may be referred to the shoulder or scapula or in acute pancreatitis when epigastric pain may be referred to the back. This occurs when there is convergence of visceral and somatic afferents onto a common dorsal horn neuron in the spinal cord. Sensitization of dorsal horn neurons distal to the site of predominant visceral afferent input can result in a situation where visceral pain may be perceived to originate from the area supplied by the corresponding somatic afferent. Activation of the visceral afferent therefore results in the perception of pain in the area supplied by the somatic afferent.

Chronology

The chronology or temporal characteristics of pain provide valuable information on the etiology of the pain. A sudden onset of severe pain which is rapidly progressive usually indicates life-threatening pathology for which urgent treatment is required. Examples include perforation of viscera or major vascular events, such as embolic mesenteric ischemia or a dissecting aortic aneurysm, which can progress over minutes. Progression of pain can also occur relatively slowly over hours or days, such as that seen in acute appendicitis.

The classification of abdominal pain into constant or colicky pain is very useful. Pain due to parietal inflammation and capsule distension is usually constant, while pain from obstruction of viscera with peristaltic activity tends to be colicky.

The frequency of the colic can also help in narrowing the possible causes of pain. Colicky pain from the small and large bowel usually occurs repeatedly over seconds or minutes, while the time course of biliary or renal colic may occur over hours to days. The chronology of the different types of abdominal pain is illustrated in Figure 63.2.

Aggravating/Relieving Factors

Factors which aggravate or alleviate the pain are also useful in the clinical evaluation of abdominal pain. Parietal pain is worsened by movement, which includes deep inspiration and coughing. However, one needs to distinguish parietal pain from muscular pain of the abdominal wall, which is also worsened by movement. In contrast, patients with intestinal obstruction or renal colic tend to writhe about in an attempt to find relief of pain without success. Posture can exacerbate or relieve certain types of abdominal pain. For example, pain from retroperitoneal

TABLE 63.2

CAUSES OF ACUTE ABDOMINAL PAIN AND ASSOCIATED FEATURES

Diagnosis	Location	Onset	Chronology	Aggravating/ relieving factors	Associated features
Parietal Inflammation					
Acute cholecystitis	• Right upper quadrant, sometimes epigastric • Localized • Radiates to shoulder/ scapula	Rapid	Constant	Aggravated by food and deep inspiration	• Fever • Leukocytosis
Acute cholangitis	• Right upper quadrant/ epigastric • Localized • Radiates to scapula/back	Rapid	Constant, pain may be colicky if no parietal involvement	Aggravated by food	• Fever; shaking chills • Jaundice • Leukocytosis • Hyperbilirubinemia • Abnormal liver function test (LFT): cholestatic or mixed pattern
Acute pancreatitis	• Epigastric/periumbilical • Localized • Radiates directly through to mid-back	Rapid	Constant	Aggravated by supine position Relieved by sitting up and adopting fetal position	• May have history of heavy alcohol intake, prior pancreatitis, hyperlipidemia, or on certain drugs • Fever • Vomiting prominent • Leukocytosis • Hyperamylasemia
Acute appendicitis	• Periumbilical initially, then right lower quadrant • Diffuse pain initially, then localized	Gradual	Usually constant, may be colicky initially	When localized to right lower quadrant, aggravated by movements, coughing	• Fever • Leukocytosis
Acute diverticulitis	• Usually left lower quadrant, may be right lower quadrant in right-sided disease • Localized	Gradual	Constant	Aggravated by movement if severe	• Bloody stools • Fever • Leukocytosis
Perforated viscus	• Generalized pain	Sudden	Constant	Aggravated by movement	• Fever • Rigid abdomen; rebound tenderness • Absent bowel sounds • Leukocytosis
Spontaneous bacterial peritonitis	• Generalized, but some patients do not have pain	Gradual	Constant	None	• Significant ascites • Stigmata of chronic liver disease • May have fever but this may be low grade or absent in patients with chronic liver disease • Leukocytosis, may be normal in advanced liver disease • Peritoneal fluid—increased cell count, low albumin

TABLE 63.2

CONTINUED

Diagnosis	Location	Onset	Chronology	Aggravating/ relieving factors	Associated features
Visceral Inflammation					
Infectious enterocolitis	• Variable, usually below umbilicus • Diffuse	Rapid	Colicky	• Aggravated by food, may be partially relieved by defecation	• Diarrhea, may be bloody depending on pathogen • Tenesmus • Leukocytosis • Stool tests for bacteria parasites or *C. difficile* may be positive
Vascular					
Acute ischemic colitis	• Periumbilical/ lower abdomen • Diffuse	Sudden (if caused by embolus) or rapid	May be constant or colicky	Aggravated by food	• Bloody stools • Pain out of proportion to physical examination • Atrial fibrillation, left-sided cardiac murmurs • Leukocytosis
Dissecting aortic aneurysm	• Epigastric/ periumbilical • Diffuse	Sudden	Constant	None	• Described as "tearing pain" • Radiates to back • Unequal femoral pulses • Expansile abdominal mass • Bruit over abdomen • Hypotensive
Splenic infarct	• Left upper quadrant	Sudden	Constant	None	• Rub may be auscultated over spleen • Risk factors for embolic events
Visceral Obstruction					
Intestinal obstruction (volvulus, intussusception, adhesions, cancer, strangulated hernia)	• Central, may be generalized • Diffuse	Gradual/rapid depending on etiology	Colicky	Aggravated by food	• Vomiting is prominent • "Tinkling" bowel sounds

Choledocholithiasis	• Epigastric/right upper quadrant • Diffuse	Rapid	Colicky, episodes usually last hours	Aggravated by food	• Jaundice • Increased bilirubin • Abnormal LFT: cholestatic or mixed pattern
Ureteric stones	• Either flank • Diffuse	Rapid	Colicky	None	• Hematuria • Radiates to testes or inner thigh or groin
Acute urinary retention	• Suprapubic • Localized	Rapid	Constant	Aggravated by movements/cough	• Palpable bladder • Prostatomegaly or fecal impaction may be present
Capsule Distention					
Liver congestion (heart failure, Budd-Chiari, alcoholic hepatitis)	• Right upper quadrant • Localized	Gradual	Constant	None	• Heavy alcohol intake • Jaundice • Hepatomegaly • Features of heart failure • Absent hepatojugular reflux in Budd-Chiari • Abnormal LFT • May have exquisite tenderness to palpation over liver
Pyelonephritis	• Either flank • Localized	Gradual	Constant	None	• Fever • Hematuria • Increased cell count in urine
Ectopic pregnancy	• Right lower quadrant or left lower quadrant • Localized	Gradual (sudden if ruptured)	Constant	None	• Amenorrhea • Nonmenstrual vaginal bleeding • Adnexal mass • Pregnancy test positive
Tubo-ovarian abscess	• Right lower quadrant or left lower quadrant • Localized	Gradual	Constant	None	• Fever • Adnexal mass • Leukocytosis

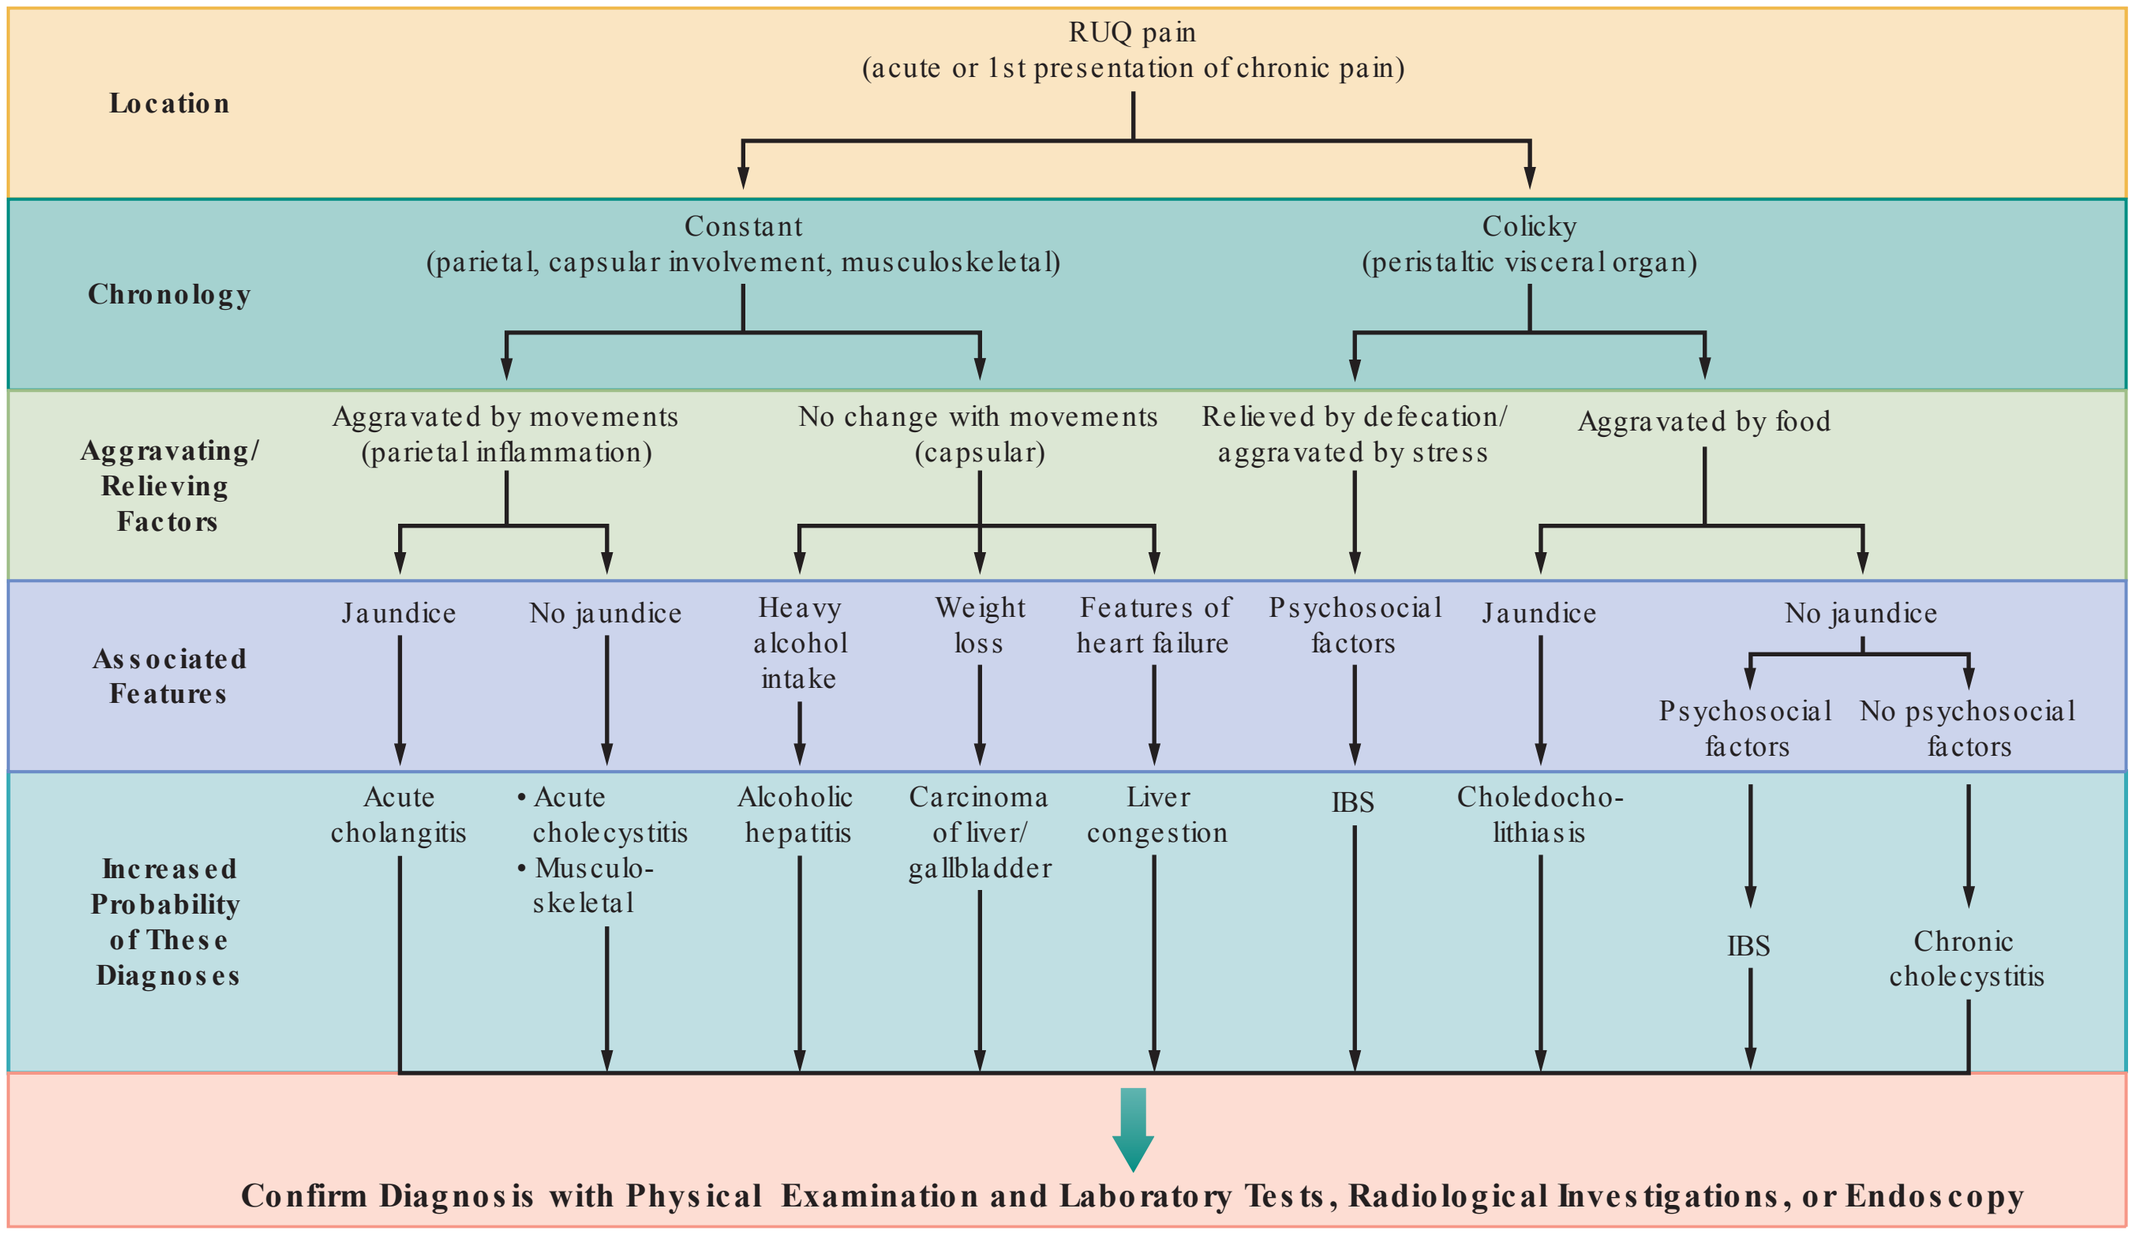

FIGURE 63.1 Example of diagnostic workup for acute right upper quadrant pain (with permission from Wong and Mayer[147]).

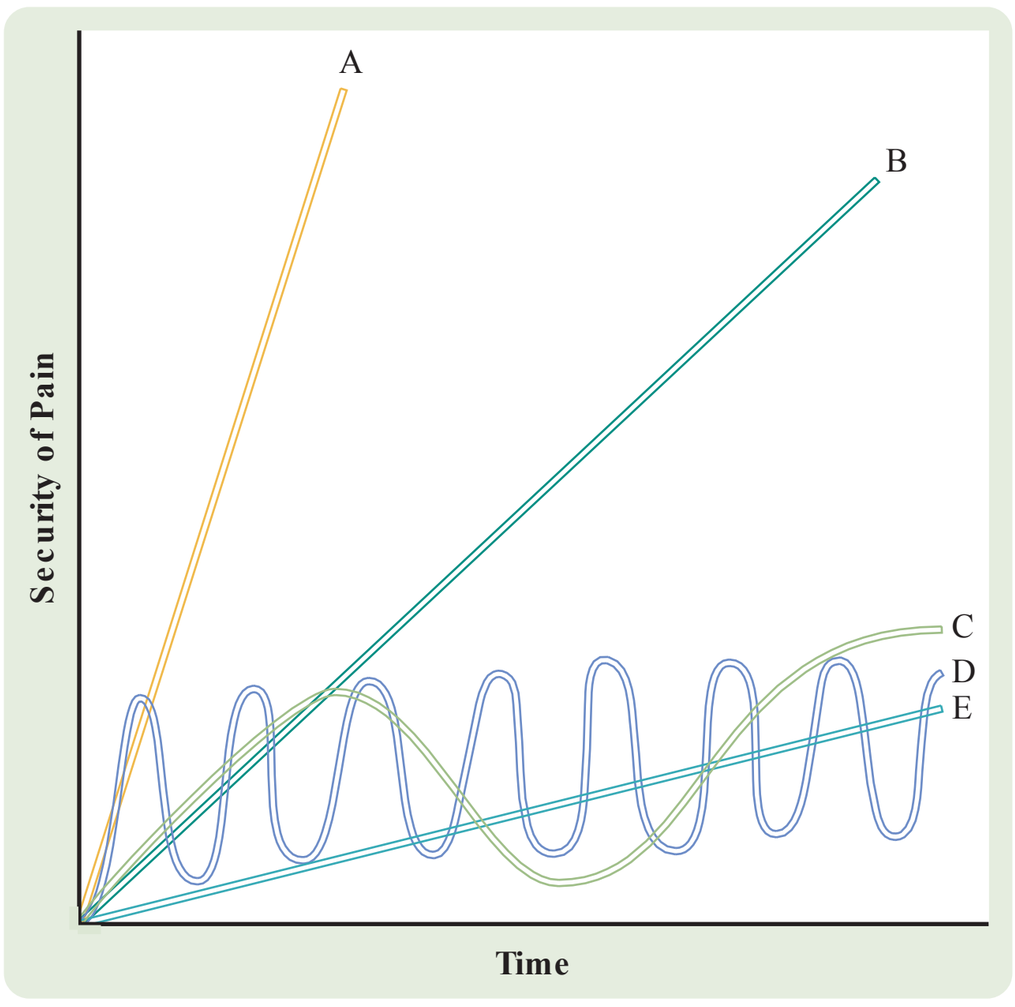

FIGURE 63.2 Typical chronologies of abdominal pain. **(A)** Pain of sudden onset that progresses very rapidly (e.g., rupture of aortic aneurysm). **(B)** Pain that occurs with rapid onset (e.g., acute pancreatitis). **(C)** Colicky pain with long time course (e.g., choledocholithiasis). **(D)** Colicky pain with short time course (e.g., small bowel obstruction). **(E)** Pain that occurs gradually (e.g., acute appendicitis). (With permission from Wong and Mayer.[147])

structures, such as the pancreas, is worsened in the supine position and relieved by leaning forward or assuming a fetal position.

Pain from the GI tract may be exacerbated by intake of food. However, it is important to distinguish between exacerbation of pain directly related to food intake, and nausea or loss of appetite. Many causes of abdominal pain may cause nausea and avoidance of food, while food intake may not necessarily worsen the pain. Examples would be abdominal pain due to liver congestion and ureteric obstruction. The temporal relationship between food intake and the exacerbation of pain should also be considered in the evaluation. For example, pain from the upper GI tract worsens within minutes after food intake, while pain from the small bowel or colon may worsen after hours of food intake. However, it is important to note that pain within minutes of food intake may also occur from colonic contractions due to the gastrocolic reflex. In this clinical scenario, the pain is frequently accompanied by the urge to defecate. On the other hand, food may relieve upper GI lesions, and this usually occurs from the buffering of acid in conditions such as gastroduodenal ulcers or gastroesophageal reflux disorder.

The relief of pain after vomiting suggests pathology in the stomach or proximal small bowel, while relief after defecation or flatulence suggests colonic disease.

Quality

The quality of pain is generally not helpful in the clinical setting as the description of pain is frequently subjective. A useful exception is the "tearing" pain of a dissecting aortic aneurysm. In patients with a previously known cause of abdominal pain, a similar quality experienced during the current episode is useful in the diagnosis. For example, in a patient with a history of acute diverticulitis, the development of a similar episode of pain would point toward another episode of diverticulitis, whereas a different type of pain would suggest an alternative diagnosis.

The description of the severity of pain is also often subjective and is of little diagnostic value. However, if the pain is associated with features of autonomic activation, such as sweatiness and nausea, the pain is likely to be severe. This is particularly useful in situations when the pain is episodic and the patient is asymptomatic at the time of giving the history of pain. Examples include the pain of renal colic and choledocholithiasis.

Associated Factors

Certain features associated with abdominal pain are particularly useful in the diagnosis of acute pain. Patients with abdominal pain and jaundice are likely to have hepatobiliary pathology, while patients with abdominal pain and hematemesis are likely to have an upper GI lesion. The presence of abdominal pain and bloody stools suggest distal colonic pathology. Frank hematuria associated with loin pain suggests ureteric obstruction from renal calculi. Fever is often associated with acute abdominal pain of organic origin, but not with chronic functional abdominal pain or with an acute exacerbation of chronic functional abdominal pain. Weight loss is not a feature of acute abdominal pain, and, if present, there is a likely chronic element to the abdominal pain. Vomiting is commonly associated with many causes of acute abdominal pain, but is rare in functional pain syndromes (despite the common presence of nausea). In obstruction of the proximal small intestine, vomiting is particularly prominent with onset immediately following food intake. In the later stages of large bowel obstruction, the vomitus may look feculent. Abdominal pain associated with heavy alcoholic intake may be related to alcoholic hepatitis or acute pancreatitis.

Past Medical History

A patient's past medical history provides valuable clues in assessing acute abdominal pain. For example, patients with hyperuricemia may be more prone to the formation of renal calculi and the development of renal colic. Patients with atherosclerosis and hypertension would have a higher risk of having an aortic aneurysm and mesenteric ischemia. In patients with poorly controlled diabetes mellitus, one needs to consider the possibility of diabetic ketoacidosis as a cause of acute abdominal pain. In patients with previous abdominal surgery, adhesion colic with intestinal obstruction may occur.

Drug History

Certain medications may be related to the development of abdominal pain. For example, patients taking nonsteroidal anti-inflammatory drugs (NSAIDs) have an increased likelihood of peptic ulcer disease, and patients taking bisphosphonates may develop gastro-esophageal reflux disease. Recent ingestion of antibiotics in patients with bloody diarrhea may point to a diagnosis of pseudomembranous colitis.

Physical Examination

By the time the physical examination is performed, the physician would have determined from the history a list of likely causes of abdominal pain. The physical examination serves to narrow down the possibilities even further.

The physical examination should always start with a general inspection of the patient as the initial appearance helps the clinician determine if the patient is gravely ill and requires immediate treatment. Drowsiness, diaphoresis, and tachypnea are features that point toward a life-threatening condition that demands attention. The vital signs must be taken to exclude hypotensive shock, which may be due to sepsis or hypovolemia. Patients who are curled tightly in the fetal position and lying still are likely to have peritoneal irritation, while patients who writhe about are more likely to have visceral pain. The presence of cachexia suggests an underlying chronic cause of the acute abdominal pain.

The presence of jaundice is an important finding, as this would indicate a hepatobiliary source of the pain. Stigmata of chronic liver disease such as palmar erythema, spider naevi, and Dupuytren's contracture should be sought as this would point toward a hepatic cause of pain and possibly a pancreatic source, since chronic liver disease and pancreatitis often coexist in patients with high alcohol intake. The abdomen may also be grossly distended with intestinal obstruction or with severe ascites. The abdomen should also be inspected carefully for scars, hernia, or bruises.

Palpation of the abdomen should begin at a site distant from that of the presenting pain as this allows the patient to get accustomed to the physical examination, and hence reduce voluntary guarding. Careful palpation will often identify organomegaly and mass lesions and can localize areas of tenderness. Involuntary guarding is due to a reflex contraction of the abdominal muscles following pressure on inflamed peritoneum. Its presence suggests peritonitis, but in practice it is difficult to distinguish peritonitis from voluntary guarding by the patient. With severe peritonitis, the abdomen will feel "board-like" from generalized abdominal wall contraction. Rebound tenderness is another feature of peritonitis and is elicited by gradually applying pressure on the abdomen and suddenly removing the examining hand. Pain on percussion also occurs in peritonitis, and the pain can be brought on by coughing or movement. Percussion is useful in a distended abdomen as it can distinguish between grossly dilated bowel and ascites. Absent bowel sounds on auscultation suggests ileus, which is often present in peritonitis, while tinkling bowel sounds are heard in intestinal obstruction. Bruits may be heard over a hepatoma or an aortic aneurysm.

Rectal examination is an integral part of the physical examination and should always be performed. The presence of bloody stools indicates lower colonic pathology while melena suggests upper GI pathology. A vaginal examination should also be performed to exclude adnexal masses and pelvic inflammatory disease. A systemic examination is also essential as causes of abdominal pain may be associated with pathology in other systems. For example, the presence of atrial fibrillation and left-sided cardiac murmurs predispose to embolic mesenteric ischemia. In addition, the systemic examination may detect extra-abdominal causes of abdominal pain, such as pneumothorax and pneumonia.

Chronic Abdominal Pain

While chronic abdominal pain is rarely life-threatening and seldom requires emergency treatment, chronic abdominal pain can be disabling and significantly affect an individual's health-related quality of life. Although functional GI disorders account for the majority of chronic abdominal pain, mortality and complications can occur as a result of organic GI disease. The challenge is therefore to distinguish functional conditions from chronic organic GI disease. Certain features pointing to organic disease include weight loss, prolonged fever, bloody or melenic stools, steatorrheic stools, jaundice, a strong family history of carcinoma, a palpable mass on physical examination, or anemia (particularly iron deficiency anemia) on laboratory investigation.

The approach to the patient with chronic abdominal pain is similar to that highlighted above for acute abdominal pain. However, certain features such as psychosocial factors, comorbid conditions, and extraintestinal manifestations may be more relevant in chronic abdominal pain. Application of the relevant features in coming to a diagnosis of chronic abdominal pain is illustrated in Figure 63.3. Some of the common causes of chronic abdominal pain are listed in Table 63.3.

Site of Pain

Chronic abdominal pain has even more inconsistent localization than acute abdominal pain, particularly in functional GI disor-

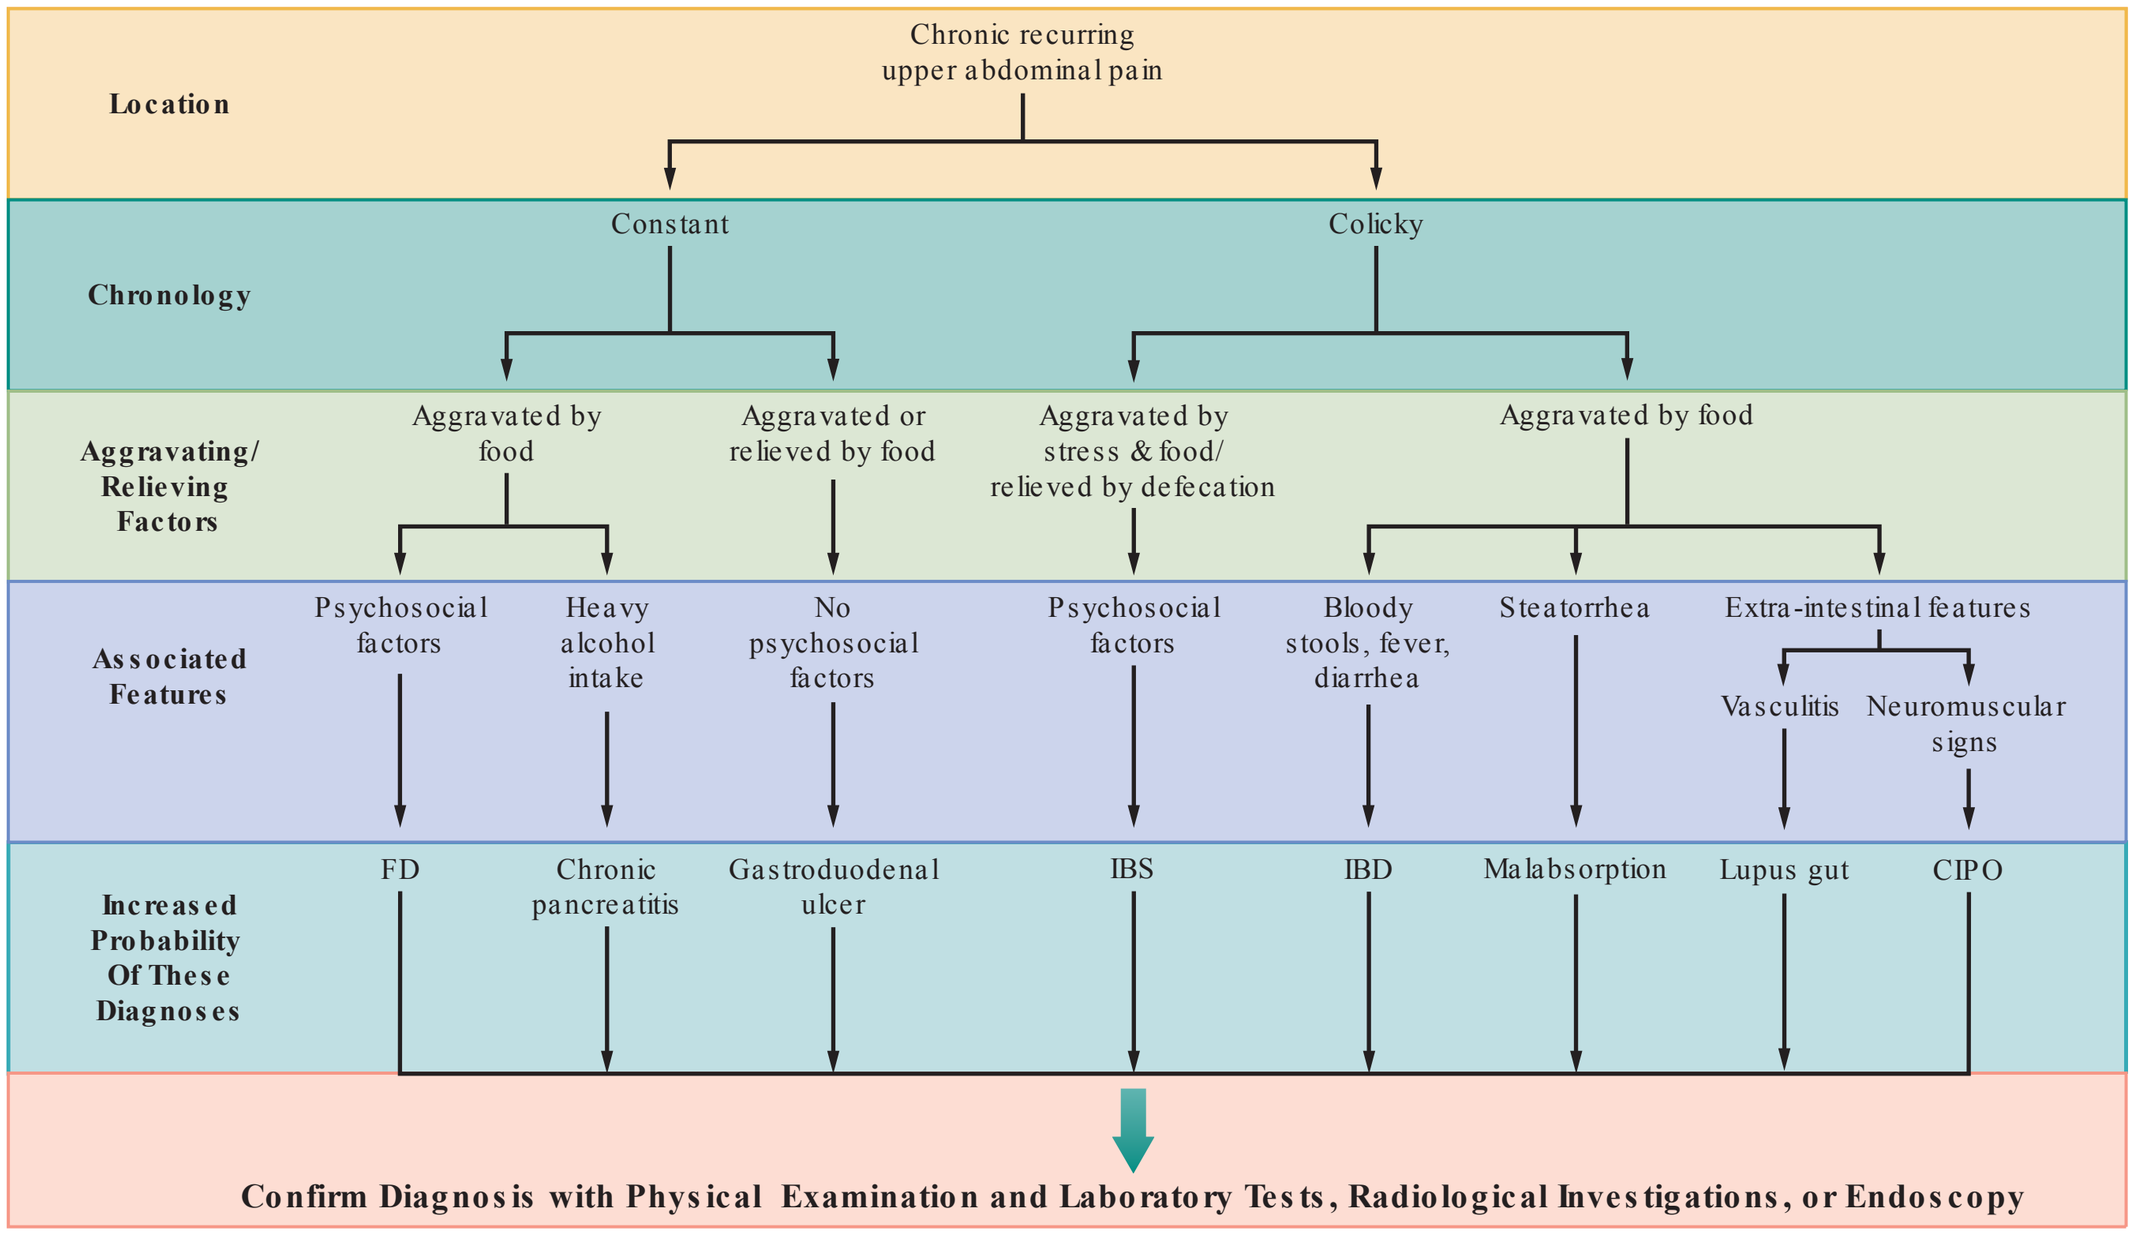

FIGURE 63.3 Example of diagnostic workup for chronic upper abdominal pain. (With permission from Wong and Mayer.)[147]

ders. The atypical pain referral areas in chronic abdominal pain occurs as a result of sensitization, both centrally and peripherally, and the recruitment of previously silent nociceptors. For example, chronic pancreatitis may present as back pain, while patients with FGID tend to report abdominal pain that is diffuse and in atypical regions of their abdomens or even in extra-abdominal sites. For example, patients may experience sigmoid pain to the left upper quadrant or right lower quadrant, and gastric pain at the right upper quadrant. In rare cases, patients report radiation of abdominal pain into the lower extremities, the back, or the entire side of their body. This alteration in viscerosomatic referral area has been reproduced experimentally. When intraluminal balloons were distended at different sites in the colon or stomach, patients with IBS or functional dyspepsia (FD) localized pain to different and larger areas in the abdomen compared to healthy controls.[2]

Pain from carcinoma tends to occur late in the disease. The pain in carcinoma of the solid abdominal organs (e.g., liver, pancreas, kidney) is due to stretching of the organ capsule from tumor growth or from tumor invasion of the capsule, and small early lesions therefore do not usually cause pain. As the pain is secondary to stimuli to the capsule, the pain is well localized. Pain from carcinoma of the GI tract occurs only when the tumor has resulted in a luminal obstruction or has invaded adjacent tissues.

Chronology

Functional GI disorders tend to undergo periods of exacerbation and remission over time, the exception being Functional Abdominal Pain Syndrome (FAPS) where the pain may be constant. In contrast, the pain from advanced carcinoma of the solid visceral organs is constant, and in the absence of intervention is invariably progressive, usually over weeks to months. It is frequently assumed that lower abdominal pain that occurs monthly in relation to menses is related to the pelvic organs. However, GI transit has been reported to be related to the phase of the menstrual cycle, and both healthy individuals and IBS patients have reported increased GI symptoms during menses compared to other menstrual phases. In functional GI disorders, abdominal discomfort, particularly bloating, is frequently better in the morning on awakening and worse in the evening. The reason for this observation is not clear, but it may be related to the beneficial effects of sleep, as good sleep has been associated with fewer symptoms the following day.

Aggravating/Relieving Factors

Food Intake. A significant number of patients with chronic pain arising from the GI tract report that their symptoms are exacerbated by food intake. This symptom aggravation may be related to specific food items (oily foods, milk products, spicy food), to the volume of food ingestion, to food intake in general, or may even be triggered solely by the thought, smell, or sight of food prior to any food entering the GI tract. Food-induced exacerbation of symptoms is more characteristic for FD and gastroesophageal reflux disease (GERD), than for IBS. Unlike other FGIDs, pain from FAPS is characteristically not affected by food intake.

Bowel Movement. The association of chronic abdominal pain to bowel movements suggests the involvement of the lower GI tract. This point is important to elicit in the history and may help with the diagnosis, particularly if the pain is at an atypical site. This association between chronic abdominal pain and bowel movements is part of the diagnostic criteria of IBS. In patients with IBS, the abdominal pain is associated with a change in stool consistency or stool frequency, and is typically relieved with defecation.

Stress. A history of aversive early life events, such as loss of the primary caregiver, divorce of parents, or a history of physical or sexual trauma, greatly enhances an individual's vulnerability for

FGIDs later in life, a typical example being IBS. Apart from increasing susceptibility to FGIDs, stress is also associated with the initial onset or exacerbation of symptoms in FGIDs and common examples of severe stressors include bereavement, divorce proceedings, or financial distress. However, the role of stress in symptom exacerbation is not limited to functional GI pain, but has also been reported in inflammatory bowel disease (IBD) and GERD.[3] For example, a population-based study found that 64% of patients with GERD had exacerbation of symptoms with stress, and GERD patients who are chronically anxious and exposed to long periods of stress are more likely to exhibit stress-induced symptom exacerbation. Stress has also been reported to be associated with exacerbations in patients with IBD.

Psychiatric Comorbidity. Psychiatric comorbidity is strongly associated with FGIDs and should be evaluated when assessing a patient with chronic abdominal pain. It is not uncommon for patients with FGIDs to have a history of anxiety and depression. In a subset of IBS patients who develop IBS-like symptoms following an enteric infection (i.e., postinfectious IBS [PI-IBS], hypochondriasis, anxiety, neuroticism, and somatization) have been reported to be risk factors predisposing to the development of PI-IBS.[4]

Lifestyle Factors

Lifestyle may be relevant in the assessment of chronic abdominal pain. For example, a history of heavy alcohol intake may lead to chronic pancreatitis and alcoholic liver cirrhosis, which is in itself a risk factor for hepatoma. Sexual orientation or intravenous drug abuse may be related to the probability of chronic hepatitis B or C and human immunodeficiency virus (HIV), which are risk factors for hepatoma and opportunistic infections, respectively. Travel to the tropics may predispose to chronic infections such as tuberculosis of the abdomen, giardiasis, and tropical sprue.

Quality of Pain

As in the assessment of acute abdominal pain, the quality of pain is generally unhelpful in evaluating chronic abdominal pain, an exception being the ‘‘burning’’ sensation that is typical of GERD. Heartburn is defined as ‘‘a burning feeling rising from the stomach or lower chest up toward the neck’’ and when heartburn is a major or sole symptom, GERD is the cause in at least 75% of patients.[5] However, distension (and possibly contractions) of the distal esophagus can also be experienced as a burning sensation. In patients with a known history of recurrent chronic abdominal pain, the quality of pain is useful in assessing if the pain is due to another recurrence or if the pain is from an alternative cause.

Associated Factors

One of the challenges in the assessment of chronic abdominal pain is to distinguish FGIDs from organic disease. Factors that point to an organic disease and deserve detailed investigations include the presence of fever, jaundice, bloody stools, or significant weight loss. Persistent fever is not a feature of FGIDs, and when present, one needs to search for chronic infections, inflammatory disease, or malignancy. Jaundice would point toward pathology of the hepatobiliary system while the chronic passage of bloody stools mandates colonic evaluation. While weight loss can be present in severe FGIDs, one needs to exclude organic disease before making the diagnosis of FGIDs. It is commonly thought that abdominal pain that wakes a patient from sleep is of an organic origin, but it has been reported that nocturnal pain is a common symptom in patients with FGIDs.[6]

Nongastrointestinal Symptoms

Patients with FGIDs, particularly IBS, commonly have associated chronic pain conditions such as migraine, fibromyalgia, chronic fatigue, interstitial cystitis, dysmenorrhea, and dyspareunia. In some of these patients, the extra-GI symptoms may be more distressing than the GI symptoms. The identification of extra-GI symptoms is valuable in the overall management of patients with FGIDs. In IBD, extraintestinal manifestations may be present. These include erythema nodosum, pyoderma gangrenosum, sacroiliitis, and uveitis. Patients with lupus gut may have a malar rash and vasculitic skin lesions.

Drug History

In addition to the risk of acute peptic ulcers, chronic NSAID usage is associated with NSAID colitis. The frequent use of antispasmodics and antidiarrheal agents to treat colicky abdominal pain can lead to the development of chronic constipation and subsequent constipation colic. This needs to be recognized, as continued use of antispasmodic agents would only temporarily alleviate the symptoms and lead to worsening of the underlying constipation. Similarly, chronic use of opiate analgesics can lead to chronic constipation.

Family History

The family history is particularly useful in evaluating chronic abdominal pain as there is a genetic predisposition to inflammatory disorders such as IBD and celiac disease, as well as carcinoma. FGIDs are also more common in patients who have a family history, and this predisposition is thought to be due to both genetic and environmental factors.

Physical Examination

The presence of spider naevi and palmar erythema would alert the clinician to the possibility of liver pathology or alcohol-related disease. In patients with advanced malignancy, masses may be palpable in the abdomen. The presence of blood on rectal examination would indicate organic disease rather than functional disorders. In FGIDs, the physical examination does not usually add more information than that obtained from the history.

FUNCTIONAL GASTROINTESTINAL DISORDERS

General Considerations

FGIDs comprise a wide a spectrum of GI disorders in both the adult and pediatric population. Unlike organic disease, FGIDs are currently classified purely by symptoms, and the diagnosis of FGIDs requires the absence of pathology that may account for the symptoms. The use of symptom-based diagnosis has been validated in a study in which the use of the Rome criteria demonstrated a positive predictive value of 98% in IBS when alarm features such as weight loss, blood in stools, use of antibiotics, nocturnal symptoms, a family history of colon cancer, and abnormalities on physical examination were absent.[7] However, the lack of a discriminatory value between abdominal pain and discomfort in some of these symptom-based criteria puts into question their ability to identify a homogenous group of disorders. For example, chronic abdominal discomfort (in the form of urgency) relieved by bowel movement, but without associated pain, is a nonspecific symptom occurring in different types of organic colitis, such as collagenous and microscopic colitis. Unless these diagnoses are ruled out by biopsies from the colonic mucosa with specialized histological examinations, a large number of these organic conditions will be included under the Rome criteria for IBS.[8] Another problem with symptom-based criteria is the difficulty in classifying FGIDs which have similar symptoms such as those encountered in FD and GERD.

Some FGIDs are characterized by pain or discomfort (e.g., IBS, FD, and FAPS), while others are characterized by altered bodily functions such as functional diarrhea, functional constipation, and aerophagia. This section will focus on FGIDs in the adult population in which chronic abdominal pain is a prominent feature.

Despite the benign prognosis of FGIDs, the health-related quality of life in FGID patients can be affected significantly by their symptoms. For example, the reduction in health-related quality of life in IBS has been reported to be similar to that for patients with diabetes mellitus or renal failure. Similarly, the health-related quality of life in FD was poorer than that experienced by patients with chronic liver disease.[9]

Pathophysiology

Despite considerable progress in the understanding of epidemiological, clinical, and some pathophysiological aspects of FGIDs over the past decade, there is currently no general agreement on the relative contribution of central and peripheral mechanisms involved in the pathophysiology of these disorders. However, a consensus is evolving around the following general concepts: (a) FGIDs are currently defined by symptom criteria, but each diagnostic category may comprise heterogeneous group of pathophysiologies, presenting with similar symptoms. Different subsets of patients may therefore show alterations in GI motility, secretion, gut immune function, or dysregulation of the brain-gut axis, either in isolation or in combinations thereof[10]; (b) despite this heterogeneity, the FGIDs share certain features, which are characteristic for functional disorders in general. These include enhanced stress sensitivity which is associated with autonomic nervous system and hypothalamic-pituitary-adrenal axis dysfunction, comorbidity with psychiatric and chronic pain disorders, greater prevalence in women, and enhanced perception of visceral events. These features have been conceptualized in terms of alterations in the emotional motor system (EMS), a set of parallel output pathways from the brain coordinating autonomic, neuroendocrine, and pain modulatory responses associated with anxiety, anger, and other emotions.[11]

Enhanced Perception of Visceral Pain

A common feature in patients with FGIDs associated with pain or discomfort appears to be an alteration in the perception of visceral afferent stimuli ("visceral hypersensitivity") in which a normally innocuous stimulus, such as contractions or distensions of the gut, leads to the sensation of pain or discomfort. The stimuli may be spontaneous peristaltic activity or from distension by luminal contents such as gas, ingested food/liquids, or feces. Visceral hypersensitivity may be quantified as lowered discomfort thresholds, increased intensity, and affective stimulus ratings, and atypical viscerosomatic referral areas (the somatic area of the body at which a subject localizes a visceral stimulus) in which the referral area is both atypical in location and of a larger area. It has been reported that patients with IBS, FD, or noncardiac chest pain have reduced perception thresholds to balloon distension of the rectosigmoid, stomach, and esophagus, respectively.[10,12]

Fifty to 70% of IBS patients have been reported to have a lower perception threshold for pain and discomfort in response to rectal, sigmoid, and left colonic balloon inflation.[10] When other measures of visceral hypersensitivity (i.e., reported intensity of pain and altered viscerosomatic referral area) were grouped with lowered perception thresholds to rectal balloon distension, 94% of IBS patients showed evidence for altered visceral perception.[13] Visceral hypersensitivity may be relevant clinically as there is a correlation between the experimentally observed pain thresholds and the reported severity of the symptom of pain in IBS.[10]

Similarly, increased sensitivity to gastric distension has been reported in FD and may be relevant clinically as the pain reproduced on gastric distension was associated with nausea and bloatedness, similar to that of FD which occurred after a meal.[14] The reduction in threshold to gastric distension was observed in 34% to 65% of FD subjects compared to controls.[15,16] Using combined measurements of viscerosomatic referral areas and gastric distension thresholds, 87% of FD subjects had evidence for altered perception of gastric stimuli.[15]

This perceptual abnormality appears to be unique to FGIDs, since it is not observed in patients with mild, uncomplicated chronic inflammatory disorders of the upper or lower gut. For example, abdominal pain is not a prominent feature in ulcerative colitis despite extensive chronic inflammation of the colonic mucosa. In contrast to FGIDs, patients with ulcerative colitis,[17] chronic organic dyspepsia,[15] and GERD[18] had no difference in mechanical visceral hypersensitivity compared to controls. It has been suggested that in chronic inflammatory conditions, patients are able to activate adaptive endogenous central pain modulation pathways, while patients with FGIDs have a compromised ability to activate these adaptive mechanisms.[19] It has been reported that IBS patients have a reduced ability to activate descending endogenous pain modulation mechanisms in response to rectal balloon inflation.[20]

Stress Sensitivity

Stress sensitivity is a key feature of FGIDs and may play an important role in both the etiology of and symptom exacerbation in IBS, FD, and FAPS. It is also present in affective disorders and other chronic pain disorders such as fibromyalgia and interstitial cystitis, and may be the reason for the common coexistence of these disorders with FGIDs.

Etiology

IBS patients report more lifetime stressful events including severe abuse history[10] and early childhood aversive events than controls.[21] Poor quality of life has also been reported to predispose to the onset of IBS.[22] PI-IBS is a subset of IBS in which patients with infective gastroenteritis develop persistent symptoms even after the initial infection has resolved. In these patients, the presence of sustained psychological stressors before, during, or after the period of infection increases the probability of developing PI-IBS.[4] Aversive events in childhood experiences may also predispose to other FGIDs, such as FD[23] and FAPS.[24] The onset of pain in FAPS is frequently associated with stressful events such as bereavement of a spouse or close relation or stillbirth during pregnancy.[24] It is currently assumed that early life stress may interact with genetic predisposition to determine the vulnerability of an individual to adult stressors and subsequent development of FGIDs (Fig. 63.4).

Symptom Exacerbation

Psychosocial stressors are commonly associated with exacerbation of symptoms in FGIDs. For example, stressful events are more likely to lead to abdominal pain and change in stool pattern in IBS patients compared to healthy controls, and stress has been correlated with bowel symptoms and physician visits.[25] A detailed history will identify sustained or traumatic stressful life events preceding symptom exacerbation in the majority of IBS patients even though patients may not offer this information initially. Studies in experimental animal models support the concept of acute stress-induced visceral hypersensitivity and it has been reported that auditory stress enhances perception of visceral stimuli in IBS patients.[26] Several studies reported an association be-

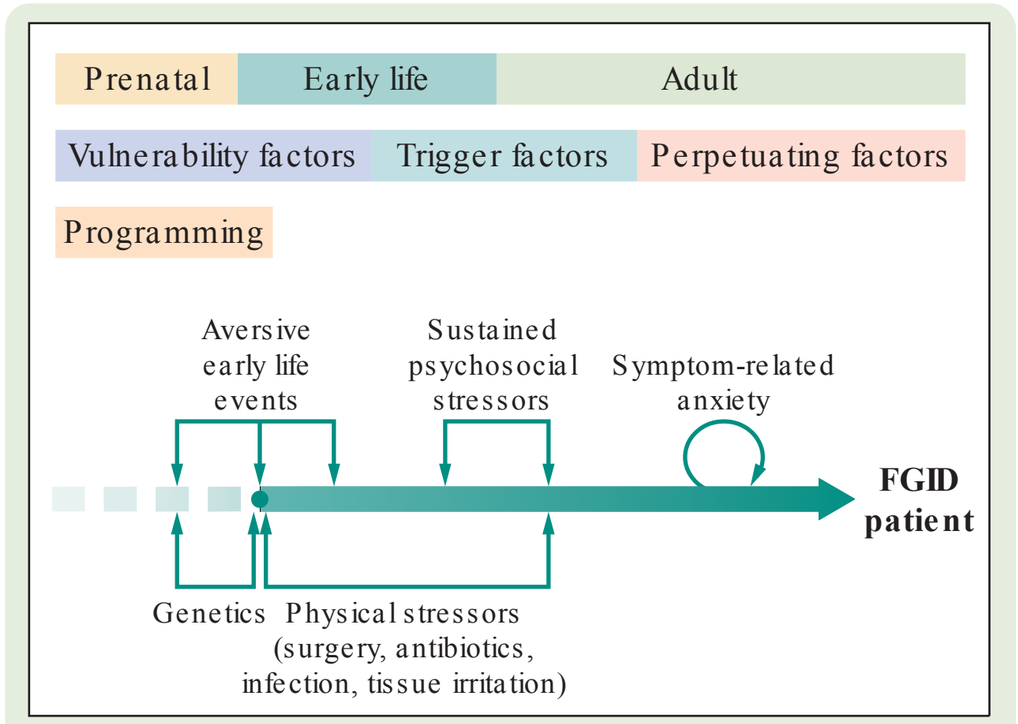

FIGURE 63.4 Putative role of stress in the pathophysiology of functional GI disorders. Upper section: (1) The top bar indicates the phases in life from prenatal to adulthood. (2) The second bar indicates the role of different factors in the etiology of FGIDs in relation to the different phases of life. Vulnerability factors are thought to mediate their effects in utero until early life. Trigger factors manifest in early life to adulthood and lead to FGIDs. Perpetuating factors (such as symptom-related fears and anxiety) play a role in the chronicity of FGIDs. (3) The third bar indicates the role of an individual's programming by prenatal environmental influences. Lower section: Various vulnerability, trigger, and perpetuating factors interact with genetic predispositions to result in the development of chronic FGIDs. (With permission from Wong and Mayer.[147])

tween stress and FD,[27,28] but this has not been demonstrated in other studies.[29]

In addition to its effects on the etiology and symptom exacerbation of IBS, a history of emotional, physical, or sexual abuse, stressful life events, chronic social stress, and maladaptive coping style have been shown to adversely affect the illness experience and treatment outcome.[10] Similarly, a history of physical or sexual abuse in FAPS is associated with poorer health status, medical refractoriness, increased health care visits, and increased diagnostic and therapeutic procedures.[30]

TREATMENT OF ABDOMINAL PAIN

General Principles in the Treatment of Acute Abdominal Pain

Acute abdominal pain generally signals visceral pathology that may require immediate surgery or medical intervention. The treatment of an organic cause of acute abdominal pain is dependent on the specific diagnosis as treatment is targeted against the underlying pathophysiology, such as surgery in perforated viscera and in acute appendicitis or acid suppression in peptic ulcer disease, and is beyond the scope of this chapter. One of the hallmarks of acute abdominal pain is that it will subside with effective treatment of the underlying pathology.

General Principles in the Treatment of Chronic Abdominal Pain

The treatment of chronic abdominal pain is targeted against the underlying pathophysiology if an organic cause of the pain can be identified. However, in the majority of cases, chronic abdominal pain occurs as a result of FGIDs for which the treatment is much less satisfactory. Treatment for functional abdominal pain disorders is tailored for symptom relief rather than specific disease processes (which are largely unknown), and treatment is often suboptimal. This section will focus on the management of FGIDs and will discuss general therapeutic principles as well as specific treatment modalities for the respective FGID.

Doctor-Patient Relationship and Patient Education

The doctor-patient relationship is of utmost importance in the treatment of FGIDs and cannot be overemphasized. The physician must listen to and determine the patient's understanding of the illness and related concerns as patients frequently seek validation from the physician that their symptoms are real. It is likely that many patients have been told previously that their symptoms are "all in their head" and their worries brushed aside. The reason for many patients with FGIDs to visit a physician is a flare of their usual symptoms, and it is important to identify such trigger factors, in particular various psychosocial stressors.

A thorough explanation of the symptoms and relationship to FGIDs should be given to the patient, including the natural history and benign prognosis of the disorder as many patients have inappropriate coping styles, incorrect beliefs about their symptoms, and a significant amount of anxiety related to their symptoms. It has been reported that patients who are not properly informed tend to have more health care visits, and that symptoms are reduced when diagnostic and prognostic information are explained to the patient. The physician must then set realistic short- and long-term goals, including methods of adapting to symptoms that are not amenable to treatment.

Lastly, the patient must be involved in the treatment; the keeping of a symptom diary is an example. Apart from providing the patient with a sense of empowerment, the symptom diary can help identify lifestyle or dietary factors that exacerbate symptoms, and modifications based on this information may provide symptomatic relief to the patient that is cost-effective and devoid of drug side effects.

Dietary Modification

Patients with FGIDs often complain that certain types of food exacerbate their symptoms. Food sensitivity of symptoms may be related to conditioned fear responses related to anticipatory anxiety, food intake in general, volume of the meal, or sensitivities to certain food items. For example, some FD patients may get a worsening of symptoms with large meals, while some IBS patients report symptom exacerbation with fatty food, gas-producing foods, alcohol, and caffeine. In the latter category, the offending agents tend to differ from person to person, and it is useful for the patient to maintain a symptom diary in order to determine their individual food sensitivities.

Pharmacological Agents

Pharmacological therapy in FGIDs can be broadly classified into peripheral and central agents. Peripherally targeted drugs are aimed at a wide range of presumed (but largely unproven) pathophysiologies including altered GI motility and secretion, visceral hypersensitivity, and altered intestinal flora. Categories of drugs include antispasmodics, prokinetics, visceral analgesics, antibiotics, and probiotics. Centrally targeted drugs are given based on the following rationales: (a) reduction of central mechanisms which modulate visceral afferent signals, pain, and emotions (the targets of these treatments are central stress and emotion-generating circuits involving various neurotransmitter systems, such as substance P/neurokinin receptors, corticotropin releasing factor [CRF]/CRF_1 receptors, serotonin/5-HT_3 receptors, and norepinephrine/alpha-2 receptors); and (b) treatment of psychiatric comorbidity, in particular anxiety disorders and depression.

Altered central processing of peripheral afferent input from the viscera appears to be a feature shared by different FGIDs and centrally acting drugs, such as low-dose tricyclic antidepressants (TCAs), selective serotonin reuptake inhibitors (SSRIs), combined serotonin and norepinephrine reuptake inhibitors (SNRI), and compounds used in the treatment of neuropathic pain, such as gabapentin, carbamazepine, and lamotrigine, may be useful in selected patients. However, evidence from high-quality randomized, controlled trials to support the use of the majority of these agents is lacking, and use is largely based on personal clinical experience. Furthermore, in the case of antidepressants, it is unclear if reported benefits are secondary to drug-induced improvement in mood and affect, or represent a direct effect on the brain-gut axis.

The observation that much lower doses of TCAs are required and a shorter lag time to onset of therapeutic effect is present in treating functional GI symptoms (as well as chronic pain in a variety of other disorders) suggests that their action may be mediated in part by their various postsynaptic effects, rather than their inhibitory effect on the reuptake of serotonin and norepinephrine. Interestingly, in addition to their presumed central mechanisms of action, TCAs have also been found to have an analgesic effect on visceral afferent neurons as well as an effect on neuropathic pain.

Patients frequently use anxiolytics and sedatives, and many of the popular IBS drugs in the past were combinations of such centrally acting drugs with "antispasmodics." There appears to be a small benefit of benzodiazepines over placebo in the treatment of IBS, but the risk of physical dependence potentially outweighs the benefits of this class of drugs for chronic therapy.

Psychological Therapy

Several trials have shown the benefit of different forms of psychological therapy for FGIDs,[10,31–35] while others did not reveal any advantage compared to standard medical treatment.[36,37] A major problem with conducting studies on the efficacy of psychological therapy is the inability to blind the therapists to the treatment arms. Similarly, blinding the subjects to treatment arms is difficult. A related problem is a lack of a credible placebo treatment arm seen in many of the studies on psychological therapies. For example, studies often employed standard medical treatment or the monitoring of symptoms while awaiting therapy as their placebo arms. However, these placebo arms are associated with a negative expectancy as the subjects were often referred to these trials when they failed standard medical treatment and were not expected to improve while waiting for therapy. Therefore, the placebo effect of psychological therapy cannot be clearly separated from its true effects. This is particularly relevant in FGIDs where the improvements to placebo occur in up to 50% of patients. Lastly, unlike pharmacological therapy, psychological therapy is dependant largely on the skills of the therapist, and results obtained in one center may not be reproducible in another center.

IRRITABLE BOWEL SYNDROME

IBS is defined as abdominal pain or discomfort that is associated with defecation or a change in bowel habits, and requires the absence of detectable organic disease that may explain the symptoms. The recently revised Rome III diagnostic criteria used in the diagnosis of IBS are listed in Table 63.4. Given the high prevalence of IBS in the general population, comorbidity of organic GI syndromes with IBS is to be expected. Such comorbidity has been reported for ulcerative, microscopic, and collagenous colitis, and celiac disease. This comorbidity has important implications for the treatment of these patients when IBS-like symptoms persist despite optimal management of the underlying organic disease.

TABLE 63.4

ROME III DIAGNOSTIC CRITERIA FOR IBS[38]

Recurrent abdominal pain or discomfort at least 3 days per month in the last 3 months (but with symptom onset for at least 6 months) associated with 2 or more of the following:
- Improvement with defecation
- Onset associated with a change in frequency of stool
- Onset associated with a change in form (appearance) of stool.

Symptoms that cumulatively support the diagnosis of IBS
- Abnormal stool frequency: ≤3 bowel movements per week or >bowel movements per week
- Abnormal stool form: lumpy/hard stool or loose/watery stool
- Defecation straining
- Urgency
- Feeling of incomplete bowel movement
- Passing mucus
- Bloating or feeling of abdominal distention

IBS is further subdivided into IBS with diarrhea (IBS-D), IBS with constipation (IBS-C), or IBS with mixed bowel habits (IBS-M), depending on the predominant bowel habit. When patients do not fulfill any of the criteria for IBS-D, IBS-C, or IBS-M, they are classified as unspecified IBS. Lastly, there is another subset termed PI-IBS which includes patients who develop persistent IBS symptoms despite the resolution of infection from a bout of bacterial gastroenteritis.

Epidemiology

IBS is a common disorder and the worldwide prevalence range is about 10% to 20%.[38,39] Like many related functional pain disorders, it is more common in women with a female:male ratio of 2–2.5:1.[40] It is generally assumed that IBS most commonly presents between the ages of 30 and 50 years; however, recent surveys indicated that IBS is also common in the pediatric population where such symptoms have traditionally been referred to as recurrent abdominal pain.

The socioeconomic burden attributed to IBS is significant, with IBS patients taking three times as many days of sick leave than individuals without IBS,[40] and 8% of IBS subjects retiring early because of their symptoms.[41] It accounts for 12% and 19% of the patient load in primary care and gastroenterology clinics, respectively. In the United States, IBS was estimated to account for $1.6 billion in direct and $19.2 billion in indirect costs.[10]

Symptoms

The location of abdominal symptoms in IBS is highly variable and is diffuse because it is related to the visceral component of abdominal pain and there is an altered central perception of pain, as discussed previously. The pain is frequently aggravated by emotion or stress, poor sleep, and after food intake, but these aggravating factors cannot be elicited in all patients. By definition, abdominal symptoms are relieved by defecation. If symptoms are unrelated to defecation or food intake, and if patients indicate that symptoms are constant and not relievable by any physiological intervention, the differential diagnosis of FAPS should be considered. It is important to note that weight loss is uncommon in IBS (in the absence of depression or eating disorders), and its presence mandates investigation of an underlying organic cause. IBS symptoms occur mainly during wakefulness, but may also awaken patients from sleep.

Symptom severity in IBS varies widely from mild to very severe. The majority of patients in population-based surveys fall into the mild symptom category, while the majority of chronic specialty clinic attendees report their symptoms as severe. Even though present in mildly symptomatic patients as well, the latter group of patients tends to have a higher prevalence of coexisting psychiatric disorders and health-seeking behavior. The presence of coexisting depression predicts a poorer response to both pharmacological and psychological treatment.[34]

IBS symptoms tend to recur frequently as it has been reported that in a 12-week period, IBS patients experience an average of 12 episodes of symptom exacerbation with intervening periods of remission. However, taken over a long time course, the natural history of IBS is that of periods of exacerbation followed by periods of remission. Two longitudinal studies done 1 year and 5 years apart have shown that about 40% of IBS subjects become asymptomatic at the end of the respective studies.[42,43] In a more recent population-based longitudinal study, 55% of subjects who initially reported symptoms of IBS did not report these symptoms at the time of the final survey.[44] Although the IBS symptoms resolved in the majority of subjects, transitions to other complexes of GI symptoms, such as functional dyspepsia, were also observed.

Psychiatric Comorbidity

Psychiatric disorders, such as anxiety disorders (e.g., generalized anxiety disorder, panic disorder, and posttraumatic stress syndrome), depression, somatization, hypochondriasis, and phobias,[45,46] commonly coexist with IBS. The prevalence of coexisting psychiatric disorders varies with the target population studied, and has been reported to range from 40% to over 90% in tertiary referral centers. The high comorbidity seen in such referral centers is likely to reflect an overestimate as patients with coexisting psychiatric disorders, in particular depression, tend to exhibit greater health care-seeking behavior. It has been suggested that individuals with IBS who do not consult physicians regarding their symptoms (''IBS nonconsulters'') may be similar psychologically to the healthy controls.[10,47] However, several population-based surveys tend to contradict this conclusion, demonstrating the presence of more GI symptoms in individuals with affective disorders[45,48] and that somatization and interpersonal sensitivity were independently associated with FGIDs.[48] Regardless of psychiatric comorbidity, stress still plays an important role in IBS nonconsulters, as their symptoms show greater reactivity to stress than healthy controls[25] and total life event stress was independently associated with FGIDs.[48]

Comorbid Conditions/Extraintestinal Manifestations

IBS is associated with several chronic functional pain syndromes. Population-based studies have reported that 13% to 30% and 6% of IBS patients have fibromyalgia and migraine, respectively. In contrast, non-IBS patients had a prevalence of 4% to 5% and 2% for fibromyalgia and migraine, respectively.[49,50] Similarly, 25% of patients with chronic widespread pain had IBS, compared to 5% of controls.[51] IBS also frequently coexists with chronic fatigue syndrome and 63% of patients with chronic fatigue syndrome have IBS symptoms.[52] Interstitial cystitis, chronic prostatitis, and chronic pelvic pain are also common in IBS patients. The association between IBS and comorbid conditions, such as fibromyalgia, chronic fatigue syndrome, migraine headaches, and interstitial cystitis, occurs more commonly in females.[53] This is partially explained by the greater prevalence of such non-GI pain disorders in women. For example, the sex ratio for interstitial cystitis is 10:1.

IBS patients often complain of extraintestinal symptoms such as dyspareunia, fatigue, loss of energy, impotence, urinary frequency, backache, and dysmenorrhea.[54,55] These extraintestinal symptoms are clinically relevant and patients with FGIDs consult primary care physicians for non-GI complaints three times more than healthy subjects.[56] In addition, extraintestinal symptoms, such as loss of libido, poor sleep, and increased fatigue, rather than the GI symptoms per se, may play a prominent role in negatively influencing the patient's health-related quality of life.[57] Like comorbid conditions in IBS, extraintestinal symptoms are more common in females.[53]

Pathophysiology

Even though IBS is the most common and best studied FGID, there is no general agreement on the pathophysiology and the relative contributions of the peripheral and central components. Numerous putative pathophysiologies have been described in the literature but these abnormalities frequently involve only a proportion but not all IBS patients. This may be due to the problem of heterogeneity inherent in symptom-based diagnostic groups as discussed earlier. Moreover, some studies did not segregate IBS patients into the subsets of IBS-C, IBS-D, or IBS-M, and there is evidence that the underlying pathophysiology may differ among these patients.

Evidence for Peripheral Mechanisms

Altered Gastrointestinal Motility. There are quantitative but not qualitative differences in GI motility in IBS compared to controls. These differences appear to be present in only 25% to 75% of IBS subjects, are frequently not reproducible in different laboratories, and currently cannot be used as diagnostic markers.[10] However, differences in GI motility may play a role in determining the predominant bowel habit in IBS subgroups. For example, colonic transit is accelerated in IBS-D[58] and high amplitude propagating contractions occur more frequently in IBS-D subjects than controls. The increased frequency of high amplitude propagating contractions may be clinically relevant as they were correlated with abdominal pain[59] and may be the mechanism underlying urgency and diarrhea. Exaggerated or prolonged colonic motility responses to food intake (''gastrocolonic response'') may be present in the subset of patients who report an exacerbation of abdominal pain by food intake. It is important to differentiate these patients with GERD or FD for whom the treatment is different.

Mucosal Inflammation. Evidence for mucosal inflammation in the pathophysiology of IBS was based on early studies on PI-IBS. Even after resolution of the initial infection, changes in intestinal permeability, as well as increases in intraepithelial lymphocytes and enteroendocrine cells, could be detected in PI-IBS.[4,60] However, mucosal changes alone do not fully account for the pathogenesis of PI-IBS as clinical symptoms have not been found to correlate with the observed mucosal inflammatory changes, the majority of patients with bacterial gastroenteritis do not develop IBS symptoms postinfection, and the prevalence of IBS is not greater in countries with endemic GI infections.[61] There is good evidence that concurrent central factors, such as comorbid psychiatric diagnoses and the presence of concurrent psychological stressors at the time of GI infection,[4,62] contribute to the probability of developing PI-IBS.

More recently, it has been reported that patients meeting current diagnostic criteria for IBS can have increased inflammatory cells on mucosal biopsies which were detected by immunohistochemistry but not by conventional histology. These patients had increased intraepithelial lymphocytes and increased CD3+ and CD25+ cells in the lamina propria.[8] In addition, increased mucosal mast cells in the colonic mucosa of IBS patients have also

been reported.[63] In patients with severe intractable abdominal pain meeting current diagnostic criteria for IBS, surgical biopsies of the ileum revealed the presence of lymphocytic infiltrates within the myenteric plexus and longitudinal muscle hypertrophy.[64] Fecal calprotectin, a surrogate marker of inflammation, is increased in the large majority of patients with proven organic GI disease, but it has also been detected in a small subset of IBS patients.[65]

Activation of immune cells in the intestinal mucosa has been considered as a possible mechanism underlying chronic sensitization of peripheral visceral afferent pathways.[66] A small subset of patients with IBD, especially those with ulcerative colitis who are in clinical remission, exhibit IBS-like symptoms and have demonstrable changes in colonic motility. It has been suggested that the inflammatory process may induce long-term changes in the enteric nervous system and possibly extrinsic sensory afferents, resulting in IBS-like symptoms.[66] However, rectal balloon studies of ulcerative colitis patients with mild disease and without IBS-like symptoms did not reveal evidence for visceral hypersensitivity.[17] Moreover, in Crohn's disease patients with isolated small bowel disease, rectal distension thresholds were elevated, consistent with the activation of endogenous antinociceptive pathways.[67] Taken together with the clinical observation that pain is not a major feature in ulcerative colitis despite extensive mucosal inflammation, these findings may be explained by the hypothesis that the majority of IBD patients are able to activate adaptive mechanisms (descending antinociceptive pathways) which modulate afferent activity from the chronically inflamed gut, but these mechanisms may be inadequate in a minority of patients who develop IBS-like symptoms subsequently.[68]

A mast cell-nerve interaction has been implicated because more mast cells were observed to be in close proximity to nerve endings in IBS patients compared with controls. Furthermore, there was a positive correlation between the nerve-to-mast cell proximity and rate of degranulation of mast cells, suggestive of a functional purpose of the close spatial relationship of the mast cell and nerve ending. This interaction was also reported to be clinically significant, as there was a correlation between the proximity of mast cells to nerve endings and symptoms of abdominal pain and discomfort.[69] Although the observations of the mast cell-nerve interaction can be interpreted to suggest a role of mast cells in the sensitization of colonic nerve endings, it is also possible that activity of the nerve endings result in mast cell degranulation. It has been reported that stress is associated with the degranulation of mast cells in the jejunum in humans.[70]

Altered Intestinal Flora. There is some recent data suggesting that the bacterial flora may be altered in patients with IBS and that these alterations may differ between IBS groups according to predominant bowel habit.[71] It has been proposed that small bacterial overgrowth may be involved in the pathophysiology of IBS and treatment with nonabsorbable antibiotics (neomycin, rifaximin) may be associated with IBS symptom relief.[72–74] Qualitative changes in colonic flora, such as a decrease in Bifidobacterium, have been described in IBS patients. There may be a functional role of the Bifidobacterium as a recent study on the use of *Bifidobacteria infantis* as a probiotic reported a beneficial effect on IBS symptoms compared to placebo.[75,76]

Evidence for Central Alterations

Altered Modulation of Visceral Pain. Enhanced perception of visceral events may be a common abnormality shared by several FGIDs, in particular IBS, FD, noncardiac chest pain, and FAPS. The pathophysiologic mechanisms responsible for this visceral hypersensitivity are not known, even though various animal models exist to support a possible role for both peripheral as well as central mechanisms. As discussed previously, low-grade immune activation of the intestinal mucosa has been suggested to play a role in maintaining a chronic state of peripheral and central sensitization, even though this has never been demonstrated in patients. On the other hand, compelling evidence from brain-imaging studies suggests a central component to visceral hypersensitivity.[77] Studies in IBS patients suggest normal activation of viscerosensory regions, such as the insular cortex, during controlled rectal distension, but altered activation of pain modulation regions, including subregions of the anterior cingulate cortex and the periaqueductal gray.[78,79] Abnormal activation of areas associated with emotional and autonomic responses to stimuli (e.g., ventromedial prefrontal cortex, infragenual cingulated cortex, and perigenual ACC) and subcortical areas (e.g., amygdala, dorsal pons, and hypothalamus) have also been reported in IBS patients.[80] These central abnormalities are clinically relevant as brain imaging studies showed an effect of alosetron, a $5HT_3$ receptor antagonist with proven efficacy in IBS-D, on areas such as the amygdala and dorsal pons that correlated with an improvement in IBS symptoms.[81] Similarly, amitriptyline is effective in the treatment of IBS and has been reported to alter activity in the anterior cingulate cortex.[82]

Altered activation of anterior cingulate subregions has also been reported in patients with fibromyalgia,[83,84] supporting the general notion that different functional pain disorders may share central abnormalities consistent with central pain amplification.

Autonomic Nervous System. Converging results from animal, experimental, and human studies suggest that stress-induced activation of central autonomic circuits play an important role in the regulation of gut motility, secretion, and immune modulation. Acute stress-induced activation of contractions and secretions of the hindgut is mediated by sacral parasympathetic pathways, and increased activation of these pathways in IBS patients has been demonstrated in response to severe laboratory stressors.[85] Evidence suggesting tonic hyperactivity of the sympathetic nervous system comes from studies in female IBS patients who have been shown to have elevated urine catecholamine levels[86] and higher plasma norepinephrine levels during sleep. Abnormalities of the autonomic activity of the heart in IBS patients have also been demonstrated.

Psychoneuroendocrine Axis. The central nervous system is able to influence inflammation in the periphery as anxiety has been reported to be associated with higher levels of TNF-alpha in monocytes from IBS patients compared to controls. This may be mediated via the hypothalamic-pituitary-adrenal axis as abnormalities of this axis have been described in IBS. During infusions of corticotropin-releasing hormone, IBS patients had an exaggerated adrenocorticotropic hormone (ACTH) and cortisol response, and the ACTH response correlated with plasma IL-6.[87] Under conditions of stress, IBS patients were reported to have higher cortisol levels compared to controls in one study[88] but this difference was not seen in another study.[89]

Treatment

Symptomatic treatment (usually aimed at normalizing bowel habits or decreasing abdominal pain) by a reassuring health care provider typically provides relief for patients with mild symptoms who are seen in primary care settings. However, the treatment of patients who have more severe symptoms remains challenging. Only a small number of pharmacologic and psychological treatments are supported by well-designed randomized, controlled trials involving patients with IBS. Treatment of IBS with currently available drugs usually is targeted to the management of individual symptoms, such as constipation, diarrhea, and abdominal pain.

Tricyclic Antidepressants

Low doses of TCAs (e.g., nortriptyline or amitriptyline 10–50 mg at bedtime) are generally used in the treatment of IBS, even though definitive evidence for their effectiveness from well controlled clinical trials is lacking. Doses should be started as low as 5 mg once daily, and gradually advanced to a maximum of 75 mg once daily. The therapeutic effect should be expected within days to 2 weeks of starting the TCA. If no beneficial effect is observed at 75 mg once daily or if significant side effects are experienced, the TCA should be discontinued. Due to the significant side effects of this class of drugs at the higher dose range, doses should not be escalated into the antidepressant dose range (e.g., 100–200 mg every night). To maximize compliance, the patient should be informed about the rationale of the treatment choice (i.e., goal is the treatment of pain and not psychiatric symptoms) and informed about the much lower risk for side effects at the low-dose range, compared to full psychiatric doses. The choice and dose of TCA should be individualized in every patient. For example, TCAs with prominent anticholinergic effects (amitriptyline) may be most useful in the patient with prominent abdominal pain and diarrhea-predominant bowel habit (utilizing their peripheral anticholinergic effect on gut motility and secretion) and in the patient with sleep problems (utilizing their sedative effect).

The efficacy of antidepressants in FGIDs was studied in a meta-analysis by Jackson et al.[90] Data were obtained from nine trials of IBS patients and three trials of FD patients. TCAs were used in all studies apart from one study in which a tetracyclic antidepressant was used. Both high and low doses of the antidepressants were used in these studies. Overall, there was a significant benefit of antidepressants on global GI symptoms and standardized pain scores with a number needed to treat (NNT) of 3.2 (i.e., 3.2 patients needed to be treated to improve symptoms in 1 patient).[90]

A large randomized, placebo-controlled trial of the TCA desipramine in IBS (median dose: 100 mg) reported that by an intention-to-treat basis, there was no significant benefit of desipramine over placebo. However, if the results were analyzed on a per protocol basis and excluded patients who withdrew from the study, there was a significant effect in IBS patients (NNT = 5.2). Moreover, this effect was greater in patients who had detectable plasma levels of desipramine in whom the NNT was 4.3. This suggests that, while desipramine is useful, the side effects are bothersome and compliance with TCAs is an issue. Since doses well beyond 75 mg were used in this study, it is unclear if the observed beneficial effects on IBS symptoms were secondary to a decrease in anxiety. However, consistent with the notion that the TCAs' effect on pain is not related to their antidepressant effects, IBS patients with depression did not show any benefit in the measured composite outcome with desipramine in this trial.[34] Subgroup analyses showed that desipramine was more effective for IBS patients with moderate symptoms, history of physical or sexual abuse, and diarrhea.

Selective Serotonin Reuptake Inhibitors

SSRIs are better tolerated than TCAs in terms of their side-effect profile, but the role of SSRIs in the treatment of IBS has never been demonstrated in large well-controlled clinical trials, even though evidence exists from several smaller trials. Creed et al.[33] reported that paroxetine 20 mg once daily for 3 months improved the physical component of the health-related quality of life at 1 year compared to routine care, and also improved abdominal pain and the mental component of the health-related quality of life at 3 months, although these effects were not sustained at 1 year. The main limitation of this trial was that no placebo drug was administered to patients in the control arm in which routine care was provided, and the efficacy of paroxetine may be contributed by a placebo effect. Other smaller trials examined the role of SSRIs compared to placebo and, while some reported beneficial effects,[91–93] others reported no significant benefit.[94] In the absence of evidence from large well-controlled trials, it would be reasonable to use SSRIs in selected patients, particularly those with psychiatric comorbidity.

Antispasmodics

Antispasmodic medications relax the smooth muscle of the intestines, thereby relieving contractility. They comprise anticholinergic agents, calcium channel blockers, and opioid receptor antagonists. Although antispasmodic medications are frequently used in the treatment of IBS, evidence from well-controlled clinical trials for this class of medication is lacking. A meta-analysis of several low quality studies reported a possible benefit of smooth muscle relaxants such as mebeverine, trimebutine, octylonium bromide, pinaverium bromide, and cimetropium bromide over placebo.[95] The problems with most of the studies were small numbers, lack of adequate blinding, and short duration.

Antispasmodic medications are frequently combined with anxiolytic or sedative agents in the treatment of IBS. However, the evidence is not strong and the data supporting the use of this combination is derived from small studies.[96]

Serotonin Receptor Targeted Drugs

Serotonin (5-HT) receptor antagonists and agonists have been developed and used in the treatment of IBS-D and IBS-C, respectively.

Alosetron is a selective 5-HT_3 receptor antagonist that has been demonstrated to improve symptoms in female IBS-D patients. The exact sites of action of alosetron are not known, but it probably interacts with both peripheral and central targets. It has been reported in a placebo-controlled trial using functional positron emission tomography brain imaging that alosetron reduces resting activity in limbic structures, in particular the amygdala.[81] Moreover, alosetron did not reduce activity in the insula, the viscerosomatic cortex.[97] This suggests that alosetron may not have a direct antinociceptive effect, but that it acts on limbic pain modulation circuits. Unfortunately, alosetron was associated with ischemic colitis in 0.1% to 1% of patients and was subsequently withdrawn from the market in 2000. It has recently been reintroduced for restricted use.

Tegaserod is a partial 5-HT_4 receptor agonist which has been extensively evaluated and demonstrated to be efficacious in the treatment of female IBS-C patients. However, it was recently reported to be associated with an increased incidence of cardiovascular events compared to placebo and has recently been withdrawn from the market.

Psychotherapy

Psychotherapy has been reported to be useful in patients with severe IBS.[31,33] Interestingly, coexistent depression appears to predict a worse outcome with psychotherapy,[33] suggesting that psychotherapy may exert a positive effect independent of coexisting psychiatric comorbidity. It was reported that subjects with a history of sexual abuse did better than those without abuse. The significance of this observation is not known, but it is notable that a history of abuse was also a predictor of better response with desipramine as discussed above.[34]

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) is the best-studied psychological treatment for IBS.[31,98] Cognitive techniques (typically administered in a group or an individual format in 4 to 15 sessions) are aimed at changing catastrophic or maladaptive thinking patterns underlying the perception of somatic symptoms. Behavioral techniques aim to modify dysfunctional behaviors through relaxation techniques, contingency management (rewarding healthy

behaviors), or assertion training. Some randomized, controlled trials have also shown reductions in IBS symptoms with the use of gut-directed hypnosis, which involves relaxation, change in beliefs, and self-management.[99] Data from head-to-head comparisons of psychotherapy with pharmacotherapy for IBS or psychotherapy plus pharmacotherapy with pharmacotherapy alone are lacking. The magnitude of improvement that has been reported with psychological treatments seems to be similar to or greater than that reported with medications studied specifically for bowel symptoms in IBS, although comparisons are limited by, among other things, the lack of a true placebo control in trials of psychotherapies. In a meta-analysis of 17 randomized trials of cognitive treatments, behavioral treatments, or both for IBS (including hypnosis), as compared with control treatments, those patients who were randomly assigned to CBT were significantly more likely to have a reduction in GI symptoms of at least 50% (odds ratio, 12; 95% CI, 6 to 260), and the estimated number needed to treat with CBT or hypnotherapy for one patient to have improvement was estimated to be two.[98] In several studies, coexisting depression was a predictor of poor response to CBT.[33,34] It has been postulated that the presence of depression may reflect a more severe illness or that depressed subjects may be less willing or able to engage in psychological therapy or to be compliant to an antidepressant regimen.[33]

Hypnotherapy

Hypnotherapy may improve symptoms in patients with severe IBS in the short term,[100,101] as well as in the long term over a period of at least 5 years.[102] The beneficial effects of hypnotherapy were observed in both depressed and nondepressed subjects. However, male subjects with IBS-D and subjects over 50 years old did not respond as well as other IBS subjects.[101,103] A recent systematic review reported that hypnotherapy may be beneficial in the treatment of IBS, but the main problem with current data is that the trials comprised small number of patients.[104] The mechanism(s) underlying the beneficial effects of hypnotherapy in IBS are not known but may involve changes in brain responses to painful stimuli,[105,106] reduction of central pain amplification, and normalization of colonic motility.

FUNCTIONAL DYSPEPSIA

As with other FGIDs, the diagnosis of FD is based on the exclusion of organic diseases and the presence of a set of key symptoms. FD is defined as the presence of symptoms thought to originate from the upper GI tract for which there is no detectable organic disease that can explain the symptoms. These symptoms include epigastric pain, epigastric burning, postprandial fullness, or early satiation. Symptoms of bloating and nausea may be experienced by FD patients, but they appear to be less specific and are not considered cardinal symptoms of FD.[107] The Rome III criteria for FD are listed in Table 63.5.

TABLE 63.5

ROME III DIAGNOSTIC CRITERIA FOR FD[91]

1. One or more of:
   - Bothersome postprandial fullness
   - Early satiation
   - Epigastric pain
   - Epigastric burning

AND

2. No evidence of structural disease (including at upper endoscopy) that is likely to explain the symptoms

*The criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

TABLE 63.6

ROME III DIAGNOSTIC CRITERIA FOR FD SUBGROUPS[91]

Postprandial distress syndrome

One or both of the following:

1. Bothersome postprandial fullness, occurring after ordinary sized meals, at least several times per week
2. Early satiation that prevents finishing a regular meal, at least several times per week

*The criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

Supportive criteria:

1. Upper abdominal bloating or postprandial nausea or excessive belching can be present
2. Epigastric pain syndrome may coexist

Epigastric pain syndrome

One or both of the following:

1. Pain or burning localized to the epigastrium of at least moderate severity at least once per week
2. The pain is intermittent
3. Not generalized or localized to other abdominal or chest regions
4. Not relieved by defecation or passage of flatus
5. Not fulfilling criteria for gallbladder and sphincter of Oddi disorders

*The criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

Supportive criteria:

1. The pain may be of a burning quality but without a retrosternal component
2. The pain is commonly induced or relieved by ingestion of a meal but may occur while fasting
3. Postprandial distress syndrome may coexist

The symptoms of FD overlap with atypical manifestations of GERD, and previous studies on FD may have inadvertently included patients with atypical GERD symptoms, especially since 24-hour pH measurements are not frequently used to exclude GERD patients. This may be particularly relevant in the context of large community-based studies or questionnaire-based studies. It is therefore important to be mindful of this possibility when reviewing research literature on FD.

Several attempts have been made to subdivide FD into distinct subsets on the basis of predominant symptoms. In the Rome III criteria, symptoms have been divided into meal-related (Postprandial Distress Syndrome) and meal-unrelated (Epigastric Pain Syndrome). These proposed subsets of FD are defined in Table 63.6. The clinical utility of these subgroups is controversial, since there is considerable overlap between them. Moreover, the concept of distinct pathophysiologies correlating with distinct symptom patterns has not been confirmed.

Epidemiology

FD is a common disorder with an estimated prevalence of 15% to 20%.[108] Unlike IBS, there does not appear to be a sex-related difference in prevalence.[109] The socioeconomic burden of FD is significant, as FD patients take three times as much sick leave as patients with duodenal ulcers.[110] Two to 5% of primary care visits and more than 10% of primary care drug expenditure in the United Kingdom are related to FD.[111,112] Approximately 1

out of 2 individuals with FD seek health care for their symptoms at some time in their life.[113] It is therefore not surprising that in the United Kingdom, the annual indirect and direct cost of dyspepsia to society is US $1.46 billion and US $730 million, respectively.[114]

Comorbidity With Irritable Bowel Syndrome

FD and IBS frequently coexist in patients, and a third of FD patients have concurrent symptoms of IBS[115] while approximately 40% of IBS patients also report FD symptoms. Frequently, pain or discomfort in the upper abdomen is assumed to be related to the upper GI tract, but on detailed questioning, the "dyspepsia" may be related to bowel disturbances. As discussed earlier, the localization of visceral pain, especially in FGIDs, is often imprecise. In a 1-year follow-up of patients with IBS or dyspepsia, 22% of IBS patients reported a change in their symptom profile to that of FD, and 16% of FD patients reported a change to an IBS symptom profile.[116] This transition of patients between different diagnostic categories (e.g., IBS and FD), which has also been demonstrated in a recent 12-year longitudinal study,[44] puts into question the concept that these symptom-based entities are really distinct syndromes.

Psychiatric Comorbidity

Anxiety, depression, and neuroticism appear to be more common in FD clinic patients.[117] Similar to the situation in IBS, this association in clinic attenders may be biased, as anxiety has been reported to be associated with health-seeking behavior in FD. Compared to patients with nonlife-threatening organic GI disease, FD patients have higher anxiety, but not depression or neuroticism scores.[118]

Pathogenesis

The pathophysiology of FD is not fully understood, and both central and peripheral mechanisms have been proposed. While enhanced perception of gastric stimuli may be a key central mechanism, the role of gastric acid, acute and chronic gastric mucosal infections, and gastroduodenal dysmotility remains to be determined.

Visceral Hypersensitivity

As with IBS patients, visceral hypersensitivity is common in FD and a significant subset of FD patients (34%–65%) report pain and discomfort at lower volumes of gastric distension compared to healthy control subjects[15,16] or compared to patients with dyspepsia from organic causes.[15] Chemical sensitivity to capsaicin has also been reported in FD patients.[119]

Central pain amplification is likely to contribute to the observed gastric hypersensitivity. For example, the presence of lipids in the duodenum increases the sensitivity of FD patients to gastric balloon distension compared to controls.[120] This abnormal modulation of gastric perception thresholds to distension by lipid in a distant site supports the concept of a centrally mediated mechanism. Furthermore, it has been reported that in response to gastric balloon distension, about half the patients with FD experienced altered viscerosomatic referral patterns.[15]

IBS coexists with FD in a substantial proportion of patients, and studies show that sensitivity to balloon distension in the small intestine was similar in IBS and FD.[121] These findings support the concept that IBS and a subset of FD patients share similar pathophysiologic mechanisms.

Gastric Acid

Several large multicenter studies have demonstrated that only a small subset of FD patients (10%–15%) benefited from acid suppression therapy.[122,123] This suggests that such patients either represent a subgroup of patients characterized by hypersensitivity to intraduodenal or intra-antral acid[124,125] or that they suffer from atypical manifestations of GERD.[126] There is some recent evidence against the latter as it was reported that responsiveness to acid suppression therapy in FD did not correlate with abnormal 24-hour pH studies.[127]

Helicobacter Pylori

Chronic *H. pylori* infection has been postulated to be related to sensitization of visceral afferent pathways. Two large prospective studies have reported improvement of symptoms in FD following eradication of *H. pylori*.[128,129] However, three other trials failed to demonstrate a beneficial effect from *H. pylori* eradication.[130–132] Furthermore, no differences in perceptual responses to controlled gastric distension have been observed between FD patients with and without *H. pylori* infection.[133] A recent meta-analysis reported that the relative risk reduction at 12 months with *H. pylori* eradication was 9% compared with placebo, and 15 patients needed to be treated for 1 patient to benefit.[134] Chronic *H. pylori* infection may be related to dyspeptic symptoms in a small subset of FD subjects, and *H. pylori* eradication in patients with FD has been recommended by a consensus conference.[135]

Presumed Postinfectious Functional Dyspepsia

About 20% of patients with FD develop symptoms after an acute episode of presumed gastroenteritis based on symptoms such as fever, myalgia, vomiting, or diarrhea.[136] A similar observation has been reported in patients following *Giardia* infection.[137] This is analogous to the group of PI-IBS patients who develop persistent symptoms of IBS following a bout of gastroenteritis. Patients with presumed postinfectious FD were younger and had lower body mass index than those with unspecified-onset FD.[136] A greater proportion of patients with presumed postinfectious FD patients had impaired gastric accommodation but not hypersensitivity to distension when compared to patients with unspecified-onset FD.[136]

Gastroduodenal Motility

Forty percent of FD subjects have evidence of impaired gastric accommodation.[138,139] It has been suggested that impaired gastric accommodation may cause rapid transit of food from the proximal stomach, resulting in early antral distension, which in turn results in dyspeptic symptoms. There is limited data that improved gastric accommodation by sumatriptan resulted in a reduction of meal-induced symptoms.[140] In addition, postprandial antral hypomotility has been demonstrated in manometric studies in about half of FD subjects and this abnormality correlates with delayed gastric emptying, which has been demonstrated in a third of FD subjects.[141] A correlation between delayed gastric emptying and dyspeptic symptoms of postprandial fullness has been reported in FD patients.[142]

Treatment

In general, therapy of patients with FD can be directed at peripheral and central targets. The peripheral targets are based on the proposed pathophysiological abnormalities outlined above. Central nervous system-directed therapy is analogous to that used in the treatment of IBS.

Acid suppression therapy is safe and may have a beneficial

effect over placebo in approximately 10% of patients meeting current symptom criteria for FD. It is currently assumed that the subset of responsive patients comprises those with either atypical GERD or with duodenal hypersensitivity to gastric acid. The choice of acid suppressive agents is open to debate, and both histamine (H2) receptor antagonists and proton pump inhibitors have been reported to be more effective than placebo.[143] A small subset of FD patients improve with eradication of *H. pylori* and the likelihood of a positive response is comparable to that with acid suppression. This form of treatment is reasonable given that the treatment is of short duration and can also reduce the risk of subsequent peptic ulcer disease, atrophic gastritis, and gastric cancer.[135] There are no well-designed clinical trials in defined populations of FD patients supporting the use of prokinetic drugs. The use of low dose TCAs has not been as extensively evaluated in FD compared to IBS. Small studies have reported a beneficial effect of TCAs in the treatment of FD.[15,144] A recent small study looking at a combination of melitracen (TCA) and flupentixol (an antipsychotic drug) reported a significant benefit over placebo in FD patients.[145] The benefits of psychological therapy on FD are not well established, but may be a reasonable option in patients who do not respond to pharmacotherapy.

FUNCTIONAL ABDOMINAL PAIN SYNDROME

FAPS is defined as a continuous or near continuous abdominal pain that is present for at least 6 months, is poorly related to gut function, and is associated with some loss of daily activities.[146] The diagnostic criteria for FAPS are listed in Table 63.7.

The main feature that distinguishes FAPS from IBS and FD is that the abdominal pain in FAPS is present all or most of the time, while the abdominal pain in IBS and FD is generally related to physiological events such as defecation or food intake, respectively. The abdominal pain in FAPS is constant and generally referred to the entire abdomen rather than a specific location. Sometimes atypical referral patterns to extra-abdominal regions (thighs, chest, and back) and to an entire side of the body are reported.

Epidemiology

FAPS is uncommon compared to IBS with a prevalence of 0.5% to 2%. FAPS is more common in women with the highest prevalence in the fourth decade of life. Like IBS, FAPS is responsible for a disproportionately large portion of health care resources and high work absenteeism. Patients with FAPS tend to have about three times as many days of sick leave and number of physician visits as subjects without bowel symptoms.[24]

TABLE 63.7

ROME III DIAGNOSTIC CRITERIA FOR FAPS[146]

Must include all of the following:
- Continuous or nearly continuous abdominal pain
- No or only occasional relationship of pain with physiological events (e.g., eating, defecation, or menses)
- Some loss of daily functioning
- The pain is not feigned
- Insufficient symptoms to meet criteria for another functional gastrointestinal disorder that would explain the pain

*The criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

Psychiatric Comorbidity

The psychiatric comorbidity seen in FAPS is prominent and bears many similarities to that in IBS. The majority of FAPS patients have psychiatric diagnoses of anxiety, depression, and somatization.[146] Unresolved losses, such as demise of a spouse or parent, personally meaningful surgery (e.g., hysterectomy), or termination of pregnancy, are common in FAPS.

Pathophysiology

The pathophysiology of FAPS is poorly understood and literature in this area is scarce. As there is no definite relationship to physiological events like eating, defecation, or menses in FAPS, a neurologic etiology is likely. The abnormal viscerosomatic referral patterns could result from either sensitization of primary afferent origin or from increased resting activity of spinal, thalamic, or cingulate neurons, all of which have large receptive fields. The epidemiological and psychosocial similarities between IBS and FAPS and the frequent history of IBS in a patient with FAPS suggest shared pathophysiological mechanisms such as alteration of central pain modulation pathways.

Treatment

There are no well-controlled clinical trial results that would guide the treatment of FAPS, which is largely empirical. Treatment options include the use of TCAs, SSRIs, SNRIs, and anticonvulsants (e.g., gabapentin, carbamazepine, and lamotrigine).

CHAPTER 64 ■ PELVIC PAIN IN FEMALES

KATY VINCENT AND JANE MOORE

INTRODUCTION

Pelvic pain is common in women, frequently leading to disability, social disruption, and loss of economic productivity. Many women do not seek help, often having lived with the pain since adolescence and accepting it as normal. In New Zealand, only 34% of a community sample of women aged between 18 and 50 years reported no pelvic pain, with 55.2% reporting dysmenorrhea, 25.4% chronic pelvic pain (CPP), and 19.7% dyspareunia.[1] In the United States, 14.7% of women of the same age range reported CPP with estimated outpatient medical costs of $881.5 million per year, 15% reporting work absenteeism, and 45% reduced productivity.[2] Similarly in the United Kingdom, 24% of 18 to 49 year olds reported CPP[3] and 37 of every 1000 women consulting their general practitioner presented with CPP[4]; this was comparable to asthma (37/1000) and back pain (41/1000) and higher than migraine (21/1000).

Pelvic pain is a frustrating symptom for both the patient and the doctor. Presentation can be variable, involving many organ systems, and severity can fluctuate over time. The frequent lack of an obvious initial diagnosis in both acute and chronic pelvic pain means that women frequently undergo large numbers of investigations and often unnecessary surgical procedures with associated morbidity and mortality. There is often a long interval between presentation and diagnosis with 25% remaining without a diagnosis after 3 to 4 years and more than 30% of women having had their pain for more than 5 years.[4]

The aim of this chapter is to provide an overview of the common causes of pelvic pain as well as to detail some of the less well known, but easily treated causes with up-to-date evidence and a clear rationale for investigation and treatment. Because of the complexity of the innervation of the pelvis and the anatomical proximity of pelvic viscera, there is frequently overlap between what has traditionally been considered the domain of gynecology, urology, or gastroenterology. Therefore, some conditions will only be briefly discussed here when they are considered in more detail in other chapters of this book.

We discuss acute and chronic pelvic pain separately as, although there are overlaps, presentation and management are often very different. The Royal College of Obstetricians and Gynecologists' (RCOG) definition of CPP will be used: ''intermittent or constant pain in the lower abdomen or pelvis of at least 6 months' duration, not occurring exclusively with menstruation or intercourse and not associated with pregnancy.''[5] In addition, we also consider pelvic pain in pregnancy, dysmenorrhea, and mittelschmerz, and that associated with the complications of assisted conception. Finally, we discuss dyspareunia and the vulval pain syndromes which frequently coexist with other pelvic pain and whose etiology and management may be similar.

ACUTE PELVIC PAIN

Introduction

The maxim that ''acute pelvic pain in a woman of reproductive age is an ectopic pregnancy until proven otherwise'' needs always to be borne in mind as ruptured ectopic pregnancies are associated with high morbidity and mortality and the consequences of a missed diagnosis are severe. However, there are many other causes of acute pain in the lower abdominal/pelvic area that also need to be considered in the differential diagnosis. Many of these are not gynecological (Table 64.1), though the symptom fre-

quently presents, or is referred, to the gynecologist. Unless the patient is extremely unwell, assessment should begin as always with a detailed history followed by examination and appropriate investigations.

Overview of Assessment

Where at all possible, the history should be taken in private, allowing the woman (whatever her age) to have with her only those people she requests to be present. A detailed history of the pain should be taken and associated bowel and urinary symptoms and vaginal discharge/bleeding should be enquired about directly. It is also important to ascertain with accuracy the date of her last menstrual period (LMP) and whether this was normal, as well as a contraceptive history and any recent episodes of unprotected sexual intercourse (UPSI). In all cases, but particularly with adolescents, these areas need to be approached sensitively. The presence of any risk factors for ectopic pregnancy (Table 64.2) should be established and the woman's obstetric history ascertained. With an acute exacerbation of a chronic pain, it is important to enquire whether any precipitating factors (either physical or psychological) are present. At all times, clinicians should be alert to the possibility of assault and know where to access appropriate help locally if required.

Initial examination should ascertain that she is hemodynamically stable before examining the abdomen. The exact site of the pain should be established and evidence of an acute abdomen or abdominal/pelvic masses looked for. Pelvic pain in a sexually active woman (especially with a positive pregnancy test) should prompt a gentle digital internal examination, looking specifically for adnexal tenderness/masses and cervical excitation. Any discharge should be noted and appropriate swabs taken. If vaginal bleeding is present, a speculum examination should also be performed. Rectal examination may be indicated depending on the history. Again, privacy should be ensured, although a chaperone is recommended.[6]

All women should have a urinary pregnancy test, but otherwise investigations should be prompted by the history and examination findings rather than routinely ordered. Initially, investigations should be kept to a minimum in the case of an acute exacerbation of CPP. Investigations that might be considered are listed in Table 64.3.

Gynecological Factors

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is a common cause of acute pelvic pain and the incidence is increasing. It is an upper genital tract infection and can include one or more of the following: endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. Prompt treatment and effective contact tracing are important as long-term sequelae include CPP, subfertility, and ectopic pregnancy. While infection usually ascends from the cervix, cervical swabs can be negative even when pathogenic organisms are isolated from the fallopian tubes. The pain is thought to be due to inflammation, tissue destruction, irritation of peritoneal surfaces, and distortion of anatomy. Right upper quadrant pain and perihepatic adhesions occur in the Fitz-Hugh-Curtis syndrome, which is seen in 10% to 20% of women with PID.[7,8] Clinical features of PID lack sensitivity and specificity, but include lower abdominal pain and tenderness, deep dyspareunia, abnormal vaginal/cervical discharge, cervical excitation and adnexal tenderness, and fever.[9] Evidence of acute infection will not always be seen on diagnostic laparoscopy and therefore this investigation should be reserved for cases where alternative pathology needs to be excluded or if a pelvic mass is seen on ultrasound (US).[10] Where there is a high index of suspicion, it is recommended that empirical antibiotic treatment should be commenced once swabs have been taken without waiting for culture results or performing further investigations.[10] A number of different organisms are associated with PID, including *Chlamydia trachomatis*, *Neisseria gonorrhoea*, *Mycoplasma genitalium*, and anerobes.[9] The most commonly implicated organisms vary geographically and therefore local guidelines for appropriate antibiotic treatment regimens should always be consulted. There are now high rates of quinolone-resistant gonorrhoea in the Unites States and, since April 2007, fluoroquinolone antibiotics have no longer been recommended for the treatment of PID there,[11] though this is not yet the case in the United Kingdom. Antibiotic treatment is usually continued for 14 days (with intravenous doses converted to oral once apyrexial), and therefore patient compliance can be an issue. The presence of an intrauterine contraceptive device (IUCD) only increases the risk of developing PID in the first few weeks after insertion. Leaving the device in situ while mild PID is being treated does not appear to affect the outcome. In severe cases, however, it is recommended that the IUCD be removed.[10]

When there is definite evidence of a pelvic abscess or severe disease, surgery is recommended (either laparoscopy or laparotomy), to drain the abscess and divide adhesions.[10] Depending on location, it may also be possible to drain pelvic collections under US guidance. This has been shown to be effective with fewer complications than surgery.[12]

To prevent reinfection, contact tracing and treatment of all sexual partners from 6 months prior to presentation is recommended.[10] This may be best done through a local genitourinary medicine (GUM) clinic, which will have experience of contact tracing and counselling about the long-term consequences of sexually transmitted infections. If admission is not required and appropriate facilities exist, it may be more effective to refer the woman to a GUM clinic immediately, to be seen the same day, before treatment is started. Sexual intercourse should be avoided

until both the patient and her partner have completed a full course of treatment.

Adnexal Pathology

The adnexae comprise the fallopian tubes and the ovaries, the overlying peritoneum, and accompanying blood vessels. Common adnexal problems causing pain are discussed here.

Adnexal Torsion. Unlike the testes, it is rare for a normal adnexa to undergo torsion. However, the ovaries and the distal ends of the fallopian tubes hang free and, if enlarged by an ovarian cyst or hydrosalpinx for example, are able to twist and cause ischemia and thus pain, with necrosis ensuing if the torsion is not resolved. Initially, the pain may be a dull ache which comes and goes; however, once necrosis occurs, the pain becomes constant and severe and may be accompanied by pyrexia, nausea, leucocytosis, and raised inflammatory markers. Clinically, a tender pelvic mass will be found on internal examination and this can be confirmed with US. Management is surgical, ideally by urgent laparoscopy. If the adnexae appear healthy, then the torsion can be untwisted and the cyst/hydrosalpinx dealt with appropriately; however, if the tissues are gangrenous, it is recommended that the whole mass is removed intact without first attempting to resolve the torsion.

Other Ovarian Cyst Accident. As well as undergoing torsion, an ovarian cyst (either functional or pathological) can also cause pain by rupturing or by hemorrhaging into itself.

Ruptured cysts usually cause acute pain followed by a generalized dull ache; however, if enough fluid/blood is released into the pelvis to irritate the diaphragm, then shoulder pain may also be present. Diagnosis is usually clinical, although, an US may show fluid in the pelvis and the absence of a previously noted ovarian cyst. Pregnancy must always be excluded (usually with a urinary pregnancy test), but if the pain is resolving and the woman is hemodynamically stable, then management is conservative, providing symptom relief. However, if she is unstable or a significant amount of fluid is present in the pelvis, laparoscopy may be required. In this instance, it is obviously important to be sure the diagnosis is correct and that an ectopic pregnancy, for example, has not been missed.

Hemorrhage into a cyst may be self-limiting or require surgery. Again this decision should be based on the clinical picture.

In all these cases, if there is any doubt as to the nature of the cyst, then surgery should be performed so that tissue for histology can be obtained.

Hematometra/Hematocolpos

A relatively rare cause of acute, or acute-on-chronic, pelvic pain is a hematometra or hematocolpos (literally blood in the uterus or blood in the cervix). This can be primarily from a congenital anomaly or secondary to procedures such as transcervical resection of the endometrium if cervical stenosis occurs. With congenital anomalies where a bifid uterus exists with one blind ending horn, it is possible to have normal menstrual flow from one horn and a gradually increasing hematometra in the other.

Diagnosis is by US or magnetic resonance imaging (MRI) and management is surgical, which may be as simple as cervical dilatation or incising an imperforate hymen. The discovery of a congenital müllerian anomaly should prompt a thorough investigation of the renal and urogenital system as many of these anomalies coexist.[13]

Acute Exacerbation of Chronic Pelvic Pain

An emergency presentation with acute pelvic pain can be an exacerbation of a much more chronic problem. Often the patient is known to the department, but for others the sudden worsening of chronic pain can be the final straw that causes the woman to present for the first time. As well as organizing appropriate analgesia (remaining alert to the possibility of an opioid addiction) and treating any associated symptoms, a careful search for the factor(s) precipitating the exacerbation should be made. This may be disease-related, such as an ovarian cyst accident; treatment-related, such as reactivation of endometriosis by add-back hormone replacement therapy (HRT) or constipation secondary to increased analgesia use; or lifestyle-related, such as increased activity worsening musculoskeletal pain or a bereavement worsening psychological status. If such precipitating factors can be identified, they should be discussed with the patient. Coping strategies can be taught to prevent future emergency presentations, which may also be reduced by easy access to a health care professional who knows the woman well.

Complications Specific to Pregnancy

A number of complications specific to pregnancy can present with pelvic pain and need always to be borne in mind in a woman of reproductive age. It is also worth noting, however, that the physiological and anatomical adaptations of pregnancy can alter the presenting features of many nonpregnancy-related conditions such as appendicitis. When treating pain in a possibly ongoing pregnancy, nonsteroidal anti-inflammatory drugs (NSAIDs) are contraindicated because of effects on implantation, fetal renal function, and premature closure of the ductus arteriosus. Acetaminophen (paracetamol) and opioids, however, are safe. Reassurance and explanation are perhaps more important than ever in these cases to avoid anxiety about the pregnancy further clouding the clinical picture.

Ectopic Pregnancy

An ectopic pregnancy is one in which the conceptus implants outside the uterine cavity. Most commonly, this is within the fallopian tube (98.3%) but more rarely can be in the abdominal cavity, on the ovary, or on the cervix. The incidence is approximately 1 in 100 pregnancies[14]; however, this is likely to increase with the increasing incidence of pelvic infection and assisted conception. Rarely, a heterotopic pregnancy can occur, which is effectively a twin pregnancy in two different sites (e.g., one intrauterine and one ectopic pregnancy). These cases can be easily missed with false reassurance given once the intrauterine pregnancy is seen on US. With the rising prevalence of assisted conception techniques the incidence of heterotopic pregnancies is increasing.[15]

Classically, presentation is with a period of amenorrhoea followed by brown vaginal loss and then onset of pelvic pain. Realistically, however, presentation is varied, ranging from asymptomatic (an incidental finding at routine scan), through any combination of pain and/or old or fresh vaginal bleeding, to collapse secondary to hypovolemia. Initial pain is thought to be secondary to stretching of the peritoneum covering the distended fallopian tube; however, with rupture of the tube, peritonitis occurs and tracking of the blood up to the diaphragm can cause shoulder tip pain.

In the collapsed patient with a positive pregnancy test, diagnosis is assumed and resuscitation commenced with surgery performed immediately when she is stable. At the opposite extreme, in a hemodynamically stable woman with minimal symptoms, diagnosis can be difficult. In early pregnancy an intrauterine gestation may not be visible even with transvaginal US (TVUS). A combination of serial human chorionic gonadotrophin (hCG) levels and repeated US may be required to determine the location and viability of the pregnancy. If a high index of suspicion is present or the woman is isolated socially, this observation may best be done as an inpatient; however, in the majority of cases, early pregnancy clinics facilitate safe outpatient management.

Appropriate management depends on the severity of presentation. With an unstable patient, urgent laparotomy or laparoscopy should be performed depending on the skills of the available surgeon. With a stable patient, the majority of cases should be able to be managed laparoscopically, reducing postoperative pain, recovery time, and hospital stay. Some units now manage appropriate cases medically using methotrexate; however, this is not without risks and requires careful surveillance and a motivated patient.[16]

However the pregnancy is managed, the risks of an ectopic pregnancy in the future are considerably higher than in the background population, and the woman should be counselled about this prior to discharge and advised to get an early scan in her next pregnancy. It should not be forgotten that a pregnancy has been lost and many women/couples value the opportunity to talk this through either at the time or at a later date.

Miscarriage

Miscarriage is defined as pregnancy loss prior to viability (currently considered to be 24 weeks) and occurs in 10% to 20% of clinical pregnancies.[17] Because of connotations of blame, the medical term abortion should no longer be used when pregnancy loss is spontaneous. The different types of miscarriage are shown in Table 64.4. Bleeding is not always the presenting feature. Classically, bleeding precedes pain in a miscarriage as opposed to an ectopic pregnancy where the pain occurs first. As this is not reliable, all pain or bleeding in early pregnancy should be referred to an early pregnancy unit for further assessment and management. Management may be expectant, medical (using prostaglandin analogues ± antiprogesterone) or surgical (evacuation of retained products of conception [ERPC]). If the woman is hemodynamically unstable or the bleeding is very heavy, then surgery is recommended; otherwise the choice of management should be made by the woman. Nonsurgical options are associated with longer periods of bleeding, but avoid the risks of a general anesthetic and may allow the woman to feel more in control. Contrary to previous beliefs, there is no increase in infection rate with expectant management.[18] All nonimmunized, Rhesus-negative women who miscarry after 12 weeks' gestation should be given prophylaxis with anti-D immunoglobulin. Prior to 12 weeks, anti-D immunoglobulin should be given for medical or surgical evacuation or if the bleeding is very heavy and associated with pain.[17] The negative psychological impact of early pregnancy loss can be enormous, both for the woman and her family, and therefore counselling and support should be offered. Ideally, this should be at a local level, although national support groups also exist.

TABLE 64.4

TYPES OF MISCARRIAGE[125]

Threatened	May be continuing to bleed Viable pregnancy
Inevitable	Bleeding Cervical os open
Complete	Bleeding settled All products of conception passed
Incomplete	May be continuing to bleed Products still present
Delayed	No/minimal bleeding Fetal demise, all products still present
Anembryonic pregnancy	May have bleeding Gestational sac present but no fetal pole

Fibroid Degeneration

Uterine fibroids (leiomyomas) are benign tumors of the uterus which are found in approximately 20% of women of reproductive age. They are usually asymptomatic and are more common in older women and women of African origin. They possess estrogen receptors and are thus stimulated to grow during pregnancy. As their blood supply is mainly peripheral, central areas can suffer from ischemia if enlargement is rapid, causing pain. This is known as red degeneration. The pain is generally well localized with tenderness over the area of the fibroid only (as opposed to placental abruption where the whole uterus is tender and woody hard) and may be accompanied by a mild pyrexia and leukocytosis. Opioid analgesia is often required and admission may be necessary, if only for observation and fetal monitoring if there is any doubt about the diagnosis.

Ovarian Cyst Accident

As in the nonpregnant state, hemorrhage into or rupture or torsion of an ovarian cyst can occur during pregnancy. In general, presentation and management are as for the nonpregnant woman; however, symptoms can be masked and nonspecific during pregnancy. Rupture of a cyst can present with severe pain and shock, and in early pregnancy laparoscopy may be necessary to exclude ectopic pregnancy. However, if pain is resolving and no other symptoms are present, conservative management is recommended.

If surgical management is required beyond early pregnancy, laparotomy may have to be considered because of the risks and technical difficulties of a laparoscopy with an enlarged uterus.

Ligamentous Stretch

As the uterus enlarges, it moves out of the pelvis and becomes an abdominal organ. During this process, the supporting round ligaments are stretched and cause pain in the late first/early second trimester in 10% to 30% of pregnancies. Management is by simple analgesia and reassurance; however, it is important to ensure that other causes of pain are not missed, such as rupture of a heterotopic pregnancy or acute appendicitis.

Urinary Retention and Uterine Incarceration

Uterine retroversion occurs in up to 15% of pregnancies in the first trimester but by 15 weeks gestation spontaneous anteversion almost always occurs. It is reported that retroversion persists into the second trimester in 1 in 3000 pregnancies.[19] Rarely, it may not be noticed until a cesarean section is performed at term; however, it can become impacted and present with urinary frequency, urgency, abdominal pain, and urinary retention. Pelvic adhesions secondary to infection or endometriosis and posterior wall fibroids can predispose to incarceration. Diagnosis can be aided by US or MRI (Fig. 64.1); however, fetal parts may be palpable vaginally and an enlarged bladder abdominally. Gentle manual decompression is usually possible after emptying the bladder with a Foley catheter. Intermittent catheterization is occasionally necessary for a few days subsequently, but an indwelling catheter is not recommended because of the risk of infection.[20] If asymptomatic retroversion persists until term, delivery should be by cesarean section and a classical incision is often required.[19]

Complications of Assisted Conception

Ovarian Hyperstimulation Syndrome

Ovarian hyperstimulation syndrome (OHSS) is a serious and sometimes fatal complication of assisted conception techniques.

FIGURE 64.1 MRI of persistent retroversion of the uterus at 20 weeks gestation. The uterine fundus containing the breech (*curved arrow*) can be seen in the Pouch of Douglas. The placenta (*) is attached to the posterior uterine wall with a large intramural fibroid (*arrowheads*) superiorly on the lower portion of the anterior wall, and the cervix (*arrows*) just below, above the level of the symphysis pubis (*P*). (From Hamoda H, Chamberlain PF, Moore NR, et al. Conservative treatment of an incarcerated gravid uterus. *BJOG* 2002;109:1074–1075, with permission.)

It is a systemic disease secondary to the release of vasoactive products from the hyperstimulated ovaries. It can be subdivided into early, within 9 days of the ovulatory hCG dose, or late and is classified according to severity (Table 64.5). Mild disease has been reported to complicate up to 33% of in vitro fertilization (IVF) cycles, while the severe form can occur in up to 8%. OHSS is more likely in women with polycystic ovaries, young women, and in cycles where conception occurs, especially of multiple pregnancies.[21] Presentation is variable depending on severity (see Table 64.5) but should always be borne in mind in a woman with abdominal/pelvic pain who has recently undergone assisted conception. Mild and moderate disease can be managed on an outpatient basis, but more severe forms or concerns about a worsening condition require admission. In general, management involves symptom control: analgesia with either acetaminophen (paracetamol) or codeine but avoiding NSAIDs, and antiemetics suitable for early pregnancy (e.g., prochlorperazine, metoclopramide); continuing progesterone luteal support but stopping hCG support and avoiding strenuous exercise and sexual intercourse because of the risk of ovarian torsion. In severe cases, multidisciplinary management is advised to deal with issues of fluid balance and thromboembolic risk (0.7% to 10%).[22] Paracentesis may be necessary, but should always be done under US guidance because of the risk of injury to enlarged, vascular ovaries. Importantly, women should be reassured that pregnancy may continue normally despite OHSS.[21]

TABLE 64.5

SYMPTOMS AND SIGNS OF OVARIAN HYPERSTIMULATION SYNDROME (ADAPTED FROM JENKINS ET AL.[21])

Mild OHSS	Abdominal bloating Mild abdominal pain Ovarian size usually <8 cm
Moderate OHSS	Moderate abdominal pain Nausea ± vomiting US evidence of ascites Ovarian size usually 8–12 cm
Severe OHSS	Clinical ascites (occasionally hydrothorax) Oliguria Hematocrit >45% Hypoproteinemia Ovarian size usually >12 cm
Critical OHSS	Tense ascites or large hydrothorax Hematocrit >55% White cell count >25000/mL Oligo/anuria Thromboembolism Acute respiratory distress syndrome

Pelvic Infection

Pelvic infection can occur after investigation of tubal patency with a hysterosalpingogram (HSG) or laparoscopy and dye test, or after oocyte retrieval. Prior to such investigations being arranged, all women should have cervical swabs performed and any infection should be treated with an appropriate antibiotic regimen. Oocyte retrieval is usually performed transvaginally under US guidance. Rates of pelvic infection secondary to this procedure vary between units and published series but are generally low, between 0% to 1%.[23] Initial management is with antibiotics and US to exclude a pelvic abscess. Progressive worsening of symptoms or failure to improve should prompt a further search for a pelvic collection and consideration of the possibility of bowel damage, for which laparoscopy or laparotomy would be required.

DYSMENORRHEA

Dysmenorrhea is defined as pain with menstruation and is thus separate from CPP. It is common, with estimates of prevalence ranging from 20% to 90%. It has a major social and economic impact and is the leading cause of school and work absenteeism in young women.[24] Traditionally it has been subdivided into primary and secondary dysmenorrhea. Primary (functional) dysmenorrhea is not associated with other pathology, is thought to be because of overproduction of prostaglandins and leukotrienes in the myometrium causing strong, painful contractions of the uterus, and is common in adolescents.[25] It is frequently considered to be a "normal" part of development and assumed to improve with age or after pregnancy, though this has not been shown to be true in longitudinal studies. Secondary dysmenorrhea is associated with other pathology (Table 64.6) and therefore

TABLE 64.6

CAUSES OF DYSMENORRHEA

Endometriosis
Adenomyosis
Müllerian anomalies
PID
Fibroids
Cervical stenosis
Pelvic venous congestion
Intrauterine device

often occurs with other symptoms such as dyspareunia and menorrhagia. It is traditionally considered to affect women in their thirties and over but it is worth remembering that children as young as 10 years old have been shown to have biopsy-proven endometriosis,[26] and congenital uterine anomalies probably occur in around 4% of the population, increasing to 10% in adolescents with pelvic pain.[25] Clinically, therefore, we find this distinction to be unhelpful, and will consider dysmenorrhea as a symptom which deserves to be treated and investigated as appropriate, no matter what age the patient.

Initial assessment should include a detailed history, including risk factors for pathology associated with dysmenorrhea and other symptoms. In young girls who are not sexually active and without associated symptoms, a pelvic examination is not necessary before commencing empirical treatment. If there are concerns about structural anomalies, an abdominal US can offer reassurance, but cannot diagnose or exclude endometriosis.

Nonsteroidal Anti-Inflammatory Drugs

Many women, especially teenagers, self-medicate for their dysmenorrhea and NSAIDs are often the drugs of choice. NSAIDs act by inhibiting cyclo-oxygenase and therefore reduce prostaglandin production and associated uterine contractions. Mefenamic acid has been shown to also inhibit the lipoxygenase pathway.[27] Systematic reviews have concluded that NSAIDs are an effective treatment for dysmenorrhea but that there is insufficient evidence to determine which, if any, is the most effective.[28] A greater improvement of symptoms can be obtained if treatment is started 24 hours prior to the onset of bleeding and, if a loading dose of twice the regular dose is used initially, followed by regular doses as needed.[29]

Hormonal Treatments

The combined oral contraceptive pill (COCP) has been used as a treatment for dysmenorrhea for many years. It acts to inhibit ovulation and limit endometrial growth, reducing progesterone and subsequent prostaglandin and leukotriene production.[25] A number of trials have shown a significant improvement in dysmenorrhea with COCP use, both high[30] and lower dose formulations.[31] Tricycling the COCP (i.e., taking three packets of pills back-to-back without having a withdrawal bleed in between packets) has also been shown to reduce symptoms as well as decreasing the frequency of menstruation[32] and thus may be a good alternative to other forms of longer term contraception in some women.

Depot medroxyprogesterone acetate (DMPA), a long-acting injectable contraceptive, also reliably inhibits ovulation in both its intramuscular and subcutaneous formulations[33] and amenorrhea is common. In one study, 64% of adolescents reported an improvement in dysmenorrhea symptoms with DMPA[34]; however, concerns about loss of bone mineral density (BMD) limit its prolonged use in adolescence. For women also requiring long-term contraception, a levonorgestrel releasing intrauterine system (LNG-IUS) is another alternative. The majority of women are amenorrheic with the system in place and, even for those who continue to bleed, menses tend to be lighter and less painful, though bleeding can be erratic for the first 6 months. In some instances, this may be the most appropriate option for nulliparous young adults, in which case a brief general anesthetic may be necessary for insertion. For severe symptoms, a therapeutic trial of a Gonadotrophin Releasing Hormone agonist (GnRH agonist) (see below) could also be considered.

Surgical Treatments

Surgery for dysmenorrhea should only be considered as an investigation for other pathologies if there is no response to medical treatment (e.g., diagnostic laparoscopy) or as a last resort. Systematic reviews suggest that there is insufficient evidence to support the use of surgical nerve interruption[35] (either laparoscopic uterine nerve ablation [LUNA] or presacral neurectomy [PSN]) in dysmenorrhea, and the rates of complications are high.

Nonpharmacological Interventions

A number of other interventions have been studied to improve dysmenorrhea with varying success. Both high-frequency transcutaneous electrical nerve stimulation (TENS) and acupuncture have shown benefit in some studies[36] as has topical heat therapy[37]; however, psychological interventions have not been shown to be beneficial in pure dysmenorrhea.[38] As always, the role of education and validation of symptoms cannot be emphasized strongly enough, and this is particularly true for adolescents.

MITTELSCHMERZ

Mittelschmerz (literally "middle pain" in German) is one-sided, lower abdominal pain that occurs at or around ovulation. It can last from minutes to 48 hours and requires no treatment other than simple analgesics. It is thought to occur in approximately 50% of women at some point. What causes the pain is not known exactly, but possible suggestions include tubal, uterine, or cecal spasm, increased tension in the ovary or Graafian follicle, or peritoneal irritation due to leak of blood or fluid from the follicle. However, the latter is probably unlikely as in one study, 33 out of 34 women experienced the pain prior to follicular rupture (as confirmed with US)[39] and pain is on the same side as follicular rupture in only 86% of women.[40] Mittelschmerz probably causes most concern when a woman recommences ovulation after a long period of treatment with an ovulation inhibitor. Because it is not expected, the sudden, acute pain can then lead to investigation for other conditions such as appendicitis or an ovarian cyst accident. Similar, but more severe, pain can occur with trapped ovary syndrome and endometriosis, as discussed below.

CHRONIC PELVIC PAIN

Introduction

CPP is a symptom, not a diagnosis. As will be seen, the causes are diverse, often multifactorial, and not always evident on routine examinations or even laparoscopy. As well as the economic impact already alluded to, CPP has major psychological, social, and cultural consequences not only for the woman but for her partner, family, and society as a whole. It is acknowledged that it is frequently poorly managed, yet it is as common as migraine and back pain and affects all races and social classes.

Factors Associated with Chronic Pelvic Pain

A number of factors are thought to be associated with CPP and should be explored during the consultation at an appropriate point.

Social

CPP is seen in women of all social classes with no variation in prevalence depending on marital or employment status.[41] How-

ever, social support can be an important factor in how a woman deals with her pain and social isolation can make the situation very difficult. It is easy to see how a vicious circle is set up with pain leading to the loss of the woman's social role and thus her self-esteem, causing isolation and contributing to further pain.

Abuse

Although frequently alluded to, the relationship between physical or sexual abuse and CPP is still not clear. The majority of studies are retrospective and only target women who have already developed the symptom. It appears that women in secondary care with any chronic pain condition are more likely to report a history of childhood abuse than pain-free women. When CPP is considered, sexual abuse is more commonly reported than in other pain conditions. It could be, however, that childhood sexual abuse is a predisposing factor for the development of depression, anxiety, and somatization which may then lead to the development of CPP.[5] In a rare prospective study,[42] children who had been abused were followed until their twenties and were not found to have an increase in medically unexplained symptoms when compared to a population who were not known to have been abused. However, those with unexplained symptoms were more likely to report their abuse. Thus, a revealed abuse history should not be assumed to be the cause of the pain, but failure to respond to treatments should perhaps prompt an exploration of these areas if a good therapeutic relationship already exists.

Psychological

Women with CPP display an increased incidence of "negative" psychological features, such as depression, anxiety, and catastrophisation.[43] This is common with other chronic pain conditions, such as fibromyalgia and irritable bowel syndrome (IBS). However, it is not possible to know whether these factors predispose a woman to develop CPP, contribute to a perpetuation of the pain, or are a consequence of years of living with pain and attempts to justify its severity or even existence to friends, family, and health care professionals. What is known is that psychological state can alter the experience of pain, and this is the area that should be emphasized to the woman when a referral to a psychologist is suggested. Improving sleep patterns alone can both improve mood and have a significant effect on ability to function.

Personality

Similarly, whether personality types predispose to the development of chronic pain conditions or merely alter the way in which they are dealt with is not known. Some personality traits can make recovery more difficult. "Driven types," for example, are unable to pace themselves and do too much on a "good day" so that on the following day, symptoms are worse again. On the other hand, those who take easily to the "sick role" can be hard to persuade to engage in therapeutic options and may also fail to respond. Women with diagnosed personality disorders should be managed in conjunction with a psychiatrist.

Overview of Assessment

The initial assessment of a woman with CPP is very important. Complete recovery at follow-up is associated with a favorable patient rating of the quality of the initial consultation.[44] The woman needs to be given time to tell her story, without interruptions, but with the support of whomever she would like to be present (which may be no one but the doctor). The extra time taken to listen to the history in the patient's own words may well give valuable information about the context of the pain, its effects on her life, and her beliefs about its cause and prognosis. In fact, an explanation for the pain has been shown to be one of things women with CPP most want out of their consultation (Table 64.7).[45] The process of telling her story and of the examination can, in itself, be therapeutic. Once a cycle of chronic pain has been set up, it is unlikely that a single cause for the pain will be identified, and the clinician should be alert for any contributing factors that may be revealed.

TABLE 64.7

WHAT WOMEN WOULD LIKE FROM THE CPP CONSULTATION[45]

Personal care
To be understood and taken seriously
Explanation
Reassurance

History

A detailed history of the pain should be taken including when and how it began, its associations, such as bowel, bladder, and psychological symptoms, and the effects of posture and movement. The circumstances surrounding the start of the pain and whether they recently changed should be discussed, as should the reasons why she has presented now. Cyclicity of symptoms or exacerbation with intercourse need to be established as does her current and future fertility aspirations. Relevant information may well be gleaned from her obstetric history, and a contraceptive and smear history should also be taken. It should be ascertained that no "red flag" symptoms, such as rectal bleeding or weight loss, exist. While a history of past or present abuse (verbal, physical, or sexual) may also be present, it may not be appropriate to discuss this at the first consultation. If abuse is revealed, these experiences need to be accepted as stated, and it is important to know where to access specialist help locally should this be required.[5]

Examination

Examination requires more time than is routine in gynecology and, as it is the time when the patient is most vulnerable, new information is often revealed at this point.[46] The decision as to whether to have a chaperone present is a personal one that will depend upon both the doctor's and patient's wishes. However, the presence of a third person may alter the dynamic and prevent certain information being revealed. Examination should begin, as always, with observation. This includes evidence of skin alterations or damage and posture, but also of both the patient's attitude to the examination and the doctor's response to this. Evidence of altered sensation (hypersensitivity or allodynia) should be sought before abdominal palpation is performed. The effect of movement should be assessed, which might suggest musculoskeletal pain. The extent to which an internal examination is performed will depend on the history. With marked vaginismus, anything more than a gentle, one finger examination may be inappropriate. Altered sensation on the vulva and perineum should be looked for and pelvic floor muscle tone assessed if possible. Rectal examination should only be performed if there is a clear indication in the history.

Investigations

Investigations should be guided by the history, but care should be taken to avoid over-investigation initially. Many women will have already seen a number of doctors, often of many specialities, and had a variety of frequently invasive investigations. One par-

ticularly useful strategy is to ask the woman to keep a detailed pain diary over 1 to 2 months. This can reveal information about the timing of the pain and its associations to the doctor and to the patient.[5]

Therapeutic Trial

Very cyclical symptoms are usually gynecological in origin, although pain perception itself may vary with the menstrual cycle as can symptoms of both interstitial cystitis (IC) and IBS. Where symptoms are markedly cyclical, a therapeutic trial of a GnRH analogue should be considered before a laparoscopy is performed.[5] This group of drugs, given initially as monthly subcutaneous injections, cause a prolonged activation of the GnRH receptor leading to an initial worsening of symptoms (the "initial flare"). This is followed by a reduction in luteinizing hormone (LH) and follicle stimulating hormone (FSH), such that serum estradiol levels are suppressed by 21 days and remain at levels equivalent to postmenopausal women with continued dosing. Common adverse effects are shown in Table 64.8. The most common complaints of hot flushes and emotional symptoms are often well tolerated if pain is relieved. The biggest concern, however, is the loss of BMD which can be up to 6% after 6 months of treatment.[47] If the trial is successful, then treatment can continue with the addition of low-dose combined HRT, and this combination has been shown to be safe and effective for up to 2 years.[47] After this time, many women are not prepared to continue with monthly injections (though three monthly preparations exist and can be effective in some women) and seek alternative management options. However, in those that would like to continue with treatment, there is now evidence from small studies that the combination is safe for up to 10 years, with one of these women having stopped treatment to conceive and then recommenced treatment after delivery.[48]

Diagnostic Laparoscopy

If no relief is gained from a therapeutic trial of GnRH analogue or if there are other indications such as subfertility or a pelvic mass, diagnostic laparoscopy should be performed. However, laparoscopy is not without risks with large series quoting approximately 3% risk of minor complications and 0.6–1.8/1000 risk of major complications such as bowel perforation and vascular damage.[49] Furthermore, although it was initially thought that a negative laparoscopy would reassure a woman, more recent studies have shown this not to be the case[50] and it may reaffirm her beliefs that the doctors do not believe her and think the pain is of psychological origin.

Empirical Treatment

Even if no clear cause of the pain can be found on investigation, the pain should still be treated empirically. Analgesia or hormonal treatments may be appropriate, but it is often worth considering drugs such as amitriptyline, gabapentin, and pregabalin in addition. These drugs are effective in neuropathic pain and may have a role in reducing visceral hypersensitivity.[51] Topical capsaicin cream on the skin of the abdomen (not the vulva) may be useful for hyperalgesia and allodynia. Nonpharmacological treatments such as acupuncture, TENS, chiropractic, and osteopathic manipulations may be beneficial, and pain management techniques and support groups can also be of value.[52]

The Importance of Visceral Hyperalgesia in Chronic Pelvic Pain

Visceral hyperalgesia (and subsequent viscero-visceral/viscero-somatic referral) is thought to have an important role in CPP.[53] It can be the primary pain generator, perpetuating factor, or cause of secondary symptoms. Visceral hyperalgesia should therefore always be borne in mind, especially when symptoms from multiple organs are present or where there is no clear demonstrable cause. This area is covered in more detail in Chapters 3, 4, and 65. Sex steroid hormones are known to act at multiple sites throughout the peripheral and central nervous system, and it is

TABLE 64.8

HORMONAL TREATMENTS FOR ENDOMETRIOSIS RELATED PAIN[126]

Treatment	Main adverse effects
COCP[127] (continuous or tricycling)	Thromboembolic disorders, altered serum lipid profile, hypertension, skin reactions, migraine, intermenstrual bleeding, depression, altered libido
Danazol[128]	Deepening of voice, acne, hirsutism, clitoral hypertrophy, vaginal dryness, hematological disturbances, altered serum lipid profile, thromboembolic disorders, depression, weight gain, altered libido, muscle cramps
Gestrinone[129]	Headache, depression, weight gain, voice changes, acne, hirsutism, intermenstrual spotting, gastrointestinal disturbances, muscle cramps
Progestogens (e.g., medroxyprogesterone acetate)[129]	Depression, weight gain, altered libido, acne, vaginal bleeding, breast tenderness, thromboembolic disorders, gallbladder disease, worsening of ovarian cysts
LNG-IUS[130]	Irregular vaginal bleeding, depression, weight gain, reduced libido, breast tenderness, vaginal discharge, uterine perforation, ovarian cysts
GnRH agonists[131]	Initial flare in symptoms, bruising/pain at injection site, depression, emotional lability, reduced libido, vaginal dryness, hot flushes, headache, pituitary apoplexy
GnRH antagonists	Same as for GnRH agonists except that no initial flare occurs

thus not surprising that these symptoms often show cyclicity and can respond to hormonal manipulation.

Gynecological Factors in Chronic Pelvic Pain

Endometriosis

Endometriosis is defined as "the presence of endometrial-like tissue outside the uterus, which induces a chronic, inflammatory reaction."[53a] While it is a common cause of CPP and dysmenorrhea, it is also a common incidental finding in asymptomatic women. Therefore, it is imperative that a detailed history and examination are undertaken even in a woman who has previously been diagnosed with endometriosis, as it may not be the sole cause of, or even related to, her pain.

Endometriosis is a complex condition, with much still unknown about its etiology, natural history, and incidence. In 1927, Sampson suggested it was due to retrograde menstruation.[54] However, this process can be demonstrated in more than 90% of women, therefore a combination of retrograde menstruation and an altered immune environment,[55] allowing implantation and the development of a nerve and blood supply, is currently considered to be the most likely etiology. In order to make a definitive diagnosis of endometriosis, direct visualization of ectopic endometrial implants must occur,[56] preferably with biopsy and histological confirmation.

The prevalence of endometriosis is difficult to establish, as the vast majority of implants are in the pelvic cavity (though extrapelvic disease does occur) and not every woman will have a laparoscopy or laparotomy. Clinical presentation can be variable (Table 64.9), and to confuse matters further, the extent of disease seen at laparoscopy correlates poorly with the severity of symptoms.[57]

Although laparoscopy and lesion histology is the criterion standard diagnostic test, current guidelines recommend that if the history and clinical examination are suggestive of endometriosis, a definitive diagnosis is not required before commencing empirical treatment.[56] There are a large variety of treatment options currently available for endometriosis, and the appropriate treatment(s) should be decided in discussion with the woman depending on her specific constellation of symptoms and current and future fertility wishes. A full discussion of these options is beyond the scope of this chapter; however, an overview of the management of endometriosis-related pain (but not infertility) is given below. More detailed reviews can be found elsewhere.[58–60]

Medical Management of Endometriosis. As with dysmenorrhea, traditionally NSAIDs have been used to treat pain secondary to endometriosis. However, there is no evidence to suggest that they have any greater effect than placebo.[61] Women need to also be informed of the inhibitory effect of NSAIDs on ovulation when taken midcycle. The enzyme cyclo-oxygenase 2 (COX-2) is involved in both pain and inflammation, and specific COX-2 inhibitors have shown promising results in human studies of endometriosis-related pain.[62] However, because of concerns over the safety of this class of drugs,[63] they cannot currently be recommended.

The majority of endometriotic tissue is hormonally sensitive, and hormonal suppression has been shown to reduce endometriosis-associated pain.[56] The available hormonal treatments are shown in Table 64.8. They all appear to be equally effective at controlling endometriosis-related pain but have differing adverse effect profiles. In general, however, symptoms return over time after stopping the treatment. For example, in one study, the median time to recurrence of pain was 6.1 months after stopping danazol and 5.2 months after a GnRH analogue.[64]

Over recent years, it has become apparent that endometriotic deposits express aromatase and are thus able to synthesize estradiol,[65] possibly explaining why some women continue to have symptoms while in a hypoestrogenic state. Recent small trials of nonsteroidal aromatase inhibitors (AI) in combination with hormonal treatments have shown promising results, especially as the women concerned were refractory to other treatments.[66] AI, such as anastrazole and letrozole, are used in the treatment of postmenopausal women with estrogen-sensitive breast cancers and are known to have a mild adverse effect profile, though, as with GnRH analogues, there are concerns about loss of BMD.[67]

The recent discovery that endometriotic implants in a rat model develop a sensory and autonomic innervation[68] may explain some of the pain symptoms suffered by women with endometriosis which were previously thought to be due to scarring and inflammation. It is possible that a neuropathic component to the pain may exist, and therefore in women who only show a partial response to hormonal treatment, the addition of a drug such as amitriptyline or gabapentin may be beneficial.

Surgical Management of Endometriosis. As can be seen from the discussion of medical treatments, these options only keep the disease suppressed but do not affect a cure: once treatment is stopped, symptoms may recur. Complete surgical excision of disease can be performed and has been shown to significantly reduce pain scores, improve sexual function, and improve quality of life. In one series, for example, 67% of women reported an improvement following surgery, 8% felt their symptoms to be unchanged, 25% were worse, but only 33% required further surgery during the 5-year follow-up period.[69] However, particularly with deeply infiltrating endometriosis (DIE), there are significant risks associated with surgery (including bowel perforation, fistula formation, and ureteric damage), and this should therefore only be undertaken at specialist centers by a multidisciplinary team with the necessary expertise.[56] However, if a diagnostic laparoscopy is being undertaken and mild disease is seen, then current recommendations are that this should be excised or ablated at the time.[56] Neither pre- nor postoperative hormonal treatment have been shown to improve outcome measures including pain scores[70] and therefore cannot be recommended. However, the LNG-IUS did significantly reduce the risk of recurrence of moderate–severe dysmenorrhea at 1 year[71] and is therefore worth considering.

TABLE 64.9

SYMPTOMS AND SIGNS OF ENDOMETRIOSIS

Symptoms	Signs
Dysmenorrhea	Fixed, retroverted uterus
Dyspareunia	Enlarged ovary
Dyschezia	Uterosacral nodules
CPP	Rectovaginal nodules
Infertility	
Hematuria	
Hematochezia	
Chronic fatigue	

Adenomyosis

Adenomyosis is defined as the presence of endometrial glands and stroma within the myometrium.[72] Typically, the surrounding myometrium is hypertrophic and hyperplastic. Very little research has been undertaken on adenomyosis specifically, with much of the management being extrapolated from that of endometriosis—a condition with which it has many similarities but also a number of differences. Previously, the diagnosis was made histologically after hysterectomy, and it was a common finding in women undergoing hysterectomy for menorrhagia. It is now

possible to make the diagnosis radiologically with MRI or TVUS.[73] In experienced units, these two methods are equally accurate, but MRI is less user-dependent and usually considered to be the investigation of choice. However, a relatively high rate of false positives will be seen, with, for example, uterine contractions being falsely diagnosed as adenomyosis. Without reliable diagnostic criteria, clinical trials of treatments are difficult and a true prevalence is unknown.

There appear to be two distinct forms of the condition: diffuse, where endometrial cells are widely distributed throughout the myometrium, and focal, where a discrete collection of cells are seen, also known as an adenomyoma.[74] Surgical excision of the former is not possible, thus treatment options are limited to either medical management or hysterectomy. While some cases of focal disease may be amenable to surgical management, it is possibly not as responsive to hormonal treatment. In a similar manner to fibroids, it has been suggested that it might be possible to embolize adenomyotic tissue. So far, this has not proved to be successful, but promising preliminary results are emerging with the use of focused US to ablate the abnormal tissue.[75]

Adenomyosis is thought to cause menorrhagia, metrorrhagia, dysmenorrhea, and infertility, although some authorities dispute its effect on fertility.[76] It is thought to occur secondary to a breach in the integrity of the myometrial-endometrial junction, such as occurs in pregnancy, especially those complicated by abnormal placentation and surgery (including ERPC and cesarean section), or after blunt trauma to the abdomen. As with endometriosis, the ectopic endometrial tissue is hormone sensitive and has been shown to express aromatase.[77] GnRH agonists, Danazol, and the LNG-IUS have all been shown to be successful in the treatment of adenomyosis, though all have side effects. Perhaps the most promising of these is the LNG-IUS because of its mild adverse effect profile and apparent tolerability by patients. Unfortunately, no studies have been done on AI and adenomyosis to date.

Adhesions

Adhesions are a common finding in women with and without pelvic pain. They are formed after trauma to the visceral or parietal peritoneum and so can be secondary to surgery, infection, and endometriosis. Between 70% and 85% are thought to occur after surgery[78] and are thus iatrogenic. The relationship between adhesions and pain is still unclear. A prospective, blinded randomized controlled trial of 116 women with CPP undergoing laparoscopy and followed for 1 year showed there to be no benefit of adhesiolysis over diagnostic laparoscopy alone.[79] In another prospective, randomized trial at 9–12 months follow-up, there was no significant difference in pain between the groups who had or had not undergone adhesiolysis at laparotomy. However, in a subgroup analysis of this data, those women who had dense, vascular adhesions involving the bowel did have a significant improvement in pain after adhesiolysis.[80] Therefore, although adhesiolysis cannot be recommended in general as a treatment for CPP, in those women who have severe adhesions involving the bowel, it may be successful.

There are two other distinct cases where adhesions are known to cause pain: trapped ovary syndrome and ovarian remnant syndrome. In the former, a retained ovary becomes trapped in dense adhesions after hysterectomy, while in the latter, a small piece of ovary is unintentionally left behind at oophorectomy and again becomes trapped in adhesions. In both cases, the pain is cyclical and can be suppressed with a GnRH analogue. It may be possible to surgically remove the ovary/remnant; however, with distorted anatomy this is not without risk, and some women may prefer to remain on the combination of GnRH analogue and low-dose HRT instead.[5]

Chronic Pelvic Inflammatory Disease

Chronic inflammation with scar tissue and distortion of pelvic structures can be seen in women who have had repeated episodes of acute PID or those in whom infection has been asymptomatic initially (as is frequently the case with *Chlamydia*). US may demonstrate features of chronic salpingitis, such as dilated fallopian tubes and poor mobility,[81] and severe adhesions may be seen at laparoscopy. These can be divided surgically, especially if they are causing anatomical distortion. However, although this may improve fertility as has been discussed, it may not have any effect on the pain. Chronic inflammation can cause sensitization of peripheral nerves, and therefore a trial of amitriptyline or gabapentin/pregabalin may be indicated, especially if there are other symptoms suggesting a generalized visceral hypersensitivity syndrome. An exploration of the woman's attitudes to and beliefs about her pain may be beneficial. Guilt about earlier sexual behavior or concerns about current or future fertility may be revealed.

Pelvic Venous Congestion

Congestion of dilated pelvic veins has been suggested to be a cause of pelvic pain with menstrual exacerbation.[82] In one study of women with unexplained CPP, dilated pelvic veins were found in 30%,[83] but they are also found in at least 10% of the general population with increasing incidence in multiparous women. There is therefore some doubt as to whether the condition causes pain or is an incidental finding. One trial suggested continuous medroxyprogesterone acetate in combination with psychological support to be a successful treatment; however, no benefit was obtained after stopping treatment.[84] Embolization of ovarian veins or hysterectomy and bilateral oophorectomy have also been advocated as treatments.[85]

Gastrointestinal Factors in Chronic Pelvic Pain

As with acute pelvic pain, CPP secondary to a nongynecological cause can present to gynecologists because of the site of the pain and its presumed etiology. It is therefore important that a detailed history of bowel function and its relation to and/or effect on the pain is taken. The gastrointestinal (GI) tract can be both the initial pain generator and the cause of secondary symptoms in a visceral hypersensitivity syndrome. IBS and constipation are very common and may be provoked by other conditions or medication, and thus need to always be borne in mind. DIE frequently presents with bowel symptoms; however, it is important to remember that similar symptoms can be the presenting features of GI tract malignancies and inflammatory bowel disease and to fully investigate any "red flag" symptoms, such as rectal bleeding or unexplained weight loss.

Irritable Bowel Syndrome

IBS is a functional disorder of the GI tract and is discussed in detail in Chapter 63. We have mentioned it here, however, to draw attention to the fact that cyclical changes in the severity of symptoms are seen. Healthy, pain-free women frequently show alterations in their bowel habit around menstruation, possibly secondary to prostaglandin release, and this is often amplified in women with IBS.[86] It has been shown that rectal sensitivity to balloon distension varies with the menstrual cycle in women with IBS, but not in those without.[87] Interestingly, in women whose IBS is clearly cyclical even without evidence of other gynecological symptoms, the use of GnRH analogue treatment to suppress endogenous hormone production has been shown to be successful.[88]

Constipation

Constipation is a common cause of pelvic pain and can be easily avoided. It may be due to poor diet, lack of exercise, or reduced fluid intake; however, it is frequently iatrogenic, secondary to

opioid use. It is therefore important to emphasize the need for fluid intake and dietary fiber, as well as prescribing laxatives whenever such analgesics are required.

Urological Factors in Chronic Pelvic Pain

Pain originating in the urinary tract will also often be pelvic and therefore present to gynecologists. Again, symptoms may be cyclical or associated with symptoms in other organs. This coexistence of symptoms and the common embryological origin of the structures involved have led to the suggestion of a "urogenital pain syndrome," including some or all of interstitial cystitis, vulvodynia, urethral syndrome, coccyodynia, and perineal pain.[89]

Interstitial Cystitis

Interstitial cystitis is characterized by pelvic pain and urinary urgency and frequency which may be associated with other symptoms, particularly dyspareunia sometimes relieved by voiding.[90] Frequently, women give a history of repeated urinary tract infections but with negative cultures. The etiology is unknown but is likely to be multifactorial and leads to chronic inflammation of the bladder wall. Hunner's ulcers or glomerulations may be seen at cystoscopy, but are not pathognomonic and, in 10% of patients, cystoscopic findings will be normal.[89] In these women, painful bladder syndrome may be a more appropriate diagnosis as bladder inflammation is not present. Multidisciplinary treatment regimens are likely to be most successful, including a combination of dietary modification, pharmacological agents such as pentosan polysulfate sodium, and physical therapy.

Urethral Syndrome

Urethral syndrome is also characterized by urinary urgency, frequency, dysuria, and suprapubic/lower back pain without any obvious cause. Dysfunction of the pelvic floor may be involved as success is often achieved with skeletal muscle relaxants or electrostimulation and biofeedback. Because of similarities in presentation to prostatitis in men, a chronic low-grade infection of the paraurethral glands has been suggested to be a possible cause. If tenderness can be elicited just lateral to the urethra through the anterior vaginal wall, this may be a possibility and a prolonged course of antibiotics may be justified.[91]

Musculoskeletal Factors in Chronic Pelvic Pain

Dysfunction in the musculoskeletal system can be both the primary cause of CPP or secondary to pathology elsewhere. Though it may not be the first thought in a gynecological consultation, it is surprisingly common, with one retrospective study suggesting that 75% of 132 nonconsecutive patients with CPP had musculoskeletal abnormalities.[92] It is therefore important that the musculoskeletal system is appropriately assessed and any issues dealt with in order that a good response to treatment occurs. A detailed description of appropriate assessment is not possible here, but can be found elsewhere.[93] Some of the important musculoskeletal factors to be borne in mind are discussed briefly below, and in more detail in Chapters 34 and 35.

Fibromyalgia

Two of the 18 tender points of fibromyalgia are in the gluteal muscles in the upper outer quadrants of the buttocks. Pain here can easily be confused with the lower back pain often described by women with CPP. Furthermore, fibromyalgia may have cyclical exacerbations[94] and therefore symptoms are often assigned to a gynecological cause.

Trigger Points

Trigger points are frequently found in abdominal and pelvic floor muscles causing or exacerbating both CPP and dyspareunia. These can be the primary pain generator or can be secondary, either to other musculoskeletal abnormalities such as sacroiliac joint dysfunction or to repeated episodes of visceral pain as occurs in adenomyosis. The continued presence of a trigger point can explain a partial response to treatment of the underlying pathology and is an indication for a careful reexamination of the patient at her follow-up visit.

Pelvic Floor Abnormalities

In women, pelvic floor abnormalities can be secondary to postural alterations caused by pain or other musculoskeletal conditions, viscero-muscular referral patterns, or trauma as occurs during childbirth or certain surgical procedures. Unilateral or bilateral pelvic floor abnormalities can cause CPP, dyspareunia (with secondary vaginismus), perineal pain, and dyschezia yet are frequently overlooked. In a woman with dyspareunia, demonstrating that pressure on a tender, tense pelvic floor muscle recreates her pain during intercourse can help toward relieving concerns about her reproductive organs. Good response to treatment is frequently obtained from physiotherapy and recent studies on the injection of botulinum toxin into the pelvic floor muscles have shown promising results.[95]

Hernia

Acute obstruction of a hernia will cause acute pain; however, a number of different types of hernias can also be responsible for CPP, though the exact mechanism by which they cause pain is debated. Most commonly these include inguinal, femoral, and obturator hernias. Imaging modalities such as computed tomography or MRI may be useful in making the diagnosis if a clear examination finding is not present. Surgical repair is usually the recommended treatment, and this can either be open or laparoscopic with both having their own advantages and disadvantages.[96]

Sacroiliac Joint Pain

The sacroiliac joint (SIJ) is the largest axial joint in the body. A network of muscles support the joint and deliver regional muscular forces to the pelvic bones. The associated ligaments are weaker in women to allow mobility and facilitate parturition. The innervation of the joint is still debated, but probably includes fibers from L2-S4.[97] It is widely accepted that SIJ dysfunction causes lower back pain, and pelvic pain appears to occur in a significant percent of patients. In general, the pain is unilateral (unless both joints are affected) and below the L5 spinous process, sometimes radiating down as far as the foot.[98] SIJ dysfunction and pain can occur for a number of reasons, including pregnancy, trauma, and prolonged bending and lifting. A number of possible treatments exist with varying degrees of success. Conservative options include physiotherapy and joint stabilization which have been shown to be successful in some series.[97] Intra-articular joint injections under radiological guidance have been shown to produce good to excellent pain relief in most studies. Surgical fusion of the joint may be required in some cases, though adequately powered, prospective studies are lacking.

Neurological Factors in Chronic Pelvic Pain

It has already been mentioned that in many conditions causing pelvic pain, secondary sensitization of the peripheral or central nervous system can occur, perpetuating or increasing pain and extending referral areas and involving other organ systems.[99]

There are also situations where damage to a nerve or nerve roots can be the primary cause of the pain. The specific nerve(s) involved will determine the precise distribution of pain and associated symptoms; however, a number of general features are usually associated with a neuropathy. Classically, the pain is shooting, burning, or stabbing in nature. Initially at least, the pain will be in a clearly defined area, though secondary changes may blur this. Trophic skin changes may also be present. Symptoms may be exacerbated or relieved by movements which stretch/relax the nerve or increase/decrease compression by surrounding structures. Local anesthetic blockade of the specific nerve may relieve the pain entirely; however, it is also possible that pain can be worsened by this procedure, perhaps because the injected fluid volume worsens compression. Because of the complex innervation of the pelvis, there are many different neuropathies that can occur. We will discuss in detail here only the most common, pudendal neuropathy; however, a careful consideration of innervation patterns may point to an unusual neuropathy in a woman whose symptoms cannot otherwise be explained. We also consider neuropathies secondary to a Pfannenstiel incision because of the prevalence of this procedure in obstetrics and gynecology. More information on other pelvic neuropathies can be found elsewhere.[100]

Pudendal Neuropathy

The pudendal nerve arises from the sacral plexus in the ventral rami of sacral nerves 2, 3, and 4 (S2-S4), and exits the pelvis through the greater sciatic foramen between the piriformis and coccygeus muscles. It then winds around the sacrospinous ligament and passes through Alcock's canal to enter the pelvis again through the lesser sciatic foramen before branching into the clitoral, superficial perineal, deep perineal, and posterior rectal branches (Fig. 64.2).[101] It can be seen that there are many points where nerve entrapment could occur and many situations in which this nerve could be damaged including surgery and childbirth.[102]

Pain is felt in the distribution of the nerve and is exacerbated by sitting and relieved to a variable extent by standing or lying on the unaffected side. Perineal sensation is usually preserved as is muscle tone, though pain may be recreated during rectal examination. Local anesthetic nerve blocks may be successful and can also aid with diagnosis; however, they may have to be repeated regularly. While surgical decompression may be an option, damage to the nerve may not be reversible.

Neuropathy Secondary to a Pfannenstiel Incision

A Pfannenstiel incision is a low transverse abdominal incision which was first described in 1900.[103] It is commonly used for cesarean sections and many benign gynecological procedures but more rarely in general surgery. Aesthetically, it is more pleasing to the woman, being below the "bikini" line. It also has a number of advantages over other abdominal incisions, including lower incisional hernia rates, fewer wound infections, less hematoma formation, and less direct postoperative pain.[104] However, the ilioinguinal and iliohypogastric nerves have a superficial course and are relatively easily injured by a Pfannenstiel incision. In the literature, the reported incidence of nerve damage after a Pfannenstiel incision is 3.7%[104]; however, the true incidence may well be higher as many cases are not reported or diagnosed. Typically, the pain is burning or lancinating near the incision and radiates to the area supplied by the nerve with associated sensory impairment. The nerves can be damaged in a number of ways: direct nerve trauma with neuroma formation, suture incorporation of the nerve during fascial closure, and constriction of the nerve during scar or wound healing.[105] Optimal treatment is still unclear. In many cases, the symptoms resolve over time without treatment. The nerve can be blocked with local anesthetic, which will at least confirm the diagnosis even if the pain is not entirely removed. In some cases surgery is required; even in these cases, however, long-term recovery is good.[105] Education is clearly required, about both careful surgical technique to reduce the incidence of nerve entrapment and the presentation, such that diagnosis and treatment occur more rapidly.

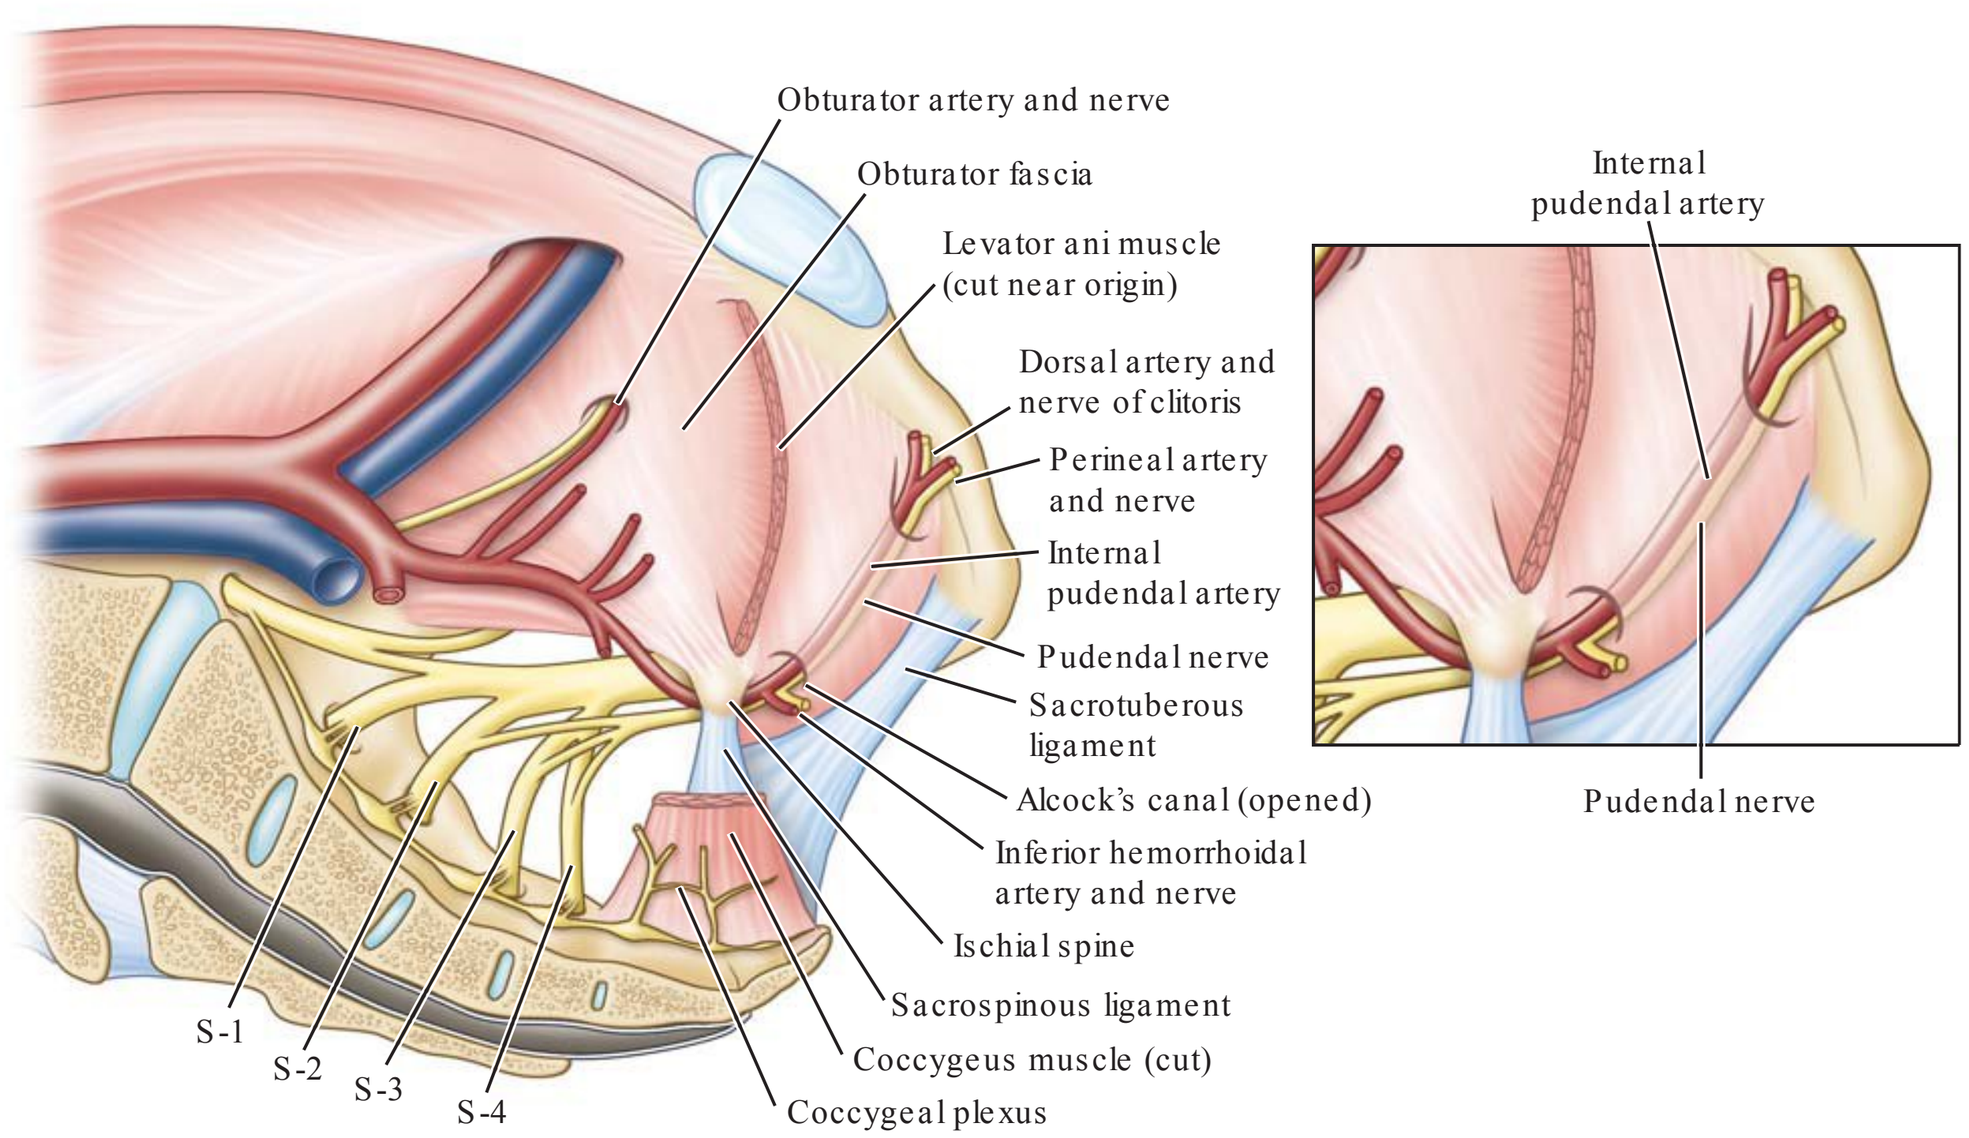

FIGURE 64.2 Course of the pudendal nerve.

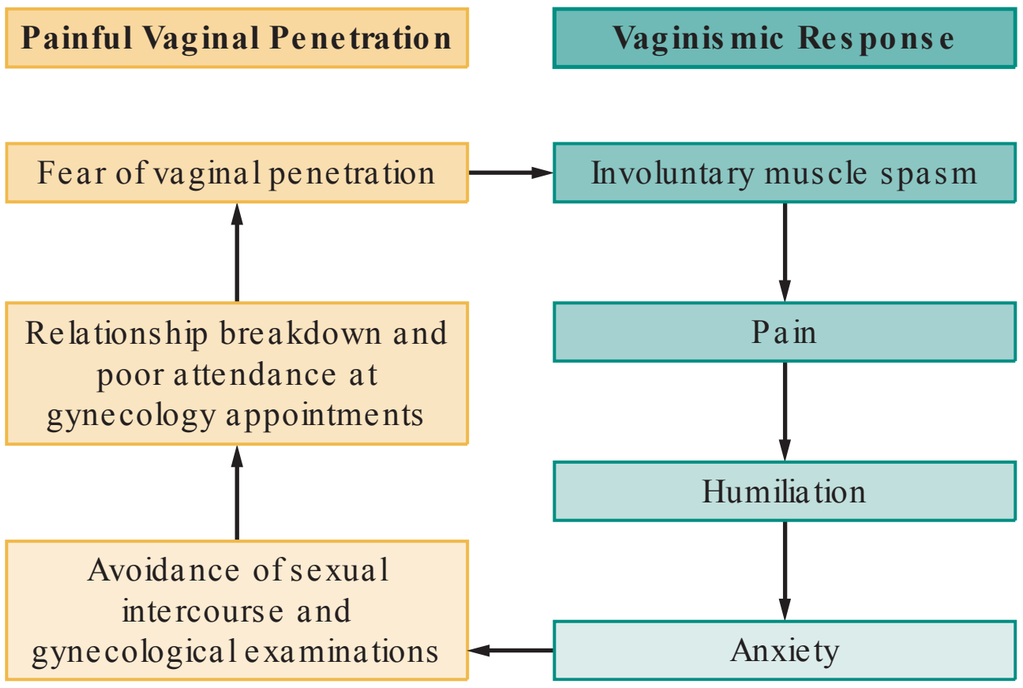

FIGURE 64.3 Cycle of vaginismus. (Adapted from Butcher J. Female sexual problems II: sexual pain and sexual fears. *BMJ* 1999;318: 110–112.)

DYSPAREUNIA

Overview

Dyspareunia is defined as genital pain just before, during, or after sexual intercourse. It can be subdivided into primary, having always occurred in association with intercourse, and secondary, having developed after a period of pain-free sexual activity. Perhaps more usefully, it can also be divided into superficial, with pain only on entry, and deep, thought to be associated with organic pathology.[106] As with so many pain conditions, these subdivisions are oversimplistic and frequently clinically unhelpful. Whatever the initial trigger for an episode of painful intercourse, fear of further pain can set up a cycle of muscular tension and vaginismus (Fig. 64.3) ensuring that future episodes will be painful, reinforcing that fear. Furthermore, the psychological consequences of an inability to have pain-free intercourse on both the woman and her partner should not be underestimated. Psychological morbidity can worsen the experience. However, dyspareunia should not be assumed to be psychological in origin just because no pathology is evident at initial examination.

Possible causes of dyspareunia are listed in Table 64.10. Superficial vulval pain is a common cause of dyspareunia and is discussed in detail in the following section. If superficial dyspareunia occurs after childbirth, time should be taken to explore the woman's fantasies and to reassure her. Occasionally, hypoestrogenism may be the cause, but it is very rare for surgery to be required in these cases. Deep dyspareunia can be secondary to many abdominopelvic pathologies, but is also often positional. If a woman complains of pain on contact with the cervix, this may be due to inadequate arousal and failure of the upper vagina to balloon and therefore move the cervix out of reach.[107] Whatever the initial cause of pain, vaginismus is a frequent sequela and is therefore discussed here in more detail.

Vaginismus

The term "vaginismus" was first used in 1862[108] and is now thought to be one of the commonest female sexual problems. The true prevalence is unknown; however, it is identified in 10% to 20% of women requesting help for sexual dysfunction.[109] Definitions vary as to whether spasm of the muscles surrounding the lower third of the vagina is included or whether it is difficulty in allowing vaginal entry, often associated with involuntary pelvic muscle contraction.[110] Though pain with intercourse is usually the presenting feature, there is often fear of any object being placed in the vagina, thus tampons are not used and gynecological examinations not well tolerated. Some women are so fearful that they avoid smear tests and other essential health checks.

Vaginismus is thought to occur as a conditioned response secondary to adverse physical or psychological stimuli. Early traumatic experiences are thought to predispose to the condition, including traumatic sexual experiences, unsympathetic gynecological examinations, and assault,[110] although a history of abuse (physical or sexual) is not usually associated with vaginismus.[111] A background of religious orthodoxy has however, been shown to be associated.[112] Psychosexual fantasies often coexist such as that the vagina is too small to accommodate a penis or that it is a delicate, fragile organ which will be damaged during intercourse.[110] These can arise secondary to comments made inadvertently, for example at the time of episiotomy repair, and clinicians should therefore think carefully about what is said at vulnerable times. Male sexual dysfunction can develop as a consequence of vaginismus,[113] although the reverse can also occur with vaginismus arising secondary to a male partner's impotence.

Treatment should be individualized to the specific woman/couple and her/their desires. For most women, successful vaginal penetrative intercourse and an improved sexual experience for both partners is the aim. However, in some instances the woman may not feel comfortable with intercourse even after the vaginismus has resolved. Current guidelines suggest that the basis of treatment should be to enable the woman to become more comfortable with her genitals, followed by graded exposure to different types of vaginal penetration in order to overcome her fear of penetration.[110] At all times during treatment, the woman should feel that she is in control and the extent to which her partner is involved should be her decision, though involvement should be encouraged. For some couples, fertility is the ultimate aim and an appropriate referral may need to be made.

A number of different approaches are described, one of which is a combination of behavioral and desensitization exercises using relaxation and graded vaginal trainers. Education is also important, and there may be a need for exploration of fantasies before they can be dispelled.[110] Hypnotherapy,[113] physiotherapy using biofeedback, amitriptyline, and local injections with botulinum toxin[114] have all been reported to have good results. If physical

TABLE 64.10

CAUSES OF DYSPAREUNIA

Vulval	Vaginal	Pelvic	Musculoskeletal	Systemic
Vulvodynia	Vaginismus	Endometriosis	Pelvic floor tension	Hypoestrogenism
Vestibulodynia	Congenital abnormality	IBS	Pelvic floor trigger point	Inadequate arousal
Herpes simplex	Inadequate lubrication	IC/urethral syndrome		Psychological
Postepisiotomy	Radiation vaginitis	Chronic PID		Abuse history
		Adnexal pathology		

causes have been excluded, treatment is usually highly successful with some authors reporting up to 100% success.[110]

Vulval Pain Syndromes

Although not truly pelvic pain, the vulval pain syndromes (vulvodynia and vestibulodynia) exhibit many features which are similar to CPP, and the two can coexist in a urogenital pain syndrome. Much of what has already been discussed in relation to the assessment and multidisciplinary management of CPP is just as relevant for vulval pain. It is therefore appropriate to include a brief overview of these conditions in a chapter devoted to pelvic pain in females.

As with CPP, there is frequently a delay between presentation and diagnosis, and many unsuccessful, often inappropriate and sometimes damaging treatments may have already been tried.[115] It is therefore not surprising that many of these women report anger and frustration and that psychological morbidity is more prevalent than in asymptomatic women.[116] There is no evidence to suggest that these psychological features are a cause rather than a consequence of the conditions. Because vulval pain syndromes are almost invariably associated with dyspareunia in sexually active women, sexual dysfunction is also common, with secondary problems such as vaginismus and anorgasmia developing. However, there is no evidence of higher rates of previous sexual or physical abuse in these women as compared to healthy controls.[117]

The vulval pain syndromes were first described in the late 1800s[118]; however, there has been confusion surrounding their nomenclature, etiology, and management ever since. Further difficulties occur as vulval pain can present to gynecologists, dermatologists, or genitourinary medicine specialists, each of whom historically had different preferred treatments. The International Society for the Study of Vulvovaginal Disease (ISSVD), a multispecialty society, is working to redress this and has recently reclassified these syndromes as either vulvodynia (which can be localized or generalized, and provoked or unprovoked) or vestibulodynia.[119] These terms replace dysesthetic vulvodynia and vestibulitis. Many women will, however, present with symptoms of both conditions.

The ISSVD defines vulvodynia as "vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder."[119] The term vestibulodynia has replaced vestibulitis as there is no evidence of inflammation and is defined by the ISSVD as "provoked vulval dysesthesia localized to the vestibule."[119] Pain can also occur on urination and defecation.

By definition, therefore, a thorough history and examination with appropriate investigations should be undertaken to exclude other causes of vulval pain, such as those listed in Table 64.11, before a label of a vulval pain syndrome is given. To date, the true prevalence remains unknown, with the large reported variation in numbers of women attending clinics likely due to variation in the type of clinic and known interests of the consultants. However, as more specialized vulval clinics become established, the number of referrals for vulval pain syndromes continues to increase. The etiology remains unknown, but is likely to be multifactorial.[115] Although it is unlikely that irritation from topical agents (e.g., antifungal agents, bubble bath, etc.) is the precipitating factor, their use may well exacerbate symptoms and should be discouraged. Examination will reveal either focal or generalized pain in response to light touch with a cotton-tipped swab, but is otherwise unremarkable.

A number of treatments have been shown to be successful; however, treatment needs to be carefully tailored to the individual patient and a multidisciplinary approach is usually of benefit. Basic advice on vulval care should be given, recommending careful hygiene but with avoidance of perfumed products and overdrying. Though topical products in general should be avoided, fragrance-free emollient creams can be soothing and local anesthetic gel such as topical lidocaine can be particularly useful prior to intercourse acting as both a pain reliever and a lubricant.[115] There is no evidence to suggest that topical corticosteroids, antifungal preparations, or testosterone are helpful and only minimal evidence to support the use of topical estrogens.[119] Recent work has suggested a central component to vulvodynia which may explain the success of drugs such as amitriptyline and gabapentin in the condition.[120] One study quotes a 47% complete response to tricyclic antidepressants in a cohort of 33 women with either generalized or localized vulvodynia.[121]

Whether tension in the pelvic floor muscles (a common finding in women with vulvodynia) is involved in perpetuating the pain remains unknown; however, physiotherapists can be very successful in treating vulval pain syndromes. In one series, 71% of women had a greater than 50% improvement in symptoms, 62% experienced improvement in sexual functioning, and 50% had an increase in quality of life.[122]

Surgery should be considered as a last resort. However, it can be successful in a subgroup of women and should not be dismissed entirely. In general, it appears to be less successful in women with coexisting vaginismus and more successful in women who had a good response to lidocaine gel preoperatively. Postoperative psychosexual counseling and the use of dilators and physical therapy have been shown to improve outcome.[119]

As with other chronic pain syndromes, the value of patient support groups, such as the Vulval Pain Society, should not be underestimated as the vulval pain syndromes are a particularly isolating group of disorders. The effect of the conditions on relationships can be devastating and, unlike conditions such as endometriosis which are coming more and more into the public's awareness, vulval pain is still seen as a taboo subject and not discussed.

TABLE 64.11

CAUSES OF SECONDARY VULVAL PAIN

Infection
Candida albicans
Herpes simplex

Inflammation
Lichen sclerosus
Eczema
Contact dermatitis
Psoriasis
Crohn's disease

Iatrogenic
Postepisiotomy
Postsurgical scar

Hormonal
Hypoestrogenism

Trauma

Rare
Symptomatic dermographism
Aphthous ulceration
Bullous disorders
Sacral meningeal cysts
Pudendal nerve entrapment

CONCLUSION

Research in many fields over recent years has led to an improved understanding of both the basic science of visceral pain and of many of the conditions causing pelvic pain. However, time to listen to and explore a woman's story as well as to perform a careful examination must be invested in order to make the best use of this knowledge. Sociological research has identified the recurrent theme of the social meaninglessness of pain without a medical diagnosis[123] and encouraged us to consider chronic pain in a biopsychosociocultural context.[124] The more recent move toward multidisciplinary CPP clinics is a positive step forward in these respects and acknowledges that the secondary consequences of the pain (be they musculoskeletal, psychological, gastrointestinal, sexual, etc.) must also be managed in order to facilitate a full recovery.

CHAPTER 65 ■ PELVIC PAIN IN MALES

ANDREW BARANOWSKI

INTRODUCTION

This chapter is about pain *perceived* to be in the male pelvis—the pelvic pain syndromes. For the purpose of this chapter, the pelvis will be considered as the anatomical bony pelvis, the structures both within and adjacent to it, including the male external genitalia, nervous system structures, and soft tissue/muscular structures; that is, the pelvis in its broadest sense. Although this chapter will focus primarily upon the male urogenital pelvic pain syndromes, the importance of other systems, particularly the musculoskeletal and nervous systems, will be emphasized when appropriate.

There are many well-recognized, well-defined pathologies that may result in pain perceived within the male urogenital system, such as infections of the organs, infiltration of somatic and nervous tissue by cancer, and referred sensations from the musculoskeletal system; however, for less-defined pathologies, the mechanisms underlying the pains have been less widely appreciated outside of pain medicine. The mechanisms for this second group, which is probably the majority of male pelvic pain patients, involve neurological mechanisms and, in particular, central sensitization that may involve the whole neuroaxis.

The latest classification approaches have taken this dichotomy of mechanisms into account. To emphasize the differences, those conditions where the main mechanisms are related to central sensitization are known as the pelvic pain syndromes and they are considered separately from those conditions with ongoing nociceptive, acute pain mechanisms, such as those due to chronic infection. The pelvic pain syndromes are defined by their symptoms and signs and often by the presence of central sensitization and the subsequent visceral hyperalgesia, viscerovisceral hyperalgesia, and viscerosomatic hyperalgesia. Often an important part of the process of diagnosing the pelvic pain syndromes is excluding other pathologies.

Classification of the pelvic pain syndromes involves terminology, phenotype, and taxonomy. The phenotype describes the condition in terms of symptoms, signs, and, where possible, mechanisms. Incorporating the phenotype into a hierarchy of phenotypes produces a taxonomy that allows comparisons between phenotypes. This approach enables appropriate prognosis and treatment. The terminology used can be very emotive and careful description of the meaning of the terms is often required. The classification of pelvic urogenital pain has been rapidly evolving over the past 10 years and is likely to continue to do so.[1,2,3,4,5,6,7,8] This ongoing change in classification reflects our increasing knowledge, but also has caused problems for research and evidence-based treatment. The classification will be covered in depth as it is the key to understanding male pelvic pain syndromes.

The central nervous system mechanisms of central sensitization and the psychological responses that result in the chronic pain syndrome are covered in other chapters within this book; those processes that are specific to urogenital pain will be expanded upon in this chapter. There are some obvious differences between the male and female urogenital systems that will result in specific pain syndromes; however, it is important to recognize that there is much overlap as well. Those differences due to gender and sex are covered in Chapter 7.

This chapter supports that in most men with chronic pain perceived in the pelvic organs, the cause of the pain is not often due to classical pathologies of infection or infiltration, but more commonly due to chronic pain mechanisms involving a number of systems with referred pain, functional consequences (e.g., urinary and fecal incontinence, urinary hesitance, impotence), and chronic pain psychological responses.[8]

TAXONOMY AND PHENOTYING CHRONIC PELVIC PAIN

A realization has occurred that pain **perceived** within the pelvis may be associated with classical pathology of the pelvic structures OR that it may result secondary to central nervous system pain mechanisms. It is the latter conditions that this chapter will primarily concentrate on.

Classical Pathologies

Classical pathologies include infection, inflammation, degeneration, and neoplastic and autoimmune mechanisms of any of the pelvic or adjacent pelvic structures (referred pain). In the case of classical pathology, chronic persistent pain is the result of ongoing local pathology, persistent nociception activation with peripheral sensitization, and possibly a central sensitization process. Treatment will primarily be focused on managing the underlying

pathology and the use of analgesics where required. Removing the peripheral cause should resolve the pain.

Pelvic Pain Syndromes and Nonpelvic Pain Syndromes

Most of the recent attempts at classification, taxonomy, and phenotyping have tried to separate out the classical pathologies from those conditions without classical pathology that have become known as the pelvic pain syndromes.[3,7,9] The pelvic pain syndromes are the conditions where there is no peripheral stimulus maintaining the pain experience. In its attempt to separate out the pelvic pain syndromes from those with a nociceptive cause, the European Association for Urology (EAU) in their 2004 classification system called those conditions associated with classical pathology as ''well-defined'' conditions and The European Society for the Study of Interstitial Cystitis (ESSIC) called them ''confusable diseases.''[3,9] Both of those terms have a disadvantage. The term well-defined suggests that the pain syndromes are poorly defined; however, as an understanding of chronic pain mechanisms (including visceral pain mechanisms) and central sensitization develops, this is clearly not the case. ESSIC used the term ''confusable'' to separate out the pain syndromes from those conditions that they might be confused with the pain syndromes, a very difficult concept. In future classifications, one way forward is that chronic pelvic urogenital pain syndromes will become a differential diagnosis with the classical pathologies, and the taxonomy will be divided into pelvic pain syndromes and nonpelvic pain syndromes.[10] The emphasis is thus on the pelvic pain syndromes, which is probably correct as in most patients classical disease processes are not present. Table 65.1 illustrates the division of chronic pelvic pain into pain syndromes and nonpelvic pain syndromes. Table 65.2 provides the definitions for chronic pelvic pain and the pelvic pain syndromes.

Male Urogenital Pain Syndromes

Traditionally, pelvic pain conditions would be classified into those of the male, female, or both. This approach is currently being reconsidered, as the mechanisms discussed above may be common to both sexes with the only difference being the sex organ that the pain is perceived in. However, as there has been a lot of research looking at the end organ pain syndromes and their treatment, this is summarized below as relevant for the male.

Male Specific Pelvic Pain Syndromes

The unique male pelvic pain syndromes are those where the pain is **perceived** in the male sex organs. Table 65.3 summarizes these conditions. The definitions serve to emphasize that classical pathologies are absent.

Subclassification of the Pelvic Pain Syndromes by Organ

Much discussion has been had about whether it is appropriate to divide the pelvic pain syndromes by the end organ that the pain is perceived in. Many would rather maintain a more generic approach and keep to the term pelvic pain syndrome to cover all pains perceived within the pelvis and not associated with a classical pathology. The EAU approach (Table 65.1) uses a progressive step-by-step approach to classification.[3,10] That is, classification starts at the left end of the table if pain is perceived within the pelvis or the external sex organs. Further subclassification only occurs if there are distinct localizing factors within an end organ. Such an approach to taxonomy is very similar to that used to classify life and the animal and plant kingdoms. For instance, we would progress from animal to mammal to elephant only as the evidence allowed. The primary localizing factor for pelvic pain is pain produced by local physical stimulation, such as palpation. If an end organ is clearly associated with the area of perceived pain, then the pain may be labelled with that end organ name as in Table 65.1. If more than one organ is deemed to be involved then either two names may be given to the condition, or it may be more appropriate to consider the pain in more generic terms as a pelvic pain syndrome.

The Importance of Taxonomy and Phenotyping

The above taxonomy (hierarchical classification of conditions) and phenotyping (identifying of the physical characteristics—symptoms and signs—and mechanisms of the diseases within the taxonomy) is important.

Appropriate taxonomy and phenotyping is a prerequisite for epidemiology, diagnosis, management, and prognosis. With traditional management of pelvic pain there has been a tendency to use inappropriate treatments with inappropriate expectations; the result is increased distress and a worse prognosis.[8]

Currently, it is not unusual for inappropriate treatments to be instigated due to a failure to understand the pain syndromes.[1] For example, classic mismanagement would be the recurrent use of antibiotics, or the use of surgery for the complaint of pain. Whereas surgery may have a role for functional reasons (e.g., incontinence), there is a serious debate about its use for pain management. Appropriate taxonomy and phenotyping allows appropriate expectation of both the patient and those providing medical care. Unfortunately, many patients and doctors have inappropriate expectations for treatments aimed at cure. This produces distress and the increased distress is associated with a worse prognosis.[11,12]

An appropriate taxonomy and phenotyping encourages interdisciplinary and multidisciplinary management. In the case of most pelvic pain syndromes, where there may be a reduction in symptoms with appropriate treatment, cure is often not possible. The best outcomes in terms of reduced disability and improved quality of life will come from a symptom management approach involving multiple interdisciplinary teams (e.g., urology, pain medicine, neurology) and multiple members of the team (e.g., nurses, doctors, psychologists, physiotherapists). This is a standard approach for other pain syndromes and should be the standard approach for the urogenital/pelvic pain syndromes.

EPIDEMIOLOGY

Epidemiology requires a clear understanding of the disease that is being studied. Unfortunately, as the phenotyping and taxonomy of male pelvic pain is ongoing, clear-cut epidemiological data for specific pelvic urogenital pain syndromes are not available.

Incidence/Prevalence

Prostate Pain Syndrome

Male pain perceived deep within the pelvis is usually labelled as prostatitis, despite the absence of infection and, frequently, the absence of inflammation within fluids extracted from the prostate. The NIH classification[4] of *prostatitis* includes pain perceived in the prostate without evidence of inflammation or infection and

TABLE 65.2

DEFINITIONS OF PELVIC PAIN

- *Chronic pelvic pain* is nonmalignant pain perceived in structures related to the pelvis of either men or women. In the case of documented nociceptive pain that becomes chronic, the pain must have been continuous or recurrent for at least 6 months. If nonacute pain mechanisms and central sensitization mechanisms are well documented, then the pain may be regarded as chronic, irrespective of the time period. In all cases, there often are associated negative cognitive, behavioral, sexual, and emotional consequences.[3,10]
- *Pelvic pain syndrome* is the occurrence of persistent or recurrent episodic pelvic pain associated with symptoms suggestive of lower urinary tract, sexual, bowel, or gynecological dysfunction. There is no proven infection or other obvious pathology.[3,10]

has reinforced this misnomer. Therefore, most of the data relating to pain perceived within the prostate stems from the prostatitis literature. As well as pain, these patients often have urinary urge (constant need to void as a result of a sensory disturbance), frequency (secondary to the urge), hesitancy and poor flow, but they do not have urgency (need to void because of a fear of incontinence).

Several studies have looked at the demographic distribution of the disease. Prostatitis appears to be more common in men younger than 50 years of age, though there may be a second cohort aged greater than 74 years.[13,14] The Nickel et al. study[14] identified 9.7% of men as having "chronic prostatitis-like" symptoms as defined by the NIH Chronic Prostatitis Symptom Index. This index includes urinary "irritative" and "obstructive" symptoms as well as measures of quality of life, as these are frequently disrupted.[15]

Scrotal Pain Syndrome

Testicular pain in isolation and without obvious cause is well defined as an example of chronic visceral pain. It is essential to rule out pain referred to the testis, such as from an adductor enthesitis or from the spine. Thoraco pathology with or without involvement of the nerve roots may also produce pain perceived in the testis.

Despite being well defined, the testicular pain syndrome is poorly researched and information about its incidence is scanty. The majority of the information stems from postvasectomy surgery, where the incidence may be as high as 19% following this operation. Once more the problem appears to be more frequent in younger men.[16,17,18,19]

Penile Pain Syndrome

There are very few data on this condition, which also appears to be unusual in the pain clinic. The condition must not be confused with the penile pain of pudendal neuralgia or pain sensation referred from the bladder or urethra. This condition is also quite different from the psychiatric obsession associated with the sex organs that can occur in certain patients. A painful penis without obvious cause has been seen to follow circumcision and may represent a central sensitization process.

Precipitating Factors

Very little is known about the factors that predispose men to urogenital pain syndromes.[20,21] In certain, but probably only a small proportion of, cases some form of trauma or infection may be the precipitating factor. Surgical trauma in the form of vasectomy may result in testicular pain.[22] Recurrent minor injury may be a predisposing factor, as for any pain syndrome.

The role of the pudendal nerve is disputed by different experts in the field. There is no doubt that pudendal neuralgia (pain associated with pudendal nerve damage) exists.[23] The mechanism(s) presumably will be the same as for all nerves and the pain would be perceived in the appropriate dermatome. Depending on the site of damage the pain may be perceived in the anus, peri-

TABLE 65.3

PHENOTYPE CLASSIFICATION OF THE MALE PELVIC UROGENITAL PAIN SYNDROMES

- *Penile pain syndrome* is the occurrence of pain within the penis that is not primarily in the urethra, with the absence of proven infection or other obvious pathology.[3,10]
- *Prostate pain syndrome* is the occurrence of persistent or recurrent episodic prostate pain, which is associated with symptoms suggestive of urinary tract and/or sexual dysfunction. There is no proven infection or other obvious pathology.[3,10] (This definition of prostate pain syndrome was adapted from the National Institutes of Health [NIH] consensus definition and classification of prostatitis[4] and includes those conditions that they term "chronic pelvic pain syndrome." Using their classification system, prostate pain syndrome may be further subdivided into: type A, inflammatory, and type B, noninflammatory.)
- *Scrotal pain syndrome* is the occurrence of persistent or recurrent episodic scrotal pain that is associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven epididymo-orchitis or other obvious pathology.[3,10]
- *Testicular pain syndrome* is the occurrence of persistent or recurrent episodic pain localized to the testis on examination that is associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven epididymo-orchitis or other obvious pathology (this is a more specific definition than scrotal pain syndrome).[3,10]
- *Postvasectomy pain syndrome* is a scrotal pain syndrome that follows vasectomy.[3,10]
- *Epididymal pain syndrome* is the occurrence of persistent or recurrent episodic pain localized to the epididymis on examination that is associated with symptoms suggestive of urinary tract or sexual dysfunction. There is no proven epididymo-orchitis or other obvious pathology (more specific definition than scrotal pain syndrome).[3,10]

neum, deeper within the pelvis, the bladder base, or the penis.[24] Whether the sexual function and the central sensitization of the sexual process imparts any specific properties on the damaged pudendal nerve is not known. As may be expected, the nerve damage may be associated with a range of sensory abnormalities such as dysesthesia, allodynia, or numbness. The pudendal nerve is suggested to be at risk from recurrent injuries (such as cycling or long hours of sitting) and from acute trauma, including surgical interventions, such as for cancer or orthopedics.[25,26,27,28] Sitting while working at a computer appears to be a predisposing factor among young men (personal observation).

The role of the musculature is also highly debated.[29,30,31,32,33,34,35,36] In general, it is now well accepted that the pelvic muscles (including the core muscles of the abdomen and spine) may be involved in the pelvic pain syndromes and that these muscles are subject to the same causes as any other muscle. Trauma, as during sports injury, birth injury for women, and accidents may produce a muscle-based pain. Stress is said to be responsible for pelvic muscle tension and hence pain in certain cases, though it must be appreciated that chronic pain will also be associated with psychological responses and even psychiatric disorders.[37,38,39]

The role of negative sexual encounters (NSE) continues to be disputed.[40,41] The prevalence of childhood male sexual abuse may be as high as 16% in some countries; in the UK it has been estimated as 5%. Three percent of male adults may also have had an NSE. Victims of torture are frequently subjected to sexual abuse. What is not clear is the relationship of this abuse to male urogenital pain syndromes. In our editorial,[8] it was suggested that there is little sound evidence to support NSEs as a cause of chronic urogenital pain in patients. However, there is no doubt that in a patient who has suffered a NSE, that incident may require management in its own right.

There are now several articles that indicate that the psychological status of the patient is relevant to the pelvic pain experience. Patients exhibiting high distress associated with catastrophizing and poor coping strategies do less well.[42,43,44,45]

MECHANISMS

Differences Between Visceral and Somatic Pains

In a proportion of patients with pain perceived to be in the pelvis, ongoing classical visceral pain mechanisms may be involved. A number of these mechanisms are listed in Table 65.4 and com-

TABLE 65.4

DIFFERENCES BETWEEN VISCERAL AND SOMATIC PAINS

	Visceral pain mechanism	Somatic pain mechanisms
Effective painful stimuli	Stretching, distension, ischemia, inflammation, producing poorly localized pain	Mechanical, thermal, chemical, and electrical stimuli, producing well localized pain
Summation	Widespread stimulation produces a significantly magnified pain	Widespread stimulation produces a modest increase in pain
Autonomic involvement	Autonomic features (e.g., nausea and sweating) frequently present	Autonomic features less frequent
Referred pain	Pain perceived at a site distant to the cause of the pain is common.	Pain is well localized
Referred hyperalgesia	Referred cutaneous and muscle hyperalgesia common as is involvement of other viscera. **This is very important.**	Hyperalgesia tends to be localized
Innervation	Low density, unmyelinated C fibers and thinly myelinated Aδ	Dense innervation with a wide range of nerve fibers
Primary afferent physiology	Intensity coding. As stimulation increases afferent firing increases with an increase in sensation and ultimately pain	Two fiber coding; there are separate well defined peripheral nerves for nociceptive pain and normal sensation. For pain to be perceived, under normal circumstances without central sensitization, the smaller C and Aδ associated nociceptors have to be activated.
Silent afferents	50%–90% of visceral afferents are silent until the time they are switched on. These fibers are very important in the central sensitization process.	Little evidence for silent afferents
Central mechanisms	Play an important part in the hyperalgesias, viscerovisceral, visceromuscular and musculovisceral hyperalgesias. Sensations not normally perceived become perceived and nonnoxious sensations become painful	Responsible for the allodynia and hyperalgesia of chronic somatic pain
Abnormalities of function	Central mechanisms associated with visceral pain may be responsible for organ dysfunction	Somatic pain associated with somatic dysfunction
Central pathways and representation	As well as classical pathways, there is evidence for a separate dorsal horn pathway and central representation	Classical pain pathways

pared to somatic pain mechanisms. In certain patients with persistent pelvic pain, chronic central sensitization mechanisms are predominant.

Peripheral Mechanisms[46,47,48,49]

Sensitization of visceral afferents and activation of silent afferents by endogenous mediators, including nerve growth factor (NGF), is considered pivotal for the development of visceral pain. NGF is able to both directly activate primary afferents and indirectly activate them (such as through the regulation of the expression of bradykinin[50]). Multiple tachykinins are implicated in both the normal control of bladder contraction and in the heightened stimulation and sensitization of the afferent loop of the micturition reflex after inflammation. Similar mechanisms are known for the other organs. ATP released from hollow organs, such as when the bladder is distended, acts upon purinergic P2X3 receptors found on visceral afferents and on small diameter DRG neurons. Once more these mechanisms may be involved in normal function as well as pain. Voltage gated ion channels (tetrodotoxin resistant sodium channel, NaV1.8) are also implicated in the visceral pain states.

Central Mechanisms[51,52,53,54,55]

In visceral pain excitatory amino-acid receptors such as N-methyl-D-aspartate (NMDA) and alpha-amino-3-hydroxy-5-methyl-4-isoxazoleeproprionic acid (AMPA) play a vital role in the production of viscerovisceral, musculovisceral, and visceromuscular hyperalgesia. Both clinical studies and basic science support that central mechanisms activated as a result of an insult in one organ can result in non-noxious sensations being perceived and noxious sensations becoming more painful both in the same organ and in different organs and the muscles. Such mechanisms explain why many patients have multiple end organ sensitivities. For example, patients with the bladder pain syndrome may also have muscle trigger points and anorectal sensitivity (e.g., irritable bowel syndrome). Once triggered, the changes in the central nervous system can persist for great lengths of time.

Muscles and Pelvic Pain

As with any pain syndrome, muscle tenderness and trigger points may be implicated as a source of pain in the urogenital pain syndromes. Central mechanisms are of great importance in the pathogenesis of these muscle hyperalgesias. The muscles involved may form a part of the spinal, abdominal, or pelvic complex of muscles. It is not unknown for adjacent muscles of the lower limbs and the thorax to become involved. Pain may be well localized to the trigger points but is more often associated with classical referral patterns. As well as trigger points, inflammation of the attachments to the bones (enthesitis) and of the bursa (bursitis) may be found.[56,57,58,59]

Numerous events have been suggested as causative factors. A local infection, such as a bladder infection, may produce local muscle spasm and subsequent muscle associated pain. Renal stones are clearly associated with spinal muscle hyperalgesia.[60] The onset of pain may be due to some form of minor strain or may be associated with a more obvious injury, such as those associated with sports.[61] Certain postures will affect the different muscles in different ways and, consequently, may either exacerbate the pain or reduce it. Stress has been implicated as being both an initiator of pelvic myalgia and as a maintenance factor; as a consequence, negative sexual encounters may also have a precipitating effect.[62]

Pelvic Muscle Pain Syndromes[63,64]

The following are some examples of pelvic muscle pain syndromes.

Piriformis.[65,66] This muscle originates from the anterior part of the sacrum and inserts onto the greater trochanter. The muscle produces external rotation of the leg. It starts within the pelvis, leaving it by the greater sciatic foramen. It is the relationship of the piriformis at this level to the nerves that allows the possibility of nerve irritation by the piriformis (see below). Pain associated with this muscle refers to the buttock and is worse on passive internal rotation or active external rotation against resistance. Trigger points are usually identified at the level of the greater sciatic foramen.

Obturator Internus.[67,68] This muscle arises from the inner surface of the anterolateral wall of the pelvis, where it covers the majority of the foramen ovale and is attached to the obturator membrane, the inferior rami of the pubis, and the ischium. It leaves the pelvis via the lesser sciatic notch to attach to the greater trochanter. It may develop trigger points deep in its body (detected by internal pelvic examination) or in its external part. Pain may refer anteriorly, deep within the pelvis, and to the genitalia and/or posteriorly to the rectum and buttocks. Bursitis may occur as the muscle passes out of the pelvis and around the ischium. This muscle may be associated with pudendal nerve irritation (see below).

Levator Ani.[69] The levator ani is inserted into the inner surface of the anatomical lesser pelvis and is composed of three parts–iliococcygeus, puborectalis, and pubococcygeus. The muscles form a sling with fibers uniting in the midline, and blending with the sphincters of the pelvic organs (Fig. 65.1). Trigger points produce a range of referral patterns from the anus to the penis and into the testis. It has been suggested that levator plate hyperalgesia, trigger points, and referred pain are responsible for the prostate pain syndrome.[70,71]

The relationship of these muscles to the pelvic organs results in a wide range of other symptoms, such as urinary urge with associated frequency. Pain may be exacerbated by use of the muscles, such as during intercourse, ejaculation, voiding of urine, and defecation.

Coccygeus.[71] The coccygeus originates from the spine of the ischium and inserts into the coccyx.

Psoas.[72] The psoas originates from the transverse process of the lumbar vertebrae; leaving the pelvis below the inguinal ligament, it inserts into the lesser trochanter of the femur. Pain can refer to the back, pelvis, and groin.

Spinal and Abdominal Muscle Pain Syndromes

The spinal and abdominal muscle pain syndromes often have a close relationship with the pelvic muscle pain syndromes. Muscle pains may be seen to spread from the site of the original pain (either the pelvis or the spinal/abdominal muscles) to involve adjacent muscles. Sometimes this progression may be picked up from the history; in other patients it may be impossible to separate out the history around what appears to be total body pain. Kinesophobia and subsequent immobility are predisposing factors to the spread of muscle pain.[73,74] Stress and tension are also negative prognostic factors.

The thoracolumbar junction is an important source of referred pain to the buttocks, hips, groin, and testicles.[75]

As in the pelvic muscle pain syndromes, spasm of the abdominal and spinal musculature may be associated with local nerve irritation, such as the genitofemoral nerve with psoas spasm and

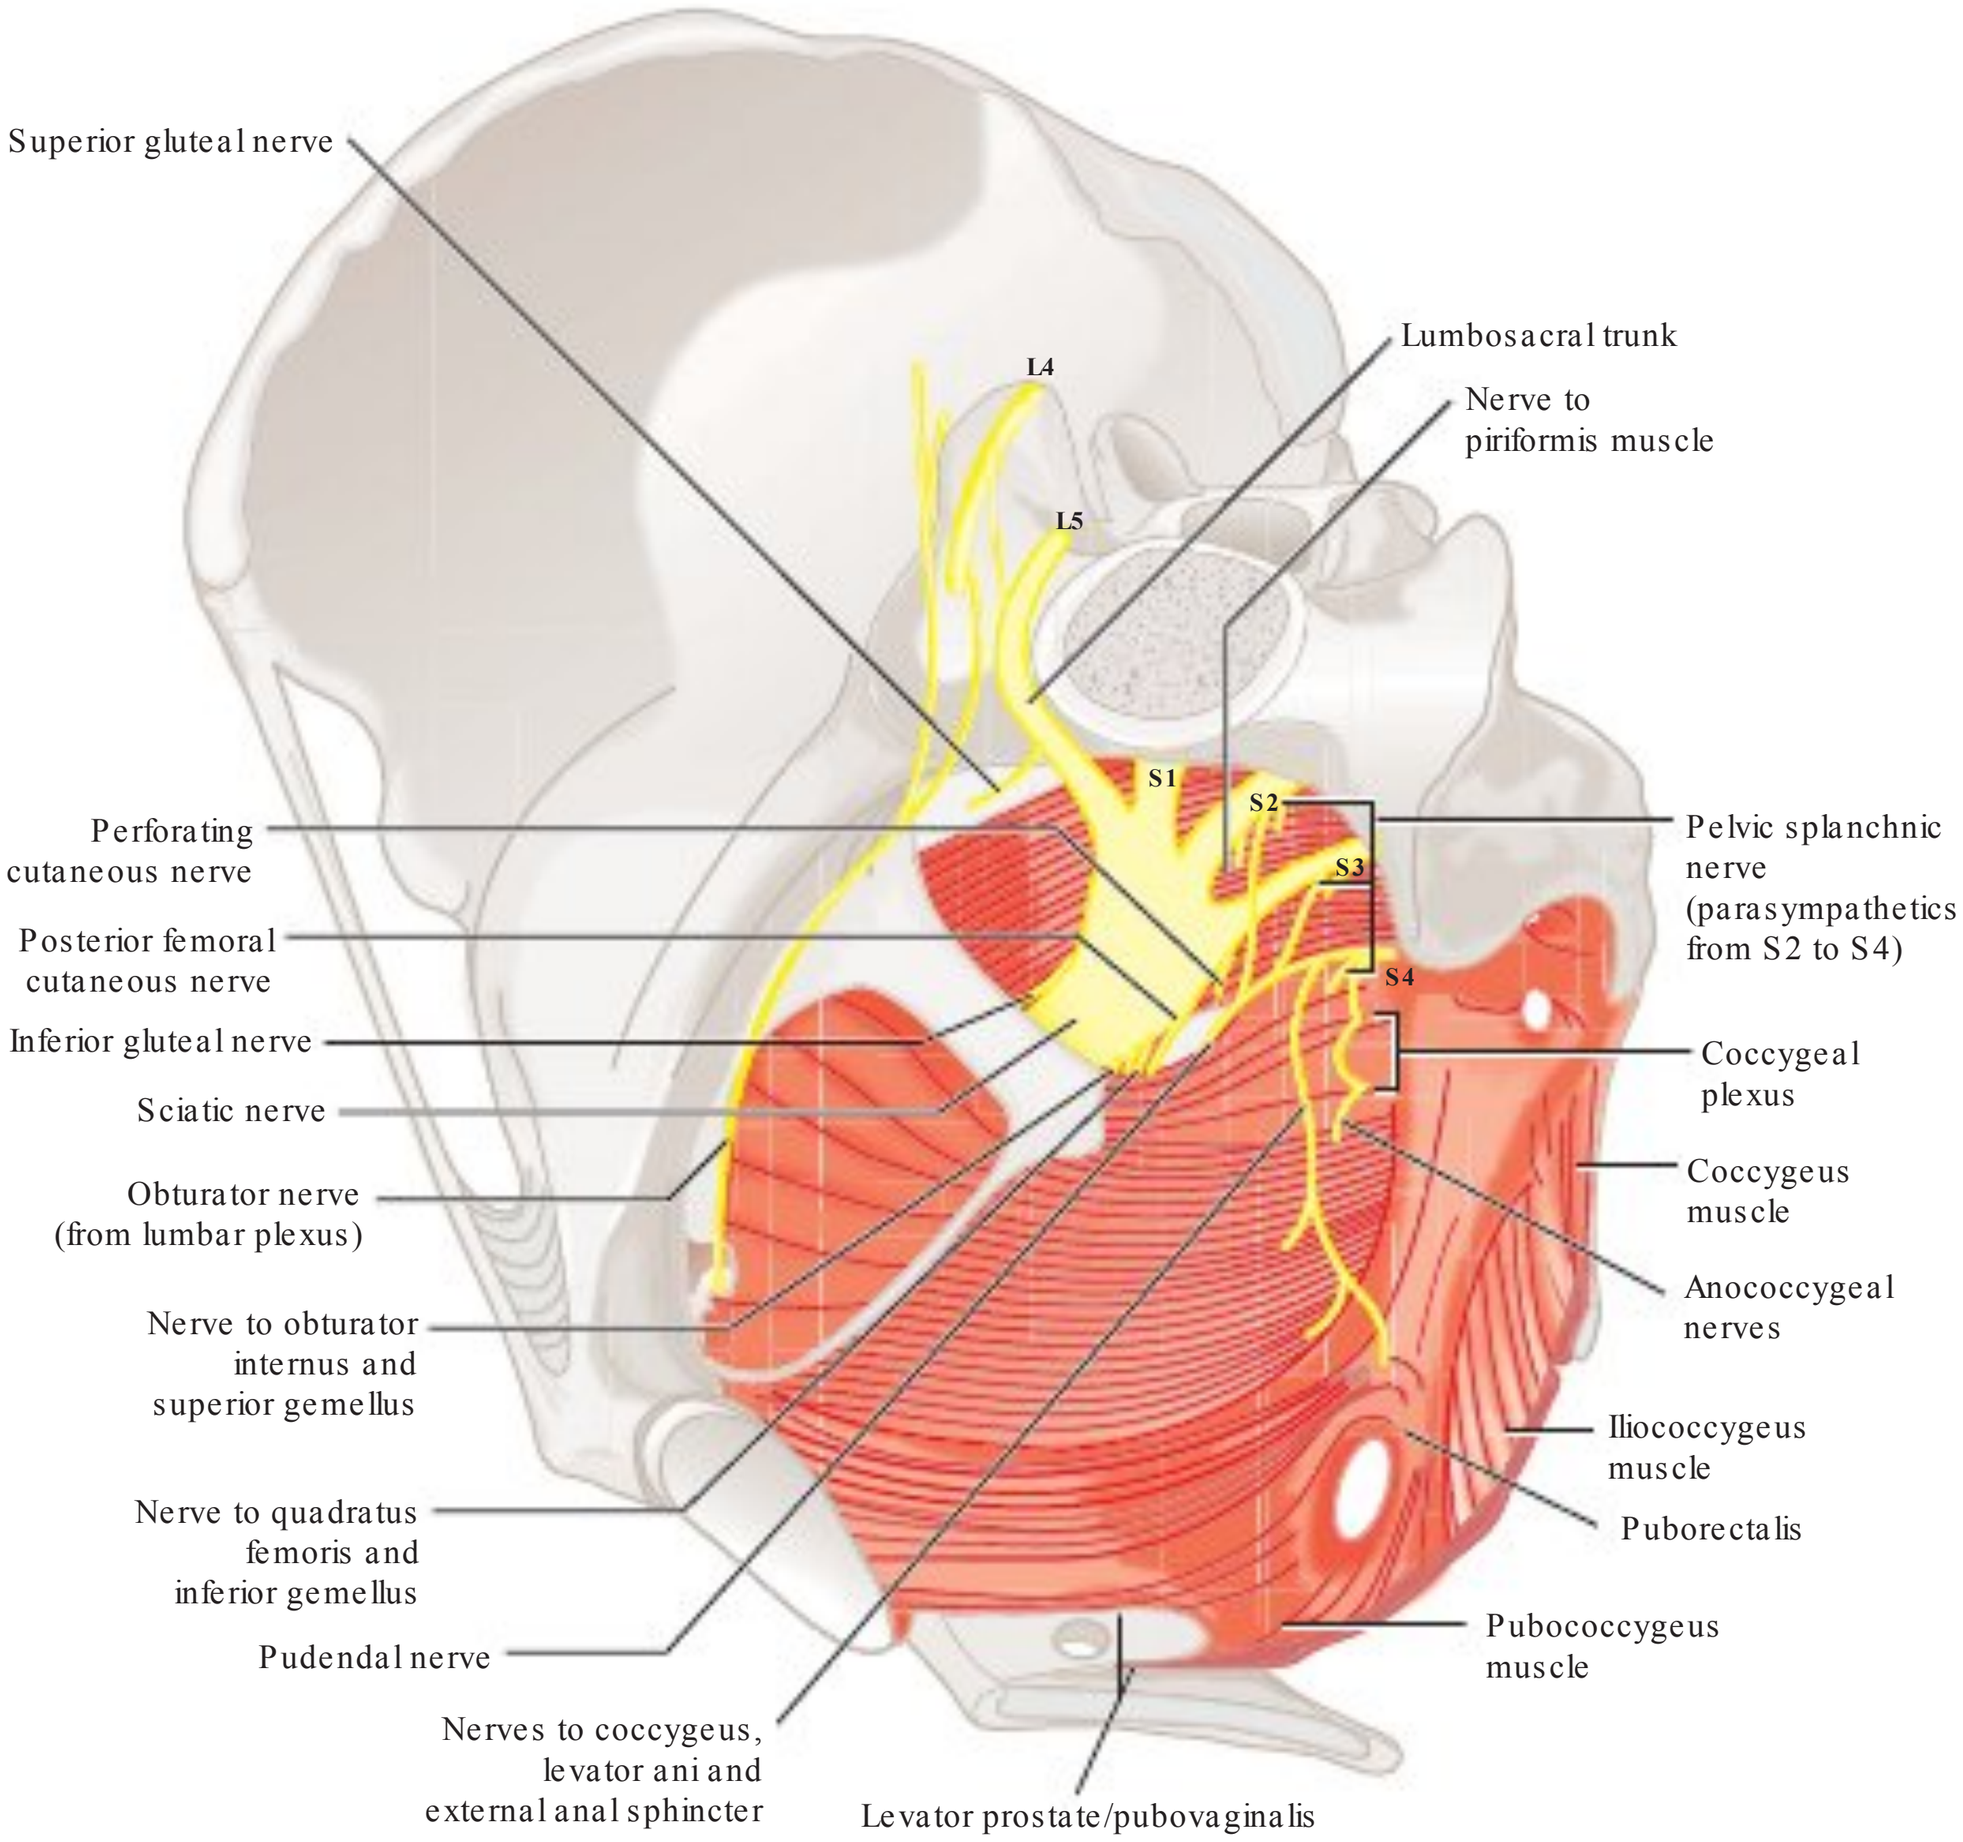

FIGURE 65.1 Male pelvic anatomy.

the anterior cutaneous branches of the intercostals nerves as they transgress the rectus abdominis. Disease at the thoracolumbar junction may result in L1 and or T12 root irritation and, consequently, pain perceived in the groin and testicles.

Pelvic Nerves and Pain

It is well established that nerve injury may be associated with a range of symptoms that include dysesthesia, allodynia, hyperalgesia, and constant or intermittent pain. The mechanisms are well established (see other chapters in this book). In some cases the onset of pain is clearly associated with the nerve damage. However, in many cases arriving at the diagnosis of peripheral nerve injury generated pain can be difficult. This is particularly so for the urogenital pains:

1. Due to the difficulty in identifying the nerves and examining their relevant dermatomes.
2. Pelvic dermatomes overlap widely and, consequently, signs of nerve injury are difficult to identify.
3. Many pelvic nerves are primarily sensory or autonomic and as a result there is little somatic motor data available to aid the diagnosis of nerve damage.
4. Even when there are motor fibers present, significant nerve damage has to be present for there to be abnormal neurophysiology and the muscles are difficult to access.
5. Referred sensations (including cutaneous dysesthesia, allodynia, and hyperalgesias) from the muscle hyperalgesias, tendonitis, and enthesitis are common and frequently confuse the picture.

Peripheral Nerve Pain Syndromes

Nerves and the Male Genitalia. The afferents from the skin of the male genitals pass via a complex of multiple sensory nerves and this makes the diagnosis of nerve injury as a cause of pain difficult. The anterolateral part of the scrotum has afferents primarily associated with the genitofemoral nerve; there is some possible involvement of the ilioinguinal and iliohypogastric nerves. The posterior scrotal branches of the pudendal nerve

transmit sensation from the posterior scrotum. The penis shaft is innervated on its dorsal surface by the genitofemoral, ilioinguinal, and iliohypogastric nerves, and the ventral surface by the perineal branches of the posterior femoral cutaneous nerve and cutaneous branches of the pudendal nerve. The glans penis is associated with the dorsal nerve of the penis, the terminal branch of the pudendal nerve. All the nerves that are associated with the scrotum may also receive afferents from the testis, though classically the nerves from the testis are usually associated with the genitofemoral nerve. The superficial branches of the pudendal's superficial perineal nerve and the perineal branch of the posterior femoral cutaneous nerve receive afferents from the perineal skin. Deeper afferents from the perineum and from some of the pelvic organs pass to the pudendal nerve via its deep perineal branch.

The course of the afferents from the pelvic organ is well described in most anatomy books as are the sources of innervation. For the aims of this chapter the involvement of the pudendal nerve must be emphasized. It must also be recognized that the pelvic plexus is both associated with the parasympathetic and sympathetic nerves and that, as well as efferents associated with these pathways, afferents may travel back to both the sacral roots and the thoracolumbar roots with these autonomic nerves. Sites for injury and for possible intervention may thus include the ganglion impar, superior hypogastric plexus, inferior hypogastric plexus, and lumbar sympathetic trunk, as well as more central spinal root areas.

Pain Arising from Damage to the Anterior Groin Nerves. The iliohypogastric nerve arises from L1 and its anterior branch supplies the skin above the pubis where its lateral cutaneous branch is distributed to the anterolateral part of the buttock. Nerve damage may be associated with surgical trauma during operations on the groin or loin. More proximal lesions are rare, but should be considered as they may represent sepsis or neoplastic infiltration.

The ileo-inguinal nerve is smaller than the iliohypogastric nerve; arising from L1, it is distributed to the skin of the groin and mons pubis. Nerve damage may be associated with surgical trauma during operations on the groin or loin. More proximal lesions are rare, but should be considered as they may also represent sepsis or neoplastic infiltration.

The genitofemoral nerve arises from L1 and L2. It passes through the psoas, then down it to emerge through the deep inguinal ring. Its genital branch supplies the cremaster and a part of the antero and lateral scrotum. The femoral branch passes close to the external iliac artery, the deep circumflex iliac artery and the femoral artery to be distributed to the upper part of the femoral triangle. As the two branches of the genitofemoral nerve may separate at any level, sensory phenomena associated with nerve damage will depend upon the level of the lesion and individual variability. Genitofemoral neuralgia may suggest a vascular aneurysm, local sepsis, or be associated with loin or groin surgery.

Lateral cutaneous nerve of the thigh arises from L2 and L3 and passes to eventually leave the abdomen behind or through the inguinal ligament at a variable distance medial to the anterior superior iliac spine. In the thigh it divides into an anterior branch that supplies the anterolateral skin of the thigh, approximately 10 cm down from the inguinal ligament to the knee. The posterior branch supplies the skin more laterally from the greater trochanter, down to midthigh.

Obturator nerves L2, L3, and L4 descend through the psoas, around the pelvis closely approximated to the obturator internus muscle and obturator vessels to leave the pelvis via the obturator foramen. This nerve has significant motor innervation; its cutaneous branch is distributed primarily to the inner thigh.

Pain Arising from Damage to the Posterior Triangle Nerves. The posterior triangle area is the area defined by the upper border of the piriformis superiorly, the lower border of quadratus femoris inferiorly, the greater trochanter laterally, and the lateral border of the sacrum, lateral border of the sacrotuberal ligament, and lateral border of the ischial tuberosity medially. It is in this region that the sciatic nerve, the posterior femoral cutaneous nerve (this branches into the posterior cutaneous perineal branch as well as the cluneal nerves), the nerve to obturator internus muscle, and the pudendal nerve can be found; they pass deep to the piriformis and superficial to the superior gemellus and obturator internus muscles.

The pudendal nerve has its roots at the S2, S3, and S4 levels. It has three main branches, the inferior anal/rectal nerve, the superficial perineal nerve (which terminates as cutaneous branches in the perineum and posterior aspect of the scrotum), and the deep perineal nerve, which is distributed to the pelvic structures (possibly innervating parts of the bladder, prostate, and urethra) and terminates as the dorsal nerve of the penis, innervating the glans penis. It has been suggested that the pudendal nerve may be damaged at the level of the piriformis muscle, the sacrospinal ligament, or within Alcock's canal, medial to the obturator internus muscle. The site of injury will determine the site of perceived pain and the nature of associated symptoms (e.g., the more distal the damage, the less likely the anal region will be involved). There is also a school of thought that suggests that the fine nerve endings of the pudendal may become trapped in the muscle planes producing neuropathic pain, possibly with mechanisms similar to complex regional pain syndrome.[24,76]

FUNCTIONAL PROBLEMS AND MALE PELVIC PAIN

In addition to pain, many patients with urogenital pain syndromes suffer with abnormalities of organ function. The exact mechanisms involved may not be clear. It is well described that certain drugs (Table 65.5) and surgical interventions can produce organ dysfunction.

The mechanisms, both central and peripheral, involved in the production of the pain may also be the cause of some of the functional disorders. Certainly those functions that are reliant on voluntary control may be affected by changes in sensory perception. The sensation of urge perceived with a more or less empty bladder may be associated with urinary frequency and, similarly, the sensation of rectal fullness may be associated with frequent attempts to defecate. Because of convergence of visceral afferent input within the central nervous system abnormalities of sensation perceived primarily in one organ may result in functional abnormalities further afield[77,78,79] and widespread muscle spasm.[78,80] Abnormal visceral motor function may also occur.[81]

TABLE 65.5

DRUGS PRESCRIBED IN PAIN CLINICS AND SOME OF THEIR EFFECT ON ORGAN FUNCTION

Drugs	Effects
Opioids, including tramadol	Constipation Urinary hesitance Reduced sexual desire and erectile ability
Antidepressants	Constipation Urinary hesitance and retention Reduce orgasmic sensation Delay or inhibit ejaculation
Anticonvulsants	Carbamazepine may block testosterone production with subsequent: testicular atrophy, gynecomastia, galactorrhea May inhibit ejaculation

The role of the neuro-endocrine and neuro-immune systems is poorly understood. The effect of these conditions on fertility is also poorly understood.

PSYCHOLOGICAL CONSEQUENCES OF MALE PELVIC PAIN

The effect of gender on illness and illness behavior is clearly established; however, there is little research on the effect of illness on gender identity and sexual psychology. One may assume that disorders of the male urogenital system will be prone to produce problems within both of these areas with a risk that the male either fails to achieve meaningful relationships or that established relationships have an increased chance of breaking down. All chronic pain is associated with depression and cognitive behavioral problems. The severity of the pain appears to be the main determinant. Depression and catastrophizing are poor prognostic factors. Trip et al.'s paper and more recent work by the same group[45] are key studies. Problems with work, relationships, sex, and loss of meaning of life appeared to be as equally important as the pain itself. For the successful management of a patient with chronic pelvic pain, a multidisciplinary team approach is essential (see below).

MALE UROGENITAL PELVIC PAIN SYNDROMES-TREATMENT

Sex Differences and Therapies

There are some fundamental differences between males and females that may affect drug pharmacokinetics and pharmacodynamics. In contrast to women, men usually have greater muscle mass, lower percentage body fat, and less fluctuations in hormones. Other genetic-related factors may be at play. Men appear to require significantly more morphine than women per kg body weight[82] and women seem to achieve statistically significantly more analgesia with kappa agonists (nalbuphine, buprenorphine, and pentazocine) than do men. The effect of sex differences on other therapies is poorly researched.

Specific Pain Syndrome Treatments

A more complex review can be obtained in the current EAU guidelines for chronic pelvic pain.[10]

Prostate Pain Syndrome

Because the exact nature of this condition is poorly understood, specific drug treatment options do not exist. Most patients will receive one or more courses of antibiotics. The use of antibiotics remains controversial. However, the current EAU guidelines[10] indicate that "because some patients have been observed to improve with antimicrobial therapy[83,84,85,86] a trial treatment with antibiotics is recommended." They go on to say that "patients responding to antibiotics should be maintained on the medication for 4 to 6 weeks or even longer. If relapse occurs after discontinuation, continuous low-dose antimicrobial therapy should be reintroduced and sustained if effective. Long-term results with trimethoprim-sulphamethoxazole have remained poor."[87,88,89] Results of therapy with quinolone, including norfloxacin,[90] ciprofloxacin,[91,92] and ofloxacin,[93,94,95] appear to be more encouraging.

Symptom control is primarily aimed at reducing spasm in the bladder outflow system (smooth and/or striated muscles) or the use of simple analgesics.[96,97]

Striated muscle relaxants may help if there is pelvic floor muscle spasm or in the presence of pelvic floor muscle trigger points.[84]

There are some studies that demonstrate an improvement of symptoms in patients with NIH III a/b prostatitis when alpha adrenoceptor blockers are used. Alpha adrenoceptors are found in the bladder neck and prostate and alpha adrenoceptor blockers are conventionally used to improve flow in the presence of lower urinary tract obstructive symptoms.[98,99,100,101] Whether improvement in pain is due to improving urinary outflow is not known.

Analgesics are often considered the mainstay of symptomatic management. Simple analgesics containing paracetamol are often first line, unfortunately in many cases with little benefit. Nonsteroidal anti-inflammatory medications can be considered but should only be used long term if there is evidence of inflammation. Opioids should only be used if one or the other of the national guidelines has been followed (e.g., The British Pain Society guidelines).

Studies have looked at the role of hormone manipulation with the 5-alpha-reductase inhibitor finasteride. In a small percentage of patients finasteride has been found efficacious with an improvement in voiding and a reduction in pain.[84,102,103] The role for anticholinergics is debatable. Meares has suggested they may be beneficial in reducing urinary urgency.[104]

Prospective studies on the effects of phytotherapy and pentosanpolysulphate (PPS) need to be undertaken; there have been some positive case reports.[105]

There is little evidence for immune modulation using cytokine inhibitors.[106,107]

There are advocates for therapies, such as biofeedback, relaxation exercises, lifestyle changes (e.g., diet, discontinuing bike riding, changing a work station), acupuncture, massage therapy, chiropractic therapy, and meditation.[84,96] Pelvic floor exercises and biofeedback pelvic floor training, independent of other influences, may benefit this group of patients.[109] The debate about exercise versus trigger point therapy continues with very little research.[109] It appears that managing the associated muscle hyperalgesia is important, whether it is the primary problem or secondary. If we draw comparisons with other musculoskeletal-related pain syndromes, managing the patient as a whole appears appropriate. The physical treatment options should probably consist of exercises, postural/core work, trigger point release, and pacing. Maintaining the locus of control with the patient is important.

Heat therapy, such as transrectal hyperthermia[110,111,112] and transurethral thermotherapy,[113,114,115] has been reported to produce favorable results in some patients. Generally, the evidence is weak and the treatments rarely used.

Scrotal/Testicular/Epididymal Pain Syndromes

There is very limited research on this condition and, as a result, the evidence for efficacy is limited.[8] Some groups have advocated the use of antibiotics but, as with the prostate pain syndrome, there appears to be limited supporting evidence in the absence of an identified infection.

If urinary symptoms are present then those symptoms may be managed as in the prostate pain syndrome. Similarly, the use of NSAIDs may have a role if inflammation is present. Analgesics, including opioids and neuropathic analgesics, may be tried; the effect must be monitored and appropriate guidelines adhered to.

There is still debate as to what scrotal contents may be associated with pain. However, there is a suggestion that in the presence of a hydrocele, spermatocele, or varicocele, on average 50% of patients may see benefit from surgery.[116,117,118] In the absence of such a lesion, the role of surgery is debatable and may even be detrimental.[8]

In the scrotal pain syndrome, microsurgical testicular denervation has been advocated; however, the number of studies are limited and not double blind for technical reasons.[119,120] The results of epididymectomy and orchidectomy are considered even worse (though 20% and 60% success rates, respectively, have been suggested).[121,122] It should be of concern that these procedures are still undertaken despite the fact that pain may be increased by the procedure.

Nerve blocks (L1 dorsal root renal/sympathectomy, groin blocks, and pudendal/perineal [posterior triangle] blocks) are regularly used in the treatment of scrotal pain syndrome. As well as a possible therapeutic role (for which there are no supporting studies), they are also important for the differential diagnosis process. Although the evidence for therapeutic benefit is limited, the risks are either small or extremely rare.

Generic Treatment Approach

Urogenital pain syndromes should be managed with the same general approach that is used for any of the pain syndromes. Where possible, the consultation and therapeutic procedure environment should be purpose-built, allowing privacy and comfort (many of these patients would prefer to stand or lie for the consultation). Anatomical models and diagrams, including drawings or photographs of genitalia, that will facilitate the consultation should be available. As well as doctors, nurses skilled in the management of this group of patients should be at hand to reinforce the discussion from the consultation.

Psychology and Sexual Counselling

In view of the psychological consequences of urogenital pain, experienced pain management psychologists should be at hand. The full range of their skills utilized for chronic pain management will be required, but psychosexual counselling and relationship work is often required as well. For the sexual problems, we operate a system where the medical and nursing staff undertake the medical management of the sexual problems but also provide medical information on normality and variants to enable the patient to place their sexual problems in context. Psychological interventions are instigated early and often while physical treatments are ongoing—the aim is to support and prevent psychological and sexual problem deterioration. Under such circumstances both the patient and the psychologist have to be able to work with this model of early psychology and ongoing physical treatment.

Trigger Point Therapy

As discussed above, trigger points and hyperalgesic muscles should be managed as appropriate with treatment options that include drugs, stretching, exercise, relaxation, and injections. Injections into pelvic trigger points are no different than injections into muscles elsewhere, but require the expertise of a specialist with skills using imaging such as CT, ultrasound, or possible procedural MRI. The agent injected is not agreed upon, but usually is a local anesthetic and steroid mixture. Botulinum toxin injections into some of the deeper pelvic muscles has been advocated.[123,124]

Nerve Blocks

Nerve blocks may have a role in the management of specific nerve injuries but may also serve to relax muscles. Nerve blocks may be therapeutic or diagnostic.

Surgery

Surgery was discussed above and, in view of the risks with minimal proven benefit, should not be undertaken without a good surgical reason. If the surgery is significant, psychological evaluation and intervention should be considered first.[125,126]

Drugs

Centrally Acting Analgesics. Chong and Hester[127] summarized the current knowledge in relation to the role of targeting neuropathic pain in urogenital pain syndromes. There is a debate as to when and whether such drugs have a role in the management of the pelvic pain syndromes. Tricyclic and tetracyclic antidepressant drugs may have a role if there are neuropathic qualities to the pain. The best evidence is for amitriptyline. SSRIs and SNRIs are also considered to have a role. Venlafaxine has the strongest evidence but is troubled with cardiac side effects. Duloxetine may have an advantage where stress incontinence is a problem.

Gabapentin and pregabalin have become very popular in the management of chronic pelvic pain and several studies have suggested they may have a role (still to be published). Other antiepileptics could be considered, as for the management of any neuropathic pain.

Opioids should be considered providing appropriate precautions are undertaken and guidelines adhered to.

Neuromodulation

The evidence base for neuromodulation in chronic pelvic/urogenital pain is limited. However, some very good guidelines do exist for the use of neuromodulation in peripheral nerve injury and complex regional pain syndrome.[128] Hence, one would expect neuromodulation to help certain urogenital pain conditions. Case history reports support this. The main problem is achieving stimulation in the appropriate area, and although some specialists do claim to gain benefit by stimulating the lower thoracic region, it appears that most specialist implanters would now stimulate the sacral roots either by a lumbar retrograde or trans-sacral approach. The stimulation is thus preganglionic/ganglionic and not dorsal horn or true peripheral sensory nerve only. The transsacral approach is easy to trial and also has the benefit of some excellent guidelines for bowel and bladder dysfunction neuromodulation.[129,130] It is our policy to try transforaminal/transsacral neuromodulation first, and if that fails to reduce the pain, but the patient wishes to try other approaches, we then try lumbar retrograde or lumbar anterograde approaches.

OVERVIEW AND CONCLUSION

Male urogenital pain may arise from the specific male urogenital organs. However, there is a strong literature pointing out that in many men the pain may arise from other sources but is perceived in the male sex organs. It is now well established that when a man presents with urogenital pelvic pain, the nervous system, musculoskeletal system, and other organs should be looked at as potential sources of the pain. The role of the central nervous system in altering afferent perception and producing efferent dysfunction is now well understood. The central nervous system is also key as a cause for the widespread distribution of the pain syndrome. Often multiple organs and systems are involved. The nervous system may also be key in the association between the pelvic pain syndromes and systemic disorders such as fibromyalgia and chronic fatigue syndrome. In view of this complex of interacting mechanisms, a single therapeutic option is rarely rewarding. Antibiotics and surgery for pain are also rarely rewarding. Multimodal approaches to pain management appear to provide the best results. Management should not only be aimed at the pain, but also the other sensory symptoms and functional disorders. The more distressed the patient, the worse the prognosis; hence, early pain management and early psychological, sexual, and relationship support is crucial to a good outcome.

CHAPTER 66 ■ CRANIAL NEURALGIAS

ANITA H. HICKEY, STEVEN SCRIVANI, AND ZAHID BAJWA

INTRODUCTION

Since the last edition of this book was written, advancements in various diagnostic capabilities have improved our understanding of the etiology and pathogenesis of the neuralgias of the face, head, and neck. Recent modifications in the nomenclature have also occurred which reflect a more accurate organization and classification of the cranial neuralgias and facial pain. Although the nomenclature of these severe and often incapacitating pain syndromes remains controversial, immense efforts have been made to scientifically categorize these syndromes based on causal factors, when known, or strict diagnostic criteria, when causal factors are not known.[1–3] Although not perfect, this classification system continues to be refined and to serve as a valuable instrument to further advance the scientific understanding and treatment of these disorders.[4] The importance of accurate diagnosis and classification of these conditions is particularly critical as it pertains to treatment of many of the neuralgias for which successful medical and surgical treatments have been developed.

Cranial neuralgias refer to paroxysmal pain in the distribution of a specific cranial nerve. Previous classifications separated facial pain into "typical," "atypical," and "secondary" neuralgias. Because a great portion of the current literature continues to utilize these terms, it is important to understand the meaning of both the previously used nomenclature and the revised nomenclature.[2] Other features ascribed to the previous classification system are described in Table 66.1.

The revised classification system utilizes the terms "classical" and "symptomatic." The term classical refers to trigeminal neuralgia (TN) of unknown etiology. Classical rather than primary has been applied to those patients with a typical history even though a vascular or other source of compression or demyelination may be discovered during its course. The term symptomatic or secondary can then be reserved for those patients in whom a neuroma, tumor, multiple sclerosis (MS), or other cause has been demonstrated.

The term persistent idiopathic facial pain has replaced atypical facial pain in the taxonomy. This change reflects a lack of known mechanisms, continued recognition of the potential contribution of multiple etiologic factors to this syndrome, and an emerging knowledge of the pathophysiology of diffuse pain syndromes previously not well understood.[5–8]

This chapter is organized around the current classification of neuralgias of the cranial nerves and associated disorders. We cover most of these but particularly emphasize TN as this single disorder is best studied amongst cranial neuralgias and offers the

TABLE 66.1

CHARACTERISTICS OF FACIAL PAIN SYNDROMES

Feature	Typical Neuralgia	Atypical Neuralgia Unilateral Facial Pain	Persistent Idiopathic Facial Pain (Formerly Atypical Facial Pain)
Frequency	Intermittent: every few moments to once a day or less	Constant, can fluctuate	Constant, not much variation
Pain-free Intervals	Always	Rarely	Never
Description	Electric shock, stabbing, shooting	Burning, aching, can have superimposed shocks	Burning, aching
Location	Unilateral; usually trigeminal, rarely nervus intermedius, glossopharyngeal, vagus, upper cervical	Trigeminal or upper cervical. Unilateral, rarely bilateral	Not restricted to specific cranial nerve distribution. Intraoral or facial. Can extend to neck. Starts unilateral. May progress to bilateral
Sensory Changes	None or mild hypesthesia	Often hypesthesia	Common hypesthesia Dysesthesia, paresthesias
Precipitating Factors	Triggered by nonnoxious stimulation, often in anterior face and remote from face	Rarely triggered; trigger usually in area of pain	Not triggered
Autonomic Changes	None	Rarely present	None
Local Tenderness	None	Rare	Rare
Causative Factors	Vascular compression of nerve in subarachnoid space; rarely MS	Tumor, infection, trauma or mechanical impingement on nerve; MS, often no cause found	None known
Common age at onset (year)	>50	30	Variable
Gender	60% female	75% female	90% female

most reports of diverse clinical experiences. Emphasis will also be made on updates in classification, diagnosis, and treatment of cranial neuralgias. A narrative bridge from past literature and understanding is included to enhance the reader's understanding of more recent research, insights, and therapeutic approaches.

CLASSICAL TRIGEMINAL NEURALGIA

History

TN was described as early as the first century AD in the writings of Aretaeus (Fig. 66.1). Treatments at that time included bloodletting and the application of bandages containing arsenic, mercury, hemlock, cobra, and bee venom as well as other poisons. Eleventh century Arab physician Jurjani advanced the vascular compression theory as the causative factor of the severe pain and spasm of this syndrome.[9] The first clinical descriptions of TN in the European literature has been ascribed to Johannes Bausch in 1672 and John Locke in 1677. French physician Nicolaus André, who in 1756 described five cases of "unbearably painful twitch," is credited with first recognizing this condition as a unique medical entity. It was André who coined the term tic douloureux ("painful spasm"). English physician John Fothergill similarly published a full account of the syndrome and presented the paper to the Medical Society of London in 1773 and thus the disorder has sometimes been referred to him.[9–11] Other historical names for TN include prosopalgia and neuralgia of the fifth.

In a treatise on neuralgia published by Massachusetts physician E.P. Hurd in 1890, the following description of the clinical presentation of TN is found: "Probably no more atrocious suffering is known. . .During the attack, the patients utter loud outcries, toss about on their beds and smite their heads. The muscles of the affected side of the face are often the seat of rapid contractions, convulsive shocks, which have given to this disease one of the names by which it is known,(tic douloureux). These contractions may be limited to single groups of muscles, as the zygomaticae, or the frontal part of the occipito-frontales. . .then the paroxysmal shocks diminish in frequency and intensity, and all becomes calm; the storm has passed, to be renewed again under the same form in a time not far distant."[12]

In the nineteenth century, susceptibility to this condition was thought to be secondary to hereditary factors (with "the ancestors of the neuralgic subject being either neuralgic or sufferers from hysteria, epilepsy, or other neurosis"), in combination with other factors such as disease, intemperance, or insufficient diet. Medical treatment was ineffective until the introduction of trichloroethylene inhalation in the 1920s. Prior to this, treatment in the late 1800s focused on advocating a nutritious diet, adequate sleep, hydrotherapy, vigorous exercise, and moderation in all things. Patients were advised to avoid strain, reading, and brain work, which were felt to be instrumental in initiating an attack, as well

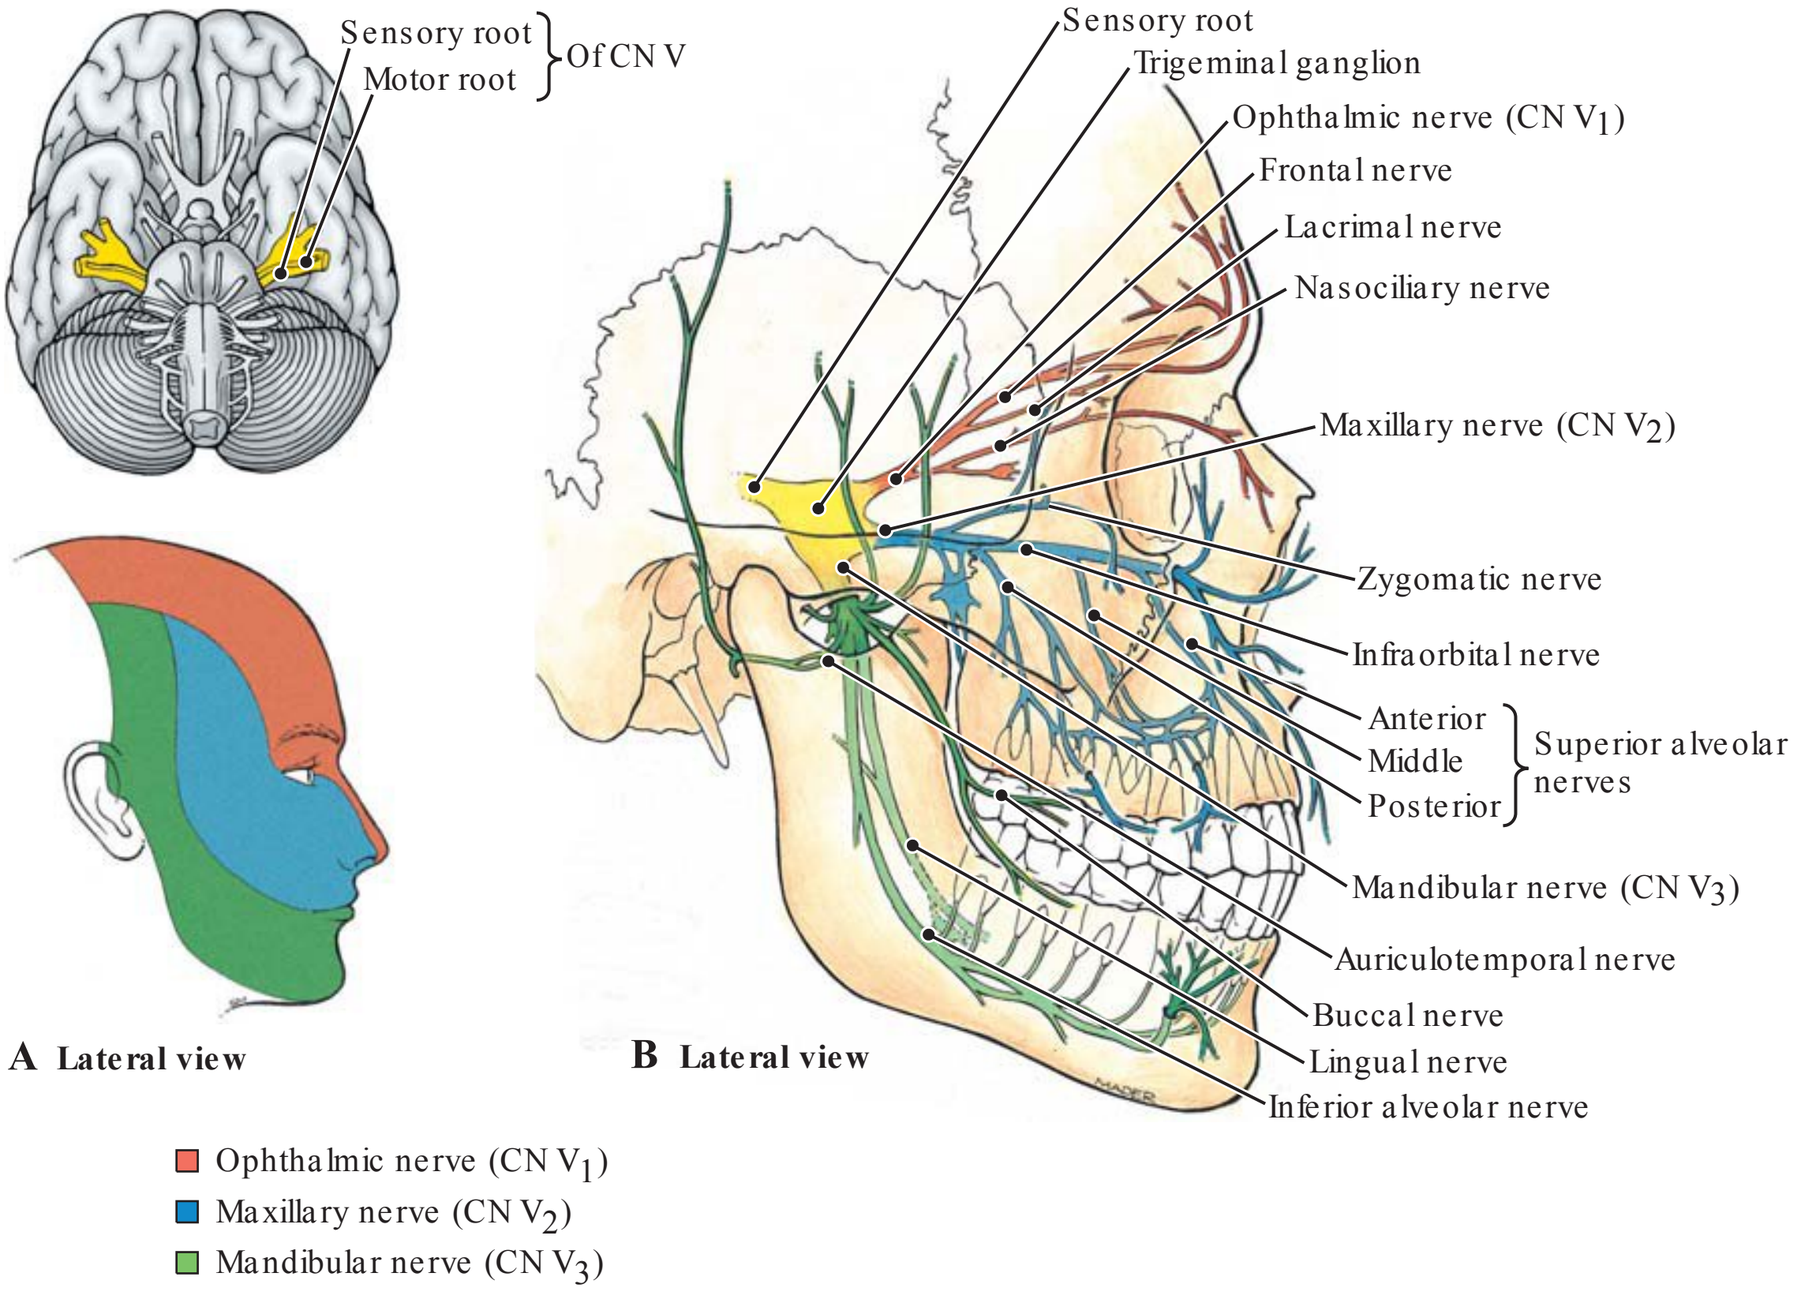

FIGURE 66.1 Distribution of the trigeminal nerve (cranial nerve V). The trigeminal nerve gives rise to three divisions: V1, the ophthalmic nerve, V2, the maxillary nerve, and V3, the mandibular nerve. Each division provides sensory innervations to the skin, subcutaneous tissue, and dura mater. The sensory fibers from each division pass through an autonomic ganglion and project the postsynaptic parasympathetic fibers from that ganglion (V1 for the ciliary ganglion, V2 for the pterygopalatine ganglion, and V3 for the submandibular and otic ganglia). V3 additionally supplies motor innervations to four pairs of muscles: temporal, masseter, lateral and medial pterygoid muscles. (From Moore KL, Dalley AF. *Clinically Oriented Anatomy*. 5th ed. Baltimore: Lippincott Williams & Wilkins; 2006.)

as alcohol, tobacco, and other stimulants. Successful nonsurgical treatment for TN was reported by such notable nineteenth century physicians as Wilhelm Erb and Duchenne de Boulogne. These included the use of electrotherapy in the form of interrupted current and galvanism.[11,12]

Although early attempts at surgical treatment of TN by Mareschal, surgeon to King Louis XIV of France, around 1750 and Veillard and Dussans in 1768 were unsuccessful, Bell and Magendie's clarification of the anatomy and function of the trigeminal and facial nerves in the early nineteenth century is thought to have contributed to subsequent effective surgical treatments for facial pain. Successful neurectomy of the inferior maxillary nerve was reported by Dr. Joseph Pancoast of Philadelphia in 1840 and in 1851. Dr. J. M. Carnochan described successful resection of the maxillary nerve and removal of Meckel's ganglion from the foramen rotundum to the infraorbital foramen. Subsequent surgical advances in technique were made by Horsley, Taylor, and Coleman in 1891 (middle fossa approach) and Hartley and Krause in 1892 (subtemporal approach). Cushing's modification to this approach, reported in 1900, involved approaching the trigeminal ganglion from below the middle meningeal artery. His contribution was credited with decreasing the mortality rate of the surgery to 5%. In 1921, Frazier suggested electrical stimulation to clearly define and spare the motor root, and in 1928, Stookey recommended differential sectioning of the sensory fibers of only the affected divisions of the trigeminal nerve. In 1925, Dandy reported a novel lateral suboccipital or cerebellar approach which preserved the motor root and was associated with little blood loss. Because of his posterior fossa approach, he was able to observe vascular loops impinging on the root entry zone (REZ) in many patients and inferred that this was the cause of trigeminal neuralgia.[11,12]

In 1967, Peter Jannetta reported use of the posterior fossa approach with the aid of an operating microscope.[13,14] He was able to confirm Dandy's observations of vascular loops compressing the REZ and subsequently performed a large series of successful surgical treatment of patients with TN using a technique that became known as microvascular decompression (MVD). MVD involves decompression of the nerve by moving the offending vascular loop(s), which are then restrained with nonabsorbent Teflon felt. Due to its low complication and high success rates, MVD has become the surgical procedure of choice for the treatment of intractable trigeminal neuralgia. The history of the medical and surgical treatments for TN has recently been thoroughly reviewed by Cole, Liu, and Apfelbaum.[1,11,12]

Epidemiology

Several epidemiological studies have collected data on the incidence of TN during the last 60 years. Although there is some variation in the reported incidence, in all cases it continues to be reported as a rare neurologic disorder. A U.K. study by Brewis et al.[15] published in 1966 reported an incidence of 2 per 100,000. This number was thought to be low due to lack of inclusion of patients seen by otolaryngologists. U.S. studies by Kurtzke[16] in 1982 and Katusic et al.[17] in 1990 reported an incidence of 4 and 4.8, respectively (age and sex adjusted per 100,000 per year). A prospective U.K. study by MacDonald et al.[18] reported an incidence of 8 per 100,000 per year. The most recently published epidemiological study was also performed in the United Kingdom and reported an incidence of 26 per 100,000 per year between January 1992 and April 2002.[19] This study reviewed patients diagnosed with TN by general practitioners rather than those referred to specialists.

The incidence of TN has consistently been found to be higher in females with a 1.74:1 female/male ratio. Onset is usually after age 40 with peak occurrence between ages 50 and 80. Occurrence in patients younger than age 40 should raise suspicion of secondary causes such as tumor or MS. TN occurs rarely in children.[20,21]

Etiology and Pathophysiology

The various pathologic findings reported and complex theories advanced in the TN literature attempt to explain the combination of unique clinical features of TN such as:

- Stereotyped paroxysms of lancinating pain which occur in a limited part of the trigeminal territory
- Separation of the trigger area from the painful region
- Nonnoxious triggers
- Absence of sensory or motor deficit
- Characteristic response of TN to antiepileptic medications

New diagnostic techniques are now challenging theories that were previously advanced to resolve the many questions which remain regarding the etiology and pathophysiology of TN.

Observation of surgical findings led to the twentieth century vascular compression theory of TN. This theory was proposed when Dandy, Gardner, and Miklos and recognized the presence of a groove or distortion of the trigeminal nerve root by vessels, or rarely tumors. Jannetta produced convincing evidence that this was the cause of TN by his large series of effective microvascular decompression surgeries using the operating microscope. He also demonstrated the absence of trigeminal nerve compression in patients undergoing suboccipital craniotomy for other reasons and in a series of fresh cadaver studies.[11,13,14] Jannetta's[22] review of 4400 operative procedures from 1969 to 1999 revealed a rostroventral superior cerebellar artery loop compressing the trigeminal nerve either at the brainstem or distally to be the most common cause of vascular compression. Compression by the posterior inferior cerebellar, vertebral, and anterior inferior cerebellar arteries has been also been found. Other reported causes of compression of the trigeminal nerve have included meningiomas, epidermoid cysts, arachnoid cysts, and schwannomas arising from the nerve root itself.[23] Malis[24] proposed petrous ridge and fibrous dural band compression as a cause of TN and demonstrated successful alleviation of TN in a case series of 43 patients undergoing decompression of these fibrous bands.

Kerr[25] and King further argued a peripheral versus a central mechanism for TN. Kerr's[25] peripheral hypothesis, based on epidemiology, surgical resections, and cadaver and animal studies, suggested that the paroxysmal neuralgic pain of TN with associated trigger zones is consistent with minor mechanical or pulsatile compression superimposed upon predisposing axonal degenerative changes due to hypertension, atherosclerosis, or disease such as MS. He also noted that with aging, replacement of the bony roof of the carotid canal with connective tissue is known to occur. He argued that that these degenerative bony changes would permit pulsatile contact with areas of the ventral ganglion which correlate with the anatomic area in which most trigger zones are known to occur.[14,25]

King argued a central etiology for TN based on injections of alumina gel into the spinal nucleus of the fifth nerve in cats which resulted in a syndrome of dysesthesia of the face with over reaction to tactile stimulation.[21,25] Calvin et al.[26] proposed electrophysiologic mechanisms which required both peripheral and central events to produce the symptoms of TN. Fromm and colleagues[27] published studies which implicated an initial peripheral injury followed by failure of central inhibitory mechanisms as causative factors leading to the onset of TN.

The compression theory of TN, described by the findings of Dandy, Gardner, Miklos, Jannetta, and others, postulates a mechanism for production of the complex of TN symptoms that involves degenerative changes to the central peripheral myelin transitional zone of the trigeminal nerve, due to either direct or indirect effects of compression along the course of the nerve from

the pons to its entry into Meckel's cave.[28] Recent ultrastructure analysis of trigeminal root biopsy specimens of patients with TN obtained during surgery for microvascular decompression support this theory. They reveal axonopathy, axonal loss, demyelination, and axon apposition without intervening glial processes consistent with the "ignition hypothesis" of TN. This model correlates the above pathophysiologic changes with the paroxysmal symptoms of TN based on similar foci of nerve root demyelination and juxtaposition of axons which have been demonstrated in patients with MS and TN together with experimental studies which indicate that this anatomic arrangement favors the ectopic generation of spontaneous nerve impulses and their ephaptic conduction to adjacent fibers. These studies also demonstrate that spontaneous nerve activity is likely to be increased by deformity of the nerve and frequently associated pulsatile vasculature.[29–32]

More conclusive evidence supporting both peripheral and central etiologies of TN can be found in recent electrophysiological studies. One such recent study has revealed evidence of peripheral damage to small A delta fibers of the trigeminal nerve near the REZ in the brainstem. Findings revealed demyelination and axonal degeneration or isolated advanced axonal damage on the symptomatic side in patients with classic TN (CTN). In patients with CTN and concomitant chronic facial pain, facilitation of central trigeminal processing at the supraspinal level was found. This is consistent with divergent results of MVD in these two groups of patients. Outcome data from MVD in patients with CTN shows excellent or good pain relief in 97% immediately postoperatively and in 80% of those with 5-year follow-up. In patients with TN and concomitant persistent facial pain, previously defined as "atypical," only 51% show good or excellent pain relief at 5 years.[33,34] Pre- and postoperative electrophysiological recording sessions revealed that relief of pain correlates with normalization of previously prolonged trigeminal reflex responses. Electrophysiological testing has also been able to differentiate CTN from symptomatic TN (STN) with a high degree of sensitivity and specificity (92% and 95%).[34,35] Although not practical for routine patient diagnostic purposes, this research is helpful in understanding the decreased response rates in these distinct groups of patients.

Symptoms and Signs

Clear and concise criteria are essential in establishing a diagnosis and conducting research for TN. This is particularly true for a condition such as TN where there is no objective laboratory test to confirm the clinical diagnosis. White and Sweet[36,37] helped to achieve these goals by publishing precise and succinct criteria which facilitated early and accurate clinical recognition of TN and facilitated subsequent research (Table 66.2). The International Headache Society recently established new clinical diagnostic criteria for TN as part of the International Classification of Headache Disorders, Second Edition (ICHD-II) (Table 66.3),[2] which have gained wide acceptance and reflect a significant advance that should further promote communication and stimulate research regarding TN.

TABLE 66.2

SWEET CRITERIA

1. The pain in TN is paroxysmal.
2. The pain in TN may be provoked by light touch to the face.
3. The pain in TN is confined to the trigeminal zone.
4. The pain in TN is unilateral.
5. In a patient with TN, the clinical sensory examination is normal.

TABLE 66.3

INTERNATIONAL CLASSIFICATION OF HEADACHE DISORDERS, SECOND EDITION, DIAGNOSTIC CRITERIA FOR CLASSICAL AND SYMPTOMATIC TRIGEMINAL NEURALGIA

ICHD-II Diagnostic Criteria for Classical TN

A. Paroxysmal attacks of pain lasting from a fraction of a second to 2 minutes, affecting one or more divisions of the trigeminal nerve and fulfilling criteria B and C
B. Pain has at least one of the following characteristics:
   1. Intense, sharp, superficial, or stabbing
   2. Precipitated from trigger areas or by trigger factors
C. Attacks are stereotyped in the individual patient
D. There is no clinically evident neurologic deficit
E. Not attributed to another disorder

ICHD-II Diagnostic Criteria for Symptomatic TN

Pain indistinguishable from CTN but caused by a demonstrable structural lesion other than vascular compression.

A. Paroxysmal attacks of pain lasting from a fraction of a second to 2 minutes, with or without persistence of aching between paroxysms, affecting one or more divisions of the trigeminal nerve and fulfilling criteria B and C
B. Pain has at least one of the following characteristics:
   1. Intense, sharp, superficial, or stabbing
   2. Precipitated from trigger areas or by trigger factors
C. Attacks are stereotyped in the individual patient
D. A causative lesion, other than vascular compression, has been demonstrated by special investigations and/or posterior fossa exploration

There may be sensory impairment in the distribution of the appropriate trigeminal division. STN demonstrates no refractory period after a paroxysm unlike CTN.

CTN has well-described pathognomonic features which differentiate it from other types of facial pain. It is characterized by intense paroxysmal, electrical pain which may be accompanied by muscular spasms on the affected side of the face. The attacks generally last from fractions of a second to 2 minutes and are followed by a refractory period during which no pain can be triggered. Pain is abrupt in onset and termination. Between paroxysms, "the patient is in dreaded fear of the next flash of pain."[38] Occurrence of spontaneous remission of pain for weeks, months, or years is another feature of TN which may complicate accurate assessment of therapies.[39]

The pain of TN is limited to the distribution of one or more divisions of the trigeminal nerve and occurs most frequently in V2, V3, or a combination of V2 and V3. First division pain is rare in TN.[40] The pain of TN occurs on the right side of the face more often than the left with predominance ranging from 59% to 66%. Reviews have reported a 3% to 5% occurrence of bilateral pain. Pain rarely occurs on both sides simultaneously. Rather, the painful spasms occur on one side for weeks or months and then, following a period of remission, occur on the opposite side.[38,41–43] Pain occurring on both sides simultaneously or the presence of an abnormal neurologic exam should raise concerns of a secondary etiology such as tumor or MS.[44,45]

Trigger zones, or areas of the face or head that upon nonnoxious stimulation elicit a TN episode, are also a characteristic feature of TN. In two large series of patients with TN, trigger zones were reported to be present in 91%.[36,46] Trigger zones may be

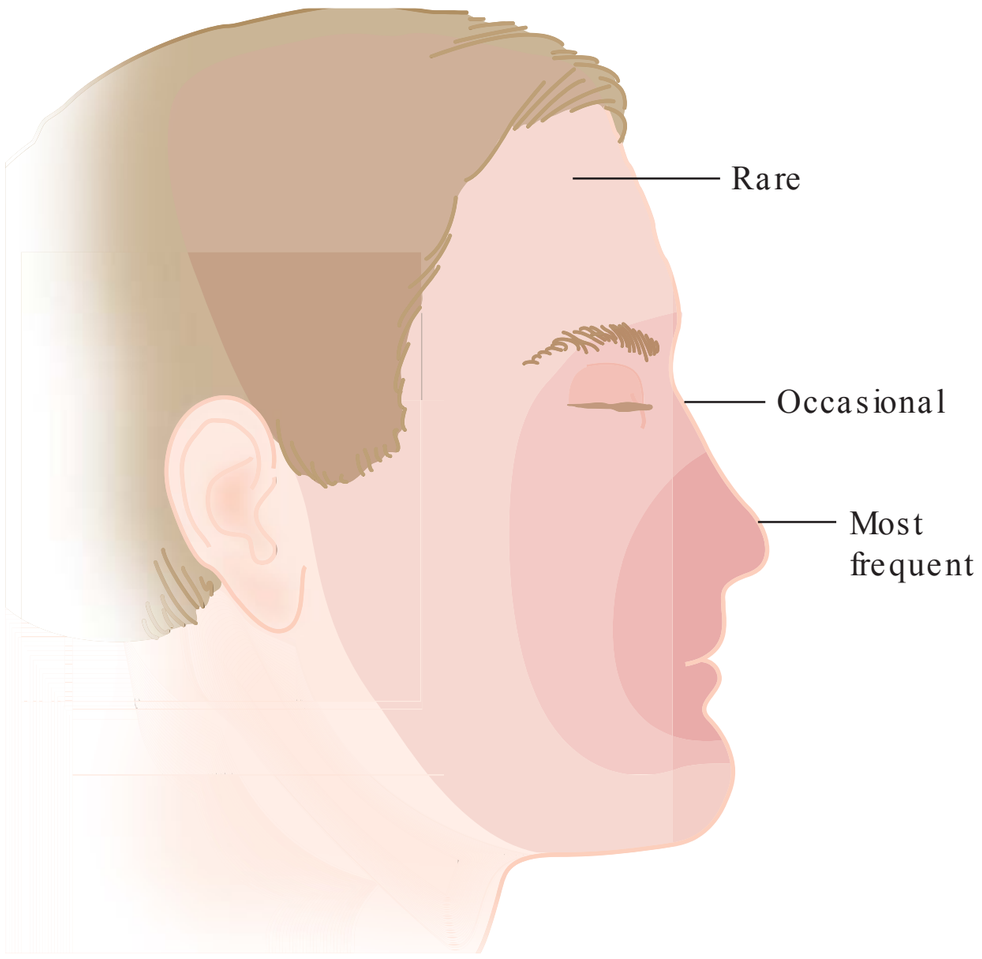

FIGURE 66.2 The most likely sites of triggering for tic douloureux are in the anterior face.

found in more than one division of the trigeminal nerve. The pain can also be triggered in a different zone from the trigger. The central part of the face near the nose and lips is the area in which triggers most often occur (Fig. 66.2). Touch and vibration have been found to be the most effective stimuli.[47] Attacks are reported to be set off by washing the face, shaving, talking, chewing, brushing of the hair and scalp, or a light breeze on the face of a patient. This can lead to poor hygiene, weight loss, dehydration, and social withdrawal. The ICHD-II criteria also list precipitation of pain paroxysms by "trigger areas" or "trigger factors." These triggers may include stimuli outside of the trigeminal distribution, such as a limb movement, and may include other sensory stimulation such as bright lights, loud noises, or tastes.[2]

Over time, some patients with CTN develop a persistent background pain in addition to their paroxysmal pain. This presentation is referred to as atypical TN in much of the past and current literature. Many studies report that these patients are significantly less responsive to pharmacologic and interventional therapies than those with CTN. This may be due to central facilitation of trigeminal nociceptive processing in these patients in accordance with recent electrophysiological findings.[33]

Pre-TN is an additional syndrome reported initially in 1949 by Symonds.[48] In these patients, a dull aching or burning pain involving a part of the upper or lower jaw develops for hours, days, or weeks and may be triggered by jaw movements or liquids. They may have several bouts of this pain with remissions for weeks, months, or years followed by sudden onset of the paroxysmal pain of CTN. Carbamazepine and/or baclofen have been effective in most cases. Unfortunately, some patients undergo multiple dental procedures before the syndrome is recognized as an early sign of TN.[48–50]

Differential Diagnosis

The diagnosis of TN is made essentially upon clinical information. Differentiating CTN from STN and other causes of facial pain is of great relevance in treating underlying disease or lesions and for instituting effective medical or surgical therapy. This requires a thorough history to obtain the patient's detailed description of defining characteristics, frequency and duration of pain, exacerbating factors, presence or absence of triggers, and associated symptoms. A complete physical exam is necessary to confirm the presence or absence of neurologic deficits. Appropriate tests, including more advanced testing with computed tomography (CT) or magnetic resonance imagining/angiography (MRI/MRA) is often indicated to confirm the suspected diagnosis and exclude secondary causes.

Since TN is itself a rare disease, rare presentations of other disease processes fulfilling the diagnostic criteria of TN may require close examination. Rare cases of sinusitis presenting as CTN involving first and second division of the trigeminal nerve have been reported with one report of fatal progression in a diabetic patient.[51,52] Since involvement of the ophthalmic branch occurs in less than 5% of TN patients, a high degree of suspicion is indicated in such cases.

As the example above illustrates, it is important to differentiate CTN and STN since STN may be secondary to a progressive lesion or disease process. Expedient treatment of the underlying disease process or lesion in these cases may limit patient morbidity and mortality and improve overall patient outcome. Although most patients with malignant and benign tumors present with sensory deficit or persistent idiopathic facial pain, the literature does contain reports of patients with tumors initially presenting with TN and no neurologic deficits.[53,54].

MS is a common cause of symptomatic TN which should be considered in any person under 50 who presents with TN. Brainstem auditory evoked potential and blink reflex testing are sensitive methods for examining patients with TN. When the patient's neurologic exam is abnormal or if the patient does not respond to standard medical therapy, increasingly sensitive methods of CT or MRI/MRA result in accurate diagnosis in almost all cases.[55–59]

The cranial neuralgias covered in greater depth later in this chapter must also be differentiated from TN. Glossopharyngeal neuralgia presents with paroxysmal, electrical pain, spontaneous remissions, and triggers associated with swallowing, chewing, coughing, and talking in some patients. Pain occurs most frequently in the ear, tonsils, larynx, and tongue and may radiate to the neck, shoulder, or face. In less than 10% of cases there is an association with TN. Glossopharyngeal neuralgia is also rarely found in patients with MS.[60]

Intense and stabbing pain localized in the depth of the ear canal is also described in by patients with geniculate ganglion or nervus intermedius neuralgia, a rare disorder affecting the sensory branch of the facial nerve. Other cranial neuralgias which may be confused with TN include "tic convulsif" and hemifacial spasm.

Patients with tic convulsif present with severe otalgia combined with unilateral facial spasm. This rare neuralgic disease is thought to be due to vascular compression of the sensory and motor components of the facial nerve at their junction with the brainstem. Hemifacial spasm is a neuralgia involving the facial nerve which is characterized by intermittent, involuntary, irregular, unilateral contractions of muscles supplied by the ipsilateral facial nerve.[61–63]

Cluster headache pain is unilateral and usually occurs in the ocular, frontal, and temporal areas (though it may occur in the infraorbital and maxillary regions). It usually presents initially in men who are between 18 and 40 years old. Pain is severe, constant, stabbing, burning, and throbbing with associated ipsilateral ptosis, miosis, tearing, and rhinorrhea. Bouts often occur for several weeks to months with 1–3 attacks in a 24-hour period. Patients will not infrequently be woken from sleep with an attack. Pain-free intervals of several months may occur between bouts of attacks. These headaches tend to respond to ergot preparations, prednisone, and methysergide.[64]

Pain arising from a group of disorders known as trigeminal autonomic cephalgias may also be confused with TN. These include cluster headaches, chronic paroxysmal hemicranias, and short-lasting unilateral neuralgiform headaches with conjunctival

injection and tearing (SUNCT). Knowledge of their epidemiology and a careful history will assist with accurate diagnosis.[65]

Chronic paroxysmal hemicrania usually occurs in women. It generally involves the ocular, frontal, and temporal areas. Occasionally, it may involve the occipital, infraorbital, aural, mastoid, and nuchal areas on the same side. Attacks vary in frequency in duration but may last 5–45 minutes. Pain is excruciating and is associated with ipsilateral conjunctival injection, lacrimation, nasal stuffiness, and rhinorrhea. These headaches respond well to indomethacin.[66]

SUNCT is a rare syndrome which typically affects males between age 23 and 77 years of age. It is characterized by unilateral burning, stabbing, or electric pain which is usually near the eye. Episodes generally last from 15 to 120 seconds and multiple episodes can occur daily. Patients present with cutaneously triggered attacks in up to 75% of cases. These attacks are differentiated from TN by lack of a refractory period and presence of associated conjunctival injection, tearing, rhinorrhea, and facial sweating or flushing. As in TN, primary and secondary forms occur. Secondary forms may be due to cerebellopontine angle arteriovenous malformation, infection, and pituitary tumors.[65,67,68]

Painful ophthalmoplegia such as seen in Tolosa-Hunt syndrome, ocular diabetic neuropathy, ophthalmic herpes zoster, and ophthalmoplegic migraine must also be differentiated from TN.

Tolosa-Hunt syndrome is a painful ophthalmoplegia caused by granulomatous inflammation in the cavernous sinus. It is characterized by episodic unilateral or bilateral orbital pain associated with paralysis of one or more of the third, fourth, or sixth cranial nerves. Involvement of the V2 and V3 divisions of the trigeminal nerve, the optic nerve, and the facial nerve has been reported. The pain is typically described as steady gnawing or boring. Spontaneous resolution may be followed by remissions and relapses of symptoms. Involvement of the optic, facial, acoustic, or trigeminal nerves has been reported. Treatment with corticosteroids results in resolution of pain and paresis in most cases within 72 hours. Failure of response to steroids or recurrence of symptoms should prompt further work-up.[2]

Ocular diabetic neuropathy may present as eye and forehead pain associated with ocular cranial nerve paresis (usually cranial nerve III). As in other diabetic neuropathies, pain improves with glucose control, treatment with tricyclics, and anticonvulsant medications.[2]

Herpes zoster (HZ) involving the trigeminal ganglion affects the ophthalmic division in the majority of cases. Ophthalmic herpes may be accompanied by palsies of the third, fourth, and/or sixth cranial nerves or with facial palsy. Burning pain, sometimes accompanied by neuralgic pain, is typically followed by vesicular eruption within 7 days. Pain may resolve or persist as postherpetic neuralgia.[2]

Ophthalmoplegic migraine is a rare clinical entity presenting as recurrent migraine like headaches accompanied by paresis of one or more of the ocular cranial nerves in the absence or other intracranial lesion. There may be a latent period of up to 4 days from onset of headache to onset of ocular cranial nerve paresis. Demonstration on MRI of thickening and enhancement of the cisternal part of the occulomotor nerve in these patients suggests the etiology of recurrent demyelinating neuropathy.[2]

Other common causes of facial pain include pain caused by sinusitis or other inflammatory conditions involving the eyes, tumors of the nose or sinuses, disorders of the teeth, jaws, or related structures such as temporomandibular joint (TMJ) pain and posttraumatic pain of the peripheral branches of the trigeminal nerve.

Sinusitis presents with pain involving the periocular, frontal, nasal, and maxillary areas. It is generally described as deep and constant and is associated with purulent discharge, fever, and fullness of the nose and ears. CT reveals opacification of the sinuses. In older patients or immunocompromised individuals, tumors or mycoses should be ruled out.[69]

Pain related to the teeth is often triggered by chewing or by hot, cold, sweet, and sour substances. It may have occasional sharp and shooting characteristics but usually will also have a diffuse, continuous aching, throbbing, or burning component which is difficult to localize. This type of pain is also differentiated from TN by lack of trigger zones or periods of spontaneous remissions. TMJ pain and myofascial pain related to the jaw is described as aching, burning, or cramping pain associated with use of the jaw or muscles of mastication. Clicking and other signs of joint dysfunction are associated features.[70,71] These topics are discussed in further detail in Chapter 67 on facial pain within this text.

Trauma to peripheral branches of the trigeminal nerve after surgery, blunt or penetrating trauma, or dental procedures generally presents as constant pain with burning, tingling, or stabbing components as well as a dull background pain. One study comparing patients with facial pain after nerve injury to patients with pain of spontaneous origin found decreased temperature and tactile thresholds and abnormal temporal summation of pain in patients with nerve injury but not in patients with spontaneous pain.[72]

Persistent idiopathic facial pain is typically described as a continuous, dull ache that is poorly localized. It fluctuates in intensity and is generally unresponsive to analgesics. It occurs most frequently in women with a mean age of 44.6 years and range of 17–87 years. Most of these patients have multiple diagnoses including depression, headache, neck and back pain, and irritable bowel disease. Neurologic and radiologic exams are normal by definition. These patients often have undergone multiple dental procedures.[73]

Treatment

Treatment—Medical Management

The use of the antiepileptic medications for the treatment of TN was first suggested by Bergougan in 1942.[74] His trial of phenytoin in these patients was based on Trousseau's theory that the paroxysmal pain of TN was similar to the paroxysmal brain activity occurring in patients with epilepsy.[75]

Medical therapy of TN is largely based on the efficacy of drugs that have undergone double-blind evaluation. This is particularly important in light of the need to obtain expedient relief of the excruciating pain of the paroxysms suffered by these patients with proven therapies. The occurrence of unpredictable periods of prolonged spontaneous remission in patients with TN creates a greater likelihood of attributing successful treatment of this disease to ineffective agents. Surgical consultation should be sought early for patients with structural lesions and in patients refractory to medical treatment. For patients unresponsive to medical therapy who are not surgical candidates due to coexisting medical conditions, treatment with radiation or percutaneous therapies, as described in the following paragraphs, may be effective.

Of the medications studied in the treatment of TN, carbamazepine is considered the drug of choice according to the European Federation of Neurological Societies and the Quality Standards Subcommittee of the American Academy of Neurology.[76] Current evidence suggests that oxcarbazepine should be the first line agent in patients with intolerable side effects or inadequate pain control with carbamazepine.[77] The combination of carbamazepine with baclofen or lamotrigine has been shown to be effective in cases where patients do not respond to carbamazepine alone or in whom it loses efficacy.[77]

Carbamazepine is a tricyclic antiepileptic that is metabolized at the same site targeted by the tricyclic antidepressant imipramine in the cytochrome P450 isoenzyme center. Carbamazepine slows the recovery rate of voltage-gated sodium channels, modulates activated calcium channel activity, and activates the de-

scending inhibitory modulation system. Although it is one of the oldest antiepileptic drugs and many new drugs in this class exist with fewer side effects and fewer drug-drug interactions, four placebo-controlled studies and a systematic review have established its effectiveness in reducing the intensity and frequency of attacks and the number of triggers with a combined number needed to treat of 1.7.[78–82]

Although carbamazepine has been shown to have an initial response rate of over 70% in TN patients, one long term study which evaluated its efficacy over a 16-year period reported that by 5–16 years only 22% of participants continued to have effective relief with 44% requiring additional or alternative treatment.[83] The recommended starting dose is 100 to 200 mg twice daily with gradual increase by 200 mg until pain relief or intolerable side effects occur. The typical maintenance dose of carbamazepine is 600 to 1200 mg daily in divided doses. Side effects occur in up to 40% of patients initially but generally subside in most patients after a few weeks. The biologic half-life of carbamazepine is 30–35 hours when first administered. This decreases to 12 hours with autoinduction of liver enzymes which occurs after a few weeks. Since pain relief appears to be closely related to serum level, slow-release formulations may be effective in maintaining serum drug concentration.[84]

The efficacy of carbamazepine is limited by side effects that include drowsiness, dizziness, constipation, nausea, and ataxia. More severe adverse effects include rashes, leucopenia, abnormal liver function, and rarely, aplastic anemia and hyponatremia due to inappropriate secretion of antidiuretic hormone. Compared with placebo, it has a number needed to harm of 3 for minor side effects and 24 for major side effects. Monitoring of complete blood count, liver function, and sodium is recommended.[85–87]

Oxcarbazepine is the 10-keto analogue of carbamazepine. A large double-blind, crossover trial comparing oxcarbazepine with carbamazepine and three multicenter, double-blind randomized trials comparing oxcarbazepine to carbamazepine revealed equal efficacy with fewer adverse effects. Tolerability was reported as ''good'' to ''excellent'' by 62% of patients receiving oxcarbazepine, compared with 48% of patients receiving carbamazepine.[86,88]

Lamotrigine also decreases repetitive firing of sodium channels by slowing the recovery rate of voltage-gated channels. In a small, double-blind, crossover, randomized controlled trial evaluating patients on carbamazepine or phenytoin who were refractory to treatment with these medications, lamotrigine (400 mg) versus placebo increased the number of patients who improved after 4 weeks of treatment.[89] A case series also suggests its efficacy as monotherapy for TN. Side effects include dizziness, constipation, nausea, and drowsiness. Stevens-Johnson's syndrome has been reported to occur in 1 in 10,000 patients taking lamotrigine. Its utility as a single agent may be limited by its long titration schedule.[90,91]

Phenytoin is one of our oldest anticonvulsants with a molecular structure similar to the barbiturates. It acts by blocking sodium channels in rapidly discharging neurons and by inhibiting presynaptic glutamate release. Although it is has been used longer than any other antiepileptic drug in the treatment of TN, there are no controlled trials supporting its efficacy. Uncontrolled observations report that it is effective in relieving symptoms in 23 of 30 patients when 3–5 mg/kg was given intravenously for acute therapy.[92–94] Phenytoin interacts with many drugs including digoxin and warfarin. Severe rashes can occur in 1 of 10 to 20 patients. There is also a possibility of hyperglycemia, hepatotoxicity, gingival hyperplasia, and megaloblastic anemia. Fosphenytoin, a prodrug of phenytoin that is better tolerated intravenously, also appears to be effective in acutely ill patients.[95]

Baclofen is an analog of the neurotransmitter gamma-aminobutyric acid. Its effectiveness in the treatment of TN may be due to depression of excitatory synaptic transmission in the spinal trigeminal nucleus.[96] In three small randomized controlled trials, baclofen was shown to be effective as both monotherapy and add-on therapy to carbamazepine in the treatment of patients with TN. The starting dose is 5 to 10 mg three times a day, with gradual titration to a maintenance dose of 50 to 60 mg per day. Sedation, dizziness, and dyspepsia can occur with treatment. The dose should be adjusted in patients with decreased renal function since baclofen is excreted primarily by the kidneys. Baclofen has central nervous system and cardiovascular depressant effects and thus careful titration should occur in patients on other sedating medications and on antihypertensive agents. Antidiabetic medications may need to be adjusted secondary to increases in blood glucose. Baclofen should be discontinued slowly since seizures and hallucinations have been reported with upon withdrawal.[97–99]

Other medications that have shown efficacy in recent trials include subcutaneous sumatriptan and intranasal lidocaine. Two randomized, placebo-controlled crossover studies with a total of 38 patients show significant relief of painful paroxysms of TN after subcutaneous sumatriptan but not placebo. Continuation of oral sumatriptan, 50 mg orally twice a day, resulted in continuous analgesia following the subcutaneous injection in one of the studies.[100,101] Intranasal 8% lidocaine spray was examined in 25 patients with V2 division TN in a randomized controlled trial crossover study resulting in moderate or better pain relief in 23 of 25 subjects receiving lidocaine spray and 1 subject receiving placebo. Relief lasted from 0.5–24 hours.[102]

Uncontrolled observations and case studies have shown efficacy in the treatment of TN with valproic acid, clonazepam, and pimozide.[103–106] The efficacy of pimozide is severely limited by its significant side effects which include parkinsonism, mental retardation, and memory impairment. The newer anticonvulsant drugs gabapentin and topiramate have been shown to be effective in the treatment of neuropathic pain; however, there are no controlled studies of their effectiveness in the treatment of TN. Small case series report their effectiveness in the treatment of symptomatic TN secondary to MS.[107–109] A small prospective randomized study and a case report demonstrated relief of TN symptoms with injection of botulinum toxin (16–100 units).[110,111] A six patient retrospective analysis and an eight patient prospective trial of intravenous lidocaine, in doses ranging from 2 to 5 mg/kg/hour, resulted in partial or complete relief of TN pain paroxysms provoked by vibratory symptoms.[112,113]

In summary, the current literature supports carbamazepine as first-line therapy for TN, although data also supports use of oxcarbazepine as first-line therapy, particularly in patients refractory to carbamazepine monotherapy or who have intolerable side effects. Those patients who do not respond to monotherapy may benefit from combination therapy with gabapentin, lamotrigine, topiramate, or baclofen. The newer anticonvulsant medication, pregabalin, has been shown to be effective in treating neuropathic pain; however, its use has not been reported in patients with TN. Intravenous phenytoin, fosphenytoin, or lidocaine, subcutaneous sumatriptan, or botulinum toxin injections may be effective in refractory cases of TN or for abortive treatment of severe, frequent acute attacks which may affect the patient's ability to eat or drink. Infusions should be conducted in a carefully monitored setting with appropriate medical attention and emergency equipment available. Due to reports of spontaneous intermittent or permanent remissions of TN, periodic withdrawal of medications is warranted in patients who have prolonged pain-free periods on oral medications.

Treatment—Nerve and Neurolytic Blockade

Local anesthetic injection or infusion has been used for diagnostic purposes and for temporizing treatment in patients with unbearable pain refractory to medical therapy and/or awaiting MVD.[114] No controlled studies of nerve blockade for relief of TN have been reported and controlled studies are needed to validate this

approach. Small case series include significant reduction of pain and triggers in 5 elderly patients for a median of 2 months subsequent to injection of the infraorbital nerve in patients with second division TN using a combination of 4% tetracaine dissolved in 0.5% bupivacaine. Another study looking at relief of pain following injection of the infraorbital nerve reported greater than 3 months of relief with 4% tetracaine and 0.5% bupivacaine (compared to 3 days or less with 0.5% bupivacaine or 1% mepivacaine alone).[115,116] A combination of ketamine, morphine, and bupivacaine produced similar pain relief and duration as reported following a series of injections of symptomatic peripheral trigeminal nerve branches in patients with TN.[117]

A case report of stimulator-guided mandibular and maxillary division nerve blockade using a combination of lidocaine, bupivacaine, clonidine, and fentanyl at monthly intervals for 1 year in 2 patients describes prolongation of relief after 3 months and pain-free status with no recurrence at 9 month follow-up. No sensory or motor disturbances were reported.[118] Peripheral injections are of value in elderly patients who have not responded to medical or other surgical therapies. Standard precautions to avoid intravascular injection of drugs should be taken and care should be taken when performing V2 and V3 blockade as total brainstem anesthesia with respiratory arrest following extraoral trigeminal V2–V3 blocks has been reported.[119]

Careful aspiration, fluoroscopic guidance when available, utilizing contrast (when no contraindication exists), and digital subtraction can decrease the risk of intravascular or intrathecal injection. As with intravenous infusions, injections should be performed in a monitored setting with appropriate medical attention and readily available emergency equipment.

Alcohol, phenol, or glycerol injection has long been reported in the treatment of TN. Percutaneous gangliolysis using glycerol is discussed under surgical techniques. A retrospective case audit of patients who received peripheral alcohol injections for TN from 1994–1999 found a mean duration of effect of 11 months.[120] Effectiveness of peripheral alcohol injections in TN is believed to be comparable to peripheral cryotherapy. Glycerol injections provided a mean of 7 months of pain relief.[121] A retrospective analysis of 157 cases of intractable idiopathic TN treated with peripheral glycerol injections reported an initial 98% success rate with 60 patients having recurrent pain between 25 and 36 months. The study reports complete or near complete pain relief in 154 patients at 4 years (with inclusion of patients with recurrent pain who were reinjected).[122] Postinjection facial swelling, discomfort, and numbness are reported complications of alcohol injections. More serious complications occurred in 3 of 413 injections over a 20-year period.[123] A small case series of 60 peripheral injections in 18 patients of the infraorbital, supraorbital, and mandibular nerves using 10% phenol in glycerol reported 87% initial marked or total pain relief and a median of 9 months of continued relief. Most patients with recurrent pain requested a repeated procedure rather than surgery or a ganglion nerve block. No serious complications or dysesthetic pain were reported. In patients with facial sensory loss, sensation was recovered within 6 months and was well tolerated.[124]

Treatment—Surgical

Surgical therapies are aimed at either damaging or destroying pain transmitting nerve fibers or relieving pressure on the nerve from vascular loops, fibrous bands, or mass lesions. Radiation therapy may relieve pain in patients who are not surgical candidates and who are refractory to medical management of TN.

Microvascular Decompression. MVD is performed under general anesthesia using a microscope to visualize the trigeminal nerve as it leaves the pons via a suboccipital craniectomy. Compression of the nerve by a vein or artery is relieved by repositioning the artery or coagulating the vein. Although MVD is invasive, it is associated with the best long-term outcome and overall mortality and complication rates are low. A recent analysis of long-term follow-up data of 1324 patients with TN who underwent MVD between 1976 and 2000 revealed an increase in the postoperative cure rate from 92.9% to 96.7% in patients operated on after 1986. Recurrence rate decreased from 10.2% to 6.5% in the patients operated on between 1986 and 2000 compared to the patients who underwent MVD between 1976 and 1986.[125] Barker[126] recently reported results of 1185 patients who underwent MVD over a 20-year period. It was noted that the rate of complications was significantly reduced and no deaths occurred after 1980 when intraoperative monitoring of brainstem evoked response was used. Female sex, symptoms lasting more than 8 years, venous compression of the terminal REZ, and the lack of immediate postoperative cessation of pain were significant predictors of eventual recurrence.[126] In a retrospective comparative analysis of 225 patients who underwent MVD and 206 having undergone percutaneous trigeminal radiofrequency rhizotomy, 64% of patients who underwent MVD remained completely pain free 20 years postoperatively versus 50% risk of recurrence of pain 2 years after radiofrequency rhizotomy.[127] Hospital and surgeon volume was found to be a significant factor affecting morbidity in a study conducted from 1996–2000 by Kalkanis and associates.[128] The overall mortality rate was 0.3% with volume and mortality not statistically related. The rate of discharge other than to home was 3.8%, with hospitals and/or surgeons who performed the surgeries at low volumes being 5.1% as compared to 1.6% for high volume.[128] Percutaneous rhizotomy or gangliolysis is useful in treating the elderly or debilitated patient who is refractory or intolerant to medical therapy and for whom surgery is not warranted due to risk factors. Gangliolysis is performed under fluoroscopic guidance by placing a needle percutaneously through the foramen oval and advancing it to the trigeminal cistern.

The three techniques currently used for gangliolysis include percutaneous radiofrequency ablation/thermocoagulation, trigeminal ganglion compression, and retrogasserian glycerol rhizolysis. Percutaneous radiofrequency trigeminal gangliolysis involves the use of radiofrequency to create anatomically distinct lesions in cycles of 45–90 seconds at 60° to 90° C. Percutaneous trigeminal ganglion compression is performed under general anesthesia utilizing a Fogarty catheter that is inserted via a 14-gauge catheter into the trigeminal cistern and inflated with radiocontrast to compress the gasserian ganglion. Careful observation of heart rate and blood pressure is required due to the possibility of severe bradycardia and hypotension which may require treatment with atropine and vasopressors. Percutaneous glycerol rhizolysis is performed in a sitting position. After confirmation of needle location with radiocontrast, 0.1 to 0.4 mL of anhydrous glycerol is injected into the cistern of Meckel's cave.

A recent systematic review of radiofrequency ablation/thermocoagulation techniques for the treatment of TN demonstrated complete pain relief without medication in a median of 88% in patients undergoing radiofrequency thermocoagulation at 6-month follow-up.[129] This dropped to 61% at the 3-year follow-up. Retrospective analysis of patients undergoing percutaneous glycerol rhizolysis showed complete pain relief in 84% of patients with or without medication at 6 months following treatment. This dropped to a median of 54% at 3-year follow-up. There is insufficient data to compare pain relief from percutaneous balloon compression of the gasserian ganglion with the other ablative techniques.[129]

Complications with any of the ablative techniques described above have been noted to include dysesthetic disturbances in 4% to 10% of patients treated. Up to 30% of patients treated with radiofrequency thermocoagulation experienced significant permanent sensory loss. Other complications included corneal numbness and keratitis, anesthesia dolorosa, transient masseter weakness, cranial nerve deficits, and vascular injuries. The com-

plication rate was highest in patients undergoing radiofrequency thermocoagulation though most complications were transient.[129]

Ablative procedures are less invasive than MVD and are generally associated with a high initial response rate. Recurrence is common, however, and the incidence of facial numbness is higher than with MVD. Patients who have a recurrence of TN after an ablative procedure can successfully undergo MVD.[126]

Peripheral Neurectomy. Surgical destruction of the peripheral branches of the trigeminal nerve is indicated for patients who have failed medical therapy, who have failed gangliolysis, or who have severe cardiopulmonary disease and are unable to tolerate a suboccipital craniectomy and MVD. Duration of good to excellent relief varies from less than 1 year to a range of 2–5 years in reported series. The median pain-free period among 88 patients in one series was 41 months with a mean of 52.5 months. A more recent analysis of 40 patients reported excellent to good results in all patients for a period of time ranging from 2–5 years.[130,131] The procedure can be repeated; however, the risk of neuroma as well as diminished success is increased. Dense numbness in the distribution of the eradicated nerve results following neurectomy.

Cryoablation of the peripheral branches of the trigeminal nerve can be performed using a 1.4 to 2 mm probe which incorporates a nerve stimulator to test both sensory and motor function as well as a thermistor to identify temperature at the tip of the probe. A 3.5 to 5.5 mm ice ball is produced which results in disruption of the nerve structure with wallerian degeneration while leaving the myelin sheath and endoneurium intact (axonotmesis).[132] The use of cryotherapy to successfully treat patients with TN has been reported by several authors to provide analgesia for periods ranging from 6–13 months. There was no permanent sensory loss although, in one review, up to one third of patients developed atypical facial pain following the procedure.[133–135]

Stereotactic Radiosurgery. The first radiosurgical device was developed in the 1950s by Professor Lars Leksell at the Karolinska Institute in Stockholm. This work resulted in the development of the gamma knife which is able to precisely irradiate small intracranial targets with gamma ray photons. The patient's head is immobilized by the use of an external metal frame which is attached to the skull by four screws. A large helmet with 201 fixed ports allows radiation from radioactive cobalt-60 sources to converge on the intracranial target. The goal of radiosurgical treatment for TN is the delivery of energy to the proximal trigeminal root with minimal injury to surrounding structures.[136,137] Improved targeting with MRI has resulted in pain-free results in 21.8% to 75% of patients and pain improvement in 65% to 88%. Gamma knife surgery (GKS) produces lesions aimed at target area with the use of a stereotactic frame.[138] Data on radiosurgery for TN is predominantly observational and of generally poor quality.[139–141]

In a recent outcome study reviewing 151 patients treated with GKS, patient age, right-sided pain, and previous neurectomy correlated with pain-free outcome. One study found that treatment response did not correlate with the dose of radiation.[142] Treatment response correlated with vascular compression of the trigeminal nerve, as visualized on high resolution MRI, in some[143] but not all[142,144] reports. Pain relief with GKS occurs after a lag time of about 1 month.[145,146] A systematic review of these data found that approximately 75% of patients report complete relief within 3 months, and 50% of patients can permanently stop drug therapy after surgery. Sensory disturbances (e.g., numbness, paresthesias, and dysesthesias) are the most frequent complications.[146] Although radiosurgery is less effective than MVD, it is an effective, minimally invasive treatment option for patient's refractory to medical therapy who are not surgical candidates or who wish to forego the risks of surgery. Patients who fail to respond to radiosurgery or who have recurrence of symptoms may respond to repeat treatment.[147,148]

Linear accelerator radiosurgery is an alternative to the gamma knife developed in the mid 1980s. Unlike the radioactive cobalt-based gamma knife, linear systems use x-ray beams generated from a linear accelerator. This system also uses a metal head frame which is attached to the patient's skull. Recent developments include intensity modulated radiation therapy, which employs computer-controlled "beam-shaping" to more precisely conform the beam to the shape of the target.[149] A case series of 22 patients who had failed medical therapy and either declined or were unsuitable to undergo a surgical procedure found that radiosurgery by this technique was safe and effective.[150]

CyberKnife radiosurgery is a more recently developed system to incorporate a miniature linear accelerator mounted on a flexible, robotic arm. This system offers targeting accuracy without the need for the invasive head frame and is able to treat tumors anywhere in the body. While GKS has the advantage of over 30 years of clinical use, recent observational studies using the CyberKnife system for the treatment of CTN report a 92.7% initial success for pain relief at a median latency to pain relief of 7 days. Long-term response rate at 11 months was 78%.[151] Larger study groups and longer follow-up is needed to further evaluate long-term pain relief and complications.

SYMPTOMATIC TRIGEMINAL NEURALGIA

STN is differentiated from CTN through demonstration by special studies of a causative lesion other than vascular compression. Sensory impairment and bilaterality may be present as well as lack of a refractory period after a paroxysm.[2] MS and benign or malignant neoplasms are the most common cause of STN, although fungal infection and bacterial sinusitis with intracranial extension, scrub typhus, hardened felt from previous microvascular decompression surgery, and TN as the first manifestation of mixed connective tissue disorder have also been reported.[151–156]

Multiple Sclerosis

MS is an inflammatory autoimmune systemic disease which is characterized by demyelinating lesions and plaques within the central nervous system. Widespread neuronal loss with periods of remyelination may be associated with periods of remission.

MS affects women more than men with a cumulative ratio of females to males of 1.77 to 1.0. Median and mean age of onset of MS is 23.5 and 30 years of age, respectively.[157] TN occurs in up to 2% of patients with MS although this represents only about 0.5% of patients presenting with TN.[158,159] These patients can present with symptoms which mimic CTN but often present with bilateral symptoms and persistent background facial pain.[159]

The pathophysiology of TN in MS continues to be debated. Although demyelinating lesions affecting the trigeminal REZ have been found on autopsy and on MRI, 24 MS patients out of a series of 851 studied at one institution were found to have entry zone lesions which were clinically silent.[160,161]

Although MVD was once thought to be contraindicated in MS patients with STN, a recent report of MVD performed in 35 MS patients with severe neurovascular compression at the REZ resulted in a 39% excellent and 22% fair to good long-term pain relief. Seventy-four percent of these patients had demyelinating lesions affecting the brainstem trigeminal pathway on the painful side in addition to neurovascular compression.[162] In a series of five patients with STN and MS who were refractory to medical treatment and had undergone multiple unsuccessful percutaneous procedures, those patients undergoing MVD combined with par-

tial sectioning of the nerve did better than those undergoing MVD alone.[163]

In general, patients with STN secondary to MS respond less favorably to medical and interventional therapies and may require significantly more treatment than their cohorts with CTN.[164]

Neoplasm

The presentation of CTN does not rule out the presence of a tumor. Some authors advocate advanced imaging of all patients presenting with CTN due to delayed neurologic symptoms in patients with space-occupying lesions.[155] Among 2972 patients diagnosed with TN at the Mayo Clinic between 1976–1990, tumors were the cause of facial pain in 296 patients. Sex and pain distributions paralleled those in CTN; however, patients presenting with tumors were younger than those with CTN. Delay in tumor diagnosis averaged 6.3 years. The development of neurologic deficits prompted further imaging and diagnosis of tumor in 47% of these patients. These patients were often successfully treated medically for many years prior to onset of neurologic symptoms.[165,166]

Meningioma and epidermoid and acoustic neuroma are the most frequent posterior fossa tumors associated with STN. In a review of 161 and 80 consecutive posterior fossa tumors from 1993–1999 and 1979–2003 at separate institutions, cranial nerve dysfunction was the most common neurologic sign on admission. Intracranial hypertension and disturbance of gait also presented in up to 44% of these patients.[167,168] Twenty cases of TN caused by contralateral tumors of the posterior fossa have been reported. Only 4 of these cases symptomatically conformed to CTN. The mechanism of contralateral tumor causing TN is thought to be distortion and displacement of the brain stem and compression of the contralateral Meckel's cave.[169,170]

Pain in all three divisions of the trigeminal nerve is the first symptom of a tumor in Meckel's cave in over 65% of cases. The most common cavernous sinus tumors are trigeminal schwannomas and meningiomas. Tumors in this location make up only 0.5% of all intracranial tumors.[171] Case reports of metastatic disease to Meckel's cave presenting as TN include colorectal cancer, esophageal cancer, breast cancer, renal cell carcinoma, and lymphoma.[171–175] Primary melanoma, adenocarcinoma, and lymphoma involving Meckel's cave and associated with TN have also been reported.[176–179] TN with subacute onset of numbness in one or more divisions of the trigeminal nerve is thought to be associated with rapidly expanding tumor in this region.[175]

Other reported causes of symptomatic TN include platybasia (a skull base deformity),[180] sarcoid granuloma of the trigeminal nerve, and infarction of the REZ of the trigeminal nerve in the pons.[181–182] TN has also been seen in adults and children as the only manifestation of Chiari type I malformations.[183–185] Patients with hydrocephalus from remote causes such as a lumbar myxopapillary ependymoma and a quadrigeminal arachnoid cyst have also presented with TN.[186,187] Shunting and relief of hydrocephalus resulted in resolution of symptoms in these cases.

Five to 10% of TN has been reported to be STN secondary to brain tumors.[188] Although persistent pain, numbness, palsies, and gait disturbances along with other neurologic signs often differentiate these patients from those with CTN, delay in the presentation of neurologic deficits is not infrequent. Expedient work-up including advanced imaging is indicated in cases of TN with new onset of neurologic signs such as numbness or palsies.

Herpes Zoster and Postherpetic Neuralgia

Etiology

Acute HZ results from the reactivation of the varicella zoster virus which is referred to as "chicken-pox" in children or "shingles" in adults. The virus remains dormant in the dorsal root ganglia of cranial or spinal nerves after resolution of the original infection. As cellular immunity wanes with disease, chemotherapy, or age, the virus is reactivated and is transported along peripheral nerves producing an acute neuritis. Viral replication results in direct nerve sheath and neuronal injury. Destruction of tissue and inflammation result in excitation of nociceptors and dorsal horn sensitization. The dorsal horns of patients who do not develop postherpetic neuralgia show less tissue damage and more rapid resolution of inflammatory changes.[189]

Epidemiology

The rate of HZ and the rate of HZ-associated complications increase with age, with 68% of cases occurring in those aged 50 years and older. Postherpetic neuralgia occurs in 18% of adult patients with HZ and in 33% of those aged 79 years and older.[190]

In HZ involving the trigeminal nerve, neuronal spread of the virus occurs along the ophthalmic (first) and less frequently the maxillary (second) division of the fifth cranial nerve. Vesicular eruptions usually occur at the terminal points of sensory innervation, causing extreme pain. HZ involving the ophthalmic ganglion of the trigeminal nerve, or zoster ophthalmicus, accounts for as many as 10% to 25% of HZ cases. Nasociliary involvement will most likely cause ocular inflammation. Inflammation of the eye can lead to impairment of vision and in some cases temporary blindness. Such cases are considered emergent and prompt treatment is required to prevent chronic inflammation or long-term vision loss.

Contiguous spread of the virus may lead to the involvement of other cranial nerves, resulting in optic neuropathy (cranial nerve II) or isolated cranial nerve palsies (cranial nerve III, IV, or VI).

Symptoms and Signs

Acute HZ typically presents with a prodrome consisting of hyperesthesia, paresthesias, burning dysesthesias, or pruritus along the affected dermatome(s). This prodrome is usually accompanied by fever and general malaise. It generally lasts 1 to 2 days but may precede the appearance of skin lesions by up to 3 weeks. Manifestation of prodromal symptoms without development of the characteristic rash may occur in some patients. This presentation is known as "zoster sine herpete," and may delay correct diagnosis and treatment.

Following the prodromal period, a vesicular skin rash appears along the affected nerve. Involvement of the trigeminal nerves characteristically respects the vertical midline. The vesicles will discharge fluid and begin to scab over after about 1 week. The pain is extreme during the inflammatory stage. Vesicles at the tip of the nose are known as Hutchinson's Sign and signal a 75% likelihood of ocular sequelae which may include follicular conjunctivitis, epithelial and/or interstitial keratitis, dendritic keratitis, uveitis, scleritis chorioretinitis, optic neuropathy, and palsies of the third, fourth, or sixth cranial nerves.

Pain that persists beyond healing of the rash but which resolves within 4 months of onset is referred to as subacute herpetic neuralgia. Postherpetic neuralgia refers to pain persisting longer than 4 months from initial onset of rash.[191] Affected patients usually report constant, severe, burning, lancinating pain in the distribution of the affected nerve(s). Patients may also complain of pain in response to nonnoxious stimuli (allodynia). Even the slightest pressure from clothing, bed sheets, or a slight breeze may elicit severe pain.

Diagnosis

The diagnosis of acute HZ is essentially clinical, based on the characteristic unilateral appearance of a vesicular rash limited to the distribution of a specific nerve or nerve root. As discussed in

the section on signs and symptoms above, this is preceded most commonly by a painful prodrome characterized by burning dysesthesias or paresthesias along the affected dermatome. The criterion standard of laboratory diagnosis is polymerase chain reaction testing together with direct identification of varicella zoster virus in culture. Immunocompromised patients may benefit from IgG- and IgA-anti varicella zoster virus antibodies.[192,193]

Treatment

The goals of treatment of acute HZ include treatment of the acute viral infection, treatment of the severe acute pain associated with HZ infection, and prevention of postherpetic neuralgia.

Acute HZ infection should be treated with antiviral medication within 72 hours of vesicular eruption to reduce the duration and severity of pain associated with the infection. The use of antivirals may produce a moderate reduction in the risk of development of postherpetic neuralgia. Oral steroids may also be beneficial in reducing the severe pain of acute HZ.[194]

Acute treatment of acute HZ with neuropathic analgesics (i.e., anticonvulsants or tricyclic antidepressants) starting within 48 hours of onset of rash may also reduce acute pain and incidence of postherpetic neuralgia.[195–198] Patients with ocular involvement should have immediate evaluation and treatment of ophthalmic complications by a specialist.

The varicella zoster vaccine approved in May 2006 by the U.S. Food and Drug Administration was found to reduce the incidence of shingles by 51% in a randomized double-blind study. Pain was reduced by 61% in those who received the vaccine but still developed the infection, and postherpetic neuralgia was reduced by two thirds compared with placebo.[199]

Nutritional counseling may also be indicated in populations at risk for HZ. In a review of 243 HZ cases, it was determined that individuals, particularly those over age 60, who ate less than one serving of fruit or vegetables weekly had a three-fold greater risk of HZ compared to those who ate more than three servings daily independent of vitamin supplement intake.[200] An association between deficiency of vitamin A (a key immune modulator involved in the synthesis of lymphocytes, neutrophils, cytokines, and immunoglobulins) and increased risk of HZ has also been observed.[201]

Systematic reviews of the literature have concluded that pharmacologic therapies shown to be more effective than placebo for postherpetic neuralgia include tricyclic antidepressants, opioids, gabapentin, pregabalin, tramadol, capsaicin, and lidocaine 5% patch. Intrathecal methylprednisolone was shown to be of benefit in patients refractory to pharmacologic therapies.[202,203] Safety and tolerability should be considered when selecting pharmacologic treatments. Older patients may have more intolerable side effects at standard doses and thus may require smaller doses and more gradual titration. They may also be on multiple medications for coexisting medical conditions with potential for drug-drug reactions.

Sympathetic blockade, including stellate ganglion block, has commonly been used to provide pain relief of variable duration in both acute HZ and in postherpetic neuralgia. Although a recent review of sympathetic blocks in the treatment of acute HZ and postherpetic neuralgia found the evidence to be inconclusive due to lack of properly controlled studies, it found available data to suggest that sympathetic blocks may provide considerable pain relief during acute HZ but appear to provide only short-term relief in postherpetic neuralgia.[204]

NERVUS INTERMEDIUS NEURALGIA

Nervus intermedius neuralgia is an uncommon disorder affecting the sensory branch of the facial nerve (cranial nerve VII) (Fig. 66.3). It is located between the motor component of the facial nerve and the vestibulocochlear nerve (cranial nerve VIII). Sensory fibers contained in the nervus intermedius nerve carry afferent sensory input from the skin of the external auditory meatus, mucous membranes of the nasopharynx and nose, and taste from the anterior two-thirds of the tongue, floor of the mouth, and the palate. The geniculate ganglion contains the cell bodies of the sensory fibers of the nervus intermedius. Compression of the geniculate ganglion therefore can also result in nervus intermedius neuralgia.

The cell bodies of parasympathetic axons within the nervus intermedius are contained within the superior salivatory nucleus. These axons synapse with neurons which supply parasympathetic innervations to the lachrymal gland as well as the submandibular and sublingual glands.

Nervus intermedius neuralgia involves severe pain deep in the ear which may radiate to the outer ear, mastoid, or eye region. The syndrome was reported as "Tic Douloureux of the sensory filaments of the facial nerve" by Clark and Taylor in 1909.[205] Rare cases continue to be reported.

Etiology

Vascular compression is suggested as the cause of many cases of nervus intermedius neuralgia. Jannetta described relief of nervus intermedius and other cranial neuralgias following MVD in 1976.[206] He more recently reviewed 14 cases of nervus intermedius neuralgia, which, after failed conservative treatment, went on to MVD. Over 71% experienced an excellent outcome, over 21% experienced partial relief, and 7% had no relief following MVD. Good long-term results were seen in 90% of patients.

In a 1991 review of 18 cases of "primary otalgia" seen over a 15-year period, vascular loops, adhesions, thickened arachnoid, and benign osteoma were among abnormalities involving the nervus intermedius. The authors reported decompression of cranial nerves V, IX, X, the tympanic nerve, and the chorda tympani in addition to the nervus intermedius in many of these cases.[207,208] Nonetheless, the existence of nervus intermedius as a unique entity has been questioned due to the similarity of its presentation to that of glossopharyngeal neuralgia.

Symptoms and Signs

The pain of nervus intermedius neuralgia is sharp, lancinating, and paroxysmal. Painful attacks are unilateral and can be triggered by cold, noise, swallowing, or touch. Patients may also experience symptoms such as increased salivation, bitter taste, tinnitus, and vertigo during paroxysms. Patients with nervus intermedius neuralgia may also rarely have pain in the trigeminal distribution. This may be due to cross compression of cranial nerve V in addition to the nervus intermedius (as has been seen on surgical exploration).[209]

Diagnosis

Sensation is supplied to the area of the ear by the cranial nerves V, VII, VIII, IX, and X and the second and third cervical nerves. A thorough history should be taken to ascertain the exact distribution and character of the pain as well as any triggers or precipitating factors. A comprehensive examination should rule out other causes of otalgia before the diagnosis of geniculate ganglion neuralgia can be made. This should include examinations of the nose, paranasal sinuses, mouth, teeth, nasopharynx, pharynx, and larynx to rule out other causes of pain, audiogram, auditory evoked response potentials, and vestibular tests. MRI with gadolinium enhancement of the brain, cerebellopontine angle, and

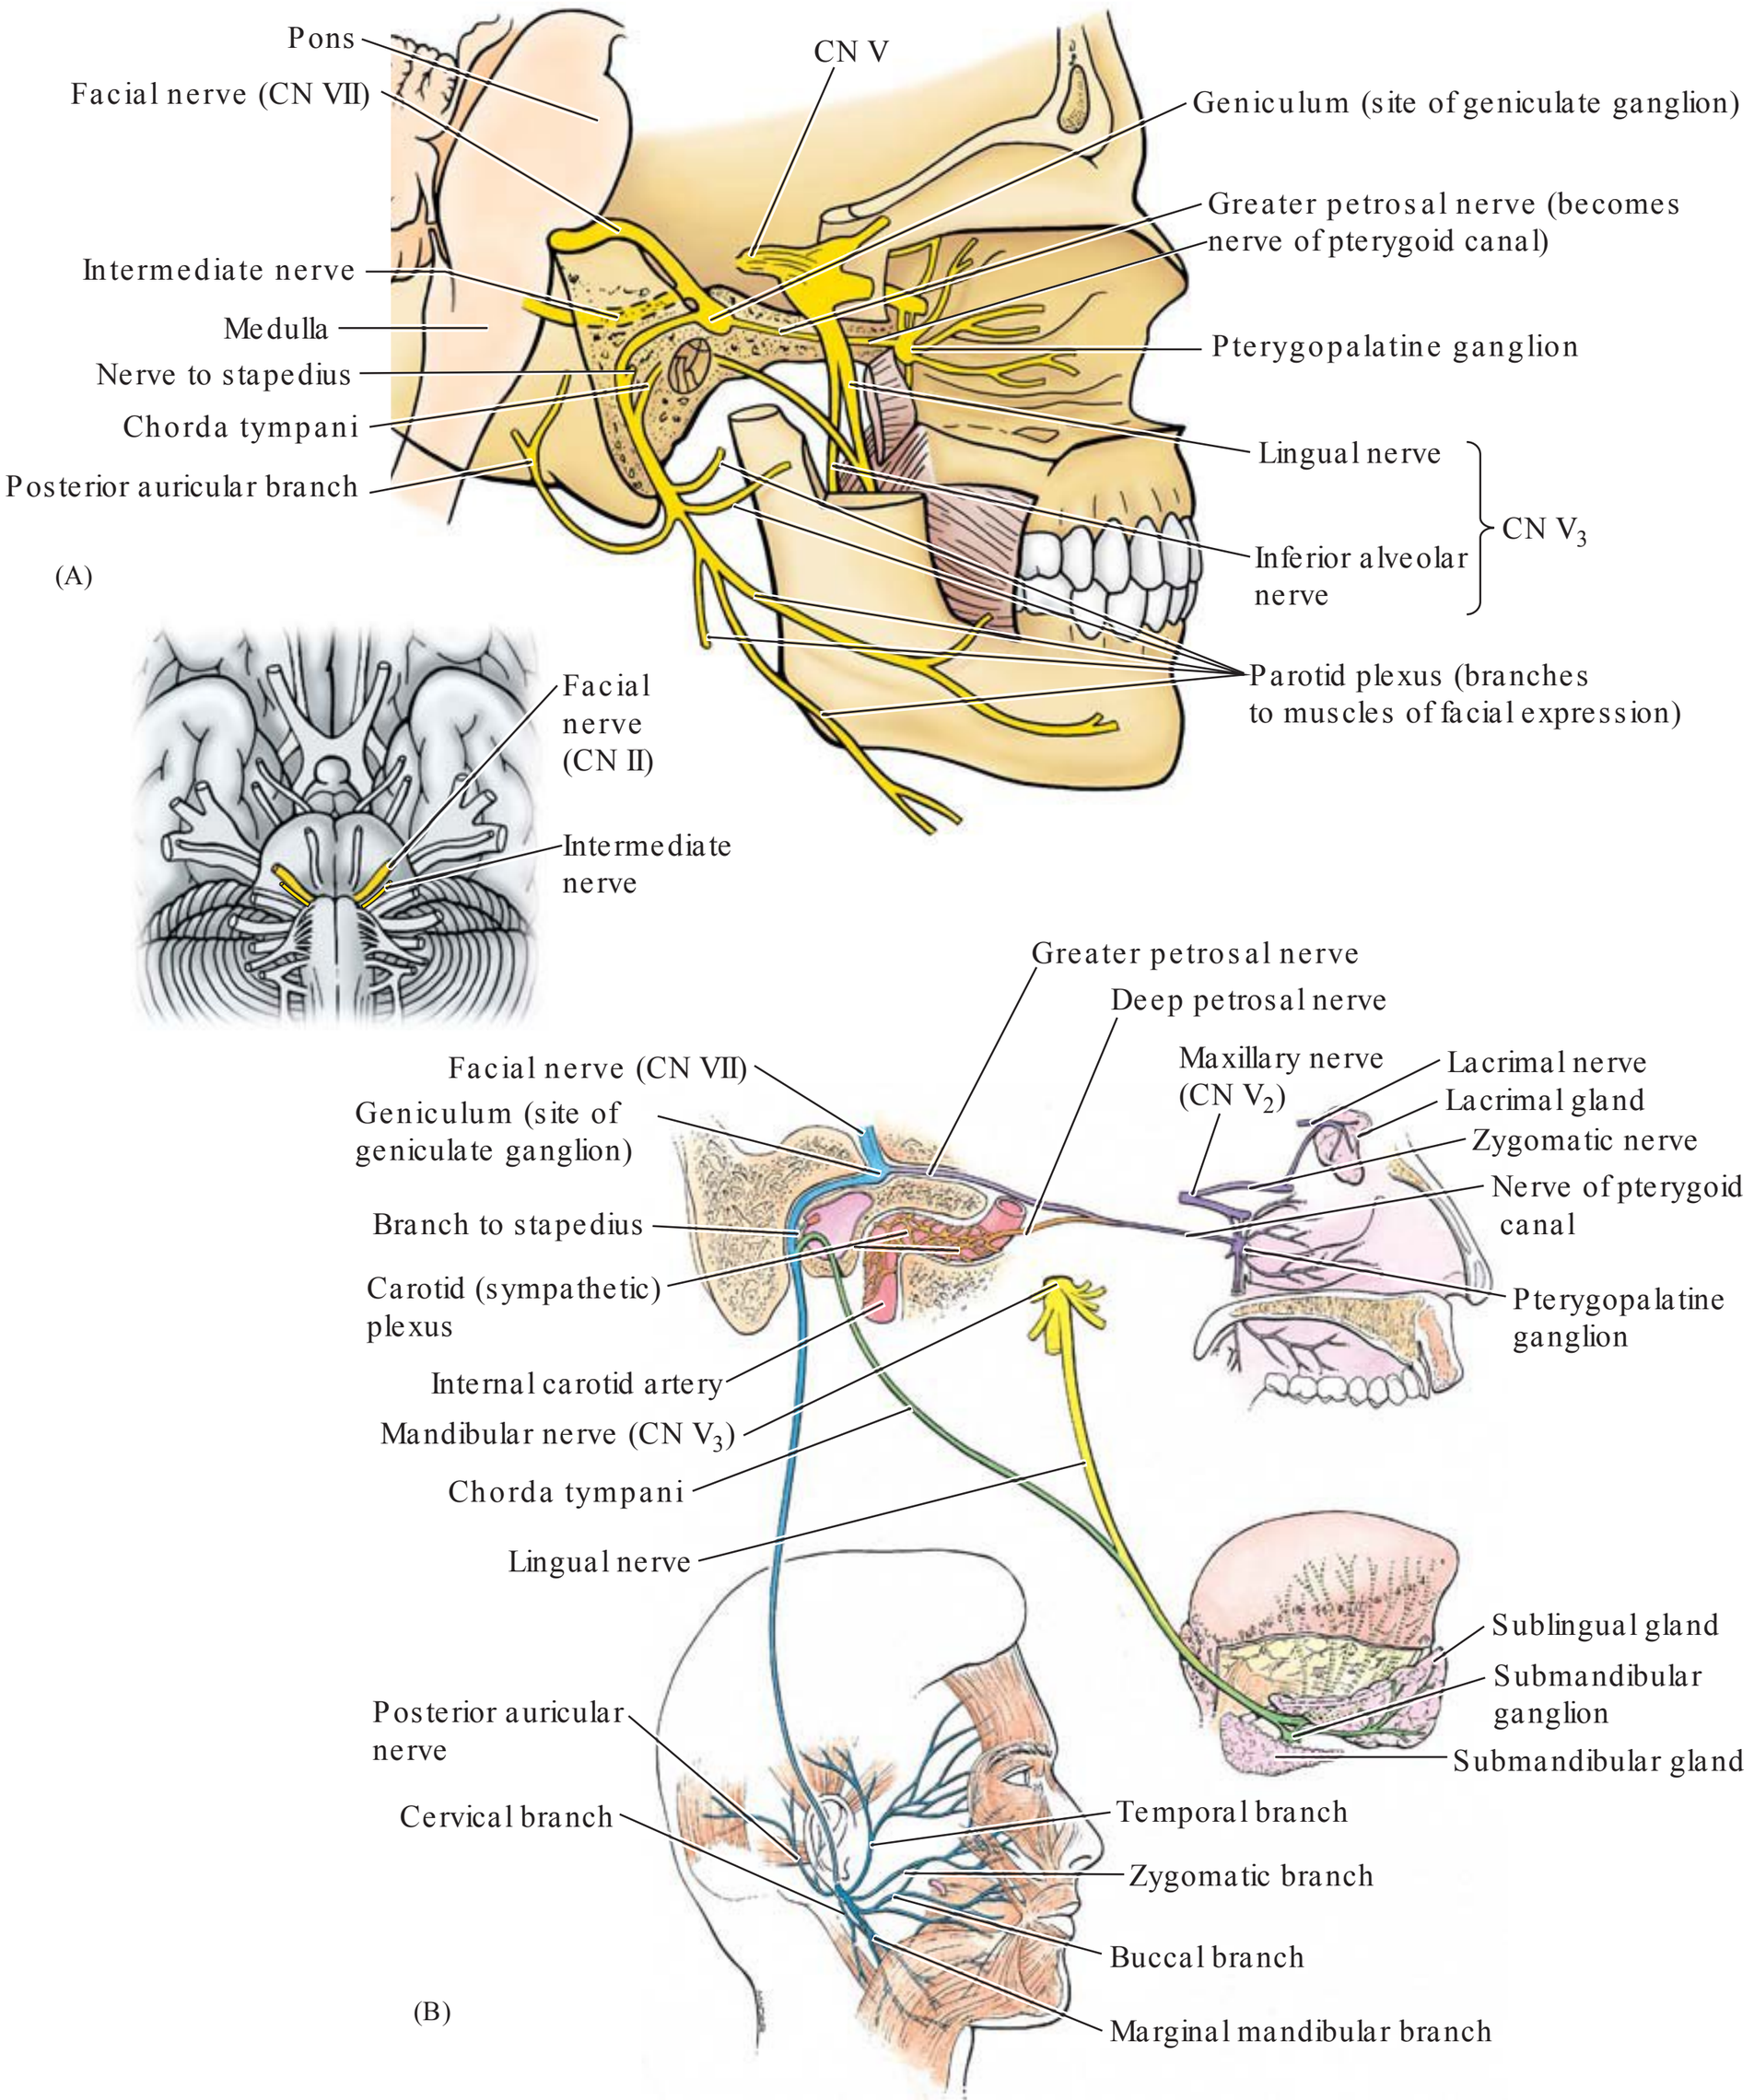

FIGURE 66.3 A, B. Distribution of the facial nerve (cranial nerve VII). The facial nerve emanates from the brainstem between the pons and the medulla. The motor part of the facial nerve arises from the facial nerve nucleus in the pons and divides into five branches after coursing through the petrous temporal bone, the internal auditory meatus, the facial canal, the stylomastoid foramen, and the parotid gland. It is responsible for muscles of facial expression and supplies preganglionic parasympathetic fibers to ganglia of the head and neck. It also supplies taste sensation to the anterior two thirds of the tongue, partial afferent innervations of the oropharynx, as well as a some cutaneous sensation around the auricle. (From Moore KL, Dalley AF. *Clinically Oriented Anatomy*. 5th ed. Baltimore: Lippincott Williams & Wilkins; 2006.)

facial nerve and MRA should be performed. As described above, vascular compression or other pathology may involve more than one of the cranial nerves in the middle fossa.

As described in the previous section, nervus intermedius neuralgia can be caused by HZ infection. The pain from acute HZ involving the geniculate ganglion is usually constant and burning as opposed to the lancinating paroxysmal pain of nervus intermedius neuralgia. Onset of the pain from acute HZ is generally followed by a vesicular eruption involving the ear drum and external auditory canal.

Treatment

Pharmacologic treatment of nervus intermedius neuralgia is similar to that of TN. When conservative management fails, a thorough work-up to exclude other causes of pain should be investigated. The nervus intermedius or geniculate ganglion cannot be injected with local anesthetic or other solution; however, blockade of other nerves supplying the area of the ear can be anesthetized to exclude them as causes of the otalgia. Surgical management consists of MVD or section of the nervus intermedius. Excision of the nervus intermedius and geniculate ganglion has also been advocated along with selective retrolabyrinthine V nerve section in extreme cases.[208]

GLOSSOPHARYNGEAL NEURALGIA

Glossopharyngeal neuralgia is a rare neuralgia with a reported relative frequency of 0.75% to 1% compared to TN.[210,211] It is defined as paroxysmal pain in the areas supplied by cranial nerves IX and X. The glossopharyngeal or ninth cranial nerve exits the upper medulla just rostral to the vagus nerve. Sensory fibers carried in the glossopharyngeal nerve supply the posterior one third of the tongue, the tonsils, pharynx, the middle ear, and the carotid body. The glossopharyngeal nerve also supplies parasympathetic fibers to the parotid gland via the otic ganglion, motor fibers to the stylopharyngeus muscle, and contributes to the pharyngeal plexus. The symptoms associated with glossopharyngeal neuralgia can be better understood upon review of its branches, which include the tympanic nerve, stylopharyngeal nerve, tonsillar nerve, nerve to the carotid sinus, branches to the posterior third of the tongue, lingual branches, and a communicating branch to the vagus nerve (Fig. 66.4).

Etiology

Classical or idiopathic and secondary or symptomatic forms of glossopharyngeal neuralgia exist similar to TN. Symptomatic causes include tumors, peritonsillar abscess, carotid aneurysm, Chiari type I malformations, and Eagle syndrome (in which cranial nerve IX is compressed against an ossified stylohyoid ligament).[212–214] Idiopathic glossopharyngeal neuralgia occurs most commonly from vascular compression of cranial nerve IX (often in association with cranial nerve X) at the nerve REZ. The vertebral artery or posterior inferior cerebellar arteries are most often implicated on surgical exploration.

Symptoms and Signs

The character of pain in the patient with glossopharyngeal neuralgia is similar to that of TN. The unbearable, electrical, lancinating pain is located unilaterally in the ear, larynx, tonsillar fossa, or base of the tongue. It is rarely bilateral. It may radiate toward the ear, the angle of the jaw, or the upper and lateral aspect of the neck. Paroxysms of pain are often triggered by swallowing, yawning, coughing, or talking.

Diagnosis

A careful history and physical exam is essential in the evaluation of a patient suspected of suffering from glossopharyngeal neuralgia. MRI/MRA should be performed to rule out a mass lesion or vascular pathology. An ossified stylohyoid ligament (consistent with Eagle syndrome) may be identified on roentgenogram. As in TN, the paroxysms of glossopharyngeal neuralgia may last from seconds to minutes. Dozens of attacks may occur daily with episodes lasting from weeks to months followed by periods of remission. The patient is generally free from pain between attacks although dull background pain may persist. Investigation should also exclude MS in younger patients with bilateral symptoms or neurologic deficits. The branch of the glossopharyngeal nerve to the carotid sinus is involved in maintenance of blood pressure and is thought to play a role in some profound cardiac arrhythmias or even asystole which occur in some patients in association with pain paroxysms. The differential diagnosis includes geniculate or nervus intermedius neuralgia. Rare glossopharyngeal zoster has been reported.[215]

Treatment

The pharmacologic treatment of glossopharyngeal neuralgia is similar to TN. When conservative therapy has failed, surgical exploration and vascular decompression has been shown to be highly effective on long-term follow-up with a low complication rate.[216,217] When a source of neurovascular compression is not found, successful relief of symptoms has been obtained with section of the glossopharyngeal nerve together with the upper fibers of the vagus nerve.[218,219]

VAGAL NEURALGIA

The two sensory branches of the vagus nerve, the auricular branch and the superior laryngeal nerve, are involved in this rare neuralgia (Fig. 66.5). The auricular branch of the vagus nerve, or Alderman's nerve, divides into two branches: the posterior auricular nerve and the nerve supplying the auricula and posterior part of the external acoustic meatus. The superior laryngeal nerve descends behind the internal carotid artery and divides into the internal and external laryngeal nerves. The internal laryngeal nerve supplies sensation to the base of the tongue, epiglottis, and the larynx to above the vocal cords. The external laryngeal nerve supplies the cricothyroid muscle, the inferior pharyngeal constrictor, and communicates with the superior cardiac nerve behind the common carotid artery.

Etiology

Idiopathic or classic vagal neuralgia is characterized by lack of a known precipitating lesion or by vascular compression of the upper fibers of the vagal nerve as they leave the brainstem. Secondary or symptomatic vagal neuralgia involving the superior laryngeal branch has been reported to be secondary to multiple causes including deviation of the hyoid bone, lateral pharyngeal diverticulum, and as a complication following carotid endarterectomy.[220–222]

Symptoms and Signs

Vagal neuralgia is characterized by severe pain paroxysms in the submandibular region, throat, and/or under the ear. Attacks are

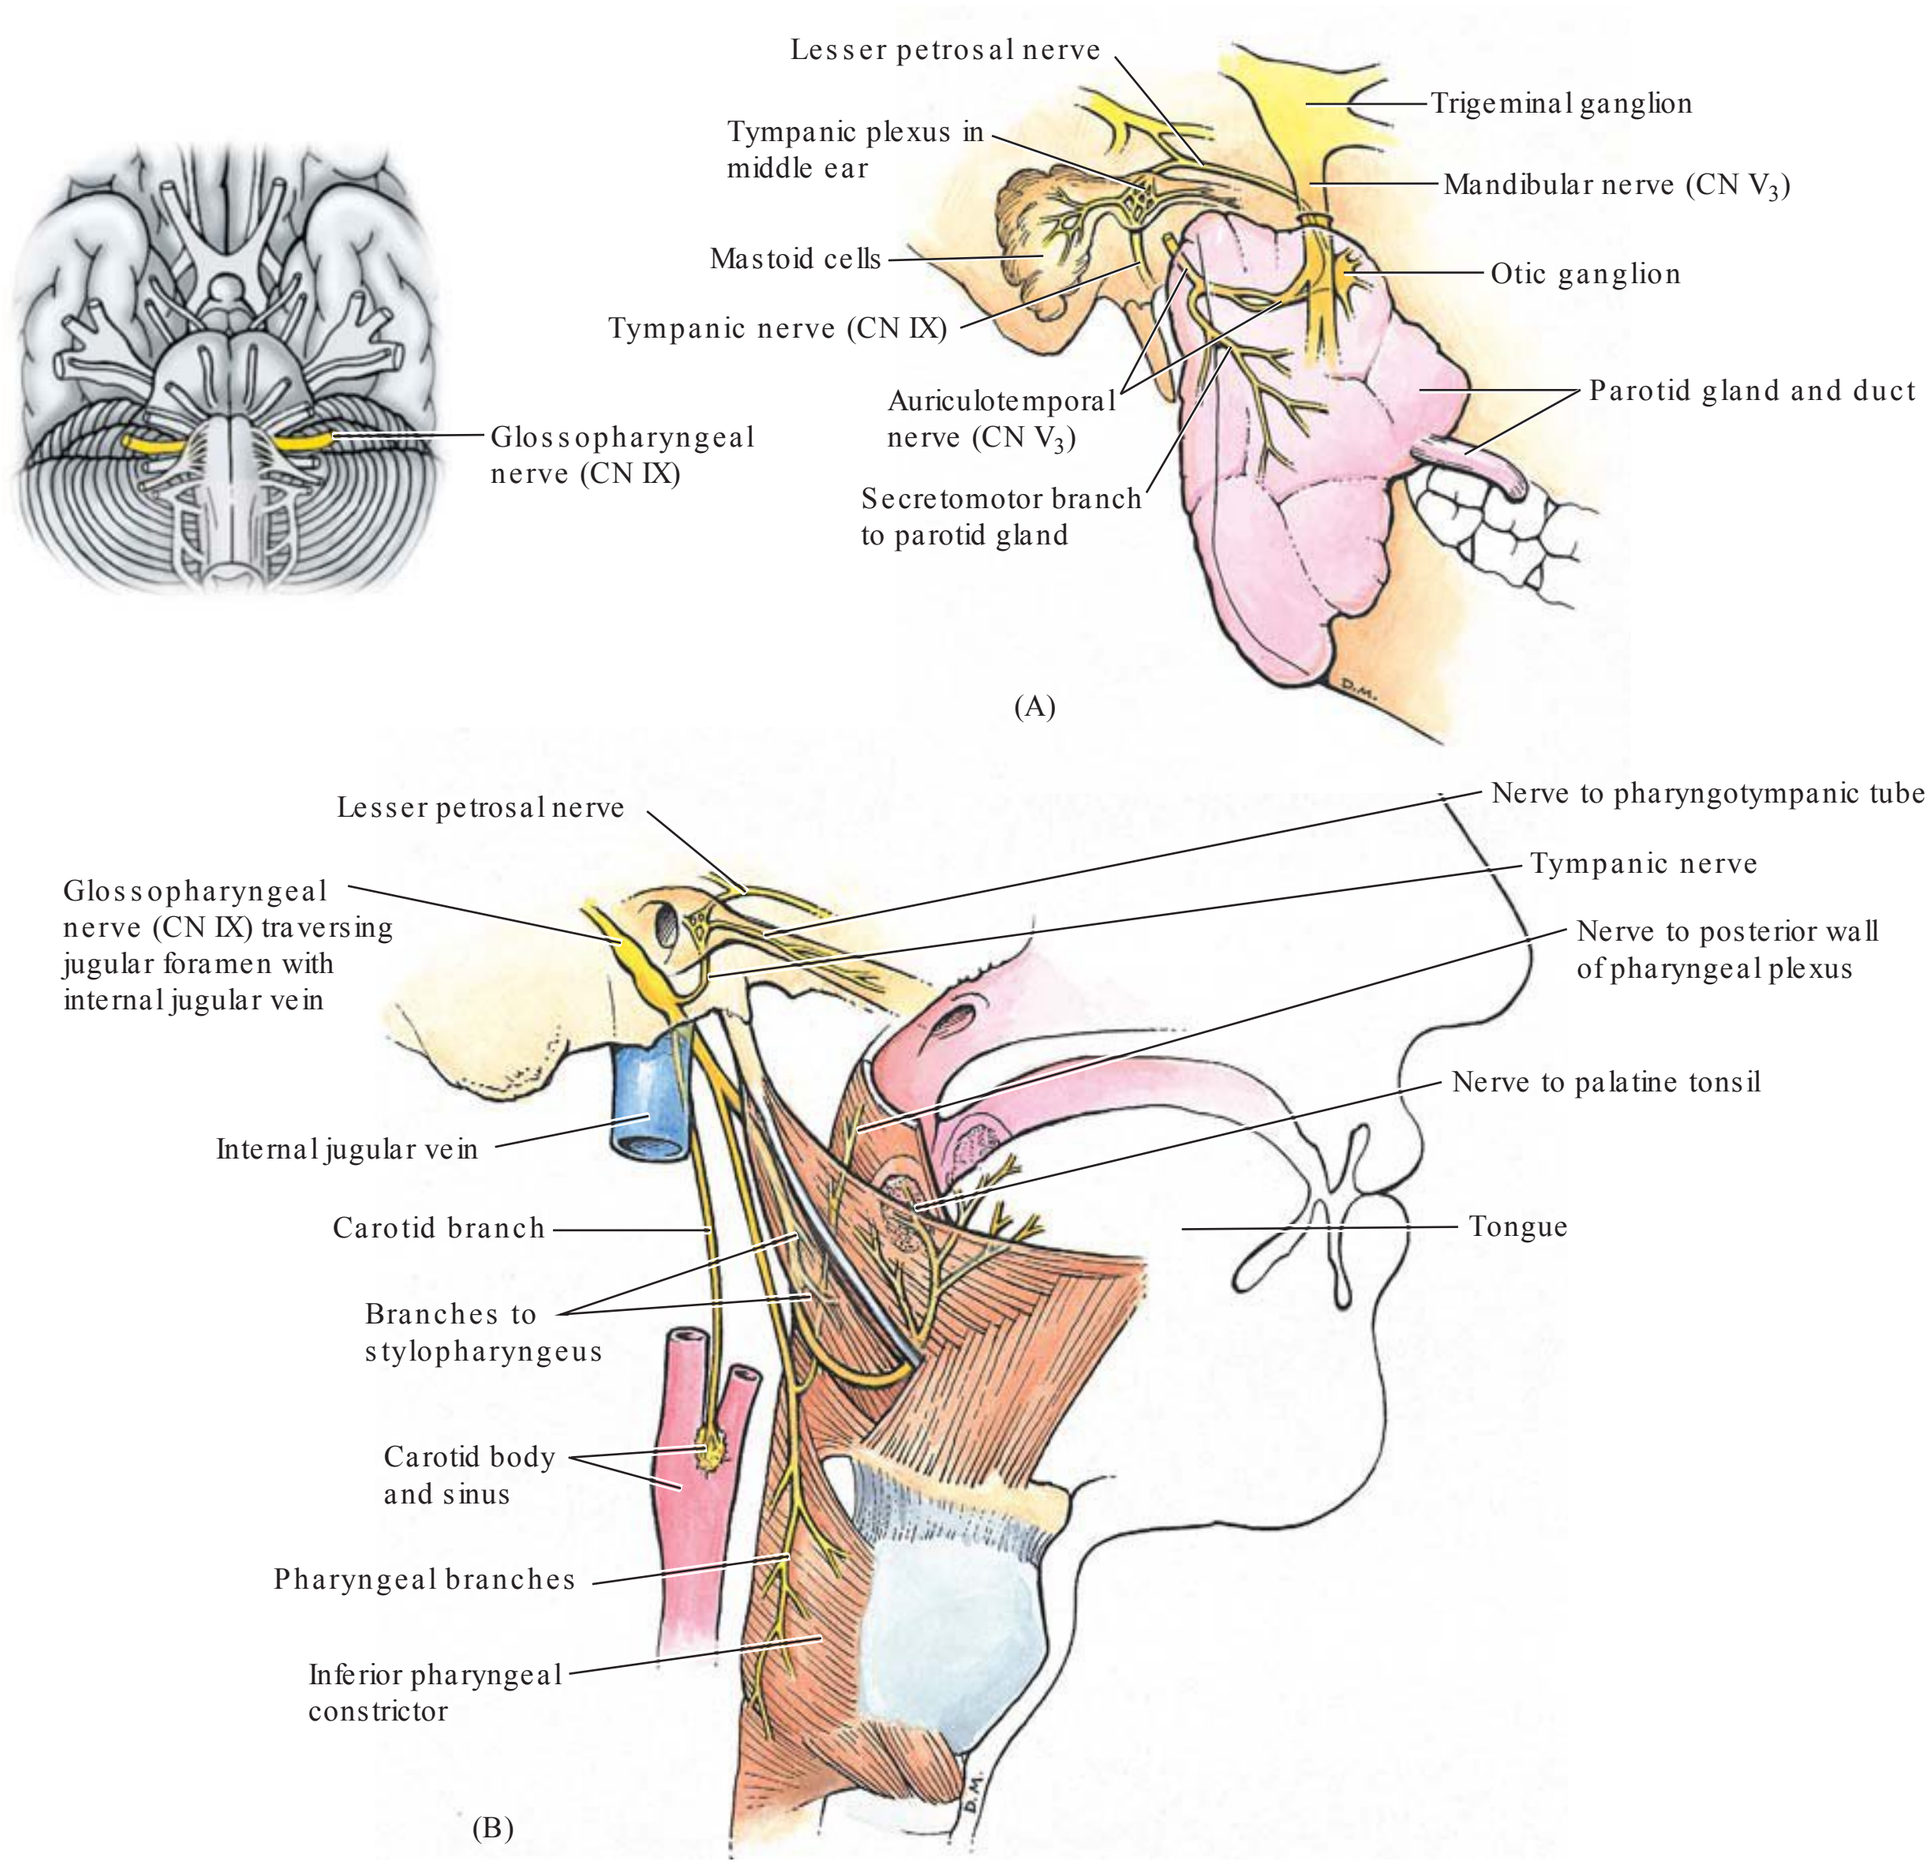

FIGURE 66.4 Distribution of the glossopharyngeal nerve. **A.** The glossopharyngeal nerve exits the skull via the jugular foramen between the internal jugular vein and internal carotid artery, lateral and ventral to the vagus and accessory nerves. It receives general sensory fibers via the tympanic nerve, the nerve to the palatine tonsils, and pharyngeal nerve branches. It receives special sensory fibers (taste) from the posterior one third of the tongue and visceral sensory fibers from the carotid bodies and carotid sinus. **B.** The parasympathetic component of the glossopharyngeal nerve supplies the postsynaptic innervations to the parotid gland via the otic ganglion. The glossopharyngeal nerve is responsible for the afferent limb of the gag reflex and thus the gag reflex is absent in patients with damage to the glossopharyngeal nerve. The efferent limb of the gag reflex is supplied by the vagus nerve. (From Moore KL, Dalley AF. *Clinically Oriented Anatomy*. 5th ed. Baltimore: Lippincott Williams & Wilkins; 2006.)

triggered by swallowing, talking, yawning, coughing, or straining and turning the head. A trigger zone is generally present in the larynx or lateral aspect of the throat overlying the hyoid bone. Compression of the vagus nerve has also reported to be associated with intractable hiccups, coughing, spontaneous gagging, and dysphagia.[223,224]

Diagnosis

The diagnosis of vagal neuralgia is based on a thorough history to define the distinct characteristics and precipitating factors of the patient's pain. A careful exam of the head and neck should be performed to rule out other pathology. MRI/MRA should be performed to rule out compressive mass lesions or neurovascular compression. Hoarseness of speech and a trigger point superolateral to the thyroid cartilage may be noted on exam of the patient. Differential diagnosis includes glossopharyngeal neuralgia, geniculate neuralgia, and carotidynia.

Treatment

Pharmacologic therapy of vagal neuralgia is identical to that of TN. Successful treatment of superior laryngeal neuralgia with

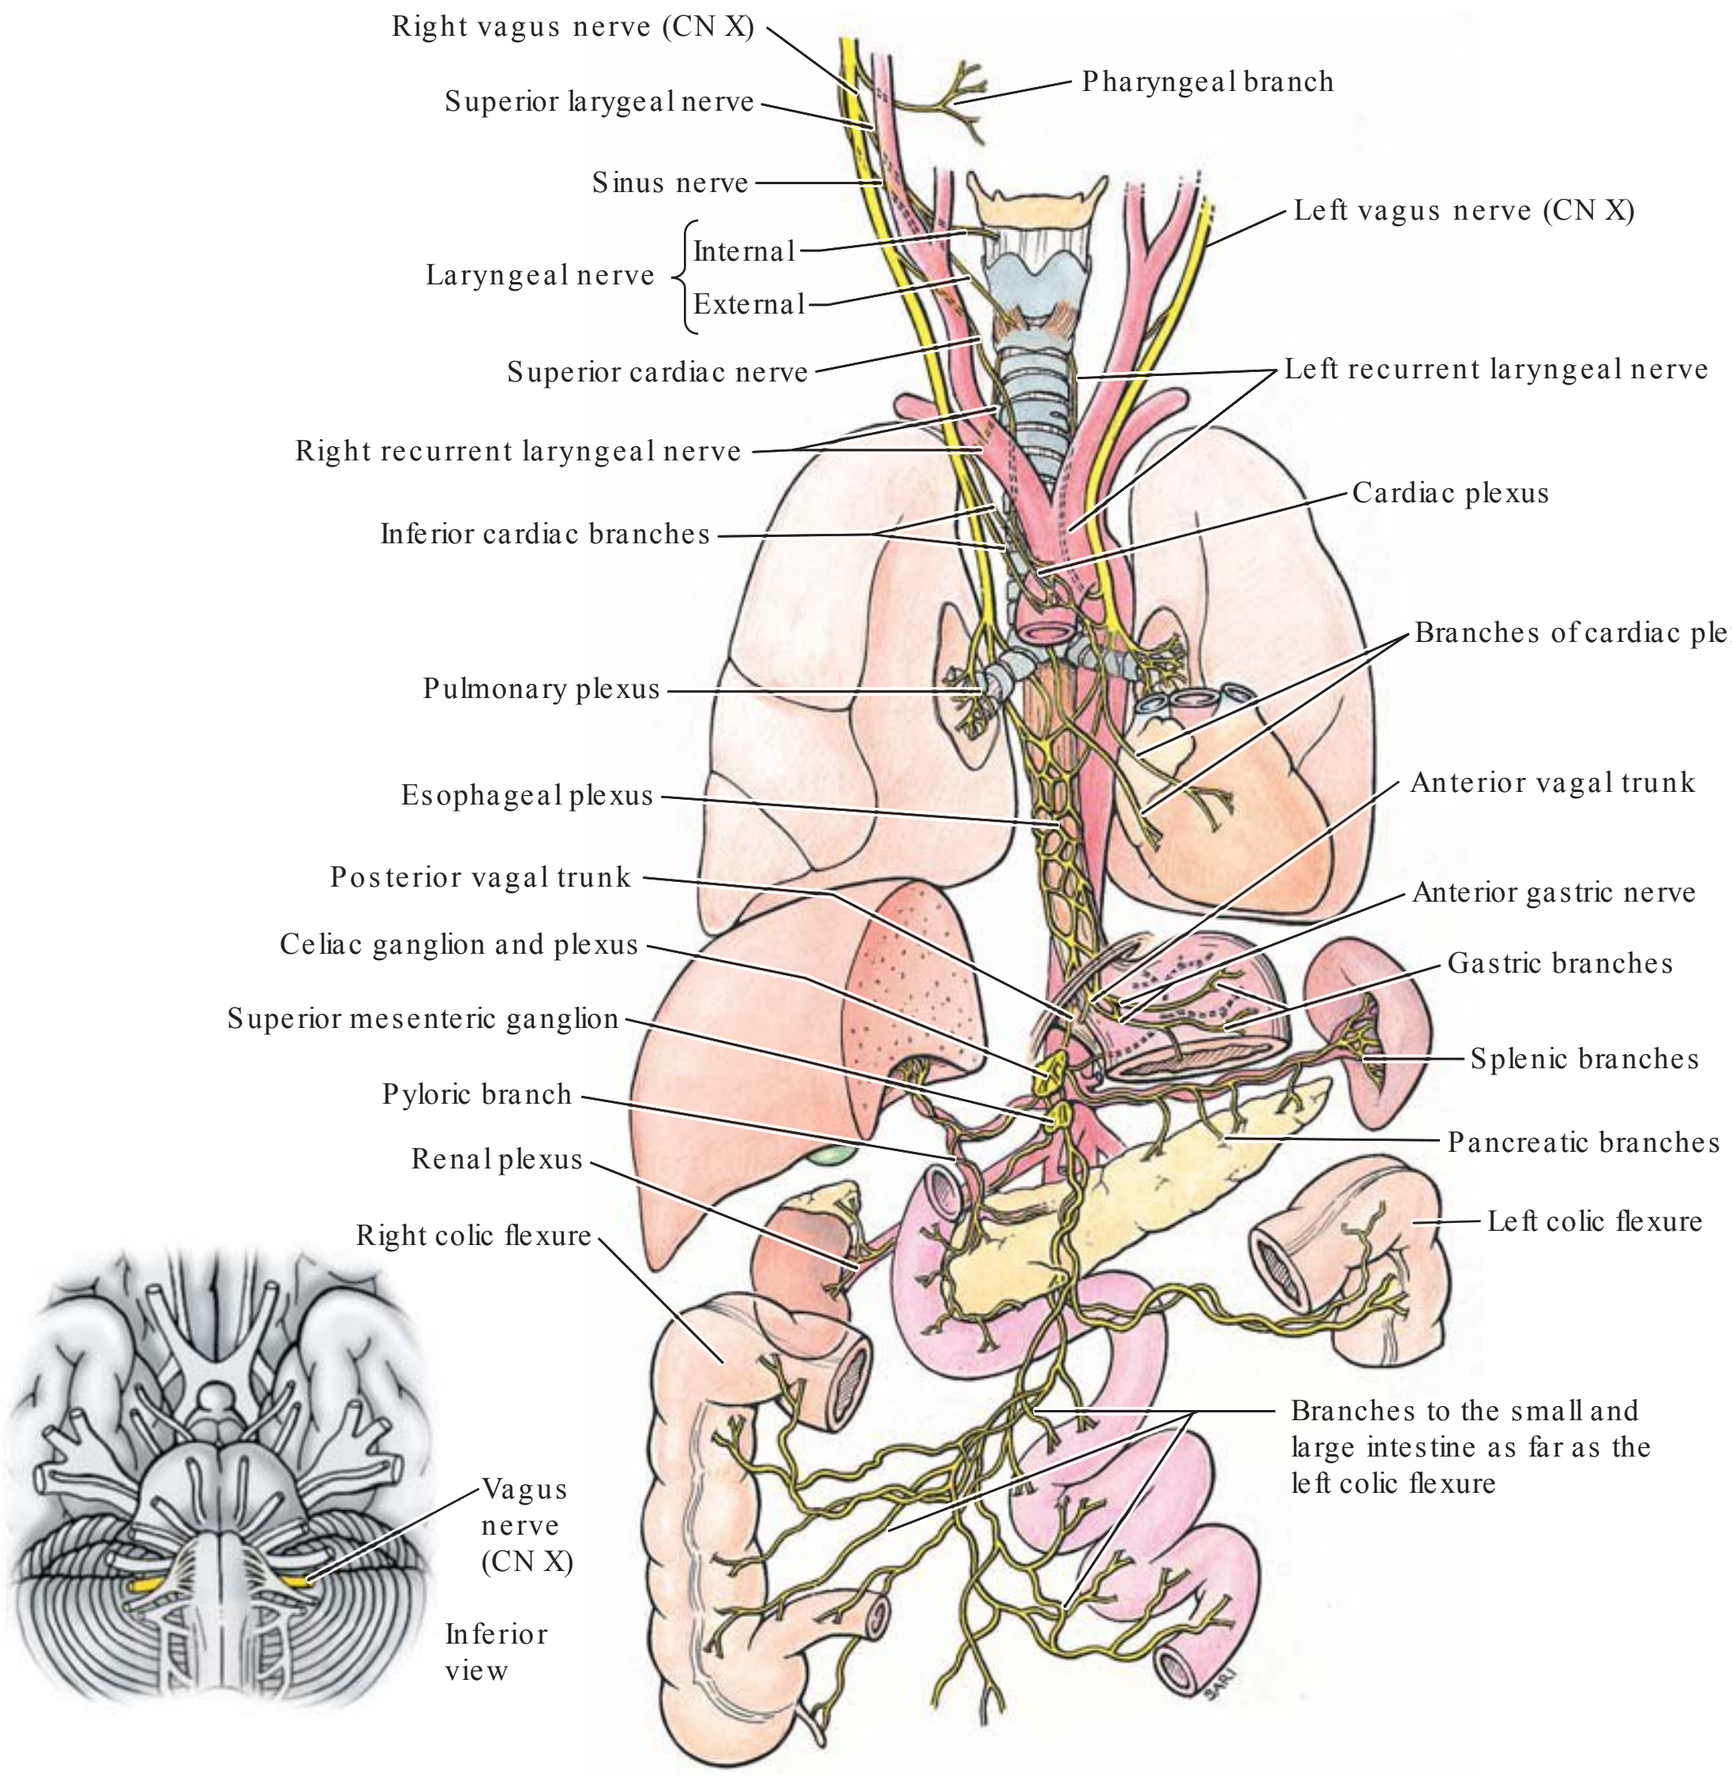

FIGURE 66.5 Distribution of the vagal nerve (cranial nerve X). The vagus nerve originates in the brainstem and courses through the jugular foramen to extend into the head, neck, thorax, and abdomen where it provides efferent motor parasympathetic innervation to viscera as well as afferent innervation that delivers information about the state of organs to the brain. (From Moore KL, Dalley AF. *Clinically Oriented Anatomy*. 5th ed. Baltimore: Lippincott Williams & Wilkins; 2006.)

high concentration lidocaine injections after carbamazepine treatment failure has been reported.[225] Surgical treatment following pharmacologic therapy failure warrants consideration. MVD has been successful when neurovascular compression of the vagus is identified. When no compressive lesion is identified, relief of pain can be obtained following section of the glossopharyngeal nerve and the upper rootlets of the vagal nerves. The medial aspect of the descending trigeminal tract has also been sectioned in refractory cases to produce loss of pain and temperature sensation in the pharynx.[226]

OTHER TERMINAL BRANCH NEURALGIAS

Rare neuralgias involving branches of the trigeminal nerve have been reported. These include supraorbital neuralgia, nasociliary neuralgia, infraorbital neuralgia, and nummular headache. Injury or entrapment of other peripheral branches of the trigeminal nerve such as the lingual, alveolar, or mental nerves may result in pain in the area supplied by that branch.

Supraorbital neuralgia is characterized by paroxysmal or constant pain in the region of the supraorbital notch. It is unilateral and radiates to the medial aspect of the forehead in the area supplied by the supraorbital nerve. It can be caused by injury or entrapment of the supraorbital nerve at its outlet. The pain is transiently relieved by injection of a small volume of local anesthetic at the supraorbital notch. Medical treatment is often unsuccessful when entrapment of the nerve is present. Successful treatment with cryoablation and surgical release of the nerve at its outlet has been reported.[227,228]

Nasociliary neuralgia, or Charlin's neuralgia, is a rare condition characterized by stabbing pain lasting seconds to hours in one side of the nose. The pain radiates to the medial frontal region and is triggered by touching the lateral aspect of the ipsilateral nostril. Temporary relief from pain following local anesthetic blockade of the nasociliary nerve is diagnostic. Inflammatory cu-

taneous lesions and chronic sinusitis have been implicated as secondary causes of nasociliary neuralgia.[229,230] Relief following surgical section of the nasociliary nerve, turbinectomy, and septoplasty has been described.[231]

Infraorbital neuralgia has been reported most frequently in association with posttraumatic entrapment syndromes.[232] If pain is not successfully alleviated by reduction of zygomatic fracture and mobilization of surrounding soft tissue and bone, pharmacologic therapy with antiepileptic agents alone or combined with antidepressants such as the tricyclics or serotonin norepinephrine reuptake inhibitors may be effective.

Nummular headache is thought to be neuralgia related to a terminal cutaneous branch of the trigeminal nerve. It has been described as a primary disorder characterized by head pain felt exclusively in a small round area generally 2–6 cm in diameter. The pain is not attributed to another disorder and neurologic and neuroimaging exams are normal by definition. A constant background pain may be described as well as exacerbations which are spontaneous or triggered by combing the hair or touch in the affected area. In patients refractory to pharmacologic therapy, reduction of pain was reported for an average of 14 weeks after initial and repeat injection with botulinum toxin A.[233]

In all cases of idiopathic neuralgia of the terminal branches of the trigeminal nerve, a careful history and physical exam to rule out other causes of facial pain the is imperative. Age less than 40 and presence of neurologic deficit should prompt further diagnostic radiologic exams to rule out compressive lesions.

OTHER CRANIAL NEURALGIA-RELATED CAUSES OF PAIN: ANESTHESIA DOLOROSA

Etiology

Anesthesia dolorosa is defined as perception of pain in an area that is anesthetic. It is a dreaded complication of trigeminal nerve surgery, including partial nerve sections, MVD, percutaneous gangliolysis, neurolytic injections, and stereotactic radiosurgery. It has also been reported after penetrating cranial injury.[234] The area of persistent and painful anesthesia is in the distribution of the injured nerve.

Symptoms and Signs

The patient with anesthesia dolorosa complains of burning, pulling, or stabbing pain which can also include a sharp, stinging, shooting, or electrical component. The pain often increases with cold or with rapid temperature changes.

Diagnosis

As it pertains to the head and face, anesthesia dolorosa typically involves the territory of a specific branch or branches of the trigeminal nerve or the occipital nerve. Quantitative sensory testing may be used to confirm lack of sensation.

Treatment

There are no controlled trials evaluating pharmacologic therapy for anesthesia dolorosa. Empiric treatment of pain by clinical characteristics has led to use of anticonvulsants in patients with lancinating and electrical pain, tricyclic antidepressants and serotonin norepinephrine reuptake inhibitors in patients with burning pain, and intravenous lidocaine and ketamine infusions in patients unresponsive to other pharmacologic therapy.[235,236] Motor cortex stimulation was the recommended surgical treatment of choice for facial anesthesia dolorosa according to authors of a recent review of the literature on central and neuropathic pain over the last 15 years. Motor cortex stimulation may act by replacing nociceptive with nonnociceptive sensory input at the cortical, thalamic, brainstem, and spinal level. It may also interfere with the emotional component of nociceptive perception.[237] In a prospective study of 10 patients undergoing trial and treatment with motor cortex stimulation, patients with facial weakness and sensory loss regained both strength and discriminative sensation during stimulation.[238] Multicenter randomized studies are now in progress to further evaluate this modality of treatment. Anesthesia dolorosa did not appear to respond to deep brain stimulation according to one 15-year series of 141 patients.[239]

CONCLUSION

Knowledge of the features of neuralgic pain, a thorough understanding of the unique characteristics and specific anatomic distribution of each cranial nerve, and a familiarity with the distinctive features of other pain syndromes involving the structures of the head and neck is essential to establishing a diagnosis of trigeminal or other cranial neuralgias. Although the cranial neuralgias are rare when compared with other neuropathic pain syndromes, the extreme suffering encountered in patients who present with these syndromes, together with the need to distinguish between classical and symptomatic presentations, mandates advanced neuroimaging in all cases to rule out progressive processes such as intracranial tumors, infection, or MS. Pharmacologic, surgical, and percutaneous therapies for the cranial neuralgias have continued to advance with development of new agents and techniques which are associated with fewer side effects and complications. Improved monitoring in the case of surgical and percutaneous therapies have also been instrumental in reducing patient morbidity and mortality.

CHAPTER 67 ■ FACIAL PAIN

STEVEN J. SCRIVANI, NOSHIR R. MEHTA, DAVID A. KEITH, M. ALAN STILES, RAYMOND J. MACIEWICZ, AND RONALD J. KULICH

INTRODUCTION

Facial pain syndromes are common in clinical practice. Many of these syndromes are also unique, given the complex anatomy and specialized sensory innervation of the head, face, and neck, and so can pose diagnostic challenges.

The common descriptive terms for facial pain complaints are frequently misleading. To avoid confusion, clinicians should be familiar with the International Headache Society's Diagnostic Classification for Head, Face, and Neck Pain Disorders (Tables 67.1 through 67.6).[1] Clinicians need to be able distinguish among painful conditions that arise from structural pathology, headache syndromes, oral and facial structures, temporomandibular joint disorders, myofascial pain disorders, and primary cranial neuralgias.

TABLE 67.1

INTERNATIONAL HEADACHE SOCIETY INTERNATIONAL CLASSIFICATION OF HEADACHE DISORDERS II

14 CATEGORIES
- The Primary Headaches: 1–4
- The Secondary Headaches: 5–12
- Cranial Neuralgias, central and primary facial pain and other headache disorders: 13–14

Adapted from Headache Classification Subcommittee of the International Headache Society. The International Classification of Headache Disorders: 2nd edition. *Cephalalgia*. 2004;24(Suppl 1):9–160.

ORGANIZATION OF THE TRIGEMINAL NOCICEPTIVE SYSTEM

Although nociceptive transmission in the trigeminal and spinal systems is similar, the two systems have important differences. In the perioral region, the trigeminal divisions contain afferents that subserve the dermatomes, which include the lips, teeth, gingival, anterior two thirds of the tongue, upper pharynx, uvula, and soft palate. In addition to this cutaneous distribution, the trigeminal nerve contains afferents that provide sensory innervation to a variety of deep structures in the head, including the muscles of mastication and facial expression, the nasal and oral mucosa, the cornea, tongue, tooth pulp, temporomandibular joint, dura mater, intracranial vessels, external auditory meatus, and ear (partially, and with cranial nerves VII, IX, and X).

The trigeminal system carries somatosensory information from these cutaneous and deep afferent structures as well as from specialized organs that have principally nociceptive innervation.

TABLE 67.2

THE PRIMARY HEADACHES (1–4)

1. Migraine
   *without aura
   *with aura
2. Tension-type headache
3. Cluster headache and other trigeminal autonomic cephalalgias
4. Other primary headaches

TABLE 67.3

THE SECONDARY HEADACHES (5–12)

5. Attributed to head and/or neck trauma
6. Attributed to cranial or cervical vascular disorder
7. Attributed to nonvascular intracranial disorder
8. Attributed to a substance or its withdrawal
9. Attributed to infection
10. Attributed to disorder of homeostasis
11. Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
12. Attributed to psychiatric disorder

TABLE 67.4

HEADACHE OR FACIAL PAIN ATTRIBUTED TO DISORDERS OF CRANIUM, NECK, EYES, EARS, NOSE, SINUSES, TEETH, MOUTH, OR OTHER FACIAL OR CRANIAL STRUCTURES (11.1–8)

11.1—Cranial bones
11.2—Neck
11.3—Eyes
11.4—Ears
11.5—Rhinosinusitis (Sinus disorders)
11.6—Teeth, jaws, or related structures
11.7—TMJ disorders (TMD)
11.8—Other

TABLE 67.5

CRANIAL NEURALGIAS, CENTRAL AND PRIMARY FACIAL PAIN, AND OTHER HEADACHES (13.1–19)

13.1—Trigeminal neuralgia
13.2—Glossopharyngeal neuralgia
13.8—Occipital neuralgia
13.12—Constant pain caused by compression, irritation, or distortion of cranial nerves or upper cervical roots by *structural lesions*

TABLE 67.6

CRANIAL NEURALGIAS, CENTRAL AND PRIMARY FACIAL PAIN, AND OTHER HEADACHES (13.1–19)

13.15—Head or facial pain attributed to herpes zoster
postherpetic neuralgia

13.18—Central causes of facial pain
anesthesia dolorosa
central poststroke pain
facial pain attributed to multiple sclerosis
persistent idiopathic facial pain
burning mouth syndrome

Most nociceptive afferents relay through the trigeminal brainstem complex, with oral and perioral structures represented more rostrally than peripheral sites on the face.[2] In addition, nociceptive afferents from the other cranial nerves and the upper cervical spinal segments (C2–C4) also are relayed through the trigeminal brainstem complex.

In the subnucleus caudalis, cells relaying nociceptive signals (nociceptive-specific cells and wide–dynamic-range cells) are primarily localized to analogous regions of lamina I and V in the spinal cord. Deep afferents also converge on cells that also receive cutaneous nociceptive input, providing a substrate for referred pain in the head, face, and neck through the trigeminal system. Finally, the trigeminal nociceptive relay cells are strongly modulated by central pathways (descending opioidergic, noradrenergic, and serotonergic) that may dynamically modulate nociception under a variety of environmental situations and behavioral states.[2]

Although the trigeminal dermatomes do not generally overlap those supplied by the adjacent cervical spinal nerves and other cranial nerves, they overlap extensively in the spinal afferent system. Three adjacent spinal roots must be injured to render any one region anesthetic. In the trigeminal system, under normal conditions, a section of one trigeminal division renders almost the entire dermatome anesthetic. Because the peripheral sensory nerves overlap so little with the trigeminal system, nerve lesions may result in more pronounced central somatosensory changes than those evoked by similar lesions in spinal nerves. These changes may partly underlie trigeminal neuropathic pain disorders. Additionally, the trigeminal system may be developmentally and functionally distinct as a result of three hypothetical factors: (1) it innervates highly specialized tissues that are engaged in highly specialized functions; (2) it experiences two developmentally unique events: one programmed pain event and one programmed denervation event (eruption and exfoliation of teeth); and (3) it can be affected by dental surgery procedures performed with local anesthesia, which alters the afferent input into the system. These factors may also influence the development of chronic facial pain.

DIAGNOSTIC EVALUATION

Pain in the mouth or face is one of the most common presenting symptoms in clinical practice. The majority of symptoms are related to dental disease and, in most cases, the cause can readily be established, the problem dealt with expeditiously, and the pain eliminated. However, in a few patients, pain may be persistent and defy attempts at treatment. Intractable oral and facial pains can be diagnostically challenging, given the many potential causes of pain, the anatomic complexity of the region, and the psychosocial importance of the face and mouth. A rigorous protocol for evaluating these patients includes a thorough history and an appropriate clinical examination (see Chapter 24).

A detailed history should always be obtained before examining the patient or ordering special tests or imaging studies because the history will establish a diagnosis in a majority of cases.

Chief Complaint

The patient's description of the pain may provide clues to its cause. Primary neuralgias are frequently described as sharp and lancinating, secondary neuralgias have a burning quality, vascular headaches are throbbing, and muscle pain is described as a deep and dull ache. The patient may not be able to give all these descriptions at the first interview, and corroborating information from relatives and friends may be needed to build a general picture of the pain as it affects the patient. Each pain complaint should be listed in order of severity.

History of Present Complaint

The intensity of the pain needs to be measured against the patient's own experience of pain, need for medication, and effect on lifestyle. For example, does the pain interfere with work, sleep, or social activities? How severe is it on a 10-point scale? Does it fluctuate over time? The origin of the pain should be determined by asking the patient to indicate the site of the pain or the site of its maximum intensity. Its anatomic distribution should be accurately traced in terms of local anatomy.

The patient should be encouraged to remember the events surrounding the onset of the pain, even if it was several years ago. Any other instance of similar pain should be ascertained, even though the patient may not associate these with the present problem. The time relations of the pain should be clarified in terms of duration and frequency of attacks, as well as possible remissions.

Aggravating factors should be determined. Is the pain aggravated by the ingestion of specific foods or beverages, by lying down, during times of stress, talking, brushing the teeth, shaving, applying make-up, or by other identifiable factors? In addition, relieving factors (e.g., lying down, sleeping, heat, and cold) are important clues.

The effects of previous treatments need to be clarified. Which medications have helped? Has surgery altered the nature of the pain? Has endodontic treatment or extraction affected the pain? Finally, the presence or absence of associated factors (e.g., swelling of the face, flushing, tearing, nasal congestion, or facial weakness) needs to be ascertained.

Medical History

Take a detailed history of the patient and the reported pain. Especially, note any trauma to the head, face, and mouth. Identify current and past medications, relevant family history, and the use of over-the-counter medications, supplements, and alternative or complementary therapies. Identify any jaw habits, such as clenching, grinding, posturing the jaw, or gum chewing, including occupational or vocational habits (e.g., playing a wind instrument, scuba diving, and so on). A comprehensive psychosocial history is imperative for all patients with chronic pain disorders (see Chapter 21). Establish the details of any pending or planned disability claims or litigation (see Chapter 22).

Physical Examination

The purpose of the physical examination is to discover any possible anatomic or physiologic basis for the pain; therefore, it is important to proceed systematically. Patients with facial pain should have a complete head and neck examination, not an examination directed by a presumed diagnosis.

Neurologic Function

The most important evaluations are of those of the cranial nerves (CN) V (trigeminal) and VII (facial) and the upper cervical nerves (C2–C4). The three divisions of the trigeminal nerve—supraorbital, infraorbital, and inferior alveolar nerves—supply the majority of sensation to the mouth and face. Examine the skin distribution of all three divisions, as well as the intraoral distribution of the second and third divisions. Directional sense, two-point discrimination, and sensory perception with von Frey hairs may help with the diagnosis. Heat, cold, and taste may need to be tested in certain situations. Pain to pressure over the six foramina may indicate trigeminal involvement. Corneal and gag reflexes should be assessed. The size and strength of the masticatory muscles reflect the motor division of CN V. Facial nerve function can be assessed by asking the patient to whistle, purse the lips, smile, close the eyes, and frown.

Upper cervical nerve sensation can be assessed on the scalp for C2 and at the angle of the jaw and upper neck for C3. Pressure over the midsuperior nuchal line directly affects the greater occipital nerve and may reproduce the headache in occipital neuralgia.

Because of the overlap of CNs V, VII, IX, and X and their convergence on the spinal trigeminal nucleus, a more detailed examination of these nerves may be necessary. CN IV and VI nerve palsies may indicate increased intracranial pressure.

Muscle Function

Pain in the masticatory muscles, face, posterior cervical spine, and upper back (the suprascapular and pectoral girdle) are common causes of head, face, and neck pain, so the neck, shoulder, and masticatory muscles should be thoroughly assessed. The size of the muscles can be assessed visually (e.g., temporal hollowing, masseteric hypertrophy). The muscles should be palpated, trigger points noted, and head and neck posture should be assessed. A more thorough evaluation of the masticatory muscles includes measuring the maximum interincisal opening and lateral and protrusive excursions. Tremors and fasciculation should also be noted.

Temporomandibular Joint

Palpate the lateral pole of the mandibular condyle for tenderness with the mouth open and closed. Course and fine crepitation should be noted and joint noises auscultated. Clicks and pops and the position in the opening or closing cycle should be observed. Determining whether or not these are eliminated by separating the teeth with a tongue blade or by posturing the jaw forward will help focus on the functional importance of these joint noises.

Intraoral Examination

Note how the maxillary and mandibular teeth interdigitate when the mouth is closed (dental occlusion) as well as the state of the dentition and oral hygiene. Look for evidence of wear on the teeth, excessive toothbrush abrasion, or palatal erosion from repetitive vomiting. The health of the oropharyngeal mucosa should be recorded, as well as the moistness of the mucosa and pooling of saliva. The parotid and submandibular glands can be milked to evaluate the quality and quantity of saliva expressed. The tongue and soft palate should be centered midline and freely mobile. Excessive draping of the soft palate, as seen in sleep apnea, should be noted.

Diagnostic Imaging (see Chapter 19)

Periapical dental films and panoramic maxillofacial radiographs are inexpensive, readily available, do not expose patients to excessive radiation, and offer detailed information about the teeth and jaws. Computed tomography (CT) can provide more detailed images of the bony structures of the jaws, temporomandibular joints, and base of the skull. Three-dimensional imaging can be helpful in some instances. Magnetic resonance imaging (MRI) is best for evaluating the soft tissues and can be used for assessing the deep oro- and nasopharyngeal anatomy and the internal anatomy of the temporomandibular joints. In addition, the brain can be evaluated with MRI with and without gadolinium contrast. MRI studies can help determine whether the vasculature is impinging on the trigeminal ganglion, which can cause trigeminal neuralgia.

Bone scan with technetium-99m will highlight areas of metabolic activity within the bone and can help identify areas of infection, tumor extension and continued growth, or degenerative change in the temporomandibular joint.

Laboratory Studies

Routine blood tests include complete blood count and differential to exclude anemia and blood dyscrasias. Erythrocyte sedimentation rate may be elevated in temporal arteritis. Rheumatoid factor and Lyme titer may be helpful in evaluating temporomandibular joint disease.

FACIAL PAIN DISORDERS

Pain Attributed to Disorders of the Oral Cavity

Facial Pain of Dental Origin (Odontogenic)

Tooth pulp has a specialized and possibly exclusively nociceptive innervation.[3] In contrast, periodontal tissues are innervated by a wide variety of sensory afferents. Pain of dental origin is extremely variable and can simulate nearly any pain syndrome. Dental pain may be spontaneous or induced in various ways, and it can be intermittent or continuous (Table 67.7). Because of the extreme variability of toothache, all pains about the mouth and the face should be considered to be of dental origin until proven otherwise.

Dental pain is typically provoked by thermal or mechanical stimulation of the damaged tooth, but it can also be provoked by light touch, tooth-tooth contact (in eating and talking), and pressure. Dental pain is usually described as an aching sensation and sometimes as throbbing. When mild, it may be felt only as a tenderness or soreness. When severe, it may have a burning or electric- or shock-like quality.

Patients often cannot localize pain arising solely from the dental pulp. They often cannot determine whether the offending tooth is mandibular or maxillary, much less which tooth is involved. The pain is felt diffusely in the teeth, jaws, face, and head.[4] Clinical and radiographic findings of dental decay, fractured dental restoration, tooth fracture, or abscess drainage (fistula) may confirm dental pain as the source of the complaint (Tables 67.8 and 67.9).

Reversible and Irreversible Pulpitis. Dental pain occurs most commonly secondary to dental caries, which represent a loss of integrity of tooth enamel. When enamel integrity is sufficiently breached, sensitivity to cold or sweet stimulus may result. Carious progression occurs more rapidly with dentinal involvement. At this stage, the vital dental pulp is exposed to the oral environment, and inflammatory changes in the pulpal tissue are evident histologically.

Localized pain (diagnosis-specific)
Pain qualities (sharp, dull, aching, throbbing)
Sensitivity to temperature
Sensitivity to pressure, palpation, percussion
Pain reduction by local anesthetic injection?

The pulpal inflammatory process is initially reversible. Reversible pulpitis is characterized by inflammation of the pulp that may recover or heal when the insult is removed. Continued stimuli jeopardizes the pulp's ability to respond and repair itself. Irreversible pulpitis can be distinguished from reversible pulpitis by the duration of symptoms. Both require a stimulus to initiate the pain; however, the duration of pain is measured in seconds in reversible pulpitis but in minutes or hours in irreversible pulpitis. Spontaneous odontogenic pain most frequently marks pulpal death or necrosis. Pain elicited with heat is most commonly associated with pulpal necrosis.[5] The general clinical characteristics displayed by toothache of pulpal origin are described in Table 67.8.

Cracked Tooth. Incomplete fractures of a vital tooth may trigger intermittent pain when biting on the offending tooth. Risk factors include older age, extensive dental restoration, and parafunctional habits, such as teeth grinding. Unfortunately, the cracks are often difficult to find and do not appear on all radiographs. The pain is often confused with that of pulpitis or trigeminal neuralgia, which may result in unnecessary treatment (see Table 67.9). Careful clinical examination, including staining or meticulous bite tests on each tooth cusp, may be useful.[6,7]

Acute dental pain typically responds to local treatments (e.g., ice packs and reduced mechanical stimulation) or systemic nonsteroidal anti-inflammatory drugs (NSAIDs). Opioid analgesics (and combinations) are also indicated, depending on the extent of the pain. In many cases, treatment with antibiotics is appropriate and palliative until a definitive dental intervention is performed. Definitive dental procedures are generally curative.

Disorders of the Periodontium (Periodontal Disease)

Chronic periodontal disease is an immune-mediated inflammatory process initiated by pathogenic oral microorganisms,[8,9] destroying either focal or generalized areas of tooth-supporting structures and the surrounding bone. Chronic periodontitis is generally not a chronically painful disorder. Typically, patients notice gingival sensitivity and tenderness or gingival enlargement secondary to inflammation and bleeding with brushing or probing examination. A tooth with lost bone support may have lost the gingival attachment surrounding the necks and soft tissue of the root, which may result in tooth sensitivity, tenderness, and mobility. In acute periodontal infection, tenderness to the touch, erythema, and bleeding may be evident. An acute periodontal abscess may cause swelling and purulence (see Table 67.9). When inflammation or infection (i.e., acute pericoronitis) occurs in the soft tissue or bone around an erupting or partially erupted tooth (particularly third molars, otherwise known as wisdom teeth), similar signs and symptoms may be seen, with pain as a primary complaint.

The pain of periodontal disorders also generally responds to NSAIDs, opioid analgesics, or combination analgesics. An acute abscess may also have to be locally incised and drained. Areas of generalized periodontitis may be treated with tooth scaling and

TABLE 67.9

ODONTIC PAIN

Diagnosis	Pulpitis	Peridontal	Cracked Tooth	Dentinal
Diagnostic Features	Spontaneous and/or evoked deep/diffuse pain in compromised dental pulp. Pain may be sharp, throbbing, or dull.	Localized deep continuous pain in compromised periodontium (e.g., gingiva, periodontal ligament) exacerbated by biting or chewing.	Spontaneous or evoke brief sharp pain in a tooth with history of trauma or restorative work (e.g., crown, root canal).	Brief, sharp pain evoked by different kinds of stimulus to the dentin (e.g., hot or cold drinks).
Diagnostic Evaluation	Look for deep caries and recent or extensive dental work. Pain provoked/exacerbated by percussion, thermal, or electric stimulation of affected tooth. Dental radiographs helpful (periapical).	Tooth percussion over compromised periodontium provokes pain. Look for inflammation or abscess (e.g., periodontitis, apical dental radiographs helpful (bitewings, periapical).	Presence of tooth fracture may be detectable by radiograph. Percussion should elicit pain. Dental radiographs are helpful (periapical taken from different angles).	Exposed dentin or cementum due to recession of periodontium. Possible erosion of dentinal structure. Cold stimulation reproduces pain.
Treatment	Medication: NSAIDs, nonopiate analgesics. Dentistry: remove carious lesion, tooth restoration, endodontic treatment, or tooth extraction.	Medication: NSAIDs, nonopiate analgesics, antibiotics, mouth-washes. Dentistry: drainage and débridement of periodontal pocket, scaling and root planning, periodontal surgery, endodontic treatment, or tooth extraction.	Medication: NSAIDs, nonopiate analgesics. Dentistry: depends on level of the tooth fracture-restoration, treatment, or extraction of the tooth.	Medication: mouthwash (fluoride), desensitizing toothpaste. Dentistry: fluoride or potassium salts, tooth restoration, endodontic treatment. Patient education, diet, tooth brushing force and frequency, proper toothpaste.

curettage of the gingival pocketing and possibly local or systemic antibiotic therapy.

Acute Necrotizing Ulcerative Gingivitis

Acute necrotizing ulcerative gingivitis (ANUG) is an aggressively destructive process. The diagnostic triad includes pain, ulcerated or "punched out" interdental papillae, and gingival bleeding. Secondary signs include fetid breath, pseudomembrane formation, "wooden teeth" feeling, foul metallic taste, tooth mobility, lymphadenopathy, fever, and malaise. The cause of ANUG is poorly understood. It appears to be an opportunistic infection in a host of lowered resistance. The most important predisposing factor is human immunodeficiency virus infection and the second, a history of necrotizing gingivitis. Other contributing factors include poor oral hygiene, unusual emotional stress, poor diet, inadequate sleep, recent illness, alcohol use, tobacco use, and various infections, such as malaria, measles, and intestinal parasites. Treatment consists primarily of bacterial control. Chlorhexidine oral rinses, professional débridement and scaling, and adjunctive antibiotic therapy with a soft diet rich in protein, vitamins, and fluids are important in treating and preventing the disease.[10]

Oral Mucous Membrane Disorders

Diseases of the oral mucosa are numerous and have a variety of local and systemic causes. Typically, these diseases present with pain and oral mucosal lesions, including vesicles, bullae, erosions, erythema, or red and white patches (Table 67.10). Pain may be a symptom of the primary disease process, secondary to an associated process (i.e., infection), or related to damaged oral mucosa (i.e., mouth movements, chewing foods, thermal, chemical) and is often treated with both systemic and local analgesic agents.

Disorders of the Maxilla and Mandible

Numerous disorders of the bony substrate of the jaws may present with pain. These disorders are generally classified as being of odontogenic or nonodontogenic origin, cystic, cystic-like, or tumor, and benign or malignant (either primary or metastatic disease). Often, additional historical or examination findings warrant further evaluation (i.e., swelling, mass, discoloration, numbness, weakness, bleeding, drainage, tooth loss, or mobility). Pain can be treated symptomatically until a definitive diagnosis is established and definitive therapy is initiated (Table 67.11).

Salivary Gland Disorders

Disorders of the three major pairs of salivary glands (parotid, submandibular, and sublingual) and many hundreds of minor salivary glands in the mouth may also produce pain as a primary or associated symptom. These disorders are often accompanied by other signs and symptoms (including swelling, drainage, cervical adenopathy, or generalized signs of systemic infection), depending on the cause of the disorder. Disorders of the parotid gland can locally extend to produce otologic symptoms or CN (V, VII, or IX) involvement. Disorders of the submandibular gland may result in symptoms of impaired swallowing or impairment of CNs V, IX, XII (Table 67.12).

Burning Mouth-Tongue Syndrome (Oral Burning)

Burning mouth-tongue syndrome (BMS) is an idiopathic pain condition of the oral mucous membranes akin to idiopathic neu-

syndrome-dry mouth, fungal infections) and systemic diseases (i.e., vitamin deficiencies, diabetes mellitus, immune connective tissue disorders, vasculitides). More recent evidence suggests that BMS is more likely a neuropathic pain disorder of either peripheral or central origin. Some recent taste-testing data and functional brain imaging studies support this hypothesis (Table 67.13).[11–15] Current treatments for BMS focus on this hypothesis and use both topical (oral mucosa) and systemic antineuropathic pain medications (see neuropathic pain section below); however, there is little evidence that such treatments are effective.

Pain Attributed to Disorders of the Eye

Pain in and around the eye is a common presenting problem (Table 67.14). Most ophthalmologic conditions producing eye pain are associated with obvious ocular symptoms, signs, or histories that implicate the eye as the origin of pain. Several facial pain and headache syndromes present with ''eye pain'' as the chief symptom (Table 67.15). In addition, during the history and physical examination, several signs and symptoms warn of more serious eye disease and even of potential life-threatening problems (Table 67.16).

History and Ocular Examination

A complete ocular history should include any prior visual loss, ophthalmic diseases (e.g., corneal infections, uveitis, and glaucoma), use of contact lenses, recent or remote ocular surgery, and ocular trauma. In addition to noting the specific features of pain when taking the history for eye pain, such as time of onset, severity, exacerbating and palliating factors, radiation, quality, duration, and frequency, ask about the specific location of pain; for example, intraocular, retrobulbar, periocular, or frontal and associated symptoms, such as tearing, loss of vision, double vision, photophobia, and discharge.[16]

Simple instruments are required to perform the basic eye examination, in which the pain specialist can triage patients with eye pain and identify those who require formal ophthalmologic consultation. Such equipment includes a near vision card (Snellen card), a hand light, and a direct ophthalmoscope. The Snellen card is used to check the visual acuity (VA). The VA should be tested using the patient spectacle correction and each eye should be tested individually. The pupil response to light, the regularity of the pupil, and relative afferent papillary defect should be evaluated using a hand light. Also, examine extraocular motility examination and the eyelids. Use a hand light to assess the conjunctiva for chemosis, injections, and foreign bodies and the cornea for keratitis, corneal foreign bodies, and lacerations. Evaluation of the optic nerve using the direct ophthalmoscope should be sufficient to exclude gross optic atrophy, fundoscopic abnormalities, and papilledema.

Ocular and Orbital Causes of Eye Pain

Although a large percentage of patients with headache attribute their pain to their refractive errors and present with many pairs

TABLE 67.13

TRIGEMINAL NEUROPATHIC PAIN DISORDERS

Diagnosis	Trigeminal neuralgia	Deafferentation pain	Acute and postherpetic neuralgia	Burning mouth syndrome
Diagnostic features	Brief severe lancinating pain evoked by mechanical stimulation of trigger zone (pain free between attacks). Usually unilateral, affects the V2/V3 areas (rarely V1). Possible pain remission periods (for months/years).	Spontaneous or evoked pain with prolonged after-sensation after tactile stimulation. Trigger zone due to surgery (tooth extraction) or trauma. Positive and negative descriptors (e.g., burning, nagging, boring).	Pain associated with herpetic lesions, usually in the V1 dermatoma. Spontaneous pain (burning and tingling), but may present as dull and aching. Occasional lancinating evoked pain.	Constant burning pain of the mucous membranes of the tongue, mouth. Hard or soft palate or lips. Usually affects women age >50 years.
Diagnostic evaluation	MRI for evidence of tumor or vasocompression of the trigeminal tract or root (cerebropontine angle). Rule-out multiple sclerosis, especially in young adults.	Etiologic factors such as trauma or surgery in the painful area. Order MRI if the area is intact to rule-out peripheral or central lesions.	Small cutaneous vesicles or scarring, usually affecting V1. Loss of normal skin color. Corneal ulceration can occur. Sensory changes in affected area (e.g., hyperesthesia, dysesthesia).	Rule-out salivary gland dysfunction (xerostomia) or tumor, Sjögren's, candidiasis, geographic or fissured tongue, and chemical or mechanical irritations. Nutrition and menopause.
Treatment	Medication: anticonvulsants (e.g., carbamazepine, gabapentin); antidepressants (e.g., amitriptyline, nortriptyline, desipramine); nonopiate analgesics, botulinum toxin. Combination of baclofen and anticonvulsants can produce good results. Surgery: microvascular decompression of trigeminal root, ablative surgeries (e.g., rhizotomy, gamma knife).	Medication: anticonvulsants (e.g., carbamazepine, gabapentin); antidepressants; nonopiate analgesics; topical agents (e.g., lidocaine 5% patches). Surgery: ablative surgeries (e.g., rhizotomy, gamma knife).	Medication: acyclovir (acute phase) anticonvulsants, antidepressants; nonopiate analgesics; topical agents (e.g., lidocaine 5% patches). Surgery: ablative surgeries (e.g., rhizotomy, gamma knife).	Medication: anticonvulsants, benzodiazepines, antidepressants; nonopiate analgesics; topical agents (e.g., lidocaine, mouth washes). Cognitive-behavior: biofeedback, relaxation, coping skills.

of "incorrect" glasses, correcting the refractive errors helps few patients. The eye is rarely the source of headache localized to the eye and orbit without clinical signs, such as red eye, or symptoms, such as decreased vision or a history of eye trauma. If the basic eye history and examination are normal, an intraocular cause for the pain is less likely. However, in some ocular causes of eye pain, the eye is superficially normal. The pain specialist should be able to recognize the features of these uncommon causes of eye pain.

Ocular Causes for Eye Pain with a White Eye ("Quite Eye") Other causes of eye pain include acute angle-closure glaucoma, anterior or posterior uveitis, posterior scleritis, intraocular tumors, optic neuritis, and corneal disorders (Tables 67.17 and 67.18).

Glaucoma. Glaucoma may cause acute or chronic eye pain. Glaucoma is a broad term for a large array of clinical disorders that are characterized by damage to the optic nerve with visual field defects generally associated with elevated intraocular pressure. Pain in glaucoma is entirely a function of the rate of rise of intraocular pressure, so only acute forms are likely to be painful.[17] The aqueous humor is produced by the ciliary body in the posterior chamber; it flows through the pupillary aperture and exits the anterior chamber through the trabecular meshwork in the anterior chamber angle. Disorders of elevated intraocular pressure are of two types: open angle, in which the aqueous humor can flow through the trabecular meshwork, and angle-closure, in which the iris or some other structure is physically blocking access to the trabecular meshwork. These types are further subdivided into primary and secondary forms.[18]

Primary open-angle glaucoma is the most common type of glaucoma and is almost always entirely asymptomatic. Therefore, this form of glaucoma is rarely the cause of ocular pain in patients with a "quite eye."[18] Interestingly, the miotic eye drops used to treat primary open-angle glaucoma are more likely to cause eye and brow ache. In contrast, acute angle-closure glaucoma is associated with severe, acute eye pain. Fortunately, it is far less common than primary open-angle glaucoma. Even though patients with angle-closure glaucoma can have a normal appearing eye, they typically present with a red eye, edematous cornea, blurred vision, a pupil that is often partially dilated, irregularly shaped, and poorly reactive to light, and intense eye pain.[19,20] The pain may radiate widely and often is associated with nausea and vomiting. Teeth have been extracted to treat this disorder, as well as laparotomies for the accompanying gastrointestinal complaints.

TABLE 67.14

PARANASAL, PERIOCULAR, PERIAURICULAR, AND HEAD AND NECK CANCER PAIN

Diagnosis	Paranasal sinus pain	Periocular pain	Periauricular pain	Head and neck cancer
Diagnostic features	Bilateral or unilateral throbbing or pressure frontal area pain, exacerbated by leaning forward or palpitation over the sinus.	Pain or tenderness with or without eye movements, deep orbital pain, and referred pain.	Diffuse aching or sudden pain with or without aural discharge (e.g., otitis media).	Variety of symptoms. Pain may be due to tumor, nerve compression, secondary infection, secondary myofascial pain, deafferentation, radiotherapy, chemotherapy.
Diagnostic evaluation	History of chronic allergies, frequent upper respiratory infections, sinusitis, headaches of various types, sinus surgery Refer to ear, nose, and throat specialist for endoscopic and/or CT study (e.g., sinus opacification).	Examine eyelids, lacrimal function, conjunctiva, and sclera. Ophthalmoscopy and ophthalmology referral. Rule-out primary headache, temporal arteritis, orbital pseudotumor.	The area is innervated by multiple cranial and cervical nerves so complete functional and structural exam necessary (e.g., inspect tympanic membrane, TMJ, and myofascial). CT and MRI invaluable for mastoiditis and cholesteatoma.	Complete evaluation by multidisciplinary team, CT, MRI, endoscopy, biopsy and surveillance. Treatment coordination by oncologist.
Treatment	Ear, nose, and throat specialist evaluation/ treatment Medication: sinusitis-topical decongestants; systemic antibiotics. Chronic sinus pain-NSAIDs; nonopiate analgesics; topical agents (lidocaine spray); anticonvulsants, antidepressants; botulinum toxin. Surgery	Proper ophthalmologic evaluation and treatment. Medication: NSAIDs; nonopiate analgesics; systemic antibiotics, topical corticosteroids, botulinum toxin across forehead and glabellar areas in selected cases. Surgery	Proper ear, nose, and throat specialist evaluation and treatment. Medication: NSAIDs; nonopiate analgesics; systemic antibiotics, topical corticosteroids, botulinum toxin in selected cases. Surgery	Oncologist evaluation and treatment. Medication: anticonvulsants, antidepressants, opiate or nonopiate analgesics, topical agents, muscles relaxants. Surgery: ablative surgeries.

Temporal arteritis
Eye pain, headache, and lung cancer

Early diagnosis of this disease is important; key features are summarized in Table 67.17.[21,22] This disease is easily diagnosed, and patients should be referred immediately to an ophthalmologist because it can usually be quickly reversed.

Corneal Disorders. Corneal abrasion is a scraping away or denuding of the corneal surface by external forces on the corneal surface. Eye pain caused by corneal disease is typically described as "scratchy" or a "foreign body sensation." Corneal epithelial defects typically occur after trauma, after ultraviolet light keratitis, in contact lens wearers, or from corneal infections. Some patients with corneal disease may present with no conjunctival signs and with an apparently normal eye; however, most patients have some visible external findings such as red eye, corneal opacity, or abrasion. A corneal abrasion can cause photophobia and excruciating eye pain that often radiates to other parts of the head and face.[17,20] Corneal abrasions are best seen by placing a drop of fluorescein in the eye and looking through a slit lamp using a cobalt blue light. If the cornea is abraded, antibiotic ointment should be applied.[16,23] However, most abrasions are self-limited and heal within 24 to 48 hours.[23]

Uveitis. The uveal tracts are the pigmented middle ocular tissue, iris, ciliary body, and choroids. Uveitis could have a pure anterior involvement iritis, which occurs in half the cases. These patients may present with eye pain, photophobia, and decreased vision with a relatively quite appearing eye. The other patients with uveitis have posterior involvement chorioretinitis with inflammation of the ciliary body, the choroids, or both. Posterior uveitis is more likely to cause visual loss than anterior uveitis.[24,25]

TABLE 67.18

PAIN IN OR AROUND THE EYE: "QUITE EYE" AND OPHTHALMOLOGIC FINDINGS

Ocular processes—glaucoma, corneal disease, uveitis, scleritis, intraocular tumors, ocular ischemia, hemorrhage
Processes affecting the optic nerve—optic neuritis, ischemic, compressive or infiltrative optic neuropathy
Orbital processes—tumor, infection, inflammatory, vascular, posttraumatic
Cavernous sinus/retro-orbital processes—aneurysm, tumor, thrombosis, infection, inflammatory, C-C fistula, posttraumatic
Intracranial processes—tumor, pseudotumor cerebri, infection, inflammatory, vascular, intracranial pressure changes

Scleritis. Inflammation of the deeper layers of the eye wall, known as scleritis, usually presents with severe, intense, and boring pain.[23–25] The pain is often localized to the eye but may radiate into the sinuses, jaw, or frontal region. The sclera may appear thin or have a bluish hue, and the globe is usually tender. About half the cases are idiopathic, with other causes including herpes simplex virus, herpes zoster, and collagen vascular disease.[23]

Intraocular Tumors. Primary intraocular tumors typically do not cause pain, but orbital extension of tumors may produce trigeminal involvement (neuropathic pain). Intraocular tumors may also produce pain by secondary inflammatory reaction (uveitis) or elevated intraocular pressure induced by the tumor.

Ocular Causes of Eye Pain with a Red (Inflamed) Eye.[16,23]

Conjunctivitis. Conjunctivitis, or "pink eye," is the most common cause of a red, irritated eye. Because the conjunctiva has fewer pain fibers than the cornea, conjunctivitis is generally less painful than corneal epithelial defects, and visual acuity is usually only slightly reduced. The three most common types of conjunctivitis are viral, allergic, and bacterial. The viral type is often associated with an upper respiratory tract infection, cold, or sore throat, with adenovirus infection being the most common viral cause. The condition is characterized by a watery discharge, mild foreign-body sensation, and photophobia. Bacterial infection tends to produce more mucopurulent exudates. Allergic conjunctivitis is extremely common and is often mistaken for infectious conjunctivitis. Itching, redness, and epiphora are typical. The palpebral conjunctiva may become hypertrophic with giant excrescences called cobblestone papillae. Irritation from contact lenses or any chronic foreign body can also induce formation of cobblestone papillae.

Keratoconjunctivitis Sicca. Also known as "dry eye," keratoconjunctivitis sicca produces a burning, foreign-body sensation, as well as injection and photophobia. In mild cases, the eye appears surprisingly normal, but tear production, as measured by wetting of a filter paper (a Schrimer strip), is deficient. A variety of systemic drugs, including antihistamines, anticholinergic, and psychotropic medications, cause dry eye by reducing lacrimal secretion. Disorders that involve the lacrimal gland directly, such as sarcoidosis or Sjögren syndrome, also cause dry eye. Patients may develop dry eye after radiation therapy if the treatment field includes the orbit.

Blepharitis. Blepharitis refers to inflammation of the eyelids. The most common form occurs in association with acne rosacea or seborrheic dermatitis. The eyelid margins are usually colonized heavily by staphylococci. Upon close inspection, they appear greasy, ulcerated, and crusted with scaling debris that clings to the lashes. A chalazion is a painless, granulomatous inflammation of the meibomian gland that produces a pea-like nodule within the eyelid. Basal cell, squamous cell, or meibomian gland carcinoma should be suspected for any nonhealing, ulcerative lesion of the eyelids.

Dacryocystitis. Dacryocystitis is inflammation of the lacrimal drainage system and usually occurs after obstruction of the system. It can produce epiphora and ocular injection. Gentle pressure over the lacrimal sac evokes pain and reflux of mucous or pus from the tear puncta.

Herpes Simplex Infection. Primary ocular infection is generally caused by herpes simplex type 1, rather than type 2. It manifests as a unilateral follicular blepharoconjunctivitis and is easily confused with adenovirus conjunctivitis, unless vesicles appear on the periocular skin or conjunctiva. A dendritic pattern of corneal epithelial ulceration revealed by fluorescein staining is pathogno-

monic for herpes infection but is seen in only a minority of primary infections. Recurrent ocular infection arises from reactivation of the latent herpes virus.

Herpes Zoster Infection. Herpes zoster recurrence from reactivation of latent varicella virus causes a dermatomal pattern of painful vesicular dermatitis, which is covered in detail elsewhere in this text.

Disorders with Eye and Periocular Pain as the Primary Presentation. Several facial pain syndromes present with prominent ophthalmologic signs and symptoms (Table 67.19). The more common ones are discussed below.

Primary Headache Disorders (see Chapter 61). Many of the primary headache disorders can present with frontotemporal area head pain or sometimes with periorbital and eye pain (migraine, tension-type headache). Some of these disorders have a primary presenting symptom of pain in and around the eye (cluster headache, paroxysmal hemicrania, conjunctival injection and tearing [SUNCT], and short-lasting unilateral neuralgiform headache attacks with autonomic symptoms [SUNA]). In addition to the pain, other signs and symptoms consistent with the diagnosis of a headache disorder are often present (i.e., aura, autonomic phenomenon, etc.).

Carotid Artery Disease. Head, face, and neck pain are frequently reported by patients with subarachnoid hemorrhage, intracranial aneurysms, arteriovenous malformations, and carotid and vertebral artery dissections. Patients describe headache, eye pain, facial pain, and neck pain. Associated symptoms may also be present, depending on the vascular source of the pain.

Subarachnoid hemorrhage can also present with meningismus, neck pain, nausea, altered consciousness, and seizure. The headache and facial pain is highly variable, ranging from mild pain to the "first and worst headache of my life."

Aneurysms can present with head and face pain with cranial nerve palsies, visual disturbances and sudden blindness, and retinal abnormalities. Imaging and lumbar puncture are often warranted for the diagnosis before definitive treatment.[26]

The primary symptom of carotid artery dissection is often headache, either alone or with other symptoms. Frequently, carotid artery dissection also presents with eye pain, facial pain, and neck pain. The headache can be focal or diffuse, whereas the facial pain is generally ipsilateral. Other findings may be pulsatile tinnitus, visual disturbance, central retinal artery occlusion, and Horner syndrome.

Orbital Inflammatory Pseudotumor. Orbital inflammatory pseudotumor is a pain syndrome thought to be caused by idiopathic orbital inflammation, which presents typically with eye pain and other orbital findings (proptosis, injection, chemosis, or ophthalmoplegia). The pain may be either unilateral or bilateral.[16,20,23] Imaging (CT or MRI) typically shows evidence of idiopathic inflammation, enlargement, and contrast enhancement of orbital structures suggesting pathologic involvement. Orbital biopsy may be required to exclude other causes.

Idiopathic Intracranial Hypertension ("Pseudotumor Cerebri"). Idiopathic intracranial hypertension ("pseudotumor cerebri") and facial pain occur primarily in young, obese women of childbearing age. The common presenting findings are daily headache, transient visual obscurations (seconds), pulsatile intracranial noises, and double vision.[16,20] Typically, visual acuity and color representation are preserved, but many patients have optic nerve-related, visual-field defects (e.g., enlarged blind spots, generalized constriction, and inferior nasal field loss). Several predisposing factors have been identified, including the use of oral contraceptives, anabolic steroids, tetracycline, and vitamin A.

Tolosa-Hunt syndrome. Tolosa-Hunt syndrome is an idiopathic inflammatory granulomatous process involving the cavernous sinus. Patients present with painful, steroid-responsive ophthalmoplegia and have episodic, unilateral orbital, or retro-orbital pain. The ophthalmoplegia (CN II, III, IV, VI) occurs simultaneously or within the first 2 weeks after the onset of pain. Facial sensation and visual acuity may be diminished.[16,27] Other pathologic conditions should be excluded by physical examination or neuroimaging. Tolosa-Hunt syndrome is thought to be caused a nonspecific, granulomatous inflammatory infiltrative process with no obvious specific pathologic trigger in the region of the posterior superior orbital fissure, orbital apex, or cavernous sinus. The syndrome typically responds quickly (within 72 hours) to treatment with steroids.

Raeder's Paratrigeminal Syndrome (Paratrigeminal Oculo-Sympathetic Syndrome). This uncommon facial pain syndrome presents with first division trigeminal neuropathic pain, sensory loss, or both, sympathetic dysfunction (miosis, ptosis, or both), but with normal forehead sweating (compared to Horner syndrome). The symptom cluster is localized to the middle cranial fossa medial to the trigeminal ganglion and lateral to the anterior clinoid process. Neuroimaging is necessary and important and, if negative, should be repeated over a period of time to avoid missing an underlying abnormality. This syndrome is not specific to any known pathologic condition.[20]

Herpes Zoster Ophthalmicus (Postherpetic Neuralgia). Herpes zoster ophthalmicus is caused by reactivation of latent herpes zoster virus in the gasserian ganglion, which typically involves the ophthalmic division of the trigeminal nerve. Ocular symptoms can occur after zoster eruption in any branch of the trigeminal nerve but are particularly common when vesicles form on the nose, reflecting nasociliary nerve involvement (Hutchinson's sign). Cranial neuropathies can also occur, usually weeks after the skin eruptions.

Temporal Arteritis. Temporal arteritis presents with periorbital or temporal headache, facial pain, and occasional neck pain. There may be "jaw claudication," scalp tenderness, and visual loss. The headache is mild to severe and of acute or gradual onset; the patient is typically without a history of headache or of changes in headache pattern. Occulomotor disturbances, dizziness, vertigo, and hearing impairment and cervical myelopathy may be present, and very frequently, the superficial temporal artery is thickened, nodular, and pulseless.

Patients with temporal arteritis are generally male, smokers, and over age 50. The disorder may be associated with polymyalgia rheumatica, especially in elderly patients. If untreated or inad-

TABLE 67.19

FACIAL PAIN SYNDROMES WITH PREDOMINANT OPHTHALMOLOGIC FINDINGS

Ocular motor nerve palsy
Carotid artery disease
Orbital inflammatory pseudotumor
Increased intracranial pressure and pseudotumor cerebri
Intracranial hemorrhage and stroke
Intracranial arteriovenous malformation
Trigeminal neuropathies
Tolosa-Hunt syndrome
Raeder's paratrigeminal syndrome
Gradenigo's syndrome
Postherpetic neuralgia

equately treated, it may result in unilateral or bilateral blindness, brainstem strokes, and transient ischemic attacks. A careful history and physical examination gives a high index of suspicion for this diagnosis. Additionally, blood studies (elevated Erythrocyte sedimentation rate, C-reactive protein) and temporal artery biopsy may be necessary. However, biopsies can have false negatives as a result of skipped lesions; therefore, bilateral biopsies are often recommended. Treatment consists of immediate high-dose corticosteroids.

Temporomandibular Disorders

Temporomandibular disorder (TMD) typically presents with facial pain, limited and dysfunctional mandibular movements, temporomandibular joint noises (clicking, popping, crepitus), and a change in the way the teeth meet on mouth closure. In addition, reports of eye and periorbital pain, ear pain and stuffiness, headache, neck pain, dizziness, and limitation of neck movement are often present. For a more detailed description of evaluation and treatments for TMD, see the section on TMD in this chapter.

Pain Referred to the Eye from Intracranial Disease

Pain from intracranial diseases, especially those involving the dura and cavernous sinus, may be referred to the eye and orbit. The ophthalmic division of the trigeminal nerve serves the eye and the orbit. Interestingly, a tentorial-dural branch joins the ophthalmic division in the cavernous sinus, receiving sensory innervations from much of the intracranial dura, the arteries at the skull base, and the major venous structures. Inflammation, neoplasm, or ischemia involving intracranial structures may cause pain, which is often referred to as the ipsilateral eye. Therefore, eye pain that remains unexplained after a thorough ophthalmic evaluation may require neuroimaging to rule out an intracranial disorder.[16,23,28]

Pain Attributed to Disorders of the Ear

Otalgia is defined as pain localizing to the ear. Primary otalgia is pain that originates from the ear (see Table 67.14). Referred otalgia does not have a distinct otologic cause and is also called secondary, nonotogenic otalgia. Although earache is a frequent symptom, systematic population-based studies of the epidemiology of the different forms of pain associated with diseases of the ears have not been conducted. However, 97% of cases of otitis media present with earache,[29] and otalgia was found to be referred in as many as 50% of adults in a general medicine population.[29] An analysis of the symptoms of nasopharyngeal carcinomas revealed that deafness and earache, encountered in 85% of patients, were the most common symptoms beside swelling of the throat.[30]

The cranial and cervical nerves supply sensory innervation to the ear. The auriculotemporal branch of the mandibular division of the trigeminal nerve supplies sensation to the anterior aspect of the auricle helix (including the tragus), the anterior aspect of the external auditory canal, and the anterior aspect of the lateral tympanic membrane. The great auricular nerve derived from the cervical nerve plexus (C2 and C3) innervates the remaining parts of the lateral surface of the auricle and the medial surface as well. Afferents from facial, glossopharyngeal, and vagus nerves supply the posterior aspect of the external auditory canal, the posterior aspect of the lateral tympanic membrane, the posteromedial aspect of the auricle, and a patch of skin on the mastoid process. The middle ear receives sensory afferents primarily from the glossopharyngeal nerve as part of the tympanic plexus. The sensory afferents of the tympanic plexus are largely formed by Jacobson's branch of the glossopharyngeal nerve. The vestibulocochlear nerve does not mediate pain afferents from the inner ear because it does not carry pain fibers. Therefore, marked inner ear pathology may develop without otalgia (see Table 67.14).[30,31]

In the ear's embryologic development, the otic vesicles come to rest between branchial nerves 1, 2, 3, and 4. The sensory and motor nerves of these arches are CNs V, VII, IX, and X, respectively.[32–34]

Four distinct regions of afferent innervations of the head and neck sites refer pain to the ear: (1) the inferior gingiva, floor of the mouth, inferior buccal mucosa, and the anterior two thirds of the tongue, all of which are innervated by the third branch of CN V; (2) the tonsillar fossae, lateral bases of the tongue, and some of the inferior nasopharynx innervated by branches of CN IX; (3) the posterolateral oropharynx, hypopharynx, medial base of the tongue, and occasionally a small portion of the inferior nasopharynx innervated by mixed branches of CNs IX and X; and (4) the supraglottic larynx and lingual and laryngeal surfaces of the epiglottis innervated solely by branches of CN X.[32–34]

Otalgia may have otologic (primary) or nonotologic (secondary) causes. A systemic approach to diagnosis is necessary to prevent overlooking a serious condition and to establish the diagnosis and proper therapy.

Primary Otalgia

Primary otalgia is pain with a cause in the ear. Usually, it can be diagnosed by examination of the pinna, auditory canal, and tympanic membrane.

Pinna

Primary pinna pain may be caused by injuries or trauma, such as lacerations, burns, frostbite, or infections. Persistent minor lesions should be biopsied to rule out underlying malignancy.

External Auditory Canal

Otitis externa, sometimes referred to as "swimmer's ear," is an inflammation of the external auditory meatus with resulting edema, otorrhea, pruritus, and otalgia. The otalgia of otitis externa is mediated by sensory afferents of the auriculotemporal nerve, the complex of facial glossopharyngeal and vagus nerves, and the cervical nerves. External otitis arises from acute inflammation after an ear trauma, inadequate cleansing of the external auditory canal, or lengthy contact with liquids in bacterially contaminated water, especially in lakes or swimming pools. Ear wax buildup also may be responsible for earache and pressure in the ear.

The diagnosis is based on physical examination of the external auditory canal for edema, erythema, debris (desquamated epithelium), and otorrhea. Physical findings may be minimal, with only slight edema or hyperemia. In such cases, a history of recent water exposure or preceding ear instrumentation may be useful. Management includes suctioning of any debris or fluids from the external auditory canal, treatment with antibiotic and steroid otic drops, and dry ear precautions.[29,35]

Malignancy must be considered when evaluating a patient with otalgia and an apparent refractory otitis externa. A primary neoplasm of the external auditory canal will too often be misdiagnosed as an otitis externa, potentially resulting in a costly delay in treatment. Patients with malignant otitis externa may have severe otalgia, a severe form of otitis externa that has involved the bone and marrow of the skull base. It is usually found in diabetics or otherwise immunocompromised patients, so this diagnosis must be carefully considered in these patients with otalgia. Timely diagnosis and prompt referral of a patient with malignant otitis externa is crucial because progression from bone involvement to death is rapid.[29,35]

Middle Ear

Infection of the middle ear, otitis media, is likely the most common cause of primary otalgia.[36] The pain from inflamed mucosa

in these patients is mediated by way of the glossopharyngeal nerve, which supplies sensation to the middle ear and medial aspect of the tympanic membrane. An acute infection of the mucous membrane of the middle ear usually stems from an infection of the upper air passages with dysfunction of the eustachian tube. Rhinitis and adenoid inflammation may also be causes of acute otitis media. The tympanic membrane will be red and swollen. Occasionally, a purulent discharge is present.

Gradenigo syndrome, defined as the triad of otalgia, otorrhea, and abducens nerve palsy, results from bacterial infection of the petrous apex air cells. Such an infection causes dysfunction of the abducens nerve because it passes through a dural tunnel in proximity to the petrous apex. These complications must be considered in a patient with otalgia and a history of recent otitis media.

Other Primary Causes

Primary neoplasms arising from within the ear or skull base may cause primary otalgia. Such lesions may originate from the skin of the external ear or from glandular tissues of the external or middle ear. A careful otologic and CN examination will help make the diagnosis. The sternocleidomastoid muscle attaches to the mastoid process, and overuse or spasm may manifest as a dull, aching otalgia.

Secondary (Referred) Otalgia

In the absence of otologic factors, the pain is termed secondary, nonotologic, or referred otalgia. The classic definition of referred pain is pathology in one part of the body that gives rise to pain in another nonpathologic site. Referred ear pain may result from pathologic factors involving the sensory supply of the CN V, IX, and X and the spinal nerves C2 and C3. Irritation of the sensory branch of the facial nerve (CN VII) is not true reflex or referred pain. It is usually the initial symptom of Bell palsy or Ramsay Hunt syndrome, and the diagnostic finding of facial paralysis usually occurs within 24 to 48 hours after the onset of pain.[33,34]

Trigeminal Nerve Referred Pain. Pain referred to the ear from the second and third divisions of the trigeminal nerve is usually located anterior to the tragus and along the anterior wall of the external auditory canal, which is supplied by the auriculotemporal nerve. Any disease process involving the anterior two thirds of the tongue, the floor of the mouth, gingiva, mandible, anterior half of the palate, teeth, infratemporal fossa, paranasal sinuses, and the submandibular or parotid glands may result in trigeminal-nerve referred pain. The most common otalgia of fifth nerve origin are dental disorders.

Glossopharyngeal Nerve (CN IX) Referred Pain. Referred pain over the glossopharyngeal nerve may result from infections, ulcerations, and tumors of the palatine tonsil, nasopharynx, eustachian tube, posterior half of the palate, and the posterior third of the tongue. This pain is usually felt deep in the ear, in contrast to the more superficially located pain mediated by the trigeminal nerve. Such ear pain is frequently the only symptom after tonsillectomy and adenoidectomy.

Vagus Nerve (CN X) Referred Pain. Ulcerative lesions due to malignancy or chronic infections in the larynx or hypopharynx may irritate the superior laryngeal branch of the vagus nerve, causing pain referred to the ear.

Spinal Nerves C2 and C3 Referred Pain. Pain in the mastoid area and over the posterior portion of the pinna is mediated by the great auricular nerve, which is derived from the spinal nerves C2 and C3. The most common cause of cervical pain is trauma to the cervical spine. Cervical arthritis, cervical disks, cervical tumors, and muscle traction headache should be considered in the differential diagnosis. The differential diagnosis for referred otalgia is extensive: the more common causes are described below.

Temporomandibular Disorders. In addition to otalgia, otologic manifestations of temporal mandibular joint (TMJ) disorders can include aural fullness, tinnitus, and vertigo.[4,6,37] A study of approximately 450 patients with TMJ pain found that otalgia was the presenting symptom in 48%.[34] In this study, the TMJ syndrome (and hence otalgia) was successfully managed with conservative therapies such as heat, massage, patient education, occlusal splints, and pain control.

Eagle Syndrome. Eagle syndrome is defined as otalgia, facial pain, sore throat, globus, or dysphagia secondary to elongation of the styloid process or ossification of the stylohyoid ligament. The abnormal styloid process may produce pain through different mechanisms, one of which is direct compression and irritation of the trigeminal, facial, glossopharyngeal, or vagus nerves. The styloid process is typically 20 to 30 mm long. However, 4% of the population has a styloid process longer than 30 mm and of these, only 4% are symptomatic. The degree to which an elongated styloid process causes pain is somewhat poorly defined and controversial.[6,38]

Gastroesophageal Reflux Disease. A large number of symptoms have been linked to extraesophageal reflux of gastric contents, including laryngitis, hoarseness, pharyngitis, bronchospasm, laryngospasm, and chronic cough.[39] Gastroesophageal reflux disease (GERD) can cause otalgia by irritating the upper aerodigestive tract in the sensory distribution of the glossopharyngeal and vagus nerves. Because these nerves also innervate the ear, irritation and damage from acidic gastric secretions may be perceived as originating within the ear. The reflux of gastric secretions can also potentially extend superiorly to the eustachian tubes, irritating the ear directly. The diagnosis of reflux-related otalgia should be considered in all patients with otalgia, a normal otoscopic exam, and other symptoms of GERD. Consultation with a gastroenterologist may be beneficial in managing these patients.[39,40]

Neoplastic Process (see Table 67.14). Malignancies of the upper aerodigestive tract and tumors in various sites of the head and neck can cause otalgia. Tumors on the anterior aspect of the tongue can also manifest as otalgia if they affect the chorda tympani branch of the facial nerve. Nasal and sinus malignancies may present with otalgia secondary to eustachian tube dysfunction or direct neural involvement. In the latter case, the otalgia is mediated by the afferents from the posterior lateral nasal nerves by way of the sphenopalatine ganglion, which is associated with the second division of the trigeminal nerve. Lesions arising from the infratemporal fossa can cause otalgia by involvement of Arnold's nerve (the auricular branch of vagus nerve) or Jacobson's nerve (the tympanic branch of the glossopharyngeal nerve). Many of these patients face a costly delay in diagnosis if malignancy is not considered as a cause.

Treatment of referred otalgia must be directed specifically to the relevant local causes. Such causes may include pulpitis, periapical dental abscess, glossitis, sinusitis, benign or malignant growth in the mouth or sinuses, dental malocclusion, Ramsay Hunt syndrome, tonsils, hypopharynx, or larynx inflammation, or growths in the nasopharynx or eustachian tube.

Pain Attributed to Disorders of the Nose and Paranasal Sinuses (see Table 67.14)

These disorders are grouped together because the paranasal sinuses communicate with the nasal passages through small ostia. Most important among these disorders is sinusitis as it is com-

monly linked to headache by physicians and the general public alike. "Sinus trouble" as a cause of headache is a source of many controversies, including how to name them: "sinus headache," "rhinosinusitis headache," and "sinogenic facial pain" are used to refer to the same disorder.

Rhinosinusitis

Rhinosinusitis is the inflammation of the nasal passages (rhinitis) and one or more of the paranasal sinuses (maxillary, ethmoid, frontal, or sphenoid). The term is more accurate than "sinusitis" because rhinitis usually precedes sinusitis, the mucosa of the nose and sinuses are contiguous, both conditions may involve nasal obstruction and discharge.[41,42]

Sinusitis is overdiagnosed as a cause of headache and facial pain because of the belief that pain over the sinuses must be related to the sinus. Many of the 60% of patients with unrecognized migraine attribute their symptoms to sinusitis.[41,43] Rhinosinusitis is an uncommon cause of facial pain: more than 80% of patients with purulent secretions visible on nasal endoscopy have no facial pain, most patients with nasal polyposis do not have pain, and facial pain persists in a large proportion of patients after endoscopic sinus surgery.[44–47] Paradoxically, sinus disease also tends to be underestimated, and a potentially dangerous condition, sphenoid sinusitis, is frequently missed.[48]

Clinical Features. Diagnostic criteria for rhinosinusitis are defined in the ear, nose, and throat literature.[49] In this diagnostic scheme, rhinosinusitis is subdivided into acute, recurrent acute, subacute, chronic, and acute exacerbations of chronic. Acute sinusitis lasts from 1 day to 4 weeks, subacute sinusitis from 4 to 12 weeks, and chronic sinusitis for more than 12 weeks. Headache is considered a minor criterion for the diagnosis of acute rhinosinusitis, and headache in the absence of other diagnostic criteria is not considered to be diagnostic of sinusitis.[41,50,51]

Key points in the history of pain secondary to rhinosinusitis are exacerbations of pain during an upper respiratory tract infection, an association with rhinological symptoms, pain that worsens when flying or skiing, and pain in response to medical treatment. Rhinosinusitis usually presents with facial tenderness and pain, nasal congestion, and purulent nasal discharge. Common signs and symptoms include anosmia or hyposmia, pain on mastication, and halitosis. Most cases of infectious rhinosinusitis that last less than 7 days are viral. Acute bacterial sinusitis in adults most often presents with 7 or more days of purulent anterior rhinorrhea, nasal congestion, postnasal drip, facial or dental pain or pressure, and cough, frequently at nighttime. Although approximately 50% of adults have fever and 60% of children have headache, headache, facial pain, and fever often are of little value in diagnosing sinusitis. Williams et al.[52] found that maxillary toothache was highly specific in making the diagnosis of rhinosinusitis: 93% of their patients with toothache had rhinosinusitis. However, only 11% of their patients had maxillary toothache.[52,53]

The headaches associated with rhinosinusitis are usually continuous. The location of the pain and the position that improves the headache varies on the sinus involved (Table 67.20).

Pain in acute maxillary sinusitis is usually in the cheek, gums, and maxillary teeth on the affected side. Acute frontal sinusitis causes frontal headache with tenderness over the sinus and on the medial side of the orbital floor, under the supraorbital ridge, where the frontal sinus is thinnest. Frontal sinusitis can result in brain abscess, meningitis, subdural or epidural abscess, osteomyelitis, orbital edema, and orbital cellulitis. Acute ethmoid sinusitis typically produces pain in between the eyes. Coughing, straining, and lying supine can worsen the pain, whereas keeping the head upright lessens it. Complications of ethmoid sinusitis include meningitis, orbital cellulites, and cavernous sinus thrombosis.[54]

TABLE 67.20

INTERNATIONAL HEADACHE SOCIETY CRITERIA FOR ACUTE SINUS HEADACHE

- Diagnostic criteria: pain in one or more regions of the head, face, ears, or teeth.
- Clinical, laboratory, or imaging evidence of acute rhinosinusitis (e.g., purulence in the nasal cavity, nasal obstruction, fever, CT, MRI, or fiberoptic nasal endoscopy findings).
- Simultaneous onset of headache and rhinosinusitis.
- Headache lasts <7 days after remission or successful treatment of acute rhinosinusitis.

It is necessary, therefore, to differentiate headaches caused by rhinosinusitis from so-called "sinus headaches," which are chronic headache attacks fulfilling the criteria for migraine without aura with prominent autonomic symptoms in the nose or migraine without aura triggered by nasal changes.

Acute sphenoid sinusitis, which accounts for only 3% of all cases of acute sinusitis, is frequently misdiagnosed.[48] Although sphenoid sinusitis rarely causes headache, it can lead to marked morbidity and mortality and so must be identified early and managed aggressively.

As mentioned above, the cavernous sinus is lateral to the sphenoid sinus. The cavernous sinus contains the internal carotid arteries and the third, fourth, fifth, and seventh CNs. The maxillary division of the CN V may indent the wall of the sphenoid sinus. The sphenoid walls can be extremely thin, and sometimes the sinus cavity is separated from the adjacent structure by just a thin mucosal barrier. Because of this proximity, infection may spread to these structures and present as a central nervous system infection or neurologic catastrophe.[48,54]

Headache is always present in acute sphenoid sinusitis and it may be frontal, occipital, or temporal and most commonly is a combination of these locations. Periorbital pain is common and vertex pain is rare. Nasal pain and discharge are present in only 30% of cases, and fever occurs in more than 50% of patients. Also, pain or paresthesias in the facial distribution of the fifth nerve and photophobia or eye tearing suggest sphenoid sinusitis.[48] The headache and associated symptoms may lead to a misdiagnosis of migraine, meningitis, trigeminal neuralgia, or brain tumor. A severe, intractable, new-onset headache that interferes with sleep and is not relieved by simple analgesics should raise the suspicion of sphenoid sinusitis. Neuroimaging is necessary for a definitive diagnose. Complications include bacterial meningitis, cavernous sinus thrombosis, subdural abscess, ophthalmoplegia, and pituitary insufficiency.[48,54]

Acute sinus headache is defined by the International Headache Society (IHS) diagnostic criteria in the setting of an infectious process requiring verification through imaging and confirmation by response to appropriate antibiotics. The IHS established the following diagnostic criteria for acute sinus headache (rhinosinusitis headache) (see Table 67.20)[1]:

A. Purulent discharge in the nasal passage, either spontaneous or by suction
B. Pathologic findings on radiographic examination, CT, or transillumination
C. Simultaneous onset of headache and sinusitis
D. Headache location (see Table 67.3 for location of pain with infection of corresponding paranasal sinus)
E. The disappearance of the headache after treatment for acute sinusitis

These criteria may not be valid for diagnosing sphenoid sinusitis because the purulent discharge is often missing and headache may precede sinus drainage. The IHS has not validated chronic

sinusitis as a cause of headache or facial pain unless it relapses into an acute stage.

Obviously, the term "acute sinus headache" or what is referred to as "rhinosinusitis headache" in this chapter does not address the primary headache disorder with secondary nasal symptomatology, commonly referred to as "sinus headache."[41,55,56]

Plain sinus radiographs can diagnose acute maxillary or frontal sinusitis but are often inadequate for ethmoid or sphenoid sinusitis. CT is the optimal imaging study to assess the paranasal sinuses. The mucosa of the normal, noninfected sinus approximates the bone so closely that it cannot be visualized on CT. Therefore, any soft tissue seen within a sinus is abnormal. CT may reveal mucosal thickening, sclerosis, clouding, or air-fluid levels. Scans of the sinuses without contrast in the coronal plain are highly sensitive for detecting nasal and paranasal sinus disease, including disease in the ethmoid and sphenoid sinuses.[57] The prevalence of reversible sinus abnormalities visualized by CT in patients who have the common cold is high. This fact suggests that CT may not be specific for bacterial infections. Anterior ethmoid sinus infection is found in every patient who had frontal or maxillary sinusitis.

MRI is more sensitive than CT in detecting fungal infections. In MRI, T2-weighted images are highly sensitive for detecting retained fluid and inflamed tissue of the sinuses, a fact that may lead to exaggerating the importance of otherwise unremarkable sinus disease, such as mild inflammation, small polyps, and retention cysts. Transillumination and ultrasonography of the sinuses have low sensitivity and specificity for detecting similar findings. Diagnostic endoscopy with the flexible fiberoptic rhinoscope permits direct visualization of the nasal passages and sinus drainage areas.[58]

Differential Diagnosis. Migraine and tension-type headache are often confused with true sinus headache because of their similar locations.[43,55,56] Some patients, in addition to having all the features of migraine without aura, have head pain in the face, associated congestion of the nose, and headache triggered by weather changes. These patients do not have purulent nasal discharge or other diagnostic criteria of acute rhinosinusitis. The diagnostic criteria of rhinosinusitis and migraine are similar. Although facial pressure or pain, facial congestion, and nasal blockages are considered major criteria for rhinosinusitis, headache and fatigue are minor criteria, meaning that these symptoms have less diagnostic value but are not necessarily less frequent or less intense. In migraine, the seminal emphasis for diagnosis is the severity, quality, and location of a headache associated with gastrointestinal or sensory symptoms. Nasal symptoms, including congestion, facial pressure or pain, and rhinorrhea, are commonly reported symptoms associated with migraines but are often ignored because they are not considered essential for the diagnosis of migraine. Therefore, it is important to differentiate headaches caused by rhinosinusitis from headaches fulfilling the criteria of migraine without aura with prominent autonomic symptoms in the nose or of migraine without aura triggered by nasal changes, the so-called "sinus headaches" (Table 67.21).[43,55,56]

Management (see Table 67.21). Acute rhinosinusitis causes excruciating pain; therefore, analgesia is important. In one study, analgesia successfully treated nearly 80% of patients with maxillary sinusitis.[59]

Emergency treatment goals are to facilitate drainage of the congested nasal sinuses and to eliminate the pathogenic bacteria. Steam and saline prevent crusting of secretions in the nasal cavity and facilitate mucociliary clearance. Locally active decongestants provide symptomatic relief by shrinking inflamed and swollen nasal mucosa. Oral decongestants should be used if prolonged treatment (>3 days) is necessary. These agents are α-adrenergic agonists that reduce nasal blood flow without the risk of rebound vasodilation. Mucoevacuant (guaifenesin) and intranasal steroids may improve the symptoms, but antihistamines are not helpful.[60]

TABLE 67.21

AN OTOLARYNGOLOGY, NEUROLOGY, ALLERGY, AND PRIMARY CARE CONSENSUS ON DIAGNOSIS AND TREATMENT OF SINUS HEADACHE

Diagnostic Recommendations:

- Stable pattern of recurrent, self-limiting headache associated with rhinogenic symptoms are most likely migraine
- Prominent rhinogenic symptoms associated with fever, purulent discharge with headache as one of several complaints (pain) is likely rhinogenic in origin
- MRI or CT as appropriate based on headache history, patterns, changes, and physical signs
- Referral to headache specialist for new onset, frequent headache, headache associated with neurological symptoms or signs, or headache that does not respond to appropriate therapy (migraine or rhinogenic)

Therapeutic Recommendations:

- Migraine with no evidence of infection should be given a trial of migraine-specific medication and scheduled for follow-up evaluation
- Noninfectious rhinogenic symptoms with headache as a minor complaint should be provided with a trial of nasal steroids and/or selective antihistamines and/or oral decongestants

Adapted from Levine HL, Setzen M, Cady RK, et al. An otolaryngology, neurology, allergy, and primary care consensus on diagnosis and treatment of sinus headache. *Otolaryngol Head Neck Surg* 2006;134(3):516–523.

Most patients with rhinosinusitis respond to treatment with antibiotics. Amoxicillin is the first choice, unless the patient has been treated within the previous month or lives in an area that has a high prevalence of β-lactamase–resistant H influenza. There is no clear evidence that culturing purulent secretions contribute to managing acute rhinosinusitis, but obtaining a culture and defining its antibiotic sensitivity may help, particularly if there are orbital or intracranial complications.

Acute frontal and sphenoid sinusitis require immediate referral to an otolaryngologist for treatment to avoid intracranial complications. Consultation should also be considered when the symptoms are not relieved with at least two consecutive 2-week courses of antibiotics.[59]

Sometimes rhinosinusitis does not respond to medical treatment and surgical intervention is necessary to relieve worsening and excruciating pain. The goal of surgery is to improve sinus drainage by enlarging the orifices, removing obstructive anatomic structures, or both. Endoscopic sinus surgery alleviates the facial pain in 75% to 83% of cases,[44,60] producing greater improvement in headache than in facial pain.

Isolate Rhinogenic Disorders Causing Headache

Rhinogenic headache and facial pain can be caused by septal impaction or contact, rhinitis (allergic or vasomotor) and nasal polyps, trauma, intranasal tumors, and septal hematoma. In patients without evidence of acute or chronic sinusitis, nasal polyps, or a tumor, Chow[61] found that pain was caused by a septal spur in 12 of 18 patients who had rhinologic sources for their primary symptom of facial pain or headache.

Deviated Nasal Septum. A deviated nasal septum can produce symptoms similar to those of nasal obstruction. Symptoms may be marked if the deviation is in the region of the nasal valve. However, deflection of the nasal septum is not important as a possible cause of headache.

Inflammatory Rhinitis. Inflammatory rhinitis is accompanied by rhinorrhea, fever, pain affecting the middle part of the face and the distribution of the first and second trigeminal branches, and symptoms of an infection of the upper respiratory tract. Inflammatory rhinitis differs from allergic rhinitis in having more neutrophils on a nasal swab, whereas allergic rhinitis will show an increase in eosinophilic leucocytes.

Allergic Rhinitis. As a rule, allergic rhinitis does not cause primary pain, but it may give rise to acute sinusitis in which facial pain is a secondary development.

Vasomotor Rhinitis. The symptoms of vasomotor rhinitis are similar to those of allergic rhinitis but with less sneezing, and the patient does not test positive for allergies. The pathophysiology involves an imbalance between the parasympathetic and sympathetic autonomic nerve supply of the nasal mucosa. The former predominates, the increased vascularity causing nasal obstruction.

Pain Attributed to Temporomandibular Disorders

TMD are defined as a subgroup of craniofacial pain disorders that involve the TMJ, the masticatory muscle system, and the associated head, face, and neck musculoskeletal complex (muscles, ligaments, and joints).[62] Patients with TMD most frequently present with pain, limited or asymmetric mandibular motion, and TMJ sounds. The pain or discomfort is located around the jaw, TMJ, and the muscles of mastication. Commonly associated symptoms include ear pain and stuffiness, tinnitus, dizziness, eye pain, neck pain, arm and shoulder pain, and dysfunction and headache. In some cases, the onset is acute and symptoms are mild and self-limiting. Other patients experience chronic TMD with persistent pain in association with a combination of physical, behavioral, psychologic, and psychosocial symptoms similar to those of other chronic pain syndromes.

An estimated 75% of the U.S. adult population has experienced one or more of the signs and symptoms of TMD.[63] Epidemiologic studies indicate a prevalence of 40% to 75% of adults having at least one sign of joint dysfunction and approximately 33% of persons having at least one symptom of TMD.[64,65] Some signs appear to be relatively common in the general population; TMJ sounds and deviation on opening occur in approximately 50% of healthy people.[66] Other signs are relatively rare; limited mouth opening and occlusal changes occur in fewer than 5% of the population.[67] These disorders are disorders of middle-aged adults (ages 20 to 50), with women seeking care more than men (female:male ratio ranges from 3:1 to 9:1).[68] Despite large numbers of people experiencing signs and symptoms of TMD over their lifetime, only 5% to 10% of these individuals are believed to actually need treatment.

Temporomandibular Disorders: A Triad of Dysfunctions

At least three distinct and separate dysfunctions create or affect the symptoms described by the TMD patient[69]:

I. Muscle disorders (myofascial pain dysfunction) are related to muscle dysfunction, often leading to muscle spasms, pain, and dysfunction. This type of dysfunction can occur in any skeletal muscle. The triggering area lies in the fascial coverings and attachment zones of the muscles, thus the term myofascial. This syndrome is sometimes incorrectly referred to as myofacial pain dysfunction.
II. Temporomandibular joint articular disorder (TMJD) is related to specific problems in the TMJs. These problems may range from joint sounds to locking, pain, and degenerative changes of the joints themselves. Invariably, muscle dysfunction is a secondary effect of true TMJD.
III. Cervical spinal dysfunction is related to the spinal column, vertebrae, and the associated ligaments and muscles. The majority of symptoms not directly related to the jaw muscles are triggered or affected by this syndrome.

TMDs are classified in the eleventh major category of the IHS's *Classification and Diagnostic Criteria for Headache Disorders, Cranial Neuralgias, and Facial Pain* as headache or facial pain associated with disorders of the cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures (see Table 67.3).[1] The American Academy of Orofacial Pain adopted a part of this classification and broadened it to include a more focused classification of TMD (Tables 67.22 and 67.23). In this classification, TMDs are broadly divided into two major groups: the masticatory muscle disorders and the articular disorders.[70] The masticatory muscle disorders include myofascial pain, myositis, myospasm, local myalgia, myofibrotic contracture, and neoplasia. The articular disorders include congenital and developmental disorders, disc derangement disorders, temporomandibular dislocation, inflammatory disorders, osteoarthritis, ankylosis, and fracture. The most common muscle disorders are localized myalgia and myofascial pain syndrome. The most common articular disorders are disc derangement disorders and osteoarthritis.

Treatment of TMD has included, among other therapies, oral orthopedic jaw appliances, occlusal adjustment, prosthetic reconstruction, orthodontic correction, biofeedback, biobehavioral stress management, psychotherapy, nutritional guidance, physical therapy, acupuncture, pharmacotherapy, and surgical management. Each of these techniques is supported by some degree of success and therefore merits notice. However, the key to successful treatment is an accurate diagnosis, which relies on knowing the symptoms and their probable causes on an interdisciplinary approach (Table 67.24).

11.7.2.6—Myofibrotic contracture
11.7.2.7—Neoplasia

Clinical Presentation

The most common symptom of TMD is muscle pain. It is usually accompanied by restricted movement. Patients often also present with reduced jaw opening, as well as impaired range of motion in the cervical vertebrae, shoulders, and arms. Other commonly associated symptoms of TMD are listed below.

Headache. Symptoms of TMD-related bilateral head and face pain involve multiple postural muscles, the muscles of mastication, or both. The pain is typically of moderate intensity, dull and aching in quality, and described as deep and constant.[71–75] Pain is often exacerbated by use of the affected muscles. Morning headaches may be related to nocturnal bruxism or sleep disorders,[76] whereas increasing pain during the day may be related to masticatory muscle use or head posture.[77]

Front of Head. Patients reporting pain in the front of the head often refer to it as "sinus headache." The pain is usually accompanied by pressure along the upper anterior teeth, bridge of the nose, and behind the eyes. Chronic front of the head pain and facial pain generally indicate a primary headache disorder, not chronic sinus disease. These symptoms can also be caused by a reduced posterior occlusal dimension, causing heavy incisal contact, resulting in pain of pressure in the anterior vortex of the face. A band-like feeling of the front of the head can also be brought about by posterior neck muscle contractions or muscle tension of the frontalis muscle.

Side of the Head. Temporal headaches are mainly related to muscle contraction and fiber spasm of the temporalis muscle. The temporalis muscle has three groups of muscle fibers: anterior, middle, and posterior. The anterior fibers bring the lower jaw up and forward, and the middle and posterior fibers swing the jaw to full closure and retract the mandible.

Clenching, grinding, or biting on objects while the jaw is displaced anteriorly (edge-to-edge) generally creates pain in the anterior temporal group (i.e., the patient has pain in the "temple" area). Individuals who work at desk jobs with their heads forward and down tend to clench and grind in this position because gravity

TABLE 67.24

TEMPOROMANDIBULAR DISORDERS

Diagnosis	TMJ Articular disorders	Muscle disorders	Myofascial disorders
Diagnostic features	Pain localized in the preauricular area during jaw function. Usually presence of painful click or crepitus during mouth opening. Limited opening (<35 mm), deviated or painful jaw movements.	Tenderness of the masticatory muscles. Dull, aching pain exacerbated by jaw function or palpation.	Diffused dull or aching pain affecting multiple groups of muscles of the head and neck region, as well as other parts of the body.
Diagnostic evaluation	Internal derangement of the TMJ with abnormal function of the disc-condyle complex, and/or degeneration of the joint surface. Palpation is painful. Possible joint swelling in acute phases. MRI, CT, etc., of the joint may rule-out tumors and advanced degenerative stages.	Tenderness during palpation of the masticatory muscles and tendons. Possible limited range of jaw movement and during passive stretching exam. Can be associated with a parafunctional habit (bruxism-early morning pain).	Presence of trigger or tender points in one or more groups of muscles. Pain can radiate to distant areas with stimulation or not of the trigger points. Rule out presence of lupus erythematosus.
Treatment	Patient education and self-care. Medication: NSAID, nonopiate analgesics. Physical Therapy: exercise program. Occlusal splints Oral maxillofacial surgery: arthrocentesis, arthroscopic surgery, open surgery	Patient education and self-care. Medication: topical and systemic NSAIDs., nonopiate analgesics, muscle-relaxants, antidepressants, (usually tricyclic antidepressants), anxiolytics, anticonvulsants, botulinum toxin, trigger point injections, and vapocoolant spray. Physical therapy: transcutaneous electrical nerve stimulation, massage, exercise program. Occlusal splints Cognitive-behavior: biofeedback, relaxation, coping skills.	Same as muscle disorders.

has a greater affect on the mandible. This condition is further aggravated by habits such as pencil or pen biting, pipe smoking, or gum chewing.

Clenching or grinding during sleep or clenching with the jaw in a posterior position tends to tire the middle and posterior group of fibers, and the pain is more posteriorly located. Generally, the temporalis is affected in any dysfunction of the lower jaw.

Back of Head. Deep, dull pain, constant and aggravating in the back of the head, is usually a result of spasms of the trapezius and sternocleidomastoid muscles. These muscles are long and strong, and under tension, they pull on their bony attachments to the skull—the occiput and mastoid areas. This pulling leads to soreness in the bone and to deep dull pain radiating up the back of the head and down the neck. The muscle tension may be independent of, or secondarily related to, displacement of the cervical and upper thoracic vertebrae.

Face Pain. Pain in the sides of the face or pain described by the patient as "sinus" pain in the zygomatic or orbital area may also have a musculoskeletal origin.[69] Clenching, acute or chronic stress, and reduction of dental height related to the loss of posterior teeth combined with daytime tooth clenching and acute or chronic stress can create muscle trigger points or muscle fatigue. Patients are often aware of this condition after meals and report "a heavy and tired feeling" in the jaw muscles. Face pain related to sinuses and other pathologies are discussed separately in this chapter.

Eye Pain. Orbital pain symptoms are often described as unilateral, constant, and "boring." Orbital pain is frequently seen in patients with TMD that includes pain involving the eye and periorbital region.[69,78–80] Patients with a history of trauma, chronic upper cervical vertebral subluxations, or nerve root impingements related to the occiput and the atlantoaxial region may present with orbital symptoms. In addition, entrapment of the greater occipital nerve at the occiput level can also produce this type of pain, which is often diagnosed as occipital neuralgia. Orbital pain often responds to physical medicine, along with changes in head posture and mandibular position through the use of dental bite appliances.

Ear Symptoms. Pain, stuffiness, and tinnitus may have a musculoskeletal cause.[81,82] Mandibular posture in relationship to the maxilla affects the masticatory elevator muscles. The medial pterygoid muscles help stabilize the left-to-right balance of the mandible on tooth closure. Innervation from the nerve to the medial pterygoid also supplies the middle ear muscles. The tensor tympani and tensor palati are actually one muscle with a raphe that wraps around the hamulus notch of the maxilla. Growth and development problems related to the proper expansion of the maxilla can affect eustachian tube function and can precipitate middle ear infections in children, as well as ear stuffiness with changes in pressure in the ear in adults. Maxillary and mandibular dysfunctions aid in the development and maintenance of such symptoms.

Tinnitus and other types of ear sounds may also have a peripheral musculoskeletal cause. Specifically, cervical and mandibular postural factors are found in patients with tinnitus. A combination of physical medicine and dental jaw appliance therapy has been effective in some cases where trauma or aberrations in childhood growth and development have affected the proper expansion of the maxilla.

Sharp, jabbing ear pain upon movement of the mandible is often seen in patients who have an internal derangement of the TMJ. Usually this derangement presents unilaterally and ipsilateral to the joint in question.

Ear pain and symptoms such as stuffiness in the absence of positive otologic findings are among the most common reasons to evaluate the patient for dental and maxillomandibular imbalance. Treatment often alleviates or reduces the impact of the symptoms on the patient.[83–88]

Temporomandibular Joint Symptoms. Pain and sounds related to the TMJs are very common.[89,90] Patients commonly report clicking or grating noises in the "jaw joints." Generally, clicking is not accompanied by pain. Grating noises are usually unilateral and accompanied by pain radiating to the ear on movement. These noises may be related to trauma or bruxism in the presence of missing posterior teeth, resulting in injury or anterior disc displacement without reduction "locking" of the temporomandibular joint.

Clicking. Much has been written about clicking of the TMJs. Clicks can be classified as immediate-opening clicking, midopening clicking, late-opening clicking, and reciprocal clicking.

The reason for the click, however, remains the same. When the mouth opens, the condyle hits the back of, and "clicks under," the articulator disc. This situation can happen at any point during movement, depending on the relative position of the condyle and disc.

Typically, the articular disc is attached to the head of the condyle on the medial and lateral poles. The superior head of the lateral pterygoid is inserted into the anterior portion of the disc and soft, elastic tissue borders the disc posteriorly.

This arrangement holds the articular disc in position with the condyle in various jaw movements. If the joint is anatomically healthy, there cannot be a click. Tearing or stretching of the articulator attachments are a prerequisite for clicking.

Clicking can be caused by acute trauma, such as an automobile accident, whiplash, or a blow to the face. It can also be caused by chronic microtrauma, such as loss of posterior vertical dimension of occlusion or loss of teeth.

Dental interventions can also create this problem by retruding the condyle posteriorly during reconstruction or orthodontic retrusion. Difficult extractions can also affect the joint-disc assembly.

Grating Sounds. Grating sounds generally occur in a later stage of TMJ articular dysfunction, along with articular cartilage degeneration. The disc is either torn and shredded or missing completely. The grating is caused by bone-to-bone friction and usually indicates osteoarthritic degenerative changes in the joint.

Locking of the Joint. The jaw lock mainly occurs after clicking has been evident for a while. The articular disc, which is biconcave under normal circumstances, loses its shape and becomes spherical or ball-like if anteriorly displaced for a period of time. In this case, the condyle cannot travel normally along the anterior wall of the glenoid fossa. The patient perceives this restriction as an inability to open the mouth fully. Sometimes the cartilage may fold on itself with the same clinical effect.

Hypermobility. Increased movement in the jaw comes when the TMJ ligaments are stretched or torn. This loss of integrity allows excessive movement, sometimes to the point of anterior open dislocation in a wide opening movement, such as yawning.

Treatment is often a combination of dental therapies, jaw appliance therapy, and physical medicine and can be supplemented with treatment for bruxism and stress management through biofeedback relaxation and sleep medicine.

Neck Pain. Neck stiffness and pain are commonly part of the TMD complex.[91–93] Trauma, poor posture, and musculoskeletal tension can have chronic effects on the cervical spine, creating pain, stiffness, and trigger point flare up in the muscles of the head and neck. The trigeminal and cervical nerves help maintain head, neck, and jaw posture.[94] Mastication and jaw function rely on all the anterior and posterior cervical muscles. In addition,

mandibular and head postures interact to maintain the airway space during function and sleep.

Studies of maxillomandibular position and the cervical spine have shown that reductions of the vertical dimension of the teeth and a deep bite can adversely affect cervical muscle function, leading to chronic stiffness, pain, and reduced range of motion.[95] It is therefore important to assess the dental factors in patients with chronic neck pain.

Arm and Back Symptoms. Patients presenting with TMD may also commonly present with shoulder pain: pain radiating down the arm that may or may not be accompanied by tingling and or numbness. Physical examination often reveals thoracic outlet syndrome, costoclavicular syndrome, vertebral subluxations or nerve impingement of the brachial plexus, and even previously undiagnosed rotator cuff injuries.[96]

Temporomandibular Joint Articular Disorders (see Tables 67.22 to 67.24)

The TMJ is a synovial diarthrodial joint that allows the temporal bone to articulate with the condylar head of the mandible. The joint allows for sliding as well as hinge movement of the mandible during functional mastication. The condyles are not perfectly round but are wider medio–laterally than anterior–posteriorly. Individual variations follow functional loads and depend on the thickness of connective tissue layers covering the articulating surfaces.[97,98]

The condyles travel within their respective mandibular fossae. Each mandibular fossa or glenoid fossa forms the temporal component of the TMJ. This component is a concave area on the inferior border of the squamous part of the temporal bone and is also referred to as the articular fossa.[99]

Between the bones that form the TMJ are interposing discs or articular cartilages.[100] Each articular disc is formed of dense fibrous connective tissue and divides the joint cavity into two separate compartments: the upper discotemporal space and the lower discomandibular space. Both compartments are lubricated by synovial fluid.[101] The inferior surface of the disc is concave to match the articular surface of the condyle, whereas the superior surface of the disc is convex to follow the concave surface of the articular fossa. The articular disc is firmly attached to the medial and lateral poles of the condyle. The lateral ligamentous attachments are relatively thin and weak compared to the medial pole attachments and tend to tear more frequently than the medial ligamentous attachments. This weakness is the reason for more anterior medial than lateral disc displacements.

Viewed sagittally, the articular disc is divided into three parts: a thicker anterior section called the anterior band, a middle thinner intermediary zone, and a broader posterior band that is the thickest of the three (Fig. 67.1). The thinner intermediary zone, along with the two broader anterior and posterior zones, gave the articular cartilage its classic bowtie appearance on MRI (Fig. 67.2).

In the adult, the central part of the articular disc is avascular and lacks innervations, which allows for changes in the central thin part of the disc to occur without pain. The articular disc has a relatively random arrangement of type I collagen fibers, elastic fibers, and glycosaminoglycans comprised of chondroitin sulfate, dermatan sulfate, and hyaluronic acid. The discs allow for rotation in the upper joint compartment and translation in the lower joint compartment.[102] Thus, rotation is approximately the first 22.5 mm of mouth opening, and translation from that point to full mouth opening ranges from 45 to 55 mm between the front teeth.[102]

In each joint, the anterior part of the articular cartilage attaches to the superior head of the lateral pterygoid muscle, and the inferior head of the lateral pterygoid muscle attaches into the fovea of the condyle. In humans, this attachment of the superior head of the lateral pterygoid is variably inserted into 40% to 60% of the articular disc.[103] The posterior part of the articular cartilage blends into loose retrodiscal tissue consisting of blood vessels, loose connective tissue, and nerves.

On mouth closure, the retrodiscal tissue is squeezed like a sponge and allows the condyle to be fully seated in its fossa. As the mouth opens and the condyles move forward in their respective fossa, the blood vessels in the retrodiscal tissues expand to fill the void left by the translating condyles and their interposing articular cartilages. This act of a sponge being squeezed and then being filled is repeated during jaw function. This region can be injured if the mouth suddenly opens and closes as a result of a blow or injury to the mandible. This injury can lead to bleeding in the joint space, followed by pain and limitation of movement.

Congenital or Developmental Disorders. Congenital or developmental disorders, such as aplasia, hypoplasia, hyperplasia, and neoplasia, can be odontogenic or nonodontogenic and primarily present as esthetic and functional problems. Neoplastic lesions, such as osteomas and osteoblastomas of the bone, produce pain in more advanced stages,[104] as do other primary tumors, such as chondroblastoma and benign giant cell tumors. The most common metastatic tumors are squamous cell carcinoma, nasopharyngeal tumors, and parotid gland tumors, such as adenoid cystic carcinomas.[105]

Disc derangement disorders or articular disc displacements, by far the most common TMJ articular disorders, are characterized by an abnormal position of the articular disc relative to the head of the condyle or temporal fossa. Disc displacement is usually marked by a ‘‘clicking or popping’’ sound in the TMJ when the mouth is opened and closed. Pain is initially not part of the presenting symptoms, as long as there is full function. Disc displacements suggest torn or stretched collateral discal ligaments that bind the disc to the condyle.

Disc displacements are usually anterior or anteromedial, although posterior and lateral displacements have been described. Anterior or anteromedial displacement may be related in part to the fact that the thinnest discal attachments are on the lateral pole of the condyle, as well as the medial direction of pull by the lateral pterygoid and the inward condylar movement during mouth opening.[106]

Disc Displacement With Reduction. A clicking sound on mouth opening and closing is classified as disc displacement with reduction. The term reduction describes the process of the misaligned disc temporarily coming back (or slipping back) to its proper interposition between the condyle and fossa during full mouth opening (see Fig. 67.2). On closing the mouth, the disc again displaces as the teeth come closer together. This repetitive, ongoing displacement on opening and closing produces a reciprocal noise (clicks) and is hence termed ‘‘reciprocal clicking.’’ Given the very common nature of its occurrence, this displacement may actually represent a stage of physiologic accommodation that need not be treated. Where displacement progresses, the incidence of intermittent ‘‘locking’’ may increase as a result of the momentary impedance of the disc as it follows the path of the condyle. This stage generally occurs as a sequel of a chronic clicking condition in patients who tend to clench and grind their teeth at night (nocturnal parafunction) and who have missing posterior teeth with subsequent overclosure of the bite. The teeth act as the doorstop for the TMJs and support the ultimate position of the TMJ on full closure. Good dental vertical dimension without shift on closure is essential in reducing the risk factors for progression. Bite appliance therapy is effective in treating muscular as well as disc displacement problems.[107–109]

Disc Displacement Without Reduction. Progression to the next stage is sometimes referred to as a ‘‘closed lock.’’ In this stage, the disc has been permanently displaced, and its shape has been deformed so that it prevents the condyle of the mandible from translating to a full open position (Fig. 67.3). Jaw opening is

A B

FIGURE 67.3 TMJ disk displacement without reduction.

usually limited to 22 to 25 mm, or about the length of the tips of two fingers inserted between the upper and lower incisors. Pain may reduce chewing capacity, the mandible deviates to the side of the lock, the joint becomes inflamed, and normal occlusion or "bite" may be disrupted. MRI is the standard for assessing the soft tissue of the articular cartilage and its displacement, whereas CT is generally done to assess hard tissue for chronic osteoarthritic or bony changes.[110,111]

Temporomandibular Joint Dislocation. In TMJ dislocation, or open lock or condylar subluxation, the condyle translates beyond the anterior eminence of the articular fossa and becomes trapped in this open-mouth position. Chronic hypertranslation can usually be managed by having the patient physically manipulate the jaw back into position. The patient learns to relax the jaw-closing muscles and to slip the condyle back into position. The most common subluxation occurs during yawning or opening the mouth widely when eating.

If the problem is related to trauma or a sudden acute translation, the subluxation is considered to be an acute dislocation. Acute dislocation requires medical intervention in which the muscles are relaxed by anesthesia, analgesics, or injected into the muscles and joint, followed by manipulating the joint downward and backward to let it slip past the anterior eminence of the glenoid fossa. Follow-up with anti-inflammatory medication, ice, and rest or a dental appliance may be necessary until the acute stage passes.[112]

Inflammatory Disorders. Capsulitis and synovitis are relatively common in the TMJ secondary to macro- or microtrauma, irritation, or infections. These insults are accompanied by pain on movement and inflammation with extreme tenderness of the TMJ or on distraction of the joints. MRI may show effusions in the T2-weighted signal, the teeth may not be brought together completely, and pain may occur in the ear.

Joint inflammation may also be a result of systemic polyarthritis. Symptoms are similar to those in other joints of the body and are secondary to connective tissue diseases that affect the same population of patients.

Osteoarthritis (Noninflammatory). Primary osteoarthritis is a degenerative condition of the joints characterized by hard-tissue abrasion and degradation of the articular surface of the condyle related to overload. The condition is frequently seen in patients with a long history of missing and unreplaced teeth or in patients with dentures due to remodeling effects. Remodeling is usually slow and generally painless in the early stages. Slow progression may remain relatively benign over the life span of the patient.

Primary osteoarthritis is usually identified by radiography, such as a dental panoramic image, tomography, or a dental CT scan and grating (crepitus) noises in the joint during movement (Figs. 67.4 and 67.5). Secondary osteoarthritis is usually associated with a single prior event, such as trauma or infection, or by rheumatoid arthritis. An idiopathic degenerative condition primarily affecting adolescent girls is termed condylysis. It is seen as a sudden lysis of the condyle, which can creates a shift of the jaw to the affected side and an anterior open bite. The cause of condylysis is not clear but the condition is associated with young women with rheumatoid arthritis.[113]

Ankylosis. Ankylosis is usually related to joint trauma, with subsequent bleeding and restricted mandibular movement. Ankylosis maybe fibrous or bony in nature. Fibrous ankylosis usually is seen in the upper joint compartment as a result of adhesions forming after a joint bleed and prolonged immobility. The jaw still opens slightly, usually enough to accommodate 1 or 2 fingers placed horizontally between the central incisors. Bony ankylosis has no movement associated with it. Both conditions may require surgical release and postsurgical mobilization.[114]

FIGURE 67.4 Sagittal view MRI of osteoarthritis of the temporomandibular joint.

Fracture. Trauma to the chin, mandible, or any part of the face may result in bony fractures of the condylar neck, condylar head, bodies of the mandible and maxilla, and temporal fossa. Untreated, these fractures will generally result in reduced range of jaw motion, pain, and fibrosis or bony ankylosis. If the fracture is uncomplicated and results in a nondisplaced fracture fragment, immediate treatment may not be necessary, as long as function is not compromised (Fig. 67.6).[115]

Muscular Disorders

Muscular pain and dysfunction are the most common symptoms of a patient with TMD. The muscles of the masticatory system are affected in the same way as other striated skeletal muscles of the body. Ligaments, nerves, and muscles all function as a complex system to stabilize the head on the shoulders, maintain a functional airway space, and allow three-dimensional movement of the mandible. This system is called the craniocervical-mandibular or the stomatognathic system. Breakdown in this complex and finely tuned system ultimately affects the musculoskeletal system, most commonly in the form of muscular disorders leading to pain in the head, face, and neck.

Myalgia due to Trauma. Masticatory muscles can be injured by acute muscle strain or by direct trauma. It is difficult to completely eliminate movement in the masticatory muscles because of the need for speech, swallowing, and chewing. If this is further compounded by dental parafunctional activities, the healing process takes longer.

Soft tissue injury results in bleeding, inflammation, and swelling, causing the muscle to respond with myalgia, muscle spasm, muscle splinting, or myositis.[116] Myofascial trigger points occur in various combinations in the muscle and are considered by Travell[117] to be the primary source of muscular pain.

Injury results in a deep, sharp ache on contraction of the

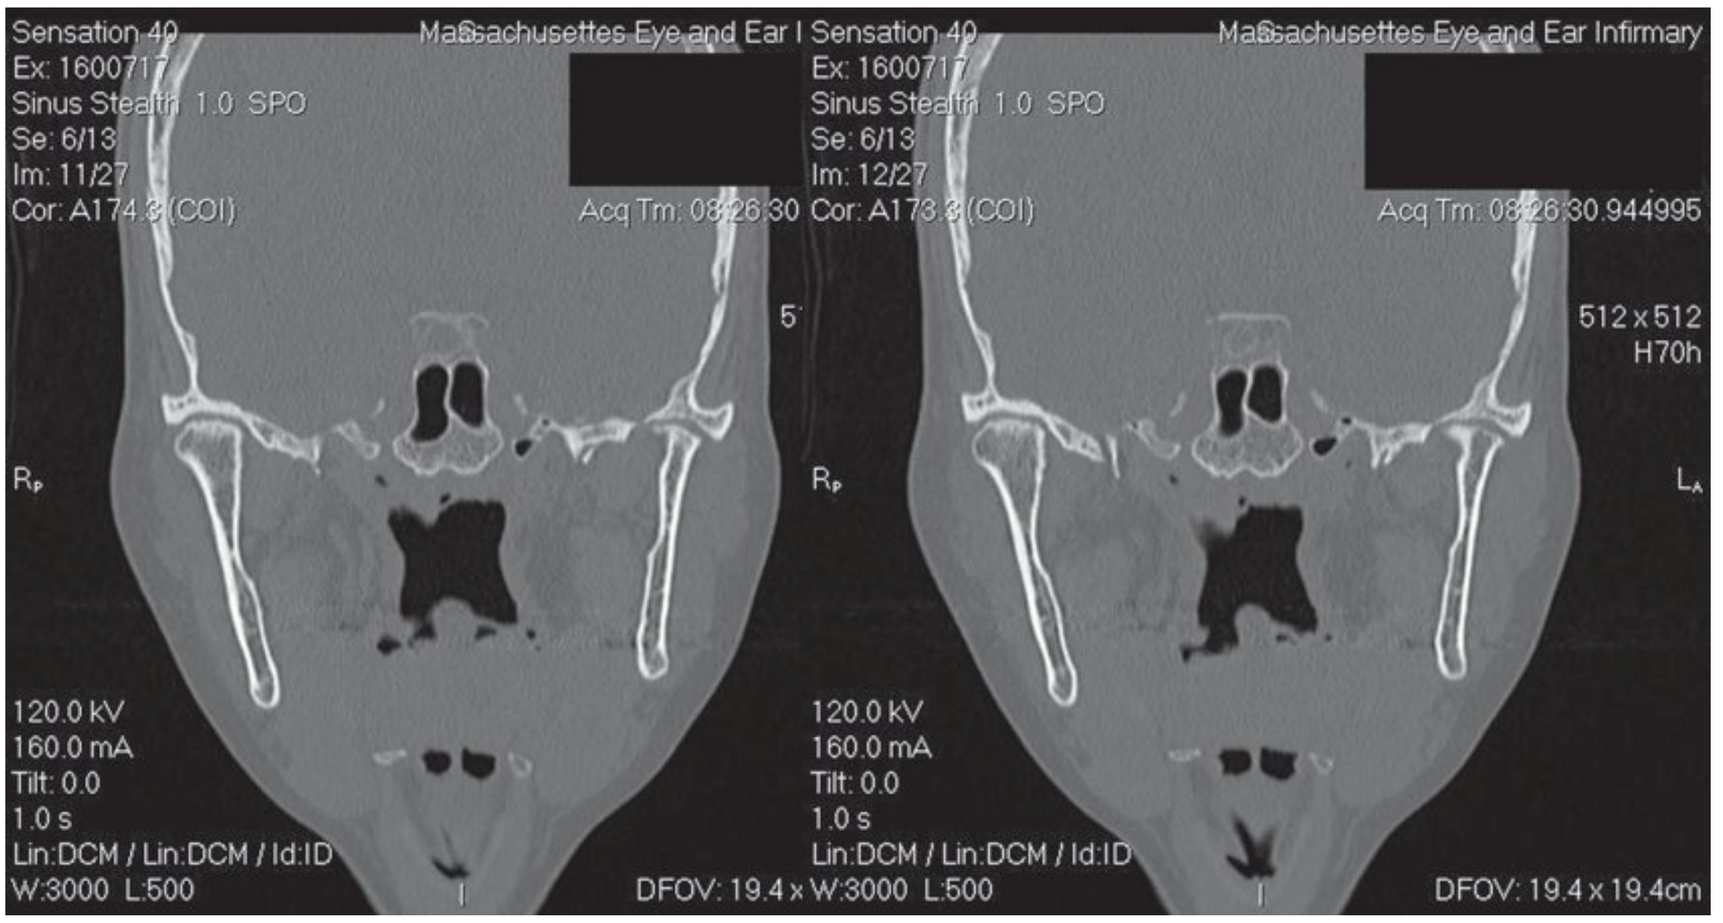

FIGURE 67.5 Coronal view CT scan of osteoarthritis of the temporomandibular joint.

muscle. Depending on the area of injury, the pain may emanate from the tendon attachments (tendonitis), the fascial component (myofascitis), or the body of the muscle (myospasm and myositis). The temporalis tendon attachment to the coronoid process is the most frequent site of masticatory tendonitis.

In acute or chronic internal derangement of the TMJ complex, the muscles that support and move the joints can be secondarily affected. Protective muscle splinting helps prevent further injury to the joint. The injured joint is often immobilized by anterior disc displacement without reduction (closed lock). Splinting of the masticatory elevator muscles is maintained until the joint is healed.

If the internal derangement is not adequately treated, the muscles remain chronically shortened and may eventually undergo contracture.[118–120] The combination of acute trauma, loss of posterior teeth, and moderate to severe parafunction may bring about an anterior disc displacement with intermittent locking of the TMJ. Patients will often report histories of trauma that are followed by a variable period of clicking, progressively increasing in frequency and culminating in an abrupt disappearance and an inability to open the mouth. Differential diagnosis of a patient who has limited mouth opening must include internal derangement as well as muscle trismus.

Myalgia secondary to injury of the cervical spine can cause headaches, facial pain, and masticatory muscle pain. Affected masticatory muscles then affect mandibular position. Mandibular dysfunction results in tightening the muscles of the cervical spine, thereby perpetuating the cycle. This interaction is the reason that a substantial proportion of TMD patients also present with a history of cervical injury. This craniofacial and cervical syndrome requires multidisciplinary treatment of both the jaw and the neck.[121]

Disc herniations can affect the cervical muscles through protective splinting, which can eventually lead to chronic postural changes. Nerve impingement and nerve root injuries can also affect muscle function. Cervical problems are frequently comorbidities in TMD patients.[121,122]

A reduction in the space between the posterior spine of the atlas and the base of the occiput as reported by Rocabado[123] may cause pain by compression of the suboccipital tissues. The pain will be perceived as a headache starting from the back of the head.[124]

Acute or chronic trauma can shift the occiput-atlas relationship and may lead to chronic tension in the suboccipital muscles with resulting fixation and irritation of nerves C1 and C2. The pain will be referred from the back of the head to the eye, along the side of the head, along the skin over the TMJ, and down along the angle of the mandible, radiating into the neck.

Rotation of the atlas is commonly seen in patients with TMDs and may be linked to changes in occlusal contact patterns and instability of mandibular position.[125] Osteoarthritic degeneration and ligament and muscle injury also occur at this level in acceleration-deceleration injuries.

Hypermobility caused by a disruption of the C1-C2 articulation also may result in excessive stretching or kinking of the vertebral artery and may lead to temporary vertebrobasilar syndrome with symptoms of vertigo, nausea, tinnitus, and visual disturbances.[125]

The patient with a combined craniofacial-cervical syndrome will have a history of direct or indirect injury to the head and neck. The injury is usually not a direct trauma to the part, but rather a low-grade impact to the body that suddenly twists, flexes, or extends the neck.

Symptoms may range from headache, nausea, visual disturbances, neck weakness, and pain, to stiffness accompanied by noises on rotation, flexion, and extension of the head. Depending on the level of the initial injury, branches of the cervical and brachial plexus and the areas they supply can also be affected.

FIGURE 67.6 Fracture of the left condyle (*arrows*) shown on panoramic radiograph.

Secondary muscles affected can cause superimposed acute or chronic pain, requiring a specific cervical evaluation.

Depending on how the cervical problem affects the masticatory system or vice versa, occlusal appliances may reduce muscle tension.[125]

Myalgia Secondary to Parafunction. Oral parafunction includes bruxism, clenching, lip biting, thumb sucking, and any other oral habit not associated with chewing, swallowing, or speaking. Bruxism and clenching are the most common activities, with a prevalence of up to 90% in the general population.[126–130]

In most patients, parafunction is mild and intermittent and does not require treatment. Moderate or severe bruxism and clenching can damage oral structures, causing wear of the teeth, breakdown of the periodontium in the presence of inflammation, and internal derangement and muscular dysfunction.[130]

Bruxism and clenching can create excessive force for extended periods, whereas normal tooth contact during chewing and swallowing over a 24-hour period is about 20 minutes.[131] Parafunctional forces exceed normal masticatory forces, and the resultant force vector is primarily horizontal. Under such conditions, the teeth and periodontium are likely to be damaged. Ironically, most treatments are designed to protect the occlusion in function rather than in parafunction.

If the teeth, periodontium, TMJ, and muscles are considered to be "links in a chain" working together for proper function, the parafunction usually disrupts the weakest of these structures. The other structures remain relatively healthy or become secondarily affected. For example, parafunctional wear of the canines may shift force to the other teeth. If these teeth are strong enough to withstand the excessive force, the pathology may shift to the TMJ. The patient can therefore present with both tooth and joint pathology.[132–134]

Patients may present with pain in the cervical muscles as a result of chronic bruxism and clenching. Cervical muscle activity is related to occlusal contact. The patient may report restless sleep, waking up with limited mandibular range of motion, headache, facial pain, and neck pain. The pain and stiffness usually improve as the day progresses.

If a patient reports that stiffness and pain increase as the day progresses, diurnal activity should be suspected. The patient may report marked stress and depression. Palpable muscle soreness will primarily affect the elevators and the lateral pterygoid. Clenching on the wear facets by moving the mandible laterally—a provocation test—will increase the pain.

A testing device known as a Bruxcore can quantify nocturnal activity (Fig. 67.7).[135] A portable electromyographic biofeedback instrument has also been used to monitor bruxism.[136]

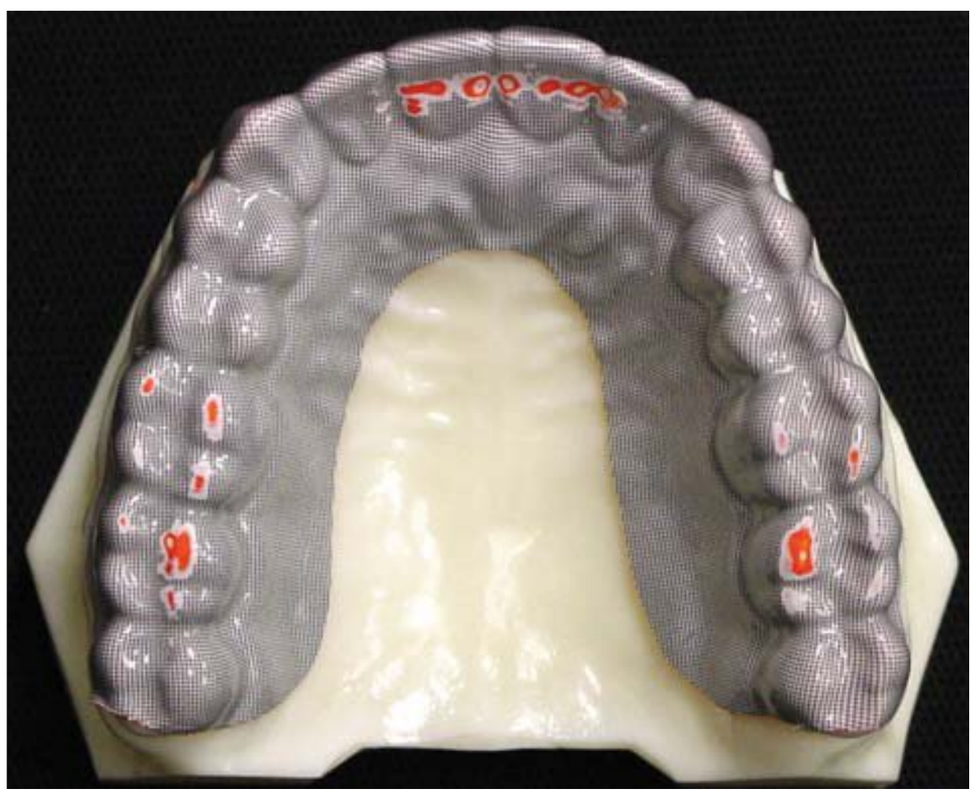

FIGURE 67.7 Bruxcore tooth grinding indicator.

Repeated monitoring on different nights at a sleep laboratory is the most accurate assessment of parafunction; however, it is rarely necessary. Electromyographic analysis may show a higher resting tension level than normal, but tension depends on the specific type of muscle disorder and the specific muscle being analyzed.

Treating the parafunctional activity includes reducing the stress leading to parafunctional activity through biofeedback, stress management, medication, and counseling. The goal is to decrease the parafunction to within the adaptive capacity of the individual.

Oral structures are best protected with occlusal appliances worn at night, during the day, or both, to reduce loading on the TMJ, stress on the dentition and periodontium, and muscle activity (Fig. 67.8).[137]

Myalgia Secondary to Postural Hypertonicity. As stated above, the stability and function of the cervical region affects the position of the mandible relative to the maxilla and depends on the position of the head on the shoulders. This position is affected by gravity and the functional adaptation of the individual.[69]

A healthy craniocervical complex stabilizes head position through a series of learned and complex antagonistic muscle interactions. Forward head posture (FHP) leads to shortening and greater tension of the posterior cervical muscles.[138] The trapezius, sternocleidomastoid, and deeper muscles contract to prevent the head from tipping forward, leading to hyperactivity and chronic tension.

Chronic hyperactivity, such as working on a computer or in an office, can cause the shortened muscles to develop trigger points and the accompanying symptoms. The cervical spine is forced to adapt to the forces applied by strong cervical muscles, which may affect normal cervical lordosis.[138]

The body adapts to FHP by rounding the shoulders, leading to chronic shortening of the pectoral muscles, which further maintains FHP. Pectoral muscle tension along with FHP leads to upper thoracic breathing and tighter intercostal muscles. The anterior and middle scalenes may entrap the brachial plexus at the thoracic outlet, or the first rib can be pulled up to the clavicle, resulting in costoclavicular entrapment.[138]

Mehta and Forgione[139] have discussed the effect of chronic FHP and the relative position of the occiput, atlas, and axis with respect to each other and the craniomandibular complex. FHP and cervical muscle tension can lead to changes in occlusal contacts. Analyzing occlusal contact in maximum intercuspation with the patient in a supine position does not allow an accurate evaluation of occlusion in function. Likewise, measures to improve posture and cervical stability should be considered before definitive occlusal therapy is instituted.

Proper positioning during sleep is important for resting the postural muscles. A patient who habitually sleeps prone with the neck twisted at 90 degrees experiences the same effects as someone whose head is turned to one side all day long. In people who sleep on their sides with the lower arm outstretched under the pillow and head, the brachial plexus tends to become entrapped at the costoclavicular level. This side position can be stressful to the cervical muscles and can result in acute torticollis of the sternocleidomastoid muscle. Neck stiffness and trigger points are observed in patients with sleep habits that involve strained head positions.

Standing posture may be affected by leg-length discrepancies, hip rotation, and flat feet. Individuals who lean over machinery are likely have cervical and low-back symptoms. Shoes that are unevenly worn or that have extremely high heels affect balance and tend to cause a secondary protective adjustment of the postural muscles. This adjustment may result in chronic muscular shortening, trigger points, and spasm. Shifts in body posture and compensatory cervical changes affect mandibular position and tooth contact patterns.[69]

FIGURE 67.8 A,B. Oral orthosis appliance for the jaws.

Radiographs CT scans or MRI scans may be needed to evaluate spinal curvature and to rule out other pathologies.

Short-term exercise can increase range of motion and improve posture, muscle re-education can strengthen the muscles in the therapeutic postural position, and home exercise programs can maintain therapeutic postural position.[115]

Myofascial Pain and Trigger Points. In 1952, Travell and Rinzler[116] introduced the concept of myofascial pain and trigger points. They defined a myofascial trigger point as a hyperirritable locus within a taut band of skeletal muscle located in a muscle or in its associated fascia or tendon. The spot is painful on compression and can evoke characteristic referred pain and autonomic phenomena.[116]

Trigger points may be active or latent. Active trigger points may cause pain spontaneously or during movement. Latent trigger points afflict nearly half of the population by early adulthood.[140] Latent trigger points are usually not painful, but create weakness and restrict movement. Trigger points can be activated by a sudden overloading contraction, viral infection, cold temperatures, fatigue, and increased emotional stress.

The complex nature of myofascial trigger points and their common presence in acute and chronic muscle dysfunction require an understanding of their clinical features. According to Travell and Simons,[140] there are seven such features:

- local tenderness over the trigger point
- referred pain, tenderness, and autonomic phenomena
- a palpable taut band associated with the trigger points
- a local twitch response of a trigger point in a palpable taut band
- perpetuation of trigger points
- a therapeutic effect when stretching the muscle containing the trigger points
- weakness and fatigability of muscles afflicted with trigger points relative to unafflicted muscles

Myofascial pain often refers to pain at the head and neck and is considered by some to constitute tension-type headaches. Myofascial pain and trigger points of the masticatory muscles can send pain to the eyes, ears, TMJ, and teeth, depending on the specific muscles. The pain is usually a dull or intense ache that varies daily and is strongly related to posture and muscle activity. The pain can usually be localized by the patient and can be indicated on a diagram of the body. Trigger points commonly affect the muscles of posture and mastication, and pain may occur in the same dermatome, myotome, or sclerotome. Satellite trigger points may occur within the pain reference zone. Clinically, movement is restricted, passive stretching is painful, and strong contractions markedly increase the pain. Resistive testing reveals weakness from protective splinting.

Trigger points are palpated by rubbing the fingertip lightly along the long axis of the muscle. If present, a taut band will be located first, and then the more sensitive trigger point. Applying pressure on a trigger point elicits a grimace or an involuntary sound from the patient called the "jump sign." A snapping palpation of the taut band will produce a latent trigger response confirming the presence of the trigger point. Final confirmation comes on reproducing the patient's pain by digital pressure on the point.[139]

Pressure algometers quantify the amount of pressure applied to the trigger point, which allows the clinician to document the severity of the trigger point. It may also be used to objectively record the efficacy of treatment.

Treating myofascial trigger points includes spray-and-stretch techniques with ethyl chloride or fluoromethane for its cooling effects, followed by stretching, hot compresses, and range-of-motion exercises. Trigger point injections of procaine (0.5% solution in saline) or lidocaine (2% without epinephrine) have also been the standard in pain management programs (Fig. 67.9). More recently, botulinum toxin (Botox) has been added to this arsenal.[140–144]

Other techniques involve ischemic compression for 30 to 60 seconds, acupressure, and pharmacologic therapy, including analgesics, muscle relaxants, antidepressants, and NSAIDs. Physical therapy modalities such as myofascial release and craniosacral techniques, including postural correction and exercise, have also

FIGURE 67.9 Trigger point injection of the masseter muscle.

been effective in managing myofascial trigger points. Stress and nutritional and hormonal factors should also be addressed.[137]

In case of the masticatory muscles, occlusal appliances may be used.[138] Dental appliances are effective in reducing muscle symptoms and trigger points in mandibular elevators. These appliances are usually flat plane and fully cover either the upper or lower teeth, depending on when they are to be worn.

Muscle Splinting. Muscle splinting is a reflex by which skeletal muscles stabilize an injured area to protect it from further injury. The involved muscles become hypertonic and painful. The associated feeling of weakness, although alarming to the patient, is a normal protective reaction to discourage moving the affected part.

Muscle splinting is often a sequela to muscle injury and follows myositis. If splinting is protracted, muscle spasm may follow with or without trigger points, leading to a chronic cycle of myofascial pain and dysfunction.[140]

Initially, injections are not indicated; ice, rest, and relaxation are the basis of acute therapy. Stretching, ultrasound, or light massage can be used in the initial stages. Once the muscles have started to heal, splinting decreases, at which point therapy to regain mobility can begin. Mobilization techniques, gentle stretching, and range-of-motion exercises are required to prevent ongoing myospasm, contracture, and atrophy.

Muscle Spasm (Sustained). A muscle spasm is the painful contraction of a striated muscle caused by trauma, tension, or disease.[113,125] The spasm manifests as pain and interference in function. Muscular fiber contractions occur in response to increased excitability of alpha motoneurons.

Prolonged muscle spasm is thought to be caused by the ischemia induced in a skeletal muscle by its continued contraction. The muscle fatigues and lactic acid builds up, leading to the release of bradykinin, causing pain.

In the masticatory musculature, spasm of the masseter or temporalis muscle limits range of motion, which in turn causes the jaw to deflect to the ipsilateral side on mouth opening. If a spasm is isometric, the muscle will be rigid and resistant to stretch. Condylar position can be affected in true spasm of the elevator muscles and may predispose a patient to internal derangement. As with all chronic pain, the severe pain and inability to function can bring about psychosocial problems.[113]

Spastic muscles must be differentiated by palpation from: the painful soft muscle of myositis; relatively normal, albeit painful, muscle splinting; and localized taut bands and areas of myofascial trigger points. In contrast, a muscle in spasm has a stiff hard surface that is painfully resistant to stretch.

Electromyographic recordings show high standing tension in the affected muscle but lower electromyographic activity relative to the unaffected side. Pressure threshold meters and tissue compliance measurements may help identify the muscles in spasm. Thermography is also being investigated for routine diagnostic use.[145–146]

Initial treatment should be directed to eliminating the cycling spasm. The patient should restrict movement to within painless limits, but some function is necessary to regain a normal stretch reflex, which helps relax the muscle. In spasm of a masticatory muscle, the teeth can be disengaged with a stabilization (flat plane) appliance if the mouth can open enough to insert a temporary emergency splint. Splints are thought to work by shutting off proprioceptive input from the teeth that may help maintain spastic activity.

Muscle relaxants administered judiciously can help reduce dysfunction and spasm and can be adjuncts to other therapy, such as injection of spastic muscles. Spray-and-stretch techniques and massage and acupressure techniques may also be effective.

As the muscle starts to respond to treatment, stretching and range-of-motion exercises will help prevent contractures and bring the muscle back to full function. Ongoing passive jaw motion exercises will help maintain range of motion. In the masticatory system, structural factors, such as the bite, should be corrected only after the muscle is pain-free and fully functional.[138]

Myositis. A direct blow to a muscle can trigger a localized inflammatory response accompanied by swelling, pain, and immobilization.[138] The main presenting symptoms will be localized soreness, swelling, and pain, along with weakness and immobilization of the affected structure. Pain is generally dull, deep, boring, and constant. Episodes of sharp pain related to movement of the affected structure may also be reported.

Injury to the head and neck muscles will result in an accompanying reduction in neck movement and changes in shoulder height and head posture as a means of protecting against further trauma. The pain may be perceived by the patient as a headache. An accompanying feeling of weakness in the neck may be experienced.

Patients with myositis of the masticatory muscles may report pain in the face or jaw accompanied by a change in the bite with the inability to chew, swallow, and speak comfortably. Locally, the area may appear swollen and discolored because of extravasations of inflammatory products. An inflamed muscle will present as a soft, painful mass on palpation. Pain will be associated with active as well as passive movement of the affected structure. The skin may be warmer to the touch than the surrounding area. The patient may present with low-grade fever if secondary infection is involved. Pressure threshold measurements with a threshold meter will indicate that discomfort occurs at a lower threshold than before the injury. Proximal to the injury, there may be a cold spot caused by vasoconstriction, which may affect healing.

Initial therapy of the acute symptoms of myositis includes immediately applying ice to the affected structure to reduce swelling, limiting movement to within painless boundaries, and resting the affected part. In injured mandibular muscles, restricting mouth opening during function and using a dental intraoral bite guard to control closure should be supported by NSADIs. In a severe case, immediately applying a methylprednisolone dose pack can control the amount of the immediate swelling. Antibiotics can be used if secondary infection is possible.

After the acute symptoms have subsided, treatment should include increased heat and mobilization of the affected structure, then an exercise program to regain full range of motion, and finally a muscle strengthening program.

Fibrosis and Contracture. Myotatic contracture occurs in muscles that are not allowed to function within their full range of motion. The muscle will lose its stretch reflex capabilities and will gradually shorten. Prolonged pain or immobilization can lead to myotatic contracture.[113]

Contracture can occur in the masticatory muscles if patients are unwilling or unable to open their mouths fully. Patients often report avoiding opening wide for fear of hearing clicking or crepitus, and others may not open wide because of past or present pain. Over time, this practice leads to the development of a habituated protective pattern, causing myotatic contracture. Likewise, restricted movement of the cervical region results in myotatic contracture.

Myofibrotic contracture often occurs as a result of infection that leads to fibrous changes in the muscle or its sheath. Trauma to a muscle and the resultant inflammation and splinting may lead to fibrosis—an irreversible condition. Radiation therapy, incision through a muscle with fibrotic healing, and disuse for long periods (more than 6 weeks) can also result in myofibrotic contracture.

In patients with masticatory muscle involvement, myotatic or myofibrotic contracture will appear with limited interincisal opening. If the elevator muscles are involved, deviation will occur

on opening but not on protrusion. Lateral movement will be normal. Pain will not be present without sudden and forceful stretching or biting.

The treatment for myotatic contracture is to gradually stretch the involved muscle. Ultrasound with 5% to 10% hydrocortisone cream can be used as adjunct therapy. Massage and myofascial release along with daily stretching and exercise will bring the muscle slowly back to function. Myofibrotic contracture is irreversible and requires surgical intervention for a patient whose function is severely impaired.

Muscle Disorders Secondary to Internal Derangement. In the presence of acute or chronic internal derangement, the muscles that support and move the joints can be secondarily affected. Splinting helps prevent further injury to the joint. In cases of anterior disc displacement without reduction (closed lock), the joint will often be immobile. The masticatory elevator muscles should be splinted until the joint is healed.

The clinical finding of elevator spasm often causes the physician or dentist unfamiliar with TMD to prescribe muscle relaxants. These medications override the body's defense mechanisms and so may do more harm than good. If the internal derangement is not adequately treated, the muscles remain chronically shortened and may eventually undergo contracture. A patient with acute closed lock often presents with a history of joint clicking. The patient may or may not be able to pinpoint an eliciting event. Sometimes the patient wakes up with the jaw locked. Other times, it locks during chewing. The patient will often have loss of posterior support through tooth wear, tooth breakdown, or missing or poorly restored posterior teeth.

Closed lock may be accompanied by a change in occlusion resulting from disc displacement, accompanying spasm of the lateral pterygoid, or both. The occlusion may shift to the contralateral side with a corresponding posterior open bite developing on the ipsilateral side. The patient may attempt to position the posterior teeth into contact but is hampered by joint pain and the lateral pterygoid, which pulls the mandible in the opposite side.

After acute trauma, the occlusion settles back to its preinjured state once the TMJ inflammation has subsided. However, if the patient has a parafunctional habit or has lost vertical dimension, the joint will continue to be unevenly loaded, and healing will be delayed. In such instances, the joint may become chronically inflamed and the muscles of mastication may continue to be in a state of protective splinting, spasm, or both.

If a patient has a combination of acute trauma, loss of posterior teeth, and moderate-to-severe parafunction, anterior disc displacement with intermittent locking of the TMJ is likely. Patients often report histories of trauma that are followed by a variable period of clicking, progressively increasing in frequency and culminating in an abrupt disappearance and an inability to open the mouth. Differential diagnosis of a patient who has limited mouth opening must include internal derangement, as well as muscle trauma.

Muscle Disorders Secondary to Cervical Spinal Dysfunction. Muscle disorders may occur secondary to rotations, fixations, fusions, or injury or locking of the facets of the cervical, thoracic, lumbar, and sacral vertebrae. The history, physical examination, and radiographic evaluation, often done in conjunction with a physiatrist or orthopedist, will reflect the acuteness and severity of the vertebral problem.

Disc herniations can secondarily affect the cervical muscles through protective splinting, which can eventually lead to chronic postural changes. Nerve impingement and nerve root injuries can also affect muscle function. Commonly seen cervical problems in relation to TMDs occur at the following cervical levels.

Occiput-Atlas. A reduction in the space between the posterior spine of the atlas and the base of the occiput, as reported by Rocabado,[147] may cause pain by compressing the suboccipital tissues. The pain will be perceived as a headache starting from the back of the head.

Acute or long-standing trauma can shift the occiput-atlas relationship and may lead to chronic tension in the suboccipital muscles with resulting fixation and irritation of the C1 and C2 nerves. The pain will be referred from the back of the head to the eye, along the side of the head, along the skin over the TMJ, and down along the angle of the mandible, radiating into the neck.

Rotation of the atlas is commonly seen in patients with TMDs and may be linked to changes in occlusal patterns and instability of mandibular position.[139,147] Osteoarthritic degeneration and ligament and muscle injury also occur at this level in acceleration-deceleration injuries.

Atlas/Axis Level. Trauma to this level may disrupt the transverse ligament holding the odontoid process of the axis against the anterior arch of the atlas, allowing forward subluxation or dislocation of the atlas on the axis. A disruption of the C1-C2 articulation may also result in excessive stretching or kinking of the vertebral artery secondary to hypermobility. This may lead to temporary vertebrobasilar syndrome with symptoms of vertigo, nausea, tinnitus, and visual disturbances.

Cervical rotation will be reduced because 40% to 50% of rotation occurs at the atlas-axis articulation.[147] Pain also limits movement. Fractures are always to be considered in trauma to this region.

C4, C5, and C6. The level of greatest instability against acceleration-deceleration forces appears to be in the C4 to C6 region, with C4-C5 being primarily affected in hyperextension and C5-C6 in hyperflexion. Trauma may be to the ligaments, discs, and vertebral bodies, depending on the direction and magnitude of the force.

The cervical curve can be affected, and the patient will often have a compensatory forward head posture, further perpetuating the problem.

Cranial Neuralgias

Trigeminal Neuralgia

The cranial neuralgias, particularly trigeminal neuralgia, affect the face and have specific diagnostic criteria and treatment modalities. These disorders are covered in Chapter 66.

Neuropathic Facial Pain (see Table 67.13)

The International Association for the Study of Pain (IASP) defines neuropathic pain as "Pain initiated or caused by a primary lesion or dysfunction in the nervous system."[148] Thus, neuropathic pain results from pathology in the peripheral or central nervous system.[148] These disorders are particularly common in the head and neck, probably as a result of the dense and specialized sensory innervation of this region. Unfortunately, these disorders greatly affect the patient's life by interfering with important functions, such as feeding and speech.

In the past, any facial pain disorder without a definable cause was considered to be an idiopathic, "atypical" facial pain syndrome. Over the years, many inappropriate "descriptive" diagnoses were given to these disorders (atypical trigeminal neuralgia, atypical facial pain, atypical odontalgia, phantom tooth syndrome, and so on.) Under the current IHS classification[1] (see Tables 67.5 and 67.6), these disorders are considered "central" causes for headache and facial pain and are classified as "persistent idiopathic facial pain" (category 13.18).[1]

Complex regional pain syndrome (CRPS), a form of neuropathic pain can occur in the face.[149] CRPS is covered in detail in Chapter 25. Likewise, postherpetic neuralgia commonly affects the face and is covered in detail in Chapter 27.

PSYCHOSOCIAL CONSIDERATIONS

Assessment

As with other chronic pain conditions, psychosocial factors explain much of the variance in the outcome of persistent facial pain disorders. Affective and anxiety symptoms, especially emotional trauma, have been implicated in precipitating and maintaining chronic orofacial pain.[150] Marked somatic overconcern or somatization disorder can also compromise treatment in these disorders. Similarly, chronic disability behavior further compromises the patient's status.

It has become a minimum standard of care to address critical psychosocial factors within the diagnostic interview, as underscored by the IASP Curricula on Pain for Dental Schools.[151,152] Consistent with this attention, the Research Diagnostic Criteria includes a 31-item questionnaire addressing psychosocial and physical domains of chronic TMD. Other validated self-report facial pain scales also address psychosocial issues, and their use within multidisciplinary facial pain facilities is common.[153–155]

Treatment

As in other areas of chronic pain management, behavioral interventions have been a mainstay of treatment for persistent facial pain. Time-limited, structured relaxation training is as effective as conventional occlusal splint therapy for temporal joint dysfunction and related chronic myofascial facial pain disorders. Combined treatment is even more effective and provides longer lasting effects.[156] Similarly, improving cognitive coping skills reduces pain and improves function.[157] Behavioral interventions target reducing anxiety and improving perceived control over pain. Biofeedback-assisted relaxation can also be effective, perhaps more so in limited subpopulations.[158–160] More intensive, interdisciplinary treatment is often indicated for patients with a constellation of severe psychosocial and disability behaviors.

Cost-effective behavioral group programs have also been used in the early stages of facial pain syndromes and have reduced pain and improved coping skills. Most recently, Stowell et al.[161] compared a brief behavioral treatment program emphasizing early intervention to a standard approach in patients with "acute TMD" (pain of less than 6 months duration). One-year follow-up data revealed clinical improvement and substantially fewer jaw-related health care dollars for the early intervention program. Overall, conservative interdisciplinary treatment appears to have the most promising results. Ideally, these programs will be implemented before the chronic concomitants of facial pain develop.

CONCLUSION

Craniocervical pain is a common clinical problem and often a diagnostic challenge. Given the complex anatomy of the region and the numerous discrete syndromes, a multidisciplinary approach is frequently indicated for evaluating difficult or refractory cases.

CHAPTER 68 ■ NECK AND ARM PAIN

ANITA H. HICKEY AND ZAHID H. BAJWA

INTRODUCTION

The unique anatomy of the cervical spine and upper extremity balances the attributes of strength and stability with those of flexibility and range of motion. The biomechanical properties which allow for these combined properties are associated with a high incidence of degenerative change which increases with aging and is associated with episodic or chronic pain. Although the origin of pain in the neck is often divided into axial versus radicular pain and musculoskeletal pain versus neuropathic pain, the patient presenting for treatment in the clinical setting may not always be representative of these categorical descriptions.

An understanding of the normal anatomy of the neck and upper extremity, pathophysiology of common disorders of the cervical spine, diversity of clinical presentations of neck and arm pain, and the potential contribution of systemic and psychologic factors is critical in forming a differential diagnosis, referring the patient for appropriate diagnostic tests and evaluations, and instituting timely and appropriate treatment. This chapter will focus on the anatomy of the cervical spine and upper extremity, recent data regarding the epidemiology of neck and arm pain, the critical role of the clinician in performing a thorough and targeted history and physical examination, and finally a discussion of the etiology and treatment of neck and arm pain.

The common causes of mechanical neck and arm pain, including cervical spondylosis and myelopathy, cervical radiculopathy, cervicogenic headache, brachial plexopathy, peripheral nerve entrapment syndromes of the upper extremity, and thoracic outlet syndrome, will be discussed in this chapter. Myofascial pain syndromes, fibromyalgia, and acute musculoskeletal disorders can involve the neck and upper extremities and are covered in detail elsewhere in this text. Neck and arm pain may also be secondary to primary or metastatic disease. Cancer pain is discussed more thoroughly elsewhere as well. Therapeutic modalities are covered more extensively in Part V: Methods for Symptomatic Control.

ANATOMY OF THE NECK AND ARM

Cervical Spine

The anatomy of the cervical spine is complex in order to allow for support of the weight of the cranium, to provide protection and support of the neurovascular elements of the cervical spine, and to simultaneously permit functional mobility in relationship to the surrounding structures. It is composed of 7 vertebrae, 5 intervertebral disks, 12 joints of Luschka, and 14 zygapophyseal joints, uniquely bound and connected to numerous ligaments and muscles which both limit and permit varying degrees of motion of the cervical spine.[1]

With the exception of the first two cervical vertebrae, which have unique characteristics, each of the seven cervical vertebrae is comprised of a segmental unit, which includes a vertebral body, an intervertebral disc, four uncovertebral joints of Luschka, two pedicles, two lamina, two inferior, and two superior zygapophyseal (articular facet) joints. Between each vertebral segment, a spinal nerve, radicular blood vessels, and the sinuvertebral (recurrent meningeal) nerves pass through neural openings or foramina on each side of the cervical spine (Fig. 68.1).[1]

The upper two segments of the cervical spine have unique anatomic and biomechanic characteristics when compared with the lower five segments of the cervical spine. The atlas, or C1 vertebra, is a ring shaped vertebra with paired lateral pillars which function as articulating joints or facets. The upper ellipsoid facets articulate superiorly with the occipital condyles to form the atlantooccipital joints, while the round and concave inferior facets articulate inferiorly with the axis to form the atlantoaxial joints. The anterior arch of the atlas incorporates an articular surface which contacts the anterior surface of the dens or odontoid process of the axis. The atlas is the widest of the cervical vertebrae, allowing for the spinal cord, dens, and a surrounding cushion of spinal fluid. It has a mean internal, anteroposterior dimension of approximately 31.7 mm and an internal width of 32.2 mm. The atlas is the only cervical vertebra not associated with an intervertebral disk. Its transverse process is longer than the other cervical vertebrae to support the attachments of the muscles that rotate the head, and its transverse foramen contains the vertebral artery, veins, and sympathetic nerves (Fig. 68.2).

The axis, or C2 vertebra, has a small body anteriorly from which the odontoid process arises and projects upward. Its oval shaped anterior face articulates with that on the anterior arch of the atlas. The posterior surface of the odontoid process articulates with the transverse ligament. The facets on the upper and lower surfaces of the lateral masses of the axis articulate with the atlas above and the C3 facet joints below. The atlas also has a large palpable bifid spinous process and small transverse processes with transverse openings or foramina through which the vertebral artery, veins, and the vertebral sympathetic plexuses pass. Because both the atlas and the axis lack pedicles and intervertebral foramen, the nerve roots of the first and second spinal nerves pass above and posterior to the articulating lateral masses of each vertebrae. The hypoglossal nerves traverse the occipital condyles anterolaterally through the hypoglossal foramen a mean of 12.2 mm from the posterior margin of the occipital condyle (see Fig. 68.2).[1]

The five lower cervical vertebrae share common characteristics in that they are composed of a vertebral body, an intervening intervertebral disc, two pedicles, two laminae, two vertebral arches, and a spinous process. The upper and lower surfaces of the pedicles form the articulating facets of the cervical zygapophyseal joints. The transverse processes are situated anterolaterally to the facet joints. Their trough-shaped surfaces contain the roots of the cervical spinal nerves and a foramen through which the vertebral artery, veins, and vertebral sympathetic nerve pass.[1]

The anterior portions of the C2 through C7 vertebral bodies, like those of the thoracic and lumbar spine, are connected at their upper and lower surfaces by intervertebral disks which make up the main joints of the spinal column. Each disk is made up of a central nucleus pulposis surrounded by a thick ring of fibrous cartilage called the annulus fibrosis. The disk is connected to the vertebral body above and below by a hyaline cartilage endplate whose fibers interface with the disc and the vertebral body.[1]

The nucleus pulposis contains collagen and elastin fibers embedded in a colloidal proteoglycan gel which is osmotically

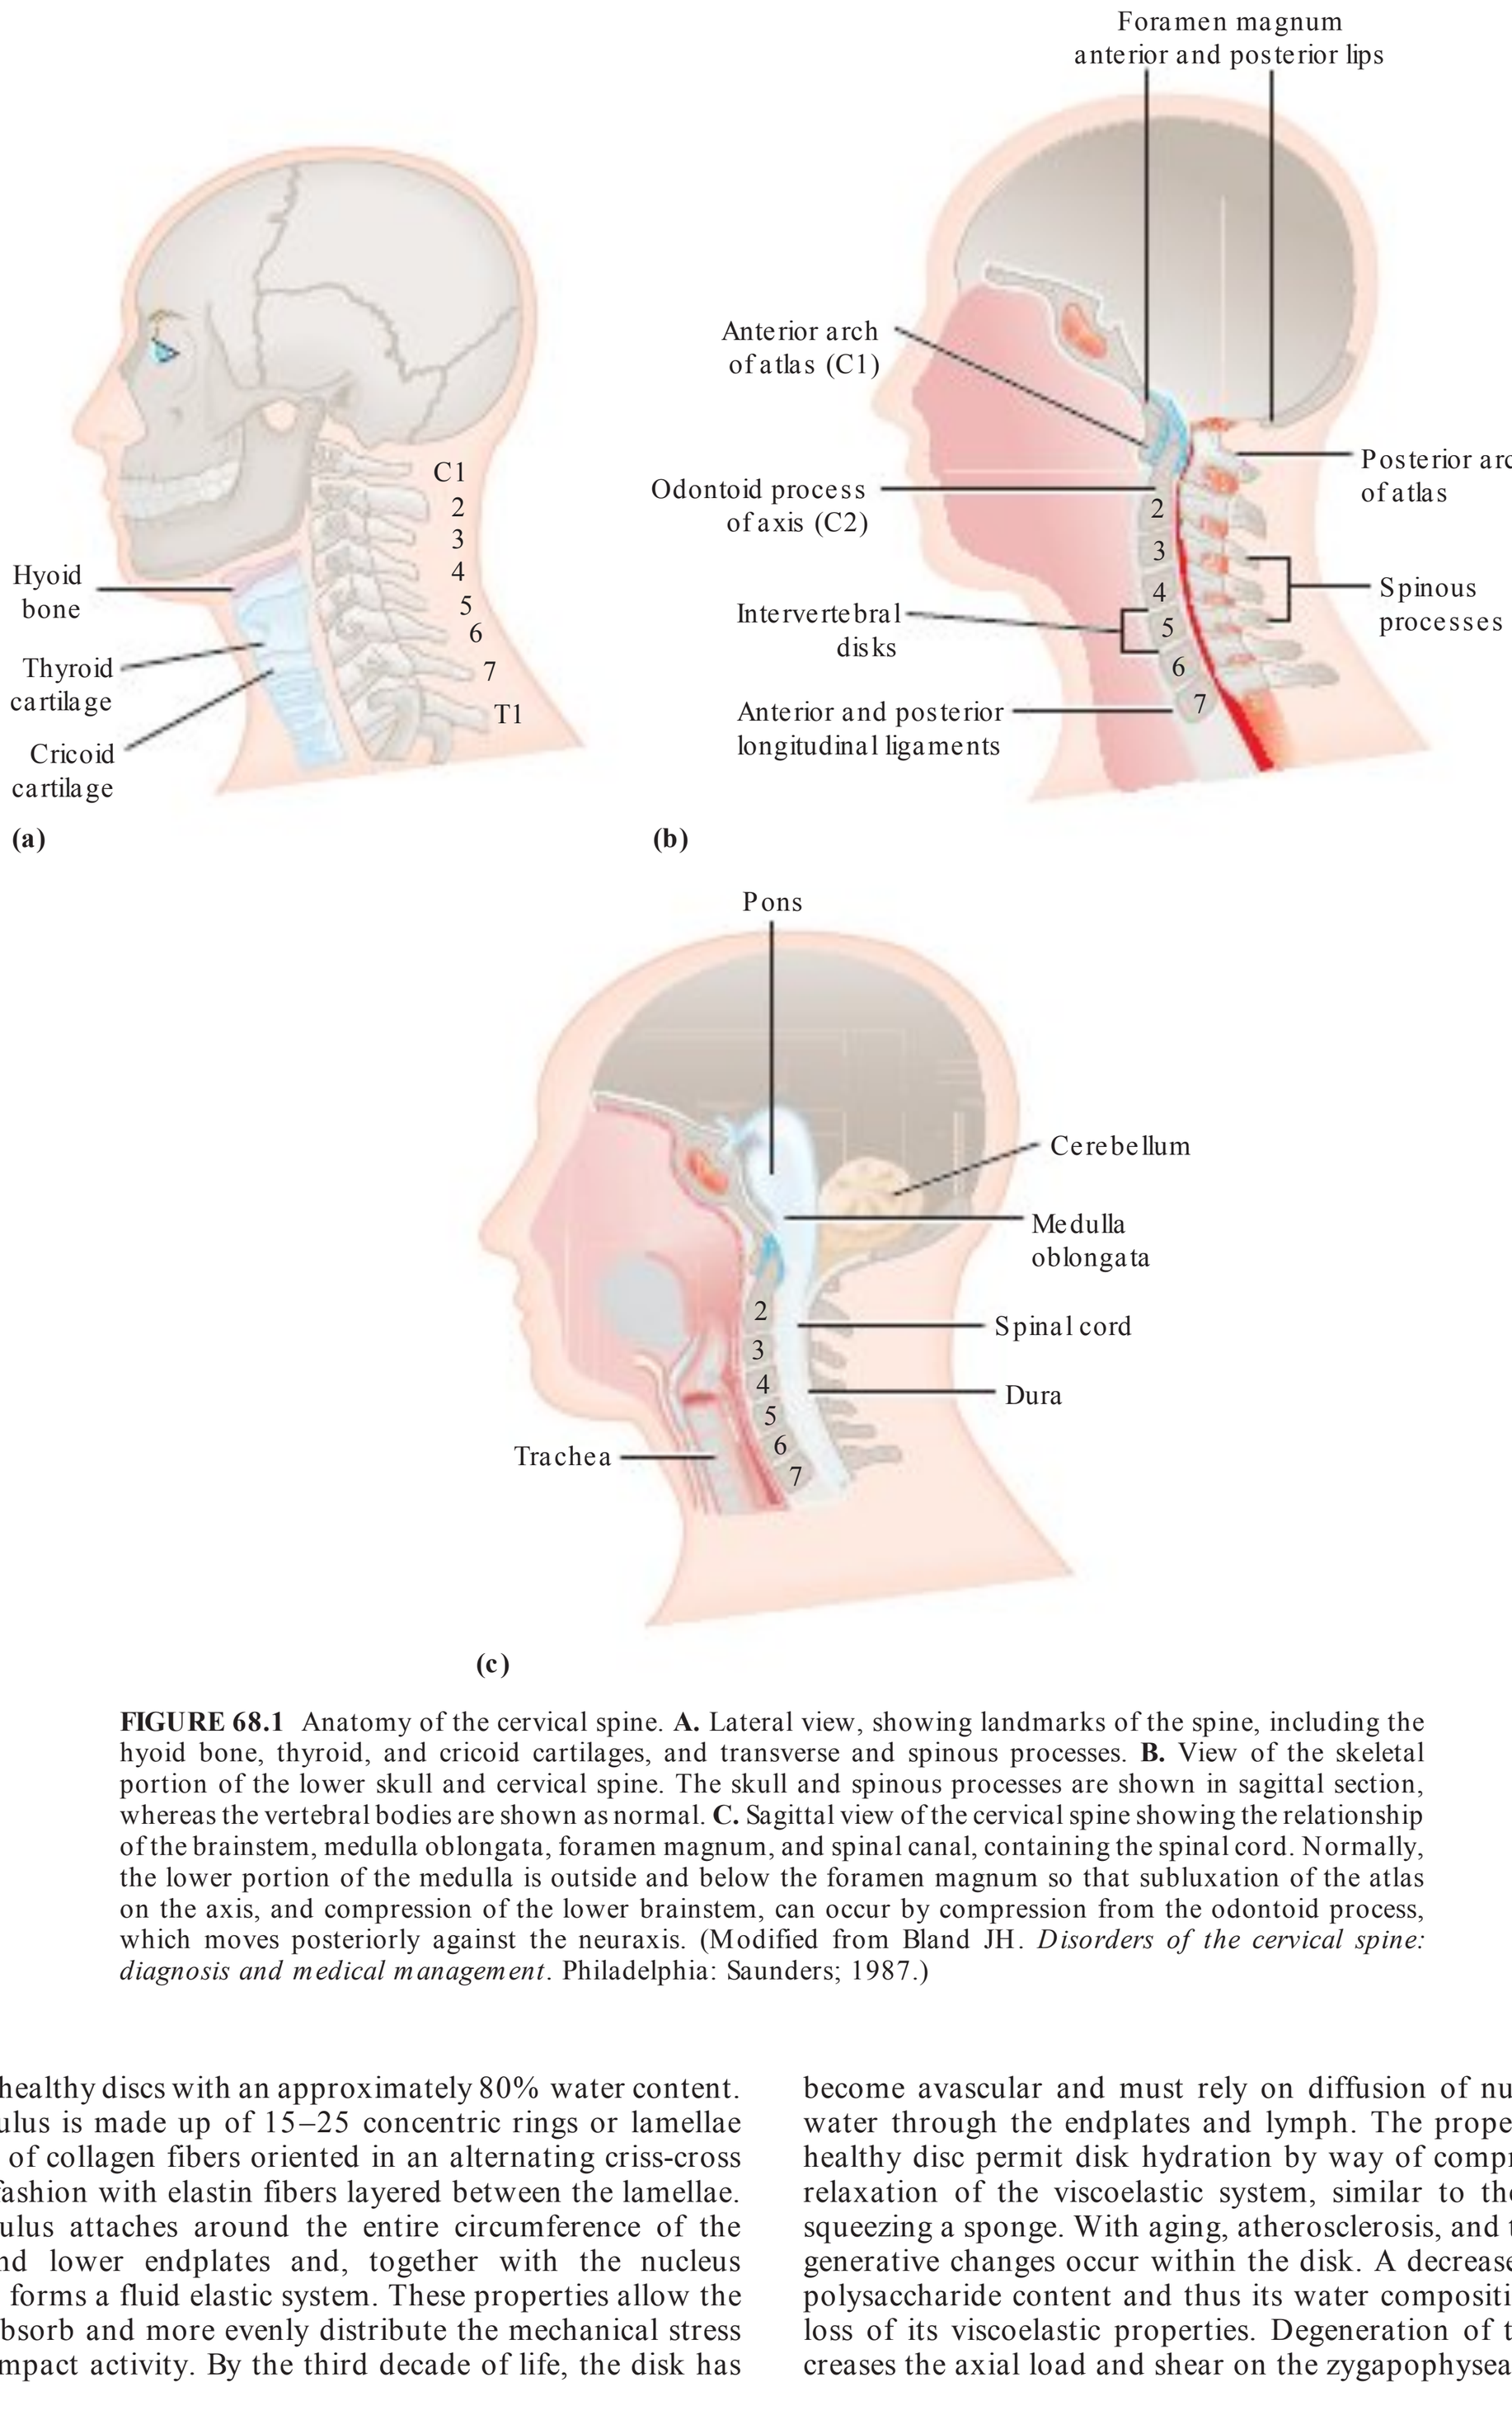

FIGURE 68.1 Anatomy of the cervical spine. **A.** Lateral view, showing landmarks of the spine, including the hyoid bone, thyroid, and cricoid cartilages, and transverse and spinous processes. **B.** View of the skeletal portion of the lower skull and cervical spine. The skull and spinous processes are shown in sagittal section, whereas the vertebral bodies are shown as normal. **C.** Sagittal view of the cervical spine showing the relationship of the brainstem, medulla oblongata, foramen magnum, and spinal canal, containing the spinal cord. Normally, the lower portion of the medulla is outside and below the foramen magnum so that subluxation of the atlas on the axis, and compression of the lower brainstem, can occur by compression from the odontoid process, which moves posteriorly against the neuraxis. (Modified from Bland JH. *Disorders of the cervical spine: diagnosis and medical management*. Philadelphia: Saunders; 1987.)

active in healthy discs with an approximately 80% water content. The annulus is made up of 15–25 concentric rings or lamellae made up of collagen fibers oriented in an alternating criss-cross oblique fashion with elastin fibers layered between the lamellae. The annulus attaches around the entire circumference of the upper and lower endplates and, together with the nucleus pulposis, forms a fluid elastic system. These properties allow the disk to absorb and more evenly distribute the mechanical stress of high impact activity. By the third decade of life, the disk has become avascular and must rely on diffusion of nutrients and water through the endplates and lymph. The properties of the healthy disc permit disk hydration by way of compression and relaxation of the viscoelastic system, similar to the action of squeezing a sponge. With aging, atherosclerosis, and trauma, degenerative changes occur within the disk. A decrease in protein polysaccharide content and thus its water composition leads to loss of its viscoelastic properties. Degeneration of the disk increases the axial load and shear on the zygapophyseal joints and

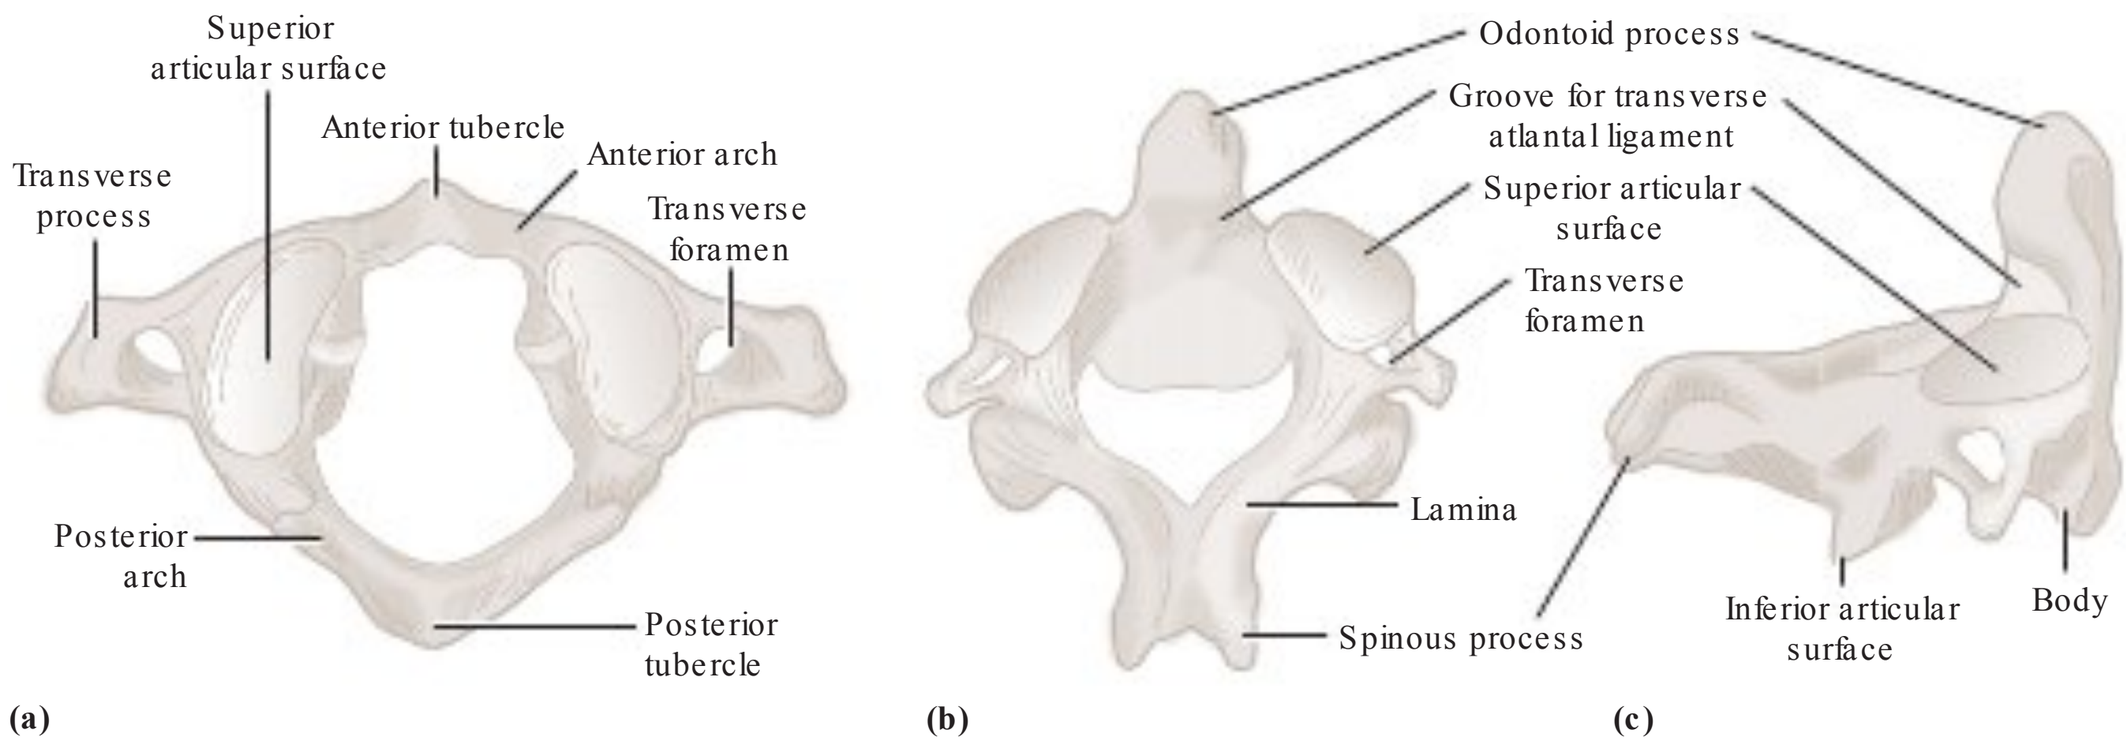

FIGURE 68.2 Anatomy of the atlas and axis. **A.** Superior view of the atlas. **B.** The axis viewed from a superior and posteroanterior aspect. **C.** Lateral view of the axis.

contributes to simultaneous degenerative changes of these posterior spinal elements (Fig. 68.3).[1]

The posterior elements of the lower segments of the cervical spine consist of two vertebral arches, a central posterior spinous process, two transverse processes, and a paired articulation. The transverse processes and posterior spinous processes serve as sites for attachment of supporting ligaments and neck muscles. The zygapophyseal facet joints are true joints with cartilaginous surfaces lined with synovium, containing synovial fluid and surrounded with a ligamentous joint capsule. As such, they are subject to the same inflammatory and degenerative diseases found in other synovial joints. The cervical zygapophyseal joints provide a guiding and gliding movement between the adjacent cervical vertebrae. The movements allowed at the atlantooccipital and atlantoaxial joint are much different than those allowed at the C2-C3 through C7-T1 joints. Differences between the cervical and lumbar spine are summarized in Table 68.1 and Figure 68.4.[1]

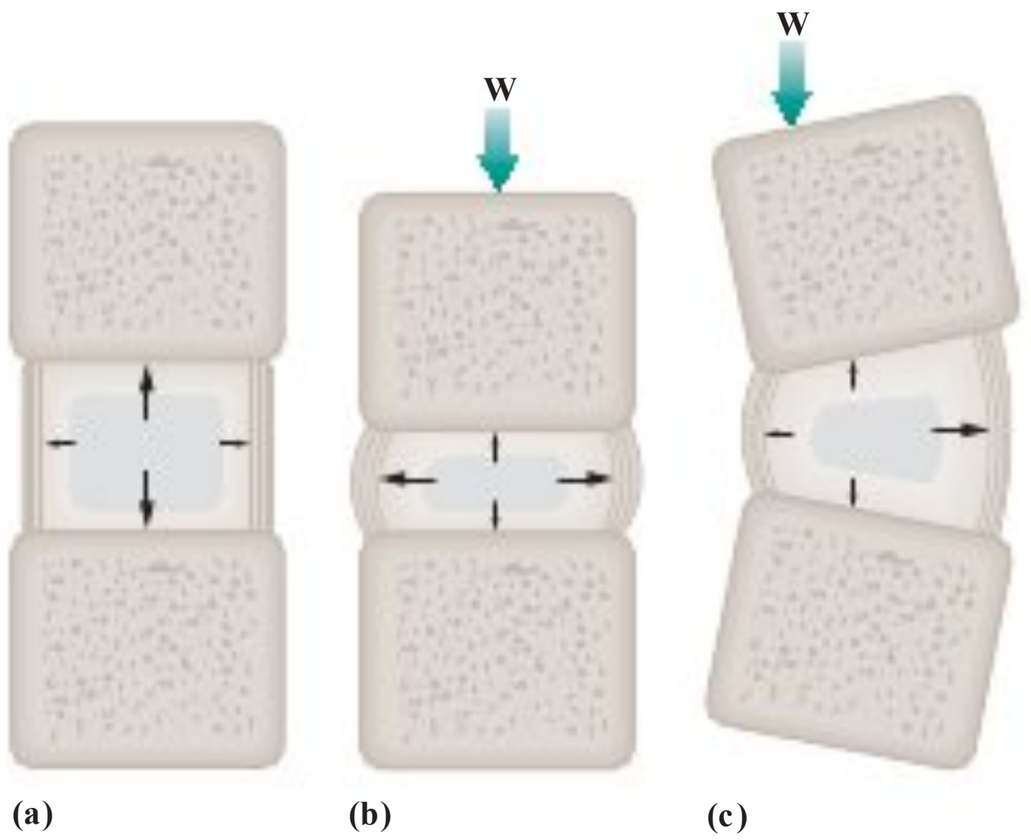

FIGURE 68.3 Schematic depiction of the hydraulic mechanism of the intervertebral disk. **A.** Normal disk at rest. The internal pressure is exerted in all directions, and the fibers of the annulus are taut. **B.** When the disk is compressed the fluid within the nucleus pulposus cannot compress, so the annulus must bulge. **C.** With flexion of the spine, the fluid shifts within the intervertebral disk; the cubic contents remain the same but the fluid shift causes fibers of the anterior annulus to shorten and those of the posterior annulus to elongate (*W, weight*). (From Cailliet R. *Neck and arm pain*. 2nd ed. Philadelphia: FA Davis; 1981.)

Ligaments of the Cervical Spine

The ligaments of the cervical spine provide essential protection to the spinal cord and nerves during various stresses which occur owing to a top-heavy and eccentrically balanced head atop a relatively narrow elastic cervical spine. The greatest range and amplitude of movement in the cervical spine occurs between the occiput and the C3 vertebra, whereas nodding in an up and down

TABLE 68.1

DIFFERENCES BETWEEN THE CERVICAL AND LUMBAR SPINE

Characteristic	Cervical	Lumbar
Disk to vertebral body height ratio	1:2	1:3
Vertical height of disk	Anterior height 2× that of posterior height/ wedge shaped	Anterior height slightly greater anterior
Vertebral endplates	Convex and concave, nucleus in anterior portion of disk	Flat and parallel, nucleus centrally located
Joints of von Luschka	False joints or pseudoarthrosis, appear at 10–20 years of age	Not present in lumbar or thoracic spine
Posterior longitudinal ligament	Double layered between vertebrae Broad, thick, and complete across postvertebra	Incomplete posteriorly from L3–S1
Movement between vertebrae	Forward and backward gliding motion	Rocking movement

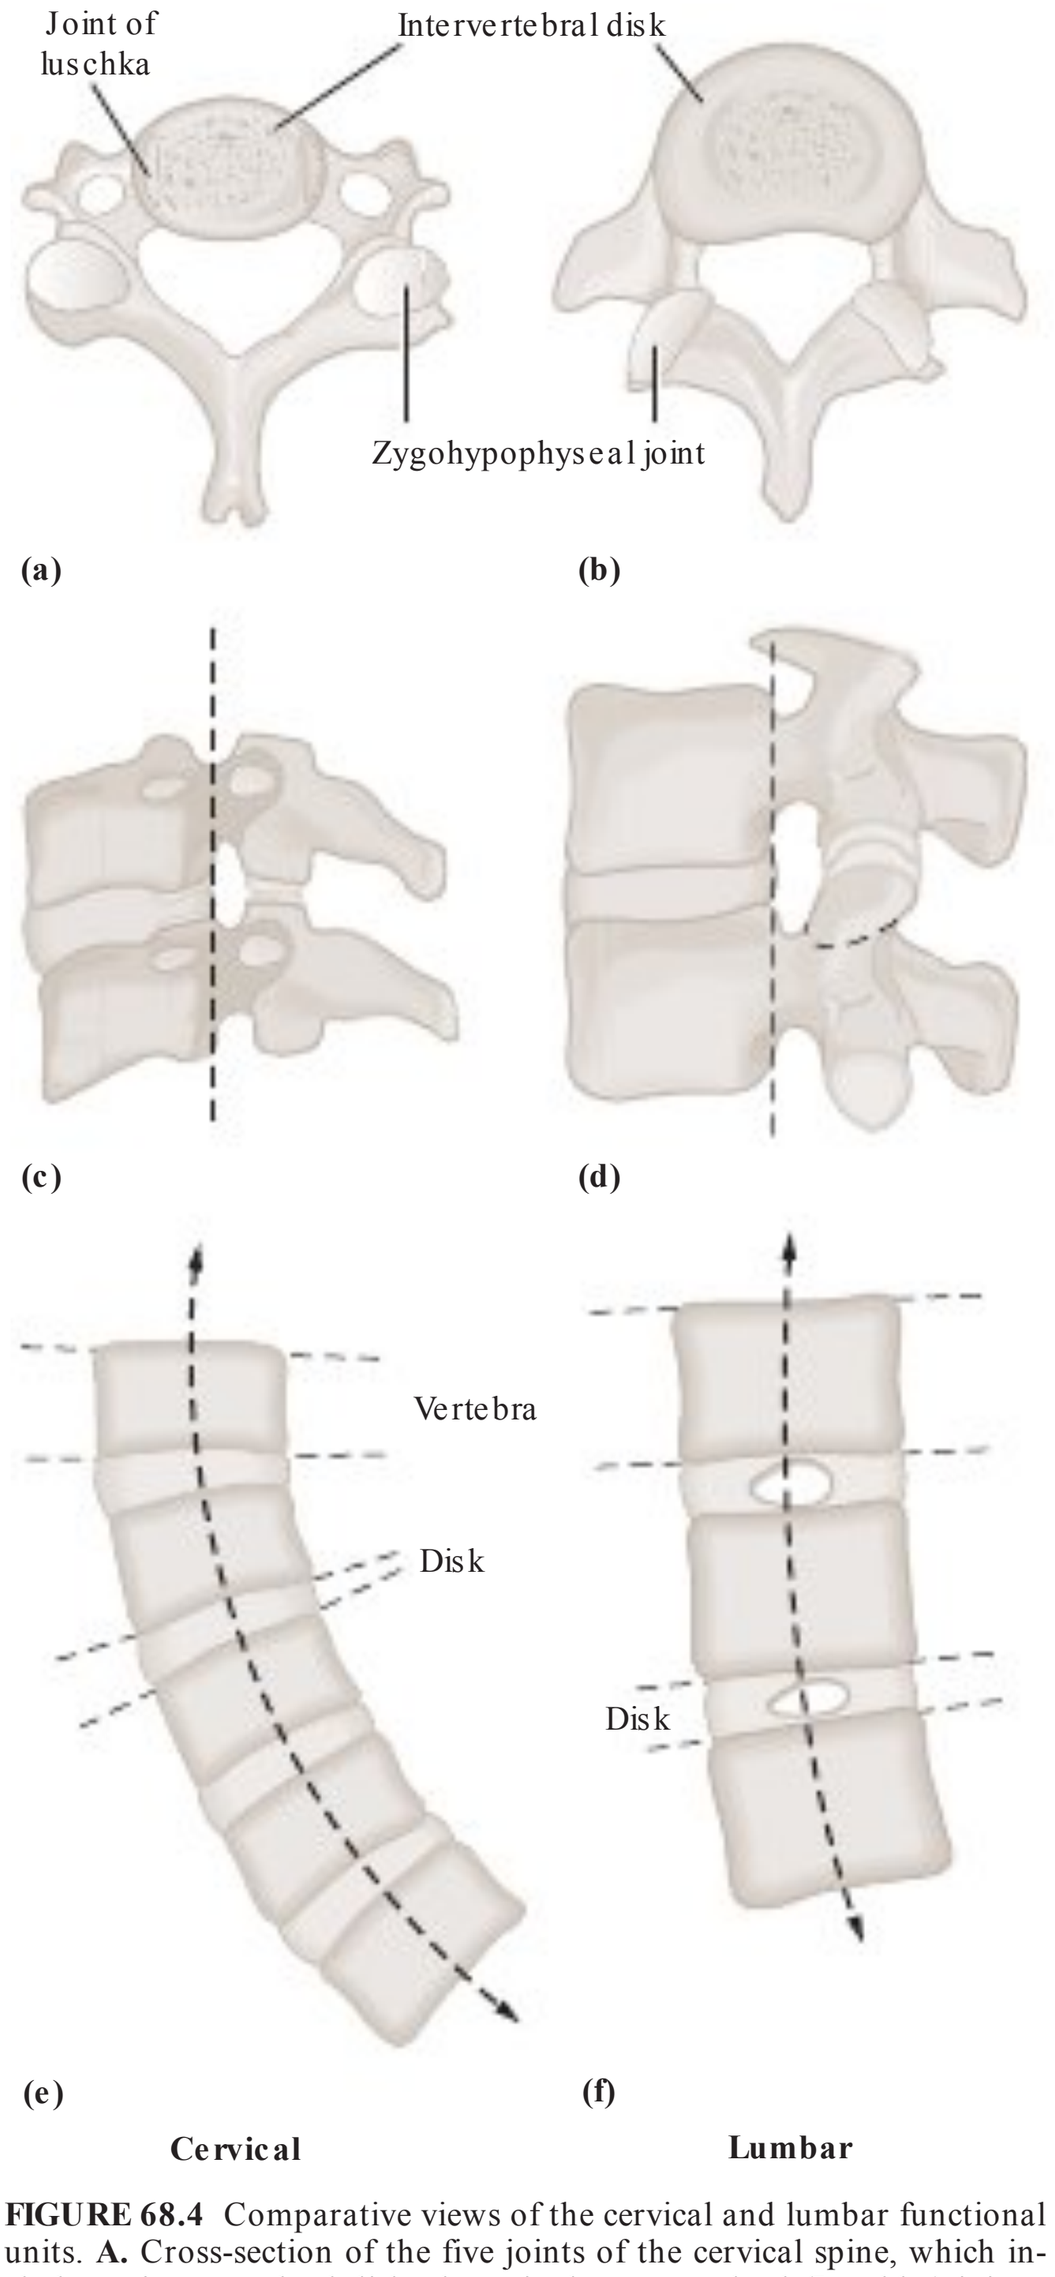

FIGURE 68.4 Comparative views of the cervical and lumbar functional units. **A.** Cross-section of the five joints of the cervical spine, which include an intervertebral disk, the paired uncovertebral (Luschka) joints, and the paired posterior articulations. **B.** Cross-section of the three joints of the lumbar spine, which include an intervertebral disk and the paired posterior articulations. **C,D.** Lateral views of the same vertebrae shown in **A** and **B**. The dashed lines divide the anterior supporting portion from the posterior gliding portion of each functional unit. **E,F.** Lateral views of the bodies of the vertebrae of the cervical and lumbar spines, depicting particularly the shapes of the intervertebral disks. Note that in the cervical region the anterior portion of the disk is larger (higher) than the posterior portion, whereas in the lumbar region the difference between the anterior and posterior portions is much less. (Modified from Cailliet R. *Neck and arm pain*. 2nd ed. Philadelphia: FA Davis; 1981.)

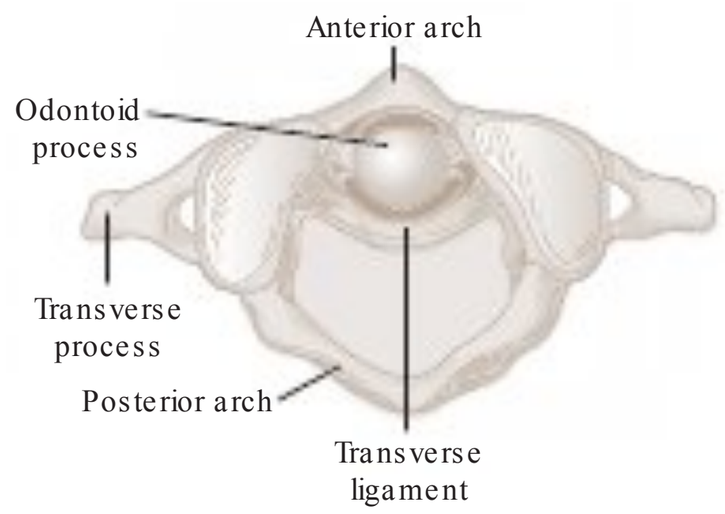
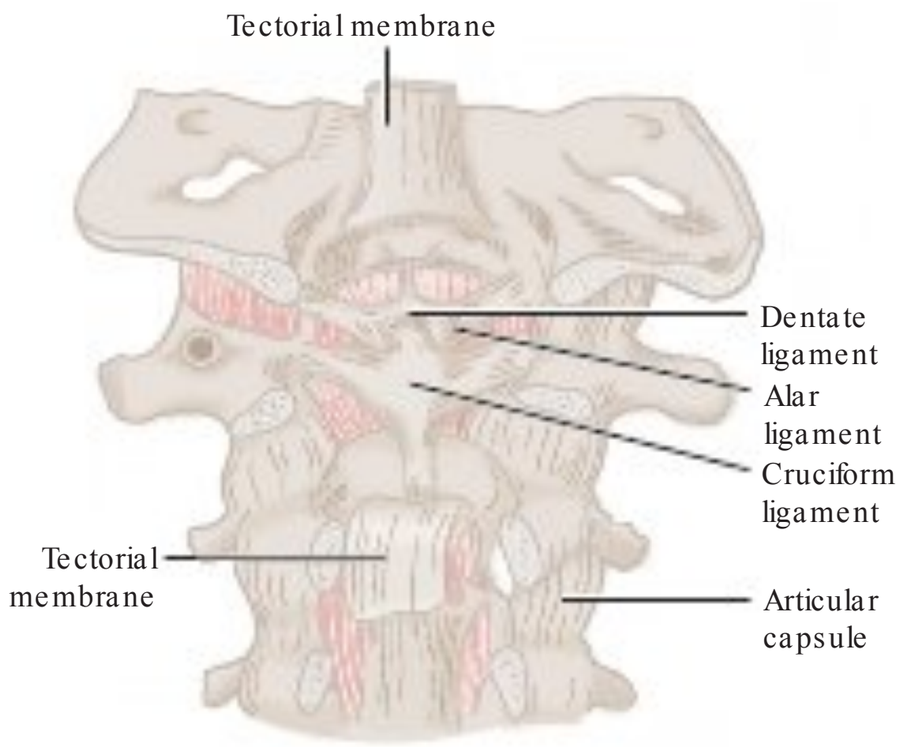
movement in the sagittal plane occurs between the atlas and the axis.[1]

Atlantooccipital Unit. Flexion and extension at the occiput to C1 level is limited to 23–24.5 degrees by impingement of the tip of the dens on the foramen magnum in flexion and the tectorial membrane in extension. The tectorial membrane is a fan-shaped continuation of the posterior longitudinal ligament to the base of the occiput where its fibers connect with the dura mater. Lateral bending is resisted by the anatomy of the occipital-C1 articulation and the alar ligaments, and averages 3.4 to 5.5 degrees per side. The alar ligaments are enclosed in a synovial membrane and extend to the margin of the foramen magnum from each side of the odontoid process. Axial rotation is also limited by the atlantooccipital joint and the alar ligament to 2.4 to 7.2 degrees per side. Lateral translation, stretch and compression, and sagittal plane translation is restricted by the tectorial membrane, the alar, and the apical ligaments, as well as the occiput-C1 articulation. The apical ligament is a vestigial remnant of the notochord and attaches from the peak of the odontoid process to the anterior foramen magnum. Other ligaments at this level include the posterior atlantooccipital membrane, which forms the connection between the anterior margin of the foramen magnum and the anterior arch of the atlas and the posterior atlantooccipital membrane, which extends posteriorly over the vertebral artery.[1]



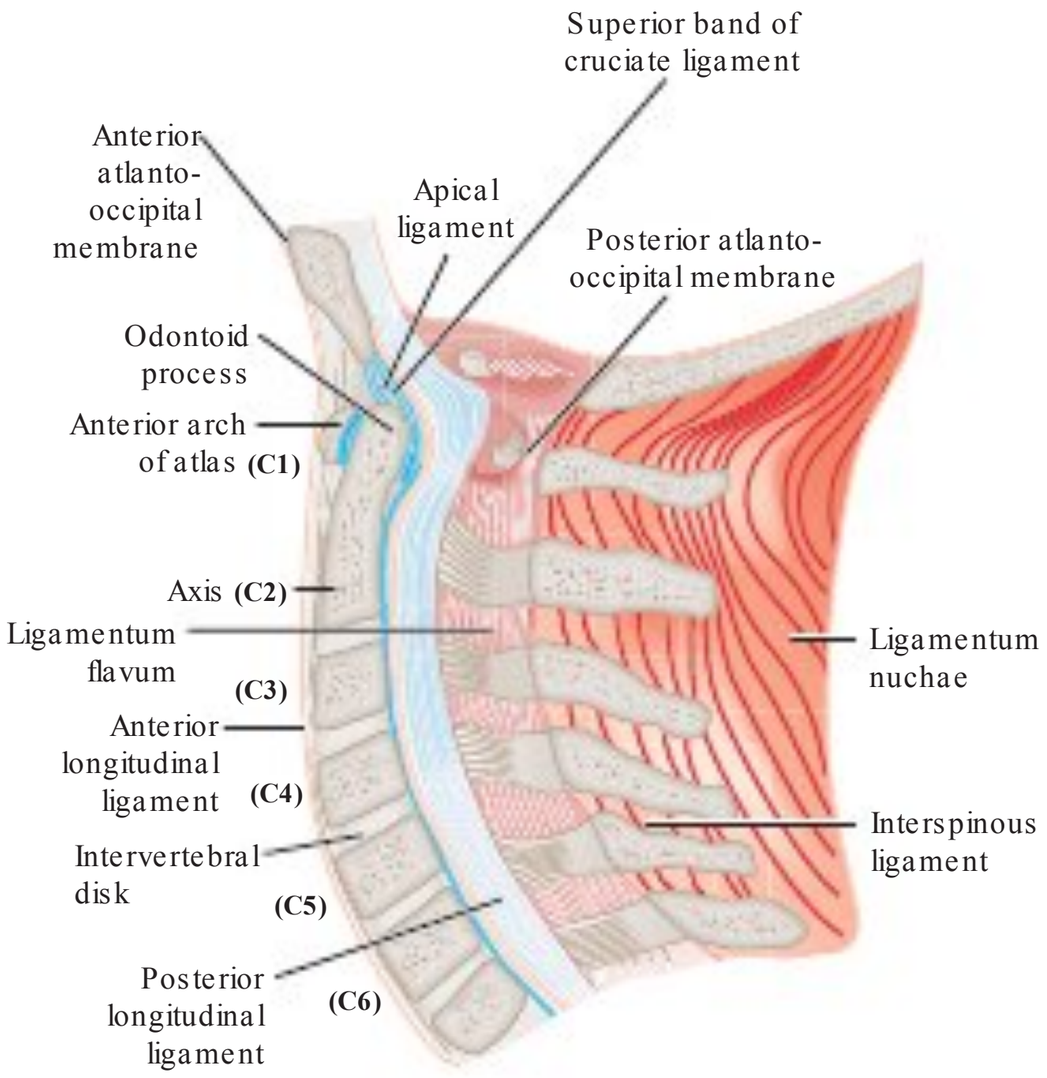
Atlantoaxial Unit. Axial rotation is the primary movement of the C1-C2 segment. The average 23.3–38.9 degree per side rotation is limited by the atlantoaxial joints, the transverse ligament of the ipsilateral side, the alar ligaments of the contralateral side, and capsular ligaments. Flexion-rotation is 10.1–22.4 degrees and is resisted by the transverse ligament during flexion, the tectorial membrane and joint anatomy. Lateral bending is limited to 6.7 degrees mostly by the alar ligament. Posterior movement or translation at this level is resisted by abutment of the dens on the arch of C-1. The transverse ligament extends posteriorly to the odontoid process between the lateral pillars of the atlas. The destabilizing effect of a tear of the transverse ligament is equal to that of a fracture of the odontoid process.[1,2]

Other Cervical Ligaments. The posterior longitudinal ligament and the anterior longitudinal ligaments limit the degree of flexion, extension, and transverse sliding of the C2 to C7 vertebrae. The anterior longitudinal ligament blends with the annulus as it crosses the disk spaces and adheres to the front of the vertebral bodies. The posterior longitudinal ligament is a double-layered structure which is firmly bound to the posterior surface of the cervical disks and loosely bound to the posterior cervical vertebrae. It reinforces the capsular ligaments and the anterior border of the cervical spinal canal.[1]



The ligamentum flavum are paired structures forming the posterior border of the epidural space. Collectively referred to as ligament flava, they extend between the anterior inferior surface of the lamina above and to the posterior superior surface of the lamina below. Posterior to the ligamentum flavum, the interspinous ligaments extend between and connect each spinous process. The ligamentum nuchae is the superior continuation of the supraspinous ligaments of the thoracic and lumbar vertebrae. It is a strong fibrous posterior ligament which extends from the base of the skull to the tips of the posterior cervical spinous process and vertebra (Fig. 68.5).[1]

Musculature of the Neck



The capital movers are the muscles of the neck that flex and extend the head. The capital extensors include the posterior rectus capitis minor and major and the obliquus capitis superior and inferior. The groups of longer muscles that act as capital extensors while working together bilaterally include the longissimus capitis, semispinalis capitis, and splenius capitis. The capital flexors are

(a)

(b)

(c)

FIGURE 68.5 A–C. Ligaments of various parts of the cervical spine (see text for details). (Modified from Clemente CD, ed. *Gray's anatomy of the human body*. Philadelphia: Lea & Febiger; 1985:343–344; and from Netter FH. *CIBA collection of medical illustrations. Vol 1. The nervous system*. Summit, NJ: CIBA Pharmaceutical Products; 1983.)

the short recti and the longus capitis muscles. The most extension and extensor musculature is at the atlantoaxial and C6 through T1 joints. The cervical extensors include the splenius cervicis, longissimus cervicis, and semispinalis cervicis. Maximum flexion of the cervical spine and maximum cervical lordosis occurs at C4-C5. The flexors of the cervical spine consist of the scalenus anterior, medius, and posterior. Unilateral rotators of the head include the splenius cervicis, splenius capitis, longissimus capitis, and sternocleidomastoid. The erector muscles of the vertebral column are also involved in movement of the neck (Fig. 68.6).[1]

The Vertebral Canal

A transverse cut through the cervical vertebral canal reveals its triangular shape with the base or anterior wall made of the vertebra, disk, posterior longitudinal ligament, pedicle, and neural foramina. The lateral and dorsolateral aspects of the other two sides of the triangle include the zygapophyseal joints, laminae, and ligament flava. The canal has its largest sagittal diameter, a range of 16–30 mm, at the C1-C2 level and its smallest sagittal diameter, a range of 14–23 mm, at the C5-C6 level. The cervical canal lengthens and the intervertebral foramina enlarge during flexion, whereas shortening of the cord and a decrease in the size of the foramen occurs with extension. Lateral flexion or rotation causes the ipsilateral foramina to decrease in size and the contralateral foramina to enlarge. These changes in size of the foramen become significant in the degenerative spine (Fig. 68.7).[1]

The spinal cord is covered by meninges which consist of the delicate pia matter attached to the cord, the web-like arachnoid membrane, and the strong outer dura mater. The dura mater is attached to the foramen magnum and the dorsal surfaces of the C2 and C3 vertebra. The spinal cord is suspended in and protected by surrounding cerebrospinal fluid and is attached laterally to the dural sheath by the dentate ligaments, which are thickenings of the pia mater between and anterior and posterior roots. The anterior and posterior rootlets join the anterior and posterior roots respectively at the inner aspect of the intervertebral foramina (Fig. 68.8). An enlargement of the cervical cord occurs from the C3 to T1 levels. It is larger than the lumbar enlargement as it contains the ascending and descending long tracts for the trunk as well as the upper and lower limbs. The transverse diameter of the cervical spinal cord is greater than its sagittal diameter, and the cervical cord occupies approximately 40% of the canal. With neck extension, the dura relaxes to form a corrugated appearance and the vertebra above approximates the arch of the vertebra below causing encroachment into the cervical canal. These factors, together with shortening of the cord during extension, increase the risk of impingement of the cord during neck extension.[1]

Vertebral Arteries

The vertebral arteries are the first branches from the subclavian trunk and pass cephalad as they course through the transverse foramina of C6 to C2 anterior to the cervical nerves. They are

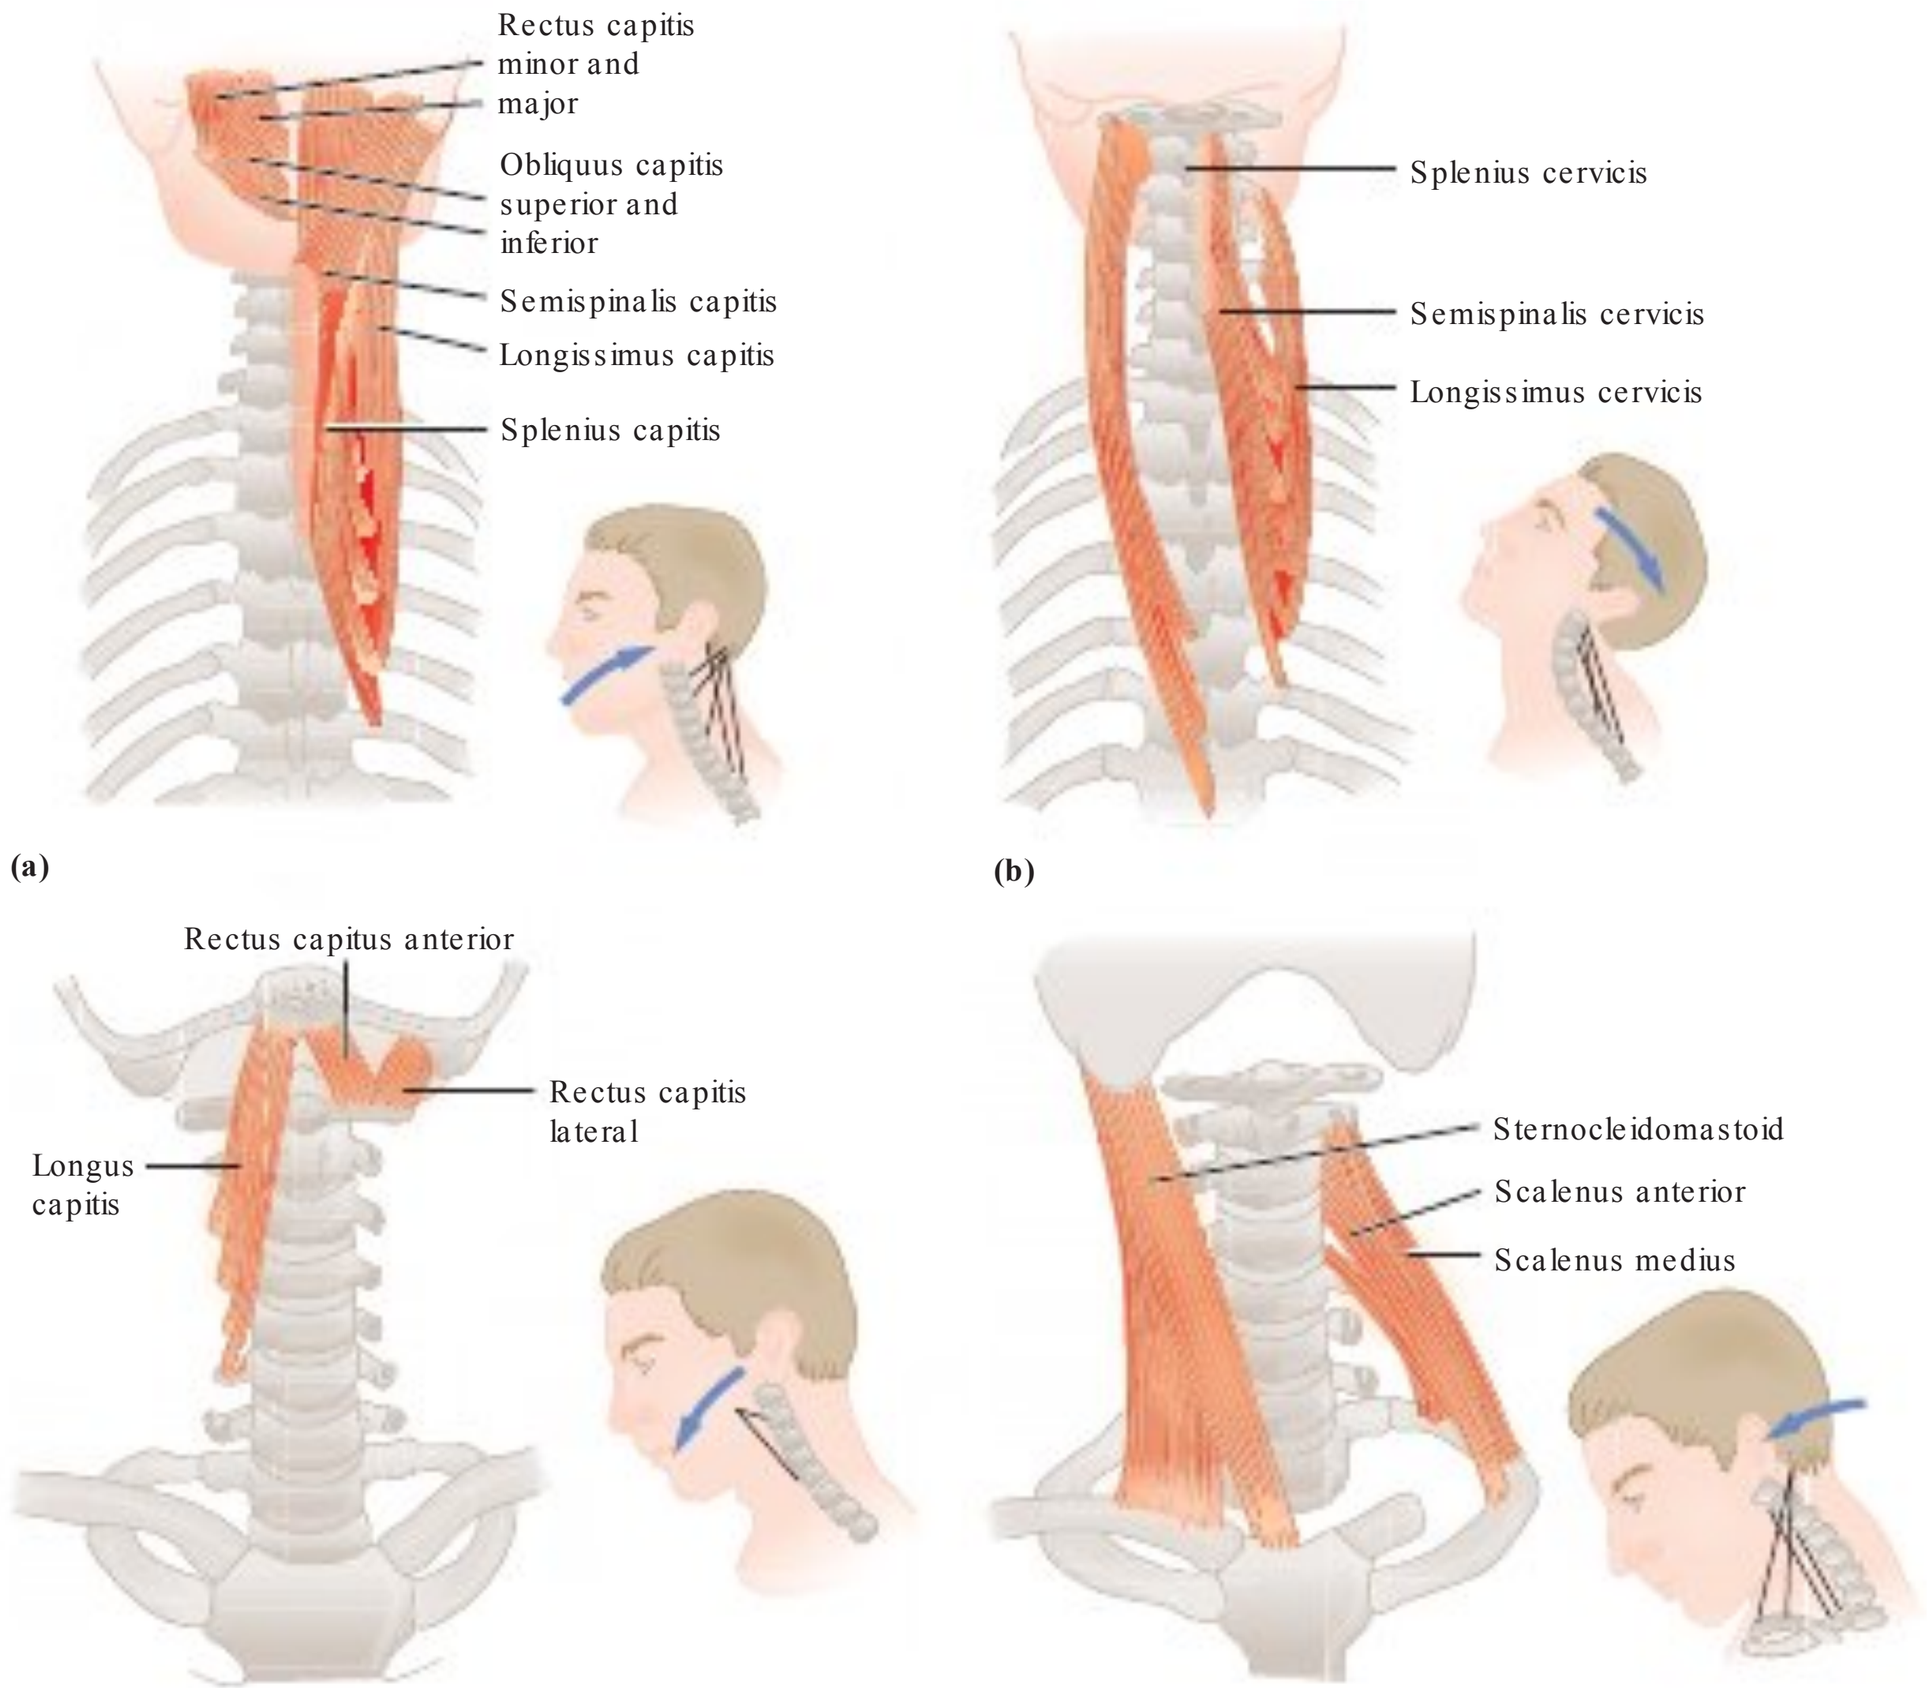


FIGURE 68.6 Musculature of the head and neck. **A.** The capital extensors attach on the skull and move the head on the neck. **B.** The cervical extensors originate from and attach on the cervical spine and alter the curvature of the spine. **C.** The capital flexors flex the head on the neck. **D.** The cervical flexors attach occlusively on the cervical vertebrae and have no significant functional attachment to the skull. (Modified from Clemente CD, ed. *Gray's anatomy of the human body*. Philadelphia: Lea & Febiger; 1985; and from Cailliet R. *Neck and arm pain*. 2nd ed. Philadelphia: FA Davis; 1981.)

accompanied by the vertebral venous plexus and the vertebral nerve and sympathetic plexus, whose fibers originate from neurons in the stellate and intermediate cervical sympathetic ganglia. Branches from the vertebral artery pass through the intervertebral foramina where they supply ligaments, dura, and bone and communicate with the posterior and anterior spinal arteries, which are also branches of the vertebral arteries. The vertebral arteries are supplied by fibers from the vertebral sympathetic plexus as are the basilar artery, circle of Willis, superior cerebellar, and posterior cerebellar artery (Fig. 68.9).[1]

Cervical Nerves

A more detailed discussion of peripheral and spinal pain mechanisms and applied anatomy relevant to pain can be found in earlier chapters of this text. The spinal nerve roots are composed of a dorsal sensory root and a ventral motor root. The posterior root breaks into 12 or more rootlets which attach in series to the dorsolateral sulcus of the cord near Lissauer's tract and then project into the dorsal and ventral horns. Peripherally, the sensory rootlets converge into the fascicule radiculae which unite to form the dorsal root ganglion. A smaller number of rootlets make up the anterior root which arises from the ventrolateral sulcus of the cord. Each rootlet is covered by pia mater and, as they coalesce to form dorsal and ventral roots, they become separately covered in arachnoid-dural sleeves which are attached to the bony margin of the intervertebral foramen. The anterior roots are in contact with Luschka's joint, and the disk annulus and the dorsal root approximates the articular process and zygapophyseal joint capsule as they pass through the cervical intervertebral foramen. The dorsal and anterior roots join slightly beyond the dorsal root ganglion to form the composite spinal nerve.[1]

The figure eight-shaped intervertebral foramina are largest at

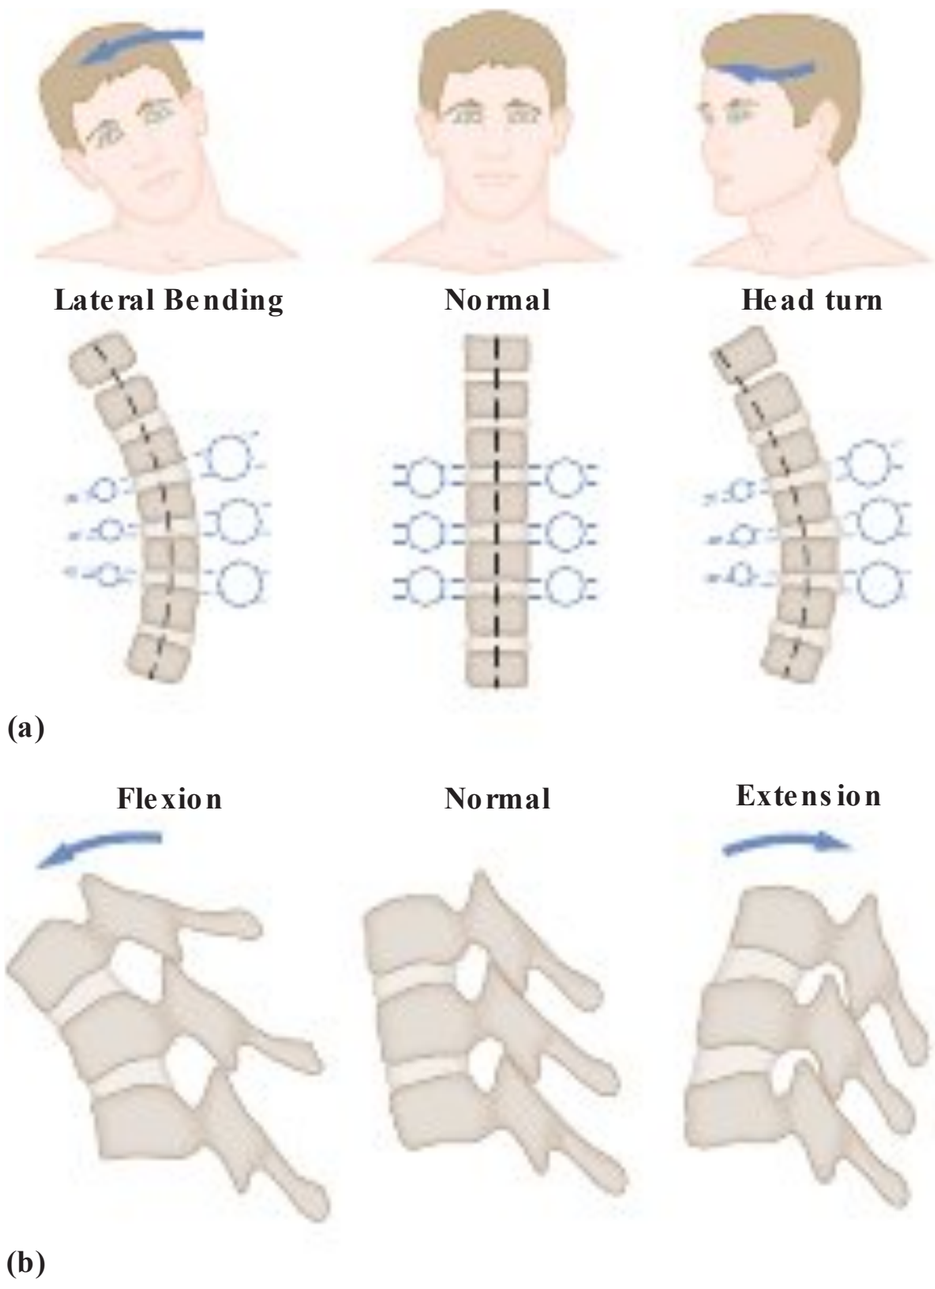

FIGURE 68.7 Changes in the size of the intervertebral foramina with movement of the neck. **A.** With lateral flexion and rotation of the head the foramina become smaller on the side of the head to which the head flexes laterally or rotates, and they are open on the opposite side. **B.** With forward flexion the intervertebral foramina become larger, whereas with extension they become smaller. (Modified from Cailliet R. *Neck and arm pain*. 2nd ed. Philadelphia: FA Davis; 1981.)

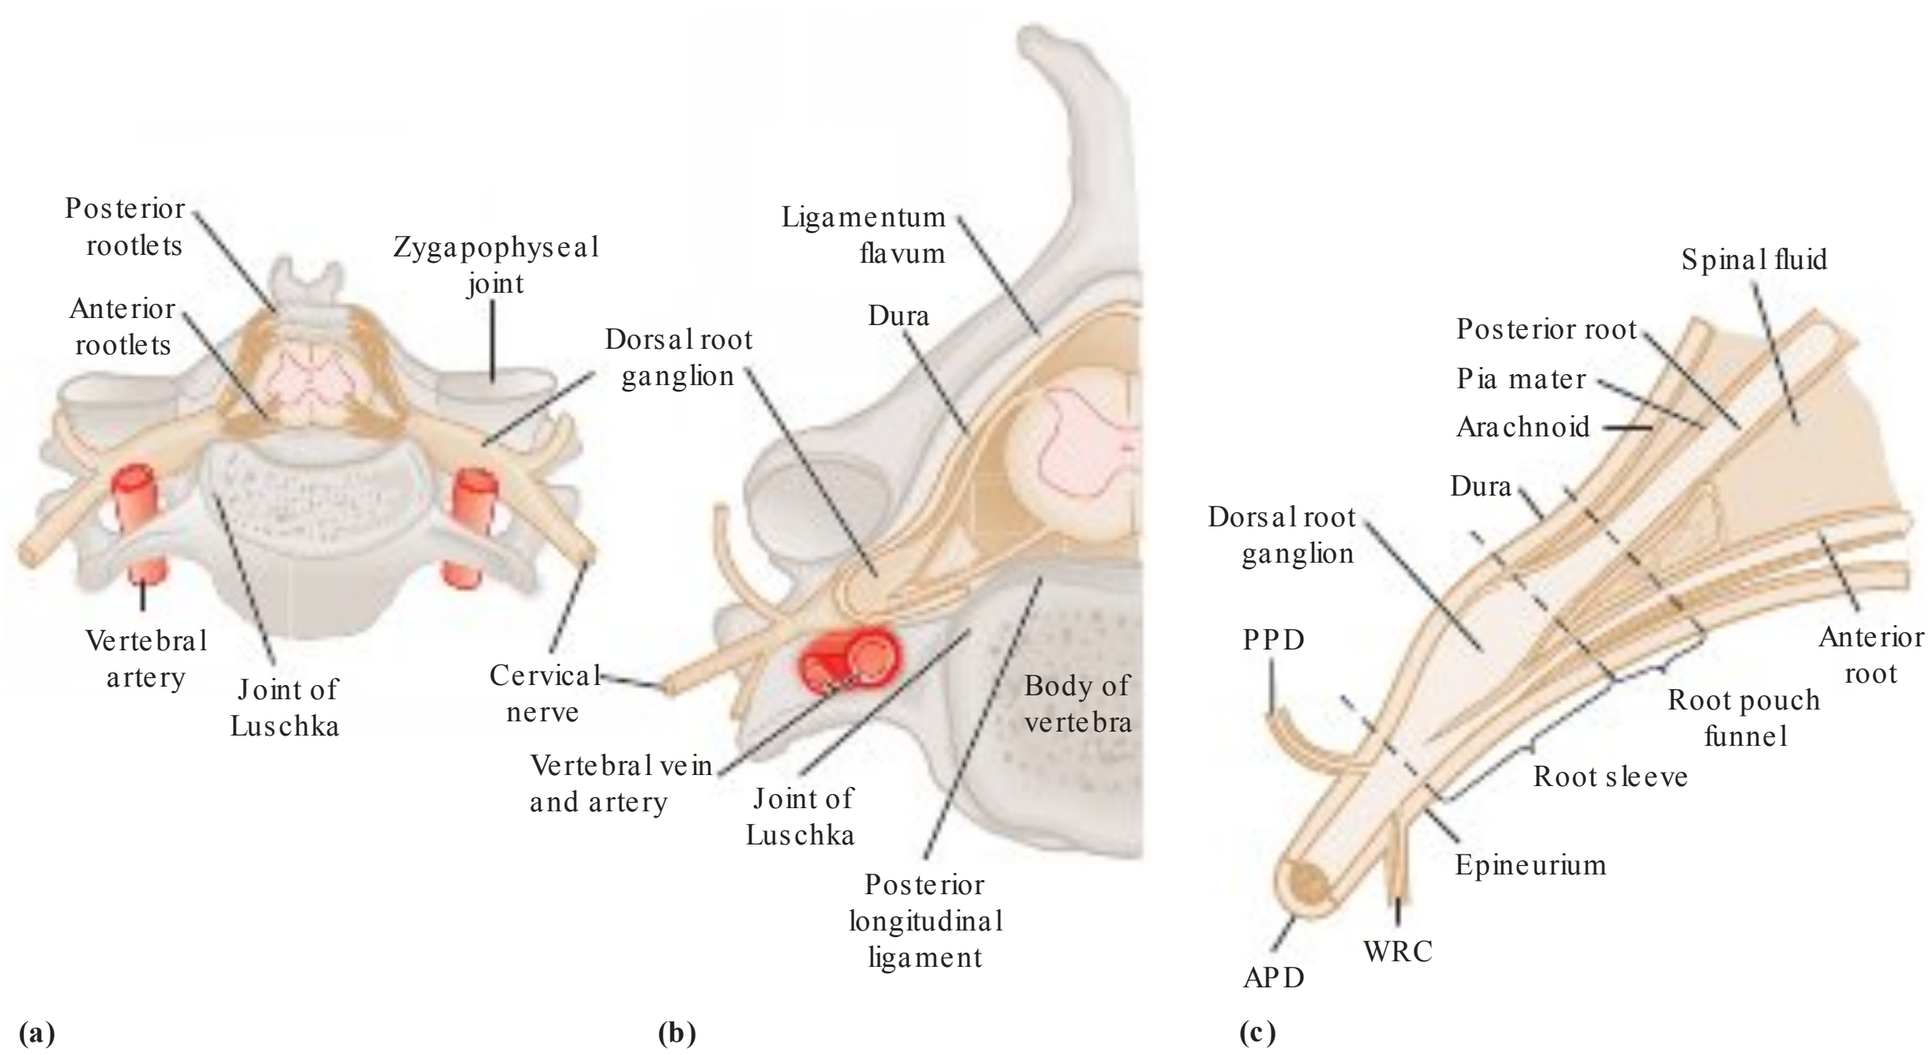

FIGURE 68.8 Transverse sections of the cervical spine. **A.** The spinal cord and anterior and posterior rootlets join to form the spinal nerve. Note the relationship of the nerves to the Luschka and zygapophyseal joints and the two vertebral arteries, which pass through the transverse foramina and are located just anterior to the nerve. **B.** Cross-section of a cervical vertebra showing some details of the relationship of the posterior root to the lateral aspect of the ligamentum flavum, which covers the zygapophyseal joint just posterior to it. The anterior root and its dural covering are close to the lateral part of the posterior longitudinal ligaments and to the capsules of the joint of Luschka. The proximal portion of the dorsal root ganglion is in the outer portion of the intervertebral foramen, whereas the remainder is in the gutter of the transverse process. **C.** Detailed anatomy of a nerve root and its meningeal covering. Note the extent of the root pouch and root sleeve. Just distal to the joining of the anterior and posterior roots is the short spinal nerve covered by epineurium (the continuation of the dura), which promptly divides into the anterior primary division (*APD*) and posterior primary division (*PPD*) and gives off a white ramus communicantes (*WRC*). (**A** modified from Bland JH. *Disorders of the cervical spine: diagnosis and medical management*. Philadelphia: Saunders; 1987; **B,C** modified from Cailliet R. *Neck and arm pain*. 2nd ed. Philadelphia: FA Davis; 1981.)

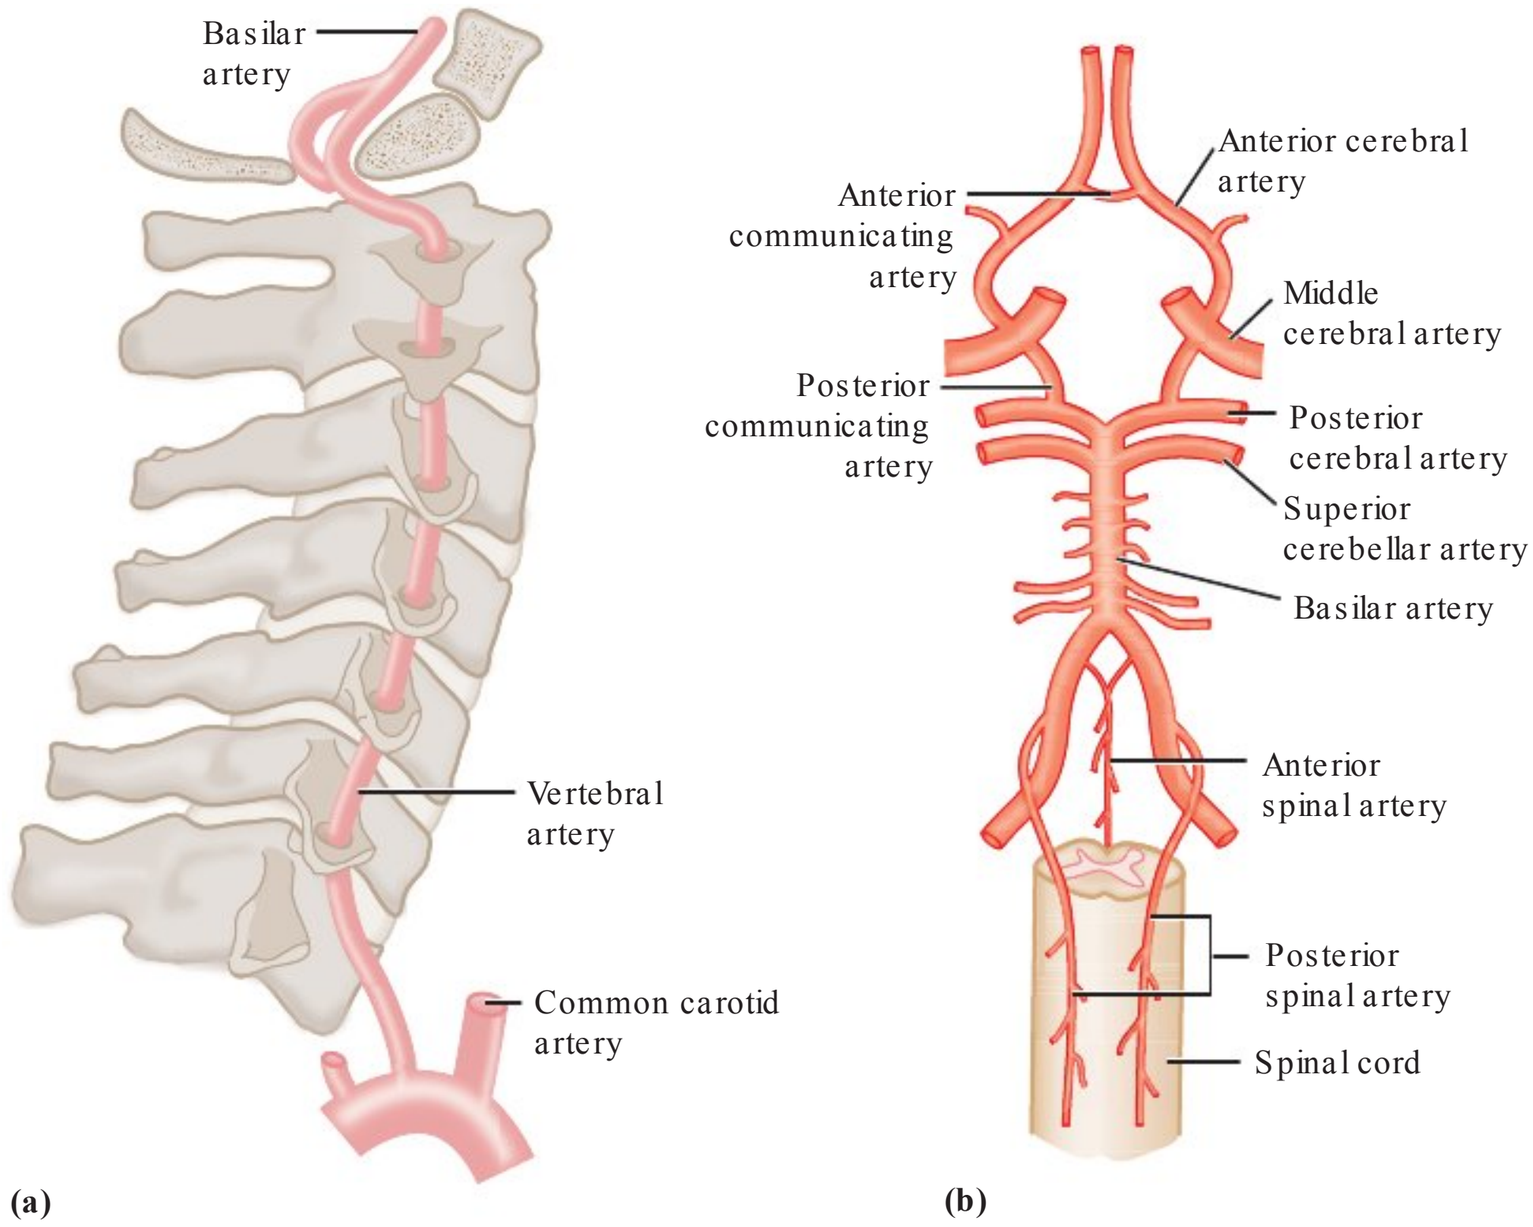

FIGURE 68.9 A. Lateral view of the cervical vertebrae depicting the course of the vertebral artery from C6 to C1 through boney ridges of the foramina transversaria. Note the double U-turn the artery makes from C2 to C1 in its posterior course around the lateral mass of the atlas. **B.** The two vertebral arteries join to form the basal arteries. Also shown is the circle of Willis. Note the origin of the anterior spinal artery and the two posterior spinal arteries from the two vertebral arteries.

the C2 to C3 level and progressively narrow and shorten to the C6 to C7 level with an average vertical diameter of 10 mm and transverse diameter of 5 mm. The first and second cervical nerves are unique in that they do not pass through an intervertebral foramen. The first cervical nerve passes between the occiput and C1 lateral to the occipital condyle and the second between C1 and C2 posterior to the lateral pillars.[1]

In addition to the nerve roots, the foramina contain the spinal radicular arteries, intervertebral veins, and venous plexuses together with loose areolar tissue and fat from the adjoining extension of the epidural space. These provide a protective cushion in the healthy spine. Each spinal nerve receives one or more gray rami communicantes from the cervical sympathetic ganglia after exiting the spinal canal. Spinal nerves one through four receive fibers from the superior cervical sympathetic ganglion, spinal nerves five and six from the intermediate ganglia, spinal nerves seven and eight from the inferior cervical ganglion, and spinal cervical nerve eight and thoracic one from the first thoracic ganglion. The meninges are supplied from a branch of the cervical spinal nerve at each level (see Figs. 68.8 and 68.10).[1]

Lateral to the intervertebral foramen, posterior to the vertebral artery, the spinal nerves separate into posterior and anterior primary divisions with the anterior motor divisions being much larger than the posterior divisions, with the exception of C1. Each spinal nerve supplies muscles (myotomes), skin (dermatomes), as well as ligamentous and boney structures (sclerotomes). The posterior primary division passes over the posterior portion of the transverse process around the articular pillar and divides into the medial sensory and lateral muscular branches, with the exception of the C1 nerve.[1]

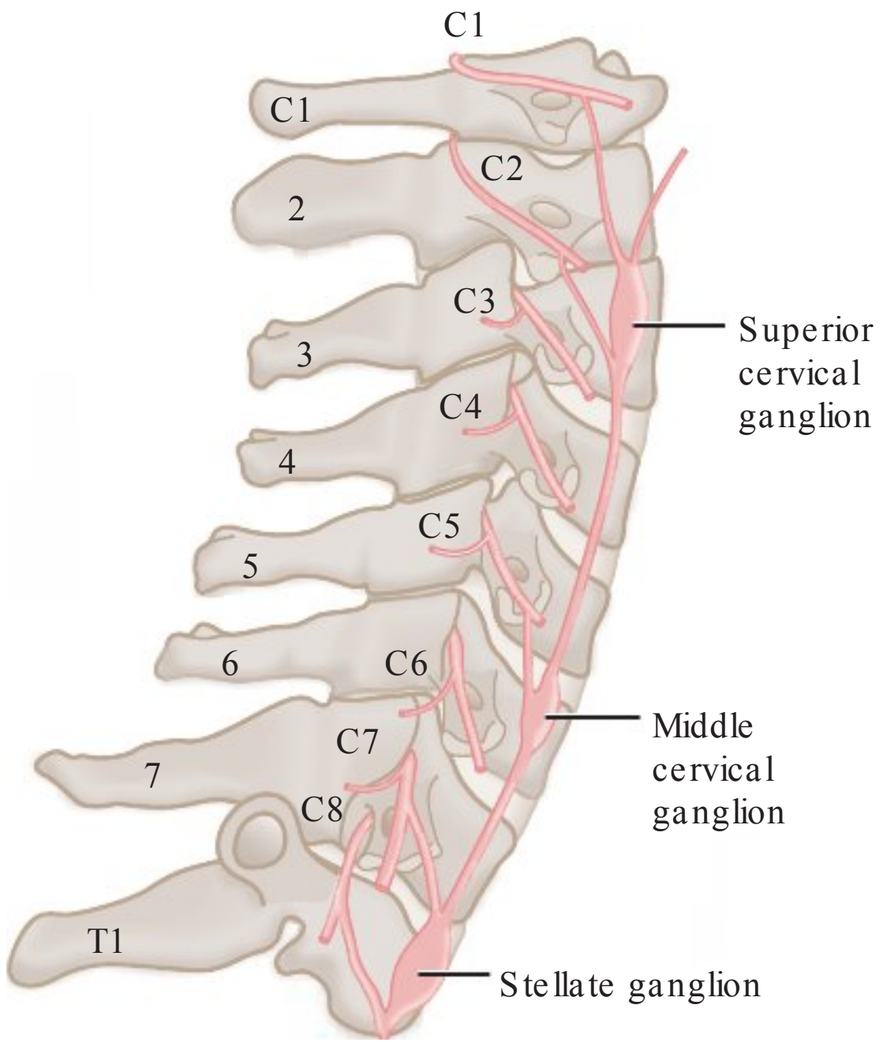

FIGURE 68.10 Lateral view showing the course and relation of the cervical nerves and the cervical sympathetic chain. (From Cooper G, Bailey B, Bogduk N. Cervical zygapophysial joint pain maps. *Pain Medicine* 2007;8[4]:344–853, with permission.)

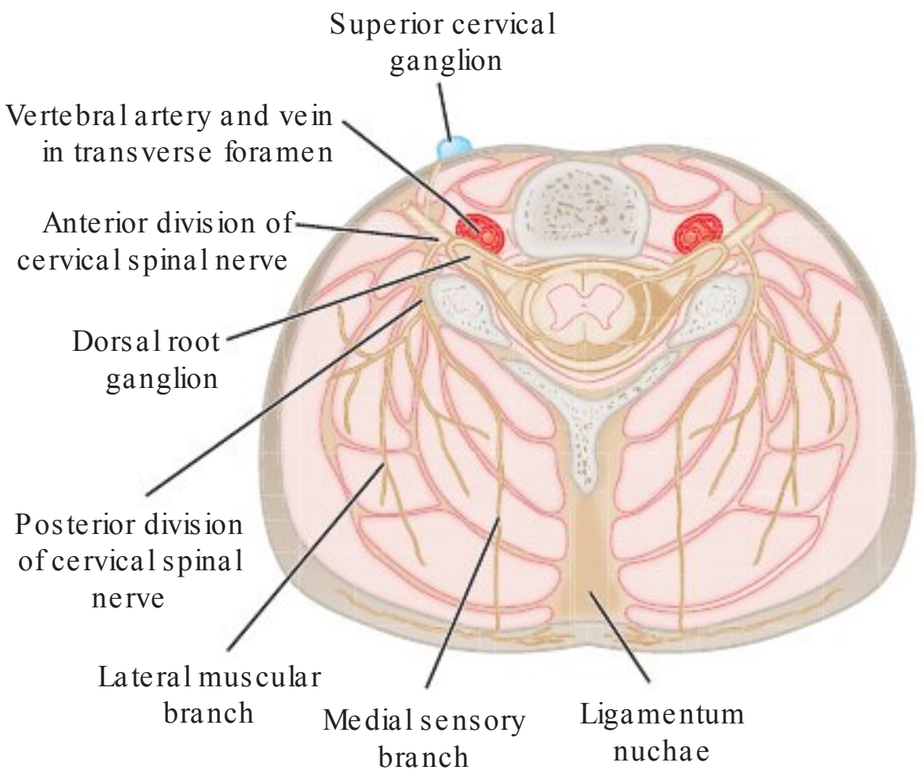

FIGURE 68.11 Cross-section of the third cervical segment showing the course and distribution of the posterior primary division, with its medial branch passing posteriorly to supply the skin and subcutaneous structures and the lateral branch supplying the muscles. Also shown is a cross-section of the superior cervical ganglion and its connection to the nerve by the white ramus communicantes. Note the vertebral vessels just anterior to the nerve.

The first cervical nerve or suboccipital nerve remains as one trunk and supplies the muscles of the suboccipital triangle. Sensory fibers from the C1 nerve supply the periosteum and body of the atlas and occiput, the atlantooccipital and atlantoaxial joints, and ligaments around these joints. It may occasionally supply skin of the scalp and communicate with the greater and lesser occipital nerves. The posterior primary divisions of the other cervical spinal nerves supply the muscles of the posterior neck (lateral branches) and skin of the neck (medial branches).[1]

The greater occipital nerve is the medial or sensory branch of the posterior division of the second cervical nerve. It communicates with the third cervical nerve to supply the scalp over the vertex and top of the head and gives muscular branches to the semispinalis capitis. The third or least occipital nerve arises from the medial sensory branch of the posterior division of the third cervical nerve (Figs. 68.11 and 68.12).[1]

The Cervical and Brachial Plexus

The cervical plexus is made up of the anterior primary divisions of the upper four cervical nerves. The brachial plexus is formed from the lower four cervical nerves, C5 through C8, together with T1 (Fig. 68.13).[1]

The anterior trunks from cervical nerves two through four divide into ascending and descending branches which form a series of three loops. These are located lateral to the vertebrae, anterior to the levator scapulae and scalenus medius muscles, and beneath the sternocleidomastoid muscle. The deep branches of the cervical plexus lie beneath the sternocleidomastoid muscle and are divided into the lateral or external group and the medial or internal group. The lateral group of branches supplies muscular branches to the scalenus medius, sternocleidomastoid, trapezius, and levator scapulae. It also sends communicating branches to the spinal accessory nerve. The medial or internal branches send off communicating fibers which join the vagus, hypoglossal and descendens hypoglossi nerves, the superior cervical sympathetic ganglion, and, by means of the ansa hypoglossi, supply the thyrohyoid, geniohyoid, omohyoid, sternothyroid, and sternohyoid muscles. The medial branches also supply the rectus capitis, lateralis, and anticus, the longus capitis and longus colli muscles, as well as the diaphragm by way of the phrenic nerve.[1]

The superficial or cutaneous branches of the cervical plexus are often referred to as the superficial cervical plexus and include the lesser occipital nerve, the great auricular nerve, the anterior cutaneous nerve, and the supraclavicular nerve. The lesser occipital nerve joins with the greater occipital and greater auricular nerves to supply the posterior scalp. Its auricular branch supplies the upper and posterior auricula and communicates with the mastoid branch of the great auricular nerve. The great auricular nerve supplies the skin of the face over the parotid gland and communicates with the facial nerve via its anterior or facial branch. Another branch supplies the lobule and lower part of the concha of the ear and communicates with the lesser occipital nerve, the auricular branch of the vagus, and the posterior auricular branch of the facial nerve. The anterior cutaneous nerve supplies the cranial, ventral, and lateral aspects of the neck as far as the sternum.[1]

Finally, the supraclavicular nerve supplies the skin and superficial fascia of the clavicular region as well as the periosteum and bone of the clavicle. Via its medial or supraclavicular branches known also as the suprasternal nerves, it supplies the skin of the infraclavicular region medially as far as the midline and laterally

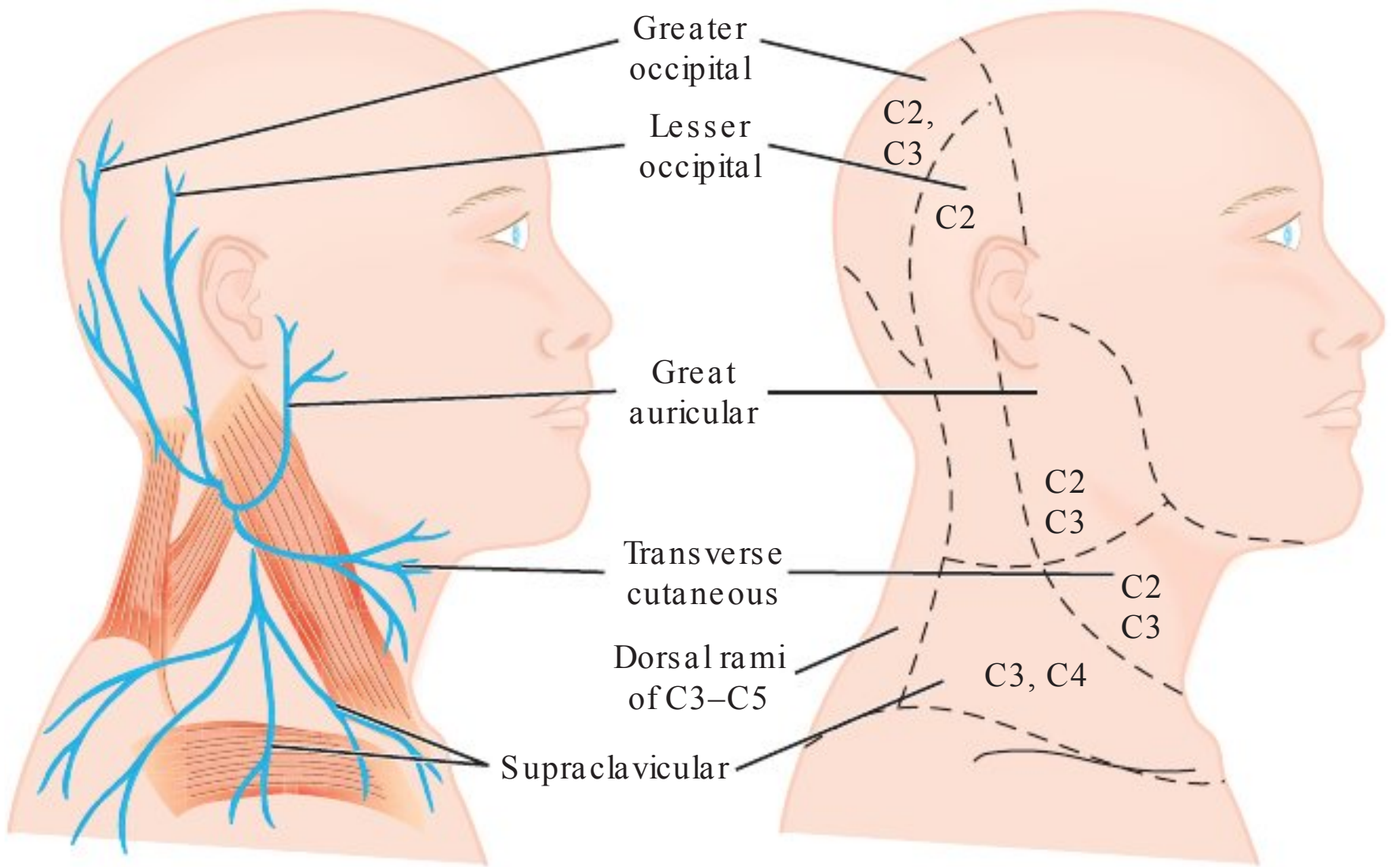

FIGURE 68.12 Cutaneous nerves derived from the cervical plexus (see text for details).

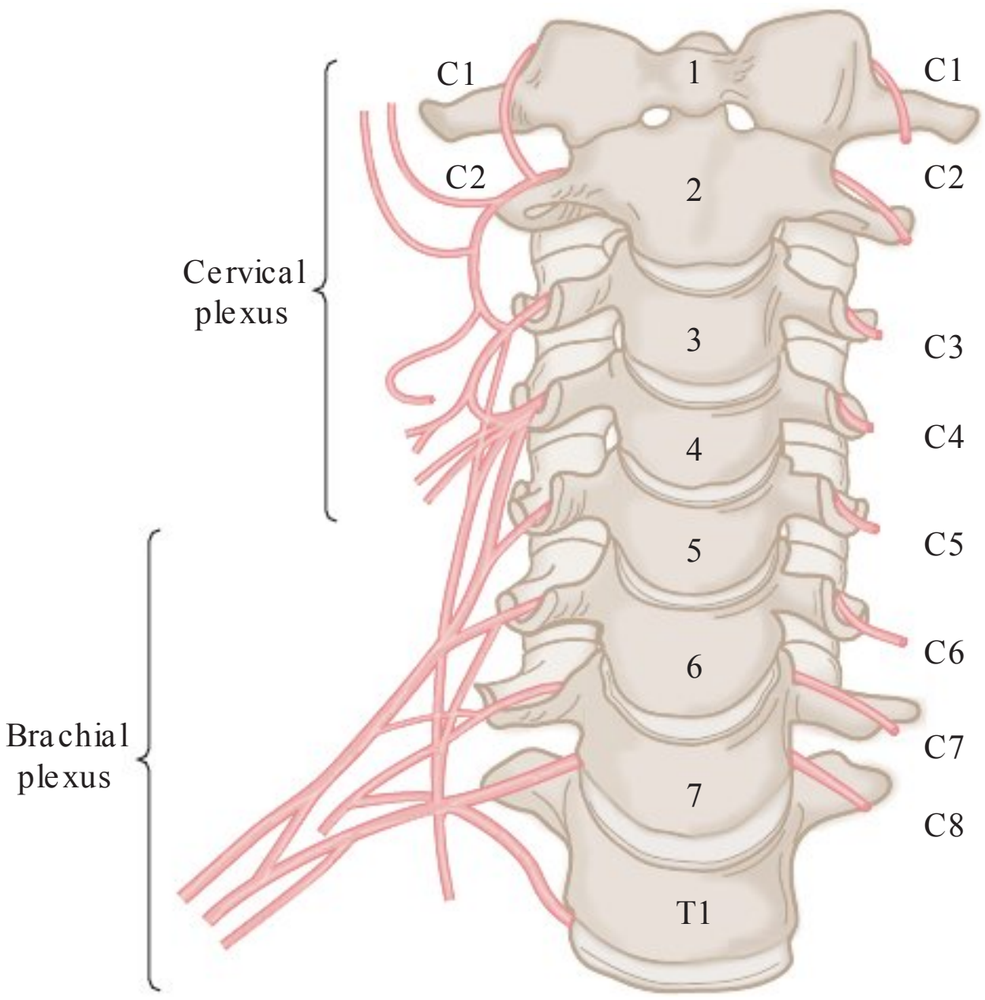

FIGURE 68.13 Anterior view showing the formation of the cervical and brachial plexuses.

to the junction of the medial and middle third of the clavicle. The intermediate supraclavicular nerve supplies the skin over the pectoralis major as far as the second or third rib and communicates with the cutaneous branches of the second and third intercostals nerves. The lateral supraclavicular nerves or supraacromial nerves supply the skin of the top and dorsal parts of the shoulder (Figs. 68.14 and 68.15).[1]

The brachial plexus is formed from the primary anterior divisions of the fifth through eighth cervical nerves and the first thoracic nerve with occasional contributing branches from the anterior primary divisions of the fourth cervical and second thoracic nerves. These combine to form three trunks which include: (1) the upper trunk, formed from the primary divisions of the fifth and sixth cervical nerves; (2) the middle trunk, formed from the seventh primary division; and (3) the lower trunk formed from the eighth cervical and first thoracic primary divisions.[1] The upper trunk gives off the suprascapular nerve which supplies the shoulder joint, the supraspinatus and infraspinatus muscles, and the subclavius nerve, which supplies the subclavius muscle.

The three trunks continue from the interscalenus space in an anterolateral and inferior direction toward the first rib. These further divide into anterior and posterior divisions which pass beneath the midclavicular region to enter the apex of the axilla. Within the axilla, the anterior and posterior divisions form the lateral, medial, and posterior cords. The anterior divisions of the upper and middle trunks, containing fibers from the fifth, sixth, and seventh cervical nerves, form the lateral cord. The anterior division of the lower trunk continues as the medial cord and contains fibers from the eighth cervical and first thoracic nerves. The union of all the posterior divisions makes up the posterior cord, which thus contains fibers from all nerves of the brachial plexus. The three cords divide to give rise to the peripheral nerves of the upper extremity at the lateral border of the pectoralis minor. The lateral aspect of the median nerve and the musculocutaneous nerves derive from the lateral cord. The medial cord divides into the medial

TABLE 68.2

ORGANIZATION AND BRANCHES OF THE BRACHIAL PLEXUS

Structure	Neurotome
Branches of cervical nerves	
To phrenic nerve	C5
To longus colli and scaleni muscles	C5 to C7
Branches from roots	
Dorsal scapular nerve	(C4), C5
Long thoracic nerve	C5 to C7
Branches from trunks (superior trunk)	
Nerve to subclavius	C5, C6
Suprascapular nerve	C5, C6
Posterior cord origin (from all trunks)	C5 to C8, T1
Branches	
Superior subscapular nerve	C5, C6
Inferior subscapular nerve	C5, C6
Thoracodorsal nerve	C6 to C8
Terminal branches	
Axillary	C5, C6
Radial	C5 to C8, T1
Lateral cord origin (superior and middle trunk)	C5 to C7
Branches	
Anterior pectoral	C5 to C7
Terminal branches	
Musculocutaneous nerve	C5 to C7
Median nerve, lateral portion	C6, C7
Medial cord origin (inferior trunk)	C8 to T1
Branches	
Medial brachial cutaneous nerve	C8 to T1
Medial antibrachial cutaneous nerve	C8 to T1
Terminal branches	
Median nerve (medial portion)	C8 to T1
Ulnar nerve	C8 to T1

head of the median nerve, the ulnar nerve, the medial antebrachial and brachial cutaneous nerves, as well as a branch to the intercostobrachial nerve. The axillary and radial nerves are terminating branches from the posterior cord.[1]

In addition to supplying terminal branches to the upper extremity, the brachial plexus carries postganglionic sympathetic fibers from the cervical and thoracic sympathetic chain to the upper limbs. The brachial plexus also supplies branches to the longus colli muscle and the scalene muscles. The fifth cervical nerve sends fibers to the phrenic nerve, the rhomboid muscles, and the levator scapulae muscles via the dorsal scapular nerve. Fibers from the anterior divisions of the fifth, sixth, and seventh cervical nerves supply the serratus anterior muscle via the long thoracic nerve (Table 68.2, Figs. 68.16 and 68.17).

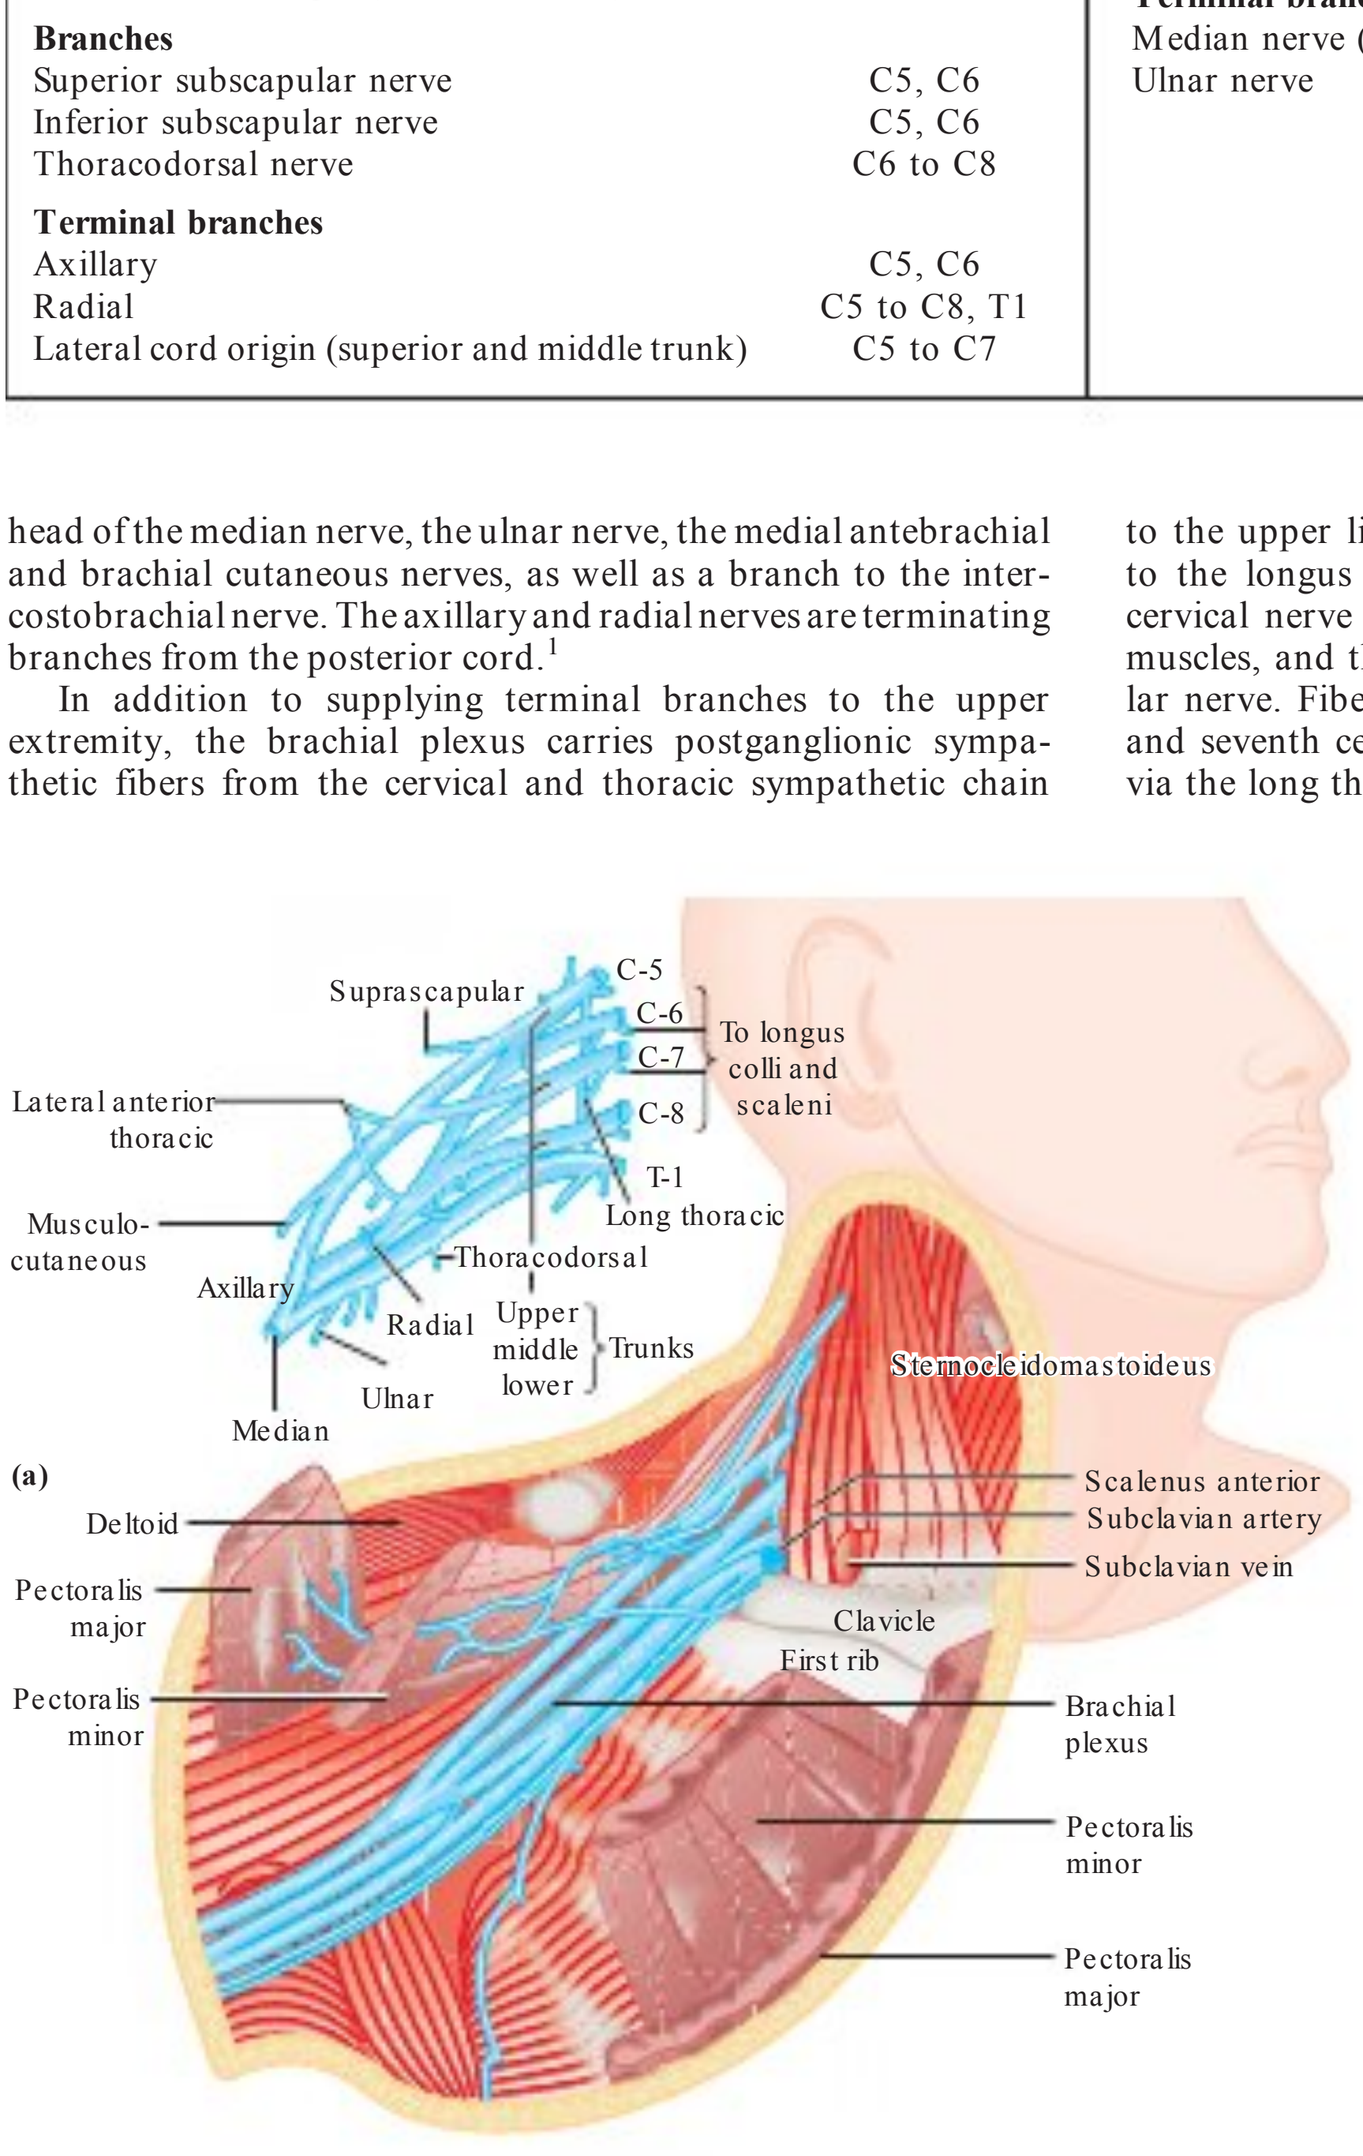

FIGURE 68.16 Anatomy of the brachial plexus. **A.** Schematic depiction of the brachial plexus. **B.** Relation of the roots of the brachial plexus to the scalene muscles showing the position of the plexus over the first rib and its course into the axilla.

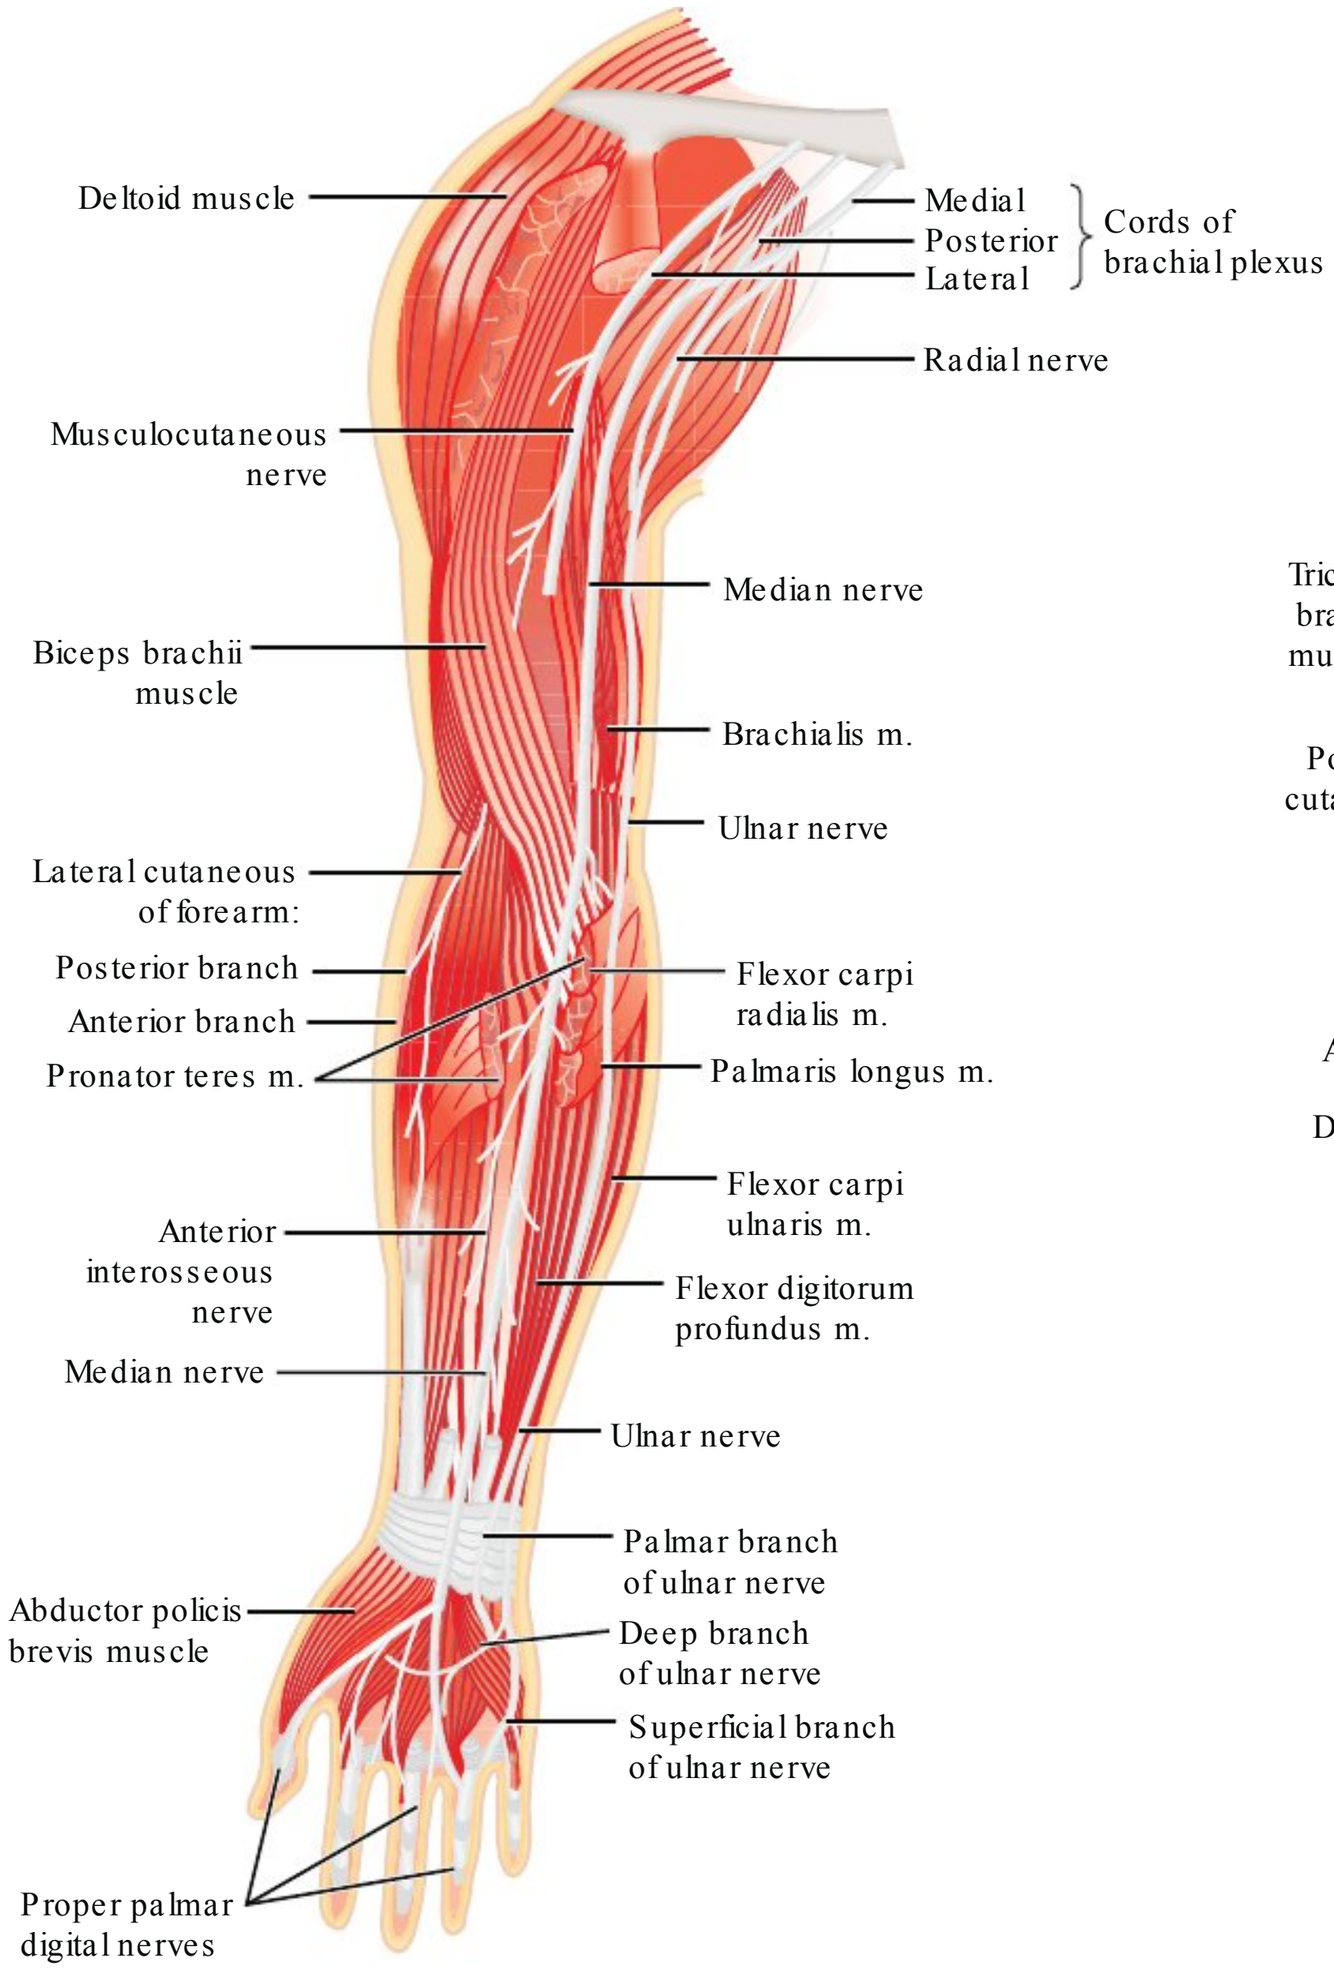

FIGURE 68.17 Anatomy of the median, ulnar, and radial nerves. Anterior view **(A)** and posterior view **(B)** of the upper limb showing the course of the three nerves and some of the muscles (m.) they supply.

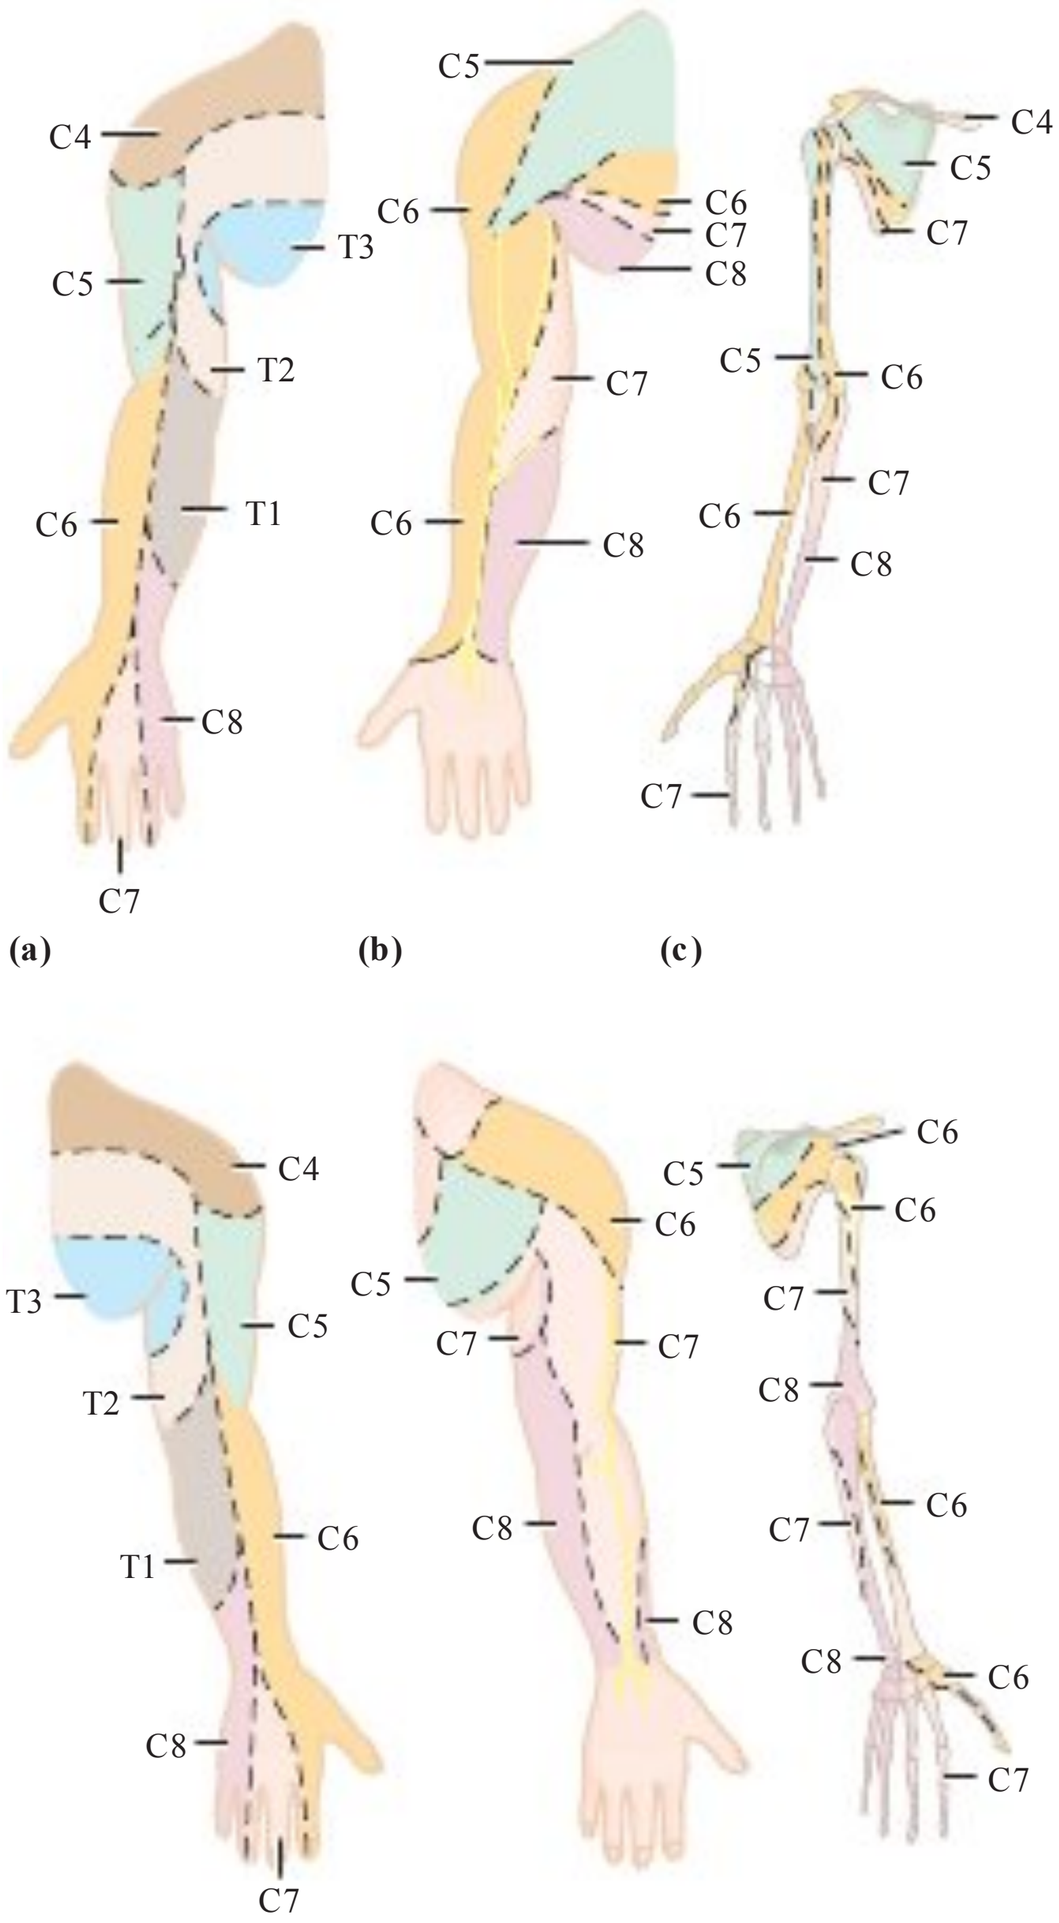

FIGURE 68.18 Segmental nerve supply to the upper limb showing the anterior view (*above*) and posterior view (*below*). **A.** Dermatomes. **B.** Myotomes. **C.** Sclerotomes.

The segmental and peripheral nerve supply of the neck and arm is summarized in Figures 68.18 and 68.19 as well as Tables 68.3, 68.4, and 68.5. Sympathetic nervous system contributions to the upper extremity from the cervical and thoracic preganglionic neurons are illustrated and described in Figure 68.20. Contributions from the anterolateral and posterolateral subclavian sympathetic nerves, which supply the subclavian artery and its branches distal to the scalene muscles, contain both sympathetic and sensory fibers.[1]

Pectoral Girdle and Shoulder Anatomy

The differential diagnosis of neck and arm pain includes many disorders of the pectoral girdle and shoulder which can result not only in shoulder pain, but also in radiation of pain to the neck and/or arm. Common disorders involving the shoulder and pectoral girdle include rotator cuff tears, tendonitis, impingement syndromes, and arthritis (Figs. 68.21 and 68.22). An understanding of the complex anatomy and biomechanics of pectoral girdle and shoulder is essential for the diagnosis and treatment of pain in this region.[1]

The pectoral girdle is made up of the scapula and clavicle, the sternoclavicular and acromioclavicular joints, and the scapulothoracic and humeroacromial interfaces. Unlike the lower limb, which is built for weight-bearing as well as locomotion, the upper limb function is primarily to allow mobility and a wide range of motion for the arm and hand. The girdle does not articulate with the vertebral column, as does the pelvic girdle, but with the thoracic cage at the saddle-shaped sternoclavicular joint. The sternoclavicular joint is divided into two spaces by an articular disk and is surrounded by a strong, lax capsule. In addition to the capsule, the joint is stabilized by the interclavicular ligament superiorly, inferiorly by the costoclavicular ligament (which limits elevation and rotation of the clavicle and serves as the fulcrum of movements at the sternoclavicular joint), and the posterior sternoclavicular ligament. Dislocation of the costoclavicular joint is rare, but tends to occur

(text continues on page 1017)

†Main root is underlined.

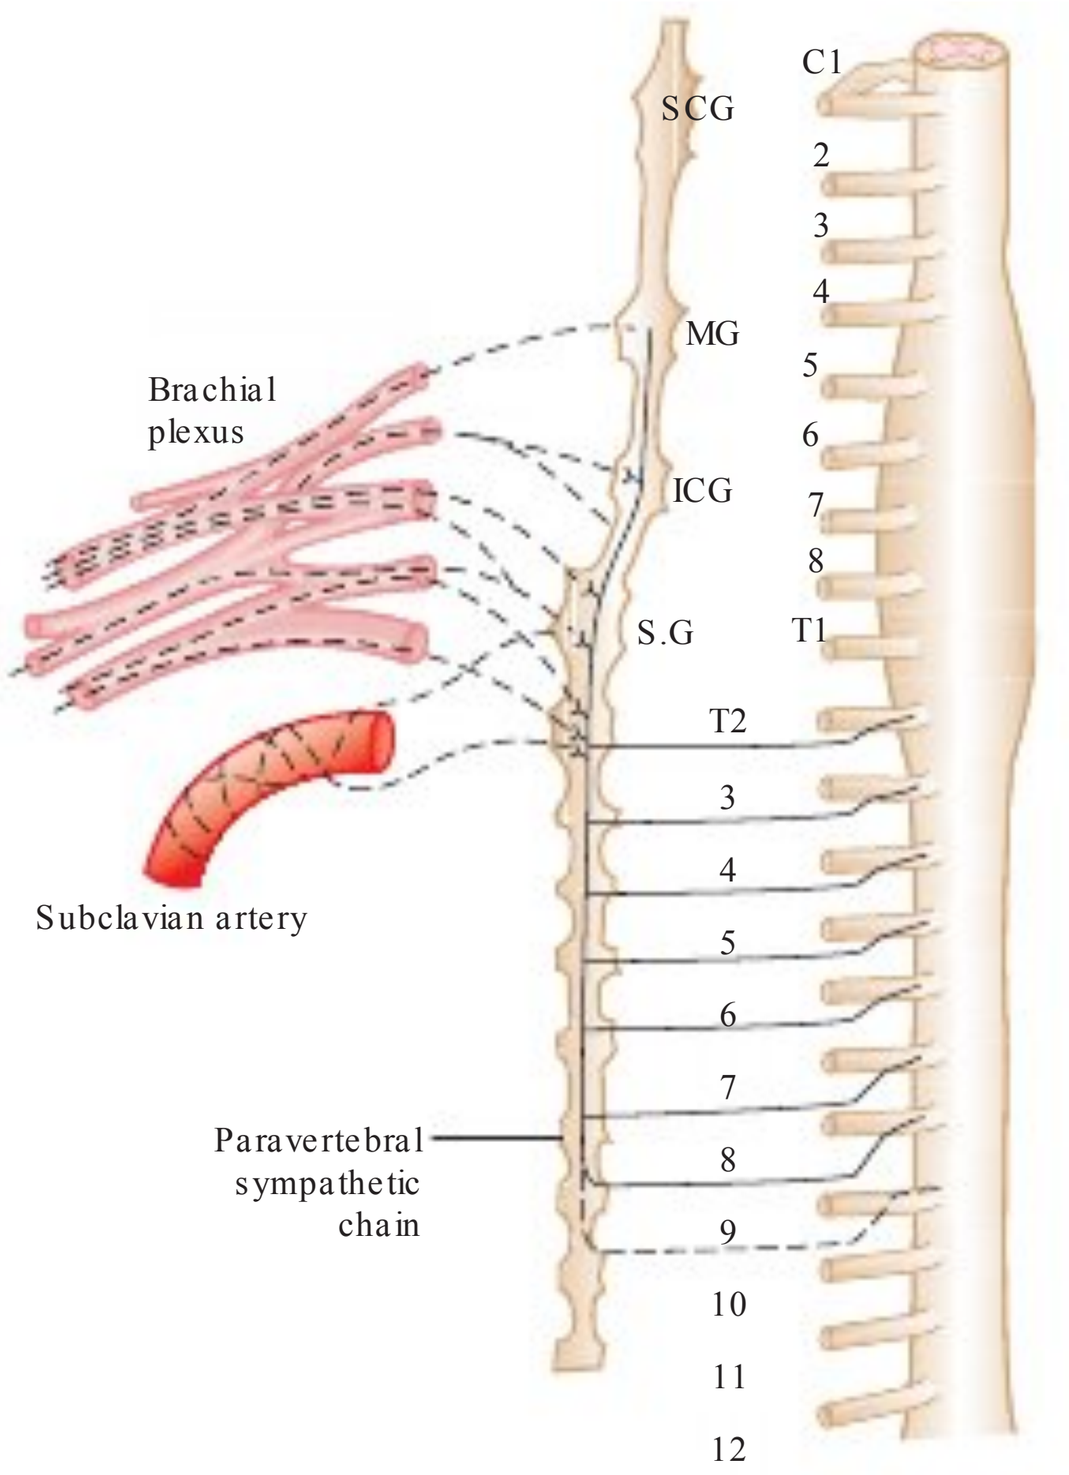

FIGURE 68.20 Schematic depiction of the origins and courses of preganglionic sympathetic neurons destined to supply the upper limbs. Note that the axons of the preganglionic neurons, which are located in spinal segments T2 to T8 (and occasionally T9), pass through the anterior root as white rami communicantes and from there to the paravertebral sympathetic chain, where they ascend and synapse with postganglionic fibers primarily in the second thoracic, stellate, and intermediate and middle cervical ganglia, and occasionally in the third cervical ganglion (not shown). Some of the postganglionic fibers pass directly to the subclavian artery, but most pass as gray rami communicantes to the roots of the brachial plexus. (From Bonica JJ. *Clinical application of diagnostic and therapeutic nerve blocks*. Springfield, IL: Charles C Thomas; 1959.)

anteriorly where the joint is weakest when it does occur (Fig. 68.23).

The acromioclavicular joint of the pectoral girdle is surrounded by a weak and lax capsule. It is stabilized by the acromioclavicular ligament superiorly, the fan-shaped coracoclavicular ligament, which serves as a vertical axis for scapular rotation, and the trapezoid ligament which serves as a hinge for scapular motion about the horizontal axis. A partial or complete disruption of the coracoclavicular ligament, resulting in separation of the acromioclavicular joint, may occur with a fall on the shoulder.

The scapulothoracic interface allows a gliding movement between the ventral surface of the scapula and the thorax overlying the second through the seventh ribs. The scapula is held in close approximation to the thorax by the serratus anterior, the trapezius, and the rhomboid muscles. For full abduction and forward flexion of the shoulder to occur, the scapula must undergo upward rotation. Movements of the pectoral girdle consist of upward-downward rotation, protraction-retraction, and elevation-depression (Table 68.6, Figs. 68.24 and 68.25).

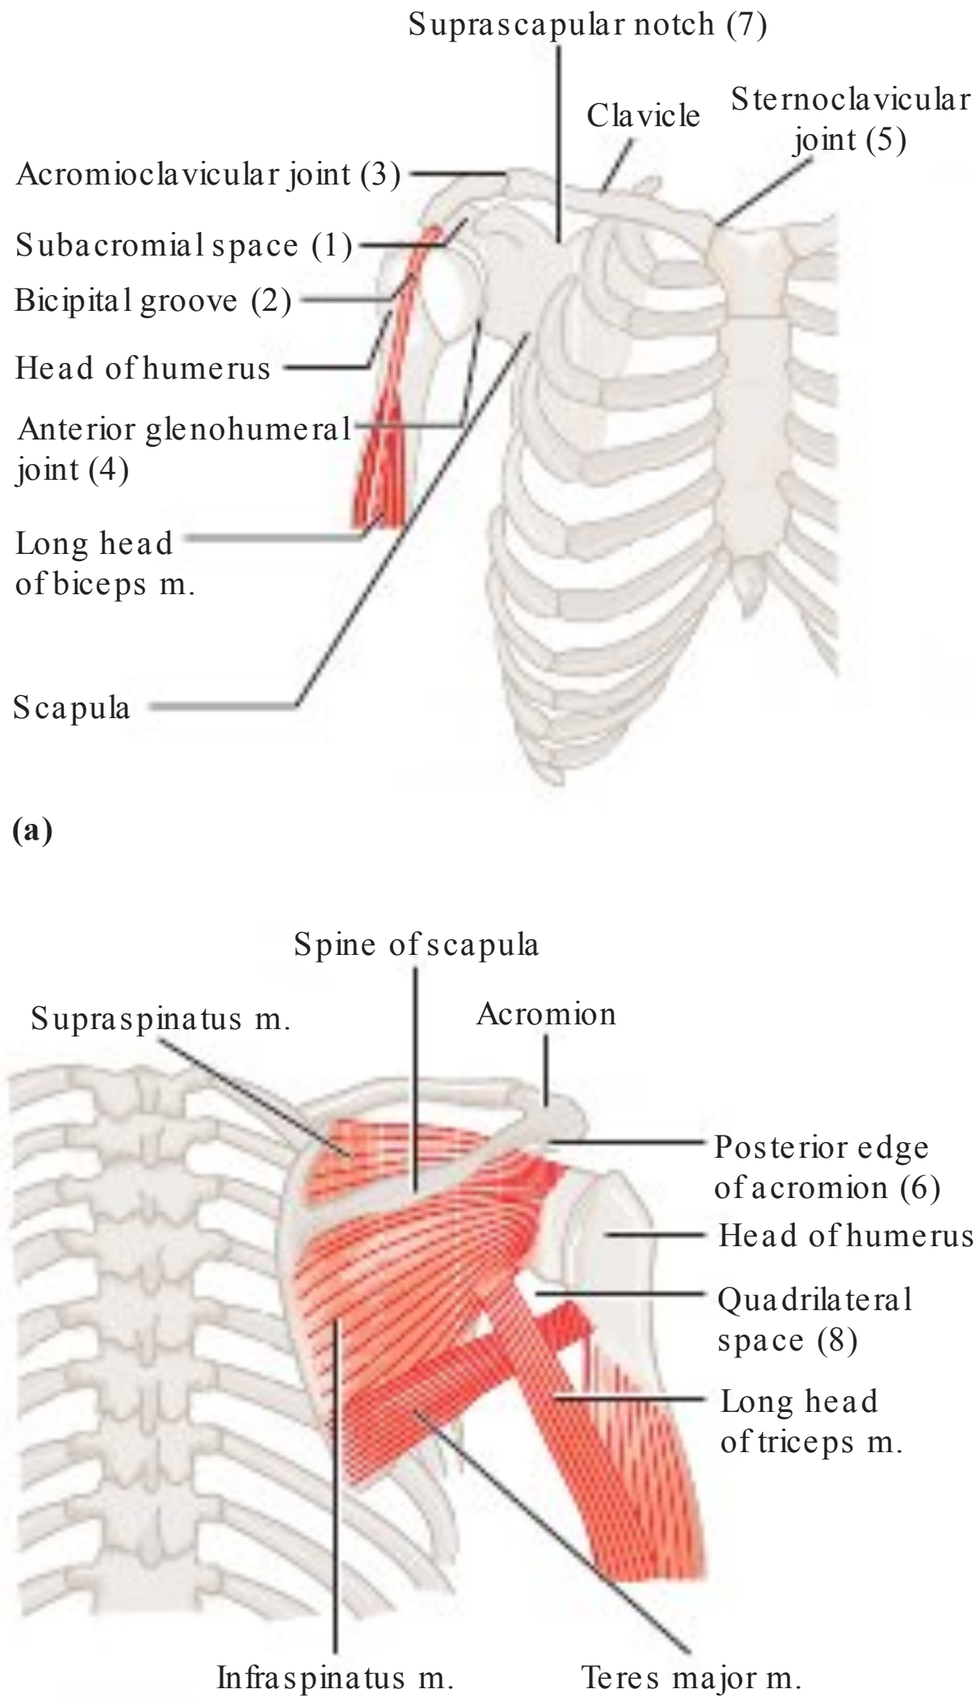

FIGURE 68.21 Anterior **(A)** and posterior **(B)** views of the shoulder identifying the various bones and joints and also the sites of pathologic processes that produce pain and tenderness. (1) Subacromial space, which can be involved with calcific tendinitis, rotator cuff tendinitis and impingement syndrome, and rotator cuff tear; (2) bicipital groove, which can be involved in bicipital tendinitis and biceps tendon subluxation and tear; (3) acromioclavicular joint, which can be involved with degenerative and infectious processes; (4) anterior glenohumeral joint, which can be the site of glenohumeral arthritis, osteonecrosis, glenoid labial tears, and adhesive capsulitis; (5) sternoclavicular joint, which can be the site of pain caused by infection, degenerative changes, or trauma; (6) posterior edge of the acromion, which can contribute to rotator cuff tendinitis, calcific tendinitis, and rotator cuff tear; (7) suprascapular notch, which can be the site of suprascapular nerve entrapment; and (8) quadrilateral space, which can be the site of axillary nerve entrapment.

The glenohumeral joint is a synovial joint which consists of the interface of the head of the humerus with the pear-shaped glenoid cavity and ring of fibrocartilage known as the glenoid labrum. These deepen the socket of the scapula and assist with stability of the glenohumeral joint. The supraglenoid and infraglenoid tubercles above and below the glenoid cavity are attachment sites for the long head of the biceps and triceps, respectively.

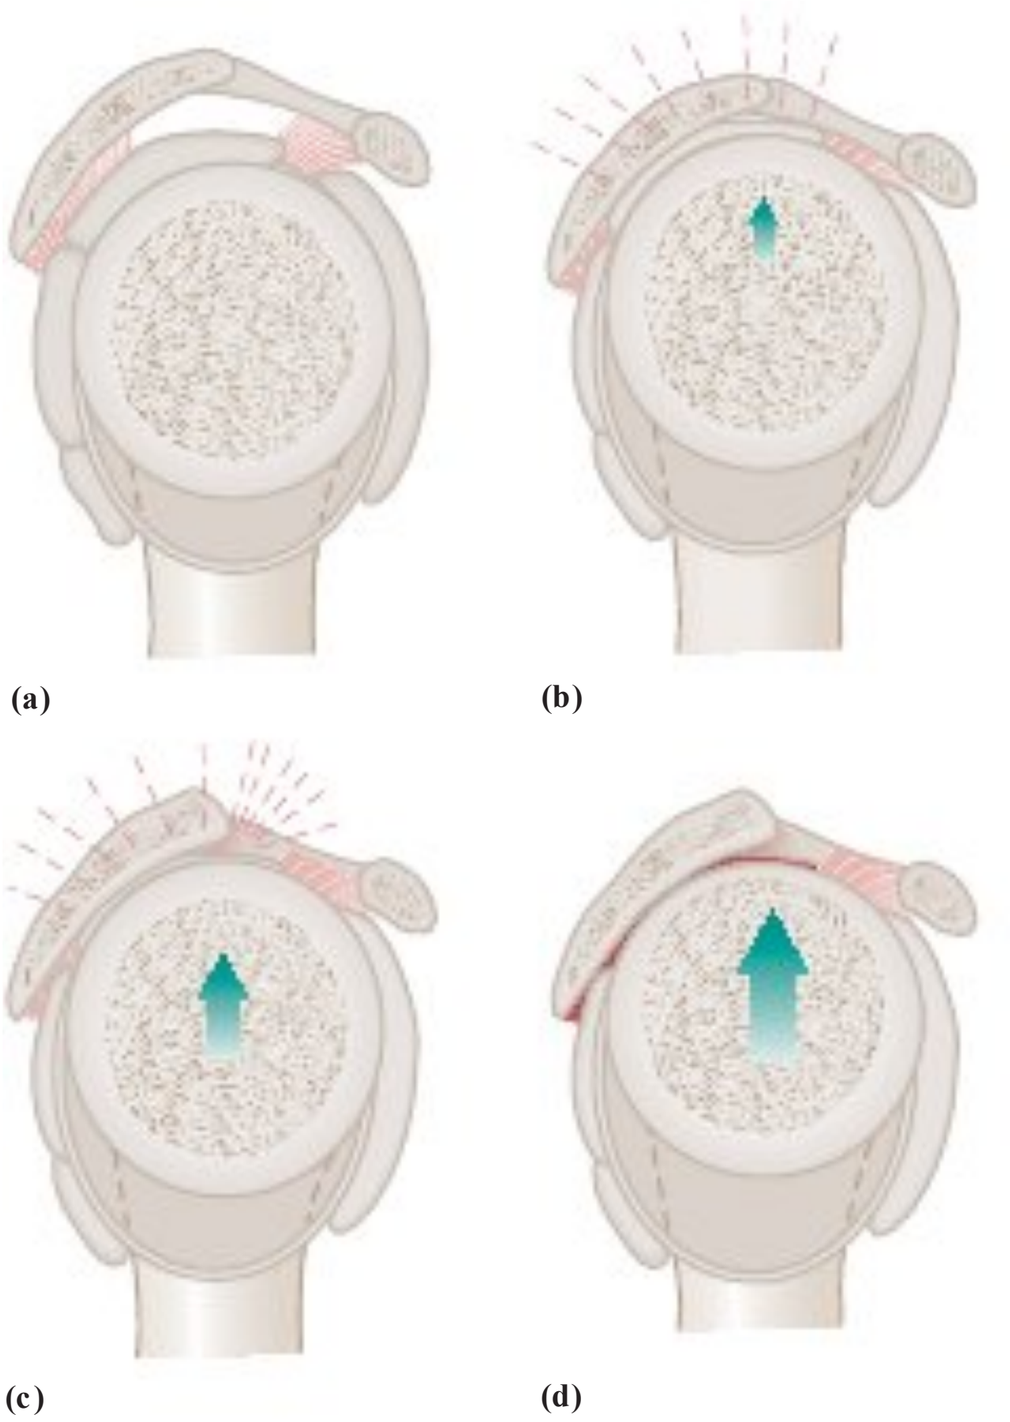

FIGURE 68.22 With progressive cuff fiber failure, the head moves upward against the coracoacromial arch. **A.** Normal relationships of the cuff and the coracoacromial arch. **B.** Upward displacement of the head, squeezing the cuff against the acromion and the coracoacromial ligament. **C.** Greater contact and abrasion, giving rise to a traction spur in the coracoacromial ligament. **D.** Still greater upward displacement, resulting in abrasion of the humeral articular cartilage and cuff tear arthropathy. (From Matsen FA. *Practical evaluation and management of the shoulder*. Philadelphia: Saunders; 1994:123, with permission.)

The joint capsule is strong but lax, to allow for mobility, and attaches to the scapula proximally and distally to the articular margins of the head of the humerus superiorly and the surgical neck of the humerus inferiorly. The ligaments of the glenohumeral joint consist of the superior, middle, and inferior glenohumeral ligaments (thickenings of the anterior capsule), the coracohumeral ligament (which attaches to the greater and lesser tuberosities and limits flexion and extension), and the coracoacromial ligament (which extends from the undersurface of the acromion to the coracoid process and acts as an articulating surface for the head of the humerus). The subacromial and subdeltoid bursae lie between the coracoacromial arch and the rotator cuff tendons and have been implicated in shoulder impingement (see Fig. 68.24).

Movement at the shoulder requires the combined motion of the glenohumeral joint and the pectoral girdle for flexion or abduction greater than 90 degrees. For example, the abduction or elevation of the arm to 180 degrees requires 60 degrees of scapular rotation to alter the angle of the glenoid fossa during its articulation with the head of the humerus (Figs. 68.26 and 68.27). Prime movers of the pectoral girdle and glenohumeral joint are listed in Tables 68.6 and 68.7.[1]

EPIDEMIOLOGY OF NECK AND ARM PAIN

Methodology and definition of neck pain varies significantly in epidemiologic studies of neck and arm pain. A critical review of the literature on the incidence of neck complaints between 1980 and 2006 was published by the Bone and Joint Decade 2000–2010 Task Force on Neck Pain and its Associated Disorders. They found that the incidence of neck complaints per 1000 patient years in the general population ranged from 0.037, when defined as patients presenting as inpatients or to hospital emergency rooms for soft tissue injuries (not from motor vehicle collisions), to 213 initially pain-free adolescents reporting pain onset over the last 3 months via questionnaire. An average of 30% to 50% 12-month prevalence among adults and 21% to 42% among children and adolescence was found. Neck pain which limited activities was less common at 2% to 11%.[3]

Other associated conditions identified with neck and arm pain include poor psychologic health, exposure to secondhand smoke in childhood, current smoking, and genetics. Associated poor

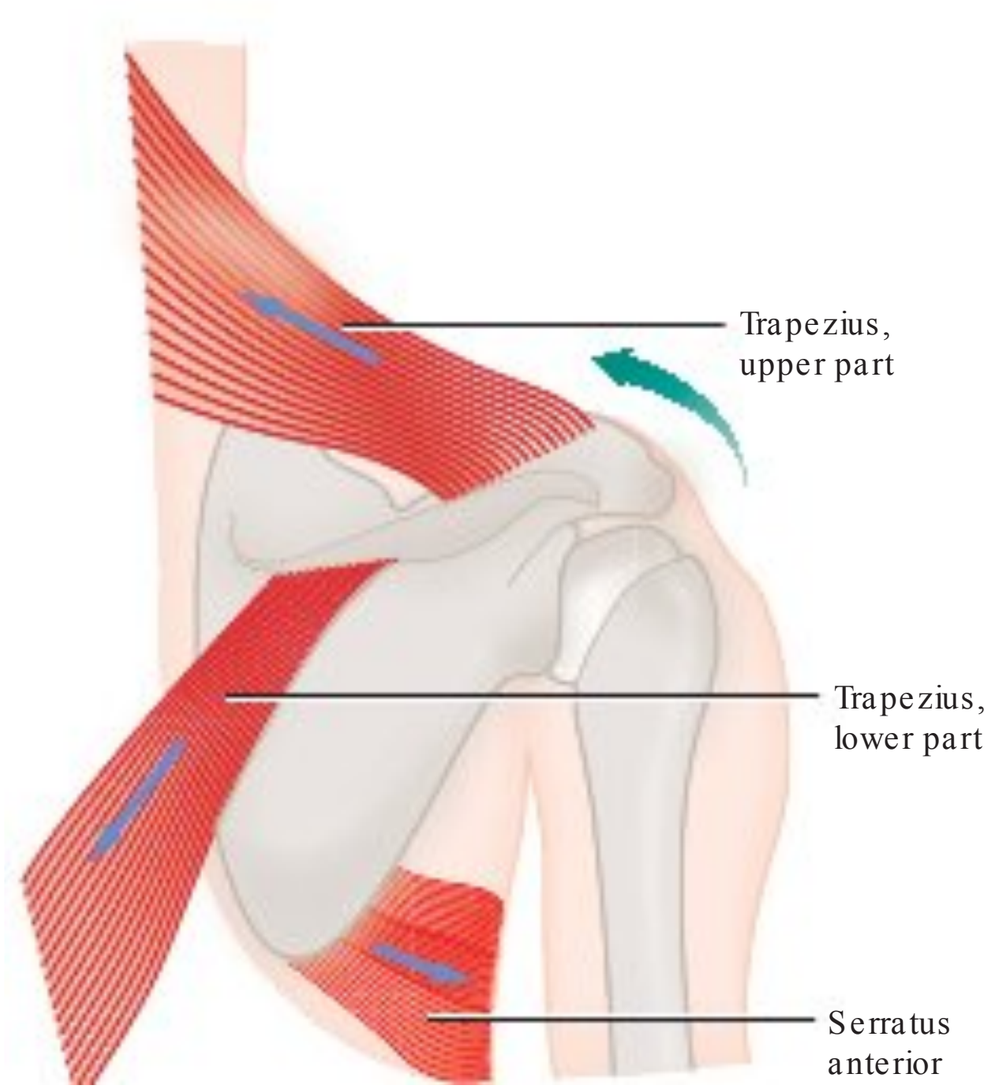

FIGURE 68.25 The muscles that rotate the scapula upward during abduction of the arm. Note that the upper part of the trapezius, which is attached to the outer part of the scapular spine, pulls upward, and that the lower part of the serratus anterior, attached to the lower part of the scapula, pulls the inferior angle laterally, while the lower portion of the trapezius, attached to the medial part of the scapular spine, pulls downward. (From Rosse C, Gaddum-Rosse P. *Hollinshead's textbook of anatomy*. 5th ed. Philadelphia: Lippincott–Raven; 1997:235, with permission.)

health, as well as musculoskeletal and psychologic health complaints, were prognostic for poor outcome. Prevalence was found to be overall higher in females with prevalence peaking in middle age. Neck pain prevalence associated with previous trauma to the neck via exposure to a motor vehicle collision was associated with subsequent neck pain prevalence at 7-year follow-up only when there had been a report of whiplash-associated disorder or pain following the collision.[3]

Controversy exists regarding the relationship between radiologic evidence of cervical spine degeneration and neck pain. One recent study reported no significant difference in the degree of neck pain in patients with or without radiographic evidence of cervical spine degenerative changes,[4] whereas another study correlated neck pain with increasing grade of disc degeneration.[5] Zlapetal et al.[6] showed increasing evidence of neck pain with increasing prevalence of atlanto-odontoid degenerative changes.

Up to 78% of asymptomatic subjects have been found to have degenerative changes on magnetic resonance imaging (MRI) accompanied by positive findings such as disc bulging and protrusion, foraminal stenosis, and abnormal spinal cord contour. This evidence suggests that degenerative findings are common in both asymptomatic and symptomatic individuals, increase linearly with age, and cannot be assumed to be the definitive cause of neck pain in symptomatic individuals.[7–9] One study comparing cervical spine MRIs of fighter pilots to age-matched controls showed premature cervical disc degeneration among pilots exposed frequently to high +Gz forces.[10]

Neck pain following whiplash-associated disorders is common with more than 300 persons per 100,000 population evaluated for this complaint each year according to recent data.[11] Increased symptom severity and presence of neurologic signs is predictive of poor prognosis. Postinjury feelings of helplessness in controlling the consequences of pain, fear of movement, catastrophizing, and postinjury anxiety have also been found to be associated with higher risk of long-term disability,[12] as has changing the insurance system from a no-fault to a tort system of compensation.[13] Studies from hospital populations report that at an

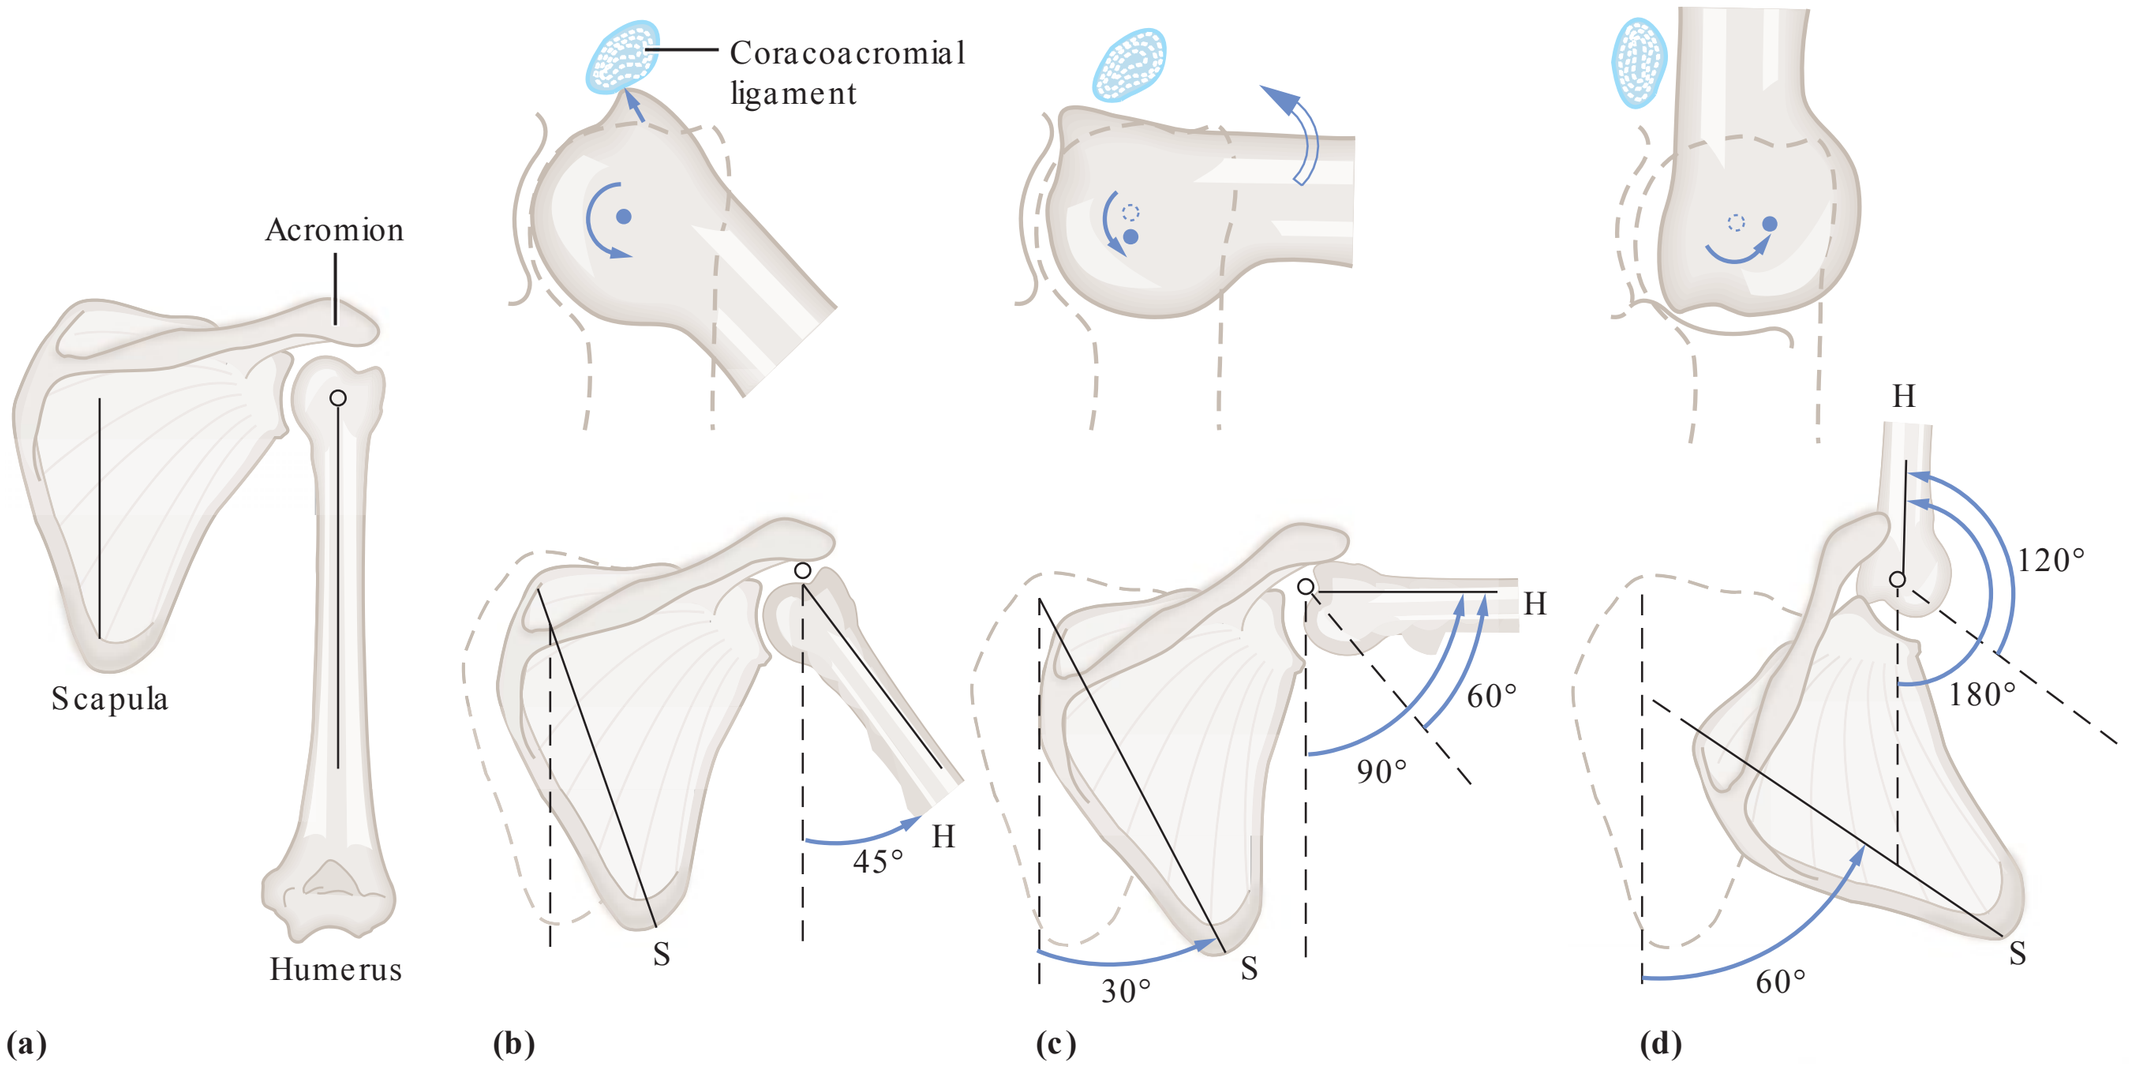

FIGURE 68.26 Biomechanics of the glenohumeral movements of arm abduction. **A.** Normal position of the head and shaft of the humerus (H). The circle in the head of the humerus indicates the center of rotation. **B.** Humerus abducted 45 degrees and the scapula (S) beginning upward rotation. The upper panel shows that the incongruity of the articulating surface of the head of the humerus, and the surface of the glenoid cavity causes the greater tuberosity of the humerus to impinge on the coracoacromial ligament. The upper panel in **(C)** shows that to allow the greater tuberosity to pass under the coracoacromial hood during arm abduction, the humeral head is depressed (depicted by downward movement of the center of rotation) and the humeral head rotated (*thin arrow*). The abduction movement of the arm is accomplished in a smooth coordinated movement during which for each 15 degrees of arm abduction, 10 degrees of motion occurs at the glenohumeral joint, and 5 degrees occurs because of scapular rotation on the thorax. Thus, as noted in **(C)**, abduction of the arm to 90 degrees is accomplished by 60 degrees rotation of the humerus and 30 degrees rotation of the scapula. Full abduction of the arm, as shown in **(D)**, is accomplished by 120 degrees of rotation at the glenohumeral joint and 60 degrees rotation of the scapula. (Modified from Cailliet R. *Shoulder pain*. 2nd ed. Philadelphia: FA Davis; 1981.)

average follow-up of 2 years, 20% to 45% of patients with soft tissue neck injuries following whiplash reported discomfort sufficient enough to interfere with their capacity to work.[14]

Onset of neck and arm pain in the workplace varies widely across various occupations. Highly repetitive work, low job satisfaction and a high level of fear avoidance are associated with development of neck and arm pain as are jobs which require prolonged bending or flexion of the neck such as computer work.[15–18]

EVALUATION OF THE PATIENT

History and Physical Examination

The patient in pain is prompted to seek help, not only to alleviate the suffering which accompanies their condition, but to address the accompanying condition of impairment or disability. The psychologic, physical, or functional handicap which coexists with pain results in loss of ability to perform normal activities and fulfill roles that are fundamental to personal identity. Ultimately, the goal of a successful evaluation should be the ability to answer the patient's three fundamental questions: (1) "What's happening to me?"; (2) "What's going to happen to me?"; and (3) "What can be done to improve what happens to me?"[19]

The differential diagnosis of neck and arm pain is broad and encompasses acute pain from work-related injury, motor vehicle trauma and infection, emerging symptoms from enlarging tumors, vascular abnormalities or infections, manifestations of complex systemic disease processes, and exacerbation of chronic degenerative or inflammatory processes. The initial evaluation should be comprehensive in order to ascertain not only the etiology of physical symptomology, but also the impact the patient's disability has on their psychosocial environment.

History

A thorough history of the patient with neck and arm pain is essential to separate acute from chronic, emergent from urgent and routine complaints, and focal and regional injuries and degenerative changes from systemic disorders. Pain in the neck and arm may also be referred from the thorax or abdomen requiring a thorough review of systems. The differential diagnosis is frequently based on the history, which then guides further focus during the physical exam and diagnostic testing.

Immediate consideration must be made regarding the severity and urgency of the complaint. Emergent conditions can often be discerned at the time of phone request for urgent evaluation or by nurses when the patient is screened at check-in. Severe neck pain accompanied by progressive disturbance of gait, progressive motor or sensory deficits, or urinary and fecal incontinence requires prompt physician evaluation. Enlarging tumor, acute infection, and unstable inflammatory spondyloarthropathy can progress to respiratory failure and death if not treated promptly and requires immediate surgical and medical intervention. Acute

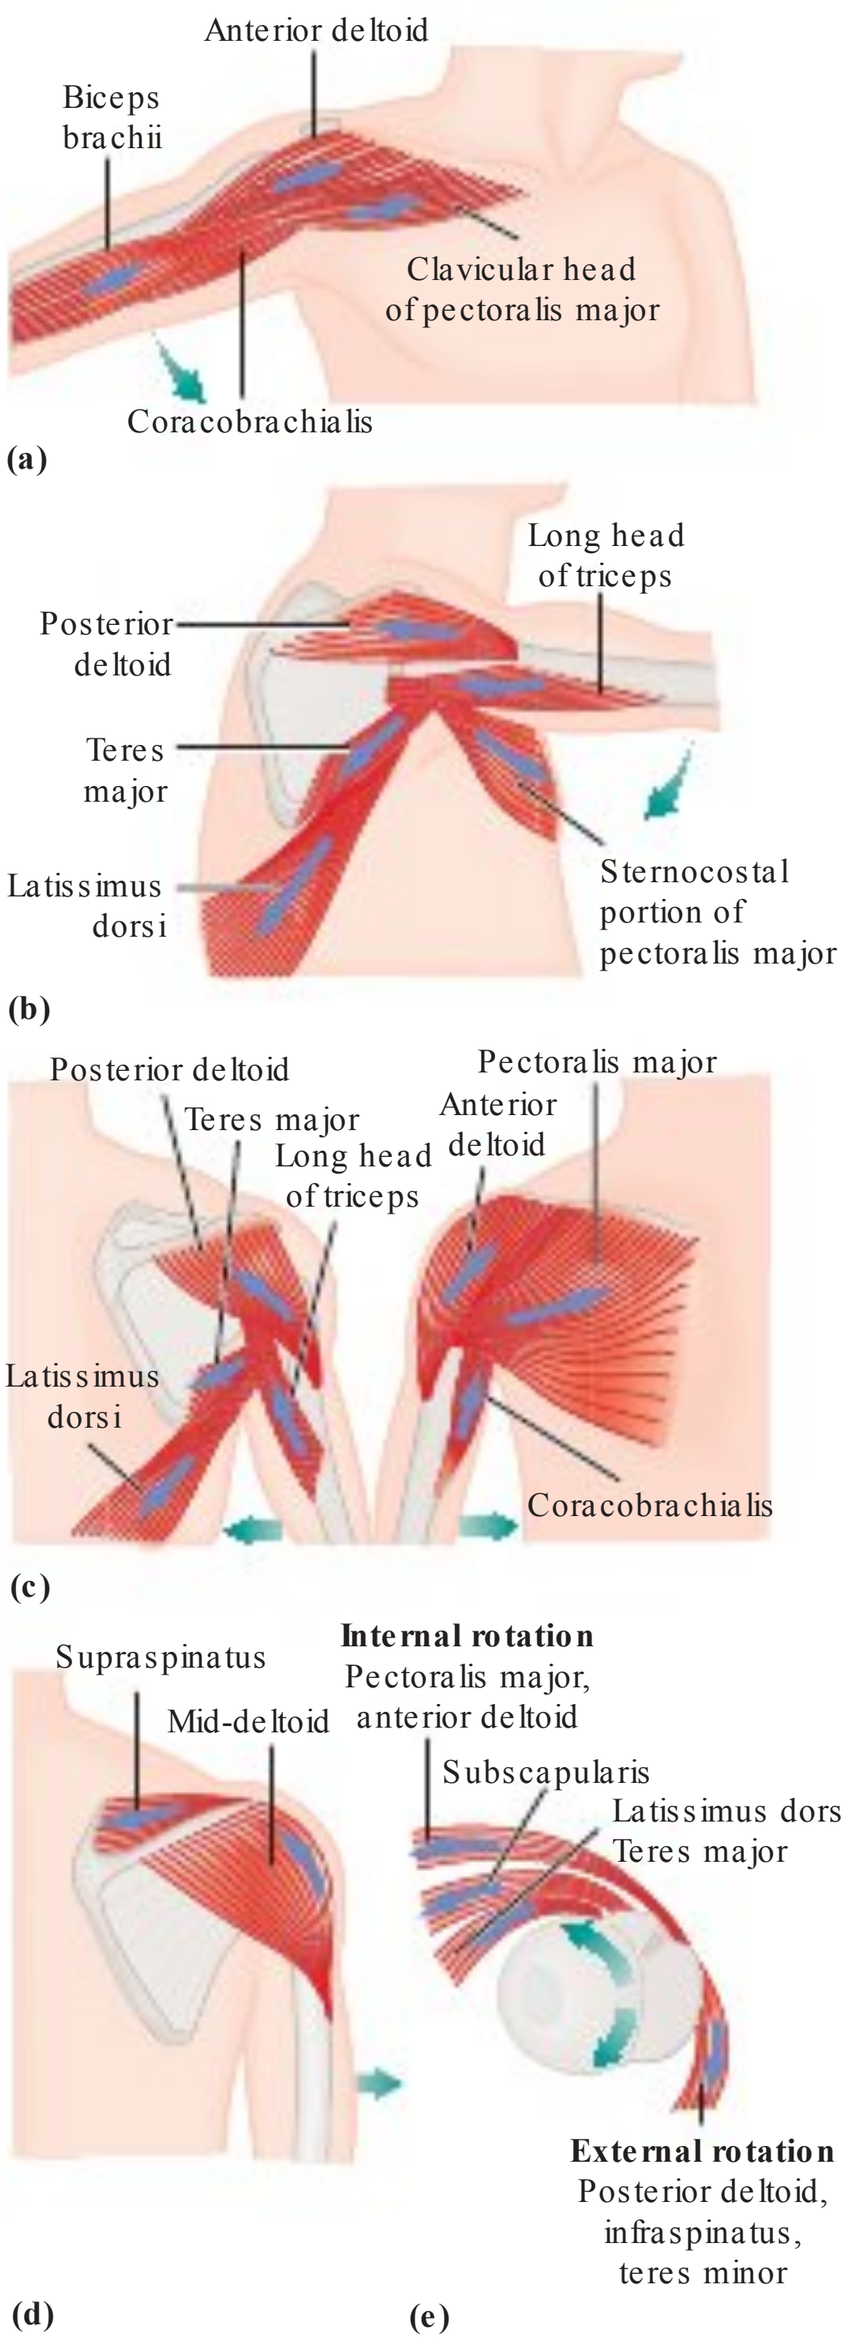

FIGURE 68.27 Muscles that move the shoulder and arm: flexors **(A)**, extensors **(B)**, adductors **(C)**, abductors **(D)**, and rotators **(E)**. (Adapted from Hollinshead WH. *Anatomy for surgeons. Vol 3: The back and limbs.* 3rd ed. New York: Harper & Row; 1982:325–330.)

progressive neurologic and cognitive deficits accompanied by hemodynamic instability may also present with dissecting vertebral and extracranial carotid artery aneurysms.[20,21] Other red flags include significant head trauma in the presence of a neurologic deficit. Night pain or unrelenting pain with associated weight loss is suggestive of a neoplastic or infectious process.

External rotation	Infraspinatus Teres minor Deltoid (posterior fibers)
Abduction	Deltoid Supraspinatus
Adduction	Pectoralis major Latissimus dorsi Teres major Subscapularis

Location/Radiation

Pain in the neck and arm may be skeletal, myofascial, or neuropathic. Neuropathic pain can be further divided into peripheral or segmental nerve pathology versus autonomic and central nervous system pathology or sensitization. Cohen[22] suggests the diagnostic construct of mechanical versus nonmechanical pain. Mechanical pain is exacerbated by movement and occurs in the essentially well patient. Nonmechanical pain is often related to a medical source such as infection, neoplasm, or an inflammatory process generally seen in patients with systemic manifestations of their disease process.[22]

The purpose of a thorough history with determination of the location, pattern, and distribution of the patient's pain is to establish an initial differential diagnosis which can subsequently be confirmed or ruled out by physical examination, diagnostic laboratory, radiologic, and electrophysiologic testing. Localized pain is usually caused by disorders of joints and muscles. Segmental pain conforming to dermatomal distributions may implicate lesions of nerve roots. Pain conforming to a peripheral dermatomal and/or myotomal distribution suggests lesions of the cervical or brachial plexus or their branches. Knowledge of dermatomal, myotomal, sclerotomal, and zygapophyseal referral patterns as well as distribution of peripheral nerves of the cervical and brachial plexus are essential for determining a rational differential diagnosis (see Figs. 68.11 through 68.19 and Tables 68.3 through 68.5).

In addition to cervical nerve root inflammation or impingement, cervical and brachial referral patterns may be secondary to myofascial trigger points or referred pain from cervical zygapophyseal joints. Widespread pain may implicate fibromyalgia syndrome, rheumatologic disease such as mild systemic lupus erythematosus, polyarticular osteoarthritis, rheumatoid arthritis, polymyalgia rheumatica, hypermobility syndromes, and even osteomalacia. Nonrheumatologic syndromes must also be considered in patients presenting with widespread pain. These include neoplastic and neurologic diseases, hypothyroidism, and other endocrine disorders, chronic infections, and a variety of psychiatric conditions.[23]

Location of the patient's pain cannot in isolation lead to a correct diagnosis. All aspects of the history of present illness, past medical and surgical history, family history of hereditary illness, social, occupational, behavioral, psychologic, and demographic information are necessary to identify predisposing factors or

mechanisms of injury. A review of systems and detailed physical exam are essential to rule out manifestations of systemic disease and presence or absence of significant neurologic deficits. Even then, further diagnostic tests as well as pharmacologic and interventional trials may be required in complex cases to confirm or rule out etiologic hypothesis.

Onset

Acute onset of pain may occur after trauma, injury, or following an unaccustomed increase in activity in a deconditioned patient; however, an acute exacerbation of a chronic condition cannot be excluded. More gradual or insidious onset is common in progressive degenerative, inflammatory, or malignant process. It is important to elicit the time at which the pain first occurred, characteristics of the pain during the interval between onset, and evaluation of precipitating events or factors.

Intensity and Pattern of Severity With Time. A cardinal principle of diagnosis is assessment of the intensity of pain both at baseline and in response to time, activities, and treatment. Although the visual analogue or numerical rating pain score system is subjective and may be influenced by psychologic, social, and occupational factors, it is essential to evaluate the trend of each patient's pain over time in order to assess the effects of pharmacologic, psychologic, behavioral, physical, and interventional therapies. Patterns of pain severity over time are often associated with certain diseases. Chronic unrelenting pain may be due to inflammatory disease or a more centralized pain syndrome. Pain due to cervical spondylosis and stenosis may be severe with activities requiring neck flexion and rotation and absent or significantly reduced when the patient's neck is held in a neutral position. Patient complaint of night pain or pain of spontaneous onset which is constant and not relieved by rest or modified by movement may raise suspicion for an infectious or neoplastic process.

Quality. Electrical, shooting, stabbing, lancinating, burning, tingling, and pins and needles are common terms used to describe neuropathic pain. Dull, aching, cramping, or throbbing pain is more often associated with pain of a musculoskeletal nature. Stiffness is often described in association with degenerative arthritis or diffuse idiopathic skeletal hyperostosis (DISH). It is not unusual for the patient to include sensory changes (numbness, pins and needles, or burning) as well as cramping and aching pain in their description of cervical radiculopathy. This is most likely due to both the cutaneous or dermatomal and muscular or myotomal distribution of the cervical nerve roots. Burning pain associated with allodynia and thermohyperesthesia suggests Complex Regional Pain Syndrome (CRPS). The more chronic the pain condition, the more likely the patient will report a poorly localized, widespread, nondermatomal pain pattern due to changes in central pain processing known to occur following persistent painful peripheral input.[24]

Modifying Factors and Drug History

Asking the patient the question, "What makes your pain better or worse?" will assist in further narrowing of the differential diagnosis. Coughing or sneezing and lateral head rotation and extension may cause exacerbation of cervical radicular pain. Chronic inflammatory pain is often worse after a period of inactivity and improves with exercise. Degenerative arthritis is often exacerbated by exercise and improves with rest. In patients with multiple pain complaints, response to medication may help guide diagnosis. In patients who have failed multiple medication trials, it is important to elicit specific reactions to medications, duration of use, dosages reached, and titration schedules implemented. An elderly patient, for example, who gives a history of intolerable sedation with an antiepileptic medication, may have been started at a standard adult dose and subsequently titrated upward using an aggressive titration schedule. This patient may be able to benefit from this same medication if it is titrated more gradually from a low dose.

Associated Symptoms

A history of neck and arm pain associated with frequently dropping objects, difficulty with writing, or other fine motor skills is useful in separating motor weakness from guarding secondary to pain. Associated symptoms may help to broaden or further refine the differential diagnosis. A patient with neck and arm pain which occurs with increased activity and is associated with diaphoresis and shortness of breath may broaden the differential diagnosis to include coronary artery disease. Indeed, the first clinical description of cervical radiculopathy by Semmes and Murphy in 1943 was titled, "The syndrome of unilateral rupture of the sixth cervical vertebral disc with compression of the seventh cervical root: a report of four cases with symptoms simulating coronary disease."[25] Association of neck and radicular arm pain with positional headaches accompanied with nausea, photophobia, and blurred vision may lead the physician to rule out low pressure headache.[26]

Family History

In addition to more common hereditary arthridites such as rheumatoid arthritis (more common in females), ankylosing spondylitis (predominantly seen in males), psoriatic arthritis, and Reiter's syndrome, there are also more uncommon hereditary diseases which can involve the cervical spine. Compression of the cervical cord from cervical root neurofibromas in patients with neurofibromatosis type 1 has been reported to present with progressive neurologic deficit.[27] Tophaceous gout of the odontoid process and larynx, epidural, mediastinal, and subcutaneous emphysema in a patient with Marfan's disease following forceful coughing, and cervical dystonia in spinocerebellar ataxia type 2 are other inherited disorders manifesting with neck pain.[28–31]

Age and Psychosocial History

The patient's age, sex, occupational, and social history is important in determining risk factors known to be associated with the development of persistent neck and upper limb pain. While sports or trauma injury and congenital defects such as Chiari I malformations are common causes of neck pain in pediatric or adolescent patients, degenerative changes are common in older patients. Jobs or activities which require repeated lifting of heavy objects, prolonged bending of the neck, working with arms at/above shoulder height, and which involve little job control and little social support are associated with the development of neck pain. Specific jobs and activities associated with the development of neck pain include prolonged computer work and bicycling.[16,17,32] Extensive neck and upper extremity pain is independently associated with psychologic ill-health, female sex, unemployed status, and smoking.[18]

Questions regarding use of pillows at night and bifocals as well as any other activities which put the patient's neck under prolonged flexion strain should be included in the social and occupational history. In some cases, simple correction of repetitive strain with postural reeducation may result in relief of symptoms.

Depression and anxiety may occur as a reaction to persistent pain and are also independent risk factors for the development of chronic pain. The depressed individual may lack the psychologic and social capabilities to cope with the complex physical, emotional, cognitive, and behavioral components of the pain experience.[33] Patients with coexisting histories of depression and anxiety may benefit from referral to a psychopharmachologist and from psychologic consultation for cognitive and behavioral therapies to assist the patient with coping strategies.

Past Medical History and Review of Systems

The past medical history, past surgical history, and review of systems may provide essential clues tying the patient's symptoms to an associated disease process. Table 68.8 lists a few coexisting diseases which may present with neck pain and radiculopathy, while Table 68.9 lists a review of systems checklist which may identify systemic involvement or an urgent, rapidly progressing process.

Surgical History

A past surgical history of neck fusion may signal risk of pseudoarthrosis or increased risk of recurrent disk disease above or below the level of fusion. Poststernotomy lesions following cardiac surgery with the clinical appearance of a C8 radiculopathy have been described. The causal mechanism is thought to be related to an occult fracture of the first thoracic rib. These are often mistaken for ulnar neuropathy at the elbow thought to be associated with surgical positioning.[34]

Physical Examination

General Observations. Many important observations can be made during the initial interview and even as the patient travels from the waiting area to the exam room. The general health and independence of the patient can be surmised from skin and muscle tone, posture, gait, and use of assistive devices. Cachexia may be a sign of debilitation due to cancer or long-standing depression. Mood, affect, and cognitive state can be ascertained during questioning as well as during the physical exam. Other important general observations include symmetry of the shoulders, abnormal head positions including lateral flexion, rotation or protrusion and evidence of muscle wasting or deformity of the neck, shoulders, or upper limbs.

A complete physical exam is paramount in the patient with neck, shoulder, and arm pain. Inspection of the skin for lesions may reveal psoriasis which may be associated with psoriatic arthritis. Vesicles typifying herpes zoster may be found in a patient complaining of radicular symptoms. Lesions typical of erythema nodosum may be indicative of inflammatory disease or cancer, and needle marks (intravenous drug abuse) may raise suspicion for vertebral column infections. Acute pain from viscera sharing the same embryologic segmental derivation as the cervical spine can present as neck, shoulder, or arm pain. These include the submandibular glands, lymph nodes, thyroid, esophagus, heart, lungs, stomach, gallbladder, pancreas, and diaphragm, necessitating a general inspection and palpation of these areas.[35] In general, a systematic approach which includes a neurologic exam, inspection, palpation of bony and soft tissue structures, followed by range of motion and special tests used in the diagnosis of neck pain should supplement, but not replace, the full physical examination.

TABLE 68.8

NONCOMPRESSIVE INFECTIOUS, INFLAMMATORY, AND NEOPLASTIC CAUSES OF NECK PAIN AND RADICULOPATHY

Infection (most common in immune suppressed patients)
Herpes Zoster, human immunodeficiency virus, Cytomegalovirus, Tuberculosis, Borrelia burgdorferi (Lyme disease)
Inflammatory
Systemic lupis Erythematosus, Sarcoidosis, Bruns-Garland syndrome (diabetic radiculopathy), Parsonage-Turner syndrome (Neuralgic amyotrophy), Multiple Sclerosis "pseudopolyneuropathy," Gout

Exam of the Neck.

Neurologic exam. Examination of the neck must include a neurologic exam. Tumors, infections, and carotid dissections which present as neck pain are also associated with cranial nerve palsies and sensory deficits. Delay in recognition of neurologic deficits in these cases can lead to progression of tumor or infection with poor surgical or medical outcome and prognosis.[36–38] A summary of the motor, sensory, and autonomic functions of the cranial nerves is found in Table 68.10.

In addition to examination of the cranial nerves, general head,

TABLE 68.10

SUMMARY OF THE MOTOR, SENSORY, AND AUTONOMIC FUNCTIONS OF THE CRANIAL NERVES

Cranial Nerve (CN)	Cranial Point Exit	Peripheral Innervation of Head	Function	Symptom/Sign of Damage
Olfactory (CNI)	Cribiform plate	Mucosa of nasal cavity	Smell	Anosmia
Optic (CNII)	Optic foramen	Retina of eye	Vision	Blindness
Occulomotor (CNIII)	Superior orbital fissure	All extraocular eye muscles except superior oblique and lateral rectus	Eye movement (elevation, adduction)	Eye deviates down and out Loss of papillary accommodation reflexes
Trochlear (CNVI)	Superior orbital fissure	Superior oblique (extraocular eye muscle)	Eye movement (depression of adducted eye)	Diplopia, lateral deviation of eye
Trigeminal (CNV)	V1-Superior orbital fissure V2-Foramen rotundum V3-foramen ovale	V1-Cutaneous sensation of nose, eyes, and scalp V2-Sensation of face: maxilla, nasal mucosa, upper lip, and teeth V3-Cutaneous sensation of lower face: mouth mucosa, lower jaw teeth, TMJ, anterior two-thirds of tongue Motor supply to muscles of mastication	Facial sensation mastication	Facial anesthesia Loss of pain sensation Weakness/loss of mastication
Abducent (CNVI)	Superior orbital fissure	Lateral rectus (extraocular eye muscle)	Eye movement (abduction)	Medial eye deviation
Facial (CNVII)	Entry: Internal acoustic meatus Exit: stylomastoid foramen	Motor: muscles of facial expression and scalp	Facial expression Taste Salivation, lacrymation	Paralysis of facial muscles Loss of taste (anterior two-thirds of tongue) Dry mouth, loss of lacrymation
Vestibulocochlear (CNVIII)	Internal acoustic meatus	Inner ear labyrinth structures (semicircular canal and cochlear apparatus)	Balance hearing	Vertigo, disequilibrium, Nystagmus, hearing loss
Glossopharyngeal (CNIX)	Jugular Foramen	Posterior one-third of tongue Parotid gland Mucosa and elevator muscles of pharynx	Taste salivation Innervation of pharynx	Loss of taste (Posterior one-third of tongue) Loss of gag reflex
Vagus (CNX)	Jugular foramen	Palatal muscles, pharyngeal constrictors, vocal cords Taste and sensation to epiglottis	Swallowing and talking Cardiac, gastrointestinal tract Respiration Taste	Dysphagia and hoarseness Loss of cough reflex, loss of taste
Cranial accessory	Jugular foramen	Motor supply to larynx and pharynx	Pharynx/larynx muscles	Head turning
Spinal accessory (CNXI)		Head rotation and shoulder shrugging	Trapezius, Sternocleidomastoid	Shoulder shrug weakness
Hypoglossal (Xii)	Hypoglossal canal	Intrinsic and some extrinsic tongue muscles	Tongue movement	Atrophy of tongue muscles, deviation on protrusion, Fasciculations

neck, and upper extremity sensory, motor and deep tendon exam, sensory, motor, and deep tendon exam of the lower extremities is essential. Exam findings signaling a possible cervical myelopathy include unilateral or bilateral spastic, ataxic, spastic-ataxic or Trendelenberg gait, hypereflexia of lower extremity deep tendon reflexes and Babinsky sign, and decreased sphincter tone or loss of the anal "wink."

Sensory exam. The sensory exam is particularly useful in the patient with neuropathic pain. Sensory testing should include brush touch for allodynia, light pressure for tenderness and hyperalgesia, palpation for painful areas, as well as vibration, hot, cold, and sharp versus dull discrimination. Positive sensations, stimulus-evoked hypersensitivities such as allodynia to innocuous stimulation including light touch and cold, and hyperalgesia to noxious stimulation such as pinprick, occur focally in mononeuropathies and distally and symmetrically in polyneuropathies. In neuropathic pain syndromes such as CRPS, allodynia, and hyperalgesia may spread outside the area of the original injury or to homologous sites in the opposite limb. These sensory findings are often associated with focal autonomic abnormalities such as sweating, skin temperature and color changes, and edema are also present in CRPS. In central pain and anesthesia dolorosa, allodynia, hyperalgesia, and aftersensation (persistence of pain after the stimulus has ceased) can occur in areas demonstrated to have loss of sensation. In small fiber neuropathies, loss of thermal, pain, and sometimes touch perception with sparing of large-fiber functions such as muscle strength, deep tendon reflexes, and vibratory and proprioceptive perception is seen. These functions are all compromised in combined large- and small-fiber polyneuropathies.[39] The sensory exam should include evaluation for dermatomal patterns of sensory abnormality and for altered sensation in peripheral nerve distributions in patients with suspected peripheral nerve injury or entrapment syndromes. A "cord" level of sensory disturbance may be confined to the upper extremities due to "central cord syndrome" with involvement of decussating anterior sensory fibers.[40]

Motor exam. Motor exam is tested using the standard muscle strength scale from 0–5 (Table 68.11).

In addition to testing of motor function of the cranial nerves, myotomal or segmental nerve root motor supply should be systematically evaluated (Table 68.12).

Deficits consistent with peripheral nerve lesions or injury should also be ruled out (Table 68.13).

Reflex testing should include upper and lower extremities since lesions of the cervical spine may manifest with hypoactive reflexes at the level of the lesion, hyperactive reflexes below the lesion, and pathologic reflexes. Cutaneous reflexes will also be lost below the lesion. Reflexes are tested using the following standard scale:

- 0: absent reflex
- 1+: trace or seen only with reinforcement
- 2+: normal
- 3+: brisk
- 4+: nonsustained clonus (i.e., repetitive vibratory movements)
- 5+: sustained clonus

1+, 2+, or 3+ reflex are considered normal unless there is a significant difference between sides. 0, 4+, and 5+ are considered abnormal.

Upper extremity normal and pathologic reflexes are outlined in Table 68.14.

Inspection and palpation. After observation for abnormal posture such as abnormal loss of cervical lordosis, torticollis, and obvious atrophic musculature of the neck or upper extremity, the patient should be asked to lay supine to relax the musculature of the neck. This allows optimal examination of the boney structures of the neck.[35] While standing at the patient's side, one hand supports the neck from behind while the other is used to palpate the anterior neck structures.

The most superior boney structure of the anterior neck is the hyoid bone. It is the only bone in the skeletal structure not articulated to any other bone. It supports the root of the tongue and in turn is supported by the muscles of the neck and suspended by the stylohyoid ligaments from the styloid processes of the temporal bones. The body of the hyoid bone is palpated in the midline while the lesser and greater cornu are palpated laterally to each side of the body forming a horseshoe-like structure. The hyoid bone lies at the lower level of C3 or at the intervertebral disk between C3 and C4. Although injuries of the hyoid bone are rare outside of strangulation, fractures of the hyoid due to trauma, cardiopulmonary resuscitation, and sports injuries have been reported with complications including carotid pseudoaneurysm, pharyngeal laceration, and airway compromise.[41–44] Insertion tendonitis of the hyoid bone has also been reported as an unrecognized source of neck pain with recognizable radiologic features.[45] Below the hyoid bone, at the level of C4 to C5, is the thyroid cartilage. The first cricoid ring forms the upper border of the trachea. It lies at the level of C6. The carotid tubercle, also known as Chassaignac's tubercle, is the anterior tubercle of the C6 trans-

Ulnar nerve: Claw hand
Radial nerve: Wrist drop
Median nerve: Cannot make "OK" sign

TABLE 68.14

UPPER EXTREMITY DEEP TENDON REFLEXES AND PATHOLOGIC REFLEXES

Reflex	Nerve Root or Function Tested	Location	Response
Scapulohumeral reflex	Tests integrity of cord segments from C4-C6	Lower aspect of medial border of scapula	Adduction and lateral rotation of the arm
Biceps reflex	C5, C6	Tap thumb placed over biceps tendon in antecubital fossa	Flexion of forearm
Brachioradialis reflex	C6	Proximal to radial aspect of wrist	Radial and dorsiflexion at wrist
Triceps reflex	C7	Tendon of triceps muscle as it crosses olecranon fossa	Extension at elbow
Hoffman's sign (pathologic if positive; upper extremity equivalent of Babinsky sign)	Test for upper motor neuron lesion	Patient's long finger in slight extension DIP flicked downward by examiner's thumb	Involuntary flexion of thumb and little finger to make "OK" sign
Jaw reflex	Upper motor neuron lesions	Tap finger placed over mental area of chin	Jaw closing (abnormal if hyperactive)
Chvosteck's sign (pathologic if positive)	Hypocalcemia or other metabolic abnormality	Tap over facial nerve anterior to ear	Hyperactive response

DIP, Distal interphalangeal joint.

verse process and can be palpated approximately 3 cm lateral to the first cricoids ring. The carotid arteries overlie the tubercles. Caution should be taken to examine the carotid pulses individually to prevent bradycardia and/or syncope.

Soft tissues of the anterior neck include the H-shaped thyroid gland which extends from the thyroid cartilage cranially to the fourth to sixth tracheal rings inferiorly. This area should be inspected to preclude generalized enlargement of the gland and palpated to exclude thyroid masses. The exam should include inspection for palpable lymph nodes which may be due to infection or metastatic disease. Unknown primary carcinoma presents as painless enlarged cervical lymph nodes and accounts for approximately 5% of all head and neck malignancies. If malignancy is suspected, the patient should be referred for more advanced imaging and diagnostic testing.[46] By having the patient turn their head to the opposite side, the sternocleidomastoid muscle may be examined from the origins on the sternum and clavicle to its insertion on the mastoid process of the temporal bone. The anterior border of this muscle from origin to insertion defines the lateral limit of the anterior triangle of the neck and the posterior border, the anterior limit of the posterior triangle of the neck. The exam should include palpation for painful or painless masses, trigger points with associated referral patterns, and pain associated with swallowing.

Palpation of the boney landmarks of the posterior cervical spine includes the inion or external occipital protuberance in the midline, which makes the midpoint of the superior nuchal line extending laterally from the inion bilaterally. The occipital nerves run medial to the occipital arteries over the occiput approximately 3 cm from the midline. Tenderness or pain with examination of this area may be seen with occipital neuralgia. Palpation of the cervical spine is performed in a systematic way, starting with the spinous processes, and followed by the zygapophyseal joints. Pain over the midline structures may indicate a structural problem of the cervical spine. The zygapophyseal joints are located 2–3 cm from the midline. Palpation of the lateral atlantoaxial joint of C1-C2 is undertaken by rotating the patient's head to the ipsilateral side. C2, C3, C4, and C5 are usually difficult to palpate because of the normal cervical lordosis but can be easily identified if it is remembered that the C3-C4 joint is at the level of the hyoid bone and the C4-C5 joint is at the superior aspect of the thyroid cartilage. The C6 spinous process can be easily identified as it is usually easily palpable and disappears under the examining finger on extension of the neck. The level of the C6-C7 joint can also be confirmed by its location at the level of the cricoid ring. The largest "fixed" prominence is the spinous process of C7. Referral patterns from the zygapophyseal joints have recently been studied in patients with neck, head, and shoulder pain with the most common referral patterns based on areas in which patients are relieved of pain by controlled blocks are depicted in Figures 68.28 through 68.33.[47]

Examination of the soft tissues of the posterior neck includes palpation of the suboccipital muscles and trapezius which, like the sternocleidomastoid, may be a source of cervicogenic headache. The trapezius extends from the external occipital protuberance, the medial third of the superior nuchal line of the

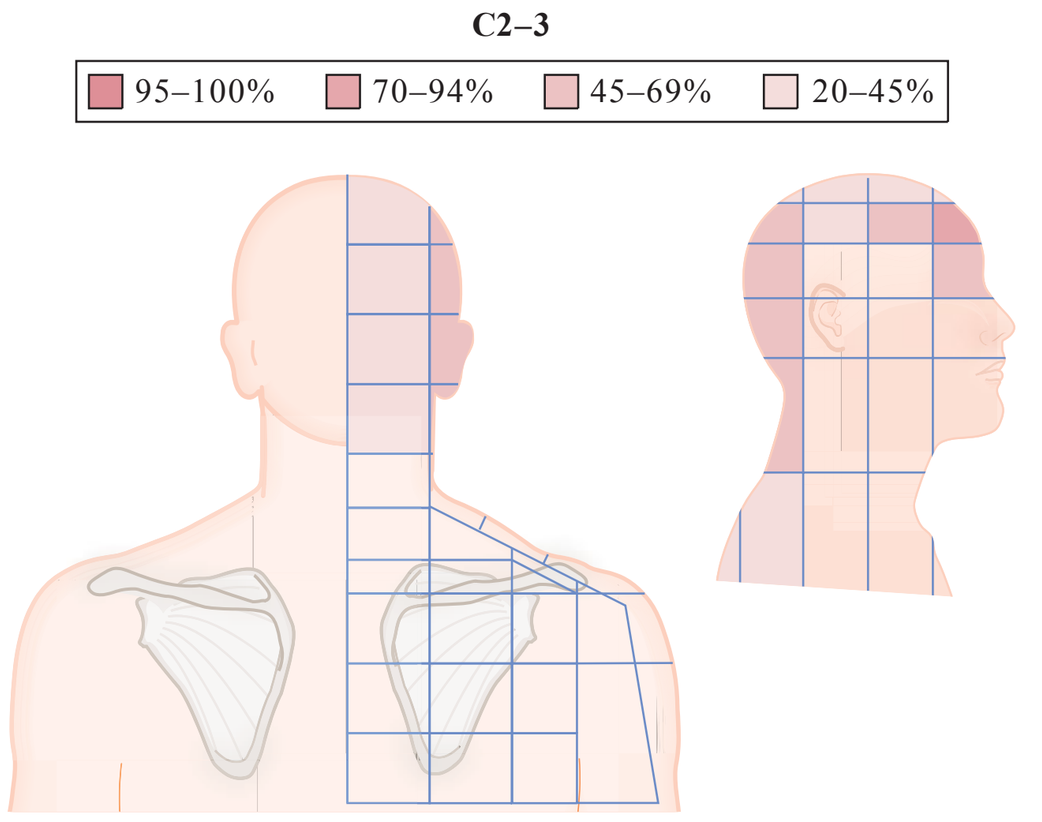

FIGURE 68.28 Distribution of pain and pain frequency in each grid area as reported by patients with pain originating from C2-C3. (From Cooper G, Bailey B, Bogduk N. Cervical zygapophysial joint pain maps. *Pain Medicine* 2007;8[4]:344–853, with permission.)

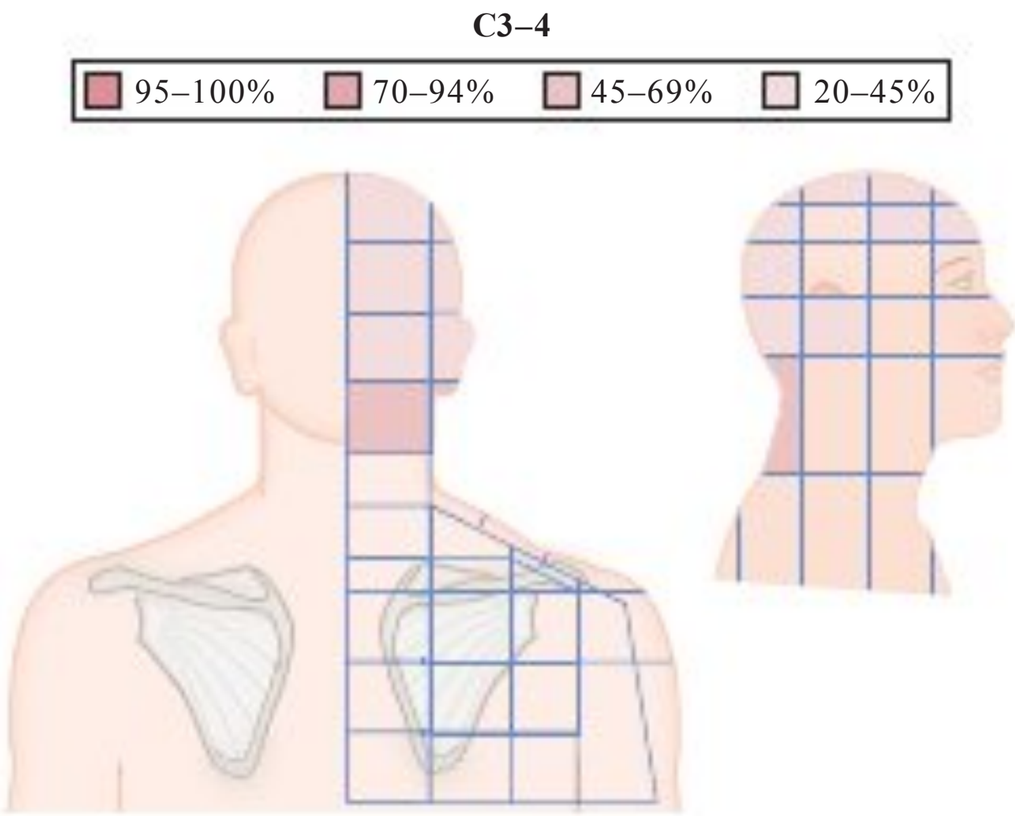

FIGURE 68.29 Distribution of pain and pain frequency in each grid area as reported by patients with pain originating from C3-C4. (From Cooper G, Bailey B, Bogduk N. Cervical zygapophysial joint pain maps. *Pain Medicine* 2007;8[4]:344–853, with permission.)

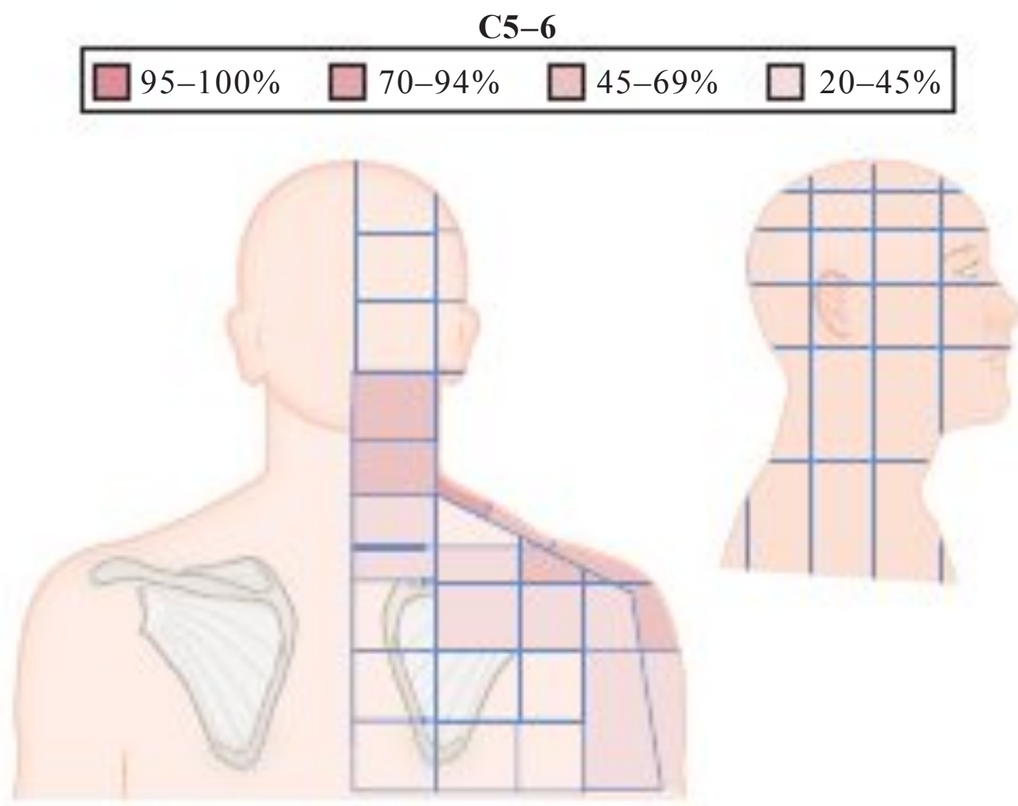

FIGURE 68.31 Distribution of pain and pain frequency in each grid area as reported by patients with pain originating from C5-C6. (From Cooper G, Bailey B, Bogduk N. Cervical zygapophysial joint pain maps. *Pain Medicine* 2007;8[4]:344–853, with permission.)

occipital bone, the ligamentum nuchae, spinous processes of the seventh cervical, and all thoracic vertebrae to the posterior border of the lateral third of the clavicle, the medial margin of the acromion, and the posterior border of the scapular spine. The scalene muscles should be not be neglected in patients with neck, arm, and head ache. Neck pain, occipital headache, extremity paresthesia, pain, and weakness may occur from scarring of the scalene muscles secondary to neck trauma such as whiplash injuries.[48] As with examination of the anterior neck, a chain of lymphnodes lies along the anterolateral border of the trapezius. Enlargement or tenderness of these may indicate infection or metastatic disease.

Special tests for neck and upper extremity

SPURLING'S MANEUVER. This maneuver is used to confirm the presence of a cervical radiculopathy. It is performed by extending and rotating the head to the right or left. This narrows the intervertebral foramen by 20% to 30%. It has been shown to have a sensitivity of 30% and a specificity of 93% on 235 individuals referred for electrodiagnosis of upper extremity nerve pain.[49] It also increases pressure on the cervical facet joints and may intensify facet mediated pain.

VALSALVA TEST. This test is performed by having the patient place their thumb in their mouth and blow, as if to push the thumb out of their mouth. This maneuver increases the intraspinal pressure and may reveal the presence of space-occupying lesions of the cervical spine such as large intervertebral disk herniations, tumors, and stenosis due to spondylosis or osteophytes. If the mass involves the area of the spine adjacent to nerve roots, radicular pain may be reproduced.

DISTRACTION TEST. This test reduces pressure on the intervertebral disk and exiting nerve roots and simulates the effect that traction may have on treatment of neck and radicular symptoms.

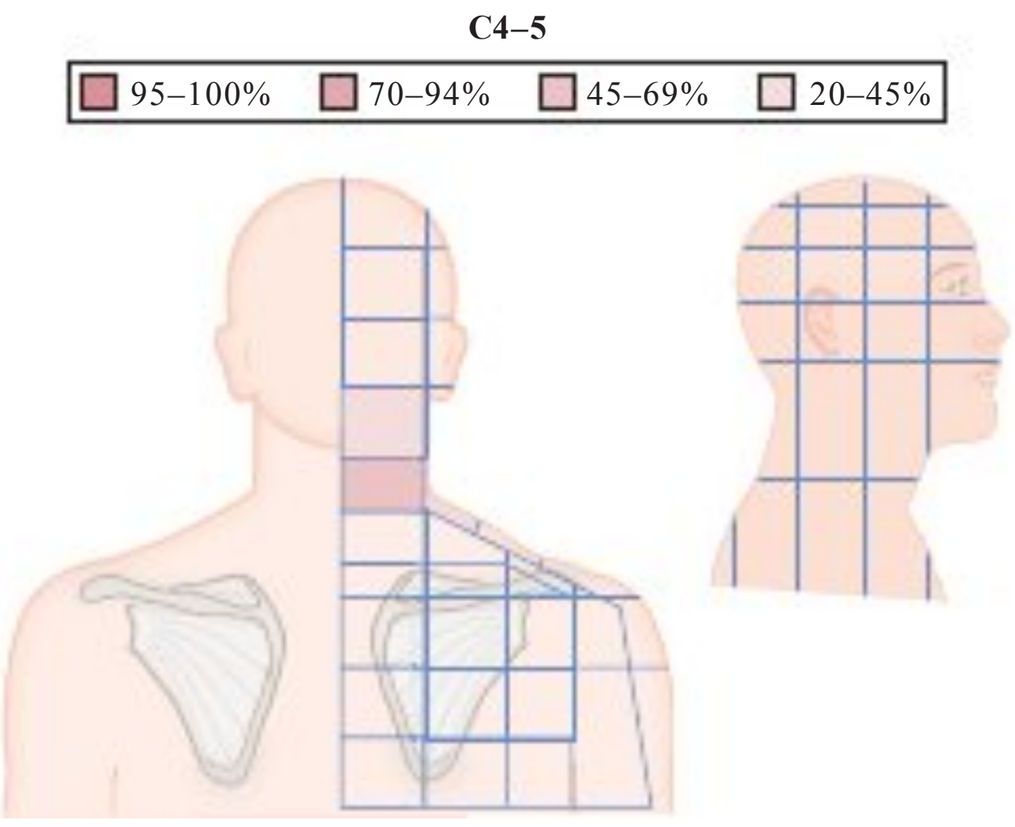

FIGURE 68.30 Distribution of pain and pain frequency in each grid area as reported by patients with pain originating from C4-C5. (From Cooper G, Bailey B, Bogduk N. Cervical zygapophysial joint pain maps. *Pain Medicine* 2007;8[4]:344–853, with permission.)

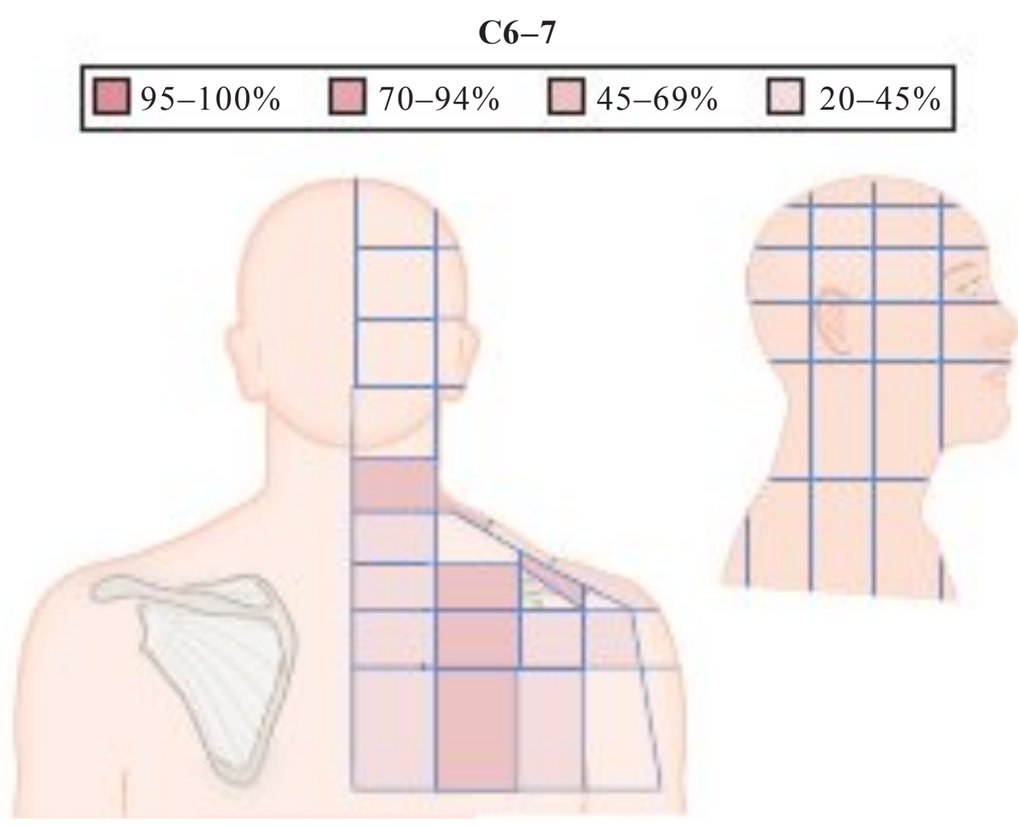

FIGURE 68.32 Distribution of pain and pain frequency in each grid area as reported by patients with pain originating from C6-C7. (From Cooper G, Bailey B, Bogduk N. Cervical zygapophysial joint pain maps. *Pain Medicine* 2007;8[4]:344–853, with permission.)

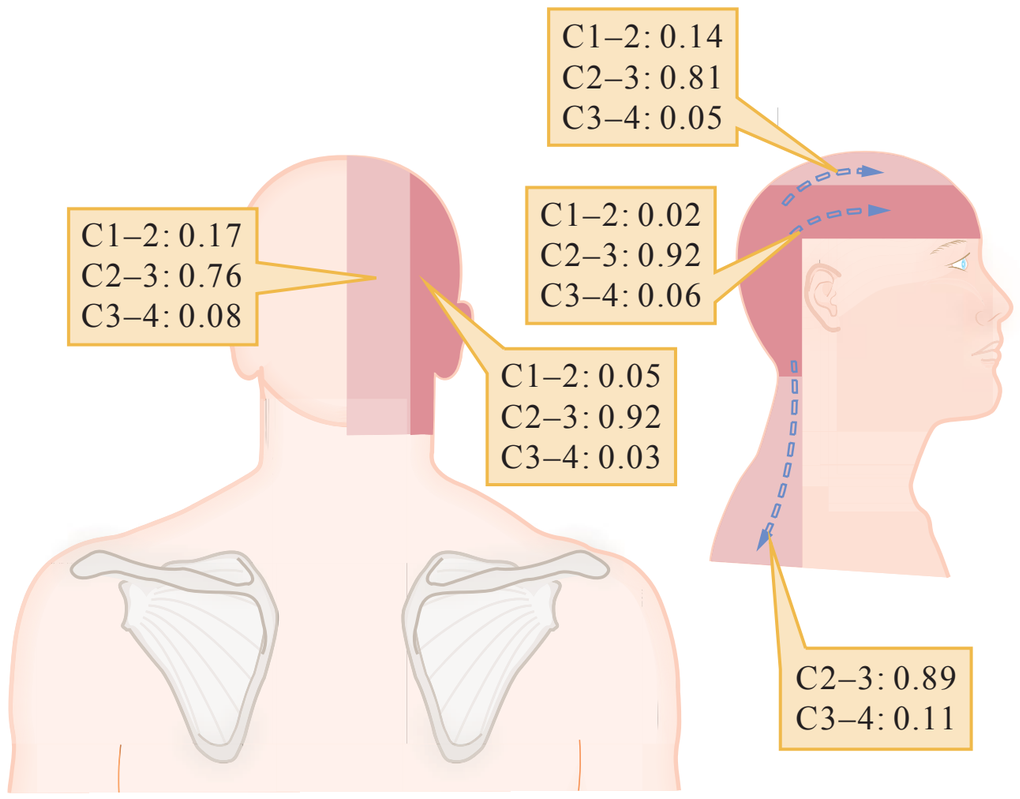

FIGURE 68.33 The probability of neck and head pain in areas depicted being secondary to C1-C2, C2-C3 and C3-C4 segments. (From Cooper G, Bailey B, Bogduk N. Cervical zygapophysial joint pain maps. *Pain Medicine* 2007;8[4]:344–853, with permission.)

It is performed by placing one hand underneath the jaws, the other beneath the occiput, and applying gentle upward pressure over 30–60 seconds. Increased pain with this maneuver may be due to inflammatory or degenerative disease, or muscle or ligamentous pathology.

JACKSON'S COMPRESSION TEST. As with Spurling's Maneuver, this test places increased pressure on the cervical facet joints and causes narrowing of the neural foramen. It may reproduce neck pain due to facet arthropathy and/or upper extremity radicular pain due to nerve root compression. To perform this test, the patient is instructed to rotate his or her head first to the right and then to the left. The examiner exerts gentle pressure to the top of the patient's head after each movement.

LHERMITTE'S SIGN. Lhermitte's sign is the production of a sensation of lightening-like paresthesias or dysesthesias in the arms or legs upon flexion of the cervical spine. It may be caused by a large disc herniation or boney compression of the anterior cord in patients with a narrowed central canal. It may also occur in patients with rheumatoid arthritis with associated instability or in patients with multiple sclerosis affecting the cervical spinal cord, tumors, and syringomyelia.[50]

SHOULDER DEPRESSION AND ABDUCTION TESTS. The shoulder depression and abduction tests are useful for evaluation of radicular pain. The shoulder depression test is performed by having the patient laterally flex his or her neck while placing downward pressure on the shoulder opposite the direction of flexion. This produces stretch on irritated nerve roots and may accentuate or reproduce radicular symptoms. The shoulder abduction test relieves pressure on the cervical nerve roots and may relieve or reduce cervical radicular symptoms. It is performed by having the patient place the hand from the painful side on the top of their head. This maneuver shortens the distance between the cervical spine and the coracoid process, thus relieving tension on the nerve root.

In vivo studies using kinematic magnetic resonance imaging of 21 patients with cervical spine disc herniations or cervical spondylosis demonstrated an increase of foraminal size with flexion combined with axial rotation to the opposite side of the pain. Foraminal size decreased at extension combined with axial rotation to the side of the pain. A decrease or no change of foraminal size was observed at either extension or axial rotation to the side of the pain alone. Cervical cord rotation or displacement was noted with axial rotation in 24% of these patients.[51] Active versus passive range-of-motion testing is advised in patients with neurologic symptoms or those at risk of instability of the cervical spine (i.e., patients with progressive rheumatoid arthritis involving the cervical spine). In these patients, limitation of active range of motion due to pain may be protective.

ADSON'S MANEUVER. This test is used to rule out compression of the subclavian artery by an extra cervical rib or scalene muscle bands, which may result in thoracic outlet syndrome. The patient's arm hangs at their side and the head is extended and rotated toward the affected side. The patient is then instructed to breathe deeply and hold their breath while the radial pulse is monitored. The test is considered positive if the radial pulse disappears. More current testing methods include use of doppler ultrasound to record significant changes in subclavian artery flow characteristics during the above maneuvers. Although the clinical validity of the Adson's test has been questioned,[52] a recent study of 16 patients showed complete relief of symptoms following surgery in 87% of patients with a positive Adson's test using doppler ultrasound compared to a significant relief of pain in only 50% of patients with a negative doppler-assisted Adson's test.[53]

HALSTED MANEUVER (EXAGGERATED MILITARY POSITION). The Halsted maneuver is a test of neurovascular compression at the costoclavicular space. The patient assumes a military posture with the shoulders rolled backward and downward so to narrow the costoclavicular space. The radial pulse is monitored. The maneuver is considered positive if the radial pulse disappears.

Further diagnostic tests for shoulder pathology are outlined in Table 68.15.

Examination of the Shoulder and Arm. Detailed anatomy of the neck, shoulder, and upper extremities, including normal range-of-motion, is covered in the initial part of this chapter and is essential to understanding the anatomic and functional correlates of this portion of the physical exam. Physical examination of the shoulder, arm, elbow, forearm, wrist, and hand should include:

- Blood pressure
- Inspection of position, shape, muscle atrophy, swelling
- Inspection of skin for allodynia, changes in color, temperature, or trophic changes
- Palpation of muscles and tendon for tenderness, pain, trigger points, dysesthesias, and radiation patterns
- Palpation over joints during range of motion testing for crepitus, popping, or locking
- Active and passive range of motion at shoulder: abduction, adduction, internal and external rotation, flexion, and extension at shoulder
- Other tests for shoulder, see Table 68.15
- Range of motion at forearm: flexion, extension, pronation, and supination
- Range of motion at wrist: dorsal flexion, palmar flexion, ulnar flexion, and radial flexion
- Range of motion of fingers: flexion, extension, adduction, abduction, opponens, and grip
- Observation of effect on pain of each movement

Waddell signs. In their study of illness behavior, Waddell and Main[54] described 5 categories of nonanatomic signs (Table 68.16) and reported that the presence of at least three signs was indicative of significant psychosocial stress. Although the presence of three or more signs is often interpreted as a sign of malingering, no association with malingering or secondary gain has been demonstrated in controlled studies.[55] Fishbain et al.[56] reported that Waddell's signs decreased following comprehensive pain management. Pain behaviors are known to be a means for patients to communicate pain and distress. They can be positively reinforced by attention from family members or by being excused

TABLE 68.15

TESTS USED IN SHOULDER PAIN DIAGNOSIS AND SIGNIFICANCE OF POSITIVE FINDINGS

Test	Maneuver/Description	Diagnosis Suggested by Positive Result
1. Apley scratch test	1. Patient touches superior and inferior aspects of opposite scapula	1. Loss of range of water: rotator cuff problem
2. Neers sign	2. Arm in full flexion	2. Impingement syndrome
3. Hawkin's test	3. Flexion at shoulder to 90 degrees and internal rotation—arm lowered slowly to waist	3. Impingement syndrome
4. Drop-arm test	4. Supraspinatus isolated against resistance	4. Rotator cuff tear
5. Empty can test	5. Hand against back of waist with 90 degrees flexion of elbow	5. Rotator cuff tear
6. Lift-off test	6. Forward elevation to 90 degrees and active adduction	6. Rotator cuff tear (subscapularis)
7. Cross-arm test	6. Shoulder flexion to 90 degrees and 20 degrees adduction, resisting downward force exerted by examiner	7. Acromioclavicular joint
8. O'Brian's test (active compression test)	7. Anterior pressure on humerus with exterior rotation	8. Pain with thumb up may indicate acromioclavicular
9. Apprehension test	8. Post force on humerus with external rotation	9. joint arthritis or injury and thumb down a SLAP lesion
10. Relocation test	9. Pulling downward on elbow or wrist	10. Anterior glenohumeral instability
11. Sulcus sign	10. Elbow flexed to 90 degrees with forearm pronated	11. Anterior glenohumeral instability
12. Yergason's test	11. Elbow flexed to 20–30 degrees with forearm pronated	12. Inferior glenohumeral instability
13. Speed's maneuver	12. Rotation of loaded shoulder from extension to forward flexion	13. Biceps tendon instability or tendonitis
14. Clunk sign	13. Arm elevated to 160 degrees in scapular plane, loaded axially along humerus with maximal internal and external rotation	14. Biceps tendon instability or tendonitis
15. Crank test		15. Labral disorder
		16. Labral tear

from undesirable obligations. Pain behaviors may also be "unlearned," using cognitive and behavioral therapies.[57,58]

Laboratory Evaluation

Pain must be seen as a diagnosis of exclusion, for the consequences of treating pain symptomatically in the face of progressive systemic disease can result in a tragic delay of diagnosis and treatment. In general, laboratory testing is guided by the patient's history of present illness, past medical history, and physical exam. A patient who is systemically ill requires more extensive testing guided by affected organs and systems. For example, patients who are febrile or those with weight loss, anorexia, and other signs suggesting infection or neoplasm would benefit from complete blood count and differential analysis. Those with a history of hepatitis or other risk factors for liver disease would benefit from a liver enzyme panel. Patients with cold intolerance, weight gain, and lethargy should undergo thyroid function test analysis.

Morning stiffness, polyarticular involvement, rigidity, or cutaneous manifestations suggest an inflammatory arthritic component requiring a more extensive rheumatologic evaluation. Patients with a diagnosis of fibromyalgia should undergo testing of both thyroid function and vitamin D levels since hypothyroidism and vitamin D deficiency can both result in diffuse pain syndromes which mimic fibromyalgia.

Laboratory analysis of the erythrocyte sedimentation rate and C-reactive protein may also assist in evaluating inflammatory phenomena such as an autoimmune disease, infection, or neoplasm. These may be significantly elevated with an upward trend in patients who are afebrile, who have a normal white blood cell count, and who culture negative (even in the face of sepsis).[59,60]

Other laboratory tests which may be useful in ruling out systemic disease in select patients include serum calcium, which amongst other diagnoses may be elevated in patients with malignancy, and serum alkaline phosphatase, which is elevated in metastatic spine tumors and Paget's disease.[1]

TABLE 68.16

WADDELL'S SIGNS

1. Superficial and widespread tenderness or nonanatomic tenderness (it's "one" sign).
2. Stimulation tests: Axial loading and pain on simulated rotation (it's another "one" sign).
3. Distracted straight leg raise.
4. Nonanatomic sensory changes: Regional sensory changes and regional weakness (it's another "one" sign).
5. Overreaction.

Radiographic Studies

Diagnostic and functional imaging is covered in detail in Chapters 18 and 19. In general, imaging of the neck and arm should be performed in patients with a history of trauma, persistent or progressive pain, and in patients with neurologic deficits involving the neck and/or upper extremities in order to confirm or rule out treatable organic causes of pain or neurologic deficits and to guide therapeutic decision making.

Although the clinical usefulness of cervical spine radiographs for evaluation of neck pain has been questioned,[61,62] cervical spine fractures occur frequently following relatively minor trauma in the elderly patient[63] with a relative risk of up to three

TABLE 68.17

NEXUS CRITERIA FOR RADIOLOGIC EVALUATION OF THE NECK IN PATIENTS STATUS POST TRAUMA

- No midline cervical tenderness
- No focal neurologic deficit
- Normal alertness
- No intoxication
- No painful, distracting injury

times more fractures in elderly versus younger adults evaluated in the emergency room.[64] Though significant cervical spine injury is infrequent in younger patients, diagnosis is often delayed following motor vehicle and sports trauma. In published series, missed cervical spine injuries following trauma have been reported to occur in 4.6% to 33% of patients.[65,66] C2 and C5-C6 level fractures are the most commonly seen injuries.[67–69] In a recent report of 100 consecutive patients who underwent operative fixation or halo stabilization for cervical spine injuries, 10% of injuries were missed due to failure to perform plain cervical films versus failure of interpretation or failure to utilize more advanced imaging techniques.[68] A recent prospective, multicenter U.S. study designed to validate clinical criteria developed to evaluate patients with neck pain following blunt trauma[70–73] confirmed sensitivity of the set of five criteria (Table 68.17) approaching 100% for clinically important injuries.[74]

Even fewer injuries were missed in a more recent multicenter study, when the Canadian C-spine rule was applied (Fig. 68.34).[75] Anteroposterior, neutral lateral, and odontoid plain film views are recommended. A patient with persistent neck pain or tenderness despite normal plain film radiology or suspected ligamentous injury may benefit from flexion-extension views to evaluate for listhesis or instability. These views may also be helpful in determining the amount of motion occurring with flexion and extension in patients with degenerative spondylolisthesis. Prior to flexion-extension imaging, the patient should perform active range-of-motion in the presence of a physician to confirm that no significant neurologic deficit occurs during these maneuvers.

In patients with chronic neck pain, plain film views can reveal degenerative changes such as loss of disc height, bone spurs, endplate irregularity, and endplate sclerosis. In patients with prior cervical spine fusion, instability secondary to pseudoarthrosis can be appreciated.

Computerized tomography (CT) is recommended for patients with acute or chronic neck pain who have normal plain films and clinically suspected cervical spine pathology or to further define abnormalities seen on plain films.[76] It is also useful for evaluating the size and shape of the spinal canal, facet and uncovertebral joints, and transverse foramina.[77,78] When possible, patients with neurologic deficits or pain due to suspected neurologic or soft tissue injury or pathology should undergo MRI. According to a systematic analysis and multicenter study comparing CT to MRI for assessment of cervical spine injuries following trauma to the cervical spine, midsagittal T1- and T2-weighted MRI provides an objective, quantifiable, and reliable assessment of spinal cord compression that cannot be adequately assessed by CT alone.[79] MRI and magnetic resonance myelography are comparable to CT myelography in assessing spinal stenosis and spinal nerve roots. Although CT is superior in imaging canal foraminal osteophytes, MRI is superior to CT in assessment of spinal cord gray matter and nerve root signal changes and well as ligamentous and intervertebral disk changes.[80] Use of gadolinium-enhanced MRI in symptomatic patients who have undergone surgery of the cervical spine is valuable in identifying changes consistent with postoperative infection in the acute postoperative period and in defining the extent of epidural scar formation versus reherniation of intervertebral discs in patients with recurrent neck and radicular pain.[81]

If MRI is contraindicated (i.e., due to a pacemaker or spinal cord stimulator), CT using 45-degree oblique reconstruction is superior to sagittal reconstructions oriented at 90 degrees for evaluation of the foramen for bony spurs.[82]

In regard to imaging of the shoulder, a standard series of shoulder radiographs excludes or confirms arthritis, bursitis, tendonitis, calcification, dislocation, tumor, and old or new fractures.[83] CT is useful for diagnosing bony lesions, subtle dislocation, labral tears, and full rotator cuff tears. MRI is more expensive, time consuming, less readily available in some areas, and certain pathologies such as the glenoid labrum and the surrounding ligaments may be difficult to evaluate with MRI. MRI is able to evaluate partial or full rotator cuff tears and has the advantages of noninvasive nature, lack of contrast exposure, nonionizing radiation, high degree of resolution, and ability to evaluate multiple pathologies.

Ultrasound is used to diagnose rotator cuff tears, is noninvasive, rapid, and relatively inexpensive; however, it has been shown to have more interoperator variability in performance and interpretation of imaging.[83–87]

Advanced imaging as well as electromyography and nerve conduction velocity testing should be performed as needed for the purpose of guiding treatment decision making. Electrodiagnostic evaluation of acute and chronic pain is discussed in Chapter 16.

Multiple plain radiographic views are often needed to visualize the elbow, forearm, wrist, and hand and can also be used to confirm or rule out fractures, tendonitis, and dislocations. Minimal evaluation of the elbow should include anteroposterior views for the distal humerus and proximal forearm, as well as lateral views in maximal flexion and extension. Additional views such as radiocapitellar, cubital tunnel, oblique, and stress views may be utilized based on history or mechanism of injury and physical exam findings.[1]

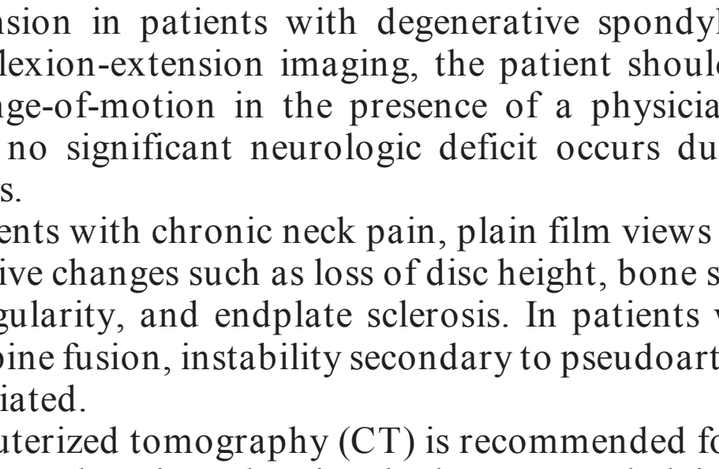

FIGURE 68.34 Canadian C-Spine rule.

COMMON CAUSES OF NECK AND ARM PAIN

Mechanical Neck Pain and Cervicogenic Headache

Neck pain from similar mechanisms may be axial, associated with radicular pain, headache, and/or symptoms suggesting spinal cord compression. The complex and highly interdependent structures of the neck may preclude identification of a single pain generator in patients with advanced disease. Muscle and ligamentous injury or pain may result from factors related to posture, poor ergonomics, stress, injury, and/or chronic muscle fatigue. Pain may also result from degenerative changes of the cervical facet joints and discs and atlantooccipital and atlantoaxial joints and irritation, inflammation, and mechanical distortion of the

cervical nerve roots and spinal cord. These processes may occur independently or concurrently and require a careful history and physical examination together with the judicial use of diagnostic tests to rule out systemic disease and rapidly progressive processes. Recent data reports a 12-month prevalence of 30% to 50% for neck pain and associated disorders in adults.[3] A knowledge and application of recent prospective studies, systemic reviews, and meta-analysis proposing guidelines for evaluation and treatment of these patients may assist with assessing the risk versus benefit for effective conservative versus interventional and surgical therapies in this large and heterogeneous population.

Cervical Spondylosis and Radiculopathy

Degenerative changes of the cervical spine reach a prevalence of nearly 95% by age 65. These changes are associated with positive changes such as disc protrusion, neural foraminal narrowing, and spinal cord contour changes in up to 78% of asymptomatic individuals.[7–9,88] In symptomatic individuals, the risk versus benefit of surgery and other interventional therapy[89] mandates an understanding of the natural course of symptomatic patients with cervical spondylosis and radiculopathy. Although the outcome of these patients when treated conservatively versus surgically is controversial,[90,91] recent investigations reveal clinical and radiographic correlates with outcome in this population, which may be of assistance in timely surgical referral when symptoms continue to progress following conservative treatment.[92–94]

Cervical spondylosis was first distinguished from acute cervical disc protrusion by Brain in 1948.[95] The latter occurs more commonly in individuals younger than age 55, is often traumatic in origin, and most frequently compresses the nerve roots versus the spinal cord. The former is a chronic degenerative condition of the cervical spine associated with formation of osteophytes. It is a universal finding associated with aging and is associated with compression of the spinal cord in most symptomatic cases. Patients older than age 55 are more likely to have central canal or neural foraminal stenosis due to spondylosis.[96] In a population-based study conducted from 1976 to 1990 in Rochester, Minnesota, a confirmed disc herniation was found to account for approximately 20% of all cervical radiculopathies and approximately 70% of all spondylosis. The average age-adjusted incidence rate per 100,000 population was 107.3 for males, 63.5 for females, and reached a peak of 202.9 for the age group between ages 50 to 54.[97,98]

Spondylosis refers to degenerative changes of the spine involving the intervertebral discs, uncovertebral joints of Lushcka, zygapophyseal joints, ligaments, and connective tissue of the cervical vertebrae. Degenerative changes of the cervical spine are seen in approximately 10% of individuals by age 25 and in 95% by age 65. The process is believed to begin with fibrosis and loss of elasticity of the disc which occurs with loss of water, protein, and mucopolysaccharides from the nucleus pulposis. Loss of disc space height initially occurs ventrally and leads to loss of cervical lordosis. This shift of biomechanical forces results in ventral vertebral body compression with resultant pathologic cervical spine kyphosis, dissection of the annulus fibrosus, posterior longitudinal ligament, and Sharpy's fibers away from the edges of the posterior vertebral body, formation of reactive bone on the edges of exposed dorsal vertebral bodies,and increased axial loadbearing by the uncovertebral and zygapophyseal joints, with resultant hypertrophy and osteophytic formation ventral and posterior to the neural foramen.

Spondylotic spurs may eventually span the width of the vertebral canal in some patients. Because the osteophytes form in response to increased motion or segmental instability, the levels most commonly affected, both by disc herniation and chronic spondylosis are C6-C7 followed by C5-C6 since these are the cervical segments at which the most extension and flexion occur.

The reduction in sagittal spinal canal diameter in cervical spondylosis results from a combination of static and dynamic factors. Static reduction of the sagittal diameter of the spinal canal occurs from disc herniation or bulging, vertebral body osteophyte growth into the anterior spinal canal, degenerative hypertrophy of the uncovertebral joints, facet joints, and ligamentum flavum combined with calcification of the posterior longitudinal ligament. The addition of dynamic factors such as flexion, extension, or subluxation can further increase the risk for compression and injury to the contents of the spinal canal and neural foramen including the spinal cord, nerve roots, arteries, and veins. These combined pathologic features are thought to be responsible for the production of the wide spectrum of clinical symptoms associated with cervical spondylosis including neck and shoulder pain, occipital pain and headaches, radicular symptoms, and cervical radiculopathies and cervical spondylotic myelopathy. Compression of the spinal cord may occur from spondylotic bars and calcified posterior longitudinal ligament ventrally or from the hypertrophic ligamentum flavum dorsally. Cumulative repetitive injury to the spinal cord is thought to occur with flexion, due to a "bowstring effect" over the ventral spondylotic bars and kyphotic spine, and compression dorsally by buckling of the ligamentum flavum. MRI flexion and extension studies observed increased cervical stenosis in twice as many patients during extension versus flexion. Risk for compression of the spinal cord is increased in individuals with congenital narrowing of the spinal canal.

Cervical spondylotic myelopathy (CSM) refers to clinically evident spinal cord dysfunction with the presence of long-tract signs due to compression of the spinal cord. Weakness or stiffness in the legs with unsteady gait together with weakness or clumsiness of the hands is pathognomonic of cervical spondylotic myelopathy. Progression of weakness may be gradual in some patients or sudden in others following minor trauma. In a prospective study at a U.K. regional neuroscience center, 23.6% of 585 patients admitted with tetraparesis or paraparesis were found to have cervical spondylotic myelopathy. Some patients may complain of hesitancy on urination; however, loss of sphincter control or urinary incontinence is rare and considered a late sign of myelopathy.

Patients with CSM generally present with neck and shoulder pain and stiffness. The patient may also present with pain in the arm, elbow, wrist, or fingers described as combined or isolated sensations of stabbing, dull, or aching pain. Arm pain may be nondermatomal in distribution and accompanied by numbness or tingling in the hands. Pain which conforms to a dermatomal distribution with associated motor and sensory deficits is referred to a radiculopathy rather than myelopathy. Some patients may present with both myelopathy and radiculopathy.

Signs of CSM on physical exam include an electrical sensation radiating down the back to the legs with flexion of the neck (Lhermitte's sign), atrophy of the intrinsic musculature of the hands, and variable sensory, vibratory, or proprioceptive loss in the extremities. Deep tendon reflexes may be reduced or absent at the level of compression with hypereflexia below the level of the lesion together with upper motor signs such as clonus, Hoffmann's, and Babinski's sign.[95,99–101]

There are two commonly used classification systems for CSM. The classification of Crandall and Batzdorf[102] divides CSM patients into five groups of spinal cord dysfunction. These include the transverse lesion syndrome, the motor system syndrome, the central cord syndrome, the Brown-Séquard syndrome, and the brachalgia cord syndrome. These are summarized in Table 68.18. Ferguson and Caplan[103] categorize CSM into four overlapping syndromes, which are summarized in Table 68.19.

The differential diagnosis of CSM includes amyotrophic lateral sclerosis, multiple sclerosis, hereditary spastic paraplegia, spinal cord tumors, and subacute combined degeneration of the spinal cord associated with vitamin B12 deficiency.

MRI is the imaging technique of choice for evaluating the

TABLE 68.18

CRANDALL AND BATZDORF[102] CLASSIFICATION OF CLINICAL SYNDROMES IN CERVICAL SPONDYLOTIC MYELOPATHY

Transverse lesion syndrome	Most common lesion. Involves posterior column, spinothalamic and corticospinal tracts, and often anterior horn cells. Posterior column involvement uncommon and late.
Motor system syndrome	Involves anterior horn cells and corticospinal tracts primarily. Little sensory involvement. Upper and lower extremity weakness, gait disturbance, and spasticity.
Central cord syndrome	Upper extremities weaker than lower extremities. Profound hand weakness. Posterior column involved often presenting as painful paresthesias of hands.
Brown-Séquard syndrome	Unilateral spinal cord dysfunction. Involvement of corticospinal tract. Posterior column sensory loss (position, vibration) and long tract motor signs (hemiplegia) are found ipsilateral to the lesion, whereas pain and temperature are lost contralaterally. One or two levels below highest level of motor involvement.
Brachalgia cord syndrome	Upper extremity nerve root compression combined with long tract signs (analogous to Ferguson and Caplan's[103] combined medial and lateral syndrome).

patient with CSM. T2- and T1-weighted signals on MRI have been found to correlate with various degrees of injury to the spinal cord on histologic studies. Edema is seen as a high-intensity T2-weighted image. Necrotic changes in the gray matter correspond to low signals on T1-weighted studies but high signals on T2-weighted studies. T1-weighted hypointensity is an expression of irreversible damage and, therefore, the worst prognosis.[94,104] A less favorable surgical outcome is predicted by the presence of a T1-weighted hypointense signal and the presence of clonus or spasticity. A high intramedullary T2-weighted signal without clonus or spasticity is associated with a more favorable surgical outcome with a greater likelihood of reversal of MRI signal changes.[105] A recent investigation reported multiple regression analysis of various risk factors associated with surgical outcome. According to this analysis, the most significant prognostic factor was the transverse area of the spinal cord, followed by the duration of symptoms and the presence of multisegmental areas of high signal intensity on T2-weighted MRI. The latter was associated with upper extremity muscle atrophy and less favorable surgical recovery of neurologic function.[93]

Controversy exists regarding optimal treatment for patients with cervical spondylotic myelopathy, and many authors recommend conservative treatment due to significant risks associated with surgery and lack of data supporting long-term improved outcome in patients undergoing surgery versus conservative care.[106–109] A recent prospective 3-year follow-up study did not show, on average, that the effects of surgery in the treatment of mild and moderate forms of CSM were better than the conservative approach. Nevertheless, there was a slight but statistically significant increase in the number of patients with a negative trend in the score for daily activities in the conservatively treated group. The authors of this study recommend conservative treatment for patients with mild SCM along with careful follow-up evaluation and reassessment 3 months after the start of conservative treatment. Decompression surgery is recommended for patients who experience neurologic deterioration during this period.[90] A prospective, multicenter study with independent clinical review evaluating conservative versus surgical treatment for patients with moderate to severe CSM found that although surgical treatment was not found to improve neurologic outcome, overall pain and functional status improved significantly. When medical and surgical treatments were compared, surgically treated patients appeared to have better outcomes, despite exhibiting a greater number of neurologic and nonneurologic symptoms and greater functional disability before treatment.[91]

Conservative treatment for CSM consists of intermittent cervical immobilization with a soft collar, the use of anti-inflammatory medications, active discouragement of high-risk activities, and avoidance of risky environments involving physical overloading, excess cold, movement on slippery surfaces, manipulation therapies, or vigorous or prolonged flexion of the head. Additional conservative measures include physiotherapy with institution of a rehabilitation program and referral to a multidisciplinary pain team. Patients with moderate to severe symptoms on presentation

TABLE 68.19

FERGUSON AND CAPLAN[103] CLASSIFICATION OF CLINICAL SYNDROMES IN CERVICAL SPONDYLOTIC MYELOPATHY

Lateral syndrome	Represents a spondylotic radiculopathy. Absence of long tract signs.
Medial syndrome	Upper motor neuron symptoms. Variable weakness of all extremities, gait abnormalities, spasticity below level of compression.
Combined medial and lateral syndrome	Most common clinical presentation.
Vascular syndrome	Acute onset and rapid progression of myelopathy. Thought to represent insufficiency or compression of anterior spinal artery and its branches to the spinal cord.

and progressive neurologic symptoms should be referred for surgical evaluation. The aim of the surgery in these patients is to stop the progression of neurologic deterioration and prevent sudden deterioration after minor injury or in particular situations such as swimming, cycling, and physical overloading.[90,91]

Cervicogenic Headache

The term cervicogenic headache (CEH) was coined by Sjaastad in 1983.[110] He later organized the Cervicogenic Headache International Study Group (CHISG), and diagnostic criteria for CEH were published by the CHISG in 1990.[111] A revision of criteria for CEH was published by the CHISG in 1998.[112]

CEH was recognized as a unique category of headaches by the International Association for the Study of Pain in 1994, using criteria similar to that published by Sjaastad et al.[113] Revised criteria for CEH were published by the International Headache Society (IHS) in 2004.[114]

Although controversy exists regarding the defining characteristics and prevalence of CEH, there is emerging evidence of valid clinical, diagnostic, and therapeutic criteria which differentiates this syndrome from migraine headache, tension-type headache, hemicrania continua, and chronic paroxysmal hemicrania.[115,116]

CEH is defined as unilateral head or face pain which starts in the neck and is triggered by neck movement or sustained awkward neck posture. Although pain begins in the neck or occipital region, it may spread to the retroorbital, temporal, and frontal areas of the head and face where maximum pain may be perceived. Pain may occur to a lesser degree on the contralateral side; however, profound unilateral dominance should exist. Cervicogenic headache is typically described as deep and nonthrobbing with intermittent attacks lasting hours to days. In time, headaches may become constant with superimposed attacks of more intense pain. Pain in CEH should be reproducible upon palpation or stimulation of cervical spine or neck structures. It is accompanied by reduced range of motion of the neck and ipsilateral nonradicular neck, shoulder, or arm pain. Nausea, vomiting, photophobia, dizziness, blurred vision, lacrymation, and conjunctival injection may occur.

The new IHS criteria requires clinical, laboratory, or imaging evidence of a lesion or disorder within the neck or cervical spine known to be associated with the causation of headache. This should be validated by reproducible clinical signs or by controlled diagnostic blockade (Tables 68.20 and 68.21 show comparison of IHS and CHISG criteria for CEH).

TABLE 68.20

INTERNATIONAL HEADACHE SOCIETY DIAGNOSTIC CRITERIA FOR CERVICOGENIC HEADACHE

A. Pain referred from a source in the neck and perceived in one or more regions of the head and/or face fulfilling criteria C and D.
B. Clinical, laboratory, and/or imaging evidence of a disorder or lesion within the cervical spine or soft tissues of the neck known to be, or generally accepted as, a valid cause of headache.
C. Evidence that the pain can be attributed to the neck disorder or lesion based on at least one of the following:
   1. Demonstration of clinical signs that implicate a source of pain in the neck.
   2. Abolition of headache following diagnostic blockade of a cervical structure or its nerve supply using placebo or other adequate controls.
D. Pain resolves within 3 months after successful treatment of the causative disorder or lesion.

TABLE 68.21

CERVICOGENIC HEADACHE INTERNATIONAL STUDY GROUP CERVICOGENIC HEADACHE DIAGNOSTIC CRITERIA[112]

Major Criteria

A. Symptoms and signs of neck involvement; it is obligatory that one or more of the phenomena 1 to 3 are present.
   1) Precipitation of head pain, similar to the usually occurring one:
      a) By neck movement and/or sustained, awkward head positioning, and/or
      b) By external pressure over the upper cervical or occipital region on the symptomatic side.
   2) Restriction of the range-of-motion in the neck.
   3) Ipsilateral neck, shoulder, or arm pain of a rather vague, nonradicular nature, or, occasionally, arm pain of a radicular nature.
B. Confirmatory evidence by diagnostic anesthetic blockages.
C. Unilaterality of the head pain, without side shift.

Head Pain Characteristics

D. Moderate–severe, nonthrobbing pain, usually starting in the neck
   Episodes of varying duration, or
   Fluctuating, continuous pain.

Other Characteristics of Some Importance

E. Only marginal effect or lack of effect of indomethacin.
   Only marginal effect or lack of effect of ergotamine and sumatriptan.
   Female sex.
   Not infrequent occurrence of head or indirect neck trauma by history, usually of more than only medium severity.

Other Features of Lesser Importance

F. Various attack-related phenomena, only occasionally present and/or moderately expressed when present.
   1) Nausea
   2) Phono- and photophobia
   3) Dizziness
   4) Ipsilateral "blurred vision"
   5) Difficulties on swallowing
   6) Ipsilateral edema, mostly in the periocular area

The prevalence of CEH in the literature varies widely from 0% to 80%, depending on the population of patients studied, diagnostic criteria, and methodology.[115] A recent Norwegian study reported that 75% of tractor drivers suffered from moderate to severe generalized headache only when working on their tractor because of consecutively turning or twisting their neck for many hours daily.[117] In a series of 100 consecutive patients with neck pain following whiplash, Lord et al.[118] reported a prevalence of associated headache in 88%. Of those patients with headache as the dominant symptom, 54% were found to have neck pain originating from a C2-C3 cervical zygapophyseal joint following diagnostic blocks. This was associated with tenderness over the affected joint on physical examination.[118] In a study of 34 patients with the complaint of headache emanating from the occipital region, tenderness to exam over the tip of the transverse process of C1 and worsening of their usual headache with passive rotation of the C1 vertebra, 60% were found to have complete relief of their pain following diagnostic blockade of the atlantoaxial joint.[119] Pain maps based on regions of the head and neck in which patients were relieved of pain following controlled blocks revealed radiation of pain from the C1-C2 through the C3-C4

facet joints to the suboccipital and occipital regions as well as the vertex, frontal, orbital, and temporoparietal region of the head.[47]

The anatomic basis by which pain from the cervical spine and neck can be perceived in the face and head derives from the convergence of afferents from the trigeminal nerve with those of the first three spinal nerves in the caudal aspect of the trigeminal nucleus in the brainstem.[120,121] Musculoskeletal structures innervated by the first three cervical nerves are outlined in Table 68.22. Convergence with the spinal trigeminal nucleus and the extradural convergence of the first three cervical nerves may account for the difficulty encountered in localizing the pain in patients with CEHs.

The anatomy of the sinuvertebral nerve may also contribute to the variation of pain patterns among patients and the presence of diffuse neck and head pain in the presence of discrete injuries. The sinuvertebral nerves supply structures within the spinal canal. They arise from the rami communicantes and enter the spinal canal by way of the intervertebral foramina. Branches ascend and descend one or more levels, interconnecting with the sinuvertebral nerves from other levels and innervating the anterior and posterior longitudinal ligaments dura mater and blood vessels, as well as sending nociceptive fibers to degenerative intervertebral discs.[122,123] Neurogenic inflammation from compression ischemia of the cervical nerve and inflammatory response following exposure of spinal tissues to proinflammatory mediators such as phosholipase A2 from extruded nucleus pulposis may also contribute to neck pain and CEH.

In addition to the evidence of atlantoaxial and zygapophyseal joint evidence discussed above, there is evidence that CEH may arise from a discogenic origin. Reproduction of patient's usual headache by cervical provocation discography has been reported, as has relief of headache following decompressive surgery of the upper and lower cervical spine.[124,125] The mechanisms by which headaches are provoked by levels below C3 have caused speculation regarding the possibility of convergence of afferents from lower spinal nerves with trigeminal afferents in the spinal trigeminal nucleus. An alternate explanation could lie in the anatomy of the sinuvertebral nerves, which descend from higher levels in the cervical spine to communicate with those at lower levels. An inflammatory response could also be causative with proinflammatory mediators resulting from disc degeneration at lower cervical spinal segments precipitating a nociceptive response at adjacent spinal segments.[122]

Greater and lesser occipital nerve injections using local anesthetic and/or steroid have been reported as useful for diagnosis and short-term relief of CEH. Many authors consider entrapment of the greater occipital nerve to be one of the major underlying causes of CEH.[126–128] A recent controlled trial of nerve stimulator-guided greater and lesser occipital nerve blocks with adjuvant agents provided greater than 50% relief versus placebo with significant reduction of associated headache features and medication use in the treatment group.[129] A case report of pulsed radiofrequency for the treatment of intractable occipital headache reported 70% relief for 4 months followed by an additional 5 months of 70% relief with repeat pulsed radiofrequency.[130]

Percutaneous radiofrequency cervical medial branch neurotomy has been shown, in a rigorous double blind controlled trial, to provide relief in 70% of patients diagnosed with cervical zygapophyseal joint pain following whiplash injuries. Other therapies found to have efficacy in the treatment of CEH include the physical therapy modalities of manipulation and/or mobilization in conjunction with exercise and intramuscular lidocaine injections. In chronic neck disorders associated with a radicular component, epidural injection of methylprednisolone and lidocaine improved pain greater than cervical intramuscular injections with the same solution at 1 year follow-up.[131–133]

TABLE 68.22

MUSCULOSKELETAL STRUCTURES OF THE NECK INNERVATED BY C1 THROUGH C3

- Muscles: Capital flexors and extensors, cervical spine flexors including the scalenus medius, scalenus posterior, longus colli and sternocleidomastoid, cervical spine extensors, head rotators and other neck muscles including the hyoid muscles, the sternothyroid, and diaphragm.
- Periosteum and body of the atlas, axis and C3 vertebra and clavicle, atlanto-occipital, atlantoaxial, intervertebral, Luschka, sternoclavicular and zygapophyseal joints associated with the C1 to C3 spinal segments, associated ligaments.

Diffuse Idiopathic Skeletal Hyperostosis

DISH is a form of osteoarthritis which is characterized by the calcification and ossification of soft tissues including ligaments and tendons. It may involve both the peripheral joints and the axial skeletal structures in 25% and 15% of men and women, respectively, who are older than 50 years of age. Its prevalence increases to 35% and 26%, respectively, in individuals older than 70 years. Classical axial involvement results in calcification of the ligamentum flavum in the lumbar spine, the anterior longitudinal ligament in the thoracic spine, and the posterior longitudinal ligament in the cervical spine. It is distinguished from degenerative spondylosis of the spine by earlier onset, sparing of the intervertebral disc, and its association with a number of risk factors including diabetes mellitus, obesity, hyperuricemia, dyslipidemia, hypertension, coronary artery disease, and prolonged use of isoretinal (vitamin A supplementation).

The patient with DISH typically presents with stiffness and decreased range-of-motion. Older patients with cervical spine involvement may complain of dysphagia due to pharyngeal encroachment from large anterior osteophytes. Other potential sequelae include cervical myelopathy and cervical spine fractures following relatively trivial trauma. The diagnosis of cervical spine fractures is often delayed due to the presence of baseline neck and spine pain.

The diagnosis of diffuse idiopathic skeletal hyperostosis is radiographic and is based on the criteria established by Resnick and Niwayama. These include the presence of "flowing" ossification along anterolateral margins of at least four contiguous vertebrae and the absence of changes associated with degenerative spondylosis. Treatment consists of conservative measures similar to cervical degenerative spondylosis. Operative treatment is reserved for those patients who fail to respond to conservative measures.[134]

Cervical Radiculopathies

The classical definition and clinical manifestation of cervical radiculopathies is pain, sensory loss, and motor weakness in the distribution of the affected nerve root. Although the cause of radicular symptoms has been presumed to be secondary to compression of the nerve root because of adjacent soft disc herniation or progressive degenerative changes of the cervical spine, the poor correlation between radiologic evidence of degenerative change and incidence of painful symptoms in the cervical spine has been well documented.[136–140] Other factors thought to contribute to the pathogenesis of radiculopathic symptoms include vascular insufficiency, venous engorgement, nerve root fibrosis, and inflammation. Type C cell distortion in dorsal root ganglion of cervical nerve roots has been proposed as a mechanism of accentuated neuropeptide production and increased hypersensitivity in pa-

tients with acute and chronic neural foraminal compression or edema.[141]

The patient with cervical radiculopathy typically complains of burning, aching, cramping, electrical, or sharp pain which radiates to the neck and head, shoulder, arm, or chest depending on the involved nerve root(s). In acute radiculopathy, pain classically presents in a myotomal distribution versus a distal dermatomal distribution. The pain is generally accompanied by numbness and paresthesias. Motor weakness and diminution or loss of deep tendon reflexes may also be seen. Spurling's maneuver, Valsalva, coughing, and sneezing will often provoke or aggravate the patient's symptoms while the shoulder abduction sign (having the patient abduct the shoulder and place their hand on top of their head) will generally relieve their pain.

The C1 nerve passes between the occiput and C1. It is also known as the suboccipital nerve and supplies sensory fibers to the periosteum and body of the atlas, occiput, atlanto-occipital joint, and atlantoaxial joint. It is also distributed to the muscles of the suboccipital triangle. The C2 nerve passes between C1 and C2. The medial or sensory branch of C2 is also known as the greater occipital nerve. It supplies the scalp over the vertex and top of the head and supplies muscular branches to the semispinalis.

C3 arises between C2 and C3. The medial sensory branch of the posterior division of the third cervical nerve forms the third or least occipital nerve. The anterior rami of the upper four cervical nerves communicate to form the cervical plexus. Pathologic processes which affect the C1 through C3 nerves cause pain radiating to the head and neck. Pain of the upper cervical spine was covered in more detail in the section on CEHs.[142,143] The greater auricular nerve and the anterior cutaneous nerve are also derived from the second and third cervical nerves. Processes affecting these nerves can also result in pain involving the mastoid process, the lobule and concha of the ear, the skin of the face over the parotid gland, and the skin of the anterolateral aspect of the neck as far as the sternum. Via the deep cervical plexus, the second and third cervical nerves also communicate with the vagus, the hypoglossal nerve, the superior cervical sympathetic ganglion, and the diaphragm by way of the phrenic nerve (see Table 68.3).

Radiculopathy of the fourth cervical nerve root results from pathologic changes between the C3 and C4 vertebrae and is more common than a C3 radiculopathy. The supraclavicular nerve arises mainly from the fourth cervical nerve and supplies the skin and superficial fascia of the clavicular region, the periosteum, and boney structure of the clavicle as far as the midline and the skin over the pectoralis major as far as the second or third rib. It additionally communicates with the cutaneous branches of the second and third rib. The lateral supraclavicular nerve supplies the skin of the top and dorsal parts of the shoulder. Involvement of the C3 nerve may be a cause of unexplained pain along the base of the neck that radiates to the superior aspect of the shoulder and posteriorly to the scapula. Pain in the distribution of the supraclavicular nerve may also be a cause of chronic breast pain in women.

The rhomboid, trapezius, and levator scapulae muscles are supplied in part by the fourth cervical nerve root, but a motor deficit may be difficult to detect. A sensory deficit may be present over the anterolateral aspect of the neck, along the distribution of the transverse cervical and supraclavicular nerves. Because the C3, C4, and C5 nerve roots innervate the diaphragm, involvement of these three nerve roots may lead to diaphragmatic weakness.

The brachial plexus is formed by the fifth, sixth, seventh, and eighth cervical nerves together with the first thoracic nerve and frequently contributing branches from the anterior division of the fourth cervical and second thoracic nerve. The variation of brachial plexus and extradural cervical nerve connections may contribute to variations in radicular patters among patients.

Pathologic changes at the C4-C5 level result in a C5 radiculopathy. The principal motor deficit seen in classical C5 radiculopathy is supraspinatus and deltoid muscle weakness with impaired shoulder abduction. Weakness of the clavicular head of the pectoralis major, biceps, and infraspinatus muscles can also occur. The pectoralis reflex and the biceps reflex, which are innervated by the fifth and sixth cervical nerve roots, may be decreased or absent. The numbness follows the C5 sensory distribution, which is located over the top of the shoulder along its midportion, and extends laterally to the midportion of the arm. The component fibers of the suprascapular nerve are derived primarily from the fifth and sixth cervical nerves. It supplies sensory, motor, and sympathetic fibers which supply the supraspinatus and infraspinatus muscles, the shoulder joint, and periarticular structures as well as an area of skin at the apex of the shoulder. Patients often present with numbness and localized shoulder pain that can be confused with a pathologic shoulder condition. The absence of pain with a range-of-motion of the shoulder and the absence of impingement signs at the shoulder help to differentiate radiculopathy of the fifth cervical nerve root from a pathologic shoulder condition.

The sixth cervical nerve root is the second most commonly involved in cervical radiculopathy. Patients with pathology at this level typically present with pain radiating from the neck to the lateral aspect of the biceps, lateral aspect of the forearm, dorsal aspect of the web space between the thumb and index finger, and into the tips of those digits. Numbness occurs in the same distribution. Motor deficits are best elicited in the wrist extensors, but weakness of the biceps, supinator, pronator, teres, and triceps muscles may be present. The brachioradialis and biceps reflexes may be decreased or absent. The pain and paresthesias of C6 radiculopathy may mimic carpal tunnel syndrome, which is caused by median nerve entrapment at the transverse carpal ligament.

The seventh cervical nerve root is most frequently involved by cervical radiculopathy according to many clinical studies. The patient with C7 radiculopathy complains of pain radiating along the back of the shoulder, often extending into the scapular region, down along the triceps, along the dorsum of the forearm and into the dorsum of the long finger. Motor weakness is most often appreciated in the latissimus dorsi muscle, the triceps, wrist flexors, and finger extensors. The triceps reflex may be lost or diminished. Entrapment of the posterior interosseus nerve may be mistaken for the motor component of seventh cervical radiculopathy and presents with weakness in the extensor digitorum communis, extensor pollicis longus, and extensor carpi ulnaris. With entrapment of the interosseus nerve, sensory changes are absent and the triceps and wrist flexors show normal strength.

Pathology at the C7-T1 level results in radiculopathy of the eighth cervical nerve root. Patients with a C8 radiculopathy generally present with sensory changes extending over the medial aspect of the arm and forearm and into the medial hand and the fourth and fifth digits. Numbness usually involves both the dorsal and volar aspects of the digits and hand and may extend proximal to the wrist over the medial aspect of the forearm. Weakness may involve the small muscles of the hand, particularly the interossei, and the flexors and extensors of the wrist and fingers (with the exception of the flexor carpi radialis and extensor carpi radialis muscles). This may cause patients to complain of difficulty using their hands for routine tasks such as buttoning shirts and grasping objects. Compression of the C8 nerve root may initially be difficult to differentiate from ulnar entrapment at the elbow. C8 nerve root compression may affect the function of the flexor digitorum profundus in the index and long fingers, the flexor pollicis longus in the thumb, and the pronator quadratus, but these muscles are not affected by entrapment of the ulnar nerve. Also, the short thenar muscles, except for the adductor pollicis, may be involved with C8 or T1 compression but are spared with ulnar nerve involvement. Furthermore, sensory changes seen with ulnar neuropathies include numbness, tingling, and/or pain in the fourth and fifth fingers and the hand just below these fingers, but not

proximal to the wrist (medial antebrachial cutaneous nerve distribution), as may be seen with C8 radiculopathy. Anterior interosseus nerve entrapment may also mimic C8 or T1 radiculopathy but lacks sensory changes, and thenar muscle involvement is absent.

Though uncommon, occurrence of T1-T2 disc herniations or other pathology at this level may result in a T1 radiculopathy. The T1 nerve is the main contributor to the adductor pollicis, the thenar muscles, the interossei, and the first two lumbricals. Classic T1 radiculopathy results in intrinsic hand weakness. Numbness occurs in the axilla, and Horner's syndrome can occur ipsilaterally.[1,101,144]

Epidemiologic data suggest that up to 90% of patients with cervical radiculopathy improve with conservative medical treatment alone.[97,98,145–147] However, due to lack of standardized diagnostic criteria and comparative randomized controlled trials comparing conservative with surgical treatment, evidence-based guidelines have been difficult to establish.

Conservative therapy in patients with cervical radiculopathy includes activity modification, education, and physical therapy with progressive passive and active modalities. Pharmacologic therapy requires a large armentarium of medications due to the heterogeneity in this patient population and the various mechanisms involved in the production of neuropathic pain. Options include over-the-counter analgesics, anticonvulsants, tricyclic antidepressants, and selective serotonin-norepinephrine reuptake inhibitors, topical anesthetic agents, nonsteroidal anti-inflammatory drugs, antiarrhythmics, muscle relaxants, nonnarcotic analgesics, and opioids.[148,149] Multiple studies suggest that epidural steroid injections may be beneficial with decreased short-term and long-term pain reported in greater than 60% of patients.[150,151] Use of flouroscopic guidance in interlaminar epidural steroid injections and use of nonparticulate steroid in transforaminal injections may significantly reduce the risk of complications.[152–154]

Outcome in patients with cervical radiculopathy following medical versus operative treatment was recently reported following a prospective, multicenter study with independent clinical review. Comparison of results of patients undergoing medical versus surgical treatments showed that, although both medically and surgically treated patients reported statistically significant improvement in their overall pain, more improvement was observed in the surgery group. Improvement in worst pain and average pain was also statistically significant in both groups. Surgically-treated patients had more neurologic and nonneurologic symptoms and more functional disability before treatment. However, despite high satisfaction in surgically-treated patients, a significant number of patients continued to report horrible or excruciating pain, multiple neurologic symptoms, and minimal or no work activity. These results are similar to those in patients with CSM in that the majority of patients improve with conservative therapy while those with persistent severe pain and progressive neurologic symptoms are generally referred for operative management, which attempts to improve pain and arrest the progression of neurologic symptoms.[91,147]

Upper Extremity Peripheral Nerve Entrapment Syndromes and Brachial Plexus Neuropathy

Acute trauma with resultant fibrosis and scar tissue, chronic trauma from overuse injuries, or space-occupying lesions can result in entrapment of peripheral nerves. Peripheral nerve entrapment syndromes typically present with pain at the site of entrapment. Pain can radiate both distally and proximally to this point. Sensory, motor, or sympathetic changes can occur in the nerve distribution distal to the site of entrapment.

The diagnosis of nerve compression or nerve entrapment is based on a careful history of the mechanism of injury or repetitive use and a thorough physical exam together with neurologic and electrodiagnostic examinations. MRI is helpful in identifying the cause of the neuropathy, identifying the site of entrapment based on muscle denervation patterns, and detecting unsuspected space-occupying lesions.[155,156] Nerve entrapment and radiculopathies may infrequently exist simultaneously. In a retrospective analysis of 12,736 cases of carpal tunnel syndrome and ulnar neuropathy at the elbow 435 (3.4%) of these cases were found to have a coexisting cervical root lesion. However, lesions were on the same nerve in only 98 (0.8%) of these cases.[157] Upper extremity nerve entrapment syndromes are characterized in Table 68.23.

Early recognition is essential for timely diagnosis and treatment of nerve entrapment syndromes involving the upper extremity as they are thought to affect the function of many individuals, including musicians, athletes, and as many as 1 in 4 office workers.[158] Most patients respond to conservative treatment including rehabilitative exercises, passive physical therapy modalities, relative rest, and correction of training and equipment use errors. Other measures may include anti-inflammatory medications, protective padding or bracing, and injections with local anesthetic and steroids. In patients with severe or progressive neurologic deficit or intractable pain, surgical decompression may be necessary.[159]

Lesions of the Brachial Plexus

Injury to the brachial plexus resulting in functional impairment of the upper extremity can occur secondary to penetrating or blunt trauma, severe traction, or acceleration-deceleration injuries. Other etiologies include congenital, developmental or exogenous compression, vascular or infectious disease, and neoplastic disease. The relative incidence of these lesions of the brachial plexus is presented in Table 68.24.

Brachial plexus injury (BPI) can be classified into preganglionic lesions, postganglionic lesions, and a combination of preganglionic and postganglionic lesions. In a preganglionic lesion, the nerve root is avulsed. A postganglionic lesion involves the nerve distal to the sensory ganglion and is further divided into nerve ruptures or lesions in continuity.

Clinical exam and electrodiagnostic and imaging studies may help in determining the location and severity of injury, which is essential in therapeutic decisions regarding these injuries. CT myelography is considered most reliable in detecting avulsion injuries. MRI, as well as new techniques such as MR myelography, diffusion-weighted neurography, and Bezier surface reformation, provides additional useful data in the evaluation and management of brachial plexus injury.[160,161]

Treatment of traumatic BPI is conservative versus surgical and is based on various factors such as the degree of damage, the site and type of injury, the time interval between injury and surgery, and the patient's age and occupation. Surgical treatment includes neurolysis, nerve grafting, nerve transfer, and other reconstructive procedures.[162–164] Physical therapy and pain control is essential for recovery of function following operative cases and for optimization of function and palliation of pain in nonoperative cases. In addition to pharmacologic treatment options, successful treatment of pain related to brachial plexus lesions has been reported following implantation of spinal cord and deep brain stimulator systems.[165,166]

Acute Brachial Plexus Neuritis

Acute brachial plexus neuritis is an uncommon disorder of unknown etiology which is commonly misdiagnosed as cervical spondylosis or cervical radiculopathy. It was first described by Spillane[167] in 1943 and is also known as Parsonage Turner syndrome or neuralgic amyotrophy due to the case series of this condition by Parsonage and Turner[168] in 1948. Other names by

TABLE 68.23

UPPER EXTREMITY ENTRAPMENT SYNDROMES

Nerve	Usual Cause	Location of Pain	Sensory Changes	Weakness
Dorsal scapular	Scalenus medius hypertrophy	Medial scapula, lateral arm	None	Rhomboids, levator scapulae
Suprascapular	Band in supraspinatus notch	Posterolateral, shoulder, lateral arm; tender at suprascapular notch	None	Supraspinatus, infraspinatus
Long thoracic	Downward pressure on shoulder	Not usually painful; can have diffuse ache in shoulder or scapula	None	Serratus anterior
Musculocutaneous	Entrapment by coracobrachialis	Anterior arm, proximal lateral forearm	Anterolateral forearm	Biceps, brachialis
Posterior interosseous	Entrapment at proximal forearm	Proximal radial forearm	None	Wrist and finger extensors and abductors
Ulnar (at elbow)	Entrapment at cubital tunnel	Elbow, ulnar forearm, and hand	Ulnar hand, fourth and fifth digits	Flexor carpi ulnaris and intrinsics
Ulnar (at wrist)	Entrapment at Guyon's canal	Ulnar side of hand, fourth and fifth digits	Ulnar hand, fourth and fifth digits	Adductor pollicis, interossei, hypothenar muscles
Median (at elbow)	Entrapment at ligament of Struthers or pronator teres	Elbow, volar forearm	Radial hand, first, second, and third digits	Pronator teres, flexor carpi radialis, flexor digitorum superior
Median (at wrist)	Entrapment at carpal tunnel	Wrist, radial hand, first, second, and third digits	Radial hand, first, second, and third digits	Thenar muscles, first and second lumbricals
Anterior interosseous	Entrapment at pronator teres or flexor digitorum superior	Elbow, volar forearm	None	Pronator quadratus, flexor pollicis longus, first and second flexor digitorum profundus
Digital nerve	Entrapment at intermetacarpal tunnel	Finger	Half of finger	None

TABLE 68.24

CAUSES OF BRACHIAL PLEXUS LESIONS

Cause	Example(s)	Incidence (% of cases)
Trauma	Penetrating injuries (e.g., gunshot, knife); closed injuries: obstetric (newborn), mechanical distortion	70
Compression	Exogenous (knapsack paralysis); congenital abnormality; developmental abnormality	10
Vascular	Local disease of major vessels; generalized vasculopathy (lupus erythematosus, arteritis); secondary to radiation therapy	5
Infectious	Viral; bacterial (local sepsis, abscess, or cellulitis)	3
Neoplastic	Primary tumors of brachial plexus; secondary involvement of plexus by tumors of surrounding tissues (Pancoast's tumor)	10
Miscellaneous causes	Electric shock; parainfectious; following serum therapy; unknown	2

which it is referred include brachial plexus neuropathy, paralytic neuritis, and acute shoulder neuritis.

The classical presentation of the patient with acute brachial plexus neuritis is the acute onset of severe burning pain in the neck, shoulder, and upper arm not associated with a precipitating injury or trauma. The pain may or may not be associated with sensory deficit and generally subsides over the following days to weeks. It is followed by a profound weakness, sometimes to the extent of flaccidity, involving the supraspinatus, infraspinatus, and deltoid and/or biceps muscles. Involvement of the sternomastoid or diaphragm has also been described, as has isolated or single nerve involvement. Bilateral brachial plexus involvement is not uncommon. Gradual recovery of muscle strength over 3 to 4 months is the usual course of brachial neuritis; however, some patients may experience several years of permanent muscle weakness. Chronic scapulocostal pain syndromes may occur due to dysfunctional mechanics following profound weakness.

Although a viral etiology has been proposed, various infections have been reported as preceding the onset of this disorder in up to 25% of cases. Onset following influenza, hepatitis B, or other vaccinations in up to 15% of cases suggests an immunologic etiology. Familial and recurrent cases are encountered. Other reported precipitating factors include childbirth, trauma, and surgery. Pathologic studies favor an immune mediated demyelinating pathogenesis over an axon-loss mechanism.[169,170]

The annual incidence of acute brachial plexus neuritis is reported to be 1.64 cases per 100,000, athough this figure is presumed to be low because of misdiagnosis. It occurs most often between age 20 and 60 years with a reported male predominance of 2:1 to 11.5:1.[169]

Diagnosis of brachial neuritis requires a high level of suspicion. A case series report of electrodiagnostic results reports no evidence of prolongation of F-latencies and no reduction of conduction velocity or conduction block in conventional peripheral ulnar and median nerve motor studies. Proximal nerve stimulation of the cervical roots and brachial plexus revealed axonal degeneration in most cases as well as evidence of proximal conduction block consistent with demyelination. MRI is useful in evaluating muscle denervation, muscle signal intensity changes, and muscle volume loss.[171]

Treatment of brachial neuritis is primarily supportive with use of analgesic medications followed by range-of-motion exercises. An arm sling may be helpful in preventing injury and strain from the weight of the arm distracting the humeral head from the glenoid fossa.[59] Full functional recovery is expected in 80% to 90% of patients, though the course may be protracted. Ten percent to 20% of patients may continue to have significant residual muscle weakness. In cases of profound and early weakness, intravenous immunoglobulin treatment has been proposed due to its usefulness in treating other focal demyelinating peripheral nerve diseases.[172,173] Acupuncture many also be effective in treating pain and improving function.[174,175]

Thoracic Outlet Syndrome

The definition, diagnosis, and treatment of thoracic outlet syndrome (TOS) are among the most disputed of any clinical entity. The syndrome generally refers to a variety of symptoms in the upper extremity due to compression of the brachial plexus, subclavian artery, and subclavian vein. Compression of the neurovascular bundle can occur as it passes through the interscalene triangle, the costoclavicular triangle, and subcoracoid space during its passage from the base of the neck to the proximal aspect of the arm. Structural compressive etiologies include fibrous bands, scar tissue, hypertrophied or fibrous muscles, anomalous soft tissue, and cervical ribs. Previous to the coining of the term TOS in 1956 by Peet,[176] the name of this syndrome was assigned according to the etiologies of compression including: scalenus anticus syndrome, costoclavicular syndrome, hyperabduction, cervical rib syndrome, or first rib syndrome. The lower trunk of the brachial plexus (C8 and T1) is most often affected. Other factors associated with the development of TOS include repetitive trauma to the brachial plexus, median sternotomy, or traumatic events such as motor vehicle accidents.[177]

TOS is variably divided into arterial, venous, or neurogenic. Alternatively, it has been classified as vascular, neurogenic, and nonspecific. The latter classification system reflects both diagnostic criteria and therapeutic recommendations and outcome.

Vascular TOS occurs in only 2% to 5% of thoracic outlet cases and is described most frequently in young individuals following vigorous arm activity or strenuous work. Patients with subclavian artery compression frequently present with pallor, pulselessness, and coolness of the affected upper extremity, transient ischemic attack, or infarcts of the hand and fingers. Decreased blood pressure in the affected arm when compared with the opposite arm of more than 20 mm Hg may also be present. Claudication may occur only with arm hyperabduction in some patients. Injury may include thrombosis, aneurysm, and/or stenosis.

Subclavian vein compression typically presents with edema and cyanosis of the upper limb with hyperabduction of the upper extremity. Thrombosis of the axillary-subclavian vein, (also known as Paget-von Schöetter syndrome), occurs in association with vigorous shoulder activity.

Doppler and duplex ultrasonography, magnetic resonance arteriography, CT angiography, and arteriography are used to confirm the diagnosis of vascular TOS. Decompression procedures or vessel reconstruction may be indicated in urgent cases and in cases not responsive to conservative therapy.[177–180]

Neurogenic and nonspecific categories of TOS comprise 95% to 98% of cases. A syndrome of painless atrophy of the hand primarily involving the abductor pollicis brevis with lesser atrophy of the interossei and hypothenar muscles known as Gilliatt-Sumner hand is the classic presentation of the true neurogenic type of TOS. This is associated with positive neurologic and electrodiagnostic findings. Sensory loss typically involves the ulnar aspect of the forearm and hand consistent with lower trunk compression, though upper trunk compression has also been reported. Pain is not the primary symptom of true neurogenic TOS; however, the patient may complain of diffuse, dull pain in the neck, shoulder, axillary region, and arm which may worsen with overhead activities and repetitive use of the arm.

The most common form of TOS is the nonspecific type. Patients generally present with the primary complaint of pain, often following a motor vehicle or work-related injury. Kelly's test and Adson's tests may be positive, but are not reliable as they have been shown to be positive in many asymptomatic individuals. Physical examination findings are often inconclusive and nonspecific and are not supported by electrodiagnostic or imaging results.[180–182] The differential diagnosis of TOS includes cervical radiculopathy or myelopathy, acute brachial neuritis, Reynaud's disease, multiple sclerosis, ulnar or median nerve entrapment syndromes, acute coronary syndrome, and CRPS.

The diagnosis of nonspecific TOS requires a detailed history and physical exam to rule out other causes of neck and upper extremity pain. Electrodiagnostic testing may help localize and quantify a brachial plexus lesion in true neurogenic TOS and rule out other segmental or systemic neuropathies.[183,184] Radiographic studies used in evaluation with the patient with suspected TOS include cervical spine and chest radiographs to rule out boney abnormalities and MRI and CT to evaluate the cervical spine for soft tissue anomalies, tumors, or degenerative disease of the cervical spine.[185]

Conservative treatment of TOS is indicated in the majority of cases and consists of activity modification education with instructions to avoid provocative positions and activities. Physical therapy programs to restore normal posture and strengthen the muscles of the pectoral girdle have also been successful in alleviating symptoms in greater than 50% of cases.[186] Surgical approaches

to treatment are undertaken in intractable or urgent cases. Surgery in the nonspecific type of TOS is associated with the least favorable outcome and is generally discouraged due to the significant risks associated with surgeries in this region. New minimally invasive techniques are now being investigated and may offer reduced risk of complications.[187,188]

SPONTANEOUS LOW PRESSURE HEADACHE

Intracranial hypotension or low pressure headache is classified as by the IHS into three categories: (1) postdural puncture headache; (2) cerebrospinal fluid (CSF) fistula headache; and (3) headache attributed to low CSF pressure.[114] Alternately, intracranial hypotension is described as primary, spontaneous, intracranial hypotension or secondary, iatrogenic, intracranial hypotension. The most common causes of secondary intracranial hypotension include diagnostic lumbar puncture, inadvertent dural puncture following surgical procedures, or epidural catheter placement and CT myelography. In the hospital setting, the symptoms associated with low pressure headache are rapidly recognized due to the associated risk factors such as iatrogenic dural puncture, postsurgical dural tear, or inadvertent overdrainage of CSF shunts.

Spontaneous intracranial hypotension (SIH) has an estimated prevalence of 5 in 100,000 individuals. It is thought to result from rupture of a spinal arachnoid membrane which allows CSF to pass into the subdural or epidural space. It may be associated with a history of minor trauma such as sports activities or severe coughing, degenerative discs or osteophytes, and patient morphology consistent with Marfan's or other connective tissue disorders. The patient with SIH is often misdiagnosed or is diagnosed following a delay due to variation in clinical presentation and diagnostic test results.[189,190]

Patients with SIH present with headaches which generally begin in the occipital region and radiate to the frontal and retroorbital area. The headaches typically worsen with sitting or standing and improve with recumbancy. Patients may report nausea, emesis, diplopia, neck pain, vertigo, photophobia, and hearing disturbances. In severe cases, patients may develop cranial nerve palsy, gait imbalances, mental status changes, and obtundation due to herniation of the cerebellar tonsil. Cervical epidural venous engorgement has been reported to produce radicular symptoms and neck pain in addition to headache in some patients. A cervical myelopathy secondary to severe compression from cervical epidural venous varicosities has also been reported and Lhermitte's sign may be present. Some patients report fluctuating headaches of many months duration.[26,191]

MRI with gadolinium of most, but not all, patients with SIH reveals diffuse pachymeningeal enhancement. Subdural fluid collections and brain descent may also be seen. Pituitary enlargement is typical in the symptomatic stage. In some case reports, epidural fluid collections and pachymeningeal enhancement is seen. Downward displacement or "sagging" of the brain may mimic a Chiari I malformation. Chronic subdural hematoma and subarachnoid hemorrhage has been reported in patients with SIH. Diagnostic tests may be inconclusive. Opening pressure may be normal, low, or even high. CSF analysis is nondiagnostic and may be normal, reveal xanthochromia, increased protein, and/or lymphocytic pleocytosis. In the case of normal CSF pressure, CSF hypovolemic syndrome rather than SIH syndrome has been proposed as a more accurate classification.[192,193]

Conservative treatment consists of bedrest, analgesics, and intravenous fluid administration together with intravenous or oral caffeine. For patients with neurologic deficit and intractable symptoms, an epidural blood patch at the lumbar level is recommended regardless of the level of the leak. Systemic or local infection, anticoagulants, or coagulopathy should be excluded prior to neuraxial procedures. The lumbar blood patch can be repeated if the patient does not respond.[194] For patients not responding to lumbar epidural blood patch, a blood patch at the level of the leak is recommended. Most CSF leaks have been found to be located at the cervicothoracic junction or in the thoracic spine. Spinal MRI with and without gadolinium appears to be more sensitive than radionuclide cisternography for detecting CSF leaks. To avoid the area of venous engorgement, the epidural blood patch may be delivered to the site of the leak via a catheter inserted from the lower cervical spine under flouroscopic or CT guidance.[193,195,196] Intrathecal saline infusion for emergent management of progressive obtundation prior to definitive treatment has been reported to reverse deteriorating mental status and neurologic deficits.[197] Surgical repair is recommended for patients failing treatment with epidural blood patch.[198]

CHAPTER 69 ■ CHEST WALL PAIN

NARASIMHA R. GUNDAMRAJ AND STEVEN RICHEIMER

GENERAL CONSIDERATIONS

The chest wall is one of the common sites of pain encountered in clinical practice. The origin of pain can be from various structures of the chest wall. These include pain from skeletal components including the spine, muscles, and nerves, or pain that is referred from outside the chest wall (Table 69.1). For instance, visceral pain from the chest can be perceived as chest wall pain. It is important to distinguish the origin of pain as arising from the chest wall or from the viscera inside. Focusing on some key points in the history and physical examination can assist in diagnosing the origin of pain. A thorough knowledge of the anatomy and physiology of the chest wall and its relationship to the vital organs enclosed inside is essential for any clinician involved in treatment of chest wall pain.

ANATOMY OF THE CHEST WALL

The chest wall is made up of skeletal structures, muscular elements, and neurovascular components. The skeletal structures of the chest wall include the ribs, vertebrae, and the sternum. From a functional standpoint, the skeletal components of the chest wall provide protection for the specialized organs that support the vital functions of the human body.

Skeletal Structures of the Chest Wall

The chest wall is made up of the vertebrae posteriorly, ribs and costal cartilages laterally, and the sternum anteriorly. The superior boundary of the thorax includes the T1 vertebra posteriorly,

TABLE 69.1

CHEST PAIN CAUSED BY NEUROPATHIC, MUSCULOSKELETAL, AND OTHER DISORDERS

I. Pain primarily of neuropathic origin
   - A. Disease of the spinal cord (myelopathy)
   - B. Lesions of the rootlets or roots of thoracic spinal nerves (radiculopathy)
   - C. Lesions of the formed spinal nerves (neuropathy)
   - D. Lesions of the intercostal nerves (intercostal neuropathy)
   - E. Disorders of the peripheral branches of spinal nerves (peripheral neuropathy)

II. Pain primarily of musculoskeletal origin
   - A. Lesions or disease of bones
     1. Disease or lesions of the thoracic vertebrae
     2. Disease or lesions of the ribs
     3. Diseases or disorders of the costal cartilages
     4. Disease or disorders of the sternum
     5. Disease of the sternoclavicular joint
   - B. Disorders of muscles
     1. Myofascial pain syndromes
     2. Chest pain caused by other disorders of muscles

III. Diseases of the skin
   - A. Burns and other trauma
   - B. Cicatrices
   - C. Postoperative pain syndromes
   - D. Mastodynia
   - E. Deep axillary abscess
   - F. Adiposis dolorosa
   - G. Phlebitis of the anterolateral chest
   - H. Other dermatologic painful disorders

IV. Chest pain caused by extrathoracic diseases
   - A. Disorders of the cervical spine and shoulder
     1. Intervertebral disk disease
     2. Thoracic outlet syndromes
   - B. Abdominal diseases
     1. Gas entrapment syndromes
     2. Disorders of the gastrointestinal tract
     3. Disease of the biliary tract
     4. Disease of the pancreas
     5. Other abdominal visceral disease
   - C. Diseases of the diaphragm
     1. Acute primary diaphragmatitis
     2. Subphrenic abscess
     3. Diaphragmatic flutter

V. Chest pain primarily of psychological origin
   - A. Abnormal emotional reactions to visceral disease
   - B. Anxiety syndrome
   - C. Depression syndrome
   - D. Conversion reaction
   - E. Hypochondriasis
   - F. Psychiatric syndromes

first rib laterally, and superior margin of the sternum (Fig. 69.1). Inferiorly the thorax is bounded by the T12 vertebra and the twelfth rib posteriorly, seventh to tenth ribs and their cartilages laterally joining anteriorly to the xiphisternum.[1,2] The anteroposterior and lateral diameter of the thorax is smaller at the top compared to the inferior portion. A compromise in the space at the thoracic inlet due to pathology of the skeletal structures or thoracic viscera can compromise the neurovascular structures and also result in chest wall pain.[3,4]

Thoracic Spine

The thoracic spine is made up of 12 thoracic vertebrae (Fig. 69.2). Each thoracic vertebra is heart shaped with long and inclined spinous processes (Fig. 69.3). Costal facets are present laterally on either side of the body for articulation with the ribs. Costal facets are also present on the transverse processes (except T11 and T12) for articulation with the tubercles of the ribs.

Ribs

There are 12 pairs of ribs attached posteriorly to the spine. The upper seven pairs of ribs are attached anteriorly to the sternum by costal cartilages and are called true ribs (Fig. 69.4). The eighth, ninth, and tenth ribs are attached to each other and the seventh rib by their costal cartilages forming small synovial joints. These ribs are called false ribs. The eleventh and twelfth ribs have no anterior attachments and are called floating ribs. A typical rib is a long, curved, flat bone. The superior border is smooth and rounded. The inferior border is sharp and thin and it overhangs the costal groove which encloses the intercostals vessels and the nerves. The head of the rib has two facets for articulation with the corresponding vertebral body and the one above it. The neck is a constricted portion of the rib after the head. A prominence on the outer surface of the rib at the junction of the shaft and the neck is called the tubercle. It also has a facet for articulation with the transverse process of the corresponding vertebra. A cervical rib arising from the transverse process of the seventh cervical vertebra is seen in 0.5% of humans. It can cause pressure on the adjacent neurovascular structures—the brachial plexus and the subclavian artery.

Sternum

The sternum is a flat bone in the middle of the anterior chest wall. It is divided into three parts: manubrium, body, and xiphoid process. The manubrium is the upper portion of the sternum that articulates with the body of the sternum at the manubriosternal joint. It also articulates at the clavicles, the first costal cartilage, and the upper portion of the second costal cartilage. The body of the sternum on each side articulates with the second to seventh costal cartilages. The xiphoid process is a roughly triangular cartilaginous structure that becomes ossified in adulthood. The angle of Louis or sternal angle is the junction between the manubrium and the body of the sternum. This useful anatomic landmark is palpated by feeling for a transverse ridge on the anterior aspect of the sternum. It correlates to the second costal cartilage anteriorly and the intervertebral disc between the fourth and fifth thoracic vertebrae posteriorly.

Joints of the Chest Wall

The chest wall includes many joints. The manubriosternal joint and xiphisternal joints are fixed joints. The costochondral connections of ribs with costal cartilages are also nonsynovial joints. These costochondral joints can become the source of painful irritation. The costal cartilages often calcify with age, reducing the flexibility of the chest wall. The joints of the heads of the ribs with the vertebral bodies, and the joints of the tubercles with the transverse processes of the ribs are synovial joints that allow for the expansion movements of the chest wall. The joints of the costal cartilages with the sternum are synovial (with the exception of the first rib), but these joints allow for only slight motion and they tend to disappear with age.

Intercostal Spaces

The intercostal space between the ribs is covered with three muscles: the external intercostals, internal intercostals, and the inner-

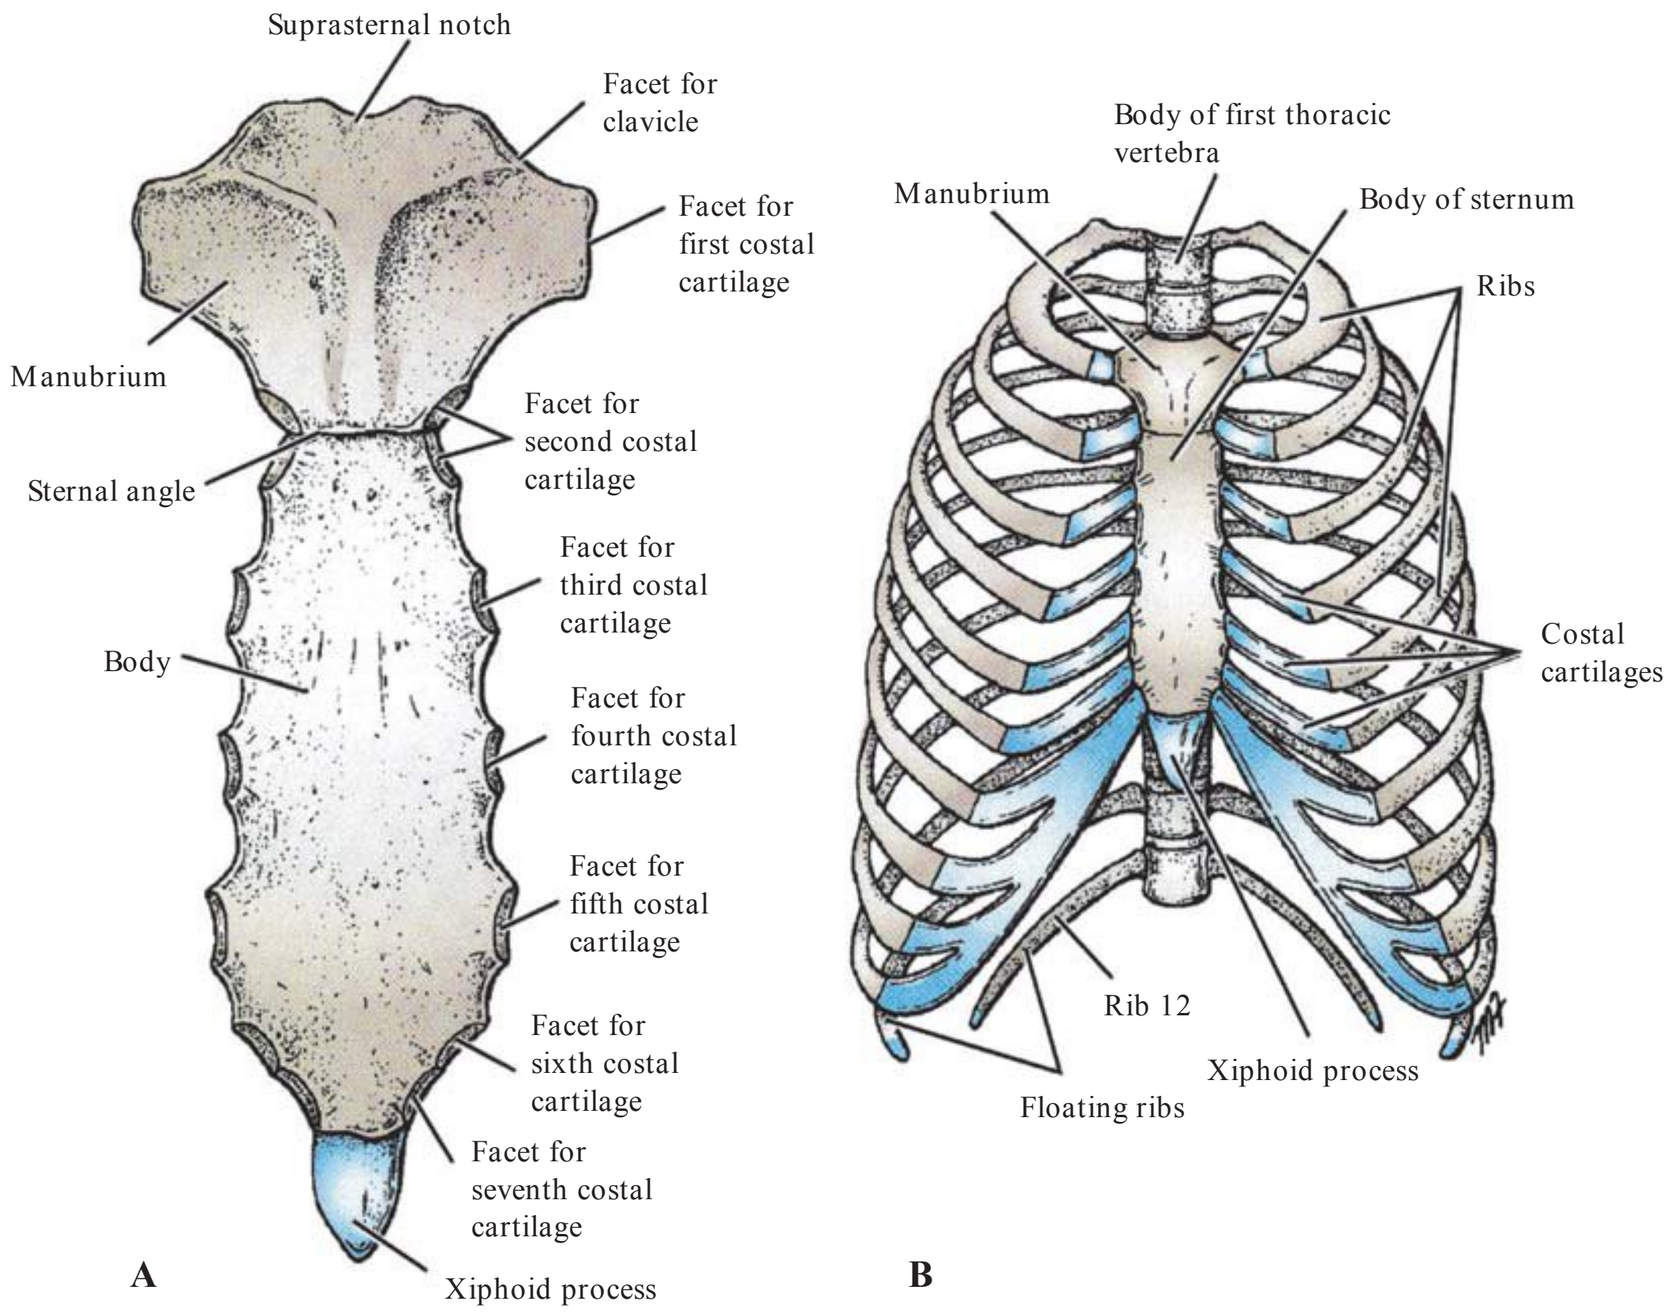

FIGURE 69.1 **A.** Anterior view of the sternum. **B.** Sternum, ribs and costal cartilages forming the thoracic skeleton. From Snell RS. *Clinical Anatomy by Regions*, 8th ed. Philadelphia: Lippincott Williams & Wilkins, 2007.

most intercostals muscle (Fig. 69.5). The innermost intercostal muscle is lined by the endothoracic fascia, which in turn covers the parietal pleura. The intercostal nerves and blood vessels run between the internal and the innermost intercostals muscles in the intercostals groove. The intercostal muscles play an important role in the mechanics of respiration. They are supplied by the corresponding intercostal nerves. The neurovascular structures in the intercostal groove are arranged from above downward as vein, artery, and nerve.

Intercostal Nerves

The anterior rami of the first 11 thoracic spinal nerves form the intercostals nerves. The anterior ramus of the twelfth nerve lies in the abdominal wall as the subcostal nerve. The rami communicantes connect the intercostals nerve to the sympathetic trunk. The collateral branch runs forward inferiorly to the intercostal nerve on the upper border of the rib below. The lateral cutaneous branch runs in the skin on the side of the chest and divides in to the anterior and posterior branches. The anterior cutaneous branch is the terminal portion of the intercostal nerves and reaches the skin near the midline anteriorly (Fig. 69.6). Muscular branches are given out to the intercostals muscles. Pleural sensory branches go to the pleura. Peritoneal sensory branches from the seventh to eleventh intercostal nerves run to the parietal peritoneum. The first intercostal nerve has a branch joining the brachial plexus. The second intercostals nerve joins the medial cutaneous nerve of the arm by the intercostobrachial nerve. In coronary artery disease, referred pain to the arm might be through this nerve.[5]

NEOPLASTIC CHEST WALL PAIN

A thorough history and physical examination is necessary to rule out pain caused by neoplasms of the thorax. Associated symptoms of cough, dyspnea, brachial plexopathy, and hoarseness due to recurrent laryngeal nerve involvement or Horner syndrome should arouse the suspicion of possible neoplastic disease. Diagnostic radiologic tests can confirm the diagnosis and the extent of involvement. If there is a high level of suspicion for neoplastic disease in a patient presenting with chest wall pain, diagnosis of the condition should be undertaken prior to any interventional procedures. Pain due to neoplastic disease is treated with a comprehensive or multimodal approach with opioid and nonopioid analgesics, physical therapy, interventional treatment with intercostal nerve blocks or epidural injections, and psychotherapy. In patients with refractory cancer pain, neuraxial delivery of opioid and local anesthetics by continuous infusion pumps or neurolytic ablation may be necessary for pain control.

Lung and breast cancers account for the majority of the thoracic neoplasms. Other neoplasms include metastatic lesions of the lung and the skeletal structures. Neoplasms of the lung present with symptoms of cough, dyspnea, hemoptysis, or obstructive symptoms due to compression of the neurovascular structures. Pain is not a common symptom with lung cancers except when there is pleural involvement. Nociceptive pain is usually localized, constant, or associated with chest wall movement and is caused by the invasion of the pleura, vertebrae, or other soft tissues of the chest wall. Deafferentation or neuropathic pain is caused by compression, infiltration, or damage to the involved spinal nerves and produces allodynia, hyperalgesia, dysesthesia, or hyperesthe-

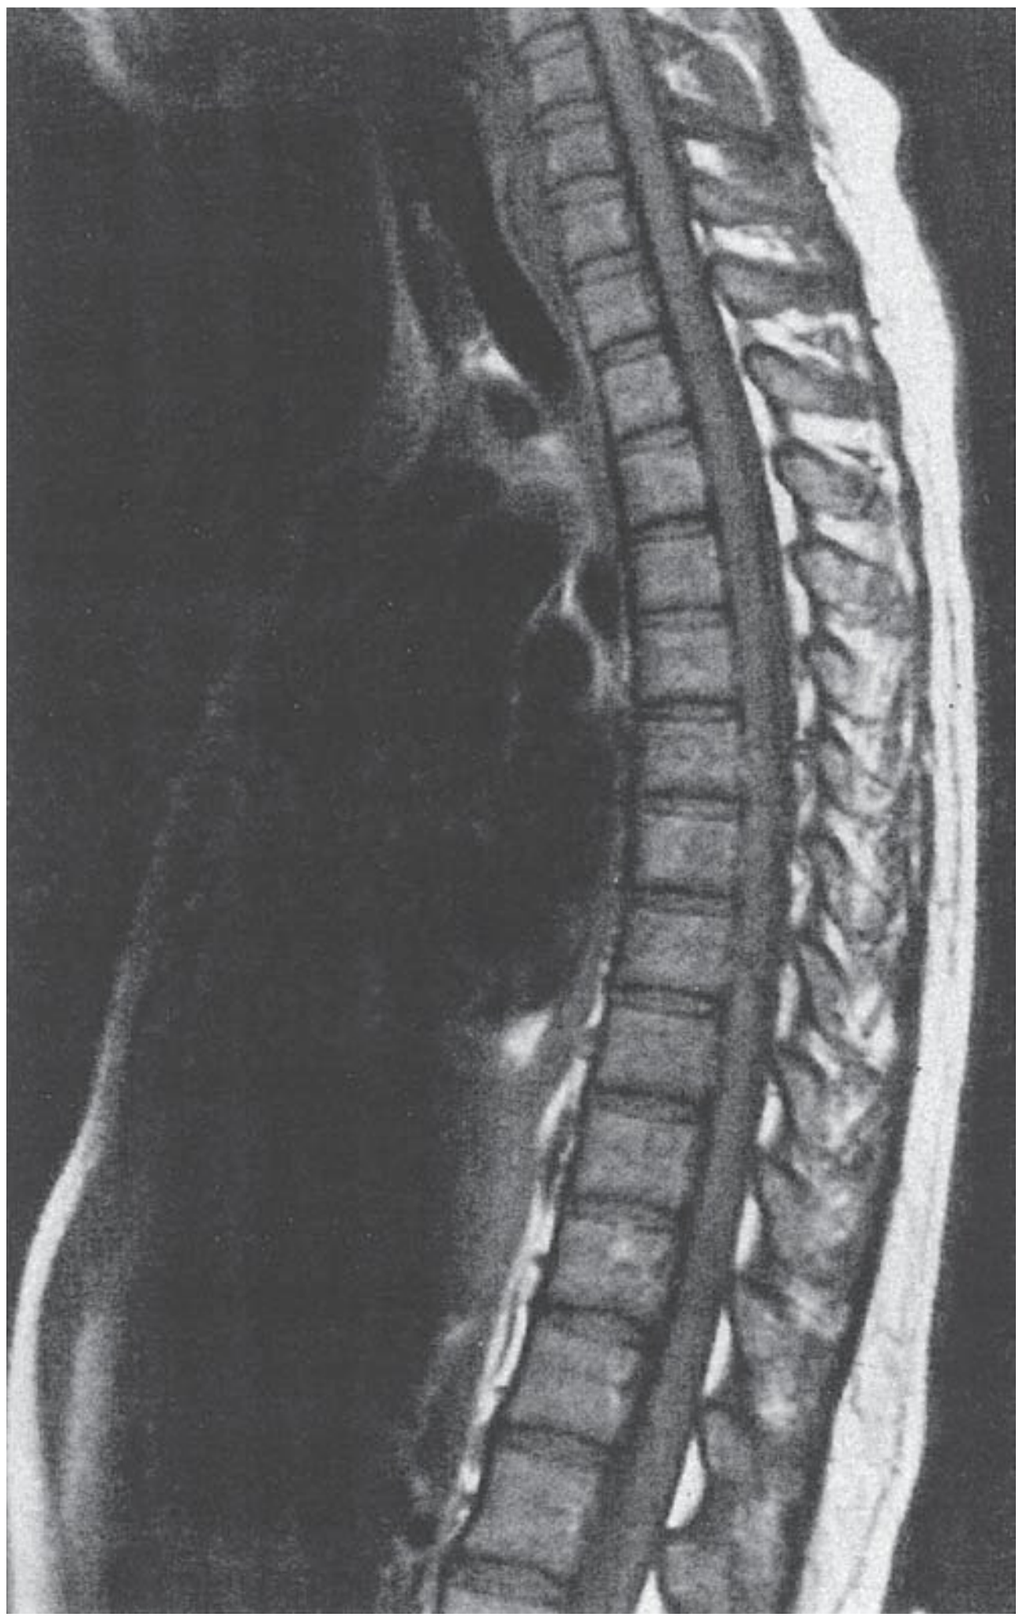

FIGURE 69.2 MRI Normal thoracic spine, midsaggittal T1-weighted image. Lee JKT, Sagel SS, Stanley RJ, et al. *Computerized Body Tomography with MRI Correlation*, 4th ed. Philadelphia: Lippincott Williams & Wilkins; 2006.

sia in a segmental fashion.[6] Involvement of the superior pulmonary sulcus produces Pancoast syndrome. It is characterized by pain in the shoulder and arm, motor weakness and wasting of muscles of the hand, as well as Horner syndrome.[7] The mass in the superior sulcus of the lung can cause compression of the lower trunk of the brachial plexus. Pain and motor symptoms are most commonly seen in the distribution of the ulnar nerve. Brachial plexopathy can also result from other causes such as metastatic tumors, radiation, or thoracic surgery.[8,9]

Epidural Spinal Cord Compression

Epidural spinal cord compression is the second most common central neurologic complication of systemic cancer. Pain is the initial symptom before the development of other neurologic signs and symptoms. The pain can be misdiagnosed as musculoskeletal in origin. Appropriate imaging studies can aid in the diagnosis. Treatment includes corticosteroids and radiation. Surgical decompression with laminectomy or vertebral body resection is recommended in patients who are relatively healthy.[10,11]

Superior Vena Cava Syndrome

Obstruction of the blood flow through the superior vena cava results in superior vena cava syndrome. The obstruction can be due to external compression from pathology of the lung, lymph nodes, or mediastinum. It can also result from internal obstruction. There can be coexistent thrombosis along with the external compression. Chest wall pain, cough, dyspnea along with venous engorgement of the chest wall and neck, and facial edema are the common signs and symptoms. Dyspnea is the most common symptom. Lung cancer is the most common cause followed by lymphoma. Malignancy accounts for 60% to 85% of all cases of superior vena cava syndrome with small cell lung cancer serving as the most common type of lung malignancy causing this syndrome.[12] Non–Hodgkin lymphoma is the most common type of lymphoma resulting in obstruction of the superior vena cava. Diagnosis is made based upon clinical symptoms and the findings of abnormal lesions in the chest radiograph. Confirmatory studies include contrast enhanced computed tomography (CT) scan and venous angiography. Current treatment strategies include chemotherapy, radiation, or endovascular stenting.[13] Radiation treatment is indicated for emergency relief of airway obstruction.

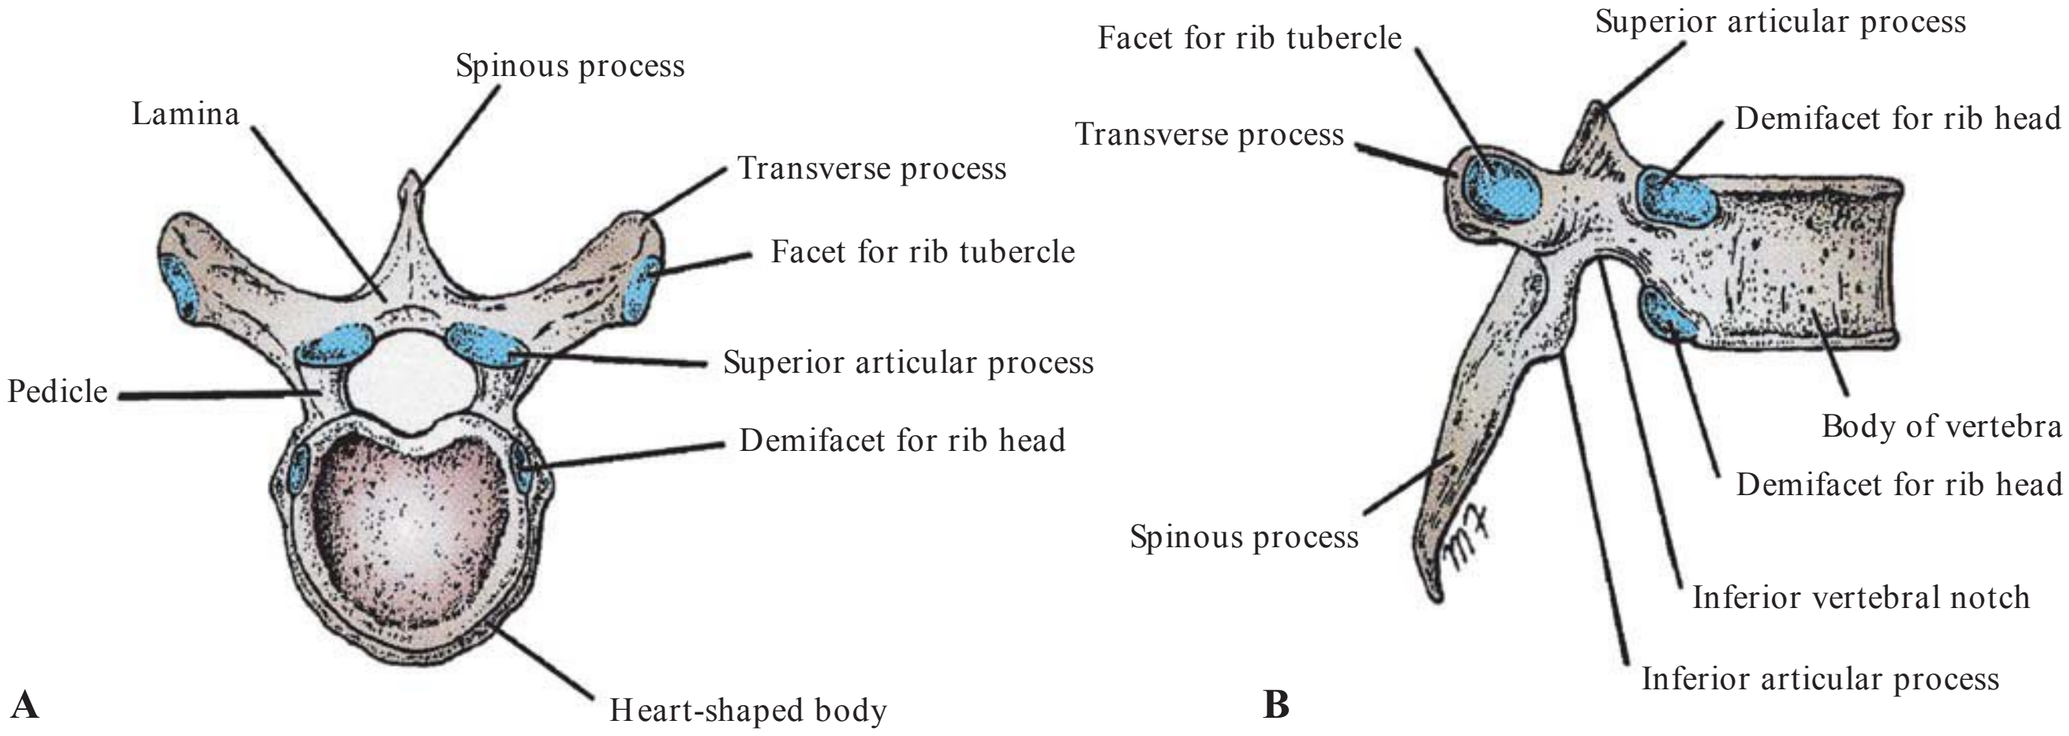

FIGURE 69.3 Thoracic vertebra **A.** Superior surface **B.** Lateral surface. From Snell RS. *Clinical Anatomy by Regions*, 8th ed. Philadelphia: Lippincott Williams & Wilkins; 2007.

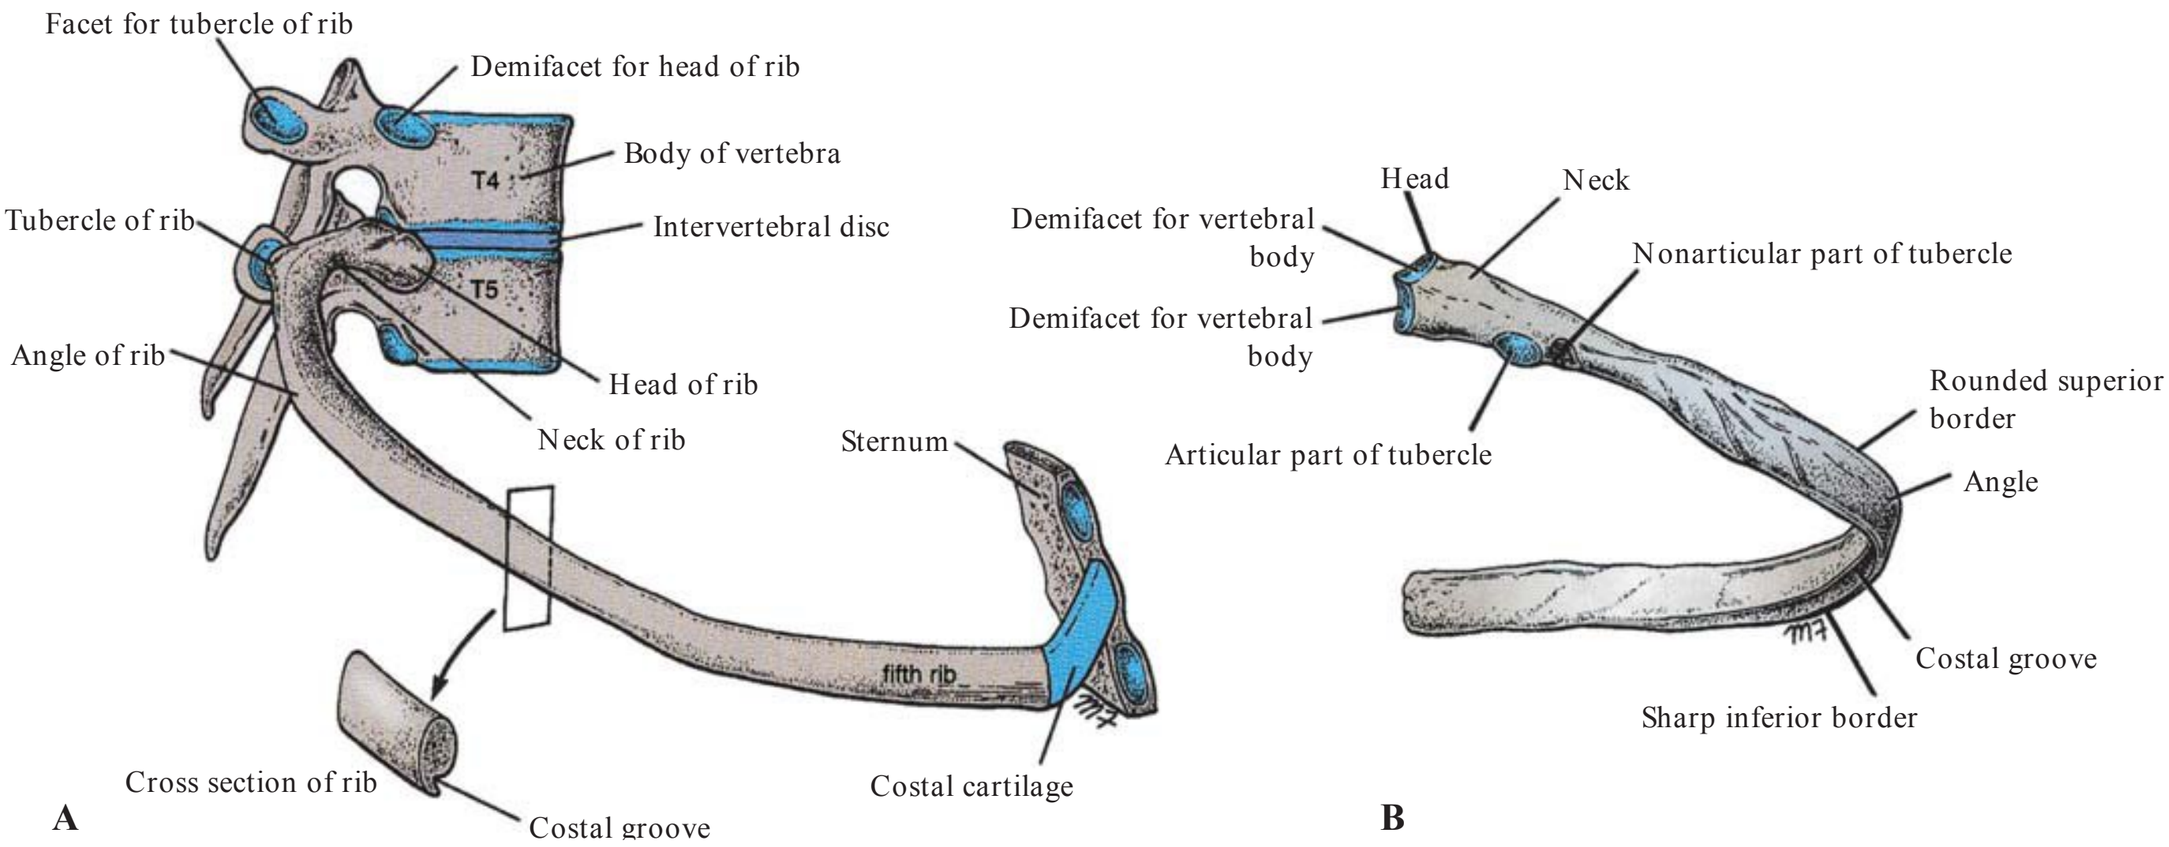

FIGURE 69.4 Fifth rib as it articulates with the vertebral column posteriorly and the sternum anteriorly. From Snell RS. *Clinical Anatomy by Regions*, 8th ed. Philadelphia: Lippincott Williams & Wilkins; 2007.

Costopleural Syndrome

Tumor invasion of the pleura, ribs, and soft tissues of the chest wall with or without involvement of the intercostals nerves can result in sharp, aching, or burning pain (Fig. 69.7). Pain is exacerbated by movements of the chest wall, deep breathing, and coughing. Lesions of the pleura closer to the diaphragm can cause localized pain in the shoulder region or referred dull aching pain in the back or upper abdomen. Mediastinal pleural involvement causes pain deep in the central portion of the chest or the shoulder region. This type of pain is often potently responsive to steroidal or nonsteroidal anti-inflammatory analgesics.

NONNEOPLASTIC CHEST WALL PAIN

Chest wall pain from other than neoplasms and visceral pain will be discussed in this section. This section includes a discussion of chest wall pain due to neuropathy including neuraxial pain, myofascial, skeletal, and joint pain.

Neuropathic Pain

Pain due to neuropathy can arise anywhere along the nervous system supplying the chest wall. The pain can be neuraxial involv-

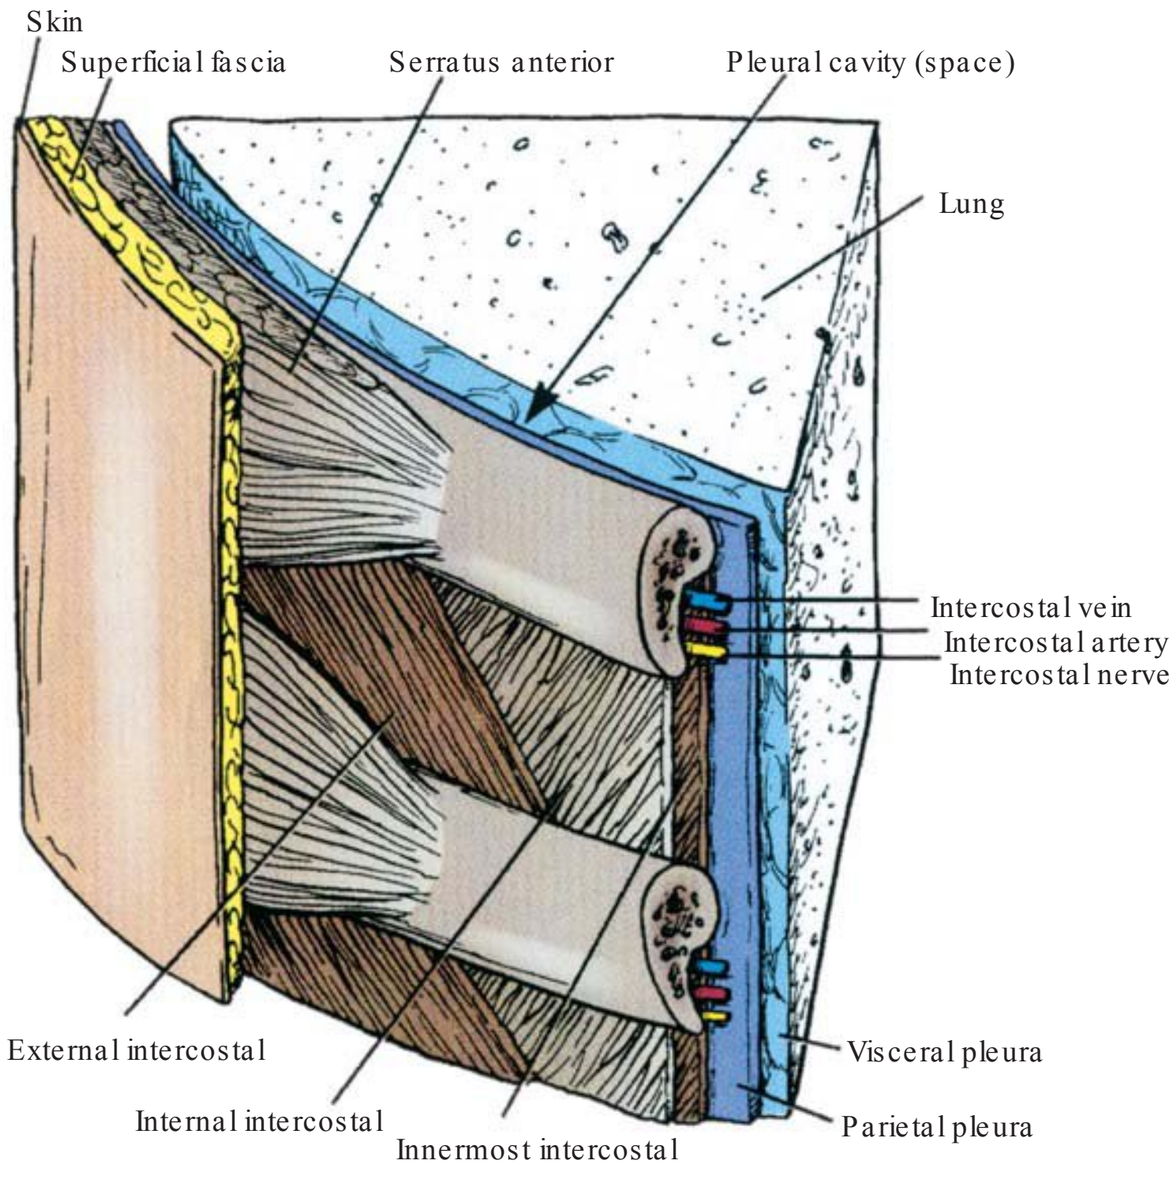

FIGURE 69.5 Intercostal space, its boundaries and contents. From Snell RS. *Clinical Anatomy by Regions*, 8th ed. Philadelphia: Lippincott Williams & Wilkins; 2007.

ing the spinal cord and nerve roots or related to peripheral nerves (Table 69.2).

Neuropathic Pain of Central Origin

Thoracic myelopathy can cause chest wall pain, back pain, or abdominal pain. Lesions can be present within the spinal cord or extramedullary or epidural spaces. Thoracic disc herniation can also result in chest wall pain (Fig. 69.8). Pain is usually the initial symptom before other neurologic symptoms. Pain is worsened in the recumbent position. If pain is the only symptom, it is often confused as myofascial or skeletal pain. Prompt diagnosis is important in light of potentially evolving cord compression. Pain that is progressive and not relieved by conventional therapy for musculoskeletal pain requires prompt attention to rule out neoplasm. Acute neurologic symptoms are initially treated with corticosteroids and radiation therapy.[14] Surgical decompression with laminectomy may be necessary if the symptoms are not relieved by nonsurgical methods. Lower cervical disc herniation can also present as neuropathic chest wall pain.[15,16] A relatively rare cause of thoracic neuropathic pain is seen in the form of an extramedullary granuloma in patients with neuraxial infusion pumps. Stopping the implanted infusion pump and radiographic exam with contrast through the catheter, CT myelography or magnetic resonance imaging can help make the diagnosis. Stopping the infusion may decrease the size of the mass. Surgical removal of the symptomatic granuloma is rarely necessary.[17]

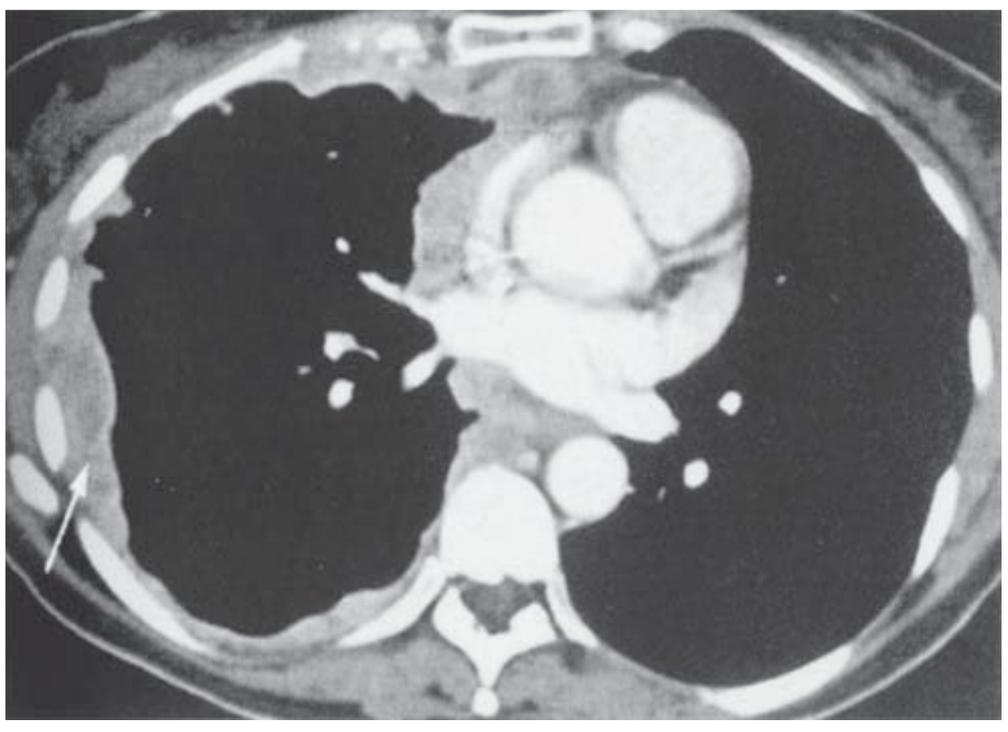

FIGURE 69.7 CT image showing right pleural thickening due to mesothelioma. Lee JKT, Sagel SS, Stanley RJ, et al. *Computerized Body Tomography with MRI Correlation*, 4th edition. Philadelphia: Lippincott Williams & Wilkins, 2006.

Peripheral Neuropathic Chest Wall Pain

Herpes Zoster and Postherpetic Neuralgia. Acute herpes zoster, also called shingles, is caused by the deoxyribonucleic acid (DNA) virus, varicella zoster. The incidence of herpes zoster is higher in older and immunocompromised patients. Factors that decrease immune function such as chronic corticosteroid use, human immunodeficiency virus infection, cancer, and chemotherapy can increase the risk of developing herpes zoster.[18,19] Following a primary varicella infection, the virus remains dormant in the dorsal root ganglia. Acute herpes zoster is characterized by the reactivation of the latent virus in the dorsal root ganglion. It typically presents as a mononeuropathy involving the intercostal nerves. Clinically the presentation begins with burning pain, hyperesthesia or tingling followed by the characteristic vesicular rash. The prodromal sensory symptoms may be present for 1 to 2 weeks prior to the appearance of the rash.[20] The characteristic rash is initially maculopapular and progresses into vesicles with erythematous bases. The rash of herpes zoster is commonly seen involving one or two contiguous thoracic dermatomes, almost always unilateral. T5 and T6 dermatomes are most commonly affected.[21] Pain is sharp, burning, and superficial in nature. Pain can be worsened with ulceration and secondary infection of the vesicles. Associated muscle spasms can worsen the pain.

TABLE 69.2

CHEST PAIN PRIMARILY OF NEUROPATHIC ORIGIN

I. Diseases of the spinal cord (myelopathy)
   A. Intrinsic spinal cord diseases: primary tumors, metastatic tumors, syringomyelia, trauma, multiple sclerosis, infarction, abscess
   B. Extramedullary intrathecal disorders
      1. Primary tumors: meningioma, neurofibroma
      2. Metastatic tumors
   C. Epidural spinal cord compression
      1. Primarily caused by vertebral pathology
      2. Metastatic neoplasm from breast, lung, prostate
      3. Epidural abscess
      4. Hematoma
      5. Adhesive arachnoiditis

II. Diseases of the rootlets and roots of spinal nerves (radiculopathy)
   A. Infection and inflammation
      1. Herpes zoster
      2. Syphilis (tabes dorsalis)
      3. Meningitis
      4. Systemic infection
      5. Tuberculosis
      6. Other infectious diseases
   B. Mechanical compression or injury
      1. Osteoarthritis
      2. Other arthritides
      3. Ruptured intervertebral disk
      4. Fracture of vertebra
      5. Abscess or tumor of the vertebra
      6. Paget disease of the spine

III. Diseases of the formed thoracic spinal nerves (neuropathy)
   A. Vertebral compression (same as IIB)
   B. Paravertebral compression
      1. Paravertebral adenopathy
      2. Mediastinal tumors
      3. Paravertebral abscess
      4. Aortic aneurysm
   C. Primary nerve tumors
      1. Neurofibroma
      2. Schwannoma
   D. Systemic infection, neuropathy
   E. Other neuritides
      1. Alcoholism
      2. Avitaminosis
      3. Intoxication by heavy metals, food, amoebae
      4. Vitamin metabolic disorders and others

IV. Disorders of the intercostal nerves (intercostal neuralgia)
   A. Compression or injury secondary to fracture or tumors of ribs
   B. External trauma (e.g., stab wounds)
   C. Postinfectious intercostal neuropathy
   D. Postoperative neuropathy
      1. Postmastectomy syndrome
      2. Postthoracotomy syndrome

FIGURE 69.8 Sagittal T2-weighted MRI image showing a central thoracic disc herniation at T11–T12 (*arrow*). The cord is displaced posteriorly. The arrow head shows a Schmorl nodule. Lee JKT, Sagel SS, Stanley RJ, et al. *Computerized Body Tomography with MRI Correlation*, 4th edition. Philadelphia: Lippincott Williams & Wilkins; 2006.

Diagnosis of the condition is made by the clinical presentation of the characteristic rash.

The main goal of treatment of acute herpes zoster infection is not only to treat the acute condition but also to prevent central sensitization and postherpetic neuralgia. Treatment of the acute condition is initially pharmacologic. Elderly patients are more susceptible to developing postherpetic neuralgia; therefore, more aggressive treatment with additional interventional modalities is recommended. Pharmacologic therapy involves initiating treatment with oral antiviral agents as soon as the diagnosis has been made. Studies have shown efficacy of antiviral agents if started within 72 hours.[22,23] Interventional treatments include segmental epidural blockade with dilute local anesthetic solutions, intercostal nerve blocks, and sympathetic blockade of the cervicothoracic chain with stellate ganglion blocks are recommended. If the elderly patient is suffering with a very painful bout of acute zoster, then aggressive interventional treatment can reduce the severity of the condition and reduce the risk of postherpetic neuralgia. Use of systemic corticosteroids for treatment is controversial. However it has not been associated any worsening of the disease. The number of interventional treatments can range anywhere from three to four in a 2-week period. Continuous segmental epidural blockade with thoracic epidural catheter is also recommended however it may require hospitalization of the patient. Continuous blockade of the intercostal nerves can be achieved by placing a catheter in the intercostals space connected to an isomeric infusion pump. Such therapy can be used effectively on an outpatient basis. Use of dilute local anesthetics with less toxicity can reduce complications due to local anesthetic toxicity in older patients.

Postherpetic neuralgia presents with persistence of severe sharp, burning pain in the affected dermatomes after the disappearance of the acute rash. About 20% percent of elderly patients with herpes zoster develop postherpetic neuralgia. The pain may persist for months to years without treatment. Hyperalgesia and allodynia of the effected dermatome is seen. The chronicity of the pain can result in behavioral changes affecting sleep and mood. Psychosocial symptoms and depression can worsen the pain. Treatment of postherpetic neuralgia includes symptomatic treatment of pain with medications and interventions. Medical management involves the use of neuropathic analgesics which are discussed extensively elsewhere in this text. These may include

tricyclic antidepressants, duloxetine, and anticonvulsants.[24–26] Topical treatment with local anesthetic patches, local anesthetic ointments, preparations with capsaicin, and compounded creams can be used to achieve symptomatic treatment of the condition.[27,28] Transcutaneous electrical nerve stimulation (TENS) can also be helpful.[29] Interventional treatment with intercostal nerve blocks or epidural injections may be required. Permanent implants like dorsal column spinal cord stimulators and peripheral intercostals nerve stimulators offer a novel approach to pain control in patients who require repeated interventional treatments. A trial of such a stimulator is recommended before permanent implantation. Along with the interventional treatments aggressive behavioral therapy is highly recommended. Chronic opioid therapy may be needed. A comprehensive approach using pharmacologic, interventional, rehabilitative, and behavioral treatments will help achieve pain relief and improve functional capacity of the patient.

Intercostal and Peripheral Neuropathy. Chronic intercostal neuralgia can result from trauma or compression of the intercostals nerves. Due to the proximity of the nerves to the inferior aspect of the ribs, any abnormalities of the ribs such as fractures and metastatic lesions can result in intercostal neuralgia. Prior thoracic or breast surgery and surgical lesion of the nerves can result in chronic intercostal neuralgia. Other causes include trauma or infection. Pain is characterized as sharp, superficial, burning, or lancinating in the distribution of the affected nerve. Pain is worsened by respirations and movements of the chest wall similar to the clinical presentation of pleuritic lesions. Localized tenderness to palpation may be appreciated in the intercostal space. A thorough history looking for previous trauma or surgeries can assist in the diagnosis.

Medical management of intercostal neuralgia consists of treatment with nonsteroidal anti-inflammatory agents, tricyclic antidepressants, and anticonvulsants. Intercostal nerve blocks with long-acting local anesthetics and corticosteroids can be effective (Fig. 69.9). Cryoablation or radiofrequency neurolysis of the intercostal nerves can provide longer pain relief.[30–32] We avoid chemolysis of the intercostals nerves because of concerns of postlysis neuralgia and neuritis. Long-term relief can also be achieved by implantable peripheral nerve stimulators.

Chest Wall Pain of Skeletal Origin

Skeletal chest wall pain can originate from the thoracic spine, ribs, costal cartilages, or sternum.

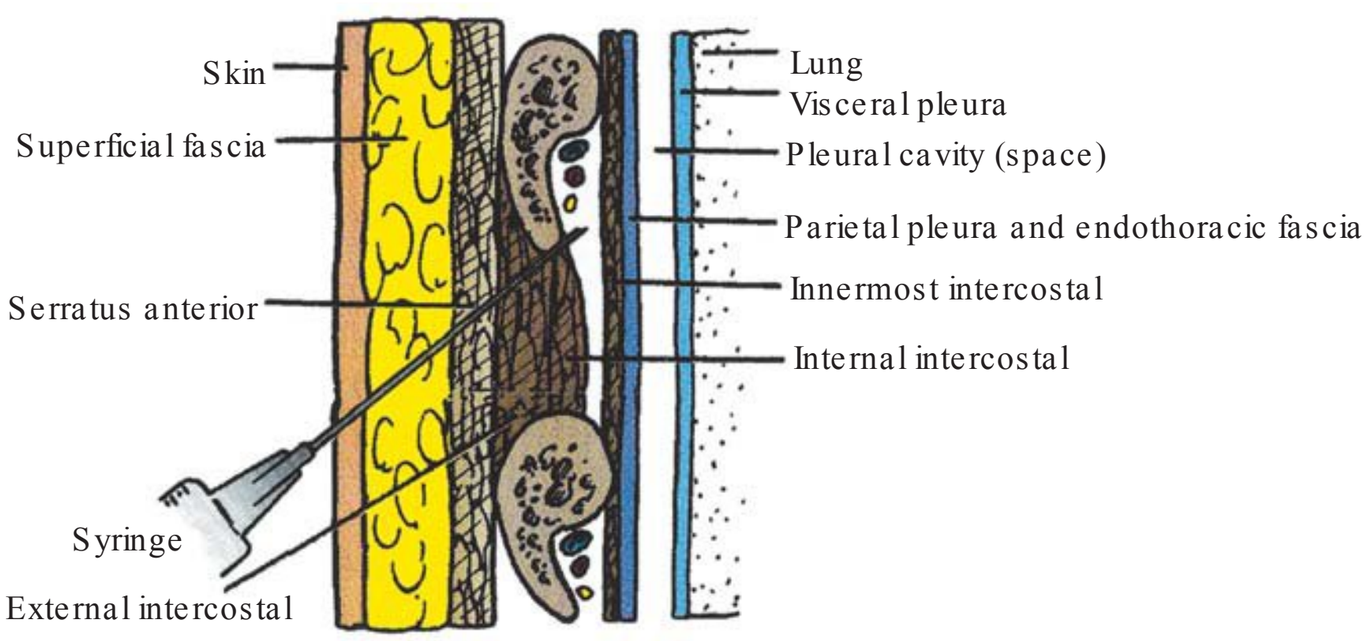
Abnormalities of the Thoracic Spine. Localized pain in the back can result from abnormalities of the thoracic spine. Pain is caused by stimulation of nociceptive fibers in the periosteum, joints, and ligaments. Reflex muscle spasms of the paraspinal muscles are also associated with pain. Deep palpation of the thoracic spinous processes, the paravertebral region, and movement of the spine can elicit pain.

Congenital abnormalities of the spinal curvature resulting in scoliosis can cause chest wall pain as the patient ages. Structural changes in the thoracic spine due to postural kyphosis, trauma, or disease can result in pain. Correction of lateral scoliosis with surgical or nonsurgical interventions can help alleviate the pain. Posture training with strengthening exercises and relief of muscle spasms is helpful.

Vertebral Fractures. Fractures of the vertebral body can be very painful. The pain can be particularly severe and may radiate into the chest wall. Vertebral fractures are the result of trauma, metastatic disease, or osteoporosis. Compression fractures in younger patients are mostly due to trauma. However, corticosteroid use can also result in compression fractures in younger patients. Osteoporosis is a major public health concern in the modern world. It is estimated that by the eighth decade 50% of all women will develop vertebral fractures.[33] There is significant impact on the patient with an osteoporotic vertebral fracture resulting in pain, deformity, dependence, and fear of falling. More than 200,000 people per year with osteoporotic fractures require opioid pain medications.[34,35] Radiologic diagnosis with plain films, CT scan, or magnetic resonance imaging (MRI) can assist in the diagnosis of a patient who presents with acute onset posterior axial pain with or without radicular symptoms (Fig. 69.10).

Physical examination may reveal deformity of the spine. A prominent spinous process can sometimes be palpated above or below the level of the compression fracture. Pain may not be present initially and about 50% of the patients present at a later time with the onset of pain. Most of the fractures are due to a combination of flexion with axial compression resulting in collapse of the anterior portions of the vertebral body. With osteoporosis, as the load bearing capacity of the vertebral bodies decreases, minor movements such as bending or lifting can result in a fracture in older patients. Crushed fracture of the anterior and middle columns of the vertebral body, the so-called burst fractures, can result in neurological compromise. The main goal of therapy is prevention. Treatment options for pain due to vertebral compression fractures include analgesics, bracing, and interventional treatments. Surgical treatment is indicated if there is neurological compromise. However, surgery can be invasive and result in failure of fixation in the osteoporotic spine.

Vertebral body augmentations with vertebroplasty or balloon kyphoplasty have had promising results. It involves mechanical augmentation of the compressed vertebral body by injecting acrylic bone cement material. Use of polymethylmethacrylate for



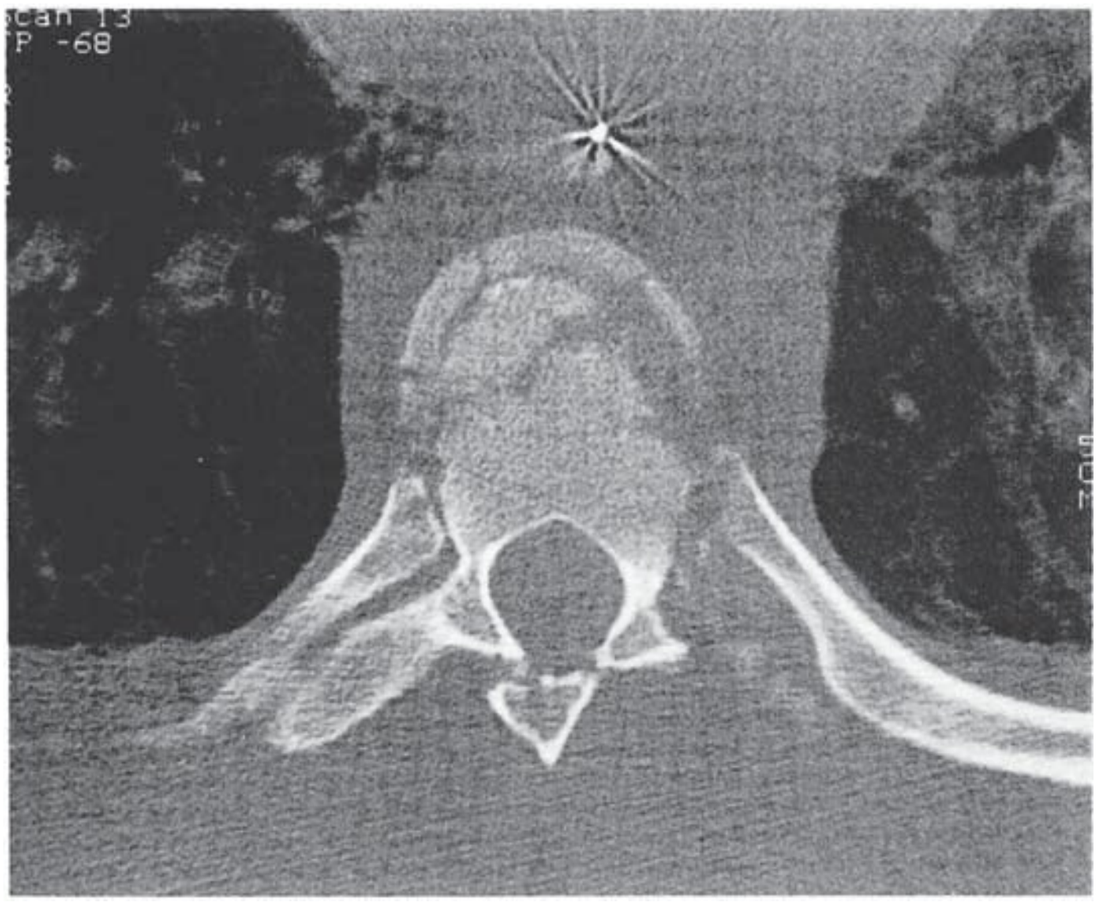


FIGURE 69.9 Intercostal nerve block. Modified from Snell RS. *Clinical Anatomy by Regions*, 8th ed. Philadelphia: Lippincott Williams & Wilkins; 2007.

FIGURE 69.10 Thoracic spine compression fracture. **A.** Axial CT shows compression fracture involving mainly the anterior aspect of T7 vertebral body. **B.** Midsaggittal T1- weighted image shows the wedged T7 vertebral body (arrow). The posterior margin is displaced into the spinal canal, producing spinal cord compression. Lee JKT, Sagel SS, Stanley RJ, et al. *Computerized Body Tomography with MRI Correlation*, 4th edition. Philadelphia: Lippincott Williams & Wilkins; 2006.

A

B

vertebral compression fractures was reported in France in 1991 with good results of pain relief. Polymethylmethacrylate is injected into the vertebral body via a posterolateral approach. The posterior cortex of the vertebral body must be intact prior to injection. Studies have recognized the best timing of interventional procedures to be within 6 weeks of the fracture.[36,37]

Ankylosing Spondylitis. Ankylosing spondylitis results in a stiff spine due to arthritic changes in the intervertebral joints including the costovertebral, costotransverse, and apophyseal joints. The sternoclavicular joints can also be involved.[38] Patients can present with mild to moderate pain in the posterior chest wall. Physical examination demonstrates limited movements of the spine with contracted tender paraspinal muscles. Diagnosis is made by plain films that show characteristic fused spine or "bamboo spine." Occasionally, involvement of the nerve roots due to arthritic changes in the joints can result in radicular pain. Secondary contracture of the paraspinal muscles can worsen the pain. Effective treatment involves physical therapy, trigger point muscle injections, and muscle relaxants. Progression of the arthropathy should be addressed with the expertise of a rheumatologist. Paravertebral blocks can provide relief from radicular pain. Thoracic facet joint injections with corticosteroid and local anesthetics can provide significant relief of pain. If good results are encountered with facet joint injections, longer-term relief of pain can be obtained with radiofrequency ablation of the nerve supply of the facet joint. The radiofrequency technique is generally considered to be safer than chemical ablation, because there are additional risks associated with the potential unwanted spread of the chemolysis agent.

Costovertebral Arthritis. Arthritis of the costovertebral and costotransverse joints can cause posterior chest wall pain. Pain is localized, aching, and deep in character. Pain can be increased with deep breathing, coughing, or lateral compression of the chest. Physical examination may reveal localized deep tenderness that may be hard to distinguish from thoracic facet syndrome. Characteristics of pain and radiologic examination can delineate the pathology.[39,40] Treatment is provided with nonsteroidal anti-inflammatory agents and physical therapy. Interventional treatment with injection of the joints with local anesthetic, corticosteroid mixture with fluoroscopic confirmation can alleviate the pain. It can also be diagnostic. Low dose opioid medications may be needed for treatment of chronic pain from the arthritis.[41] Rarely, resection of the joints is considered for refractory pain from isolated costovertebral joint arthritis.[42]

Diffuse Idiopathic Skeletal Hyperostosis. Another cause of posterior chest wall pain in elderly patients can be due to diffuse idiopathic skeletal hyperostosis (DISH), also called Forestier disease. Patients present with dull aching thoracic back pain, posterior chest wall pain, dysphagia, myelopathy due to involvement of the posterior longitudinal ligaments, fractures, subluxation, and, rarely, intercostal neuralgia. Physical findings include slight increase in dorsal kyphosis, minimal reduction in motion, and localized tenderness. Diagnosis is confirmed with radiologic exams with plain films and CT scans showing spinal hyperostosis resulting in linear ossification and bridging osteophytosis along the anterior and anterolateral aspects of the vertebral bodies. DISH most commonly affects the thoracic spine. Absence of sacroiliitis, true syndesmophytes, and ankylosing apophyseal joints distinguishes this syndrome from ankylosing spondylitis.[43,44] The syndrome of synovitis, pustulosis, hyperostosis, and osteitis (SAPHO syndrome) can also be a cause of anterior chest wall hyperostosis.[45] Treatment is symptomatic with nonsteroidal anti-inflammatory drugs (NSAIDs) and physical therapy.

Thoracic Facet Syndrome. Thoracic facet syndrome results from abnormal locking or binding of the facet joints. Sudden or rapid turning movements of the trunk, working with hands over the

head, or lifting with the trunk in a twisted position can result in this syndrome. Symptoms include moderate to severe pain on the side of the spine or anterolateral chest wall.[46,47] The pain is worsened with extension of the spine and relieved with flexion. Localized deep tenderness can be elicited to deep palpation over the facet joint. Tenderness and spasms of the erector spinae muscles can exacerbate the pain. It can mimic the pain from costovertebral arthropathy. Injection of the joint can assist in making the correct diagnosis. Treatment includes NSAIDs, physical therapy, and injection of the facet joints and medial branches with corticosteroid and local anesthetics. Radiofrequency denervation offers long term pain relief.[48,49]

Chest Wall Pain Arising from the Ribs. Rib fractures account for one of the most common causes of acute chest wall pain of skeletal origin. Blunt trauma to the ribs is the usual cause of fractures. Other causes include severe paroxysmal coughing (tussive fracture), metastatic disease, osteoporosis, osteomalacia, and Paget disease of the bone (Fig. 69.11). Elder or child abuse should be sought in unexplained rib fractures after all other etiologies are eliminated.

Fractures may involve several ribs or multiple fractures of the same rib. Acute pain from rib fractures is usually aching, sharp, and worsened with respirations. Pain from multiple fractures can restrict breathing leading to additional pulmonary complications. Acute pain from rib fractures is treated with NSAIDs, low-dose opioids, or continuous intercostal nerve blocks. Chest wall pain from multiple rib fractures in trauma patients, in which serious consequences might occur from hypoventilation due to pain-related splinting, are candidates for a thoracic epidural catheter with a continuous epidural infusion.[50–52] Multiple studies in selected trauma patients have shown better outcomes of pain relief and reduction in pulmonary complications with thoracic epidural infusion compared to systemic opioids or intrapleural catheters.[53–56]

Occasionally, rib trauma without radiographically apparent fracture can cause localized pain and swelling with point tenderness in the area. If these are related to hypoventilation due to splinting from pain, they may be considered the same as rib fractures potentially requiring neuroaxial analgesia. Local injections with local anesthetics, intercostals nerve blocks, and NSAIDs can help relieve the pain. Topical local anesthetic patches with 5% Lidocaine may be helpful for some with pain from single rib fractures or rib injuries without a fracture. Metastatic disease from the breast, lungs, and prostate can cause isolated rib tenderness. Plain radiographs and nuclear medicine bone scans can aid in the diagnosis.

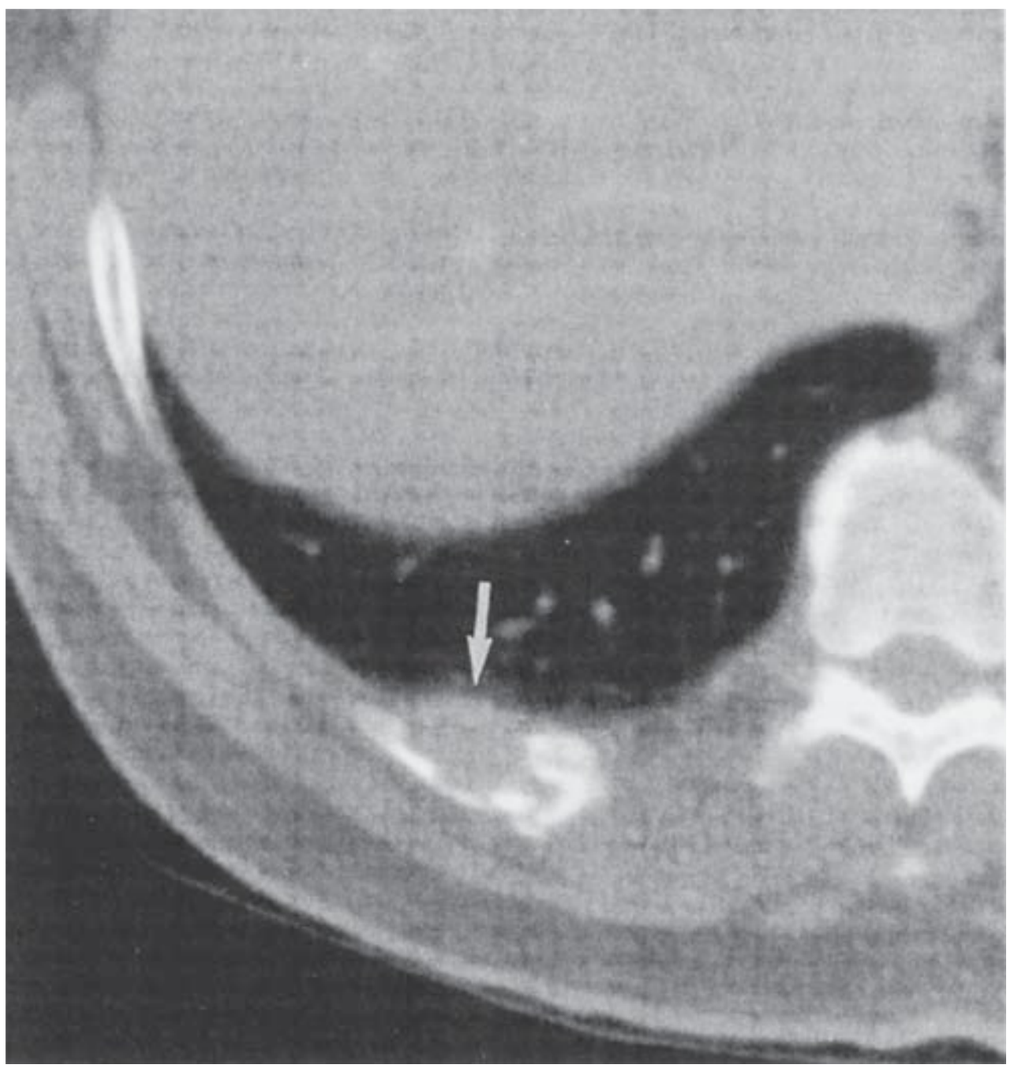

FIGURE 69.11 CT showing Rib destruction from multiple myeloma. Lee JKT, Sagel SS, Stanley RJ, et a. *Computerized Body Tomography with MRI Correlation*, 4th edition. Philadelphia: Lippincott Williams & Wilkins; 2006.

Slipping Rib Syndrome. Slipping rib syndrome was described first in 1922 by Davies-Colley.[57] It is characterized by chest wall or abdominal pain due to irritation of the intercostal nerves. The etiology is thought to be due to trauma. There is increased mobility of the costal cartilages of eighth to tenth ribs near the sternum. The syndrome is also referred to as clicking rib, gliding rib, or displaced ribs.[58] It is also seen in children.[59,60] The cause for pain is due to anatomic variation of the eighth to tenth ribs, which, instead of articulating directly with the sternum, articulate with the costal cartilages of the upper rib. As such the sternal ends of these ribs are more prone to trauma. Injury can cause separation of the cartilages causing slipping movements of the ribs with respiration. A characteristic click can be felt with the movement of the ribs over the border of the upper cartilage. Diagnosis of the condition can be accomplished by the "hooking maneuver." The examiners curled fingers are placed over the inferior border of the rib and the rib is pulled up anteriorly. A positive test produces a clicking noise and increases the pain.[61] Slipping rib syndrome is treated conservatively with reassurance and nonopioid analgesics. Injection of the painful site (between the detached cartilage and the rib) with local anesthetic steroid combination medications may relieve pain for a longer period. Surgical excision of the involved rib and costal cartilages has also been suggested for refractory cases.

Teitze Syndrome. Teitze syndrome is characterized by a benign, nonsuppurative, painful swelling of the second or third costal cartilages.[62] It was first described in 1921 by Teitze. Straining, severe cough, heavy manual work, nutritional deficiencies, and arthritic conditions have all been implicated as the possible causes. In 80% of the patients the condition is unilateral.[63] Pain is usually localized, but occasionally can radiate over the anterior chest wall, to the shoulder or neck. Pain is characterized as heaviness, tightness, or soreness. Pain is exacerbated by coughing and deep breathing. There is localized tenderness and swelling over the involved cartilage.[64,65] The overlying skin is normal. Radiologic diagnosis by bone scans is nonspecific. Treatment includes use of nonopioid anti-inflammatory medications. The condition usually is self limited with occasional exacerbations and remissions.

Costochondritis. Costochondritis is one of the most common causes of anterior chest wall pain often confusing or coexisting with the pain due to coronary artery disease.[66–68] Pain is characterized as aching, sharp, or tightness in the anterior chest wall. Unlike Teitze syndrome it involves multiple sites. No swelling is palpated. There is localized tenderness involving multiple costochondral regions of the anterior chest wall. Second to fifth costal cartilages are frequently involved. Pain is aggravated with movement of the chest. Pain can radiate anteriorly or to the back. In adolescents it can cause chest wall or abdominal pain. Firm steady pressure applied over the sternum, intercostal spaces, costochondral junctions, and the ribs can reproduce the pain. The horizontal flexion test consists of having the arm flexed across the anterior chest wall and applying steady traction in a horizontal direction, while the patient's head is rotated toward the ipsilateral shoulder. The crowing rooster maneuver involves having the patient extend the neck as much as possible by looking toward the

ceiling while the clinician, standing behind the patient, exerts traction on the posteriorly extended arms.

It is important to distinguish pain due to costochondritis (especially left-sided) from that because of coronary artery disease or abdominal pathology.[69] Pain due to costochondritis is usually located to the lateral side of the sternum unlike the substernal cardiac pain.[70] Pain can radiate to the left arm or shoulder. The patient gives a history of pain with movement and postural changes. Localized tenderness can be palpated. Pain usually lasts for a few minutes to hours, distinguishing it from pain of acute cardiac origin. Intercostal nerve blocks and injection of the tender costochondral areas with local anesthetic have been used for diagnostic purposes. Rarely, emergency room physicians experience a patient with both costochondritis and coronary artery disease. Careful history and physical exam along with treatment with sublingual nitroglycerin can aid in prompt diagnosis of the cardiac pain, which is relieved with the nitroglycerin.

Treatment of costochondritis is initiated with NSAIDs, physical therapy, heat application, and low-dose opioids. Once the diagnosis has been made, reassuring the patent about the benign nature of the condition can prevent patient anxiety and avoid unnecessary expensive diagnostic workup. Localized injection of the costochondral junction with local anesthetics and corticosteroids can help relieve the pain.

Costochondral Dislocation

Costochondral dislocation is commonly seen after trauma in young patients.[71] It is also encountered after thoracic surgery with rib retraction. The pain is typically dull, aching, or burning, and is usually continuous. Localized tenderness is present. Sometimes a mass is felt due to cartilaginous excess from the injury. Treatment is similar to other conditions as described above with oral analgesics and intercostals nerve blocks. Manipulation and reduction of the dislocation after adequate analgesia can correct the condition.

Chest Wall Pain of Sternal Origin

Sternoclavicular joint arthritis can be caused due to various arthritic conditions (osteoarthritis, rheumatoid arthritis, psoriatic) and rarely infections due to central venous catheters.[72–74] Infections are also seen in intravenous drug users. Traumatic subluxation and dislocation can also cause pain. Apart from trauma, such conditions are also seen after cardiac surgery when the sternum is retracted. Pain is localized to the affected joint. Localized tenderness of the joint is seen with palpation along with pain from shrugging the shoulders. Treatment consists of oral NSAIDs and injection of the joints with local anesthetic and corticosteroid. Such intervention must be avoided in infectious joints which are treated with antibiotics and analgesics.

Blunt injuries to the sternum can cause subluxation of the manubriosternal joint.[75] Manubriosternal arthritis can occur due to various arthritic conditions.[76–78] Septic arthritis of the joint is also seen.[79,80] Pain is localized to the anterior sternum or angle of Louis with occasional radiation parasternally. Pain is characterized as sharp aggravated with deep breathing, coughing or yawning. Pain may mimic anginal pain. Diagnosis is made by physical examination. Bone scans can be positive.[81] Treatment consists of systemic analgesics, topical lidocaine patches, heat, infiltration of the joint with local anesthetics, and corticosteroids. Rarely, surgical intervention to correct the manubriosternal displacement is necessary.

Xiphoidalgia. (Painful xiphoid syndrome, xiphoid cartilage syndrome, hypersensitive xiphoid)

Intermittent, inferior substernal or epigastric pain associated with tenderness of the xiphoid to palpation is characteristic of xiphoidalgia.[82,83] Pain is spontaneous without any obvious precipitating cause. It is sometimes seen along with coronary artery disease, intestinal disease, and metabolic disorders. Movements of the xiphoid with bending, stooping or turning, precipitates or exacerbates the pain more commonly after a full meal. Along with NSAIDs, local injection of the xiphisternal joint with local anesthetic and corticosteroid can alleviate the pain.

Chest Wall Pain of Myofascial Origin

Myofascial strain can be caused by excessive muscular activity. Repeated stress due to exercise, coughing, straining, or repetitive movements (chopping wood, painting a ceiling) can result in generalized tenderness over the anterior chest wall. Pain in the intercostals or accessory thoracic muscles is usually due to trauma. Pain from the pectoralis muscles can be exacerbated with adduction movements of the shoulder. Pain between the scapula and spine from an injured rhomboid is increased with bracing of the shoulders backward. Treatment consists of reassurance, local heat or cold, NSAIDs, topical lidocaine patches, physical therapy, and avoiding precipitating activities. Infiltration of the muscle with local anesthetic can be undertaken if there is localized tenderness. Caution regarding the risk of pneumothorax is necessary for all chest wall injections.

Precordial Catch Syndrome (Chest Wall Twinge Syndrome). This is characterized by episodes of sudden, brief, sharp precordial or periapical pain. This is a benign, self-limited condition.[84,85] Sharp pains, stitches, or catches are felt in the chest wall in the left parasternal on or near the cardiac apex. Some patients report pain from assuming a slouching or bent position. Pain may last for a few seconds to up to 3 minutes. Deep breathing exacerbates the pain while shallow breathing relieves it. There is no localized tenderness. The cause is unknown. Intercostal muscle spasms and pain from the pleura have been postulated as possible causes. Treatment consists of reassurance and correction of posture. Due to the unpredictability and the benign short duration of pain, analgesics are not necessary.

Epidemic Myalgia (Bornholm Disease, Epidemic Pleurodynia, Devil's Grip). This condition is characterized by paroxysms of intense sharp chest wall and upper abdominal pain due to viral infection with coxsackie or echoviruses.[86] The paroxysms of pain are separated by pain-free intervals. Frequently there is associated fever, headache, and pharyngitis. The condition is self-limited.

Breast Pain

Pain arising from the breast is a common and nonspecific symptom in women.[87,88] Usual causes include benign cysts, fibrocystic change, or cyclical pain due to hormonal cycle changes of the menstrual cycle. Other causes of breast pain include malignancy, mastitis, ductal ectasia, breast abscess, hormone replacement therapy, or large breasts. Careful clinical evaluation and mammography to rule out malignancy should be undertaken. Pain due to malignant breast lesions does not usually present until the tumor is large (greater than 2 centimeters in diameter). Axillary lymph node involvement can present as either localized or sharp pain in the arm with involvement of the intercostobrachial nerves. Extramammary sources of breast pain should be evaluated if no other etiology is suggestive. Causes include skeletal and myofascial pain from the chest wall, radicular pain, or pain from peripheral nerves.

Chronic severe breast pain that persists for years without any obvious cause characterizes idiopathic mastalgia. Pain can be unilateral or bilateral, cyclical, or noncyclical which is usually seen in the third or early fourth decades of life. Without any organic diagnosis, the etiology is often misdiagnosed as psychologic.[89] Cyclical mastalgia responds to Danazol, Bromocriptine, or Tamoxifen. Hormonal events such as pregnancy, menopause, or use of oral contraceptives may lead to relief.[90,91]

Breast pain is treated with NSAIDs and acetaminophen. Warm compresses, ice packs, or gentle massage can relieve pain. Pain arising from the cervical or thoracic spine requires appropriate

treatment of the cause as discussed elsewhere in this text. Peripheral myofascial and skeletal pain, also discussed elsewhere in this text, can be treated with injection of local anesthetic and corticosteroid.[92,93]

Adiposis Dolorosa (Dercum Disease). This syndrome is characterized by painful subcutaneous fatty tumors in various parts of the body, including the breast.[94] This can result in chronic pain in the breast. Treatment with intravenous lidocaine and resection of the fatty lesions is helpful.

Mondor Disease. Thrombosis of the superficial veins of the thoracic wall can cause pain in the anterolateral chest wall.[95] This is seen occasionally in patients who abuse intravenous drugs.[96] The disease is mostly seen in middle aged women with pendulous breasts and can cause pain in the breast.[97] Presence of a palpable tender cord is characteristic. The disease can cause anxiety in the patient. Mondor disease is self-limited. Treatment involves management of pain with NSAIDs.

Postsurgical Chest Wall Pain

Pain can persist for several months to years after surgery. It is often troublesome for the patient to live with pain after the original pathology has been corrected with surgery.

Chronic postsurgical pain is most commonly seen after thoracotomy, mastectomy, and cardiac surgery. Other rare causes of chronic postsurgical chest wall pain include video-assisted thoracoscopy, mediastinoscopy, breast reconstruction, and surgery of the cervical or thoracic spine.

Postsurgical Breast Pain and Postmastectomy Pain Syndrome. Persistent pain in the anterior chest wall, axilla, and the arm can be seen in a few patients after mastectomy.[98–100] It can also occur after minor breast surgeries, such as lumpectomy. Breast reconstruction or other cosmetic breast surgeries can be also associated with such pain. Submuscular implants and capsule formation around the implant can cause injury or impinge on the thoracodorsal, long thoracic, lateral, or medial pectoral nerves. Postsurgical complications such as wound infection, fluid or hematoma retention, and re-exploration can frequently result in pain. Although previous studies describe pain in less than 10% of patients, more recent studies report pain, paresthesias, and phantom sensations in about half of the patients.[101,102] In about half of the cases pain resolves with time. Pain is described as burning, sharp, or tight constriction of the axilla. Pain can be associated with surgical scar sensitivity. There can be associated dysesthesia or hyperesthesia of the anterior chest wall. It is presumed that injury to the intercostobrachial nerves and, rarely, the intercostals nerves is the cause. Patients are at risk for developing upper extremity problems due to restricted movement of the arm secondary to pain. Treatment consists of analgesic and neuropathic medications, physical therapy, reassurance, intercostal or paravertebral nerve blocks, or epidural analgesia.[103,104] Intraoperative infiltration of botulinum toxin into the chest wall musculature has also been suggested.[105] Persistent pain should arouse suspicion for recurrent breast disease.

Phantom breast syndrome has been a common occurrence after a mastectomy in the past.[106–108] The incidence has decreased with adequate psychosocial supportive therapy.[109,110] It can present as painful or nonpainful sensations in the region of the missing breast as if it is still present. It can develop within 3 months after the surgery. Risk factors for development of the syndrome include psychosocial factors, damaged body image, and impaired sexual function. Affected women are usually younger, premenopausal with children. Predisposing factors for phantom breast pain are similar to phantom limb syndrome and include pain in the involved breast prior to surgery.[111] Preoperative analgesia may be effective in preventing this syndrome; however, it has not been significantly studied.

Postthoracotomy Pain. Chronic chest wall pain after thoracotomy can be disabling to the patient.[112,113] Characteristics of postthoracotomy pain can be burning, aching, hyperesthesia, or allodynia along the surgical incision and the involved dermatome. Women experience more pain than men after major thoracotomy.[114] No difference has been seen in the incidence of acute or chronic pain with different types of thoracotomy incisions.[115] Adequate management of acute postsurgical pain can prevent the chronicity of pain.[116] Management of acute pain with thoracic epidural placed prior to surgery has been shown to decrease the severity of perioperative pain and decrease the incidence of chronic pain. Other causes of radicular chest wall pain and recurrent cancer have to be excluded, especially in postthoracotomy patients who experience onset of severe pain several months after the thoracotomy. Management is similar to treatment for intercostal neuralgia.[117,118] Thoracic paravertebral blocks are also helpful to control acute and chronic pain.[119,120] Pulsed radiofrequency of dorsal root ganglia or intercostal nerves is recommended for refractory pain.[121] Prior to any injections of the surgical scar site, a careful examination is necessary to avoid injury to herniated lung tissue in rare cases.[122,123] A multimodal approach to pain management provides higher success in controlling chronic postthoracotomy pain.

Postcardiac Surgery Pain. Persistent anterior chest wall pain has been reported in about 28% of patients after cardiac surgery.[124,125] Myocardial ischemia, infection, sternal or costosternal instability, sternal wires, and intercostal neuralgia (especially after dissection of the internal mammary artery from the chest wall), can be possible causes.[126] Pain can persist up to 2 years postoperatively. Initial attempts at treatment should be focused on eliminating obvious serious causes. Treatment consists of analgesic and neuropathic medications, costosternal joint injections, and surgical removal of sternal wires.[127]

Chest Pain and Psychological Factors

Patients with sudden acute chest pain, regardless of the cause, experience varying degrees of anxiety, apprehension, and fear, depending on their interpretation of the cause of pain. Those who believe they are experiencing a heart attack become extremely frightened of possible impending death. Patients with persistent angina develop reactive depression, which, if untreated, produces progressive physical and psychological deterioration.[128] Musculoskeletal chest pain can cause a great deal of anxiety and apprehension until the patients are reassured about the benign nature of the condition.[129,130] Adolescents can often present with chest pain that is mostly myofascial or psychogenic in origin.

Chest pain can also result from psychological mechanisms. Because of the potential seriousness of a physical cause of chest pain, thorough history, physical examination, and diagnostic work up is essential. Some of the features of psychological chest pain include pain at the apex of the heart, patients describing the character of pain dramatically, development of pain unrelated to physiologic events, and possible presence of an emotional precipitating event prior to the pain. Once the diagnosis of psychological chest pain has been made, reassurance, relaxation techniques, anxiolytic drugs, sedatives, tranquilizers, and time can reduce the anxiety.

Patients with chronic anxiety can present with chest pain and other symptoms. This syndrome has been called Da Cossta syndrome, neurocirculatory asthenia, vasoregulatory asthenia, effort syndrome, and soldier's heart.[131,132] Patients can present with symptoms of apical chest pain, shortness of breath, nervousness, anxiety, fatigue, generalized weakness, and low energy level. Treatment consists of reassurance, behavioral therapy, and treatment of underlying psychiatric disorders, if any. Other psychiatric disorders, such as depression, conversion reactions, hypochondriasis, and learned behavior can manifest as chest pain.

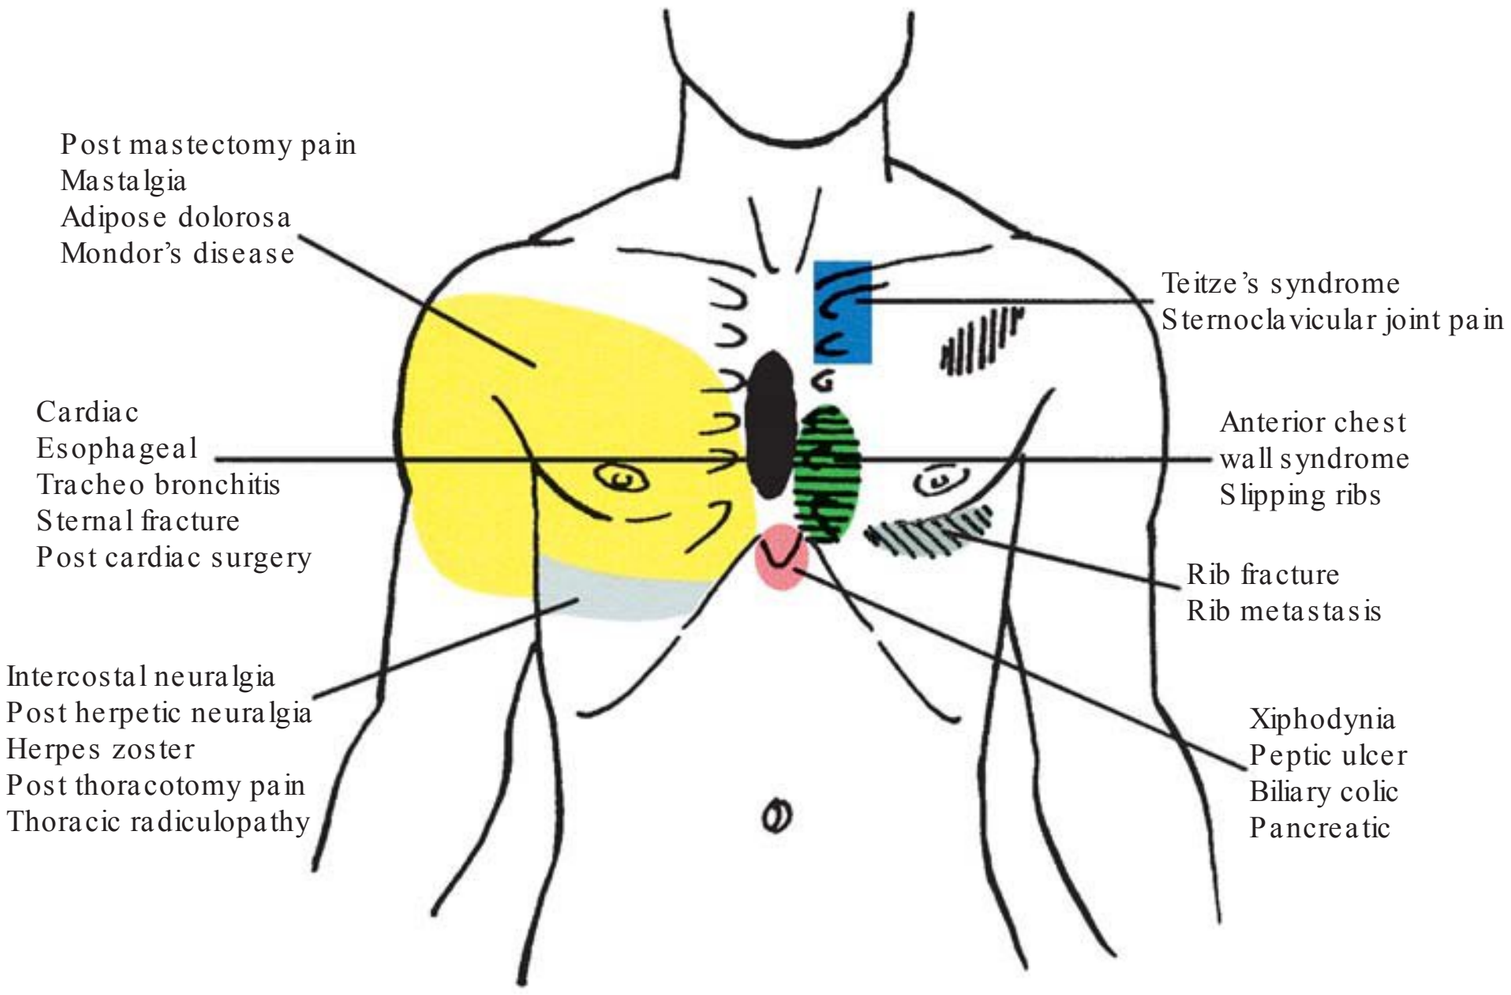

FIGURE 69.12 Common sites of anterior chest wall pain due to chest wall structures or referred pain.

Chest Wall Pain of Cardiac Origin

In any patient who presents with chest pain the differential diagnosis must include chest pain of cardiac origin. Angina presents as substernal chest pain or tightness. However, atypical presentations of chest pain or gastric symptoms can be seen from cardiac disease. Evaluation of risk factors may help assist in making the diagnosis in atypical presentations. Chronic refractory angina pectoris is a condition where patients present with chronic and disabling chest pain despite optimal medical treatment. In such patients who are not candidates for invasive cardiac procedures, spinal cord stimulation (SCS) offers adequate pain control and improvement in the quality of life.[133,134] SCS is also mentioned as an available adjunct by the task force on the management of stable angina pectoris of the European Society of Cardiology.[135] Angina due to acute myocardial infarction is not masked by spinal cord stimulation.[136]

CONCLUSION

Chest wall pain can result from lesions within the chest wall or referred pain from the thoracic viscera (Figs. 69.12 and 69.13). A comprehensive assessment and examination is needed to differentiate these and to further determine if the lesion involves skeletal, muscular, or neurological components of the chest wall or thoracic and abdominal viscera (Table 69.3).

(text continues on page 1067)

TABLE 69.3

PAIN IN THE CHEST: SUMMARY OF DIFFERENTIAL DIAGNOSIS

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	Associated symptoms and signs
I. Pain caused by disease of the heart and aorta			
A. Angina pectoris (stable angina, unstable angina, variant angina)	XVII-4	Mild, moderate, severe, or excruciating anterior chest pain felt predominantly retrosternally with radiation to parasternal region, left arm or right arm or both, epigastrium, and, less frequently, to the interscapular region, neck, and lower jaw; discomfort felt as severe oppression or heaviness on the chest, a sense of constriction or bandlike pressure, or a feeling of choking, strangling, or tight pressure on the neck; pain provoked by physical effort, severe emotional stress, or a large meal (except unstable angina, which occurs at rest or with little or no provocation); lasts 2–5 minutes with stable angina, 15–30 minutes or longer with unstable angina and variant angina; promptly relieved with nitroglycerin or discontinuation of effort	History of previous anginal attacks; can have normal ECG at rest, but ST depression and other ECG changes during stress test; positive evidence with radionuclide stress testing and coronary arteriography; demonstration of coronary artery spasm in variant angina
B. Acute myocardial infarction	XVII-5	Pain of same character, location, and reference as angina but of sudden onset, much more severe, and of longer duration (1–8 hours or more); little or no relief with nitroglycerin; intense pain often accompanied by strong alarm reaction and feeling of impending death	Frequently nausea, vomiting, and profuse sweating; many patients develop tenderness in pectoral muscle and deep muscle of interscapular region; some develop bradycardia and hypotension and others tachycardia and hypertension; ECG changes include Q-wave and ST-segment elevation and increased creatine kinase and other serum enzyme levels
C. Aortic stenosis	—	Dyspnea first symptom but angina occurs with severe aortic stenosis; chest pain occurs during physical exertion as a result of increased oxygen demand from increased myocardial mass and high ventricular systolic pressure	With severe disease exertional syncope is caused by decline in arterial pressure; left ventricular failure, palpitation, fatigue, weakness, peripheral cyanosis, narrow pulse pressure, and palpable systolic murmur; increased QRS complex and ST- and T-wave alterations
D. Aortic regurgitation	—	Asymptomatic early in disease; dyspnea on exertion; pain late symptom of severe disease that can occur at rest as well as with exertion and persists longer than angina of coronary artery disease; some patients have neck and abdominal pain	Dyspnea on exertion, flushing, sweating, palpitation; increased fatigue progresses to orthopnea and eventually to paroxysmal nocturnal dyspnea; high-pitched crescendo diastolic murmur along left sternal border
E. Mitral valve prolapse	—	Sharp, stabbing chest pain not provoked by exertion and unresponsive to nitroglycerin; more frequent in female subjects	Cardiac arrhythmia produces palpitation and rarely dizziness, syncope, or even sudden death; midsystolic click and late systolic murmur
F. Hypertrophic cardiomyopathy	—	Most patients asymptomatic; symptomatic patients have dyspnea on exertion because of increased stiffness of left ventricular walls; typical angina pectoris with exertion	Atrial and ventricular arrhythmias produce palpitation, dizziness, and syncope; ECG shows QRS changes of left ventricular hypertrophy and abnormal Q wave

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	**Associated symptoms and signs**
G. Acute pericarditis	XVII-6	Severe, sharp chest pain; worse in supine position, partially relieved by sitting; markedly aggravated by deep breathing; pain usually retrosternal (central), radiates to the neck and trapezius ridge but not to the arms	Dyspnea occurs because of marked increase in pain with normal respiration; triphasic pericardial friction rub occurs with atrial systole, ventricular systole, and ventricular diastole, occasionally only biphasic; ECG initially shows ST-segment elevation and later T-wave flattening
H. Diseases of the thoracic aorta			
1. Dissecting aneurysm	—	Sudden, severe excruciating pain with maximal intensity at its onset; location of pain helps to localize dissection: ascending aortic dissection produces anterior chest pain in 65% of patients and posterior chest pain in 50%; dissection in descending thoracic aorta produces back pain in nearly all patients; radiation to the neck, throat, jaw, and abdomen in a small percentage of patients	Nausea, vomiting, diaphoresis, bradycardia, and hypotension or tachycardia and hypertension; loss of one or more arterial pulses; sense of impending death, apprehension
2. Nondissecting aneurysm	XVII-7	Mild to severe continuous burning, aching pain with bouts of lancinating pain; radiation to the chest, shoulder, and back caused by mechanical compression or injury of thoracic spinal nerves; erosion of bone causes boring, agonizing, intractable back pain	Dyspnea, cough, dysphagia, hoarseness; Horner syndrome; pulsating mass; radiographic evidence
II. Diseases of the respiratory system			
A. Diseases of the tracheobronchial tree			
1. Acute tracheobronchitis (infectious, irritative, thermal injury)	—	Mild to moderate burning, aching pain in the retrosternal and parasternal regions; pain severe with thermal injury; associated with sore throat	Preceded by upper respiratory infection: coryza, malaise, chilliness, slight fever, back and muscle pain; with bronchitis, initially dry and nonproductive cough but later mucoid or mucopurulent, dyspnea might be present
2. Bronchiectasis	—	Mild to moderate aching pain in retrosternal and parasternal regions	Chronic cough and sputum production; with progression, cough becomes more productive, hemoptysis common, recurrent pneumonia frequent; wheezing, dyspnea in severe cases
B. Diseases of the pulmonary circulation			
1. Acute pulmonary hypertension	—	Severe crushing, gripping pain in the center of the chest simulating that of acute myocardial infarction, but does not radiate to arms or jaw and seldom to back	Usually decrease in arterial P_{O_2} can have dyspnea, cyanosis, sweating
2. Chronic pulmonary hypertension (primary, secondary)	—	Pain in anterior chest, primarily retrosternal; radiation to neck; some patients have typical angina pectoris complicated by myocardial ischemia	Primary hypertension usually in female subjects; dyspnea, easy fatigue, less frequently syncope; right ventricular hypertrophy can progress to failure

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	**Associated symptoms and signs**
3. Pulmonary embolism	—	With large embolus pain is sudden, severe, crushing, and of a visceral central type; simulates pain of myocardial infarction but does not radiate to the jaw or arms; lasts for minutes to several hours; small embolus produces localized severe pleuritic pain that is persistent and lasts a week or longer; aggravated by deep breathing or coughing	Feeling of impending death (*angor animi*), pressure on throat, desire to defecate; history of thrombi in leg, pelvis, occasionally in upper extremity; rarely, embolic fluid or fat emboli; initially the large embolus usually produces pulmonary hypertension from increased pulmonary vascular resistance, leading to decreased cardiac output, hypotension that can progress to shock, with sweating, tachypnea, dyspnea, arterial hypoxemia; hemoptysis, pleural friction rub with small embolus; radiography reveals wedge-shaped shadow
C. Diseases of the lungs			
1. Pneumonia	—	With lobar pneumonia patient develops pleuritis with moderate to severe pain in lateral chest or shoulder aggravated by deep breathing and coughing (because of involvement of central diaphragmatic pleura); little or no pain with bronchopneumonia	Systemic symptoms and signs of infection: fever, cough, occasionally nausea, vomiting, malaise, and muscle pain; blood-streaked sputum, occasionally hemoptysis; rhonchi; percussion reveals dullness; radiographic evidence
2. Lung abscess	—	Typical pleuritic chest pain if abscess produces pleuritis; characteristics similar to those of lobar pneumonia (see above)	Malaise, anorexia, sputum-producing cough, sweats, severe prostration, and fever; putrid odor (anaerobic infection); fine moist rales
3. Atelectasis	—	Rapid occlusion with massive lung collapse causes moderate to severe pain on the affected side	Rapid collapse causes dyspnea, cyanosis, hypotension, tachycardia, fever, and shock; percussion, dullness, or flatness; diminished or absent breath sounds; decreased chest excursion of affected side
D. Disorders of the pleura			
1. Pneumothorax (spontaneous)	—	Sudden moderate to severe stabbing, sharp pain felt across the chest or over abdomen or corresponding shoulder, can simulate pain of acute myocardial infarction or acute abdomen	Dyspnea, absent breath sounds; with large or tension pneumothorax tympany on percussion; decreased excursion of affected side; cardiac dullness and apex felt away from affected side; radiographic evidence
2. Pleuritis (pneumonitis, pulmonary infarct, pleural tumors, lung abscess, actinomycosis, coccidiomycosis, other infectious processes)	—	Localized, sharp, knifelike stabbing, piercing pain in various regions of the chest depending on the site of pathology (side, shoulder, epigastrium); markedly aggravated by deep breathing, coughing, laughing, movement of the chest; pain can be continuous with pleural carcinoma	Diagnostic pleural friction rub; history and systemic symptoms and signs of infection; chest signs (rales, rhonchi); radiographic evidence
3. Epidemic pleurodynia (Bornholm disease)	—	Severe paroxysmal sharp pain in side of chest wall, epigastrium, costovertebral region, and abdomen	Fever, headache; occasionally orchitis, encephalitis, and pericarditis occur during epidemic pleurodynia

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	**Associated symptoms and signs**
E. Bronchogenic and metastatic carcinoma of the lung, bronchial pleura (squamous cell carcinoma, undifferentiated small or large cell adenocarcinoma, bronchoalveolar carcinoma)	—	Location, quality, and severity of pain depend on location and type of spread: a. Endobronchial carcinoma □ sternal and parasternal pain b. Intrapulmonary carcinoma □ vague central (visceral) pain c. Pleural spread □ sharp, stabbing, chest wall pain markedly aggravated by breathing, coughing, movement d. Mediastinal spread □ neuropathy with segmental pain e. Pancoast syndrome (brachial plexopathy) □ pain in shoulder, scapula, medial arm	Weight loss; paraneoplastic syndromes; other signs and symptoms: a. Cough, hemoptysis b. Hypoxia, dyspnea, atelectasis c. Signs and symptoms of pleuritis (see above) d. Compression of superior vena cava □ superior vena cava syndrome e. Horner syndrome, hoarseness, weakness of all muscles supplied by the ulnar nerve
III. Diseases of the esophagus			
A. Esophagitis			
1. Gastroesophageal reflux disease	XIX-4	Retrosternal pain extends from suprasternal notch to xiphoid process; radiation to epigastrium, neck and back, and, rarely, arms; simulates pain of myocardial ischemia; lasts seconds to many hours; aggravated by stooping or lifting, recumbency, citrus juices, exercise, heavy meal, coffee, alcohol, aspirin, tobacco, and obesity; relieved by antacids	Dysphagia, odynophagia, regurgitation, and occasionally aspiration; diagnosis helped by pH monitoring, acid perfusion test, and esophagoscopy
2. Acute and chronic esophagitis caused by infection or chemical agents	XIX-4	Corrosive agents: immediate, severe, burning pain in throat and behind the whole length of the sternum down to epigastrium, pain is constant with periodic increases in intensity produced by esophageal spasm; infection: pain appears gradually over a period of hours or days and is constant, mild to moderate, and burning in character; both are markedly aggravated by swallowing (odynophagia) and by citrus juices and other factors listed previously for gastroesophageal reflux disease	Infection: signs and symptoms of inflammation (e.g., fever, chills); chemical esophagitis: pharyngeal erythema; moniliasis; typical soft white patches in tongue, tonsil, and buccal mucosa; other associated symptoms as above (e.g., dysphagia, odynophagia)
B. Esophageal motor disorders (achalasia; diffuse spasm unclassified motor disorders)	XIX-3	Moderate to severe retrosternal pain; radiation to epigastrium and back, neck, jaw, teeth, left arm, or both arms; aggravated by cold liquids, solids, and emotional stress; partially relieved by nitroglycerin; lasts seconds to many hours and can awaken patient from sleep; simulates pain of myocardial infarction	Dysphagia, odynophagia; diagnosis aided by manometry, scintigraphy, provocative tests (e.g., edrophonium or methacholine-induced esophageal spasm)
C. Esophageal laceration and rupture (Mallory-Weiss syndrome, Boerhaave syndrome)	—	Mallory-Weiss syndrome: laceration of distal esophagus and proximal stomach during retching, vomiting, or hiccup causes pain in lower sternum and epigastrium; Boerhaave syndrome: spontaneous rupture occurs during intense vomiting following a large meal and causes sudden, severe, excruciating crushing or tearing pain in lower retrosternal region and epigastrium, with radiation to the back	Dysphagia, odynophagia; rupture □ mediastinitis □ acute illness, epigastric tenderness, and later subcutaneous emphysema and left pleural effusion

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	**Associated symptoms and signs**
D. Carcinoma	—	Moderate to severe retrosternal pain; radiation to epigastrium with lower lesions and to upper sternum with upper lesions; radiation to neck, interscapular region; pain continuous and aggravated by food ingestion	Dysphagia, odynophagia, weight loss; esophageal obstruction; radiographic, CT, and esophagoscopic evidence
E. Paraesophageal hiatal hernia	XIX-2	Generally asymptomatic; might be feeling of epigastric fullness and lower retrosternal discomfort; with incarceration and strangulation severe, excruciating epigastric and retrosternal pain	Possible massive gastrointestinal hemorrhage; radiographic and esophagoscopic evidence
IV. Diseases of the mediastinum and diaphragm			
A. Mediastinal disorders			
1. Spontaneous mediastinal emphysema	—	Sudden intense, violent, agonizing retrosternal or precordial pain; radiation to nape of neck and shoulder associated with pleural pain; persists for hours	Signs of emphysema: crunching sound in area of pain, decreased or obliterated cardiac dullness, pneumothorax, subcutaneous emphysema (crepitus); radiographic evidence
2. Acute or chronic mediastinitis	—	Continuous; mild to moderate; retrosternal, central; oppressive or burning, aching sensation; can be severe	Systemic signs of infection; history of esophageal rupture or other trauma
3. Neoplasms (anterior compartment, superior compartment, middle compartment, posterior compartment)	—	One-third of patients asymptomatic: remainder have chest pain, cough, dyspnea, and symptoms caused by compression or invasion of structures in mediastinum	Middle compartment: dysphagia, hoarseness; anterior compartment, superior compartment: retrosternal and suprasternal discomfort, local chest pain from pressure on sternum; posterior compartment: neurogenic tumors, vague chest pain, cough, radicular pain from neuropathy, superior vena cava syndrome
B. Diseases of the diaphragm			
1. Diaphragmatic pleuritis	—	Sharp, stabbing *pleuritic* pain along the nape and shoulder or in the posterior and lateral parts of the lower chest and upper abdomen, or both; aggravated by diaphragmatic motion	Signs and symptoms of pneumonitis or infectious processes with inflammation of diaphragmatic pleura
2. Acute primary diaphragmatitis (Hedblom syndrome)	—	Moderate to severe pain in lower chest, upper abdomen, and shoulder	Chills and fever; muscle spasm of abdomen; decreased lung expansion on inspiration; radiographic evidence of flattened diaphragm
3. Diaphragmatic spasm	—	Precordial pain; radiation to shoulder	Dyspnea during sustained spasm of the diaphragm can cause occlusion of esophagus; some patients develop progressive dyspnea, pallor, sweating, hypotension, and angor animi simulating that of acute myocardial infarction; occlusion of the esophagus causes dysphagia and odynophagia
4. Diaphragmatic flutter	—	Lower chest pain felt along the diaphragmatic attachment in the epigastrium, precordium; radiation to the shoulder and occasionally to the neck and arm	Dyspnea, palpitation; symptoms and signs of various causative factors (e.g., encephalitis, intoxication)

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	Associated symptoms and signs
V. Pain of neuropathic origin			
A. Lesions or diseases of the spinal cord (myelopathy)			
1. Intramedullary lesion (tumor, syringomyelia, trauma, multiple sclerosis, abscess, hemorrhage)	I-6	Spontaneous, burning, diffuse, poorly localized pain; bouts of explosive pain; later radicular pain involving several segments, depending on the size of the lesion	Dissociation of sensation, loss of pain and temperature sensation, but little effect on proprioception; sensory changes often "spotty"; lower motor neuron signs; with multiple sclerosis spotty paresthesia, pain, symptoms and signs of other involved parts of CNS
2. Extramedullary lesion (primary or metastatic tumor; abscess; hemorrhage)	I-6	Initially localized back pain but subsequently pain is radicular; aggravated by increase in CSF pressure, such as that caused by straining, sneezing, coughing	Paravertebral tenderness, paresthesia, followed by sensory loss, muscular weakness; lower motor neuron signs at level of lesion; increased deep reflexes; CSF changes early and marked; spinal cord compression with large lesion
3. Epidural spinal cord compression (primary or metastatic tumor, hemorrhage, posterior disk protrusion, abscess, hemorrhage)	—	Localized back pain at level of site of lesion in 95% of patients; bilateral radicular pain in segments affected by lesion in 55%; aggravated by neck flexion, straight leg raising, coughing, sneezing, Valsalva maneuver	Back tenderness on deep palpation, fist pounding; no other early signs, but later muscle weakness ranging from mild degree to paraplegia; numbness and paresthesia in 50%; bladder and bowel dysfunction with low thoracic epidural spinal cord compression
B. Lesions of rootlets or roots of T-1 to T-12 (radiculopathy)			
1. Herpes zoster	I-1	Continuous aching, itching, or burning pain, often with superimposed bouts of severe lancinating pain; hyperalgesia; aggravated by trunk motion, palpation of vesicles; persists until healing of rash (1–4 weeks)	Appearance of rash, later vesicles form and then crust; hyperalgesia and hyperesthesia of skin in affected segments; occasionally systemic symptoms of infection; mood and behavioral changes with unrelieved pain
2. Postherpetic neuralgia	I-1	Severe, continuous, unrelenting burning pain, itching; accompanied by severe paroxysms of stabbing, lancinating pain that persist long after acute phase	Hyperalgesia, hypesthesia, hyperpathia; scar in area of vesicles; reactive depression, sleep disturbances, anorexia, lassitude, constipation, decreased libido; high suicide rate among those with unrelieved postherpetic neuralgia
3. Tabes dorsalis	I-6	Severe, sharp, lancinating, girdlelike (segmental) pain of brief duration with intervals of remission	History of syphilis; CSF evidence; other symptoms of CNS syphilis
4. Mechanical compression (tumor, disk protrusion, vertebral fracture, osteophyte, adhesive arachnoiditis)	—	Segmental sharp, burning pain; aggravated by cough, sneezing, straining, and movement of trunk	Hyperalgesia, hyperesthesia, hypesthesia, dysesthesia; radiographic evidence of pathology
C. Diseases of formed thoracic spinal nerves (neuropathy)			
1. Vertebral compression (arthritis, metastatic or traumatic fracture, tumor of vertebrae, osteomyelitis)	—	Segmental neuralgia usually present: continuous burning or sharp pain affecting part or entire segment of nerve, associated with paroxysms of stabbing pain; compression of anterior root produces dull, aching, occasionally stabbing pain in part of affected segment; both aggravated by movement of thoracic spine; often worse at night	Paravertebral tenderness and segmental hyperalgesia, hyperesthesia, hypesthesia; radiographic evidence (CT scan)

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	Associated symptoms and signs
2. Paravertebral compression (mediastinal tumors, aortic aneurysm, paravertebral abscess or adenopathy)	—	Continuous moderate to severe burning, aching segmental pain; aggravated by movement of spine; occasional bouts of lancinating pain	Paravertebral tenderness; segmental hyperalgesia, hypesthesia; radiographic evidence
3. Primary neurogenic tumors (neurofibroma, schwannoma, ganglioneuroma, neuroblastoma)	—	Possibly localized back pain and tenderness but usually continuous burning, aching pain; associated with lancinating pain in distribution of affected nerve	Sensory deficit (hypesthesia), paresthesia, dysesthesia; CT scan and radiographic evidence
4. Other neuropathies (systemic infection, alcoholism, avitaminosis, diabetes, metals)	—	Continuous or intermittent mild to moderate burning pain; associated with paroxysms of stabbing pain in one or more dermatomes	History of infection, alcoholism, nutrition deficiency, exposure to ingestion of metals; hyperesthesia, hyperalgesia, hypesthesia, paresthesia, dysesthesia; other signs and symptoms of primary disorder
D. Lesion or disease of the intercostal nerves—intercostal neuropathy (compression or irritation secondary to rib fracture; trauma; primary or metastatic tumor of ribs; pleuritis)	—	Superficial continuous burning pain in distribution of affected intercostal nerve; also, local pain with rib fracture or tumor, pleuritic pain with pleuritis	History of trauma or infection; paresthesia, hyperesthesia, dysesthesia, hypesthesia; superficial and deep tenderness; radiographic evidence; palpable tumor or fracture
VI. Pain of musculoskeletal origin			
A. Lesions of the thoracic spine			
1. Fracture (trauma, neoplasm, osteoporosis, subluxation, dislocation)	—	Initially localized dull, aching pain, often referred to anterior part of chest; aggravated by motion, worse and throbbing at night; segmental pain with root compression	History of trauma; radiographic evidence; localized tenderness paravertebrally and over spinous processes; possibly segmental hyperalgesia, paresthesia
2. Metastatic or primary tumors	—	Intense aching, boring circumscribed pain; aggravated by motion and local pressure	Local tenderness or segmental hyperalgesia and hyperesthesia; CT scan and radiographic evidence
3. Arthritis or deformity of spine	—	Usually circumscribed aching pain in back and side; segmental pain with neuropathy	Signs of arthritis in other areas; deformity of spine evident; local tenderness; reflex muscle spasm; radiographic evidence
4. Ankylosing spondylitis	—	Usually circumscribed dull aching pain in back; later paraspinal contractures develop with compression of nerve root, which causes segmental pain	Tenderness on deep palpation; radiographic evidence
5. Diffuse idiopathic skeletal hyperostosis	—	Mild to moderate localized, dull, aching pain; aggravated by inactivity and cold	Tenderness and stiffness in thoracic spine; dorsal kyphosis; reduction of range of movement and in chest expansion; characteristic radiographic evidence
6. Inflammatory disease of vertebrae (osteomyelitis, actinomycosis, tuberculosis, syphilis, subperiosteal hematoma)	—	Circumscribed, continuous, aching pain; moderate to severe; aggravated by pressure, often worse at night	Local and systemic symptoms and signs of inflammation; localized tenderness paravertebrally and over spinous process

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	**Associated symptoms and signs**
7. Costovertebral joint arthritis	—	Localized deep aching pain similar to that arising from vertebral pathology; aggravated by movement; relieved by local infiltration of joint	Tenderness on deep palpation; radiographic evidence
8. Apophyseal facet syndrome	—	Moderate to severe, dull, aching, localized pain and tenderness; aggravated by hyperextension; relieved by flexion of the spine	Tenderness; limitation of motion, flattening of normal kyphotic thoracic curve; paraspinal muscle spasm
B. Rib lesions			
1. Fracture or trauma (severe cough, osteoporosis, metastatic tumor)	—	Localized sharp pain at site of lesion; widespread chest pain with multiple rib fractures; pain aggravated by deep breathing, coughing, movement of thorax	History of accidental trauma or severe coughing; evidence of osteoporosis; exquisite tenderness on palpation of fracture site; radiographic evidence; with compound fracture can have pneumothorax and damage to lung, with respiratory symptoms and signs
2. Primary metastatic rib tumor (myeloma, chondrosarcoma, granuloma)	—	Mild to moderate or severe continuous unilateral dull, aching, chest pain; relatively localized but can also produce intercostal neuralgia	Palpable mass and tenderness to pressure; radiographic evidence
3. Other bone diseases (osteitis deformans, acromegaly, Paget disease, osteoporosis, hyperostosis)	—	Localized continuous aching pain; intercostal neuralgia if lesion irritates nerve	Evidence of disease elsewhere; tenderness on palpation; radiographic evidence
C. Disorders of the costal cartilages			
1. Costochondritis (anterior chest wall syndrome)	—	Unilateral or bilateral aching pain in lower anterior chest wall usually in region of cartilages of third, sixth to seventh ribs; aggravated by deep breathing, coughing, palpation	No swelling of costochondral region; more frequent in younger than older people; development of anxiety and concern about heart disease if pain is on left side
2. Tietze syndrome	—	Localized moderate dull, aching pain in upper anterior chest in region of second and perhaps third costochondral junction; aggravated by palpation, movement of chest wall, coughing, respiratory infection; worse when lying down; recurs between intervals of remission	Palpable tender tumorlike swelling at site of costochondral joint; occurs mostly in people older than 50 years; radiography not diagnostic; development of anxiety, fatigue, concern about heart disease
3. Slipping rib syndrome (rib tip syndrome, slipped cartilage)	XVII-10	Unilateral lower chest and upper abdominal localized aching or sharp pain; aggravated by hyperextension and raising of arms; relieved by forward bending to the affected side	Palpation produces tenderness and reveals upward curling of loosened end of cartilages of eighth, ninth, and tenth ribs; hooking flexed finger under costal cartilage and exerting pressure anteriorly produces clicking noise
4. Fracture of cartilage or dislocation of costochondral joint	—	Sudden sharp pain from fracture or dislocation followed by continuous dull aching, burning discomfort in area of costal margin; reference to back	History of injury; tenderness on palpation; displaced cartilage is palpable and feels like lump
D. Lesions or disorders of the sternum			
1. Fracture of sternum	—	Localized pain in region of sternum, usually sharp initially but then continuous and aching; aggravated by deep breathing or palpation	History of blunt trauma to anterior chest; tenderness to palpation; leads to manubriosternal arthralgia

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	Associated symptoms and signs
2. Rheumatoid arthritis or osteoarthritis	—	Continuous or intermittent pain localized to the angle of Louis; aggravated by deep breathing, coughing, sneezing, and yawning	Mild swelling of joint; exquisite tenderness to palpation; systemic arthritis present; radiographic evidence of arthropathy
3. Xiphoidalgia (hypersensitive xiphoid syndrome, xiphodynia)	—	Spontaneous deep aching or sharp pain varying in intensity from a slight to agonizing discomfort that simulates pain of myocardial infarction; aggravated by movements that act on xiphoid process (e.g., bending, stooping, turning) and by increase in intragastric pressure caused by a large meal; can be constant or recurs several times a day; lasts for minutes to several hours	Pressure on xiphoid process produces spontaneous pain that can radiate deep retrosternally and to the precordium, epigastrium, and across shoulder and back; persists for weeks or months but usually disappears spontaneously
4. Arthritis of sternoclavicular joint	—	Localized sharp or aching pain in region of joint; radiation to shoulder and upper chest	Joint swollen, tender on palpation; radiographic evidence
F. Muscle disorders			
1. Myofascial pain syndromes with trigger points			
a. Anterior chest (major and minor, pectoralis; scaleni; sternalis; intercostals)	—	Frequent cause of pain in anterior chest; pain is deep and aching; aggravated by activity; sternalis and pectoralis pain can simulate pain of angina pectoris; pain relieved by injection of trigger points with local anesthetic	History of severe strain by heavy lifting; local tenderness, trigger points present; unaffected body activity
b. Lateral chest (serratus anterior; intercostals)	—	Deep aching pain on the lateral aspect of the chest extending from the lower axilla to about the seventh to the sixth ribs; pain also in area near the inferior angle of the scapula; with intercostal syndrome site of pain varies with site of trigger points; relief with trigger point injection	Localized tenderness and trigger point about the level of the sixth rib; pressure on trigger points produces spontaneous pain
c. Posterior chest (rhomboidei, latissimus dorsi multifidi, serratus posterior superior, iliocostalis thoracis)	—	Deep aching pain in different parts of the back depending on the site of the trigger point and the muscles involved; aggravated by activity of muscles, unaffected by bodily activity	Localized tenderness and trigger points
2. Acute muscle spasm	—	Sharp localized pain in area of the spastic muscle; some radiation to anterior and posterior chest; complete relief with infiltration of muscle	Palpation of spastic muscle; generalized tenderness
3. Muscle contractures	—	Constant deep aching pain, often associated with early spondylosis	Possible localized tenderness of affected muscle or in an area of reference
4. Dermatomyositis and polymyositis	—	Rarely a cause of chest pain; when present, pain aching and aggravated by palpation	Generalized weakness; elevated serum levels of skeletal muscle enzyme
VII. Pain of tegumentary origin (including the breast)			
A. Acute disorders			
1. Burns and other trauma	—	Sharp burning pain following burns, aching pain with trauma	History of injury or burn; emotional reactions

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	**Associated symptoms and signs**
2. Postoperative pain	—	Fairly localized sharp, burning, aching pain primarily at the site of incision; can radiate to involve adjacent segments	Reflex muscle spasm, tenderness; hyperalgesia; tachycardia response; signs of neuroendocrine stress
3. Acute mastodynia (inflammatory)		Sharp, aching, burning pain in chest; radiation to axilla and inner arm; aggravated by movement of the breast	Extreme tenderness, tumefaction; evidence of infection
4. Deep axillary abscess		Sharp localized, diffuse dull, aching pain in axilla; radiation to anterior chest and medial arm	Tenderness, fluctuating mass; signs of infection
5. Acute dermatologic disorders (vesicles, furuncles, bullae, pustules, ulcers, erythema, cellulitis)	—	Aching, burning, itching pain localized to lesion	Possible evidence of local or systemic disease
B. Chronic disorders			
1. Postmastectomy syndrome 2. Postthoracotomy syndrome		Sharp, burning, aching pain; accompanied by bouts of lancinating pain in distribution of the dermatomes supplied by the injured nerve or in part of the segment; aggravated by light touch of skin, palpation of neuroma, and emotional stress	Hyperesthesia, hyperalgesia, hypesthesia, paresthesia; neuroma often palpable; evidence of recurrent cancer by use of CT scan or other diagnostic procedures
3. Adiposis dolorosa (Dercum disease)	—	Enlarged painful fatty subcutaneous nodule most commonly in the chest and arms but can affect any part except the face; usually darting, shooting, or stabbing pain; occurs spontaneously or provoked by palpation	Usually occurs in obese women; weakness, fatigue, emotional instability, occasional dementia
4. Chronic mastalgia	—	Chronic persistent pain; cyclic in two-thirds of patients and continuous in the other third; deep, aching, diffuse pain over entire breast without palpable evidence of pathology; about 20% have spontaneous intermittent relief while others have relief at menopause or pregnancy or with use of oral contraceptives; those with noncyclic pain have pain that can persist for 2–3 years or for as long as 30 years	Psychological tests usually reveal no abnormality; positive response to hormonal manipulation suggests a hormonal basis to the condition
5. Scleroderma (dermatomyositis, disseminating lupus erythematosus, polyarteritis nodosa)	—	Dull, aching, occasionally burning pain in the chest wall, usually in the area of the lesion; with scleroderma, chest pain can arise from skin, thoracic wall, or myocardial or esophageal lesions	Symptoms and signs of systemic disease; many types produce widespread visceral involvement
6. Other chronic dermatologic diseases	—	(See Chapter 31 for detailed discussion)	
7. Mondor disease (phlebitis of anterolateral chest)	—	Rare condition manifested by thrombosis of superficial vein of thoracic wall that produces palpable painful cord within the skin; usually sharp and persistent; intensified by deep inspiration or flexion of the trunk	Presence of painful, tender, subcutaneous cord running obliquely across thorax in distribution of one or more superficial veins; lesion indolent after several weeks

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	**Associated symptoms and signs**
C. Cancer of the breast	—	Early breast cancer not painful; in far advanced disease skin nodule eventually breaks down and formation also causes localized breast pain; metastasis to the pleura produces pleuritic pain; metastasis to the ribs causes localized pain and can be associated with segmental neuralgia; metastasis to the spine produces back pain and later can cause epidural spinal cord compression or plexopathy	Early: retracted nipple, bleeding, distorted areola or breast contour, skin dimpling (*peau d'orange*); later: axillary supraclavicular adenopathy; metastatic lesion demonstrated by radiography and CT scan
VIII. Chest pain referred from extrathoracic disorders			
A. Disorders of the cervical spine that cause neuropathy			
1. Posterolateral protrusion of intervertebral disk (C-7, C-8)		Pain in the neck, shoulder, medial aspect of the arm, and pectoral region of the chest; with left-sided lesion, pain can simulate that of myocardial ischemia but is differentiated by aggravation by lateral flexion and the Spurling test (see Chapter 54); unaffected by activity if neck and arms not moved	Paravertebral and pectoral muscle tenderness; hyperalgesia, hyperesthesia, and paresthesia of the arm; decrease in reflexes and some muscle weakness in the upper limbs
2. Arthritis, osteophyte, fracture or other lesion that compresses root or nerve			
3. Thoracic inlet syndromes (scalenus anticus syndrome; cervical rib or abnormal first rib; costoclavicular compression)	—	Pain most prominent in the shoulder and upper limbs; radiation to the upper pectoral region; aggravated by severe arm abduction and walking with swinging arms; unaffected by activity if arms not moved	Supraclavicular (scaleni) tenderness and fullness; neurovascular signs and symptoms in the upper extremities; radiographic evidence of abnormal cervical rib
4. Pancoast syndrome	—	Pain in shoulder, scapula, medial aspect of arm, and superior anterior chest; aggravated by extreme abduction of the arm and paravertebral pressure; unaffected by activity if neck and limbs are not moved	Signs and symptoms of plexopathy with paresthesia, dysesthesia, numbness in the medial aspects of the forearm and fourth and fifth fingers, also medial aspect of arm; marked weakness of muscles supplied by ulnar nerve; radiographic and CT scan evidence of lesion
B. Diseases of the abdominal viscera			
1. Gas entrapment syndromes (e.g., caused by aerophagia, excess production of gas in bowel)	—	Bloated sensation associated with pain in the epigastrium and central lower chest; if diaphragm irritated, pain also in shoulder; dull, aching pain worsens as day progresses; transiently relieved by belching; gas entrapment in hepatic flexure of colon produces discomfort in right upper quadrant and lower part of right chest, gas in splenic flexure causes pain in left upper quadrant and left lower chest	History of aerophagia, abdominal tympany; radiographic evidence

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	**Associated symptoms and signs**
2. Peptic ulcer disease	—	Ulcer in cardia of stomach produces pain in the epigastrium and central lower anterior chest, ulcer in other locations not associated with chest pain; duodenal ulcer causes pain that radiates to xiphoid process but not higher	Peptic ulcer confirmed by radiography and endoscopy
3. Perforated ulcer	—	Sudden severe epigastric pain that can radiate to lower chest with severe hypotension; myocardial ischemia; anginal pain	History, physical signs (e.g., muscle spasm, shock, diaphoresis, hematemesis)
4. Biliary colic	—	Sudden moderate to severe epigastric pain; radiation to back; right subcostal region, and low central portion of right chest; rarely, pain confined only to chest mimicking that of myocardial infarction, but no radiation to arm or jaw	Patient can have nausea but no vomiting; in distress but no fever; subcostal tenderness
5. Acute cholecystitis	—	Pain usually localized to right upper quadrant; lasts few days rather than a few hours; chest pain rare except in patients with coexisting coronary artery disease: in these patients, biliary pain provokes angina pectoris and ECG changes (low amplitude and inversion of T wave)	Nausea, vomiting, fever, jaundice, and tender right upper quadrant mass; abdominal muscle spasm
6. Acute pancreatitis	—	Sudden severe epigastric pain associated with retrosternal oppression; radiation to lower part of left side of chest; unaffected by effort; often provokes ECG changes similar to those of myocardial ischemia and infarction	Severe abdominal muscle spasm; often hypotension, hypoventilation, elevated blood amylase level
7. Subphrenic abscess	—	Pus from perforated viscus produces subdiaphragmatic abscess with inflammation of the diaphragm; pleuritic pain in the lower chest and often the shoulder; intrapleural rupture of amebic liver abscess; sudden severe chest pain	Dyspnea, fever, pleural effusion and, occasionally, hepatomegaly
IX. Chest pain primarily of psychological origin			
A. Acute anxiety state	—	Sudden acute diffuse pain in chest in the precordial region near cardiac apex (not retrosternal); severe, sharp, stabbing pain or dull, heavy pressure experienced after effort, not during	Dyspnea (air hunger) leading to hyperventilation, tachycardia, dizziness, palpitations, perspiration, tremor, weakness, chest tightness; psychological evaluation and testing reveal evidence of anxiety
B. Chronic anxiety (cardiac neurosis, soldier's heart, neurocirculatory asthenia, irritable heart, effort syndrome)	—	Pain usually at apex of the heart; felt as dull ache with or without attacks of sharp pain over same area; either of brief duration or continuous for hours and days; associated with fatigue rather than effort; responds poorly to all medication	Chronic anxiety and apprehension; severe dyspnea; respiratory distress both at rest and with exertion, sighing respirations; possible ECG changes; low energy level; psychological evaluation and testing reveal psychopathology

(*continued*)

TABLE 69.3

CONTINUED

Etiology (disease)	IASP code reference†	Important diagnostic features	
		Characteristics of the pain	**Associated symptoms and signs**
C. Depression	—	Endogenous depression can cause atypical chest pain described as a heavy feeling or deep ache or tightness; possible radiation to left arm; usually worse in the morning, lessens as the day goes on	Feeling of overconcern with the heart; in primary affective disorder patient complains of feelings of depression, guilt, worthlessness, withdrawal, disinterest; occasional suicidal preoccupation, anorexia, weight loss, fatigue, low energy level, malaise, insomnia; psychological evaluation and testing reveal psychopathology
D. Hypochondriasis	—	Precordial or apical pain; pain described by patient in minute detail regarding location, quality, and duration but does not fit pattern of any *organic* disease, and description of the pain changes from one visit to another	Feeling of overconcern with the heart; many other complaints (e.g., dysfunction of gastrointestinal tract); may present different complaints at different visits; psychological evaluation and testing produces evidence of psychopathology
E. Operant pain (learned pain)	—	Initially patient has chest pain from disease of the heart or lungs that persists after healing because of reinforcing environmental factors; develops chronic pain behavior and abnormal illness behavior	Progressive physical deterioration over time because of inactivity, muscle weakness, and other factors that cause pain and reinforce the behavior; psychological evaluation and testing reveal psychopathology

†See Table 2-2.

Our growing treatment armamentarium includes analgesic and neuropathic medications, nerve blocks and ablations, joint injections, implanted pumps, transcutaneous or implanted electrical stimulators, as well as behavioral medicine approaches. In many cases of chest wall pain, conservative, multidisciplinary approaches are initially preferred, saving invasive treatments for the refractive cases.

CHAPTER 70 ■ LOWER EXTREMITY PAIN

GAGAN MAHAJAN AND DAVE LOOMBA

The information in this chapter is presented in three major sections detailing: (1) specific causes of lumbosacral plexopathy; (2) specific lower extremity peripheral nerve lesions; and (3) specific causes of foot pain.

LUMBOSACRAL PLEXOPATHY

Although the lumbar and sacral plexi are separate structures, they are often referred to as a single structure—the lumbosacral plexus—that provides motor and sensory innervation to the pelvis and leg (Fig. 70.1). The lumbar plexus, which is made up of the ventral rami of the T12–L3 and a portion of the L4 nerve roots, is contained within the psoas muscle and lies anterior to the L2–L5 vertebral bodies.[1–3] The anterior and posterior divisions of the ventral rami form the terminal branches of the lumbar plexus and include the iliohypogastric (T12,L1), ilioinguinal (L1), genitofemoral (L1,L2), lateral femoral cutaneous (L2,L3), obturator nerves (L2,L3,L4), and femoral (L2,L3,L4) nerves.[3] The saphenous nerve is a branch of the femoral nerve.

The sacral plexus (Fig. 70.2), which is made up of the ventral rami of the S1–S5 nerve roots, connects with the lumbar plexus via the lumbosacral trunk. It is made up of the ventral rami of the L4–L5 nerve roots and lies just anterior to the piriformis muscle, posterior to the internal iliac vessels, and in close proximity to the hypogastric arteries and veins, lateral rectum, pelvic colon, and ureters.[2,3] Similar to the lumbar plexus, terminal branches arise from the anterior and posterior divisions of the ventral rami of the sacral plexus. The tibial nerve (made up of the anterior divisions of the ventral rami) and the common fibular (peroneal) nerve (made up of the posterior divisions) form the terminal branches of the sciatic nerve upon bifurcating from their common epineural sheath.[3] Additional terminal branches of the sacral plexus include the superior gluteal (L4,L5,S1) inferior gluteal (L5,S1,S2), posterior femoral cutaneous (S1,S2,S3), and pudendal (S2,S3,S4) nerves.[3]

There are multiple causes of lumbosacral plexopathy. These include space-occupying masses (invasive neoplasm, compression by retroperitoneal or pelvic mass), vascular/metabolic diseases (diabetes, chronic idiopathic peripheral polyneuoropathy, vasculitis, aneurysmal dilation), trauma (pelvic fractures, complications from surgery or radiation therapy), and idiopathic causes.[4] Nontraumatic lesions are the most common, as evidenced by one report of 86 cases revealing a neoplastic etiology in more than 50% and trauma in only 6%.[3] Patellar reflex impairment along with hip flexion, knee extension, and/or dorsiflexion weakness suggests lumbar plexopathy; whereas, ankle reflex impairment

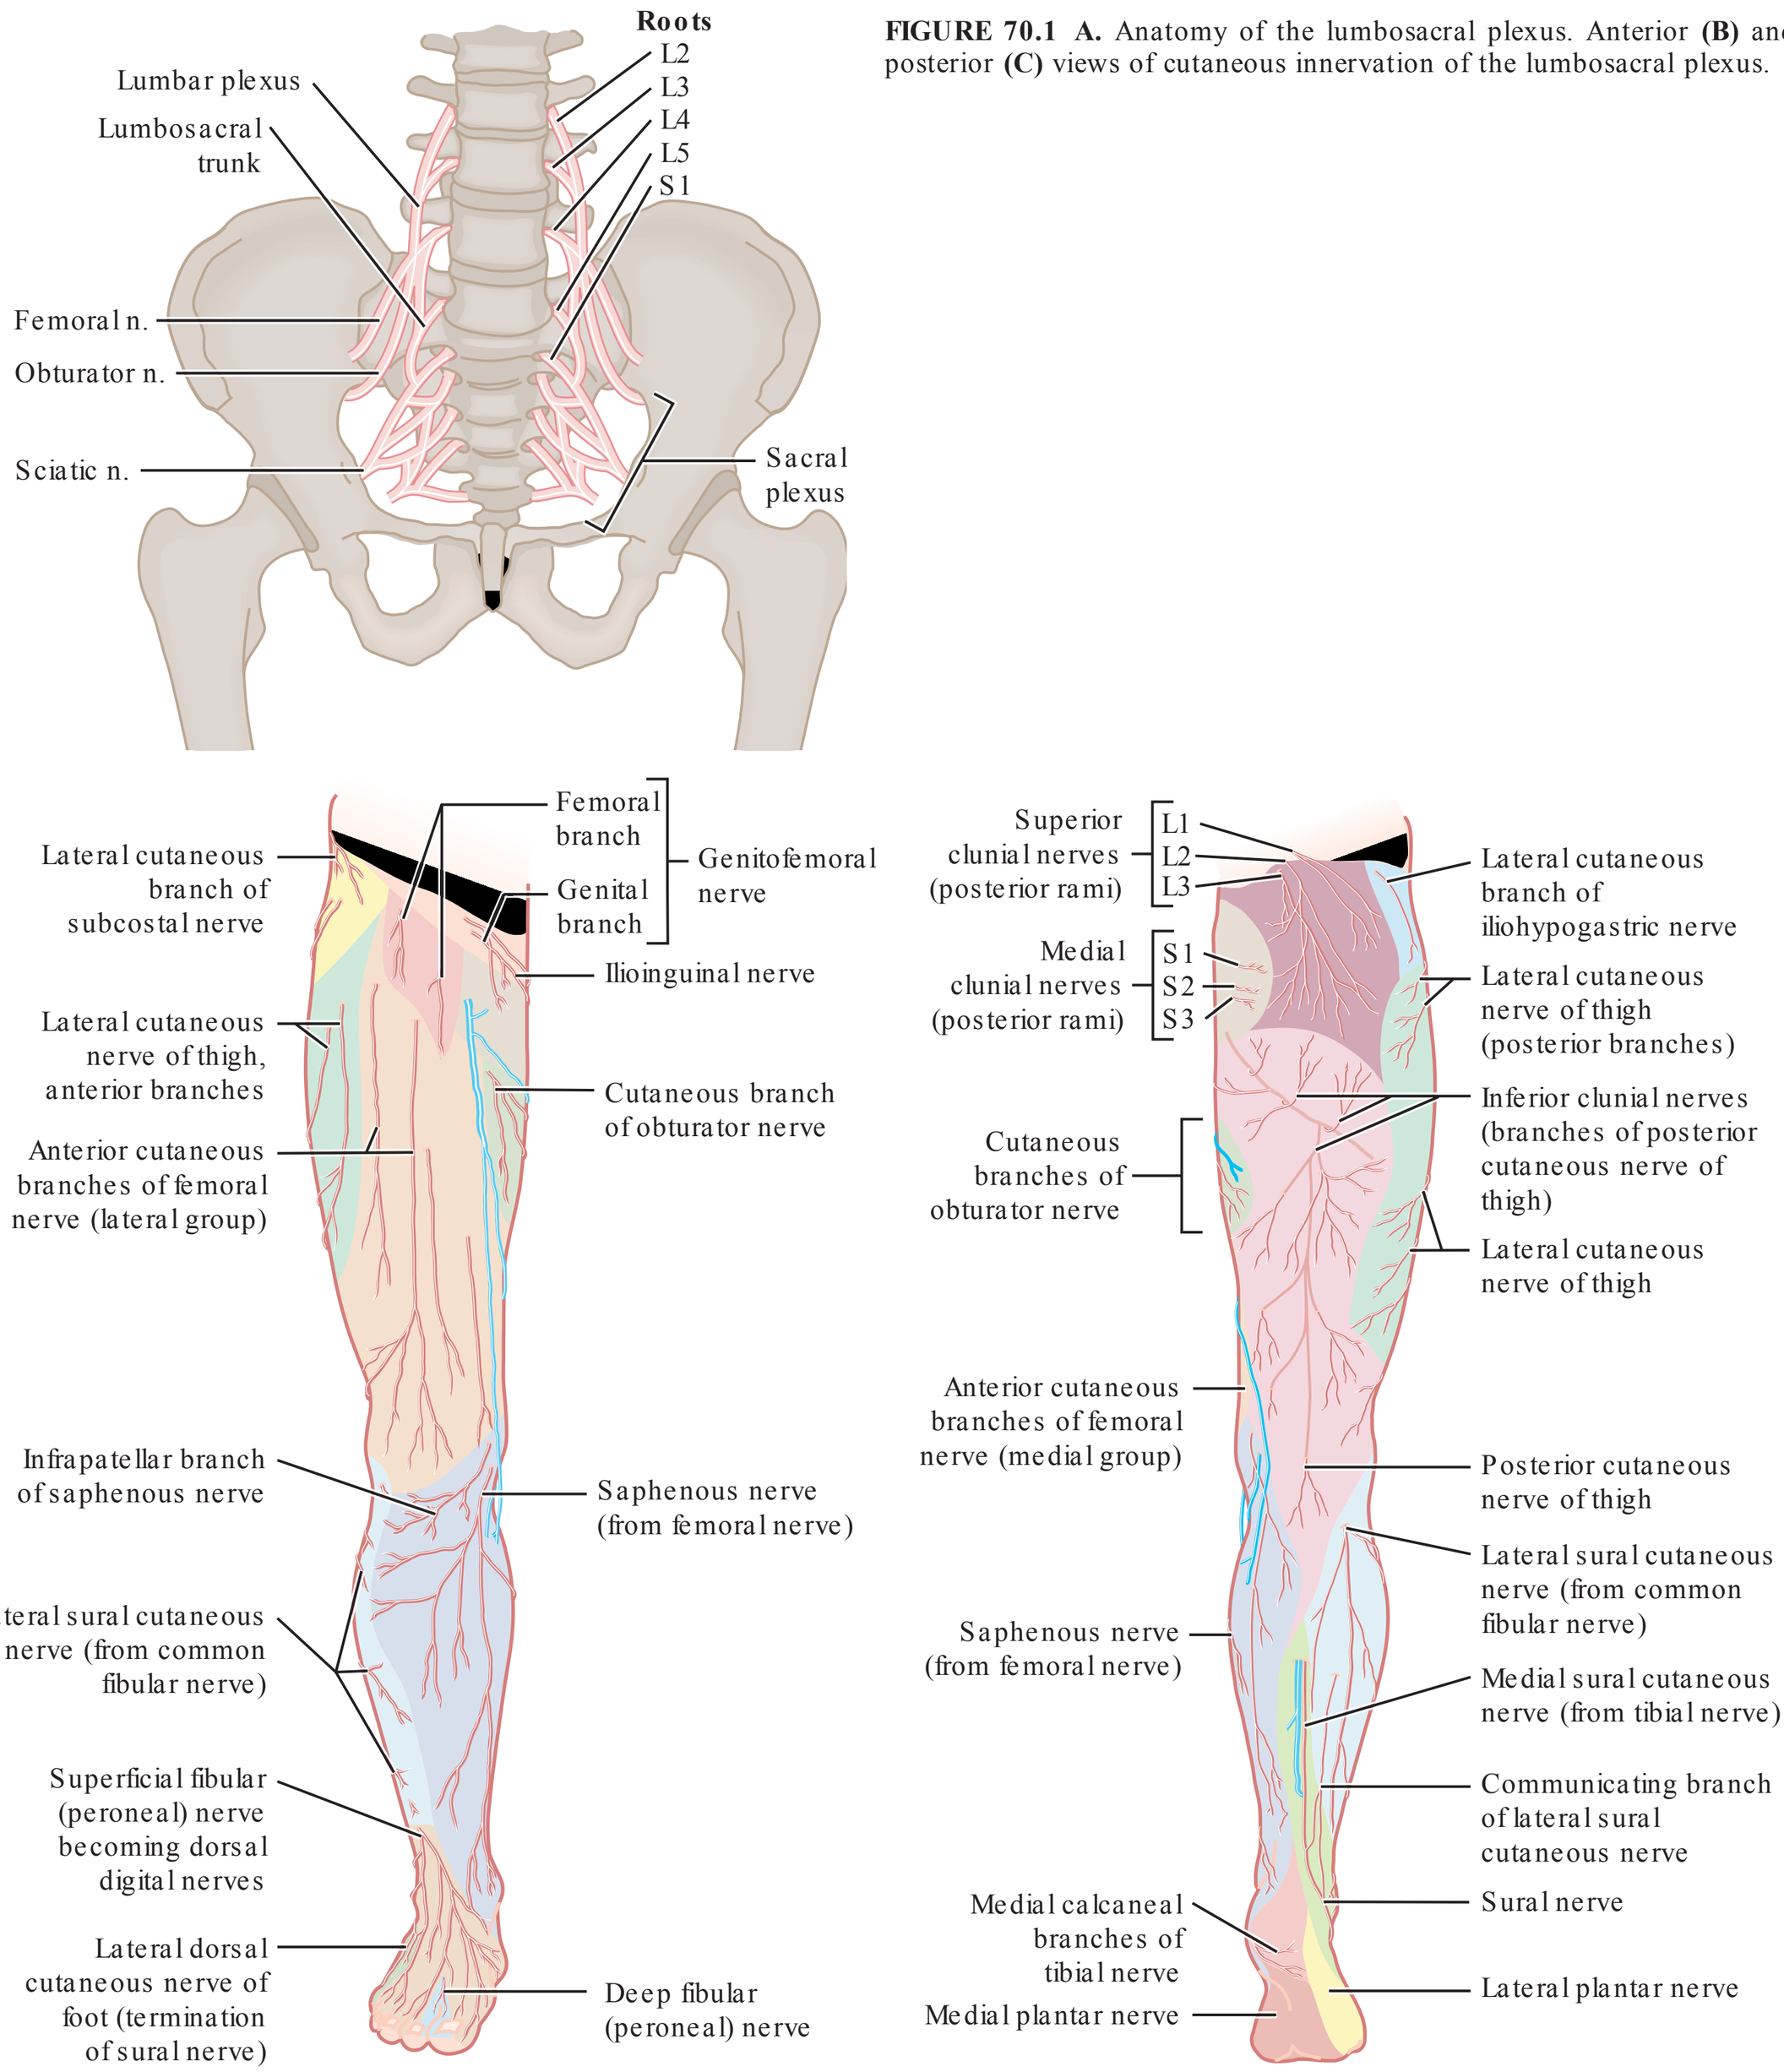

FIGURE 70.1 **A.** Anatomy of the lumbosacral plexus. Anterior **(B)** and posterior **(C)** views of cutaneous innervation of the lumbosacral plexus.

along with hip extension, knee flexion, and/or plantarflexion weakness suggests sacral plexopathy.

Depending on the cause, diagnostic workup for plexopathy can include plain film x-ray imaging, detailed neuroimaging (computed tomography [CT] and magnetic resonance imaging [MRI]), angiography, ultrasonography, electrodiagnostic studies (electromyography [EMG] and nerve conduction study [NCS]), and laboratory studies. Diagnostic studies in isolation of the patient's medical history and physical exam findings, however, have limitations. For example, neuroimaging may not be able to differentiate between benign tumor versus malignant tumor versus radiation-induced plexopathy. Likewise, electrodiagnostic studies may not be able to differentiate between peripheral neuropathy versus plexopathy.[3] Electrodiagnostic studies, however, may be

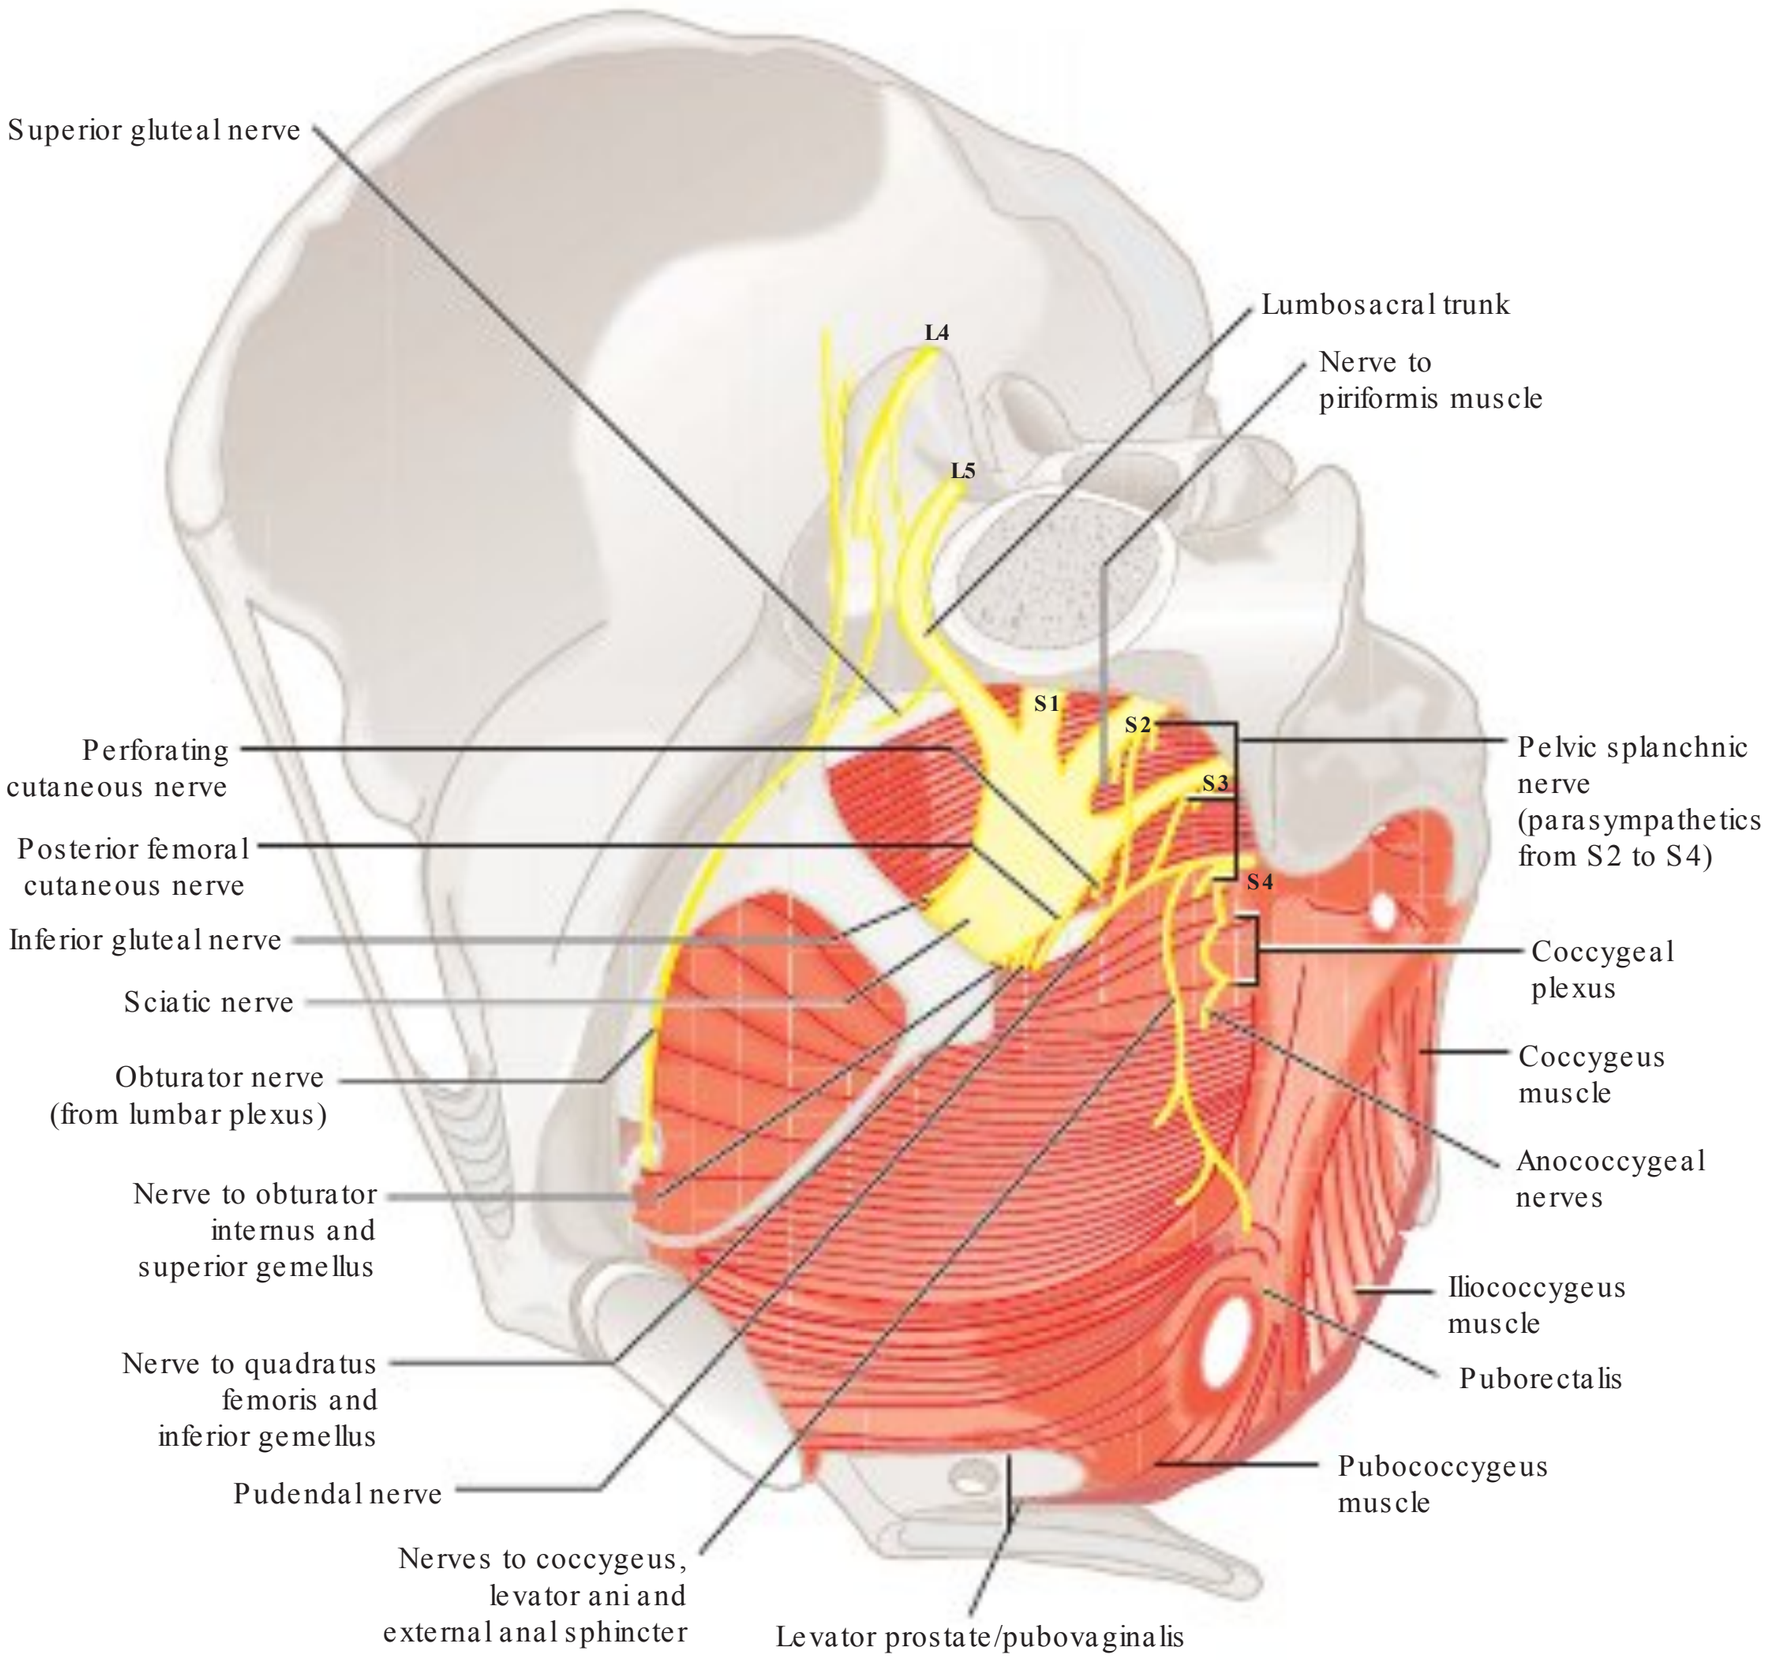

FIGURE 70.2 Oblique sagittal view of the sacral plexus.

able to provide information on the extent of motor axon loss or on the presence of muscle denervation when clinical assessment is limited by the cause of injury.

Treatment options depend on the cause, location, severity, and duration of the plexopathy.[3] In certain situations, surgery may be the initial treatment of choice, whereas in other circumstances observation and symptom management may be the preferred approach. Conservative therapy for symptomatic relief includes medications (corticosteroids, acetaminophen, nonsteroidal anti-inflammatory drugs, anticonvulsants, tricyclic antidepressants, opioids, topical analgesics, and lidocaine patch) and injections. Spinal cord stimulation or intrathecal therapies may be considered for those who have a suboptimal response to the aforementioned and/or those who are not surgical candidates. Physical therapy is important for those with evidence of motor weakness in order to minimize muscle atrophy, prevent muscle contractures, and maintain ambulatory status. Assessment for orthotic devices (e.g., ankle-foot orthosis [AFO], etc.) and gait assistive devices (e.g., crutches, cane, walker, etc.) also may be necessary in order to prevent falls.

Neoplasms

In comparison to neoplastic involvement of the lumbosacral spinal nerves, cauda equina, or conus medullaris, lumbosacral plexus involvement is relatively uncommon and has a reported incidence of 0.71%.[5,6] Neoplastic plexopathies can involve the sacral plexus (50%), lumbar plexus (33%), or lumbosacral plexus (17%).[3,7] Most are of malignant origin, with 75% occurring by direct extension (most commonly from gastrointestinal tumors, genitourinary tumors lymphomas, sarcomas), or metastasis.[3,5] Breast cancer is the most common primary source and rarely is the diagnosis of neoplastic plexopathy made before discovery of the primary neoplasm.

Neoplastic plexus involvement portends a poor prognosis, with death often occurring within 6 months of diagnosis.[5] Insidious onset of low back pain (lumbar plexus) and/or leg pain (sacral plexus) are often the primary heralding features and can precede other neurologic symptoms.[1,3,5,7] At initial onset, unilateral leg pain is present in 90% of patients and tends to be more prominent than low back pain.[8] The pain can have both nociceptive and neuropathic features and is worse with recumbency, movement, and Valsalva maneuvers.[1] Lumbar plexus involvement is also suggested by localization of pain over the costovertebral angle, anterior abdominal wall, groin, or thigh, and by painful fixed flexion of the hip worsened by passive or active hip extension (also known as malignant psoas syndrome).[1,9,10] Within 13 months of pain onset, many patients develop additional neurologic symptoms: weakness (86%), gait dysfunction, sensory loss (73%), reflex impairment (64%), and paroxysmal or continuous paresthe-

sias or dysesthesias.[1,3,5,6,8] Additional physical exam findings may include: (a) lower extremity edema (seen in 50%); (b) warm and dry foot (seen with sympathetic nerve involvement); (c) palpable rectal mass and perineal pain (seen in more than one third with sacral involvement); (d) incontinence and impotence (seen in 10%, usually implying extensive sacral involvement with bilateral sacral plexopathy); and (e) abdominal and pelvic pain.[1,3,6,11] The differential diagnosis, however, must also include radiation-induced plexopathy, peripheral neuropathy, radiculopathy, cauda equina syndrome, retroperitoneal hematoma, and vertebral compression fracture.[1]

In general, tumors can be classified as intrinsic or extrinsic. Intrinsic tumors can be benign (neurofibromas and plexiform lesions) or malignant (i.e., schwannoma or neurogenic sarcoma).[1] Neurofibromas, which are common in patients with neurofibromatosis type 1, are commonly seen in the paraspinal, sacral plexus, sciatic notch, and perirectal regions.[12] Patients may or may not have symptoms with benign or malignant tumors, and MRI alone may be insufficient to differentiate one from the other. Symptomatic relief with analgesic medications may be necessary until the tumor can be excised.

Extrinsic tumors are malignant. Lymphoma can cause a plexopathy due to enlarged lymph nodes (most common), extranodal disease in the muscle (e.g., psoas, iliacus, piriformis, and gluteal muscles) or subcutaneous fat, or direct sciatic nerve involvement (rare).[2] Carcinomas (colorectal, genitourinary, breast, lung, and prostate) and retroperitoneal sarcomas can cause a plexopathy by encasement of the plexus by the primary tumor itself, metastasis into the surrounding soft and bony tissue, or metastasis into the plexus itself.[1,2] Sacral chordomas, which can cause constipation, urinary frequency, and sciatica, are the most common primary malignant sacral tumors.[2] Imaging with MRI, CT or positron emission tomography-CT may help with the work-up of these extrinsic tumors. Chemotherapy, radiation therapy, and/or surgical resection of the tumor is usually indicated.

Radiation-Induced Plexopathy

Pelvic radiation therapy to treat urological cancers, gynecological cancers, and lymphomas can result in radiation-induced lumbar, sacral, or lumbosacral plexopathy. Unlike neoplastic plexopathy which is often associated with significant pain and weakness, radiation plexopathy is primarily associated with weakness, with significant pain being present in fewer than 25% of patients.[8] Weakness is noted predominantly in the distal L5-S1 innervated muscles and may be accompanied by reflex and sensory impairment, skin changes, and lymphedema; bowel or bladder disturbance is rare.[8,11] The mean duration of symptom onset is 5 years but can vary from a few months to more than three decades.[3,11] Skin changes and lymphedema are commonly seen.[8] Because of obvious therapeutic implications, neuroimaging studies are critically important in order to discriminate between tumor recurrence, radiation fibrosis, and surgical scar tissue. Electrodiagnostic studies should be included to help establish the diagnosis when neuroimaging findings are nonspecific. Characteristic electrodiagnostic findings include demyelinating conduction block and myokimia.[3] If electrodiagnostic findings are also nonspecific, the diagnosis usually needs to be confirmed by biopsy or surgical exploration. For those with only radiation-induced plexopathy, treatment is nonsurgical and involves symptom management.[3]

Diabetic and Nondiabetic Lumbosacral Radiculoplexus

Diabetic lumbosacral radiculoplexus (diabetic amyotrophy) involves microvasculitic ischemic nerve injury. It most commonly occurs in elderly patients with chronic type 2 diabetes mellitus and does not occur in isolation of diabetic peripheral polyneuropathy.[3] Patients usually report weight loss and low back and/or leg pain that is worse at night. These symptoms are often followed by signs of weakness, atrophy, and sensory deficits involving the anterior thigh along with an absent patellar reflex. Electrodiagnostic findings include axonal loss, demyelination, and denervation changes in muscles innervated by the obturator and femoral nerves.[3] Neuroimaging is necessary to rule out other potential causes of lumbosacral plexopathy. Because the plexopathy is due to ischemic nerve injury, treatment focuses on symptom management, physical therapy, and assessment for a gait assistive device.

Nondiabetic lumbosacral radiculoplexus is an underappreciated cause of lumbosacral plexopathy. Similar to diabetic lumbosacral radiculoplexus, it involves microvasculitic (motor, sensory, and autonomic) nerve injury, initially involves the legs, and is associated with pain, weight loss, prolonged morbidity and mortality, and incomplete recovery.[13] Both nondiabetic and diabetic lumbosacral radiculoplexus also share similar electrodiagnostic findings and treatment strategies. Unlike diabetic lumbosacral radiculoplexus, it is not associated with hyperglycemia and is probably due to an autoimmune phenomenon.[13]

Abscess

Psoas, gluteal, and pelvic abscesses can present acutely or insidiously with painful fixed flexion of the hip or pain in the abdominal, pelvic, or gluteal regions. In their retrospective analysis of 23 retroperitoneal collections related to the psoas muscle, Paley et al.[14] confirmed 5 were hematomas and 18 were abscesses; and of the abscesses, 3 were caused by primary infections and the remainder by infections of spinal, renal, or gastrointestinal origin. Because their appearance on MRI and CT can be confused with lymphoma or tumor deposits, image-guided percutaneous drainage can be of diagnostic and therapeutic value.[2]

Retroperitoneal Hematoma

Retroperitoneal hematomas can occur from anticoagulant therapy, hemophilia, ruptured aortic aneurysms, idiopathically, or iatrogenically (e.g., cardiac catheterization).[2,15] The degree of neurologic deficit depends on the size of the hematoma: (a) a small hematoma compresses the intrapelvic portion of the femoral nerve within the iliacus muscle; (b) a large hematoma compresses the lumbar plexus within the psoas muscle, affecting both the obturator and femoral nerves; and (c) a widespread hematoma affects the lumbosacral plexus.[2] Signs and symptoms may include ecchymosis (flank, low back, and/or thigh) and acute or subacute onset of lower abdominal or groin pain radiating to the anterior thigh. Neuroimaging facilitates the diagnosis. Electrodiagnostic findings include axonal loss in the distribution of the femoral nerve or lumbar plexus (though involvement of the lumbosacral plexus can also occur) and EMG abnormalities in the adductor muscle.[3] Even though retroperitoneal hematomas are considered compartment syndromes, treatment is nonsurgical.[3]

Aneurysms

Aneurysms of the distal aorta, iliac arteries, intrapelvic arteries, and hypogastric arteries and arteriovenous malformations can injure the lumbosacral plexus via direct compression or ischemia from embolism of feeding vessels.[2,3] Symptoms may include low back pain with or without radicular symptoms, sensory loss, and weakness. The diagnostic work-up initially includes an abdominal and pelvic ultrasound, followed by neuroimaging and angiography. The electrodiagnostic finding includes axonal loss, but

pinpointing the location is often challenging.[3] Treatment involves surgical repair of the aneurysm.

Trauma

Traumatic injuries to the lumbosacral plexus, in comparison to the brachial plexus, occur infrequently because the neural structures are (a) relatively distant to highly mobile structures and (b) well protected by muscle and bone.[3] Therefore, trauma-induced lumbosacral plexopathy typically results from penetrating or violent injuries—gunshot blast, high-speed motor vehicle or motorcycle accident, pedestrian versus motor vehicle accident, or fall from a tall height—and is often associated with pelvic bony fractures. Isolated fractures involving the nonweight-bearing anterior one third of the pelvic ring are often stable and do not result in neurovascular injury. Conversely, because the posterolateral two thirds of the pelvic ring is involved with weight bearing and lays in close proximity to neurovascular structures, fractures in this area lead to instability and neurovascular compromise.[3] Symptoms can include variable degrees of pain, sensory and reflex impairment, muscle weakness, atrophy, and gait abnormality. Treatment involves identifying the extent of neurovascular injury. Since most nerve traumatic injuries spontaneously improve (to a certain degree) and surgical repair can be technically challenging, surgery is not recommend as the initial treatment of choice.[3] Of those who do require surgery, outcomes are relatively better with repair of the lumbar instead of sacral plexus.[3] Neuropathic pain persisting beyond the anticipated healing process suggests the presence of a neuroma or scar tissue. Treatment may involve additional surgery to remove the neuroma or scar tissue, medication management, or implantation of a spinal cord or peripheral nerve stimulator.

Obstetric-Related Plexopathy

Compression of the lumbosacral plexus between the pelvic rim and fetal head can occur during the latter stages of pregnancy or during delivery (Fig. 70.3).[3] Katirji et al.[16] described seven patients with intrapartum maternal lumbosacral plexopathy who shared common features: short maternal stature, prolonged labor, pain and demyelination in an L5 nerve root distribution, foot drop, and complete resolution of symptoms within 5 months. A large fetal head or the use of forceps can also cause compression of the lumbosacral plexus. Neuroimaging may be of limited benefit when the fetus is present. Electrodiagnostic abnormalities include a demyelinating conduction block of nerves supplying the

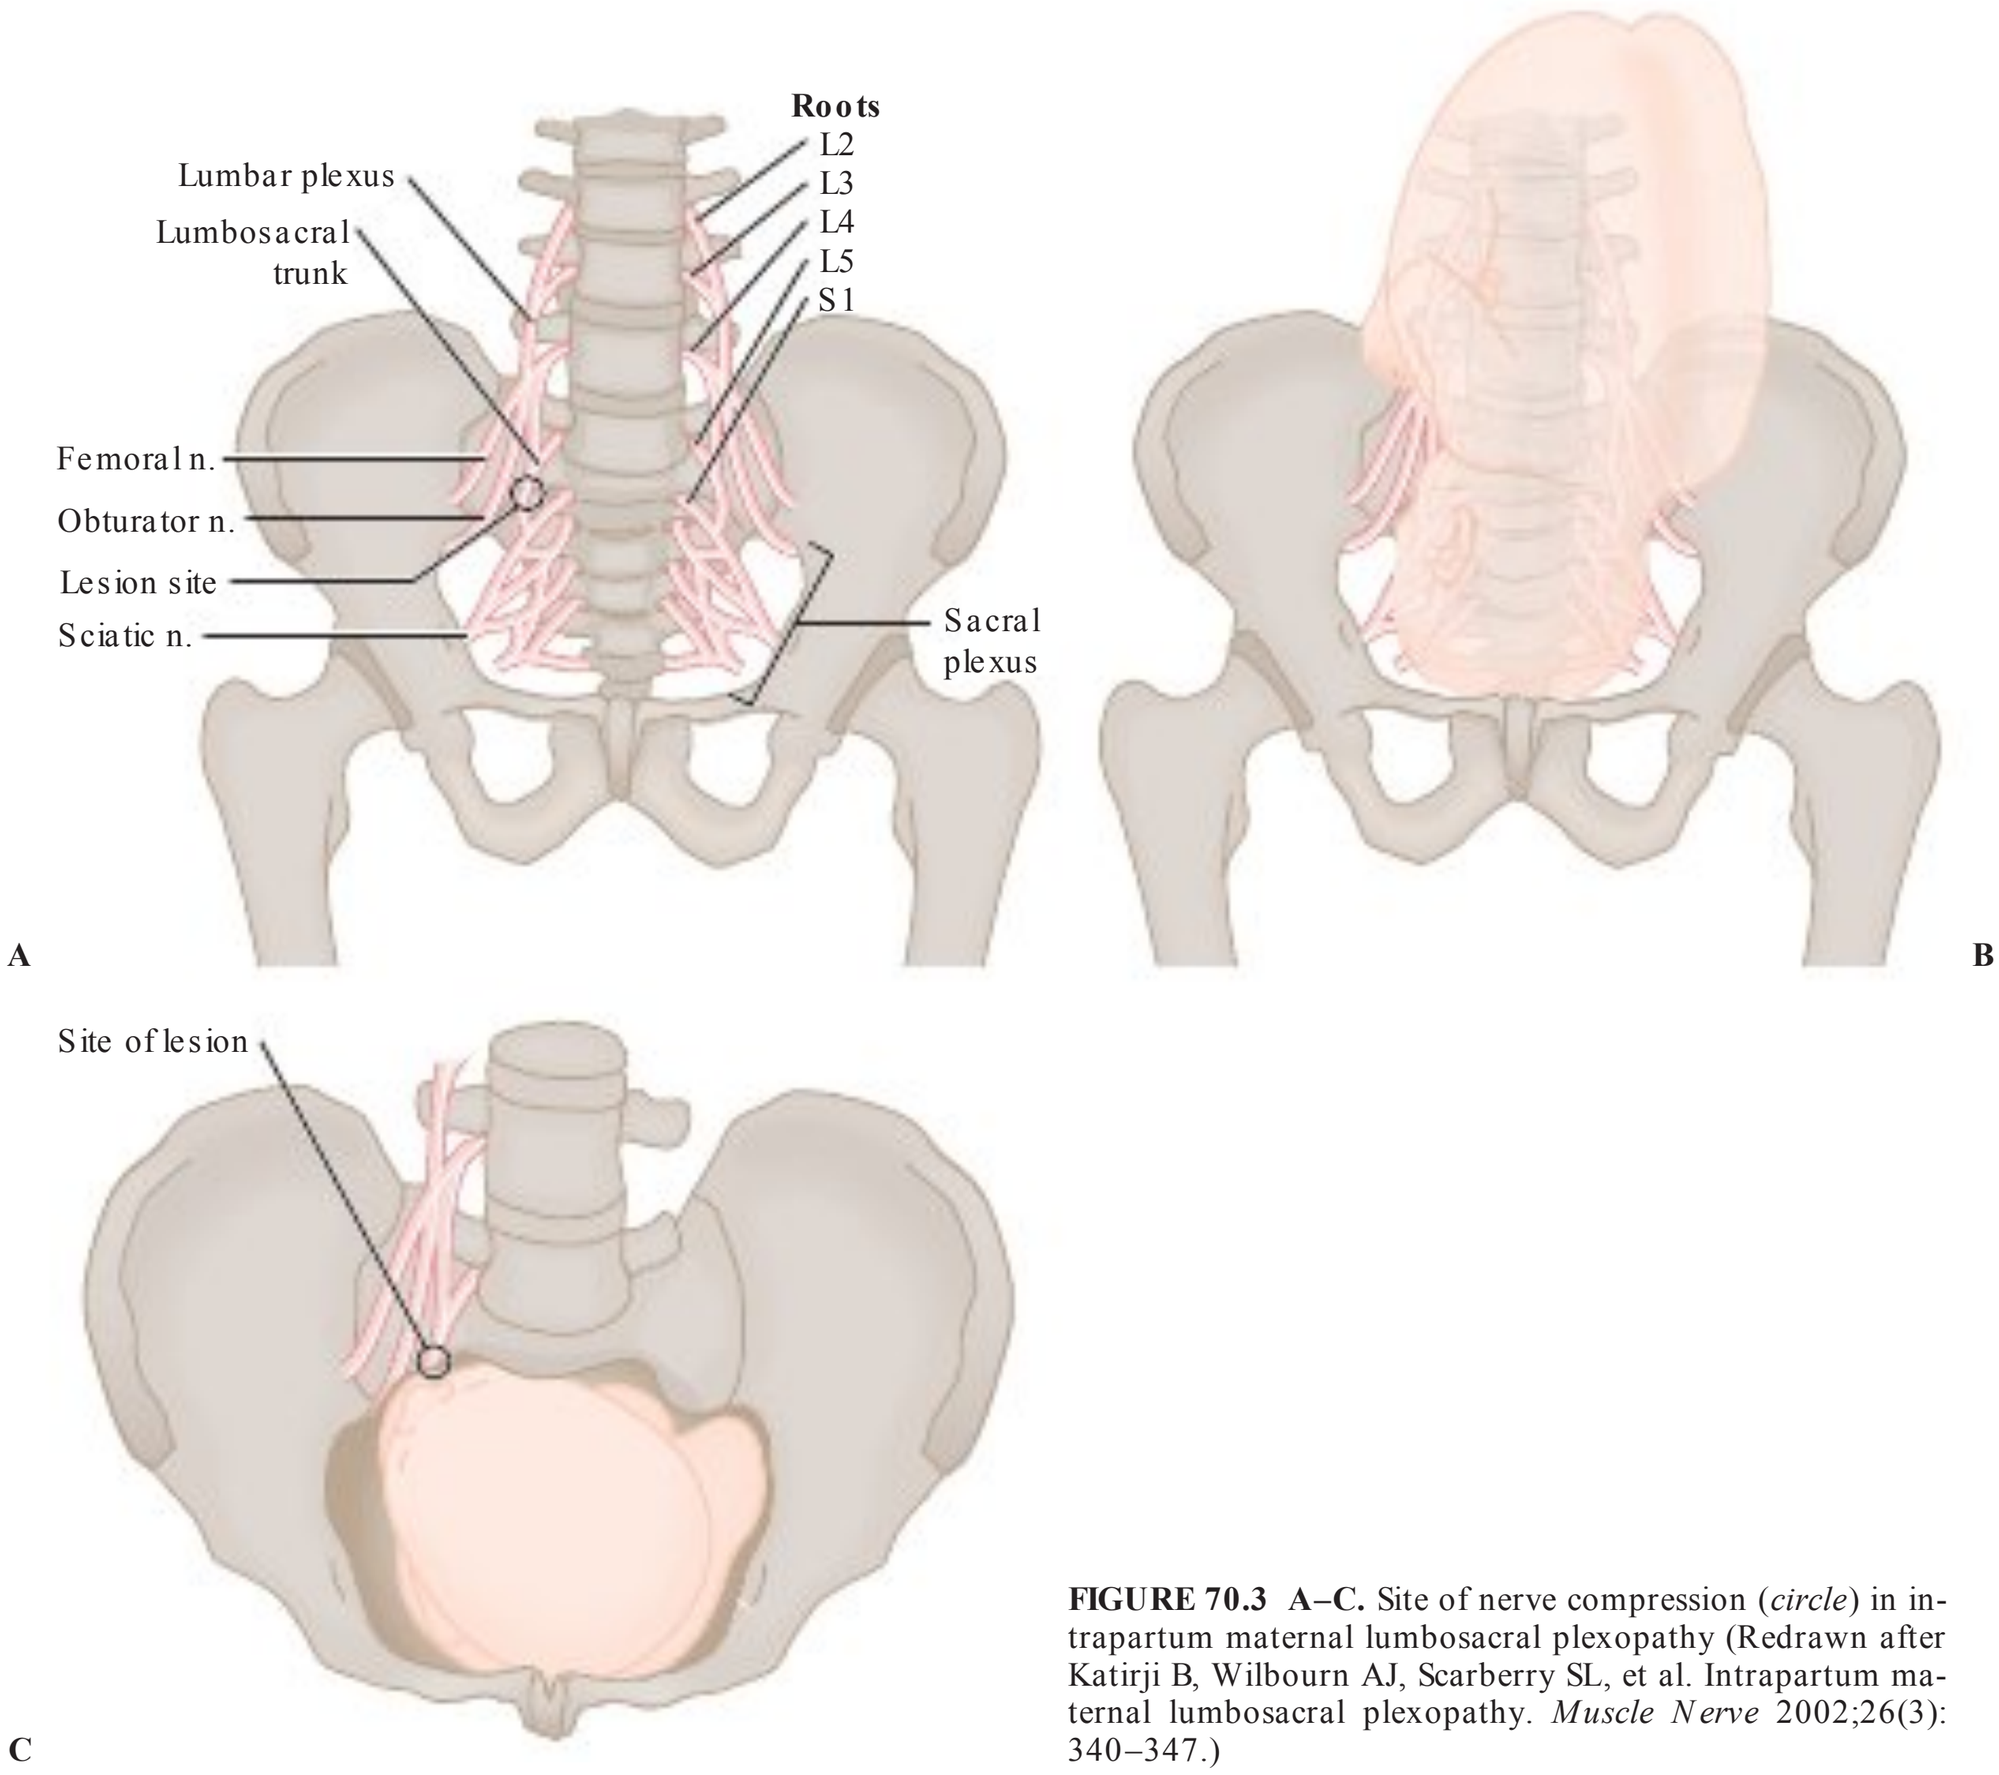

FIGURE 70.3 A–C. Site of nerve compression (*circle*) in intrapartum maternal lumbosacral plexopathy (Redrawn after Katirji B, Wilbourn AJ, Scarberry SL, et al. Intrapartum maternal lumbosacral plexopathy. *Muscle Nerve* 2002;26(3): 340–347.)

muscles of the anterolateral leg and EMG abnormalities in muscles innervated by the L5 nerve root.[3] Aside from delivery of the fetus, treatment is nonsurgical.[3]

SPECIFIC NERVE ENTRAPMENT SYNDROMES

Lateral Femoral Cutaneous Nerve Entrapment

The lateral femoral cutaneous nerve (LFCN), a purely sensory nerve, originates from the lumbar plexus and conveys fibers from posterior divisions of the ventral rami of the L2 and L3 nerve roots (Fig 70.4). Near the anterior superior iliac spine (ASIS), the LFCN divides into anterior and posterior branches and conveys sensory information from the anterolateral and lateral surfaces of the thigh, respectively. Compression of the LFCN most commonly occurs as the nerve exits the pelvis and pierces or crosses the inguinal ligament and attaches to the ASIS.[17] Entrapment of the lateral femoral cutaneous nerve (LFCN), also know as lateral femoral cutaneous neuralgia, was first characterized by Bernhard in 1878. In 1895, Roth coined the name meralgia paresthetica (MP), which is derived from the Greek words *meros* (meaning thigh) and *algos* (meaning pain).[18,19]

While MP is not rare, its exact prevalence remains unknown. It can occur at any age but is most commonly seen in patients 30 to 60 years of age.[19,20] A recent retrospective study analyzing registered patients (173,375 patient years from 1990–1998) from a computerized registration network of Dutch general practitioners probably provides the most accurate incidence of MP.[20] After looking at the relationship between comorbidity (e.g., carpal tunnel syndrome, pregnancy, hip osteoarthritis, obesity, symptoms of the pubic bone, thrombosis of the leg, diabetes mellitus, and the use of corticosteroids) and the occurrence of MP, the authors concluded the incidence rate of MP is 4.3 per 10,000 person years. Though probably underdiagnosed in children, it has been seen in as many as one third of those treated for osteoid osteoma.[19] Whether there is a true gender predilection remains unknown, as results vary depending on the study referenced.[17,20–23]

Etiology

Causes of MP have been categorized as spontaneous or iatrogenic.[21] Spontaneous causes result from entrapment due to intrapelvic (pregnancy, pelvic or abdominal tumors, uterine fibroids, degenerative pubic symphysis, diverticulitis, and appendicitis), extrapelvic (seatbelt trauma, tight garments or belts, and obesity), or mechanical (prolonged sitting, prolonged standing, and leg length discrepancy) factors; or from metabolic derangements (diabetes mellitus, hypothyroidism, alcoholism, and lead poisoning).[24,19] Rossi et al.[25] noted that obese patients (body mass index $\geq$30 kg/m^2), but not overweight patients (body mass index 25–29.9 kg/m^2),[25] showed two-fold greater risk for developing MP.[23] Interestingly, some have even reported cases of MP in patients who have lost weight.[26,27] Postulated mechanisms may include the presence of other compressive factors, lack of nutritional factors, or underlying systemic disease.[23] Iatrogenic causes of MP result from orthopaedic procedures (pelvic osteotomy, iliac crest bone graft harvest, spine surgery, and total hip replacement) and nonorthopaedic procedures (gastric bypass surgery, laparoscopic inguinal herniorrhaphy, laparoscopic cholecystectomy, laparoscopic myomectomy, coronary artery bypass grafting, aortic valve surgery, and renal transplant).[19,28]

Signs and Symptoms

While the majority of patients usually complain of unilateral sensory loss, paresthesias, or dysesthesias, the incidence of bilateral symptoms can be as high as 20%.[17] The symptoms rarely radiate proximally toward the spine.[19] Hair loss over the anterolateral thigh due to constant rubbing may be present.[19] Prolonged standing, walking, or hip extension may worsen the symptoms. Hip flexion may alleviate or worsen the symptoms. A Tinel's sign (paresthesias radiating to the anterolateral thigh) sometimes can be elicited by percussing medial to the ASIS.[23] For those patients in whom inguinal ligament LFCN entrapment is suspected, the pelvic compression test should be performed (Fig. 70.5). With the patient lying in a lateral decubitus position on the unaffected limb, the examiner maintains downward pressure on the pelvis for 45 seconds. Transient improvement of symptoms is considered a positive result. Nouraei et al.[29] showed this test had a sensitivity of 95% and a specificity of 93.3% in those with electrodiagnostically proven MP.

Symptoms extending beyond the territory of the nerve, reflex changes, muscle weakness, or muscle atrophy suggest an alternate diagnosis, such as a lumbar plexopathy, high lumbar radiculopathy, or other peripheral neuropathy.

Diagnosis

Imaging and laboratory studies should be considered when a clear cause cannot be identified: radiograph or neuroimaging of the

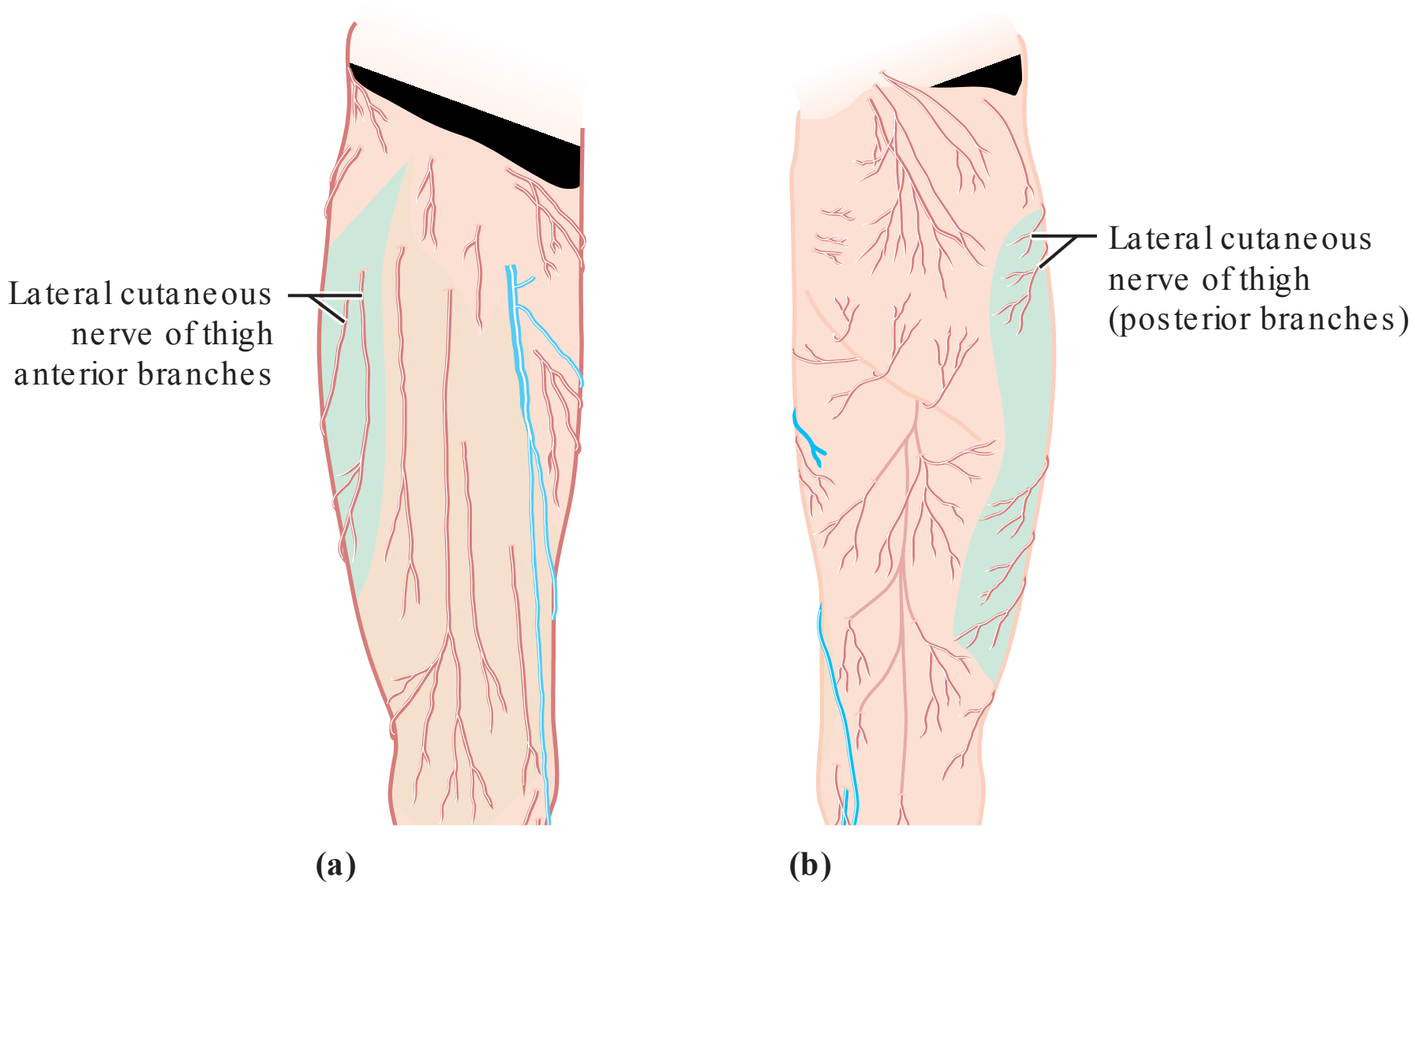

FIGURE 70.4 Cutaneous branches of the lateral femoral cutaneous nerve. Anterior **(A)** view and posterior **(B)** view.

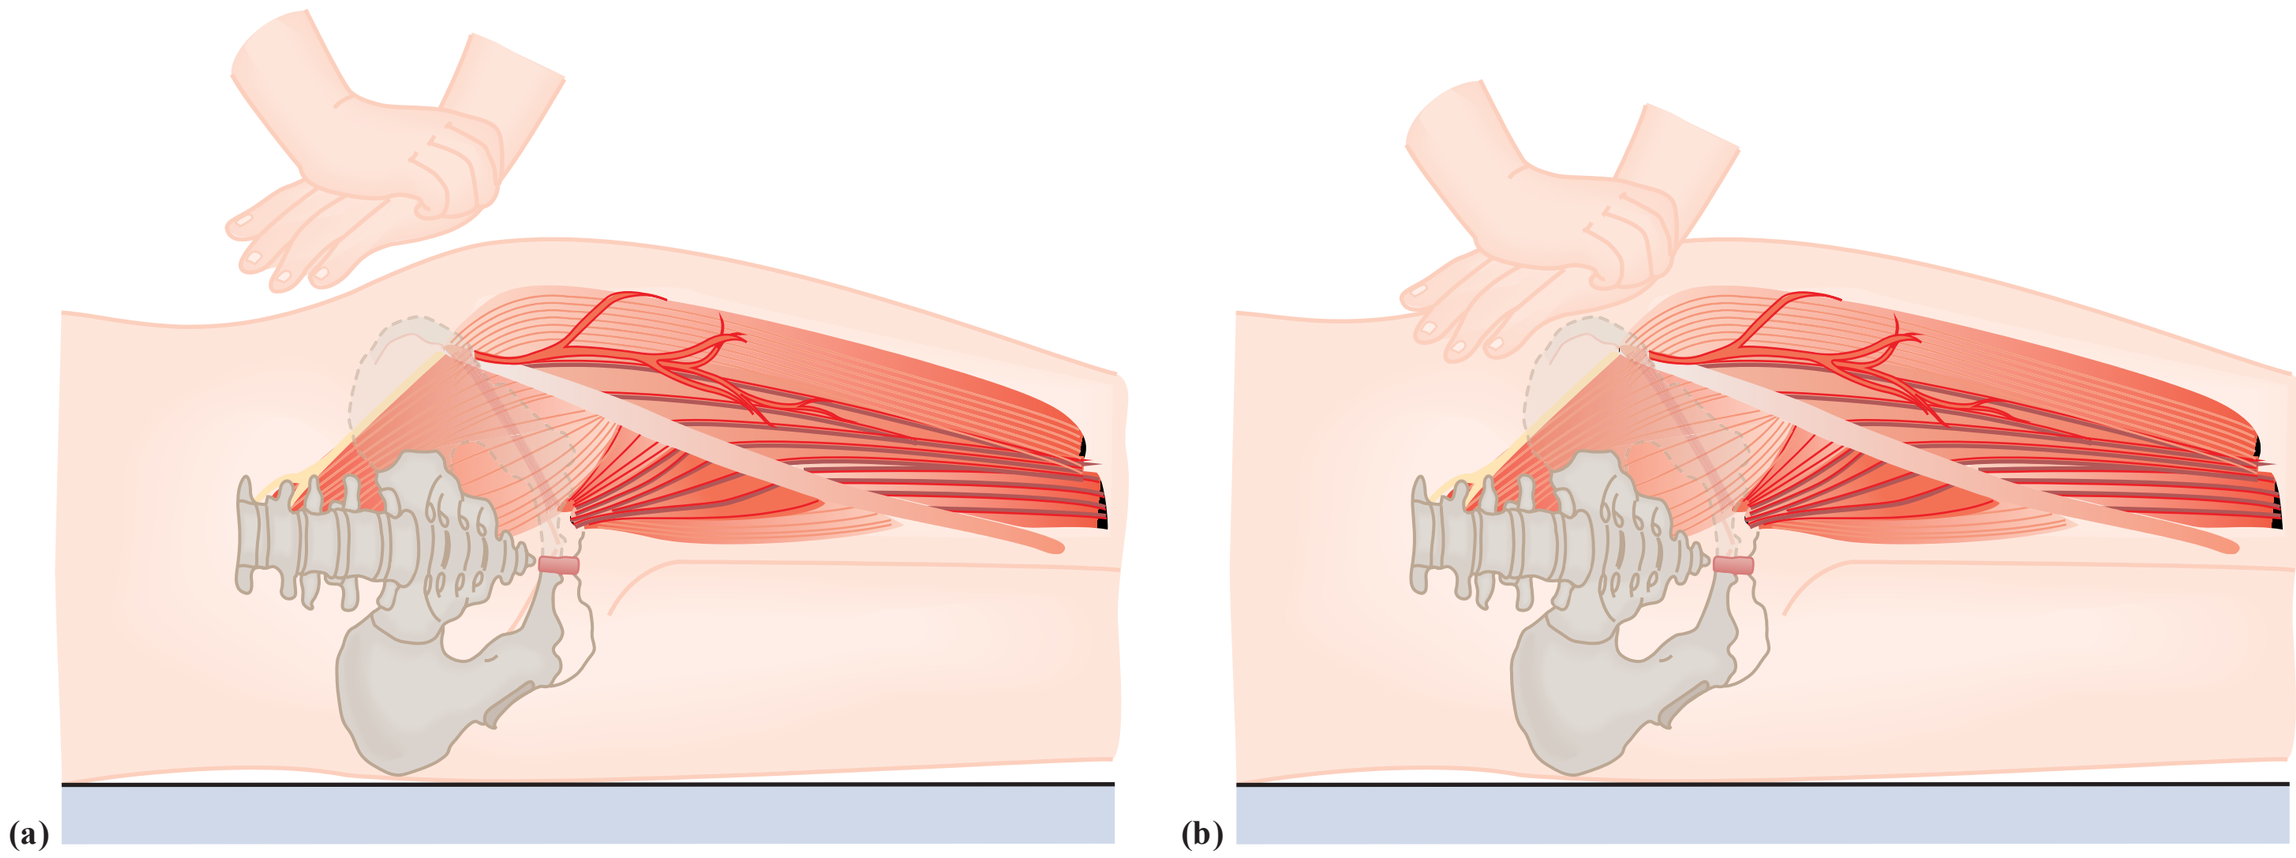

FIGURE 70.5 Pelvic compression test. Place the patient in a lateral decubitus position **(A)** and apply downward pressure on the pelvis for 45 seconds **(B)**. Transient improvement of symptoms is a positive test.

pelvis to rule out pelvic tumor or fracture and neuroimaging of the lumbosacral spine to rule out disc herniation.[19] While electrodiagnostic studies can play a role in the diagnosis of MP, some argue its utility may be hampered by inherent technical difficulty, challenges in obtaining a response in obese patients, and small recordable sensory responses (absent in 71% and prolonged in 24%).[24] Furthermore, in order to obtain the best recordings one must use needle electrodes instead of surface electrodes. Others, however, claim that electrodiagnostics should play a central role in diagnosing MP. Instead of strictly looking at the absolute value of the sensory nerve action potential (SNAP) amplitude, Seror and Seror[22] demonstrated a specificity of 98.75% in their study of 120 patients when the side-to-side amplitude ratio was greater than 2.3 and the amplitude was less than 3 microvolts. Since the nerve is purely sensory, EMG testing of muscles should be normal. The value of somatosensory-evoked potentials (SSEPs) in making the diagnosis is debatable.[19] Ultimately, the greatest benefit of performing an electrodiagnostic is to rule out other entities—high lumbar radiculopathy, lumbar plexopathy, or other peripheral neuropathy—that can cause similar symptoms.

Treatment

Nonsurgical treatment for MP is typically successful, as symptoms are often mild and self-limited. In their study of 277 patients, Williams and Trzil[30] reported conservative management was successful in 91% of patients. Initial recommendations include advising patients to avoid wearing tight-fitting garments or belts, advising obese patients to lose weight, and correcting leg-length discrepancies. If symptoms persist, other treatment options include: ice, transcutaneous electrical stimulation unit, and analgesic medications and injections. Because no controlled studies have been performed, the long-term efficacy of a local anesthetic LFCN block (with or without corticosteroids) is unclear. Furthermore, whether temporary relief of symptoms alters the long-term prognosis is unknown. Using a standard treatment algorithm in 79 patients, Haim et al.[17] showed symptomatic improvement in 21 patients requiring conservative therapy and medical management, 48 patients requiring LFCN blocks using corticosteroid and local anesthetic, and 10 patients requiring surgery. At 1-year follow-up, the authors reported none of the patients had recurrence of MP symptoms.

Traditionally, the target site of injection is identified based on anatomic landmarks (1 cm medial and 1 cm inferior to the ASIS), with a large volume of medication being injected using a fanning technique. While large volumes may increase the success rate of blocking the LFCN to obtain useful diagnostic information, it can also come at the risk of inadvertently blocking the femoral and/or obturator nerves. However, absence of immediate analgesia does not necessarily rule out the diagnosis of MP given the LCFN's anatomic variability and given failure rate of this technique being as high as 60%.[31] In a prospective, randomized, crossover study involving 20 patients, the same authors demonstrated a 100% versus 40% success rate with blocking the LFCN using a stimulating needle versus a fanning technique, respectively.[31] Use of a stimulating needle or ultrasound guidance, however, can improve the success rate of identifying the correct nerve. In their study of 10 patients, 5 of whom were obese, Hurdle et al.[32] successfully blocked the LFCN in 100%. The authors concluded that ultrasound-guided LFCN blocks offered the advantage of visualizing the adjacent structures, of using lower volumes of injectate, and of avoiding the inadvertent blockage of the femoral and/or obturator nerves.

For those who do not obtain long-term benefit from corticosteroid injections, other treatments that have been tried include cryoanalgesia of the peripheral nerve, pulsed or continuous radiofrequency (RF) of the peripheral nerve, peripheral nerve stimulation, and spinal cord stimulation. The successful outcomes reported in some of these studies need to be interpreted with caution, though, as they tend to be case reports, case series, or retrospective studies.[33–36] For those patients whose symptoms are refractory to analgesic medications, LFCN blocks, and neurostimulation, operative interventions may include surgical decompression, neurolysis, or transection of the LFCN.[30] Which of these surgical techniques is most successful remains unclear.[30,37,38] As with any neurodestructive procedure, there is a risk of nerve injury or neuroma formation.

Femoral Nerve Entrapment

The femoral nerve is a sensory (Fig. 70.6) and motor nerve and is the largest nerve of the lumbar plexus. It originates within the psoas muscle and arises from the posterior divisions of the ventral rami of the L2, L3, and L4 nerve roots (see Fig. 70.1A).[39] (The anterior divisions of the same nerve roots form the obturator nerve.) In the abdomen, the femoral nerve gives off branches to

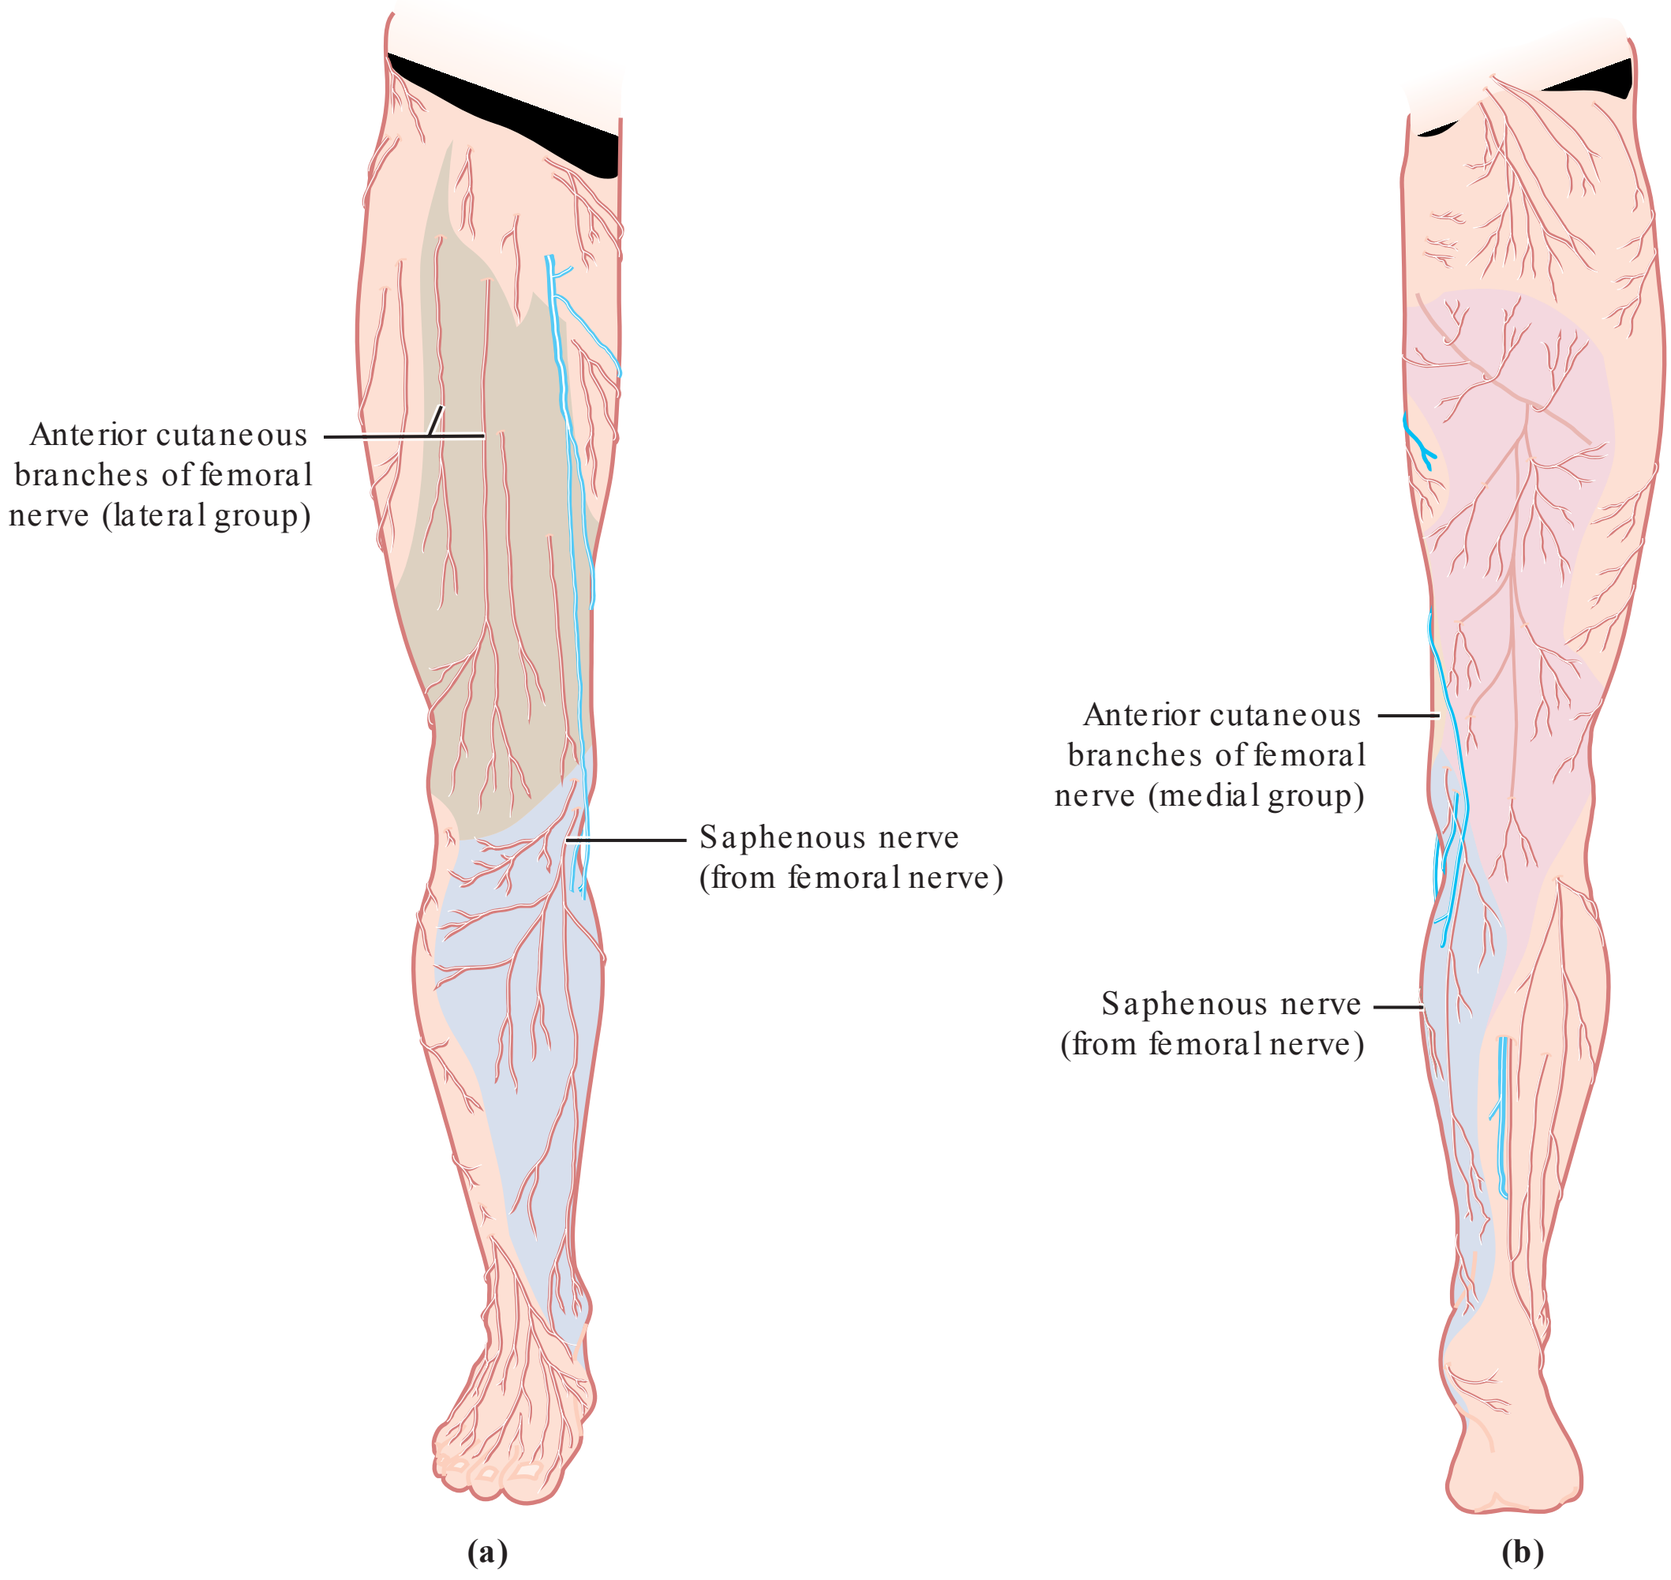

FIGURE 70.6 Cutaneous branches of the femoral nerve. Anterior **(A)** view and posterior **(B)** view.

the iliacus and psoas muscles, and as it passes under the inguinal ligament it gives off a branch to the pectineus muscle. The nerve then enters the femoral triangle lateral to the femoral artery, and upon exiting the triangle it splits into an anterior and posterior division. The anterior division provides motor innervation to the sartorius muscle and sensory innervation (via the medial and intermediate femoral cutaneous nerves) to the anterior thigh as far distally as the knee. The posterior division provides motor innervation to the quadriceps muscles (rectus femoris, vastus lateralis, vastus intermedius, and vastus medialis) and sensory innervation (via the saphenous nerve) to the anteromedial aspect of the knee, medial calf, medial malleolus, and part of the medial arch of the foot and great toe.[39,40]

Isolated femoral neuropathy, originally known as anterior crural neuritis, was first reported in 1822 in a thesis by Descot. While most lesions are unilateral, bilateral involvement has been observed.[28] Because an isolated unilateral femoral neuropathy is uncommon, its true incidence remains unknown. Kuntzer et al.[41] reported that of 7252 electrodiagnostic examinations performed at their institution between 1988 to 1994, femoral neuropathy accounted for the diagnosis is only 32 patients (0.5%). Femoral neuropathies can cause either motor and sensory disturbances or sensory disturbances only. The latter occurs when the saphenous nerve, which is the distal sensory continuation of the femoral nerve, is involved.

Etiology

The causes of femoral neuropathy may be divided into the following categories: (a) direct nerve trauma (gunshot or knife wound, hip or pelvic fracture, hip replacement, hip prosthesis displacement, thermal energy from methylmethacrylate, inguinal herniorrhaphy, or femoral nerve block); (b) nerve ischemia due to interrupted vascularization at the intrapelvic level (common iliac artery occlusion, vascular or aortic surgery, or renal transplant with graft in the iliac fossa); (c) nerve compression (femoral artery injury in the femoral triangle, retroperitoneal hematoma, retroperitoneal mass, lithotomy positioning, prolonged hyperextension of the hip, or entrapment under the inguinal ligament with hip flexion); (d) metabolic (diabetes or pelvic radiation therapy); and (e) idiopathic.[39,41–43]

Because of a somewhat differential blood supply, the left femoral nerve is more susceptible to ischemic injury than the right.[44] The most vulnerable site of injury is located 4–6 cm above the inguinal ligament, which is where the nerve exits from the psoas muscle.[28] Because most pelvic surgical maneuvers occur proximal to the psoas muscle and out of the direct path of the nerve, neuropathy due to a compressive injury from retractors is more likely than that due to nerve transection and is independent of the type of incision (horizontal, midline, or lateral).

Most surgery-related causes of femoral neuropathy are preventable as long as retractors are used with care and positional

factors are taken into account.[43] In their analysis of 32 patients with electrodiagnostically confirmed femoral neuropathy, Kuntzer et al.[41] identified an iatrogenic cause in 65% of the cases, and of these 87% were related the hip surgeries. The incidence of femoral neuropathy after total hip arthroplasty is estimated to be as high as 3%.[45] A significant number of cases of femoral neuropathy occur with gynecologic, urologic, orthopaedic, and vascular surgeries.[28,41,45] The incidence of neuropathy after abdominal hysterectomy, for example, ranges from 7% to 12%.[45] Based on their prospective study looking at femoral neuropathy subsequent to abdominal hysterectomy, Goldman et al.[46] reported the incidence of femoral neuropathy decreased from 7.45% to 0.7% when self-retaining retractors were eliminated. The compression is often indirect, as the nerve becomes entrapped between the pelvic wall and the psoas muscle upon which the retractor rests.[28] In those instances where a compressive neuropathy has occurred, direct ischemia of vasa nervorum due to deficient vascularization is the most likely mechanism of action. Urological procedures (renal transplant, radical cystectomy, transurethral resection of the bladder with exploration and biopsy of a tumor mass, percutaneous nephrolithotomy of a pelvic kidney, radical cystoprostatectomy and continent urinary diversion, and psoas hitch vesicopexy) can also be a cause of femoral nerve injury.[39] For patients undergoing renal transplant with graft in the iliac fossa, the occurrence of femoral neuropathy ranges from 0.5% to 2.2%.[28,45] Possible explanations for the cause include nerve compression combined with potential hematoma in the iliac space and prolonged vascular anastomosis or arterial clamping time.

Signs and Symptoms

Unilateral sensory loss, paresthesias, or dysesthesias in the distribution of the femoral nerve and its branches, an impaired patellar reflex, and/or hip flexion and knee extension weakness may be present. Quadriceps atrophy may be noted in chronic and severe cases. Patients with hip flexion and knee extension weakness describe frequent buckling of the knee and/or falls while ambulating.[39] Navigating stairs is often difficult, requiring patients to ascend by leading with the unaffected leg and to descend by leading with the affected leg. Kuntzer et al.[41] reported weakness and dysesthesias in 88% and 44%, respectively. Pain, if present, can be at the site of the causative lesion (iliac fossa and inguinal region) or in the distribution of the nerve itself (anterior thigh or medial calf). Inguinal pain suggests a retroperitoneal mass.[39] Pain may be exacerbated by hip extension and partially relieved with hip flexion and external rotation.[24]

Diagnosis

If femoral neuropathy is noted in the immediate postoperative period, appropriate neuroimaging and radiographic studies should be ordered to determine the cause. Because motor weakness and reflex changes can also be seen with lumbar plexopathies or radiculopathies, these diagnoses must be included in the differential. Electrodiagnostic testing can help isolate the location and extent of nerve injury. While the presence of EMG abnormalities in the vastus medialis muscle was not predictive of prognosis, the presence of NCS abnormalities, especially percentage of axonal loss, was predictive of prognosis.[47] Axonal loss, which is indicative of axonotmesis, portends a slower and possibly incomplete recovery. Kuntzer et al.[41] concluded that all patients with less than 50% axonal loss showed improvement within 1 year, whereas less than half the patients with greater than 50% axonal loss improved with conservative management alone. Furthermore, the authors found that irrespective of cause of injury, no improvement occurs after 2 years. Prognosis of recovery is greater if testing reveals only demyelinating abnormalities.[43] Abnormal EMG findings in the lumbar paraspinal muscles, however, suggest a lumbar radiculopathy or plexopathy and not a peripheral neuropathy.

Treatment

If imaging studies identify a treatable cause, then the appropriate surgery should be performed as soon as possible to minimize the extent of neurologic deficit. Based on their retrospective series (1967–2000) of 119 surgically treated patients with intrapelvic or thigh-level femoral nerve lesions (89 traumatic injuries and 30 tumors), Kim et al.[48] recommended surgery in the absence of improvement at 3 to 4 months: neurolysis if intraoperative nerve action potentials across the nerve lesion are present and resection with grafting if intraoperative nerve action potentials are absent. Though fewer patients underwent neurolysis compared to resection with grafting, the extent of recovery was greater in the former group, consistent with the severity of nerve injury. If there is no evidence of clinical or electrodiagnostic improvement after 3 to 6 months in those with iatrogenic or idiopathic femoral neuropathy, then surgical exploration with neurolysis should be considered.[43]

Assuming the femoral neuropathy is not due to traumatic injury or mass effect that necessitates surgery, recovery is typically the rule and conservative treatment is usually sufficient. The retrospective analysis, by Fanelli et al.,[49] of 2175 patients undergoing a combined sciatic-femoral nerve block showed that 45 patients (2%) experienced transient neurologic dysfunction and all but one improved within 4 to 12 weeks.[49] Extent of recovery (none, partial, or complete) and time to recovery after abdominal surgery is much more variable, the latter ranging from 2 weeks to 1 year.[43] Nonoperative treatment options include rest, analgesic medications, injections, and physical therapy. Whether temporary relief of symptoms with medications or injections alters the long-term prognosis is unknown, as the extent of recovery depends on the causative factor, extent of nerve damage, and location of injury. Longer recovery times should be anticipated when nerve damage is extensive and/or more proximal. Recovery is excellent if the etiology is due to lithotomy positioning, but is less than satisfactory when due to hip surgery or inguinal procedures.[47,50] Kuntzer et al.,[41] however, reported no association between etiology and outcome. Physical therapy is important for those with evidence of motor weakness in order to prevent muscle contractures, minimize muscle atrophy, and maintain ambulatory status. For those with significant quadriceps weakness and knee instability, orthotic and/or gait assistive devices should be considered.

Saphenous Nerve Entrapment

The saphenous nerve is the terminal sensory branch of the posterior division of the femoral nerve and is the longest cutaneous branch of the femoral nerve (Fig. 70.7). It originates near the inguinal ligament and descends within the quadriceps muscles in the subsartorial (Hunter's) canal and emerges from the canal to become subcutaneous approximately 10 cm proximal to the medial femoral condyle. The canal, which is located in the middle third of the medial thigh, also contains the femoral artery and vein. The saphenous nerve along with its two main divisions, the sartorial and infrapatellar nerves, supplies cutaneous sensation from the anteromedial aspect of the knee, medial calf, medial malleolus, and part of the medial arch of the foot.[39,40]

Etiology

Saphenous nerve injury can occur anywhere along the course of the nerve. Most saphenous neuropathies are iatrogenic or related to surgical procedures, though spontaneous neuropathies with unidentified causes can also occur.[39,51] Saphenous nerve trauma during femoral vascular surgeries and from saphenous vein harvesting for coronary artery bypass graft surgery can result in saphenous neuropathy.[52–58] After undergoing vascular reconstructions below the inguinal ligament, Adar et al.[52] reported variable

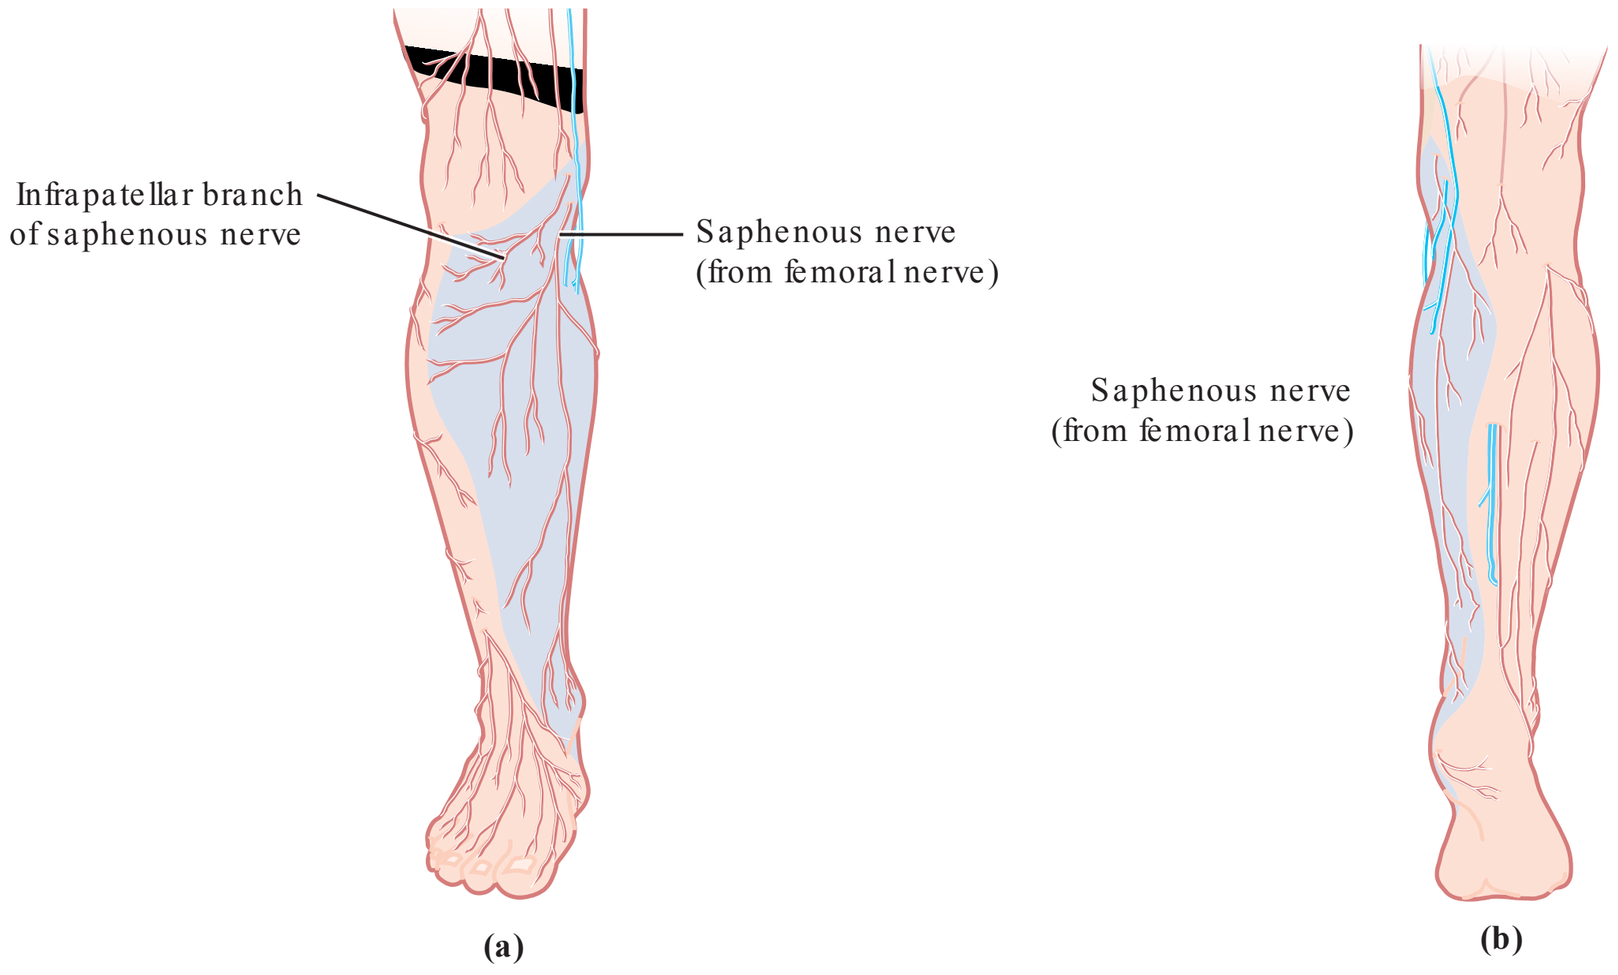

FIGURE 70.7 Cutaneous branches of the saphenous nerve. Anterior **(A)** view and posterior **(B)** view.

degrees of saphenous neuropathy in 27 of 55 (49%) of patients, which were unrelated to surgical technical flaws. Inadvertent transection of the infrapatellar or sartorial nerves, such as during knee surgery (medial arthrotomy, medial meniscectomy, patellar realignment, total knee arthroplasty, and secondary repair for medial instability with pes transfer) can occur.[40,51,59,60] Schwabegger et al.[61] reported how a retained hemostatic clip on the infrapatellar nerve after a gracilis muscle flap resulted in neuralgia due to neuroma formation and moderate fibrosis within the subsartorial (Hunter's) canal. Resection of the neuroma resolved the pain, but sensory impairment remained. Another case report describes nerve damage resulting following a medial knee joint injection.[62]

Saphenous nerve entrapment can occur as it travels through the subsartorial (Hunter's) canal.[39,51] One case report documents distal tibial pain mimicking a tibial stress fracture from entrapment of the saphenous nerve caused by pes anserine bursitis.[63] Compression or thrombosis of the superficial femoral artery within the adductor canal can cause claudication pain in the lower leg.[56] Neural compression from the femoral vessels and adductor magnus tendons, which is more proximal to the subsartorial (Hunter's) canal, has also been reported.[64] Other case reports describe compression of the nerve due to an osteochondroma and from sitting astride and gripping a surfboard between the knees.[65,66]

Symptoms and Signs

Knee pain is the main complaint, occurring in 90% of patients in one study, and tends to be worst with walking or any exercise involving active knee extension.[52,56,66] In another study involving 15 cases of saphenous nerve entrapment, patients most commonly reported medial knee and leg pain after prolonged walking (87%) and standing (47%).[51] Additional symptoms reported by these same patients included hypoesthesia (47%), no change in sensation (47%), and hyperesthesia (6%). Point tenderness over the subsartorial canal may be elicited in some of those with a suspected entrapment neuropathy, but it is unlikely to be present in those with a traumatic nerve injury.[51,52,66] Because it is a purely sensory nerve, motor strength is unaffected. Therefore, sensory abnormalities or pain beyond the territory of the nerve, reflex changes, muscle atrophy, or muscle weakness suggests a lumbar plexopathy, lumbar radiculopathy, or other peripheral neuropathy.

Diagnosis

Electrodiagnostic studies can be helpful, but performing a saphenous nerve conduction study can be challenging. Instead of strictly looking at the absolute value of the SNAP amplitude or latency in the affected limb, it is more important to compare the side-to-side SNAP amplitudes.[39] A SNAP amplitude of less than 50% of the unaffected limb suggests the lesion is at or distal to the dorsal root ganglion.[39] Since the nerve is purely sensory, the EMG result should be normal. The clinical utility of saphenous nerve SSEPs is low. A pelvic MRI or CT should be considered if one suspects a mass lesion in the subsartorial canal.

Treatment

Nonsurgical treatment options include rest, analgesic medications, and injections. For those with a suspected entrapment neuropathy, a saphenous nerve block (with or without corticosteroid) over the subsartorial canal can be tried. While the long-term efficacy remains unclear, the nerve block might yield a diagnostic answer. A local anesthetic saphenous nerve block provided relief in 12 of 32 (38%) cases described by Mozes et al.[67] but they did not provide lasting relief in any of the 15 cases described by Worth et al.[51] With corticosteroid added to the local anesthetic in 30 patients undergoing a series of saphenous nerve blocks, "favorable outcomes, no change and increased pain" were reported in 80%, 13%, and 7%, respectively.[56] Whether temporary relief of symptoms alters the long-term prognosis is unknown. Because ultrasound of the nerves around the knee has been described, an ultrasound-guided saphenous nerve block may improve chances of obtaining a successful block.[68] However, this has yet to be shown in a study. For those with unremitting symptoms, neurolysis or neurectomy may be indicated, though which surgical approach offers the best outcome with the fewest complications is debatable.[51,67]

Obturator Nerve Entrapment

The obturator nerve, which is a sensory and motor nerve, originates from the anterior divisions of the ventral rami of the L2,

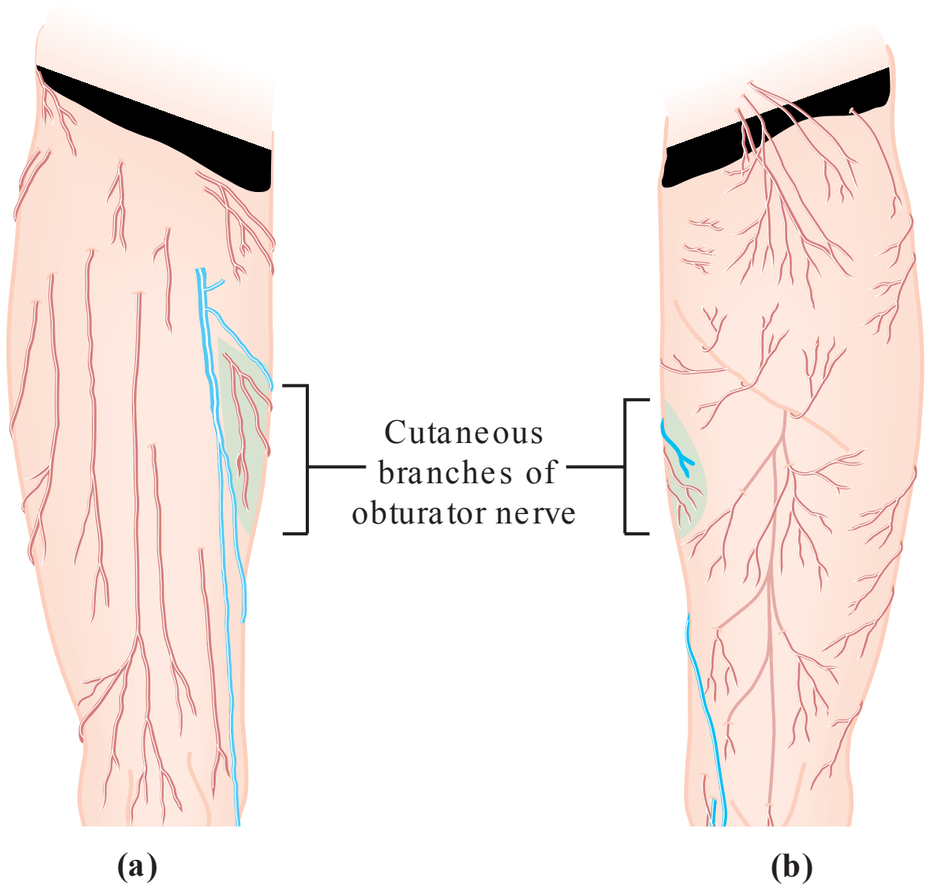

FIGURE 70.8 Cutaneous branches of the obturator nerve. Anterior **(A)** view and posterior **(B)** view.

L3, and L4 nerve roots (Fig. 70.8; see Fig. 70.1a). (The posterior divisions of the same nerve roots form the femoral nerve.) The obturator nerve emerges from the medial surface of the psoas major muscle at the pelvic brim and descends along the lateral pelvic wall where it passes through the fibro-osseous obturator foramen. Within the foramen, the obturator nerve splits into an anterior and posterior branch, finally emerging through the obturator foramen and entering the thigh. At the point of origin, the anterior branch supplies an articular branch to the hip joint followed by motor branches to the adductor longus and brevis, gracilis, and pectineus muscles. The sensory fibers of the anterior branch convey cutaneous information from the distal two thirds of the medial thigh. The posterior branch supplies motor branches to the obturator externus and adductor magnus muscles and sensory branches to the articular capsule, cruciate ligaments, and synovial membrane of the knee joint. A normal variant in approximately 8% to 13% of the population, the accessory obturator nerve supplies the pectineal muscles and hip joint.[69]

Etiology

An isolated obturator neuropathy is uncommon because the nerve is well-protected within the pelvis and medial thigh.[70,71] Causes of obturator neuropathy include entrapment (obturator hernia or local infection); compression (pelvic trauma, pelvic hematoma, pelvic tumor, retroperitoneal mass, fetal head or forceps in the pelvic canal during delivery, trauma or hematoma caused by cesarean section, acetabular labral cyst, extrapelvic synovial cyst, prolonged tourniquet use, or myositis ossificans); surgery (orthopaedic, gynecological, or pelvic laparoscopy); lithotomy positioning; and diabetes.[39,69–77] Of 22 patients with electrodiagnostic evidence of obturator neuropathy, Sorenson et al.[70] found perioperative complications or pelvic trauma were the most common causes. Because laparoscopic pelvic procedures could result in inadvertent electrocautery of the wrong nerve, careful visualization of the adjacent neurovascular structures should be undertaken.[39,71] The mechanism of entrapment is unclear, but Bradshaw et al.[69] concluded from their study of 32 athletes that electrodiagnostic and surgical findings (nerve entrapment by fascia and vessels over the obturator externus and adductor brevis muscles) suggest entrapment occurs at the level of the obturator foramen and proximal thigh, instead of within the obturator tunnel. Gender differences in the bony pelvic anatomy also play a role. Higher iliac bones, a smaller transverse pelvic inlet diameter, and a narrower subpubic angle, which all contribute to a greater bend in the obturator nerve within the obturator canal, probably accounts for the higher incidence of obturator neuropathy in men.[69]

Symptoms and Signs

Symptoms of obturator neuropathy include weakness, paresthesias, sensory loss, and/or pain along the medial thigh with extension as far distally as the knee. Sorenson et al.[70] reported that patients most commonly complained of medial thigh or groin pain (73%) followed by muscle weakness (27%) and sensory impairment (27%). Unfortunately, the complaints of pain can make it challenging to differentiate whether it is due to obturator neuropathy versus a traumatic or surgical procedure. Similar to Sorenson et al.,[70] Bradshaw et al.[69] found that self-reports of numbness or paresthesia among their 32 athletes were uncommon except in those with chronic obturator neuropathy. Additional symptoms included referred pain to the ASIS, exercise-induced exacerbation of pain with radiation from the medial thigh to knee, resolution of pain with rest, exercise-induced adductor muscle weakness and spasm, and wide-based gait. Because the femoral and sciatic nerves provide partial innervation to the adductor longus and magnus, respectively, muscle weakness may be difficult to appreciate on physical exam. With chronic and severe obturator neuropathy, though, medial thigh atrophy may occur. The adductor tendon reflex may even be diminished, but since this reflex can be absent in those without neuropathy, it must be obtainable in the unaffected limb.[39] A positive Howship-Romberg's sign—pain provocation along the medial thigh to the knee with passive abduction and extension of the affected hip or passive internal rotation of the hip—suggests the diagnosis.[78] This neural tension maneuver is felt to be pathognomonic of an obturator hernia, occurring in 15% to 50% of cases.[78,79]

Diagnosis

Because motor weakness and reflex changes can also be seen with lumbar plexopathies or radiculopathies, these diagnoses must be included in the differential. When the physical exam is nonspecific, sensory and motor findings can be confirmed with electrodiagnostic testing. Sorenson et al.[70] were able to diagnose a different disorder in 15 of 38 (39%) of patients who carried a presumptive diagnosis of obturator neuropathy.[70] Radiographs of the pelvis are typically normal, unless osteitis pubis is present, and bone scans may show increased uptake in the pubic ramus on the affected side that presumably represents an inflammatory reaction that tracks along the fascia to entrap the nerve.[69] Alternatively, the periosteal changes may represent adductor insertion avulsion syndrome (''thigh splints''). If an intrapelvic or extrapelvic lesion is suspected, neuroimaging should be obtained.

Treatment

Recovery after sustaining an obturator nerve insult appears good in those with an acute neuropathy and poor in those with a chronic neuropathy. Conservative treatment measures include rest, physical therapy to stretch the groin muscles and to strengthen the adductor and pelvic muscles, soft tissue massage, and analgesic medications. Physical therapy is important for those with evidence of motor weakness in order to prevent muscle contractures, minimize muscle atrophy, and maintain ambulatory status. Among patient with acute onset neuropathy, 14 of 15 patients improved with conservative treatment or surgical exploration, whereas none of the 4 patients with chronic obturator neuropathy improved.[70] Controversy exists as to whether severity of nerve injury affects long-term prognosis. Bradshaw et al.[69] noted failure with conservative treatment in those with electrodiagnostic evidence of denervation, instead preferring definitive

surgical neurolysis. Conversely, Sorenson et al.[70] found 3 of 4 patients with electrodiagnostic evidence of a complete lesion improved without surgical exploration. For those who have limited benefit with noninjection therapies, a fluoroscopically-guided obturator nerve block at the obturator foramen can be attempted.[69] Successful treatment of groin pain, medial and lateral thigh pain, and hip joint pain with continuous RF and pulsed RF of the articular branches of the obturator and femoral nerves has also been described in various case reports.[80–82] For those with persistent symptoms or severe injuries (pelvic trauma, intraoperative nerve laceration, or tumor) surgery is advocated.[39]

Sciatic Nerve Entrapment

The sciatic nerve arises from the lumbosacral plexus and is composed of the L4, L5, S1, S2, and S3 nerve roots (Fig. 70.9). It enters the lower extremity by exiting the pelvis through the sciatic notch. Variability exists, however, in the course the sciatic nerve takes as it exits the pelvis through the greater sciatic notch near the piriformis muscle. Beaton and Anson[83] found that among 1510 cadaveric extremities, in 88% the sciatic nerve exited below the piriformis muscle, in 11% the piriformis muscle was divided in two parts such that the fibular division of the sciatic nerve passed in between both parts of the piriformis muscle and the tibial division passed below the bottom-most part of the muscle, in 0.86% the fibular and tibial division of the nerve either passed above and below the muscle, respectively, and in 0.13% the entire sciatic nerve pierced an undivided piriformis muscle (Fig. 70.10). The two anatomic variations where the sciatic nerve or its divisions pass in between the nerves lead to the nontraumatic variant of piriformis syndrome. Upon leaving the gluteal region, the sciatic nerve travels posterior and medial to the hip joint.

Commonly perceived of as a single nerve, the sciatic nerve is composed of lateral (fibular division) and medial (tibial division) trunks that actually lay adjacent to each other. Around the middle to distal aspect of the posterior thigh, the divisions diverge to form the common fibular and tibial nerves. Prior to diverging, the fibular division innervates the short-head of the biceps femoris muscle, with tibial nerve branches innervating the remaining hamstring (semitendinosus, semimembranosus, and long-head of the biceps femoris) muscles. With the exception of the saphenous nerve, branches of the sciatic nerve supply the sensory innervation below the knee, and branches of the sciatic nerve supply the entire motor innervation below the knee.

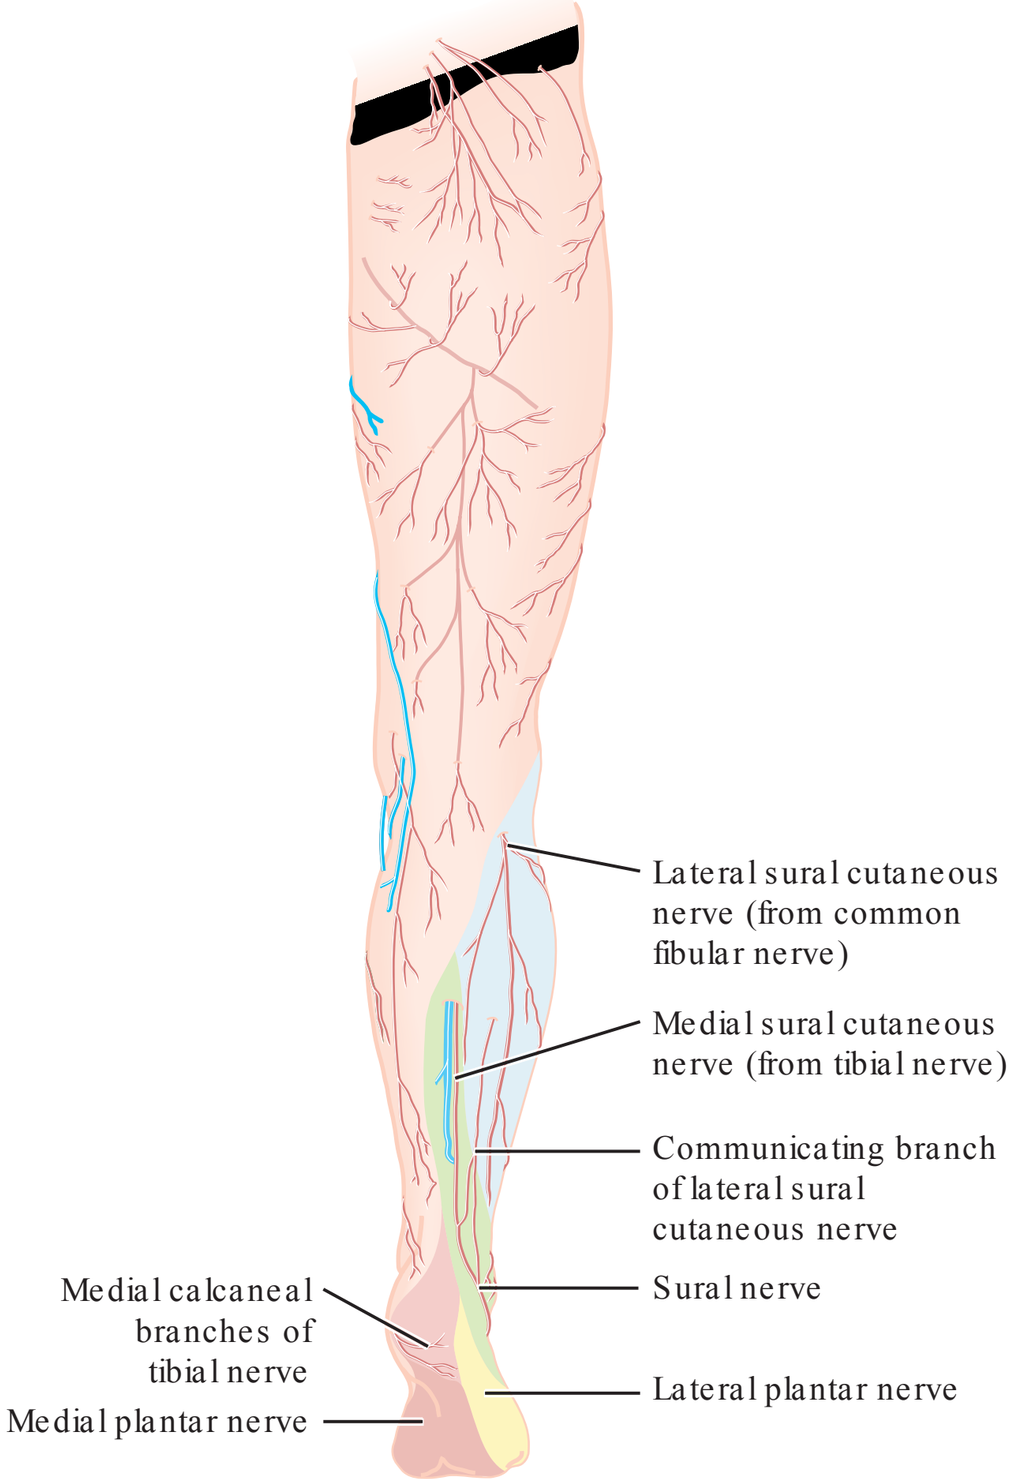

FIGURE 70.9 Cutaneous branches of the sciatic nerve.

Etiology

After fibular neuropathy, sciatic neuropathy is the second most common lower extremity peripheral neuropathy.[84] Injury can occur anywhere along the course of the nerve from the gluteal region to the posterior thigh. Causes of sciatic neuropathy include compression (hematoma, abscess, piriformis syndrome, benign or malignant tumor, myositis ossificans, endometriosis, prolonged sitting or supine positioning without adequate pressure relief, lithotomy position, vaginal delivery due to nerve compression from the fetus's head, or pneumatic thigh tourniquet); contusion (fall from a height without fracture or dislocation); trauma (gunshot wound, laceration, femur fracture, intramuscular injection of medication into the gluteal region); stretch injury (hip arthroplasty, hip dislocation, hip or femur fracture); nerve ischemia (vasculitis, arterial thrombosis, arterial bypass surgery, diabetes mellitus, postradiation therapy); and idiopathic.[47,85–87] Based on 492 reported cases of sciatic neuropathy in the English literature from 1967–1997, Plewnia et al.[87] found that the five most common causes were: hip arthroplasty (34%), intramuscular injection of medication into the gluteal region (28%), hip fracture or dislocation (9%), benign or malignant tumor (8%), and external compression (8%).

Sciatic nerve injury is the most common neurologic complication of total hip arthroplasty—with an estimated incidence of 0.6% to 6.7% of all arthroplasties—and can be caused by stretch injury, direct trauma from retractors or fixation screws, infarction, intraneural hemorrhage, hip dislocation, thermal injury from methylmethacrylate extravasation, or compression from the prosthesis or a bony prominence.[85] In their study of 100 patients with electrodiagnostically confirmed sciatic neuropathy, Yuen et al.[84] reported that hip arthroplasty occurred in 22% and accounted for the most common cause of sciatic nerve injury. Kline et al.,[85] however, discovered that of 380 patients seen from 1967 to 1991, hip arthroplasty only accounted for a minority (3%) of cases and that injection injury from intramuscular drug administration accounted for the majority (36%) of cases. While most cases of hip arthroplasty-related sciatic neuropathy occur in the perioperative setting, delayed onset can also be seen.[88]

Sciatic nerve entrapment by the piriformis muscle, also known as piriformis syndrome, can be another cause of sciatica. Though its diagnosis remains controversial, it is reported to occur with a 6:1 female-to-male predominance.[89] It is less commonly due to sciatic nerve entrapment by the piriformis muscle, and instead is more commonly associated with direct trauma to the sciatic notch and the gluteal regions; prolonged sitting; prolonged combined hip flexion, adduction and internal rotation; and certain athletes (cyclists who ride for prolonged periods of time, tennis players who constantly internally rotate their hip with an overhead serve, and ballet dancers who constantly externally rotate their hip while dancing). [83,90–93] While the mechanism of injury may be

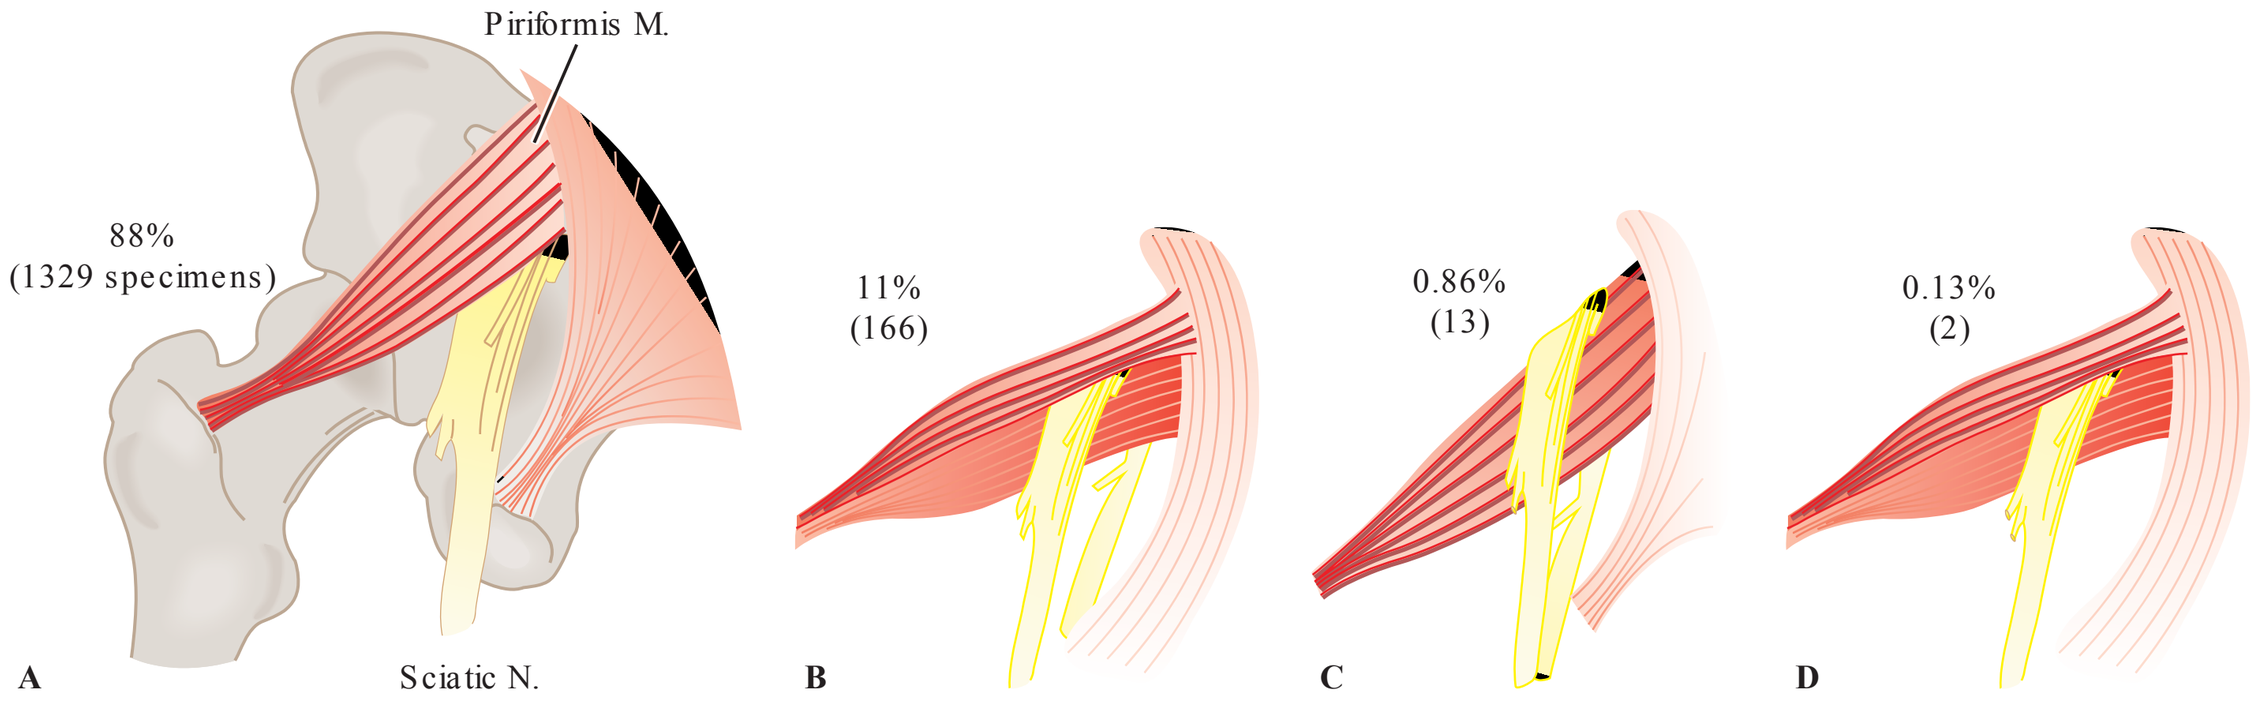

FIGURE 70.10 A–D. Relationship of the sciatic nerve to the piriformis muscle in 1510 extremities studied.[83]

postulated, the etiology of the signs and symptoms remains less clear. Traumatic injury to the piriformis muscle may generate inflammatory and edematous changes to the muscle and surrounding fascia, subsequently compressing the sciatic nerve against the wall of the pelvis and leading to a compression neuropathy.[93] The trauma itself may induce focal hyperirritability in the piriformis muscle, which can be further exacerbated by muscle spasm or hypertrophy.

Symptoms and Signs

Signs and symptoms of sciatic neuropathy include weakness, impaired ankle reflex, paresthesias, sensory loss, and/or pain in the distribution of the nerve. Weakness of toe extension and flexion, ankle dorsiflexion and plantarflexion, and ankle eversion and inversion are the most prominent signs.[86] Clinically, absence of complete weakness of ankle dorsiflexion and plantarflexion predicts earlier or better recovery.[88] Of the two nerve trunks, weakness more commonly affects fibular- versus tibial-innervated muscles.[85,86] This is especially true in sciatic neuropathy after hip replacement.[84] While it is not entirely understood why the fibular division is more selectively injured compared to the tibial division, various reasons have been postulated: (a) superficial and lateral position, thereby placing the fibular division in closer proximity to the hip joint and exposing it to injury from hip joint trauma or surgery; (b) smaller blood supply; (c) fewer and larger fascicles; (d) less supportive endoneurium and perineurium between fascicles; and (e) relative tethering of the nerve at the sciatic notch and fibular head, thereby making it vulnerable to stretch injuries.[85,94] The exception to this rule appears to be femur fractures or gunshot wounds to the thigh, in which case the tibial division can be involved to an equal or greater extent.[84] Because of preferential fibular involvement, knee flexion weakness is commonly insignificant, and isolated injury to the fibular division can masquerade as a fibular neuropathy at the knee or fibular head.

The most common presenting symptoms with piriformis syndrome are a deep, aching buttock pain that is often associated with a limp and sitting intolerance on the affected side.[93] Squatting, climbing stairs, walking, and prolonged sitting (especially on hard surfaces) typically worsen the pain. In addition, the piriformis muscle's compression of the pudendal nerve and blood vessels may cause labial pain and dyspareunia in females and scrotal pain and impotence in males. Painful bowel movements have also been reported, presumably due to the close proximity of the piriformis muscle and the rectum.[95] The two most consistent physical exam findings are tenderness to palpation in the greater sciatic notch and reproduction of pain with maximum flexion, adduction, and internal rotation of the hip.[93] Various physical exam maneuvers can be tried in an attempt to reproduce these findings: Freiberg's sign (buttock pain with passive, forced internal rotation of the hip), Lasègue's sign (pain and tenderness to palpation in the greater sciatic notch with the hip passively flexed to 90 degrees and the knee passively extended 180 degrees), Pace's maneuver (buttock pain with resisted abduction of the affected leg while in the seated position), and Beatty's maneuver (while laying in a lateral decubitus position on the unaffected side, buttock pain is elicited in the affected extremity when the patient actively abducts the affected hip and holds the knee several inches off the table).[89,96,97]

Diagnosis

Because the differential diagnosis can include radiculopathy, plexopathy, or fibular neuropathy, neuroimaging of the pelvis and/or lumbosacral spine may be necessary to help establish the cause of nerve damage based on the mechanism of injury. Electrodiagnostic testing can be performed to confirm the location of the lesion and to offer prognostic information based on the chronicity and severity of nerve damage. Because muscles innervated by the nerve roots are uninvolved, the lumbar paraspinal muscles are unaffected. In their retrospective analysis of 100 patients, Yuen et al.[84] noted greater severity of injury of the fibular division (64%), significant axonal loss (93%), tibialis anterior muscle EMG abnormality (92%), and low or absent extensor digitorum brevis (EDB) compound muscle action potential (CMAP) amplitude (80%). A more favorable prognosis—earlier or better recovery—was noted in those with a recordable EDB, CMAP, and presence of demyelination instead of axonal loss. Because normal sural and superficial fibular SNAP amplitudes were obtained in 29% and 9% of patients, respectively, the authors concluded that sparing of the tibial division does not necessarily exclude the diagnosis of sciatic neuropathy.

To diagnose piriformis syndrome, the symptoms and clinical exam findings must be correlated with neuroimaging of the pelvis (asymmetry of the piriformis muscle, mass effect, or anatomic variation consistent with entrapment) and electrodiagnostic studies (evidence consistent with extrapelvic compression of the sciatic nerve at the level of the piriformis muscle).[95,98,99]

Treatment

Conservative therapy for symptomatic relief includes analgesic medications, injections, and physical therapy. Physical therapy is important for those with evidence of motor weakness in order to prevent muscle contractures, minimize muscle atrophy, and maintain ambulatory status. An AFO should be considered for those with significant ankle dorsiflexion and plantarflexion

weakness. Spinal cord stimulation or intrathecal therapies should be considered for those who have a suboptimal response to the aforementioned and/or those who are not surgical candidates.

Surgical treatment of sciatic neuropathy is directed at identifying the cause of nerve injury. Surgery should be considered for cases of compression due to obvious mass effect or traumatic neuropathy that fails to improve with time. Surgical exploration for trauma-induced injuries, however, requires careful deliberation. Kline et al.[85] found that medical management in those patients with a partial deficit and/or improvement in function and pain resulted in an 80% and 60% chance of useful return of function in the tibial and fibular divisions, respectively. In those patients in whom surgery (neurolysis, suture repair, or nerve graft) was performed because of evidence of a nerve action potential distal to the lesion, good-to-excellent outcomes were common for the tibial division but not so common for the fibular division. Some have suggested that the paucity of successful functional outcomes with fibular division surgeries may be related to uncoordinated muscle reinnervation (as opposed to insufficient nerve regeneration), further calling into question the practicality of fibular division surgery.[85]

If the diagnosis of piriformis syndrome is confirmed and conservative management with physical therapy and medication fails to adequately relieve symptoms, intramuscular piriformis injection of corticosteroid and local anesthetic under CT guidance, fluoroscopic guidance, or combined fluoroscopic and EMG guidance can be performed.[92,100] Because the duration of analgesia with corticosteroid can be short-lived, some have even advocated the use of botulinum toxin for prolonged analgesia in those that at least respond diagnostically to the local anesthetic.[101–103] Surgical consultation for evaluation of piriformis tendon release and sciatic neurolysis should be considered as a last resort.[93,104]

Fibular (Peroneal) Nerve Entrapment

The fibular nerve is derived from the L4, L5, S1, and S2 nerve roots as a part of the sciatic nerve (Fig. 70.11). The fibular nerve, along with the tibial nerve, is a division of the sciatic nerve. Approximately 8 cm proximal to the popliteal fossa, the fibular nerve separates from the tibial nerve and forms the common fibular nerve. As it descends into the popliteal fossa, it innervates the short head of the biceps femoris muscle. Proximal to the fibular head, the common fibular nerves gives off two branches: the sural communicating branch and the lateral cutaneous branch. The sural communicating branch becomes part of the sural nerve after receiving a branch from the tibial nerve. The lateral cutaneous branch conveys sensory information from the proximal and lateral aspect of the leg. As it winds around the fibular head, covered only by skin and a thin layer of subcutaneous tissue, the common fibular nerve is most vulnerable to injury. Approximately 1 to 2 centimeters distal to the fibular head, the common fibular nerve dives into the fibular tunnel which is made up of the aponeurosis of the soleus muscle and a wide, thick, and inflexible fibrous arch.[105] Distal to the fibular tunnel, the common fibular nerve separates into the superficial and deep fibular nerves. The superficial fibular nerve innervates the ankle everters and plantar flexors (peroneus longus and brevis muscles), after which it divides into the medial and intermediate dorsal cutaneous nerves to provide sensory innervation to most of the dorsal aspect of the foot, with the exception of the web space between the first and second toes. (Ankle inversion is unaffected because the tibial nerve innervates the tibialis posterior muscle.) The deep fibular nerve innervates the ankle and toe dorsiflexors (tibialis anterior, extensor hallucis longus, extensor digitorum longus, and peroneus tertius muscles). Distal to the ankle mortise, the deep fibular nerve gives off lateral and medial branches. The former innervates the extensor digitorum brevis and extensor hallucis brevis, and the latter supplies cutaneous sensation to the web space between the first and second toes.

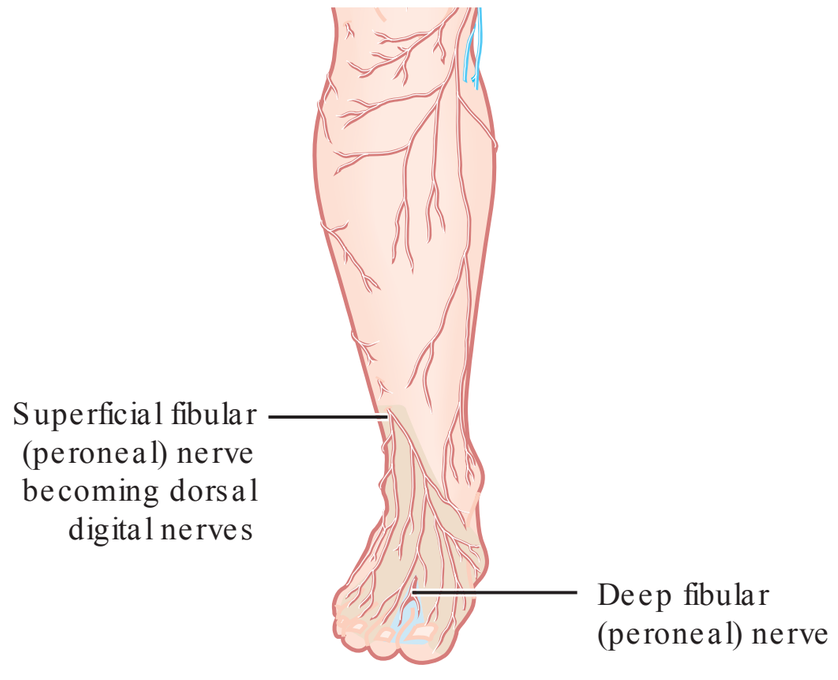

FIGURE 70.11 Cutaneous branches of the fibular nerve.

Etiology

Fibular neuropathy is the most common lower extremity mononeuropathy, but its exact gender or age prevalence is unknown.[106] In a retrospective analysis looking at 5777 trauma patients, Noble et al.[107] noted 79 lower extremity peripheral nerve injuries involving the fibular,[39] sciatic,[28] tibial,[8] and femoral[4] nerves. While fibular nerve trauma most commonly occurs at the fibular head where it is superficially protected only by the skin and thin underlying fascia, injury to the fibular nerve and its branches can occur anywhere along the course of the nerve. Aprile et al.[106] demonstrated that most (83%) causes of fibular neuropathy are identifiable, with the majority (31%) being due to perioperative issues. Various causes of fibular nerve injury include entrapment, compression (improperly applied casts or braces, tight stockings, vascular abnormality, osteophytes, and intraneural or extraneural tumor); traction (leg-crossing, prolonged squatting or kneeling, prolonged ankle plantarflexion, surgical positioning, high-heeled shoes,); trauma (fracture of the proximal fibular head, knee dislocation, ankle sprain or fracture, nerve laceration, and gunshot injury); metabolic (rapid weight loss, hyperthyroidism, diabetes mellitus, vasculitic disorders, and leprosy); surgery (orthopaedic surgery, vascular surgery, and plastic surgery); or idiopathic.[24,105,107–122] In their study of 146 fibular nerve injuries requiring surgery, Piton et al.[123] classified the causes as: fibular tunnel syndrome,[62] external compression,[16] trauma,[33] iatrogenic injury,[16] tumor,[9] wound injury,[7] contusion[2] and burn injury.[1] In a larger and more recent study involving 318 fibular nerve injuries requiring surgery, Kim et al.[124] classified the causes as: stretch or contusion without fracture or dislocation,[125] tumor,[40] laceration,[39] entrapment,[30] stretch or contusion with fracture or dislocation,[22] external compression,[21] iatrogenic,[13] and gun shot.[12] Looking at 60 patients who only had entrapment, Fabre et al.[105] classified the causes as idiopathic,[53] postural,[5] and dynamic.[2] True entrapment can be classified as postural (which is associated with kneeling, crouching, squatting, or ankle plantarflexion) or dynamic (which is associated with activities such as running).[24,126–128] For those with entrapment, it is postulated that chronic nerve irritation within the fibrous arch of the fibular tunnel causes edema, which subsequently causes scar tissue formation as the nerve glides in the narrow tunnel during knee flexion and extension.[105]

Superficial fibular nerve entrapment is relatively uncommon and usually is due to compression of the nerve as it exits the anterolateral compartment 10 cm proximal to the ankle.[129–131] While deep fibular nerve entrapment can occur anywhere along

its course, it is known as "anterior tarsal tunnel syndrome" when it becomes compressed beneath the inferior extensor retinaculum.[131–133] Postural causes of deep fibular entrapment include prolonged plantarflexion, such as with wearing high-heeled shoes.[24]

Symptoms and Signs

Symptoms of fibular neuropathy may include weakness, paresthesias, sensory loss, and/or pain in the distribution of the fibular nerve and its various branches. Patients with dynamic entrapment report activity-related leg pain with or without sensory impairment.[24] The degree and extent of neuromuscular deficit and atrophy depends on the location (common versus superficial versus deep fibular), severity, and chronicity of nerve injury. Common fibular injury typically causes dorsiflexion (ankle and toes) and eversion (ankle) weakness, leading to tripping due to dragging of toes, excessive hip and knee flexion in an attempt to clear the foot (steppage gait), and foot slap.[131] When the injury is proximal to the knee, knee flexion weakness also occurs because the biceps femoris muscle is affected. A positive Tinel's sign at the fibular head, 10 cm proximal to the ankle, or over the dorsal aspect of the ankle suggests a common fibular, superficial fibular, or deep fibular neuropathy, respectively. Fabre et al.[105] noted a positive Tinel's sign at the fibular head in 60 of the 62 (97%) cases of common fibular entrapment.[105] Sensory abnormalities, motor weakness, or pain beyond the territory of the nerve suggest an alternate diagnosis, such as a lumbar plexopathy, a lumbar radiculopathy, or other peripheral neuropathy.

Diagnosis

Electrodiagnostic studies can be performed to confirm the diagnosis, location, and extent of fibular neuropathy. Without axonal loss, the NCS reveals slowing of the nerve conduction velocity. However, when long-standing compression or direct nerve injury results in axonal loss, a decreased SNAP amplitude, a decreased compound muscle action potential amplitude, and a conduction block can be seen on NCS. The EMG portion of the study not only helps confirm axonal loss, but the extent of muscle involvement can aid in determining whether the lesion involves the common fibular, superficial fibular, or deep fibular nerve. For those with exercise-induced (dynamic) fibular neuropathy, electrodiagnostic studies may need to be done before and after exercising.[24] Once a fibular neuropathy has been confirmed electrodiagnostically, additional imaging (radiograph, CT, and MRI) or laboratory studies may be needed to isolate the cause of nerve injury.

Treatment

Nonsurgical treatment options include rest, modification of footwear or garments, analgesic medications, injections, and physical therapy. Physical therapy is important for those with evidence of motor weakness in order to prevent muscle contractures, minimize muscle atrophy, and maintain ambulatory status. Whether temporary relief of symptoms with medications or injections alters the long-term prognosis is unknown, as the extent of recovery depends on the causative factor, extent of nerve damage, and location of injury. The degree of pain relief after doing a fibular nerve block at the fibular head can provide diagnostic information. Significant fibular nerve damage resulting in ankle and foot weakness may necessitate an AFO and customized orthopaedic shoes to correct any gait disturbance.

Depending on the etiology of fibular nerve injury, surgery is advocated within 2 to 4 months if there is lack of clinical and electrophysiologic improvement.[105,123,124] In their retrospective analysis of 318 patients with preoperatively confirmed EMG evidence of knee-level common fibular nerve lesions, Kim et al.[124] reported recovery of useful function in 88% and 84% of those undergoing neurolysis and end-to-end suture repair, respectively; recovery of useful function in 75%, 38%, and 16% for those requiring nerve grafting less than 6 cm, 6 to 12 cm, and 13 to 24 cm, respectively; and preservation of preoperative clinical function in 80% of those requiring tumor resection. For patients with idiopathic entrapment, Fabre et al.[105] advocated operative decompression if symptoms fail to resolve within 3 to 4 months because they found the surgery was safe and the time needed for recovery was shorter than that associated with conservative management.

FOOT PAIN

Pes Planus

Etiology

Pes planus, a condition also known as flatfoot, refers to the loss of the normal longitudinal arch of the medial foot (Fig. 70.12). The most common cause of pes planus is insufficiency or dysfunction of the posterior tibial tendon.[134] Congenital flatfoot is used to describe a flatfoot present since birth. Trauma, such as Lisfranc joint injuries and calcaneal fractures, can also lead to pes planus due to joint subluxation. Degenerative changes secondary to arthritis can also lead to pes planus. Tarsal coalition—a congenital fibrous union or fusion between the bones of the hindfoot and midfoot—has also been implicated as a cause of flatfoot.[135]

Symptoms and Signs

Symptoms of pes planus can vary among patients with different forms of anatomic pathology and biomechanics leading to the condition. Examination of the feet should begin with the patient in standing position. Typically, the longitudinal arch flattens upon standing and appears when the foot is not bearing weight. Heel eversion often accompanies pes planus. Severe pes planus may result in significant pain, particularly along the course of the posterior tibial tendon, which may be tender upon palpation.[136]

Diagnosis and Treatment

Radiographic imaging should be performed of the foot and ankle in three weight-bearing views—anteroposterior, oblique, and lateral. Loss of the longitudinal arch is best visualized on the weight-bearing lateral radiographs.[137] MRI can also be useful in assessing this condition, particularly in evaluation of the posterior tibial tendon. Treatment is often conservative through the use of arch supports and plantar inserts. Surgical treatment may involve posterior tibial advancement, subtalar fusion, or osteotomies, depending on the initial cause of the condition.

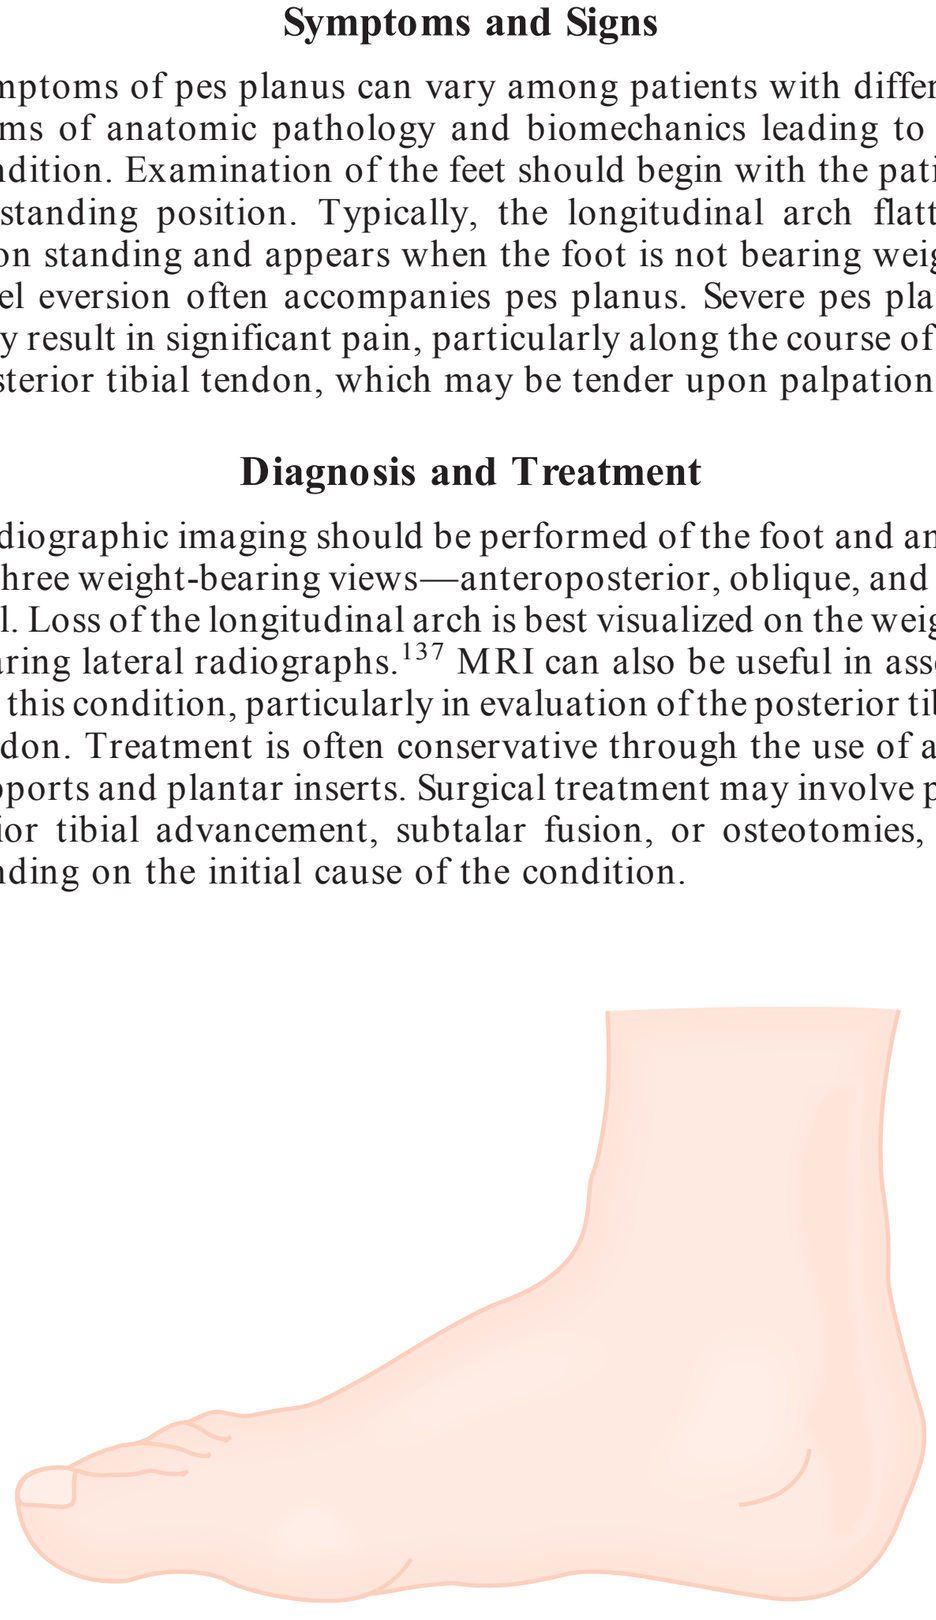

FIGURE 70.12 Pes planus.

Pes Cavus

Etiology

Cavus foot deformity is an abnormal elevation of the longitudinal arch (Fig. 70.13). This results in increased stress forces on the metatarsal heads and decreased weight bearing by the plantar region of the foot.[138] Causes of pes cavus include neuromuscular disease (such as muscular dystrophy, cerebral palsy, and spinal tumors), residual clubfoot, malunion of calcaneal or talar fractures, and burns.[138]

Symptoms and Signs

Symptomatology varies based on the extent of the deformity. Lateral foot pain can develop as a result of increased weight bearing by the lateral foot. Metatarsalgia is frequently associated with pes cavus. Intractable plantar keratosis is often seen as well. Clawing of the toes—hyperextension at the metatarsophalangeal joints and flexion of the proximal and distal interphalangeal joints—may also be present.[138] Patients may experience generalized stiffness of the joint, leading to disuse of the affected foot.

Diagnosis and Treatment

Physical examination should elucidate if the deformity is flexible or rigid. This can be determined by performance of the Coleman block test.[137] A 1-inch wood block is placed beneath the heel and lateral foot while the first, second, and third metatarsals are allowed to hang freely into plantarflexion and pronation. If heel varus corrects in this stance, the deformity is flexible. If the hindfoot does not correct, the deformity is rigid. Weight-bearing radiographs of the ankle and foot aid in the diagnosis through demonstration of hindfoot varus. MRI of the spine may be necessary to evaluate for possible spinal tumor presence if the deformity is unilateral and no inciting traumatic event is noted. In addition, neurologic consultation, electromyography, and NCS can be obtained to evaluate for polio, Charcot-Marie-Tooth disease, and other neurologic causes of pes cavus. Conservative therapy for pes cavus includes the use of orthotic shoe inserts to offset increased weight-bearing forces on the metatarsal heads. Surgical intervention is warranted if the condition is severe and is aimed at construction of a plantigrade foot. This may be accomplished through tendon transfers, osteotomies, and arthrodesis.[137]

FIGURE 70.13 Pes cavus.

Plantar Fasciitis

Etiology

Plantar fasciitis is a painful inflammatory condition involving the insertion of the plantar fascia on the medial process of the calcaneal tuberosity. Pes planus, pes cavus, leg-length discrepancy, overpronation, and running all involve increased stress forces placed on the plantar fascia, and thus can lead to plantar fasciitis.[139]

Symptoms and Signs

Patients typically complain of intense sharp heel pain after the first few steps in the morning or after a period of rest. The pain is usually located along the anterior portion of the heel, with radiation into the sole of the foot.[140] The pain is exacerbated by weight-bearing activities and relieved by rest. Patients may also experience generalized stiffness of the foot and swelling of the heel.

Diagnosis and Treatment

Pain can be reproduced on palpation of the anteromedial aspect of the calcaneus as well as the proximal plantar fascia. Passive dorsiflexion of the toes and toe-walking can also reproduce pain secondary to plantar fasciitis.[140] Radiographic imaging can reveal soft tissue calcifications in the heel and may be more useful to investigate for bony tumor or fractures as an underlying cause. Ultrasound may reveal a thicker heel aponeurosis, which can be associated with plantar fasciitis. MRI can demonstrate thickening of the plantar fascia. Because of the poor sensitivity and specificity of these imaging techniques, diagnosis of plantar fasciitis is usually made through the history and physical examination. Conservative treatment involves the use of medial arch support inserts in footwear, as well as stretching exercises focusing on the plantar fascia, ice therapy, and NSAIDs.[140] Night splints can be worn to allow the plantar fascia to heal in an elongated position as opposed to the natural plantarflexed position of the foot during sleep.[141] Extracorporeal shock wave therapy for plantar fasciitis may be beneficial, but limited evidence supports it use. Case reports have demonstrated that corticosteroid injections and botulinum toxin injections can also be useful in treating plantar fasciitis. Injection of either substance is performed with a medial or lateral approach into the site of maximal tenderness. Complications include plantar fascia rupture and corticosteroid-induced fat pad atrophy.[125] Surgical release of the plantar fascia may be indicated when these treatment modalities are unsuccessful.

Heel Pad Deficiency

Etiology

The fat pad of the heel is made of individual fibrous septa containing fat and elastic fibrous tissue. The fat pad absorbs shock and distributes mechanical forces to the calcaneus. The fat pad atrophies with age, multiple glucocorticoid injections, and trauma.[142]

Symptoms and Signs

Patients typically experience deep, diffuse plantar heel pain that is exacerbated upon standing and walking/running on hard surfaces. Direct palpation of this area reproduces this pain. There is palpable atrophy of the heel pad and underlying bone may be palpated. Scar tissue and calcification can be observed.

Diagnosis and Treatment

Diagnosis is usually made through history and physical examination. NSAIDs can provide significant analgesia. Long-acting local

anesthetics, such as bupivacaine, can be infiltrated into the affected area for severe, painful crises. Corticosteroids are contraindicated, as they can worsen the condition.[125] Shock-absorbing footwear inserts can be helpful by providing cushion and absorbing shock.

Tarsal Tunnel Syndrome

Anatomy

The tarsal tunnel is bounded by the flexor retinaculum, a strong fibrous band that extends from the medial malleolus to the margin of the calcaneus, and the medial surfaces of both the calcaneus and talus.[143] The posterior tibial nerve courses beneath the flexor retinaculum through this tunnel and divides into the medial and lateral plantar nerves, which innervate the small muscles of the foot and the skin on the plantar aspect of the foot and toes (Fig. 70.14).

Etiology

Compression of the posterior tibial nerve as it passes behind the medial malleolus in the tarsal tunnel may lead to tarsal tunnel syndrome, a painful condition of the ankle and plantar aspect of the foot. The branches of the posterior tibial nerve are vulnerable to compressive injury (restrictive footwear), entrapment from space-occupying lesions (i.e., ganglion cysts, osteophytes, and tumors), direct trauma, overuse injuries, and inflammation within the tarsal tunnel.[144] Hindfoot valgus deformities can further exacerbate tarsal tunnel syndrome symptoms due to increased neural tension that is secondary to an increase in eversion and dorsiflexion foot positioning. All of these conditions can lead to edema and scar tissue formation, which further limit the vascular supply and cause increased traction of the nerve between joint movements. This ultimately can result in axonal and Wallerian degeneration.

Symptoms and Signs

Pain or paresthesias in the heel, medial malleolus, or plantar surface of the foot may occur, depending on which nerve branch is compressed and the severity of the compression. When both plantar nerves are affected, symptoms extend from the posterior malleolus to the plantar aspect of the foot and dorsal surfaces of the distal aspect of the toes. Pain can be experienced in both the standing and reclining positions and may be worse at night.[143] Simultaneous dorsiflexion and eversion of the ankle exacerbates the pain due to increased nerve tension. Advanced disease leads to weakness of the intrinsic muscles of the foot and of the toe plantar flexor muscles. Physical examination typically reveals tenderness to palpation of the tibial nerve. Percussion at the medial malleolus (Tinel's sign) causes radiation of pain and paresthesias along the path of the posterior tibial nerve and its branches.[143] In addition, symptoms may be reproduced through continuous compression of the nerve for 30 seconds (Phalen's sign).[143] Sensory deficits are uncommon, but can affect the sole of the foot if present.

Diagnosis

Electromyography and nerve conduction velocity studies often reveal prolonged motor terminal latency of the medial or plantar nerves to the abductor hallucis and abductor digiti quinti muscles. In addition, they display abnormalities in sensory nerve conduction including absent nerve potentials or slow nerve conduction velocity.[145] While electrodiagnostic testing can aid in the diagnosis of tibial neuropathy, neuroimaging may still be necessary to demonstrate whether a space-occupying lesion within the tarsal tunnel is the source of the symptoms.[146] MRI demonstrates the anatomy of the tarsal tunnel and its contents and can prove useful in planning for surgical decompression.

Treatment

Nonsurgical treatment options include rest, medications (corticosteroids, acetaminophen [APAP], NSAIDs, antiseizure medications, opioids, tricyclic antidepressants, topical analgesics, lidocaine patch), injections, and physical therapy. Initial treatment includes nonsurgical measures such as avoidance of exacerbating activities, medications (corticosteroids, APAP, NSAIDs, antiseizure medications, opioids, tricyclic antidepressants, topical analgesics, lidocaine patch), TENS, physical therapy, shoe inserts, and utilization of night splints with the foot in plantarflexion. An injection of local anesthetic and steroid into the tarsal tunnel may provide analgesia.[145] Surgical decompression with release of the flexor retinaculum is employed if nonoperative measures fail. If present, space-occupying lesions of the tarsal tunnel, such as varicose veins and ganglions, are removed along with release of the flexor retinaculum. Decompression may also be accomplished through division of the proximal ridge of the abductor hallucis.[144]

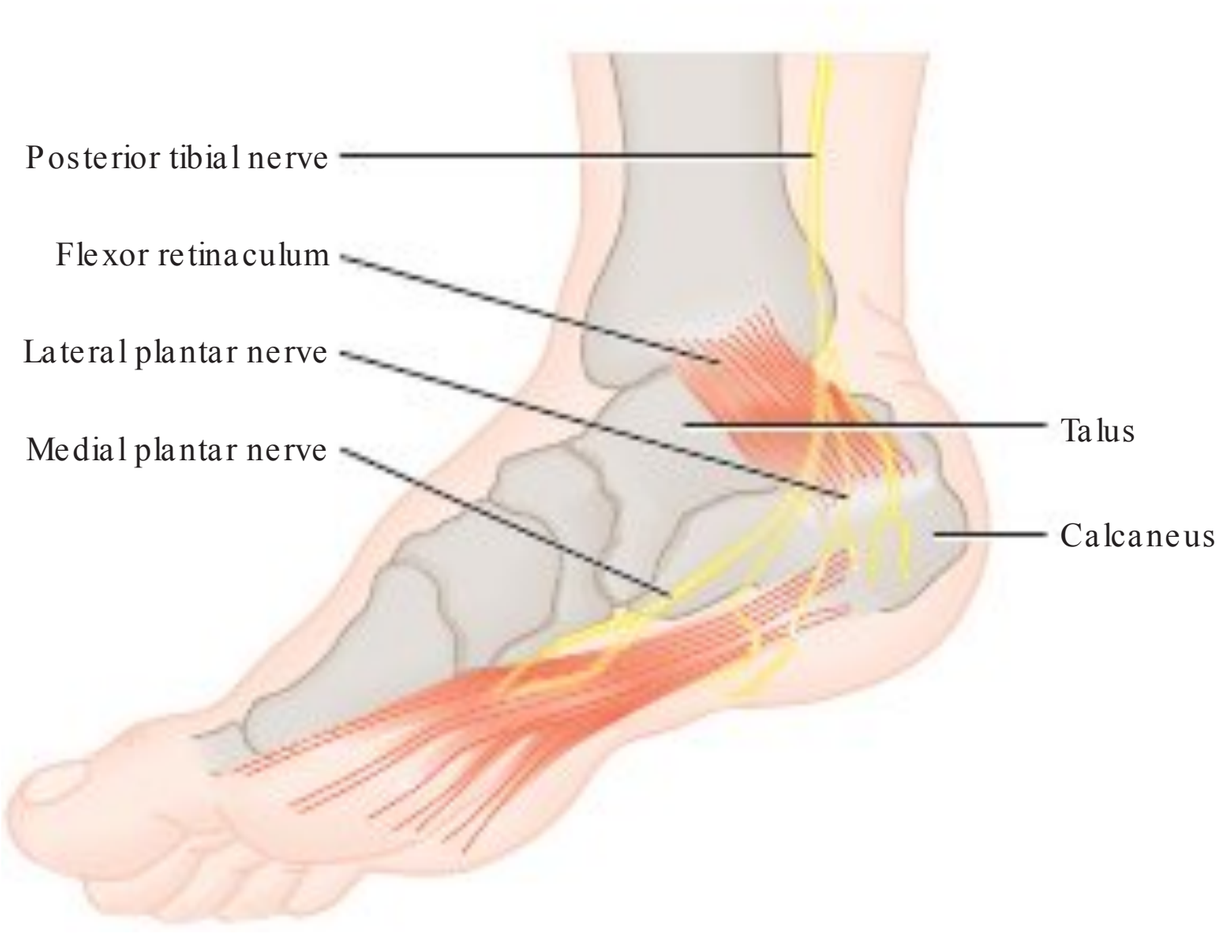

FIGURE 70.14 Anatomy of the tarsal tunnel and posterior tibial nerve.

Surgical complications primarily involve incomplete release of the flexor retinaculum, resulting in persistent pain.[144]

Lisfranc's Joint Instability

Etiology

The Lisfranc joint (tarsometatarsal joint or metatarsal cuneiform joint) is a six-bone complex that connects the forefoot and the midfoot. It is made up of the articulation of the bases of the first three metatarsals with the cuneiforms and the fourth and fifth metatarsals with the cuboid. The joint aids in pronation and supination of the foot.[147] The great majority of Lisfranc joint injuries are associated with fractures, especially the metatarsals. While injury to the joint is generally associated with high-energy mechanisms (e.g., falls or motor vehicle collisions), resulting in severe inversion or plantarflexion, low impact mechanisms (e.g., direct trauma in sports-related injuries) are also known to cause injury.[148] The Lisfranc injury may be classified by the direction of the dislocation.

Symptoms and Signs

Lisfranc's joint instability is characterized by severe midfoot pain and the inability to bear weight. Point tenderness over the midfoot is noted on exam. Bruising on the plantar surface of the midfoot represents an occult sign of an injury. Depending on the mechanism of injury, there may be soft-tissue damage, such as edema, a wound, or vascular impairment. Pain or edema that persists after soft tissue healing is expected to have occurred should raise the index of suspicion for a Lisfranc joint injury.[148]

Diagnosis and Treatment

Radiographs will reveal fractures of the joint and displacement of the metatarsals. Because sprains are more difficult to detect, weight-bearing plain radiographs and stress radiographs taken with the foot plantarflexed and inverted have been suggested to establish the diagnosis.[149] Recently, CT scanning is becoming the imaging modality of choice in diagnosing Lisfranc injuries.[150]

Treatment depends on the type and severity of the injury, as well as the length of time between injury and diagnosis. Ligamentous injury can benefit from casting or a fitted boot. If these conservative treatments fail, surgical open reduction or joint fusion may be required.

Posterior Tibial Tendon Insufficiency

Etiology

Posterior tibial tendon insufficiency is the most common cause of acquired adult flatfoot deformity.[151] Flatfoot deformities result from flattening of the medial longitudinal arch of the foot with failing of the supporting soft tissue structures of the ankle and hindfoot. The posterior tibial tendon is the principle supporting mechanism of this arch, though ligament involvement is extensive.[134] Dysfunction of the posterior tibial tendon leads to the collapse of the arch and the formation of a pes planovalgus deformity. Arthritis may develop secondary to the foot deformity. Insufficiency of the posterior tibial tendon may result from a variety of insults, including trauma and arthritic damage. Patients are most often middle-aged females and are often obese.[152]

Symptoms and Signs

Initially, patients report pain along the medial aspect of the foot and ankle due to stretching of medial ligaments and soft tissues. On physical exam, erythema, edema, and tenderness to palpation along the course of the posterior tibial tendon can be appreciated. Later, as the arch begins to collapse, the ankle starts to roll inward, resulting in pain along the lateral aspect of the foot.[152] There may be difficulty in performing a single leg heel rise. Persistent dull aching pain due to destruction of the midfoot may culminate in difficulty with standing and ambulation.

Diagnosis and Treatment

Radiographic imaging should include weight-bearing anteroposterior and lateral radiographs of the foot to evaluate the biomechanical relationships and detect secondary arthritic changes.[152] MRI is utilized to assess the integrity of the posterior tibial tendon.

Initial treatment is supportive and involves immobilization, analgesic medications, and orthotic devices to correct pronation. Steroid injections have not been proven to be efficacious and remain controversial. When supportive measures fail, treatment consists of surgical augmentation of the posterior tibial tendon, alone, or in combination with osteotomy or arthrodesis.[152]

Ganglion

Etiology

Ganglions are mucin-filled cysts that typically arise from a joint or tendon sheath. Although the etiology is uncertain, it may represent degenerative changes or reaction to inflammation or trauma.[153]

Symptoms and Signs

Ganglion cysts are generally asymptomatic. However, pain can occur as a result of inflammatory pressure points created while walking or from wearing tight-fitting footwear.

Diagnosis and Treatment

Ganglions are commonly found along the anterolateral aspect of the ankle and are usually solitary and less than 2 cm in diameter.[154] Upon palpation, they are firm and well-circumscribed. Nonsurgical treatment options include fine needle aspiration or injection of corticosteroids into the ganglion.[154] When these measures fail, surgical excision of the cyst and stalk from its origin on the ligament or joint capsule and capsular excision should be performed. The most common surgical complication is ganglion recurrence.[154]

Metatarsalgia

Etiology

Metatarsalgia refers to pain involving one or more of the metatarsal heads and distal metatarsal shafts, secondary to chronically elevated stress forces as the total body weight is transferred to the forefoot during the mid-stance and push-off phases of walking and running.[155] Abnormal biomechanics resulting from excessive pronation, cavus deformities, foot surgeries (e.g., osteotomies), and high-heeled shoes can further increase the weight distribution on the metatarsal heads.[153] The increased prevalence of metatarsalgia among women is likely due to wearing high-heeled shoes. Other causes of metatarsalgia include intermetatarsal bursitis/neuritis, metatarsal stress fracture, metatarsophalangeal joint stress syndrome, sesamoiditis, inflammatory arthritis, interdigital neuroma, and aseptic necrosis of the second metatarsal head (Freiberg disease).[153]

Symptoms and Signs

Pain severity is gradual in nature and is aggravated with walking and running activities. Over time, calluses can form over the second and third metatarsal heads and can further increase weight bearing on the metatarsal heads. On physical examination, palpable point tenderness is elicited at the distal end of the plantar metatarsal fat pad and also can be reproduced by squeezing the metatarsal head between the thumb and index finger.[153] Interdigital neuromas can lead to metatarsalgia and should be considered when pain is present in the interdigital web spaces. Over time, the pain may progress to diffuse forefoot and midfoot pain.

Diagnosis and Treatment

Radiographic imaging (weight-bearing anteroposterior, lateral, and oblique views) of the affected foot should be obtained to exclude metatarsal stress fractures, which may also lead to forefoot pain. Ultrasound and MRI may be necessary if a neuroma, cyst, bursitis, or other soft-tissue anomaly is suspected. A serum C-reactive protein, uric acid level, and erythrocyte sedimentation rate should be obtained to exclude gout, which often presents as metatarsal pain at the base of the great toe.

Conservative treatment includes the use of analgesic medications and semi-rigid orthotic inserts to reduce pressure on the metatarsal heads. Kang et al.[156] showed that the use of metatarsal pads resulted in decreased maximal peak pressures and pressure time intervals during exercise, which translated to improved function and analgesia. Athletes can achieve significant pain reduction through the use of metatarsal bar appliances that can be placed in footwear. Surgical procedures are aimed at equalizing weight-bearing forces on the metatarsal heads and may include metatarsal shaft osteotomy or metatarsal head condyle excision.[157]

Hallux Valgus

Etiology

Hallux valgus, also known as bunion deformity, is the most common deformity of the metatarsophalangeal joint.[158] Subluxation results in lateral deviation of the proximal phalanx of the great toe and the formation of a medial prominence by the first metatarsal head (Fig. 70.15). The deformity can be congenital or can result from biomechanical instability. Use of improper footwear, such as high-heeled shoes with tight-fitting and small toe boxes, may explain the higher prevalence hallux valgus among women.[158]

Symptoms and Signs

Pain occurs in the first metatarsophalangeal joint and can be described as deep, aching, and/or lancinating. Pain is worsened with ambulation and relieved upon shoe removal. Physical examination reveals a prominence on the medial aspect of the first metatarsal head and valgus deformity of the great toe. Adventitial bursa formation over the prominent medial metatarsal head can also be observed.[159] Bursitis and overlying skin inflammation may be present. Osteoarthritic changes that occur over time may result in significant reduction in joint range of motion associated with pain.

Diagnosis and Treatment

Radiographic imaging (weight-bearing anteroposterior, lateral, and oblique views) should be obtained in order to measure the angular degree of deformity, which provides diagnostic and prognostic information.[159]

Conservative treatment involves wearing footwear with wide toe boxes and placement of pads in the first web space and over the median prominence to relieve pressure-induced pain. Oral

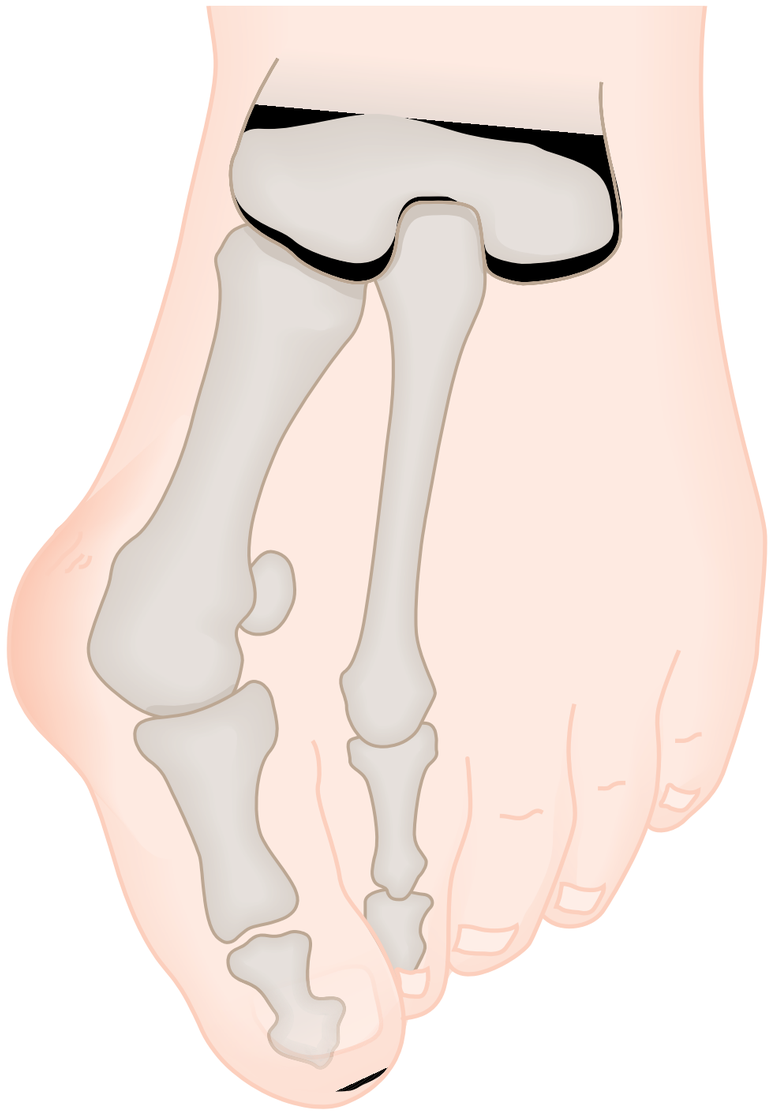

FIGURE 70.15 Hallux valgus. See text for details.

analgesic medications and corticosteroid injections into the first metatarsophalangeal joint can be used to address acute, painful inflammatory states. Surgical treatment is indicated for intractable pain associated with significant functional impairment. Surgical options include osteotomy, exostectomy, resectional arthroplasty, resectional arthroplasty with implant, capsulotendon balancing, first metatarsophalangeal joint arthrodesis, and first metatarsocuneiform joint arthrodesis.[159] A majority of these techniques involve excision of the medial prominence of the metatarsal head (bunionectomy), adductor hallucis tendon release, and occasional excision of the lateral sesamoid bone. Major surgical complications include overcorrection and recurrence.[159]

Hallux Rigidus

Etiology

Hallux rigidus is osteoarthritis of the first metatarsophalangeal joint and is associated with restricted range of motion and pain (Fig. 70.16). This results from cartilage degeneration, altered joint mechanics, and osteophyte formation. Impingement of the dorsal osteophytes results in inflammation and pressure point pain.[160] Athletic activities involving running have been associated with development of hallux rigidus.

Symptoms and Signs

Patients describe a dull, aching pain on the dorsal surface of the first metatarsophalangeal joint that occurs during weight-bearing activities involving the forefoot and often results in an antalgic gait. Unlike hallux valgus, pain from hallux rigidus is associated with or without wearing shoes. Neuropathic pain can result from first dorsal digital nerve entrapment. Physical examination reveals an osteophyte formation on the dorsal surface of the first metatarsophalangeal joint and extremely limited range of motion.

Diagnosis and Treatment

Radiographic imaging reveals degenerative changes of the first metatarsophalangeal joint. Early changes include dorsal and mar-

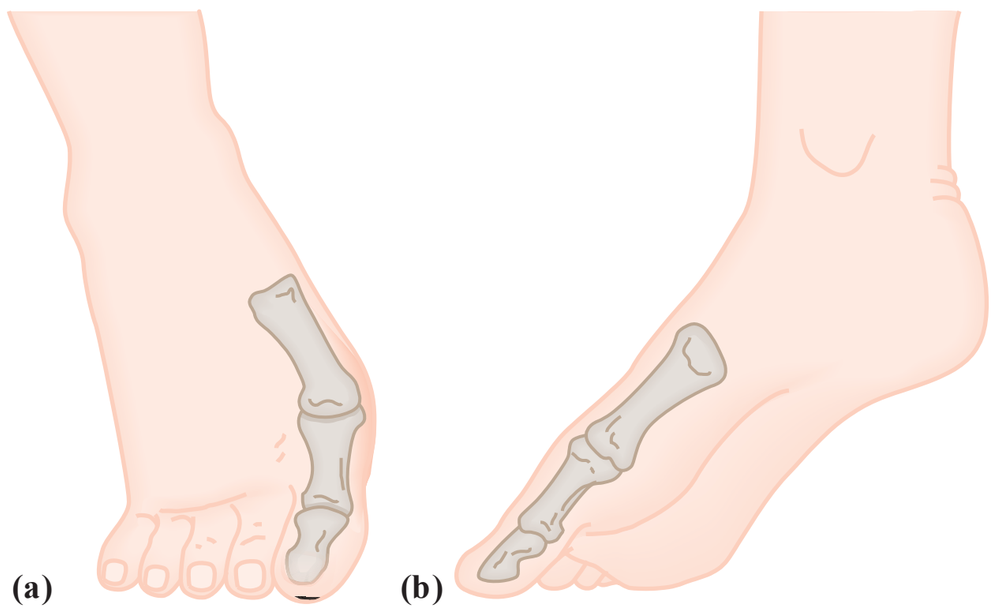

FIGURE 70.16 Hallux rigidus. **A.** Anterior view. **B.** Medial view. Arthritis of the metatarsophalangeal joint reduces motion, especially in dorsiflexion. Push-off is painful.

ginal osteophyte formation. Severe changes that can be visualized include joint space narrowing, sclerosis, joint irregularities, and sesamoid and cystic degeneration. Coughlin and Shurnas[161] proposed a Grade 0 to 4 classification system based on range of motion, physical exam findings, and radiographic results.

Conservative treatment includes rest, customized foot orthotics, and wearing low-heeled, rigid rocker bottom soled shoes with soft surfaces lining the dorsum of the foot. Corticosteroids can be injected in to the first metatarsal interspace lateral to the joint, along with local anesthetic application in the region of the first dorsal digital nerve. Several surgical treatments can be attempted to correct the condition. The least invasive, a cheilectomy, involves the excision of all irregular bony spurs contributing to decreased range of motion. This can provide significant pain relief and gain in function, although a successful outcome is inversely proportional to the degree of arthritic changes. A resection arthroplasty (Keller procedure), which involves excision of the base of the proximal phalanx, is usually reserved for patients with low functional demands.[160] A proximal phalanx and metatarsal osteotomy can also be performed. Complications, such as flaccidity and motor weakness of the hallux, are quite high.[160] Although a joint arthrodesis can provide analgesia, it results in loss of joint motion. Despite this, patients can continue to remain physically active.

Intractable Keratosis

Etiology

Intractable keratosis is characterized by hard callus formation that develops underneath the metatarsal heads due to plantar flexion.[162] Callus formation results in point pressure on the plantar fat pad.

Symptoms and Signs

Intractable keratosis presents as a painful discrete lesion that is aggravated by weight-bearing activities and causes an antalgic gait. Physical examination reveals a 1 cm focal, whitish colored lesion with circumferential erythema found on the plantar aspect of the forefoot.[161]

Diagnosis and Treatment

Radiographic imaging should be performed to exclude other pathology, including fractures, metatarsal avascular necrosis.

Conservative treatment involves wearing shoes with wide toe boxes and placing a pad underneath the uninvolved metatarsal heads in order to offload weight from the involved metatarsal head. Pumice stones and prescription creams containing lactic acid can be used to reduce the mass of the keratosis and thereby provide symptomatic relief. Analgesic medications can provide minor relief. Corticosteroid injections are controversial as the can create fat-pad atrophy and further exacerbate the condition.[163] Surgical options can include callus tissue reduction and core removal, a variety of distal metatarsal osteotomies, and segmental resection of the proximal metatarsal.[161]

Sesamoiditis

Etiology and Pathophysiology

Sesamoiditis refers to inflammation of the two sesamoid bones on the plantar of the first metatarsophalangeal joint. This state of inflammation can occur as a result of increased stress forces on the sesamoid bones. This is exhibited in lateral displacement of the sesamoid bones seen in hallux valgus.

Symptoms and Signs

Pain is localized on the plantar aspect of the foot and is aggravated by weight-bearing activities. Postural abnormalities may contribute to this condition. Physical examination reveals pain upon dorsiflexion of the metatarsophalangeal joint.[153] In addition, direct palpation of the sesamoid bones causes significant pain.

Diagnosis and Treatment

Radiographic studies should be performed to exclude fractures and other anatomic abnormalities. If plain film radiographs are nondiagnostic, a bone scan can prove useful.

Treatment includes reducing loading forces on the sesamoid bones through the use of a walking cast. In addition, NSAIDs can provide significant analgesia and decrease inflammation. Surgical resection of the sesamoids may be considered after failure to respond to conservative treatment. The major surgical complication is hallux varus.[153]

Gout

Etiology

Elevated systemic uric acid levels cause gout. It typically occurs in association with serum uric acid concentrations greater than 7.0 mg/dL, at which uric acid crystal precipitation occurs.[164] This typically occurs due to increased uric acid production, decreased renal excretion of uric acid, or both.[165] Gout typically manifests in men with a peak age of onset in the fifth decade of life and in women in the sixth decade of life.[164]

Symptoms and Signs

The natural history of gout can be divided into three distinct stages: asymptomatic hyperuricemia, acute and intermittent gout, and chronic tophaceous gout.[165] Asymptomatic hyperuricemia can last for 10 to 30 years before an acute gouty arthritis event occurs. This event is characterized by severe pain in conjunction with edema, erythema, and rubor of the affected joint, after which resolution occurs within 1 to 2 weeks. Gout typically involves only one joint in the early course of the disease, and it is usually the first metatarsophalangeal joint. The acute and intermittent phase involves asymptomatic periods interrupted by acute attacks. These intervals can vary from months to years, but over time the frequency and duration of attacks and number of joints involved increases. Although it remains uncertain, the attacks may be associated with rapid fluctuations of serum uric acid levels. Chronic gouty arthritis typically develops after more than

10 years of acute intermittent gout. There are no pain-free intervals in this stage.

Diagnosis and Treatment

Patients report multiple painful, stiff, edematous joints, particularly in the toes, ankles, and knees. Although elevated serum uric acid levels (greater than 7.0 mg/dL) are commonly seen in gout, there may be periods of time when serum uric acid levels are normal.[165] In addition to hyperuricemia, leukocytosis, elevated erythrocyte sedimentation rates, and elevated C-reactive protein levels may be present in acute attacks. The criterion standard of diagnosis, however, remains aspiration and examination of synovial fluid from an actively affected joint. Under polarized microscopy, monosodium uric acid crystals are seen as negatively birefringent needle-like structures engulfed by polymorphonuclear neutrophils.

Treatment of acute gouty arthritis focuses on decreasing the inflammation within the joints. This is best accomplished through NSAIDs. In patients who cannot take NSAIDs, corticosteroids can be given via the oral, intravenous, or intra-articular routes. If taken within the first 12 hours of an acute gouty attack, oral colchicine can have an anti-inflammatory effect and can prevent uric acid crystal deposition. While colchicine does not lower the uric acid levels, in low doses it can be used to prevent or reduce the severity of future attacks. Patients however, may not be able to tolerate the side effects of nausea, vomiting, and diarrhea. Chronic therapy to prevent recurrence of gouty arthritic attacks is aimed at normalizing serum uric acid levels. Uricosuric agents, such as probenecid, work by increasing uric acid secretion into the urine. Xanthine oxidase inhibitors, such as allopurinol, work by inhibiting uric acid synthesis. Surgical resection of large nodular deposits of uric acid crystals, also known as tophi, can offer improvement in terms of mechanical function.[166]

Interdigital (Morton's) Neuroma

Etiology

An interdigital neuroma is characterized by a well-localized area of pain on the plantar aspect of the forefoot that radiates into the web space. It typically involves the third interspace of the foot. Although this condition is termed interdigital neuroma, it is not a true neuroma. The histopathologic changes include the degeneration of nerve fibers associated with deposition of amorphous eosinophilic material that is more congruent with neuropathy secondary to an entrapment phenomenon.[167] What causes an interdigital neuroma is unclear, although it has been hypothesized that it arises from constant traction of nerve fibers against the transverse metatarsal ligament during dorsiflexion of the toes.[168] Interdigital neuromas occur approximately 10 times more frequently in women than men. This may be explained by the state of continuous dorsiflexion of the feet when wearing high-heeled shoes.[168]

Symptoms and Signs

Patients typically complain of localized pain in the region of the metatarsal head. The third interspace is more frequently involved than the second interspace, but it rarely involves the first or fourth interspace.[169] The pain is aggravated by wearing tight-fitting shoes and walking and is alleviated by rest and removal of shoes. Upon palpation of the involved interspace, patients report a sharp pain that radiates into the toes. Often, a mass located in the interspace can be palpated. Palpating the affected interspace with one hand and squeezing the entire foot at the same time with the other hand, resulting in narrowing of the intermetatarsal space and compression of the mass can often reproduce symptoms. This can elicit an audible click, known as Mulder's sign.[161] The differential diagnosis of interdigital neuroma should include stress fracture, tendon sheath ganglion, foreign-body reaction, nerve-sheath tumor, strain of the plantar capsule, and capsulitis or bursitis at the level of the plantar metatarsal-phalangeal joint. In many of these conditions, inflammation of the adjacent nerve also may be present, causing the neuritic sensation of an interdigital neuroma, thus complicating proper diagnosis. It is also important to distinguish interdigital pain from metatarsalgia, which gives rise to a host of other possible pathologies including avascular necrosis, synovial cysts, and tarsal tunnel compression.

Diagnosis and Treatment

Although interdigital neuromas are often diagnosed based solely on clinical findings, MRI, CT, and ultrasound have all been utilized for diagnostic purposes as well. MRI has emerged as the preferred imaging modality due to superior contrast resolution and precision. Interdigital neuromas are best visualized on short-axis (transverse) T1-weighted images through the metatarsal heads. Due to their highly vascular nature, intravenous contrast agents typically result in visual enhancement. They appear as bulbous masses arising between the metatarsal heads (Fig. 70.17).[170] Recent literature has demonstrated that despite being less costly and more portable, use of ultrasound involves a high learning curve and is quite heavily dependent on operator skill. Radiographs may reveal pathology at the metatarsophalangeal joint; however, they are not useful in the diagnosis of interdigital neuromas.

Conservative management of interdigital neuromas includes wearing shoes with wider toe boxes, adequate cushioning, and heels no higher than 1 in. Neuroma pads—soft support inserts that are placed proximal to the affected metatarsal head—are designed to separate the metatarsal heads and prevent rubbing or irritating the affected neuroma when stepping down. NSAIDs and corticosteroid injections into the affected interspace can be tried.[168] However, corticosteroids can result in local fat atrophy and metatarsalgia. Phenol neurolysis of the common interdigital nerve has also been reported to be effective.[171] When conservative management fails, surgical intervention may be indicated. This

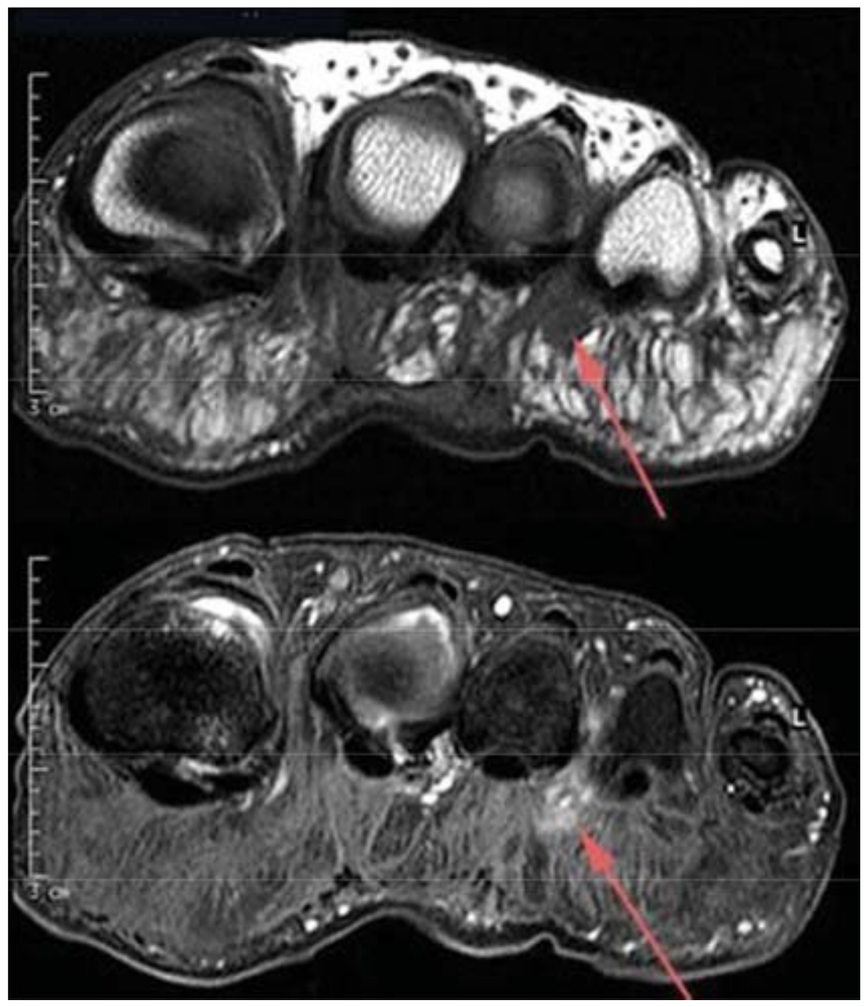

FIGURE 70.17 Interdigital neuroma. Transverse T1-weighted (top) and contrast-enhanced fat-suppressed T1-weighted (bottom). MRIs show the bulbous morphology of the perineural mass with plantar extension. The administration of contrast material reveals enhancement of the lesion.

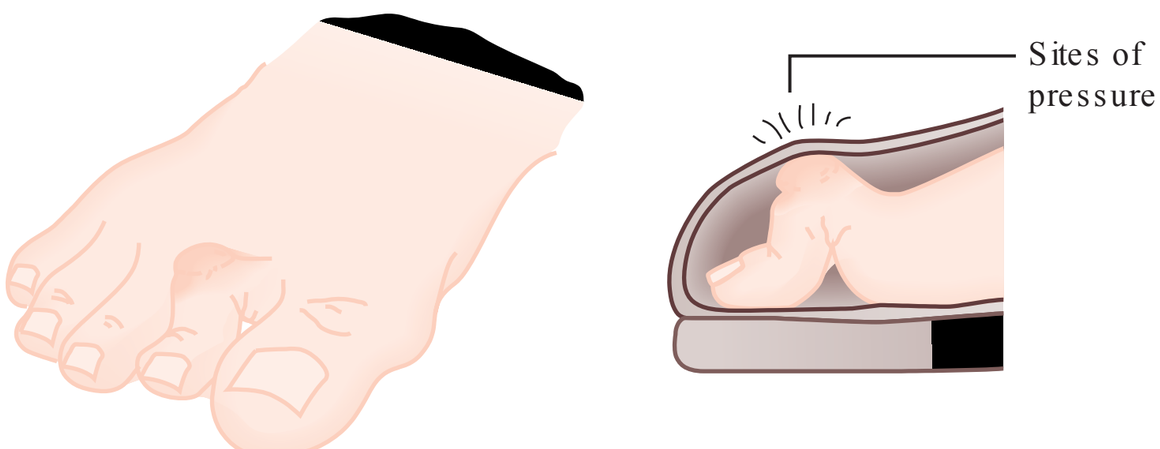

FIGURE 70.18 Hammertoe deformity, a typical small toe deformity, often causes corns and calluses with standard footwear. Extra deep shoes avoid these problems.

involves a dorsal incision in the midline of the affected interdigital space in order to release the transverse metatarsal ligament, as the nerve typically lies beneath this ligament. Postoperative recovery includes a compression dressing worn for several weeks after wound closure. Ambulation is permitted in a postoperative boot.[172] It is important to note that patients may experience decreased sensation in the interdigital web space.

Hammertoes

Etiology

Hammertoe deformities are primarily flexible or fixed plantarflexion deformities of the proximal interphalangeal (PIP) joint, with hyperextension of the metatarsophalangeal (MTP) joint and extension deformities of the distal interphalangeal joint (Fig. 70.18).[173] This results in a dorsal prominence on the PIP, which can cause pain secondary to compression and inflammation from footwear. Physical examination must include determining if the deformity is fixed or flexible. Other deformities may be present, such as hallux valgus or cavus foot deformities. Examination of the extensor surface of the PIP joint may reveal callus or ulcer formation. Intractable keratosis can develop underneath the metatarsal head of the involved toe.[153]

Diagnosis and Treatment

Radiographic imaging should include weight-bearing anteroposterior and lateral radiographs of the involved foot.

Conservative management involves the use of metatarsal pads and shoes with wide toe boxes. Surgical treatment involves MTP joint correction, but the type of surgery is influenced by whether the deformity is fixed or flexible. Fixed hammertoe deformities are corrected through resection arthroplasty of the PIP joint, with the aim of reducing soft tissue contraction forces through toe shortening. Additional procedures such as flexor/extensor tenotomies, MTP joint release, or arthroplasty may be necessary. Weil osteotomies, which primarily involve metatarsal shortening, have also been used to correct the deformity.[174] Flexible hammertoe deformities are surgically corrected with a Girdlestone flexor tendon transfer. This involves harvesting the long flexor tendon from the plantar aspect of the foot and surgically affixing this into the extensor hood. Thus, the tendon functions as both an extensor of the interphalangeal joints and a flexor the MTP joint.[169] The major complication of Girdlestone flexor tendon transfer is a failure to identify a contracture of the flexor digitorum longus tendon during surgery, resulting in inadequate correction.[173]

Clawtoe Deformity

Etiology

Clawtoe deformity results from dorsiflexion of the proximal phalanx on the lesser MTP joint and concurrent flexion of the PIP and distal interphalangeal joints (Fig. 70.19).[173] Pain results from friction between the interphalangeal joints and the shoe. In addition, patients experience pain underneath the metatarsal heads from being in plantarflexion.[169] As with hammertoes, clawtoe deformities may be flexible or fixed. They typically involve all four of the lesser toes. The clinical evaluation is similar to that of hammertoe deformities, including inspection for possible callus and ulcer formation along the extensor surface of the proximal interphalangeal joints.

Diagnosis and Treatment

Radiographic imaging should include weight-bearing anteroposterior and lateral radiographs of the involved foot.

Conservative management includes wearing shoes that have increased depth to reduce pressure on the lesser toes and placement of arch supports underneath the metatarsal heads. Shoe inserts can be positioned proximal to the MTP joints in flexible deformities that are mild. The flexible deformity is corrected with a Girdlestone flexor tendon transfer. The fixed deformity requires a DuVries proximal phalangeal condylectomy in conjunction with the Girdlestone tendon transfer procedure.[169] As with hammertoe surgical correction, the major complication is inadequate correction and subsequent recurrence of the deformity.[173]

Hard Corn (Clavus Durum)

Corns are painful, hyperkeratotic skin lesions located over bony prominences that result from excessive pressure on the skin. Histologic specimens reveal hyperplasia of the epidermis, especially

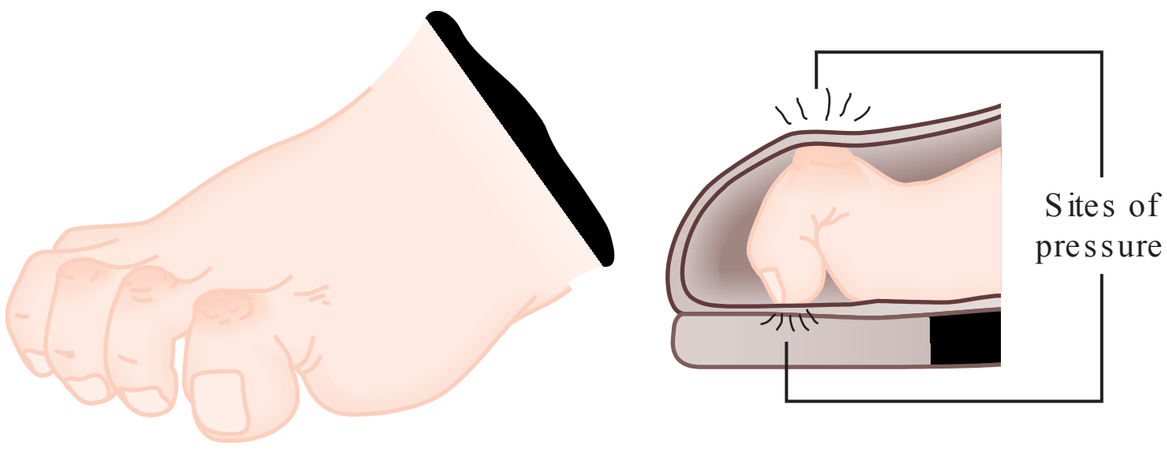

FIGURE 70.19 Clawtoe deformity, a typical small toe deformity, often causes corns and calluses with standard footwear. Extra deep shoes avoid these problems.

proliferation of the stratum corneum.[175] Hard corns are notable for their dry, horny appearance that develops over the dorsal and lateral surfaces of the fifth toe—on the lateral condyle of the proximal phalanx.

Conservative treatment is aimed at reducing pressure on the bony prominences by wearing shoes with large toe boxes. Surgical correction involves débridement of the lesion and occasionally necessitates removal of the distal portion of the proximal phalanx. The most common complication of the latter surgical procedure is excessive bone removal, resulting in a flaccid fifth toe.[176]

Soft Corn (Clavus Mollum)

Soft corns are macerated lesions that frequently occur in the fourth web space between the base of the proximal of the fourth toe and the medial condyle of the head of the proximal phalanx of the fifth toe.[169] These typically develop as a result of small bony protrusion anomalies that cause pressure points, which can then result in ulceration.[176]

As with hard corns, management first focuses on reducing pressure on the bony prominences through utilization of footwear with large toe boxes. Other treatment modalities include the use of keratolytics such as salicylic acid.[177] Surgical treatment involves removal of the bony protrusion.

Ingrown Toenail (Onychocryptosis)

An ingrown toenail is a painful condition resulting from nail plate penetration upon the medial or lateral nail fold epithelium (Fig. 70.20). This typically involves the great toe. It is associated with trauma, tight-fitting footwear, and improperly trimming the nails at the nail margins.[154] Aberrant nail curvature predisposes one to developing an ingrown toenail.

If no infection is present, initial treatment includes elevation of the nail by placing cotton between the nail plate and the skin. This can be aided by daily foot soaks and removal of any pressure points on the nail. Additional treatment involves trimming an oblique portion of the affected nail toward the posterior nail fold under a digital block.[154] The nail groove is then débrided and dressed. If infection or granulation occurs, treatment is focused on partial removal of the nail plate. This involves performing a digital nerve block, followed by a longitudinal incision from the base to the tip of the affected region of the nail plate, including the nail beneath the cuticle. The nail is then grasped with a hemostat and removed from the nail groove using a rocking motion. The nail groove is then débrided and dressed.[154]

FIGURE 70.20 Ingrown toenail is often caused by improper nail cutting techniques or by wearing ill-fitting footwear that creates pressure against the lateral nail fold producing exquisite pain and tenderness.

CHAPTER 71 ■ ACUTE LOW BACK PAIN

BRIAN E. MCGUIRK AND NIKOLAI BOGDUK

Evidence has revolutionized what might be described as the traditional approach to acute low back pain. The paradigm of making a diagnosis and then prescribing a treatment for that diagnosis has been overturned. For most patients, a diagnosis cannot be made, but nor is it required. The natural history of acute low back pain is fundamentally favorable, provided that it is managed well and not dismissed, neglected, or overmedicalized. Serious causes of acute low back pain are rare and can be identified largely on the basis of history. Investigations to establish a diagnosis or to rule out serious causes are not required. Meanwhile, many conventional interventions have proven ineffective, or no more effective than sham treatment.

These facts promote an innovative approach to acute low back pain for which there is evidence of efficacy. It requires iteration through four principal phases: triage, initial management, review, and reinforcement (Fig. 71.1).

TRIAGE

The cardinal tool for triage is taking a history. A fundamental consideration is whether the patient is describing back pain and not a different, but topographically related, complaint. If the patient does have back pain, triage involves assessing the patient, with the priority being to determine if they have a serious cause of pain.

HISTORY

A comprehensive history can be taken systematically by pursuing an inquiry strategy in several domains that, generically, are pertinent to any pain problem (Table 71.1). For acute low back pain, some of these domains are rarely relevant, but several are pivotal.

Site

The International Association for the Study of Pain[1] defines lumbar spinal pain as pain perceived anywhere within a region bounded by the last thoracic spinous process, the first sacral spinous process, and the lateral borders of the erectors spinae (Figs. 71.2A,B). They define sacral spinal pain as pain perceived anywhere in a region bounded by the first sacral spinous process, the posterior sacrococcygeal joints, and the posterior superior iliac spines.

In the light of these definitions, back pain can be defined as lumbar spinal pain or sacral spinal pain or any combination of the two (Fig. 71.2B). The significance of this definition is not so much to establish what low back pain is, but to establish what it is not (Fig. 71.2).

Pain over the posterior thorax is not low back pain, but thoracic spinal pain (Fig. 71.2C). For thoracic spinal pain, the differential diagnosis is different from that for low back pain, and a different evidence base applies.[2]

Pain over the gluteal region, not encompassing the lumbar spine or sacrum, does not constitute low back pain (Fig. 71.2C). It invites a consideration of sources in the hip joint and surrounding structures. Pain over the loin is not back pain, and invites a consideration of pain emanating from the urinary tract or other viscera (Fig. 71.2D).

If the patient has pain in any of these other regions, their management should be according to algorithms for those regions. The approach being developed in this chapter applies only to patients with low back pain.

Length of Illness

The adjectives acute, subacute, and chronic are often used to describe the period over which back pain has been perceived. Definitions vary, but largely with respect to defining chronic low back pain (see Chapter 72). Acute low back pain means pain of recent onset. In conventional usage, this means pain that has not persisted for longer than 3 months. Most of the evidence on low back pain conforms to this convention. The subcategory subacute low back pain usually means pain that has lasted longer than 5 to 7 weeks, but not longer than 12 weeks.[3] If that category is applied, acute low back pain is pain that has not persisted longer than 5 to 7 weeks.

Establishing the length of illness is both relevant and important if management is to be guided by evidence. The evidence for the causes and management of acute low back pain differs considerably from that for chronic low back pain. The evidence for subacute low back pain is more closely related to that for acute low back pain, but differs in certain respects.

Spread

Low back pain need not be restricted to the lumbar or sacral regions. From various sources in the lumbar spine and sacrum, pain can be referred into the lower limb. This type of pain is classified as somatic referred pain. It is pain perceived in a region innervated by nerves other than the nerves that innervate the actual source of pain.[1] As an approximate rule, somatic referred pain is perceived in structures that share the same segmental innervation as the source of pain.

Experiments in normal volunteers and patients have shown that pain from the lumbar zygapophyseal joints, the lumbar intervertebral discs, lumbar ligaments, posterior lumbar muscles, and from the sacroiliac joint can spread across the gluteal region, into the thigh, and even into the leg and foot (Fig. 71.3).[4–9]

The location and distribution does not help in the diagnosis of the source of pain, for they are related to the segmental innervation of the source but not to the specific source itself. However, the distribution of pain is one factor that helps distinguish somatic referred pain from radicular pain. Of all things that have been revealed by research over the last 70 years, this distinction has still failed to permeate education on back pain.

Somatic referred pain tends to spread over broad areas. The patient usually finds it difficult to identify the boundaries of where it is felt, but they can indicate its centroid. Once established, somatic referred pain is sessile in nature; although the area in which it is felt may fluctuate in size with the intensity of the pain, its location tends to be fixed. In contrast, radicular pain is typically perceived along a narrow band (Fig.71.4). Furthermore, radicular pain travels longitudinally into the lower limb. Other distinguishing features relate to the quality of pain.

Quality

Low back pain and somatic referred pain tend to be dull and aching in quality. In some instances, the pain feels like an expanding pressure. Although not diagnostic of the source or cause of pain, these features distinguish somatic referred pain from radicular pain. Radicular pain is lancinating, shooting, or electric in quality.

Making the distinction between somatic referred pain and radicular pain—on the basis of its distribution and quality—is a significant and important step in the assessment of patients. The investigation and subsequent management of lumbar radicular pain are distinctly different from those for somatic referred pain.[9,10] Whereas neurological examination and medical imaging are indicated for radicular pain, they are neither invited nor required for somatic referred pain. Failure to make this distinction has confounded much of the past literature on these entities. It is not evident the extent to which patients described in the past as having had radicular pain—or sciatica—actually had somatic referred pain. Consequently, the extent to which the efficacy of

FIGURE 71.4 The pattern of radicular pain. Radicular pain is felt along a narrow band traveling into the lower limb.

treatments have been compromised for the distinction having not been made is not evident. A different base of evidence, and a different algorithm, applies for the management of acute lumbar radicular pain.[9,10]

Intensity

A patient can provide a measure of the intensity of their pain by completing a visual analog scale[12,13] or a numerical pain rating scale.[13,14] High scores, however, are difficult to interpret in a valid manner. Although they might indicate severe pain because of serious pathology, high scores may be no more than an indication that the patient feels that they are suffering, even though the cause of their pain may not be serious. Other features help to indicate if the patient has a serious cause for severe pain.

Frequency and Duration

Variables such as the frequency of episodes of pain and their duration are of greater relevance to other forms of pain, such as headache and visceral pain. In the context of low back pain, they are not critical for diagnosis. For patients whose pain is constant they are, by definition, irrelevant. For patients with intermittent pain they are of value only for gauging the patient's overall disability.

Time of Onset

Temporal variables are of greater relevance for other types of pain that are distinctly periodic in nature. The occurrence of back pain at particular times of the day, particular days of the week, or particular weeks of the month may indicate an association with particular precipitating factors or visceral disorders, but is otherwise not material to diagnosis.

Mode of Onset

When the onset of back pain has been gradual or otherwise unremarkable, there is little relevance to this variable. A sudden onset of severe pain for no obvious reason is not diagnostic of any cause, but constitutes an alerting feature to possible serious causes. Those are distinguished by associated features.

Precipitating Factors

In the sense of pathology, there are no causes of acute low back pain that bear a relationship to particular precipitating factors. However, inquiry into precipitating factors may reveal risk factors in the way the patient undertakes work, domestic, or other physical activities.

Aggravating Factors

Back pain of virtually any cause is likely to be aggravated by movement. Thus, this variable is of little diagnostic significance when positive. More informative—and alerting—is back pain that is not aggravated by movements or particular activity. It suggests a source that is not subject to compression loading in the lumbar spine or tension in its joints and ligaments. Visceral and vascular disorders have this property, as can malignancy until it starts to affect spinal joints.

Relieving Factors

Relieving factors are the complement to aggravating factors. Pain that is not relieved by rest should invite a concerted consideration of possible sinister causes.

Associated Features

The domain of associated features is the most critical and revealing domain of inquiry about low back pain. Serious causes of pain will usually be evident through the features, other than pain, that they produce. Conversely, case reports that describe missed diagnoses often reveal elements in the history that would have revealed the cause had a thorough inquiry about associated features been conducted earlier.

Associated features encompass a variety of historical and social features as well as a review of symptoms in other body systems. A checklist of these features has been developed[15] (Fig. 71.5), and found effective in field trials.[16] The checklist serves as a reminder to ask about features that constitute so-called red flag indicators. A positive response to any of the items does not necessarily implicate a serious cause of pain; that requires other evidence. However, negative responses to all of the items render vanishingly small the probability of a serious cause for back pain.

The first column of the checklist reminds the user to check for elements in the history that constitute risk factors for fracture, infection, or cancer as the cause of pain. It also prompts consideration of what might be considered rare, or exotic, causes of pain; for example, helminthic diseases in patients who are farmers or who have been exposed to animals, fungal diseases in patients exposed to birds or caves, or other infections in patients who have traveled to undeveloped countries or regions. A particularly exotic example is exposure to spear grass (a plant found in Northern Australia), whose seed can burrow into tissues using an osmotically driven corkscrew action.

The second and third columns prompt a review of body systems, diseases of which may produce back pain or are associated with it. The cardiovascular system should be assessed to look for risk factors for peripheral vascular disease. The urinary system and skin should be assessed as possible sites of infection. The endocrine system should be assessed to look for risk factors for infection (e.g., diabetes mellitus, use of corticosteroids). As well, hyperparathy-

roidism can present with spinal pain. The urinary, reproductive, respiratory, and hemopoietic systems should be assessed for neoplastic diseases. The musculoskeletal and gastrointestinal systems and skin should be assessed for features of spondylarthropathies. The neurological system should be assessed for features of intrinsic or extrinsic lesions of the spinal cord or nerve roots.

Fractures are an uncommon cause of acute low back pain, and when they are there should be a reason for a fracture to have occurred. Fractures may occur in patients exposed to severe trauma, but in the absence of trauma, fractures will not be the cause of back pain unless the patient has a reason for pathological fracture. The risk factors for pathological fracture are osteoporosis, prolonged use of corticosteroids (causing osteoporosis), and a past history of cancer.

Stress fractures of the pars interarticularis are a distinctive entity. In the general population their prevalence is no greater in patients with back pain than in subjects with no pain.[17] Therefore, they cannot be invoked as causes of pain in that population. However, their prevalence is far greater among athletes, particularly those who perform extension, rotation, or combinations of extension and rotation of their lumbar spine. In such individuals the challenge lies in identifying stress reactions before they fracture, for then the fracture can be avoided. Inquiring about a patient's sporting activities is, therefore, pertinent in the triage of patients presenting with acute low back pain.

Although infection can be a cause of back pain, accurate figures on its prevalence are not available. One estimate puts the figure at less than 0.01%,[18] but this may be an underestimate. The alerting features for infection as a possible cause are factors that explain why a patient should have a spinal infection. These include a history of body penetration (by illicit drug use, tattooing, recent surgery, catheterization, venipuncture, or a known site of infection) or compromised resistance to infection (immunosuppression, diabetes, alcohol abuse). Overt indicators are fever and night sweats.[19]

Cancer is responsible for acute low back pain in less than 0.7% of patients, and is four times more likely in patients over 50.[20] The cardinal indicators for cancer as a cause are past history

of cancer, unexplained weight loss, age over 50, and symptoms of visceral dysfunction, particularly the lungs, thyroid gland, prostate, and kidney, which are the most common sources of metastases to the spine.

The significance of aortic aneurysm as a cause of back pain has possibly been understated in the past. In many cases of deaths from ruptured aortic aneurysms, the presenting feature was back pain, and the condition was overlooked.[21] In terms of history, the cardinal features are risk factors for peripheral vascular disease.

Because serious causes of acute low back pain are uncommon, the likelihood of a patient having a serious cause is very low. Moreover, the likelihood is virtually zero if the patient has no other feature of the serious disorder. Serious disorders, therefore, can effectively be ruled out if the responses to the checklist are all negative.

Positive responses do not mean that a serious cause is present. They serve only to raise suspicion. The actual diagnosis is confirmed or excluded by other actions. The clinical features that should raise suspicion about particular serious causes are listed in Table 71.2. This table also lists the appropriate confirmatory investigations (see Investigations, below).

Physical Examination

Examination of the lumbar spine has traditionally involved palpation for tenderness, and assessing active and passive ranges of movement. Some craft groups contend that passive intervertebral motion can and should be tested. The evidence from the available literature indicates that conventional physical examination procedures lack reliability, validity, or both.[22] Nothing found by various maneuvers or tests reliably implicates any source of cause of pain with any validity.

The exception to this may be spinal assessment by the McKenzie method. Two studies have shown that careful, specialized examination can identify patients with sacroiliac joint pain[23] and patients with internal disc disruption.[24] These studies, however, were based on patients with chronic low back pain, in whom these two conditions are common. Their prevalence in patients with acute low back pain is not known and, therefore, the validity of the McKenzie assessment in these patients has not been established.

Nevertheless, there are two reasons for conducting a physical examination. In the first instance, patients expect to be examined, and performing an examination is an indication that the physician is interested in the patient and concerned about them. The fact that nothing found on examination is diagnostic is immaterial in this context. The second reason is ironic. Of greater significance than finding positive features on examination is finding no physical features in the lumbar spine. Absence of somatic signs prompts a serious consideration of visceral and vascular causes of low back pain. A pertinent aphorism is: if the patient has no signs in their back, turn them over and examine their abdomen and pelvis.

Although classical teaching prescribes a neurological examination for patients with low back pain it is neither warranted nor justified. If a patient reports a history of neurological symptoms, such as weakness or numbness, a neurological examination becomes mandatory, but in that context the indication for neurological examination is the neurological symptoms—not the back pain. Neurological diseases do not present with back pain as the only feature. In patients with back pain as the sole feature, physicians might elect to perform a neurological examination in order to appear thorough, but they should be under no illusion that it serves to establish a diagnosis. This guideline should not be confused with neurological examination in a patient with radicular pain. Neurological examination is indicated if the patient has radiculopathy, but in that context, it is pain in the leg—not pain in the back—that is the indication for neurological examination.

TABLE 71.2

CLINICAL INDICATORS AND PREFERRED INVESTIGATIONS FOR POSSIBLE SERIOUS CAUSES OF SPINAL PAIN

Suspected Pathology	Clinical indicators	Preferred test	
Fracture	Severe trauma	1st line	X-ray
Stress fracture	Sporting activity involving spinal extension, rotation, or both	1st line 2nd line	Bone scan or MRI X-ray
Pathological fracture	Osteoporosis Prolonged use of corticosteroids Past history of cancer	1st line 2nd line	X-ray MRI
Infection	Fever, sweating Risk factors for infection: (invasive medical procedure, injection, illicit drug use, trauma to skin or mucous membrane, immunosuppression, diabetes mellitus, alcoholism)	1st line 2nd line	ESR, FBC, CRP MRI
Tumor	Past history of malignancy Age greater than 50 Failure to improve Weight loss Pain not relieved by rest	All cases 1st line 2nd line Prostate Myeloma	 1: ESR, CRP 2: MRI PSA IEPG, serum protein electrophoresis
Aortic aneurysm	Cardiovascular risk factors Anticoagulants No musculoskeletal signs	1st line	Ultrasound

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; FBC, full blood count; IEPG, immuno-electrophoretogram; MRI, magnetic resonance imaging; PSA, prostate specific antigen.

A component of physical examination that has not been formally studied pertains to the demeanor of the patient. This can be helpful in identifying patients with serious causes of pain. Patients with infections and cancer are typically serious, subdued, or quietly guarded in their presentation. They avoid movement, and are apprehensive about being examined. Their general demeanor is grim—as if, intuitively, they know that something serious is wrong. That appearance is distinctly not histrionic. Although they may rate their pain as severe, they do not incessantly draw attention to it. Beware the quiet patient with severe pain.

Investigations

Much research has overturned past habits of routine investigations for acute low back pain. Investigations, such as plain radiography, CT scanning, or magnetic resonance imaging (MRI), are not justified either "just in case" or to reveal something that is not evident on history. In the absence of specific clinical indicators, the yield of these investigations is next to zero.

Plain radiography lacks sensitivity and specificity for any cause of back pain other than fractures. It is indicated only for those patients who have risk factors for fracture (Table 71.2).

Neither CT nor MRI has ever been shown to demonstrate a cause of back pain in patients with no clinical indicators of fracture, infection, or cancer, or in the absence of neurological signs. In that regard, the use of CT or MRI in patients with back pain should not be confused with its use in patients with radicular pain or neurological signs. In those conditions it is the neurological features that are the indication for investigation—not the back pain.

Apart from not being diagnostic, medical imaging has the liability of needlessly alarming patients. To the uninformed patient, the vocabulary of radiology reports sounds serious and significant. Terms such as "spondylosis," "spondylolisthesis," and "degenerative changes" sound like the patient has a disease that both explains their pain and requires treatment. However, the evidence shows that these conditions are not related to pain.[25]

Nor is it an argument that patients expect imaging. They do so only when they remain uninformed. A controlled study has shown that 5 minutes of explanation deters most patients from wanting unnecessary radiographs.[26] The arguments against imaging include their lack of sensitivity and specificity, the very low likelihood of finding anything, the possibility of false-positive findings and the distress that they can cause, the possible false sense of security from a negative result, and the health hazards of radiation exposure.

Investigations are indicated only if the patient has features on history of a possible serious cause of pain (Table 71.2). In that event, imaging is not the default investigation. Laboratory tests take precedence for the assessment of infection and tumor.

Studies have shown that imaging did not detect an occult cancer if patients were under 50, had no history of cancer, no weight loss, and no signs of systemic illness.[20,27] In patients over the age of 50, or with unexplained weight loss or signs of systemic illness, imaging did not detect cancer if their erythrocyte sedimentation rate (ESR) was less than 20 mm/hour. Therefore, for suspected cancer, the indications for imaging are either a past history of cancer or a raised ESR. The appropriate imaging is either bone scan or MRI. Both are equally sensitive, but MRI has greater specificity.

In athletes in whom a stress fracture is suspected, the imperative is to detect a stress reaction before actual fracture. Doing so allows the pars interarticularis to be protected from further stress and allowed to heal. Once fractures occur, there is no guarantee that they will unite. Bone scan has been the traditional investigation, but it lacks specificity; it cannot distinguish between a stress reaction and an actual fracture. MRI can detect and distinguish both, and should be the preferred investigation (Fig. 71.6).

FIGURE 71.6 An MRI scan clearly showing a fracture (arrowed) of the pars interarticularis of L5 fracture. (Courtesy of Dr. Time Maus of the Mayo Clinic, Rochester, MN.)

Formulation

The role of triage is to identify serious conditions or exclude them. If a patient has a neurological condition, possible cancer, or infection, they should be managed in a manner appropriate for the condition suspected or diagnosed. Their further management is dictated by the condition causing their pain, not by their back pain.

Mercifully, serious causes of acute low back pain are rare. Therefore, for the majority of patients, triage will not provide a diagnosis. There is no evidence as to what the causes of acute low back pain are. History alone does not provide a diagnosis, nor does physical examination or imaging in the absence of red flag indicators.

Although this may feel disheartening or contrary to the expectations of both physicians and patients, a diagnosis is not required. The natural history of acute low back pain is favorable, and successful management can be instituted without a formal, patho-anatomic diagnosis.

Physicians should also not feel obliged to make a diagnosis on the occasion of the first consultation. Indeed, it might not be possible to do so. Even serious conditions may be early in their evolution and will escape detection if investigations are undertaken too early. The protection that physicians have is vigilance. Reviewing the patient allows them to check for the evolution of new features. For that reason, review and vigilance become critical components of management.

INITIAL MANAGEMENT

The precepts of good medical management of a patient with acute low back pain can be encapsulated by the patient's cardinal complaints: "I hurt; I can't move; I can't work; and I'm scared."[28,29]

Pain

The foremost tool for the management of acute low back pain is **explanation**. That explanation has two aspects: what the patient does not have, and what the patient does have.

The practitioner should explain to the patient that the chances of a serious cause are extremely low, and are even lower because of their negative responses to the red flag checklist. If pressed, the practitioner can explain why there is no need for any special investigations. If patients ask about x-rays, the practitioner should take the time to explain why they are not indicated.

Once the red flag issues have been covered, the practitioner should provide an explanation of why the patient does have pain. It does not matter if this explanation is not academically valid; it simply has to indicate to the patient that the practitioner does know what is going on. In this regard it is not so much what the practitioner says that is important, but the manner in which they say it. Providing an explanation is the opposite of appearing uncertain or alarmed about what the problem might be. Providing an explanation is the opposite of panicking and pursuing unnecessary investigations that alarm the patient and reinforce their fears that something serious is wrong.

Individual practitioners may develop their own pattern of offering an explanation. One that has been tested[30,31] is to explain to patients, in simple terms, that they have internal disc disruption: a small injury that is presently inflamed and sore, but which will settle.[30] Depending on the situation, practitioners might prefer an alternative model. They might care to explain to the patient that they have strained their back muscles, or that their muscles are sore because they have been undertaking activities in an inefficient manner.

Whatever the model used, the art of explanation can be encapsulated by the six C's (Table 71.3). The explanation should be **credible**: It should fit the patient's circumstances and be intelligible to them. The practitioner should present the explanation in a **confident** manner; uncertainty in the explanation breeds doubts in the patient. The practitioner should be **convincing**, which requires monitoring the patient's response to the explanation and addressing any uncertainties. **Concerted** means that the practitioner should show that they are trying hard to help the patient. Throughout the explanation the practitioner should show that they **care** about the patient and their complaint. **Concern** does not mean alarm about possible serious causes of pain; it is related to caring and means taking the patient seriously. All of these attributes amount to the opposite of being fast, perfunctory, and dismissive.

The second tool at the disposal of the practitioner is the evidence on the natural history of acute low back pain. Provided that patients are managed properly, the natural history is very favorable. About 80% can be expected to fully recover.[16] Explaining this fact constitutes evidence-based practice. The practitioner should explain to the patient, in terms that they will understand, that the odds are in their favor; that there is every chance of recovering (even regardless of treatment), but that it may take time. During that time, there are certain measures that both the practitioner and the patient can take to ease the situation while this recovery takes place.

For medical practitioners, the traditional intervention for acute low back pain has been to prescribe analgesics. It is conspicuous, however, that the evidence base for this action is markedly weak.

Multiple guidelines recommend paracetamol (acetaminophen), on a time-contingent basis, as the first-line drug if analgesics are required.[2,32–35] These recommendations, however, are based on the reputation of this drug as an analgesic, and its relative lack of side effects when used in appropriate doses. Explicit evidence of its efficacy for acute low back pain is lacking. At best, its efficacy is evident only from studies in which it has been used as a control treatment. It has not been shown to be more effective than placebo.[2,36,37]

Some guidelines permit or recommend nonsteroidal anti-inflammatory drugs (NSAIDs) as a second-line drug if paracetamol proves ineffective or patients require greater analgesia. This recommendation is based on the assumption that NSAIDs are effective, or in some way more effective than paracetamol, for acute low back pain. Evidence of this is lacking. An earlier review found NSAIDs to be more effective than placebo for the outcome measure global perceived effect, but for the outcome measure relief of pain, they were not more effective than placebo.[37] A later review[38] reported that NSAIDs were more effective than placebo, but of the four studies used for the meta-analysis, two used intramuscular injections rather than oral medication. Of the remaining two studies one found no superiority over placebo,[39] but the other did find superiority.[40] The margin in favor of placebo, however, amounted to only 8 points on a 100-point pain scale, and was measured only at 7 days.

Instead of drugs, an expedient and effective alternative for the short-term relief of acute low back pain is superficial heat, in the form of low-level heatwrap therapy. Applying heat to the back has been shown to be more effective than placebo, both in general patients[41–44] and in workers with back pain,[45] and is more effective than either ibuprofen or acetaminophen.[46] It has been rated as a cost-effective intervention.[47]

Other interventions commonly used in the past for the relief of pain in patients with acute low back pain either lack formal evidence of efficacy or have been shown to be ineffective. They should be avoided, not only because they are ineffective, but also because they conflict with the precept of empowering the patient to become responsible for their own rehabilitation.

Bed rest is ineffective for acute low back pain.[48] Its use denies patients the proven benefits of staying active (see Movement, below). Although antidepressants are used to relieve pain, there is no evidence that they are effective for acute low back pain.[36] Although systematic reviews have concluded that muscle relaxants may be effective,[49] the source literature speaks otherwise. Orphenadrine, diazepam, and tizanidine are not more effective than placebo.[36] Dantrolene is more effective than placebo but only for reducing pain upon maximum voluntary contraction.[36] Methocarbamol is no more effective than the tranquilizer chlormezanone, which itself is no more effective than mefenamic acid.[36] Carisoprodol reduces pain to a greater extent than placebo but has been tested only at 4 days.[36] Baclofen reduces pain more than placebo, but only by 20%.[36] The reduction of pain by cyclobenzaprine (by 5.5 points on a 10-point scale) is barely greater than the reduction achieved by placebo (4 points), but cyclobenzaprine is not more effective than NSAIDs.[36]

For the relief of pain in patients with acute low back pain, exercises have been shown to be no more effective than other conservative interventions, including no intervention.[50,51] The role of exercises lies in restoring movement, rather than in relieving pain (see Movement, below).

For acute low back pain, belts or corsets,[52,53] traction,[54] and transcutaneous electrical nerve stimulation[55] are not effective; back school has been shown to be ineffective[55]; and there is no evidence for acupuncture.[56] Multidisciplinary pain management has explicitly been shown to be ineffective for acute low back pain.[57] It is not indicated early in the course of management. It becomes a valid option if pain persists into the subacute phase.[57]

TABLE 71.3

THE SIX C'S THAT DEFINE THE ATTRIBUTES OF GOOD EXPLANATION OF A PATIENT'S ACUTE LOW BACK PAIN

Credible
Confident
Convincing
Concerted
Caring
Concern

There is no evidence that formal behavioral therapy is effective.[54] Such evidence as might support behavioral therapy pertains to regularly reviewing the patient's progress, acknowledging any difficulties the patient has in maintaining activities of daily living and being encouraging and helpful in this regard, and promoting self-management.

Various guidelines recommend issuing patients with an educational booklet about back pain. This might serve to standardize information provided, and practitioners might consider it an aid in their endeavors, but booklets achieve little effect when used alone.[58,59] They are not a substitute for explanation, support, and encouragement provided personally by the caring practitioner.

Perhaps the most contentious intervention is manual therapy. Conclusions from systematic reviews about the evidence are mixed, and seem to reflect the inclinations or preferences of authors rather than the strength of the evidence. Whereas some reviewers accepted that there is moderate evidence that spinal manipulative therapy provides greater relief of pain in the short-term than other interventions,[60] other reviewers found that there is no evidence that spinal manipulative therapy is superior to other standard treatments for acute low back pain.[61] Moreover, manual therapy contravenes the recommendations of guidelines to avoid passive treatment.

A protocol commonly practiced in primary care is to supplement advice with either an NSAID or spinal manipulative therapy. However, when this protocol was tested, it emerged that neither adding an NSAID nor adding manipulative therapy conferred any greater benefit to patients.[62]

Movement

Multiple studies and reviews have consistently shown that maintaining activity is a crucial component in the management of acute low back pain.[16,30,48] The emphasis lies not in treating a particular pathology but in resuming or maintaining activity, in a holistic sense, in order to prevent the patient being disabled by their pain. The intervention is coupled with explanation, encouragement, and empowering the patient to take responsibility for their own management.

The practitioner should explain to the patient that the evidence shows that those who resume activities have a much more favorable prognosis and recover more quickly and more thoroughly than patients who resort to rest and avoid activities.[48] A model of explanation that has successfully been used is to explain that muscle tightness is a normal reaction to pain but one that can be deleterious; allowing the back to seize up or become stiff not only interferes with movement but can add to the pain.[30] The objective of treatment, therefore, is to prevent and overcome stiffness.

This can be achieved by teaching the patient a set of simple stretching exercises.[63] These are not exercises that require supervision or attendance at a facility, such as a physiotherapy practice or gymnasium. They are exercises that can, and should, be executed virtually anywhere that the patient needs them. In order to reduce stiffness and keep the patient mobile, the patient should perform the exercises at strategic or ceremonial times of the day, such as upon rising, before going to work, at coffee breaks, or lunchtime. In the sense of a "warm-up," they can be applied as a preparatory and preventive measure prior to undertaking a major activity, such as commencing chores. As a first-aid measure, they can be applied to ease exacerbations of pain after sustained activity or prolonged sitting. Providing a first-aid measure is one of the crucial steps in empowering the patient to be able to look after themselves. Exercises that the patient can do by themselves, and for themselves, are crucial to avoiding passive interventions and becoming dependent on them.

Work

All guidelines on occupational low back pain emphasize the benefits of returning to work or remaining at work.[64–66] Patients who do so inherit a better prognosis than those who do not.

The obstructing factor in this context lies not in the patient but in the attitude of the treating practitioner. It is easier, and faster, to write a certificate for time off work than to explain to the patient why they do not need one.[67] The attitudes of practitioners are difficult to change. Changing patients is far less of a problem.

The practitioner should share with the worker the evidence of the benefits of returning to work. They should inquire as to why the patient feels or believes that they cannot return to work.

Fears of aggravating the pain will already have been partly addressed by confidently providing a credible explanation for the pain, coupled with an explanation that activity will not do harm. That message is reinforced by helping the patient resume movements, and empowering them to do so (see Movement, above). Those movements include work.

Some patients may have pain of high intensity that temporarily impedes their ability and capacity to resume their accustomed work. For such patients modified work duties may be required. Unfortunately, there is no evidence in the form of controlled trials that vindicate the prescription of modified duties. Their reputation rests on anecdotal and observational data. The strongest evidence lies in a cohort study, which found that keeping patients at work, with modified duties as required, resulted in a greater proportion of patients fully recovered, and fewer recurrences, than did usual care.[67]

Prescribing modified duties imposes a responsibility. The practitioner should not forget the patient. The objective of modified duties is to have the patient remain at work but progressively restore their capacity for former duties. During this period, the patient and their progress need to be monitored. As soon as they are able, the patient should return to full work. A certificate and its expiration date do not magically achieve this; it is the continued involvement of the practitioner that does so.

Inquiry into the patient's beliefs about work may reveal extraneous but pertinent issues. They may resent their work environment or their supervisor. They may harbor fears about recurrences of accidents in which they were injured. Such issues raise agendas that are separate and additional to the back pain. Those agendas need to be pursued and managed parallel to the back pain itself.

In the first instance, the practitioner needs to elicit from the worker the beliefs and concerns that they have. Mistaken beliefs can be discussed and corrected. Misplaced concerns can be allayed. Otherwise, workplace intervention may be required. If the practitioner cannot exercise this, the services of a skilled practitioner in occupational medicine should be recruited.

The evidence strongly supports the efficacy of workplace intervention. Whether as an isolated intervention, or adding it to medical management, workplace intervention improves outcomes.[68] It is conspicuous, however, that the contents of the workplace intervention are immaterial. The effective ingredient does not lie in the specifics of ergonomic or related changes. What counts is that the worker has an advocate who acts on their behalf and in their interests. This is done in the context of solving problems with the participation of supervisors and management. Solutions may lie in modifying the physical work environment, social work environment, work flow, or work demands. The solution should be cast in a manner such as to benefit all parties. The worker returns to an improved environment. The employer avoids the problem of additional injuries and claims, and the burden of increased insurance premiums. Advocacy is paramount in these negotiations. Workers typically do not have access to management, whom they regard as intransigent and uncaring. The occu-

pational physician has the appropriate "social rank" to appear before management and to explain the circumstances to them.

Workplace intervention takes time and requires a particular, skilled aptitude. General practitioners and others may not have this time or aptitude. That, however, is not a pretext for overlooking or neglecting workplace intervention. Persisting problems with return to work, in a practice or in a region, are an indication that specialist skills need to be recruited.

Fear

Fear is the most damaging characteristic that a patient with acute low back pain can harbor. Their fears might pertain to what is wrong biologically, what is going to be done medically, or what is going to happen socially. Such fears inhibit the patient's recovery. It is important, therefore, that any such fears be discovered and addressed.

It is not necessary or expected for a practitioner to address the fears that a patient might have at the first consultation. However, the possibility of fears should be noted and their exploration resumed at follow-up visits.

The practitioner can explore possible fears in the course of a normal consultation, either by being alert to what the patient might mention or allude to spontaneously, or checking for fears through simple questions, such as "What do you think is the cause of pain? What do you think needs to be done? What do you think is going to happen?"

Fears about the biology of back pain are covered by providing a credible, convincing explanation, reinforced by repetition if necessary. Fears about prognosis and consequences are covered by explaining to the patient the favorable natural history of acute low back pain. Fears about management are covered by providing the patient with a concerted plan that empowers them and does not leave them abandoned. Fears about work, employment, and future are encompassed by the workplace intervention.

REVIEW

In the past, physicians believed that if the patient does not return, they must be all right. This myth has been dispelled. A longitudinal study in British primary care followed patients after they presented to general practitioners with acute low back pain.[69] They did not return to the general practitioners, who (naturally) assumed that they had recovered. Research nurses found that only 25% of patients had recovered; the remainder continued to suffer; but they did not return to their general practitioner because they felt that they were not being helped.

Patients with acute low back pain should not be abandoned, and they should not feel abandoned. The risk of doing so is that patients will exaggerate and prolong their disability, if left to fend for themselves. The singular measure against this eventuality is planned concern. The treating practitioner should schedule a follow-up with the patient. This might be a conventional consultation, or it might be no more than a telephone follow-up. If patients have recovered, and report that they do not need further care, no more need be done; however, if patients have not recovered, face-to-face follow-up is indicated.

An algorithm with scheduled follow-up allows busy practitioners to divide their management into initial triage at the first consultation, and further exploration at the subsequent consultation. This deflates the perceived burden of having to get everything done on the first occasion.

If the patient is progressing well, further follow-up can be decreased or dispensed with. If they are not progressing, the review consultation provides the opportunity for the succeeding steps in the algorithm.

VIGILANCE

A review consultation allows the practitioner to exercise vigilance. Serious disorders may not be evident at the first consultation. Repeating the checklist for red flags serves to detect the emergence of any new features, which may require changes to the management plan. Relying on clinical monitoring, in this way, obviates the need for precipitous and inappropriate use of investigations at the first consultation.

If red flag features emerge, management appropriate for those features can be pursued. If red flag features do not emerge, the previous management can continue.

REINFORCEMENT

During the review consultation, the practitioner should assess the progress of the patient. If previous management appears to be working, no change is required. If progress to recovery seems to be slow, the practitioner should assess why this might be the case. The practitioner should check if the patient understood the previous plan of management and if they are complying with it. The review consultation provides the opportunity to reinforce previous explanations, if they were not understood, and to check, for example, if the patient has been able to execute any exercises correctly. If the patient is not complying, the reasons for that need to be elicited. Misunderstandings can be corrected. If unjustified resistance is the reason, that raises an agenda in the management plan that is not back pain.

If progress is not occurring despite adequate compliance, consideration needs to be given to implementing interventions not previously used. If exercises were not prescribed at the first consultation, they can be introduced now. If the patient is having difficulties restoring movement, a supervised exercise program conducted in a cognitive–behavioral milieu can be effective.[70]

Yellow Flags

Slow progress to recovery may be due to undetected, or unrevealed, psychosocial factors, referred to as yellow flag indicators.[71] These pertain to the patient's beliefs and behaviors concerning physical activity and domestic, social, and vocational responsibilities.

When patients believe that physical activity might harm their back, and that they should not undertake activities that make their pain worse, they avoid activities. For most patients with acute low back pain, these beliefs are not justified. Explanation, reassurance, and encouragement to resume activities are the cardinal tools for overcoming these mistaken beliefs. If required, a graded plan of resuming activities can be developed and followed. Some patients may take longer to regain activities. The guiding principle is that increments should be pursued, even if they are small.

Patients may seek to avoid domestic activities and responsibilities, such as cooking, cleaning, maintenance, shopping, and housework, for fear of pain. Avoiding such activities amplifies their disability. Encouragement to resume these activities may be not enough to convince some patients. The accustomed manner in which they do things may not be efficient. They may need help to analyze how else they might acquit the required activity, in a manner that does not aggravate their pain. The guiding principle is not to abandon the activity but to find alternative means to achieve its purpose. In this regard, the practitioner provides their own intellect to help solve the patient's problem.

Patients may avoid social activities, claiming that their back pain prevents them from doing so. But back pain does not directly preclude social activity. The mediating factor is fear that social

activity will aggravate their pain. If the patient can regain movement at home, they can apply the same principles away from home. They should be helped to understand that becoming a recluse will not improve their prognosis; if anything, it will hinder their recovery. Encouragement should be coupled with suggestions of what to do if their pain threatens to be aggravated when they are "out." Instead of being an embarrassment, doing the stretching exercises can be turned into an asset (see Movement, above).

Perhaps the most destructive of the yellow flags is the aversion to work. Patients may believe that work caused their pain, work aggravates their pain, that work is too heavy for them, and that they should not work. Such beliefs require patient analysis and discussion. In the majority of cases they will not be true. The practitioner cannot afford to be dismissive and assertive. They need to understand the patient's work, and in a compassionate manner be able to indicate how work can be resumed in a safe manner. If required, the services can be engaged of an occupational physician who is familiar with the patient's industry, and can develop a return to work plan in the context of a workplace intervention.

DISCUSSION

The majority of patients with acute low back pain will not have a serious cause of pain or a serious injury. If treated well, they can expect to recover. They do not need special treatment. The measures outlined in this chapter will suffice. It has been demonstrated that following these evidence-based principles secures recovery in some 70% of patients, sustained at 12 months, with recurrence rates as low as 16%.[16] Moreover, when evidence-based care is provided in a confident, caring manner, patients overwhelmingly find it attractive.[16]

However, evidence-based care will not be universally successful. Among patients who present with acute low back pain will be two subgroups: those with serious psychosocial problems and those with undetected injuries. There are no features by which to identify these patients early in their course. They emerge by elution. As those destined to recover do so, those with difficulties remain.

The time to identify psychosocial problems is during the acute phase. If recognition and intervention are delayed until the problems become chronic, they may become too entrenched to be remediable. Confident and competent primary care practitioners should be able to address and manage psychosocial factors. They require extra time in consultations, but most are not insurmountable.[67] Early referral is required if they do prove insurmountable. Trained psychologists are more likely to achieve better outcomes if they can see patients early in the development of problems.

Patients with injuries that do not resolve with the passage of time are destined to develop chronic pain. If reiteration and reinforcement of simple interventions does not result in progress and resolution, patients at risk of becoming chronic should be identified before they do so. Appointments to pain clinics or spine specialists may take time to obtain, and they are easier to cancel than to get. Therefore, for patients with persistent pain, steps for early referral to appropriate resources become part of the closing phases of the algorithm for acute low back pain. The management of these patients follows a different algorithm, with a different evidence base (see chapter 72).

CHAPTER 72 ■ CHRONIC LOW BACK PAIN

BRIAN E. MCGUIRK AND NIKOLAI BOGDUK

By convention, chronic low back pain is defined as back pain that has persisted for longer than 3 months[1,2]; however, some authorities believe that this rubric can be applied earlier if the pain shows no signs of improving.[3] Irrespective of how it is defined, chronic low back pain is a major social problem in developed societies and, despite an abundance of research, many questions remain unresolved. There is evidence of what might be the sources of pain, but little evidence of its causes. Some entities have been refuted as causes; others remain putative but contested. Traditional approaches to assessment and investigation have been found wanting, but alternatives have not found favor. Various treatments are advocated but few have been vindicated by convincing evidence.

SOURCES

Experiments in normal volunteers have shown that noxious stimulation of the muscles of the back,[4,5] interspinous ligaments,[5,6,7] zygapophyseal joints,[8,9,10] sacroiliac joint(s),[11] and intervertebral discs[12–15] can each evoke pain in the back. Back pain can also be evoked by mechanical[15] or chemical irritation of the dura mater.[16] These structures, therefore, become the possible sources of pain in patients.

Pain evoked from these structures can also be referred to the lower limb (see Fig. 71.3). The distance to which the pain radiates seems to be proportional to the intensity of the stimulus in the

back.[8] This referred pain is not produced by irritation of the lumbar spinal nerves or their roots; it is evoked from somatic structures in the lumbar spine. Consequently, it is an example of somatic referred pain.

Somatic referred pain is not synonymous with radicular pain or sciatica, even though all are felt in the lower limb. Somatic referred pain arises because of convergence in the central nervous system between nociceptive afferents from the back and from the lower limb. Since its mechanism and sources are different from those of radicular pain, somatic referred pain needs to be distinguished from radicular pain. In that regard, somatic referred pain is typically dull, aching in quality, and tends to occur in a fixed location. Although its boundaries may be difficult to establish, the subject is well aware of its centroid. In contrast, radicular pain is lancinating in quality, and travels into the limb along a narrow band[17,18] (see Fig. 71.4).

CAUSES

Although the possible sources of back pain have been demonstrated, its causes have been more elusive. Conventional methods of assessment and investigation typically fail to identify the cause of chronic low back pain in the majority of patients. This has fostered belief in the claim that a cause cannot be found in over 80% of patients with chronic low back pain.

The source of this figure is difficult to track down, but it was endorsed and enshrined by the report of the Quebec Task Force on Low Back Pain, published in 1987.[19] An earlier source is a study, published in 1966, in which British general practitioners claimed that a diagnosis was not possible in 80% of cases.[20]

These claims were correct at the time that they were made. In 1987—and more so in 1966—the investigation of low back pain was limited to plain radiography and perhaps computerized tomography. These modalities are now known to lack the sensitivity and resolution to detect lesions that might commonly cause back pain. That restriction does not apply to modern imaging and other procedures. Whereas in the past it might not have been possible to find a cause of back pain, the situation is now different.

Refuted Causes

Research has shown that many conditions traditionally considered to be possible causes of chronic low back pain are actually not causes. Multiple studies have shown that spondylolysis or spondylolisthesis cannot be held as causes of back pain in adults. These conditions occur with equal prevalence in subjects with no symptoms and in patients with back pain.[21,22] Similarly, so-called degenerative changes (spondylosis) occur only slightly more frequently in patients with back pain than they do in asymptomatic individuals.[21,22] The difference in prevalence is so small as to render degenerative changes not diagnostic. They represent no more than normal age changes.

Accepted Causes

There is no dispute that tumors and infections can cause low back pain, but these conditions are rare. Although specialist practitioners may be accustomed to greater prevalences because they are in referral practice, the prevalence of serious causes of back pain in primary care amounts to no more than 5%.[23]

Untested Causes

In its Classification of Chronic Pain, the International Association for the Study of Pain (IASP) recognizes, in principle, certain causes of chronic low back pain that are promoted by some practitioners.[1] These include muscle sprain, ligament sprain, segmental dysfunction, and trigger points. However, the IASP requires that for the diagnosis of these conditions techniques be used that are of known reliability and validity. But no technique has been shown to be both reliable and valid for the diagnosis of these entities. Therefore, they remain only theoretical or imaginary constructs.

Known Source, Unknown Cause

It is possible to establish a source of low back pain by selectively anesthetizing structures believed to be the source[24,25] (see also Chapter 99, Diagnostic and Therapeutic Nerve Blocks). If performed under controlled conditions, using validated techniques, diagnostic blocks can identify the source of back pain in a substantial proportion of patients.

The rationale (concept validity) of diagnostic blocks is that if a particular structure is the source of pain then whenever it is anesthetized the pain should stop. Controls, however, are required to maximize construct validity. Anatomical controls involve anesthetizing the target structure on one occasion but an adjacent structure, which is not painful, on another occasion, under single-blind conditions. Physiological controls require that the patient respond in a manner consistent with the duration of action of the agent used to anesthetize the structure, which can include placebo agents.[24,25]

Sacroiliac Joint(s)

Using anatomical[26] or physiological controls,[27] studies have shown that the source of chronic low back pain can be traced to the sacroiliac joints(s) in about 20% of patients. These patients obtain complete relief of their pain when the joint is anesthetized. The actual cause, however, has not been determined. It may involve loosening of the joint following injury or pregnancy, but no method of investigation has yet been developed by which to detect such an entity reliably.

Zygapophyseal Joints

Using physiological controls, multiple studies have purported to trace the source of chronic low back pain to the lumbar zygapophyseal joints. Prevalence rates of 15%,[28] 40%,[29] and 45%[30–32] have been reported. What is contentious about these figures, however, is that complete relief of pain was not a diagnostic criterion. Rather, the investigators accepted 50% relief or 80% relief. They assumed that any pain not relieved stemmed from another concurrent source, but that source was not identified. Meanwhile, other studies have shown that patients with chronic low back pain rarely have concurrent sources of pain from the zygapophyseal joints, the sacroiliac joint, or the intervertebral discs.[26,33] Therefore, insofar as concurrent sources of pain have not been identified, partial relief of pain must be viewed as a spurious diagnostic criterion. Placebo responses have not been excluded.

When studies looked for complete relief of pain following blocks of the lumbar zygapophyseal joints, substantially lesser prevalence has been encountered. In general populations, the prevalence of complete relief of pain is about 5% or less.[34–37] Therefore, lumbar zygapophyseal joint pain may not be as common as has been held to date.

However, one study using placebo controls did find that 34% of an elderly population obtained at least 90% relief of pain.[28] Therefore, the prevalence of lumbar zygapophyseal joint pain may be population-dependent and more common in the elderly than in younger, injured workers.

The cause of zygapophyseal joint pain is not known. In patients with a history of injury upon exertion, it is conceivable that they may have suffered an articular fracture. Laboratory studies have shown that the lumbar zygapophyseal joints are sus-

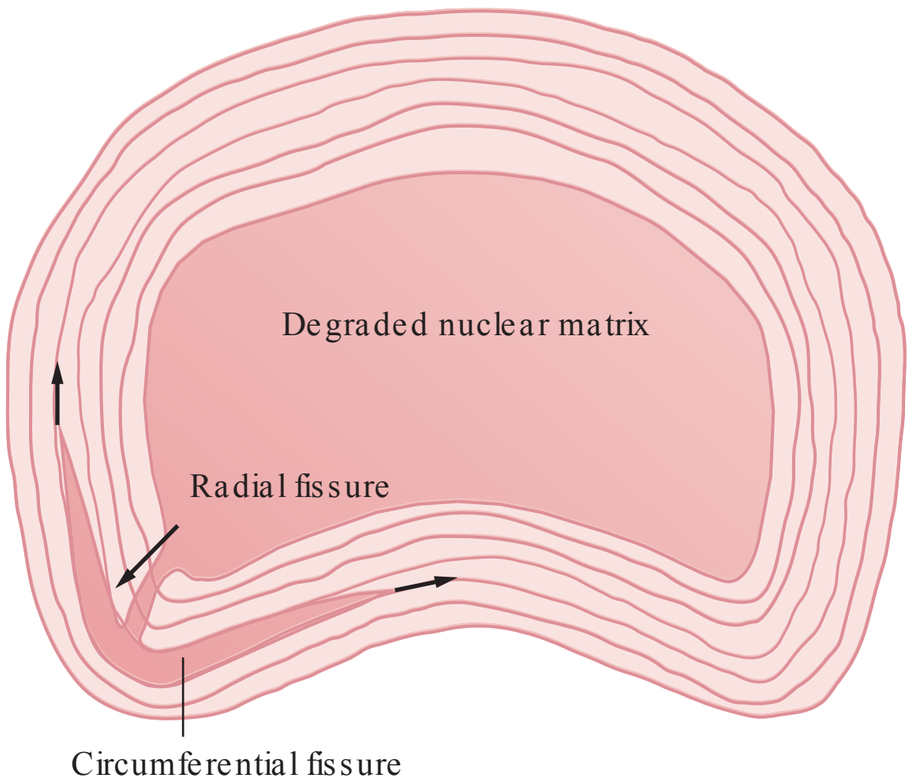

FIGURE 72.1 The features of internal disc disruption.

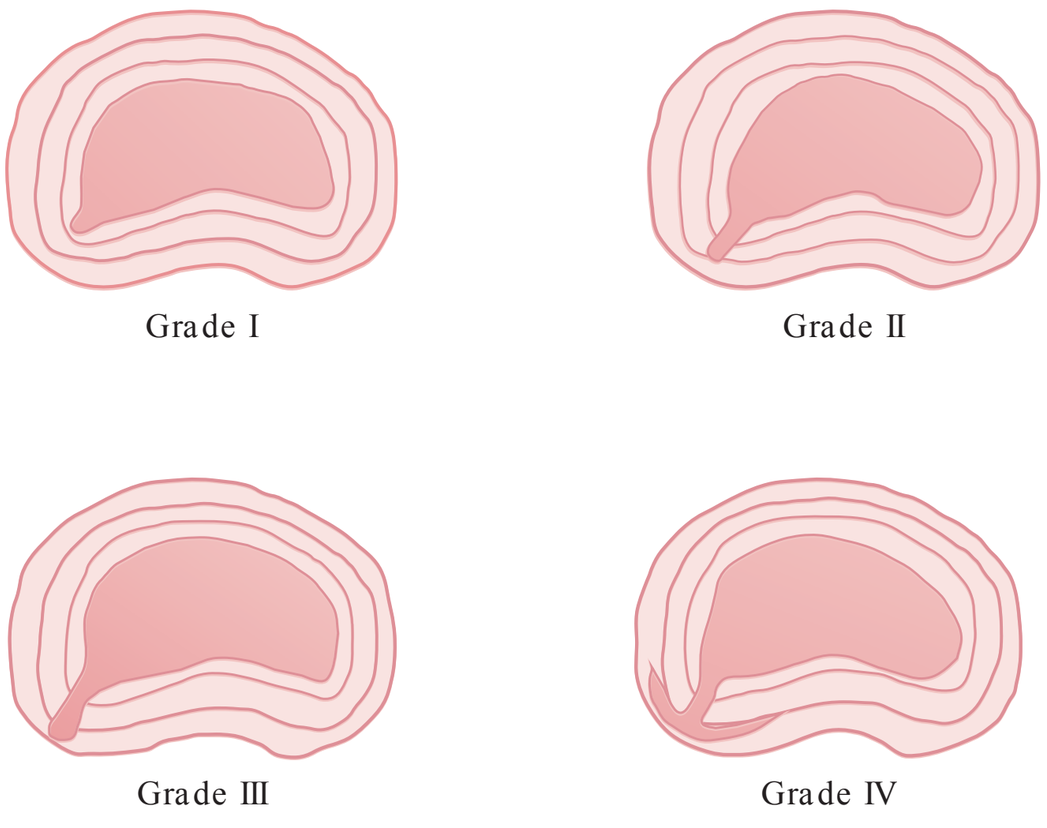
ceptible to small fractures, or avulsions of the capsule, when subjected to excessive torsion. However, no studies have validated this injury (e.g., by high resolution CT scan). In elderly patients, it is tempting to attribute their pain to osteoarthrosis, but there is no correlation between the radiologic features of osteoarthrosis on CT scan and the joint being painful.[38] An emerging proposition is that painful lumbar zygapophyseal joints express inflammatory changes evident on magnetic resonance imaging (MRI) using a fat-saturation setting.[39] This has yet to be corroborated by other studies.

Internal Disc Disruption

Internal disc disruption is a condition characterized by a set of chemical, morphological, and biophysical features. It is precipitated by a small fracture of the vertebral endplate, as a result of severe compression injury or fatigue failure under compression.[40] This results in progressive degradation of the nuclear matrix, and the development of radial fissures into the annulus fibrosus (Fig. 72.1). The degree of disruption can be graded according to the extent that fissures penetrate the annulus[41,42] (Fig. 72.2). In grade I disruption, fissures reach the inner third of the annulus. In grade II disruption fissures reach the middle third of the annulus. Grade III disruption arises when the fissure reaches the outer third, and becomes grade IV if the fissure then extends circumferentially. These chemical and morphological changes affect the biophysical properties of the disc.



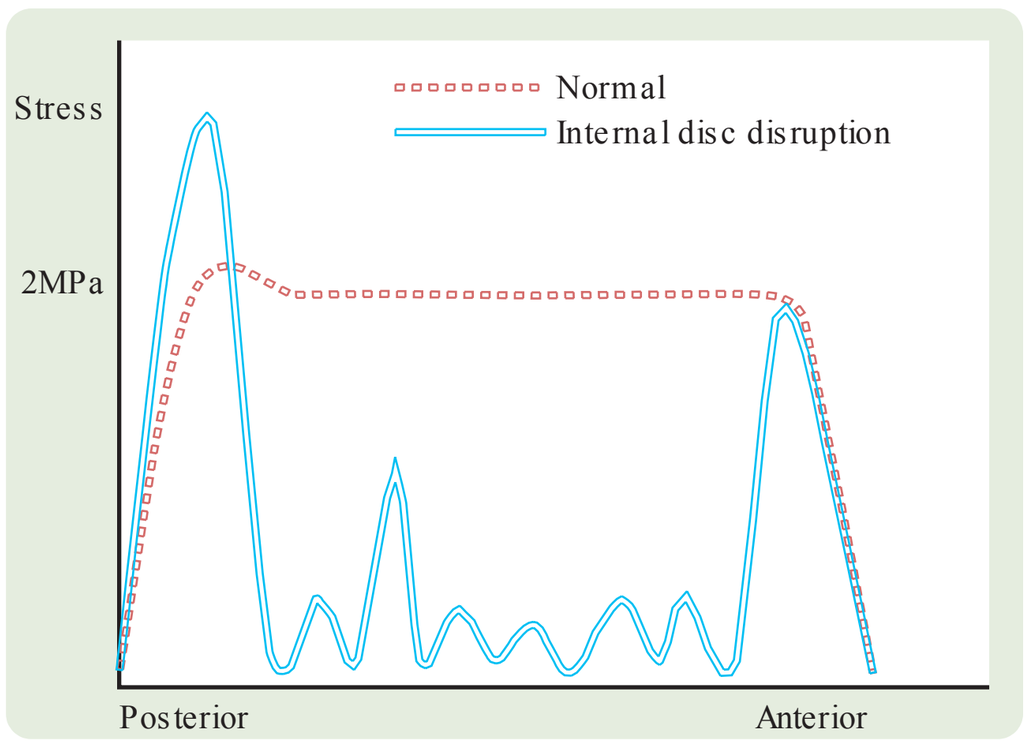


FIGURE 72.2 The grading of internal disc disruption.

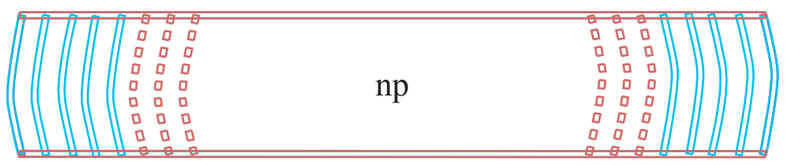

FIGURE 72.3 The biophysical features of internal disc disruption. The graph shows the stresses recorded across the diameter of normal discs and a disc with internal disruption.

Degradation of the nucleus compromises its ability to sustain compression loads. Stresses in the nucleus become irregular and reduced across the profile of the nucleus, becoming zero in some locations in some discs[40,43] (Fig. 72.3). This results in the annulus fibrosus having to bear more of the compression load. In particular, stress in the posterior annulus is increased greatly above normal levels.[40,43]

These various features correlate with the affected disc being painful on discography. Some 70% of discs with grade III or IV fissures are painful, and 70% of painful discs exhibit grade III or IV fissures.[44] Moreover, this relationship is independent of age changes in the disc.[45] Decreased nuclear stress and increased stress in the posterior annulus each, separately, correlate strongly with the disc being painful.[46]

Animal studies have shown that experimental injury to the vertebral endplate precipitates the biochemical degradation of the nuclear matrix.[47–49] Laboratory studies have shown that nuclear depressurization and increased posterior annulus stress appear immediately after fatigue failure of the vertebral endplate.[40] Endplate fractures can occur in response to as few as 100 repetitions of compression loads amounting to between 50% and 80% of the ultimate tensile stress of the endplate.[50,51] Such stresses are within the range experienced during normal, moderate to heavy lifting activities.[51]

The disc becomes painful as a result of two mechanisms acting in combination. Inflammatory chemicals, such as phospholipase, tumor necrosis factor, and nitric oxide, produced within the nucleus in response to injury, provide a basis for chemical nociception. They could stimulate nerve endings that occur normally in the outer third of the annulus, if the chemicals reach the outer annulus through radial fissures. Alternatively, or additionally, they could stimulate endings of nerves that grow into injured discs.[52,53] Meanwhile, the increased stresses in the posterior annulus constitute a stimulus for mechanical nociception in the outer annulus. Chemicals that reach the outer annulus could sensitize the nerve endings located there to mechanical stimulation.

In patients with chronic low back pain, the prevalence of internal disc disruption is 39%,[33] which is a worst-case figure. It represents the proportion of patients with single-level disease, and does not include patients with two-level disease.

ASSESSMENT

History

Taking a history is a conventional component of pain practice. However, in patients with chronic low back pain it is more ceremonial than diagnostic. For most patients, the history will not provide a diagnosis. Most patients will relate basically the same story of unremitting pain with limitation of movements and activity. However, the role of taking a history is to identify those patients who are not typical.

Determining the length of illness establishes that the pain is chronic, and is largely reassuring with respect to pathology. Patients are unlikely to have a serious cause if their condition has not deteriorated over several months. Nevertheless, practitioners need to be mindful of chronic infection. Spinal infections can remain indolent, and not produce additional features for a long time. In one study, delays of 1 to 8 years were encountered in 47% of patients.[54]

Confirming the site of pain is important to confirm that the patient has lumbar spinal pain, and not loin pain or gluteal pain[1] (see Chapter 71, Acute Low Back Pain). Loin (flank) pain indicates a visceral source, and primary gluteal pain suggests a hip disorder rather than spinal pain. Pain located in the lumbar or sacral spinal region can arise from many sources, but there is a partial rule concerning sacroiliac joint pain. Pain from the sacroiliac joint tends to be located over the joint, and radiates distally. Rarely, if ever, has it been found to extend above the L5 level. Therefore, pain located exclusively below L5 increases the likelihood of the sacroiliac joint being the source.

The radiation of pain needs to be carefully interpreted. Somatic referred pain in the buttock or lower limb can be expected with any source of pain in the lumbar spine. It should not be confused with radicular pain. The cardinal distinctions lie in the quality of pain and its behavior. Somatic referred pain is dull and aching in quality; it tends to occupy a broad area with boundaries that are hard to define but whose center the patient can readily indicate, and although the pain may extend further into the lower limb when severe, the pain is relatively fixed in location (see Fig. 71.3). In contrast, radicular pain is lancinating in quality and travels along the length of the lower limb (see Fig. 71.4). Making this distinction is pivotal because the causes of somatic referred pain and radicular pain are quite different, and invite different investigations and treatment. Some authorities maintain that somatic referred pain does not extend below the knee and that, therefore, pain below the knee must be radicular in origin. This is not correct, for it has been shown that pain from the lumbar zygapophyseal joints and intervertebral discs can be referred beyond the knee, even into the foot.[8,9,10,15]

The frequency and duration of pain are not helpful discriminating variables in the assessment of chronic low back pain. Patients will typically complain of constant pain.

Neither is the intensity of pain discriminating. Whereas severe pain is an alerting feature in patients with acute low back pain (see Chapter 71, Acute Low Back Pain), it does not carry the same connotation in patients with chronic low back pain. Serious causes of pain should already have manifested other features apart from severe pain. That is not to say that conditions such as internal disc disruption do not produce severe pain—just that severe pain, in the absence of other features, does not indicate a serious cause.

Precipitating, aggravating, and relieving factors are usually not discriminating features. Pain from all sources tends to be aggravated by movements, and may be reduced by rest.

As for acute low back pain, indicators for serious causes of pain will lie amongst the associated features. A systems review should reveal symptoms of visceral disorders if these are the cause of pain or neurological disorders. A past history of illness will reveal the possibility of cancer as a cause of pain. The red flag checklist, explained in Chapter 71, serves as a prompt for what to consider[55] (see Fig. 71.5).

Physical Examination

Conventional physical examination does not provide a diagnosis of chronic low back pain. There is no evidence that tenderness, range of motion, or other features are diagnostic of any particular source or cause of pain. Some practitioners use physical features to guide treatment (e.g., improving range of motion, or where to inject therapeutic agents), but these applications are not diagnostic in a patho-anatomic sense. Some practitioners use physical features to monitor progress, or to classify patients, but, again, this does not amount to diagnosis.

Neurological examination is neither necessary nor productive in the assessment of patients with chronic low back pain. Neurological examination is indicated if the patient has neurological symptoms, but in that event their presenting feature is the neurology, not back pain. In the absence of neurological symptoms, neurological examination serves only to satisfy the examiner that features that should not be present are actually not present.

In one arena, developments have occurred. A specialized protocol of examination, based on detecting centralization of pain and other features, has been tested. It has been shown to be valid for the detection of sacroiliac joint pain[56] and of internal disc disruption.[57] It does not detect zygapophyseal joint pain.[36,37] This protocol, however, requires special training.[58]

As for acute low back pain (see Chapter 71) physical examination is perhaps most relevant when the patient exhibits no signs in the lumbar region. In that event, consideration needs to be given to a visceral or vascular cause of pain.

Psychological Assessment

About 30 years ago, several authorities promoted the psychoanalytic concept that intractable pain is a defense against unconscious psychic conflict.[59] Chronic pain was attributed to repressed hostility and aggression, guilt, resentment, loss, masked depression, and various personality disorders. Although eloquently espoused, these concepts have not found support from evidence, particularly from controlled studies.[59] The concept of the "pain-prone" personality might be applicable to some patients, but it cannot be applied to patients at large.[59]

Nor can persisting pain be attributed to seeking compensation or to pre-existing psychological disorders. Studies purporting to show this have not controlled for selection biases, overinterpretation being an inappropriate use of psychometric tests.[60] The concept of "secondary gain" is poorly substantiated by the literature.[61]

On balance, the existing data fit a more conciliatory and understanding conclusion: Chronic pain produces anxiety, depression, and other psychological distress, all due to reduced function, unemployment, and financial insecurity, compounded by the failure of treatment to relieve the pain.[60]

In the past, various psychiatric labels have been applied to patients with chronic low back pain, usually by physicians rather than psychiatrists. Patients are now protected from such incorrect practices by the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV-TR*) of the American Psychiatric Association,[62]

which prescribes specific criteria that must be satisfied before particular rubrics can be applied.

The criteria for "conversion disorder" stipulate loss of sensory or motor function. This rubric is expressly precluded if pain is the sole symptom.[62]

The criteria for "hypochondriasis" stipulate that the patient has a preoccupation with fears of having a serious disease.[62] Although patients with chronic low back pain may appear preoccupied with their pain to the extent of seeking relief, this differs from having a preoccupation with a fear of having pain, or fear of a serious disorder.

Somatization disorder is a rubric that might seem to be a euphemism for psychogenic pain, but the diagnostic criteria for this condition stipulate that the patient must have pain in at least four different sites, as well as two gastrointestinal symptoms, one sexual symptom, and one pseudoneurological symptom, the latter not limited to pain.[62] Furthermore, the symptoms are not intentional. These criteria specify a complex disorder that some patients with chronic pain may have, but by definition the criteria do not apply to patients with pain in a single region, such as back pain.

The diagnostic criteria for "undifferentiated somatoform disorder" are more liberal than those for somatization disorder, and some physicians might be attracted to applying this rubric to patients with chronic low back pain. The notes for this disorder, however, specify fatigue, loss of appetite, or gastrointestinal or urinary symptoms.[62] Pain is conspicuously not mentioned, which suggests that this rubric was not designed to accommodate patients with pain for which there is no explanation.

"Factitious disorder" is characterized by the intentional production or feigning of physical or psychological signs or symptoms, in order to assume a sick role, but external incentives for the behavior are absent.[62] A further qualification is that individuals with factitious disorder present their history with dramatic flair but are extremely vague and inconsistent when questioned in greater detail. Pain may be the symptom produced, and distinction between a genuine and fabricated complaint may be difficult. Lack of external incentives distinguishes factitious disorder from malingering, and a patient who is consistent and lacks dramatic flair when describing their symptoms is unlikely to qualify as having a factitious disorder.

"Malingering" is not a formal psychiatric diagnosis, and the *DSM* does not provide diagnostic criteria for it. It states only that malingering should be strongly suspected if any combination is noted of medicolegal context of presentation, marked discrepancy between the person's claimed distress or disability and the objective findings, lack of cooperation during the diagnostic evaluation and in complying with the prescribed treatment regimen, and the presence of antisocial personality disorder.[62] For many patients with chronic low back pain, some of these features must be carefully interpreted lest they be unjustly incriminating. The criterion for medicolegal context pertains to overt, and deliberate, compensation-seeking behavior. It does not apply to injured patients covered by workers' compensation who cannot avoid a medicolegal context. Some causes of pain may lack objective findings. In other instances, physical findings on physical examination lack reliability and validity. Therefore, physicians will naturally fail to find a correlation between findings and symptoms. They should not misrepresent this natural feature of the disorder as malingering. A systematic review found little scientific evidence to justify malingering as a diagnosis in patients with chronic pain.[63] Expert opinion considers it to be a rare condition.[63]

The essential feature for "adjustment disorder" is a psychological response to an identifiable stressor that results in the development of clinically significant emotional or behavioral symptoms. Examples of stressors include termination of a relationship, business difficulties, living in a crime-ridden neighborhood, and natural disasters. Although pain is listed as a symptom by the handbook that accompanies the *DSM*,[64] it is conspicuously not mentioned by the manual itself.[62] Rather, the manual emphasizes behavioral symptoms such as anxiety and depression. The use of this rubric may not be valid if the physician attributes pain to a stressor because superficially it is convenient to do so, instead of pursuing a diagnosis in a more rigorous manner.

The *DSM* provides an entry that explicitly accommodates patients with chronic pain. It provides three subtypes:

- *307.80 Pain Disorder Associated with Psychological Factors*
- *307.89 Pain Disorder Associated with Both Psychological Factors and a General Medical Condition*
- *Pain Disorder Associated with a General Medical Condition*

For the first two subtypes, the critical criterion is that "psychological factors are judged to have an important role in the onset, severity, exacerbation, or maintenance of the pain." What the *DSM* does not provide are guidelines by which this judgment is to be made. Therefore, the judgment becomes a matter of the physician's opinion. For these rubrics to apply, psychological factors must overtly be responsible for onset, severity, exacerbation, or maintenance of the pain. This is not the same as finding that patients have psychological features that are secondary to the persistence of pain.

The third subtype is specified as not a mental disorder. Having pain, for which psychological factors are judged not to be important, is no more than a medical condition. Unless there is explicit evidence to the contrary, most patients with chronic pain should fall into this category, especially if it is deemed that any psychological factors are secondary to the persistence of pain. It is this category that would accommodate patients with psychological features that are caused by the pain, not vice versa.

When assessed for psychological distress using the SCL-90R, patients with chronic low back pain typically show elevated scores on the scales for somatization, depression, obsessive-compulsive behavior, and psychoticism.[65,66] Respectively, these scales reflect attentional focus on physical sensations, depression, pain-related rumination and frustration, and feelings of isolation as well as loss of control.[66] These features compound the problems already faced by these patients in terms of pain and physical disability.

It is, therefore, important to identify in patients the nature and extent of their psychological distress. These features invite, and warrant, treatment or help in their own right. Moreover, if the pain genuinely cannot be diagnosed, and genuinely cannot be relieved, the psychological domain may be the only one in which treatment might be implemented.

Various instruments are available for the psychological assessment of patients with chronic pain (see Chapter 21, Psychological and Psychosocial Evaluation). Some are more suited for research purposes than for conventional practice. Others are best administered by specialist psychologists. However, in primary care, and even in specialist care, instruments may not be required.

In the first instance, a practitioner alert to the importance of psychological factors would look for these, or elicit them, in the course of a normal consultation. Formal instruments are not required to identify fear, depression, frustration, and isolation. If required, practitioners can be prompted to explore psychological factors using the Distress Risk Assessment Method (DRAM)[67] or a checklist that summarizes the features explored by that method[68] (Table 72.1).

Having identified psychological factors, the practitioner can decide if they are able to help the patient with their distress, or if they need to engage the expertise of a psychologist. Engaging a psychologist, however, should not be a dismissive behavior. Dismissing a patient to a psychologist is tantamount to blaming the pain on a psychological disorder, or the patient might so infer. Engaging a psychologist requires that the patient understand that they have psychological problems parallel to their pain problems, and that a cooperative, interdisciplinary plan of management is required.

TABLE 72.1

ELEMENTS ASSESSED BY THE DISTRESS AND RISK ASSESSMENT METHOD[67]

Somatic perception	Depression
Heart rate increase	Feels downhearted
Feeling hot all over	Feels best in morning
Sweating all over	Has crying spells or feels like it
Sweating in a particular part of the body	Has trouble getting to sleep at night
Pulse in neck	Feels that nobody cares
Pounding in head	Eats as much as used to
Dizziness	Still enjoys sex
Blurring of vision	Losing weight
Feeling faint	Has trouble with constipation
Everything appearing unreal	Heart beats faster than usual
Nausea	Gets tired for no reason
Butterflies in stomach	Mind is as clear as it used to be
Pain or ache in stomach	Tends to wake up too early
Stomach churning	Finds it easy to do the things they used to
Desire to pass water	Is restless and can't keep still
Mouth becoming dry	Is hopeful about the future
Difficulty swallowing	Is more irritable than usual
Muscles in neck aching	Finds it easy to make a decision
Legs feeling weak	Feels quite guilty
Muscles twitching or jumping	Feels that I am useful and needed
Tense feeling across forehead	Life is pretty full
Tense feeling in jaw muscles	Feels that would be better off if dead
	Still able to enjoy the things they used to

INVESTIGATIONS

Investigations that might be used in a patient with chronic low back pain are predicated by their indications and purpose. Some investigations are indicated by clinical cues in the presenting features of possible red flag conditions. Others are designed to determine the source of pain in patients who do not have red flag conditions. There are also investigations that have no place in the management of chronic low back pain but which are nevertheless commonly used.

Red Flag Conditions

In the context of chronic low back pain, the indications and tests for red flag conditions are the same as those for acute low back pain (see Chapter 71, Acute Low Back Pain). They are designed either to rule in or rule out a serious cause of pain (see Table 71.2). The prompt for these investigations is not that they have not been done but whether or not the patient has the appropriate clinical indicator. If the patient does not express an indicator, the test is not warranted or justified.

If the patient has been well managed during their acute phase they will already have been assessed and monitored for red flag conditions. Traumatic and pathological fractures will already have been considered and investigated; tumors should have progressed and manifested new features. Indolent infections are perhaps the only condition that can persist for long periods without expressing new features. However, if a patient has not been managed well in the past, it is appropriate to follow the red flag checklist (see Fig. 71.5) to determine if specific investigations are indicated.

Screening Test

Notwithstanding the security that following the red flag checklist should provide, practitioners may still be concerned lest they have overlooked a serious condition. Conversely, they may want to "clear" the patient of serious disorders before embarking upon a pursuit of the cause of pain. For this purpose, MRI is the investigation of choice.

MRI has a high sensitivity and high specificity for all manner of possibly occult or overlooked disorders. It is, therefore, the appropriate screening test. There is no justification for progressing through plain radiography, bone scan, and CT before considering MRI. Each of those other investigations has little or limited ability to detect cryptic disorders. For screening purposes, MRI can detect fractures, which would be seen on plain radiographs (see Fig. 71.6), but MRI will also detect soft-tissue lesions, which plain radiography cannot do. The increased vascular uptake that bone scan demonstrates will be evident on MRI with greater specificity. Although CT provides better resolution of bone, bony lesions will not escape detection by MRI.

Not Indicated

Foremost amongst investigations not indicated for chronic low back pain is electrophysiological testing. There is no lesion that causes low back pain that produces a conduction block in the nerves of the lower limb. Therefore, there is nothing that nerve-conduction studies can show about back pain. Some practitioners are accustomed to using conduction studies because they confuse somatic referred pain with radicular pain, and explain that they are testing for radiculopathy. However, even that practice is without foundation. It has been demonstrated that even in patients with radicular pain, conduction studies are not diagnostic.[69,70] Conduction studies are indicated only if peripheral neuropathy is in the differential diagnosis of radiculopathy. Back pain is not radiculopathy, and peripheral neuropathy is not a differential diagnosis for chronic low back pain.

Similarly, CT is not an appropriate investigation for chronic low back pain. Its use is based on the confusion between radicular pain and somatic referred pain. CT is very useful for the detection

of disc herniations in patients with radicular pain, but somatic referred pain is not caused by disc herniations. Therefore, CT is not indicated. The only role for CT would be as a substitute when MRI is not available as a screening test. In that regard CT is not an alternative to MRI, for there are conditions that MRI can detect that CT cannot detect. CT is an alternative to MRI for social or economic reasons, not for medical ones.

Plain radiography is not indicated in patients with chronic low back pain. The lesions that it can detect are limited fractures and gross lesions of bone. Yet these are rare causes of chronic low back pain and are better detected by MRI, or CT if there must be an alternative.

Diagnostic Tests

Certain diagnostic tests can pinpoint the source of pain, and sometimes its cause, in patients with chronic low back pain in whom serious causes have been excluded. These encompass MRI and various invasive tests.

MRI

Irrelevant to the diagnosis of chronic low back pain are age-changes—so called degenerative changes—that may be evident on MRI or CT of the lumbar spine. Osteophytes, disc bulges, and even disc herniations occur commonly in subjects with no back pain and exhibit no relationship to pain.[70,72] However, there are certain features that can appear on MRI scans that are pertinent to establishing the cause of pain.

High-Intensity Zone. High-intensity zones (HIZs) are very bright signals that occur in the posterior annulus of lumbar intervertebral discs[42] (Fig. 72.4). They are distinguished from simple fissures in the annulus in that their intensity rivals that of cerebrospinal fluid on heavily T-2 weighted MRI images. In contrast, simple fissures appear grey. Biopsy has revealed that they represent sites of highly vascularized granulation tissue in anular tears.[73]

HIZs are not common. They occur in about 30% of patients with chronic low back pain. In these patients the presence of an HIZ correlates strongly with the affected disc being the source of the patient's pain. Multiple studies have investigated this relationship (Table 72.2). The studies differ in the sensitivities that they encountered. This indicates that not all painful discs necessarily exhibit an HIZ, which may be a function of the pathology suffered by the patient or a function of the scanning technique used. However, all studies agree on a high specificity, which generates substantial positive likelihood ratios. This means that if an HIZ is evident then the affected disc is very likely to be painful. Even the study that sought to refute the validity of the HIZ produced data consonant with this conclusion.[79] That study argued that that HIZ could not be held as a cause of pain on the grounds that it could occur in asymptomatic individuals.[79] However, the data provided nevertheless showed that the prevalence of an HIZ in patients with back pain (60%; 95% CI: 45% to 75%) was significantly greater than in asymptomatic subjects (24%; 95% CI: 11% to 37%). Moreover, in the original literature,[42] HIZs were not promoted as a cause of pain, but as an indicator that, in patients with back pain, the affected disc was likely to be the source. In that regard, the HIZ is a valid sign (see Table 72.2).

Modic Changes. Another feature that can occur on MR scans are signal changes in the bone marrow adjacent to a vertebral endplate. They are known as Modic changes, after the radiologist who first described them.[81] Modic type-I changes represent edema in the marrow, and are evident on both T1-weighted and T2-weighted images (Figs. 72.5A,B). Modic type-2 changes represent fatty infiltration in the marrow, and are best seen on T1-weighted images (Figs. 72.5C,D). Sequentially in time, these changes imply an acute and then chronic inflammatory response to an injury to the disc. These changes are strongly related to the affected disc being painful (Table 72.3). In that regard, Modic changes have only a low sensitivity, reflecting that only a minority of painful discs exhibit Modic changes, but their specificity and likelihood ratios are very high, which indicates that if Modic changes are evident the affected disc is very likely to be painful. This correlation is reinforced by pathology studies that show that endplates affected by Modic changes have a higher density of nerve fibers and cells that stain for tumor necrosis factor α.[53]

Medial Branch Blocks

The medial branches of the lumbar dorsal rami innervate the lumbar zygapophyseal joints. Each joint is supplied by the nerve above and the nerve below. Blocking these nerves with local anesthetic serves as a diagnostic test for pain stemming from these joints. The technique is described in Chapter 97 (Diagnostic and Therapeutic Nerve Blocks).

(Courtesy of Dr Tim Maus Lau, of the Mayo Clinic, Rochester, MN.)

Lumbar medial branch blocks have been validated. They protect normal volunteers from experimentally induced pain from the joint anesthetized.[84] They do not anaesthetize other structures that might be an alternative source of pain.[85] Single, diagnostic blocks, however, carry a high false-positive rate.[30,86,87] Therefore, in order to be valid, lumbar medial branch blocks have to be controlled. Comparative local anesthetic blocks have been used in the past, but doubts have been raised about their validity (see Chapter 97, Diagnostic and Therapeutic Nerve Blocks). Because of the low prevalence of lumbar zygapophyseal joint pain, even comparative blocks still have substantial false-positive rates (see Chapter 97, Diagnostic and Therapeutic Nerve Blocks). Consequently, operators who use comparative blocks need to appreciate that some of their positive responses will be doubtful. The only way to reduce this doubt is to perform placebo-controlled blocks.

TABLE 72.3

0.22	0.95	4.4	75

With these reservations in mind, it is possible to use lumbar medial branch blocks to determine if a patient has back pain stemming from one or more lumbar zygapophyseal joints. Algorithms for the efficient use of blocks have been described.[88] They recommend multilevel screening blocks in the first instance, in order to identify patients who do not have zygapophyseal joint pain, which is the most common response. Patients who report relief of the pain from screening blocks can then be subjected to repeat testing with controlled blocks, in order to identify the joint or joints that are the source of pain.

Because of the vicissitudes of controlled blocks and the criteria for a positive response (see Chapter 97, Diagnostic and Therapeutic Nerve Blocks), the prevalence of lumbar zygapophyseal joint pain is uncertain. In the general population of patients with chronic low back pain it may be 5% or less.[89] In older populations, with no history of trauma, it may be around 40%.[29]

Irrespective of the actual prevalence, lumbar zygapophyseal joint pain is worth investigating because, if diagnosed, it can be treated. The pain can be relieved by lumbar medial branch radiofrequency neurotomy[89] (see Chapter 101, Neurolytic Blockade).

Sacroiliac Joint Blocks

Pain from a sacroiliac joint can be diagnosed using controlled blocks of the joint. These blocks involve injecting local anesthetic into the cavity of the joint (see Chapter 97, Diagnostic and Therapeutic Nerve Blocks).

In 15% to 20% of patients with chronic low back pain the source of pain can be traced to a sacroiliac joint if controlled blocks are used.[26,27] Doing so has diagnostic utility. Establishing a diagnosis confirms for the patient that they do have a genuine

source of pain, and that the pain is not imagined. Establishing a diagnosis protects the patient from a futile pursuit of other diagnoses by bringing about closure. It protects them from undergoing treatments that do not target the sacroiliac joint and which are, therefore, doomed to failure. Knowing that the sacroiliac joint is the source of pain allows treatments to be applied that are specific for that source.

Sacroiliac Ligaments

The dorsal sacroiliac ligaments are a potential source of pain. These ligaments are not anesthetized by intra-articular blocks of the sacroiliac joint. They can, however, be anesthetized by blocking the lateral branches of the sacral dorsal rami, which innervate them.

Conventional techniques for sacral lateral branch blocks, however, have been shown to be unreliable.[90] The nerves run at variable locations and at variable depths. For blocks to be reliable they have to be performed at multiple sites and at multiple depths within the posterior ligamentous complex. Such blocks have been shown to protect normal volunteers from experimentally induced pain from the posterior sacroiliac ligaments.[91] They can be used to identify patients who might be treated with radiofrequency neurotomy of the sacral lateral branches.

Discography

Lumbar discography is a procedure designed to determine if a lumbar intervertebral disc is the source of back pain. If supplemented by postdiscography CT, it allows a diagnosis of internal disc disruption to be established.

The procedure involves introducing fine needles into the center of the disc suspected of being the source of pain, and into adjacent discs.[92] A small volume of contrast medium is injected through the needles in order to stress the disc by pressurizing it internally. The principle is that when a symptomatic disc is stressed, the patient's accustomed pain should be reproduced, but pain should not be reproduced if asymptomatic discs are stressed.

Because discography is a provocation test, certain precautions need to be observed in order to maximize its validity. Specifically, anatomic controls and a manometric control combined with pain intensity need to be exercised.

For discography to be valid, stressing one disc should be painful but stressing discs at adjacent levels should not be painful. This criterion guards against false-positive responses owing to hyperalgesia. Validity is compromised, to an unknown degree, if two discs appear symptomatic, for in that event the number of apparently positive discs typically outnumbers the number of control discs. If no disc is asymptomatic the test cannot be regarded as positive.

Manometric controls are required because, in principle, any disc might be rendered painful if stressed with sufficient intensity. In practice, some discs withstand an excess of 100 psi internal pressure without becoming painful; others become mildly painful at high pressures up to 100 psi.[93] Conversely, normal discs are rarely painful, if at all, at low pressures of stimulation, and are minimally or only mildly painful. A sensitivity analysis allows for operational criteria to be defined.

If discography is painful at less than 50 psi and evokes pain at an intensity greater than 4 on a 10-point numerical pain rating scale, the probability of the response being false-positive should be less than 0.10.[93,94] However, the probability of a false-positive rate reduces to zero if the required pain score is held at 4 and the threshold pressure of injection is lowered to 30 psi; or if the required pressure is held at 50 psi and the pain score required is raised to 6.[93,94] Two sets of operational criteria are offered because the low-pressure criterion has high specificity but detects fewer patients as positive, whereas the more liberal, 50 psi threshold detects more patients with only a marginal reduction in specificity.

Postdiscography CT scanning allows the demonstration of the distribution of contrast medium with the discs tested. Radial fissures are the hallmark of internal disc disruption (see Internal Disc Disruption, above). Demonstrating radial fissures upgrades the diagnosis from discogenic pain to internal disc disruption.

Warnings have been raised about possible false-positive responses to lumbar discography. In studies of normal volunteers, patients with chronic pain, and patients reportedly with "somatization," the reported false-positive rates have been 10%, 40%, and 75%, respectively.[95] However, if the operational criteria for anatomical and manometric controls are satisfied, these false-positive rates reduce to 0%, 0%, and 25% respectively.[92–94,96] Consequently, operators who adhere to the operational criteria need to be concerned about false-positive responses only in patients with somatization.

The virtue of lumbar discography lies in its diagnostic utility, both in a positive and a negative sense. Establishing a diagnosis of discogenic pain or internal disc disruption protects the patient from further pursuit of diagnosis, and from treatments that are unlikely to work because they do not stop discogenic pain. Conversely, finding discography to be negative should protect the patient from surgery to the disc based only on assumptions that the disc is the source of pain.

The therapeutic utility of lumbar discography still remains unproven. No studies have yet shown that any treatment can reliably and consistently relieve pain if directed at the disc found to be symptomatic by discography. There is some evidence that outcomes of arthrodesis are better if planned on the basis of discography than if planned on imaging alone,[97] but this has not been confirmed by other studies. Most studies of arthrodesis have not used discography to select patients. Otherwise, discography is used to select patients for a variety of intradiscal therapies that are still being evaluated (see Intradiscal Therapies, below).

TREATMENT

Metaphorically, the treatment of chronic low back pain is a political minefield. It is occupied by several schools of thought. Each school believes that its treatment is the correct one, each tries to produce evidence of its efficacy, and each zealously defends itself against any criticism from other schools. The major schools represent multidisciplinary pain management or functional restoration, interventional pain medicine, surgery, individual therapies, and salvage or palliative care.

The plight of patients with chronic low back pain can be encapsulated, in cartoon form, as a journey through a five ring circus (Fig. 72.6). The patient may start with individual therapies, trying one then another. They may be referred for multidisciplinary pain management or functional restoration. They may find their way to interventional pain medicine, where they may be treated, or subjected to diagnostic tests that lead to surgery. When surgery or other interventions fail, the patient resorts to salvage treatment or what might be called palliative care. The patient may remain for a while in a particular cycle, before passing to one or more others. They may revisit cycles.

The various schools differ in certain key characteristics. Those who promote multidisciplinary pain management or functional restoration believe that a diagnosis is not possible; some even abjure pursuing a diagnosis.[98] Their objective is to help patients improve their function and cope with their pain. Relief of pain is not a primary objective. Proponents of individual therapies do not necessarily make a diagnosis. They apply a treatment that they believe works and that they believe the patient requires or should have. Surgeons believe that particular operations will relieve the patient's pain. A valid diagnosis may or may not be

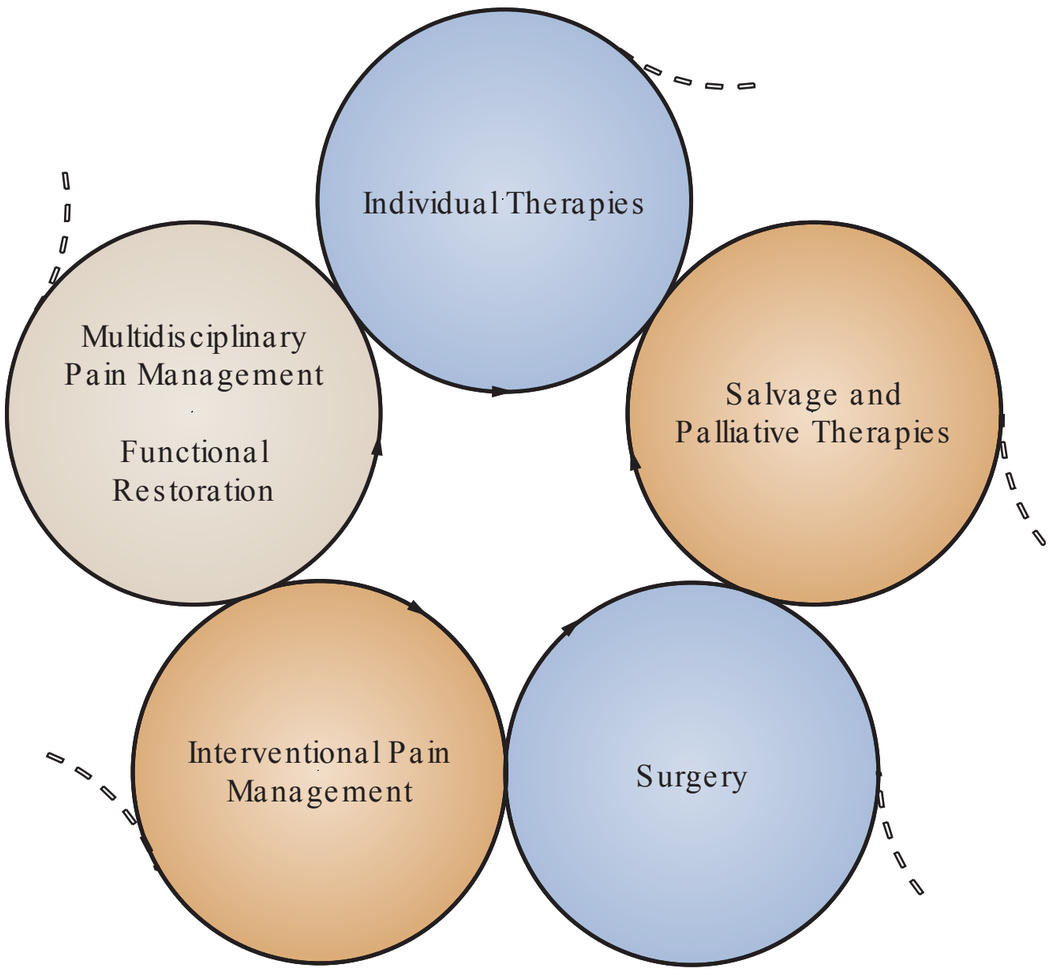

FIGURE 72.6 The-five ring circus of chronic low back pain. Patients cycle within or between various schools of treatment.

made. Interventional pain management strives to pinpoint a source of pain, and direct treatment to that source with the aim of stopping the pain. Those who undertake salvage and palliative care seek to relieve pain by interfering with nociception rather than treating its source.

Individual Therapies

Many individual therapies are available for patients with chronic low back pain. These include, but are not limited to drug therapy, exercise, manual therapy, massage, transcutaneous electrical nerve stimulation (TENS), acupuncture, back school, traction, and injections. Some practitioners may offer more than one. They may be tried serially; sometimes they are used in combination.

Most individual therapies are offered without the need for a diagnosis. For example, exercise does not require a patho-anatomical diagnosis; nor does drug therapy, TENS, or back school. Other therapies may be preceded by a diagnosis, but these diagnoses lack reliability, validity, or both. For example, acupuncture may be prescribed on the basis of pulse diagnosis or disturbed flows of energy along meridians, but these concepts have not been validated. Similarly, manual therapy may be predicated by purportedly diagnostic abnormalities of segmental motion, but these lack reliability and validity.[99,100]

The evidence supporting individual therapies is meager. At best it attests to small effect-sizes or effects for limited durations only.

Drugs

The drugs most often prescribed for chronic low back pain are simple analgesics, nonsteroidal anti-inflammatory drugs (NSAIDs), muscle relaxants, antidepressants, and tramadol. Opioids might also be used, but usually not as a first-line agent. The use of opioids is covered below under Salvage Therapy.

No studies have established the efficacy of paracetamol (acetaminophen) for chronic low back pain. Its use for this condition is based on the reputation of this agent as a relatively safe, simple analgesic. One study found that fewer patients had reduction of pain when taking paracetamol than when taking diflunisal,[101] but the difference was not statistically significant.

Systematic[102–104] and other reviews[105] of the literature indicate that NSAIDs are statistically more effective than placebo for relieving pain, but the effect-sizes have been modest or small.[106] Moreover, many studies followed patients for only 2, 4, or 6 weeks, and none beyond 12 weeks. No studies have indicated what proportion of patients achieved satisfying relief for sustained periods, and required no other treatment. NSAIDs, therefore, may have a role for the short-term relief of chronic low back pain, but there is no evidence that they are effective as a long-term alternative to other treatment.

The efficacy of muscle relaxants has been studied only for 1, 2, or 3 weeks.[105,107] Over such short periods agents such as tetrazepam and flupirtin have been found to be more effective than placebo in reducing pain, but the difference is small. For example, patients taking tetrazepam had an average reduction in pain of 50%, whereas those taking placebo had a reduction of 30%.[108] Other agents, such as diazepam and tolperisone, have not proved more effective than placebo in reducing pain.[105,107] There are no long-term data on the effectiveness of muscle relaxants.

Although antidepressants are promoted as a co-analgesic for chronic low back pain, evidence of their efficacy is limited.[109,110] They have not been studied for longer than 8 weeks. Some tricyclic antidepressants, but not others, are slightly more effective than placebo for reducing pain. Serotonin selective reuptake inhibitors are conspicuously ineffective for chronic low back pain.[110]

The available data on tramadol for chronic low back pain are curious. A compound analgesic, consisting of tramadol and acetaminophen, has been shown to be more effective than placebo in studies lasting 3 months.[111,112] The agent improves pain as well as function. What is not evident is the extent to which the improvements are due to the tramadol component or the acetaminophen component. The one study that assessed tramadol alone selected patients who tolerated tramadol and benefited from it during an open-label screening phase.[113] In those patients, tramadol was found to be more effective than placebo for relief of pain and improvement in function. Fewer patients (20.7%) discontinued tramadol for lack of adequate pain relief than did patients (51.3%) who took placebo. This effect was demonstrated in a 4-week study. Longer term data are not available.

What is evident from these data on drug therapy is that the evidence is not commensurate with the way drugs are used for chronic low back pain. Short-term data are extrapolated to imply long term efficacy, but this has not been shown. Long-term data are not available to justify long-term use. Unknown is the proportion of patients who are satisfied with the relief that they obtain and who do require other treatment.

Physiotherapy

Although medical practitioners are accustomed to referring patients with chronic low back pain for ‘‘physiotherapy’’ it is difficult to define exactly what this treatment constitutes. Individual physiotherapists may differ in exactly what they offer to patients. For some interventions that physiotherapists may offer, data on efficacy are available, and these are covered separately below (see Exercises, Manual Therapy, and TENS). For what might be called ‘‘routine physiotherapy’’ the data are fewer. A British study found that ‘‘routine physiotherapy’’ was neither more effective nor more cost-effective than providing advice for patients with chronic low back pain.[114]

Exercise

The European Guidelines for the Management of Chronic Non-Specific Low Back Pain recommend exercise as a first-line treatment.[103] However, exercise is not a powerful treatment. A systematic review found that exercise for chronic low back pain is more effective than no treatment and at least as effective as

treatments such as usual care by a general practitioner, massage, and home exercises.[115,116] The effect-size of exercise, however, is quite small, measuring 0.57 when expressed as a standardized mean difference.[106] This amounts to a mean difference of 10 points (on a 100-point scale), when compared to no treatment, and 7.3 points when compared with other treatments.[115,116]

Proponents of high-intensity strengthening exercises have sought evidence of efficacy within the general literature on exercise for chronic low back pain, but found no clear evidence of benefit over other exercises or other interventions such as physiotherapy and massage.[117] Others likewise found trunk-strengthening exercises to be more effective than no exercises but not more effective than aerobics or McKenzie treatment.[118]

Proponents of core stabilization exercises found moderate evidence that this form of exercise is effective in improving pain and function, but strong evidence that it was not more effective than physiotherapy, manual therapy, general exercises, and minimal care.[119] Another review found that stabilization exercises were superior to usual medical care and education but not to manipulative therapy, and no additional effect was found when stabilization exercises were added to a conventional physiotherapy program.[120]

McKenzie Therapy

Systematic reviews found limited evidence concerning the efficacy of McKenzie therapy for chronic low back pain.[121,122] Advocates of the treatment cite a study that showed no superiority over stabilization exercises, and a study that showed slightly better outcomes than those of strengthening exercise at 2 months after treatment but not at 8 months.[123]

Massage

A systematic review lists several studies of massage for chronic low back pain,[124] but many are flawed by limitations such as lack of blinding and lack of follow-up after treatment. Those studies with long-term follow-up indicate that massage may be slightly more effective than acupuncture, education, or self-care at 10 weeks, but not after 52 weeks.[124]

Manipulative Therapy

Spinal manipulative therapy is perhaps the most hotly contested intervention for chronic low back pain, and the most extensively studied and most often subjected to systematic reviews. Individual studies have differed in their design and rigor. Reviews have differed in what they consider evidence of efficacy. A synthesis of the literature ventured limited and specific conclusions[125]:

> "Spinal manipulative therapy combined with strengthening exercises is as effective as prescription NSAIDs combined with exercises; flexion-distraction mobilization is more effective than exercises, for the relief of pain although not for improving disability."

In other respects, manipulative therapy appears more effective than some other interventions in the short-term, but evidence for long-term differences is either inconclusive or lacking.[125] In studies that enrolled mixed populations, with some patients having chronic low back pain, the evidence is conflicting as to whether the efficacy of spinal manipulative therapy is superior or similar to that of medical care or physiotherapy.[125] The calculated effect-size of manipulative therapy is small (0.35).[106]

Electrical Therapies

Systematic reviews of the literature have found several studies of the efficacy of transcutaneous electrical nerve stimulation (TENS) for chronic low back pain, but most assessed outcomes only immediately after treatment.[126–128] Even then, the effect size of TENS is small (0.22).[106] Only one study provided long-term follow-up (3 and 6 months) and found no significant difference from placebo.[129] An attempted systematic review found no studies suitable for review of interferential therapy, electrical muscle stimulation, or ultrasound therapy.[126]

Traction

Multiple studies have shown that sustained traction is no more effective than sham treatment for chronic low back pain.[130] The evidence on intermittent traction is limited to two studies with opposing results.[130]

Trigger Point Injection

Despite the popularity of trigger point injection as a treatment, there are few studies of its efficacy, and even fewer of its efficacy specifically in patients with chronic low back pain.[131] Studies limited to immediate and short-term outcomes (7 days) report conflicting results. No studies have provided long-term data.

Prolotherapy

Multiple reviews have found no evidence of efficacy for prolotherapy.[132–134] Studies that used co-interventions have found positive results, but studies in which prolotherapy alone was tested found negative results.[132]

Acupuncture

Many studies have explored the efficacy of acupuncture for chronic low back pain. They vary in quality and conclusions. The pattern in the evidence is that acupuncture is better than no treatment; it may be better than TENS, but it is not more effective than sham acupuncture, massage, or self-care education.[135]

Epidural Injections

Epidural injections, by the caudal or interlaminar route, are used for the treatment of chronic low back pain, but there is no evidence of their efficacy for this condition. Epidural injections have been tested for radicular pain (see Chapter 100, Epidural Steroid Injections), but not in patients with back pain but no radicular pain. Despite this lack of evidence, some authorities curiously still recommend their use.[136]

Back School

As a stand-alone intervention, outside the context of multidisciplinary pain management (see below), back school is not an effective intervention for chronic low back pain.[137] It is not more effective than no treatment or placebo treatment.[137]

Brief Education

Brief education involves contact with a health care professional in sessions of short duration to encourage self-management, provide advice to stay active, and reduce potential concerns about back pain.[137] It is more effective than usual care in promoting return to work, but not for reducing pain or disability, although it is more effective than no treatment or massage in reducing disability.[137]

Fear-Avoidance Training

Fear-avoidance training is an intervention that has started to be assessed in recent years. It involves a physician or a psychologist encouraging patients to return to normal activities and physical exercise in order to overcome fears of aggravating pain and to reduce avoidance of activity. It has been shown to reduce pain and disability better than does usual care, and is no less effective than spinal surgery.[137]

MULTIDISCIPLINARY PAIN MANAGEMENT

In its original forms, multidisciplinary pain management involved the collaboration of various disciplines in the management of patients with chronic pain. Physicians would attend to the medical assessment of the patient and provide pharmacological interventions and perhaps other interventions. Physiotherapists would assess the patient's musculoskeletal disabilities, and provide interventions in that realm. A psychologist or psychiatrist would address the patient's psychological distress. Others, such as occupational therapists and social workers, would address the patient's vocational, social, and financial problems. If required, additional specialists, such as neurologists or surgeons, could be consulted.

Functional restoration had a separate, and later, origin. Although it, too, was multidisciplinary in nature, it was more prompted by sports medicine. In the way that athletes were known to overcome musculoskeletal injuries by concerted training and perseverance, it was proposed that injured workers could rehabilitate by work hardening. The objective was to restore function, virtually regardless of the pain.

It has now become difficult to disentangle multidisciplinary pain management from functional restoration, particularly when it comes to analyzing the literature on efficacy. Multidisciplinary pain management has adopted some of the principles and practices of functional restoration, particularly those of intensive training, whereas functional restoration adopted behavioral therapy from multidisciplinary pain management.

It is unclear the extent to which behavioral therapy is a critical component of functional restoration. As evidence of behavioral therapy for chronic low back pain, advocates cite reviews of behavioral therapy for chronic pain in general.[138] Those reviews are weighted by evidence pertaining to the treatment of temporomandibular pain, fibromyalgia, and arthritis. The literature specifically on chronic back pain is less compelling. For chronic low back pain, behavioral therapy has a moderate positive effect on pain, and a small positive effect on functional status when compared with no treatment, placebo treatment, or being put on a waiting list; however, adding behavioral therapy to usual care has no short-term or long-term effect on pain, functional status, or behavior.[139,140] Nor is behavioral therapy more effective than exercise.[141] More recent studies have shown that a group program of exercise or education using a cognitive behavioral approach is not significantly more effective than providing an educational booklet[142]; and that active physical treatment is as effective as cognitive behavioral treatment or a combination of active physical treatment and cognitive behavioral treatment.[143]

The critical component of multidisciplinary rehabilitation would appear to be the intensity of the program, particularly its physical component. A systematic review found strong evidence that intensive, multidisciplinary rehabilitation with functional restoration improves function when compared with inpatient or outpatient rehabilitation that was not multidisciplinary, and moderate evidence that it reduces pain.[144,145] It also found that less intensive multidisciplinary rehabilitation did not provide improvements in pain, function, or vocational outcomes when compared with nonmultidisciplinary rehabilitation or usual care.

Although the conclusions about intensive multidisciplinary rehabilitation are favorable, it is conspicuous that it is not a treatment that effects a cure. The outcomes are cast in terms of reductions in pain and improvements in disability. When the original literature is consulted, the magnitudes of improvement are from 6.1 to 5.7 for pain, 16.9 to 12.1 for function in one study,[146] and a 17-point reduction on a 100-point scale for pain, in another study.[147] Despite these limitations, the European Guidelines recommend multidisciplinary rehabilitation for chronic low back pain.[103]

SURGERY

Surgeons offer a variety of operations for the treatment of chronic low back pain. They include various ways of fusing the lumbar spine and various forms of disc replacement. Some surgeons select the segmental level to be treated on the basis of discography. For others, the indication for surgery seems to be persistent pain and evidence on medical imaging of disc degeneration.

Surgery has not avoided scientific scrutiny; there have been many studies of surgery for back pain, but most have only compared one technique with another. Few studies have addressed critical issues such as clinical outcome in comparison with other less invasive, less destructive, and less irreversible interventions. Only three randomized, controlled trials have done this.

One study found spine fusion to be more effective than physiotherapy, but only marginally so.[148] The continuous outcome data for pain show a distinct improvement in the surgery group at 6 and 12 months, which did not occur in the nonsurgical group; however, at 24 months there was decay in outcomes of the surgery group, such that considerable overlap occurred in the outcomes of the two groups (Fig. 72.7). The categorical outcome data are more revealing. No patient was reported to have been cured of their pain, by either intervention. The advantages of surgical treatment were only that a greater proportion of patients reported feeling much better or better (Table 72.4). Reciprocally, a greater proportion of patients who had nonsurgical treatment were unchanged. The success rate of surgery for making patients "better" was 63%. For a major intervention, this is a disappointing figure,

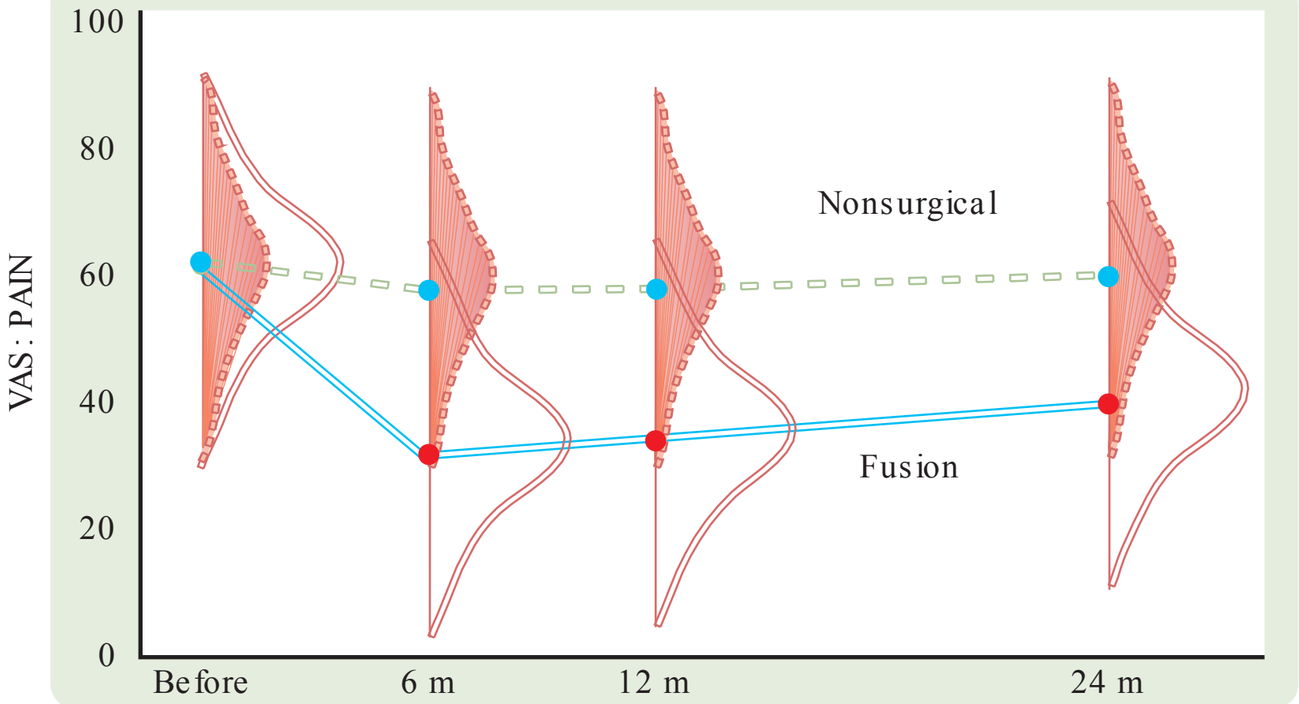

FIGURE 72.7 The outcomes at 6 months, 12 months, and 24 months of the study by Fritzell et al,[148] which compared fusion with nonsurgical therapy for chronic low back pain. Depicted are the mean visual analog scores (VAS) for pain, and their distributions based on the standard deviations reported in the study.

TABLE 72.4

THE CATEGORICAL OUTCOMES OF THE STUDY OF FRITZELL ET AL,[148] OF SURGERY COMPARED WITH NONSURGICAL CARE FOR CHRONIC LOW BACK PAIN

	Treatment group	
	Surgery	Nonsurgical
Much better	29%	14%
Better	34%	15%
Unchanged	24%	45%
Worse	14%	26%

and is dissonant with the public expectation that surgery "fixes" problems. Other conservative interventions might be just as effective if making patients "better" is the only objective. This is borne out by other studies.

A second study compared surgery with an intervention consisting of exercises and a cognitive-behavioral rehabilitation program.[149] In terms of pain and disability, the outcomes were indistinguishable statistically (Fig. 72.8). A third study also found no differences in outcomes between surgery and cognitive therapy coupled with intensive rehabilitation.[150]

Surgical treatments other than fusion have not yet been studied in this way.

INTERVENTIONAL PAIN MANAGEMENT

The objectives of interventional pain management are to pinpoint the source of a patient's pain and to direct treatment specifically to that source. If the lesion responsible for the pain cannot itself be treated, then interventions can target the nerves that mediate the pain in order to block nociception.

In terms of volume of publications, interventional pain management has attracted substantially less research than more conventional and traditional interventions for chronic low back pain, for several reasons. Interventional pain management requires expensive, specialized facilities, a license to practice invasive procedures, and the training to do so. Consequently, the procedures cannot be practiced anywhere or by anyone. As well, the number of individuals with skills in this field, who also hold academic appointments and might undertake the necessary research, number barely a handful worldwide. As a result, the literature is meager compared with that of other disciplines in chronic low back pain, but not without merit.

Zygapophyseal Joint Pain

A diagnosis of lumbar zygapophyseal joint pain can be established using controlled, diagnostic blocks of the medial branches that innervate the painful joint (see Chapter 97, Diagnostic and Therapeutic Nerve Blocks). This pain can be treated by percutaneous lumbar medial branch radiofrequency neurotomy (see Chapter 101, Neurolytic Blockade). In this procedure, electrodes are used to coagulate the nerves in order to provide long-lasting relief of pain.

The benchmark for outcomes was established in a small observational study.[151] Patients were selected on the basis of positive responses to controlled diagnostic blocks. Anatomically correct technique was meticulously executed. At 1-year follow-up, some 60% of patients maintained at least 80% relief of their pain, and 80% maintained at least 60% relief.

Two controlled trials have established that lumbar medial branch neurotomy is not a placebo.[152,153] Patients treated with the active procedure achieved superior outcomes, in terms of relief of pain and improvement in function, than did patients who underwent sham treatment.

Outcome studies have shown that, when the operation is successful, good relief is maintained.[154] If pain recurs and requires treatment, relief can be successfully reinstated by repeating the neurotomy.[155]

Patient selection is critical to a successful outcome. The patient must be shown to have zygapophyseal joint pain. Long-term outcomes are substantially and significantly better when a diagnosis is correctly established than when it is assumed.[156] Correct technique must be used.[157,158] Studies purporting to discredit medial branch neurotomy have not used anatomically accurate techniques.[157]

Sacroiliac Joint Pain

Although pain can be traced to the sacroiliac joint by using controlled diagnostic blocks, a successful treatment has proved elusive. A variety of conservative therapies are advocated,[159] but none has been validated in controlled trials. Arthrodesis of the joint is advocated and appears successful in small observational studies,[160] but has not been tested in controlled trials.

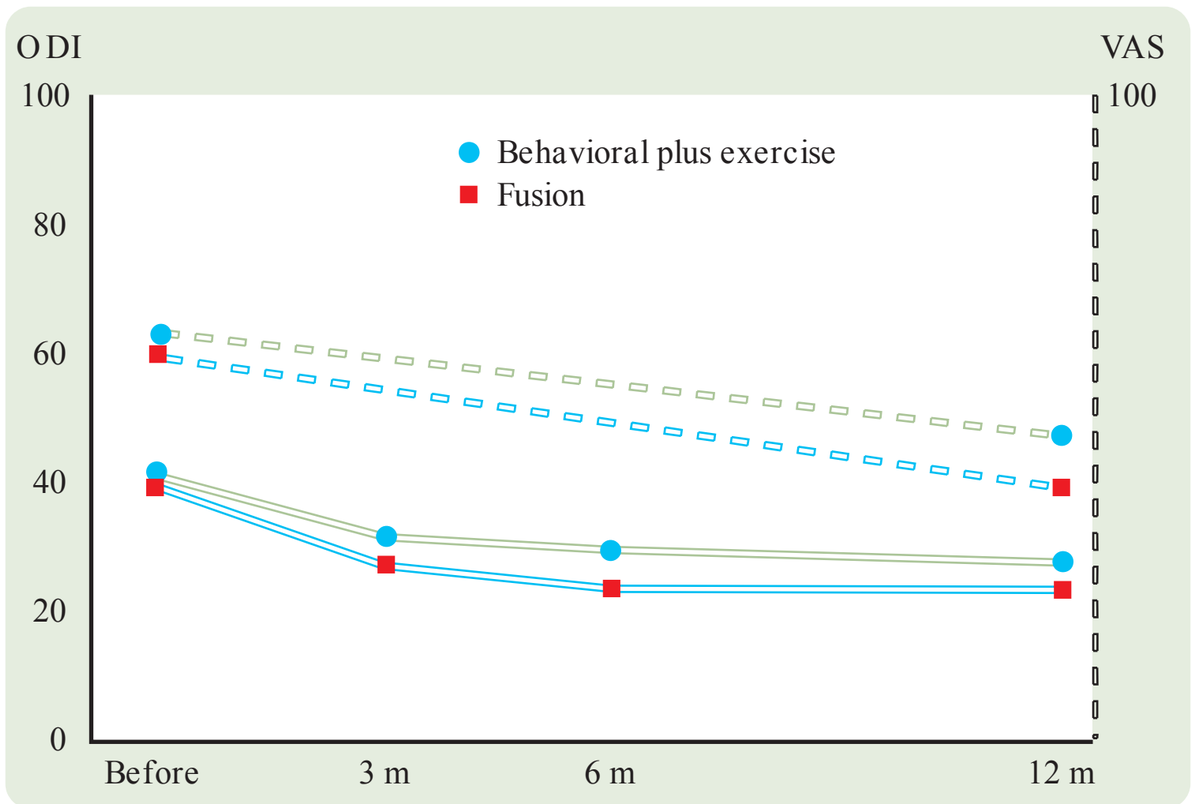

FIGURE 72.8 Outcomes of the study of Brox et al[149] that compared fusion with behavioral therapy and exercises.

Practitioners of interventional pain medicine have explored methods of denervating painful sacroiliac joints (see Chapter 101, Neurolytic Blockade). The target nerves are the lateral branches of the sacral dorsal rami. These can be coagulated using radiofrequency neurotomy.

A controlled trial has shown that sacral lateral branch radiofrequency neurotomy is undoubtedly more effective than sham treatment.[161] The duration of effect, however, is limited. Whereas 80% of patients achieved at least 50% relief of their pain at 1 month, this proportion had dropped to 60% at 6 months and 10% at 12 months.[161]

Discogenic Pain

A variety of interventions are being explored for the selective treatment of lumbar discogenic pain (see Chapter 100, Interventions for Vertebral Body and Disc Pain). Variously these target the pathology of internal disc disruption at a macroscopic or molecular level, or the nerves that transduce the pain. To date, however, only one intervention has been subject to controlled trials.

Intradiscal electrothermal anuloplasty (IDET) involves inserting a flexible electrode circumferentially into the posterior annulus of the painful disc. The electrode is heated to around 85° to 90°C, ostensibly to seal radial fissures, coagulate algogenic material within those fissures, or to coagulate the nerve endings around them.[162] The indications for the procedure are positive responses to discography, demonstration of a radial fissure on postdiscography CT scan, and preservation of sufficient disc height to enable introduction of the electrode to a suitable location.[162]

The first controlled study of IDET was conducted at a time when the efficacy of the procedure was still unknown.[163,164] It was not randomized, but instead used a convenience sample of patients denied permission to have the procedure by their insurer. These patients underwent conventional functional restoration. IDET proved significantly more effective at 1-year and 2-year follow-up. Of those treated with IDET, 54% achieved at least 50% reduction in pain, returned to work, and no longer required opioids. The corresponding figure for those who underwent rehabilitation was 10%. Furthermore, 20% of patients treated with IDET had complete relief of pain, returned to work, and did not require opioids. In the rehabilitation group, none achieved this outcome. The complement of these figures, however, is that some 50% of patients obtain no benefit from IDET. This fact affects the utility of the procedure, which emerged in latter studies.

A randomized, placebo controlled study reported an intriguing result.[165] No patient benefited from IDET, and no patient benefited from sham treatment. The placebo response rate was zero. This is curious, for it is rare for any control treatment of pain to have absolutely no effect. Failure to respond suggests substantial nocebo effects. The authors concluded that their study showed that IDET was no better than a placebo. This is somewhat egregious because no placebo effect was encountered. The study would have been more convincing if the investigators had encountered even a small response rate, commensurate with that reported in observational studies of the procedure (see Chapter 102, Interventions for Vertebral Body and Disc Pain).

The second placebo-controlled trial yielded more realistic results.[166] Patients responded both to IDET and to sham treatment, but the magnitude of improvement in pain was significantly greater in those who had active treatment. A greater proportion of patients treated with IDET (8/32) achieved at least 75% relief of pain than did patients who had sham treatment (1/24). What prevents these differences being convincing statistically is the fact that IDET fails to relieve pain in 50% of patients.

It is the failure rate that limits the utility of IDET. Even if patients are stringently selected, half will not benefit. Cynical observers might use that failure to discredit IDET as an inadequate procedure. However, for the patients who do benefit, IDET is an attractive alternative to other interventions that are recommended to them but for which there is little or no evidence of efficacy. In that regard, reviewers[167] and investigators[168] have argued that IDET is an entertainable option before embarking on surgical treatment.

The limited efficacy of IDET has been attributed to the small radius of the lesion produced by the electrodes used.[169] With such a small field of influence, the electrodes cannot be guaranteed to capture fissures within the annulus in their entirety, or to capture all the nerves that mediate the pain. This concept has prompted the development of techniques by which to produce larger thermal lesions within the annulus.

One such technique is biacuplasty, in which a broad thermal lesion is produced across the posterior annulus between a pair of water-cooled electrodes. An observational study has produced somewhat encouraging results,[170] and a controlled trial is being conducted.

SALVAGE AND PALLIATIVE CARE

Salvage or palliative care is what patients turn to when other interventions have failed. In the past, it was typically the care to which patients resorted when surgery failed to relieve their pain (see Chapter 74, Failed Back Surgery Syndrome). Nowadays it includes patients who fail interventional pain management, or even functional restoration.

The notion of "salvage" pertains to salvaging patients from the failure and complications of other interventions. The notion of "palliative care" means providing some degree of relief when a definitive cure is not possible. Three main interventions fall into this domain: intrathecal opioids, spinal cord stimulation, and oral opioids.

Intrathecal Opioids

If applied to the spinal cord, opioids can exert analgesic effects at doses substantially less than those required if they are administered by the oral route. They can be delivered from a subcutaneous reservoir connected to a catheter inserted into the intrathecal space (see Chapter 99, Neuraxial Drug Delivery).

Intrathecal opioids are provided by practitioners who have the skills to implant the devices required and who are prepared to monitor patients—to deal with obstructions and infections in the delivery system, to replenish agents in the reservoir, and to minimize dose escalation.

The efficacy of intrathecal opioids for chronic low back pain rests on reputation and experience. There is some literature that describes the experience of practitioners, but it covers heterogeneous patients: ones with other pain problems as well as patients with low back pain. No studies have described the effectiveness of intrathecal opioids exclusively in patients with chronic low back pain. Moreover, no controlled studies have been reported. The practice of intrathecal opioids is sustained by position statements.[171]

Spinal Cord Stimulation

Nociception can be reduced or blocked by electrically stimulating the posterior surface of the spinal cord. This can be achieved by electrodes placed in the epidural space or implanted in the posterior dural sac. The electrodes are driven by a battery that is implanted into a subcutaneous pocket, like a pacemaker. Patients suitable for treatment are screened using electrodes temporarily placed. In those who respond, the hardware can be permanently implanted.

Spinal cord stimulation is the mainstay of treatment for failed back surgery syndrome (see Chapter 74, Failed Back Surgery Syndrome) particularly when patients have neuropathic pain rather than somatic pain. In the past, the use of spinal cord stimulation was based exclusively on observational studies and reputation. Of late, the challenge for controlled studies has been answered.

For patients with persistent or recurrent radicular pain after spine surgery, spinal cord stimulation is more often successful than reoperation[172] and is more cost effective.[173] Adding spinal cord stimulation to conventional medical management is more effective than conventional medical management alone, in terms of achieving 50% relief of pain, and improving quality of life and functional capacity.[174]

Spinal cord stimulation is not a cure for chronic back pain. It is an option for patients who have exhausted other options. Moreover, the cardinal indication is leg pain rather than back pain, although both types of pain benefit. However, success is limited. Only about 50% of patients achieve greater than 50% relief of pain,[174] and only about 15% are able to return to work.[175]

Oral Opioids

As pain medicine matured as a specialty, previous fears and restrictions about the long-term use of opioids in patients with pain not due to cancer were gradually overcome. Patients with chronic low back pain became eligible for treatment with long-term opioids. This has become the cardinal resort for patients in whom a diagnosis cannot be made or who have not responded to interventional pain management, for whom surgery is not indicated, in whom surgery has failed, or who have not benefited from functional restoration or individual therapies.

Opioids were used for such patients in the expectation that they would relieve their pain. Indeed, in lay circles, opioids are referred to as "pain-killers," which implies eradication of pain. This has proved not the case.

There is conspicuously little evidence for the use of opioids for chronic low back pain. One review[176] identified one study of dextropropoxyphene, one of tramadol, one pertaining to topical morphine, and one of oxycodone published only in abstract form. For classical opioids, it only found one study of oxymorphone[177] and one of oxycodone.[178] The former study found oxymorphone to be more effective than placebo, but the follow-up period was only 18 days. The latter study reported oxycodone to be more effective than naproxen, but a Cochrane review[179] recalculated the differences and found them to be not statistically significant.

A third review[180] identified two additional studies. Both from the same institution, these studies found oxymorphone to be superior to placebo for relief of pain during a 12-week period of assessment.[181,182] Other studies identified by this review only compared different opioids or different formulations of the same drug.

This paucity of data has led reviewers to conclude that opioids may be efficacious for short-term relief of pain, but their long-term efficacy is not clear,[176,180] or that the benefits for the long-term management of chronic low back pain remain questionable.[179]

It is also evident from the literature that opioids are not universally effective. During the titration phase of some studies, 37%,[181] 15%,[177] or 43%[182] of patients discontinued treatment because of adverse side effects. Once the dose was stabilized, a further 17%,[181] 14%,[182] 20%,[178] or 30%[177] ceased treatment because of side effects or for lack of efficacy.

Of increasing concern are the problems of opioid-induced hyperalgesia, tolerance, and abuse.[183] In studies that have reported abuse, its prevalence ranges between 3% and 43%.[176] The literature on opioids for chronic pain in general helps little to support their use for chronic low back pain. The controlled studies have all had short periods of follow-up.[183] Open-label follow-up studies indicate that up to 56% of patients abandon the treatment because of lack of analgesic efficacy or side effects.[183,184] The one consolation is that those patients who stay on treatment seem to maintain their analgesia.[183,184]

Despite these limitations and problems, guidelines still allow opioids for chronic low back pain[103]—perhaps reluctantly, perhaps in recognition that there is no alternative.

DISCUSSION

In light of the available evidence, it should not be surprising that patients with chronic low back pain get lost in a five-ring circus (see Fig. 72.6). None of the treatments, in any of the rings, are properly—let alone perfectly—effective. Many treatments are no more effective than sham treatment or placebo. Some are more effective than no treatment. Others are more effective than usual care, but some are not. Most offer partial reduction in pain, if any, and perhaps improvement in function or psychological state. Few treatments approach what patients seek—elimination of pain.[185]

The objective of any treatment should be to reduce the burden of illness: Once treated, patients should not need to seek other care. This is not evident in the treatment of back pain. Treatment with drugs and physical, electrical, and like therapies has not been shown to be successful. Once patients exhaust those options they seek other avenues. Multidisciplinary rehabilitation helps some patients, but does not eliminate their problem. Surgery offers the promise of a cure, but succeeds in making only some patients better.

It is only in interventional pain management that the objective has been to eliminate pain, or at least substantially reduce it. This is possible with lumbar medial branch neurotomy, but ironically this treatment appears suitable for only a minority of patients with chronic low back pain. Treatments for more common causes of pain, such as IDET, are not universally effective.

Salvage treatment and palliative care are portrayed as last resorts or ports of final call, but even they are incompletely effective. While opioids can palliate some patients, others are intolerant of them.

The reasons for this parlous state have not been explored or revealed. It is perhaps that the treatment of chronic low back pain is practice-driven, not problem-driven. Practitioners of various disciplines have been taught to treat patients by particular methods. They have chosen, or have been taught, to believe that their treatment should and does work. When the evidence proves otherwise, a dilemma arises. Established practitioners are reluctant to abandon their craft. They must persevere or face oblivion. Surgeons are not likely to stop operating just because an outsider writes that surgery does not work. Nor are physiotherapists or chiropractors going to cease prescribing exercises and manipulation. It is easier to find faults in hostile studies or reviews, and thereby deflect the burden of self-effacement and responsibility.

Research has been conducted into back pain and continues to be conducted; however, the bulk of that research is not the sort that is required. Studies focus on defending or proving contentious interventions that have been traditional, or which sounded like a good idea. What are needed are not so much answers but the right questions. Why do these patients continue to suffer, and can we fix it? The answers should not come in the forms of opinions, conjectures, or so-called theories, but with objective tests that decide the answer free of personal bias.

CHAPTER 73 ■ SURGERY FOR LOW BACK PAIN

YOUSSEF GHABRIAL AND NIKOLAI BOGDUK

Surgery is a distinctive form of therapeutic intervention. It is characterized by identifying a lesion or abnormality that is then resected, repaired, reconstructed, reinforced, or replaced. In other fields of medicine, surgery has an esteemed history. Injured viscera can be repaired; tumors can be resected; blood vessels can be reconstructed or replaced. In orthopedics, fractures can be immobilized, externally or internally, and painful joints can be replaced or fused.

For the treatment of low back pain, the history of surgery is less esteemed. Whereas individual surgeons have developed and promoted various surgical techniques by which to treat back pain, the evidence of effectiveness has often been less than convincing. Failures are common, and pain clinics are familiar with patients whose pain persists despite surgical intervention (see Chapter 74).

HISTORICAL PERSPECTIVE

The origin of spine surgery is attributed[1,2] to Hibbs[3] and Albee[4] who devised techniques by which to fuse the spine to control the progressive deformity that occurred in patients with spinal tuberculosis. The technique involved applying bone grafts to the spinous processes and laminae in order to fuse the posterior elements of the spine.

Progressively, posterior fusion was modified in various ways, with respect to the source of the bone graft, and the supplemental use of wires, rods, screws, and plates to reinforce the fusion.[1,2] A particular modification was to place the graft posterolaterally, between the transverse processes.[5–7] Known as posterolateral (PL) fusion, this has become one of the standard techniques of lumbar spinal fusion (Figs. 73.1 and 73.2).

Anterior lumbar interbody fusion (ALIF) also arose for the treatment of spinal tuberculosis.[8] Idiomatically, ALIF was not simply the surgical fixation of a joint, ultimately resulting in bone fusion (arthrodesis). Rather, the critical component of the procedure was excision of the tuberculous lesion in the disc and vertebral bodies. Bone graft and fusion was then a necessary supplement to replace the missing parts and to secure spinal integrity and stability.

Progressively, these various techniques and their modifications were applied to correct deformity, such as scoliosis, and to secure stability of the spine in patients with destructive lesions. Unlike its predecessors, posterior lumbar interbody fusion (PLIF) lacked a connection with tuberculous lesions. It was developed as a supplement to removal of herniated intervertebral discs,[2,9,10] in order to secure stability.

The history of fusion for low back pain is difficult to trace. Three streams of consciousness seem to apply.

In one stream, surgery was undertaken to treat radicular pain, caused by disc herniation or by spondylolisthesis. Decompression was the cardinal component of the surgery. Posterior elements of the spine had to be removed in order to gain access to the nerve roots. Fusion was not an active component of the intervention, but was undertaken in the interests of stabilizing the spine when too much of the posterior elements had to be sacrificed in order to gain access to the vertebral canal. The apparently good results achieved for the treatment of radicular pain predisposed surgeons to believe that fusion might also work for low back pain.

In the second stream, the logic was that if back pain was aggravated by movement it should be relieved by eliminating movement. The techniques available for securing stability and correcting deformity could, therefore, be applied to treat back pain.

According to the third stream, if an intervertebral disc is the

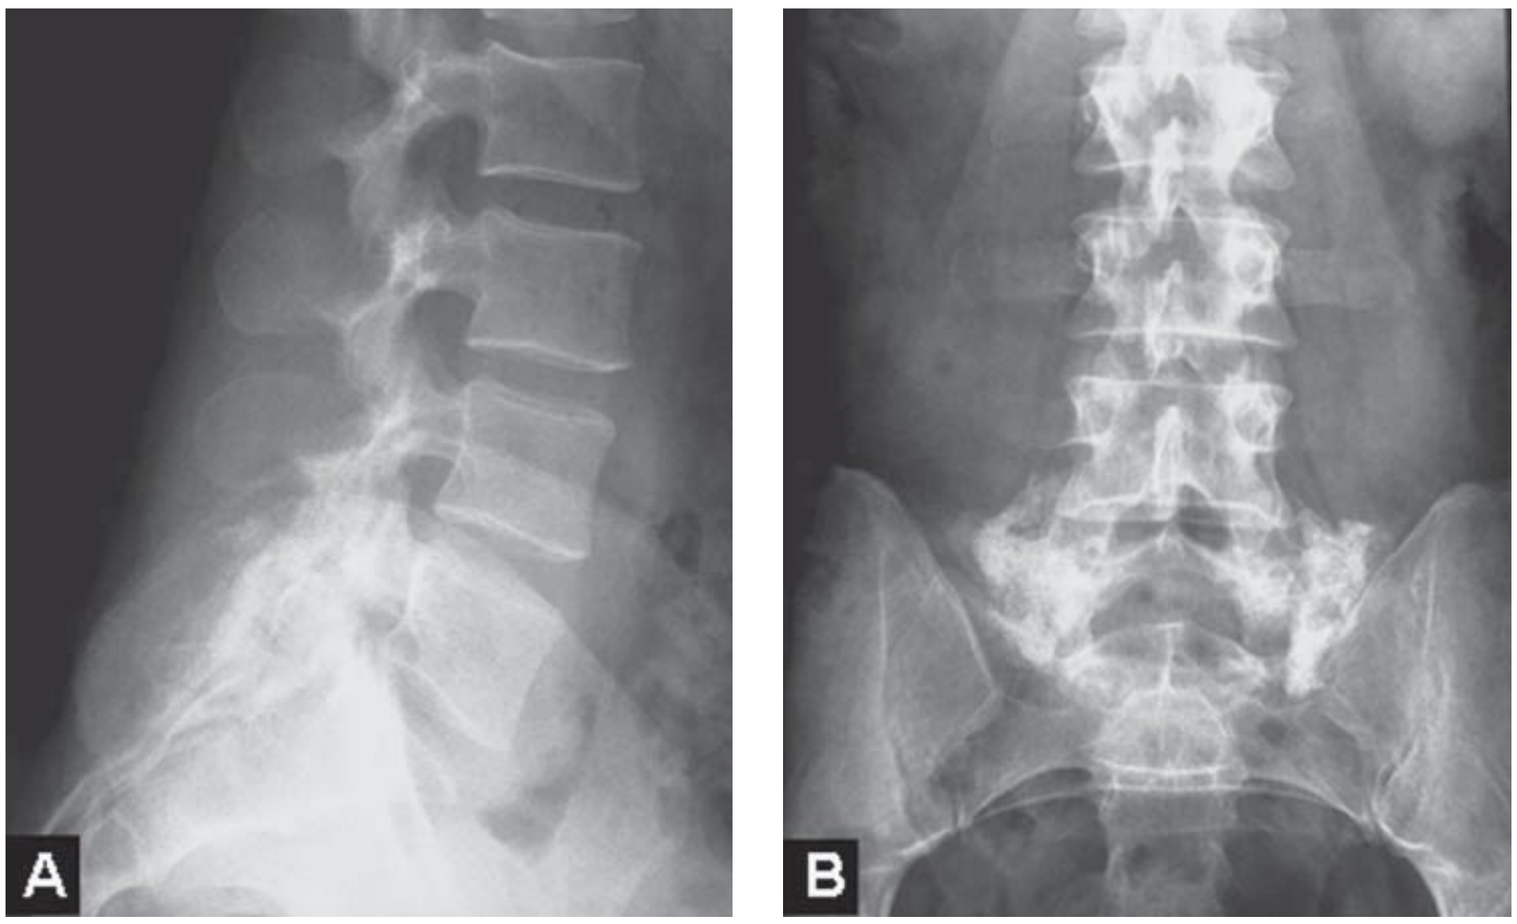

FIGURE 73.1 Radiographs of a posterolateral (intertransverse) fusion (PLF) at L5-S1, using bone graft alone. **(A)** Lateral view. **(B)** Anteroposterior view.

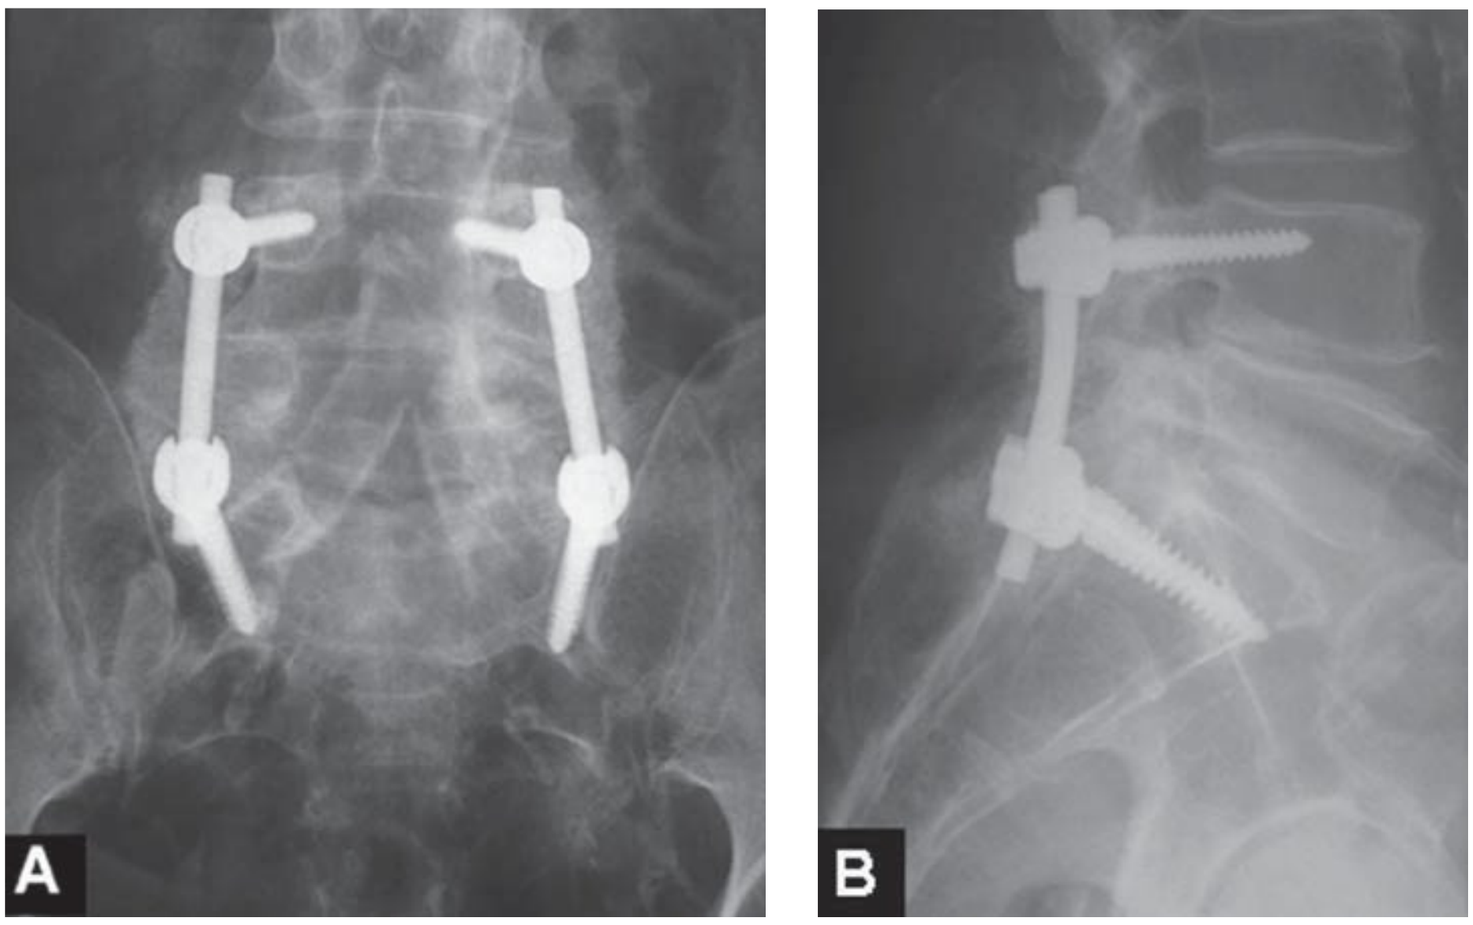

FIGURE 73.2 Radiographs of a posterolateral (intertransverse) fusion (PLF) from L4 to the sacrum, supplemented by instrumentation in the form of pedicle screws and rods. **(A)** Anteroposterior view. **(B)** Lateral view.

source of pain, excision of that disc should relieve the pain. Excision, therefore, is a cardinal component of the intervention. Fusion was required to fill that defect and restore spinal stability.

Of late, the third stream has evolved into disc replacement. Instead of fusing the spine after excision of the painful disc, the disc is replaced with a prosthesis, in the interests of retaining spinal movement. No doubt, this approach has been inspired by the success of total hip replacement for the treatment of hip pain.

TECHNIQUES

A variety of techniques has evolved for the surgical treatment of low back pain. They differ with respect to whether the surgery is performed from the front, from the back, or both; whether or not discs are excised; whether bone grafts, instruments, or both are used; and where they are placed (Fig. 73.3).

Fusion to eliminate motion has been the traditional approach for treating back pain. The opposing school of thought is that movements should be retained, in which case the offending disc should be replaced with a prosthesis.

Some surgeons believe that fusion is all that is required. The offending source of pain can be left in situ because elimination of motion should relieve the pain. Others believe that the source of pain should be removed. If a disc is perceived to be the source of pain, that disc is removed. The space it vacates can be filled with a bone graft or a prosthesis.

Noninstrumented fusion involves introducing a bone graft,

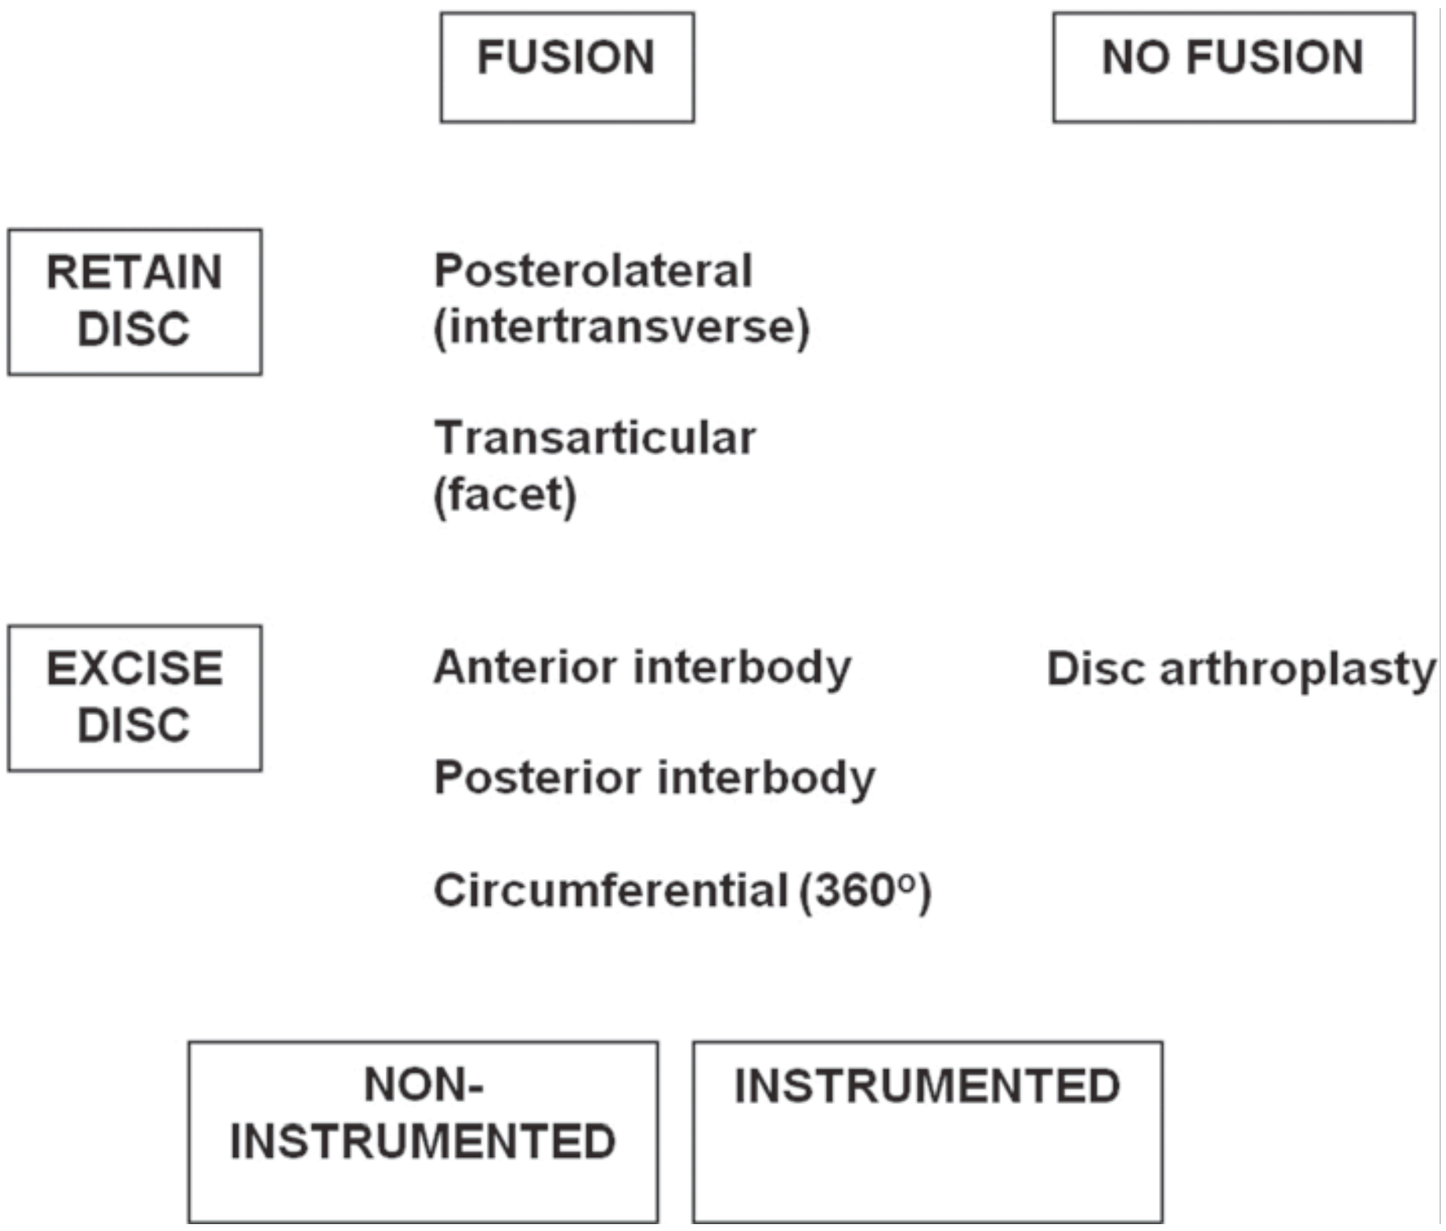

FIGURE 73.3 A classification of types of surgery used for low back pain.

which may be autologous bone or an allograft from a bone bank. If discs are retained, the graft is placed between transverse processes, in order to eliminate segmental motion. If discs are removed, the graft is placed in the intervertebral space. The bone graft alone can be placed between the vertebral bodies, or a metal cage or other device can be placed in order to hold the graft in place.

Fusion by bone grafting can be supplemented by instrumentation, in the form of screws and rods or plates, designed to hold the fused segments in place in order to prevent instability and to optimize the strength of fusion.

APPLICATIONS

The lumbar spine can be affected by tumors, infections, and fractures. In these cases, the lesion is identifiable by imaging and is remediable by surgery. However, back pain is not the indication for surgery. Surgery is indicated by the lesion demonstrated. For such conditions, the use of surgery is not contentious. Indeed, it is often the only option.

Surgery becomes a contentious treatment when back pain is the only feature, and no lesion is evident, or when the validity of the purported lesion is disputed. The contentious issues are the indications for surgery and its outcomes. The available evidence centers around three principal conditions or indications: spondylolisthesis, idiopathic back pain, and discogenic back pain.

SPONDYLOLISTHESIS

Spondylolisthesis is defined by forward subluxation of one vertebra on the next. Typically, the L5 vertebra subluxates on the sacrum. Less commonly, the L4 or L3 vertebra may be the one affected.

Spondylolisthesis has attracted surgical treatment for various reasons: it is an obvious deformity, it appears to be unstable, and it appears to be associated with pain. Surgery is invited in order to correct the deformity, or to stabilize it, and to relieve pain. However, the available evidence confounds this rationale.

Other than in severe cases, the deformity of spondylolisthesis does not cause disability. In lesser grades, the condition is not noticeable clinically; it becomes evident only when detected on radiographs. In children and adolescents, severe grades of spondylolisthesis may be evident if they cause gibbus deformity, which becomes a cosmetic issue. Other than correcting this cosmetic appearance, the deformity of spondylolisthesis alone neither attracts nor warrants surgery.

By some, spondylolisthesis is perceived to be an unstable state. However, in adults, instability has not been detected radiographically.[11–14] Indeed, some investigators have commented that the affected segment appears paradoxically more stable than its neighbors.[14] Therefore, the simple presence of spondylolisthesis is not evidence of instability, and should not attract surgical intervention for the purposes of securing stability. Arthrodesis might be indicated if instability was demonstrated preoperatively, but this has seldom been done in the literature on surgical treatment of spondylolisthesis.

Some patients with back pain have spondylolisthesis. This has been interpreted by some surgeons as meaning that the spondylolisthesis is the cause of back pain. The epidemiologic data speak otherwise. Spondylolisthesis is equally prevalent in subjects with no pain as in subjects with back pain.[15] Consequently, in patients with back pain, spondylolisthesis assumes the status of no more than an incidental finding and back pain is not a valid indication for surgery.

The cardinal feature of spondylolisthesis, and the only one that justifies surgery, is the onset of radicular pain. In such cases, nerve roots can be compressed or stretched by the axial and forward subluxation that the affected vertebra undergoes, or by a concurrent disc herniation; and this nerve root impairment can be demonstrated on computed tomography (CT) or magnetic resonance imaging (MRI). The objective of surgery in such cases is to decompress the affected nerve or nerves.

The cardinal component of surgery for spondylolisthesis is, therefore, decompression. However, decompression may require extensive removal of the posterior elements, including the laminae, spinous process, and even the zygapophyseal joints, in order to fully decompress the nerves. Removal of these posterior elements threatens introduction of iatrogenic instability. Fusion is, therefore, added to the intervention in order to stabilize the spine. In this regard, it has been clearly demonstrated that clinical outcomes are distinctly better in patients who undergo supplementary fusion than in those who undergo decompression alone.[16–18]

Against this background, a consideration of spondylolisthesis should be irrelevant in the context of surgery for low back pain. Since spondylolisthesis does not cause back pain, it is not an indication for the surgical treatment of back pain. However, the reputation of surgery as a successful treatment for spondylolisthesis is part of the foundation of surgery for back pain.

Many studies have not always been clear about their indications. In patients with spondylolisthesis, the clinical indications have variously been: neurogenic claudication alone, back pain or neurogenic claudication, radicular pain alone, back pain or radicular pain, back pain without or without sciatica, and back pain or leg pain. Some studies have not stated their clinical indications. Other studies have included spondylolisthesis as one of several indications for surgery, but did not report results separately for spondylolisthesis.

A literature review summarized the success rates of surgery for spondylolisthesis as reported in 34 original studies.[19] For posterior fusion alone, the success rates ranged between 37.5% and 98%, with an average of 74.8%. For anterior fusion, the success rates ranged between 80% and 95%. These data, however, were based on irregular and sometimes ill-defined criteria for clinical success. Some studies measured success in terms of patients achieving complete relief of symptoms, whereas others reported only the proportion of patients achieving some degree of improvement. Few studies, however, reported the degree of impairment before surgery and rarely have outcomes been corroborated by quantitative measures of pain, disability, return to work, and use of other health care.

Two controlled studies provide accurate and interpretable data. Both initially compared surgical treatment with conservative care, but one also compared different forms of fusion. Both provide data on the effectiveness of surgery.

The study of Weinstein et al.[20] showed a small advantage of surgery over conservative care, with respect to relief of pain, improvement of physical function, and reduction of disability. These advantages, however, were modest, amounting to 18 points difference for bodily pain and physical functioning on the SF-36, and 16.7 points on the Oswestry Disability Index (ODI). Differences in favor of surgery were evident at 3 months and at 1 year after treatment, and diminished only slightly at 2 years. Notwithstanding the comparative data, the outcomes for surgery were not great. Scores for bodily pain improved from 30 to 60, as did scores for physical functioning, but remained below normal levels. Disability reduced from 40 to 20.

The study of Moller et al.[21] showed that surgery was more effective than exercise at 2 years after treatment, but it also revealed the same curious outcomes. Although 55% of patients who underwent surgery were "much better" and 19% were "better," mean pain scores fell from 63 before treatment to only 37 at 2 years after treatment, with a range of 0 to 96.

Among the patients treated surgically, no significant differences in outcomes arose when patients were treated with instrumented or noninstrumented fusion[22]; but the same perplexing issues arose. About 50% of patients were "much better" at 2

years after treatment, and a further 20% or so were "better." The pain scores, however, showed little change. The mean pain score was 63 before treatment and 40 at 2 years after treatment. (No ranges of these scores were reported.) These data reflect clinical improvement, but do not portray resolution of the pain.

A long-term follow-up[23] of the original study[21] found that, 5 to 13 years after treatment, pain scores improved in the exercise group but not functional disability; but in the surgery group functional disability deteriorated. Pain and disability were no longer significantly different between the exercise and surgery groups. Of the patients treated surgically, 33% of the instrumented patients and 44% of the noninstrumented patients rated themselves as "much better." Mean pain scores had stabilized at 40/100.

These results, from controlled studies with good follow-up and assessment, are dissonant with the claims from descriptive studies of success rates of 80% and 90%. Either some surgeons achieve better results than others, or the success rates reported in descriptive studies have been inflated because of less rigorous assessment.

IDIOPATHIC BACK PAIN

Lumbar spinal fusion has been used extensively to treat idiopathic low back pain, that is, lumbar spinal pain of unknown origin.[24] The indications for surgery have been ambiguous or contentious, as have been the outcomes.

The indications have variously been "degenerative disc disease" or simply persisting back pain. The fact that degenerative disc disease is equally prevalent in patients with no pain, or barely more prevalent in patients with back pain,[15] has not deterred surgeons from attributing back pain to disc degeneration. The absence of any significant correlation between disc degeneration and pain renders it no more than a normal age change and an incidental finding on CT or MRI.

Another perception is that back pain arises because of instability of the lumbar spine, but no form of instability has been objectively demonstrated, using validated measures, in patients with idiopathic low back pain, which might attract spinal fusion. That rationale for spinal fusion in patients with undiagnosed low back pain appears to be little more than if movement aggravates pain then elimination of movement should relieve it. On balance, the available evidence contradicts this rationale more than it supports it.

The first systematic review of spinal fusion[25] provided little information about its efficacy for low back pain. It provided data separately and specifically on fusion for herniated discs and for spondylolisthesis. For low back pain as the indication for surgery, it found only six eligible studies, which reported successful outcomes in between 47% and 90% of patients, with an average success rate of 61%.

A later review, which limited its search to controlled studies, found no adequate scientific evidence about the efficacy or long-term effects of fusion. That absence of evidence has since been corrected. Three controlled trials have appeared, each of which compared surgery to some form of conservative care, and each of which provided outcome data for fusion.

The Friztell study[27] showed that fusion was more effective than nonsurgical therapy. For patients treated surgically, pain scores fell from 64 at inception to 30 at 6 months, but then regressed to 43 at 2 years, with a standard deviation of 25. The ODI improved only from 47 to 36. Beforehand, the authors defined an excellent outcome as no pain, no functional restrictions, and no analgesics; and a good outcome as sporadic pain, slight restriction of function, and occasional analgesics. However, when reporting their results, these two categories were grouped together: 45% of patients achieved an excellent or good outcome. The proportion of patients with complete relief was not stated. Some 29% of patients rated themselves as "much better" and a further 34% rated themselves as "better," with neither of these terms being defined. For a major invasive intervention, these are not particularly flattering outcomes.

The Brox study[28] found fusion to be no more effective than cognitive behavioral therapy coupled with exercises. In the fusion group, scores for back pain improved from 62 at inception to 39 at 1 year; the ODI improved from 42 to 26. For both outcome measures, these outcomes are less than modest.

The Fairbank study[29] found surgery to be minimally more effective than an intensive rehabilitation program. Pain scores were not reported, but ODI scores improved from 46.7 ± 14.5 (mean ± standard deviation) at inception to only 33.3 ± 20.8 at 24 months.

In reviewing these controlled trials, Mirza and Deyo[30] noted that, other than low back pain lasting longer than 12 months, a diagnosis was not made in any of the studies. Other observations pertained to outcomes. The improvements in ODI ranged from 8.9 to 15.6. This exceeds the threshold of 4 which is regarded by some authorities as the minimal clinically important difference, but the U.S. Food and Drug Administration (FDA) regards a change of 15 points as the threshold. This was exceeded only in the Brox study,[28] by 0.6 of a point.

For back pain, the minimal clinically important change is at least 20, according to some,[31] but 25 according to others,[32,33] and as high as 5.5 for initially intense low back pain.[33] Improvements of 21[27] and 23[28] barely exceed the minimal threshold.

These data bespeak only a modest efficacy of fusion for undiagnosed low back pain. Although some patients benefit, they are rendered only "better"; few, if any, are totally relieved of their presenting problem.

Data from another source corroborate this impression. Thomsen et al.[34] conducted a controlled trial designed to compare the effectiveness of fusion with and without pedicle screw instrumentation. The clinical indications for treatment were chronic, motion-induced back pain. The study enrolled 35 patients with isthmic spondylolisthesis, but the majority (94) were diagnosed as having instability. Outcomes at 2[34] and 5[35] years were reported. Improvements in scores on the Dallas Pain Questionnaire were modest to small, amounting to improvements from 65 to 40 for work, 60 to 50 for daily activities, 40 to 25 for anxiety and depression, and 35 to 15 for social concerns. Pain scores at inception were not reported, but at 5 years mean scores were 2 for leg pain and 4 for back pain, each with a range of 0 to 10.[35] Fusion did not achieve return to work, and some 50% of patients received a pension because of continuing back pain.

DISCOGENIC BACK PAIN

Some surgeons undertake surgical treatment for low back pain only in patients in whom a diagnosis of discogenic pain has been established. The diagnostic test is provocation discography (see Chapter 102). Various forms of treatment apply. The affected segment can be treated by leaving the symptomatic disc in situ, but fusing that segment using a posterolateral fusion. The affected disc can be resected and the disc space filled with a graft, using anterior lumbar interbody fusion or posterior lumbar interbody fusion, with either fusion being with or without instrumentation.

No controlled trials have been reported, apart from a few in which different types of fusion have been compared. The reputation of fusion for diagnosed discogenic pain rests on a small collection of descriptive studies (Table 73.1).

Although impressive outcomes are claimed by many of these studies, few were rigorously conducted and reported. Inception data were not reported, surgeons performed their own assessments, and outcomes were not corroborated by quantitative outcome measures.

Of this collection of studies, only those of Penta et al.[43] and Greenough[44] provided interpretable outcome data. Both studies

TABLE 73.1

OUTCOMES REPORTED BY VARIOUS STUDIES THAT USED DISCOGRAPHY TO SELECT SEGMENTS FOR TREATMENT BY FUSION

Source	Criteria	Success rate
Blumenthal 1988[36]	Normal activities and no medications or NSAIDs only	74%
Kozak 1990[37]	At least 75% relief of pain and return to work, or Slight restriction of activities and no analgesics	74%
Kostuik 1990[38]	Absence of significant back or leg pain Occasional use of non-narcotic analgesics	31%
Gill 1992[39]	At least 75% relief of pain and return to work, or Return to normal activities and no opioids	66%
Lee 1995[40]	No pain Mild pain No medications No opioids No restricted activities Mild or moderate restriction Return to full work Return to restricted work	26% 61% 59% 30% 50% 30% 81% 11%
Wetzel 1994[41]	Minimal symptoms and no analgesics, or Marked improvement, and rare use of analgesics	46%
Parker 1996[42]	Pain less than 4/10 No medications other than NSAIDs Return to at least 75% previous work capacity	39%
Penta 1997[43]	Complete relief or Good deal of relief	39% 39%
Greenough 1998[44]	Complete or almost complete relief A good deal of relief	17% 23%

came from the same center. Outcomes were assessed by an independent observer. In one study the follow-up was at least 2 years[44]while in the other it was at a minimum of 10 years.[43]

Fusion had a modest success rate at 2 years. Only 39% had complete relief, but a further 39% had what the patients called a good deal of relief.[44] These figures attenuated to 17% and 23%, respectively, in the 10 year study.[43] However, the investigators highlighted an enigma or paradox. Although 78% of patients reported a successful result, only 34% fell into the categories of "excellent" or "good" outcomes, as defined for the Low Back Outcome Score.[43] Nevertheless, these data—on patients diagnosed by discography—suggest outcomes superior to those achieved in patients in whom no diagnosis was made. An outcome of 39% with complete relief of pain[44] outweighs 29% feeling just "much better."[27]

DISC ARTHROPLASTY

Commentators have heralded intervertebral disc arthroplasty as offering the potential of restoring joint mechanics and, thereby, reducing pain and improving function; preserving motion appears to lessen adverse loading and changes in range of motion at adjacent segments.[45] Preliminary results from descriptive studies are good in some studies[46] and have yielded outcomes comparable to those of fusion for low back pain.[45] Recovery time seems to be less than for fusion.[46]

Because the advent of arthroplasty has been subjected to strong scrutiny, controlled trials and good descriptive studies have appeared early in the evolution of this technology. The available studies provide sobering insights.

Blumenthal et al.[47] compared disc arthroplasty, using a particular device, with a form of anterior lumbar interbody fusion. Zigler et al.[48] compared arthroplasty, using a different device, with circumferential fusion. These studies provide outcome data not only on disc arthroplasty but also on the conventional fusion procedures with which it was compared.

Although the Blumenthal study[47] found disc arthroplasty to be not inferior to fusion, the outcomes of both arthroplasty and ALIF were modest. Mean pain scores improved from 70 to 30, which exceeds the minimal clinically important change (MCIC) of 20 points and ODI improved from 50 to 25; but 64% of patients treated by surgery still took opioids and, although 64% returned to work, 53% had been working before surgery. These latter figures do not attest to any substantial decrease in the burden of illness; surgery did not seem to alter the patients' use of other health care or their ability to work. The proportion of patients who were completely relieved of pain was not reported. One reviewer recommended that these data argue for caution by patients and surgeons.[49]

The Zigler study[48] found disc arthroplasty to be slightly more effective, on average, than circumferential fusion, but it too reported only modest results for both surgical treatments. For arthroplasty, ODI improved from 63.4 at inception to 34.5 at 24 months, but with a standard deviation of 24.8. This latter figure indicates that a substantial proportion of patients were still substantially disabled. Pain scores improved from just above 70 to 37 with a standard deviation of 30.1. This study judged out-

comes as a success if the ODI improved by 15 points, which is the MCIC required by the FDA.[30] On this basis, a 72% success rate was claimed. But this misrepresents MCIC. The MCIC does not amount to the least value at which success occurs. It is no more than the least value that patients equate with a detectable level of improvement. The study did not report the proportion of patients rendered substantially better, or free of pain. Of patients considered to have a successful outcome, 39% still took opioids, which seems contradictory. Reviewers concluded that this study lacked sufficient detail for the interested reader to perform an independent evaluation of the data to confirm or reject the authors' conclusions.[50]

These results from controlled trials of arthroplasty are starkly inferior to those of a well-reported descriptive study. In the study of Bertagnoli et al.,[51] mean pain scores improved from 7.5 to 3, and ODI improved from 54 to 29. At 2 years, 32% of patients had no back pain and a further 59% had only occasional pain, 90% took no opioids, and only 41% required NSAIDs for pain.

DYNAMIC STABILIZATION

A number of devices have been invented that can be inserted between lumbar spinous processes in order to reduce lordosis and to limit extension, without affecting flexion and other movements of the lumbar spine. Their application has been described, generically, as dynamic stabilization.

These devices were developed originally as a treatment for neurogenic intermittent claudication caused by spinal stenosis. For that indication, they have been shown to be more effective than conservative care.[52] Outcomes have been reasonable in some hands,[53] but less satisfying in others.[54,55] Others have warned against their use in spondylolisthesis.[56]

Some surgeons have taken to using these devices to treat idiopathic low back pain, but there is no published evidence of efficacy or effectiveness for that indication.

CONCLUSION

Patients look to surgery as an ultimate cure for their back pain. For them, surgery has concept validity. They are familiar with surgery being the cure for abdominal pain caused by appendicitis or cholecystitis. They are familiar with the wondrous success of hip arthroplasty for osteoarthritis of the hip. Because of such comparators, patients could be forgiven for having the same expectations of spine surgery for back pain. They are not to know that back pain is not caused by infection, or that the ball and socket joint of the hip is biomechanically simpler than a spinal motion segment.

Surgeons also are subject to concept validity. The history of spinal surgery is riven with examples of a surgeon who thinks of a good idea. The idea sounds sensible. Movement aggravates pain; therefore, eradication of movement should stop pain. The disc hurts, so removing the disc should stop pain. Motion should be preserved, so arthroplasty should replace fusion.

These concepts, however, are only superficially valid. Techniques have not been developed and validated that might test if temporarily eradicating movements succeeds in relieving pain; or that show that temporarily anesthetizing a disc completely relieves a patient's pain. Fusing or replacing a disc is a large, irreversible step. Taking this step amounts to subjecting patients to a trial by treatment. The empirical data indicate that these trials fail. An insufficient proportion of patients is completely relieved of pain to vindicate the rationale for surgery and too many patients remain unchanged or worse.

In an editorial, Fritzell[57] posed the question, "Is surgical treatment consistent with evidence-based medicine?" and answered it with, "Yes, in selected patients." But surgeons have not yet articulated the definition of the correctly selected patient and tested it prospectively. The reputation of surgery rests on the observation, after treatment, that some patients sometimes do well with some procedures. That is little solace to the majority of patients who do not do well, who suffer complications, or who are rendered worse by surgery.

There is a major mismatch between what surgeons report as their outcomes and what epidemiologists count in communities. Descriptive studies, some controlled studies, claim success rates of 60% or more. Such claims predict that, on the average, large proportions of patients should do well after surgery and that the burden of back pain should be decreasing. In contrast, epidemiologists report observations such as 67.7% of patients' back pain was worse, and in 55.8% quality of life was not better or worse.[58] Others report that surgery for back pain is palpably less effective than surgery for spinal stenosis or disc herniation, and nowhere near as effective as hip replacement.[59] Indeed, whereas patients undergoing the other orthopedic operations improve on average, those who have surgery for back pain tend to deteriorate.[59]

One explanation for this pattern might be that spine surgery for back pain is highly demanding technically and that only expert surgeons can achieve good outcomes while average surgeons do not publish but are responsible for the poorer results seen in community studies. If that is the case, then surgeons—or someone else—have a responsibility to accredit surgeons, both in the interests of patients and in the interests of optimizing outcomes and, therefore, the reputation of surgery.

The other explanation is a recurrent one. It is that patients need to be carefully and properly selected before undertaking surgery. Yet, little has been done in this regard despite repeated proclamations of the need.

The seductive feature of surgery for back pain is that, perhaps more than occasionally, patients do very well. This phenomenon reinforces faith in the concept validity of surgery for back pain. But it is a false inference statistically. It amounts to remembering the few good cases, but ignoring those who do not benefit and those who do worse.

Two reforms are necessary to change the course of spine surgery significantly. One is for surgeons to abandon their traditional style of reporting results. The quality of the literature needs improving. Quoting percentages of patients who, reportedly, had "excellent or good" outcomes might attract surgeons, but no longer convinces their critics. A convincing set a data would describe the state of the patients before treatment in terms of pain, function, and use of health care, using validated instruments. After treatment, the data should show not just the mean scores in these variables, but the proportions of patients who achieve not just the MCIC but also endpoints of value, such as complete relief of pain and minimal pain, normal function, return to work by those previously not working, and reduction of use of other health care.

The second reform is abstract and intellectual. It is a call for surgeons to reflect. Perhaps fusion or arthroplasty is a valid concept, but the means by which they are secured confounds successful implementation of the treatment. It might be that the tissue destruction required to implement these treatments interferes with the outcome. Evidence on this contention is likely to arise as more surgeons adopt minimally invasive techniques of spinal surgery.

Conversely, however, there is a conjecture that surgeons have not yet faced. It is a paradox that fusion, or arthroplasty, does not consistently work or does not last. That paradox might have an answer. An explanation that fits the enigmatic and variable outcomes of spine surgery is that arthrodesis per se, or arthroplasty per se, is not the active component of spine surgery for back pain. Rather, what relieves pain is the extensive debridement of the lumbar spine that occurs during these procedures. Denervation, not fixation or replacement, is what relieves the pain; and pain recurs as the spine is reinnervated. This conjecture, rather than ill-defined placebo effects, is what surgeons will need to consider into the 21st century.

CHAPTER 74 ■ FAILED BACK SURGERY SYNDROME

JEROME SCHOFFERMAN

Failed back surgery syndrome (FBSS) is a nonspecific term that implies the final outcome of surgery did not meet the expectations, which were established *before* surgery, of *both* the patient and the surgeon.[1] It does not and should not mean that the patient failed to get total pain relief or did not return to full function. A surgeon's expectations for the outcome in a specific patient should be based on published medical evidence, the structural problem, the number and types of prior surgeries the patient has had, the psychological health of the patient, and the skills and experience of the surgeon. The patient must also have realistic expectations and must rely to some degree on the surgeon's input regarding possible outcomes and reasonable expectations from surgery.

In the subjective realm of pain for which there is no objective test, we must rely on the patient's report to judge whether the surgery resulted in a clinically important difference.[2,3] In patients with subacute nonspecific low back pain (LBP), the minimal clinically important difference (MCID) on a 0 to 10 numerical rating scale (NRS) is about 2.5 to 4.5 units.[3] In chronic LBP, results vary according to the research methods. If baseline NRS was <7 the MCID was 1.5 to 3.2. If the baseline pain was ≥ 9, the MCID was 2.5 to 6.8.[4] In chronic neuropathic pain, an improvement in NRS of 1.8 units is equivalent to a change of about 30%, an improvement that most patients will consider a "somewhat satisfactory result."[2] An improvement in NRS of 3 units or more is equivalent to a change in pain of about 50%, which most patients consider an "extremely satisfactory result."

There are many options for the treatment of patients with FBSS. The patient should receive the treatment with the highest level of evidence consistent with his or her specific structural pathology while considering that person's individual values and circumstances. To achieve this, cross referrals back and forth among pain specialists, surgeons, and other providers are often necessary. For some patients, the best and most conservative treatment for FBSS is repeat surgery. At other times, surgery is a poor option and medical management, a functional restoration program, neuroaugmentation, or neuroablation might be the best treatment. Collaborative care and consultation should result in the best outcomes and the resultant cross-fertilization will provide mutual education.

In order to be prepared to treat these challenging patients, physicians should know the reasons spine surgery might fail, the structural causes of FBSS, and the best treatment options for each situation.

CAUSES OF FBSS

It has been said that the best surgical outcome occurs when the right surgeon does the right surgery on the right patient at the right time. There is a significant risk for FBSS when any of these rights goes wrong. There are several models for classifying patients with FBSS.[1,5] One valuable method is to determine whether there is a structural cause for the pain. Residual or recurrent structural pathology may be due to inadequate evaluation before surgery or mismatch of the surgery needed versus the surgery performed, unrecognized complications, or technical failure. New structural problems may have developed after surgery. Another model is based on the time course of the residual or recurrent pain after surgery. Patients who never improve or who deteriorate in the first 4 weeks after surgery are more likely to have residual pathology, a complication, or a technical failure. Patients who get somewhat better initially but then deteriorate may have developed instability, instrument failure, recurrent disc herniation, or delayed infection. Those who get better but then deteriorate after 6 months may have new pathology at the same or adjacent segment or pseudarthrosis. This first section of this chapter discusses some of the more common issues that may result in FBSS using each model.

Mismatch of the Surgery Needed versus the Surgery Performed ("Wrong Surgery")

It is axiomatic that the best results of a spine surgery require the surgeon to perform the surgery indicated for the clinical condition ("right surgery"). When a surgeon chooses an operation that is not appropriate for the structural problem, the operation is likely to fail.

There is a paradigm that I have found to be quite useful. There are surgeries aimed at improving leg pain (e.g., decompression of a nerve root or discectomy for radicular symptoms) and surgeries that are directed toward improving axial low back pain (e.g., fusion for discogenic pain or instability). It follows that if a patient had predominantly axial LBP, but had a decompression or discectomy without fusion, it was not the best surgery for the clinical problem and there is a high likelihood the surgery will fail. In other words, there was a mismatch between the clinical problem and the surgery. The surgeon performed a "leg pain operation" for low back pain.

A second type of mismatch occurs when the surgery does not address all of the patient's pathology. For example, there are patients who have pathology such as disc degeneration, disc herniations, spinal stenosis, or combinations at multiple motion segments. The surgeon may have elected to operate on only the worst segment or segments, which leaves the patient with residual problems at the adjacent segments. This type of patient required multilevel surgery or, if the number of levels is excessive, perhaps no surgery at all. Another example is the patient with both central and foraminal stenosis. The surgeon does a good decompression of the central canal but inadequate decompression of the lateral canal. The patient may be left with leg pain due to remaining foraminal stenosis, which may be incorrectly thought to be neuropathic pain. Yet another example is the patient with severe foraminal stenosis. A surgeon may decide to perform a limited decompression for fear of causing instability, which might necessitate fusion. As a result, there is inadequate decompression and the patient does not get better. The patient needed decompression and fusion, but only had decompression. This is another mismatch between the surgery needed and the surgery performed.

Another example of a mismatch between the surgery needed and the surgery performed occurs when the surgeon fails to fully consider the effect of surgery on the motion segment. For example, consider a patient with spinal stenosis and very slight spondylolisthesis who has leg pain. If the surgeon chooses decompression without fusion, many times the spondylolisthesis progresses and the patient develops progressive LBP.

Incomplete Evaluation and/or Diagnosis ("Residual Pathology")

If a patient has not been fully or correctly evaluated, it is again likely that the surgery will fail. One of the reasons for the mismatches discussed in the previous section is incomplete evaluation. Surgery performed after an incomplete evaluation may leave significant structural pathology unattended. Incomplete evaluation is often due to overreliance on imaging studies, particularly magnetic resonance imaging (MRI). Many spine specialists depend on confirmatory diagnostic spinal injections to complement the history, physical examination, and MRI scan, particularly in the complex patient. A simple study, plain radiographs done standing with flexion and extension views, is too frequently not performed before surgery. These x-rays may disclose spondylolisthesis or deformity that was not seen on supine MRI. Pain relief after transforaminal epidural injection would suggest any foraminal stenosis seen on MRI is in fact the pain generator.[7–9] Discography can be useful to identify a painful disc.[10–14] It is certainly not a good test when used in isolation, but can add additional information when used in conjunction with other testing.

Psychological health is one of the most important variables with respect to the outcome of surgery.[15] Therefore, psychological evaluation is especially important for patients ("right patient") with longstanding pain and impairment or when the surgeon has any inkling that there may be a psychological problem. It is very likely that any psychological problems present after surgery were in fact present before, but overlooked or underestimated. Most patients with chronic LBP have some psychological illness, most commonly depression, anxiety disorder, and substance abuse disorder.[16,17] Although these disorders may not cause surgery to be cancelled, treatment before surgery and psychological follow-up afterward might prove useful to increase the chances of a good result. In addition to these familiar illnesses, there is growing evidence that a patient's coping abilities, fear and fear-avoidance behavior, and past history of sexual or physical abuse may play important roles in continuing pain, impairment, and disability.[18–22]

Complications

Many of the complications of spinal surgery occur early in the postoperative period and will be recognized by the surgeon. Infection usually occurs early, but occasionally does not appear for weeks or months. Incidental durotomy, if not recognized, can lead to late pseudomeningocoele. Misplaced pedicle screws can cause new leg pain, usually in a single dermatome, and is often present immediately after surgery. Neural injury during surgery has similar symptoms and early appearance after surgery. Complications that usually occur later include facet or pedicle fractures; problems with pedicle screws; and bone graft collapse, resorption, or dislocation (after interbody fusion). Another complication is surgery performed at the wrong level. Even now with extra care being paid to marking the operative level and more, this complication still occurs. It may not be noted until a plain radiograph or CT scan is obtained during the evaluation for FBSS.

Pedicle screws can cause LBP by any of several mechanisms. There can be loosening of screws, which can result in a "windshield wiper effect" at the bone–screw interface and be painful. There can be pain over the screws, sometimes attributed to chronic irritation of overlying soft tissues and bursa formation. As mentioned previously, pedicle screw misplacement can cause leg pain if a screw breaches a pedicle and irritates or injures a nerve. This can be mistaken for neural injury due to surgical trauma. Therefore, if there is leg pain in a single dermatome, it is necessary to obtain a CT scan to see if there has been even slight breach of the pedicle. Removal of the internal fixation may be helpful.[24] Pseudarthrosis is a failure of fusion. Some patients with nonunions have pain, but others do not. Therefore, one cannot assume that the nonunion is the cause of the pain. Plain radiographs are not reliable to show if a fusion is solid. However, if standing films with sagittal flexion and extension views show motion, it would indicate nonunion. The most useful test is a CT scan that includes reformatted curved coronal sections that are taken out to the tips of the transverse processes in addition to the usual sagittal and axial images.[25] CT also allows visualization of the anterior column to look for lucency surrounding an interbody fusion (bone or cages).

Some patients that have undergone surgery develop instability defined as greater than 3 mm translation on standing flexion/extension x-rays. We frequently see patients who had very slight spondylolisthesis before surgery for disc herniation or spinal stenosis in whom no fusion was done because the slip was so slight. Then, some months after surgery, the back pain worsens and plain x-rays reveal progression of the slip.

Technical Failure

Despite the fact that the surgery was appropriate for the symptoms and pathology, the surgeon may not have been able to accomplish the technical goals. Technical failure is usually apparent on good quality imaging studies. There may be inadequate decompression of a foramen even though stenosis was recognized and the surgeon attempted decompression. There may be incomplete removal of a disc herniation, especially if it was a far lateral herniation. There may be misplacement of screws or incorrect connection of internal fixation.

Residual Pathology

Spinal Pathology

Residual pathology implies that the surgery did not correct all of the structural problems that were painful. There are many explanations why pathology might have been left behind. These are discussed previously.

Extra-Spinal Pathology

Residual pathology might also be due to extra-spinal disorders that can mimic spinal problems. Most likely, when an extra-spinal disorder is the cause of pain, it was present prior to surgery but not recognized. Some of the common problems that can mimic spine pain are shown in Table 74.1 and include primary hip disorders (especially osteoarthritis and osteonecrosis), greater trochanteric pain syndromes (GTPS), peripheral nerve injury or entrapment, and perhaps pirifomis syndrome.[26–30]

Painful disorders of the hip region most often are independent of spinal pathology, but at times they can coexist with a spinal disorder, especially in older patients. This is a challenging problem because there is considerable overlap between their respective symptoms and signs. Osteoarthritis of the hip is common in elderly patients with spinal stenosis. Brown et al. studied a referral population with leg pain to determine if there were signs or symptoms that might differentiate between osteoarthritis of the hip

TABLE 74.1

DIFFERENTIAL DIAGNOSIS OF SOME OF THE MORE COMMON EXTRA-SPINAL CAUSES OF FBSS BY SYMPTOMS, SIGNS, RADIOLOGY, AND INJECTIONS

Diagnosis	Symptoms	Signs	Radiology	Injections
Hip osteoarthritis	Groin pain	Limp and limited IR	Standing x-rays of pelvis and hips	Relief with intra-articular
Non-OA intra-articular hip pathology	Groin pain	Limp and limited or painful IR	If standard x-rays nondiagnostic, MRI of hip	+/− relief with intra-articular
Trochanteric bursitis	Lateral thigh pain	Tender over GT	Not generally helpful	Relief with injection of GT
Tendonitis	Pain at tendon insertion	Pain with resistance	MRI may show tendonopathy	+/− relief with injection
Nerve entrapment or neuroma	Pain in peripheral nerve distribution	Allodynia, hypoalgesia Tinel's sign	MRI	Relief with anesthesia of affected nerve
Peripheral arterial insufficiency	Arterial claudication	Poor pulses? Pain with bicycling test and treadmill	Positive arterial studies	N/A

CT, computed axial tomography; GT, greater trochanter; IR, internal rotation; MRI, magnetic resonance imaging; SIJ, sacroiliac joint pain; +/−, may be helpful.

and a spinal disorder.[27] Unfortunately the types of spinal disorders were not detailed and there was no special attention paid to the sacroiliac joint (SIJ), a condition that might easily be confused with a hip disorder. The factors that were strongly suggestive of primary hip pathology were the presence of a limp, groin pain, or limited internal rotation of the hip. Factors more suggestive of spinal stenosis were lateral thigh pain, buttock pain, and pain below the knee, particularly in the absence of groin pain.

There may be clues to hip disease in the history and examination. Groin pain with each step is highly indicative of intrinsic hip pathology. Patients at risk for osteonecrosis of the hip may have a history of dislocation, alcohol abuse, or corticosteroid use. Patients with hip pathology will often present with a limp or Trendelenburg gait as opposed to patients with spinal stenosis who usually walk in lumbar flexion. However, osteoarthritic patients with hip flexion contractures also walk bent at the waist. Limitation of or pain during hip range of motion testing, particularly internal rotation, are excellent indicators of intrinsic hip disease.[27] Weight-bearing radiographs of the hip are the standard for diagnosing hip pathology. A single, weight-bearing anteroposterior pelvis view can serve as a screening tool in patients felt to be a risk for hip osteoarthritis.

Disorders of the structures near the hip that can mimic spine pain include greater trochanteric pain syndromes (GTPS), subtle sacral fractures, piriformis syndrome, gluteal tendonitis, hamstring syndrome, ischial bursitis, or tendonitis. Most have been described in patients with FBSS.[30,32,33] Patients with GTPS typically complain of pain in the proximal lateral thigh, often with radiation to the distal thigh and occasionally below the knee.[30,32,33] Pain is usually increased by lying on the affected side, climbing stairs, and transition from sitting to standing.[33] Pain may arise from the bursa itself or from the gluteal and short external rotator tendons or iliotibial band.[32] On exam, there is tenderness over the greater trochanter but, in the variants of GTPS, there may be tenderness at other sites. Diagnosis is confirmed by relief of pain with the injection of local anesthetic and steroids into the bursa or other tender structure. Some authors feel it is necessary to use fluoroscopy to accurately inject the greater trochanteric bursa.[34]

There is controversy regarding piriformis syndrome.[31,35] On the one hand are those who feel it is a diagnosis that occurs in two-thirds of patients with sciatica of unclear etiology.[31] Others feel that, at least based on cadaver studies, anatomical causes for piriformis syndrome are rare.[35] It must be considered that the pain is actually referred from the sacroiliac or facet joints. Signs that might be suggestive of piriformis syndrome include gluteal pain and tenderness in the sciatic notch, and buttock pain with flexion, adduction, and internal rotation of the hip (FADIR). Imaging modalities are rarely helpful, although MR neurography has been suggested as useful.[31,36] After more common problems are eliminated, injection of the muscle has been reported to provide intermediate and long-term relief in many patients.[31]

Peripheral nerve trauma or entrapment can mimic radiculopathy.[28] In the patient with FBSS, the most relevant problems are lateral femoral cutaneous nerve entrapment or injury (meralgia paresthetica), which presents with pain in the lateral or anterolateral thigh; peroneal nerve entrapment; and sciatic nerve entrapment.[28,29] With entrapments, pain will be in the distribution of the peripheral nerve involved, not in a true lumbar dermatome. There may be a positive Tinel sign over the area of pathology. Diagnosis can often be confirmed by nerve conduction studies, and there will be temporary relief of pain after injection with local anesthetic in the area of presumed entrapment.

Recurrent Pathology

Pathology can recur even after perfect surgery. Disc herniations recur in up to 15% of patients after discectomy. Foraminal stenosis can recur if there is progressive degeneration of the same motion segment.

New Pathology

Pain after prior spine surgery may be totally unrelated to the index surgery. The usual structural causes of LBP can be seen in these patients.

STRUCTURAL ETIOLOGIES OF FAILED BACK SURGERY

Despite the many reasons for failed spine surgery, there are a limited number of structural etiologies for the residual or recur-

TABLE 74.2

MOST COMMON SPINAL CAUSES OF FAILED BACK SURGERY IN THREE REPORTED STUDIES[37–39]

Diagnosis	Burton (1981)	Waguespack (2002)	Slipman (2002)
Lateral stenosis	58	29	25
HNP	12–16	7	12
Painful discs	N/A	20	22
Neuropathic pain	6–16	10	10
Total %	76 to 90	66	69

All numbers are %; HNP, herniated disc.

rent pain. The three studies that looked at the most common structural causes of FBSS had very similar findings (Table 74.2).[37–39] The most common structural causes of FBSS are lateral canal stenosis (foraminal stenosis), recurrent or residual disc herniation, one or more painful degenerated discs, neuropathic pain, facet joint pain, and SIJ pain.

In 1981, Burton et al. reported an analysis of several hundred patients with FBSS.[37] About 58% had foraminal stenosis, 7% to 14% had central canal stenosis, 12% to 16% had recurrent (or residual) disc herniations, 6% to 16% had arachnoiditis, and 6% to 8% had epidural fibrosis. Other less common causes in their series included neuropathic pain, chronic mechanical pain, painful disc above a fusion, pseudarthrosis, foreign body, and surgery performed at the wrong level. They were not able to establish a diagnosis in less than 5% of their patients despite the fact that their patients were evaluated early in the CT scan era and well before MRI scans. They did use discography.

There have been major advances in diagnostic testing since the Burton paper. In 2002, Waguespack et al. and Slipman et al. reported the results of their evaluations of patients with FBSS.[38,39] In a retrospective review of 187 patients with FBSS seen at a tertiary care spine center, the authors were able to make a diagnosis in 95%. Slipman et al. were also able to make a diagnosis in more than 90% of patients.

Several authors have presented their unquantified opinions and experiences regarding the structural causes of FBSS.[40,41] Fritsch reviewed 136 patients who had revision surgeries after clinical failure of an initial laminectomy and discectomy and found a high prevalence of recurrent disc herniations and instability.[40] Kostuik discussed some of the potential causes of failure of decompression, but provided no quantitative data.[41]

In the following section, I have used functional definitions of structural abnormalities that are a composite of those proposed by the North American Spine Society[42] and the International Association for the Study of Pain[43] modified by my clinical experiences. The differential diagnosis of some of the more common causes of FBSS along with some helpful symptoms, signs, radiological findings, and response to injections are shown in Table 74.3.

Lateral Canal Stenosis

Lateral canal stenosis (foraminal stenosis) was found in 2% to 29% of FBSS patients in the Waguespack and Slipman studies, half of what was seen 25 years ago.[37–39] The lower prevalence may be due to increased awareness of the problem, improved imaging studies, and/or better understanding of the need for meticulous decompression. Patients with lateral stenosis have pain that is predominantly in the leg or buttock region, often in the distribution of a single dermatome. Pain is usually worsened by standing and walking and relieved by sitting. MRI or CT scan shows narrowing of the canal at the index level or an adjacent segment. Stenosis can be subclassified as "up-down stenosis" due to loss of disc space height or "front-back stenosis" due to facet hypertrophy and osteophyte formation. Potential confirmation that the visualized stenosis is the cause of pain is at least temporary relief of leg pain after transforaminal epidural blockade of the suspected nerve root.[6–8] There may be longer relief if corticosteroids are administered.[9]

Lateral canal stenosis must be differentiated from neuropathic pain and mixed pain syndrome, which have similar presentations, because the treatments are different. Spinal stenosis is treated with flexion-biased body mechanics, medications, transforaminal corticosteroid injections, and/or decompression. Neuropathic pain is treated with medications or spinal cord stimulation (SCS). Mixed pain syndromes may require multiple treatments including decompression followed by medications and SCS.

TABLE 74.3

DIFFERENTIAL DIAGNOSIS OF COMMON CAUSES OF FBSS BY SYMPTOMS, SIGNS, RADIOLOGY, AND INJECTIONS

Diagnosis	Symptoms	Signs	Radiology	Injections
Lateral canal stenosis	Leg pain > LBP; relief with sitting	Loss of lumbar lordosis	MRI: foraminal stenosis	Relief with transforaminal epidural
Painful disc	LBP; ? worse with sitting	Restricted flexion in standing	MRI: degenerated disc(s)	Not indicated
Neuropathic pain	Leg pain Burning dysesthesia	Hypoalgesia Allodynia	No alternative diagnosis	Not indicated
Facet pain	Left or right LBP	?Facet tenderness	Not specific	Medial branch block relieves pain
Recurrent HNP	Vary with location. Leg pain > LBP	Variable	HNP on MRI	Epidural may provide temporary relief
SI joint pain	Gluteal pain with referral to leg and groin	May have + provocative testing	Not helpful	SI joint injection relieves pain

HNP, herniated nucleus pulposus; LBP, low back pain; MRI, magnetic resonance imaging; SIJ, sacroiliac joint pain.

Painful Disc (Discogenic Pain)

Pain that arises from within a disc without extrinsic neural compression is often referred to as discogenic pain.[42,43] One or more painful discs were the cause of FBSS in about 21% of patients.[37–39] Painful discs can occur at the index level of prior surgery, at an adjacent segment, or rarely at the index level, even in the presence of prior posterolateral fusion.[44–47] When there is a residual painful disc at the index surgical level, it is likely that it was not treated adequately by performing a fusion. When there is a painful disc at an adjacent segment, it was either present prior to surgery and not addressed or the disc degenerated after surgery.

It is clear that discs have the neural substrate to be painful.[48–50] In the normal disc the superficial layers of the annulus have sensory nerve endings that are potentially nociceptive.[50] In degenerated discs nerve fibers may extend deeper and even reach the inner third of the annulus in 50% of painful degenerated discs.[48,50] It is theorized that, in painful discs, these nerve endings become sensitized and thereby respond to innocuous stimuli with pain. In addition, recent evidence suggests that the sensory nerve supply of the disc resembles the innervation of certain enteric structures and may represent a variant of visceral pain. This may partly explain why discogenic pain seems to ''behave'' differently from other musculoskeletal pain.[50]

Several authors have tried to correlate symptoms and signs to identify with the presence of discogenic pain.[51–53] However, the correlations are neither sufficiently sensitive nor specific to be relied upon. Schwarzer et al. found no symptoms or signs to be specific for discogenic pain.[51] Young et al. found factors that increased the likelihood of a positive discogram were centralization of pain during mechanical (McKenzie) evaluation, pain provoked or increased when rising from sitting to standing, and midline pain.[52] In a systematic review, Hancock et al. found centralization of pain was predictive of a discogenic source.[53] Hancock et al. also found that MRI findings of high intensity zone, endplate changes, and disc degeneration correlated with discogenic pain using provocation disc injection as the reference standard.[53] Absence of degeneration on MRI was the only test that reduced the likelihood of discogenic pain being present.

An MRI scan is a picture of anatomy, not of pain. It is well established that patients without LBP might have an abnormal MRI.[54,55] Therefore, there have been efforts to find a means to determine if an abnormal disc visualized on MRI is in fact a pain generator in a particular patient.[11] Discography, perhaps more properly called provocation disc injection, can be quite useful to distinguish between discs that are and are not painful. Discography is not a definitive or perfect test, but when interpreted cautiously and in light of the history, physical examination, psychological status, imaging studies, and other diagnostic injections, it can prove very helpful.[10–14] The value of discography in patients with FBSS, especially with respect to a disc that has been operated on, has not been well examined. In this setting provocation disc injection might prove most useful when painless to exclude a disc as source of pain. When the diagnosis of discogenic pain is suggested by history and examination, MRI shows a single degenerated disc, and other potential causes of chronic LBP have been excluded, there is little need to perform discography.

Although there is no perfect reference standard, based on published reports and my personal experience, there may be a typical clinical presentation for discogenic LBP. Patients usually have dominant midline LBP that frequently radiates to the left and right of the midline, the gluteal regions, and often to the leg in a nondermatomal fashion. Pain is usually worse sitting and during transition from sitting to standing. It may improve with standing or walking. Physical examination is not specific. There may be decreased flexion in standing because of pain. There may be tenderness over the spinous processes, but not over the facet joints. Centralization of pain with mechanical examination is common.

Disc Herniation

Recurrent or residual disc herniation was seen in 7% to 12% of patients with FBSS.[37–39] There are two common presentations of pain from a disc herniation: radicular and axial. The topography of the pain is primarily due to the location of the herniation. A posterolateral herniation is more likely to compress or irritate a nerve root and therefore present with predominant leg pain. A midline herniation, unless very large, does not compress neural elements and presents with predominant LBP. A disc that is degenerated with a herniation can cause both leg and LBP. In the presence of epidural or perineural fibrosis, a disc herniation may cause more leg pain than expected than if there were no fibrosis.

Diagnosis of recurrent or residual disc herniation is inferred from the history and physical examination, and confirmed by MRI. There is no advantage to using gadopentate with modern scanners 6 months or more after surgery.

Facet Joint Pain

The facet joints are the cause of pain in 15% to 30% of patients with chronic LBP, and the cause of residual or recurrent pain in 3% to 16% of patients with FBSS.[39,56–58] The facet joint (FJ) is a diarthrodial joint with chondral surfaces, synovium, and meniscoid tissue. FJs are susceptible to chondral damage, inflammation, and degeneration. Injury may occur during surgery, as a result of progressive degeneration of the motion segment at the surgical level, or degeneration due to the mechanical stresses of fusion at an adjacent segment.

Shah et al. and Moshirfar et al. described a 33% and 24% incidence respectively of FJ violation in patients undergoing lumbar fusion with pedicle screw fixation.[59,60] Neither study reported the clinical status of the patients. There has been increased interest in the role of FJs since the introduction of total disc arthroplasty (TDR). Van Ooij et al. reported that FJ arthrosis was responsible for clinical failure in 11 of 27 patients.[61] Shim et al. reported radiological degradation of the facets in 32% to 36% of 61 patients after TDR.[62]

Facet arthrosis has been suggested as a relative contraindication to TDR.[63]

Although there are no reports that correlated symptoms and signs of FJ pain in patients with FBSS, several investigators and expert panels have tried to define the clinical pattern of FJ pain in chronic LBP.[52,56,64,65] Schwarzer et al. found no specific symptoms or signs that correlated positively with FJ pain, but noted that the presence of midline LBP had a negative association.[56] Young found that patients with FJ pain did not have increased pain when rising from sit to stand.[52] Laslett found symptoms and signs of facet joint pain ''to be elusive.''[64] A panel of physical therapist and physician experts arrived at consensus regarding features of symptoms and signs that were suggestive of FJ pain.[64] These included localized unilateral back pain, replication or aggravation of pain by unilateral pressure over the FJ or transverse process, lack of pain below the knee, pain eased in flexion (sitting), pain in extension, and pain in extension plus side bending or rotation to the ipsilateral side. Imaging studies were not felt to be helpful.

Given the ambiguities in the literature and lack of data in patients with FBSS, it is reasonable to perform medial branch blocks on most patients as part of the routine evaluation of predominant LBP unless there is another obvious cause for the problem. Features of the history that increase the likelihood of FJ pain being present are age greater that 65 and improvement in pain by lying supine. Other features include pain that is not worse

with forward flexion including sitting, not worse when rising from sitting to standing, and not worse with coughing. Features from the examination include tenderness to palpation over the FJs or transverse processes. The diagnosis of FJ pain is made when there is excellent relief of the target pain on two occasions after medial branch block (MBB), or less definitively pain relief after intra-articular injection of local anesthetic into the joint.[66]

Sacroiliac Joint Pain

There is sufficient and consistent evidence that shows that the SIJ can be a cause of pain in up to 15% to 30% of patients with chronic LBP.[67,68] The prevalence of SIJ pain is at least 2% to 3% in patients with FBSS, and may be higher in patients who have had fusion to the sacrum.[39,69] The SIJ can be injured during graft harvesting, but more likely the joint becomes painful owing to transfer of stress after fusion.[70] Finally, SIJ pain could have been present before surgery due to acute or cumulative trauma, but not recognized.[71]

Again, there are no specific signs or symptoms specific for SIJ pain, but there are definite clues to the diagnosis.[52,53,68,72] Virtually all patients have pain distal to the posterior iliac crest and lateral to the midline spine. Some patients will point directly over the SIJ when asked to show where the pain is centered. Pain is frequently referred to the groin, thigh, calf, and occasionally the foot—patterns that might otherwise suggest radiculopathy or even hip joint pathology. The patient may report pain is worsened during transition from sitting to standing.[52] Pain may increase with single leg weight bearing. Most often there is tenderness directly over the SIJ. Although signs are not specific, diagnosis is probable when tenderness and three or four other provocative tests are present.[53] Plain radiographs, MRI, and CT are not definitive. The confirmation of SIJ pain requires relief of the target pain after fluoroscopically guided local anesthetic SIJ injection.[73]

Spinal Stenosis and Axial Low Back Pain

The classic symptom of central spinal stenosis is leg pain with walking (neurogenic claudication) or standing. In addition, many if not most patients with spinal stenosis also report LBP.[74–77] However, it has not been established that patients with central spinal stenosis can have primarily LBP and gluteal pain with little or no leg pain. I believe this clinical presentation is not rare, but there are no data to support this observation. In my experience, the characteristic pain pattern is LBP, especially gluteal pain, with standing or walking, and complete or near complete relief of pain sitting. This symptom complex is quite the opposite of discogenic pain, but similar to FJ pain. Patients usually experience at least temporary relief of pain after epidural steroid injection and no relief after MBB, just the opposite of FJ pain. The patients with FBSS and predominant LBP might have spinal stenosis at the index level or an adjacent segment that developed after surgery or was not addressed at surgery.

Neuropathic Pain

Neuropathic pain is defined as pain due to injury or physiological dysfunction of the peripheral or central nervous system (CNS). Neuropathic pain was the predominant problem in 5% to 9% of FBSS patients.[37,38] It is likely that there is an increased awareness and, therefore, recognition of neuropathic pain rather than an increased prevalence.

There are several potential mechanisms for neuropathic pain after spine surgery. A nerve root could have been damaged prior to surgery because of either sudden injury (acute disc herniation) or prolonged compression from foraminal stenosis or disc herniation. In this instance, radicular type pain continues despite technically successful surgery. Alternatively, a nerve could be damaged during the surgery itself, which is sometimes referred to as a ‘‘battered nerve.’’ The incidence of new cases of arachnoiditis has probably decreased, perhaps because oil-based myelography is no longer performed, but it still occurs. There can be peripheral nerve injuries such as cluneal neuroma owing to nerve injury at an iliac crest donor site and meralgia paresthetica.[29,78,79] In theory at least, it is also possible that total or near total discectomy alters the nervous system in a model akin to phantom pain.

Neural injury or dysfunction can be responsible for both amplification and persistence of pain.[80,81] Neuropathic pain of spinal origin usually presents with a predominance of leg pain in one or two adjacent dermatomes or along the path of a peripheral nerve. In classic presentations, the pain is described as burning, dysesthetic, or electrical, but in neuropathic disorders after spine surgery, pain is more frequently described as aching and stabbing. Pain may be constant or intermittent. It is often precipitated or aggravated by simple activities because the damaged nerves are hyperexcitable and respond abnormally to even minor biomechanical changes.

By definition, in pure and uncomplicated neuropathic pain, there is no evidence of nerve root compression on imaging studies. It is important to distinguish neuropathic pain from what I’ll call neurogenic pain. Neurogenic pain implies that a nerve is being compressed or irritated rather than its being permanently damaged. To further complicate matters, some patients have both neuropathic pain plus ongoing neural compression (neurogenic), which is referred to as a mixed pain syndrome.

Neuropathic pain can also be due to physiological dysfunction in the peripheral or central nervous systems without structural nerve damage. As a result of prolonged or repeated chemical or mechanical damage to afferent nerves, these nociceptors may become sensitized and hyperexcitable (peripheral sensitization). There is lowering of their activation thresholds and subsequent increased responsiveness to all stimuli.[80] In this physiologically altered setting, innocuous stimuli may be perceived as painful (allodynia), minimally noxious stimuli may be perceived as very painful (hyperalgesia), and thereby be stimulus-independent pain as well.

A similar sensitization can develop in the CNS as a result of ‘‘constant bombardment’’ by painful afferent stimuli (central sensitization). The site of dysfunction is thought to be primarily at the dorsal horn of the spinal cord and brainstem. Once again, normal or minimally painful stimuli are perceived as very painful. In patients with persistent axial LBP (rather than the more typical extremity pain) despite perfect surgery and no other explanation for pain, one might be able to hypothesize that this represents central sensitization and a variant of neuropathic pain.

Epidural Fibrosis

Epidural fibrosis occurs after most, if not all, posterior lumbar surgeries. There is a school of thought that fibrosis is responsible for many or most of the failures of lumbar spine surgery. The other point of view is that in most instances fibrosis is an innocent and incidental finding that does not cause pain, but has the potential to make other problems worse, such as radiculopathy due to disc herniation or spinal stenosis.

Coskun et al. performed a prospective analysis of 29 patients with FBSS to determine the relationships among the severity of epidural fibrosis, psychological factors, LBP, and disability.[82] They found that neither the postoperative pain scores nor the postoperative Oswestry Disability Index scores differed significantly with relationship to the severity of the epidural fibrosis. Moreover, postoperative pain scores were positively correlated with the scores of the mini-Minnesota Multiphasic Personality Inventory (MMPI). They concluded that epidural fibrosis was an

incidental radiological finding that did not correlate with patients' complaints. Annertz et al. compared the MRI scans of eight patients with and eight patients without sciatica after lumbar discectomy.[83] Fourteen patients had focal or diffuse epidural fibrosis. There were no differences between the symptomatic and nonsymptomatic groups with respect to the presence or extent of epidural or perineural fibrosis.

Trescot et al. performed a systematic review of the effectiveness of adhesiolysis in patients with chronic spinal pain.[84] They concluded that there was strong evidence for short-term relief (>50%) and moderate evidence for relief lasting greater than 3 months of both LBP and leg pain. Some studies included patients with no prior back surgery.

Deconditioning

Deconditioning has long been considered to be at least partially responsible for the persistent pain and pain-related impairment and disability in many patients with FBSS.[85–89] There are three models for this so-called deconditioning syndrome. The pure physical deconditioning model holds that loss of muscle strength and endurance is responsible for reduced activity, impairment, and disability.[88] The cognitive-behavioral model emphasizes the fear-avoidance paradigm, which holds that some patients with LBP avoid activities out of pain-related catastrophic thinking and fear.[88] They believe that attempts to increase their function will result in increased pain and progressive structural damage and, as a result, they markedly curtail their activity. A third model is a combination of the two in which patients have both the maladaptive fear-avoidance and true physical deconditioning. As a result of the fear-avoidant decreased activity, there is disuse (perhaps better termed underuse) with progressive loss of muscle strength and endurance.[88,89]

In patients with chronic LBP and deconditioning, the paraspinal musculature is most affected.[90] There is MRI, CT scan, and ultrasound evidence that after spine surgery, many patients have decreased cross-sectional area (CSA) of their lumbar muscles.[91,92] Gejo et al. showed both decreased CSA and decreased muscle strength in 20 patients after posterior lumbar surgery.[92] In addition, four of eight patients with longer retraction times during surgery had LBP at 6 months versus none in 12 patients with shorter retraction times. Motosuneya et al. looked at the changes in muscle CSA after 5 different types of spine surgery and surprisingly found some loss of muscle strength even in those patients who had anterior spine surgery. They opined that rigid fixation and resultant protection of the paraspinal muscles was at least partly responsible.[94]

Weber et al. found that posterior spine surgery caused changes in muscle histology, but found no correlation between pain and these changes.[93] Airaksinen et al. compared muscle density by CT scan in patients after decompression for spinal stenosis.[95] There was a marked decrease in lumbar extensor muscle density that the authors felt could be explained by disuse or inactivity. The density of the lumbar flexors was higher in the group with excellent results than those with poor outcomes. Sihvonen et al. studied a select subgroup of 14 patients with good results and 21 with poor results 2 to 5 years after laminectomy.[96] They concluded that disturbed back muscle innervation and loss of muscular support leads to increased biomechanical strain and might be one important cause of the failed back syndrome.

In summary, there is consistent evidence that posterior spine surgery (and possibly anterior as well) often causes loss of muscle density, histologic changes, and probably decreased strength. There is a trend in the evidence that suggests a correlation between greater muscle changes and LBP after surgery.

Multiple studies have shown decreased muscle strength and endurance in patients with chronic LBP and no prior surgery.[85,86,95,97] Recently, some investigators have questioned the idea that patients with chronic LBP have meaningful losses of muscle strength and endurance, feeling that the evidence for the physical deconditioning model is inconclusive.[98] Bousema et al. measured the muscle strength, muscle endurance, and aerobic capacity in 124 patients with subacute LBP at presentation and at 1 year.[99] Patients who had persisting pain did not show signs of physical deconditioning. Interestingly, most patients did not show evidence of decreased physical activities either. Their study did not validate and, in fact, partially contradicted the deconditioning paradigm.

That said, virtually all investigators agree there is clear evidence that exercise is effective in reducing impairment and disability.[88,90,97,98,100,101] Many, but not all, studies also show decreases in LBP. It is suggested that the improvements are more likely due to reduction of fear, fear-avoidance, and pain catastrophizing rather than increases in strength and endurance.[102,103]

PSYCHOLOGICAL FACTORS IN FAILED BACK SURGERY ("RIGHT PATIENT")

Most patients with FBSS have some form of psychological response. In some, their psyche can be helpful; in others it can be harmful. The most common psychological illnesses in patients with chronic LBP are depression, anxiety disorder, and substance abuse disorder (although current definitions and better understanding of opioid use might change the prevalence of the latter).[17] It is most likely that these psychological illnesses make pain and function worse rather than being the underlying cause of pain. In most chronic LBP patients, psychological disorders developed after the back injury. Accordingly, they would have been present prior to surgery, and either not recognized or not considered important.[15,16] Patients with more severe psychological illnesses such as thought disorders, bipolar disorder, antisocial personality, or active addictive disease have illness that is usually very apparent. These patients are less likely to have had spine surgery.

Fear-Avoidance

In addition to the more classic psychological illnesses mentioned briefly previously, there is increasing recognition of the importance of cognitive-behavioral factors in patients with chronic LBP. The most important of these are catastrophic thinking, pain-related fear, and fear-avoidance.[18] Although not always the case, these cognitive-behavioral factors often correlate more strongly with impairment and disability than does pain severity.[14,18,19]

Fear-avoidance is the avoidance of movements or activities because of fear of one or more aspects of pain. The fears reported most often are the fear that pain will get worse due to activity, the fear that activity will lead to further structural damage, and the fear that residual pain means that something seriously wrong has been overlooked.[89,105] Any or all of these fears may lead to avoidance of normal activity and subsequent disuse (underuse), deconditioning, impairment, and disability. Physicians may contribute to its development and perpetuation by advising patients to avoid certain activities.[106]

Catastrophic thinking is an exaggerated negative orientation toward pain.[102] Patients dwell on the most negative conceivable consequences.[18] Every flare is a crisis. Every good day is just the calm before the proverbial disaster. Pain-related catastrophic thinking is the cognitive aspect of fear-avoidance behavior. In patients with acute LBP, pain catastrophizing is a powerful predictor of chronicity. Pain-related catastrophic thinking may lead to avoiding activities that might increase pain, which results in progressive limitations of function with impairment and disabil-

ity. The progressive downhill spiral of catastrophic thinking, fear, fear-avoidance, and physical deconditioning is appealing as an explanation for progressive impairment and disability.[107]

Coping Abilities

Another model that is useful and correlates well with the fear-avoidance model is based on coping abilities. Coping has been defined as the purposeful strategies used to manage internal and external stressful events—in this case, pain.[108] Coping can be broadly characterized as either active or passive. Patients with active coping strategies take personal responsibility for their pain and believe they can control it. They work to maximize their function despite pain. They accept their problem and have realistic expectations. On the other hand, patients with passive coping resort to strategies that are not useful such as prayer and hoping, wishful thinking, guarding, and resting excessively.[109] Some may blame others for their pain and give responsibility for managing their pain to an outside source. They reduce their activities to avoid increasing their pain, and may develop a fear-avoidance lifestyle. Passive coping is a significant risk factor for chronicity in patients with subacute LBP and for persons in the general population who develop acute LBP.[20]

Kerns et al. described three types of patients based on their mechanism of coping: adaptive copers, interpersonally distressed, and dysfunctional.[110] For practical clinical purposes the latter two might be combined. It is sometimes useful in understanding these issues to consider adaptive copers as "persons with chronic pain" and the dysfunctional patients as "chronic pain patients." Adaptive copers have active coping strategies. Their pain seems appropriate for the peripheral stimulus, function is appropriate for the pain, and mood is consistent with the pain and impairment. They tend to stay with one physician and have reasonable expectations. They are generally easy to care for and respond to most treatments as might be expected based on the evidence.

On the other hand, dysfunctional patients are much more difficult to treat. Their pain is typically far greater than expected for the peripheral stimulus, their disability and impairment seem out of proportion to the peripheral stimulus, their mood is depressed, their expectations are not reasonable, and their behavior is demanding. They tend to go from doctor to doctor seeking an almost magical cure. In general they tend to respond poorly to most treatments—medications, rehabilitation, interventional pain techniques, and surgery.

Childhood Abuse

Persons who had a very dysfunctional childhood and subsequent LBP may be at special and higher risk for chronic pain, impairment, disability, and failed back surgery.[111,112] One explanation lies in the realm of attachment theory. As children they suffered severe disruption of parental attachments. Identified disruptions include childhood physical or sexual abuse, abandonment, or parents who had addictive disease, chronic pain syndromes, or severe psychological illness.

ESTABLISHING THE DIAGNOSIS

Role of the History

The history is the most important part of the evaluation of a patient with FBSS. It establishes the foundation for the remainder of the evaluation as well as the information necessary to interpret other diagnostic elements. The most important elements of the history include a thorough description of the current pain, a comparison of the pain before and after surgery, the time course of the reappearance of the pain, and the response of the pain to specific activities. It is also very valuable to analyze whether the type of surgery performed was appropriate for the preoperative symptoms and condition. The history should lead to a limited differential diagnosis, suggest the emphasis for the physical examination, and provide guidelines for selecting appropriate imaging studies and diagnostic injections. It is important to remember there may be more than one diagnosis present.

Preoperative Versus Current Pain

Pain that is essentially the same before and after surgery in terms of severity, location, quality, and response to mechanical maneuvers suggests that the original problem was not corrected. There may have been an error in diagnosis, an error selecting the correct surgery, or an incomplete surgery. On the other hand, when symptoms have changed significantly, it is most likely that there is new pathology, either a complication of surgery, technical failure, or progression of the underlying disease.

Location of Pain (Especially LBP vs. Leg Pain)

It is useful to divide FBSS patients into those with predominantly LBP and those with predominantly leg pain. In general, when LBP is greater than leg pain, the most common causes are discogenic pain at the level of the index surgery or at adjacent levels, FJ pain, SIJ pain, or instability (spondylolisthesis). If fusion was attempted, there may be a pseudarthrosis, although pseudarthrosis itself may not be the cause of pain. When leg pain predominates, the more common causes include residual foraminal stenosis, recurrent or residual disc herniation, neuropathic pain, or less likely hip disease or peripheral nerve injury.

Response to Mechanical Changes

There are no studies that document the changes in pain in response to common activities in patients with FBSS. Therefore, these correlations are based on personal experience and the studies in patients with chronic LBP and no prior surgery. These responses to biomechanical stresses are clues, but obviously cannot be considered definitive.

Response to Sitting. LBP or leg pain that increases with sitting and with flexion in standing is more likely due to one or more painful discs or instability (spondylolisthesis). Leg pain that improves with sitting is usually due to spinal stenosis.

Transition from Sitting to Standing. LBP that worsens during the transition from sit to stand suggests disc pain or SIJ and speaks against FJ pain.[17] LBP that increases with standing suggests posterior element pathology such as FJ pain. Leg pain that increases with standing or walking suggests spinal stenosis.

Quality of Pain

The word the patient uses to describe the pain is occasionally helpful. Burning, electric shock-like pain, dysesthesia, or superficial (skin) tenderness to light touch (allodynia) suggests neuropathic pain. However, neuropathic pain after spine surgery may not fit these classical descriptors.

Time Course of Appearance of Pain

Preoperative LBP or Leg Pain Never Improves or Early Onset of Old Symptoms

When LBP never improves or recurs within days to a month or so after surgery, it is most likely that the symptomatic structural

pathology was not adequately addressed by surgery, there was a complication such as wrong level surgery, or the wrong procedure for this particular patient was done.[5] Partial pain relief implies correction of only part of the structural problem.[5] This outcome falls in the category of residual pathology, and the differential diagnosis has already been outlined.

New Leg Pain Soon After Surgery

The early appearance of new leg pain suggests direct neural injury during surgery, misplacement of a pedicle screw, or venous thrombosis.[5,78]

Pain Improves but Recurs One to Six Months After Surgery

Pain that improved initially but recurred in 1 to 6 months may be due to residual, recurrent, or new pathology. If pain location and description resemble preoperative symptoms, residual or recurrent pathology is likely. Pain that has new characteristics is more likely due to new pathology. There may be recurrent disc herniation, failure (loosening of pedicle screws) of internal fixation, instability, and late infection.

Pain Improves but Recurs and Is Different

Pain that recurs late and has a different location or quality compared to the preoperative pain is more likely due to new pathology. Examples include painful disc at an adjacent segment, disc herniation, or FJ pain. SIJ pain from donor site injury or stress from fusion to the sacrum also can occur at this stage.

Role of Radiological Evaluation of FBSS

Herzog discussed the requirements for imaging patients with FBSS and much of the following section is a summary of his work.[1,25] Radiological examination usually includes x-rays and either MRI or CT scan. There are only rare indications for nuclear imaging studies (infection, possible malignancy, possible rheumatological illness), myelography (pseudomeningocele), or CT myelography in the setting of FBSS.

Standard radiographs with standing flexion and extension lateral views are used to assess alignment, extent of disc space narrowing, spondylolisthesis, and, when fusion has been attempted, perhaps pseudarthrosis.[25,111] MRI is the optimal exam for most FBSS patients unless the issue is pseudarthrosis, in which case plain radiographs with flexion-extension views and CT scan with multiplanar reformations is much better.[1,25,111] With MRI it is necessary that the study visualizes the left and right extraforaminal zones so as to avoid missing foraminal or extraforaminal pathology. Angled T2-weighted sections from T12-L1 to L5-S1 through the disc spaces are done to evaluate the cross-sectional area of the thecal sac, to evaluate the central canal, and to define the exact relationship of the structural changes to all the neural elements.

In evaluating patients who had surgery for disc herniation, contrast enhanced MRI became the standard, but with newer equipment and imaging sequences, nonenhanced MRI imaging is usually adequate if the radiologist monitors the study and administers contrast only if the routine sequences are not definitive. MRI is an excellent study for spinal stenosis and can detect hypertrophy of facet joints and ligamenta flava, synovial cysts, or prominence of epidural fat. It will show if decompression was adequate to decompress the nerve root. Arachnoiditis can easily be detected with MRI. In patients with spinal instrumentation using titanium alloys, there should be no significant distortion with a high field-strength MRI if the sequences are optimized for the presence of metal using fast spin echo T2-weighted sequences without fat saturation to reduce artifacts. The central canal and neural foramina can be adequately assessed even with the presence of pedicle screws.

Role of Diagnostic Injections

Anesthetic Injections

Diagnostic anesthetic injections are the reference standard for the diagnosis of FJ and SIJ pain.[66,73] A transforaminal epidural (TFE) injection is sometimes used to determine if a nerve that appears compressed on MRI or CT scan is in fact the pain generator.[6,8] A positive TFE may be defined as relief of the target pain after anesthetizing a specific spinal nerve. In addition, pain relief during the corticosteroid phase is reported to predict a good outcome for surgery.[9]

Provocation Disc Injections (Discography)

MRI scan demonstrates disc anatomy. Findings such as hydration status, disc height, changes in adjacent vertebral body or endplates, the presence of high intensity zones, and disc herniations are all visible on MRI. However, perhaps except for high intensity zones, findings on MRI do not reliably indicate whether a disc is a source of pain. Many investigators and clinicians believe there is sufficient published evidence to suggest that discography can help identify a painful disc.[11–13] However, others feel discography is unreliable and extremely difficult to interpret.[14] It is clear that discography must be interpreted in light of the history, physical examination, psychological evaluation and status of the patient, radiological testing, and other diagnostic injections.

Provocation disc injection is based on the theory that during disc injection, a disc that is causing a patient's pain should reproduce concordant pain and, if it does not, that disc is not the pain generator. In addition, injection of adjacent discs should not be painful. In addition, in order to improve diagnostic accuracy, pressure manometry has been suggested. A disc that is painful at low pressure is more likely to be a true pain generator. The results of discography in patients with FBSS may be particularly hard to interpret because patients frequently have conditions that have been associated with false positives such as longstanding pain, psychological distress, and dorsal horn sensitization. Discography is described in detail elsewhere in this text.

TREATMENTS

There is a spectrum of treatments for FBSS that ranges from manual therapy, exercise, and medication through interventional pain management and repeat surgery (Table 74.4). Treatment of an individual patient should be based on the published evidence integrated with the physician's clinical expertise and each patient's values and circumstances. It must be recognized that just as pain management is not necessarily a failure of spine surgery, neither is corrective spine surgery a failure of pain management. Some patients with FBSS are most appropriately treated with medications, radiofrequency neurotomy (RFN), or spinal cord stimulation, but for others the best treatment might be a properly performed repeat surgery.

Nonspecific Treatments

Rehabilitation

Rehabilitation is often the first line of treatment for patients with FBSS. In most publications, the specific spinal disorders have not been reported but, interestingly, that does not seem to matter. There is a wide variety of program type, intensity, and duration.

TABLE 74.4

TREATMENT OPTIONS FOR THE STRUCTURAL CAUSES OF FBSS

Problem	Preferred treatment	Other options	Comment
Foraminal stenosis	• Decompression	• TFE • ? gabapentin	
Recurrent HNP	• Discectomy for radiculopathy	• Functional restoration may equal surgery	• Fusion if surgery needed for primary axial LBP
Painful disc	• Severe pain: fusion; • Moderate pain: rehab = fusion	• Opioid analgesics	• Intradiscal RX not studied in FBSS
Facet joint pain	• RFN		
SIJ pain	• Corticosteroid injections	• Rehabilitation • RFN • Rarely SIJ fusion	• Research re: SIJ RFN not conclusive
Spondylolisthesis	• Fusion	• RFN if facets are source of pain	
Neuropathic pain	• Medications	• SCS	
Psychological	• Cognitive-behavioral functional restoration	• Psychotherapy • Medications	

HNP, disc herniation; RFN, radiofrequency neurotomy; SIJ, sacroiliac joint; SCS, spinal cord stimulation; TFE, transforaminal epidural.

Kernan and Rainville used a 6-week, two sessions per week plus independent exercise physical therapy only program and demonstrated clinically important improvements in pain, OSI, and kinesiophobia.[112] Patients were only modestly impaired at entry. LBP (0–10) improved from 5.8 to 3.7 at discharge and 3.0 at 1 year. OSI improved from 38 to 23 to 19. At the other end of the intensity spectrum, Brox reported outcomes in patients treated for FBSS after discectomy.[100] The program was 25 hours per week for 3 weeks and included cognitive-behavioral therapy and lectures by physicians. At 1 year, LBP (0–100) improved from 65 to 51 and OSI improved from 45 to 32. Smeets et al. compared active physical therapy, cognitive-behavioral therapy without specific exercise but with graduated increases in tasks, a combined program, and waiting list.[88] There were no significant differences among the three treatment groups and all were better than waiting list.

The Cochrane review of randomized controlled studies on the effect of exercise therapy for chronic LBP concluded that "exercises may be helpful for patients with chronic LBP to increase return to normal daily activities and work."[113] Rainville et al. did a narrative review of exercise as treatment for chronic LBP and included case series and cohort studies.[114] There was no literature to suggest exercise increased LBP or caused harm. The large body of evidence they reviewed demonstrated strength training and exercise can improve LBP-related endurance performance and disability in a large proportion of patients. They found reductions in pain of 10% to 50% in most studies. Their work and the work of others confirms that, although there were improvements in strength and endurance, it may be that much of the gains occurred through desensitization of fear, altering attitudes and beliefs about pain, and improving depression.[115] Smeets et al., after their literature review, opined that it is the reactivation caused by the active treatment that is most important, not the physical reconditioning itself.[90] Miller et al. compared the outcomes of chronic LBP and FBSS patients in an interdisciplinary functional restoration program.[116] Both groups did well. The no surgery chronic LBP patients had greater reductions in pain and disability, but the FBSS patients were significantly more improved in strength and endurance measures, activities of daily living, and fear of exercise.

There can be no doubt that exercise is effective treatment that serves both to improve physical impairments and, perhaps equally important, help overcome the catastrophic thinking and fear-avoidance. In patients who have physical and cognitive-behavioral impairments that are mild to moderate, active exercise alone is sufficient. In patients who are more severely disabled, programs that include an educational program that targets negative attitudes and beliefs may be more effective than exercise alone. It may be that the necessary intensity and duration of treatment depend on the degree of impairment and maladaptive cognitive-behavioral factors.

Medications

Medication management of chronic pain is discussed in detail elsewhere in this text. There are no specific studies of the efficacy of medications for patients with FBSS. However, there are multiple studies with high levels of evidence that have demonstrated the efficacy of opioid analgesics for moderate to severe refractory chronic LBP.[117] Many of these studies did contain patients with FBSS.

There has been a systematic review and a meta-analysis on the effect of antidepressants in the treatment of chronic LBP.[118,119] Both concluded that noradrenergic, but not serotonergic, antidepressants provided modest relief of pain, but there was no evidence of improvement in function. Yaksi et al. did a randomized controlled trial of gabapentin in 55 patients with neurogenic claudication due to spinal stenosis. The gabapentin group had improved walking distance, pain, and sensory findings compared to placebo.[120] The anticonvulsant topiramate has been studied in patients with axial LBP and leg pain.[121,122] In a randomized placebo-controlled study of patients with lumbar radiculopathy, topiramate reduced the mean leg score by 19% compared to placebo, which indicated a trend but did not quite reach statistical significance.[121] However, reductions in average back pain score, worst leg pain, and others did reach statistical significance. The number needed to treat was 5.3. In a 10-week randomized controlled trial of topiramate in 96 patients with chronic LBP, Muelbacher et al. found significant improvements in pain,

function, and health-related quality of life for topiramate compared to placebo.[122]

Specific Treatments

Discogenic Pain

Discogenic pain, especially in the setting of FBSS, may prove the most difficult to treat among the structural causes of chronic LBP. Only rehabilitation and fusion surgery have been thoroughly evaluated in this setting. For patients with mild to moderate pain after discectomy, a 3-week interdisciplinary functional rehabilitation program has been shown to be equal to fusion surgery.[100] This is consistent with several studies comparing intensive rehabilitation with fusion in mixed populations of idiopathic chronic LBP that included some patients with prior back surgery.[123,124] It appears that most of these studies excluded patients with severe pain and severe functional impairment. Medication management can be useful, but most studies showing efficacy evaluated nonspecific LBP, and were not limited to discogenic pain.

Facet Joint Pain

There is high quality evidence to support the efficacy of properly performed RFN for FJ pain.[125,126] Successful RFN relieves pain to a meaningful degree for about 9 to 12 months.[125] When pain recurs, RFN can be repeated. Repeat RFN is usually successful unless there has been disease progression or technical failure.[127]

Sacroiliac Joint Pain

There are no treatment options that are supported by high levels of evidence, and most of the recommendations are expert opinion or at best case series. Treatment usually begins with rehabilitation, anti-inflammatory drugs and transdermal lidocaine, support belts, and perhaps spinal manipulative therapy. If there is no meaningful improvement, best available evidence would suggest SIJ corticosteroid injection is the next step.[129] The duration of relief after steroid injection varies greatly. Some patients achieve long-lasting relief after one to three injections, but others require several injections each year.[129,130] For patients who do not respond to these treatments, SIJ RFN has been useful in a limited number of patients.[131,132] Finally, for patients with severe and refractory pain, SIJ fusion has been reported to be helpful.[133]

Spinal Stenosis

As previously noted, spinal stenosis may involve the central, lateral, or both canals. Although there are multiple nonrandomized and randomized studies comparing operative with nonoperative care, most of the data regards central stenosis or the type of stenosis was not defined. Lateral canal or foraminal stenosis is far more common than central stenosis in patients with FBSS. Central stenosis can be treated initially with medications, rehabilitation, and epidural corticosteroid injections.[134] Patients who fail with medications and rehabilitation usually do well with surgery.[135–137] The same paradigm seems appropriate for foraminal stenosis. If stenosis is severe and extensive decompression is needed, fusion may be required. For mixed pain syndromes, if decompression is not sufficient, medications and/or spinal cord stimulation may be useful.

Neuropathic Pain

Neuropathic pain is best treated sequentially. Most often medications (anticonvulsants, noradrenergic antidepressants, opioid analgesics) are used first. If there is limited success, spinal cord stimulation (SCS) is often useful. Kumar et al. randomized 100 patients with FBSS and predominant leg pain to receive either SCS plus conventional medical management to medical management alone.[138] The primary outcome measure was 50% reduction in leg pain, which was achieved in 48% of the SCS plus medication group versus only 9% of the medication only group. In addition, the SCS plus medication group had improved low back pain, quality of life, and function as well as greater treatment satisfaction. There were 32% who experienced device-related side effects. There are case series regarding the treatment of cluneal nerve injuries with injections of corticosteroids and with alcohol.[139,140]

Psychological Issues

Psychological illness is treated according to its severity and type. Patients with depression and anxiety disorders may benefit from individual psychotherapy, groups, and medications. Active addictive disease should prompt consultation by a specialist in addiction medicine.

As previously noted, cognitive-behavioral factors can be dominant, especially in the perpetuation of impairment and disability. Treatment of these problems has been discussed as well. It bears repeating that there can be significant improvements in catastrophic thinking, fear, fear-avoidance, and depression by virtue of an active supervised exercise program. The addition of an educational program and directed cognitive-behavior treatment and graduated exposure to those activities perceived by the patient as noxious may improve the outcomes in moderately or severely impaired patients, but may not be necessary in those with lesser degrees of illness.

CHAPTER 75 ■ PSYCHOLOGICAL SCREENING OF SPINE SURGERY CANDIDATES

ANDREW R. BLOCK

INTRODUCTION

Spine surgery is being used with increasing frequency in the United States. A recent study by the Center for Evaluative Clinical Sciences of Medicare enrollees indicates that the rate of lumbar fusion has increased from 0.3 per 100,000 to 1.1 per 100,000 during the period from 1992 to 2003.[1] By 2003, spending on lumbar fusion equaled $482 million, accounting for 47% of total spine surgery spending. However frequent its use, the outcome of spine surgery is quite variable. Deyo and Mirza,[2] for example, found that 2 years after the surgery there was no significant difference between back pain patients of similar diagnosis who were treated surgically or nonsurgically. This lack of uniform positive response to spine surgery echoes other earlier data. Turner et al., reviewing all published research on spinal fusion, found that only approximately 65% to 75% of all patients achieved satisfactory clinical outcomes.[3] In these studies, poorer outcome was associated with a number of factors, including greater numbers of fused levels and the use of instrumentation.[3] Similarly, Hoffman and colleagues, in a literature review on laminectomy and discectomy, found that the mean success rate of this procedure for relief of spine pain was 67%.[4] The popular media have pounced on these and similar results, which appear to provide support for declarations such as that of *Consumer Reports*[5] identifying back surgery as the number one item in their list of "overused medical tests and treatments."

Such pessimistic appraisals of spine surgeries are contradicted by other data demonstrating that some of these procedures can lead to dramatic improvements in the patients' experience of pain and functional abilities. For example, Malter and colleagues, examining the effectiveness of laminectomy and discectomy in the treatment of spine pain, found that those patients receiving such surgery had significantly greater quality of life at 5 years postoperation than did patients provided conservative care alone.[6] The results of this study also showed that the cost-effectiveness of laminectomy and discectomy exceeded that of the medical treatment for hypertension, as well as that of single artery bypass grafting in coronary heart disease. In similar fashion, the Spine Patient Outcomes Research Trail (SPORT: 7) found that patients who underwent discectomy had significantly less pain, and greater reported functional ability than did patients receiving conservative treatment, at a 2-year follow-up. Hence, a balanced view of spine surgery is that it can be effective, although not universally so.

Failed spine surgery significantly impacts the patient, the physician, the employer, and the third-party payer. The patient, of course, continues to remain disabled, with perhaps even greater pain, increased medication dependence, and more emotional difficulty than prior to the surgery. The pain may be so great, or the surgery so unsuccessful, that reoperation is required, as is the case in 10% of those who undergo laminectomy and discectomy,[4] and 23% of those who undergo spinal fusion.[3]

The patient after failed surgery places many demands on the health care system, often requiring increasing medications and expensive multiple treatments. Patients often feel frustrated and discouraged. The physician may become angry with the patient for not responding to treatment, and the employer is always concerned about his or her obligation to pay compensation to a permanently disabled worker.

Given that spine surgery can be quite effective, and that the implications of failed spine surgeries can be so profound, it becomes critical to determine factors that may lead to poor results from such procedures. Certainly, surgical results can be less than optimal if appropriate diagnostics are not performed, or if less-than-expert surgical techniques are utilized. Improper pre- and postoperative information and treatments may also decrease surgery results. However, a growing body of research indicates that psychosocial factors are among the most significant influences on spine surgery results. For example, DeBerard et al.[8] compared the outcomes of spinal fusion in patients who had been referred for preoperative psychological evaluation (based on surgeon recognition of the presence of psychosocial concerns) versus those who were not referred for such evaluations. The referred patients had much higher medical treatment costs than those who were not referred. Similarly, Trief et al.[9] found that good emotional health, as assessed by the Mental Component Score of the SF-36, was associated with higher levels of physical functioning at 12 months and 24 months post fusion.

The purpose of this chapter is to review the major psychosocial variables that have been shown to be associated with reduced surgery outcomes. These studies demonstrate that *even when surgery is performed correctly, and is based on appropriate diagnostics, patients may fail to achieve satisfactory results due to psychosocial issues*. For a much more comprehensive review see Block et al.[10]

PERSONALITY AND EMOTIONAL FACTORS

Most spine surgery aims to correct an underlying pathological physical condition that would appear to be the source of the pain. Pain, however, is a subjective experience, one which can be assessed only indirectly, through patient self reports, behavioral changes, and utilization of pain medication. As a subjective experience, pain influences and is, in turn, influenced by psychological process such as perception, emotion, and communication. Thus, the pathophysiology underlying pain becomes only the point of initiation for a complex process, the end result of which is the presentation of the patient in the surgeon's office, desperately seeking pain relief.

There are many psychosocial factors tied to pain perception and response, but the largest research focus has been centered on issues of "personality." The American Psychiatric Association defines *personality* as "deeply ingrained patterns of behaviors, which include the way one relates to, perceives and thinks about, the environment and oneself."[1] According to this description, personality can exert wide-ranging influences over both thoughts

and actions. These characteristics can determine, for example, whether people typically become depressed, anxious, or angry in response to stress. Personality may also influence one's need to maintain control, to draw attention to himself or herself, or to withdraw and become sullen. More germane to presurgical psychological screening (PPS), personality factors can exert strong influences on perception of the pain, the emotional impact of pain, and the actions one takes to achieve pain relief.

Personality factors can be reliably identified through the use of *objective* psychological tests, such as the Minnesota Multiphasic Personality Inventory, version 2 (MMPI-2). The MMPI-2 has been frequently used in studies attempting to predict outcome following spine surgery. Table 75.1 lists the major studies that have used the MMPI-2 (and its predecessor, the MMPI) with spine surgery patients. The results demonstrate that elevations on several MMPI-2 scales have been found to be associated with poorer surgical outcomes. In examining this table we must recognize that the MMPI-2 not only assesses enduring personality traits, but also more acute emotional reactions. For example, depression, as assessed by the MMPI, may be a reaction to the pain and lifestyle changes engendered by the spine injury or may be more of a chronic feeling state. The results of the MMPI-2 cannot be used to make such a differentiation. However, as is discussed in the following section, the relatively enduring nature of many of the traits displayed on the MMPI-2 may significantly influence the outcome of spine surgery. A number of other more brief, more focused, and less complicated psychometric measures have been studied in connection with spine surgery outcome, and these are reviewed below, in the context of the MMPI-2 scales with which they have some overlap.

Pain Sensitivity

Pain is a sensation primarily arising from the stimulation of nociceptors, specialized sensory neurons indicating tissue damage, or the potential for damage. However, if the subjective experience of pain was directly tied to tissue damage, then there would be a perfect correlation between nociceptor output and pain experience. Obviously, this is not the case, and there is a large body of research demonstrating that certain chronic pain patients report higher levels of pain than expected on the basis of identifiable physical pathology, a phenomenon termed excessive *pain sensitivity*. For example, patients with functional gastrointestinal pain syndromes may be hypersensitive to pain signals arising from the gut. Using balloon distension of the esophagus in patients with noncardiac chest pain, Barish and colleagues found that distension caused pain in 56% of patients compared with 20% of normal controls.[12] Similarly, Coffin and colleagues reported that patients with nonulcer dyspepsia showed greater sensitivity to balloon distension of the stomach than did normal subjects.[13] Fibromyalgia patients, too, have been shown to be more pain sensitive than normal subjects to pressure, noxious heat, and electrical impulses.[14] Finally, Schmidt and Brands reported that

TABLE 75.1

STUDIES EXAMINING THE RELATIONSHIP OF MINNESOTA MULTIPHASIC PERSONALITY INVENTORY TO SPINE SURGERY OUTCOME

Authors	Subjects	Evaluation interval	Minnesota Multiphasic Personality Inventory results
Cashion and Lynch (1979)	78 laminectomy patients, no previous surgery	1 yr	Significant differences between good and bad outcome scales Hs, D, K, F, Es
Doxey et al. (1982), Dzioba and Doxey (1984)	116 workers' compensation patients, no previous surgery; 74 received surgery, 43 not	1 yr	Hs, Ma, Pt higher in poor outcome patients
Kuperman et al. (1979)	37 discectomy patients, no previous surgery	1 yr	Hs, Hy, D, significant r^2 with outcome; r^2 of Hs + Hy + D with outcome = .58
Long (1981)	44 surgery patients, referred because of suspected nonorganic factors	6–18 mo postoperatively	Hy, Hs, Pd higher in poor outcome group
Pheasant et al. (1979)	90 patients, various procedures	6 mo, 1 yr	Hs, Hy higher in poor outcome group
Riley et al. (1996)	71 fusion patients, 30% previous surgery, 37% workers' compensation	Average 20 mo postoperatively	Cluster analysis: poorest outcome in patients with high Hs + Hy, and "depressed-pathological"
Smith and Duerksen (1979)	31 patients, various procedures, 3 previous surgery	Unclear	Hs, Hy, D significant r^2 with outcome
Sorenson and Mors (1988)	57 discectomy patients, no previous surgery	6, 24 mo postoperatively	r^2 with poor outcome: Hs = .37, D = 0.37, Hy = 0.47; also Sc, Ma
Spengler et al. (1990)	84 discectomy patients, no previous surgery	1 yr or more	Hs + Hy significantly associated with poor outcome; also Pd, Sc
Turner et al. (1986); Uomoto et al. (1988)	106 discectomy patients, 25 previous surgery	1 yr	Discriminative function using Minnesota Multiphasic Personality Inventory predicted 69.7% of outcome, function including Hs, K, L
Wiltse and Rocchio (1975)	130 chemonucleolysis patients, no previous surgery	1 yr	Success predicted by Hs + Hy, not predicted by physical findings

D, depression; Es, ego strength; Hs, hypochondriasis; Hy, hysteria; L, lie; Ma, hypomania; Pd, psychopathic deviate; Pt, psychasthenia; Sc, schizophrenia.

chronic low back pain patients were extremely sensitive to a cold pressor test (immersion of the forearm into an ice water bath), reporting higher pain levels and tolerating the ice water for a shorter period of time than did a control, nonpatient group.[15]

These studies by Barrish et al. and Coffin et al. demonstrate that patients with various clinical syndromes can display heightened pain sensitivity to controlled stimulation of tissues associated with their pain syndromes. In the field of spine pain it is much more difficult to stimulate nociceptors in a controlled fashion. There is, however, one medical test frequently used in diagnosing intervertebral disc problems that does provide for such a demonstration. This procedure, termed discography, involves injection of radiographic dye into the nucleus of a putatively disrupted disc. The injection, performed under fluoroscopy and combined with postdiscogram CT, gives evidence of the presence and extent of disc disruption. The most interesting feature of this test, as far as the present discussion is concerned, is that the injection of a disrupted disc has been demonstrated to act as a stimulus that provokes pain, often with a pattern and intensity similar to the patient's normally occurring pain. For example, Vanharanta et al.[16] found that injection of moderately to severely disrupted discs provoked pain which was similar or an exact reproduction of normally occurring pain in approximately 65% of cases. On the other hand, injection into normal-appearing discs provoked exact or similar reproduction of pain in only 18% of cases. Even stronger results along the same lines were obtained by Walsh et al.[17] Thus, discography may provide a laboratory for providing controlled stimulation of the disc in order to assess whether certain patients with low back pain display heightened pain sensitivity.

We[18] have administered the MMPI-2 to low back pain surgical candidates undergoing three-level lumbar discography, a procedure which frequently provides for a "control level," that is, injection into a nondisrupted disc. Such a test should lead to pain reproduction upon injection of disrupted discs and no pain response on injection of a normal disc, in the same subject. However, we found that many patients had at least one "false positive" pain report—that is, reproduction of pain upon injection of a normal disc level. Results showed that hypochondriasis (Hs) and hysteria (Hy) elevations were associated with false-positive reports of pain. In fact, 75% of patients with elevated Hs scores displayed at least one level with such a false positive (compared to a false-positive rate of 30% in patients no having elevated Hs scores). Interestingly, the majority of patients who had such false-positive pain reports at one disc level also had concordant pain reports (i.e., pain reproduction on injection of an abnormal or disrupted disc) at another level. Thus, these results demonstrate that excessive pain sensitivity significantly influences pain perception even in patients with objectively identifiable pathophysiology.

Pain sensitivity, as a personality factor, can be assessed by the MMPI-2 Hs and Hy scales.[19] These scales are the ones most commonly elevated in general chronic pain syndromes and in spine surgery candidates.[20] The major difference between the two scales is that Hy, in addition to pain sensitivity, measures a tendency to deny psychological and emotional problems, as well as to minimize discomfort experienced in social situations. There is a strong correlation ($r = .53$) between the two scales, and thus they are often both elevated at about the same level. Most studies examining the value of the MMPI-2 in predicting spine surgery outcome have found at least one, if not both, of the scales Hs and Hy to strongly predict poor surgical outcome (see Table 76.1). In some studies, the predictive value of these two scales far exceeds that of medical diagnostic tests, such as radiography, CT scans, or neurologic signs.[22] Such results parallel those in other chronic pain syndromes, finding that Hs and Hy elevations predict poor treatment outcome for syndromes as diverse as temporomandibular joint dysfunction, gastrointestinal disorder, and nonsurgical back pain.[23–25]

Anger

Patients with chronic pain are often filled with anger. They are frequently mad about past medical treatment, the ways they have been treated by employers, and the fact they people they considered friends now avoid them. Anger is often seen by the physician, and is frequently the impetus for a referral for PPS. A study by Fernandez and Milburn demonstrates just how frequently patients experience this emotion. These researchers asked chronic pain patients to endorse the intensity of 10 different emotions they were experiencing and found that anger was given the highest ratings of all emotions assessed.[26]

Anger as a personality trait is assessed by the psychopathic deviate (Pd) scale of the MMPI, which also evaluates rebelliousness toward authority and aggressiveness.[19] Elevations on the Pd scale have been found in at least five studies to be associated with poor surgical outcome.[21,27–30] There are numerous reasons why anger may have a negative impact on reduction of pain. First, anger may lead to maladaptive lifestyle changes, such as poor health habits, lack of physical exercise, or excessive use of drugs or alcohol.[31] Such maladaptive behaviors may have a negative impact on the patient's commitment to postoperative rehabilitation. Furthermore, anger has been shown to have an adverse effect on many health conditions, such as cardiovascular disease, headaches, asthma, and many others.[32,33] Such adverse effects may be mediated by excessive activation of sympathetic nervous system efferents or changes in the immune system, perhaps influencing the healing process.[32] Finally, a fascinating series of studies by Burns[34] demonstrates that anger may increase pain sensitivity in chronic low back pain patients, by increasing muscle tension near the site of the injury.

Of course, anger may have effects not just on the experience of pain, but also on its meaning and expression. Anger often leads to the desire for vindication or revenge, and certainly this can influence treatment results. DeGood and Kiernan have found chronic pain patients who are angry and blame their employer for their injuries report high levels of emotional distress and have poorer response to treatment.[35] It may be that for patients who experience intense anger, continued postsurgical pain reports may be tied more closely to the feelings that they have toward those they perceived have wronged them than to any improvement in the pathophysiological basis of the pain.

Clinical Depression

Many chronic pain patients experience some level of depression. For up to 85%, the intensity of this emotional experience is sufficient to meet the diagnostic criteria for clinical depression.[30] Depressive symptoms include depressed mood, diminished interest in almost all activities, weight loss or gain, insomnia or hypersomnia, agitation or psychomotor retardation, fatigue or energy loss, feelings of worthlessness or guilt, impaired concentration, and recurrent thoughts of death.[11] Depression can be assessed by scale D of the MMPI. Elevations on scale D are found in most studies to be associated with poor outcome of elective spine surgery,[27,28,30] although in several studies no relationship was reported.[21,36–38]

Several other studies have assessed depression using different instruments and found that it can be predictive of reduced spine surgery results. Kjelby-Wendt, Styf, and Carlsson[39] examining discectomy results found that patient satisfaction with surgery was strongly related to elevated scores on the Beck Depression Inventory—in fact, elevated scores were found in 55% of dissatisfied patients but in only 18% of satisfied patients. Schade et al.[40] found that depression, as assessed on a simple Likert-type scale, had strong negative correlations with return to work and overall recovery. Trief et al.[41] found that high scores on the Zung depression inventory were associated with little reduction in back pain

and elevated work disability after spine surgery. Finally, DeBerard et al.[42] found that depression, assessed using the DSM-IV criteria, was strongly related to total medical costs in workers' compensation patients undergoing spinal fusion.

Chronic pain patients who are depressed may fail to respond well to spine surgery for a number of reasons. First, individuals with depression have been found to be more likely to focus on negative rather than positive events.[43] Kremer and colleagues[44] demonstrated that such tendencies can affect the chronic pain patient's perception of the improvements in function that result from treatment. In this study, activity levels of patients undergoing interdisciplinary rehabilitation were unobtrusively observed by trained staff members. Patients also recorded their own activity levels on an hourly basis. Although all patients demonstrated objective improvement in activity levels as a result of treatment, those who were depressed tended to underreport their improvements. Thus, depressed patients who undergo spine surgery may also fail to see the gains they have made.

Depression may affect the patient's viewpoint about the surgery. It is clear from research that chronic pain patients tend to have negative cognitions about their health.[45] It is not a great leap, therefore, to assume that depressed patients might experience pessimism about any treatment, including surgery. This is of great significance as den Boer et al.[46] found that negative outcome expectations for lumbar disc surgery were associated with elevated disability and elevated pain at 6 weeks and 6 months postoperatively.

Finally, depression has also been shown to be associated with a low threshold for induced pain.[47] Perhaps the depressed surgical patient may be focused on the body and hypervigilant for pain even if its pathophysiological basis has been corrected and the nociceptive stimulation greatly reduced.

In examining depression, one must consider whether the symptoms predate the back injury or are of relatively recent onset. For many patients, depression may be a personality style or a chronic emotional condition (i.e., dysthymia). For others, depressive symptoms, such as decreased concentration, sleep disturbance, and weight change, may be a direct result of the experience of protracted pain or disability.[48] Chronically depressed patients may respond more poorly to any surgical procedure aimed at pain relief compared with those patients whose depression is reactive to their medical condition and symptoms. Surgical recovery in more acutely depressed patients may actually be facilitated if clinical depression is adequately treated, through a combination of antidepressant medication and short-term psychotherapy. The improvement in depressive symptoms, including a likely decrease in pain sensitivity, may lead the patient to feel relieved by surgery beyond the correction of pathological changes in the spine.

Anxiety and Fear

Chronic back pain engenders many difficulties for the patient. Often patients are quite anxious, worrying about paying their bills and fearing that they will lose their jobs. They may be concerned about the many changes in family interaction caused by pain and limitations. Most of all, the spine surgery candidate has to face uncertainty about improvement in pain and functional ability. Such fears and worries, combined with more chronic tendencies toward emotional distress, obsessions, and compulsions, are assessed by the MMPI-2 psychasthenia (Pt) scale. Patients with Pt elevations tend to be stubborn, rigid, and self-critical.[11] In four studies, Pt elevations have been found to be associated with adverse outcomes of spine surgery (see Table 76.1).

As with the other major emotional/personality issues, the relationship of anxiety to surgical outcome has been assessed using devices other than the MMPI. Trief et al.[49] found that patients with elevated state anxiety scores on the State Trait Anxiety Inventory (STAI) achieved less pain relief and lower return to work rates after surgery than did patients with lower anxiety. One particularly troublesome type of anxiety centers on the belief that increasing function and activity may increase the likelihood of re-injury. This type of fear measure has been assessed by several questionnaires including the Tampa Scale of Kinesophobia.[50] Den Boer et al.[51] found that elevated scores on the Tampa scale were associated with delayed return to work after lumbar disc surgery. One plausible explanation for this result is that patients with a heightened fear of movement might be less likely to engage in aggressive postoperative rehabilitation.

Anxiety may influence spine surgery outcome for any number of other reasons. First, anxiety may increase awareness of pain, as experimental pain studies have shown that anxiety can reduce the threshold for pain perception as well as pain tolerance. Kiecolt-Glaser et al.[52] have suggested that anxiety/fear may diminish surgical results by slowing healing perhaps through reduced production of pro-inflammatory cytokines, such as a interleukin 1. Recently, Starkweather et al.[53] expanded on this notion, finding that patients about to undergo spine surgery, whether discectomy or fusion, are highly stressed and have reduced Natural Killer Cell activity (NCKA). Kiecolt-Glaser et al.[52] also suggest that anxiety may increase postoperative pain, and such increased noxious sensations could then down-regulate immune function, further compromising the surgery healing process. In summary, then, anxiety may reduce surgical outcome by increasing pain sensitivity, slowing the healing process and/or reducing postoperative activity levels.

COGNITIVE FACTORS

A growing body of research is examining the ways in which patients' thoughts and beliefs concerning their pain, independent of personality or emotional factors, can strongly affect treatment outcome.[54,55] Such cognitions and coping strategies have been demonstrated to influence the level of pain experienced by the patient, level of functional ability, and adjustment to the pain and efforts to overcome it.[56–58]

Coping Strategies

Coping strategies may be defined as specific thoughts and behaviors individuals use to manage their pain or their emotional reactions to pain.[57] Coping strategies may affect the patient's level of attentiveness to pain, the ability to persist in the face of pain, and the extent to which the patient feels entitled to be taken care of as a result of the pain. There are a number of questionnaires available to assess pain-related coping strategies, including the Vanderbilt Pain Management Inventory.[57] However, the largest body of research on coping in chronic pain (and the only research directly applied to surgical screening) has used the Coping Strategies Questionnaire (CSQ).[58]

Gross administered the CSQ preoperatively to 50 lumbar laminectomy candidates.[59] Patients who obtained good results from surgery indicated on the CSQ that they felt better able to control the pain and also indicated they were more self-reliant. Other coping strategies assessed by the CSQ, such as hoping and praying and catastrophizing, were associated with poor surgical outcomes. These results are consistent with several other studies demonstrating that more passive coping strategies and perceived lack of pain control tend to be associated with greater pain levels, higher opioid consumption, greater levels of depression, and poorer treatment outcome.[58,60,61] Additional studies on cognitive aspects of pain, using questionnaires other than the CSQ, have identified similar findings. Worse subjective symptoms and poorer treatment outcome are found in chronic pain patients who tend to have negative self-statements, tend to catastrophize (e.g.,

greatly overestimate the impact of minor negative events), and have strong beliefs that all pain should be avoided.[55,56,62]

Recent research by den Boer et al.[51] provides further support for the strong influence of coping strategies on surgical outcome. In these studies, 336 patients undergoing spine surgery for lumbar radicular syndrome were examined. "Passive Pain Coping" was assessed preoperatively using the Pain-Coping Inventory.[63] Results indicated that passive pain coping, along with negative surgical outcome expectancy, predicted more severe disability and reduced work capacity at 6 months postsurgery. Taken together with the just-cited study by Gross, these results demonstrate that the effectiveness of surgery may be partially mediated by the manner in which the patient thinks about the experience of pain and the strategies he or she has available to cope with the pain.

BEHAVIORAL FACTORS

All the psychosocial factors discussed up to this point are internal to the patient—thoughts, feelings, and personality. Factors external to the patient can also exert profound influences upon recovery from spine surgery. Especially powerful in this regard are the responses of others to the patient's pain. Pain behavior almost always occurs in a social context, communicating to observers that the patient is in distress. Observers, in turn, may react to such behavior with attempts to relieve the patient's pain, help him or her to avoid further problems, or be supportive of limitations in activity. Employers, and even the insurance system, may also inadvertently support pain behaviors through provision of disability benefits or time off of work. Unfortunately, such solicitous responses from others, while well-intentioned, may serve to reinforce or reward pain behaviors, increasing the likelihood that patients will continue to show and experience pain.[64] Failure to alter reinforcement of pain behavior may contribute to prolonged disability after spine surgery and noninvasive treatment of spine injury.

Litigation

Chronic pain often arises from a specific injury—a motor vehicle accident, a fall, lifting an excessively heavy object, etc. In our litigious society the party injured in such situations will often consider suing the person or company perceived as being partially or fully responsible for the injury. The settlement received in such litigation has the potential to act as a reinforcer for the patient's pain complaints and behaviors, as (correctly or incorrectly) the patient may receive advice that greater disability will lead to larger sums received. Kennedy, in a frequently cited quotation about patients involved in litigation, coined the term *compensation neurosis*, "a state of mind born out of fear, kept alive by avarice, stimulated by lawyers, and cured by verdict."[65] Studies of chronic pain patients provide only limited support for the concept of compensation neurosis. Yet, it is clear that cultural and social factors can influence chronic pain behaviors. In countries other than the United States, where litigation for accidents is uncommon, continuing pain from injuries is less common. In Lithuania, where few drivers are covered by insurance, virtually no individuals involved in car accidents report disabling *whiplash* type pain at 1 to 3 years postaccident.[66] In New Zealand, which has a no-fault system for work-related injuries, workers experience less intense pain and have fewer emotional and behavioral difficulties than do injured workers in the United States.[67] Thus, patients who are in litigation do appear to have greater pain complaints and levels of disability than do nonlitigating patients.

However, when an examination is made of the effects of litigation on treatment outcome, the results are complex. Schofferman and Wasserman found that low back and neck pain patients improved despite litigation.[68] Norris and Watt found no statistically significant changes in the symptoms of litigating patients after their claims were settled.[69] For conservative pain management it appears that, while litigating patients may have significantly increased pain complaints, for most claimants, disability from injury does not resolve following the settlement of litigation.[70]

Despite the previously mentioned results, it appears that litigation surrounding an injury can exert greater influence on spine surgery outcome than on the conservative treatment of pain. LaCaille et al.[71] found that total compensation costs for lumbar fusion patients who had attorneys averaged $41,657 versus $24,837 for those without lawyers, even though there was no correlation between total compensation cost and the likelihood of achieving successful fusion. Finneson and Cooper[72] found that both "history of law suits for medicolegal problems" and "secondary gain" predicted negative results of disc surgery, a result corroborated by Manniche et al.[73] Junge et al. found that Swiss patients who were applying for disability pensions had poorer discectomy outcomes than did nonapplicants.[74] Such results do not mean that litigation patients are making up their symptoms (i.e., malingering), because surgical candidates do have a pathophysiological basis for the pain. Furthermore, an often-cited survey of orthopedic and neurosurgeons by Leavitt and Sweet found that malingering occurred in less than 5% of patients.[75] However, the results with litigating surgical patients imply that, in some cases, reinforcement of pain in the form of anticipated financial gains may increase sensitivity to pain, making patients "somatically hypervigilant"[76] and less responsive to treatment.

Workers' Compensation and Disability Payments

Another source of potential reinforcement for pain comes in the form of workers' compensation and other disability payments to those injured on the job. Such payments often begin at the time of injury and continue until the patient has been declared to have reached *maximum medical improvement*. A number of studies have shown that spine surgery outcome is reduced in patients receiving workers' compensation payments.[77–79] Hudgins, for example, examining patients 1 year postlaminectomy, found that those receiving workers' compensation were the least likely to be working and to report pain relief.[80] Klekamp, McCarrty, and Spengler[81] found that 81% of patients obtained a good result from lumbar discectomy, compared to a success rate of 29% of litigating workers' compensation patients. Similarly, Trief et al.[82] found that receiving disability funds was negatively associated with return to work and improvement in work-leisure functions at 12 months postoperatively.

Poor treatment results among workers' compensation patients may not arise solely from economic considerations. Rather, workers' compensation patients have a number of additional issues that may lead to reports of high pain levels and poor treatment outcome. First, these patients have frequently been unable to work for extended periods at the time of surgery. Research on chronic pain has clearly shown that the length of time a patient has been nonfunctional strongly influences treatment outcome. Dworkin et al., using multiple regression to examine the relationships among compensation, litigation, and employment status (time off work) in 454 patients undergoing treatment for chronic pain, found that only time off work (and not workers' compensation or litigation) predicted treatment outcome.[83] In similar and even more dramatic fashion Anderson et al.[84] found that patients who were working up to the time that they went in for anterior lumbar interbody fusion were 10.5 times more likely to have returned to work by 1 year postoperative than were individuals who had not been working prior to surgery. Interestingly, this association was independent of workers' compensation status, and number of levels treated.

Responses to treatment by patients receiving workers' com-

pensation may be influenced by a number of other job and workplace factors such as job dissatisfaction,[85] heavy physical job demands,[51,74,77] and high levels of anger or blame toward the employer.[35] Regardless of the cause, workers' compensation is so widely recognized as a risk factor that Frymoyer and Cats-Baril have proposed that *compensability* is one of the strongest predictors of excessive disability among back injury patients.[86] Thus, compensation status should be noted as a strong potential risk factor for poor outcome following surgery, especially if the patient is not working up to the date of the surgery. We should be cautious, however, in noting that compensation is a *relative risk* factor and may not be predictive of treatment response in any particular case. Rather, it should be included as one factor along with others described throughout this chapter (see Table 76.3).

Spousal Reinforcement of Pain Behavior

Chronic pain has a profound effect on those closest to the patient. Family income and family roles often change as a result of the pain. Spouses may become confused or depressed themselves in response to all these lifestyle alterations. A number of studies have shown that pain-reinforcing responses by the spouse can exert a strong influence on patients' pain behaviors. Such reinforcing actions might include taking over the patient's jobs or responsibilities, giving the patient medication, and encouraging rest while discouraging activity. Family members may be more likely to pay attention to the patient when the pain appears greatest and to ignore the patient at other times, such as when Block and colleagues, for example, found that patients who receive a high level of attention or solicitous responses from their spouses were more likely to report high pain levels in the spouses' presence than were patients with nonsolicitous spouses.[87] Lousberg and colleagues extended this result, finding that patients with solicitous spouses showed decreased physical exertion on treadmill performance in the presence of the spouse.[88] Similar results have been obtained in a number of other studies.[89,90] By extension, it would appear that spousal solicitousness may have a negative impact on surgical recovery and should be assessed prior to surgery, by measures such as the West Haven-Yale Multidimensional Pain Inventory.[91]

Why should some spouses, who profoundly desire that the patient get better, provide reinforcement for pain complaints and pain behavior? The explanation may rest on the finding that certain spouses experience strong empathy with the patient, experiencing an increase in their own arousal level when the patient appears to be experiencing pain.[92,93] Such physiological and cognitive responses to pain displays may motivate the spouse to behave toward the patient in a solicitous fashion, unwittingly reinforcing pain behavior.

Family members may provide emotional disincentives for improvement in another way. Numerous studies have demonstrated that marital distress is high among chronic pain patients.[94,95] We have shown that dissatisfied spouses have more negative outcome expectations for the patient and tend to attribute the patient's pain to psychological causes.[96] It is likely that spouses who are dissatisfied would be less supportive of the patient. Social support, particularly from the spouse, has been found to be an important influence on compliance with medical treatment recommendations[97] and recovery from invasive surgery, such as hip replacement.[98] Thus, patients who report high levels of marital distress, or have unstable or unsupportive marital relationships, may have a poorer surgical prognosis. Marital dissatisfaction should be assessed in the surgical candidate, using measures such as the Locke-Wallace Marital Adjustment Inventory, which focuses on marital satisfaction.[99]

HISTORIC FACTORS

The ways in which individuals respond to and cope with painful spine injuries are strongly influenced by their previous life experiences. Research has demonstrated a number of historic elements in the background of the spine surgery candidate that can negatively impact surgical recovery.

Abandonment and Physical and Sexual Abuse

A disproportionately high number of chronic back pain patients have been the victims of abuse or abandonment as either adults or as children. In one study, more than half of the patients evaluated at a multidisciplinary pain clinic had a history of at least one form of such abuse. In 90% of the cases the abuse occurred during adulthood.[100] These figures are substantially higher than the base rate in the U.S. population.

One unfortunate consequence associated with victimization is that such patients respond poorly to spine surgery. Schofferman and colleagues[101] found an 85% failure rate from spine surgery among patients with a significant history of childhood abuse and abandonment, compared with a 5% failure rate among patients lacking such a traumatic history. A study by Linton[102] suggests that experiences of sexual and physical abuse may predispose individuals, especially women, toward chronic pain, thereby reducing overall spine surgery results. This study surveyed a sample of the general population in Sweden, as well as chronic pain patients, about their history of physical and sexual abuse. All subjects, whether patients or not, were also questioned about any chronic pain symptoms they might have had. Among the female chronic pain patients, 35% had an abuse history. Many of the nonpatient women also reported experiencing chronic pain. For nonpatient women reporting "pronounced pain," frequency of physical abuse was 8% and frequency of sexual abuse was 46%. For the nonpatient women reporting no pain, frequency of physical abuse was 2% and frequency of sexual abuse was 23%. Further analyses of the results determined that the chances of developing chronic pain were increased fivefold by physical abuse and fourfold by sexual abuse. In this study there appeared to be little association of abuse with pain for the men. The above results suggest that for some patients, while surgery may eliminate the physical cause of pain, a history of abuse and the patterns of self-esteem and pain coping such an abhorrent situation engenders may confound the outcomes of surgery.

Premorbid Psychiatric Diagnosis and Emotional Distress

Many chronic pain patients have diagnosable mental health problems. Kinney et al.,[103] for example, found that among those reporting low back pain, 100% with chronic pain and 61% with acute pain had diagnosable psychological conditions. Lower incidence rates were reported by Coste and colleagues.[104] As noted previously in the discussion of depression, psychological problems may predate the injury. For example, Fishbain and colleagues found that 58.4% of the chronic pain patients they studied had diagnosable long-term personality disorders, while Reich and colleagues reported a 37% incidence of such disorders.[105,106] Preexisting psychological problems, whether emotional or personality based, have been found by a number of authors to be associated with poor results from spine surgery.[107,108] It would seem likely that patients with preexisting psychological problems, especially those who have had prior psychiatric treatment, might be less well equipped to deal with the stress and difficulties involved in recovering and rehabilitation following spinal surgery.

Previous Medical Use

Not only is a history of previous psychological treatment associated with poor outcome, but a preinjury history of multiple physical problems also does not bode well for surgical outcome. A number of authors have found that patients who report many illnesses and physical symptoms do not respond well. Frymoyer et al.,[109] for example, found that a history of multiple physical complaints was associated with high levels of back-related disability. Ciol and colleagues[110] reported that higher numbers of previous hospitalizations were associated with greater risk of lumbar spine re-operations in a Medicare population. Wiltse and Rocchio[38] determined that high scores on the Cornell Medical Index, a measure of past illnesses and current bodily symptoms, were associated with poor outcome of chemonucleolysis.

The influence of previous medical problems on surgical outcome appears to parallel results reported earlier in this section noting that excessive pain sensitivity, as assessed by the MMPI-2 Hs and Hy scales, is also a predictor of poor surgical outcome. It appears that patients whose personality and medical history predispose them toward reporting many physical symptoms may have more difficulty experiencing a reduction in back pain and disability as a result of spine surgery, perhaps related to their preoccupation with bodily processes and hypervigilance to noxious sensations.

Substance Abuse

Excessive use and abuse of opioid medication and alcohol appear to be red flags for poor surgical outcome. To the extent that patients depend on such substances, their responsibility for pain relief and improvements in functional ability through participation in postoperative rehabilitation may be diminished. It is clear that many chronic pain patients use excessive amounts of opioids. For example, Polatin and colleagues[108] found that 19% of spine pain patients entering a work-hardening program had a substance abuse history, and even higher rates were reported in other studies. Unfortunately, there is little research addressing the relationship of substance abuse and spine surgery outcome. The only study to directly report such results is that of Spengler and colleagues,[111] who examined 30 of their spine surgery failures and found that 25 were "continually abusing medication and alcohol."

Determining when a patient is abusing drugs or alcohol is not as easy as it might seem. In recent years there has been an increasing acceptance of the use of analgesic substances, including opioids, in patients with chronic pain. A number of studies have demonstrated that chronic opioids provide significant pain relief in chronic pain patients.[112,113] Thus, some surgical candidates may be taking doses of opioids at the time of evaluation, which, just a few years ago, would have been considered unacceptable. One could argue that patients who are denied opioids by their physicians are not necessarily abusing substances when they seek pain relief through street drugs or alcohol. However, the argument is complex, as is exemplified in a research extensive review by Martell et al.[114] This study found that the efficacy of long-term opioid use in reducing chronic pain was no more effective than placebo. Further, the prevalence of lifetime substance abuse in chronic pain patients taking opioid therapy was 36% to 56%, and the current level of substance abuse disorders was 43%. In sum, these studies indicate that substance abuse should only be considered a risk factor if the patient meets DSM-IV criteria for substance abuse, and especially when these medications or alcohol provide inadequate pain relief and do not help to maintain the patients' functional ability.[11]

CONCLUSION

A growing body of research reviewed in this chapter indicates that psychosocial factors can strongly influence spine surgery outcome. These results suggest that PPS should be included as a component of the diagnostic process in many spine surgery candidates. Table 75.2 provides a set of general referral guidelines that a physician can keep in mind when considering the need for PPS. When the surgeon, comparing a patient with other spine surgery candidates he or she has evaluated, judges that the patient displays four or more of these points listed in Table 75.2, a referral for PPS should be initiated. Such a referral is especially critical to the extent that the planned surgery is highly invasive (involving multiple levels, instrumentation, and so forth), is exploratory, involves a reoperation, or when the pain is particularly protracted (greater than 1 year in duration).

The major psychosocial factors contributing to poor surgical outcome are listed in Table 75.3. PPS surgical prognosis is based on the number of these risk factors identified. Research from our laboratory[115] has found that patients with nine or more risk factors are at risk for poor surgical outcome. In our study, 204 spine surgery candidates underwent PPS, using a semistructured interview and psychological testing including the MMPI. Outcome of spine surgery was assessed at approximately 6 months postoperatively. Poor outcome (measured in terms of continued pain greater than 4 on a 10-point scale, continued use of opioid medications, and severe activity restrictions) was obtained in 83% of patients having nine or more risk factors. Poor results were obtained in only approximately 18% of patients with fewer than nine risk factors. Such findings parallel those of other researchers who found, using a similar *scorecard* approach to identifying risk factors, that patients with a high level of overall risk respond poorly to spine surgery.[21,72,74] For a more complete discussion of determination of prognosis, as well as psychological intervention in surgical candidates, see Block.[10]

The results reviewed in this chapter demonstrate that spine surgery may not be very effective when applied to patients having a high level of psychosocial risk. For such patients, more conservative intervention appears more appropriate and effective. Fortunately, a cost-effective alternative to spine surgery exists—the multidisciplinary chronic pain management program (CPMP).

TABLE 75.2

REFERRAL GUIDELINES FOR PRESURGICAL PSYCHOLOGICAL SCREENING

- Excessive pain behavior
- Symptoms inconsistent with identified pathology
- High levels of depression or anxiety
- Sleep disturbance: insomnia or hypersomnia
- Excessively high or low expectations about surgical outcome
- Marital distress or sexual difficulties
- Negative attitude toward work or employer
- Emotional lability or mood swings
- Inability to work or greatly decreased functional ability (<3 mo)
- Escalating or large doses of narcotics or anxiolytics
- Litigation or continuing disability benefits resulting from spine injury
- Referral considerations
  - 0–1 items: not necessary to refer unless desired by patient
  - 2–3 items: consider referral for presurgical psychological screening
  - 4+ items: strongly consider referral for presurgical psychological screening

TABLE 75.3

PRESURGICAL PSYCHOLOGICAL SCREENING RISK FACTORS FOR POOR SURGICAL OUTCOME

Personality Factors (assessed by objective tests, such as the MMPI-2)
- Pain sensitivity
- Anger
- Depression
- Anxiety and obsessions

Poor Coping Strategies (assessed by objective tests)
- Catastrophizing
- Low self-efficacy or pain control

Behavioral Factors
- Spousal reinforcement of pain (West Haven-Yale Multidimensional Pain Inventory)
- Litigation pending
- Workers' compensation
- Blaming employer for injury

Historic Factors
- Abuse and abandonment
- Past psychological treatment
- Multiple previous medical problems
- Substance abuse

Presurgical Psychological Screening Prognosis
- Good: 0–4 risk factors
- Fair: 5–8 risk factors
- Poor: 9–14 risk factors

Such programs teach patients to manage and cope with pain and its impacts, through a combination of physical conditioning, education, psychological treatment, relaxation training, and vocational counseling. Several recent studies have shown that the CPMP approach can be as effective in treating spine pain patients as is spine surgery. Brox et al.[116] studied 64 Swedish patients with evidence of severe disc degeneration lasting more than 1 year. These patients were randomly assigned to undergo either: (1) lumbar fusion with posterior transpedicular screws and postoperative physical therapy; or (2) a modified CPMP involving cognitive-behavioral intervention with three daily physical exercise sessions for 3 weeks. At 1-year follow-up, both groups had significant improvements in function, as measured by the Oswestry Disability Index (ODI), but there was no significant difference in functional improvement between those treated surgically and those treated nonsurgically. In addition, there were no significant differences in pain, use of analgesics, emotional distress, and return to work. Fear-avoidance beliefs were reduced significantly more in the non-surgically treated group.[117] The early complication rate for the surgically treated group was 18%.

Additional support for the use of CPMP has been obtained by Fairbank et al.[118] who examined 349 patients who were uncertain if they should undergo spine surgery. These patients were randomly assigned to spinal fusion or to "intensive rehabilitation"—a CPMP. The surgical group underwent spine stabilization procedures. Subjects were followed for 24 months. The patients treated with spine surgery showed a slightly greater improvement in function as measured by the ODI, but no other comparisons between the two groups reached significance. Intraoperative complications occurred in 19 patients who underwent surgery. An additional study of these same patients[119] found that the cost of CPMP was far less than that for surgery (£4256 vs. £7830), while the percentage of patients returning to work at 2 years' was equivalent.[17] Thus, CPMP was much more cost-effective than spinal fusion. Turk and Burwinkle,[120] in a separate review of the literature, confirm and extend such findings.[18] They found that the CPMP approach is approximately 26 times more cost-effective in returning patients to work than is spine surgery. The studies comparing CPMPs to spine surgery suggest that, even when medical diagnostics reveal spinal pathology potentially amenable to surgery, many patients may achieve comparable results, with less long-term risk, by undergoing treatment at a CPMP.

In summary, through the use of PPS the surgeon can reduce the costs arising from futile procedures and can help the high-risk patient avoid a downward slide into increasing pain and disability. Based on the PPS, surgeons may decide to (1) refer the patient for treatment at a CPMP; (2) postpone elective surgery until psychosocial factors are addressed; (3) avoid surgery and other treatment altogether; or (4) proceed with surgery but involve psychologists early during rehabilitation. PPS, thus, offers the potential to sharpen patient selection for spine surgery, and tailor treatments to both the patient's physical and psychological needs.

CHAPTER 76 ■ RATIONAL PHARMACOTHERAPY FOR PAIN

ARTHUR G. LIPMAN

Pharmacology is the science that deals with the origin, nature, chemistry, effects, and uses of drugs. Commonly, pharmacology is subdivided into pharmacodynamics (how drugs work; mechanisms of action) and pharmacokinetics (how drugs are absorbed, distributed, biotransformed [metabolized], and eliminated) in the body. Pharmacology is laboratory (nonclinical) nonclinical science done largely in animal and in vitro models in the laboratory setting. Clinical pharmacology, often termed therapeutics in the UK and some other countries, is the discipline intended to translate finding from the laboratory bench to the patient bedside. Despite attempts in the U.S. to develop clinical pharmacology as a subspecialty of internal medicine, and subsequently pediatrics and psychiatry, very few clinical pharmacologists are in practice and fewer still are in training programs today. By definition, the term pharmacology and even clinical pharmacology are somewhat restrictive.

Pharmacotherapy is, simply put, the treatment of disease by medicines. This is now a recognized health science discipline and describes the practice of clinicians including many physicians, pharmacists, advanced practice nurses, pharmacologically oriented psychologists, and others. Pharmacotherapy encompasses what those who attempted to develop clinical pharmacology envisioned without restricting practice to subspecialty-certified physicians. It is an academic discipline and numerous respected journals and an increasing number of health science textbooks now have pharmacotherapy in their titles. This more inclusive term includes those aspects of pharmacology and findings from clinical pharmacology that apply directly to the use of pharmacologically active substances in patient care.

Clinicians must have access to contemporary information on how drugs work to use them optimally in managing pain. Pharmacology is the science of how the drugs work, not their application in treating patients. Thus this section of *Bonica's Management of Pain* has been redesignated Pharmacotherapy.

Pharmacotherapy is a potent tool in pain management. However, we must use drugs wisely to provide optimal patient benefit. Several core concepts in rational pharmacotherapy are introduced in this chapter as a prelude to the four subsequent chapters on specific pharmacotherapy for pain management.

DRUGS ARE BOTH UNDERUSED AND OVERUSED IN PAIN MANAGEMENT

There is a broad consensus among pain clinicians that pain, especially chronic nonmalignant pain, often is undertreated.[1] One of the reasons for this is concern about medication misuse. Increasing reports of adverse events and even fatalities associated with analgesic use indicate that some practitioners may use analgesic pharmacotherapy unwisely or excessively. It is important to view drugs as tools that can be used well or poorly. Adverse events are not due to the drugs, per se, they are due to the way the drugs are used. Clinicians are encouraged to not label any class of drugs as "good" or "bad," but to recognize that they only become so designated because of the way they are used. However, there are some drugs within various classes that one should consider suboptimal, for example, meperidine,[2] as discussed in more detail in the opioids chapter. This section will attempt to identify medication use that is more apt to have positive than adverse outcomes.

PHARMACOTHERAPY ALONE IS RARELY OPTIMAL THERAPY FOR CHRONIC PAIN

Analgesic pharmacotherapy often is appropriate alone for acute pain. However, chronic malignant and nonmalignant pain usually responds better to multimodal treatment.[3] Many adverse events due to medications might not occur if lower drug doses are used, and concurrent nonpharmacological therapy often reduces drug dose requirements (Table 76.1). Using multiple drugs to address symptoms of other drugs sometimes leads to complex regimens with adverse events, that is, polypharmacy.[4] Although it is usually wise to simplify drug regimens, use of more than one drug in combination may reduce the risk of adverse events when the drugs are additive or synergistic and the adverse events are commonly dose related. A common example is concurrent use

TABLE 76.1

EXAMPLES OF PAIN INTERVENTION ALTERNATIVES TO INCREASING OPIOID DOSE

Etiology	Treatment
Bony pain	NSAID with opioid
Neuropathic pain	TCAs, anticonvulsants, local anesthetics, topical capsaicin, nerve blocks
Infectious damage	Incision and drainage, anti-infectives
GI spasm	Anticholinergic agents
Constipation	Stimulating laxatives
Lymphedema	Physical therapy, compression

From Lipman AG. Efficacy of opioids in cancer pain syndromes. *Pain* 1995; 63:135–136.

of an opioid and a nonsteroidal antiinflammatory drug (NSAID) because these two drug classes are mutually dose sparing. One might consider such use of multiple drugs for pharmacotherapy as "rational polypharmacy."

It often is useful to consider medications for chronic nonmalignant pain as temporary interventions to facilitate the patient's adapting self-management techniques such as physical activation, cognitive restructuring, or responding to medical procedures such as serial nerve blocks.

Every Use of Medication for Pain is an Experiment

It is axiomatic that every drug has the potential to do harm. We should only use pharmacotherapy when the potential benefit outweighs the potential harm; that is, there is a favorable risk to benefit ratio. Clinicians should consider pain pharmacotherapy a trial to determine outcome before committing to ongoing pharmacotherapy. All medication orders should expire at a predetermined time and only be continued after it is clear that the benefits outweigh the risks. It is helpful in most cases to tell patients that new medications are being ordered for a limited time to determine if they should be continued. This practice would eliminate many adverse outcomes from ongoing drug therapy. This practice might also lessen inappropriate patient expectations about their drug therapy for pain. It is usually unwise to continue any medication without a clear determination that it is more helpful than harmful.

In addition to risk to benefit considerations, clinicians should always consider cost to benefit issues. Frequently, new drugs and dosage forms offer incremental advantages over previously available agents, but the new agents do so at a markedly greater cost. The pharmaceutical industry often aggressively markets new and patent-protected drugs and dosage forms while there is rarely a financial incentive for a pharmaceutical manufacturer or distributor to promote generic drugs because pharmacists can legally substitute generic equivalent drugs unless the prescriber specifies otherwise. At the extreme, entire older classes of drugs, which may still be agents of choice, have been largely replaced by newer, far more expensive agents. For example, tricyclic antidepressants still are drugs of choice for neuropathic pain, but no company promotes them. Aggressive marketing of various antiepileptic and serotonin-norepinephrine reuptake-inhibiting drugs that are as effective or nearly as effective as the tricyclic antidepressants for this indication has resulted in the newer, more expensive drugs being considered by many clinicians as the only drugs for neuropathic pain.

Patient Preference: Symptom Control versus Side Effects

Patients vary both in their desire to take medications to manage their pain and in their response to the medications. Many patients are highly averse to taking medications, especially opioids, even when those medications can greatly reduce the pain. This aversion may be due to fears or misconceptions about the medications, and clinicians should inquire about their patients' beliefs and preferences when considering pharmacotherapy. When a patient with allergies indicates a preference for a particular antihistamine, we normally provide that medication. However, when a chronic pain patient expresses a preference for a particular opioid, many clinicians become suspect that there is an ulterior motive for specifying a drug of choice. The perceived preference may be due to prior experience, observation of other patients' good or bad response to opioids, or misconceptions. We should ascertain the basis for our patients' expressed preferences when feasible rather than draw our own—often inaccurate—conclusions. Obviously, we should correct wrong information on which patients express preferences.

Some chronic pain patients prefer to be more alert even though the trade-off may be more intense pain. Others prefer as much pain relief as possible with the accompanying dulling of their senses. Neither preference is right or wrong. It is very reasonable to counsel patients about the side effects of the analgesics and adjuvants we are considering and ask them their preferences regarding comfort versus alertness. One of the most problematic misconceptions among chronic pain patients is that medication will "cure" their pain. It is important to determine if the patient harbors such beliefs and to correct them when possible.

There is great interpatient variability in response to analgesics. We see this commonly with NSAIDs but cannot explain the mechanism. With opioids, it also is common and we know several sources of genetic polymorphism that cause interpatient variability[5] as described in more detail in Chapter 78. Clinicians should actively counsel patients about the need to adjust medications and doses to optimize response: one size does not fit all.

Whenever Possible Treat the Cause of the Pain

A commonly espoused concept in opioid pharmacotherapy is to increase the medication dose until the patient experiences either adequate pain relief or unacceptable side effects. While there may be some wisdom in this approach, it also has two major problems.[6] One is that opioids are not the therapy of choice for all types of pain. For example, bone pain in which there is inflammation often responds better to NSAIDs than to opioids, and nearly always responds better to a combination of these two drug classes than to opioids alone. Likewise, neuropathic pain nearly always responds better to a combination of opioids and tricyclic antidepressants or anticonvulsant medications with fewer side effects than will be seen with one class alone. Again, a combination of both a neuropathic pain-specific agent with an opioid is usually synergistic. Opioids can actually blunt pain from constipation, but would probably exacerbate the constipation. It is far better to identify the cause of the pain and to treat it with specific modalities than to simply use opioids and increase the dose to response. Examples of painful conditions that are indications for such alternate modalities include incision and drainage with anti-infectives for painful infected cysts, physical therapy for myofascial pain, and massage with pressure for pain due to painful lymphatic drainage blockade.

The second limitation is that several opioid dosage forms, most notably the newer long acting ones, are very expensive. The great interpatient variability in response to opioids supports changing drugs when a patient does not respond as expected after two or three dose increments. Such patients may well respond better to other opioids to which they are rotated in such cases. Thus, serial trials of different opioids to find the optimal drug are sometimes indicated.

Synergism and Potentiation

Additive effects may occur when we use two pharmacological agents concurrently and the combined effect equals the sum of the two agents' effects. Unless doing so provides a specific benefit, for example, dose sparing with drugs that have problematic dose-related adverse effects, additive pharmacotherapy usually is not warranted. It simply complicates the regimen reducing patient adherence (compliance) and often increases cost. Synergism occurs when two drugs act together to produce a supradditive action. This often is desirable. An example is using an NSAID with an opioid for their mutually synergistic effects. Synergism occurs because of the two different mechanisms and the NSAID being

anti-inflammatory with the opioid acting largely centrally while NSAID provides peripheral anti-inflammatory activity. Potentiation is an effect in which one drug enhances the action of another. An example is the concurrent use of acetaminophen and morphine, which has been demonstrated in rat model.[7] Both drugs are simple analgesics, that is, they have no anti-inflammatory activity. The opioid is far more active than the acetaminophen but the latter increases the effectiveness of the former by acting at the serotonergic system in the brain. Although the concurrent use of acetaminophen can be clinically useful, the net clinical advantage of combination therapy is less than occurs when an opioid is used with an NSAID producing the two-way advantage of synergism.

Outcomes Analyses of Pain Pharmacotherapy

Clinical studies of analgesics have traditionally focused largely, if not exclusively, on efficacy. Efficacy is defined simply as the ability of an agent to have a desired effect. Studies of analgesic efficacy for chronic pain typically last only 3 to 6 weeks. Commonly, reduction in pain intensity is the measured outcome. Every pain clinician knows that long-term effectiveness is the outcome measure needed to determine the usefulness of a drug for chronic pain and that patients' ability to function, to carry out activities of daily living, is often more important than pain intensity, per se. These should be the criteria for effectiveness.

The pharmaceutical industry is beginning to conduct true effectiveness studies in support of their products. When more clinicians insist upon such evidence before adopting new drugs that are supported only by the short-term efficacy studies needed for the drugs to be approved for human use, we will see more true effectiveness studies.

Clinical outcomes studies comprise only one of the three types of studies needed to assess the place of drugs in pain management. Health-related quality of life (HRQoL) research is a relatively new discipline that provides important information for such subjective complaints as pain.[8] The gold standard for HRQoL is the Medical Outcomes Study Short Form 36 (MOS SF-36).[9] While this instrument provides useful population data, it lacks the specificity and sensitivity needed for utility as a clinical monitoring tool in chronic pain management. The Treatment Outcomes of Pain Survey (TOPS) is a pain-enhanced SF-36 that is useful for monitoring outcomes of chronic pain patients.[10] HRQoL studies provide valuable clinical information on how interventions affect patients' ability to function, not just their subjective pain intensity report.

The third type of study that is becoming increasingly important is pharmacoeconomic (PE) analyses. Pain management has become more complex, more invasive, and more expensive in recent years. Five types of PE studies that help define which interventions are apt to provide the most benefit are listed in Table 76.2.[11]

Approved Drugs and Drugs for Nonapproved Uses

For a drug to be available for routine clinical use in the United States, the manufacturer or distributor (sponsor) must hold an approved new drug application (NDA) from the U.S. Food and Drug Administration (FDA). The FDA can legally issue an NDA only after the sponsor has completed three phases of clinical studies under a license for those studies called an investigational new drug exemption (IND). The IND specifies exactly how and in whom the investigators can use the drug and use outside of those restrictions can lead to criminal penalties. Only clinicians explicitly named on the IND or persons under their direct supervision can legally participate in the studies. Once the FDA licenses a new drug for human use, any licensed prescriber can legally use it for any human use. However, the sponsor cannot legally advertise or market the newly approved drug for indications outside of the labeling even when good scientific evidence supports such use. This includes any continuing professional education activities directly supported by the sponsor. Furthermore, the indications that are listed in the labeling (package insert) for the newly approved drug can, by law, only include those indications approved by the FDA based on clinical studies submitted by the sponsor in support of the NDA.

If the sponsor provides an unrestricted educational grant to a professional society, hospital, or other such uninterested party, that organization can sponsor continuing professional education in which presenters can discuss nonapproved uses of the drug based on scientific and professional publications and findings. Thus, for example, a sponsor cannot legally promote an antiepileptic drug that is not FDA approved for neuropathic pain management for that indication even if there is good scientific evidence of the efficacy of the drugs for that indication. Neither can professionals paid directly by the sponsor make continuing education presentations in which they discuss "off-label" use in any program. That would be defined as marketing the drug for an unapproved use. However, this in no way constrains licensed prescribers from prescribing the medication for off-label use as long as an NDA has been issued for another human use.

If a patient suffers an adverse event from a drug prescribed off label, the harmed parties can initiate civil (malpractice) litigation against the prescriber and the health care facility where this occurred. There normally are no grounds for criminal action against the practitioner for prescribing an approved drug even though it was for an unapproved indication. Published scientific evidence supporting the use of the drug as prescribed is normally a good defense in such actions. The lack of such evidence greatly increases the prescribers' exposure to civil litigation.

Pain patients often have comorbid mood disorders and sometimes they are already involved in litigation relating to the cause of their pain. These factors may increase the risk of litigation against pain clinicians if the patients are dissatisfied with the care they receive. Therefore, pain clinicians should remain aware of legal issues when planning an implementing pharmacotherapy for such patients. Opioids and other such potent medications are essential in pain management, however, and clinicians should not hesitate to use such pharmacotherapy when indicated. Clinicians should always carefully document what they are doing as recommended by the Federation of State Medical Boards of the United States. In its 2004 Model Policy for the Use of Controlled Substances for the Treatment of Pain (http://www.fsmb.org/pdf/2004_grpol _Controlled_Substances.pdf) the Federation explicitly states that quality medical practice dictates pain relief and that inadequate care results from lack of knowledge. The Model Policy further states that (state medical) boards should define boundaries of practice. Criteria for evaluating the use of con-

TABLE 76.3

GUIDELINES FOR EVALUATING THE USE OF CONTROLLED SUBSTANCES FOR PAIN CONTROL

- Evaluation of the patient
- Written treatment plan with stated objectives
- Informed consent and agreement for treatment
- Periodic review at reasonable intervals
- Consultation as necessary for additional evaluation
- Accurate and complete medical records to include
  - —The medical history and physical examination
  - —Diagnostic, therapeutic, and laboratory results
  - —Evaluations and consultations
  - —Treatment objectives
  - —Discussion of risks and benefits
  - —Treatments
  - —Medications (including date, type, dosage, and quantity prescribed)
  - —Instructions and agreements
  - —Periodic reviews
- Compliance with controlled substance laws and regulations

Federation of State Medical Boards of the United States, Inc. Model policy for the use of controlled substances for the treatment of pain. Available online at: http://www.fsmb.org/pdf/2004_grpol_Controlled_Substances.pdf. Accessed June 25, 2009.

trolled substances and information to document in the medical record when doing so are listed in Table 76.3.

Rational Pharmacotherapy

The criteria for rational pharmacotherapy are simple. The drug must be legal, that is, there must be an NDA for at least one human use. If the drug is used for a nonapproved use, the clinician should assure that there is good evidence supporting that use. The clinician must be confident that the potential benefit for use of the drug in that specific patient in the regimen prescribed presents potential benefits that outweigh the potential risks. To make that determination, the clinician must understand both the pharmacodynamics and pharmacokinetics of the drug. The recent increase in deaths due to methadone is attributable in part to the prescribers not understanding the long elimination half-life of the opioid. When any opioid dose is increased before the drug has reached steady-state serum levels, there is risk of accumulation toxicity. Due to the relatively high cost of commercially available long acting opioids, several third party payers encouraged primary care clinicians to change their patients from the more expensive analgesics to methadone. However, methadone, a pharmacologically long acting opioid, has a much longer half-life than pharmaceutically long acting opioids such as sustained-acting oxycodone. That difference in half-life without necessary changes in the opioid regimen when initiating methadone appears to be at least one factor in the increased number of methadone deaths observed in the last decade.[12]

CONCLUSION

Pharmacotherapy is essential in the management of nearly all acute pain and the majority of chronic pain patients. Safe and rational use requires attention to the risk to benefit ratio in each clinical situation. It is not logical to provide analgesics for every patient in pain, nor is it reasonable to deny analgesic medication when it is needed.

Pharmacotherapy is the most common modality used to treat pain. Too often pharmacotherapy is used as a sole intervention. Most patients with moderate to severe acute pain or any chronic pain would benefit more from multimodal therapy.

Recent statements and publications emphasizing the risks of pharmacotherapy without providing a balanced discussion of the benefits of these drugs have discouraged some clinicians from using needed medications for pain. The U.S. Drug Enforcement Administration (DEA) has taken positions that discourage opioid pharmacotherapy [13] and the American Heart Association has discouraged NSAID use due to cardiovascular risk without addressing the major improvement in quality of life that millions of patients receive from these medications.[14] The DEA posits that reducing opioid use will reduce opioid abuse. While that may be true, it would occur at the cost of countless pain patients suffering unnecessarily. The American Heart Association position looks at the cardiovascular risks associated with NSAIDs. However, it does not consider the impact of painful inflammatory diseases such as osteoarthritis, which erode the quality of life of millions of patients.

Pain clinicians must be effective advocates for rational pharmacotherapy for their patients. To do so, we must be knowledgeable about the drugs we use. We also must assure that our patients and their families have accurate information to help them use the medications correctly. The following four chapters provide a scientific basis for that advocacy and use.

CHAPTER 77 ■ NONSTEROIDAL ANTI-INFLAMMATORY DRUGS AND ACETAMINOPHEN

ASOKUMAR BUVANENDRAN AND ARTHUR G. LIPMAN

INTRODUCTION

Nonsteroidal anti-inflammatory drugs (NSAIDs) are a diverse group of compounds with analgesic, antipyretic, and anti-inflammatory activity. The prototypical NSAID, aspirin, has been largely replaced by newer NSAIDs which often are better tolerated and which do not present the aspirin-associated risk of Reye's syndrome in children who are exposed to influenza viruses.[1] Today, NSAIDs are the most widely prescribed drugs in the world, with sales greater than 2 billion dollars in the United States and 6 to 8 billion dollars worldwide. They are valuable in the management of both acute and chronic painful and inflammatory conditions and are administered by both systemic and local (topical) routes.

The earliest agent in this class, which has been used in folk medicine for millennia, is willow bark. Hippocrates wrote about the use of powdered willow bark for pains and fever in the fifth century BCE. Edward Stone formally reported salicylic acid extracted from the bark and leaves of willow, myrtle, and a number of other plants, as a medication for fever in 1763. Felix Hoffmann, a chemist at Bayer Pharmaceuticals in Germany, rediscovered the acetylsalicylic acid formulation which Bayer then named Aspirin and began marketing it for pain, fever, and inflammation early in the twentieth century. Only in the mid-twentieth century did aspirin become the generic name for that compound.

The newer NSAIDs were introduced in the 1960s, the first being indomethacin which was soon followed by ibuprofen. Numerous other NSAIDs promptly followed, most of which claimed better efficacy and safety than earlier compounds. In the past two decades, several NSAIDs have been removed from commercial availability due to potentially lethal side effects after they were in general use. Phenylbutazone and oxyphenbutazone lost popularity and were withdrawn due to blood dyscrasias. Suprofen caused nephrotoxicity. Benoxaprofen, bromfenac, and ibufenac (which was marketed in the United Kingdom, not the United States) caused serious hepatotoxicity. Two of the three cyclooxygenase-2 (COX-2) selective NSAIDs approved in the United States in the 1990s were subsequently withdrawn from the market as noted below in the discussion of the COX-2 selective agents. Today, over two dozen NSAIDs are commercially available in the United States for clinical use (Table 77.1) and several others are available in other countries as well.

MECHANISM OF ACTION

Prostaglandin Synthesis and Pharmacology

NSAIDs act by inhibiting prostaglandin synthesis in vivo. Prostaglandins (PGs) are derived from arachidonic acid and other polyunsaturated fatty acids; the 20-carbon polyunsaturated essential fatty acid (arachidonic acid) is the major source in mammalian tissues. PGs derived from arachidonic acid contain two double bonds. These are PGE_2, thromboxane and prostacyclin. Analogous compounds synthesized from eicosatrienoic (linoleic) and eicosapentaenoic acids contain one fewer or one more double-bond in the side chains (PGE_1, PGE_3, respectively).[2] The PGs, thromboxanes, hydroxy acids, and leukotrienes which retain the 20-carbon unsaturated fatty acid backbone are collectively known as eicosanoids.[3] Their release, usually as a result of trauma, is the major stimulus for eicosanoid production, as PGs cannot be stored and are released as soon as they are synthesized.[4] Cell membrane disruption causes phospholipid release, which is converted to arachidonic acid by the action of phospholipase A_2. Arachidonic acid then acts as a substrate for the COX enzyme.

PGs also are involved in the pyretic response. After injection of pyrogens, cerebrospinal fluid (CSF) PG levels rise. That effect can be prevented by pretreatment with aspirin.[5] Acetaminophen (paracetamol) is analgesic and antipyretic but lacks clinically useful peripheral anti-inflammatory activity. Acetaminophen blocks PG synthetase within the blood brain barrier, but not peripherally in a clinically meaningful way. Therefore, it is not an NSAID, per se, although it is commonly used for many of the same indications as NSAIDs. Acetaminophen is discussed in more detail later in the chapter.

Prostanoids do not generally activate nociceptors directly; they sensitize them to mechanical stimuli and chemical mediators of nociception such as bradykinin.[6] PGE_2 is the predominant eicosanoid released from endothelial cells of small blood vessels[7] and is a key mediator of both peripheral and central pain sensitization.[3] Because it is the prostanoid most associated with inflammatory responses, the formation of PGE_2 at inflammatory sites is often considered an indicator of local COX activity and suppression of PGE_2 is an indicator of a decreased inflammatory process.[8] The production of PGE_2 is slow in onset and of long duration in response to inflammation.[9]

COX is encoded by 2 genes.[10] Although the isomerization of PGH_2 into PGE_2 has been well-characterized biochemically and pharmacologically, the enzyme responsible, PGE synthase (PGES), was only recently purified and cloned.[11,12]

COX-1 and COX-2 Selectivity

The existence of more than one COX isoform, and specifically one that is positively regulated by cytokines and negatively regulated by glucocorticoids, was long suspected. In the early 1990s, an inducible COX isoenzyme was cloned.[13] The recognition of two COX isoforms, then designated COX-1 and COX-2, generated intense efforts to characterize the relative contribution of each isoform to prostanoid production in specific situations (Fig. 77.1).

COX-1 and COX-2 are membrane-associated enzymes with a 60% amino acid sequence homology.[14] In spite of their structural similarity, the two COX isoforms have different gene expression profiles, distinct kinetic properties, and different interactions with PLA_2s and synthases.[15] COX-1 is expressed constitutively and produces prostanoids that fine-tune physiologic processes requiring instantaneous or continuous regulation such as hemos-

TABLE 77.1

ACETAMINOPHEN AND NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS) AVAILABLE IN THE UNITED STATES

Medication	Proprietary (trade) name	Half-life (H)*	Percent protein bound	Usual 24-hour adult dose range	Adult daily dose and frequency		Usual daily pediatric dose mg/kg/per 24 hours
					Dosage	Schedule	
Para-aminophenol derivative							
Acetaminophen	Tylenol, others	2	20–50	2–4 g	325–650 mg 650 mg–1 g	Q4H QID	Dose varies with body weight and age
Salicylates							
Aspirin	Multiple	2–3	~90	2.4–6 g	600–1500 mg	QID	80–100 mg/kg/24h
buffered aspirin	Ascriptin, Bufferin, others			2.4–6 g	600–1500 mg	QID	80–100 mg/kg/24h
enteric-coated aspirin	Ecotrin, others			2.4–6 g	600–1500 mg	QID	80–100 mg/kg/24h
Choline magnesium trisalicylate	Trilisate Tricosal	2–3	90	1.5–3 g	500–1000 mg 750–1500 mg	TID BID	50–65 mg/kg/24h
Diflunisal	Dolobid	8–12	99	1–1.5 g	500–750 mg	BID	NA
Salsalate	Disalcid	1	90	1.5–3 g	750–1500 mg	BID	NA
Propionic acid derivatives							
Fenoprofen	Nalfon	2	99	1.2–2.4 g	300–600 mg	QID	900 mg–1.8 g per body surface area meter^2
Flurbiprofen	Ansaid	2	99	200 mg	100 mg	BID	NA
Ibuprofen	Motrin, Advil, others	6	99	1.2–2.4 g (pain) 2.4–3.2g (inflammation)	OTC: 200–400 mg Rx: 400, 600, 800 mg Maximum: 3200 mg	QID QID	30–40 mg/kg/day as 3–4 doses
Ketoprofen	Orudis	2–4	99	225 mg	75 mg	TID	NA
Naproxen	Naprosyn, others	14	99	750 mg–1 g	250, 375, 500 mg	BID	10–20 mg/kg/24h as 2 doses
Naproxen Sodium	Aleve, Anaprox	14	99	550–1100 mg	275–550 mg	BID	10–20 mg/kg/24h as 2 doses
Oxaprozin	Daypro	40–60	99	1.2 g	1.2 g	Once daily	1 =20 mg. kg/d

Fenamates							
Meclofenamate	Meclomen	2–3	99	150–400 mg	50–100 mg	TID, QID	NA
Diclofenac	Voltaren, in Arthrotec	1–2	99	150–200 mg	50 mg 75 mg	TID BID	2–3 mg/kg/24h
Tolmetin	Tolectin	5	99	800–2400 mg	400, 600, 800 mg	TID, QID	20–30 mg/kg/24h as 3–4 doses
Ketorolac	Toradol	4–6	99	Oral: not >60 mg/day Parenteral 30–60 mg, then 15–30 mg	Oral: 10 mg Q6H for not >5 days total	QID	IV: 0.5 mg/kg/day single dose only IM: 1 mg/kg/day single dose only
Mefenamic acid	Ponstel	3–4	99	1.0–4.0 g	250 mg	QID	NA
Enolic acid derivatives (oxicams)							
Meloxicam	Mobic	15–20	99	7.5–15 mg	7.5 mg (OA) 15 mg (RA)	Once daily Once daily	NA
Piroxicam	Feldene	40–50	99	20 mg	10, 20 mg	Once daily	NA
Nabumetone	Relafen	24	99	1.0–1.5 g	500–750 mg	BID	NA
Acetic acid derivatives							
Etodolac	Lodine	7	99	400–1200 mg	200–300 mg maximum: 1200 mg	BID, TID, QID	15–20 mg/kg/24h
Indomethacin	Indocin Indocin SR, others	2.–4.5	90	<200 mg	25–50 mg SR: 75 mg; rarely >150 mg	TID or QID BID	2–4 mg/kg/24h
Sulindac	Clinoril	8–16	99	400 mg	150, 200 mg	BID to TID	NA
COX-2 selective NSAID (coxib)							
Celecoxib	Celebrex	6–12	97	200 mg	100–200 mg 400 mg acute pain	1–2 times daily	3 mg/kg BID

NA, not applicable; OTC, over-the-counter; Q4H, every 4 hours; QID, four times/day; TID, three times/day; Rx, prescription; SR, sustained release.

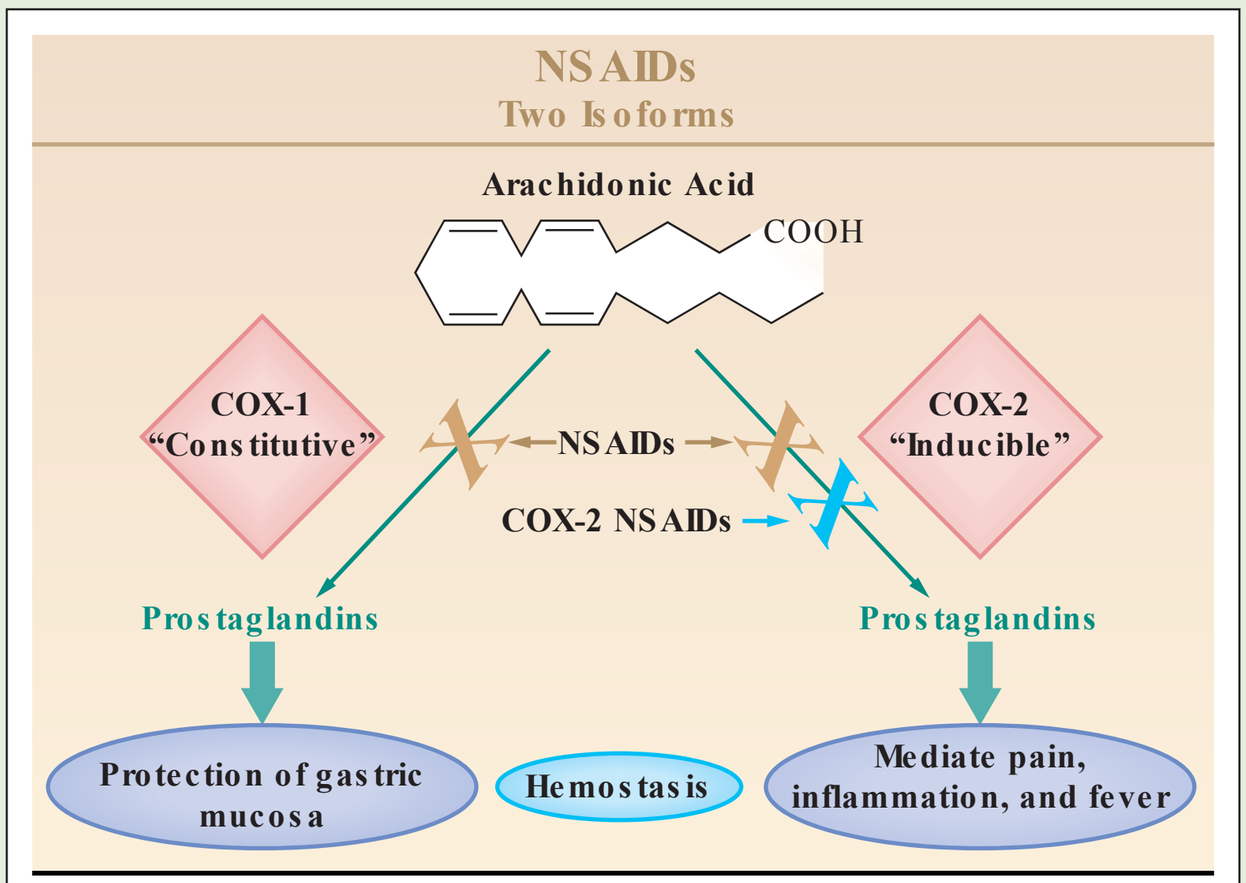

FIGURE 77.1 Simplified arachidonic acid pathway differentiating COX-1 and COX-2 effects.

tasis.[14] COX-2 expression is usually low but can be induced by numerous factors including neurotransmitters, growth factors, proinflammatory cytokines, lipopolysaccharide, calcium, phorbol esters, and small peptide hormones.[16] However, there are exceptions to the original constitutive versus inducible theory of COX expression. COX-1 expression can be induced in some stress conditions, such as nerve injury, and many tissues, including the central nervous system (CNS) and the kidney, constitutively express COX-2.[16] In the spinal cord, there are detectable basal levels of both COX-1 and COX-2 that might enable immediate reactions to transmitter release that result in prostanoid production.[17] A third isoform designated COX-3, that was identified in dogs, is formed as a splice variant of COX-1.[18] Because canine COX-3 can be inhibited by therapeutic concentrations of acetaminophen, initial reports postulated that COX-3 inhibition was the mechanism of action of acetaminophen. However, this does not appear to be true; more recent evidence indicates that COX-3 is not expressed in humans.[19]

Peripheral and Central Induction of COX-2

The original hypothesis formulated by John Vane in his Nobel Prize-winning work on the mechanism of action of NSAIDs was that these compounds inhibited prostanoid production in the periphery preventing a sensitizing action of PGE_2 on the peripheral terminals of sensory fibers.[20] Peripheral inflammation induces an increase in COX-2[21] and PGES expression in the CNS. The proinflammatory cytokine interleukin 1β (IL-1β) is up-regulated at the site of inflammation and plays a major role in inducing COX-2 in local inflammatory cells by activating the transcription factor $NF\text{-}_kB$.[22] IL-1β is also responsible for the induction of COX-2 in the CNS in response to peripheral inflammation. However, this is not the consequence either of neural activity arising from the sensory fibers innervating the inflamed tissue or of systemic IL-lβ in the plasma. Rather, peripheral inflammation produces some other signal molecule that enters the circulation, crosses the blood-brain barrier, and acts to elevate IL-lβ, leading to COX-2 expression in neurons and nonneuronal cells in many different areas of the spinal cord.[3,23] An elevation of COX-2 also occurs at many levels in the brain and spinal cord, mainly in the endothelial cells of the brain vasculature.[24] Thus, there appear to be two forms of input from peripheral inflamed tissue to the CNS. The first is mediated by electrical activity in sensitized nerve fibers innervating the inflamed area, which signals the location of the inflamed tissue as well as the onset, duration, and nature of any stimuli applied to this tissue.[21] This input is sensitive to peripherally acting COX-2 inhibitors and to neural blockade with local anesthetics, as with epidural anesthesia.[25] The second is a humoral signal originating from the inflamed tissue, which acts to produce a widespread induction of COX-2 in the CNS. Regional anesthesia does not affect this[23,26]; it only is blocked by centrally acting COX-2 inhibitors.[23,25] One implication of this is that patients who receive neuraxial anesthesia for surgery might also need a centrally acting COX-2 inhibitor to optimally reduce postoperative pain and the postoperative stress response.[25] Therefore, the permeability of the blood-brain barrier to both nonselective and COX-2 selective NSAIDs is important.[27,28] Inhibitors of COX-2 that better penetrate the blood-brain barrier might represent more efficient analgesics and could also act to reduce many of the more diffuse aspects of inflammatory pain, such as generalized aches and pains, depression, and loss of appetite, which are key aspects in determining the "quality of life" response to treatment.[29] The main process by which a drug passes from the circulation into the CNS is passive diffusion. Lipophilicity and ionization are critical determinants of this transfer.[30] The CSF represents a convenient sampling point for drugs that enter the CNS; however, there are very few NSAIDs for which the CSF pharmacokinetics have been defined.[31] The high lipid solubility of indomethacin allows it to rapidly cross into the CSF and equilibrate with the free plasma concentration.[32] Similar results are seen with ketoprofen.[33]

PHARMACOKINETICS

NSAIDs are weak acids with pK_a values typically lower than 5. Since weak acids will be 99% ionized two pH units above their pK_a, these anti-inflammatory agents are present in the body mostly in the ionized form. Although NSAIDs differ in their individual pharmacokinetic properties, some general factors affecting NSAID pharmacokinetics can enable clinicians to select among the different agents available.

Absorption

Most NSAIDs are rapidly absorbed following oral administration, with peak plasma concentrations generally reached within

2 to 3 hours, though slow-release dosage forms have been developed to maintain active plasma levels for prolonged times. Factors affecting gastric emptying may profoundly affect the time course of the clinical effect of an NSAID. The extent of drug absorption from the gastrointestinal (GI) tract is more important than the rate.[34] Rectal and topical administration minimize GI side effects that are common with these agents. In general, the rate and extent of NSAID absorption is comparable for the rectal and oral routes.[35] Rectal NSAIDs have been used effectively, primarily for short-term postoperative analgesia[36] in some European countries. They are not commonly used in the United States largely due to cultural preferences.

There is good evidence that topical NSAIDs can be safe and effective and that they produce less GI toxicity than systemic forms of the same drugs.[37,38] These topical forms can be effective for inflammation of the knee and surface tissues; they generally are not effective for deeper structures. Topical NSAIDs must be properly formulated. Although extemporaneously compounded topical NSAIDs have been used, these are often ineffective. The vehicle and formulation can profoundly influence the efficacy of the topical dosage form.[39] In the United States, both a diclofenac topical patch (Flector, King Pharmaceuticals, Inc., Bristol, TN) and gel (Voltaren Gel, Novartis Consumer Health, Inc., Parsippany, NJ) were commercially available at the time of this writing. A Canadian topical solution formulation (Pennsaid, Nuvo Research Inc., Mississauga, Ontario, Canada) that is not yet available in the United States at the time of this writing is also supported by good clinical studies.[40] Topical NSAID dosage forms available in several countries are listed in Table 77.2.

Intravenous and intramuscular NSAIDs forms are available in several countries. Ketorolac is the only parenteral NSAID available in the United States. Parecoxib, an injectable analog for the COX-2 selective NSAID valdecoxib was under study, but those trials ceased when valdecoxib was withdrawn. Parenteral administration may be advantageous in renal colic due to a more rapid onset than oral administration, but has demonstrated no advantage over oral forms for any other indication.[41] Several injectable NSAID dosage forms, such as diclofenac and ibuprofen, were in phase II and III trials at the time this chapter was written.

Distribution

NSAIDs other than aspirin are generally lipid soluble, weakly acidic, and highly bound to plasma proteins, primarily albumin. In most cases, less than 1% of the total plasma concentration exists in the unbound form. Hypoalbuminemia increases the free fraction of NSAIDs in the plasma, thus affecting the distribution and elimination of these agents.[42] The high degree of serum protein binding increases interaction risk with other highly serum protein bound drugs. Most NSAIDs have distribution volumes between 0.1–0.15 L/kg.

In inflammatory joint disease, NSAID effectiveness corresponds to the affected joint synovial fluid drug levels. Those correlate closely with the drug concentration at the active site, since there is simple transport of drugs across the synovial membrane.[43,44] The amount of drug in synovial fluid is dependent on the amount of albumin in the joint, which is lower than in plasma.[45]

Elimination

Hepatic biotransformation is the major elimination pathways for most NSAIDs[46] which are metabolized by cytochrome P-450-mediated oxidation and/or glucuronide conjugation. Renal excretion of unmetabolized drug is a minor elimination pathway for most NSAIDs, accounting for less than 10% of the administered dose. Some NSAID metabolites are excreted to a significant extent via the bile.

Pathophysiologic Conditions Affecting the Kinetics of Nonsteroidal Anti-Inflammatory Drugs

Renal Failure

Renal failure influences NSAID kinetics by reducing renal excretion of the drugs and metabolites normally eliminated in the urine and by affecting the distribution and biotransformation of drugs.

Absorption and Distribution. The absorption of NSAIDs is not impaired in renal failure patients. However, the plasma protein binding of many acidic compounds such as the NSAIDs is impaired in renal failure patients.[47] The result is an increase in the volume of distribution of the unbound fraction of the drug in plasma.

Elimination. An increase in the unbound fraction of the drug in plasma may lead to an increase in total plasma clearance of the NSAID. The clearance of those NSAIDs for which formation of acyl glucuronides is a major elimination pathway is significantly reduced in patients with renal failure.[48] The acyl glucuronide forming NSAIDs (diflunisal, ketoprofen, naproxen, indoprofen, benoxaprofen, tiaprofenic acid) are usually rapidly excreted in urine, but accumulate in plasma of patients with renal failure. The effect of renal failure on the oral clearance of several NSAIDs (e.g., ibuprofen, fenbufen, isoxicam, and piroxicam) is small.[49] Most of these compounds are metabolized by oxidative pathways. All NSAIDs are very highly bound to plasma proteins, and hemodialysis will not likely result in increased elimination of these agents. No dosage adjustments are therefore necessary for hemodialysis patients receiving NSAIDs.[48]

Hepatic Disease

Absorption and Distribution. Because the majority of NSAIDs are low clearance drugs, mild to moderate liver disease should theoretically not interfere with their oral bioavailability. Since the liver is the major organ for the synthesis of albumin, the major binding protein for NSAID in plasma, hepatic dysfunction would be expected to cause alterations in the unbound drug fraction in plasma.

Elimination. Since most NSAIDs have a small total intrinsic clearance (oral clearance) relative to blood flow, hepatic clearance is essentially independent of flow and reflects drug metabolizing capacity. The elimination of ibuprofen does not seem to be affected in patients with mild to moderate liver disease.[50]

SPECIFIC DRUGS

All NSAIDs are analgesic, anti-inflammatory, and antipyretic. Differences among the drugs in their approved label indications reflect the studies submitted for approval rather than the actual indications for which the drugs are effective. Characteristics and available dosage forms of commercially available NSAIDs in the United States and much of the world are listed in Table 77.1. Initial selection of an NSAID for a specific patient should be based on the patient's past experience, dosing frequency compatibility with the patient's lifestyle, and cost. No population studies suggest that any one NSAID is more effective than another, but interpatient variability in response does occur. Because patients respond differently to various NSAIDs for reasons that are not

well understood, it is appropriate to try an NSAID at full dose for about 3 weeks and then to rotate to another NSAID if the desired effect does not occur. There is no evidence that a patient who does not respond to an NSAID in one chemical subclass (e.g., propionic acid derivatives) will respond any better to an NSAID from another chemical subclass class than to a different propionic acid derivative NSAID.

Salicylates

Aspirin

The aspirin elimination half-life increases from 2.5 hours at low doses to 19 hours at high doses. It is well absorbed from the stomach and small intestine, with peak blood levels achieved 1 hour after an oral dose. There is then rapid conversion of aspirin to salicylates from a high first-pass effect, which occurs in the wall of the small intestine and the liver. The metabolic pathways follow first-order and zero-order kinetics.[51]

Aspirin inhibits the biosynthesis of prostaglandins through irreversible acetylation and consequent inactivation of COX. This differs from the newer NSAIDs, which are reversible COX inhibitors.[52] Most cells can synthesize COX; platelets cannot. Thus, the acetylation of their microsomal enzyme lasts for the life of the platelet (10–14 days). The ability of aspirin to acetylate proteins helps explain its anti-inflammatory superiority over most other salicylates. Aspirin is the only NSAID that has been associated with Reye's syndrome, a potentially lethal disorder that produces seizures and coma. It has occurred with the use of aspirin during a viral illness in children,[53] and aspirin is now rarely, if ever, used in pediatrics.

Diflunisal

Diflunisal has potentially better GI tolerability than aspirin because diflunisal is not metabolized to salicylic acid in plasma according to the results of a study comparing it at 250 mg and 500 mg twice a day to aspirin at 600 mg four times a day.[54] Diflunisal has a shorter half-life and causes less inhibition of platelet aggregation than aspirin.

Acetic Acid Derivatives

Indomethacin

Indomethacin is well absorbed following oral and rectal administration, but the extent of absorption varies widely among patients. There is also a large interpatient variability in elimination half-life caused by extensive enterohepatic recirculation of the drug. It is highly bound to serum albumin. Metabolism involves demethylation and deacetylation in the liver with subsequent excretion of inactive metabolites and unchanged drug in the bile and urine.[55] Its clinical application is somewhat limited by a relatively high incidence of gastritis and renal dysfunction. It is used in patients with acute gouty arthritis and osteoarthritis. Indomethacin is often used in neonatology to facilitate closure of patent ductus arteriosus.

Sulindac

Sulindac resulted from the search for a drug similar to indomethacin but with less toxicity. Sulindac is an inactive prodrug that is converted after absorption by liver microsomal enzymes to sulindac disulfide, the active metabolite.[56] As few as 25% of patients on sulindac have GI problems, primarily constipation.[57] Sulindac was considered in early studies to be the least nephrotoxic of the NSAIDs, but subsequent studies failed to support this contention.[58]

Tolmetin and Etodolac

These two NSAIDs claim fewer side effects than others in the class. Tolmetin is excreted in the urine partly unchanged, partly conjugated, and as an inactive dicarboxylic acid metabolite.[59] Tolmetin can cause edema due to sodium retention and abnormal liver function, both of which are reversible upon discontinuation of this NSAID.

Etodolac is an acidic compound with a pK_a of 4.65 and is available as tablets and capsules with a dosage of up to 1 gram daily, and maximum of 1.0 gram/day. Clinical doses of 200 to 300 mg twice a day for the relief of low back or shoulder pain have been equated to analgesia with naproxen 500 mg twice a day.[60] Large clinical trials demonstrated a similar incidence of abdominal pain and dyspepsia is similar to several other NSAIDs, and gastrointestinal ulceration occurs in less than 0.3% of patients.[61] Dyspepsia occurs with etodolac in 10% of patients with a somewhat lower incidence of abdominal pain.

Ketorolac

Ketorolac is currently the only parenteral NSAID available for clinical analgesic use in the United States. It is almost entirely bound to plasma proteins (>99%). This results in a small apparent volume of distribution with extensive metabolism by conjugation and excreted renally.[62] The analgesic effect occurs within 30 minutes with maximum effect between 1–2 hours and duration of 4–6 hours (FDA-approved labeling).[63] It has antipyretic effects 20 times that of aspirin and thus can mask febrile response when given routinely to patients postoperatively. Several studies have demonstrated efficacy comparable to or exceeding that of morphine for treatment of moderate postoperative pain treatment but with fewer side effects.[64] Although ketorolac prolongs bleeding time, it does not do so excessively; however, postoperative bleeding associated with intraoperative ketorolac use has been reported.[65] There is evidence that ketorolac may act at the CNS in addition to the peripheral mode of action.[32] Dental surgery studies with ketorolac also indicate that ketorolac acts centrally[66]; however, measurements of the drug in CSF demonstrate poor penetration of the compound from plasma.[67]

When first used postoperatively at an initial dose of 60 mg followed by 30 mg doses every 4 hours, ketorolac was associated with acute tubular necrosis, especially in patients who had undergone fluid-restricted procedures. Some deaths resulted. Subsequently, to minimize this risk, doses were commonly reduced by 50% to 75%, but concerns about nephrotoxicity continue. The appropriate analgesic dose of parenteral ketorolac is controversial. There have been reports of death due to GI and operative site bleeding[69] resulting in the drug being recalled in Germany and France. In a response to these adverse events, the drug's manufacturer recommended reducing the dose of ketorolac from 150 to 120 mg per day.[63] The European Committee for Proprietary Medicinal Products recommended a further reduction of the maximum daily dose to 60 mg for the elderly and to 90 mg for the nonelderly.[70] Currently, there is consensus that the dose should be as low as 7.5–10 mg every 6 hours.[71,72] The intranasal route of administration may often produce higher levels of the drug in the CNS and CSF[73] with minimal GI side effects. Studies are underway to determine the efficacy of this drug when administered intranasally.[74]

Oral ketorolac was approved for use in the United States approximately 3 years after the parenteral form and has an efficacy similar to that of naproxen and ibuprofen.[68] The parenteral form can be administered at single doses of 30 to 60 mg or as 30 mg intramuscularly or intravenously every 6 hours, whereas the oral dose is limited to 10 to 20 mg every 4 to 6 hours for no more than 5 days because of toxicity.

Diclofenac

Oral diclofenac is a carboxylic acid functional group with rapid and complete absorption. Substantial concentrations of drug are

attained in synovial fluid, which may be one of the sites of action of diclofenac.[75] Concentration-effect relationships have been established for total bound, unbound, and synovial fluid diclofenac concentrations.[76] Diclofenac is eliminated following biotransformation to glucuronidated and sulphated metabolites that are excreted in urine with very little drug eliminated unchanged. Diclofenac has a greater high effect than other NSAIDs producing less systemic availability. Diclofenac may also have a significantly higher incidence of hepatotoxicity than other NSAIDs. The excretion of conjugates may be related to renal function. Conjugate accumulation occurs in end-stage renal disease; however, no accumulation is apparent upon comparison of young and elderly individuals.[77] Dosage adjustments for the elderly, children, or for patients with certain comorbidities (e.g., hepatic disease or rheumatoid arthritis) may not be required. Significant drug interactions occur with aspirin, lithium, digoxin, methotrexate, cyclosporin, cholestyramine, and colestipol.[78]

Parenteral diclofenac is used in Europe, and there is evidence that it reduces opioid dose requirements and pain after thoracotomy.[79] Experimental diclofenac sodium topical gel has produced effective pain relief for superficial burns.[80] Commercially available transdermal diclofenac patches provide pain relief from minor sports injuries[81] and have recently been demonstrated to be effective for postoperative pain relief.[82]

Propionic Acid Derivatives

This class of NSAIDs includes ibuprofen, fenoprofen, ketoprofen, flurbiprofen, and naproxen. A newer drug in this class is oxaprozin, which permits a once-daily dose regimen, but no other advantage over other NSAIDs.[83]

Ibuprofen

Ibuprofen was the first NSAID to become available without prescription in the United States. It is well absorbed; peak plasma levels of 15–20 μg/mL are achieved about 1 to 2 hours after a single dose. The half-life is about 3.5 hours. The drug is primarily hepatically metabolized with less than 10% excreted unchanged in the urine and bile.[84] Ibuprofen at a dose of 1200 mg/day has a predominately analgesic effect in arthritis patients. Normally, a minimum dose of 1600 mg a day is needed for clinically useful anti-inflammatory activity. At 2400 mg per day, it produces GI side effects of which nausea and dyspepsia are predominant. Renal side effects of ibuprofen appear to be dose-dependent and were not reported at the recommended dosage as over-the-counter drug (200 to 800 mg per day). Even at anti-inflammatory doses of more than 1600 mg per day, renal side effects are almost exclusively encountered in patients with low intravascular volume and low cardiac output, particularly in the elderly.[85]

Concomitant administration of ibuprofen and aspirin antagonizes the irreversible platelet inhibition induced by aspirin. Therefore, the treatment with ibuprofen in patients with increased cardiovascular risk may limit the cardioprotective effects of aspirin.[86] Other routes of administration of this drug are under study.

Ketoprofen

Oral ketoprofen reaches peak plasma levels in 1.5 to 2 hours. The half-life is 2.4 hours with an analgesic duration of 4 to 6 hours.[87] The maximum recommended dose is 300 mg. An investigational topical patch contains 100 mg of the drug. Pharmacokinetic data indicate that the plasma levels of ketoprofen 100 mg administered orally are higher than when applied by patch. Because the patch facilitates ketoprofen delivery over a full day, the drug remains continually present in the tissue adjacent to the site of application. High tissue but low plasma ketoprofen concentrations produce a therapeutic effect while plasma concentrations remain low enough to minimize systemic adverse events.[88]

Fenoprofen

The calcium salt of fenoprofen is more common; it is well absorbed and achieves a peak plasma level of 20–30 μg/mL two hours after a single oral dose with a plasma half-life of 2 to 3 hours.[89] Steady state plasma levels are reached within the first 24 hours of therapy. Fenoprofen is well tolerated compared to aspirin and causes minimal occult GI bleeding; nevertheless, dyspepsia remains the most common side effect. Most of the drug is excreted as glucuronide in the urine.

Naproxen

Naproxen sodium is also available without a prescription in the United States. Naproxen is well absorbed from the upper GI tract. Its long half-life of 13 hours makes it suitable for twice-daily administration,[90] and it takes more than 2 days to reach steady state serum levels. Excretion is almost entirely renal, primarily as an inactive glucuronide metabolite.

Naproxen has been used for the treatment of arthritis and other inflammatory diseases with superior efficacy to aspirin.[91] It causes less GI irritation than aspirin. Naproxen increases bleeding time by inhibiting platelet aggregation. When given during pregnancy, it can cross the placenta in 20 minutes and cause neonatal jaundice. Naproxen appears to have one of the safest cardiovascular profiles of all NSAIDs.

Oxaprozin

Oxaprozin is approved for the management of adult rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, soft tissue disorders, and postoperative dental pain. Oxaprozin has a high oral bioavailability (95%), with peak plasma concentrations at 3 to 5 hours after dosing.[92] It is metabolized in the liver by oxidative and conjugative pathways and is readily eliminated by the renal and fecal routes. Oxaprozin inhibits nuclear translocation of NF-kappa B and metalloproteases and modulates the endogenous cannabinoid system.[93] In a randomized study of patients with refractory shoulder pain, oxaprozin (1200 mg) once a day was superior to three doses/day of diclofenac (50 mg) in reducing pain and improving quality of life.[94]

Oxaprozin diffuses readily into inflamed synovial tissues after oral administration.[95] Although discovered more than 20 years ago, it is now under intensive investigation because of its unusual pharmacodynamic properties. Other than being a nonselective COX inhibitor, the drug is capable of inhibiting both anandamide hydrolase in neurons, with consequent potent analgesic activity, and NF-kappaB activation in inflammatory cells.[93] Moreover, oxaprozin induces apoptosis of activated monocytes in a dose-dependent manner. As monocyte-macrophages and NF-kappaB pathways are crucial for synthesis of proinflammatory and histotoxic mediators in inflamed joints, oxaprozin appears to have pharmacodynamic properties exceeding those presently assumed as markers of classical NSAIDs.[96]

Oxicam Derivatives

Piroxicam, the first drug in this class, provides peak serum concentration following oral dosing slowly and has a long elimination half-life of 48.5 hours. This allows once daily dosing, but piroxicam may take up to 1 week to achieve steady state blood concentrations.[97]

Meloxicam

Meloxicam is approved for the treatment of osteoarthritis in the United States. It has also been evaluated for the treatment of

rheumatoid arthritis, ankylosing spondylitis, and acute rheumatic pain.[98] Meloxicam is a nonselective COX inhibitor that has been shown to be somewhat COX-2 preferential at low therapeutic dose. It is unclear that this is clinically meaningful at normal therapeutic doses. Therefore, meloxicam should be considered a nonselective NSAID.

In clinical trials at a low dose, meloxicam was as effective as piroxicam, diclofenac, and naproxen with less GI toxicity,[99] but this may not hold true at the commonly required higher dose. Meloxicam's half-life of approximately 20 hours makes it appropriate for once daily dosing.[99] Meloxicam has not been reported to cause deterioration in renal function in patients with moderate renal failure, and there is no evidence of drug accumulation with continued use. However, the FDA-approved labeling recommends that only the 7.5 mg dose be used in patients with renal insufficiency. Dose adjustment is not required in the elderly. Meloxicam interacts with some medications, including cholestyramine, lithium, and some inhibitors of cytochrome P450 -2C9 and -3A4. Consequently, increased clinical vigilance is indicated when using it concurrently with other medications metabolized by those enzymes. Concentration-dependent therapeutic and toxicological effects have yet to be extensively elucidated for meloxicam.[100] Its pharmacokinetic profile is characterized by a prolonged, almost complete absorption, and the drug is more than 99.5% bound to plasma proteins. Meloxicam is metabolized primarily to four biologically inactive metabolites, which are excreted in both urine and feces. Steady state plasma concentrations are achieved within 3–5 days. The pharmacokinetic parameters of meloxicam are linear over the dose range 7.5–30 mg, and bioequivalence has been shown for a number of different formulations.

COX-2 Selective Nonsteroidal Anti-Inflammatory Drugs

COX-2 selective NSAIDs were developed to reduce the incidence of serious GI adverse effects associated with the administration of traditional NSAIDs on the assumption that these side effects were COX-1 mediated. Marketing efforts to differentiate these drugs from nonselective NSAIDs led to the term COX-2 specific inhibitors. That is misleading because these drugs are selective, not specific, in their COX-2 affinity. The initial COX-2 selective NSAIDs approved by Food and Drug Administration (FDA) were celecoxib and rofecoxib.

Celecoxib

Celecoxib, the first COX-2 selective NSAID, was approved by the FDA on December 31, 1998. It now has approval for the relief of pain from osteoarthritis, rheumatoid arthritis, acute pain, dysmenorrhea, and for familial adenomatous polyposis. It has good selectivity for the COX-2 enzyme. Peak plasma levels occur 3 hours after oral administration, and the drug crosses into the CSF.[27] Celecoxib is 97% serum protein bound with an apparent volume of distribution of 400 L. It is metabolized via cytochrome P450 -2C9 and is eliminated predominantly by the liver. It is not indicated for pediatric use and is a category C drug for pregnancy. The drug has a half-life of about 11 hours.[101] Adverse events noted in the various clinical trials include headache, edema, dyspepsia, diarrhea, nausea, and sinusitis. It is contraindicated in patients who have a sulfonamide allergy or a known hypersensitivity to aspirin or other NSAIDs.

Because celecoxib does not interfere with platelet function[102] (there is no COX-2 in human platelets), it can be administered perioperatively as a multimodal analgesic without increased risk of bleeding.

The efficacy and upper GI safety of celecoxib compared with nonselective NSAIDs was evaluated in 13,274 patients with osteoarthritis (SUCCESS-I study).[103] Patients were randomly assigned to receive either celecoxib 100 or 200 mg twice daily or nonselective NSAID therapy (diclofenac 50 mg twice daily or naproxen 500 mg twice daily) for 12 weeks. Both celecoxib doses were as effective as the nonselective NSAIDs in treating osteoarthritis and significantly more gastric ulcer-related complications occurred in the nonselective NSAID patients (0.8/100 patient-years) compared with the celecoxib group (0.1/100 patient-years) (odds ratio $=7.02$; $p = 0.008$). The number of cardiovascular thromboembolic events was low and not different between the groups. The results of the SUCCESS-I study are different from the "CLASS" trial.[104] which did not demonstrate an advantage of celecoxib in reducing the incidence of upper GI ulcer complications, which is attributed by the SUCCESS-I study authors to the low dropout rate and design of the newer study.

Rofecoxib

Rofecoxib is a selective COX-2 inhibitor that was originally indicated for use in osteoarthritis, rheumatoid arthritis, dysmenorrhea, and acute pain following its approval in 1999. Rofecoxib was withdrawn from the worldwide market voluntarily by its manufacturer after data indicated an increased incidence of myocardial infarctions associated with its use. Subsequent studies suggest that the cardiovascular toxicity was due, at least in part, to dose-related blood pressure elevations. Had lower doses of rofecoxib been used more frequently, the recall may not have been necessary. Consistent clinical reports indicate that some patients who responded well to rofecoxib do not benefit as much from celecoxib, and vice versa.

Valdecoxib and Parecoxib

Valdecoxib is a derivative of isoxazole, and binds noncovalently to COX-2, forming a tight and relatively stable enzyme-inhibitor complex. It is a potent inhibitor of PGE_2 production in humans.[105] Valdecoxib has good oral bioavailability (83%) and a minimal first-pass effect. It achieves maximal plasma concentration in 3 hours with an elimination half-life of about 8–11 hours.[106] Valdecoxib was approved for use in osteoarthritis (10 mg), rheumatoid arthritis (10 mg),[107] and acute pain (up to 40 mg). Clinical studies in high-risk cardiac patients demonstrated a significant increased incidence of major cardiovascular adverse events, and the identification of increased risk for serious skin reactions (toxic epidermal necrolysis, Stevens-Johnson syndrome, erythema multiforme) led the FDA to recommend the withdrawal of this COX-2 inhibitor from the U.S. market in 2003. Parecoxib is a parenteral derivative of valdecoxib that has not been approved for marketing in the United States largely because of cardiovascular toxicity concerns.

Use in Postoperative Care. A meta-analysis of clinical studies evaluating these drugs compared to nonselective NSAIDs (which do not differentiate between COX-1 and COX-2 effects) for postoperative pain showed that the analgesic efficacy of COX-2 inhibitors in the 6 hours after surgery was similar to or better than ibuprofen.[108] A meta-analysis examined whether there is any advantage of multimodal analgesia with acetaminophen, nonselective NSAIDs, or COX-2 selective NSAIDs when added to morphine patient-controlled analgesia.[109] The results suggested that all of the analgesic agents provided an opioid dose-sparing effect (25%–55%) and the addition of NSAIDs to morphine was associated with a decrease in the incidence of postoperative nausea and vomiting and sedation. Clinical trials of COX-2 selective NSAIDs used preoperatively and into the postoperative period (2 weeks) for patients undergoing both major surgery[110] and minimally invasive surgery[111] demonstrated improved clinical outcomes. Preoperative administration of oral COX-2 selective NSAIDs can reduce the CSF PGE_2 levels in humans during the perioperative period resulting in improved outcomes following

hip replacement surgery.[25] In addition to the reducing CSF PGE_2 levels, the COX-2 selective NSAIDs were able to modulate the CSF interleukin-6. The exact mechanism responsible for the reduction in the interleukins has yet to be determined, but is probably related to the PGE_2 pathway.[25]

Other COX-2 Selective Nonsteroidal Anti-Inflammatory Drugs. Additional drugs in the class have been formulated and shown efficacy in clinical trials. None has been approved by the FDA, although etoricoxib is commonly used in several other countries. Clinical experience consistently shows that some patients respond to one NSAID better than another and that applies to the COX-2 selective NSAIDs as well. It is unfortunate that celecoxib is the only such drug currently available in the United States.

Nonsteroidal Anti-Inflammatory Drug Controversies

NSAIDs are indicated in a multimodal analgesic approach. Recent practice guidelines for acute pain management in the perioperative setting specifically state "unless contraindicated, all patients should receive around-the-clock regimen of NSAIDs, COX-2 inhibitors, or acetaminophen."[112] The routine perioperative use of nonselective NSAIDs may predispose patients to an increased risk of bleeding.[113] In contrast, the COX-2 selective agents can be administered preemptively to surgical patients without the added risk of increased perioperative bleeding reported with nonselective NSAIDs.[114] The lack of perioperative bleeding with COX-2 selective NSAIDs offers a significant advantage compared to nonselective NSAIDs for a variety of orthopaedic surgical procedures. Although some animal studies with high dose NSAIDs suggest inhibition of bony in-growth postoperatively, there is no clinical evidence at normal doses to support that. As a result, many orthopaedic surgeons resist postoperative NSAID analgesia while others embrace it.

For chronic pain management, the concurrent use of an NSAID with an opioid or another analgesic with a different mechanism of action than the NSAIDs represents a rational combination in most cases. NSAIDs and opioids are mutually dose-sparing, and nearly all opioid and NSAID adverse effects are dose related.

Cardiovascular Effects

A more recent concern about the perioperative administration of NSAIDs, especially the COX-2 selective agents for short-term use, has been their possible role in increasing cardiovascular morbidity.[115] A joint meeting of the FDA Arthritis Advisory Committee and the Drug Safety and Risk Management Advisory Committee was convened in February 2005 to discuss the safety of COX-2 selective and nonselective NSAIDs. These committees jointly reaffirmed that COX-2 selective agents are important treatment options for pain management and that the preponderance of data demonstrate that the cardiovascular risk associated with celecoxib is similar to that associated with commonly used, older nonselective NSAIDs. Their rationale was that COX-2 selective NSAIDs collectively increased cardiovascular risk compared with placebo but not when compared with nonselective NSAIDs. The Committee concluded that short-term use of NSAIDs does not appear to increase cardiovascular risk and that rigorous scientific studies are needed to characterize the longer-term cardiovascular risks of these analgesics. Subsequently, on April 7, 2005, the FDA announced a series of labeling changes for all NSAIDs, including nonprescription forms. These included a FDA boxed warning for the potential increased risk of cardiovascular events and GI bleeding associated with all prescription NSAIDs, including celecoxib. The manufacturers were asked to revise their labeling to include a medication guide for patients to help make them aware of the potential for cardiovascular and GI adverse events. In addition, the FDA asked manufacturers of all over-the-counter NSAIDs to revise their labels to include more specific information about potential cardiovascular and GI risks and information to assist consumers in the safe use of these drugs.

Allergy and Hypersensitivity

All NSAIDs, including aspirin, may induce hypersensitivity reactions of two general types. Both may be related to the inhibition of PG synthesis. The two types of hypersensitivity are the syndrome of asthmatic attacks in patients with vasomotor rhinitis, nasal polyposis, and bronchial asthma and the syndrome of urticaria and angioedema. Prostaglandin E_2 is a bronchodilator. It stabilizes histamine stores in mastocytes and thus helps to inhibit the inflammatory response.[116] In a susceptible person, the result of the inhibition of PG biosynthesis may be spontaneous degranulation of mastocytes with release of histamine in the respiratory tract and skin, leading to bronchoconstriction and asthma as well as urticaria syndrome called Samter's triad which is COX-1 mediated. Therefore, COX-2 selective NSAIDs may be safely administered to these patients. The general recommendation is to use any NSAID for the shortest time and at the lowest dose that is clinically appropriate. For many patients with chronic, painful, inflammatory disorders, chronic NSAID therapy continues to present a favorable risk to benefit ratio. Those patients should be monitored, especially for blood pressure elevation and renal function.

Gastrointestinal Toxicity

The first evidence that aspirin could damage the stomach was reported in 1938 based on gastroscopic observations.[117] In the 1950s and 1960s, case control studies demonstrated NSAID-associated melena. NSAIDs cause hemorrhagic gastric erosions in the corpus and antrum. The mortality rate attributed to NSAID-related GI toxicity is 0.22%/year with an annual relative risk of 4.21. An estimated 16,500 NSAID-related deaths occur due to gastric complications, which is similar to the number from acquired immunodeficiency syndrome (16,685) and exceeds the number of deaths due to multiple myeloma and asthma. Risk factors identified for the development of NSAID-induced ulcers include advanced age, history of ulcer, concomitant use of corticosteroids, higher doses of NSAIDs, including the use of more than one NSAID, concomitant administration of anticoagulation, serious systemic disorder, cigarette smoking, consumption of alcohol, and concomitant infection with *Helicobacter pylori*.

The mechanisms by which NSAIDs cause ulceration in the stomach are contact irritation of the epithelium and suppression of PG synthesis.[118] NSAID-induced gastropathy correlates with the time and dose for gastric PG suppression.[119] Inhibition of PG synthesis reduces the gastric mucosa ability to defend itself against luminal irritants because bicarbonate secretions, blood flow, and epithelial cell turnover are influenced by PG. Gastric bleeding from pre-existing ulcers can also occur due to NSAID suppression of platelet aggregation.[120] Mediators in the pathway by which decreased PG levels cause gastric irritation and damage have been extensively studied. These include leukotrienes,[121] TNF-$\propto$,[122] and neutrophil adherence substances.[122]

NSAID-induced enteropathy has been documented in the small intestine and colon, although the exact mechanism is not fully understood. Various strategies can reduce NSAID gastroenteropathy.[123] Agents used to prevent NSAID-induced ulcers include sucralfate (efficacy controversial), H_2-receptor antagonists (famotidine), proton-pump inhibitors (omeprazole), and prostaglandins (misoprostol). Enteric-coated and slow-release NSAID dosage forms have not reduced ulcer risk.

NSAID-induced gastric complications prompted development of COX-2 selective agents. Preferential use of those selective agents to minimize gastropathy resulted in increased cardiovascu-

lar toxicity culminating in the withdrawal of two of the three. But cardiovascular toxicity is not specifically related to the selective NSAIDs. Celecoxib appears to have one of the safer cardiovascular profiles of all NSAIDs.

For patients with no cardiovascular risk factors and who have low risk for GI complications, monotherapy with nonselective NSAIDs is appropriate. For patients who do not require aspirin prophylaxis and are at risk for NSAID-induced GI complications, an initial approach would be to prescribe either a COX-2 selective NSAID or a traditional NSAID and a proton-pump inhibitor.

Hematologic and Cardiovascular Effects

All NSAIDs, not just the COX-2 selective agents, may increase risk of serious cardiovascular thrombotic events, myocardial infarction, and stroke. As noted above, NSAIDs inhibit prostaglandin formation. But different prostaglandins have different, sometimes opposing, functions. Thromboxane$_{A2}$ (TX_{A2}) is a platelet activator and vasoconstrictor, whereas prostacyclin (PGI_2) is a platelet inhibitor and vasodilator. Furthermore, activated platelets divert some of their endoperoxides to vascular cells (“endoperoxide steal”) to further provide substrate for PGI_2 formation.[124] Platelet activity results from a balance between PGI_2 effects on endothelium and TX_{A2} effects on platelets. Platelets are especially vulnerable to COX inhibition because, unlike most other cells, platelets cannot regenerate this enzyme. Aspirin irreversibly acetylates the COX enzyme and that inhibits platelet aggregation for the 10 to 14 day lifespan of the platelet.[124] Other nonselective NSAIDs reversibly inhibit COX causing only a transient reduction in TX_{A2} formation. As a result, platelet activation inhibition resolves after most of the drug is eliminated.[124] A single 300 to 900 mg dose of ibuprofen can inhibit platelet aggregation for 2 hours after administration, and the effect is largely dissipated by 24 hours.[125] Similarly, both sulindac and diclofenac also inhibit platelet aggregation for less than 24 hours. The antiplatelet effects of long-acting NSAIDs such as piroxicam can last for several days after the drug is discontinued.[126] Overall nonaspirin NSAIDs cause “transient, dose-dependent, and modest bleeding time abnormalities,” which often do not exceed normal limits.[124]

While in vitro studies examining the effect of NSAIDs on platelet function provide useful information, the clinical effect in patients is more important. The test primarily used to assess platelet function is bleeding time, but this test is highly operator-dependent and is subject to technical artifact. In addition, its clinical utility as a preoperative tool for predicting intraoperative bleeding remains controversial. Studies show variable effects of NSAIDs on bleeding. In one total hip arthroplasty study, 140 patients taking NSAIDs had more intraoperative and postoperative blood loss than those who did not.[127] In addition to potentially increasing perioperative bleeding, NSAIDs may increase myocardial infarction and stroke. An unbalanced biosynthesis of PGI_2 and TX_{A2} may play a role in atherogenesis and thrombosis. Prolonged administration of COX-2 selective NSAIDs may cause adverse events through inhibition of PGI_2. These include a blood pressure elevation, initiating and early development of atherosclerosis, and the architectural and functional response of blood vessels to stress. All of these effects may predispose individuals to an exaggerated thrombotic response upon rupture of an atherosclerotic plaque.[128] Aspirin and nonselective NSAIDs suppress both COX-1 and COX-2 and therefore reduce both TX_{A2}, and PGI_2. In contrast, COX-2 selective NSAIDs suppress PGI_2 production without affecting TX_{A2} synthesis.[129] Some authors posit that this may increase acute myocardial infarction risk that has been observed with prolonged use of some of the COX-2 selective agents. However, the fact that this outcome has not been associated with celecoxib suggests that it is not a coxib-specific effect. A more probable mechanism that others posit is that the risk of myocardial infarction with all NSAIDs results more from modest, renally-mediated systolic blood pressure elevations over time.[130]

Renal Toxicity

Aspirin and all other NSAIDs can transiently decrease renal function. This effect may occur more often in patients with underlying renal disease.[129] The postulated mechanism is the inhibition of the renal PG synthesis, which may be important in the autoregulation of renal blood flow. Aspirin may also block the diuretic effect of spironolactone by inhibiting its binding to the tubular-cell receptor.

The renal profile of NSAIDs appears related to sodium retention, which is COX-2 inhibition mediated, and glomerular filtration rate changes due to inhibition of COX-1/COX-2. All NSAIDs are associated with hypertension and edema. Most of these events are of minor clinical significance with discontinuation rates due to hypertension and edema when used for short term.[130] Most cases resolve with discontinuation of therapy, which is generally seen over 1 to 8 weeks. The risk factors for NSAID-induced renal toxicity include the following: chronic NSAID use, multiple NSAID use, dehydration, volume depletion, congestive heart failure, vascular disease, hyperreninemia, shock, sepsis, systemic lupus erythematosus, hepatic disease, sodium depletion, nephrotic syndrome, diuresis, concomitant drug therapy (diuretics, angiotensin-converting enzyme inhibitors, beta blockers, potassium supplements), and age 60 years or older.[129]

Hepatic Toxicity

Aspirin is hepatotoxic in certain situations and this effect is non–dose-dependent. The effect is reversible when the drug is discontinued.[131] As noted above, diclofenac appears to be the most potentially hepatotoxic agent of the newer NSAIDs.

Central Nervous System Effects

Direct toxic reactions are of several types. Tinnitus or deafness are usually early warning signs of toxicity. Toxic manifestations are directly related to free drug levels, and those vary inversely with albumin levels. The adverse event is typically reversed when the dose is reduced or discontinued. NSAIDs are the most frequently implicated drugs in hypersensitivity-induced aseptic meningitis. Ibuprofen, sulindac, tolmetin, and naproxen have been implicated in causing drug-induced aseptic meningitis. Patients typically complain of fever, headache, and stiff neck that generally commences within weeks of beginning therapy.[132]

Acetaminophen

Acetaminophen is a para aminophenol derivative with analgesic and antipyretic properties similar to aspirin. Antipyresis is likely from direct action on the hypothalamic heat-regulating centers via inhibiting action of endogenous pyrogen.[133] Recent reports suggest that acetaminophen may act via the serotonergic pathway to provide analgesia.[134] Although equipotent to aspirin in inhibiting central PG synthesis, acetaminophen has no significant peripheral PG synthetase inhibition. Therefore, it lacks clinically useful peripheral anti-inflammatory activity, which makes it less desirable than NSAIDs for painful, inflammatory disorders. Doses of 600 to 650 mg are more effective than doses of 300 to 325 mg, but little additional benefit is seen at doses above 1000 mg, indicating a possible ceiling effect.[135]

Acetaminophen has few side effects in the usual dosage range; no significant GI toxicity or platelet functional changes occur. However, recent studies demonstrate that acetaminophen can cause blood pressure elevations. It is not clear if this presents risk of cardiovascular side effects similar to NSAIDs in light of the finding that NSAID-induced blood pressure elevation over time is associated with cardiovascular thrombotic effects.[136]

Nephrotoxicity also can occur with acetaminophen but less frequently than it occurs with NSAIDs. Acetaminophen is almost entirely metabolized in the liver, and the minor metabolites are responsible for the hepatotoxicity seen in overdose.[137] Inducers of the P-450 enzyme system in the liver (such as alcohol) increase the formation of metabolites and therefore increase hepatotoxicity. In certain patients (chronic ethanol users, malnutrition, and fasting patients), repeating therapeutic or slightly excessive doses may precipitate hepatotoxicity. A dose of 2600 to 3200 mg per day may represent a safer chronic daily dose, and acetaminophen dosing should not exceed 4 g/day.[138] Toxic doses appear to be a function of baseline glutathione levels and other dose-related factors. Genetically-determined glutathione is an important factor in overdose toxicity. Patients with high glutathione stores may tolerate much higher doses, but the 4 gram limit is important for safety because many patients lack sufficient glutathione stores to safely tolerate higher daily doses. Clinicians should carefully inquire and educate patients about other over-the-counter symptom-control products that patients may be taking which also contain acetaminophen.

Acetaminophen is completely and rapidly absorbed following oral administration. Peak serum concentrations are achieved within 2 hours and therapeutic serum concentrations are 10–20 mcg/mL.[139] About 90% of acetaminophen is hepatically metabolized to sulfate and glucuronide conjugates for renal excretion with a small amount secreted unchanged in the urine.[140]

The bioavailability of rectal acetaminophen is variable and is approximately 80% of that following oral administration. The rectal rate of absorption is slower, with maximum plasma concentration occurring 2 to 3 hours after administration.[141] Doses of 40–60 mg/kg of rectal acetaminophen have been shown to have opioid-sparing effect in postoperative pain models.[142] Propacetamol, an injectable prodrug of paracetamol, is completely hydrolyzed within 6 minutes of administration and 1 gram of propacetamol yields 0.5 grams of paracetamol. Injectable paracetamol has been shown to reduce opioid consumption by about 35%–45%[143] in postoperative pain studies,[143,144] including after cardiac surgery.[145] There is widespread use of the intravenous form in many other countries, but it was not available in the United States at the time of this writing. Acetaminophen has been reported to produce a dose ceiling effect at intravenous doses of 5 mg/kg, which resulted in a serum concentration of 14 mg/mL.[146]

CONCLUSION

The NSAIDs are important drugs which provide excellent analgesic, antipyretic, and anti-inflammatory effects as monotherapy and can be especially useful in combination with opioids for more severe pain. Acetaminophen provides comparable analgesic and antipyretic activity but lacks clinically useful anti-inflammatory activity. Like NSAIDs, acetaminophen administered concurrently with opioids often is opioid dose-sparing due to synergistic analgesic activity. Acetaminophen often is better tolerated than NSAIDs, most notably due to its lack of GI distress and chronic use-associated blood pressure elevations, ulcerogenicity, and nephrotoxicity. However, acetaminophen, like all drugs, does have toxicities, and chronic use requires monitoring for blood pressure and renal effects.

CHAPTER 78 ■ OPIOID ANALGESICS

CHARLES E. INTURRISI AND ARTHUR G. LIPMAN

Opioid analgesics remain the most effective and commonly used treatment modality for moderate to severe pain.[1] Not every pain patient will benefit from opioid therapy, and more patients benefit from these strong analgesics when the drugs are used as one component of multimodal therapy.

During the past 20 years there has been a dramatic increase in our knowledge of the sites and mechanisms of action of opioids.[2] The development of analytical methods has also been of great importance by facilitating pharmacokinetic (PK) studies of the disposition and fate of opioids in patients. These PK studies and recent discoveries about pain and opioid receptor-related genetic polymorphisms have begun to provide a better understanding of some of the sources of interindividual variation in the response to opioids and suggest ways to minimize some of their adverse effects.[1,3] Although major gaps remain in our knowledge of opioid pharmacology, ultimately, the rational and appropriate clinical use of these drugs is based on the knowledge of their pharmacological properties derived from well-controlled clinical trials.

The term *analgesic* (from the Greek an-, without + algesis, sense of pain) refers to a drug that relieves pain without a significant loss of other sensations. *Opioid* (the preferred term) is any compound that binds to an opioid receptor. Opioids include the exogenous opioid receptor agonists and antagonists as well as the endogenous opioid peptides. The term *opiate* originally referred to any drug derived from opium but now includes the natural opium products (e.g., morphine), the semisynthetic derivatives (e.g., hydromorphone), or completely synthetic congeners (e.g., methadone). The term *narcotic* was originally associated with the opioids. It is now used in a legal context to refer to any drug considered to possess abuse or addictive potential. Because it is a value-laden word, avoidance of the term narcotic when discussing opioids with patients is often advisable.

CLASSIFICATION BASED ON INTERACTIONS WITH AN OPIOID RECEPTOR

Opioid analgesics can be classified based on their interactions with opioid receptors, namely mu (μ), delta (δ), and kappa (κ). Mu opioid receptor agonists (agents that occupy and activate the receptor) are the major source of clinically used opioid agonist and antagonist drugs. Kappa opioid receptor ligands provide a few drugs; however, their clinical pharmacology is complicated by concurrent mu opioid receptor antagonist activity (see later). Delta opioid receptor ligands were in clinical investigation at the time of this writing; none was yet available for clinical use.

Each of the opioid receptors is a G protein-coupled receptor (GPCR) and signals via a second messenger, cyclic adenosine monophosphate (cAMP), or an ion channel.[2] Alterations in the levels of cAMP and the transcription factor, CREB (cAMP response element binding protein) during chronic morphine treatment are associated with numerous cellular changes, some of which can lead to the development of tolerance and physical dependence.[4] Molecular genetic approaches have used gene-targeting (knockout) technology to disrupt the gene that codes for each of the three opioid receptors. Mice that lack the mu opioid receptor (MOR-deficient mice) do not respond to morphine with analgesia, respiratory depression, constipation, physical dependence, reward behaviors, or immunosuppression.[5] These results confirm and extend previous pharmacologic and receptor binding studies and demonstrate that the mu receptor mediates the analgesic and adverse effects of morphine. Pharmacologic evaluation of the effects of the microinjection of morphine and other opioids has been combined with anatomic characterization of the distribution of opioid receptors to provide insight into the sites of action of morphine and other clinically used mu opioids. Thus, mu opioid receptors (MORs) are found in the periphery (following inflammation), at pre- and postsynaptic sites in the spinal cord dorsal horn, and in the brainstem, thalamus, and cortex, in what constitutes the ascending pain transmission system.[6] In addition, MORs are found in the midbrain periaqueductal grey, the nucleus raphe magnus, and the rostral vental medulla where they comprise a descending inhibitory system that modulates spinal cord pain transmission.[6] Activation of the high density of mu opioid receptors in the human colon appears to be the major mechanism of opioid-induced constipation.[7] At a cellular level, opioids decrease calcium ion entry resulting in a decrease in presynaptic neurotransmitter release (e.g., substance P release from primary afferents in the spinal cord dorsal horn). They also enhance potassium ion efflux resulting in the hyperpolarization of postsynaptic neurons and a decrease in synaptic transmission. A third mode of opioid action is to inhibit GABAergic transmission in a local circuit, for example, in the brainstem, where GABA acts to inhibit a pain inhibitory neuron. This disinhibitory action of the opioid has the net effect of exciting a descending inhibitory circuit.

The opioid receptors are part of an endogenous system that includes a large number of endogenous opioid peptide ligands. Based on cloning, three distinct families of classical opioid peptides, the enkephalins, endorphins, and dynorphins, have been identified.[2] The physiologic roles of the endogenous opioid peptides are not completely understood. They appear to function as neurotransmitters, neuromodulators, and, in some cases, as neurohormones.[5] They play a role in some forms of stress-induced analgesia and in the analgesia produced by electrical stimulation of discrete brain areas such as the periaqueductal grey.[2,6]

Animal studies suggest that the reinforcing and rewarding properties of opioids (e.g., euphoria) that are associated with opioid abuse involve the mesolimbic dopamine system, not the supraspinal systems most prominently involved in the production of analgesia and physical dependence.[8]

CLASSIFICATION BASED ON OPIOID AGONIST OR ANTAGONIST ACTIVITY

The expression of agonist or antagonist activity is an important pharmacodynamic property used to classify opioids. The morphine-like agonist drugs represent one end of the pharmacody-

namic spectrum. They bind predominately or exclusively to MORs and produce analgesia and the other mu opioid receptor-mediated effects described later. The opioid antagonists, such as naloxone, represent the other end of the spectrum since their binding to an opioid receptor does not trigger the signaling cascade that leads to the pharmacodynamic effects seen with opioid agonists. Rather, receptor occupancy by a sufficient concentration of an opioid antagonist prevents or reverses opioid receptor-mediated agonist effects.

Between these two types of pharmacodynamic actions fall the effects of the mixed agonist-antagonist drugs. These opioid drugs (see Table 78.1) can demonstrate agonist (at the kappa receptor) or antagonist (at the mu receptor) activity. What occurs clinically depends on whether the patient is opioid-naïve or has prior exposure to a mu opioid agonist. Buprenorphine is a partial agonist opioid. This classification derives principally from its pharmacodynamic activity observed in preclinical test systems wherein the difference in efficacy between a full agonist and a partial agonist can be more readily measured. Clinically, the consequences of buprenorphine's partial agonism can be observed as its ability to precipitate opioid withdrawal in some patients who have been receiving repeated doses of a mu agonist.

OPIOID PHARMACODYNAMICS

Receptor-Mediated Cellular, Synaptic, and Circuit Level Events Inhibit Pain Transmission

At the cellular level, activation of an opioid receptor (mu, kappa, or delta) by an opioid inhibits voltage gated (VG) calcium (Ca^{++}) channels and the opening of certain potassium (K^{+}) channels. The presynaptic block of VG Ca^{++} channels reduces transmitter release, while the increase in outward K^{+} currents hyperpolarizes postsynaptic neurons (increasing an inhibitory postsynaptic potential). These effects on transmitter release are believed to decrease synaptic transmission of pain signals in the spinal cord dorsal horn.

At the neuronal circuit level, opioids can disinhibit an inhibitory interneuron. This is the basis of descending modulation of pain transmission as discussed below.

Functional Localization of Opioid Receptors

Each of the three types of opioid receptors is expressed in defined patterns throughout the central nervous system (CNS). The MORs exist in peripheral tissues following activation by injury or inflammation, then in the spinal cord dorsal horn, the thalamus, limbic system, and in the somatosensory cortex (Fig. 78.1A). This distribution provides an anatomic basis for the modulation of ascending pain transmission by mu opioids. MORs also are located in the midbrain periaqueductal grey, the nucleus raphe magnus, and rostral ventral medulla (Fig. 78.1B). Opioids inhibit GABAergic neurons and remove the tonic *inhibition* of the pain inhibitory neurons (PIN) that project from the rostral ventral medulla to the spinal cord dorsal horn. Thus, opioids produce a disinhibition of the PIN, which results in the *activation* of descending inhibition and the descending modulation of pain transmission (Fig. 78.1C).

Mu opioid receptors are also located peripherally and the development of peripheral mu opioid antagonists has provided a new class of drugs to manage opioid bowel dysfunction. See Peripheral effects of opioids later.

THE PHARMACODYNAMIC EFFECTS OF OPIOIDS

The pharmacodynamic effects of opioids are discussed using the prototype morphine and the morphine-like opioids. In some cases the term *opioids* refers to properties common to both morphine-like and mixed agonist–antagonist opioids. Later individual opioids are discussed in the context of how they compare to and differ from morphine and other morphine-like opioids.

The desirable and undesirable effects of morphine can be divided into those that may occur with a single dose and those that occur with repeated administration including tolerance, physical dependence, and addiction (Table 78.2).

CENTRAL NERVOUS SYSTEM OPIOID EFFECTS

Analgesia

The relief of pain by morphine is relatively selective in that other sensory modalities are not affected. While continuous dull pain has been relieved more effectively than sharp intermittent pain, morphine-like opioids can relieve severe, acute pain associated with renal or biliary colic. Some patients report that they still perceive pain, but that it is no longer as distressing as it was prior to morphine. Recent reports and long-standing clinical observations support the concept that pain includes both sensory-discriminative aspects (e.g., perception of the location, type, and intensity) and reactive or affective meaning of the pain experience (e.g., its unpleasantness). Under experimental conditions, positron emission tomography (PET) imaging studies localized and separated these two dimensions of pain. The sensory-discriminative aspects are processed in the somatosensory cortex (SSC) while the affective component is processed in the anterior cingulate cortex (ACC).[9] The presence of MORs in both of these brain areas is consistent with the ability of morphine-like opioids to alter both dimensions of pain.

In contrast to nonopioid analgesics, there is no easily measurable ceiling to the dose-dependent analgesic effects of morphine-like opioids. Nevertheless, there is often a practical ceiling imposed by the dose-dependent adverse effects including sedation, mental clouding, nausea and vomiting, or respiratory depression (Table 78.2). The actual dose required for analgesia can vary greatly depending on the type or source of pain and a variety of patient factors. The most important principle that derives from these properties of the morphine-like opioids is to titrate the dose for each patient to an acceptable level of analgesia that balances the degree of pain relief with the limits that are imposed by concomitant adverse effects.

Mood Effects

The morphine-like opioids can produce alterations in mood including the relief of anxiety, euphoria (pleasant feelings), as well as dysphoria (unpleasant feelings). Chronic pain patients receiving opioids often report initial relief of depression (a common concomitant of chronic pain), but this usually proceeds to exacerbation of depression after a few days to weeks. Thus, the mood effects appear as both desirable and undesirable effects in Table 78.2. Reports of euphoria or dysphoria usually depend on the individual and the circumstances of the morphine experience. Most "normals" not in pain as well as many patients in pain, report some dysphoria after receiving morphine. That is associated with difficulty in mental activities, dizziness, and decrease in physical activity.

The reinforcing and rewarding properties of these drugs that are associated with opioid abuse involve the mesolimbic dopamine system and appear to be distinct from those systems involved in analgesia and the production of physical dependence.[8]

TABLE 78.1

OPIOID ANALGESICS COMMONLY USED FOR SEVERE PAIN

Name	Equianalgesic parenteral dose[a]	Parenteral/ oral potency	Starting oral dose range (mg)	Comments	Precautions
			Mu (morphine-like) Agonist Opioids		
Morphine	10	6[b]	30–60[b]	Standard of comparison for opioid analgesics. Extended-release preparations (MS Contin[R], OramorphSR[R], and Kadian[R])	Those with impaired ventilation, bronchial asthma, increased intracranial pressure and liver failure. Lower doses for elderly.
Hydromorphone (Dilaudid[R])	1.5	5	4–8	Slightly shorter acting. High potency parenteral dosage form for tolerant patients.	Like morphine.
Methadone (Dolophine[R])	10	2	5–10	Good oral potency. Long but variable plasma half-life. Rotation dose depends on prior opioid dosage. See text.	Like morphine. May accumulate with repetitive dosing causing excessive sedation.
Levorphanol (Levo-Dromoran[R])	2	2	2–4	Like methadone.	Like methadone.
Oxymorphone (Opana[R])	1	6[b]	5–10	Immediate-release (Opana[R]) and extended-release (Opana ER[R]) oral dosage. Also available as a rectal suppository.	Like morphine. Do not take with food or alcohol.
Oxycodone	15	2	5–20	Immediate- release (Roxicodone[R] and OxyIR[R]) and extended-release (OxyContin[R]) oral dosage. Also in combination with nonopioids for less severe pain.	Like morphine.
Fentanyl	0.1	—	—	Transdermal fentanyl (Duragesic[R]). Also as Oral Transmucosal Fentanyl Citrate (Actiq[R]) for breakthrough pain.	Transdermal creates skin reservoir of drug and 12-hr delay in onset and offset. Fever increases absorption.

Meperidine, pethidine (Demerol[R])	75	4	not recommended	Slightly shorter acting than morphine. Used orally for less severe pain.	Normeperidine metabolite accumulates with repetitive dosing causing CNS excitation. Not for patients with impaired renal function or receiving monoamine oxidase inhibitors.[c]
Codeine	130	1.5	30–60	Used orally in combination with nonopioids for less severe pain.	Like morphine.
Hydrocodone	—	30	2.5–10	Used orally in combination with nonopioids for less severe pain (Vicodin[R], Lorcet[R], Lortab[R]. and many others).	
Mixed agonist-antagonist opioids					
Pentazocine (Talwin[R])	60	3	- see comments -	Used orally for less severe pain. A mixed agonist-antagonist—see precautions.	May cause psychotomimetic effects. May precipitate withdrawal in opioid dependent patients. Not for myocardial infarction pain.
Nalbuphine (Nubain[R])	10	- see comments -	- see comments -	Not available orally. Like IM pentazocine but not Scheduled.	Incidence of psychotomimetic effects lower than with pentazocine.
Butorphanol (Stadol[R])	2	- see comments -	- see comments -	Not available orally. Like IM nalbuphine.	Like nalbuphine.
Partial mu agonist opioid					
Buprenorphine (Buprenex[R])	0.3	- see comments -	- see comments -	Not available orally. Only parenteral form approved in U.S. for pain. Does not produce psychotomimetic effects.	May precipitate withdrawal in opioid-dependent patients. Not readily reversed by naloxone. Avoid in labor.

For these equianalgesic parenteral doses (based on intramuscular administration studies, also see comments) the time of peak analgesia in nontolerant patients ranges from one-half to one hour and the duration from four to six hours. The peak analgesic effect is delayed and the duration prolonged after oral administration.

[a]These doses are recommended starting parenteral doses from which the optimal dose for each patient is determined by titration and the maximal dose limited by adverse effects. For single IV bolus doses use half the parenteral dose.

[b]A value of 3 is used when calculating an oral dosage regimen of every 4 hrs around-the-clock.

[c]Irritating to tissues on repeated administration.

IM, intramuscular; IV, intravenous.

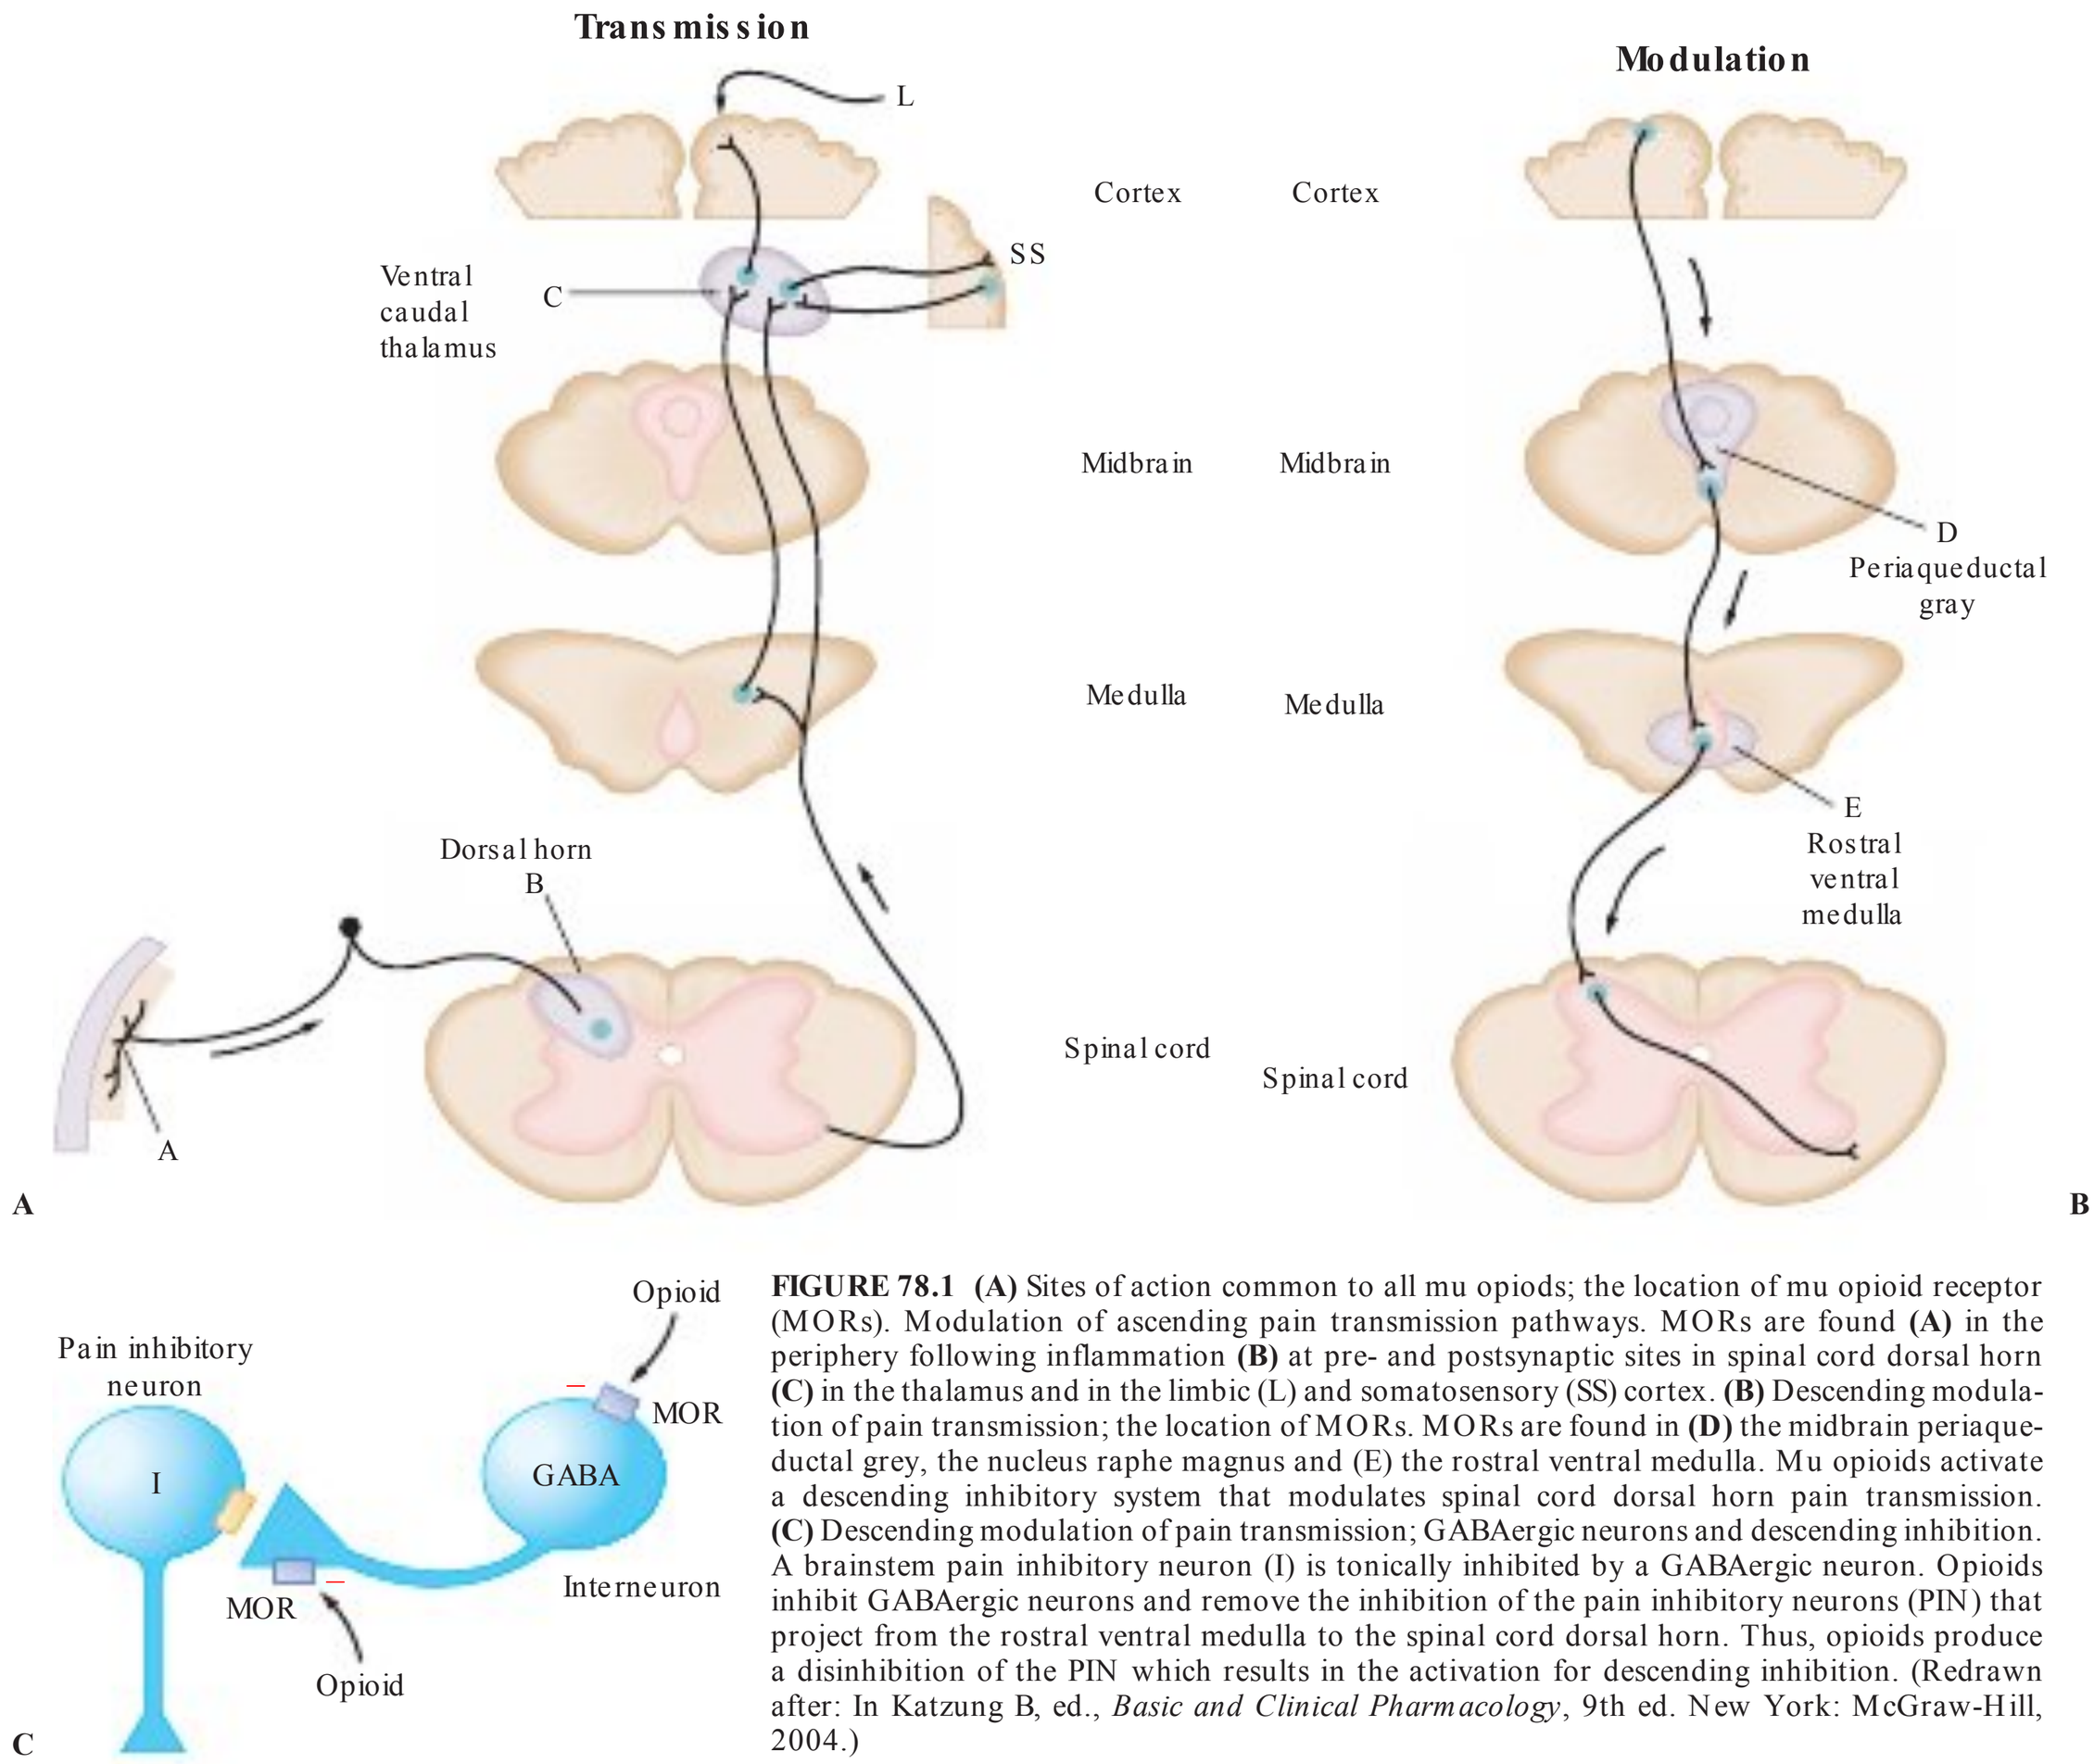

FIGURE 78.1 **(A)** Sites of action common to all mu opiods; the location of mu opioid receptor (MORs). Modulation of ascending pain transmission pathways. MORs are found **(A)** in the periphery following inflammation **(B)** at pre- and postsynaptic sites in spinal cord dorsal horn **(C)** in the thalamus and in the limbic (L) and somatosensory (SS) cortex. **(B)** Descending modulation of pain transmission; the location of MORs. MORs are found in **(D)** the midbrain periaqueductal grey, the nucleus raphe magnus and (E) the rostral ventral medulla. Mu opioids activate a descending inhibitory system that modulates spinal cord dorsal horn pain transmission. **(C)** Descending modulation of pain transmission; GABAergic neurons and descending inhibition. A brainstem pain inhibitory neuron (I) is tonically inhibited by a GABAergic neuron. Opioids inhibit GABAergic neurons and remove the inhibition of the pain inhibitory neurons (PIN) that project from the rostral ventral medulla to the spinal cord dorsal horn. Thus, opioids produce a disinhibition of the PIN which results in the activation for descending inhibition. (Redrawn after: In Katzung B, ed., *Basic and Clinical Pharmacology*, 9th ed. New York: McGraw-Hill, 2004.)

Sedation

Morphine-like opioids produce drowsiness and sedation, which may be useful in certain clinical situations (e.g., pre-anesthesia) but usually are not desirable concomitants of analgesia, particularly in ambulatory patients. The CNS depressant actions of these drugs are at least additive to the sedative and respiratory depressant effects of sedative-hypnotics such as alcohol, barbiturates, and benzodiazepines.

Reducing the dose and interval, that is, giving a lower dose more frequently, produces a lower peak opioid serum concentration, which may counteract excessive sedation. In addition, other CNS depressants including sedative-hypnotics and antianxiety agents that add to or potentiate the sedative effects of opioids should be discontinued if possible. Concurrent administration of a central stimulant (e.g., dextroamphetamine, methylphenidate) twice daily helps counteract the sedative effects of opioids. Tolerance usually develops to the sedative effects of opioid analgesics within the first several days of repeated administration.

Nausea and Vomiting

The morphine-like analgesics produce nausea and vomiting by stimulating the chemoreceptor trigger zone (CTZ) in the area postrema of the medulla. The incidence of nausea and vomiting is markedly greater in ambulatory patients suggesting that these drugs also alter vestibular sensitivity. The ability of opioid analgesics to produce nausea and vomiting appears to vary with drug and among patients; some advantage may result from opioid rotation. Alternately, a centrally acting antiemetic such as a phenothiazine (e.g., prochlorperazine), a gastric prokinetic agent (e.g., metoclopramide), or a $5HT_3$ receptor antagonist (e.g., ondansetron) may be used in combination with the opioid. For some patients initiating treatment by the parenteral route and then switching to the oral route may reduce the emetic symptoms.[10]

Respiratory Depression

Respiratory depression is potentially the most serious adverse opioid effect. The morphine-like agonists act on brainstem respi-

TABLE 78.2

THE DESIRABLE AND UNDESIRABLE PROPERTIES OF MORPHINE AS AN ANALGESIC

Desirable	Undesirable
Analgesic	Sedation
Mood effects	Mental clouding
Sedation	Dizziness
	Mood effects
	Dysphoria
	Nausea and vomiting
	Respiratory depression
	Suppression of the cough reflex
Tolerance (to respiratory depression)	Tolerance (to analgesia)
	Physical dependence
	Substance dependence or addiction
	Spasmogenic
	Constipation

ratory centers to produce dose-related respiratory depression to the point of apnea. In humans, death due to overdose of a morphine-like agonist is nearly always due to respiratory arrest. Therapeutic doses of morphine may depress all phases of respiratory activity (rate, minute volume, and tidal exchange). However, as CO_2 accumulates, it stimulates central chemoreceptors, resulting in a compensatory increase in respiratory rate, which masks the degree of respiratory depression. At equianalgesic doses, the morphine-like agonists produce an equivalent degree of respiratory depression. Therefore, individuals with impaired respiratory function or bronchial asthma are at greater risk of experiencing clinically significant respiratory depression in response to usual doses of these drugs. Respiratory depression and CO_2 retention produces cerebral vasodilation and increased cerebrospinal fluid pressure unless the PCO_2 is normalized by artificial ventilation. Respiratory depression occurs most commonly in opioid-naïve patients following acute opioid administration and it is associated with other signs of CNS depression including sedation and mental clouding. Tolerance develops rapidly to this effect with repeated drug administration, often allowing use of opioids in the management of chronic pain without significant risk of respiratory depression. Obstructive sleep apnea is common in overweight chronic pain patients and it presents risk for opioid-induced respiratory depression, especially when the patients are sleeping. Recent reports suggest that opioids, and perhaps more so methadone, may induce potentially life-threatening central sleep apnea.[11,12] Respiratory depression can be reversed by timely administration of the opioid antagonist naloxone. In patients chronically receiving opioids who develop respiratory depression, naloxone diluted 1:10 should be titrated carefully to prevent the precipitation of severe withdrawal symptoms while reversing the respiratory depression. An endotracheal tube should be placed in the comatose patient before administering naloxone to prevent aspiration associated respiratory compromise with excessive salivation and bronchial spasm. In patients receiving meperidine chronically, naloxone may precipitate seizures by blocking the depressant action of meperidine and allowing the convulsant activity of the active metabolite, normeperidine, to be manifest.

The mixed agonist-antagonists, pentazocine, nalbuphine, butorphanol, and the partial agonist buprenorphine have different dose-response characteristics for their respiratory depression curves from the morphine-like opioids. While therapeutic doses of pentazocine produce respiratory depression equivalent to that of morphine, increasing the dose does not ordinarily produce a proportional increase in respiratory depression. Whether this apparent ceiling to respiratory depression offers any significant clinical advantage has not been determined. Also, naloxone reversal of the respiratory depression produced by buprenorphine requires relatively large doses (5–10 mg) and is delayed in onset.[13]

Constriction of the Pupil

Opioids stimulate the Edinger-Wesphal (parasympathetic) nucleus of the oculomotor nerve to produce miosis. Pinpoint pupils (along with respiratory depression and loss of consciousness) are the three pathognomonic signs of opioid overdose. These effects are antagonized by the opioid antagonist, naloxone. However, severe anoxia results in mydriasis.

Antitussive Effect

Opioids depress the cough centers in the medulla and, in turn, depress the cough reflex. However, the receptor mechanisms involved with cough differ from those involved with other opioid effects such as analgesia. Therefore, the dextrorotatory isomers of opioids (e.g., dextromethorphan), which do not bind to opioid receptors, are nevertheless effective antitussives.

Hypothalamic Effects

Morphine affects both body temperature and circulating neuroendocrine hormone levels by actions on the hypothalamus. Morphine alters hypothalamic heat-regulating resulting in a slightly lower body temperature. The release of corticotrophin-releasing hormone (CRH) and gonadotropin-releasing hormone (GnRH) are inhibited resulting in a decrease in luteinizing hormone (LH), follicle stimulating hormone (FSH), and adrenocorticotropic hormone (ACTH). Prolactin and antidiuretic hormone (ADH) release are increased. Based on observations in methadone maintenance patients, tolerance develops to the effects of morphine on these hypothalamic releasing factors.

The term *opioid-induced androgen deficiency* (OPIAD) describes clinically meaningful decrease in testosterone levels that occurs in the majority of men receiving ongoing morphine or other potent mu agonist opioid pharmacotherapy for chronic nonmalignant pain.[14] Worsening of pain, depressed mood, and refractoriness to treatment are common in such patients. Trials of androgen supplements have been helpful and this phenomenon also appears to occur in women, presumably due to progesterone suppression.

Central Nervous System Excitation

In contrast to the obvious opioid CNS depressant effects, there are excitatory effects. Dose-dependent convulsions occur in rodents but are rare in humans. However, normeperidine, a principal metabolite of meperidine, causes anxiety, tremors, myoclonus, and generalized seizures when it accumulates with repetitive dosing.[15] Naloxone does not reverse, and may even exacerbate, this hyperexcitability. The morphine-like opioids can produce multifocal myoclonus when administered in high doses to opioid-tolerant patients.

Opioid Tolerance, Dependence, and Addiction

The properties of the opioid analgesics that are most likely to lead to their being misused, or the patient mistreated, are effects mediated in the CNS that are seen following chronic administra-

tion. These include tolerance, physical dependence, and psychological dependence (addiction) (Table 78.2). It must be emphasized that while the development of tolerance and physical dependence are predictable pharmacologic effects seen in humans and laboratory animals in response to repeated administration of an opioid, these effects are distinct from the behavioral pattern seen in some individuals and described by the terms *substance dependence* (DSM IV) or *addiction*.[16] See Chapters 21 and 32 for more on addiction and dependence.

The Opioid Tolerant Patient and Opioid-Induced Hyperalgesia

Clinically Observable Tolerance

Tolerance to opioid effects occurs, but it is widely misunderstood by many. It is useful to subdivide tolerance into three dimensions: (1) tolerance to analgesia, (2) tolerance to other CNS-depressing effects and nausea, and (3) tolerance to opioid-induced constipation. Effective ongoing opioid therapy for chronic pain often requires increasing the dose numerous times in the first days to weeks of therapy until a consistently effective dose is found. This may be initial tolerance or simply reflect a dose-finding period. Once an effective dose is found which keeps the patient reasonably comfortable for a few days, it is relatively uncommon to have to increase the dose further unless the painful pathology increases or a new painful disorder occurs, the patient skips doses, the dosage form is changed, a drug interaction occurs or some other nonpharmacological event such as diversion occurs. These types of events probably account for the majority of patient requests for increasing opioid doses. This phenomenon has been termed "pseudotolerance." Clinically meaningful tolerance to analgesia occurs unpredictably in a minority of patients receiving opioids chronically for management of pain with a physiological basis. Many chronic cancer and noncancer pain patients remain comfortable without increasing pain complaints for months or even years without an increase in opioid dose. A minority require escalating opioid doses for reasons that remain unclear. When a patient no longer responds to increasing doses of a particular opioid that was previously effective, consider rotation to another opioid.

Conversely, nearly everyone develops some meaningful degree of tolerance to opioid-induced sedation, respiratory depression, nausea, and inhibition of coordination after 5 to 7 days of ongoing (around the clock) opioid pharmacotherapy. At the initiation of opioid therapy, an antiemetic may be needed, but commonly it is not needed after a few days of therapy. Many patients cannot drive a motor vehicle or operate machinery safely in the first days of opioid treatment. However, after a week of regularly scheduled opioid, most people can drive safely. When the dose is increased or if the patient abstains from the medication for a few days, another week may be required to reacquire tolerance to impaired eye-foot-hand coordination.

Tolerance to opioid-induced constipation does not appear to occur. Management of this common and sometimes debilitating side effect is discussed later.

Proposed Mechanisms of Tolerance

Opioid tolerance may be classified as associative or pharmacologic. Associative or contextual tolerance refers to changes in response that result when an opioid is administered in the presence of specific environmental cues that can induce tolerance specific to that setting.[17] Pharmacologic (nonassociative) tolerance is divided into pharmacodynamic tolerance, which is the result of neuronal adaptations that reduce the sensitivity of the system to the drug, and pharmacokinetic tolerance wherein the disposition of the drug is increased so that the effective concentration is reduced. Generally, pharmacodynamic mechanisms are thought to be most responsible for in vivo opioid tolerance. However, a contribution by associative tolerance cannot be excluded.

In the clinical setting, pharmacodynamic tolerance (hereafter simply tolerance) develops when a given dose of an opioid produces a decreasing effect, or when a larger dose is required to maintain the original effect. Some reports suggest that a degree of tolerance to analgesia appears to develop in most patients receiving opioid analgesics chronically.[18] Although tolerance to opioid analgesia appears to develop rapidly in animal models, it does so much more slowly in humans. Other reports however document that many patients do not experience tolerance to analgesia, that is, the same dose of opioid continues to provide effective analgesia over days to years unless there is increasing pathology.[19]

An early sign of the development of tolerance is the patient's complaint of a decrease in the duration of effective analgesia. The rate of tolerance development varies greatly among cancer patients; some demonstrate tolerance within days of initiating opioid therapy while others will remain well-controlled for many months on the same dose.[20] Unfortunately, pharmacodynamic tolerance cannot be adequately evaluated in the clinical situation. Factors described previously as causing "pseudotolerance" should be considered and addressed before concluding that pharmacodynamic tolerance has occurred. Both an increase in pain and the development of tolerance often respond to an increase in the opioid dose. Since the analgesic effect is a logarithmic function of the dose of opioid, a doubling of the dose may be required to restore full analgesia. Although controversial, the experience with cancer patients suggests that there appears to be no limit to the development of tolerance and with appropriate adjustment of dose, many, but not all patients can continue to obtain pain relief without intolerable adverse effects. Titration to effect remains the hallmark of effective opioid therapy.

Preclinical studies suggest that apparent opioid tolerance may result from excitatory CNS changes that facilitate transmission of and increase sensitivity to pain.[21] This condition is termed opioid-induced hyperalgesia (OIH). The basic phenomenon appears to result from the up-regulation of pronociceptive systems. The neuroanatomic substrates and signaling pathways involved in OIH are emerging.[21] However, the magnitude of the contribution of OIH to clinical opioid tolerance and its consequences for continued opioid therapy remain controversial. There is general agreement that during opioid withdrawal, OIH may occur and contribute to an exacerbation of pain.[22] Therefore, avoid acute withdrawal. Switching from a morphine-like opioid to a mixed agonist-antagonist (pentazocine, nalbuphine, and butorphanol) or the partial agonist buprenorphine must be avoided because of those drugs' ability to induce abrupt opioid withdrawal and cause concomitant hyperalgesia in opioid-dependent individuals.[1] Using a combination of an opioid with a nonopioid can enhance analgesia and reduce the rate of tolerance development since tolerance does not develop to the nonopioid component of the mixture. Opioid dose-sparing strategies can be used at the initiation of opioid therapy. Rotation to an alternative mu opioid agonist usually results in a relative reduction of opioid dosage due to incomplete cross-tolerance (see later) among this class of opioids.[23] The use of bolus or continuous epidural local anesthetics in patients with localized pain, for example, perineal pain, can dramatically reduce the need for systemic opioids and thus diminish opioid tolerance.

Animal study data on tolerance do not translate well to humans. The rates of development and loss of tolerance are not well defined in patients. The rate and extent of tolerance can vary greatly among different opioids and among patients receiving the same doses of a single opioid.

Cross-tolerance refers to the effects of one drug that confers tolerance to another drug, usually of the same class. While some cross-tolerance appears to occur among mu opioid agonists, the

more relevant observation is that this cross-tolerance is incomplete. Therefore, when rotating from one opioid to another, this phenomenon must be taken into account in dosage calculations by initiating dosage with 25% to 50% of the calculated equianalgesic dose and titrating as required for pain relief.

The Opioid Dependent Patient

Physical dependence is the term used to describe an altered physiological state produced by repeated administration of an opioid which requires the continued administration of an opioid to prevent the emergence of a stereotypical withdrawal or abstinence syndrome that is characteristic for the particular opioid. The signs and symptoms of opioid withdrawal are described elsewhere.[24] The administration of an opioid antagonist to a physically dependent individual produces an immediate withdrawal syndrome. Patients who have received repeated doses of a morphine-like agonist, to the point at which they are physically dependent, may experience an opioid withdrawal reaction when given a mixed agonist-antagonist. Prior exposure to a morphine-like drug can greatly increase a patient's sensitivity to the antagonist component of a mixed agonist-antagonist. The severity of withdrawal is a function of the dose and duration of administration of the opioid just discontinued, that is, the patient's prior opioid exposure. The time course of the withdrawal syndrome is a function of the elimination half-life of the opioid to which the patient has become dependent (Table 78.3). Abstinence symptoms will appear within 6 to 12 hours and reach a peak at 24 to 72 hours, following cessation of a short half-life drug such as morphine, while onset may be delayed for 36 to 48 hours with methadone, a long half-life drug. Therefore, even for a patient in whom pain has been relieved by a procedure or treatment, it is necessary to slowly decrease the opioid dose to prevent withdrawal.

There is not one best method to taper opioids. Several different approaches have worked well. For patients who are anxious about tapering an opioid and those who may be especially sensitive to mild withdrawal effects, a slower taper may be indicated. A tapering rate of 10% to 20% per day is usually well tolerated.[25]

TABLE 78.3

PLASMA HALF-LIFE VALUES FOR OPIOIDS AND THEIR ACTIVE METABOLITES

1. Shorter half-life opioids	Plasma half-life (hours)
Morphine	2 to 3.5
Morphine-6-glucuronide	2
Hydromorphone	2 to 3
Oxycodone	2 to 4
Fentanyl	3.7
Codeine	3
Meperidine	3 to 4
Pentazocine	2 to 3
Butorphanol	2.5 to 3.5
Buprenorphine	3 to 5
Nalbuphine	5
Longer half-life opioids	
Oxymorphone	7.5 to 9.5
Levorphanol	12 to 16
Propoxyphene	12
Normeperidine	14 to 21
Methadone	13 to 50
Norpropoxyphene	30 to 40

Experience indicates that the usual daily dose required to prevent withdrawal is approximately one-fourth of the previous daily dose. This dose is called, for want of a better term, the detoxification dose and is typically given in four divided parts. Commonly, the initial detoxification dose is given for 2 days and then decreased by one-half (administered in four divided doses) for 2 days until a total daily dose of 10 to 15 mg per day (in morphine equivalents) is reached. After 2 days on this dose, the opioid can be discontinued. Thus, a patient who had been receiving 240 mg per day of morphine equivalent for pain would require an initial detoxification dose of 60 mg given as 15 mg every 6 hours. This dose is decreased by 50% per day over the next 3 to 5 days.

Cross-dependence refers to the ability of one opioid to substitute for another in preventing the withdrawal syndrome. Cross dependence among the opioids allows rotation as described previously, and allows detoxification with an alternate opioid. For example, methadone can be substituted for morphine in the previous example by switching the patient to oral methadone at one-fourth to one-eighth of the patient's morphine dose and decreasing the dosage as described above.

The Opioid Addicted Patient With Pain

The terms *substance dependence* (DSM IV) and *addiction* describe a pattern of drug use characterized by a continued craving for an opioid that is manifested as compulsive drug seeking behavior leading to an overwhelming involvement with the use and procurement of the drug. Within these definitions most, but not all individuals, who are addicted to opioids will have acquired some degree of physical dependence. However, the converse is not true, so that an individual can be physically dependent on an opioid analgesic without being addicted. Fear of addition is a major concern limiting the use of appropriate doses of opioids. Recent national surveys indicate a significant increase in nonmedical use of prescription opioids. Increased reports of this problem coincided with attempts to make opioids more widely available to patients in pain. It is important to recognize the responsibility of clinicians to assess and monitor patients who are receiving long-term opioid treatment for pain to limit the abuse of these drugs.

Peripheral Effects of Opioids

In addition to the central effects, opioids have several important peripheral effects. The colon contains a large population of mu opioid receptors, and opioid-induced constipation can be a difficult clinical problem. Occupation and activation of those receptors by mu opioid agonists inhibits peristalsis. Stimulating laxatives are the most appropriate type of laxative to manage this and they often, but not always, are effective. Stool softeners alone usually are not.

Peripherally acting mu opioid antagonists are a new class of drugs useful in managing opioid-induced constipation that is not responsive to laxatives.[26] Methylnaltrexone, the first such drug in the class, was approved to manage opioid-induced constipation in advanced illness in 2008 as a subcutaneous injection.[27] At the time of this writing, an oral formulation was under study. Alvimopan, an oral peripheral mu opioid receptor antagonist, is the second drug in the class. It was approved soon after methylnaltrexone, but only for limited term use under strict controls for the management of postoperative ileus.[28]

Itching has been associated with morphine, presumably due to morphine-induced release of histamine from mast cells.[29] This phenomenon has not been well studied, but clinical reports suggest that it is more common with morphine than with other opioids. This is not indicative of an immune reaction that presents

risk of anaphylactoid events. Systemic antipruritic agents have been used empirically. Rotation to another opioid is the most common management strategy.

Other peripheral opioid effects are associated with muscle relaxation. These include the cardiovascular system and cardiac rhythm, and relaxation of the ureter and bladder.

Opioid Effects in Pregnancy and on the Neonate

Pregnant women taking opioids may deliver an opioid-dependent infant. An estimated 1% to 2% of pregnant women take opioids.[30] A recent retrospective study[31] found that women on methadone maintenance had better outcomes than those who underwent methadone-assisted withdrawal and remained off methadone during pregnancy.

Routes for Opioid Administration

The oral (PO) route is generally the preferred route for opioid administration in ambulatory care due to convenience and relatively low cost. Immediate release oral opioid dosage forms include solutions, compressed tablets, and gelatin capsules. Although solutions are absorbed more promptly, it is not clear that this offers a clinically important advantage for most patients. The risk of patients incorrectly measuring the volume producing inconsistent and sometimes excessive doses is real.

Opioids can be administered systemically by oral, parenteral, rectal, sublingual, transdermal, and transmucosal routes. The mu agonists can be categorized as short-acting, long-acting, and ultra-short acting. Short half-life morphine-type opioids require frequent administration to maintain analgesia. Immediate-release morphine products provide about 4 hours of pain relief, and need to be dosed accordingly. Pharmaceutically formulated long-acting formulations (e.g., Avinza, Kadian, MS Contin, Opana ER, Oramorph-SR, OxyContin orally, and Duragesic transdermally) provide alternatives to frequent opioid administration of inherently short-acting drugs. Pharmacologically long-acting opioids, methadone and levorphanol, that have longer half-lives (Table 78.3) provide analgesia for 6 to 12 hours. Although methadone protects against opioid withdrawal for 24 or more hours, an oral dose only provides effective analgesia for about 8 hours. Pharmaceutically long-acting opioid dosage forms are generally relatively expensive, although generic forms of the original 8-hour formulations are now reasonably priced. The pharmacologically long-acting opioids, methadone and levorphanol, are relatively inexpensive.

Clinicians should be cautious about using extemporaneously compounded sustained release opioids. Although there are franchised compounding pharmacies that prepare these—and some market them aggressively—most inconsistently and unreliably release the active ingredient over time. Uneven pain control, exacerbation of pain and even overdose may result. The rapid onset of action of fentanyl mu agonists favors their use as a preoperative adjunct and their high lipophilicity facilitates transdermal and subcutaneous administration. When these highly lipophilic opioids are absorbed through or injected under the skin, they create a depot in subcutaneous fat from which the drug is slowly released. This depot effect also makes them very difficult to titrate to response.[32] However, when these medications are administered transmucosally or sublingually they are rapidly absorbed due to the lack of the buccal and sublingual fat. This prompt onset makes those routes useful in managing breakthrough pain.

Buprenorphine also has been formulated as a long-acting transdermal patch which was available in some countries, but not in the United States at the time of this writing.

The intravenous (IV) route of administration is generally preferred in immediate postoperative and intensive care settings. Intramuscular (IM) injection is painful and may produce uneven absorption. The subcutaneous (SC) route is preferred for injection when the intravenous route is impractical. The pharmacokinetics of SC administered opioids result in levels comparable to the IM route with the advantages that the SC route is far simpler to use and more comfortable for the patient. There is little or no rationale for IM opioid injections.

Table 78.1 lists relative equianalgesic doses and durations of action for commonly used opioids.

Alternative Noninvasive Routes

When oral administration is not possible, consider alternative noninvasive routes before resorting to injections, infusions, or the placement of epidural or intrathecal catheters.

Sublingual Administration

Transmucosal absorption occurs following sublingual administration of a reasonably lipophilic opioid. Oral transmucosal dosing may provide less consistent absorption than oral administration due to anatomical and physiological variability in the mucosa, for example, thickening due to pathology, pH. This route generally should not be considered when patients can take medications orally because oral administration is simpler and oral solid dosage forms provide more exact doses than liquid doses that must be measured before administration.

Sublingual administration entails placing of a small volume of concentrated liquid or a readily dissolvable solid dosage form under the tongue. Other locations in the mouth that can be used are the cheek pouch (buccal administration) and the anterior lip pouch. Clinical experience supports these routes but they have not been systematically studied. Patients should not eat or drink anything for about 15 minutes after taking an oral transmucosal dose. Doing so may increase the amount of drug that is swallowed, causing inconsistent interdose absorption.

Because opioids often cause dry mouth, it is important to counsel patients about this restriction. Some of an oral transmucosal dose tends to trickle down the throat or be actively swallowed, in which case that portion will undergo normal gastrointestinal absorption. Factors that influence the percentage of the dose that is swallowed include the volume of liquid and the condition of the oral mucosa. In general, no more than 1 mL of liquid should be placed under the tongue or in a mucosal pouch. Larger volumes tend to increase the amount of drug that is swallowed. Additional doses can be administered in a few minutes if necessary. It is necessary to moisten the mouth before dosing if it is dry as the result of disease or therapy. Stomatitis and excessive keratinization of the oral mucosa may make absorption inconsistent. The oral pH can influence absorption across the oral mucosa. Whereas normal mouth pH is 6.5, for many cancer patients receiving therapy it is above 7. The percentage of sublingual opioid absorbed increases with higher pH.[33] Because recently ingested foods and liquids can influence oral cavity pH, it is advisable to rinse the mouth with water before taking or administering an oral transmucosal dose, and to not eat or drink anything for the next 15 to 20 minutes.

The rectal route of administration is an alternative for patients unable to take drugs orally.

Table 78.4 lists rectal opioid times to peak and duration of action. This route of administration is generally acceptable for short-term use, but some patients find it esthetically objectionable.

This route is most commonly considered for short-term use and in care of terminal patients. The advantages of the rectal route include ease of use, lack of equipment, and low cost. Rectal

TABLE 78.4

RECTAL OPIOID TIMES TO PEAK AND DURATION OF ACTION

Morphine immediate release oral tablets	
peak	1.1 hour
duration	<6 hours
Morphine controlled release oral tablets	
peak	5.4 hours
duration	8–12 hours
Morphine oral solution	
peak	0.5 hours
duration	4–6 hours
Morphine rectal suppositories	
peak	1.1 hours
duration	<6 hours
Hydromorphone rectal suppositories	
peak	1 hour
duration	4–6 hours
Methadone oral tablets	
peak	2 hours
duration	6–8 hours
Oxycodone oral tablets and solution	
peak	3.1 hours
duration	8–12 hours

Table adapted from Warren D. Practical use of rectal medications in palliative care. *Pain Symptom Manage* 11:378–387, 1996.

administration is contraindicated for patients with painful anal lesions.[34]

Several opioid rectal suppository dosage forms are commercially available, some of which contain doses that are too low to be practical in advanced disease and palliative care. Therefore, extemporaneously compounded dosage forms are often needed. For such extemporaneously prepared forms, the rate and consistency of release of active ingredient from the dosage form and the risk of dose dumping resulting in toxicity are concerns.[35]

Rectally and orally administered morphine provides similar analgesic effect and serum levels. Although there is far less absorption following a rectal dose, a significant portion of an orally administered dose undergoes first-pass metabolism which is avoided with rectal administration. This effect may be unique to morphine and may not apply to other opioids. Immediate-release oral tablets, liquids, and suppositories of morphine have been used rectally with good effect.[36] Do not assume dose equivalency for other oral opioid dosage forms given rectally because of differences in physicochemical and pharmacokinetic properties. Controlled-release dosage forms do not necessarily have the same effects and duration of action when administered orally and rectally. Lower peak serum levels and more interpatient variability occur with all controlled-release dosage forms when they are given rectally rather than orally. MS Contin administered rectally produces clinical effects similar to those obtained with the same dose taken orally, and may produce less rectal irritation than commercially available rectal morphine suppositories.[37] Some palliative care nurses administer tablets rectally in a small mass of butter or an empty gelatin capsule. This is unnecessary and may delay absorption of the opioid. Simply ensure that the rectum is empty before inserting the tablets.

Oxycodone produces similar areas under the curve (AUCs) when administered rectally and orally.[38] Although rectal oxycodone suppositories are available in some countries, only oral solid and liquid forms are marketed in the United States. The commercially available oral liquid could be used rectally, but administration would be required every 3 to 4 hours for continual analgesia.

Informal, anecdotal reports of both immediate-release and controlled-release oral solid dosage forms administered via the vagina and through colostomy and ileostomy stomas also have been mentioned, but no data to support such use have been published. A comparative study of morphine administered rectally and through a colostomy led the investigators to conclude that the opioid should not be given through a colostomy due to poor and inconsistent absorption.[39] Animal studies of methadone administered vaginally indicate possible usefulness of that route.[40] But clinical data to support that hypothesis were not identified in a comprehensive literature search.

Nebulized opioids have been used and may provide good pain relief. However, that is not a cost-effective administration method for analgesia. Nebulized opioids are sometimes used as an alternative to sublingual administration to treat dyspnea (air hunger) in advanced disease.[41] Very small particles are needed to deliver drug to the alveoli. Use of an administration method other than a high quality small particle nebulizer can result in drug deposition on the palate with little clinical effect. Hand-held, squeeze bulb devices are not useful. Nebulized opioid administration requires sterile solutions, which increase expense as compared to oral and sublingual routes.

Epidural, Intrathecal, and Intraventricular Administration

The term spinal administration is sometimes unclear due to inconsistent differentiation between epidural and intrathecal administration. It is therefore better to avoid the term spinal and specify either epidural or intrathecal (subarachnoid). Both of these routes are being used increasingly, the former commonly for postoperative pain control and the latter more for chronic administration. In obstetrical analgesia, a single intrathecal dose followed by continuous or intermittent epidural administration often is used. Epidural patient-controlled analgesia also is used in some settings.[42]

The epidural space is a fat-filled potential space that contains blood vessels (Fig. 78.2). Therefore, epidural opioid administra-

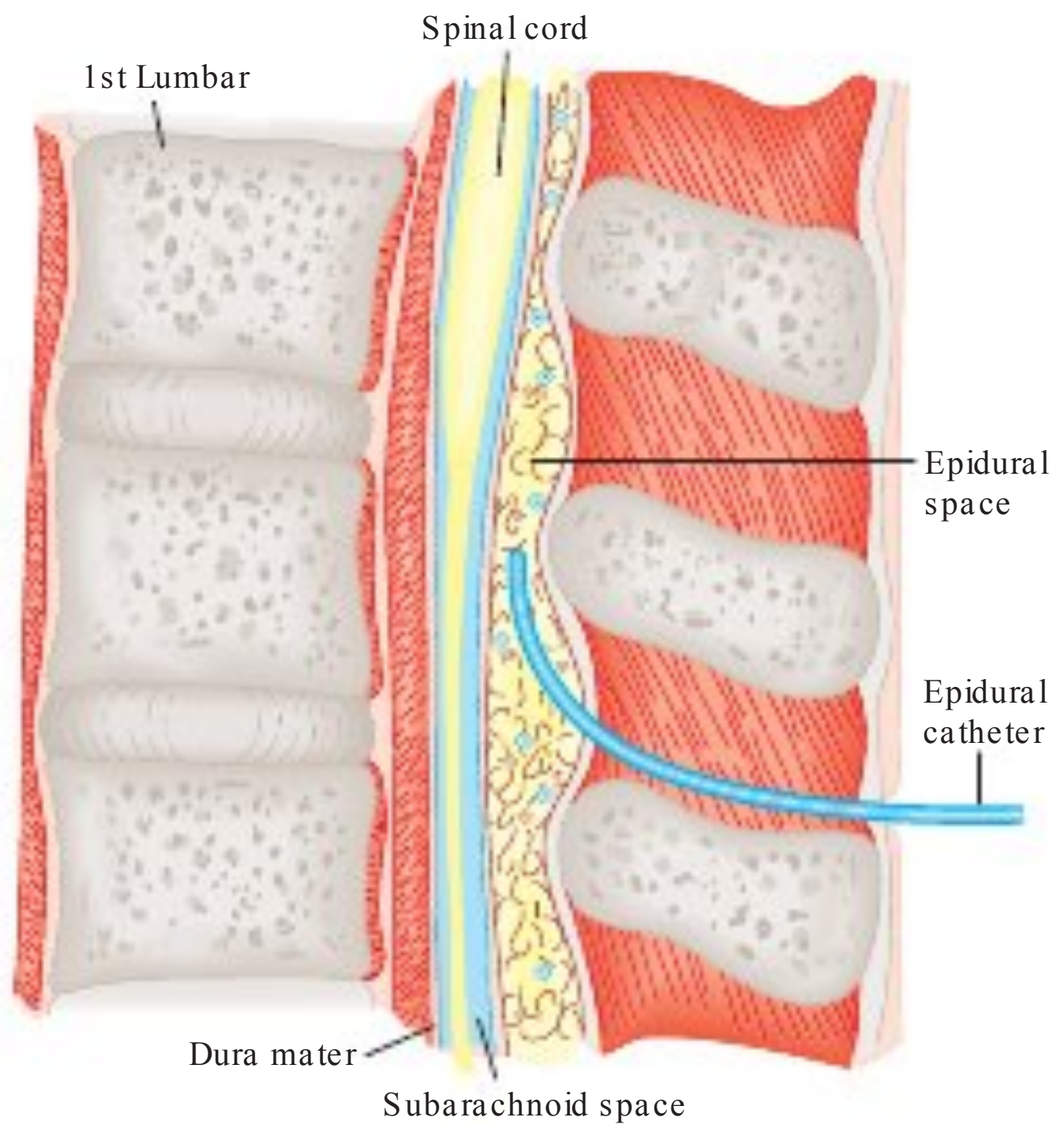

FIGURE 78.2 Drug delivery catheter in the epidural space.

tion can cause systemic effects albeit much more slowly and less than with intravenous and other systemic routes. The intrathecal route avoids some of the supraspinally mediated toxicity associated with the systemic delivery of these medications. The epidural and intrathecal routes each have advantages and disadvantages. Epidural administration allows opioid placement at any dermatomal level and does not require puncturing of the dura. However, larger doses are required and systemic effects may occur with epidural administration, increasing the risk of adverse effects. For morphine, intrathecal doses are typically one-tenth of those needed for an equianalgesic epidural dose. Intrathecal administration requires puncturing the dura, which delivers drug closer to the spinal cord receptors. Disadvantages of intrathecal use include increased potential for meningitis and risk of postdural puncture headaches. Dose-related problems associated with spinal analgesia include pruritus, urinary retention, and delayed respiratory depression.

Intraventricular administration has been used in cancer patients unresponsive to opioids administered by other routes.[43] The Ommaya reservoir has been used for this method of drug delivery.

With any direct central administration method, the pharmacokinetics of the opioids can vary greatly from systemic administration. Physicochemical drug characteristics, especially lipophilicity, become very important with these routes.

SOME SPECIFIC OPIOID CHARACTERISTICS

Morphine

The oral bioavailability of morphine varies from 35% to 75%, which helps to explain some of the interpatient variability in response. Its average plasma half-life of 3 hours is somewhat shorter than its 4- to 6-hour duration of analgesia; this limits accumulation. With repetitive administration, its pharmacokinetics remain linear and there does not appear to be autoinduction of biotransformation even following large chronic doses.[44] These pharmacokinetic properties contribute to the safe use of morphine over time. The two major morphine metabolites are morphine-3 glucuronide (M3G) and morphine-6 glucuronide (M6G). M6G appears to contribute to the analgesic activity of morphine.[45,46] M6G is eliminated by the kidney and, because it has a somewhat longer half-life than the parent compound, will accumulate relative to morphine in patients with renal insufficiency. A survey of steady-state morphine and M6G levels and adverse effects in 109 cancer patients indicated that myoclonus or cognitive impairment was not associated with M6G accumulation.[47] For a subset of the 20 patients with the highest M6G levels (>2000 ug/mL), the M6G level and concurrent organ failure was associated with the most severe toxicity (respiratory depression and/or obtundation).[47] It is appropriate to consider an alternate opioid for a patient receiving morphine who experiences a decrease in renal function and a concomitant increase in undesirable effects.

M3G is the predominant metabolite of morphine in humans. It lacks opioid activity but has excitatory effects in animals after direct injection into the CNS. This has led to the suggestion that M3G may be responsible for the neuroexcitatory effects sometimes seen with large chronic morphine dosing.[48] M3G has an elimination half-life even longer than M6G, and accumulated M3G has been associated with myoclonus and hyperalgesia although that association is not clear.[49]

Based on single dose studies in patients with either acute or chronic pain, the relative potency of intramuscular to oral morphine is 1:6. However, with repeated administration, when patients are dosed on a regular schedule (around the clock), the parenteral to oral dose ratio is reduced to 1:2 or 1:3 (Table 78.1). This presumably is due to accumulation of the M6G metabolite, which is active and has a longer half-life than the parent drug.

The sustained-release morphine preparations provide analgesia with a duration of 8 to 12 hours (MS Contin, Roxanol-SR) or 12 to 24 hours (Kadian, Avinza) and allow patients greater freedom from repetitive dosing, especially during the night. Patients may be titrated using the immediate release morphine and, once stabilized, converted to the sustained-release preparation according to a schedule appropriate for the form used. To manage acute "breakthrough" pain, "rescue" medication (immediate release morphine) should be made available to the patient receiving delayed-release preparations.

Allergy to morphine has historically been associated more with trace plant protein in morphine derived from natural sources (opium). Today, most morphine formulations are very pure and contain so little plant protein that this problem is relatively uncommon. When it does occur, a synthetic opioid is indicated. True allergy to the morphine molecule is rare.

Hydromorphone

Hydromorphone is a short half-life opioid used as an alternative to morphine by the oral and parenteral routes. It is a semisynthetic compound. It is more soluble than morphine and is available in a concentrated parenteral dosage form at 10 mg/mL which can be advantageous for opioid tolerant patients and cachectic patients in whom the volume of the opioid solution must be limited.

Methadone

Methadone use in pain management has dramatically increased in recent years with mixed effects. The original interest in methadone was based on its high (1:2) oral to parenteral potency ratio, which is a reflection of its high oral bioavailability that averages 85%. It was found to be useful in opioid rotation, because its incomplete cross-tolerance with opioids like morphine allow a significant reduction in dose when switching from morphine to methadone. Methadone is relatively inexpensive and its metabolites do not have opioid activity or apparent toxicity. As with other opioids, it may provide a larger therapeutic window in a particular patient although this cannot be determined prior to a therapeutic trial. Preclinical studies demonstrated the NMDA receptor antagonist activity of both isomers of methadone. In animals this NMDA receptor antagonist activity included antihyperalgesic activity and the ability to prevent the development of morphine tolerance.[1,50] However, it remains to be determined whether effects occur in humans at the doses of methadone used clinically.

A major limitation on the use of methadone as a first-line opioid for pain management relates to its safety. Its population pharmacokinetics are variable with a plasma half-life that averages 24 hours but may range from 13 to 50 hours. Since initially the duration of analgesia is often only 4 to 8 hours, repetitive analgesic dosing of methadone can lead to drug accumulation, because of this discrepancy between its plasma half-life and the duration of analgesia during initial dosing. Sedation, confusion, and even death can occur when patients are not carefully monitored and dosage adjusted during the accumulation period that can last from 5 to 10 days. More recently a second safety issue relates to concerns about the potential for methadone to prolong the QTc interval and predispose patients to torsade de pointes (TdP), a life-threatening arrhythmia.

Finally, there is the stigma among pain patients and the public attached to the use of methadone for the treatment of opioid addiction.

Oxycodone

Oxycodone is a mu opioid agonist that also may have kappa agonist activity. The latter may be advantageous in visceral pain such as occurs in gallbladder and pancreatic disease.[51]

Oxymorphone

Oxymorphone, a congener of morphine, is parenterally approximately 10 times more potent than morphine. Immediate- and extended-release oral formulations (Opana and Opana ER) have recently been released. The extended release dosage is indicated for every 12 hour dosing. As with other extended release dosage forms, it should not be used on an-as-need (PRN) schedule or used in opioid naive patients. It is contraindicated in patients with severe hepatic impairment. Opana ER is available in 5 to 40 mg tablets. The usual starting dose oral dose is 5 mg. Food enhances the bioavailability, so Opana ER should be taken 1 hour prior to a meal or 2 hours after a meal. Coingestion of alcohol with Opana ER may also increase plasma levels of oxymorphone. Oxymorphone remains available for parenteral and rectal (suppository) administration.

Levorphanol

Levorphanol is a longer half-life opioid (Table 78.3) that sometimes can be a useful alternative to morphine, but it must be used cautiously to prevent accumulation. For patients who are unable to tolerate morphine and methadone, levorphanol represents a useful medication with a good oral to parenteral potency ratio of 1:2.

Meperidine

The primary metabolite of meperidine (pethidine), normeperidine, has a unique neurotoxicity, which can lead to symptoms ranging from irritability to grand mal seizures. Because the metabolite half-life is much longer than the parent compound, the metabolite accumulates rapidly. Therefore, meperidine should not be used for longer than 24 to 48 hours. Many hospitals and health centers have removed it from their formularies for this reason.

Meperidine may have a relatively unique usefulness in managing rigors associated with anesthetics and amphotericin.[52] Other opioids and benzodiazepines have been suggested as alternatives for managing rigors, but controlled trials to document that are lacking.

Codeine

Codeine is an analgesic of limited usefulness because it is actually a prodrug that must be metabolized to morphine for effect. Because over 10% of the population lacks the cytochrome P-450 hepatic enzyme isoform needed for that metabolism, many patients get poor or no analgesia from codeine. Toxicity has occurred in nursing infants whose mothers ingested relatively low dose codeine when the mothers were rapid metabolizers, a more rare polymorphism than the poor metabolism phenotype, causing morphine levels that can be lethal to the infants.[53] Codeine is observed to produce more nausea and undesired central effects per unit of analgesia than equianalgesic morphine doses. While many clinicians believe that codeine is safer than other opioids, data do not support that contention. Codeine's usefulness is more as an antitussive and antidiarrheal agent than as an analgesic.

Codeine abuse is common. This may be due in part to its availability in antitussive formulations, for example, elixir terpin hydrate with codeine, which are only Schedule V controlled substances that can be purchased without a prescription in many jurisdictions.

Hydrocodone

Hydrocodone is a pure mu agonist much like morphine or oxycodone. Despite its name, hydrocodone is far more similar to morphine than codeine. Hydrocodone is the only opioid that is scheduled in the United States Federal Controlled Substances Act, which specifies it is to be a Schedule III controlled substance when formulated as a combination dosage form, for example, hydrocodone plus acetaminophen. Single ingredient hydrocodone dosage forms would be Schedule II. As such, the combinations are the most widely prescribed and, therefore, most widely abused opioids in the United States. There is no scientific rationale for hydrocodone being scheduled differently than oxycodone. The dose limit on hydrocodone-acetaminophen tablets and capsules is due to the acetaminophen, not the opioid.

Propoxyphene

Propoxyphene is a weak analgesic which also has a toxic metabolite resulting in being included on the Beer's List of inappropriate medications for elderly patients.[54] Studies have long supported the position that most of the efficacy of the commonly used propoxyphene-acetaminophen combination is due to the acetaminophen.[55]

Propoxyphene has been removed from many leading hospital formularies.

Tramadol

Tramadol is a weak mu agonist and weak norepinephrine-serotonin reuptake inhibitor. Neither mechanism alone explains its analgesic efficacy. The probable mechanism is synergism between these two weak effects. Tramadol at a dose of 100 mg four times daily may produce analgesia similar to that of oral morphine 5 to 10 mg, four times daily. Higher doses of tramadol offer no advantage and produce greater toxicity. Due to its mechanism, tramadol is more useful in neuropathic than nociceptive pain and it appears more appropriate as a chronic than acute use analgesic because the dose must be titrated up slowly to minimize risk of lowering seizure threshold.[56] A combination of tramadol 75% with acetaminophen 25% appears to be as effective as the single ingredient analgesic. Tramadol is not a controlled substance but it does have abuse potential and can be highly toxic when misused.[57]

Table 78.5 lists metabolites of commonly used opioids.

SELECTING AMONG THE OPIOIDS FOR CLINICAL USE

Table 78.1 lists other morphine-like agonists that may be substituted for morphine. An alternative opioid to morphine may be selected based on the need with a particular patient to overcome an adverse effect of morphine (e.g., vomiting or sedation). Other reasons include the cost, a patient's favorable prior experience with another opioid or even local availability of other morphine-like opioids. There is no evidence to suggest that any other opioid has greater analgesic efficacy than morphine in the population as a whole but interpatient variability does exist. Only clinical

TABLE 78.5

OPIOID METABOLITES

Parent drug (% eliminated unchanged)	Duration of analgesia	Metabolites (% if known)	Metabolite half-lives (hours)	Primary metabolite elimination	Comments
Morphine (~7.2% IV), (~3.7% PO)	4–6				In renal failure, Vd may be smaller producing increased plasma levels; enterohepatic circulation of parent drug and glucuronide metabolites
		morphine-3-glucuronide (57–74)	2.8–4	Renal	$T\frac{1}{2}$ –41–141 hours in renal failure, contributes to dose dependent myoclonus and seizures
		morphine-6-glucuronide (4.7–12)	Duration 2 × longer than parent drug	Renal	$T\frac{1}{2}$–89–136 hours in renal failure; may cause narcosis in renal failure; Intrathecally –100 times more potent than morphine; accumulates with chronic dosing
		morphine-3-ethereal sulfate (5–10)			
		normorphine (3.5)			
		morphine-N-oxide			
Codeine 11.1%[5]	4–6				
		codeine-6-glucuronide			primary elimination form; profound narcosis has occurred in chronic renal failure
		norcodeine		Renal	equipotent to codeine in analgesic activity
		morphine (10)			formation dependent on CYP 450 2D6; genetic polymorphism impacts effectiveness and toxicity
Fentanyl (<10%)	1–2				may be extensively liver metabolized
		norfentanyl		renal, hepatic	metabolized to despropionyl fentanyl may cause neurotoxic side effects structurally similar to normeperidine
		4-N-anilinopiperidine			
Hydromorphone (5.6%)					clearance dependent on hepatic blood flow
		hydromorphone-3-glucuronide			shown to accumulate in renal failure in one patient
		hydromorphone-6-glucuronide		Renal	formed from intermediate metabolites, dihydroisomorphine, and dihydromorphine
		nor-metabolites			
Levorphanol	6–8	levorphanol glucuronide		Renal	liver metabolized by glucuronide conjugation
Meperidine 5% (uncontrolled urine pH)	2.5–3.5				bioavailability increases from 50% to 80% in cirrhosis; $T\frac{1}{2}$ of meperidine and normeperidine prolonged in cirrhosis; urinary pH affects elimination of unchanged meperidine in urine; 25% in acidic urine vs. 1% to 2% in alkaline urine
		normeperidine (5–30)	15–30	Renal, hepatic	$T\frac{1}{2}$ prolonged in renal failure(>30 hr); double the CNS excitatory effects and half the analgesic effect of meperidine; urinary elimination is pH dependent: uncontrolled pH f_e = 0.05–0.06, acidic urine f_e = 0.30, alkaline urine f_e <0.031
		meperidinic acid			inactive metabolite

Methadone 21% (acidic urine increases the fraction of elimination [f_e])	4–6 initially; 6–8 after steady state (1–2 days)				in an anephric patient, 98% of methadone was found in feces as metabolite, suggesting a shift in metabolism from renal to fecal urinary excretion of methadone and metabolites is dose dependent and is the major route of elimination in doses >55 mg/day; 10% to 45% of methadone is eliminated in feces as metabolites
		1,5-demethyl-2-ethyl-3, 3-iphenyl-1-pyrroline		renal, biliary	unpredictable $T^1/_2$ with chronic dosing long term analgesia is 10 times morphine; major metabolite f_e = 0.30
		2-ethyl-5-methyl-3, 3-diphenyl-1-pyrroline			minor metabolite
		methadone-N-oxide			minor metabolite
Oxycodone	3–6				renally excreted, primarily as metabolites
		noroxymorphone			
		oxymorphone		hepatic, renal	active metabolite; renally excreted as oxymorphone-glucuronide
		noroxycodone			
Propoxyphene 1.5%	4–6				may depress cardiac conduction secondary to anesthetic properties; half-life not altered in renal failure
		norproproxyphene (25)	22.9–36.6	renal	local anesthetic properties; cardiac conduction abnormalities can result with accumulation (not reversed by naloxone); not hemodiazlyzable
Buprenorphine	6–8				one source says it is almost completely metabolized in the liver, but another source says the majority is excreted unchanged in feces and undergoes enterohepatic circulation with metabolites
		glucuronidation products		renal	
		norbuprenorphine		renal	may have weak analgesic properties
					primary route of elimination is renal; hepatic, biliary, and fecal routes also involved
Butorphanol 5%	3–4				extensively liver metabolized; Cl_{Cr} <30 mL/min half-life increased from 5.75 to 10.5 hours in single-dose, intranasal administration
		norbutorphanol		biliary	no analgesic activity
		hydroxybutorphanol		renal	analgesic activity; major metabolite; 60% to 80% renally excreted
Nalbuphine 7%	3–6				hepatic metabolism; metabolites and parent compound excreted in urine and feces
					major route of elimination is biliary secretion
Pentazocine 4.9%	3–6				(l) isomer responsible for analgesic activity; large interpatient variability in metabolism and oral bioavailability
					bioavailability in cirrhotic patients increased to 60% to 70%
		alcoholic and carboxylic acid metabolites		renal	inactive metabolites
		pentazocine glucuronide		renal	inactive metabolite

trial can adequately determine the opioid that is the best choice for a specific patient.

CONCLUSION

Opioids are essential analgesics for the management of severe pain. The risk to benefit ratio can be favorable when they are used properly. Respiratory depression is a risk particularly in the opioid naïve while the chronic toxicity may be related to endocrinopathy, especially androgen deficiency.

Titration to response remains the only effective way to determine the optimal opioid and dose for a specific patient. The initial opioid to be used should be based on past patient experience, dosing schedule compatibility with the patient's life style and probable adherence to the regimen, and cost. Regular observation for adverse effects is essential. When adverse events occur, consider whether changing to a different opioid may be preferable to additional drugs to treat the adverse effect. If opioid efficacy wanes, consider whether nonopioid therapy might then suffice and if androgen deficiency is a contributor. Opioid rotation also should be considered. Because of the comorbidities that occur with chronic pain, opioid monotherapy is seldom indicated; rather, additional pharmacotherapies, concurrent physical therapy, and psychotherapy are often required for appropriate pain management.

Opioid pharmacokinetics and pharmacodynamics are well characterized at all stages of life. Caution is indicated in elderly and renally impaired patients due to possible opioid accumulation. Additive and synergistic effects with other central nervous system depressant medications are common. All opioid regimens should be reevaluated at regular intervals and the medication should be tapered off if it is no longer needed or is no longer providing more benefits than adverse effects.

Pain remains a major public health problem and opioids are an important part of the analgesic armamentarium. Used wisely, opioids have great value.

CHAPTER 79 ■ SKELETAL MUSCLE RELAXANTS AND ANALGESIC BALMS

KENNETH C. JACKSON AND CHARLES E. ARGOFF

SKELETAL MUSCLE RELAXANTS

The class of medications commonly termed skeletal muscle relaxants remains an ill-defined and confusing enigma to many clinicians and scientists. To some extent, this results from the assumption that these medications act in a similar fashion and that this mechanism produces reliable production of skeletal muscle relaxation. Neither is true. These medications produce a range of effects that remain poorly defined for clinicians (Table 79.1).[1–4] The class includes carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, and orphenadrine.[5] These agents are approved by the U.S. Food and Drug Administration (FDA) for the relief of discomfort associated with an acute, painful musculoskeletal conditions. Baclofen and tizanidine have FDA-approved indication of the treatment of spasticity due to multiple sclerosis, spinal cord disease, or injury. Benzodiazepines, principally diazepam, also are commonly used for adjunctive relief of skeletal muscle spasm. Chief among the challenges to clinicians using these drugs is discerning the role of the agents across the continuum of painful disorders.

Historically, skeletal muscle relaxants have been prescribed for acute and chronic conditions associated with muscle-related pain. The majority of these agents are indicated for use during the initial presentation of acute low back pain (LBP), which often results from soft-tissue mechanical injury and normally occurs in the muscles, ligaments, and/or tendon structures around the lumbar spine. Acute pain may include local pain and tenderness, muscle spasm, and limited range of motion, but what actually constitutes painful muscle spasm remains controversial.[6] Muscle spasm may be a variant of the myofascial pain presentation and, as such, not really a spasm.[7]

To better understand the potential pharmacologic benefit of these agents, consider the regulation of muscle activity in both the peripheral tissues and central nervous system (CNS). At the level of the peripheral muscle, tissues are comprised of intrafusal fibers that signal changes in muscle length. These lie in parallel with extrafusal muscle fibers that normally serve to contract or stabilize joints. When muscle tissue is stretched, the intrafusal fibers stretch resulting in an increase in neural discharges carried by afferent nerve fibers. This signal is transmitted to the dorsal horn and synapses with alpha-motoneurons in the ventral horn, producing excitatory postsynaptic potentials. The result is a type of negative feedback, with muscle contraction of the intrafusal muscle fibers where the original stretch signal originated. These muscle fibers also maintain an efferent component, facilitated by small gamma-motoneurons that originate in the ventral horn of the spinal cord and travel together with the alpha-motoneurons that innervate extrafusal muscle fibers. The gamma-motoneurons adjust the sensitivity of the muscle fibers and regulate muscle tension over a wide range of muscle lengths. This complex system of afferent and efferent signaling through the motoneurons when at homeostasis leads to stabilization of muscle structures (Fig. 79.1).

In the dorsal horn, a complex network of excitatory and inhibitory interneurons mediates motor reflexes in response to deep and cutaneous stimulation. Such reflexes mediate ipsilateral flexion and contralateral extension in response to noxious stimuli to coordinate a protective or escape response. Impulses from cutaneous afferents travel through the dorsal horn of the spinal cord and terminate on excitatory interneurons, which in turn terminate on presynaptic terminals of the intrafusal fibers further promoting excitation at the ventral horn alpha-motoneuron. Inhibitory centers in the bulbar reticular formation and facilitatory centers from several brain regions further regulate both corticospinal and reflex muscle activity.[8,9]

Excitatory neurotransmitters in the CNS play a major role in the modulation of movement in the spinal cord and include substances like glutamate, aspartate, and substance P. These neurotransmitters are released from the terminals of primary afferent fibers to mediate reflexes that enhance motor tone at the spinal level.[10] Gamma-aminobutyric acid (GABA) is a major inhibitory CNS neurotransmitter that emanates from supraspinal and interneuronal inputs. GABA is believed to play a major role in presynaptic inhibition of motoneurons in the dorsal horn.[10]

Any change in the homeostasis of the peripheral or CNS components related to maintaining proper muscle tone can lead to production of an acute reflex muscle spasm. When this occurs, there are two main potential issues. Either a reflex increase in muscle tone activates polysynaptic reflexes and produces hyperexcitability of alpha and/or gamma motoneurons, or there is supraspinal activation of descending facilitatory systems.[11] In settings of chronic muscle spasticity, the processes appear to be more involved, with pathology from supraspinal CNS descending path-

TABLE 79.1

PHARMACOTHERAPIES COMMONLY USED FOR MUSCLE SPASM

Drug	Onset	Duration	Common dosing	Side effects	Important drug interactions
Sedative					
Carisoprodol (Soma, Meda Pharmaceuticals, Somerset, NJ)	30 min	4–6 hours	350 PO QID	Ataxia, dizziness, drowsiness, N/V, withdrawal potential	Additive effects with alcohol and other CNS depressants
Chlorzoxazone (Parafon Forte)	~1 hour	3–4 hours	250–750 mg PO TID-QID	Dizziness, drowsiness, headache, N/V	
Metaxalone (Skelaxin, King Pharmaceuticals Inc., Bristol, TN)	1 hour	4–6 hours	400–800 mg PO TID	Dizziness, drowsiness, headache, N/V, rash	
Methocarbamol (Robaxin)	30 min (PO)	N/A	750–1000 mg PO QID	Blurred vision, dizziness, drowsiness	
TCA-Like					
Cyclobenzaprine (Flexeril)	~1 hour	12–24 hours	5–10 mg PO TID	Drowsiness, dizziness, dry mouth	Additive effects with alcohol and other CNS depressants; seizures with tramadol and MAOIs; additive effects with TCAs
Antihistamine					
Orphenadrine (Norflex)	1 hour (PO)	4–6 hours	100 mg PO BID	Tachycardia, lightheadedness, N/V, dry mouth	Additive effects with alcohol and other CNS depressants; coadministration with propoxyphene can lead to confusion, anxiety, and/or tremors
GABA-Type					
Diazepam (Valium)	30 minutes (PO)	Variable, depending on elimination	2–10 mg PO TID	Sedation, fatigue, hypotension, ataxia, respiratory depression	Potentiation of effects when taken with phenothiazines, opioids, barbiturates, MAOIs
Baclofen (Lioresal)	3–4 days (PO) 30 min (IT)	Variable (PO) 4–6 hours (IT)	5 mg PO TID titrated up to 40–80 mg/day	Drowsiness, slurred speech, hypotension, constipation, urinary retention	Antidepressants (short-term memory loss); additive effects with imipramine
Central Alpha-2 Agonists					
Tizanidine (Zanaflex)	2 weeks	Variable	2–8 mg PO TID–QID	Drowsiness, dry mouth, dizziness, hypotension, increased spasm/tone	Additive effects with alcohol and other CNS depressants; reduced clearance with oral contraceptives

IT, intrathecal; MAOIs, monoamine oxidase inhibitors; N/A, not applicable; N/V, nausea/vomiting; PO, oral; QID, four times daily; TID, three times daily.

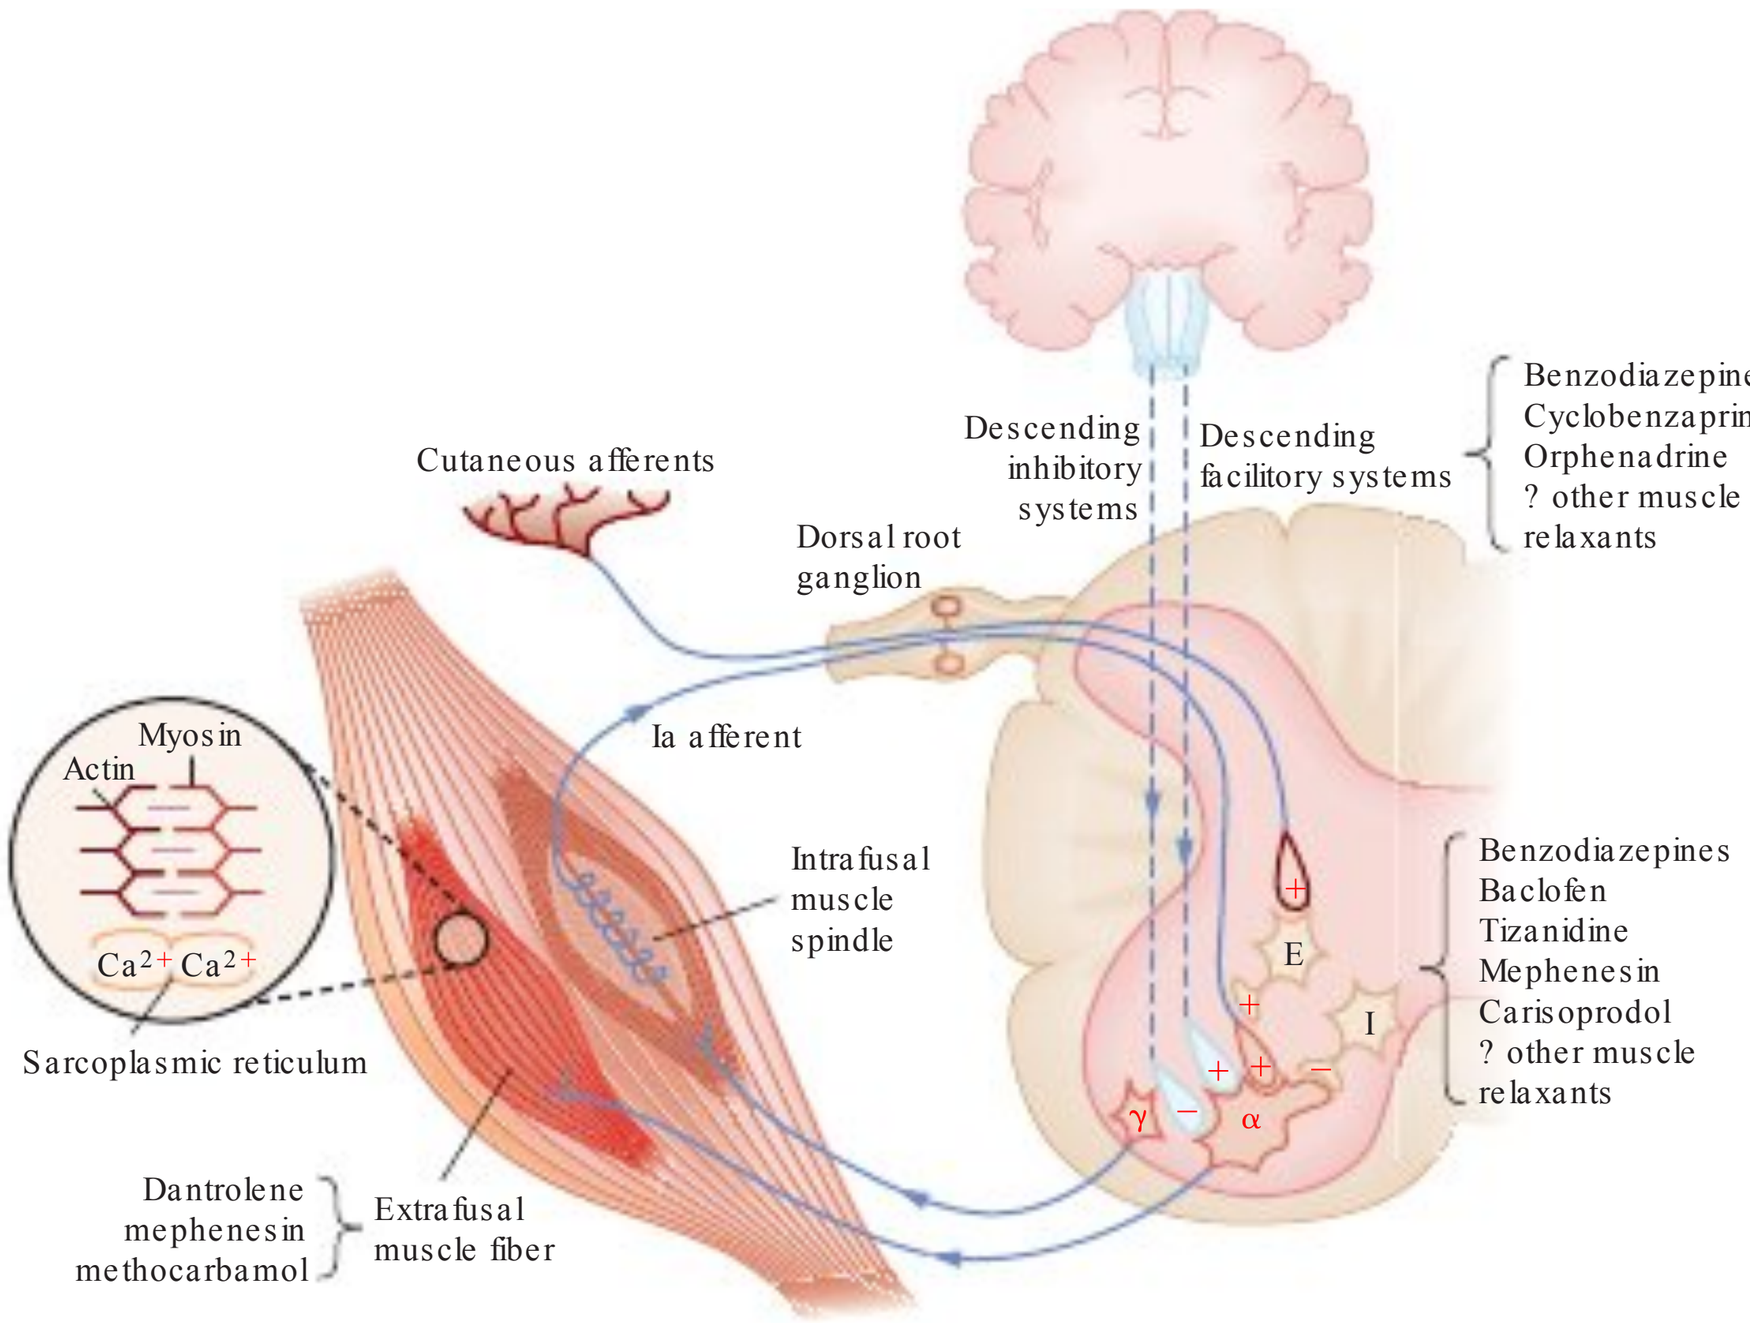

FIGURE 79.1 Neural regulation of muscle tone: possible sites of action of skeletal muscle relaxants. See text for details. (+, excitatory effect; −, inhibitory effect; α, alpha-motoneuron; Ca^{2+}, calcium ion; E, excitatory interneuron; γ, gamma-motoneuron; I, inhibitory interneuron.)

ways that produce excessive excitation or diminished inhibition of alpha-motoneurons in the dorsal horn.[12]

Mechanism of Action

In animal studies, skeletal muscle relaxants act at various CNS sites that are important in muscle activity regulation. The exact mechanism of action for these various agents is not clear. A variety of mechanisms appear to be associated with the activity of this diverse group of agents (Table 79.2). Animal models have historically shown that muscle relaxants exert their activity by blocking polysynaptic neurons in the spinal cord and inhibiting interneuronal activity within the descending reticular formation.[1] Mephenesin, an early predecessor to today's muscle relaxants, in animal models affected monosynaptic and polysynaptic reflexes.[13,14] Subsequent animal data showed that mephenesin and methocarbamol prolonged the refractory period of skeletal muscle by a direct action on skeletal muscle fibers.[15] Very little has been described about the effects of skeletal muscle relaxants such as cyclobenzaprine, methocarbamol, carisoprodol, and chlorzoxazone on neurotransmission. These medications are also known to have a significant sedative profile. This was a quality that was exploited when older treatment paradigms included significant bedrest. Interestingly, other medications with sedative properties are also known to depress polysynaptic reflexes. This situation certainly sheds some degree of confusion as to the specific utility of skeletal muscle relaxants, especially in relation to the purported effects versus nonspecific sedation.

The pharmacologic capacity of other commonly used drugs is less well characterized in specific relation to muscle spasm. Diazepam, a benzodiazepine, suppressed polysynaptic reflexes in cats, but required doses higher than would be used clinically.[16] Benzodiazepines act by potentiating the postsynaptic effects of GABA within the CNS.[12] Baclofen (parachlorophenyl GABA) is a lipophilic derivative of GABA that binds to $GABA_B$ but not to $GABA_A$ receptors and may exert its effect, in part, by inhibiting the evoked release of excitatory amino acids (e.g., glutamate) and substance P.[10] Tizanidine, a newer antispasticity agent, is an α_2-adrenergic receptor agonist that may also act by decreasing spinal excitatory amino acid release.[16]

TABLE 79.2

AGENTS BY PROPOSED MECHANISM OF ACTION

CNS depressants
- **Antihistamine**
  orphenadrine
- **Sedatives**
  carisoprodol, chlorzoxazone, metaxalone, methocarbamol
- **TCA-like**
  cyclobenzaprine

Central alpha-2 agonists
tizanidine

GABA-agonists
baclofen
benzodiazepines

CENTRALLY-ACTING SEDATIVE-HYPNOTIC MUSCLE RELAXANTS

Carisoprodol

Carisoprodol is converted in the liver to meprobamate, a schedule IV controlled substance. Meprobamate produces physical and psychologic dependence.[18–23] Substance abuse appears to be problematic with carisoprodol, probably due to meprobamate formation. In recent years, several states have begun treating carisoprodol as a controlled substance within their state formularies. Due to the dependence potential, carisoprodol should be cautiously tapered as opposed to immediately discontinued following long-term use. At the end of November 2007, the European Medicines Agency recommended the suspension of marketing authorization for carisoprodol-containing products for its 12 member states. Its Committee for Medicinal Products for Human Use concluded that the risk of their use is greater than the benefits.[24]

Chlorzoxazone

Chlorzoxazone may be less effective than the other skeletal muscle relaxants.[25] Chlorzoxazone does not have any significant drug interactions, but does have a significant adverse effect profile that includes a rare idiosyncratic hepatocellular reaction.[26] The use of this agent may be questionable considering the potential lack of efficacy and significant toxicity profile.[27]

Metaxalone

Metaxalone does not have any significant drug interactions and appears to have a fairly benign side effect profile. Hemolytic anemia and impaired liver function may occur but are uncommon. Fatalities attributed to the use of metaxalone have been reported.[28,29] Metaxalone is contraindicated in patients with severe renal or hepatic impairment. Because this drug was FDA-approved over 30 years ago, there are few published placebo-controlled studies of metaxalone for musculoskeletal pain.[30]

Methocarbamol

Methocarbamol is available in an oral form and a parenteral form for IV or intramuscular use. Complications with the injectable form include pain, skin sloughing, and thrombophlebitis. This drug also was FDA-approved over 30 years ago, and as a result, there are few published studies comparing it to placebo for the treatment of musculoskeletal pain.[31]

ANTIHISTAMINE MUSCLE RELAXANT

Orphenadrine Citrate

Orphenadrine is a derivative of diphenhydramine and accordingly exhibits antihistaminic and anticholinergic properties. There have been reports of severe adverse reactions with parenteral use (e.g., anaphylactoid reaction). Orphenadrine use with propoxyphene may cause confusion, anxiety, and tremors, perhaps because of additive effects. Anticholinergic actions of orphenadrine have been noted to produce significant adverse effects at high dosages (e.g., tachycardia, palpitations, urinary retention, blurred vision).[32]

TRYCYCLIC ANTIDEPRESSANT-LIKE MUSCLE RELAXANT

Cyclobenzaprine

Cyclobenzaprine is more structurally and pharmacologically similar to the tricyclic antidepressants (TCAs) than it is to the centrally acting sedative-hypnotic skeletal muscle relaxants. As with the other skeletal muscle relaxants, cyclobenzaprine does not act directly on muscle tissue. Animal data suggest cyclobenzaprine acts primarily at the level of brainstem, reducing tonic somatic motor activity.[33] While no evidence exists in humans to support this mechanism, it is interesting to note that the newer 5 mg dose has yielded similar clinical efficacy with less sedation than the 10 mg dose.[34] This may prove to be an important distinction from the centrally acting sedative-hypnotic muscle relaxants.

The value of muscle relaxant monotherapy remains the subject of some skepticism; these agents may be used as adjuncts to other therapies. This appears to apply to cyclobenzaprine as well. In an open-label study of patients with acute neck or low back pain associated with muscle spasm who were randomized to be treated for 7 days with either cyclobenzaprine 5 mg orally three times daily alone or with cyclobenzaprine 5 mg orally three times daily in combination with ibuprofen at doses of 400 mg orally three times daily or 800 mg three times daily, no significant treatment differences were found among these groups.[35]

Cyclobenzaprine has a similar adverse event profile as the TCAs. Thus, one might want to avoid using cyclobenzaprine and a TCA concurrently unless the combination is truly clinically indicated. Anticholinergic side effects, including dry mouth, urinary retention, and constipation, occur with cyclobenzaprine. Use of cyclobenzaprine is contraindicated in the setting of arrhythmias, congestive heart failure, hyperthyroidism, or during the acute recovery phase of a myocardial infarction. Concurrent use with proserotonergic agents such as selective serotonin reuptake inhibitors may predispose patients to life-threatening serotonin syndrome.[36]

Cyclobenzaprine labeling suggests that concomitant use with tramadol may place patients at higher risk for developing seizures.[33] Concomitant use of cyclobenzaprine with monoamine oxidase inhibitors or use within 14 days after their discontinuation is contraindicated. Cyclobenzaprine can enhance the effects of agents with CNS-depressant activity. Older patients appear to have a higher risk for CNS-related adverse reactions, such as hallucinations and confusion, when using cyclobenzaprine. Withdrawal symptoms have been noted with the discontinuation of chronic cyclobenzaprine use. Use of a medication taper may be warranted for patients with chronic use.

GABA-AGONIST MUSCLE RELAXANTS

Diazepam

Diazepam is the most commonly prescribed and referenced benzodiazepine in the treatment of muscle spasms.[37] It has hypnotic, anxiolytic, antiepileptic, and antispasmodic properties. Sedation and abuse potential are the main concerns with this agent and class. It is important to slowly taper this agent after long-term use to avoid any withdrawal symptoms.

Baclofen

Studies have shown baclofen to have superior efficacy than diazepam.[2] Baclofen is unique in that it can be administered intrathecally in cases of severe spasticity and for patients who do not tolerate or have failed oral therapy. Baclofen should be tapered slowly after long-term use to avoid a withdrawal reaction and rebound phenomena. It should be used with caution in the elderly and for patients with renal impairment.

CENTRAL ALPHA-2 AGONIST MUSCLE RELAXANTS

Tizanidine

Tizanidine is related chemically to clonidine, but has significantly less antihypertensive effect.[38] The main adverse effect for most patients with this agent is sedation.[39] Currently, tizanidine is FDA-approved for the management of increased muscle tone associated with spasticity resulting from CNS disorders, such as multiple sclerosis or spinal cord injury. Two studies report use of tizanidine in back pain or muscle spasm, either alone or in combination with ibuprofen, and another reports effectiveness in myofascial pain.[40–42] A multicenter, placebo-controlled study evaluated the efficacy and safety of tizanidine in the treatment of low back pain; tizanidine was found to provide more pain relief and less restriction of movement than placebo. Drowsiness was the most common side effect but, for acute LBP patients, this effect may actually be desired, especially at night.[40] A study of 105 patients with acute LBP received tizanidine 4 mg orally three times daily with ibuprofen 400 mg orally three times daily or ibuprofen 400 mg orally three times daily compared to placebo. The results suggested that the tizanidine/ibuprofen combination was more effective for moderate or severe acute LBP than ibuprofen only.[41] Use tizanidine with caution in renal impairment; clearance is decreased by 50% in patients with creatinine clearance <25 mL/minute. Coadministration with alcohol can increase the AUC of tizanidine by approximately 20% and increase C_{max} by approximately 15%. Use with oral contraceptives can decrease the clearance of tizanidine and place patients at higher risk for sedating adverse effects.

ACUTE LOW BACK PAIN

Available data indicate that skeletal muscle relaxants are more effective than placebo to relieve acute LBP.[25] Unfortunately, most of the data are dated and are derived from studies for which the designs and analyses would not be acceptable today. No data clearly show that any one agent is more efficacious than another. Some data suggest that chlorzoxazone may be less effective than other drugs and, as such, puts into question the use of this agent.[25,43]

Most clinical guidelines list skeletal muscle relaxants as optional agents for use individually or in combination with a nonsteroidal anti-inflammatory agent (NSAID). The federal clinical practice guideline published in 1995 specifically noted that skeletal muscle relaxants alone or in combination with an NSAID were no more effective than using an NSAID alone.[44] This conclusion has been supported in systematic reviews by van Tulder and colleagues.[25,43] Skeletal muscle relaxants have been shown to more effective than placebo for patients with acute LBP with respect to outcomes such as short-term pain relief, global efficacy, and improvement of physical outcomes.[45–48] No quality evidence allows a direct comparison of skeletal muscle relaxants to NSAIDs. Most clinicians and researchers agree that skeletal muscle relaxants may benefit patients with acute LBP by reducing the duration of their discomfort and accelerating recovery. A meta-analysis of cyclobenzaprine studies for acute LBP concluded that, despite limitations in the available evidence, the combination of a NSAID with cyclobenzaprine appears to be warranted.[49] It is probably best to consider the use of skeletal muscle relaxants as an adjunct or alternative to NSAIDs, especially in cases where NSAID toxicity is a concern or when NSAID monotherapy proves suboptimal.

Various systematic reviews have been published reviewing the randomized controlled trials of muscle relaxants in the treatment of LBP.[25,43,50] These analyses concur that there is strong evidence that muscle relaxants are more effective than placebo for acute LBP, but do not indicate superiority of a specific type of muscle relaxant. Muscle relaxants also appear to be useful in acute cervical pain presentations.[51–53]

Baclofen and tizanidine are well established for the treatment of spasticity secondary to upper motor neuron or spinal disorders.[12,17,54] Limited clinical evidence exists for the treatment of acute muscle spasm with baclofen. As noted previously, tizanidine has some evidence but can be extremely sedating, especially at doses that prove analgesic for acute back pain.

CHRONIC LOW BACK PAIN

Despite the common use of skeletal muscle relaxants, relatively few data clarify their appropriateness in the treatment of chronic back pain.[25,50] No skeletal muscle relaxant has an indication for use in chronic back pain. Despite this lack of evidence, muscle relaxants are often prescribed on a long-term basis.[55] Only baclofen and tizanidine have FDA-approved indications for spasticity. When used in acute back pain, skeletal muscle relaxants are used to treat muscle spasms and associated pain during the normal recovery period of 1 to 3 weeks. Since this correlates with the time course that most patients recover from their acute injury, it is difficult to discern the exact nature of the utility for these medications. As a group, these agents may provide some global palliative quality, but probably do not affect the course of the underlying morbidity, per se.

Skeletal muscle relaxants have CNS-depressant effects and should be used with caution, particularly for patients with concomitant use of alcohol, anxiolytics, opioid analgesics, or other sedating medications. There is strong evidence that skeletal muscle relaxants are associated with increased risk for total adverse effects, especially those related to the CNS.[25,43,50] Many chronic pain patients appear to benefit from less pharmacotherapy, especially substances that may cloud cognitive and functional capacities.[56] Pill tapers can be used where patients who are appropriate candidates for streamlining can have their muscle relaxant therapy slowly discontinued over a relatively short time (e.g., 2 weeks). In some situations, patients may require more interventions (e.g., behavioral medicine support). These patients are probably best managed by interdisciplinary pain programs or by a psychiatrist.

TOPICAL ANALGESIC BALMS

Applying medicines topically is an ancient practice that, while often perceived as pragmatic, can become quite problematic. Many ancient cultures utilized a variety of natural substances (e.g., herbs and plants) for a variety of medicinal uses, including analgesia. Today, a variety of topical remedies is available to patients with painful conditions, primarily as over-the-counter (OTC) analgesic balm, many of which have been available for decades. The majority of these preparations contain counterirritants such as camphor, menthol, and salicylates either alone or in combination with each other or a variety of other medicinal

TABLE 79.3

BENEFITS AND LIMITATIONS OF TOPICAL ANALGESICS

Benefits	Limitations
• Avoid need for oral absorption • Avoid metabolic complications and systemic adverse effects • Ease of dose termination in the event of untoward side effects • Direct access to the target site • Convenient administration • Improved patient acceptance and adherence • Alternative route when oral not viable (e.g., patient with emesis)	• Absorption pharmacokinetic issues due to molecular size, lipophilicity, and skin permeability • Topical enzymatic activity may occur and reduce efficacy. • Localized skin irritation, such as erythema, can occur.

(Adapted from Hare BD, Lipman AG. Uses and Misuses of Medication in the Treatment of Chronic Pain. In Hare BD, Fine P, eds. *Chronic pain, problems in anesthesia*. Philadelphia: JB Lippincott Co.; 1990.)

ingredients. Capsaicin, a counterirritant, and nonsalicylate NSAIDs are also available in prescription and OTC topical formulations. Lidocaine and a variety of other substances used topically are discussed elsewhere in this book.

Topical drug administration would appear to maintain many potential benefits, especially in pain presentations that have a defined local and peripheral component.[57] The most obvious benefit is avoiding potential negative sequelae common with systemic administration of analgesics (e.g., adverse effects, drug interactions, need for an effective serum concentration). At the same time, topical administration can be prone to a variety of limitations, often inversely related to the benefits of topical application. Benefits and limitations are summarized in Table 79.3. Direct topical drug application appears to avoid numerous problems that occur with systemic administration of medications. This is especially true for NSAIDs, where toxicity with systemic administration can be very difficult for many patients. As described below, topical NSAIDs appear to be useful for some acute pain presentations (e.g., soft tissue injuries and postsurgical pain).

NSAIDs have the most evidence base among the topical analgesics. Moore and colleagues[58] conducted a meta-analysis reviewing analgesic efficacy for acute pain related to soft tissue trauma, sprains, and strains. They also analyzed pain relief for chronic pain conditions, such as osteoarthritis and tendonitis. The number needed to treat (NNT) was 3.9 for the acute pain conditions and 3.1 for the chronic pain conditions. The authors noted that local skin reactions were uncommon (3.6% of patients) in the studies. As could be expected, systemic adverse effects were extremely uncommon at less than 0.5% of patients exposed to this drug class. The evidence is not as compelling for the role of topical NSAIDs when compared to oral administration.[59] While topical administration does not appear to afford the same therapeutic profile, this route of administration is also better tolerated and may be of benefit in patients who would not otherwise be able to use an NSAID orally.

Topical Counterirritants

Topical counterirritants comprise a group of substances primarily for use by patients in a variety of OTC analgesic compounds. These include capsaicin, camphor, menthol, and salicylates which appear to provide analgesic benefit by desensitizing peripheral nociceptive receptors. Galeotti and colleagues[60] suggested that menthol's analgesic properties may be mediated through selective activation of kappa-opioid receptors.

Capsaicin appears to have the best evidence for use among the topical analgesics, primarily in osteoarthritis. Analgesic activity for capsaicin is attributed to depletion of substance P from peripheral nerve terminals. This requires both time and consistent dosing. A recent systematic review of topical capsaicin for musculoskeletal pain found an NNT of 8.1 for pain relief.[61] A variety of guidelines list capsaicin as a useful adjunct for use in patients with osteoarthritis. The European League Against Rheumatism and the American College of Rheumatology both recommend capsaicin for the treatment of pain in osteoarthritis.[62,63] The main issue related to capsaicin use is the adverse effect profile, which occurs to some extent with all patients and is an expected consequence of the mechanism of action. In the aforementioned systematic review, side effects were problematic in approximately one-third of the patients.[61] Typical experiences include local adverse reactions such as pain upon application, burning, stinging, and redness at the site of application. This adverse effect profile is probably the biggest disadvantage for this medication, causing either early discontinuation or reduced patient compliance, leading to absence of efficacy.[64,65]

The other counterirritants can be classified as rubefacients, including salicylates. There are few good efficacy data for these medications, probably in part because these substances have been used for so long. The benefit of these agents may also be due to the actual administration process (i.e., rubbing), causing increased stimulation in the area.

While salicylates may also have activity similar to other NSAIDs, their topical mechanism remains poorly elucidated. Mason and colleagues[66] reviewed the use of topical salicylates for acute musculoskeletal pain. These authors noted that topical salicylates produced a significant reduction in pain compared to placebo, with a NNT of 2.1. The benefit of this medication class for chronic use is limited by both lack of efficacy data and the potential for adverse effects with continued administration.

CONCLUSION

Skeletal muscle relaxants and topical analgesic balms comprise a cadre of substances that are commonly used for a variety of pain conditions. Skeletal muscle relaxants have value for acute back pain, mainly as adjunctive agents with other forms of analgesia and physical therapy. The use of these agents in chronic pain conditions remains controversial. This is in part due to the lack of efficacy data available for the use of these substances in chronic back pain conditions. Moreover, these agents maintain a substantial adverse effect profile that often is counterproductive for patients with chronic pain.

Topical analgesic balms are commonly used for self-care in acute painful conditions. Capsaicin is the one substance within this group with potential value in osteoarthritis. The main challenge with this substance is managing expectations and adverse effects.

CHAPTER 80 ■ NEUROPATHIC PAIN PHARMACOTHERAPY

ELON EISENBERG AND DAVID PETERSON

INTRODUCTION

Neuropathic pain is chronic pain due to direct central or peripheral nerve damage. While all pain may be considered neurogenic, neuropathic pain results from damage to the nervous system, per se. An estimated 1.5% to 8% of the general population suffer from neuropathic pain.[1,2] Neuropathic pain may result from a large variety of insults, examples of which are listed in Table 80.1. Common examples of peripheral neuropathic pain include lumbar or cervical radiculopathy, painful diabetic neuropathy (PDN), and postherpetic neuralgia (PHN). Neuropathic pain of central origin includes central poststroke pain, pain due to multiple sclerosis, and postspinal cord injury pain.

Neuropathic pain may be continuous or intermittent, and is typically described as burning, aching, or paresthetic. It may or may or may not be lancinating. Allodynia, an abnormal sensitivity of the painful site to normally innocuous stimuli such as running water or cold air, is commonly associated with neuropathic pain.[3] Neuropathic pain has negative effects on multiple domains of life; the quality of life of patients with neuropathic pain is comparable to that experienced by patients suffering from cancer or chronic heart failure. This is further aggravated by the fact that neuropathic pain is often undiagnosed and undertreated.[4] Various types of neuropathic pain are discussed in more detail in Part I of this book.

Many different drugs are used to manage neuropathic pain due to the lack of specific medications that effectively treat it. Pharmacotherapy for neuropathic pain involves a wide variety of agents including, but not limited to, antidepressants, anticonvulsants, opioids, and topical agents. Even with the newest of these drugs, effective pain relief occurs in less than half of chronic neuropathic pain patients.[5,6] In patients with refractory neuropathic pain, combination therapy with two or more agents possessing different mechanisms is often indicated.[7] Additional approaches for the management of intractable neuropathic pain, for example, implantation of neuromodulation devices such as spinal cord stimulators, intrathecal drug delivery pumps, are discussed in Chapter 95.

Most pharmacological studies of neuropathic pain management have focused on a few subtypes of peripheral neuropathic pain, notably PDN, PHN, and, to some degree, trigeminal neuralgia. Thus, while evidence of treatment efficacy in these indications clearly exists, the effectiveness of these treatments in other forms of neuropathic pain is less clear.

This chapter reviews pharmacotherapy for neuropathic pain and emphasizes the strengths and the limitations of different treatments. It also addresses unresolved issues related to pharmacological treatment of neuropathic pain.

TABLE 80.1

CAUSES OF NEUROPATHIC PAIN PERIPHERAL OR CENTRAL SOMATOSENSORY NERVOUS SYSTEM (EXAMPLES)

Trauma (surgery, frostbite, amputation)
Inflammation (Guillain Barré syndrome)
Infection (AIDS neuropathy, postherpetic neuralgia)
Degenerative spine disease
Ischemic disorders
Metabolic disorders (diabetes mellitus)
Neoplastic disorders
Congenital disorders (Fabry's disease)
Toxicity (chemotherapy)
Immunologic disorders

ANTIDEPRESSANTS

Four classes of antidepressant medications have been studied in neuropathic pain treatment: tricyclic antidepressants (TCAs), selective serotonin and norepinephrine reuptake inhibitors (SNRIs), selective serotonin reuptake inhibitors (SSRIs), and monoamine oxidase inhibitors (MAOIs). Certain drugs in the first two classes are commonly considered first line recommended treatments for neuropathic pain.[5,6,8] Table 80.2 lists major properties of common antidepressants.

Tricyclic Antidepressants (TCAs)

Table 80.3 summarizes the placebo-controlled trials of various drugs for neuropathic pain and shows efficacy for amitriptyline, imipramine, nortriptyline, desipramine, clomipramine, and maprotiline at daily doses ranging from 30 to 200 mg for PHN, PDN, postmastectomy pain, central poststroke pain, and mixed types neuropathies. These results are commonly extrapolated to all types of neuropathic pain and clinical experience suggests some broad utility for the drugs. A systematic literature review presenting numbers needed to treat (NNTs) found TCAs the most efficacious antidepressants for neuropathic pain with an overall NNT of 3.1 (95% confidence interval [CI] 2.7–3.7).[5] However, a few trials failed to demonstrate TCA efficacy for spinal cord injury pain,[18] cisplatin-induced neuropathy,[19] HIV neuropathy,[20,21] phantom limb pain,[22] lumbar radiculopathy,[23] and neuropathic cancer pain.[24] Inability to demonstrate effectiveness of the TCAs in these neuropathic pain types may represent a true lack of therapeutic benefit, or it may be due to study design weaknesses or other factors. More studies are needed to clarify the value of specific TCAs in different types of neuropathic pain.

In many countries, TCAs may be overlooked as first line neuropathic pain drugs because they are generic and are not actively marketed. Newer, more expensive drugs for neuropathic pain may be selected despite comparatively lower effectiveness (higher NNTs), in part because of aggressive marketing by the pharmaceutical industry. The analgesic efficacy of the TCAs is likely to

TABLE 80.2

COMPARISON OF ANTIDEPRESSANTS IN NEUROPATHIC PAIN[9–17]

Agent	Normal adult daily dose in psychiatric disorders[a]	Usual number of doses per day	Elimination half-life ($t_{1/2}$)	Dosing adjustments	Serotonin: norepinephrine selectivity ratio[b]
Selective Serotonin Receptor Inhibitors (SSRIs)					
Citalopram	20–40 mg	1	35 hours	20 mg/day in hepatic impairment or elderly.	3500–3900
Escitalopram	10–20 mg	1	27–32 hours	10 mg/day in hepatic impairment or elderly.	7100
Fluoxetine	20–80 mg	1	24–72 hours (acute), 96–144 hours (chronic), Norfluoxetine 96–384 hours	Decrease dose in hepatic impairment	300–545
Fluvoxamine	100–300 mg	1–2	16 hours	Decrease dose in hepatic impairment and elderly.	580–620
Paroxetine HCL	20–60 mg	IR: 1 XR: 1	21 hours	Maximum dose = 40 mg/day in hepatic impairment or elderly.	300–450
Paroxetine mesylate	20–60 mg	1	33 hours	Maximum dose = 40 mg/day in renal or hepatic impairment, or elderly.	300–450
Sertraline	50–200 mg	1	62–104 hours	Decrease dose in hepatic impairment and elderly.	1400–2750
Serotonin and norepinephrine reuptake inhibitors (SNRIs)					
Desvenlafaxine	50–100 mg	1	11 hours	Decrease dose in moderate or severe renal disease.	85
Duloxetine	40–120 mg	1–2	8–17 hours	Do not give to patients with hepatic impairment. Decrease dose in severe renal disease.	9
Venlafaxine	75–375 mg	IR: 2–3 XR: 1	3–7 hours, ODV 9–13 hours	Decrease dose in hepatic or renal impairment.	115–120
Tricyclic antidepressants (TCAs)[c]					
Amitriptyline	100–300 mg	1–4	9–27 hours	Lower doses in elderly and hepatic impairment.	8
Clomipramine	100–300 mg	1–3	15–60 hours	Lower doses in elderly and hepatic impairment.	130
Desipramine	75–300 mg	1–3	10–30 hours	Lower doses in elderly and hepatic impairment.	0.05
Imipramine	100–300 mg	1–4	5–30 hours	Lower doses in elderly and hepatic impairment.	27
Maprotiline	100–225 mg	1–3	25–50 hours	Lower doses in elderly and hepatic impairment.	0.002
Nortriptyline	50–150 mg	1–4	20–55 hours	Lower doses in elderly and hepatic impairment.	0.24

IR, immediate release; ODV, O-desmethylvenlafaxine; XR, extended release.
[a]Dosing is per product U.S. approved dosing; dosing in pain syndromes may vary from that listed.
[b]These are estimates of selectivity ratio; actual selectivity ratios are concentration dependent; numbers <1 indicate greater affinity for norepinephrine than serotonin.
[c]TCAs may be safely administered once daily; some practitioners prefer to dose them more frequently.

TABLE 80.3

SUMMARY OF RANDOMIZED CONTROLLED TRIALS OF ANTIDEPRESSANTS IN TREATMENT OF NEUROPATHIC PAIN PUBLISHED AS PEER-REVIEWED ARTICLES

Study	Drug	Diagnosis	Design	Number of patients treated with active drug	Maximal dosage (mg)	Treatment duration (weeks)	Results
Leijon[147] 1989	Amitriptyline	CPSP	crossover	15	75	4	A>P
Cardenas[18] 2002	Amitriptyline	SCI	parallel	44	125	6	A=P
Max[25] 1987	Amitriptyline	DPN	crossover	29	150	6	A>P

Sindrup[41] 1990	Paroxetine	DPN	crossover	20	40	2	A>P
Sindrup[40] 1992	Citalopram	DPN	crossover	20	40	3	A>P
Max[27] 1992	Fluoxetine	DPN	crossover	46	40	6	A>P

CPSP, central poststroke pain; DPN, diabetic peripheral neuropathy; PHN, postherpetic neuralgia; SCI, spinal cord injury.
[a]The study showed significant effect of venlafaxine in the manifestations of hyperalgesia and temporal summation, but not on the ongoing pain intensity.

be independent of their antidepressant effect.[25] Over one-fifth (21%) of the patients with chronic pain have been diagnosed with depression associated with their pain.[26] Concomitant chronic pain and depression favor the use of an antidepressant (TCA or another) over other medication classes. TCAs are associated with dose-dependent adverse events, the most common being sedation, constipation, dry mouth, urinary retention, and orthostatic hypotension. Tricyclic antidepressants can be administered once daily, usually at bedtime, exploiting their sedating properties. The dose used for neuropathic pain, typically 100 mg a day or less, is below the antidepressant dose for most patients, lowering the risk of side effects. Secondary amine TCAs (e.g., desipramine, nortriptyline) are better tolerated than tertiary amine TCAs (e.g., amitriptyline, imipramine), but are equally effective.[27,28] Nonetheless, TCAs may not be tolerated by many patients. The anticholinergic effects of TCAs are a relative contraindication in patients with benign prostatic hyperplasia, cardiac conduction defects, and other morbidities sensitive to parasympatholytic action. Desipramine has only one-quarter of the anticholinergic and sedative activity of amitriptyline at comparable doses, making desipramine a TCA of choice.[29]

Use of a low initial dose and slow dose titration of all TCAs is important to minimize patients stopping the medication prematurely due to side effects. Dry mouth is the most common adverse event and it is often best managed with sugarless candies or chewing gum, especially sugarless lemon candy to stimulate serous saliva flow. Sips of water provide only transient relief. The most common starting dose for TCAs is 25 mg, but frail elderly and other highly sensitive patients may tolerate an initial 10 mg dose better. Increase the dose by the same number of mg as the starting dose every 3 to 5 days until some diminution of pain complaints occurs or the daily dose totals 100 mg. The maximal effect often occurs within 3 weeks at that dose, generally before antidepressant effects peak.

The anticholinergic effects of TCAs can cause cardiac toxicity including ventricular ectopic activity, myocardial infarction, and sudden death. A screening electrocardiogram (EKG) might be considered in patients over 40 years of age or who have other risk factors prior to initiating a TCA. According to recent recommendations, these drugs should not be used in patients who have ischemic heart disease or increased risk of sudden cardiac death.[8]

Selective Serotonin and Norepinephrine Reuptake Inhibitors

The SNRIs duloxetine and venlafaxine are newer antidepressants with effectiveness for neuropathic pain. Results with venlafaxine for neuropathic pain have been inconsistent. Venlafaxine was effective for PDN and for various forms of polyneuropathy at daily doses of 150 to 225 mg.[30,31] In one placebo-controlled trial, perioperative venlafaxine at a daily dose of 75 mg prevented the development of postmastectomy pain syndrome,[32] but in other trials on patients with postmastectomy pain[33] syndrome and mixed type neuropathies, efficacy at dose range of 75 to 150 mg could not be demonstrated.

Three large randomized controlled trials[34–36] and one open-label 52-week extension trial[37] showed that duloxetine was effective for PDN at daily doses of 60 to 120 mg. Duloxetine 60 mg per day has similar efficacy to duloxetine 120 mg per day and the lower dose but is far more tolerable. It can be administered once daily. At that dose the drug significantly improved sleep and quality of life. The most common adverse effects reported in these clinical trials were nausea, somnolence, dizziness, and constipation—all of which tended to decrease over time. Initiating treatment at a daily dose of 30 mg for one week followed by an increase to 60 mg per day during the second week is likely to improve tolerability.[38] Duloxetine has not been associated with cardiac toxicity. Do not use it concomitantly with MAOIs or in patients with markedly impaired liver function.

The relative efficacy (NNTs) of the SNRIs in the treatment of PDN have been calculated as 4.6 (CI 2.9–10.6) for venlafaxine and 5.2 (CI 3.7–8.5) for duloxetine[6] indicating that they are less effective than the far less expensive TCAs.[39]

Selective Serotonin Reuptake Inhibitors

Reports of the effectiveness of SSRIs in neuropathic pain management are inconsistent. Some reports may not have separated analgesic effect from the effects of mood elevation on pain perception. One well controlled trial documented that fluoxetine was no more effective than placebo[27] while both amitriptyline and desipramine were efficacious. Two other trials support efficacy of citalopram[40] and paroxetine[41] (both at 40 mg per day) in PDN. Although SSRIs show a favorable safety profile compared to TCAs and are generally well tolerated, they are far less efficacious in the treatment of neuropathic pain, with NNT of 6.8 (CI 4.4–441), and therefore should not be regarded as first-line agents.[5]

ANTICONVULSANTS

Some systematic reviews and evidence-based guidelines for the treatment of neuropathic pain regard selected anticonvulsants as first line therapy. Drugs include the calcium channel α2-δ ligands gabapentin and pregabalin for PHN and PDN, and carbamazepine for trigeminal neuralgia. Additionally, lamotrigine, oxcarbazepine, and, to a lesser extent, other anticonvulsants have been reported as effective in neuropathic pain in randomized controlled trials. Table 80.4 summarizes these trials.

Pregabalin

Perhaps the most extensively studied drug in this class is pregabalin, which is believed to exert its analgesic effect by binding to the α2-δ subunit of voltage-gated calcium channels on primary afferent neurons, reducing the release of neurotransmitters from their central terminals.[42] Pregabalin was effective for PHN and PDN in numerous multicenter, randomized, controlled trials.[43–51] A recent trial demonstrated better pain relief with pregabalin than placebo in patients with spinal cord injury pain.[52] It has not been studied in other types of neuropathic pain. The effective daily dose of 300 to 600 mg reduces pain and improves sleep, functioning, and quality of life. Pregabalin has several advantages compared to other anticonvulsants: it is usually administered twice daily, can be rapidly titrated, has early onset of analgesic effect, and linear pharmacokinetics. No drug interactions have been reported with pregabalin. The most commonly reported adverse events were dose-dependent and included dizziness, somnolence, dry mouth, and edema.[12,13]

Gabapentin

There is also strong evidence of gabapentin's efficacy for PHN and PDN at doses of 900 to 3600 mg per day. Although less broadly studied than pregabalin in these syndromes, gabapentin has shown efficacy in HIV-associated painful neuropathy, pain in Guillain Barré syndrome, phantom limb pain, spinal cord injury pain, and cancer-related neuropathic pain.[7,53–64] In contrast, three trials did not support the efficacy of gabapentin in various forms of neuropathic pain. In a small trial comparing gabapentin and placebo for phantom pain, the authors concluded that "gabapentin did not substantially affect pain."[65] In another study, gabapentin had only a mild effect on pain in patients with complex regional pain syndrome type I (CRPS I).[66] A more recent and larger trial did not demonstrate any benefit for gabapentin over placebo in chemotherapy-induced painful peripheral neuropathy.[67] Gabapentin is believed to have similar mechanism of analgesia to pregabalin. However, unlike pregabalin it requires thrice daily dosing, has nonlinear pharmacokinetics, and may take days or weeks to reach an effective dose. Gabapentin is relatively safe, with no clinically relevant drug interactions. The main adverse effects are somnolence, dizziness, and peripheral edema.[12,13] Clinically, some clinicians report that some patients who fail to respond to gabapentin may respond to pregabalin and vice versa.

Carbamazepine

Carbamazepine is commonly used to treat trigeminal neuralgia. Most carbamazepine studies in trigeminal neuralgia were conducted in the 1960s and 1970s using small samples sizes. In these studies pain relief was superior with carbamazepine compared to placebo.[68–71] Carbamazepine was also one of the first anticonvulsants used in PDN, and was superior to placebo in two small trials.[72,73] Pain reduction was similar between carbamazepine and the tricyclic antidepressant nortriptyline in a more recent trial.[74] Carbamazepine was more effective than placebo in patients with mixed types of neuropathic pain in one controlled trial.[75] NNT to achieve 50% pain relief with carbamazepine in trigeminal neuralgia and painful diabetic neuropathy were 2.6 (range 2.2–3.3) and 3.3 (range 2–9.4), respectively, in systematic reviews.[76,77] However, these figures are based primarily on old trials, most of which were conducted in small patient groups for relatively short treatment periods. Nonetheless, study-quality

CPSP, central poststroke pain; DPN, diabetic polyneuropathy; GBS, Guillain-Barré syndrome; HIV-N, HIV neuropathy; LR, lumbar radiculopathy; SCI, spinal cord injury; TN, trigeminal neuralgia.

A, active drug; P, placebo; > indicates that active drug was superior to the comparator in terms of pain reduction; < indicates that active drug was superior to the comparator in terms of pain reduction; = indicates that active drug was equal to the comparator in terms of pain reduction.

[a]findings from three double-blind placebo-controlled trials.

[b]No significant difference between topiramate and placebo in pain score (primary outcome measure), but significant difference in global pain relief score.

[c]In this four-arm study, gabapentin was superior to placebo but less effective than morphine and the combination of gabapentin plus morphine.

[d]A significant decrease of "unpleasant feeling" and a trend toward a decrease in both the "pain intensity" and "burning sensation."

[e]Lamotrigine was superior to placebo in patients who received antiviral neurotoxic therapy, but not in patients who did not receive this therapy.

[f]Lamotrigine was superior to placebo in patients with incomplete spinal cord injury and evoked pain, but equal to placebo in patients with complete injury and without evoked pain.

rating for carbamazepine in trigeminal neuralgia is regarded as level 1 (good quality evidence), and only level 3 (no good evidence) for diabetic neuropathy and other forms of neuropathic pain.[76,77] The analgesic mechanism of carbamazepine is related to voltage-dependent sodium channel blocking, which results in decreased ectopic nerve discharges and neural membranes stabilization.[78] Adverse events are common and include dizziness, nausea, drowsiness, blurred vision, and ataxia.[73] Rare, but serious, side effects include leukopenia, impairment of liver function, and reduction of sodium plasma levels. A limitation of using carbamazepine is its association with Stevens-Johnson syndrome.[12,13]

Oxcarbazepine

Oxcarbazepine is believed to have a similar analgesic mechanism to carbamazepine. Randomized, controlled trials[79] demonstrated its effectiveness for trigeminal neuralgia at daily doses of 600 to 1200 mg; patients with intractable trigeminal neuralgia may need doses as high as 2400 mg per day. Oxcarbazepine was more effective than placebo in reducing pain associated with diabetic neuropathy in one randomized trial.[80] In several open-label trials oxcarbazepine improved mixed types of neuropathic pain from baseline.[81] In summary, oxcarbazepine seems similar to carbamazepine for trigeminal neuralgia, but there are only limited data regarding its efficacy and safety for other types of neuropathic pain. Hyponatremia has occurred with this drug; sodium levels should be monitored.

Lamotrigine

Lamotrigine has shown efficacy in some randomized, controlled trials for painful diabetic neuropathy,[82] HIV-related neuropathy,[83,84] spinal cord injury pain,[85] central poststroke pain,[86] and trigeminal neuralgia.[87] At the same time, equivocal or negative (active therapy not superior to placebo) results were reported from studies with lamotrigine for HIV-related neuropathy,[83] pain related to complete spinal cord injury,[85] diabetic polyneuropathy,[88] and mixed neuropathies.[89] The overall safety profile for lamotrigine is dose-related. Common side effects include nausea, vomiting, sedation, drowsiness, dizziness, headaches, malaise, visual disturbances, and ataxia. Skin rash that may deteriorate to dangerous or life-threatening Stevens-Johnson syndrome or toxic epidermal necrolysis is the most serious adverse event of lamotrigine. Slow titration may reduce the risk of developing these syndromes. The appearance of skin rash requires discontinuation of lamotrigine.[90]

Other Anticonvulsants

Valproic acid and sodium valproate at a daily dose of 1000 mg were superior to placebo in reducing postherpetic neuralgia.[91] In contrast, 1500 mg of valproic acid failed to show superiority to placebo for mixed types of neuropathic pain in another randomized, controlled trial.[92] Topiramate was effective for PDN in one controlled trial,[93] but not in another, much larger trial.[94] Topiramate also yielded equivocal results in one randomized, controlled trial in patients with painful lumbar radiculopathy.[95] Topiramate was titrated up to a daily dose of 400 mg in all three trials. Several new anticonvulsants such as levetiracetam, zonisamide, tiagabine, and lacosamide have been used in open label studies or small-scale randomized, controlled trials, but currently available data are too limited to confidently assess the efficacy of any of these newer drugs. One example is levetiracetam, which initially showed some indication of efficacy for painful neoplastic plexopathies in an open-label case series report,[96] but more recently failed to relieve postmastectomy pain syndrome when compared to placebo in a randomized controlled trial.[97]

OPIOIDS

Nine randomized controlled trials tested the efficacy of oral opioids for PDN, PHN, phantom pain, nerve root pain, and neuropathic pain of diverse etiologies (Table 80.5). Eight trials demonstrated effectiveness of morphine, oxycodone, methadone, or levorphanol in reducing spontaneous neuropathic pain.[75,98–104] Efficacy was demonstrated by either superiority over placebo or a dose-dependent analgesic response. The only negative study is a recent trial in which morphine showed no superiority over placebo in patients with chronic lumbar radicular pain.[23] Six studies[98–101,103,104] were recently pooled in a meta-analysis[105] resulting in a mean pain intensity to be 14 points lower in opioid treated patients than in those treated with placebo (95% C.I. -18 to -10; $p < .001$). From a different standpoint, the overall NNT of opioids for reducing neuropathic pain by 50% is 2.5 (95% CI 2.0–3.2).[5] A systematic review of seven short-term (less than 24 hours) and two intermediate-term (4 weeks) randomized, controlled trials concluded that according to these trials opioids can reduce the intensity of dynamic mechanical allodynia and perhaps of cold allodynia in peripheral neuropathic pain. These findings are clinically relevant because dynamic mechanical allodynia and cold allodynia are the most prevalent types of evoked pain in neuropathic pain.[106]

Although opioids clearly reduce neuropathic pain, several questions related to chronic opioid use in neuropathic pain remain unanswered. Secondary outcome parameters such as physical and mental health, sleep, disability, and quality of life, which were measured in some of these trials, yielded inconsistent results. Data are limited regarding efficacy of opioids for central neuropathic pain. Opioid studies were limited to 8 weeks or less. Therefore, no data on long-term safety and efficacy of opioids in the treatment of neuropathic pain are available. This is particularly important because of emerging information regarding long-term complications of opioid use such as hypogonadism,[107,108] increased risk of bone fractures in the elderly,[109,110] immunological changes,[111] and the potential for opioid-induced hyperalgesia.[112,113] Available trials do not clearly address the issues of addiction and abuse which have major medical, legal, and social implications. These unanswered questions about opioid treatment of neuropathic pain require further assessment.

TRAMADOL

Tramadol is a unique agent with a dual mechanism of analgesia: it has a weak affinity for mu-opioid receptors and it weakly inhibits serotonin and norepinephrine reuptake.[12,13] Randomized controlled trials show that tramadol can reduce pain in patients with PHN,[114] PDN,[115] mixed forms of painful polyneuropathy.[116] and postamputation pain (Table 80.5).[117] Its efficacy for PDN and PHN seems somewhat reduced as compared to that of other opioids with NNT of 3.9 (CI 2.7–6.7).[5] Due to dose-dependent adverse effects, a gradual titration from 50 mg two to three times daily to a maximal dose of 200 mg twice daily is generally required. Common adverse events include drowsiness, nausea, constipation, dizziness, and potential for abuse. Concomitant use of serotonin reuptake inhibitors may increase the risk for serotonergic syndrome.

NMDA RECEPTOR ANTAGONISTS

In spite of numerous animal studies in which N-methyl-D-aspartic acid (NMDA) receptor antagonists yielded promising results,

clinical trials with oral drugs were generally negative (Table 80.6). Two small trials showed efficacy of the NMDA receptor antagonist dextromethorphan for PDN but not for PHN or neuropathies of mixed etiologies. Memantine, which also has NMDA receptor blocking properties, was not effective in diabetic polyneuropathy, postherpetic neuralgia, or phantom limb pain.[5] In contrast, intravenous administration of subanesthetic doses of ketamine produced short-term analgesia (lasting for hours) in multiple forms of neuropathic pain.[118] Regardless of the difference in outcomes between short- and long-term studies, a recent trial showed that short-term intravenous administration of ketamine may be useful in predicting long-term response to oral dextromethorphan.[119]

SODIUM CHANNEL BLOCKERS

Carbamazepine, oxcarbazepine, mexiletine, intravenous lidocaine, and topical lidocaine are all sodium channel blockers. The first two have already been reviewed earlier in this chapter.

Mexiletine, an orally available analog of lidocaine with antiarrhythmic properties,[12] was evaluated in several randomized, controlled trials for the treatment of painful diabetic polyneuropathy. These trials are summarized in Table 80.6. With the exception of one trial in which a relatively high dose of the drug produced modest effect, no significant pain relief was demonstrated.[120–122] High doses of mexiletine are commonly associated with adverse effects such as chest pain, dizziness, gastrointestinal disturbances, palpitations, tremor, and potential for worsening of existing arrhythmia.[12,13]

A meta-analysis of randomized, controlled trials demonstrated the effectiveness of intravenous lidocaine for various types of peripheral neuropathic pain syndromes. Pain was reduced by about 10 mm more (on a 100 mm scale) with lidocaine than with placebo.[123] Major drawbacks of this therapy are the lack of data on long-term efficacy and the apparent necessity for repeated infusions for sustained pain relief. This may therefore be an impractical approach for many patients. Interestingly, a positive correlation between the response to a single lidocaine infusion and long-term response to oral mexiletine has been reported.[124] Topical lidocaine is reviewed later in this chapter.

NONSTEROIDAL ANTI-INFLAMMATORY AGENTS

Although evidence for the role of inflammation in neuropathic pain is emerging and it is estimated that half of all clinical cases of neuropathic pain are associated with inflammation of the peripheral nerves,[125] no controlled clinical trials that tested the effectiveness of nonsteroidal anti-inflammatory agents (NSAIDs) for neuropathic pain exist. Only a pilot, randomized, open-label

[a]Combination therapy superior to each drug alone; all are superior to placebo.
[b]Combination, each drug alone, and placebo showed similar efficacy.
[c]Combination of gabapentin + oxycodone was superior to the combination of gabapentin + placebo.
[d]Combination of ketamine + amitriptyline cream, each drug alone and their combination showed similar efficacy.

clinical trial which showed comparable effectiveness of lidocaine patch 5% to that of naproxen 500 mg twice daily for the treatment of neuropathic pain associated with carpal tunnel syndrome is available.[126]

ZICONOTIDE

Ziconotide, the first N-type calcium channel blocker, is a synthetic formulation of *Conus magus* cone snail venom.[127] It produces analgesia by selectively and reversibly blocking N-type calcium channels in the CNS.[128,129] Intrathecal administration via an implanted pump or catheter is necessary because systemic ziconotide produces profound hypotension.[128] Intrathecal ziconotide resulted in significantly greater visual analogue scale (VAS) pain score reductions than placebo in chronic malignant and nonmalignant pain during clinical trials ($p < .001$).[127,130] Common adverse events include dizziness (47%), nausea (41%), nystagmus (27%), confusion (25%), somnolence (22%), gait abnormalities (18%), blurred vision (14%), headache (13%), memory impairment (13%), and vomiting (13%).[127,130] Ziconotide's narrow therapeutic index commonly results in toxicity, particularly with aggressive initial dosing and titration.[128,129] The U.S. labeling for ziconotide recommends an initial continuous infusion of 2.4 mcg/day, with dose titrations 2 or 3 times weekly.[130] Later, an expert consensus statement recommended an initial dose of only 0.5 mcg/day, with weekly dose increases of no more than 0.5 mcg/day as needed for pain control.[131] Lower starting doses and slower titration reduce the risk of serious adverse events and premature drug discontinuation.[130,131] Risks inherent with intrathecal drug delivery include infection, subarachnoid hemorrhage, catheter-tip inflammatory masses, and pump failure.[132] Ongoing studies offer promise that new N-type calcium channel blockers will provide effective and well tolerated analgesia with less invasive routes of administration.[128]

TOPICAL AGENTS

Capsaicin

Topical capsaicin cream 0.075% applied 3 to 4 times daily was effective in three of five published randomized controlled trials in painful diabetic neuropathy, in two postherpetic neuralgia trials, one trial in postsurgical pain, and one in patients with mixed neuropathies. Topical capsaicin was not superior to placebo in randomized controlled trials for postmastectomy pain syndrome and for HIV neuropathy. The NNT with topical capsaicin to reach 50% pain reduction is therefore 6.7 (95% CI 4.6–12).[5] The proposed mechanism of action is depletion of vanilloid receptors, but neurolysis may also be responsible for the activity of topical capsaicin. Capsaicin application is associated with burning sensation, particularly during the first weeks of treatment, an adverse event that may often limit its use. Therefore, therapy should begin with the lower 0.025% concentration and the higher 0.075% concentration should be used only after a full container of the weaker formulation has been used up. Patients should be instructed to avoid touching eyes and mucous membranes with the drug or fingers that have been exposed to it. Counsel patients that within a week most people become reasonably tolerant to the burning on application that is common when starting therapy especially since up to a month is required for maximal analgesic effect. Experienced clinicians consider topical capsaicin more of an adjunctive than primary therapy for neuropathic pain.

Topical Lidocaine Patches

Application of topical lidocaine 5% patches was effective for PHN in three short-term, randomized, controlled trials,[133–135] and also in patients with other focal peripheral neuropathies.[126,136] The maximal recommended daily dose is three patches applied simultaneously every 12 hours. With the exception of mild skin reactions, lidocaine patches are not associated with adverse reactions, although caution is required in patients receiving oral Class I antiarrhythmic medications (e.g., mexiletine) and in patients with severe hepatic dysfunction.[8]

Topical Ketamine

One short-term, randomized, controlled trial evaluated the analgesic effect of topical ketamine 1% as compared to topical amitriptyline 2%, a combination of both, or placebo in patients with mixed types of neuropathic pain. No difference in pain reduction between treatments was found.[137]

CANNABINOIDS

Although cannabinoids are not formally approved for the treatment of neuropathic pain by drug regulatory agencies, many patients use cannabis for pain relief.[138] A recent double-blind, placebo-controlled, crossover study showed that smoking a single high-dose (7%) or low-dose (3.5%) cannabis cigarette produced better analgesia for a few hours than placebo in 38 patients with central and peripheral neuropathic pain. No effect on evoked pain was seen. Modest cognitive effects, particularly memory, at higher doses were noted.[138] Cannabis (3.56% tetrahydrocannabinol) or identical placebo cigarettes, smoked three times daily for 5 days also was tested in patients with HIV-induced painful neuropathy.[139] The first cannabis cigarette reduced pain by a median of 72% versus 15% with placebo. Smoked cannabis produced a daily median pain reduction of 34% compared to 17% with placebo. In contrast to the aforementioned study, cannabis reduced experimentally induced mechanical hyperalgesia. All these results were statistically significant. The agent 1′,1′dimethylheptyl-Delta8-tetrahydrocannabinol-11-oic acid (CT-3), a potent analgesic cannabinoid in animals, was tested in a randomized, placebo-controlled, double-blind crossover trial in 21 patients with mixed forms of chronic neuropathic pain. The two tested doses (40 and 80 mg/day) of CT-3 produced more analgesia that placebo, but no dose response analgesic effect was observed. No major adverse effects were observed.[140] In another study, 48 patients with intractable pain related to brachial plexus avulsion were treated for 2 weeks with two different oromucosal spray preparations of whole plant extracts of delta (9) tetrahydrocannabinol (THC) with or without cannabidiol (CBD) or placebo. The active compounds, but not the placebo, significantly improved pain and sleep. The study medications were generally well tolerated.[141] The THC-CBD oromucosal spray was also tested in 66 patients with central pain due to multiple sclerosis and was superior to placebo in reducing pain and sleep disturbances. The active drug was, again, well tolerated.[142] Another study on patients with multiple sclerosis compared the efficacy of orally administered 10 dronabinol at a maximum daily dose of 10 mg versus placebo. Median spontaneous pain intensity and median pain relief score were significantly superior during dronabinol treatment than during placebo treatment. A recent meta-analysis concluded that cannabinoids are effective for neuropathic pain in multiple sclerosis, although small number of trials and patients were notable limitations of the review.[143] While the reports on cannabis efficacy in neuropathic pain management are inconsistent, it is reasonable to conclude at this time that the cannabinoids have shown effectiveness for neuropathic pain in a few recent controlled trials, and seem to be well tolerated. However, their long-term efficacy and safety have not been tested yet.

DRUG COMBINATIONS

Not uncommonly, administration of a single drug does not produce adequate analgesia. Pharmacologically, it seems reasonable to coadminister drugs with different mechanisms of action. While combination therapy is commonly used in clinical practice, limited data are available regarding the efficacy and safety of this practice. Most trials produced positive results. One trial found that concomitant use of gabapentin and morphine in patients with mixed forms of neuropathic pain produced superior efficacy and safety than each drug alone.[7] Similar results were reported for the combination of gabapentin with oxycodone[144] and for gabapentin with venlafaxine.[145] These trials imply that combination therapy could enhance analgesia while decreasing side effects. In contrast, Khoromi et al.[23] could not demonstrate superiority of morphine, nortriptyline, or their combination over placebo in patients with chronic lumbar root pain. One randomized controlled trial compared the efficacy of topical amitriptyline 2%, ketamine 1%, and a combination of both in patients with mixed types of neuropathic pain. Although reduction in pain scores was observed in all groups, there was no difference in efficacy between the groups.[137] Interestingly, an open-label trial demonstrated that topical amitriptyline 2%/ketamine 1%, given over 6 to 12 months, was associated with long-term analgesic effectiveness in treating neuropathic pain.[146]
